The HSO_3F solutions were prepared by stirring 10 mg 70% enriched dry ^{125}Te with 2 ml of ice-cold HSO_3F (3). The solutions were transferred to Teflon holders with O-ring seals and frozen and stored in liquid nitrogen until such time as the Mössbauer spectra were run. The sample referred to as $Te_4(Sb_2F_{11})_2$ was prepared by reacting 20 mg of 70% enriched, dry ^{125}Te with an excess of SbF_5 (vacuum distilled) in liquid SO_2 at −23°C (3). The SO_2 solution was drawn off and on evaporation of the SO_2 the resulting red solid was sealed in a Teflon holder and stored in liquid nitrogen. The samples referred to as $Te_4(AlCl_4)_2$ and $Te_6(AlCl_4)_2$ were prepared (6, 9) by reacting 200 mg of unenriched tellurium, to which 50 mg of 70% enriched ^{125}Te was added, with the stoichiometric

quantities of vacuum sublimed $TeCl_4$ and $AlCl_3$ according to the equations:

$$7Te + TeCl_4 + 4AlCl_3 \rightarrow 2Te_4(AlCl_4)_2$$

$$11Te + TeCl_4 + 4AlCl_3 \rightarrow 2Te_6(AlCl_4)_2$$

The reactions were carried out in the molten phase under vacuum in sealed Pyrex tubes. On cooling, the purple-black solids were then mounted and stored as before. The solutions in oleum and the subsequent oxidation steps were studied using 10 mg portions of 70% enriched ^{125}Te. Preparations and sample-mounting were carried out in a dry-box.

None of the above samples were further purified or characterized. However the consistency of the Mössbauer data within any one set of experiments lends support to the identification of tellurium species present.

The compounds $Te_4(AsF_6)_2$, $TeSbF_6$, $Te_x(AsF_6)_y$, and $Te_m(AsF_6)_n$ were kindly provided by Dr. R. J. Gillespie. The latter samples were prepared by reaction of tellurium with excess AsF_5 in SO_2 and may have corresponded to $TeAsF_6$, although they were not analysed.

The bulk of the Mössbauer spectra were recorded with the source and absorbers at 4.2 K at the PCMU Harwell using a $Pb^{125m}Te$ source prepared by neutron irradiation of a $Pb^{124}Te$ sample prepared in our laboratory. The remaining spectra were recorded in our laboratory at Simon Fraser University, again using a $Pb^{125m}Te$ source but with the source at 80 K and the absorbers at 4.2 K (Table 1). The prepared absorbers had a thickness of 5–10 mg cm^{-2} of ^{125}Te. The general procedures used in recording the Mössbauer spectra have been reported elsewhere (10). The spectra were computer fitted to Lorentzians using a program described in ref. 13. The spectrometers were routinely calibrated using an iron foil and a $^{57}Co/Pd$ source and the standard parameters quoted in ref. 14 were used. A sample of $Te(thiourea)_4Cl_2 \cdot 2H_2O$ was used as an internal calibrant and gave parameters on both spectrometers in excellent agreement with previous measurements (10) ($\delta_{PbTe} = 0.78$ mm s^{-1}, $\Delta = 15.6$ mm s^{-1}).

Acknowledgements

The author wishes to thank Dr. A. G. Maddock for his period spent in Cambridge when these experiments were initiated, Dr. B. Dale and the staff at the PCMU Harwell for their help in recording Mössbauer spectra, and Dr. R. J. Gillespie, McMaster University, for kindly providing samples of four compounds. An operating grant from the National Research Council of Canada is gratefully acknowledged.

Crystal structure studies of Group V chalcogenide compounds. I. The structure of tricyclohexylphosphine sulphide

K. ANN KERR, P. M. BOORMAN, B. S. MISENER, AND J. G. H. VAN ROODE[1]

Chemistry Department, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received November 22, 1976

K. ANN KERR, P. M. BOORMAN, B. S. MISENER, and J. G. H. VAN ROODE. Can. J. Chem. **55**, 3081 (1977).

Crystals of tricyclohexylphosphine sulphide, $C_{18}H_{33}PS$, are orthorhombic, $a = 10.906(2)$, $b = 15.836(2)$, $c = 10.362(2)$ Å, $Z = 4$, space group $Pn2_1a$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to a final R_ω of 0.058 for all 1209 reflexions with $\sin\theta/\lambda \leq 0.5377$.

Although second harmonic generation unambiguously established the correct space group as $Pn2_1a$, parameters reported here refer to the centrosymmetric space group *Pnma*. The geometry at phosphorus is approximately tetrahedral with an average P—C distance of 1.838(2) Å. Angles at phosphorus range from 105.4° to 113.2°. The P=S bond length of 1.966(2) Å is one of the longest bonds of this type so far reported. Rigid body analysis of thermal parameters suggests that the 'true' bond lengths are even longer.

K. ANN KERR, P. M. BOORMAN, B. S. MISENER et J. G. H. VAN ROODE. Can. J. Chem. **55**, 3081 (1977).

Les cristaux du sulfure de tricyclohexylphosphine, $C_{18}H_{33}PS$, sont orthorhombiques, $a = 10.906(2)$, $b = 15.836(2)$, $c = 10.362(2)$ Å, $Z = 4$, groupe d'espace $Pn2_1a$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R_ω de 0.058 pour les 1209 réflexions avec $\sin\theta/\lambda \leq 0.5377$.

Quoique la génération d'harmoniques secondes permet d'établir d'une façon non-ambigue le groupe d'espace correct $Pn2_1a$, les paramètres qui sont rapportés ici se réfèrent au groupe d'espace centrosymétrique *Pnma*. La géométrie au niveau du phosphore est approximativement tétraédrique avec une distance P—C moyenne de 1.838(2) Å. Les angles autour du phosphore varient de 105.4° à 113.2°. La longueur du lien P=S est de 1.966(2) Å et correspond à la plus longue liaison de ce type qui ait été rapportée jusqu'à maintenant. Une analyse selon les corps rigides des paramètres thermiques suggèrent que les "vraies" longueurs de liaison sont même plus longues.

[Traduit par le journal]

Introduction

Until recently the study of phosphine sulphide complexes was a neglected area of coordination chemistry. Although this situation has been rectified to some extent (1–3), discussions of P—S bonding in both free and complexed forms have been based mainly on studies of vibrational spectra. Since few crystallographic data are available and since there is wide variation in reported bond lengths among different structures and among 'chemically equivalent' bonds in the same structure, we are studying a group of ligands containing the P—S bond in both 'free' and 'bound' states. We are interested in the multiple bond character of the P—S bond and in the nature of the interaction that occurs when phosphine sulphides bond to different classes of metals. Our current structural studies complement our previous synthetic and spectroscopic work (4–6).

Experimental

The compound tricyclohexylphosphine sulphide was prepared by direct reaction between elemental sulphur and tricyclohexylphosphine in a sealed tube at 150°C, followed by extraction with ethanol (7). Recrystallization from ethanol gave clear, plate-like crystals. The sample chosen for analysis had dimensions ca. 0.30 × 0.14 × 0.40 mm (*b*-axis perpendicular to plate face) and was mounted about the *a*-axis. Preliminary unit cell and space group data were obtained by film methods. Unit cell parameters were refined by least-squares treatment of the $\sin^2\theta$ values of 12 high-angle reflexions measured on a 4-circle diffractometer with CuK_α radiation. Crystals data are:

$C_{18}H_{33}PS$ fw = 312.5
Orthorhombic, $a = 10.906(2)$, $b = 15.836(2)$, $c = 10.362(2)$ Å, $V = 1789.7(3)$ Å^3, $Z = 4$, $\rho_c = 1.160$ g cm^{-3}, $\lambda = 1.5418$ Å; $\mu = 22.75$ cm^{-1}, $F(000) = 172$. Absent reflexions: $0kl$, $k + l \neq 2n$ and $hk0$, $h \neq 2n$, space group

*Coordinates ($\times 10^4$) and their standard deviations expressed as fractions of the cell edge. Anisotropic temperature factors ($\times 10^3$) have the form $T = \exp\{-2\pi^2(h^2a^{*2}U_{11} + \ldots + 2hka^*b^*U_{12} + \ldots)\}$. Those temperature factors that must have zero value in space group *Pnma* are indicated with a dash.

Pnma or $Pn2_1a$. Strong second harmonic generation (8*a*, *b*) unequivocally confirms that the correct space group is $Pn2_1a$.[2] Intensity data were measured at room temperature on a Picker four-circle diffractometer in the θ–2θ scan mode with a scintillation counter and Ni-filtered CuK_α radiation using a scan rate of 1° min^{-1}. The scan range was determined by the expression $\Delta 2\theta = 1.0° (0.93 + 0.285 \tan\theta)$ and background counts were measured for 40 s at either end of the scan. The three standard reflexions that were measured after every 75 reflexions throughout the data collection showed no systematic trend. Both *hkl* and *hkl̄* data were collected to a maximum 2θ value of 112°. These reflexions were averaged to give 1209 independent reflexions of which 271 had intensities less than $3\sigma(I)$. These were included in the structure factor calculation but given zero weight in the refinement if $F_c \leq F_o$.

Structure Analysis

The structure was solved in space group $Pn2_1a$ using the program MULTAN (9). The 300 reflexions with $E > 1.18$ were used in a symbolic addition procedure which generated 128 sets of phases of which 64 had identical figures of merit. One of these sets was used to calculate an E-map which revealed the positions of all heavy atoms in the molecule.

The structure was refined to convergence in the centrosymmetric space group *Pnma* using full-matrix least-squares with weights based on counting statistics. During the final cycles of refinement the 167 parameters refined included scale, extinction, positional parameters for all atoms, anisotropic temperature parameters for the heavy atoms and isotropic temperature parameters for hydrogen. The refinement converged with $R_\omega = \Sigma\omega||F_o| - |F_c||/\Sigma\omega|F_o| = 0.0581$ for the 966 reflexions of non-zero weight. The conventional *R*-value was 0.0472 for the 'observed' reflexions only and 0.0787 for the full data set.

Since the correct space group is $Pn2_1a$ we attempted refinement in this space group at two stages, once at the end of isotropic refinement and once after convergence of the anisotropic refinement. In both cases, the approach to convergence was slow, estimated standard deviations of parameters were high and agreement between chemically equivalent bonds became worse than in the preceding centrosymmetric refinement. For these reasons the results reported here refer to refinement in the centrosymmetric space group *Pnma*.

The quantity minimized was $\Sigma\omega(|F_o| - |F_c|)^2$ where $\sqrt{\omega} = \{\sigma^2(F) + 0.001F^2\}^{-1/2}$ and $\sigma(F)$ was derived from counting statistics. When the refinement was terminated the mean parameter shift was 0.076σ and no parameter shift was larger than 0.407σ. The standard deviation of an observation of unit weight was 1.56. Scattering factors and anomalous scattering corrections from ref. 10 were used for all atoms. A table of observed and calculated structure factors has been placed in the Depository of Unpublished Data.[3]

Results and Discussion

Positional and thermal parameters for the heavy atoms are given in Table 1 while those for hydrogen atoms are in Table 2. General features of the molecular structure are shown in Fig. 1. Molecular packing is illustrated in Fig. 2. In the centrosymmetric refinement, the mirror plane at $y = 0.25$ bisects the molecule so that atoms S, P, C(1), and C(4) lie on the mirror. The three cyclohexyl rings are in the chair form with bond angles close to the expected tetrahedral values.

The geometry at phosphorus is slightly but significantly distorted. The S—P—C angles and the C—P—C angle across the mirror plane are

[2]In this technique, laser light of wavelength 1.06 μm with peak pulse power in the kW range is used to irradiate the sample. The fundamental beam is eliminated with appropriate filters placed after the sample and any second harmonics of wavelength 0.53 μm are then detected with a photomultiplier. This provides a highly sensitive test for the absence of centres of inversion.

[3]Complete set of data is available at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

larger than the expected tetrahedral value, while the other C—P—C angles are significantly smaller than tetrahedral. This may well be a steric effect since the direction of the distortion is consistent with relief of very short intramolecular S---C(5) contact of 3.120(3) Å. The S---C(1) contact of 3.162(4) Å is not as severe. The only other short contacts of note are between the phosphorus atom and the hydrogens on the lead carbons of the cyclohexyl rings. The P---H(1) distance is 2.33(4) Å and the P---H(5) distances are 2.24(3) Å. There are no unusual inter-molecular contacts.

A comparison of bond lengths with other values in the literature demands that the values compared be measurements of the same quantity and be drawn from the same pool. The P=S and P—C values of 1.959(2) Å and 1.798(2) Å given for an X-ray determination of $(CH_3)_3PS$ (12) are too scantily reported to allow a reader to assess their reliability. The results for triorthotolyl phosphine sulphide (3) (P=S 1.953(6) Å, 1.942(5) Å with P—C ranging from 1.773(9) Å to 1.870(9) Å) are much less precise than the present determination. The electron diffraction results on $(CH_3)_3PS$ give a P=S of 1.940(2) Å with an average P—C distance of 1.812(2) Å. These results have the desired accuracy and precision but are not strictly comparable with the X-ray results since the two experiments measure different time-average distances. However, it can be noted that our value of 1.966(2) Å is the longest bond of this type so far reported. The two independent P—C bonds are identical within the precision of the experiment, and very close to the value of 1.84 Å calculated from Schomaker–Stevenson single-bond radii with electronegativity correction.

C9 —C10	1.520
C10—C5	1.532

Orientation of the thermal ellipsoids in Fig. 1 suggests that the molecule may be librating as a rigid body (11). Thermal vibration analysis has been carried out using the method of Schomaker and Trueblood (13) with the rigid-body parameters constrained to have the same mirror symmetry as the individual U_{ij}'s. Although the analysis was successful in that the fit was reason-

able, the corrections to the bond lengths are not significant. The systematic shortening in C—C bond length with distance from the centre of the molecule suggests that internal modes of vibration may be important in the cyclohexyl rings. Corrected bond distances are shown in Table 3. Rigid-body parameters and their esd's are shown in Table 4.

There are too few structure determinations on this class of compounds to allow a meaningful comparison with spectroscopic work. We are currently studying several related ligands in both free and bound states.

The kinetics of the reaction of mercuric acetate with alkenes in methanol can be measured directly by observing the ultraviolet absorbance of the solution at 265 nm. For more reactive alkenes stopped flow techniques are required, but for less reactive substrates conventional spectrophotometers are adequate. The measured rates are in satisfactory agreement with values obtained by other methods. The rates of several cyclopropylalkenes were measured in this way, and relative reactivities of some of the same substrates were obtained by the competition method. Rates obtained by both methods are in qualitative agreement, and show very high reactivity for the cyclopropylalkenes. These rates are analyzed by comparison with model reactions involving open ions (acid-catalyzed hydration) and bridged ions (sulfenyl halide addition). The comparisons suggest that the oxymercuration of alkenes not substituted with strongly resonance electron-donating substituents, for example ethylene, proceeds through bridged rate-determining transition states that put very little positive charge on carbon, but that when strongly resonance electron-donating substituents such as cyclopropyls are present, the rate-determining transition state resembles an open carbonium ion.

I. C. AMBIDGE, STEPHEN K. DWIGHT, CAROLYN M. RYNARD et THOMAS T. TIDWELL. Can. J. Chem. **55**, 3086 (1977).

On peut mesuré la cinétique de la réaction de l'acétate mercurique avec les alcènes dans le méthanol d'une manière directe en observant l'absorption dans l'ultraviolet d'une solution à 265 nm. Pour les alcènes réactifs, on doit faire appel aux techniques de flux stoppés mais pour des substrats moins réactifs, des méthodes spectrophotométriques conventionnelles sont adéquates. Les vitesses mesurées sont en bon accord avec les valeurs obtenues par d'autres méthodes. De cette manière on a mesuré les vitesses de réaction de plusieurs cyclopropylalkènes et des réactivités relatives de quelques uns des mêmes substrats ont pu être obtenues par des méthodes compétitives. Les vitesses obtenues par les deux méthodes sont en bon accord qualitatif et indiquent une très grande réactivité pour les cyclopropylalkènes. On a analysé ces vitesses par comparaison avec des réactions modèles impliquant des ions ouverts (l'hydratation acido-catalysée) et des ions pontés (addition de l'halogénure de sulfényle). Ces comparaisons suggèrent que l'oxymercuration des alcènes non-substitués par des substituants agissant comme électro-donneurs puissants par résonance, par exemple l'éthylène, procède par des états de transition déterminant la vitesse de la réaction qui sont pontés et qui induisent très peu de charge positive au niveau du carbone; toutefois lorsque des substituants agissant fortement comme des électro-donneurs à cause de la résonance tel que le cyclopropyle, sont présents, l'état de transition déterminant la vitesse ressemble à un ion en forme ouverte.

[Traduit par le journal]

The oxymercuration reaction has been extensively studied and has been the subject of frequent reviews (1–11). Nevertheless it appears from the most recent surveys (9–11) that there is still dissension regarding the mechanism of this important reaction, although there is general agreement that its broad features can be described as in [1] and [2].

[1] $$R_1R_2C{=}CR_3R_4 + HgX_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Complex } \mathbf{1}$$

[2] $$\mathbf{1} + N \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} R_1{-}\overset{R_2}{\overset{|}{C}}{-}\overset{R_3}{\overset{|}{C}}{-}R_4 \quad (HgX,\ N)$$

It has been established that the rate of oxymercuration is first order in both alkene and mercuric salt, but there are a number of other aspects of the reaction that are open to question. For example, the identity of the attacking mercury species is unknown in most cases. For reactions in 0.01 *M* $HClO_4$ the reaction involves the fully dissociated Hg^{2+} reagent (12), but for reactions utilizing mercuric acetate in methanol solution, the most common medium for kinetic studies (13–21), it has been proposed that a

number of possible electrophiles must be considered (14, 16). These include various acetatomercury(II) complexes (eq. 3) (16), as well as

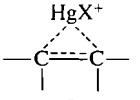
[3] $Hg(OAc)_3^-$

$$\begin{array}{ccccc} & & \uparrow\downarrow OAc^- & & \\ Hg(OAc)_2 & \overset{OAc^-}{\rightleftharpoons} & Hg(OAc)^+ & \overset{OAc^-}{\rightleftharpoons} & Hg^{2+} \end{array}$$

protonated forms of these and complexes with other ligands (14). It has been suggested that attack by $HgOAc^+$ is of primary kinetic importance (16, 22), and in agreement with this hypothesis added acetate ions usually slow the reaction (13, 14, 16, 19, 20*b*,*c*), whereas added mineral acids (14, 16, 20) increase the rate. Added acetic acid has been reported to increase the rate in some cases (16, 20*b*,*c*), and decrease it in others (13, 19, 20*a*).

There is also some disagreement as to which step in [1] and [2] is rate-limiting, as both formation of the olefin–mercury complex (12, 16, 20), and attack of the nucleophile N (usually solvent) (7, 9, 17, 23) have been proposed as the slow step in the reaction. Finally, there is sharp disagreement about the structure of the alkene–mercury(II) complex **1**.

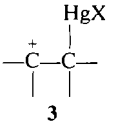
One proposal is that the complex is a rather symmetrical cyclic 'mercurinium' ion **2**. This view is endorsed in recent reviews (7–9) and



2

papers (14, 16, 17, 23). For example, the authors state "Such π-complexes were . . . called mercurinium ions. This intermediate is a commonly accepted tenet in the oxymercuration mechanism" (7); "It may well be that two polar mechanisms can operate; in one, a four-center transition state involving only the reagent and the olefin . . . while . . . a mercurinium ion or some kinetically equivalent species may be the more usual mode of reaction" (8); and "Studies of oxymercuration are generally consistent with the rapid and reversible formation of mercurinium ions" (9).

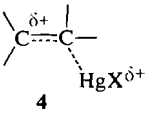
An opposing mechanistic interpretation is that oxymercuration occurs to give an unbridged open carbonium ion **3**. Recent examples of this view are "We discard the symmetrical



3

mercurinium ion in interpreting our results. We prefer the concept of electrophilic attack by the mercury species ^+HgX at the least substituted carbon atom of the double bond" (22*b*) and "oxymercuration . . . of olefins (is) considered to be electrophilic addition . . . passing through a classical carbenium ion" (24).

A viewpoint intermediate between the extremes of a symmetrical cyclic mercurinium ion (**2**) and an open β-mercuri carbonium ion (**3**) is an unsymmetrical ion (**4**) with partial charge on one carbon and on mercury (25). The positive charge in such an ion is partly delocalized onto mercury by hyperconjugation (25). It may be



4

that the energy difference between transition states **2**–**4** are small and that structural differences in the alkenes determine which is involved in each case. Other more complex ions have been proposed for some special cases (26).

Most of the discussions in the literature have tacitly assumed that the olefins under consideration are symmetrically substituted and have neglected the role of unsymmetrical substitution on the double bond. It has been pointed out (27) that unsymmetrical substitution would of necessity require mercurinium ions to be unsymmetrical, and some of the kinetic data have been interpreted in terms of such intermediates (18).

The evidence for the different formulations of the oxymercuration intermediate has been thoroughly reviewed (1–11) and it is only briefly summarized here.

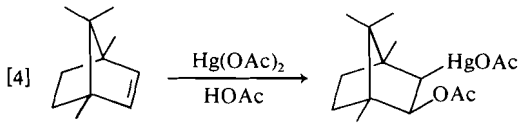
It would be anticipated that a reaction involving a bridged species would occur in an *anti* fashion, and oxymercuration usually (28–30), but not always, fulfils this expectation. The reverse reaction, deoxymercuration, also occurs in an *anti* fashion (28). Furthermore alkenes such as *tert*-butylethylene (18*b*) and 1-methylnorbornene (22*b*), which are prone to rearrangement during reactions involving carbonium ions, give unrearranged products in oxymercuration. Kinetic studies have been interpreted as

favoring a bridged intermediate (14, 16, 17, 20*a*,*b*), as have theoretical studies (25*a*,*b*, 31), and an nmr examination of stable ion complexes of Hg^{2+} and alkenes (27).

Evidence that oxymercuration involves open ions includes the fact that many strained species, such as norbornene (**6**) (32*a*), bicyclo[2.1.1]-hexene (**7**) (33), and cyclopropene (**8**) (34) add mercuric salts in a *cis* fashion. We discovered that even when there are *syn*-7 substituents in

6 **7** **8**

the norbornyl nucleus the addition still occurs *cis*,*exo*, [4] (22*b*, 32*b*), and a general correlation has been proposed that such behaviour is diagnostic of unbridged intermediates (22*b*).



Further evidence that bridging is not a dominant factor in oxymercuration comes from the comparison of the oxymercuration and arylsulfenyl halide additions to the *cis*- and *trans*-1,2-di-*tert*-butylethylenes. The latter reaction is generally accepted to involve a strongly bridged intermediate, and occurs in an *anti* fashion to each of these compounds (35). Oxymercuration however, leads to the same product from each of these isomeric alkenes (17*b*). Although the results of the oxymercurations were interpreted in terms of a bridged intermediate the contrast with the arylsulfenyl halide results strongly suggests that bridging is less significant in the former reaction.

Some authors also conclude that the kinetic results do not provide compelling evidence for bridged ions (12, 22). Others believe that an asymmetrically bridged ion is implicated by the kinetics (18). Also the investigators of the long-lived ions stated "While these observations do lend credence to those reports in which mercurinium ions have been implicated as reaction intermediates, they do not prove that mercurinium ions are present under any other set of conditions" (27).

In view of the conflicting views and contradictory experimental findings regarding the oxymercuration reaction, as well as continuing interest in this reaction (36–38), it appeared that further studies were warranted.

Previous kinetic methods applied to this reaction have not been completely satisfactory. Because of the great rate of the reaction direct kinetic measurements have been confined to the less reactive alkenes (14–16, 19, 20, 39). More recently competition methods have been utilized (17, 18, 22*a*) but these are more subject to uncertainties in interpretation, and do not allow examination of the effects of variables such as concentration, solvent, and added ions. Direct measurement by ultraviolet absorption has been applied to rates in aqueous $HClO_4$, but the reactions in this medium are so fast that no alkene more reactive than isobutene could be measured, even using stopped flow techniques (12).

It appeared highly desirable therefore to develop an ultraviolet method for measuring rates in methanol solution. It was hoped that the use of both conventional and stopped flow spectrophotometers would allow the complete range of alkene reactivities to be observed, and furthermore the rates could be compared to all of the previous kinetic studies carried out in methanol solution (13–21).

In order to probe the possible structures of the methoxymercuration transition state it was of particular interest to test the influence of a strong resonance electron-donating substituent on the reaction. We have previously found the cyclopropyl substituent is a useful probe for the examination of the transition states of electrophilic additions to alkenes (40). Accordingly this investigation deals with the development and testing of the ultraviolet method for direct measurement of methoxymercuration and the use of this method to examine cyclopropyl-alkenes. To establish the validity of the method we began with a comparison with rates obtained by the competitive method and with rates measured by direct methods which have previously been reported.

Results

Relative rate constants for methoxymercuration of alkenes have been obtained by two different methods. Pritzkow and co-workers (18) reacted a mixture of alkenes with a smaller amount of mercuric acetate and analyzed the amounts of residual olefins by gas chromatography. Bach and Richter (17) carried out the

reaction in a similar fashion, but reduced the product organomercurial with $NaBH_4$ and analyzed the resultant ethers by gas chromatography [5].

[5] 
In our work competitive rates of vinylcyclopropane (**9**), 1-methyl-1-cyclopropylethylene (**10**), 1-phenyl-1-cyclopropylethylene (**11**), and 1,1-dicyclopropylethylene (**12**) were measured relative to cyclohexene by analysis of the yields of methyl ethers. The authentic methyl ethers corresponding to Markovnikoff addition were prepared by oxymercuration–demercuration or by reaction of the alkoxides with methyl iodide. Preparative scale oxymercuration–demercurations were also carried out and in every case the product expected from Markovnikoff addition without rearrangement was isolated and identified. Relative rates were calculated from the observed relative yields of methyl ethers when equimolar amounts of two different alkenes were allowed to react with a deficient amount of $Hg(OAc)_2$.

The relative rates obtained are compiled in Table 1. The cyclopropylalkenes **9**, **10**, and **12** were very reactive and no suitable standard more than one-tenth as reactive was available. Therefore, the rates of these compounds relative to cyclohexene are subject to error. The relative rates among these three compounds were measured independently and should be more precise.

The reactivities of several compounds in methanol which had previously been examined in other laboratories were also measured as a test of the reproducibility of the method. These data are also included in Table 1, along with data for some crowded alkenes. In general the agreement between methoxymercuration rates from different laboratories is quite satisfactory, although some discrepancies exist (cf, norbornene **6**).

In order to measure directly the rate of methoxymercuration it appeared that spectral measurements using fast-mixing techniques would be most suitable. The ultraviolet spectrum of mercuric acetate in methanol (Fig. 1) is characterized by a very strong absorption but no maximum above 200 nm (at 200 nm $\varepsilon = 7000$) which decreases smoothly and becomes imperceptible near 300 nm. Gowenlock and Trotman (41) in an aside reported a maximum for mercuric acetate in ethanol at 212 nm but we do not observe this feature in either methanol or ethanol, although we did confirm the maxima they report for mercuric halides in this region.

The ultraviolet spectra of 1-methyl-1-cyclopropylethylene (**10**) and the reaction product of **10** with equimolar $Hg(OAc)_2$ are also shown in Fig. 1. Above 210 nm it may be seen that the absorptivity of the alkene and the reaction product are lower than that of $Hg(OAc)_2$. We elected to follow the reactions by the decrease in absorbance at 265 nm.

Rates were monitored at 25°C using two different Durrum D110 stopped flow spectrophotometers, and Cary 14 and 118 spectrophotometers. Standard reaction conditions (0.035 *M* $Hg(OAc)_2$, alkene, and HOAc) were adopted for most runs. In some cases a 10-fold excess of alkene was present to give pseudo first-order conditions, and lower reagent concentrations were used in some of the stop-flow runs. Within the limits of reproducibility the second-order rate constants were independent of the concentrations of $Hg(OAc)_2$ and alkene, and were about 20% lower in the presence of 0.035 *M* HOAc. Equimolar NaOAc or NaOMe decreased the rates by factors of about 5.

The end-point absorptions of many of the reactions, especially for alkenes with allylic hydrogens, were unstable and drifted continually downward. For these cases the rate constants were calculated using estimated infinity points or by the Guggenheim method. Excellent linear rate plots for 1–2 half-lives were generally obtained by second-order or pseudo first-order calculations as appropriate. However the reproducibility of the rate constants was not good, despite extensive efforts at purification of reagents and solvents, and degassing of the solutions. The failure to reduce some of the average deviations below $\pm 20\%$ eliminated the possibility of a more detailed study of the effect of reaction variables. However relative reactivities

of different substrates were consistently reproduced and the rate constants presented in Table 2 appear reliable for that purpose.

In the case of the isomeric 1,2-dicyclopropylethylenes an extremely rapid increase in uv absorbance was observed, so rates of addition for these substrates are not reported.

Discussion

The relative rate constants obtained for alkenes by the direct and competitive methods are compared in Table 1. These are in reasonable agreement but some deviations are apparent. One serious difficulty with the competitive rates is that the reactions do not proceed quantitatively to single products, and often several unidentified peaks are visible in the gas chromatograms.

[6] $$-CH_2CH{=}CH- \xrightarrow{Hg(OAc)_2} -CHOAcCH{=}CH-$$

Allylic oxidation (eq. 6), alkene exchange, and vinyl mercurial formation are well known examples of side reactions that occur in oxymercurations (42–44). The lack of agreement between some of the competitive rates from different laboratories is probably a consequence of these and other experimental problems.

The direct rate measurements suffer from the fact that their degree of reproducibility is only fair, and they may also be affected by side reactions. However, we believe the rate constants obtained by this method are reasonable indicators of the relative reactivities of the alkenes as the differences in reactivity were reproducible and were quite large in some cases. Qualitative agreement of rates obtained by competitive and direct methods lends considerable confidence that these reactivities can be reliably used for mechanistic interpretations.

In the introduction the possibility of reversi-

bility of the different steps of the reaction was raised. The results available do not allow the assignment of the individual rate constants in [1] and [2]. In the discussion that follows it is assumed that the observed rates reflect the stability of the intermediate ion, so that k_{obs} is proportional to k_1 in [1]. A consistent interpretation does emerge on the basis of this assumption, but a detailed analysis of the kinetics, including the various mercury electrophiles (eq. 3), remains an unsolved problem.

Protonation is the best example of a reaction which proceeds with attack on one carbon of a double bond to form an open carbonium ion, and we have thoroughly examined the effects of structure upon reactivity in this case (40). The most clear-cut example of an electrophilic addition proceeding through rate-determining formation of a bridged three-center ion is sulfenyl halide addition to alkenes, and the structural effects on this reaction have also been well documented (45). Therefore the effect of structure on the rate of oxymercuration may be compared to these two reactions as a suitable guide to the mechanism of this reaction. The relevant data are compiled in Table 2.

It is apparent from Table 2 that there is not a direct correlation of the oxymercuration rates with the rates of hydration or of sulfenyl halide addition. However, inspection of the individual data does reveal some salient structural features that affect the rates. Most noticeably ethylene is extremely unreactive in hydration relative to 1-hexene or cyclohexene, but these three alkenes are of comparable reactivity in oxymercuration or sulfenyl halide addition. This rate comparison is what would be expected if protonation gave the very unstable open ethyl cation (eq. 7), but the other electrophiles led to bridged structures (eq. 8).

[7] $$CH_2{=}CH_2 \xrightarrow{H^+} CH_3\overset{+}{C}H_2$$

[8] $$CH_2{=}CH_2 \xrightarrow{E^+} CH_2{=}\overset{E^+}{CH_2}$$

(E^+ = HgX^+ or ArS^+)

On the other hand oxymercuration of the vinylcyclopropanes *c*-PrCR=CH_2 are accelerated relative to 1-hexene by factors of about 10^3, whereas the corresponding sulfenyl halide additions only increase by factors of 5 to 23. In these cases the behavior of the oxymercuration reactions resembles the hydrations much more than the sulfenyl halide additions and supports the formation of open ions for hydration and oxymercuration [9]. The more than 10^3 greater

[9] *c*-PrCH=CH_2 $\xrightarrow{Hg(OAc)^+}$ *c*-Pr$\overset{+}{C}$HCH_2HgOAc

reactivity of 2-cyclopropylpropene relative to the isomeric 1-cyclopropylpropenes strongly implicates an open ion in the former case.

In addition to these effects it is also apparent that steric factors are much more significant in the case of oxymercurations than in the other reactions. Thus the *tert*-butylethylenes show decreased reactivities in oxymercuration, as do the 1,2-disubstituted alkenes.

As pointed out in the introduction oxymercuration of the isomeric *cis*- and *trans*-1,2-di-*tert*-butylethylenes leads to the same product, a result which was interpreted in terms of bridged ions (17). However we believe the fact that sulfenyl halide additions to the same alkenes proceeds with *anti* attack in each case to give isomeric products indicates that bridged ions are involved in the latter case and a different mechanism in the former. The oxymercuration product was assigned *threo* stereochemistry by ^{1}H nmr but the *erythro* isomer was not available for comparison. The *threo* product could be formed by *syn* addition to a common open ion with *anti tert*-butyl groups formed directly by attack of the electrophilic mercury species on the *trans*-olefin and attack on the *cis*-olefin followed by rotation around the central C—C bond.

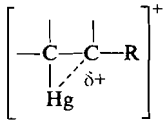
The overall picture that emerges is that the oxymercuration occurs by either open or bridged ions depending upon the particular substitution pattern. If strongly resonance electron-donating substituents are present then open ions are favored, and in the absence of electronic factors that would stabilize open carbonium ions bridging occurs. An alternative way of viewing the situation is in terms of hyperconjugatively stabilized ions such as **4** in which the degree of hyperconjugative electron donation depends on the electron demand placed on the C—Hg bond. This latter interaction in the intermediate would also give some bias towards *anti*-addition without rearrangement, as is frequently observed. We agree with the view (27) that a 'continuum' of ions is involved, and believe that the ion from ethylene resembles the bridged extreme and that the ion from **12** resembles the open ion structure.

The rapid increase in absorbance observed in the reaction of the 1,2-dicyclopropylethylenes indicates that some other reaction is occurring instead of addition to the double bond. The probable pathway is cleavage of the cyclopropane ring by electrophilic attack of mercury (eq. 10). This is a well documented reaction that

[10] 
occurs under rather mild conditions (46) that should be particularly facile in this case because of the very stable carbonium ion intermediate that can be formed (eq. 10). An alternative route involving rate-determining attack of electrophilic $HgOAc^+$ on the double bond and then ring opening would be expected to be much slower, inasmuch as the 1,2-dicyclopropylethylenes are slower than the 1-cyclopropylpropenes in hydration and of about the same reactivity in arylsulfenyl halide addition.

We were successful in analyzing rates of hydration in terms of substituent parameters (40) so it was of interest to test this approach for oxymercuration.

There have been several attempts to define the rate-determining transition state by correlation of the rates with substituent parameters. Halpern and Tinker (12*a*) plotted log k vs. σ^* and reported an 'excellent' correlation for monosubstituted alkenes. They interpreted the plot as "implying a high degree of positive charge localization (approaching carbonium ion character), in the transition state, on the carbon adjacent to the substituent R, i.e."



Kreshkov *et al.* (16), also correlated rates in terms of σ^* parameters but interpreted their results in terms of a cyclic mercurinium ion intermediate.

Charton and Charton (47) correlated part of the data of Halpern and Tinker with the equation $\log k/k_0 = \alpha\sigma_I + \beta\sigma_R$ and found an 'excellent' fit but stated "We conclude therefore that . . . the reaction . . . proceeds by way of the bridged intermediate."

Finally, Pritzkow and co-workers (18*b*) examined the correlation of the rates of methoxymercuration of 20 alkenes with σ^* and E_S parameters, and concluded that the transition state for the addition resembled an unsymmetrically bridged mercurinium ion.

We have examined the ability of each of these previously published correlations to accommodate the data for the cyclopropylalkenes, and in each case there is a very large deviation from the predicted rate. For example, the treatment of Halpern and Tinker (12*a*) predicts that vinylcyclopropane will have a reactivity of 0.4

relative to 1-butene in water, whereas the actual rate (in methanol) relative to 1-hexene is 400. The Charton correlation (47) derived from the same data also predicts the rate ratio as 0.4. The Pritzkow equation (log $k = a + \rho^*\sigma^* + \delta E_S$) (18*b*) predicts rates relative to cyclohexene of 2.2 and 4.9 for *c*-PrCH=CH_2 and *c*-PrCMe=CH_2, respectively, compared to the observed values of 10^3. Insufficient information was given in the work of Kreshkov and co-workers (16) to test for the quantitative agreement with the experimental results on vinylcyclopropanes, but qualitatively their treatment using σ^* is also unsatisfactory.

One reason for the inadequacy of these previous correlations is their failure to include the σ_p^+ parameter to account for the strong resonance electron donation by cyclopropyl. We were able to obtain a better correlation of the rates of 1,1-disubstituted alkenes with the equation log $k/k_0 = \rho\sum\sigma_p^+ + a\sum E_S$, but the correlation coefficient ($R = 0.64$) was not satisfactory.

The complexity of the steric interaction in oxymercuration contributes to the trouble in effecting a good correlation. Pritzkow, and co-workers used the multiparameter equation log $k/k_0 = \rho_1^*\sum\sigma_1^* + \rho_2^*\sum\sigma_2^* + \delta_2\sum E_{S1} + \delta_2\sum E_{S2}$ to account for the reactivities of tetrasubstituted alkenes (18*b*). This equation takes into account the unequal electronic and steric effects at the two alkene carbons due to the unsymmetrical structure of the transition state. The fact that the ratio k_Z/k_E for oxymercurations ranges between 2 and 8 (11, 18*c*, 22*a*) shows that even a more complicated equation would be required to account for this effect. However, this approach appears to us to have exceeded the limits of usefulness of the substituent parameter method and we have not pursued it further.

In summary the rates of the oxymercuration reaction show a dependence on structure that support a variable geometry for the rate-determining transition state and the intermediate as the substrate changes. At one extreme is the case of ethylene, whose rate determining transition state may best be represented as bridged, and at the other is 1,1-dicyclopropylethylene, which leads to a species closely resembling an open ion.

Experimental

Cyclopropylalkenes were obtained as in ref. 40*b*,*c*. Other alkenes were commercial samples, purified where necessary by gas chromatography before use. Mercuric acetate was crystallized twice from MeOH containing a little HOAc to give material completely soluble in MeOH under the kinetic conditions mp 175–177°C, lit (48) 178–180°C. Methanol was distilled from $Mg(OMe)_2$ (49). Nuclear magnetic resonance spectra were run on a Varian T60 instrument with tetramethylsilane as an internal standard. Gas chromatograph separations (glpc) were carried out using a Varian Aerograph 2440 flame ionization instrument, and 1420 and 920 thermal conductivity instruments.

Authentic methyl ethers for use as standards in the competition experiments were prepared by preparative oxymercuration–demercuration (50) of cyclohexene 3-hexene, 4-octene, norbornene, *tert*-butylethylene, and 1-cyclopropyl-1-phenylethylene. Methyl ethers of 2-octanol, cyclopropylmethylcarbinol, dicyclopropylmethylcarbinol, and cyclopropyldimethylcarbinol were prepared by treatment of the alcohols in dry THF with NaH followed by the addition of excess MeI and reflux. After work-up the ethers prepared by both methods were isolated by glpc and the structures confirmed by their nmr spectra.

Relative Rates by Competition

The conditions were designed to duplicate a published procedure (17*a*). Ten millilitres of a methanol solution, 0.33 *M* in each of two olefins, was stirred in a round bottom flask with a magnetic stirrer at room temperature and 10 ml of a 0.033 *M* solution in mercuric acetate was added in one portion. After 10 min 10 ml of a solution 3 *M* in NaOH and 0.5 *M* in $NaBH_4$ was added and the solution was stirred for 30 min. For the cyclopropylalkenes 2 ml of each solution was used. In all cases the solutions were freshly prepared to prevent loss of alkenes and deterioration of the mercuric acetate. The solution was suction filtered through Celite with the receiver in a dry ice bath. The filtrate was partitioned between water and ether and the ether layer was washed with saturated NaCl, dried over Drierite, concentrated to 2 ml by slow distillation through a Vigreaux column, and the relative amounts of the product ethers formed were determined by glpc. Relative rates were calculated from the peak areas using the measured glpc response factors from authentic samples.

Direct Rate Measurements

The slower rates were monitored by observing the decrease in absorbance at 265 nm using Cary 14 or 118 instruments. In a typical experiment 1.5 ml of a fresh MeOH solution 0.07 *M* in both alkene and acetic acid equilibrated at 25°C was injected into 1.5 ml of 0.07 *M* $Hg(OAc)_2$ in MeOH equilibrated at 25°C in a 1 cm cell in a thermostatted cell compartment and the absorbance change was monitored vs. time. When NaOMe or NaOAc were also present these were contained in the alkene solution. For pseudo first-order runs the alkene concentration was increased 10-fold.

More rapid reactions were followed using a Durrum D110 stopped flow spectrophotometer. The cyclopropyl alkenes were run at final concentrations between 0.005 and 0.035 *M*, and the others were measured at final concentrations of 0.035 *M*. The kinetic points were measured from the oscilloscope traces and used to calculate the second-order rate constants.

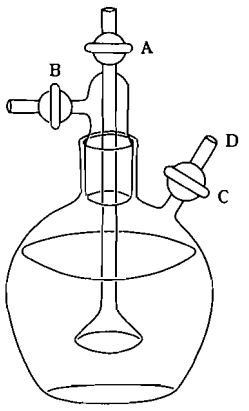


FIG. 2. Flask for dissolving ethylene in solvents. The flask is stirred magnetically and ethylene is passed through A and bubbled through the frit and vented at B. After 30 min A and B are closed, stirring is halted, and the flask left undisturbed for 15 min. Then the long needle of a syringe is inserted through a septum at D and through the bore of C into the solution. A pressure of gas is applied through B forcing the syringe to fill.

Rate constants obtained under pseudo first-order conditions (at least a 10-fold excess of alkene over mercuric acetate) were calculated graphically from plots of log $(A_0 - A)/(A_0 - A_\infty)$ vs. time. These were converted to second-order rate constants by division by the initial alkene concentration. Rate constants obtained under second-order conditions (equimolar mercuric acetate and alkene) were calculated from the formula $kt = (A_0 - A)/(A - A_\infty)c$ where c is the reactant concentration.

In the reactions of the 1,2-dicyclopropylethylenes the absorbance at 265 nm of solutions 0.035 M in each reagent on mixing immediately increased off the scale, whereas at 273 nm (with the *trans* olefin) the absorbance immediately increased from 0.5 to 1.3, then successively decreased for 90 min, increased again, and then began another decrease.

A solution of ethylene in MeOH was prepared by bubbling the gas into the stirred solution for about 30 min at 25°C. Samples were removed by applying a slight pressure of ethylene to the solution to fill the transfer syringe. These samples were either analyzed for ethylene content by injection into standard Br_2 solutions or were injected into the uv cell containing a $Hg(OAc)_2$–HOAc solution for kinetic determinations. Ethylene concentrations of about 0.09 M were obtained in this way. The apparatus for these transfers is shown in Fig. 2.

Usually excellent linearity in the rate plots was followed for 1–2 half-lives. However the reproducibility of the rate constants from day to day was sometimes erratic, and could not be improved despite strenuous attempts at degassing of the solutions and purification of the reagents. At least two and usually many more rate determinations were made on each alkene, with average deviations of as much as ±20%.

Acknowledgements

Financial support by the National Research Council of Canada and Undergraduate Research Fellowships from the Physical Sciences Division, Scarborough College, are gratefully acknowledged. We thank Professor T. G. Traylor, who first studied the kinetics of oxymercuration in methanol by uv, for providing details of his unpublished work.

Reçu le 31 janvier 1977

ALAIN GERMAIN, JEAN-LOUIS PASCAL et JACQUELINE POTIER. Can. J. Chem. **55**, 3096 (1977).

L'étude des réactions de formation de l'ion diacétylacétylium à partir de CH_3COX (X = Cl ou Br) et des acides de Lewis $AlCl_3$, $AlBr_3$ et $GaCl_3$ montre que l'anion formé est un tétrahalogénométallate. Dans le cas du tétrachloroaluminate de diacétylacétylium le cation est un monomère avec une liaison hydrogène intramoléculaire à potentiel à double minimum: ν O—H—O = ν O—D—O = 1400 cm^{-1}; *d* O—O = 2.48 Å. Un comportement identique s'observe pour le tétrabromoaluminate mais est plus complexe dans le cas du tétrachlorogallate.

ALAIN GERMAIN, JEAN-LOUIS PASCAL, and JACQUELINE POTIER. Can. J. Chem. **55**, 3096 (1977).

The study of the reaction of formation of the diacetoacetylium ion from CH_3COX (X = Cl or Br) and the Lewis acids $AlCl_3$, $AlBr_3$, and $GaCl_3$ shows that the counterion is always the tetrahalogenometallate. In the solid tetrachloroaluminate the cation is a monomer with a double minimum type of intramolecular hydrogen bond: ν O—H—O = ν O—D—O = 1400 cm^{-1}; *d* O—O = 2.48 Å. An identical behaviour is observed with the tetrabromoaluminate, but the structure of the diacetoacetylium tetrachlorogallate is more complicated.

Introduction

Les intermédiaires d'acylation de Friedel et Crafts ont fait l'objet de nombreuses études, en particulier spectroscopiques (1, 2) (ir, rmn, esca, rayons X) et théoriques (3, 4). Ainsi, il est bien établi que le mélange d'un halogénure d'acide carboxylique avec un acide de Lewis conduit, suivant la nature des espèces en cause et les conditions expérimentales, à deux types de composés: soit un composé de coordination (I), soit un sel d'acylium (II).

Récemment, avec le chlorure d'aluminium comme acide de Lewis, en présence d'un excès de chlorure d'acétyle, Germain *et al.* (5) ont observé que l'ion acétylium (Ac), initialement formé, évolue lentement pour conduire au cation "trimère": l'ion diacétylacétylium (DAA) (6).

$$3CH_3CO^+ \rightarrow (CH_3CO)_2CHCO^+ + 2H^+$$
$$\text{(Ac)} \qquad\qquad \text{(DAA)}$$

Les deux cations (Ac) et (DAA) sont caractérisés par des fréquences ν CO bien distinctes: 2300 cm^{-1} pour (Ac), 2200 cm^{-1} pour (DAA).

Les auteurs ont proposé pour (DAA) la forme énolique chélatée (fig. 2), l'abaissement de la fréquence ν CO de 100 cm^{-1} est ainsi expliqué par la participation importante de la forme mésomère céténique.

L'hypothèse de la structure énolique se trouve

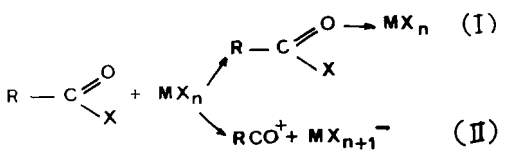

FIGURE 1

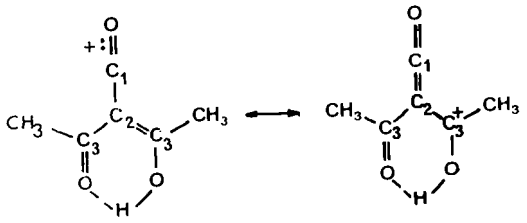

FIGURE 2

confirmée par la rmn du ^{13}C, qui montre l'absence d'hydrogène sur le carbone C_2 du carbonyle (6). Pulfer et Whitehead (7), à partir de calculs CNDO ont aussi adopté cette structure énolique plane.

Cependant, bien que la forme monomère chélatée représente la structure énolique la plus simple, aucun résultat ne permet d'éliminer la possibilité de formation de dimères ou polymères avec liaison hydrogène intermoléculaire selon les modèles de la fig. 3.

Une étude par spectroscopie de vibration doit permettre de résoudre cette ambiguité et de préciser la force et la nature de la liaison hydrogène (8–10). En plus de ce problème il paraît intéressant de rechercher le type de l'anion antagoniste en fonction de la nature de l'acide de Lewis (MX_3) et de l'halogénure d'acétyle utilisé. Ceci doit permettre également de généraliser la réaction de trimérisation et de préciser le rôle de l'acide de Lewis choisi dans le déroulement de cette réaction.

Nous analyserons d'abord les synthèses des différents sels et simultanément, nous caractériserons les différents anions présents à partir des données de la bibliographie (11, 13, 14) et ensuite nous étudierons le cation diacétylacétylium. Sur la fig. 4 nous reproduisons les spectres ir obtenus dans ce travail.[1]

Analyse des réactions et caractérisation des anions formés

(a) $CH_3COCl + AlCl_3$

Synthèse

Le produit solide est obtenu comme précédemment (5). Rappelons que l'addition de chlorure d'aluminium à un large excès de chlorure d'acétyle (rapport molaire > 3) conduit à la formation instantanée de l'ion acétylium (ν CO = 2300 cm^{-1}) suivie par l'apparition lente de l'ion diacétylacétylium (ν CO = 2180 cm^{-1}) (fig. 5*a*).

Après 6 h à température ambiante, l'ion acétylium est pratiquement totalement transformé. Le sel de diacétylacétylium est alors précipité par addition de dichloroéthane.

Caractérisation de l'anion

A priori deux anions sont possibles, $AlCl_4^-$ ou $Al_2Cl_7^-$. L'analyse des spectres infrarouge du sel cristallisé enregistrés à température ambiante est susceptible de caractériser ces anions. En effet, Manteghetti (11) a montré que la principale différence entre les spectres des ions $Al_2Cl_7^-$ et $AlCl_4^-$ est l'existence dans ceux du premier d'une bande à 300 cm^{-1}: ν_{as} AlClAl. Sur le spectre (fig. 4*a*) on note l'absence de cette bande ce qui permet de rejeter l'existence de $Al_2Cl_7^-$ dans ce sel. Par contre la présence des bandes intenses à 490 et 180 cm^{-1} sont compatibles avec la présence de $AlCl_4^-$, elles correspondent aux vibrations ν_3 et ν_4 (11). *Le sel obtenu est donc le tétrachloroaluminate de diacétylacétylium.*

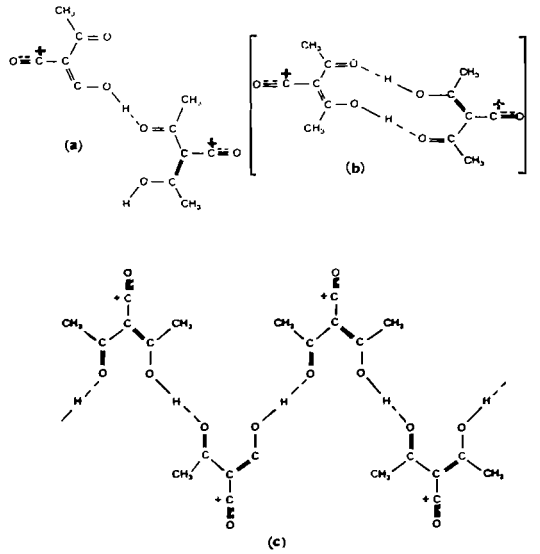

FIG. 3. (*a*) Dimère ouvert avec une seule liaison intramoléculaire. (*b*) Dimère fermé avec deux liaisons hydrogène intermoléculaire. (*c*) Polymère en chaînes.

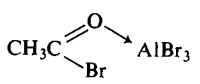
(b) $CH_3COBr + AlBr_3$

Synthèse

Bien que réalisée dans des conditions expérimentales identiques à celles des chlorures, la réaction se déroule différemment. La première espèce qui apparaît sur le spectre infrarouge (fig. 4*c*) est le composé de coordination sur l'oxygène



dont la vibration ν CO se situe à 1640 cm^{-1}.

Après 8 h à température ambiante la formation des ions acétylium et diacétylacétylium est très faible. Au bout de 5 jours, la formation de

[1]Malheureusement il n'a pas été possible d'enregistrer de spectres Raman par suite de diffusion parasite.

l'ion diacétylacétylium est nette mais loin d'être totale et même après 10 jours, il reste une grande proportion de composés de coordination. (fig. 4*c*, 4*d*). En ce qui concerne l'ion acétylium sa présence est toujours très faible. Pourtant ce cation doit être formé intermédiairement, il faut donc admettre que dans ce cas l'ion acétylium se forme lentement et se trimérise relativement rapidement (fig. 5*b*), comportement différent de celui observé précédemment. L'explication de ce phénomène peut être trouvée dans la différence de stabilité des composés de coordination du type $L \rightarrow AlX_3$. En effet, pour un même ligand L, le composé formé avec le bromure d'aluminium est généralement plus stable que celui formé avec le chlorure (12). Dans ce travail, cette différence est certainement accentuée du fait que la base est aussi un bromure. Il est, de plus, raisonable de penser que l'oxygène de l'halogénure d'acétyle est plus basique dans le cas du bromure que dans celui du chlorure.

Par évaporation sous vide de l'excès de bromure d'acétyle ou par addition de solvants, aucune cristallisation ne se produit.

Caractérisation de l'anion

Comme dans le cas du dérivé chloré deux anions peuvent être envisagés a priori: $AlBr_4^-$ et $Al_2Br_7^-$. Cependant, la bande observée à 400 cm^{-1} se situe à une fréquence trop faible pour correspondre à la vibration de valence des groupes $AlBr_3$ terminaux de $Al_2Br_7^-$ (11) et de plus, nous ne retrouvons pas dans les spectres de bandes entre 280 et 350 cm^{-1} (fig. 4*c*, 4*d*) caractéristiques des vibrations ν_s et ν_{as} AlBrAl. L'anion est donc, dans ce cas aussi, le plus simple c'est à dire $AlBr_4^-$. La bande large à 400 cm^{-1} correspond à ce qui est attendu pour la vibration triplement dégénérée ν_3 de cet anion. *Le sel obtenu est donc le tétrabromoaluminate de diacétylacétylium.*

(c) $CH_3COCl + GaCl_3$

Synthèse

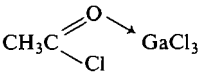
Comme avec le chlorure d'aluminium, l'ion acétylium (ν CO = 2300 cm^{-1}) se forme rapidement, suivi immédiatement de l'ion diacétylacétylium (ν CO = 2180 cm^{-1}). Après 6 h à température ambiante la trimérisation est complète. Un liquide visqueux est alors obtenu après évaporation sous vide de l'excès de chlorure d'acétyle.

Caractérisation de l'anion

Dans le domaine de fréquence de l'anion, de profondes modifications du spectre se produisent selon que l'ion acétylium est présent ou non (fig. 6*a*, 6*b*).

Lorsque la réaction de trimérisation est totale (fig. 6*a*) nous relevons dans ce domaine la présence d'une bande à 380 cm^{-1}, mais constatons l'absence de bandes vers 270 cm^{-1} (ν_{as} GaClGa). Dans ce cas, comme pour les sels d'aluminium nous concluons à la formation de l'anion le plus simple $GaCl_4^-$ (13). *Le sel de diacétylacétylium obtenu est donc un tétrachlorogallate.*

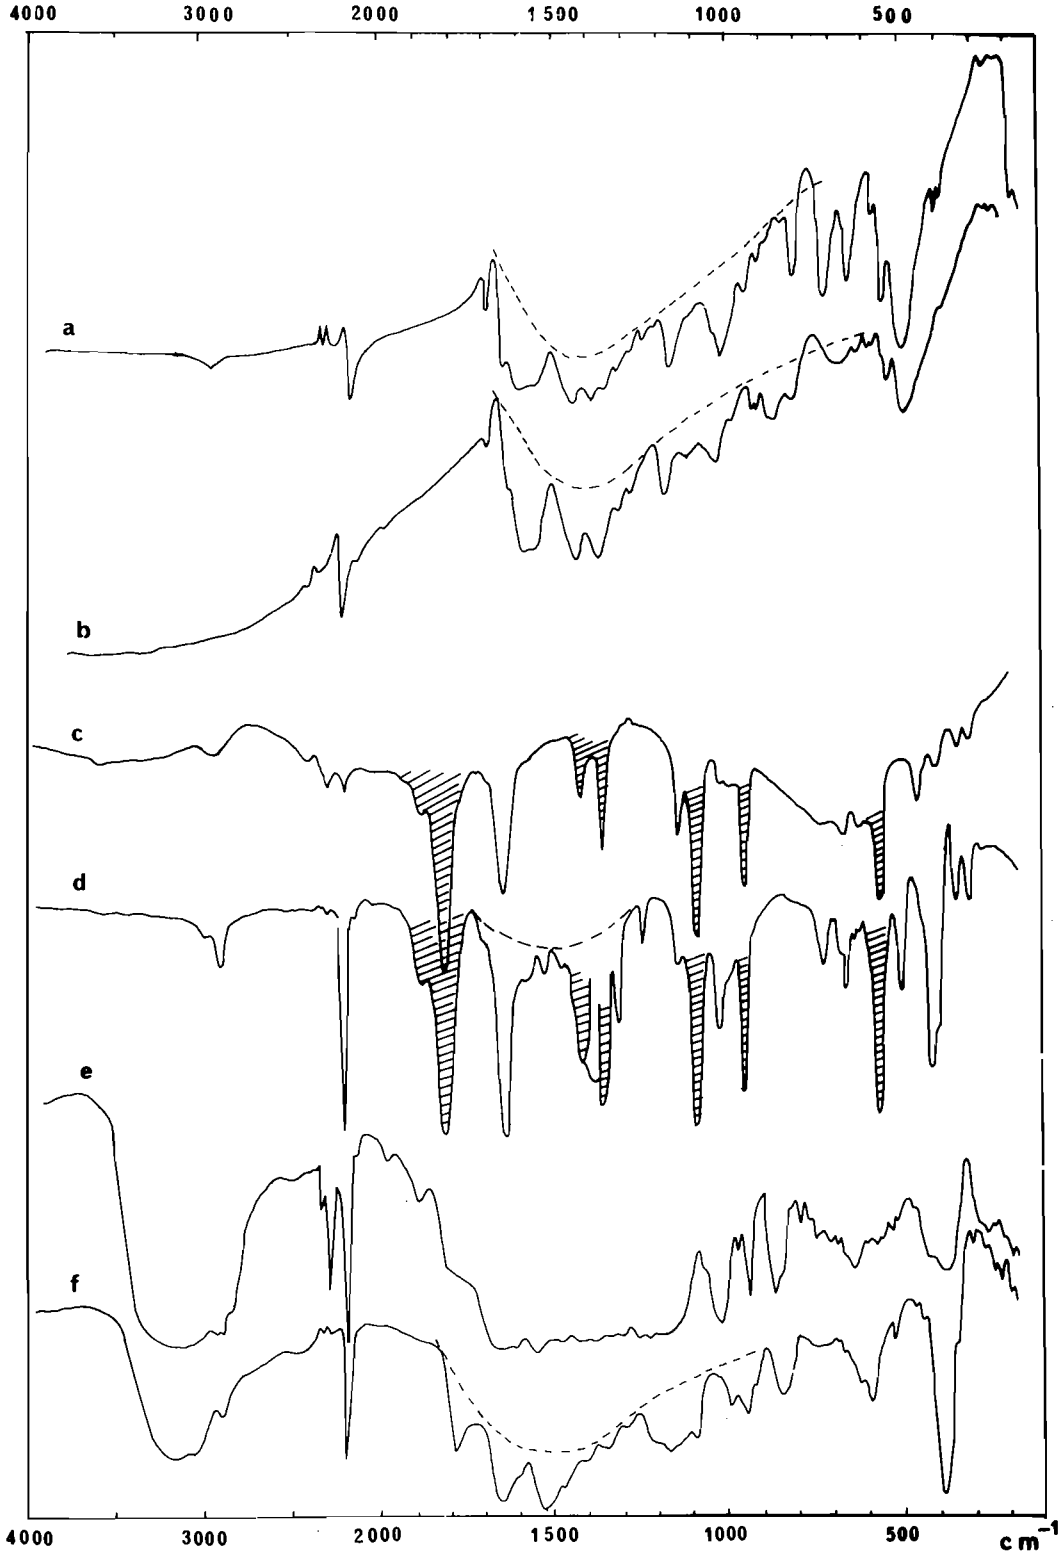
Par contre, lorsque le monomère et le trimère coexistent (ν CO à 2300 et 2200 cm^{-1}), le spectre est différent (fig. 6*b*): la bande à 380 cm^{-1} (ν_3 $GaCl_4^-$) éclate en plusieurs composantes et deux nouvelles bandes moyennement fortes apparaissent à 280 et 255 cm^{-1}. Si l'éclatement ν_3 $GaCl_4^-$ peut être dû à la formation d'un composé de coordination



un tel complexe ne peut expliquer l'apparition des bandes à 280 et 255 cm^{-1} (14). Ces bandes sont analogues à celles observées pour $Ga_2Cl_7^-$ (15) (fig. 6*c*).

Rappelons qu'elles ont été attribuées respectivement aux vibrations ν_{as} et ν_s du pont GaClGa, l'abaissement de la fréquence ν_s de 20 cm^{-1} a déjà été observé pour KGa_2Cl_7 à l'état fondu (250 cm^{-1}) (15*b*). Ceci permet d'envisager que l'anion antagoniste du cation acétylium est $Ga_2Cl_7^-$. On est apparemment en contradiction avec l'observation par analyse thermique du composé solide du type 1–1 (F = 86°C) (16), ainsi qu'avec la détermination de la structure aux rayons X du composé $CH_3CO^+GaCl_4^-$ (17). Toutefois, en solution il n'est pas illogique d'observer $CH_3CO^+Ga_2Cl_7^-$

FIG. 4. Spectres ir. (*a*, *b*) Tétrachloraluminate de diacétylacétylium solide (poudre), normal (*a*) et totalement deutérié (*b*). (*c*, *d*) Solutions de bromure d'aluminium dans du bromure d'acétyle après 8 h (*c*) et 10 jours (*d*). (Les bandes hachurées appartiennent au bromure d'acétyle en excès.) (*e*, *f*) Mélanges de chlorure d'acétyle et chlorure de gallium après évaporation de l'excès de chlorure d'acétyle à 2 stades différents de l'avancement réactionnel (20 min (*e*) et 6 h (*f*)).



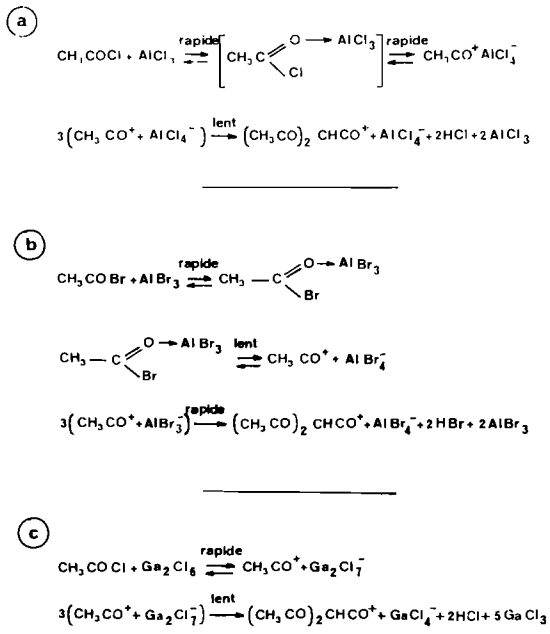


FIGURE 5

car Mascherpa-Corral (15*b*) a montré que l'existence d'ions condensés $Ga_2X_7^-$ en solution est beaucoup plus générale que dans l'état cristallin et Waddington et coll. (18) ont identifié par spectroscopie infrarouge l'existence du composé similaire $CH_3CO^+Al_2Cl_7^-$.

Le fait que l'anion associé à l'ion diacétylacétylium soit $GaCl_4^-$ est en accord avec la plus grande stabilité du cation trimère qui ne nécessite pas un anion de charge très délocalisée.

Structure de l'anion diacétylacétylium

Nous avons déjà écrit que la forme énolique de l'ion diacétylacétylium permettrait d'envisager plusieurs types de composés, suivant la nature de la liaison hydrogène.

Afin de préciser la structure de ce cation nous allons analyser plus en détails les spectres infrarouge des composés obtenus ainsi que ceux de composés énoliques voisins comme le diacétylacétate d'éthyle (DAAE) et l'acétylacétone (AA), en se référant, pour ce dernier, au travail de Nakamoto (19).

La nature de la liaison hydrogène sera analysée pour les trois sels synthétisés, mais ce n'est que pour le tétrachloroaluminate de diacétylacétylium, seul composé cristallin isolé, que nous proposerons une attribution plus complète du spectre.

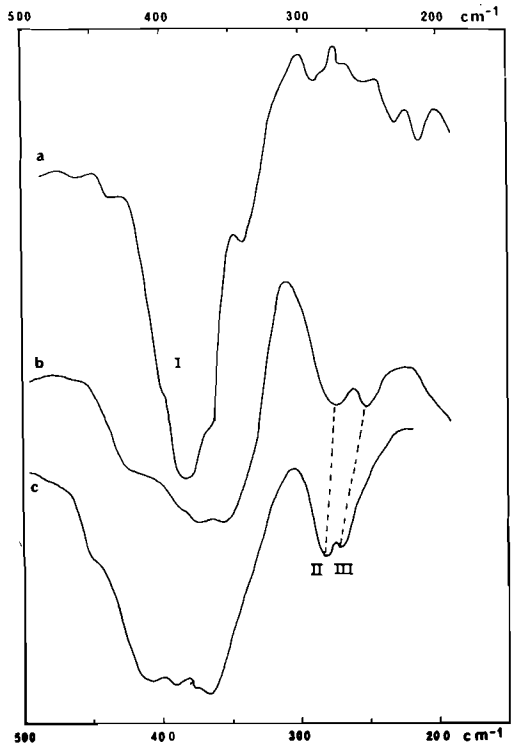

FIG. 6. Spectre ir dans la région des basses fréquences des dérivés du gallium. (*a*) Tétrachlorogallate de diacétylacétylium. (*b*) Mélange avant la formation complète de l'ion diacétylacétylium. (*c*) Heptachlorodigallate de potassium solide (avec la permission de Mme D. Mascherpa-Corral, Laboratoire des Acides Minéraux, Montpellier). I: ν_3 $GaCl_4^-$. II et III: ν_{as} et ν_s GaClGa.

Etude de la liaison hydrogène

Sur la fig. 7 sont représentés les spectres de DAAE liquide (*a*), en solution dilué dans CCl_4 (*b*) et deutérié sélectivement sur le proton énolique (*c*). Ces spectres sont semblables à ceux des différents tétrahalogénométallates de diacétylacétylium (fig. 4). Mis à part le spectre du sel de gallium (fig. 4*f*) on note en particulier, l'absence de forte absorption autour de 3000 cm^{-1}. Ce fait semble indiquer que la vibration de valence v OH dans les divers composés est perturbée par une liaison hydrogène. En 1966 Nakamoto (19) a étudié l'acétylacétone, composé voisin. Les spectres reproduits par cet auteur sont comparables à ceux observés dans ce travail, notamment absence d'absorption autour de 3000 cm^{-1}, Nakamoto positionne v OH à 2750 cm^{-1}. Cependant l'intensité de cette bande est très faible. Par contre on relève sur les différents spectres une absorption large autour de

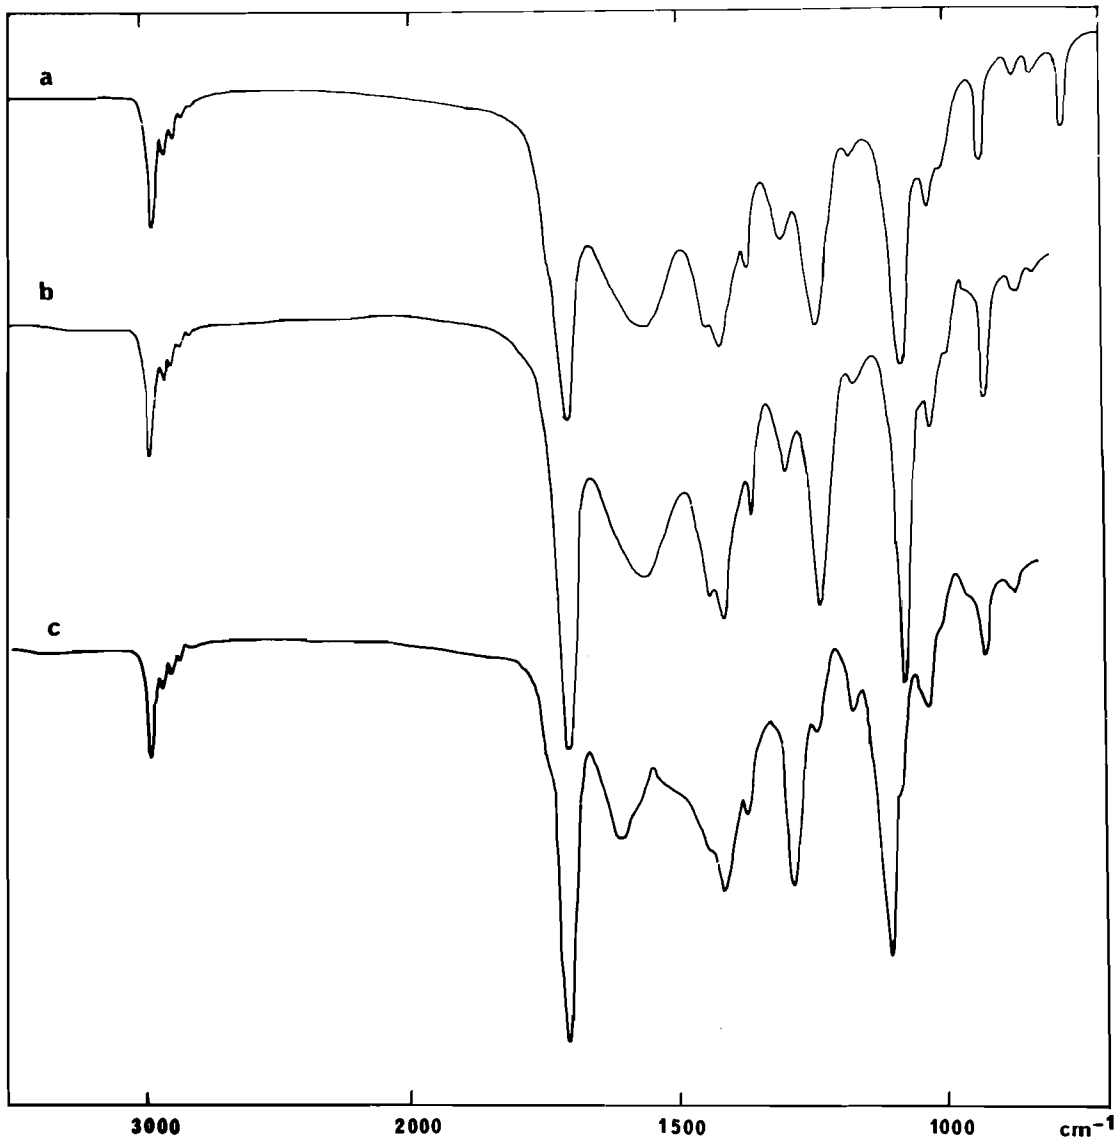

FIG. 7. Spectres ir de $(CH_3CO)_2CHCO_2C_2H_5$. (*a*) Liquide pur. (*b*) 0.2 *M* dans CCl_4. (*c*) $(CH_3CO)_2$-$CDCO_2C_2H_5$ 0.2 *M* dans CCl_4.

1500 cm^{-1} caractéristique d'une liaison hydrogène de forte (*d* O—O = 2.50 Å) liaison plus compatible avec la géométrie de cette molécule que celle déduite de l'attribution de Nakamoto (2.65 Å).

Pour notre part, quelque soit le composé étudié à l'exception du sel de gallium nous n'observons pas d'absorption sensible à la deutériation au-dessus de 2000 cm^{-1} qui puisse être attribué à la vibration ν OH. Par contre nous relevons une bande très large centrée vers 1400 cm^{-1} attribuable à la vibration ν OHO d'une liaison hydrogène forte. L'absence de déplacement par deutériation est en accord d'après Novak (10) avec l'existence d'une liaison hydrogène avec un potentiel à double minimum et une distance O—O de 2.48 Å. Cette valeur est parfaitement compatible avec la distance de 2.46 Å calculée pour un modèle d'ion diacétylacétylium plan possédant des

angles C_2—C_3—O de 120° et des longueurs de liaison C_1—C_2 comprises entre celles d'une simple et d'une double liaison (1.42 Å).

Cette constatation est donc tout à fait favorable à l'existence d'une liaison hydrogène intramoléculaire forte (9, 10, 20). Le seul argument défavorable est que, généralement la vibration ν OH d'une liaison hydrogène intramoléculaire est peu visible en infrarouge; toutefois, dans le cas des maléates acides, Hadzi[2] a très récemment montré la présence de la bande de vibration ν OH de faible intensité. De plus dans le cas de DAAE, on observe aussi bien sur le spectre du liquide pur que sur celui de la solution dans CCl_4 (0.2 *M*), une absorption large centrée à 1520 cm^{-1}. Puisque cette bande est insensible à la dilution on peut admettre *qu'elle prouve l'existence d'une liaison hydrogène intramoléculaire et non intermoléculaire.*

En ce qui concerne le spectre du tétrachlorogallate, le fait le plus marquant est la coexistence de deux bandes ν OH l'une centrée à 3200 cm^{-1} caractéristique d'un hydroxyle libre ou très faiblement lié, l'autre centrée vers 1500 cm^{-1} caractéristique d'une liaison hydrogène forte. Notons aussi la présence d'une bande à 1790 cm^{-1} attribuable à un carbonyle pratiquement libre.

Deux hypothèses peuvent expliquer ces faits; soit l'existence d'une forme dimère ouvert possédant ainsi un OH et un CO pratiquement libre[3] et un OH et un CO fortement liés; soit un équilibre conformationnel en phase liquide entre la forme liée intramoléculairement et la forme libre. Bien que la force de la liaison hydrogène soit un argument thermodynamique défavorable à l'existence d'un tel équilibre, rien ne permet de conclure définitivement.

Outre la vibration ν_{as} OHO qui traduit le mouvement du proton le long de l'axe O—O toute liaison hydrogène conduit à l'existence de deux vibrations de déformation et d'une autre vibration de valence: ν_s OHO. Cette dernière qui appartient au domaine des basses fréquences n'est généralement visible qu'en Raman. Les deux déformations δ OH et γ OH sont sensibles à la deutériation et à la force de la liaison hydrogène: plus la liaison est forte, plus leurs fréquences sont élevées. Dans le cas de l'ester, DAAE, la deutériation sélective du proton énolique entraîne une évolution au niveau de la bande à 1560 cm^{-1}, qui glisse de 60 cm^{-1} vers les hautes fréquences. Simultanément on relève dans le composé deutérié une nouvelle bande à 1280 cm^{-1}. Ces deux bandes sont attribuables à δ OH et δ OD. La faiblesse du rapport isotopique ($\rho = 1.22$) et le déplacement vers les hautes fréquences (1620 cm^{-1}) de la bande à 1560 cm^{-1} sont significatifs de l'existence d'un couplage.

La bande forte à 1240 cm^{-1} qui disparaît par deutériation sélective, est attribuée à γ OH. La vibration γ OD, attendue vers 925 cm^{-1} ($\rho = 1.34$) est peu discernable.

Pour ce qui est de l'ion diacétylacétylium nous observons un phénomène analogue bien que par deutériation l'évolution du domaine vers 1600 cm^{-1} soit peu spectaculaire. La bande centrée à 1580 cm^{-1} diminue d'intensité (participation de δ OH) tandis que δ OD est positionnée à 1260 cm^{-1} ($\rho = 1.25$). Pour γ OH et γ OD trois couples de bandes sont sensibles à la deutériation totale et sont dans un domaine de fréquence très convenable. Il s'agit de 1230–915 cm^{-1} ($\rho = 1.34$) 1205–865 cm^{-1} ($\rho = 1.39$) et 937–680 cm^{-1} ($\rho = 1.38$). Le premier couple est très proche de celui attribué à ce mouvement dans l'ester deutérié sélectivement, nous pensons que cette attribution est plus compatible avec la force de la liaison hydrogène que celle proposée par Nakamoto; 945 cm^{-1} est en effet une fréquence bien trop faible pour une liaison hydrogène de cette force.

Vibrations du squelette

Il n'est pas nécessaire de revenir sur la vibration ν C≡O de l'ion diacétylacétylium (2180 cm^{-1}). La vibration ν C=O du groupement ester du diacétylacétate d'éthyle se situe à 1710 cm^{-1}. En ce qui concerne la vibration ν C_1—C_2, nous devons nous attendre à une différence importante entre le cation et l'ester. En effet, pour le cation la participation notable de la forme céténique confère un caractère partiellement double à cette liaison, qui ne se retrouve pas dans l'ester. La bande intense à 1375 cm^{-1} (1353 dans le cas du composé totalement deutérié) est attribuée à ν C_1—C_2 dans l'ion diacétylacétylium. Pour l'ester nous la situons à 1080 cm^{-1}, bande intense que nous ne retrouvons pas dans le cation.

Pour les autres vibrations du squelette Nakamoto (19) distingue dans l'acétylacétone,

[2]Communication personnelle.

[3]Il est possible de considérer une association faible intermoléculaire entre l'hydroxyle "libre" d'un dimère et le carbonyle "libre" d'un dimère voisin, permettant ainsi la constitution d'un enchaînement polymérique.

TABLEAU 1. Fréquences comparées des vibrations de l'acétylacétone, de l'ion diacétylacétylium et du diacétylacétate d'éthyle*

*AA: acétylacétone; DAA: diacétylacétylium; DAAE: diacétylacétate d'éthyle; *d*: deutériation.

ν C=O et ν C—O et ν C=C et ν C—C. Pour notre part, nous pensons que la délocalisation des électrons le long du squelette conduit à raisonner en terme de vibrations symétriques et asymétriques. Pour DAAE l'attribution de la bande à 1560 cm^{-1} à la vibration ν_{as} C—O semble évidente. Rappelons que par deutériation partielle, cette bande glisse à 1620 cm^{-1}, valeur proche de celle trouvée par Nakamoto. Pour ν_{as} C—O le couplage signalé lors de l'étude de δ OH est donc celui de δ OH $\leftrightarrow$ ν_{as} C—O. Pour le cation DAA, par analogie, nous attribuons à la bande 1580 cm^{-1} à ce mouvement.

Dans certains spectres de DAA solide nous pouvons relever deux bandes faibles à des fréquences plus élevées (1630 et 1680 cm^{-1}) et dont les intensités varient suivant l'échantillon. Elles proviennent vraisemblablement d'impuretés comme par exemple l'acétylacétone (1630 cm^{-1}) due à une hydrolyse partielle:

$$(CH_3CO)_2CHCO^+ \xrightarrow{H_2O} [(CH_3CO)_2CHCO_2H] \rightarrow \underset{\text{instable}}{} (CH_3CO)_2CH_2 + CO_2\uparrow$$

Pour les trois autres mouvements du squelette de DAA: ν_s C—O, ν_{as} C_2—C_3 et ν_s C_2—C_3 nous avons retenu les attributions 1430, 1540 et 1260 cm^{-1}, valeurs proches de celles proposées pour AA (19).

Enfin, nous situons ν_{as} C—CH_3 et ν_s C—CH_3 à 937 et 800 cm^{-1}. Ces valeurs peuvent être comparées à celles trouvées pour AA (908 et 810 cm^{-1}). Les fréquences légèrement plus élevées pour le cation DAA s'expliquent par la présence d'une charge positive partielle sur le carbone C_3. Le tableau 1 représente l'ensemble des vibrations choisies.

Méthodes expérimentales

Produits utilisés

Le chlorure d'aluminium Schuchardt est purifié par sublimation sous vide. Le bromure d'aluminium et le chlorure de gallium sont synthétisés selon les méthodes déjà décrites (11, 13).

Les chlorure et bromure d'acétyle sont des produits Prolabo, ils ont été bidistillés. Le chlorure d'acétyle deutérié est obtenu à partir de l'acide acétique d_4 (CEA) et PCl_3, selon la méthode décrite par Vogel (21). Le diacétylacétate d'éthyle est préparé par acétylation de l'acétate d'éthyle selon la méthode de Spassow (22). La deutériation sélective sur l'hydrogène énolique du diacétylacétate d'éthyle en solution dans le tétrachlorure de carbone est obtenu par échange avec l'eau lourde.

Les tétrachloroaluminates de diacétylacétylium, non deutérié et deutérié, cristallisés sont obtenus selon (5). La même technique utilisée avec $AlBr_3$–CH_3COBr et $GaCl_3$–CH_3COCl n'a pas permis d'obtenir de produits cristallisés. Après évaporation sous vide du solvant et éventuellement de l'excès d'halogénure d'acétyle, des huiles jaunes ou rouges sont obtenues.

Etude spectroscopique

Les spectres infrarouges sont enregistrés sur un appareil Perkin-Elmer 180. Les produits solides pulvérulents sont placés entre faces en CsI et les liquides entre faces en silicium.

Conclusion

La réaction d'un halogénure métallique sur un grand excès d'halogénure d'acétyle conduit à un sel de diacétylacétylium dont l'anion est du type $M_nX_{3n+1}^-$. Dans le cas du tétrachloroaluminate obtenu cristallisé, le cation est un monomère à liaison hydrogène intramolé-

culaire forte à potentiel à double minimum. La distance O—O de 2.48 Å, estimée à partir des données de la littérature, est compatible avec la géométrie attendue pour un tel édifice.

Syntheses in the group of Nuphar alkaloids. III.[1] Total synthesis of (±)-nupharamine and (±)-3-epinupharamine[2]

JERZY SZYCHOWSKI, JERZY T. WRÓBEL, AND ANDRZEJ LENIEWSKI

Department of Chemistry, University of Warsaw, 02-093 Warsaw, Poland

Received August 12, 1976[3]

JERZY SZYCHOWSKI, JERZY T. WRÓBEL, and ANDRZEJ LENIEWSKI. Can. J. Chem. **55**, 3105 (1977).

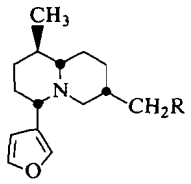
The alkaloids (±)-nupharamine and (±)-3-epinupharamine were synthesized using 3-acetylfuran as the starting material. The conditions for stereoselective reduction of pyridine derivatives are described.

JERZY SZYCHOWSKI, JERZY T. WRÓBEL et ANDRZEJ LENIEWSKI. Can. J. Chem. **55**, 3105 (1977).

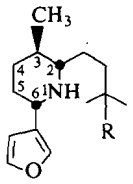
Utilisant l'acétyl-3 furanne comme produit de départ, on a synthétisé les alcaloïdes (±) nupharamine et (±) épi-3 nupharamine. On décrit les conditions permettant la réduction stéréosélective de dérivés de la pyridine.

[Traduit par le journal]

Deoxynupharidine **1** and castoramine **2** are the only alkaloids of the Nuphar type which have been totally synthesized (1). An attempted synthesis of a piperidine alkaloid, nupharamine **3**, resulted in deoxynupharamine **4** (2) since the synthetic procedure used excluded the possibility of introduction of the hydroxyl group, characteristic of this alkaloid. The common feature of the syntheses mentioned above was the construction of the A ring, or A and B rings in the first stages and the introduction of the furan nucleus in one of the last steps.



1 R = H
2 R = OH



3 R = OH
4 R = H

The syntheses of the carbon skeletons of the piperidine Nuphar alkaloids reported here were carried out using a 3-furan derivative as a substrate. Construction of the nitrogen ring was followed by that of a side chain suitable for piperidine alkaloids or serving as a precursor of the B ring in the quinolizidine system. All chiral centers were formed in the reduction step in order to ensure a high stereoselectivity.

The main steps of the synthetic procedure are shown in Scheme 1. All the synthetic steps were checked to obtain first the model 2-furan and then the 3-furan derivatives.

The Claisen condensation of the initial material, acetylfuran **5** with ethyl formate results in a purple salt of furoylacetaldehydes **6**. Condensation of this salt **6***a* with ethyl 3-aminocrotonate in the presence of piperidine acetate (3) yields enamine **7** as the only basic product. The Hantzsch condensation of furoylacetaldehydes **8** with 3-aminocrotonate in benzene results in ethyl esters of 2-methyl-6-furylnicotinic acids **9**. In view of the instability of free β-ketoaldehydes **8** they were prepared from their sodium salts *in situ* in the reaction medium. In this way furyl derivatives **9** were obtained in satisfactory yields, namely 40% and 35% for compounds **9***a* and **9***b*, respectively.

The carboethoxy group was reduced to the hydroxymethyl group by the usual procedure with lithium aluminium hydride. Alcohols **10** were obtained in a quantitative yield. The removal of the hydroxyl group in **10***a* by treatment with thionyl chloride and subsequent reduction with zinc in 80% ethanol resulted in a very low yield of the expected dimethyl derivative **11***a*. The main product was a compound containing chlorine in position 4 of the furan ring **12**, as determined by ^{1}Hmr. 2,3-Dimethyl-6-furylpyridines **11***a* and **11***b* were obtained in 85% and 63% yield, respectively, by brief (few minutes) treatment of alcohols **10** with boiling 60% HBr and subsequent reduction with zinc in acetic acid. The above conditions ensure maximum yields.

The completion of the carbon skeleton of the

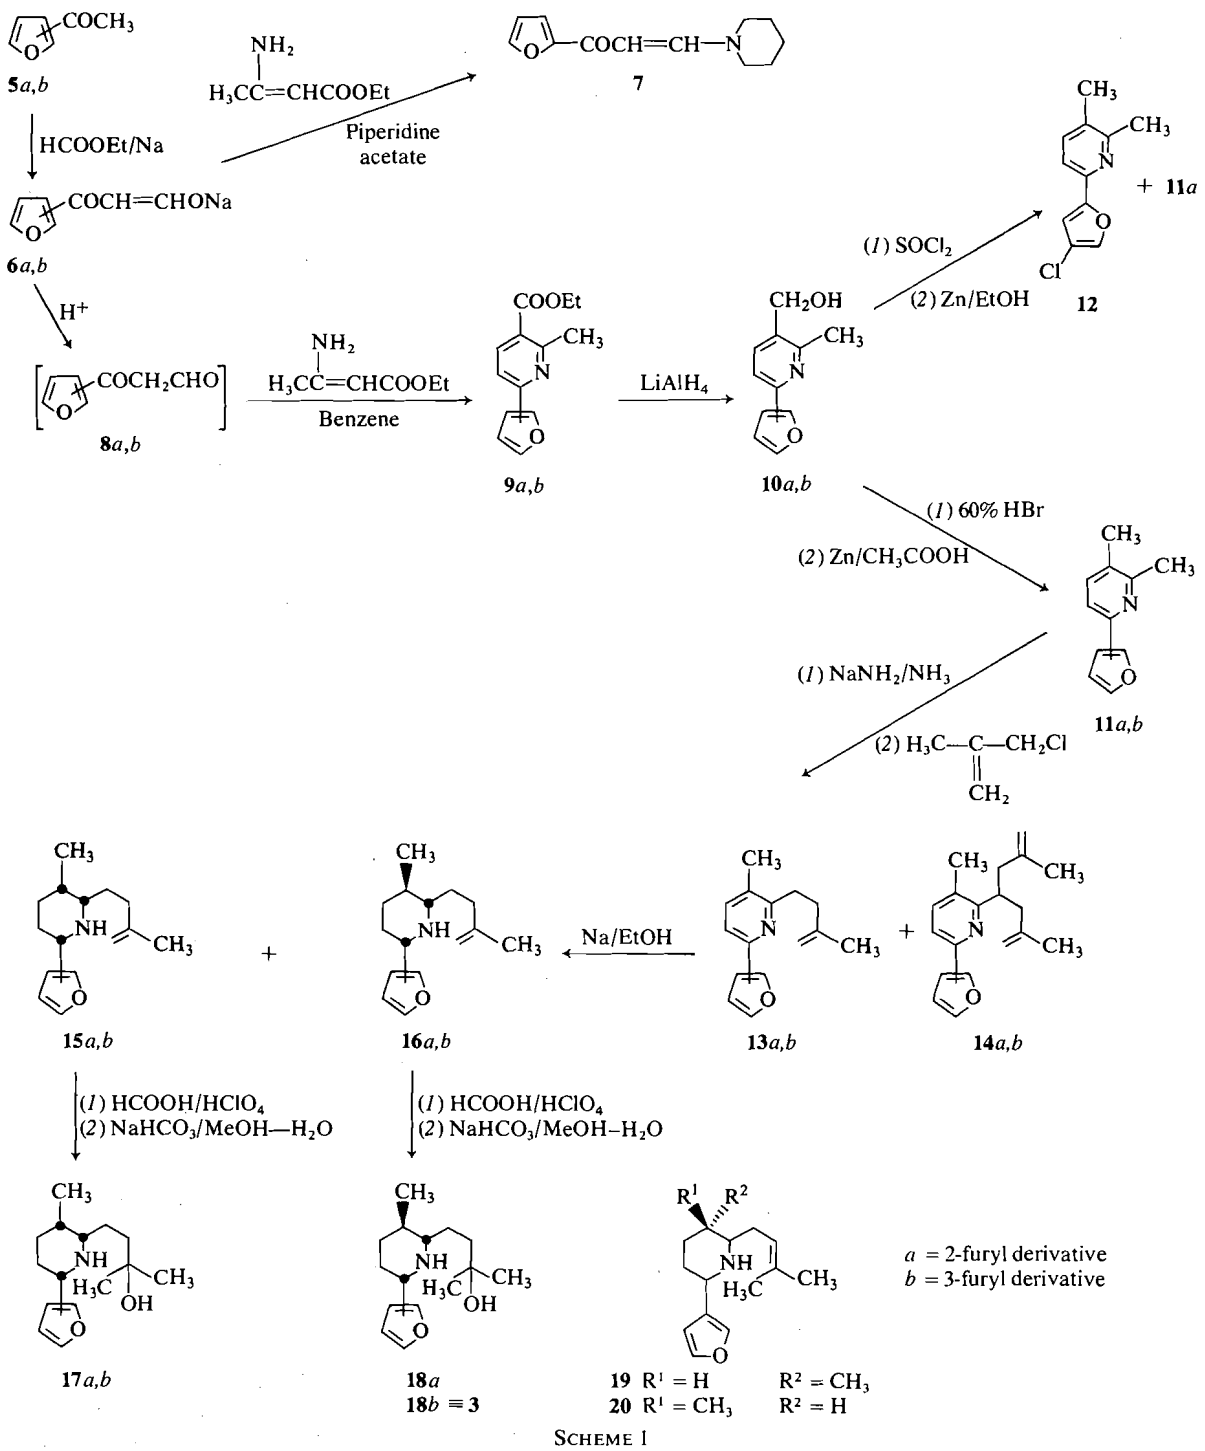
[2]Preliminary communications: Bull. Acad. Polon. Sci. Ser. Sci. Chim. **22**, 383 (1974); IUPAC, 9th International Symposium of Chemistry of Natural Products, Abstracts 4A, Ottawa, 1974.

[3]Revision received March 3, 1977.



SCHEME I

piperidine Nuphar alkaloids requires the derivative **11***b* to be extended by an isobutene side chain. This was achieved by the reaction of **11** with β-methallyl chloride resulting in **13**. Methallyl chloride contains an active chlorine atom favouring the *C*-alkylation, moreover its structure prevents the formation of unwanted compounds as a result of a possible allylic rearrange-

ment. The presence and position of the ethylene bond makes possible the introduction of a hydroxyl group as well as ring closure to form the quinolizidine system. Compound **13** with the desired structure was obtained together with a dialkylated derivative **14**. The yield of the latter decreases with decreasing temperature and shorter rate of the methallyl chloride addition reaction.

The synthesis of **13***b* paved the way to the total synthesis of C_{15} piperidine Nuphar alkaloids. Compound **13***b* used as precursor required a chemically and stereochemically selective reduction of the pyridine ring and introduction of the tertiary hydroxyl group to the side chain. The latter reaction seemed to be relatively simple in view of the ethylene bond present in **13***b*. Conversely, a selective reduction of pyridine, which would retain unaffected both the furan ring and ethylene bond, presented serious difficulties.

Compounds **13***a,b* were reduced with sodium–ethanol in xylene. The resulting products consisted of a mixture of epimers at C3, **15** and **16**. Their R_f values were virtually identical in tlc on alumina but differed on silica gel. The ratio of **15** to **16** was determined by ^{1}Hmr spectroscopy. The 3-epi isomer **15** was usually the main product.

Epimers **15***a* and **16***a* were separated by chromatography on alumina (although their R_f values were virtually identical in tlc).

The stereochemistry of **15***a* was determined by ir and ^{1}Hmr spectroscopy by a method similar to that used in the case of piperidine Nuphar alkaloids (7).

Bohlmann bands in the ir spectrum show the presence of two axial hydrogen atoms in position 2 and 6 thus indicating the equatorial conformation of the furan ring and side chain. The chemical shift of the proton signal at C2 (δ = 2.78 ppm) and the value of the coupling constant with the proton at C3 (J = 2.5 Hz) indicated the presence of an equatorial hydrogen atom and an axial methyl group at C3.

The tertiary hydroxyl group was introduced by the addition of formic acid in the presence of $HClO_4$ and by subsequent gentle alkaline hydrolysis of the resulting ester. This method proved superior to the hydration in dilute HCl (8). The hydration was accompanied by a side reaction of isomerization of the ethylene bond to nuphenine **19**.

Anhydronupharamine **16***b* and 3-epianhydronupharamine **15***b* were hydrated as a mixture.

The mixture of (±)-nupharamine **18***b* and (±)-3-epinupharamine **17***b* thus obtained was separated by chromatography on alumina.

The identity of the synthetic and natural nupharamine was proven by direct comparison with a sample obtained from Professor Y. Arata. The identity of the synthetic (±)-3-epinupharamine with the natural alkaloid was demonstrated by comparison of spectroscopic data (8).

Experimental

All melting points and boiling points are uncorrected. Spectra were obtained as follows: uv in 95% ethanol on Jena-Specord UV-VIS spectrophotometer; ir on a UR-20 or UR-10 spectrophotometers (KBr pellets for solids or films for liquids); ^{1}Hmr at 100 MHz on a JOEL JNM-4H-100 spectrometer in $CDCl_3$ using TMS as internal standard, unless otherwise indicated (δ 0.0; symbols s, d, t, q, qu, br, m, stand for singlet, doublet, triplet, quartet, quintet, broad, multiplet, respectively); ms on an LKB-9000 low-resolution instrument with a direct inlet system operating at 70 eV. Fluka Al_2O_3 type H was used for tlc and BDH neutral alumina (activity III) for column chromatography.

Sodium Salts of the Enolic Forms of Furoylacetaldehydes 6

These compounds were obtained from the corresponding acetylfurans by condensation with ethyl formate in the presence of powdered sodium in ether, as in the case of the reaction with 2-acetylselenophene (5). 2-Acetylfuran (0.5 mol) and 3-acetylfuran (0.14 mol) gave in quantitative yields **6***a* and **6***b*, respectively, in the form of brown amorphous powders which were used for condensation with ethyl 3-aminocrotonate.

Condensation with Ethyl 3-Aminocrotonate in the Presence of Piperidine Acetate. Enamine 7

The procedure used in this reaction was similar to that employed in the condensation of acetone with ethyl formate and cyanoacetamide (3). 2-Acetylfuran **5***a* (0.2 mol) gave 8.5 g of **7** as the only basic reaction product; mp 86–87°C (from a mixture of ether and ethanol); picrate mp 134–136°C (ethanol). *Anal.* calcd. for $C_{12}H_{15}NO_2$ (mol. wt. 205.3): C 70.37, H 7.03, N 6.83; found (M^+ 205(100%)): C 70.32, H 7.23, N 6.48. Spectral data: uv λ_{max}(log ε): 208(3.37), 233(3.41), 277(3.86), 360(4.49) nm; ir ν_{max}: 3131, 3105, 1650, 1588, 873 cm^{-1}; ^{1}Hmr δ: 1.63 (6H, br t, β- and γ-piperidine protons), 3.32 (4H, br t, α-piperidine protons), 5.77 (1H, d, J = 13 Hz, CO—CH=), 6.42 (1H, m, H4-furan), 7.01 (1H, m, H3-furan), 7.45 (1H, m, H5-furan), 7.73 (1H, d, J = 13 Hz, N—CH=) ppm.

Ethyl Esters of 2-Methyl-6-furylnicotinic Acids 9

Ethyl 2-Methyl-6-(2-furyl)nicotinate 9a

The enol salt **6***a* (80 g) was added portionwise at room temperature to a vigorously stirred solution of ethyl 3-aminocrotonate (64.5 g) and glacial acetic acid (30 g) in 500 cm^3 of benzene. The mixture was stirred for 1 h. The resulting precipitate was filtered and washed twice with benzene. The filtrates were evaporated to about 300 cm^3 and were distilled azeotropically with a water–benzene separator for 10–15 h until the evolution of water ceased. The solvent and the excess ethyl 3-

aminocrotonate were distilled off and the residue was distilled collecting the fraction boiling at 111–112°C/0.04 Torr. Alternatively, the residue was dissolved in 200 cm^3 of acetone and the hydrobromide was precipitated by addition of 50 cm^3 of 40% HBr. The first method gave 40–46 g (35–40% yield) of a light yellow oil which crystallized on cooling. After recrystallization from *n*-hexane the product melted at 40–41°C. The second method gave 45.5 g (29% yield) of yellow hydrobromide **9***a* which crystallized from ethanol in the form of needles mp 182–184°C; picrate **9***a* mp 154–155°C (ethanol). *Anal.* calcd. for $C_{13}H_{13}NO_3$ (mol. wt. 231.2): C 67.52, H 5.67, N 6.06; found (M^+ 231(100%)): C 67.73, H 5.65, N 6.04. Spectral data: uv λ_{max}(log ε): 210(3.52), 229(3.73), 287(3.98), 319(4.39) nm; ir ν_{max}: 3160, 3129, 1730, 1604, 1594, 1500, 1277, 890 cm^{-1}; ^{1}Hmr δ: 1.43 (3H, t, J = 7 Hz, O-CH_2-CH_3), 2.88 (3H, s, C2-CH_3), 4.37 (2H, q, J = 7 Hz, O-CH_2-CH_3), 6.50 (1H, m, H4-furan), 7.15 (1H, m, H3-furan), 7.51 (1H, d, J = 8 Hz, C5-H), 7.55 (1H, m, H5-furan), 8.20 (1H, d, J = 8 Hz, C4-H) ppm.

Ethyl 2-Methyl-6-(3-furyl)nicotinate **9***b*

This compound was obtained by a method analogous to the preparation of **9***a*. From 0.14 mol of sodium salt of enol **6***b*, after removal of the excess of ethyl 3-aminocrotonate, the remaining dark oil was dissolved in benzene and the solution was filtered through alumina (50 g). The product **9***b* (11.5 g, 35% yield) was a light yellow oil which crystallized on cooling; mp 42–43°C (*n*-hexane); hydrobromide **9***b* mp 202–203.5°C (acetone–ethanol); picrate **9***b* mp 157–159.5°C (ethanol). *Anal.* calcd. for $C_{13}H_{13}NO_3$ (mol. wt. 231.2): C 67.52, H 5.67, N 6.06; found (M^+ 231(100%)): C 67.87, H 5.92, N 5.95. Spectral data: uv λ_{max}(log ε): 206(4.19), 248(3.91), 300(4.18) nm; ir ν_{max}: 3140, 1728, 1280, 881 cm^{-1}; ^{1}Hmr δ: 1.41 (3H, t, J = 7 Hz), O-CH_2-CH_3), 2.88 (3H, s, C2-CH_3), 4.35 (2H, q, J = 7 Hz, O-CH_2-CH_3), 6.91 (1H, m, H4-furan), 7.31 (1H, d, J = 8 Hz, C5-H), 7.51 (1H, m, H5-furan), 8.13 (1H, m, H2-furan), 8.21 (1H, d, J = 8 Hz, C4-H) ppm.

2-Methyl-3-hydroxymethyl-6-furylpyridines **10**

Aminoesters **9** were reduced with $LiAlH_4$ in the usual way adding it dropwise to a 1.5 molar excess of the hydride suspended in ether and then refluxing the mixture for 3 h.

2-Methyl-3-hydroxymethyl-6-(2-furyl)pyridine **10***a*

9*a* (49.7 g) gave 39.5 g (97% yield) of **10***a* in the form of a solid. An analytical sample was crystallized from ether and gave needles, mp 84–85°C; picrate **10***a* mp 191–193°C (ethanol). *Anal.* calcd. for $C_{11}H_{11}NO_2$ (mol. wt. 189.2): C 69.83, H 5.86, N 7.40; found (M^+ 189(100%)): C 69.54, H 5.83, N 7.26. Spectral data: uv λ_{max}(log ε): 206(3.62), 269(4.06), 276(4.05), 305(4.14) nm; ir ν_{max}: 3400 br, 3182, 1601, 1503, 1052, 893 cm^{-1}; ^{1}Hmr δ: 2.48 (3H, s, C2-CH_3), 6.44 (1H, m, H4-furan), 6.99 (1H, m, H3-furan), 7.42 (1H, d, J = 8 Hz, C5-H), 7.46 (1H, m, H2-furan), 7.60 (1H, d, J = 8 Hz, C4-H), and 2.7 (1H, br s, OH), 4.57 (2H, s, -CH_2-O) ppm.

2-Methyl-3-hydroxymethyl-6-(3-furyl)pyridine **10***b*

9*b* (9.3 g) gave 7.6 g (100% yield) of **10***b*; mp 78–79°C (benzene); picrate **10***b* mp 196–198°C (ethanol). *Anal.* calcd. for $C_{11}H_{11}NO_2$ (mol. wt. 189.2): C 69.83, H 5.86, N 7.40; found (M^+ 189(100%)): C 70.01, H 5.63, N 7.51. Spectral data: uv λ_{max} (log ε): 203(4.02), 213(3.98), 218(4.00), 247(3.95), 289(3.89) nm; ir ν_{max}: 3500–3000 br, 1610, 1595, 1514, 1053, 870 cm^{-1}; ^{1}Hmr δ: 2.45 (3H, s, C2-CH_3), 4.55 (2H, s, -CH_2-O), 6.81 (1H, m, H4-furan), 7.14 (1H, d, J = 8 Hz, C5-H), 7.43 (1H, m, H5-furan), 7.52 (1H, d, J = 8 Hz, C4-H), 8.00 (1H, m, H2-furan), and 3.75 (1H, br s, OH) ppm.

2,3-Dimethyl-6-furylpyridines **11**

2,3-Dimethyl-6-(2-furyl)pyridine **11***a*

Hydrobromic acid (60%, 110 cm^3) was added to amino alcohol **10***a* (30 g) and the mixture was refluxed for 5 min. After cooling the resulting dark red solution was added dropwise to a stirred hot suspension of zinc dust (50 g) in glacial acetic acid (600 cm^3).

The mixture was refluxed for 15 min and then it was stirred without heating for 30 min. The resulting, almost colourless solution was decanted from zinc, the precipitate was washed with glacial acetic acid (2 × 50 cm^3), the decanted liquid and the washings were combined, and after evaporation to a small volume under reduced pressure they were added slowly to 500 cm^3 of concentrated ammonia solution. An oil separated which was extracted with benzene (4 × 200 cm^3). The extract was washed with water and the solvent was evaporated. The remaining red oil (26 g) was distilled and the fraction boiling at 139–140°C/8 Torr was collected (23.4 g, 85% yield). On cooling the colourless product crystallized mp 60–61°C; hydrobromide **11***a* mp 206–207°C; picrate **11***a* mp 204–206°C (ethanol). *Anal.* calcd. for $C_{11}H_{11}NO$ (mol. wt. 173.2): C 76.28, H 6.40, N 8.09; found (M^+ 173(100%)): C 76.79, H 6.54, N 7.71. Spectral data: uv λ_{max}(log ε): 204(3.94), 268(4.15), 276(4.13), 306(4.20) nm; ir ν_{max}: 3152, 3122, 1605, 1562, 1501, 890 cm^{-1}; ^{1}Hmr δ: 2.23 (3H, s, C3-CH_3), 2.49 (3H, s, C2-CH_3), 6.45 (1H, m, H4-furan), 6.94 (1H, m, H3-furan), 7.38 (2H, s, C4-H and C5-H), 7.45 (1H, m, H5-furan) ppm.

2,3-Dimethyl-6-(3-furyl)pyridine **11***b*

Analogous to the preparation of **11***a*, 7.3 g of **10***b* gave 4.2 g (63% yield) of **11***b*; bp 133–136°C/8 Torr, mp 20–22°C; picrate **11***b* mp 212–215°C (ethanol). *Anal.* calcd. for $C_{11}H_{11}NO$ (mol. wt. 173.2): C 76.28, H 6.40, N 8.09; found (M^+ 173(100%)): C 76.38, H 6.65, N 7.96. Spectral data: uv λ_{max}(log ε): 203(3.96), 213(3.85), 218(3.87), 245(3.81), 252(3.81), 289(3.80) nm; ir ν_{max}: 3153, 3140, 3125, 1608, 1580, 1564, 880 cm^{-1}; ^{1}Hmr δ: 2.25 (3H, s, C3-CH_3), 2.52 (3H, s, C2-CH_3), 6.86 (1H, m, H4-furan), 7.16 (1H, d, J = 8 Hz, C5-H), 7.35 (1H, d, J = 8 Hz), 7.46 (1H, m, H5-furan), 8.01 (1H, m, H2-furan) ppm.

Reaction of Amino Alcohol **10***a with Thionyl Chloride and Reduction with Zinc and 80% Ethanol* **12**

A solution of **10***a* (19 g) in 30 cm^3 of benzene was added dropwise to $SOCl_2$ (47 g) at 0 to 5°C. The mixture was refluxed for 15 h, the excess $SOCl_2$ and benzene were evaporated, and the dark viscous residue was dissolved in 130 cm^3 of 80% ethanol. The solution was added dropwise during 30 min to a hot suspension of zinc dust (40 g) activated with $CuSO_4$ in 100 cm^3 of 80% ethanol, the mixture was refluxed for 3.5 h and was left to stand overnight. The excess of zinc was filtered off, the precipitate was washed with 80% ethanol and then ethanol and a part of water were evaporated from the acidic filtrate. One third of the residue was made alkaline with NaOH and was steam distilled. The remaining part of the residue

was made alkaline with concentrated ammonia solution and was extracted with ether. Both the semisolid distillation product and the ether extract were identical mixtures of two substances with similar R_f values in tlc, but their purity was different. The components of the mixture were separated by crystallization and distillation. The products were: 1.3 g of solid substance identical with **11***a* and 1.8 g of **12**. **12** had mp 98–100.5°C (*n*-hexane) and bp 147–165°C/11 Torr. *Anal.* calcd. for $C_{11}H_{10}ClNO$ (mol. wt. 207.7): C 63.70, H 4.87, N 6.75; found (M^+ 207(100%), 209(34%)): C 63.67, H 5.15, N 6.43. Spectral data: uv λ_{max}(log ε): 205(3.94), 267(4.12), 275(4.10), 303(4.21) nm; ir ν_{max}: 3153, 3112, 1595, 873 cm^{-1}; ^{1}Hmr δ: 2.24 (3H, s, C3-CH_3), 2.48 (3H, s, C2-CH_3), 6.93 (1H, m, H3-furan), 7.35 (2H, s, C4-H and C5-H), 7.41 (1H, m, H5-furan) ppm.

Alkylation of 2,3-Dimethyl-6-furylpyridines ***11*** *with β-Methallyl Chloride in the Presence of Sodium Amide in Liquid Ammonia*

Alkylation of 2,3-Dimethyl-6-(2-furyl)pyridine ***11a****. 13a and 14a*

A solution of **11***a* (6.06 g) in 25 cm^3 of ether was added at −33°C to a suspension of $NaNH_2$ in liquid ammonia prepared from 100 cm^3 of dry NH_3 and sodium (1.21 g). The dark red solution was stirred for 15 min, then it was cooled to −50°C and β-methallyl chloride (4.75 g) was added dropwise as rapidly as possible. The mixture became colourless. It was decomposed with 10 cm^3 of water, ammonia was evaporated, and the residue was extracted with ether. The product was 8.67 g of red oil which, after chromatography on alumina (700 g), gave 4.75 g (60% yield) of **13***a*, 0.14 g of **14***a*, and 2.1 g of unchanged **11***a*.

13*a* is an oil bp 101–106°C/0.085 Torr; picrate mp 143.4°C (ethanol – ethyl acetate). *Anal.* calcd. for $C_{15}H_{17}NO$ (mol. wt. 227.3): C 79.26, H 7.54, N 6.16; found (M^+ 227(45%)(213 = 100%)): C 79.58, H 7.54, N 5.86. Spectral data: uv λ_{max}(log ε): 205(4.06), 268(4.12), 276(4.06), 304(4.04) nm; ir ν_{max}: 3125, 3084, 1654, 891, 880 cm^{-1}; ^{1}Hmr δ: 1.84 (3H, s, CH_3—C═), 2.32 (3H, s, C3-CH_3), 2.5–3.1 (4H, m, -CH_2-CH_2-), 4.77 (2H, s, C═CH_2), 6.53 (1H, m, H4-furan), 7.07 (1H, m, H3-furan), 7.49 (2H, s, C4-H and C5-H), 7.54 (1H, m, H5-furan) ppm.

14*a* is an oil bp 116°C/0.1 Torr; picrate mp 156–158°C (ethanol). *Anal.* calcd. for $C_{19}H_{23}NO$ (mol. wt. 281.4): C 81.09, H 8.24, N 4.98; found (M^+ 281(18%)(226 = 100%)): C 81.38, H 8.90, N 4.48. Spectral data: uv λ_{max}(log ε): 205(4.06), 268(4.12), 276(4.06), 304(4.04) nm; ir ν_{max}: 3152, 3125, 3079, 1653, 893, 880 cm^{-1}; ^{1}Hmr δ: 1.70 (6H, s, 2CH_3—C═), 2.32 (3H, s, C3-CH_3), 2.4–2.6 (4H, m, 2—CH_2—C═), 3.39 (1H, qu, J = 7 Hz, C2-CH), 4.60 (2H, m, C═CH_2), 4.66 (2H, s, C═CH_2), 6.50 (1H, m, H4-furan), 7.08 (1H, m, H3-furan), 7.43 (2H, s, C4-H and C5-H), 7.49 (1H, m, H5-furan) ppm.

Alkylation of 2,3-Dimethyl-6-(3-furyl)pyridine ***11b****. 13b and 14b*

Analogous to the preparation of **11***a* 4.0 g of **11***b* gave 5.6 g of a mixture of products from which 2.36 g (45% yield) of **13***b* and 0.43 g of **14***b* were isolated by chromatography on alumina.

13*b* is an oil. *Anal.* calcd. for $C_{15}H_{17}NO$ (mol. wt. 227.3): C 79.26, H 7.54, N 6.16; found (M^+ 227(48%)(213 = 100%)): C 79.16, H 7.96, N 6.01. 14*b* is an oil. *Anal.* calcd. for $C_{19}H_{23}NO$ (mol. wt. 281.4): C 81.09, H 8.24, N 4.98; found (M^+ 281(79%) (226 = 100%)): C 81.16, H 8.50, N 5.11. Spectral data: uv λ_{max}(log ε): 205(4.27) 220(3.91), 253(3.83), 300(3.65) nm; ir ν_{max}: 3157, 3139, 3079, 1651, 896, 879 cm^{-1}; ^{1}Hmr δ: 1.70 (6H, s, 2CH_3—C═), 2.32 (3H, s, C3-CH_3), 2.4–2.6 (4H, m, 2—CH_2—C═), 3.40 (1H, qu, J = 7 Hz, C2-CH), 4.60 (2H, br s, C═CH_2), 4.66 (2H, s, C═CH_2), 6.93 (1H, m, H4-furan), 7.17 (1H, d, J = 8 Hz, C5-H), 7.38 (1H, d, J = 8 Hz, C4-H), 7.51 (1H, m, H5-furan), 8.07 (1H, m, H2-furan), ppm.

Reduction of Bases ***13*** *with Sodium and Ethanol*

Reduction of 13a

A solution of **13***a* (4.54 g, 0.02 mol) in 20 cm^3 of absolute ethanol was added dropwise during several minutes to a suspension of sodium (9.2 g, 0.4 mol) in 100 cm^3 of boiling xylene. During the reduction three further 2 cm^3 portions of ethanol were added. When the yellow-green colour of the solution disappeared, the metal was dissolved with water. The solution was diluted with water and extracted with benzene. The extract was washed with water and with dilute HCl in order to remove basic substances. The acid extract was washed with benzene and after making alkaline with concentrated NaOH it was reextracted with benzene. On evaporation the benzene extract gave 3.91 g of a light-red oil which was chromatographed on alumina column to isolate a mixture of epimers **15***a* and **16***a* (ratio about 1:1); yield 1.28 g (27%). Thin layer chromatography on silica gel showed the presence of two compounds of similar R_f values. The ^{1}Hmr spectrum of the mixture was compared with that of **15***a* and showed the presence of an additional signal at δ 2.3 corresponding to the C2-H proton of epimer **16***a*. The ratio of these two compounds was determined on the basis of integration of signals at δ 2.8 and 3.7 ppm. The crude products from several experiments (2.8 g) were chromatographed on alumina (330 g) and gave **15***a* (0.475 g) and **16***a* (0.425 g).

15a*: A Colourless Oil*—ir ν_{max}: 3330, 3120, 3075, 2790, 2728, 1653, 886 cm^{-1}; ^{1}Hmr δ: 0.98 (3H, d, J = 6 Hz, C3-CH_3), 1.73 (3H, s, ═C—CH_3), 1.4–2.2 (9H, m), 2.5 (1H, br s, NH), 2.78 (1H, d, t, J_1 = 2.5 Hz, J_2 = 7 Hz, C2-H), 3.72 (1H, m, C6-H), 4.68 (2H, s, ═CH_2), 6.12 (1H, m, H3-furan), 6.23 (1H, m, H4-furan), 7.27 (1H, m, H5-furan) ppm; ^{1}Hmr (C_6D_6) δ: 0.92 (3H, d, J = 6 Hz, C3-CH_3) ppm; ms: 233(11%)(M^+), 164(64%), 107(100%), 94(79%) *m/e*.

16a*: A Colourless Oil*—ir ν_{max}: 3330, 3130, 2810, 2740, 1659, 889 cm^{-1}; ^{1}Hmr δ: 0.92 (3H, d, J = 5.5 Hz, C3-CH_3), 1.74 (3H, s, ═C—CH_3), 1.2–2.1 (10H with NH, m), 2.26 (1H, m, C2-H), 3.73 (1H, m, C6-H), 4.70 (2H, s, ═CH_2), 6.12 (1H, m, H3-furan), 6.26 (1H, m, H4-furan), 7.32 (1H, m, H5-furan) ppm; ^{1}Hmr (C_6D_6) δ: 0.78 (C3-CH_3) ppm; ms: 233(17%)(M^+), 164(69%), 107-(100%), 94(75%) *m/e*.

Reduction of Base 13b

Analogous to the preparation of **13***a*, 0.73 g of **13***b*

gave 89 mg (yield 12%) of a mixture of **15***b* and **16***b* (ratio about 3:1). The product was used for hydration without previous separation of epimers.

Hydration of 15a, 16a and Mixture of 15b and 16b

General Procedure

A mixture of unsaturated compound **15***a*, **16***a*, or mixture of **15***b* and **16***b*, 99% formic acid, and 72% perchloric acid in the ratio 1:10:1 (wt./wt.) was allowed to stand at room temperature for about 40 h (optimal time) and then it was diluted with about 5 times its volume of 80% methanol. The mixture was gently boiled and solid sodium bicarbonate was added portionwise until the evolution of CO_2 ceased and the solution became alkaline. Then methanol was evaporated, water was added in order to dissolve the salts, and the mixture was extracted with ether. On drying with anhydrous $MgSO_4$ and evaporation the extract gave a viscous yellow oil. The amino alcohols can be readily separated from the substrates by column chromatography on alumina using first benzene and then ether as eluting solvents. The substrates (benzene fraction) always contain the isomerization products having the structure of natural compounds nuphenine **19** (7) and anhydronupharamine **20** (9) (^{1}Hmr of the mixture: br t, at δ = 5.1 and methyl groups singlets at 1.6 and 1.7 ppm). An unsatisfactory result was obtained by the HCl hydration method (8).

Hydration of 15a

15*a* (0.47 g) treated by the method described above gave 0.45 g of an oil which, on chromatography on alumina (40 g), gave 47 mg of substrate and 0.27 g (yield 54%) of **17***a* in the form of a colourless oil. Spectral data: ir ν_{max} (CCl_4): 3610, 3400, 3200, 2817, 2790, 2728, 888 cm^{-1}; ^{1}Hmr δ: 0.96 (3H, d, J = 7 Hz, C3-CH_3), 1.20 and 1.24 (6H, s, s, *gem*-dimethyl), 1.1–1.9 (9H, m), 2.76 (1H, d, t, J_1 = 2.5 Hz, J_2 = 7 Hz, C2-H), 2.95 (2H, br s, NH and OH), 3.70 (1H, m, C6-H), 6.12 (1H, m, H3-furan), 6.24 (1H, m, H4-furan), 7.32 (1H, m, H5-furan) ppm; ^{1}Hmr (C_6D_6) δ: 0.87 (C3-CH_3) ppm; ms: 251-(7%)(M^+), 236(12%), 164(100%), 107(48%), 94(60%) *m/e*.

Hydration of 16a

16*a* (0.42 g) gave 0.23 g (yield 51%) of **18***a* in the form of a colourless oil which crystallized on standing; mp 90–90.5°C (*n*-hexane). Spectral data: ir ν_{max} (KBr): 3270, 3142, 3120, 2800, 2740, 868, 2717 cm^{-1}; ^{1}Hmr δ: 0.92 (3H, d, J = 7 Hz, C3-CH_3), 1.21 (6H, s, *gem*-dimethyl), 1.0–2.0 (11H, with NH and OH, m), 2.39 (1H, m, C2-H), 3.72 (1H, d d, J_1 = 2.5 Hz, J_2 = 10 Hz, C6-H), 6.11 (1H, m, H3-furan), 6.24 (1H, m, H4-furan), 7.29 (1H, m, H5-furan) ppm; ^{1}Hmr (C_6D_6) δ: 0.76(C3-CH_3) ppm; ms: 251(6%)(M^+), 236(11%), 164(100%), 107(56%), 94(54%) *m/e*.

Hydration of Mixture of 15b and 16b

The mixture of epimeric anhydronupharamines obtained by reduction of **13***b* (142 mg) on hydration followed by preliminary chromatography gave 86 mg of mixture of synthetic alkaloids **17***b* and **18***b* (in tlc separate spots having similar R_f values). A quantity of 69 mg was rechromatographed on 15 g of alumina collecting 15 cm^3 portions of the eluate (4 benzene fractions, 4 fractions of the ether–benzene mixtures containing 2%, 5%, 10%, and 25% ether and 2 ether fractions, making the total of 22 fractions). Fraction 15 contained 6 mg of pure (±)-nupharamine **18***b*, which by ir, ms, and tlc were identical with those of natural (−)nupharamine isolated from picrolonate.

Combined fractions 17–21 gave 50 mg of pure (±)-3-epinupharamine **17***b*. Spectral data: ir ν_{max} (CCl_4): 3400, 3170, 2976, 2934, 2862, 2805, 2738, 1507, 1457, 1386, 1368, 1225, 1159, 1120, 1069, 1032, 984, 969, 930, 913, 877 cm^{-1}; ^{1}Hmr δ: 0.96 (3H, d, J = 7 Hz, C3-CH_3), 1.18 and 1.23 (6H, s, s, *gem*-dimethyl), 1.0–2.0 (9H, m), 2.42 (2H, br s, NH and OH), 2.78 (1H, d t, J_1 = 2.5 Hz, J_2 = 6 Hz, C2-H), 3.56 (1H, d d, J_1 = 3 Hz, J_2 = 9 Hz, C6-H), 6.39 (1H, m, H4-furan), 7.32 (2H, m, H2-furan and H5-furan) ppm; ^{1}Hmr (C_6D_6) δ: 0.79 (C3-CH_3) ppm ms: 251(1.5%)(M^+), 236(6%), 164(100%), 136(7%), 107(27%), 94(38%), 81(9%) *m/e*.

Hydrobromide of 17b

Hydrobromic acid (0.1 cm^3 of 40%) was added to 33 mg of synthetic 3-epinupharamine in 0.5 cm^3 of acetone and the mixture was allowed to stand in a refrigerator. After two crystallizations from acetone the product gave colourless needles mp 179–181°C.

MICHAŁ SABAT, TADEUSZ GŁOWIAK, JERZY SZYCHOWSKI, JERZY T. WRÓBEL, and ANDRZEJ LENIEWSKI. Can. J. Chem. **55**, 3111 (1977).

Racemic 3-epinupharamine hydrobromide ($C_{15}H_{26}BrNO_2$) crystals are monoclinic, space group $C2/c$, with $a = 18.163(3)$, $b = 13.346(2)$, $c = 13.847(2)$ Å, $\beta = 100.36(1)°$, $Z = 8$. The X-ray analysis proved the structural identity of the compound obtained by the total synthesis with the natural 3-epinupharamine. The empirical criterion indicating the axial or equatorial orientation of the *C*-methyl group on the basis of the direction of changes of the chemical shifts recorded in benzene solutions does not hold for the piperidine system investigated.

MICHAŁ SABAT, TADEUSZ GŁOWIAK, JERZY SZYCHOWSKI, JERZY T. WRÓBEL et ANDRZEJ LENIEWSKI. Can. J. Chem. **55**, 3111 (1977).

Les cristaux du bromhydrate d'épi-3 nupharamine racémique ($C_{15}H_{26}BrNO_2$) sont monocliniques, groupe d'espace $C2/c$ avec $a = 18.163(3)$, $b = 13.346(2)$, $c = 13.847(2)$ Å, $\beta = 100.36(1)°$, $Z = 8$. L'analyse par rayons-X a démontré l'identité structurale du composé obtenu par synthèse totale avec l'épi-3 nupharamine naturel. Les critères empiriques permettant de déterminer l'orientation axiale ou équatoriale des groupes *C*-méthyles en se basant sur la direction des changements dans les déplacements chimiques enregistrés en solutions benzéniques ne peuvent être utilisés dans le système pipéridine étudié.

Introduction

The total synthesis of two stereoisomers: nupharamine and 3-epinupharamine was described previously (1). The identity of the synthetic and natural nupharamine was proved by a direct comparison of the respective samples. The comparison of the synthetic and natural 3-epinupharamine was carried out only on the basis of nmr, ir, and ms spectra obtained for the synthetic compounds with those reported in the literature for the natural alkaloid (2).

The structure of the natural 3-epinupharamine[1] was established (2) on the basis of the chemical correlation with another Nuphar alkaloid, nuphenine (3), and by a similar interpretation of the spectroscopic data for both compounds. The stereochemistry of the piperidine ring was established by analysis of nmr and ir spectra. The signal of the C2-H proton at $\delta = 2.78$ characteristic of all 3-epipiperidine Nuphar alkaloids has been found in the nmr spectra. Its structure indicates a coupling with two equivalent side chain protons as well as a coupling with the C3-H proton. In the latter case the value of the coupling constant $J = 2.5$ Hz, shows that the C2-H and C3-H protons can be in axial–equatorial or equatorial–equatorial positions with respect to each other. The presence of Bohlmann bands in the ir spectra lead to the conclusion that the side chain is in the equatorial and the methyl group in the axial position.

This conclusion was confirmed by the observed changes of the chemical shift of the C3-CH_3 group of 3-epinuphamine (4) in benzene solution. According to an empirical criterion found for the quinolizidine system (5) the signal of the axial methyl group is shifted downfield in benzene as compared to the chloroform solution.

The nmr spectra of the synthetic 3-epinupharamine show an opposite direction of the changes of the chemical shift of the C3-CH_3 group; in benzene the difference with respect to

[a]Anisotropic thermal parameters are defined by $\exp[-\frac{1}{4}(B_{11}h^2a^{*2} + B_{22}k^2b^{*2} + B_{33}l^2c^{*2} + 2B_{12}hka^*b^* + 2B_{13}hla^*c^* + 2B_{23}klb^*c^*)]$.

the chloroform solution is 17 Hz upfield, thus indicating the equatorial methyl group. Similar effects were found for 3-epianhydronupharamine and analogous compounds of the α-furan series (1). Thus, either (*i*) the synthetic compound differs from the natural 3-epinupharamine, or (*ii*) the empirical criterion which establishes the orientation of the *C*-methyl group in quinolizidine systems on the basis of the changes of chemical shifts in benzene solution does not hold for the piperidine system.

In order to solve this problem the X-ray structural analysis of the hydrobromide of the synthetic racemic 3-epinupharamine was carried out.

Experimental

Crystals suitable for X-ray analysis were prepared using a method described elsewhere (1). Preliminary Weissenberg photographs established that the crystals were monoclinic. The persistent absence of *hkl* reflections for $h + k = 2n + 1$, and of *h*0*l* reflections for $l = 2n + 1$, showed that the space group is either *Cc* or *C*2/*c*. The centrosymmetric space group *C*2/*c* (No. 15) (6) was determined from the statistics of $|E|$ values and satisfactory structure refinement. The cell parameters were determined by a least-squares refinement of the setting angles of 15 reflections found by automatic centering routine of Syntex $P2_1$ diffractometer (MoKα radiation, $\lambda = 0.71069$ Å).

$C_{15}H_{26}BrNO_2$ mw 332.3
Monoclinic, *C*2/*c*, $a = 18.163(3)$ Å, $b = 13.346(2)$, $c = 13.847(2)$, $\beta = 100.36(1)°$, $V = 3301.8$ Å^3, $Z = 8$, $d_m = 1.34$ g cm^{-3}, $d_x = 1.35$, μ(MoKα) = 26.4 cm^{-1}.

The density of 1.34 g cm^{-3} as determined by flotation in $CHCl_3$–benzene mixture agrees well with that calculated for a unit cell containing eight molecules of the compound.

Intensity data for a crystal of approximate dimensions 0.15 × 0.15 × 0.20 mm were collected, using MoKα radiation, on a Syntex $P2_1$ computer-controlled four-circle diffractometer equipped with a scintillation counter and graphite monochromator. A total of 1658 independent reflections were measured up to $2\theta = 45°$ by the θ–2θ scan technique. The scan rate varied from 2.0 to 20.0°/min depending on the reflection intensity. The 1122 reflections, for which $F > 3.92\sigma(F)$ were used in the subsequent calculations. The intensity of the standard reflection (040) was monitored at 15 reflection intervals. No significant variation of this intensity was observed. The intensities of reflections were corrected for the Lorentz and polarization effects. No absorption or extinction corrections were made.

Structure Determination and Refinement

The structure was established using the heavy-atom method. The bromine atom position was determined from a three-dimensional Patterson map. The remaining non-hydrogen atoms were located using a three-dimensional Fourier synthesis, which was phased on the bromine atom ($R_1 = 0.45$). Full-matrix least-squares refinement of the obtained structure model with isotropic thermal parameters yields the value of $R_1 = 0.164$. Several cycles of refinement with anisotropic temperature factors result in the agreement factor

$$R_1 = \sum||F_o| - |F_c||/\sum|F_o| = 0.080$$

and

$$R_2 = (\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2)^{1/2} = 0.074$$

At this stage coordinates of the hydrogen atoms were derived from a difference synthesis. A further five cycles of full-matrix refinement with isotropic temperature factors for hydrogen atoms gave the final values R_1 of 0.040 and R_2 of 0.026. The subsequent difference synthesis showed no unexpected features. The function minimized during the refinement was defined as $\sum w(|F_o| - |F_c|)^2$, where the weight $w = 1/\sigma^2(F)$. The atomic scattering factors were those listed by Cromer and Waber (7). The anomalous dispersion correction for Br^- was made according to Temple-

ton (8). The structure calculations were carried out using the Syntex XTL Structure Determination System (NOVA 1200 computer and additional external disk memory).[4] The figures were prepared with Johnson's ORTEP plotting program.

Table 1 contains the final atomic coordinates and anisotropic temperature factors with their standard deviations for non-hydrogen atoms. The final positional and isotropic thermal parameters for hydrogen atoms are listed in Table 2.

[4]The table of structure factors is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Description of the Structure and Discussion

The arrangement of molecules in the unit cell is shown in Fig. 1. The structural features of the molecule are illustrated in Fig. 2, while bond distances and angles are collected in Table 3. The furan ring and the side chain are equatorial, whereas the methyl group is axial (compare the distances of appropriate atoms from the plane 2, Table 4). Thus the stereochemistry of the synthetic alkaloid established by X-ray analysis re-

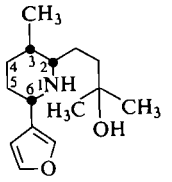
mains in good agreement with the results of spectroscopic measurements for natural 3-



1

epinupharamine **1**. Therefore, it must be concluded that the empirical criterion correlating the changes of chemical shifts with the orientation (axial or equatorial) of the methyl group does not hold for the piperidine system.

The piperidine ring of 3-epinupharamine has a chair conformation with C(6)–N(1)–C(2)–C(3) and C(3)–C(4)–C(5)–C(6) torsion angles being of 55.8° and −56.5°, respectively. The furan ring is planar (within one standard deviation, Table 4) and the dihedral angle between the plane of furan ring and that through C(2), C(4), C(5), and N(1) atoms is 29.8°.

The bond lengths in 3-epinupharamine are similar to those reported in crystal structure determination of related quinolizidine systems (9, 10) and dimeric sulphur Nuphar alkaloids (11). The observed valence angles of the piperidine and furan rings do not differ significantly from those expected for such systems. On the other hand, the C(2)–C(12)–C(13) and C(12)–C(13)–C(14) angles from the side chain are considerably larger than the value characteristic for a tetrahedral arrangement. The distortion found seems to be caused by the strains in seven-membered system formed by N(1), C(2), C(12), C(13), C(14), O(1), and H(N1a) atoms.

The strain imposed by strong, almost linear hydrogen-bonding interaction N(1)–H(N1a)···O(1) results in the increase of bond angles inside this system with the C(2)–C(12)–C(13) and C(12)–C(13)–C(14) angles being the most affected. A similar effect was observed in the maleic acid molecule (12) where the analogical angles differ from the value expected for unstrained molecule by ca. 10°.

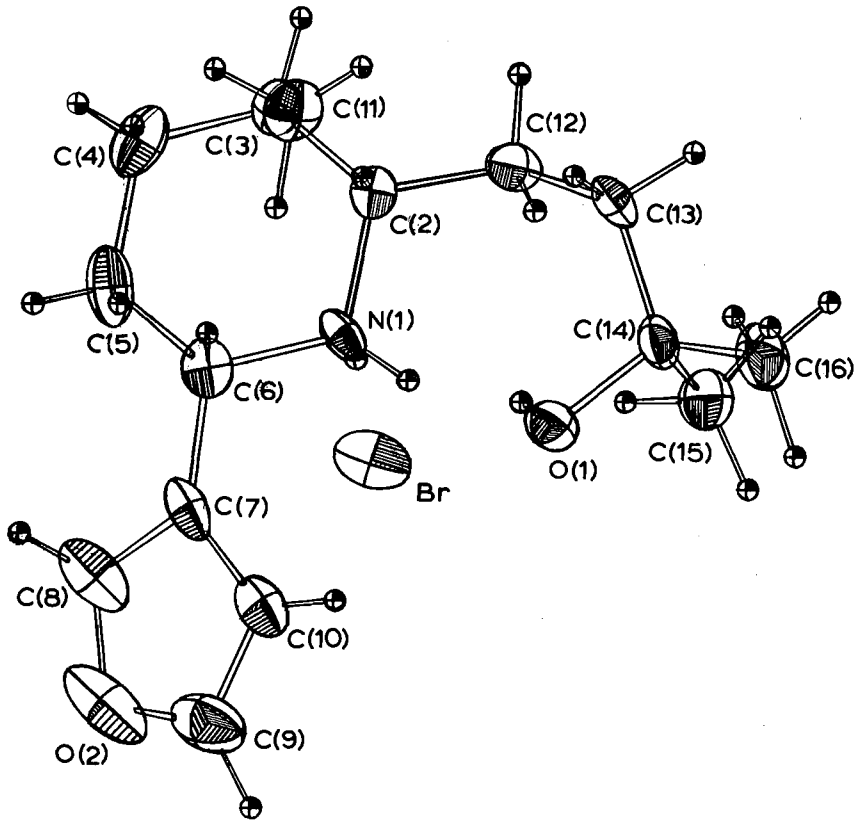


FIG. 2. A molecule of 3-epinupharamine hydrobromide with thermal ellipsoids scaled to include 50% probability. The hydrogen atoms are drawn with an arbitrary isotropic temperature factor.

TABLE 4. Equations of planes and deviations (in Å) of atoms from those planes[a]

Plane *1*: C(7), C(8), C(9), C(10), O(2)

Equation: $0.4427X + 0.0534Y + 0.8951Z = 1.8857$

Atom	Deviation	Atom	Deviation
C(7)*	0.001(9)	C(10)*	0.000(9)
C(8)*	−0.003(10)	O(2)*	0.002(8)
C(9)*	−0.002(12)	C(6)	−0.024(7)

Plane *2*: N(1), C(2), C(4), C(5)

Equation: $0.0406X + 0.0908Y - 0.9950Z = -1.9590$

Atom	Deviation	Atom	Deviation
N(1)*	−0.004(5)	C(11)	−2.187(9)
C(2)*	0.006(7)	C(12)	−0.588(8)
C(4)*	−0.014(10)	C(13)	0.337(8)
C(5)*	0.013(9)	C(14)	0.538(7)
C(3)	−0.669(8)	C(6)	0.716(7)

[a]The angle between plane *1* and plane *2*: 29.8°. Standard deviations are given in parentheses. Atoms used to define the planes are indicated by an asterisk.

There are three unique hydrogen bonds in the structure (Table 4). Each nitrogen atom is linked by an N—H···Br^- bond to the Br^- ion of the nearest neighbour molecule related by the glide plane *c*. The parameters characterizing the geometry of this bond are as follows: N–H 1.01(5) Å, N···Br^- 3.317(5) Å, N–H–Br^- 176(4)°. Another reasonably strong interaction consisting of the Br^- ion is O(1)–H(O1)···Br^-, where both donor and acceptor atom are from the same molecule. The hydroxyl bond length is 0.84(5) Å and the donor–acceptor distance is 3.244(5) Å with an O–H–Br^- angle of 159(4)°.

The O(1) atom is also involved in the intramolecular N(1)–H(N1a)···O(1) bond with the N(1)···O(1) contact being 2.751(8) Å and the N(1)–H(N1a)–O(1) angle (165°) not too much deviated from linearity.

Crystal and molecular structure of dodecamethylcyclohexaphosphazene, $(NPMe_2)_6$

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received March 9, 1977

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **55**, 3118 (1977).

Crystals of dodecamethylcyclohexaphosphazene are triclinic, $a = 13.898(1)$, $b = 8.690(1)$, $c = 10.790(1)$ Å, $\alpha = 109.84(1)$, $\beta = 92.01(1)$, $\gamma = 106.39(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.034 and R_w of 0.042 for 4217 reflections with $I \geq 3\sigma(I)$. The unit cell contains two independent centrosymmetric molecules which are virtually identical. The 12-membered rings have the 'double tub' conformation. Bond lengths not involving hydrogen have been corrected for libration. Weighted mean bond lengths (rms deviations from the mean in parentheses) are: P—N, 1.593(6), C—P, 1.808(4), and C—H, 0.95(6) Å.

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 3118 (1977).

Les cristaux du dodécaméthylcyclohexaphosphazène sont tricliniques, $a = 13.898(1)$, $b = 8.690(1)$, $c = 10.790(1)$ Å, $\alpha = 109.84(1)$, $\beta = 92.01(1)$, $\gamma = 106.39(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.034 et de R_w de 0.042 pour 4217 réflexions avec $I \geq 3\sigma(I)$. La maille unitaire contient deux molécules centrosymétriques indépendantes qui sont pratiquement identiques. Les cycles à 12 chaînons ont la conformation "double bateau". On a corrigé les longueurs de liens n'impliquant pas les hydrogènes pour la libration. Les longueurs de liaison moyennes (la déviation rms de la moyenne est indiquée entre parenthèse) sont P—N, 1.593(6), C—P, 1.808(4) et C—H, 0.95(6) Å.

[Traduit par le journal]

Introduction

This report is the third in a series dealing with the crystal structures of large ring methylphosphazenes $(NPMe_2)_n$ $(n \geq 6)$. The two previous papers in this series dealt with the structures of the heptameric (1) and octameric (2) methylphosphazenes $(NPMe_2)_7$ and $(NPMe_2)_8$. The structure of the hexamer, $(NPMe_2)_6$, is the topic of the present report.

Experimental

Dodecamethylcyclohexaphosphazene was prepared as previously described (1). Crystals suitable for X-ray analysis were obtained by recrystallization from *p*-xylene. The crystal chosen for study was mounted with (1 1 1) perpendicular to the goniostat axis and had dimensions of ca. 0.30 × 0.44 × 0.56 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares on 2 sin θ/λ values for 50 reflections measured on a diffractometer with CuKα radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{12}H_{36}N_6P_6$ fw = 450.3

Triclinic, $a = 13.898(1)$, $b = 8.690(1)$, $c = 10.790(1)$ Å, $\alpha = 109.84(1)$, $\beta = 92.01(1)$, $\gamma = 106.39(1)°$, $V = 1164.4$ (2) Å^3, $\rho_m = 1.26$ (flotation in aqueous KI), $Z = 2$, $\rho_c = 1.284$ g cm^{-3}, $F(000) = 480$, μ(CuKα) = 43.0 cm^{-1}. Absent reflections: none. Space group $P\bar{1}$ (C_i^1, No. 2).

Intensities were measured with nickel-filtered CuKα radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed; 10 s background counts were measured at each end of the scan. Data were measured to 2θ = 160°. The intensities of the check reflections, measured every 50 reflections throughout the data collection, decreased slowly to a value which was 0.758 times the initial value. The structure amplitudes were derived and an absorption correction was applied by a computer program using a Gaussian integration method (3, 4). Transmission factors ranged from 0.190 to 0.410. Of the 5086 independent reflections measured, 4242 had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were used in the solution and refinement of the structure.

The centrosymmetric space group $P\bar{1}$ was indicated by the E statistics. The structure was solved by direct methods (5). All the P and N atoms and 4 of the 12 carbon atoms were located on an E map. The structure was found to consist of two independent molecules lying around inversion centres. These atoms were refined isotropically for two cycles giving $R = 0.248$. The remaining carbon atoms were found on a difference map at this point. The non-hydrogen atoms were refined isotropically for two cycles, and then anisotropically for

two cycles, reducing R to 0.079. The positions of all 36 hydrogen atoms were determined from a difference map. The entire structure (full-matrix, including hydrogen atoms with isotropic thermal parameters) was refined for eight cycles giving a final R of 0.034 and R_w of 0.042 for 4207 reflections with $I \geq 3\sigma(I)$ (35 observed reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections, but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 5086 reflections $R = 0.044$ and $R_w = 0.045$.

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $1.56(8) \times 10^{-7}$. The scattering factors of ref. 6 were used for the non-hydrogen atoms and those of ref. 7 for the hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the non-hydrogen atoms. The weighting scheme $w = 1.00$ if $|F_o| < 16.0$, $w = (16.0/|F_o|)^2$ if $|F_o| \geq 16.0$, and $w = 0.0625$ for the unobserved reflections gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.04σ, with no shift greater than 0.4σ. The mean error in an observation of unit weight was 0.4819. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (9) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0012 Å^2. Analyses of the entire molecules as rigid bodies were unsuccessful, but each of the independent phosphorus tetrahedra behaves as a rigid body (rms $\Delta U_{ij} = 10, 10, 10, 10, 9$, and 9×10^{-4} Å^2 for P(1) to P(6) respectively).

The appropriate bond distances have been corrected for libration (10, 11), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values. Corrected angles differ by no more than $\pm 0.1°$ from the uncorrected values given in Table 4.

Results and Discussion

Figure 1 shows general views of the two independent molecules with the crystallographic numbering scheme and Fig. 2 shows the packing arrangement viewed down the b^* axis. The unique intra-annular torsion angles in the 12-membered rings are given in Table 5 and the mean structural parameters for $(NPMe_2)_6$ are compared with those of the related molecules $(NPMe_2)_4$ (12), $(NPMe_2)_5$ (13), $(NPMe_2)_7$ (1), and $(NPMe_2)_8$ (2) in Table 6.

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

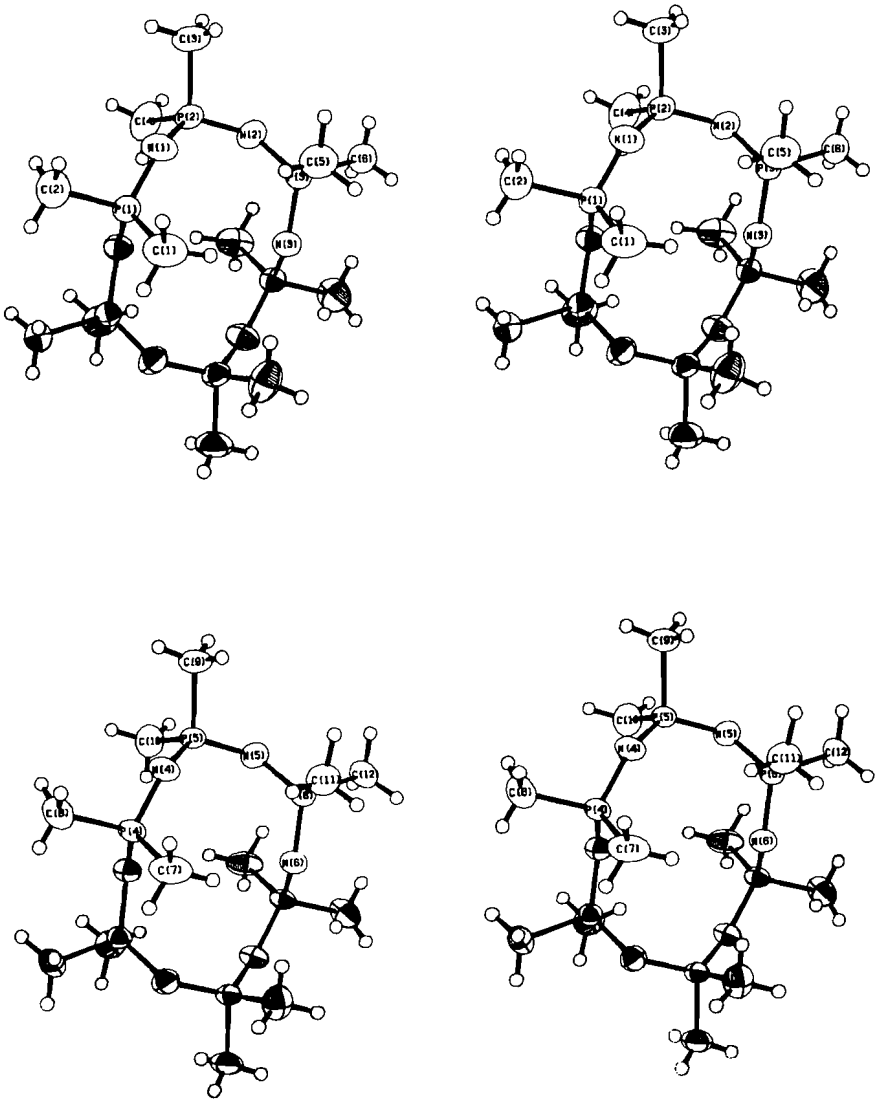

FIG. 1. Stereo views of the dodecamethylcyclohexaphosphazene molecules 1 (top) and 2 (bottom); 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

The crystal structure consists of well-separated molecules of dodecamethylcyclohexaphosphazene (see Fig. 2). The shortest non-bonded intermolecular distance (H(2*a*)...H(7*c*)[1 + *x*, *y*, *z*] = 2.46(5) Å) corresponds to a normal van der Waals interaction. The unit cell contains two independent centrosymmetric molecules. Molecule 1 is located at the crystallographic centre of symmetry ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$) and molecule 2 at (0, $\frac{1}{2}$, 0). The two independent molecules are virtually identical; corresponding bond lengths are equal within experimental error while there are some small, but significant, differences between corresponding bond angles and torsion angles. The corresponding parameters are listed side by side in Tables 3–5 for comparison. Packing forces are believed to be responsible for the minor differences between the two molecules.

Both molecules have a 'double tub' conformation closely resembling that of the centro-

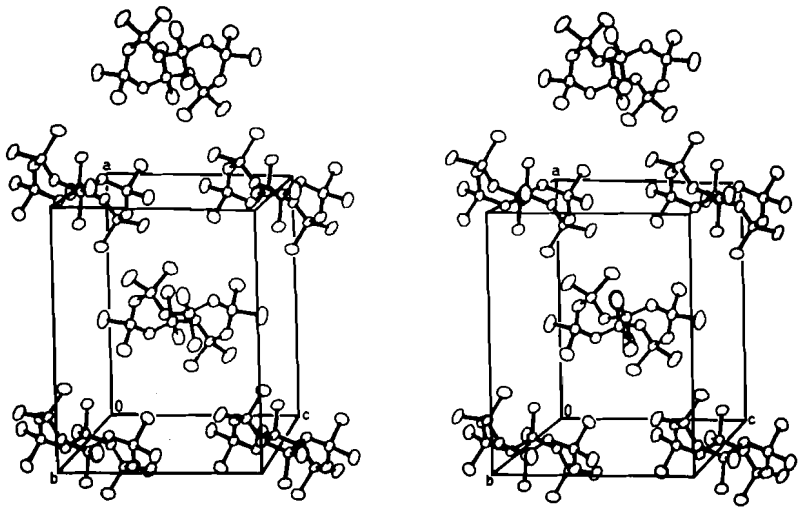

FIG. 2. The packing arrangement viewed down b^*.

*Root mean square deviations from the mean (in units of the last figure shown) in parentheses.

symmetric molecule $[NP(OMe)_2]_6$ (14). The mean intra-annular torsion angles in $(NPMe_2)_6$ differ from those in $[NP(OMe)_2]_6$ by no more than 17.2° (mean deviation = 7.3°). The conformation of the 12-membered rings is qualitatively similar to that found for $[NP(NMe_2)_2]_6$ (15) which has $\bar{3}$ symmetry and torsion angles which are alternately 17 and 97°. The local conformations (14, 16) at the phosphorus atoms are CT for P(1) and P(4), GG for P(2) and P(5), and GT for P(3) and P(6). The energetically less favorable CT conformation (14) does not occur in the larger, less-restricted rings of $(NPMe_2)_{7 \text{ and } 8}$ (1, 2).

The mean structural parameters of the methylphosphazenes in Table 6 show that the P—C and P—N bond lengths and the C—P—C angles are nearly the same in all five molecules. The N—P—N angles appear to be decreasing toward a limiting value with increasing n. The mean P—N—P angles span a range of about 8° for $(NPMe_2)_{4-8}$ and show large variations between the independent values found for each molecule (with the exception of the tetramer which has

crystallographic $\bar{4}$ symmetry). Ring strain resulting from steric and/or electronic forces in the phosphazenes is relieved primarily by distortions of the P—N—P angles. The σ-bonding orbitals at N have a high *s* component (confirmed by X_α calculations[2]), which would make them less directional. Large angles at nitrogen are therefore often associated with a large variability of the angle, as found in the structure of $[NP(NMe_2)_2]_8$ (17) where the P—N—P angles range from 145.9 (4) to 170.2(5)°.

The geometry involving hydrogen atoms is as expected for X-ray data. The weighted mean C—H distance is 0.95(6) Å and weighted mean P—C—H and H—C—H angles are 107(2) and 111(4)° respectively.

Behavior of hydrogen atoms in the fragmentation of CH_3CD_3

ISAO H. SUZUKI AND KOGORO MAEDA
Electrotechnical Laboratory, Tanashi, Tokyo, Japan

Received February 17, 1977

ISAO H. SUZUKI and KOGORO MAEDA. Can. J. Chem. **55**, 3124 (1977).

The behavior of hydrogen atoms in the fragmentation of CH_3CD_3 has been studied by use of a monoenergetic electron beam. Ionization efficiency curves for ions (*m/e* 3, 4, 15 to 18, 26 to 33) from CH_3CD_3 have been measured over ranges of 12 to 30 eV near their appearance thresholds. Mass spectra over various ranges of *m/e* have been measured at several electron energies. It has been found that at least two processes participate in the formation of $C_2X_4^+$ and CH_3^+ (X = H or D) and the rates of these processes depend on the energy of electron beam. The formations of $C_2X_2^+$ and X_2^+ are independent of the electron energy.

ISAO H. SUZUKI et KOGORO MAEDA. Can. J. Chem. **55**, 3124 (1977).

On a étudié le comportement des atomes d'hydrogène dans la fragmentation de CH_3CD_3 en faisant appel à un faisceau d'électrons monoénergétiques. On a mesuré les courbes d'efficacité d'ionisation pour les ions (3, 4, 15 à 18, 26 à 33 *m/e*) pour CH_3CD_3 à des potentiels d'ionisation de 12 à 30 eV près de leur point d'apparition. On a mesuré les spectres de masse à diverses valeurs de *m/e* à plusieurs énergies des électrons. On a trouvé qu'au moins deux processus participent à la formation de $C_2X_4^+$ et CH_3^+ (X = H ou D) et les vitesses de ces processus dépendent de l'énergie du faisceau d'électrons. Les formations de $C_2X_2^+$ et X_2^+ sont indépendantes de l'énergie des électrons.

Introduction

Many studies have been carried out on the ionization and fragmentation of ethane using mass spectra and appearance potentials (AP) of the fragment ions. Photoionization mass spectrometry provided reliable AP's for ions produced at relatively low energy (1) and a photoelectron–photoion coincidence method (2, 3) examined the quasi-equilibrium theory (4, 5) with respect to the fragmentation of the ethane ion. The theory was also compared with the breakdown curve obtained by an ion impact technique (6).

Amenomiya and Pottie measured mass spectra of normal and nine deuterated ethanes generated by 70 eV electrons and found that at least two processes contribute to the formation of $C_2X_4^+$ (X = H or D) and of CX_3^+ (7, 8). By observing metastable transitions Löhle and Ottinger reported that $C_2X_4^+$ is produced only through the detachment of two hydrogen atoms from different carbon atoms near the threshold and that CX_3^+ is produced from $C_2X_6^+$ via two processes: simple breaking of the C—C bond and hydrogen scrambling followed by bond breaking (9). The former finding is in agreement with the result by Lifshitz and Sternberg (10). Von Koch observed $C_2HD_3^+$ and $C_2H_3D^+$ from CH_3CD_3 by impact of Ar^+ but was unable to detect these ions with ground state Xe^+(6). Moreover, he found that the intensity ratios of CX_3^+ (*m/e* 15–18) by Ne^+ and He^+ impacts were different from each other (6).

The above results are summarized as follows. The mechanism of $C_2X_4^+$ formation depends upon the internal energy of $C_2X_6^+$; at least two processes participate and the thresholds of the two processes are different. The mechanism of CX_3^+ formation also depends on the internal energy.

In order to obtain more precise information on the formation of these ions, it is important to determine the thresholds more accurately and to clarify the energy dependence of the fragmentation mechanisms. In the present study ionization efficiency curves of $C_2X_4^+$ and CX_3^+ from CH_3CD_3 were measured over ranges of about 15 eV near their appearance thresholds by use of a monoenergetic electron beam. Mass spectra were measured at several electron energies and over several ranges of *m/e*. The formation of these ions was discussed on the basis of their energy dependences and isotope distributions. Similar studies were carried out on the formation of $C_2X_2^+$ and X_2^+. A total ionization efficiency curve of CH_3CD_3 was calculated from the intensity ratio and ionization efficiency curves for all ions.

Experimental

Measurements were made using the apparatus described in previous papers (11, 12). In observing the ionization efficiency curve each memory channel in the pulse height analyzer was assigned to each electron energy, while in observing the mass spectra the memory channels were used as a mass scale. The energy of the bombarding electron beam (f.w.h.m.: 0.15 eV) was scanned from 10 to 23 eV with 0.05 eV intervals for most ions measured (*m/e* 15, 18, 26 to 33). The energy was scanned from 12 to 30 eV with 0.1 eV intervals for ions of *m/e* 16 and 17, and scanned from 20 to 50 eV with 0.2 eV intervals for ions of *m/e* 3 and 4. Ion counts of about 40 cps were obtained for ions of *m/e* 30 at 23 eV and noise counts were less than 0.05 cps.

The electron energy was calibrated by using the 14.00 eV threshold of Kr. Ionization efficiency curves were processed by a computer to check reproducibility and to estimate a standard deviation at every energy (13). Error bars in the figures given in this paper were calculated from these standard deviations.

The ethane-1,1,1-d_3 (Merck Sharp & Dohme Co., Ltd., isotopic purity 98%) was introduced at about 1.7×10^{-5} Torr. No correction for isotopic purity was carried out in this study.

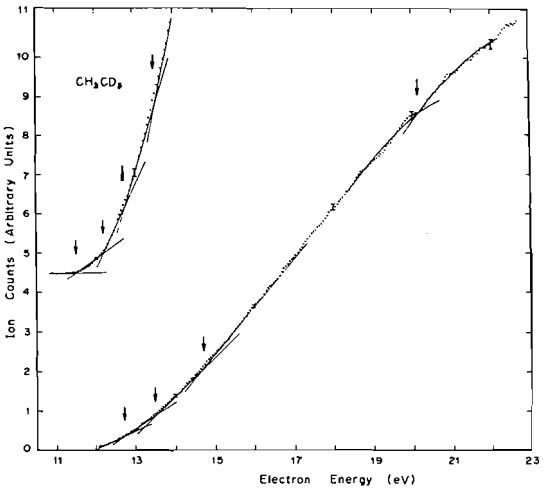

FIG. 1. Total ionization efficiency curve of CH_3CD_3. The curve near threshold is shown with an expanded scale in the upper part of the figure. Bars indicate statistical errors calculated from the standard deviations obtained in the data-processing of ionization efficiency curves.

Results

Total Ionization Efficiency Curve

A total ionization efficiency curve of CH_3CD_3 is shown over a range of bombarding electron energy from 11 to 22 eV in Fig. 1. This curve is a sum of the intensities of the ions *m/e* 15, 18, and 26 to 34. The mass discrimination effect in the present experimental system was not taken into account for the lack of established mass spectrum of CH_3CD_3 but the effect on the curve is expected to be quite small (13). The upper curve with an expanded scale indicates an onset at 11.5 eV followed by breaks at 12.2, 12.7, and 13.5 eV, slightly different from those of C_2H_6 (13). Breaks at 14.7 and 20.1 eV are supposed to correspond to third and fourth electronic states of ethane ion as seen in the case of C_2H_6 (13–16).

Ionization and Appearance Potentials

Table 1 shows IP's of CH_3CD_3 and AP's of the fragment ions including two carbon atoms from CH_3CD_3 as well as the corresponding values for C_2H_6 (13). There is no indication of an ion-pair process in the ionization efficiency curve for $C_2H_3D_2^+$ (*m/e* 31). This is probably due to the smearing out by the tailing of $C_2HD_3^+$ toward low energy and by the ethylene ion $^{13}CCH_2D_2^+$. The AP's of the ions of *m/e* 29 and 30 indicate those by $C_2X_4^+$ (X = H or D) because the vinyl ion $C_2H_3^+$ has a considerably higher AP (13). It is important to note that the $C_2H_3D^+$ produced through the detachment of two hydrogen atoms from the same carbon atom has a higher AP than the $C_2H_2D_2^+$ produced through the detachment of two hydrogen atoms from different carbon atoms. (The difference between these AP's was suggested to be 0.8 eV by Lorquet and Lorquet (22).) The AP of $C_2HD_3^+$ (*m/e* 31) is assumed to be equal to that of $C_2H_3D^+$ because both ions are produced through the same detachment process. Since $C_2H_3^+$ is responsible for the AP of 14.9 eV for *m/e* 27, the AP for C_2HD^+ is presumed to be close to that for $C_2H_2^+$, 15.5 eV.

Table 2 shows AP's of the fragment ions including one or no carbon atom from CH_3CD_3 and from C_2H_6 (13). Since CX_2^+ and CX_4^+ are lower in intensity and have higher AP's than CX_3^+, the CX_3^+ ion is responsible for AP's of ions of *m/e* 15 to 18. There is no indication of an ion-pair process in the ionization efficiency curve for CH_3^+ unlike that for CD_3^+. The two ions CH_3^+ and CD_3^+ produced through the simple breaking of C—C bond have lower AP's than CHD_2^+ and CH_2D^+ produced through the breaking of C—C bond after rearrangement of hydrogens. D'Or and co-workers measured the AP's of CX_3^+ from CH_3CD_3 by using the vanishing current method and found that the AP's of CX_3^+ from CH_3CD_3 and also from C_2H_6 were all equal to one another within their

experimental accuracy (17). In the present study, all ions of CX_3^+ from CH_3CD_3 have slightly higher AP's than CH_3^+ from C_2H_6. Appearance potentials for X_2^+ from CH_3CD_3 agree with that for H_2^+ from C_2H_6 within experimental accuracy.

Intensity Ratio of Ions

Several measurements have been reported on the mass spectra of CH_3CD_3 at 50–75 eV, but the results are not always in agreement with one another (7, 9, 18–20). In the present study mass spectra of CH_3CD_3 were measured at several electron energies and over various ranges of *m/e*. Our results are the closest to those of Stief and Ausloos (20). The intensity ratio of ions obtained at 22.7 eV is shown in Table 3 as well as that of C_2H_6 at 22.6 eV without correction for mass discrimination. Most intense is the ion of *m/e* 30 which consists mostly of $C_2H_2D_2^+$. The intensity of *m/e* 26, mostly $C_2H_2^+$, is close to 25% of that of C_2HD^+ because $C_2H_3^+$ should be much lower than C_2HD^+ in intensity. The *m/e* 16 and 17 ions are due to CH_2D^+ and CHD_2^+, not due to CD_2^+ and CH_3D^+.

Behavior of Hydrogen Atoms in the Fragmentation Process

Formation of $C_2X_4^+$

Several investigators studied the formation of $C_2X_4^+$ (X = H or D) from $C_2X_6^+$ using deuterated ethanes and concluded that the ion is produced through detachment of two hydrogen atoms from different carbon atoms in the parent ion near the threshold (9, 10, 17).

[1]  $\rightarrow CX_2CX_2^+ + X_2$

TABLE 3. Relative intensities of the ions produced from CH_3CD_3 at 22.7 eV and from C_2H_6 at 22.6 eV over ranges from *m/e* 14 to 34. Intensities of other ions are extremely low and neglected

	CH_3CD_3		C_2H_6

34	$^{13}CCH_3D_3^+$	0.004		
33	$C_2H_3D_3^+$	0.202		
32	$C_2H_2D_3^+$	0.101		
31	$C_2H_3D_2^+$, $C_2HD_3^+$	0.190	$^{13}CCH_6^+$	0.004
30	$C_2D_3^+$, $C_2H_2D_2^+$	1.000	$C_2H_6^+$	0.205
29	$C_2HD_2^+$, $C_2H_3D^+$	0.209	$C_2H_5^+$	0.173
28	$C_2H_2D^+$, $C_2D_2^+$	0.084	$C_2H_4^+$	1.000
27	$C_2H_3^+$, C_2HD^+	0.042	$C_2H_3^+$	0.135
26	C_2D^+, $C_2H_2^+$	0.009	$C_2H_2^+$	0.056
25	C_2H^+	<0.001	C_2H^+	<0.001
19	CHD_3^+	<0.001		
18	$CH_2D_2^+$, CD_3^+	0.007		
17	CH_3D^+, CHD_2^+	0.002		
16	CD_2^+, CH_2D^+	0.002	CH_4^+	<0.001
15	CHD^+, CH_3^+	0.006	CH_3^+	0.020
14	CH_2^+	<0.001	CH_2^+	<0.001

In process 1 the X_2 is expected to form a hydrogen molecule, but the present method of analysis is not altered even if the X_2 is two atomic hydrogens. Von Koch measured $C_2H_3D^+$ and $C_2HD_3^+$ from $CH_3CD_3^+$ with excess internal energy by use of the charge exchange collision with ions which have higher recombination energies than the IP of CH_3CD_3 (6). Amenomiya *et al.* proposed the possibility of $C_2X_4^+$ formation through the detachment of two hydrogen atoms from the same carbon atom in the parent ion in order to reproduce mass spectra of nine deuterated ethanes at electron impact of 70 eV (7, 8).

[2]  $\rightarrow CXCX_3^+ + X_2$

where the X_2 is similar to that of process 1.

Those results are consistent with the result shown in Table 1; the threshold for process 1 is lower than that for process 2. These suggest that the fragmentation of the ion proceeds through at least two processes and that the mechanism of the formation depends on the excess internal energy of the parent ion.

Apart from the two processes shown above, there is a possibility that a scrambling process participates in the formation of the ion (8, 12). In this process the exchange of hydrogen atoms is presumed to occur through an intermediate bridged structure

However this process is not considered in the present study, because it includes the ambiguous assumption of the intermediate; moreover the formation of the ion can be explained by adopting only two processes 1 and 2.

In the case that only process 1 participates in the formation of the ion, the intensity ratio of $C_2H_3D^+$, $C_2H_2D_2^+$, and $C_2HD_3^+$ (*m/e* 29 to 31) is 0:2:0, while in the case that only process 2 participates, the ratio is 1:0:1. Since the ratio estimated from the data observed at 22.7 eV is 0.14:1:0.12, two processes take part in the formation at this energy. When the intensity ratio is described as α:1:α at a bombarding electron energy, the rate at which process 1 participates is $1/(2\alpha + 1)$ at that energy. (In the present study the term 'rate' does not mean the velocity at which a reaction proceeds, but only the fraction of ion product formed by the process in question.) The participating rate of process 2 is $2\alpha/(2\alpha + 1)$.

In Fig. 2 are shown the energy dependence of the latter rate. The contribution of $C_2D_3^+$ to the intensity of *m/e* 30 is negligible because $C_2D_3^+$ is estimated to be less than 0.01 of $C_2H_2D_2^+$ (*m/e* 30) in intensity. In the calculation of the intensity of $C_2HD_3^+$ (*m/e* 31), the intensity of $C_2H_3D_2^+$ (*m/e* 31) was assumed to be 0.55 of that of $C_2H_2D_3^+$ (*m/e* 32) in all regions of

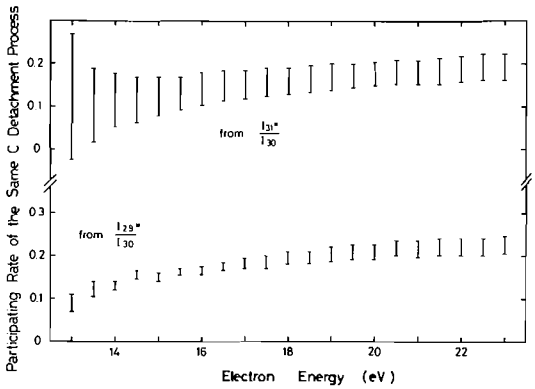

FIG. 2. Energy dependences of the participating rates of the same carbon atom-detachment process in $C_2X_4^+$ formation. The rates calculated from the intensity ratios of $C_2HD_3^+$ (*m/e* 31) to $C_2H_2D_2^+$ (*m/e* 30) and $C_2H_3D^+$ (*m/e* 29) to $C_2H_2D_2^+$ are shown in the upper and lower parts, respectively. The rates were calculated at 0.05 eV intervals and plotted at 0.5 eV intervals. Bars indicate statistical errors calculated from the standard deviations obtained in the data-processing of ionization efficiency curves. See the text with respect to I_{31}* and I_{29}*.

energy.[1] Although the factor was varied from 0.5 to 0.7, the rates calculated have similar trends. The intensity of $C_2H_2D_2^+$ including ^{13}C was considered in the calculation. In the calculation of the intensity of $C_2H_3D^+$ (*m/e* 29), $C_2HD_2^+$ (*m/e* 29) was assumed to have the same energy dependence as that of $C_2H_3^+$ from C_2H_6 and the intensity at 22.7 eV was assumed to be 0.069 of that of *m/e* 30.

The plots in Fig. 2 indicate that both rates are lower than 0.1 below 13 eV and gradually approach a plateau of about 0.2 around 20 eV. Amenomiya and Pottie estimated that the rate was 0.13 at 70 eV (8). Their rate is lower than that of the present study provided that the plateau continues towards higher energies. Most of $C_2X_4^+$ is produced from $C_2X_6^+$ through process 1 in all regions of energy with a slight contribution from process 2, at most 20%, above 12.5 eV.

On account of the AP for $C_2H_3D^+$ in Table 1, the state in which process 2 participates in $C_2X_4^+$ formation is assumed to be related to the upper state of the doublet which is caused by the Jahn–Teller effect in ^2E_g of $C_2X_6^+$ (14, 15). The lower state probably corresponds to process 1.

[1]Amenomiya and Pottie estimated the factor to be 0.57 in ref. 8.

Formation of $C_2X_2^+$

In the formation of $C_2X_2^+$ from $C_2X_6^+$, $C_2X_4^+$ has been proposed to be an intermediate by several authors (4, 9, 10, 21). The relevant ion is assumed to be produced from $C_2H_2D_2^+$ through the two following processes:

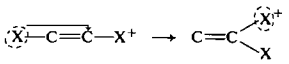
[3] 
[4] 
where X_2 is similar to that of the former section.

When the intensity ratio of C_2HD^+ to $C_2H_2^+$ is described as $1:\alpha$ at a given electron energy, the participating rate of process 4 is $2\alpha/(2\alpha + 1)$ at that energy. The energy dependence of the rate is shown at the lower part of Fig. 3. Since the intensities of $C_2H_3^+$ and C_2D^+ are expected to be extremely low over the range of the energy studied, contributions of the two ions were ignored in the calculation of the rate. The energy dependence of the intensity ratio of *m/e* 26 to 27 is shown at the upper part, with the scale indicated at the right side. Both are independent of the electron energy within the indicated accuracy.

The result suggests that processes 3 and 4 have the same threshold energy. This is, however, somewhat doubtful because the product ions differ considerably in stability (about 3 eV in a rough estimation).[2] If the present result is interpretable as a scrambling process (22), the scheme of $C_2X_2^+$ formation can be simplified to a single process.

[5] 
(scrambling state) → $CXCX^+ + X_2$

[2]The energy difference is roughly estimated from transfer of a hydrogen atom,



Thus the energy difference is calculated from an equation, $\Delta E = \{AP(C_2H^+ \text{ from } C_2H_2) - IP(C_2H_2)\} - \{AP(C_2H_3^+ \text{ from } C_2H_4) - IP(C_2H_4)\}$.

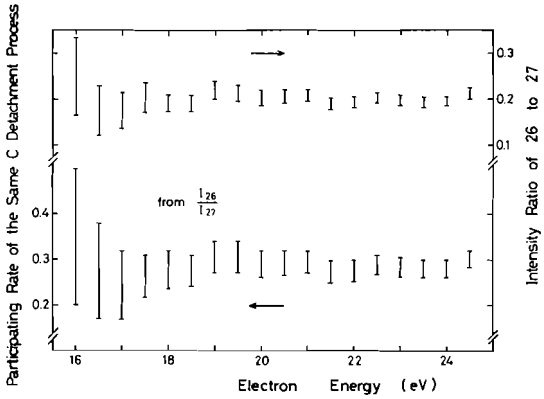


FIG. 3. Energy dependences of the participating rate of the same carbon atom-detachment process and of the intensity ratio of *m/e* 26 to 27 in $C_2X_2^+$ formation. The ratio and the rate were calculated at 0.05 eV intervals and plotted at 0.5 eV intervals in the upper and lower parts, respectively. Bars indicate statistical errors calculated from the standard deviations obtained in the data-processing of ionization efficiency curves.

As in the case of the fragmentation of ethylene ion, $C_2X_2^+$ is produced through process 5 over all ranges of energy, in which the intensity ratio of $C_2H_2^+$ to C_2HD^+ is 1:4 (12). Figure 3 is consistent with this interpretation; the indicated ratio of about 0.2 is a little smaller than the expected value 0.25 in all the energies observed. The difference of the ratios is due to the fact that the lighter neutral isotopic species departs faster than the heavier from the scrambling ion (9, 10, 12). If scrambling occurs in $C_2X_6^+$, the ratio is calculated to be 0.33. Therefore, the most probable interpretation for $C_2X_2^+$ formation from $C_2X_6^+$ is as follows: firstly $C_2X_6^+$ decomposes into $C_2X_4^+$ through process 1 and further $C_2X_4^+$ decomposes into $C_2X_2^+$ through process 5.

The state in which $C_2X_6^+$ decomposes at the first step described above is supposed to be related to the lower state of the doublet which is caused by the Jahn–Teller effect in ^2E_u (14, 15).

Formation of X_2^+

The present authors are unaware of any papers in which the mechanism of X_2^+ formation from $C_2X_6^+$ was studied. By analogy with former sections, it is assumed that X_2^+ formation proceeds through two processes.

[6]  $\rightarrow X_2^+ + CX_2CX_2$

[7]  $\rightarrow X_2^+ + CX_3CX$

In the X_2^+ formation, there are possibilities that $C_2X_4^+$ and other ions are intermediate ions. Tentatively, however, these processes were not taken into account in the present analysis because no information on these intermediate ions exists. When the intensity ratio of HD^+ to D_2^+ is described as $1:\alpha$ at an energy, the participating rate of process 7 is $2\alpha/(2\alpha + 1)$ at that energy. The energy dependence of the rate is shown over a range of bombarding electron energy from 36 to 50 eV in Fig. 4. The rate is independent of energy within the indicated accuracy. The scrambling process, however, cannot be ruled out for the following reasons. The threshold energies for HD^+ and D_2^+ are the same, as seen in Table 2. The observed intensity ratio of these ions, 1:0.4, is close to the calculated one on the assumption of the scrambling in $C_2X_6^+$, 1:0.33. (The calculated ratio is 1:0.25 in the scrambling of $C_2X_4^+$.)

Formation of CX_3^+

Löhle *et al.* measured CX_3^+ (*m/e* 15 to 18) produced through metastable transition from CH_3CD_3 and concluded that the scrambling in $C_2X_6^+$ occurs incompletely before metastable C—C bond breaking (9). This finding is consistent

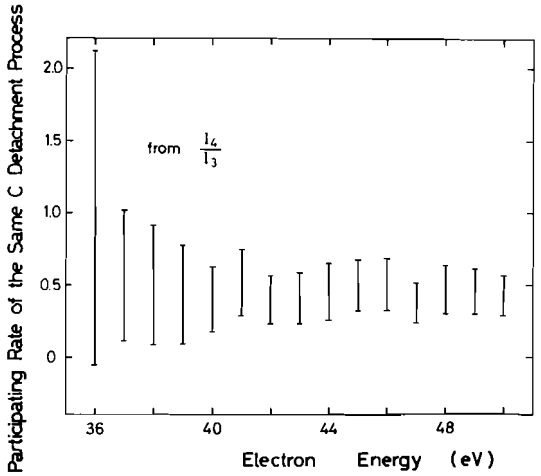

FIG. 4. Energy dependence of the participating rate of the same carbon atom-detachment process in X_2^+ formation. The rate was calculated at 0.2 eV intervals and plotted at 1 eV intervals. Bars indicate statistical errors calculated from the standard deviations obtained in the data-processing of ionization efficiency curves.

with mass spectra at 70 eV by Amenomiya and Pottie (7). By use of charge exchange collision von Koch found that the relative intensities of *m/e* 15 to 18 were dependent on the excess internal energy of $CH_3CD_3^+$ (6). Then, the CX_3^+ formation from CH_3CD_3 can be assumed to proceed through two following processes.

[8] $X_3C\text{-}CX_3^+ \rightarrow CX_3^+ + CX_3$

[9] $X_3C\text{—}CX_3^+ \rightarrow$ (scrambling state) $\rightarrow CX_3^+ + CX_3$

Table 2 suggests that the thresholds for processes 8 and 9 are about 15.5 and 17.0 eV. If only process 8 participates in CX_3^+ formation, the intensity ratio of CD_3^+, CHD_2^+, and CH_2D^+ (*m/e* 18 to 16) is 10:0:0. If only process 9 participates in the formation of CX_3^+, the ratio is 1:9:9. Since the ratio was estimated from the experimental result to be 1:0.22:0.25 at 22.7 eV, both processes took part in CX_3^+ formation at that energy. When the ratio is described as $1:\alpha:\alpha$ at an energy, the participating rate of process 9 is $10\alpha/9(\alpha + 1)$ at that energy.

The rates are shown over a range from 16 to 23.5 eV in Fig. 5. Since CX_2^+ and CX_4^+ are much lower than CX_3^+ in intensity, those ions were not taken into account in estimating the intensities of *m/e* 16 to 18. The rates are both zero at low energy and reach plateaus of about 0.2 around 18.5 eV. Decreases of the rates at 19 eV were caused by the decreases in slope in the ionization efficiency curves of *m/e* 16 and 17 at the energy, but the cause of the decreases cannot be clarified at present. The figure indicates that CX_3^+ is produced through the simple breaking of the C—C bond, process 8, at the rate of more than 80% in the region of the energy studied. The extent of reshuffling at 70 eV estimated by Amenomiya and Pottie 21% (8) corresponds to the rate of 0.23 in the present study. Therefore the plateaus in Fig. 5 are presumed to extend to 70 eV.

Löhle *et al.* detected metastable peaks of CX_3^+ produced from $C_2X_5^+$ which is produced from $C_2X_6^+$ and scrambles completely (9). Thus there

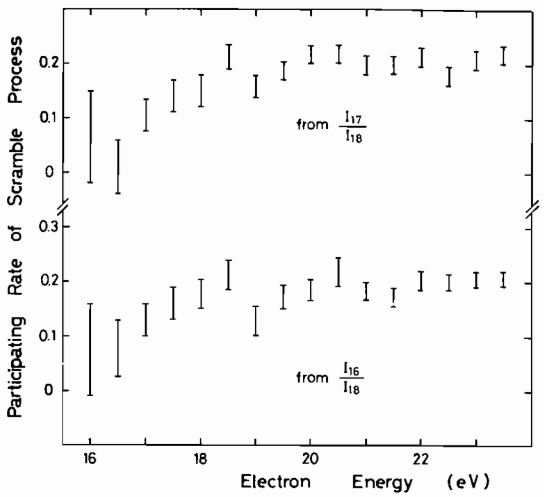

FIG. 5. Energy dependences of the participating rates of the scramble process in CX_3^+ formation. The rates calculated from the intensity ratios of CHD_2^+ (*m/e* 17) to CD_3^+ (*m/e* 18) and CH_2D^+ (*m/e* 16) to CD_3^+ are shown at the upper and lower parts, respectively. The rates were calculated at 0.1 eV intervals and plotted at 0.5 eV intervals. Bars indicate statistical errors calculated from the standard deviations obtained in the data-processing of ionization efficiency curves.

is a possibility in the present experiment that CX_3^+ is produced through the following process (23).

[10] $X_3C\text{—}CX_3^+ \rightarrow$ (scrambling state) $+ X \rightarrow CX_3^+ + CX_2 + X$

The threshold for this process is expected to be around 17 eV because AP of CH_2^+ from C_2H_6 is 17.3 eV (13) and the difference of IP's between CH_3 and CH_2 is 0.56 eV (24). The thresholds for CH_2D^+ and CHD_2^+ from CH_3CD_3 are nearly equal to the expected value. In the case that only process 10 participates in CX_3^+ formation from CH_3CD_3, the intensity ratio of *m/e* 18 to 16 is 1:9:9 on the assumption of equal probabilities in the detachment of H and D atoms before scrambling. This ratio is the same as that of process 9. Therefore the participating rate

calculated using process 10 instead of process 9 is the same as the one discussed above.

The rate of the scrambling process in Fig. 5 is interpreted to be the summed rate of processes 9 and 10. It is still uncertain which process is the main contributor to the scrambling process in CX_3^+ formation. Determination of the appearance threshold energy for each metastable peak should provide a clue to this question.

The state in which process 8 participates in CX_3^+ formation is supposed to be related to the lower state of the doublet which is caused by the Jahn–Teller effect in ^2E_u of $C_2X_6^+$. The upper state probably corresponds to the process 9 or 10 because the tail of the second band in the photoelectron spectrum extends to about 17 eV (14–16).

Photochemical decomposition of EDTA coordinated to cobalt(III): products, thermal reactions, and evidence for outer sphere alcohol oxidation by the excited state

COOPER H. LANGFORD AND GAY WIN QUANCE
Metal Ions Group, Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received March 7, 1977

COOPER H. LANGFORD and GAY WIN QUANCE. Can. J. Chem. **55**, 3132 (1977).

The photolysis of $Co(EDTA)^-$ in the ultraviolet is unlike analogous reactions of Fe(III) complexes. The ratio of products Co(II) to CO_2 is 1:1 but we find only $\frac{1}{2}$ as much CH_2O. For $Fe(EDTA)^-$, yields of photolysis products Fe(II):CO_2:CH_2O are 2:1:1. This is consistent only with a mechanism where primary photolysis yields Co(II), CO_2, and a radical which attacks EDTA in *preference* to reduction of the slowly reducible metal oxidation state, Co(III). Use of 2-propanol as a scavenger diagnostic of primary radicals is questioned because it is shown that LMCT excited states of Co(III) complexes exhibit the same outer sphere oxidations of alcohols earlier recognized in the photochemistry of a variety of Fe(III) complexes.

COOPER H. LANGFORD et GAY WIN QUANCE. Can. J. Chem. **55**, 3132 (1977).

La photolyse de $Co(EDTA)^-$ dans l'ultraviolet ne ressemble pas à la réaction analogue des complexes du Fe(III). Le rapport des produits Co(II) et CO_2 est de 1:1 mais on ne trouve que la moitié de la quantité équivalent de CH_2O. Dans le cas du $Fe(EDTA)^-$, les rendements de produits de photolyse Fe(II):CO_2:CH_2O sont de 2:1:1. Ceci est en accord uniquement avec un mécanisme dans lequel la photolyse primaire conduit à du Co(II) et du CO_2 et un radical qui attaque l'EDTA *de préférence* à une réduction lente de l'état d'oxydation III du Co. L'utilisation du propanol-2 comme piégeur pouvant servir de diagnostic pour les radicaux primaires est mise en question parce qu'il est connu que les états excités LMCT des complexes du Co(III) agissent dans l'oxydation des alcools aux sphères extérieures de la même façon que l'on a reconnu antérieurement dans la photochimie d'une variété de complexes Fe(III).

[Traduit par le journal]

Introduction

Photochemical decomposition of aminopolycarboxylates coordinated to metals in reducible oxidation states has attracted considerable interest both for the mechanistic photochemistry (1–3) and because photodecomposition may be environmentally important for aminopolycarboxylates in detergents and industrial wastes (4, 5). In the case of all the Fe(III) complexes examined (2–5), the oxidative decomposition of the aminopolycarboxylate yields CO_2 with a stoichiometry with respect to metal reductions of $\phi_{CO_2}:\phi_{Fe(II)} = 1:2$ (ϕ = quantum yield in mol einstein^{-1}). This is expected. Organic oxidations are two electron processes and that the primary radical formed reduces the second Fe(III) is not surprising. In fact, pathways are well documented (3, 4). A radical of the type

$$\geq N-CH_2^{\cdot}$$

appears to form following decarboxylation. This reduces a second Fe(III) to give

$$\geq \overset{\oplus}{N}=CH_2$$

which hydrolyses to the observed organic products, CH_2O, and a secondary amine.

The case of $Co(EDTA)^-$ (EDTA = *N*,*N*,*N*′,*N*′-1,2-ethanediaminetetraacetate) is anomalous (1). Explanation of this anomaly is the last outstanding question in this area to which our program has been addressed and we present in this article evidence showing the relation of this system to the environmentally important cases we have studied earlier. The yields of CO_2 and Co(II) are in the ratio $\phi_{CO_2}:\phi_{Co(II)} = 1:1$ and addition of 2-propanol increases the relative yield of Co(II). The organic products have not been well characterized and the significance of the 2-propanol effect is rendered ambiguous by the recent discovery that charge transfer excited states, including that of $Fe(EDTA)^-$, can oxidize primary and secondary alcohols in an outer sphere reaction (6). (Whereas it was assumed earlier (1) that 2-propanol only scavenges radicals from the primary photoprocess.)

The earlier work (1) has clearly established that photoreaction of $Co(EDTA)^-$ arises from the ligand to metal charge transfer (LMCT) excited state with an absorption maximum near

240 nm. It also clearly establishes the 1:1 ratio of Co(II) and CO_2 yields. The present article is addressed to two questions: improving understanding of the fate of EDTA especially quantifying CH_2O yield, and testing for outer sphere oxidation of 2-propanol which has previously been assumed to be simply a scavenger for free radicals.

Experimental

Crude KCoEDTA was generously supplied by Dr. J. H. Carey. It was recrystallized twice from distilled water. The spectrum agrees with earlier reports (1). $Co(NH_3)_6Cl_3$ was prepared by conventional procedures (7). It was converted to the perchlorate by precipitation with $HClO_4$. Alcohols were spectro grade materials used as supplied.

Stock solutions for photolysis were prepared in aqueous $HClO_4$ (0.15 *M* $HClO_4$). Co(III) concentrations were chosen to insure 100% absorption of incident light in a 1.8 cm diameter cylindrical quartz irradiation vessel which was inserted for irradiation at 254 nm in a Nuclear Supplies, Inc. photoreactor. The solutions irradiated were prepared by pipetting 1.0 ml of stock solution into the irradiation cell and diluting this to 5.0 ml with water or an alcohol–water mixture. The cell was then sealed with a rubber serum cap and deaerated by bubbling purified N_2 for 20 min with the aid of stainless steel needles. That this procedure did not alter Co(III) or alcohol concentrations significantly was confirmed.

The basic quantum yield determined was that for reduction to Co(II). The photolyte was analyzed by a modification of the procedure of Caspari *et al.* (8). A 4.0 ml aliquot of photolyte was mixed with 8.0 ml of 50% NH_4SCN in a 25.0 ml volumetric flask. Redistilled reagent grade acetone was added up to the mark. The absorbance of this solution was monitored at 625 nm (extinction coefficient 7.50×10^3 M^{-1} cm^{-1}). Thermal blanks were performed for each set of irradiations and thermal production of Co(II) was negligible in all systems. Irradiations were limited to 5% conversion or less to minimize product absorption and secondary photolysis. Light intensity was measured by ferrioxalate actinometry (9).

The other product assayed quantitatively in parts of this study was formaldehyde. The chromotropic acid method of Houle *et al.* (10) was employed. In this case, thermal blanks were of more significance because $Co(EDTA)^-$ has a distinct absorbance at the analytical wavelength of 570 nm.

Given a knowledge of yields of Co(II), CO_2, and CH_2O, the remaining products are dictated by stoichiometry and the need to remain within transformations having a precedent. However, the gas chromatographic procedure developed by Lockhart and Blakeley (4) can provide confirmation. This method used *N*-fluoroacetyl-*n*-butyl esters. Minor modifications of the procedure included use of 0.02 ml aliquots of solutions irradiated for 0, 2, and 30 min, immediate addition of the internal standard, 4-aminobutyric acid, and use of a 6 ft × $\frac{3}{16}$ in. column of 3% QF-1 on 100/120 mesh Chromosorb W mounted in an F and M Scientific 402 gas chromatograph with the oven temperature programmed from 110 to 250°C at 5°C/min. Thermal blanks and spiked samples containing $Co(EDTA)^-$ or Na_2H_2EDTA were also prepared. Authentic samples of *N,N,N'*-1,2-ethanediaminetriacetate (ED3A) and *N*-methyl-*N,N'N'*-1,1-ethanediaminetriacetate (MeED3A) were not available but they would be expected to be very similar and probably chromatographically unresolvable since ED3A and EDDA (*N,N'*-1,2-ethanediaminediacetate) are only minimally resolved (4). The difficulty of distinguishing these two compounds is a problem, but the *key stoichiometric question turns on CH_2O yield.*

Results and Discussion

1. The Outer Sphere Oxidation of 2-Propanol

The occurrence of outer sphere oxidation of primary and secondary alcohols by charge transfer excited states in contrast to the unreactivity of tertiary alcohols was established on the basis of the observation (6) of a limit to quantum yield as *tert*-butanol (2-methyl-2-propanol) concentration increases, whereas quantum yield in the presence of methanol, ethanol, or 2-propanol increases *linearly* with alcohol concentration in the high alcohol concentration region. This is to be understood in terms of the fact that *tert*-butanol scavenges *free* radicals (11) but reaches a limit when it captures all free radicals. The other alcohols also react with the charge transfer excited state itself and, therefore, do not approach a limiting reactivity at moderate concentrations because LMCT excited state lifetimes are shorter than radical lifetimes.

The outer sphere LMCT excited state reaction has been shown to be general over a range of oxidizable organic molecules including aldehydes, formic acid, and dicarboxylic acids as well as primary and secondary alcohols (12). It was shown to occur for the excited states of a diverse set of Fe(III) complexes including $Fe(OH_2)_6^{3+}$, $Fe(OH_2)_5Cl^{2+}$, $Fe_2(OH)_2(OH_2)_8^{4+}$, and $FeEDTA^-$. Whether the analogous LMCT states of Co(III) complexes are similarly reactive is an interesting question. Figures 1 and 2 show the dependence of Co(II) quantum yields on alcohol concentration for $Co(NH_3)_6^{3+}$ and $Co(EDTA)^-$ respectively. These figures confirm that the direct outer sphere reaction of the excited state is also occurring in Co(III) systems.

This result contains the subsidiary point that 2-propanol is an unreliable choice as a scavenger for study of the primary radical products of photolysis; for example, reduction to Co(II) could occur without leading to decarboxylation of EDTA (except perhaps in secondary reactions). Indeed, the curves in Fig. 2 where yields in the presence of *tert*-butanol are larger at low alcohol concentration than those in the presence

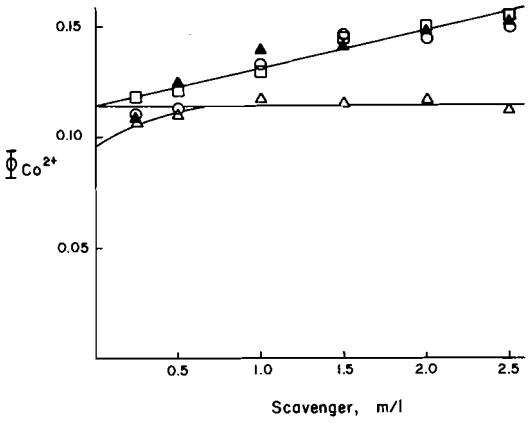

FIG. 1. The quantum yield for Co(II) production as a function of concentrations of various alcohols in the 254 nm irradiation of $Co(NH_3)_6^{3+}$: □, methanol, ▲, ethanol, ○, isopropanol, △, *tert*-butanol.

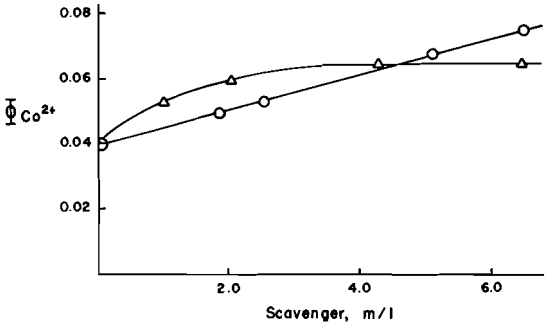

FIG. 2. The quantum yield for Co(II) production as a function of concentrations of two alcohols in the 254 nm irradiation of $Co(EDTA)^-$: ○, isopropanol, △, *tert*-butanol.

of 2-propanol suggest a plausible interpretation where the radical initially formed from photochemical decarboxylation of $Co(EDTA)^-$ reacts much more rapidly with *tert*-butanol than 2-propanol. The report (1) that ratios of Co(II) formation to CO_2 formation increase from 1.0–1.6 in 50% 2-propanol could be explained by decreases in EDTA decarboxylation associated with outer sphere reactions.

2. Stoichiometry of Photolysis of Co(EDTA)$^-$

The central result of our study is the CH_2O yield which has not previously been examined. Several runs in the absence of scavenging alcohols and using the chromotropic acid method for CH_2O determination gave $\phi_{Co(II)}:\phi_{CH_2O} = 2:1.01 \pm 0.03$. In conjunction with the results of Natarajan and Endicott (1), this establishes the stoichiometry $\phi_{Co(II)}:\phi_{CO_2}:_{CH_2O} = 2:2:1$. The implication of this is that each effective photon leads to the reduction of two $Co(EDTA)^-$ molecules and release of 2 mol CO_2. However, only one $-CH_2-$ group from an acetate of the aminopolycarboxylate is lost. In Fe(III) photochemistry the result is $\phi_{Fe(II)}:\phi_{CO_2}:\phi_{CH_2O} = 2:1:1$ (3, 4, 12). This is explained (3, 4) by the reaction sequences of eq. 1. (In the equation, partial decomposition of EDTA is indicated by writing a formula representing only the part of the molecules involved in the reaction.)

[1*a*] $Fe^{III}(EDTA)^- \xrightarrow{h\nu} {}^*Fe^{III}(EDTA)^-$

[1*b*] ${}^*Fe^{III}(EDTA)^- \longrightarrow Fe^{II}(\dot{C}H_2)N + CO_2$

[1*c*] $Fe^{II}(\dot{C}H_2)N + Fe^{III}(EDTA)^-$

$\searrow$

$Fe^{II}(\oplus CH_2{=}N) + Fe^{II}(EDTA)^{2-}$

[1*d*] $Fe^{II}(\oplus CH_2{=}N) + H_2O \longrightarrow Fe^{II}(H)N + CH_2O + H^+$

The step which differentiates Co(III) from Fe(III) is [1c]. The thermal reduction of low spin Co(III) complexes is known to be much slower than reductions of Fe(III). Thus, it is likely that the electron transfer step in Co(III) cases analogous to [1*c*] is to the EDTA ligand and initiates decomposition of a second molecule of EDTA which *yields the second* CO_2. We can write eqs. 2 to describe this mechanism.

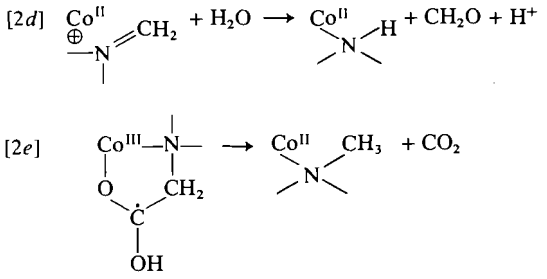
[2*a*] $Co^{III}(EDTA)^- \longrightarrow {}^*Co^{III}(EDTA)^-$

[2*b*] ${}^*Co^{III}(EDTA)^- \longrightarrow Co^{II}(\dot{C}H_2)N + CO_2$

[2*c*] $Co^{II}(\dot{C}H_2)N + Co^{III}(EDTA)^-$

$\searrow H^+$

$Co^{II}(\oplus CH_2{=}N) + Co^{III}(N{-}O{-}CH_2{-}\dot{C}(OH))N$



Mechanism [2] with electron transfer to EDTA preceding the reduction of the second Co(III) accounts for the anomalous stoichiometry of 1:1 CO_2:Co(II) and the clear accompanying requirement for only one CH_2O. (Inspection of as many alternative pathways as our research group could invent left no plausible alternative to the mechanism in [2] to account for the stoichiometry.) There is only one remaining requirement. The other organic products must be ED3A and MeED3A. In ref. 1 some nmr evidence for MeED3A was presented. (We have had some difficulty confirming these experiments and could not express confidence in this product, if the stoichiometry allowed us to ignore it.)

3. Gas Chromatography

The only acceptable mechanism (eq. 2) requires that ED3A and MeED3A be the only other products. Figure 3 shows the chromatogram of photolytes of $Co(EDTA)^-$ in the presence of the internal standard, 4-aminobutyric acid, and unreacted EDTA. The only product peak is a relatively broad one marked Q. EDTA and 4-aminobutyric acid appear at exactly the positions reported by Lockhart and Blakeley in their study of Fe(III) complexes (4). Q corresponds to the reported (4) ED3A position. But, in the context of evidence for MeED3A and the expected difficulty of resolutions of ED3A from MeED3A (*vide supra*) the chromatogram is *consistent with production of both* and the mechanism in eq. 2.

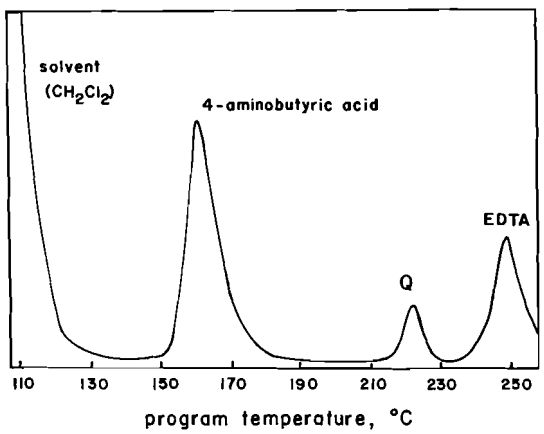


FIG. 3. Chromatogram of the photodegradation products of EDTA isolated as described in the text following 254 nm irradiation of $Co(EDTA)^-$.

Conclusion

Free radical scavenging is not the only role for alcohols. Thus, some earlier photochemical literature must be interpreted with caution. A mechanism consistent with the established aspects of reaction stoichiometry does provide a reasonable explanation of the anomalous reaction of $Co(EDTA)^-$ compared to Fe(III) complexes. It draws attention to the role of the well known *kinetic barrier to Co(III) reduction* in thermal radical pathways following photochemical initiation. Clearly, an attack on a second EDTA ligand is indicated and this is the critical point. The determination of aminopolycarboxylate products by nmr and gc remains somewhat ambiguous but is consistent with the proposed mechanism. Wide ranging exploration suggested no attractive alternatives to eqs. 2.

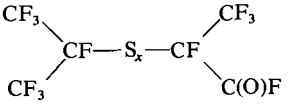
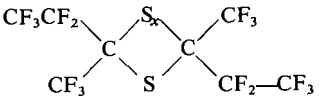
$S_8(AsF_6)_2$ reacts with C_2F_4 in SO_2 to form $(C_2F_5)_2S_x$ ($x = 2 \rightarrow 6$), $C_2F_5S_xCF_2C(O)F$ ($x = 2 \rightarrow 5$), $S_x(CF_2C(O)F)_2$ ($x = 2 \rightarrow 4$), $CF_3S_xCF_2C(O)F$ ($x = 3, 4$), $CF_3S_xC_2F_5$ ($x = 3 \rightarrow 5$), and $(CF_3)_2S_3$. Solid $S_8(AsF_6)_2$ reacts with C_3F_6 to form $(C_3F_7)_2S_x$ ($x = 2 \rightarrow 5$). In SO_2 solution, the same reactants yield the additional products



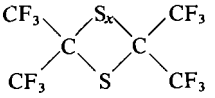
($x = 2 \rightarrow 5$)

and related species incorporating the C(O)F moiety. Solid $S_4(Sb_2F_{11})_2$ reacts with C_2F_4 to yield $(C_2F_5)_2S_x$ ($x = 1 \rightarrow 4$),



($x = 1, 2$)

and with C_3F_6 to give $(C_3F_7)_2S_x$ ($x = 1 \rightarrow 3$), and



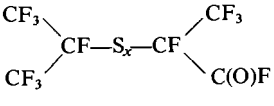
($x = 1, 2$)

Solid $Se_4(AsF_6)_2$ reacts with C_2F_4 to form $(C_2F_5)_2Se_x$ ($x = 1 \rightarrow 3$) and in SO_2 solution, the species $C_2F_5Se_2CF_2C(O)F$, $Se_2(CF_2C(O)F)_2$, $CF_3Se_2CF_2C(O)F$, $C_2F_5Se_2CF_3$, and $CF_3Se_2CF_3$ are also formed.

Products were identified by mass spectroscopy and the major species were isolated by vpc and further characterized by ^{19}F nmr. The mechanisms of these reactions are discussed.

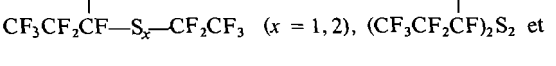
C. David Desjardins et Jack Passmore. Can. J. Chem. **55**, 3136 (1977).

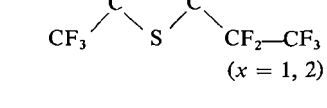
Le $S_8(AsF_6)_2$ réagit avec C_2F_4 dans le SO_2 pour former $(C_2F_5)_2S_x$ ($x = 2 \rightarrow 6$), $C_2F_5S_xCF_2$-$C(O)F$ ($x = 2 \rightarrow 5$), $S_x(CF_2C(O)F)_2$ ($x = 2 \rightarrow 4$), $CF_3S_xCF_2C(O)F$ ($x = 3, 4$), $CF_3S_xC_2F_5$ ($x = 3 \rightarrow 5$) et $(CF_3)_2S_3$. Le $S_8(AsF_6)_2$ à l'état solide réagit avec C_3F_6 pour former $(C_3F_7)_2S_x$ ($x = 2 \rightarrow 5$). En solution dans le SO_2, les mêmes réactifs conduisent aux produits additionnels



($x = 2 \rightarrow 5$)

et aux entités apparentées incorporant le groupement C(O)F. Le $S_4(Sb_2F_{11})_2$ à l'état solide réagit avec le C_2F_4 pour conduire au $(C_2F_5)_2S_x$ ($x = 1 \rightarrow 4$)





($x = 1, 2$)

---

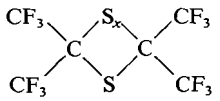
et avec le C_3F_6 pour donner $(C_3F_7)_2S_x$ ($x = 1 \rightarrow 3$) et



($x = 1, 2$)

Le $Se_4(AsF_6)_2$ à l'état solide réagit avec le C_2F_4 pour former $(C_2F_5)_2Se_x$ ($x = 1 \rightarrow 3$) et, en solution dans le SO_2, il y a aussi formation des entités $C_2F_5Se_2CF_2C(O)F$, $Se_2(CF_2C(O)F)_2$, $CF_3Se_2CF_2C(O)F$, $C_2F_5Se_2CF_3$ et $CF_3Se_2CF_3$.

On a identifié les produits par spectrométrie de masse et les produits majeurs ont été isolés par chromatographie en phase gazeuse et caractérisés par rmn du ^{19}F.

On discute des mécanismes de ces réactions.

[Traduit par le journal]

Introduction

Recently, various reactions of the Group VI polycations (1) with C_2F_4 have been studied. Tetrafluoroethylene reacts with $S_{16}(AsF_6)_2$ and $S_8(AsF_6)_2$ (2) to form $(C_2F_5)_2S_x$ ($x = 2 \rightarrow 6$), with $Se_8(AsF_6)_2$ (3) to give $(C_2F_5)_2Se_x$ ($x = 2$, 3), and with $Te_4(AsF_6)_2$ and $Te_6(AsF_6)_2$ (4) to give $(C_2F_5)_2Te_x$ ($x = 1$, 2). In SO_2 solution, C(O)F-containing species were also formed (*i.e.*, $Se_8(AsF_6)_2$ reacts with C_2F_4 in SO_2 solution (3) to yield $(C_2F_5)_2Se_2$ and $C_2F_5Se_2CF_2C(O)F$ as the major products). However, only preliminary evidence for the carbonyl fluoride species was obtained for the reaction of $S_8(AsF_6)_2$ with C_2F_4 in SO_2 solution (2). In this paper we have identified the C(O)F sulphur compounds and extended our work to reactions of $S_8(AsF_6)_2$ with $F_2C{=}CFCF_3$ and $CF_3FC{=}CFCF_3$, as well as to reactions of $S_4(Sb_2F_{11})_2$, $S_8(Sb_2F_{11})_2$, and $Se_4(AsF_6)_2$ with C_2F_4 and $S_4(Sb_2F_{11})_2$ with C_3F_6 in order to add to an understanding of the mechanism and reactivity of this system.

Experimental

A. Apparatus

Techniques used in this work have been described elsewhere (2–4). ^{19}F nmr were obtained using a Varian Associates HA-60 spectrometer operating at 56.4 MHz or with a Varian HA-100 at 94.1 MHz. Vapour phase chromatographic analysis and preparative separations were obtained as in ref. 4 but with a helium gas flow of 60 ml min^{-1}. Raman spectra were obtained using liquid samples in sealed melting point tubes and a Spex Ramalab RS2 spectrometer with a Spectra Physics 164 2W Ar–Kr ion laser as the exciting source (6471 Å). Spectra were calibrated (error ± 2 cm^{-1}) using appropriate lines from carbon tetrachloride and indene.

B. Reagents

Tetrafluoroethylene, hexafluoropropylene, octafluorobutene-2 (Columbia Organic Chemicals), selenium (Fisher Scientific Co., contains 0.1% sulphur determined by analysis), sulphur (McArthur Chemical Co.), triphenylphosphine (Eastman) were used without further purification. SO_2, HF, and AsF_5 were purified as in refs. 2 to 4. SbF_5 (Ozark–Mahoning) was purified by distillation *in vacuo*. $S_8(AsF_6)_2$ (5) and $Se_4(AsF_6)_2$ (1) were prepared by reported methods. $S_4(Sb_2F_{11})_2$ was prepared according to reaction 1 by a modification of the reported method (5).

[1] $S_8 + 12SbF_5 \rightarrow 2S_4(Sb_2F_{11})_2 + 2SbF_3{\cdot}SbF_5$

The products were mixtures of $S_4(Sb_2F_{11})_2$ and reduced species (*i.e.*, $SbF_3{\cdot}SbF_5$ and/or SbF_3).

Prep. *A*: S_8 (0.52 g, 2.03 mmol) was reacted with excess SbF_5 (7.19 g, 33.17 mmol) in AsF_3 solution for 3 days at 100°C under reflux. Volatiles were removed at room temperature under dynamic vacuum for 1 day. A Raman of the light blue solid (6.81 g) (681(s), 672(m), 646(s), 608(s), 582(vs), 540(s), 374(s), 286(m br)) contained peaks attributable to S_4^{2+}, Sb(V) fluoroanion and reduced products.

Prep. *B*: S_8 (2.0 g, 7.8 mmol) was reacted with SbF_5 (22.25 g, 102.65 mmol) at 140°C for several days under reflux, and treated as in *A* to give 18.77 g solid.

Prep. *C*: (S_8 (0.53 g, 2.07 mmol), SbF_5 (7.18 g, 33.12 mmol)) and Prep. *D*: (S_8 (2.4 g, 9.36 mmol), SbF_5 (24.75 g, 114.19 mmol)) were reacted as in Prep. *B*. We were, like earlier workers (5), unable to isolate pure $S_4(Sb_2F_{11})_2$.

$S_8(Sb_2F_{11})_2$ was prepared (5), according to reaction 2.

[2] $S_8 + 5SbF_5 \xrightarrow{SO_2} S_8(Sb_2F_{11})_2 + SbF_3$

Prep. *E*: S_8 (1.49 g, 5.6 mmol) and SbF_5 (6.3 g, 29.2 mmol) gave 6.41 g SO_2 soluble solid (6.55 g, expected for $S_8(Sb_2F_{11})_2$).

Prep. *F*: S_8 (0.37 g, 1.44 mmol) and SbF_5 (2.05 g, 9.46 mmol) in SO_2 yielded a blue solid. Half of the material obtained was filtered using SO_2 as in Prep. *E*.

Prep. *G*: In a typical reaction $Se_8(SbF_6)_2{\cdot}xSbF_5$ was made by reacting (6) selenium (3.50 g, 5.54 mmol 8Se) with excess SbF_5 (7.10 g, 32.76 mmol) in SO_2 solution for several days at room temperature. The soluble green solid (5.0 g) was filtered and dried. Insoluble products were antimony(III) containing species and a black solid.

C. Reactions

Volatile species obtained from reactions were isolated and characterized by previous methods (2–4). In SO_2 reactions, a small loss of AsF_3 and to a lesser extent perfluoroalkyl sulphides occur on removal of SO_2 solvent and therefore weights of products recovered are lower than the total produced in the reaction. Unless otherwise specified the reactions were carried out in 40 cm^3 Monel reaction vessels at room temperature. The dis-

TABLE 1. Vapour phase chromatographic retention times

Compound	Retention time (min)	Compound	Retention time (min)	Compound	Retention time (min)
AsF_3	0.1	$(C_2F_5)_2S_3$	2.2	$(C_4F_9)_2S_2$	6.9
$(C_2F_5)_2Se$	0.2	$CF_3Se_2CF_2C(O)F$	2.2	$CF_3S_4C_2F_5$	7.4
$(C_2F_5)_2S_2$	0.6	$C_2F_5Se_2CF_2C(O)F$	3.1	$C_3F_7S_3C_3F_5O$	7.8
$CF_3Se_2C_2F_5$	1.2	$C_2F_5S_3CF_2C(O)F$	4.1	$(C_2F_5)_2S_4$	9.2

tribution of the various sulphides and selenides was established by vpc analysis. A combination of vpc analysis and mass spectra data of different volatile fractions and various components isolated from preparative vpc confirmed the identity and retention times (Table 1) of the major species.

(1) Reaction of Solid $S_8(AsF_6)_2$ with C_2F_4

$S_8(AsF_6)_2$ (5.29 g, 8.34 mmol) was reacted with an excess of C_2F_4 (31.6 mmol) for 3 days. The volatile products at room temperature included C_2F_4 (26.40 mmol consumed), C_2F_6, AsF_3 (1.4 g, 62% of the available arsenic) and a clear liquid (4.32 g), consisting of 4% $(C_2F_5)_2S_2$, 68% $(C_2F_5)_2S_3$, 27% $(C_2F_5)_2S_4$, and traces of $(C_2F_5)_2S_x$, $x = 5$, 6 detected by mass spectroscopy. $(C_2F_5)_2S$ was not detected in the infrared or mass spectrum of the volatile products of this reaction. The clear liquid incorporates 82% of the available fluorine from AsF_6^- (*i.e.* 3 fluorines per AsF_6^-) and 61% of the available sulphur. An unidentified green solid (1.9 g) remained. Previously reported reactions (2) gave measurable amounts of $(C_2F_5)_2S_5$ (*ca.* 0.5%) under conditions of low pressure of C_2F_4. $S_8(AsF_6)_2$ was also reacted with C_2F_4 at −78°C for several weeks. A very low yield of similar products was obtained.

(2) Reaction of $S_8(AsF_6)_2$ with C_2F_4 in SO_2

$S_8(AsF_6)_2$ (6.36 g, 10.02 mmol) was dissolved in SO_2 (3.7 g) and treated with an excess of C_2F_4 (42.1 mmol) for 3 days.

The volatile products were C_2F_4 (27.30 mmol consumed), C_2F_6, SO_2, traces of CO, OSF_2, and a carbonyl-containing species, $CF_3C(O)F$, as identified by its infrared spectrum, AsF_3 (1.1 g, 41% of the available arsenic) and a clear liquid (3.95 g), a mixture of polysulphides containing 6% $CF_3S_3C_2F_5$, 19% $(C_2F_5)_2S_3$, 34% $C_2F_5S_3CF_2C(O)F$, 18% $(C_2F_5)_2S_4$, 14% $C_2F_5S_4CF_2C(O)F$, $CF_3S_3CF_2C(O)F$, $S_3(CF_2C(O)F)_2$, and $CF_3S_4C_2F_5$ (the latter three compounds constitute 9% of the liquid polysulphides). Molecular ions attributable to the above species were observed as well as less intense molecular ions and fragments attributable to $(C_2F_5)_2S_5$, $(C_2F_5)_2S_6$, $(C_2F_5)_2S_2$, $C_2F_5S_5CF_2C(O)F$, $S_4(CF_2C(O)F)_2$, $CF_3S_5C_2F_5$, $C_2F_5S_2CF_2C(O)F$, $(CF_3)_2S_3$, $S_2(CF_2C(O)F)_2$, and $CF_3S_4CF_2C(O)F$. 68% of the available fluorine and 51% of the available sulphur were incorporated into the liquid polysulphides. An unidentified purple solid (3.75 g) remained. In other reactions similar products were obtained with some change in the percentage distribution of products. $S_8(AsF_6)_2$ (5.60 g, 8.83 mmol) was also reacted with excess C_2F_4 (*ca.* 22.5 mmol) in SO_2 (7.45 g) at −78°C. The liquid polysulphides obtained (1.60 g, contains AsF_3) were predominantly $(CF_3)_2S_2$, $CF_3S_2C_2F_5$, and traces of $(C_2F_5)_2S_3$, $CF_3S_3C_2F_5$. A red solid mixture (4.52 g) remained that contained an unidentified reactive red volatile component.

(3) Reaction of Solid $S_8(AsF_6)_2$ with C_3F_6

The results of the reactions of solid $S_8(AsF_6)_2$ with C_3F_6 neat and in SO_2 solvent are summarised in Table 2.

(4) Reaction of Solid $S_8(AsF_6)_2$ with C_4F_8

Perfluorobutene-2 (28.8 mmol) was added in excess to solid $S_8(AsF_6)_2$ (5.03 g, 7.93 mmol) for 13 days. Volatiles contained C_4F_8 and a slightly coloured liquid (0.25 g). A vpc showed it to be essentially AsF_3. AsF_3 and traces of unidentified perfluoroalkyl sulphides were detected in the mass spectrum. A brownish blue solid mixture (4.94 g) remained.

(5) Reaction of $Se_4(AsF_6)_2$ with C_2F_4

The results of this reaction, neat, and in SO_2 solvent are summarised in Table 2. A reaction of $Se_8(SbF_6)_2 \cdot xSbF_5$ (5.21 g; see Prep. *G*) with C_2F_4 (2.61 g, 26.1 mmol) in SO_2 solution (2.93 g) for several weeks gave a mixture of polyselenides (3.49 g; $CF_3Se_2C_2F_5$ and $(C_2F_5)_2Se_2$ were major components, also contains traces of $(CF_3)_2Se_2$ and carbonyl containing species). An unidentified solid was obtained. 47% of selenium was incorporated into the liquid polyselenides.

(6) Reaction of Solid $S_4(Sb_2F_{11})_2$ with C_2F_4

Solid $S_4(Sb_2F_{11})_2$ (2.21 mmol; see Prep. *C*) (number of mmoles $S_4(Sb_2F_{11})_2$ was computed assuming 100% conversion of sulphur to $S_4(Sb_2F_{11})_2$ according to reaction 1) was placed in a Kel-F reaction vessel on a 50 cm^3 Monel vacuum line. An initial pressure of C_2F_4 (*ca.* 1.5 atm) was maintained. After one week, no further pressure drop was observed. Unreacted C_2F_4 (14.0 mmol consumed) was removed at −130°C leaving a light blue liquid (1.42 g) containing 4% $C_8F_{16}S_3$, 26% $(C_2F_5)_2S_2$ (contains shoulder due to $C_4F_9SC_2F_5$), 43% $C_4F_9S_2C_2F_5$, 16% $(C_4F_9)_2S_2$ (peak includes traces of $(C_2F_5)_2S_4$), 3% $C_8F_{16}S_2$, 4% $(C_2F_5)_2S$, and 4% unidentified component (possibly $C_6F_{12}S_2$). Less intense molecular ions and fragments were attributable to $C_4F_9S_3C_2F_5$, $C_4F_8S_2$, C_4F_8S, and $(C_2F_5)_2S_3$. Due to fragmentation patterns of higher molecular weight species in the mass spectra, unambiguous evidence could not be obtained for the

possible molecular ions $C_6F_{12}S_2$, $C_4F_8S_2$, and C_4F_8S. 83% of the available sulphur was incorporated into the liquid polysulphides. An amount of 3.14 g unidentified solid remained.

Reactions were also carried out at various pressures of C_2F_4. In one reaction (Table 3, part *a*) the polysulphides contained: 6% $C_8F_{16}S_3$, 35% $C_2F_5S_2C_4F_9$, 17% $(C_4F_9)_2S_2$, 3% unidentified component (possibly $C_6F_{12}S_2$), 25% $(C_2F_5)_2S_2$, 13% $C_4F_9SC_2F_5$, and 2% $(C_2F_5)_2S$. Traces of other species were not identified. Under the conditions of high pressure of C_2F_4, the reaction (Table 3, part *b*) gave polysulphides containing 58% (the sum of $(C_2F_5)_2S_2$ and $C_4F_9SC_2F_5$), 37% $C_4F_9S_2C_2F_5$, 2% $(C_4F_9)_2S_2$, 2% $C_8F_{16}S_2$, and 2% $(C_2F_5)_2S$. Less intense molecular ions and fragments were attributable to $(C_2F_5)_2S_4$, $(C_2F_5)_2S_3$, $C_8F_{16}S_3$, and probably $C_6F_{12}S_2$, $C_4F_8S_2$, and C_4F_8S.

(7) Reaction of Solid $S_8(Sb_2F_{11})_2$ with C_2F_4

$S_8(Sb_2F_{11})_2$ (4.37 g, 3.76 mmol; see Prep. *E*) was reacted with excess C_2F_4 (23.95 mmol) in a 30 cm^3 glass vessel and allowed to stand at room temperature for 4 days. Volatiles removed at −78°C contained C_2F_4 (13.54 mmol consumed) and traces of C_2F_6, SiF_4, OSF_2, and $(C_2F_5)_2S_3$. A volatile clear liquid (2.23 g) was removed at room temperature containing 22% $(C_2F_5)_2S_2$, 71% $(C_2F_5)_2S_3$, and 7% $(C_2F_5)_2S_4$. A grey-green solid (3.49 g) remained. 64% of the available sulphur was incorporated into the liquid polysulphides.

A reaction was carried out at low pressure of C_2F_4 (3.10 mmol consumed) (*i.e.*, pressure maintained at *ca.* 1 atm in a 50 cm^3 Monel vacuum line) (Table 3, part *c*). The light blue liquid (0.19 g) contained 80% $(C_2F_5)_2S_2$, 8% $C_4F_9S_2C_2F_5$, 5% $(C_2F_5)_2S_3$, 4% $C_8F_{16}S_2$, and 4% unidentified components. A reaction (Table 3, part *d*) was also undertaken using unpurified $S_8(Sb_2F_{11})_2$ with C_2F_4 (21.80 mmol consumed) at low pressure (*ca.* 1 atm). The sulphides contained 88% $(C_2F_5)_2S_2$, 4% $C_4F_9S_2C_2F_5$, 4% $C_8F_{16}S_2$, 2% $(C_2F_5)_2S_3$, 1% $(C_2F_5)_2S$ as well as traces of $C_8F_{16}S_3$, and unidentified components (possibly containing $C_6F_{12}S_2$, $C_4F_8S_2$, and C_4F_8S).

(8) Reaction of Solid $S_4(Sb_2F_{11})_2$ with C_3F_6

Solid $S_4(Sb_2F_{11})_2$ (3.86 g, 2.7 mmol) (Prep. *B*) was reacted with excess C_3F_6 (5.8 mmol) for 3 days. A yellow liquid (0.88 g) contained 60% $(C_3F_7)_2S_2$, 28% $C_6F_{12}S_3$, 5% unidentified component (probably $C_6F_{12}S_4$), and 7% of components possibly containing $(C_3F_7)_2S$ and $C_6F_{12}S_2$. 43% of the available sulphur was incorporated into the liquid polysulphides. An amount of 3.9 g unidentified solid was also obtained. The solid product (11.29 g) obtained from a similar reaction was further reacted with C_3F_6 (3.53 mmol) at 100°C for 3 days. The liquid polysulphides (1.98 g) obtained contained 91% $(C_3F_7)_2S$, 9% $C_6F_{12}S_2$, and small amounts of $(C_3F_7)_2S_2$. An unidentified solid (9.84 g) remained.

(9) Reaction of Solid Triphenyl Phosphine with $C_6F_{12}S_3$

$C_6F_{12}S_3$ (0.19 g, 0.48 mmol) obtained from the previous reaction and purified by preparative vpc (96% pure) was reacted with excess triphenylphosphine (0.26 g, 0.99 mmol) at room temperature in a 10 cm^3 glass reaction vessel. After 3 h, a clear liquid (0.16 g) was distilled from the reaction mixture. Vapour phase chromatography and mass spectrum analysis of the product showed 55% conversion to $C_6F_{12}S_2$.

Results and Discussion

The reactions of $S_8(AsF_6)_2$ and C_2F_4 in SO_2 solution at room temperature yield $(C_2F_5)_2S_4$, $C_2F_5S_4CF_2C(O)F$, $CF_3S_4C_2F_5$, $(C_2F_5)_2S_3$, $C_2F_5S_3CF_2C(O)F$, $CF_3S_3CF_2C(O)F$, $S_3(CF_2C(O)F)_2$, $CF_3S_3C_2F_5$, and traces of related species. This confirms our preliminary results (2). The major carbonyl species, $C_2F_5S_3CF_2C(O)F$,

TABLE 4. Schematic representation of the ^{19}F nmr spectra[a] of $(C_2F_5)_2S_x$ ($x = 2, 3, 4$), $C_2F_5S_3CF_2C(O)F$, $(C_3F_7)_2S_3$, and $C_3F_7S_3CF(CF_3)(C(O)F)$

Compound	Shift CF_3	Shift CF_2	$J_{CF_3-CF_2}$[b]

[a]$CFCl_3$ internal standard, all chemical shifts quoted are in ppm, coupling constants are in cps.
[b]Apparent coupling constants are given, although spectra are complex.
[c]Chemical shifts obtained under low resolution scan (accuracy ±1 ppm). Other chemical shifts accurate to ±0.1 ppm.

was isolated and characterized by ^{19}F nmr (Table 4) and mass spectroscopy (Table 5). The ^{19}F nmr of $S_2(CF_2C(O)F)_2$ (7) and the related sulphide $CF_3S_2C(O)F$ (8) have been reported. Similar products were observed in the reaction of $Se_8(AsF_6)_2$ and C_2F_4 in SO_2 solution. $S_8(AsF_6)_2$ reacts with C_2F_4 in SO_2 at −78°C to give $(CF_3)_2S_2$ and $CF_3S_2C_2F_5$. Compounds containing the carbonyl fluoride moiety were not observed. Low temperatures may favour increased formation of $(C_2F_5S_2CF_2C(O))^+$ $(AsF_6)^-$ involving participation of the solvent SO_2 in the reaction. Such salts may readily lose CO via routes outlined in ref. 3 yielding CF_3 derivatives (*i.e.*, $C_2F_5S_2CF_3$). Knunyants *et al.* (9) have reported a reaction of sulphur, the stronger acceptor SbF_5 and C_2F_4 in SO_2 to give $(C_2F_5)_2S_x$ and $CF_3S_xC_2F_5$ ($x = 2, 3$).

Solid $S_8(AsF_6)_2$ reacts with C_2F_4 at ambient temperature and at −78°C to yield AsF_3, $(C_2F_5)_2S_x$, $x = 2, 3, 4$. Reevaluation of the previous data (2) shows that the vpc distributions were in error due to misassignment of AsF_3 for $(C_2F_5)_2S_2$ and therefore $(C_2F_5)_2S_3$ was identified as $(C_2F_5)_2S_2$ (*i.e.*, 80% $(C_2F_5)_2S_2$ (2) should read 80% $(C_2F_5)_2S_3$). High resolution ^{19}F nmr spectra are given in Table 4. Coupling constants are quoted although the spectra are complex. Similar complexity was observed for bis(perfluoroethyl)selenides and tellurides (3, 4). The ^{19}F nmr spectra of perfluorobutane (10) has been analysed as a $(AA'X_3)_2$ system and the complexity of our spectra may, in part, be of similar origin. The ^{19}F nmr spectrum of $(C_2F_5)_2S_2$ has been previously reported (2, 9, 11). Previous results (2) were incorrect due to misassignment (see above).

Reaction of $S_8(AsF_6)_2$ and C_3F_6

Solid $S_8(AsF_6)_2$ reacts with perfluoropropylene to yield AsF_3, $S_x[CF(CF_3)_2]_2$ $x = 3, 4$, and traces $x = 2, 5$. A mass spectrum (Table 5) and ^{19}F nmr spectrum of isolated $(C_3F_7)_2S_3$ (Table 4) was consistent with the presence of

TABLE 5. Mass spectra of $C_8F_{16}S_3$, $(C_3F_7)_2S_3$, $(C_2F_5)_2S_3$, $C_2F_5S_3CF_2C(O)F$, $C_3F_7S_3CF(CF_3)(C(O)F)$, $C_6F_{12}S_3$, $C_4F_9S_2C_2F_5$, $(C_3F_7)_2S_2$, $C_8F_{16}S_2$, $(C_2F_5)_2S_2$, $(C_3F_7)_2S$ based on ^{32}S and ^{12}C[a]

Compound	Mass spectra

[a]Obvious impurity peaks were deleted. Peaks of intensity < 10, and m/e < 69 were excluded.

the isopropyl isomer, and chemical shifts are very similar to those reported for bis(perfluoroisopropyl) monosulphide (12) (78 ppm (CF_3), 166 ppm (CF)) and bis(heptafluoroisopropyl) disulphide (75 ppm (CF_3), 164 ppm (CF)) (9).

The reactions carried out in SO_2 solution gave additional products incorporating the carbonyl fluoride moiety. The structure of the major carbonyl species isolated from the reaction products, $C_3F_7S_3CF(CF_3)(C(O)F)$, has been established from its mass spectrum (Table 5) and ^{19}F nmr (Table 4). Species involving elimination of CO were not detected. Carbonyl species obtained from reactions of $S_8(AsF_6)_2$ with C_2F_4 and C_3F_6 in SO_2 solution (*i.e.*, $C_2F_5S_xCF_2C(O)F$, $C_3F_7S_xCF(CF_3)(C(O)F)$, etc.) have not been previously reported with the exception of $S_2(CF_2C(O)F)_2$ (7).

Reaction of $Se_4(AsF_6)_2$ with C_2F_4

C_2F_4 reacts with solid $Se_4(AsF_6)_2$ to yield $(C_2F_5)_2Se_2$, small amounts of $(C_2F_5)_2Se$, and probably traces of $(C_2F_5)_2SSe$ and $(C_2F_5)_2Se_3$. (Sulphur is an impurity in the selenium used to make $Se_4(AsF_6)_2$.) The reaction carried out in liquid SO_2 gives additional products containing carbonyl fluoride groups as well as those involving elimination of CO (*i.e.*, $CF_3Se_2C_2F_5$). The carbonyl fluorides and related species are similar to those obtained in reactions of C_2F_4 and $Se_8(AsF_6)_2$ in SO_2 (3).

Reactions of $S_4(Sb_2F_{11})_2$ and C_2F_4

Solid $S_4(Sb_2F_{11})_2$ containing $SbF_3{\cdot}SbF_5$ and/or SbF_3 reacts vigorously with C_2F_4 at ambient pressure and temperature. A blue liquid is obtained containing $C_8F_{16}S_3$, $(C_2F_5)_2S_2$, $C_4F_9S_2C_2F_5$, $(C_4F_9)_2S_2$, $C_8F_{16}S_2$, $(C_2F_5)_2S$, and small amounts of $(C_2F_5)_2S_4$, $(C_2F_5)_2S_3$, $C_4F_9S_3C_2F_5$, $C_4F_9SC_2F_5$. $C_4F_9S_2C_2F_5$, $C_8F_{16}S_2$, and $C_8F_{16}S_3$ were isolated by preparative vpc and further characterized by their ^{19}F nmr and mass spectra. Structural identification of $C_4F_9S_2C_2F_5$ as perfluoro(3-methyl propyl, ethyl)disulphide **1** is based on its mass spectrum (Table 5) which gives a molecular ion and major fragments $C_4F_9S_2$, $C_2F_5S_2$, and its ^{19}F nmr spectrum (Table 6) which shows the presence of the $CF_3CF_2S_x$ and $CF_3CF_2CF(CF_3)S_x$ groups. The related species $(CF_3CF_2CF(CF_3)S)_2$ has been reported (13). Structural formulation of $C_8F_{16}S_2$ as perfluoro-(2,4-dimethyl, 2,4-diethyl)-1,3-dithietane **2** is based on its mass spectrum which gives a molecular ion and fragments (Table 5) and its ^{19}F nmr spectrum (Table 6) which is consistent with the related compound **3** (14).

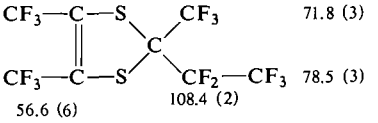
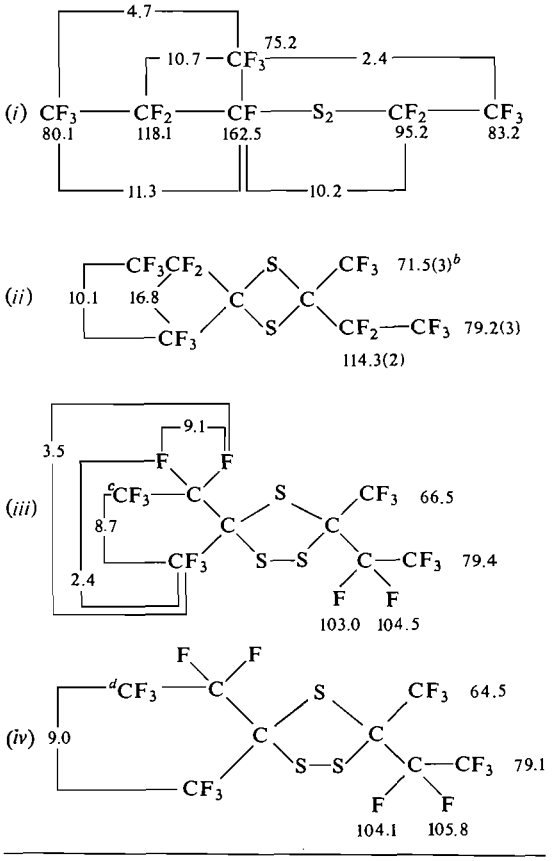
2



3

TABLE 6. ^{19}F nmr spectra of $C_2F_5CF(CF_3)S_2C_2F_5$, $C_8F_{16}S_2$, and $C_8F_{16}S_3$[a]

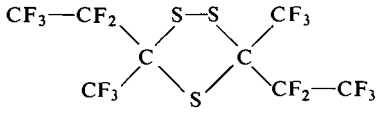


Chemical shift in ppm relative to CCl_3F (relative area in parentheses)

[a]CCl_3F internal standard, chemical shifts in ppm, coupling constants in cps.
[b]Relative area in parentheses.
[c]*cis* and *trans* isomers were both present, although we are unable to determine which data correspond to which isomer.
[d]High resolution spectra for one isomer was poor and only partial coupling constants were obtained.

High resolution ^{19}F nmr spectra of **2** reveal a complex, asymmetrical spectrum for the CF_2 group possibly due to restricted rotation about the CF_2 to ring carbon bond. Irradiation of the CF_3—C group (71.5 ppm) in a decoupling experiment resulted in collapse of the CF_2 group (114.3 ppm) to a singlet. Irradiation of the other CF_3 group (79.2 ppm) did not change

the complex structure of the CF_2 peak (114.3 ppm). **2** is designated as having the *trans* configuration although this has not been proved. Synthesis of **2** via dimerization of perfluorobutene-2-thione has been reported (13). ^{19}F nmr and mass spectra however were not given. $C_8F_{16}S_3$ assignment as perfluoro(3,5-dimethyl, 3,5-diethyl)-1,2,4-trithiolane, **4**, is consistent with its fragmentation pattern in the mass spectrum (Table 5).



4

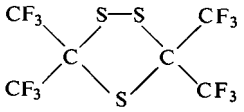
High resolution ^{19}F nmr of **4** (Table 6) combined with a series of irradiation experiments has established the presence of two sets of data consistent with the existence of two (probably *cis* and *trans*) isomers. Irradiation of the CF_3—C (66.5 ppm) group resulted in collapse of the CF_3—CF_2 (79.4 ppm) quartet and partial collapse of the CF_2 (104.5 ppm, 103.0 ppm) multiplet. Irradiation of the CF_3—CF_2 (79.4 ppm) group resulted in partial collapse of the CF_3—C (66.5 ppm) multiplet. Irradiation of the 103.0 ppm nuclei of the CF_2 group resulted in partial collapse of the CF_3—C (66.5 ppm) and 104.5 nuclei (CF_2 group) multiplet. Complementary experiments with the second isomer gave similar results and in both cases establish which nuclei are coupled. Related examples of non-equivalent methylene fluorines and hydrogens have been discussed by Mislow and Raban (15). The ^1H nmr of 3,5-dialkyl-1,2,4-trithiolanes (16) shows two isomers for each trithiolane as well as different conformers of each isomer at low temperatures.

Reaction of $S_8(Sb_2F_{11})_2$ and C_2F_4

In one reaction solid $S_8(Sb_2F_{11})_2$ reacts with C_2F_4 to yield $(C_2F_5)_2S_x$, $x = 2$, 3, 4. Other reactions gave mainly $(C_2F_5)_2S_2$ and small amounts of $C_4F_9S_2C_2F_5$, $(C_2F_5)_2S_3$, $(C_2F_5)_2S$, and $C_8F_{16}S_2$. Similar products were observed for reactions with $S_4(Sb_2F_{11})_2$ and C_2F_4 but in larger yields. In cases where $C_4F_9S_2C_2F_5$ and $C_8F_{16}S_2$ type products were found the amount of antimony pentafluoride consumed in preparing $S_8(Sb_2F_{11})_2$ was greater than that for the stoichiometric reaction. These products are therefore attributed to the presence of $S_4(Sb_2F_{11})_2$ in $S_8(Sb_2F_{11})_2$ reactant or more likely to some $S_8(Sb_3F_{16})_2$ which accounts for the formation of these species (see below).

Reaction of $S_4(Sb_2F_{11})_2$ with C_3F_6

Solid $S_4(Sb_2F_{11})_2$ reacts with perfluoropropylene at room temperature to yield predominantly $((CF_3)_2CF)_2S_2$ and $C_6F_{12}S_3$. At 100°C $S_4(Sb_2F_{11})_2$ and C_3F_6 react to yield largely $((CF_3)_2CF)_2S$ and smaller amounts of $(C_3F_7)_2S_2$ and $C_6F_{12}S_2$. $((CF_3)_2CF)_2S$ was characterized by its mass spectrum (Table 5). ^{19}F nmr spectra (Table 6) of perfluoro(3,3,5,5-tetramethyl)-1,2,4-trithiolane ($C_6F_{12}S_3$), **5**, gave a singlet at 66 (± 1) ppm suggesting rapid equilibrium between ring conformers thus rendering the CF_3 groups equivalent. The mass spectrum gave a fragmentation pattern (Table 5) quite similar to **4** suggesting their structures are similar.



5

Raman spectra obtained for **2**, **4**, and **5** are also quite similar (Table 7). Based on C—S stretch assignments for $(CF_3)_2S_x$ ($x = 1$, 2) (17), $(C_2F_5)_2S_x$ ($x = 2 \rightarrow 4$) (18), and tetrafluoro-1,3-dithietane (19), it is probable that peaks observed at 420 ($C_8F_{16}S_3$, **4**), 424 ($C_6F_{12}S_3$, **5**), and 472 cm^{-1} ($C_8F_{16}S_2$, **2**) are of similar origin.

It is expected that $C_8F_{16}S_3$, **4**, should give a strong S—S stretch in the 500–550 cm^{-1} region (17, 18) and the medium, polarized band observed at 541 cm^{-1} is given this tentative assignment. The band at 538 cm^{-1} for $C_6F_{12}S_3$ may also be an S—S stretching vibration. Bands centered at about 750 cm^{-1} for **2**, **4**, and **5** are assigned as CF_3 deformation modes consistent with other CF_3-containing molecules (17). Complexity of this mode for the fluoroalkyl trithiolane **4** (754, 750, and 740 cm^{-1}) suggests the presence of different isomers confirmed by its ^{19}F nmr spectrum (Table 6). Raasch (20) has reported that similar compounds (*i.e.* trithiolanes) undergo reaction with triphenylphosphine resulting in sulphur abstraction and conversion to 1,3-dithietanes. A similar reaction with **5** gave perfluoro(2,2,4,4-tetramethyl)-1,3-dithietane, **6**, identified by a singlet (73.4 $\pm$ 1 ppm) in the ^{19}F nmr.

This is consistent with ^{19}F nmr data reported by Knunyants and co-workers (21) (singlet +70.4 ppm; CCl_3F external standard; recalculated) and Middleton *et al.* (13) (singlet +74.8 ppm; CCl_3F external standard). The perfluoroalkyl 1,2,4-trithiolanes **4** and **5** have not been previously reported.

Solids obtained from all the reactions were not identified. In most cases they are mixtures probably containing unreacted polycation and/or the respective element. They also may contain material related to the products of the reaction of bis(perfluoroethyl) diselenide and antimony pentafluoride (22).

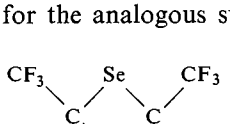
The reactions previously described complete a series of reactions of S, Se, and Te polycations with C_2F_4. The mechanism postulated for these reactions (2–4) and those of Knunyants and co-workers for a related system (9), are applicable to the formation of the straight chain products of the type $(C_2F_5)_2S_x$. We note the intermediate $S_xC_2F_5^+$ is similar to the recently characterised S_7I^+ (23). The reactivity of the polyatomic cations towards C_2F_4 appears to increase as its size decreases (*e.g.* Se_4^{2+} is more reactive than Se_8^{2+} and Te_4^{2+}).

Reactions involving electrophilic addition of C_2F_4 which is typical for olefins are much less common for perfluoroolefins and have been recently reviewed (24, 25). It has been established by Knunyants and Polishchuk (26) that increased replacement of fluorine on C_2F_4 by fluorocarbon alkyl groups leads to decreasing ease of electrophilic attack. We observe a reaction scale consistent (see [3]) with these observations.

[3] $F_2CCF_2 \approx CF_3FC{=}CF_2 > (CF_3)FC{=}CF(CF_3)$

Products of type $C_4F_9S_xC_2F_5$, $(C_4F_9)_2S_x$ (x = 1, 2, 3), and $C_8F_{16}S_x$ (x = 2, 3) which account for 50% of the liquid polysulphides obtained from reaction of $S_4(Sb_2F_{11})_2$ and C_2F_4 cannot be accounted for by previous mechanisms. In the presence of antimony pentafluoride C_2F_4 may dimerize to give $CF_2{=}CF{-}CF_2{-}CF_3$ which may then react with the polyatomic cations leading to branched chain products.

Precedence for the electrophilic dimerization of a perfluorolefin in the presence of antimony pentafluoride has been established for hexafluoropropylene (27). Knunyants and co-workers have reported a reaction of Se, SbF_5, and C_2F_4, C_3F_6 in SO_2 solution (28) to give $(C_2F_5)_2Se_2$ (C_2F_4 reaction); $(C_3F_7)_2Se_x$ (x = 1, 2) and **7** (C_3F_6 reaction). However, products of type $C_4F_9S_xC_2F_5$, $(C_4F_9)_2S_x$, and dithietanes were not reported for the analogous sulphur system (9).



7

The mechanism for formation of 1,3-dithietanes may be similar to that outlined by Knunyants

and co-workers (28) and involve thioketones. One fraction of the volatile components from our reaction products was a deep blue liquid which decolourized on standing consistent with the presence of perfluorobutane-2-thione, C_4F_8S (13). 1,2,4-Trithiolanes may be formed by a related route. Reactions involving C_3F_6 and C_2F_4 presumably occur in a similar manner.

In reactions with four membered rings, $Se_4(AsF_6)_2$ and $S_4(Sb_2F_{11})_2$, some $(C_2F_5)_2Se$ and $(C_2F_5)_2S$ are formed. These species were not detected even in trace quantities by mass spectra for reactions of $S_8(AsF_6)_2$, $S_{16}(AsF_6)_2$, and $Se_8(AsF_6)_2$ with C_2F_4. This is probably a consequence of the greater oxidizing potential in the $S_4(Sb_2F_{11})_2$ and $Se_4(AsF_6)_2$ systems leading to more extensive S—S, Se—Se bond cleavage. Yakobson and co-workers (29, 30) have shown that bis(perfluorophenyl) polysulphides and -selenides react with SbF_5 in the presence of C_6F_5H to form bis(perfluorophenyl) monosulphide and -selenide. A similar reaction may be operative for our system involving intermediates of the type $(C_2F_5Se)_3^+$ or $(C_2F_5Se)_{2n}^{n+}$ identified in our recent work (22) and related sulphur compounds by Yakobson and co-workers (31). These intermediates may further react with perfluorolefin followed by fluoride ion abstraction to give bis(perfluoroalkyl) monosulphide and -selenide. Breakdown of long chain perfluoroalkyl polysulphides and -selenides may proceed by a similar mechanism to give shorter chain products rather than direct cleavage of S—S, Se—Se bonds by AsF_5 or SbF_5 as previously suggested (2–4).

Réaction oscillante de Belousov. 2. Etude d'un nouveau modèle cinétique[1]

GUY SCHMITZ
Faculté des Sciences Appliquées, Université Libre de Bruxelles, Bruxelles, Belgium
Reçu le 28 janvier 1976[2]

GUY SCHMITZ. Can. J. Chem. **55**, 3147 (1977).

Sur base de nos résultats concernant la réaction bromate–céreux nous proposons et discutons un nouveau modèle cinétique pour la réaction oscillante de Belousov–Zhabotinskii. L'existence d'un cycle limite est prouvée à l'aide d'un calculateur analogique pour un choix semi-empirique des paramètres cinétiques.

GUY SCHMITZ. Can. J. Chem. **55**, 3147 (1977).

On the basis of our results dealing with the bromate–cerous reaction we propose and discuss a new kinetic model for the Belousov–Zhabotinskii oscillating reaction. The existence of a limiting cycle is shown with an analog computer for a set of semi-empirically chosen kinetic parameters.

Introduction

Dans la première partie de ce travail (1) nous avons étudié la cinétique de l'une des composantes de la réaction oscillante de Belousov (2): l'oxydation du sulfate céreux par le bromate de potassium en solution sulfurique. Le modèle cinétique adopté nous a permis de rendre compte de nos résultats expérimentaux dans un très large domaine de concentrations initiales et est en accord avec les observations des autres auteurs (3, 4). Notre but est maintenant de montrer que ce modèle, complété par les réactions de réduction des ions cériques par les acides maloniques et bromomaloniques, peut expliquer les oscillations de concentrations observées pendant la réaction de Belousov.

Après une brève partie expérimentale nous détaillons le modèle proposé et discutons la cinétique des réactions qui le composent. Nous indiquons ensuite comment on peut comprendre intuitivement le comportement du système au cours d'une oscillation. Ce raisonnement intuitif ne suffisant pas à prouver que le modèle possède des caractéristiques impliquant de telles oscillations, nous avons tenu à étudier le système d'équations différentielles associé. Une étude très détaillée n'est cependant pas possible, trop de constantes cinétiques étant encore inconnues. Bien plus, malgré l'important travail de Jwo et Noyes (5), le mécanisme de réduction des ions cériques par les acides maloniques et bromomaloniques n'est pas entièrement élucidé. Il faut donc renoncer à retrouver par calcul le détail des courbes expérimentales. Notre but moins ambitieux a cependant été atteint: pour un choix semi-empirique des paramètres cinétiques en variables réduites nous avons vérifié, à l'aide d'un calculateur analogique, qu'un cas particulier de notre modèle conduit à des oscillations des concentrations des ions bromures et cériques.

Résultats expérimentaux

Plusieurs caractéristiques de la réaction de Belousov sont actuellement bien établies (3, 6–11). Les oscillations se produisent en phase homogène et ne résultent pas de phénomènes de transport. Les principaux produits de la réaction sont l'acide bromomalonique et le dioxyde de carbone. Les ions bromures jouent un rôle cinétique important et leur concentration oscille avec la même fréquence que le rapport Ce(III)/Ce(IV). On peut également obtenir des systèmes oscillants en remplaçant l'acide malonique par d'autres acides carboxyliques; de même le cerium peut être remplacé par le manganèse ou la ferroine.

En solution non agitée le couplage entre la cinétique de ce type de réaction et la diffusion peut conduire à l'apparition de bandes de concentration se propageant dans le système ou structures spatiales (12–15).

Les aspects théoriques et expérimentaux des oscillations chimiques ont été passés en revue par Nicolis et Portnow (16) et tout récemment par Gray (17).

[1]La publication de cet article a été retardée à la demande de la rédaction.

[2]Revision reçue le 26 août 1976.

En utilisant la technique expérimentale décrite antérieurement (1) nous avons enregistré quelques exemples d'oscillations en phase homogène. Dans l'ensemble les courbes obtenues sont analogues à celles obtenues par d'autres auteurs et, en particulier, à celles de Noyes et coll. (10). L'avantage de notre technique est de donner simultanément et avec une très bonne précision les concentrations en ions bromures et cériques. Un exemple à une échelle montrant les détails d'une oscillation est donné par la fig. 1. On remarque qu'il n'y a pas concordance exacte entre les positions des extrema des deux concentrations.

Le comportement des solutions en fin de réaction est tout à fait différent selon que l'on a initialement un excès de bromate ou d'acide malonique (figs 2 et 3). Avec un excès de bromate les oscillations s'amortissent et leur période s'allonge suite à la diminution de la concentration des réactifs. Par contre avec un excès d'acide malonique on a un comportement plus surprenant: l'amplitude et la fréquence des oscillations varient peu mais lorsque la concentration en bromate devient trop faible les ions céreux ne sont plus oxydés. Les oscillations s'arrêtent brusquement sans amortissement alors qu'il reste à la fois du bromate et de l'acide malonique dans le système. L'addition d'une petite quantité de bromate à ce moment les fait redémarrer immédiatement. Zhabotinskii (7) avait déjà signalé cet arrêt brutal des oscillations mais sans le relier à un niveau critique de la concentration en bromate.

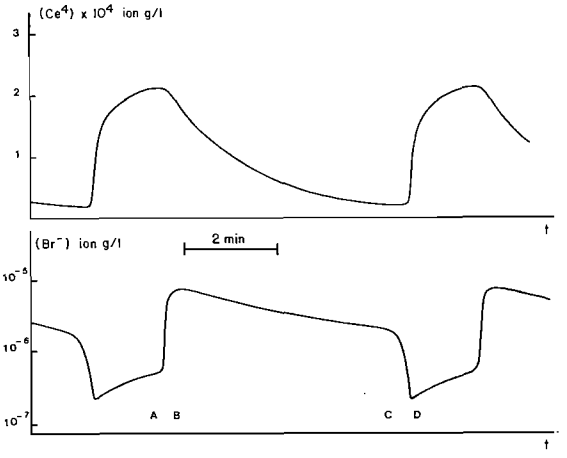

FIG. 1. Détails d'une oscillation: $-[KBrO_3] = 2 \times 10^{-2}$ *M*, $[CH_2(COOH)_2] = 3 \times 10^{-2}$ *M*, [Ce]total $= 10^{-3}$ *M*, $[H_2SO_4] = 1$ *M*, 23°C.

Modèle cinétique

Le cerium étant présent en petites quantités comme catalyseur, la réaction considérée correspond globalement à l'oxydation de l'acide malonique par le bromate. Elle résulte de trois réactions partielles que nous envisagerons successivement, l'oxydation du Ce(III) par le bromate, la formation de l'acide bromomalonique et la réduction du Ce(IV) par les acides malonique et bromomalonique. La stoechiométrie du système étudié ne résulte pas cependant d'une simple somme des stoechiométries de ces trois réactions partielles prises isolément. Par exemple l'acide formique qui semble être un produit final de la réduction du Ce(IV) par l'acide malonique ne se retrouve pas parmi les produits de la réaction oscillante (18). Jwo et Noyes ont étudié les réactions possibles du Ce(IV) et mis en évidence leur complexité (5). Ils sont cependant d'avis que cela a peu d'importance pour expliquer l'existence des oscillations (19). C'est ce que nous pensons également à condition de se limiter à l'aspect qualitatif du phénomène.

1. Oxydation du Ce(III) par le bromate

Le mécanisme de cette réaction a été établi dans la première partie de ce travail (1).

[1] $BrO_3^- + Br^- + 2H^+ \rightleftharpoons Br_2O_2 + H_2O$

[2] $Br_2O_2 + H_2O \rightleftharpoons HBrO_2 + HOBr$

[3] $HBrO_2 + Br^- + H^+ \rightarrow 2HOBr$

[4] $HBrO_2 + Br_2O_2 \rightleftharpoons 2BrO_2^{\cdot} + Br^- + H^+$

[5] $BrO_2^{\cdot} + Ce^{3+} + H^+ \rightleftharpoons HBrO_2 + Ce^{4+}$

L'acide hypobromeux formé peut être converti en brome suivant l'équilibre

$$HOBr + Br^- + H^+ \rightleftharpoons Br_2 + H_2O$$

Rappelons les caractéristiques principales de ce mécanisme. Lorsque la concentration du bromure dans le système est élevée elle maintient celles de $HBrO_2$ et de $BrO_2^{\cdot}$ très petites et le cerium n'est pas oxydé. La stoechiométrie est alors

[*A*] $BrO_3^- + 2Br^- + 3H^+ \rightarrow 3HOBr$

La concentration du bromure diminuant celle de $HBrO_2$ augmente. Lorsque l'on atteint une concentration critique la vitesse des pas [4] et [5] cesse d'être négligeable et la réaction d'oxydation des ions céreux prend une allure autocatalytique. La concentration en bromure

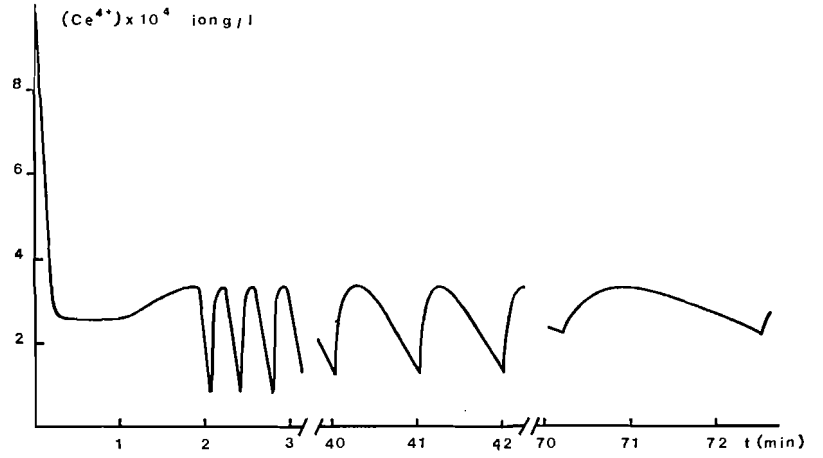

FIG. 2. Evolution de la fréquence et de l'amplitude des oscillations avec un excès de bromate: $-[KBrO_3] = 6.6 \times 10^{-2}$ *M*, $[CH_2(COOH)_2] = 3.3 \times 10^{-2}$ *M*, [Ce]total = 10^{-3} *M*, $[H_2SO_4] = 1$ *M*, 23°C.

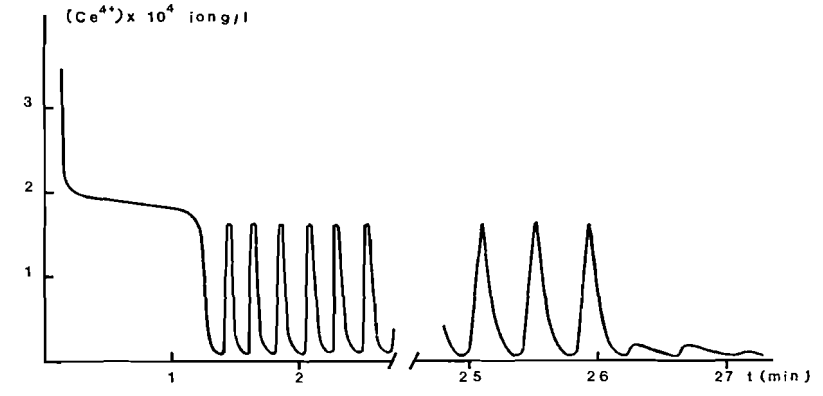

FIG. 3. Evolution de la fréquence et de l'amplitude des oscillations avec un excès d'acide malonique: $-[KBrO_3] = 5 \times 10^{-2}$ *M*, $[CH_2(COOH)_2] = 0.1$ *M*, [Ce]total = 10^{-3} *M*, $[H_2SO_4] = 1$ *M*, 23°C.

chute rapidement et la stoechiométrie principale devient

[*B*] $BrO_3^- + 4Ce^{3+} + 5H^+ \rightarrow HOBr + 4Ce^{4+} + 2H_2O$

2. Formation de l'acide bromomalonique

En milieu acide le brome et l'acide hypobromeux réagissent avec l'acide malonique pour donner de l'acide bromomalonique. On peut également obtenir de l'acide dibromomalonique mais suivant les résultats de Field et coll. (10) cette formation est négligeable dans les conditions de la réaction oscillante. Par contre il est possible que l'on forme un peu d'acide mono ou dibromoacétique (19).

La réaction de l'acide malonique avec le brome obéit à la loi cinétique (20, 21)

$$\frac{d}{dt}[BrCH(COOH)_2] = k[H^+][CH_2(COOH)_2]$$

Son étape déterminante est l'énolisation de l'acide catalysée par les ions H^+. Par analogie avec les autres réactions de ce type (22) nous admettons que l'énol réagit ensuite avec le cation Br^+ ce qui implique que les réactions avec le brome ou avec l'acide hypobromeux obéissent à la même loi cinétique.

Zhabotinskii (7) a recherché mais n'a pas trouvé de brome dans la solution oscillante. D'autre part les mesures d'absorbance à 400 et 500 nm de Franck et Geiseler (23) laissent présumer, mais ne prouvent pas, sa présence dans ce milieu complexe. Quoi qu'il en soit, il résulte de ce qui a été dit ci-dessus qu'au point

de vue cinétique on peut se borner à ne considérer que la réaction [6] pour la formation de l'acide bromomalonique.

[6] $HOBr + CH_2(COOH)_2 \rightarrow BrCH(COOH)_2 + H_2O$

3. Réduction du Ce(IV) par les acides maloniques et bromomaloniques

Les stoechiométries de ces deux réactions sont vraisemblablement (10, 24)

[7] $CH_2(COOH)_2 + 6Ce^{4+} + 2H_2O \rightarrow 6Ce^{3+} + HCOOH + 2CO_2 + 6H^+$

[8] $BrCH(COOH)_2 + 4Ce^{4+} + 2H_2O \rightarrow 4Ce^{3+} + HCOOH + 2CO_2 + Br^- + 5H^+$

Il est possible que le rapport $CO_2/HCOOH$ soit un peu supérieur à 2 (25) ou même, la concentration en Ce^{4+} restant très faible au cours de la réaction oscillante, un peu inférieur à 2. Cela n'aurait cependant aucune incidence notable sur la suite de notre raisonnement. On sait également qu'en présence d'ions bromures l'acide formique peut être oxydé par le Ce(IV) (5) mais cette réaction est lente et probablement négligeable à l'échelle de temps d'une oscillation.

La cinétique de la réaction [7] a été étudiée par Sengupta et Aditya (24) qui, avec un excès d'acide malonique, trouvent un ordre 1 par rapport au Ce(IV). Kasperek et Bruice (3) ont étudié les deux réactions. Ils concluent que le Ce(IV) est en partie complexé par l'acide et obtiennent dans les deux cas une loi cinétique de la forme

$$r = k \frac{[A]\, Ce(IV)_T}{K_m + [A]}$$

A désignant l'acide malonique ou bromomalonique et $Ce(IV)_T$ la concentration totale du Ce(IV). Jwo et Noyes (5) trouvent un ordre 1 dans des conditions ou $K_m \gg [A]$ mais observent une cassure dans leurs courbes cinétiques pour la réaction [8].

Lorsque les deux acides sont présents simultanément la situation est certainement beaucoup plus complexe (5), la présence d'acide malonique modifiant fortement la vitesse de production du bromure par la réaction [8]. Il subsiste donc une incertitude quant aux lois à adopter au cours de la réaction oscillante. Cela ne modifie certainement pas notre description qualitative du phénomène mais bien sa description quantitative.

Explication intuitive de l'évolution du système

Lorsque l'on introduit le cerium initialement sous la forme Ce(IV) on observe dès l'instant initial sa réduction rapide (figs 2 et 3), ce qui correspond évidemment à la réaction [7]. Simultanément si l'on a des traces de bromure elles sont oxydées par le bromate. Lorsque la concentration en bromure est devenue suffisamment faible le Ce(III) produit par la réaction [7] commence à être oxydé par le bromate suivant la stoechiométrie [*B*]. La compétition entre ces deux réactions donne une période où le rapport Ce(III)/Ce(IV) varie lentement. Que cette variation lente soit due à une compétition et non pas à la petitesse des vitesses de réactions est démontré par la production importante de CO_2 observée par Degn (8) au cours de cette période. L'acide hypobromeux produit par la réaction [*B*] brome l'acide malonique suivant [6]. La concentration de l'acide bromomalonique augmentant, la réduction du Ce(IV) ne résulte plus seulement de [7] mais également de [8]. C'est à ce moment qu'apparait le phénomène fondamental permettant de comprendre l'apparition des oscillations: si dans un système siège à la fois des réactions [*B*] et [8] la vitesse de cette dernière est assez grande, la concentration du bromure augmentera et finira par inhiber la réaction [*B*]. Degn (8) a montré que la période d'induction est raccourcie par l'introduction dans le système d'acide bromomalonique ou d'autres dérivés bromés, ce qui confirme que la fin de cette période soit liée à la production de bromure par la réaction [8] ou par une réaction analogue.

A la fin de la période d'induction la situation est identique à celle existant au point A de la fig. 1. La réaction bromate–céreux [*B*] se déroule avec une vitesse importante et tend à maintenir des concentrations quasi-stationnaires, très petite pour Br^- et relativement grande pour $HBrO_2$. Cependant la réaction [8] produit du bromure ce qui perturbe de plus en plus vite ces concentrations: l'augmentation de $[Br^-]$ provoque la diminution de $[HBrO_2]$ et de la vitesse de la réaction [*B*] qui s'oppose donc de moins en moins à l'augmentation de $[Br^-]$. On voit que l'allure autocatalytique prise par la courbe donnant la concentration du bromure ne provient pas de l'augmentation de sa vitesse de production (la vitesse de [8] varie peu) mais bien de la chute de sa vitesse de consommation par le pas [3].

Au point B de la fig. 1 le bromure a atteint une concentration telle que la réaction [*B*] est inhibée et remplacée par la réaction [*A*]. Le cerium n'est plus oxydé et la concentration $[Ce^{4+}]$ diminue du fait des réactions [7] et [8]. Entre les points B et C la vitesse de ces réactions diminue et la production de CO_2 tend vers son minimum (8).

Lorsque la formation de Br^- par la réaction [8] est devenue suffisamment petite l'état du système est comparable à celui existant à la fin de la période d'induction de la réaction bromate–céreux. La seule réaction importante est la réaction [*A*] qui fait diminuer $[Br^-]$ jusqu'à une valeur critique permettant le démarrage de la réaction [*B*]. $[HBrO_2]$ augmente de façon autocatalytique du fait des pas [4] et [5], $[Br^-]$ chute rapidement et les ions Ce^{3+} sont à nouveau oxydés par le bromate. L'acide hypobromeux formé brome l'acide malonique suivant [6].

Au point D de la fig. 1 le cerium est oxydé rapidement par le bromate et est réduit par les acides maloniques et bromomaloniques. La réaction [8] provoque l'augmentation de $[Br^-]$ et l'on se retrouve dans la même situation qu'au point A.

Système différentiel associé au modèle cinétique

Pour démontrer que le modèle proposé implique des oscillations du type de celles que nous venons d'expliquer intuitivement il faut étudier le système différentiel qui lui est associé. Sa complexité est cependant telle que dans le cas général et avec les moyens de calcul dont nous disposons cette étude est irréalisable. Face à ce problème on peut chercher à construire un modèle chimique moins réaliste mais plus simple dont la forme est suggérée par le modèle initial. On en trouve de nombreux exemples dans la littérature aussi bien pour la réaction de Belousov que pour d'autres réactions oscillantes.[3] Cette approche, utile sur le plan de la théorie des systèmes oscillants, ne constitue cependant pas un test sûr du modèle initial. En effet en groupant certains pas, en réduisant le nombre d'intermédiaires etc. . . . on introduit et l'on supprime certaines caractéristiques cinétiques pouvant être importantes. Nous avons donc préféré conserver le modèle général mais en limitant les développements mathématiques à des cas particuliers du système différentiel associé, choisis en fonction de leur sens physique. Si l'on peut démontrer qu'un cas particulier ainsi obtenu admet des solutions périodiques non amorties il est évident que le cas général en admet également.

Un autre résultat important de notre étude mathématique sera l'explication de la différence de comportement du système à la fin des oscillations suivant que l'on a initialement un excès de bromate ou d'acide malonique.

En désignant par r_i la vitesse globale vers la droite du pas i, le système différentiel associé à notre modèle cinétique s'écrit:

$$\frac{d[Br^-]}{dt} = -r_1 - r_3 + r_4 + r_8$$

$$\frac{d[HOBr]}{dt} = r_2 + 2r_3 - r_6$$

$$\frac{d[HBrO_2]}{dt} = r_2 - r_3 - r_4 + r_5$$

$$\frac{d[BrO_2^{\bullet}]}{dt} = 2r_4 - r_5$$

$$\frac{d[Br_2O_2]}{dt} = r_1 - r_2 - r_4$$

$$\frac{d[Ce^{4+}]}{dt} = -\frac{d[Ce^{3+}]}{dt} = r_5 - gr_8$$

Le nombre d'oscillations observées étant toujours grand les concentrations du bromate et de l'acide malonique varient très peu au cours de chaque oscillation. Mis à part les premiers temps de la réaction, il en est de même de la concentration de l'acide bromomalonique Enfin on constate expérimentalement que la concentration $[H^+]$ est quasi-constante. Nous n'écrivons donc pas d'équation différentielle pour ces concentrations et les incluons dans les constantes cinétiques.

La vitesse des pas [1] à [4] est donnée par

$$r_1 = k_1[Br^-] - k_{-1}[Br_2O_2]$$

$$r_2 = k_2[Br_2O_2] - k_{-2}[HBrO_2][HOBr]$$

$$r_3 = k_3[HBrO_2][Br^-]$$

$$r_4 = k_4[HBrO_2][Br_2O_2] - k_{-4}[BrO_2^{\bullet}]^2[Br^-]$$

Pour que la réversibilité du pas [5] apparaisse on sait (1) qu'il faut non seulement que $[Ce^{4+}]$

[3]Des modèles dans des domaines très divers ont été passés en revue récemment par Gray (17). Pour la réaction de Belousov voir les réfs 26–28.

soit grand mais également que $[Br^-]$ soit très petit. Bien que manquant d'indications quantitatives précises, nous pensons que cette réversibilité n'influence pas le déroulement de la réaction oscillante.

$$r_5 = k_5[BrO_2^{\cdot}][Ce^{3+}]$$

Si l'on tient compte de la réversibilité de ce pas on fait apparaître un nouveau point singulier instable tandis que la stabilité de celui qui nous intéressera est peu influencée.

Le pas [6] étant d'ordre zéro par rapport à HOBr sa vitesse s'écrit simplement:

$$r_6 = k_6$$

Les lois cinétiques et même la stoéchiométrie des réactions [7] et [8] prises simultanément sont, comme nous l'avons vu, mal connues. Pour des concentrations en acides malonique et bromomalonique quasi-constantes nous admettons:

$$r_8 = k_8[Ce^{4+}]$$

Le coefficient g dans l'expression de $d[Ce^{4+}]/dt$ correspond au nombre d'ions Ce^{4+} consommés par les réactions [7] et [8] lorsque la réaction [8] produit un ion bromure. Sa valeur peut être comprise entre 1 et 6 (5). Nous adopterons $g = 4$.

1. Explication de l'arrêt des oscillations à la fig. 3

On sait que des oscillations ne peuvent se produire qu'autour de points singuliers du système différentiel. Les concentrations en ces points, que nous désignerons par des valeurs surlignées, sont obtenues en annulant toutes les dérivées par rapport au temps. En posant

$$a = 3k_1k_4/4k_{-1}k_3$$

$$b = (5k_8/2k_6)c_t - 1$$

c_t = Concentration totale en cérium

$$c = 12k_{-4}k_8^2/k_1k_5^2b^2$$

on obtient notamment

$$\overline{[Br^-]} = \frac{3k_6}{5k_1}\alpha$$

$$\overline{[HOBr]} = \frac{k_3k_6}{5k_1k_{-2}}\alpha\left[1 + 3\frac{k_2}{k_{-1}}(\alpha - 1)\right]$$

$$\overline{[HBrO_2]} = k_1/\alpha k_3$$

$$\overline{[Ce^{4+}]} = 2k_6/5k_8$$

Le paramètre α étant donné par l'équation [9] on obtient deux points singuliers[4] que nous désignerons par $\alpha(+)$ et $\alpha(-)$.

$$[9] \qquad c\alpha^2 - (a - 1)\alpha + a = 0$$

Pour qu'ils aient un sens physique il faut que les trois conditions suivantes soient satisfaites.

$$[10] \qquad b > 0$$

$$[11] \qquad a > 1$$

$$[12] \qquad (a - 1)^2 > 4ac$$

La condition [10] impose une valeur minimum du rapport [acide bromomalonique]/[acide malonique] pour une concentration totale en cérium donnée. Si elle est satisfaite à un moment de l'évolution du système, elle le restera ensuite. La condition [11] impose une valeur minimale de la concentration en bromate. Dans les systèmes étudiés il est probable qu'elle est toujours satisfaite et que, comme lors de l'étude de la réaction bromate–céreux (1), on a même $a \gg 1$. La condition [12] est beaucoup plus critique car elle cessera d'être satisfaite si le rapport [bromate]/[acide malonique] devient trop petit. A ce moment les deux racines de l'équation donnant α deviennent complexes, les points singuliers du système différentiel perdent leur sens physique et dans le cas où il existait un cycle limite, il disparait. Ceci explique la différence de comportement du système en fin de réaction montrée par les figs 2 et 3. Si l'on a initialement un excès de bromate, le rapport [bromate]/[acide malonique] augmente au cours de la réaction et si la condition [12] est satisfaite, elle le reste. Si l'on a initialement un excès d'acide malonique ce rapport diminue ce qui finit par provoquer la disparition brutale du cycle limite. Une explication aussi simple d'un fait expérimental à priori assez étonnant nous parait être un argument solide en faveur de notre modèle.

2. Stabilité des points singuliers

Nous avons étudié cette stabilité par la première méthode de Liapounov (17): on linéarise le système différentiel au voisinage

[4]Bien qu'ayant toujours un sens physique le point singulier correspondant à des concentrations nulles n'apparait pas ici à cause de la loi de vitesse admise pour le pas [6]. Si la concentration en acide hypobromeux tend vers zéro cette loi ne reste évidemment pas valable et l'on doit avoir $r_6 \to 0$.

d'un point singulier et l'on étudie le signe de la partie réelle des racines de son équation caractéristique en utilisant les critères de Routh–Hurwitz (29). Les calculs, très laborieux, montrent que le point singulier correspondant à $\alpha(-)$ est toujours instable et que celui correspondant à $\alpha(+)$ peut l'être dans un domaine de valeurs des constantes cinétiques. Dans ce domaine il est possible que les solutions du système différentiel admettent un cycle limite et donc que son intégration fasse apparaître des oscillations des concentrations.

3. *Intégration du système différentiel dans un cas particulier*

L'intégration de systèmes différentiels correspondant à des modèles cinétiques tels que celui étudié ici est rendue particulièrement difficile par la présence de constantes cinétiques d'ordres de grandeur très différents. Pour ces systèmes mal conditionnés, (stiff équations) il existe des méthodes numériques (30, 31) mais les calculs sont longs et couteux. Comme de plus notre système comporte de nombreuses constantes inconnues, ce qui rend illusoire une tentative de reproduire les courbes expérimentales, nous nous sommes borné à prouver l'existence de solutions oscillantes en utilisant un calculateur analogique avec des variables réduites et l'approximation de l'état quasi-stationnaire pour les intermédiaires très réactifs $BrO_2^{\bullet}$ et Br_2O_2.

Lors de notre étude de la réaction bromate–céreux (1) nous avons considéré que l'équilibre du pas [4] n'était quasi pas perturbé. Nous admettons qu'il en est de même au cours des oscillations. En outre, ne connaissant les valeurs ni de k_1 ni de k_{-1}, nous admettons également l'équilibre du pas [1]. Cette hypothèse simplificatrice implique, outre la condition $a \gg 1$ déjà connue, que l'on oscille autour du point singulier $\alpha(+) \simeq a/c \gg 1$. Elle devrait être abandonnée pour un calcul plus élaboré car nous savons que l'équilibre du pas [1] peut être perturbé pendant la période AB de la fig. 1.

On pose:

$$[Br^-] = 10x\overline{[Br^-]} \qquad [HOBr] = 4y\overline{[HOBr]}$$

$$[HBrO_2] = 4u\overline{[HBrO_2]} \qquad [Ce^{4+}] = 2z\overline{[Ce^{4+}]}$$

$$t = \tau\overline{[Ce^{4+}]}/2k_6 \qquad a_2 = 3k_2\alpha(+)/k_{-1}$$

$$A = 10\overline{[Br^-]}/\overline{[Ce^{4+}]} \qquad B = 4\overline{[HOBr]}/\overline{[Ce^{4+}]}$$

$$C = 5\overline{[HBrO_2]}/\overline{[Ce^{4+}]}$$

Les valeurs surlignées se rapportent au point singulier $\alpha(+)$. On obtient ainsi le système différentiel que nous avons étudié.

$$A\frac{dx}{d\tau} = -a_2x + 1.6(1 + a_2)uy - 12ux + 0.4z$$

$$B\frac{dy}{d\tau} = a_2x - 1.6(1 + a_2)uy + 24ux - 0.5y/(y + \varepsilon)$$

$$C\frac{du}{d\tau} = a_2x - 1.6(1 + a_2)uy - 12ux + \frac{0.8}{b}(b + 1 - 2z)\sqrt{u}$$

$$\frac{dz}{d\tau} = \frac{0.8}{b}(b + 1 - 2z)\sqrt{u} - 0.8z$$

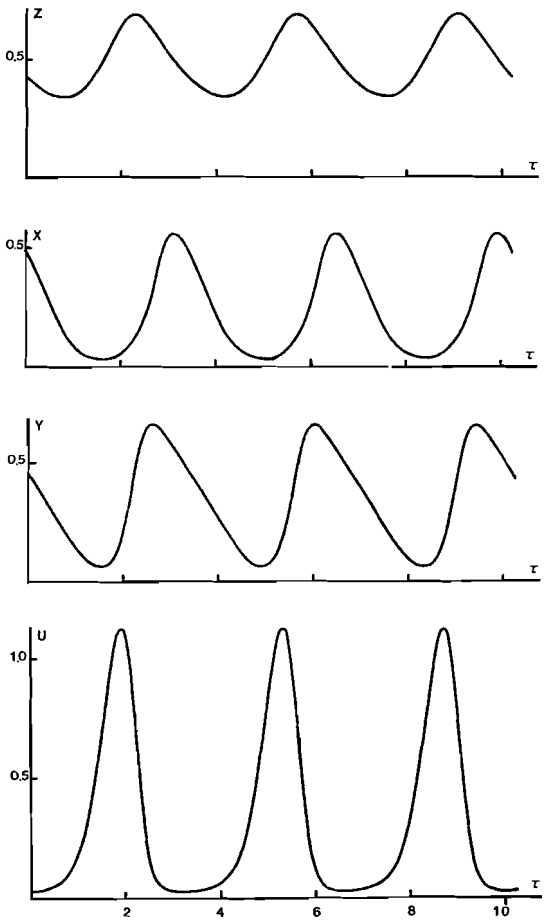

FIG. 4. Exemple d'oscillations obtenues par le calcul analogique: $a_2 = 0.1$; $b = 8$; $A = 5 \times 10^{-2}$; $B = 0.5$; $C = 0.25$; $\varepsilon = 0.01$.

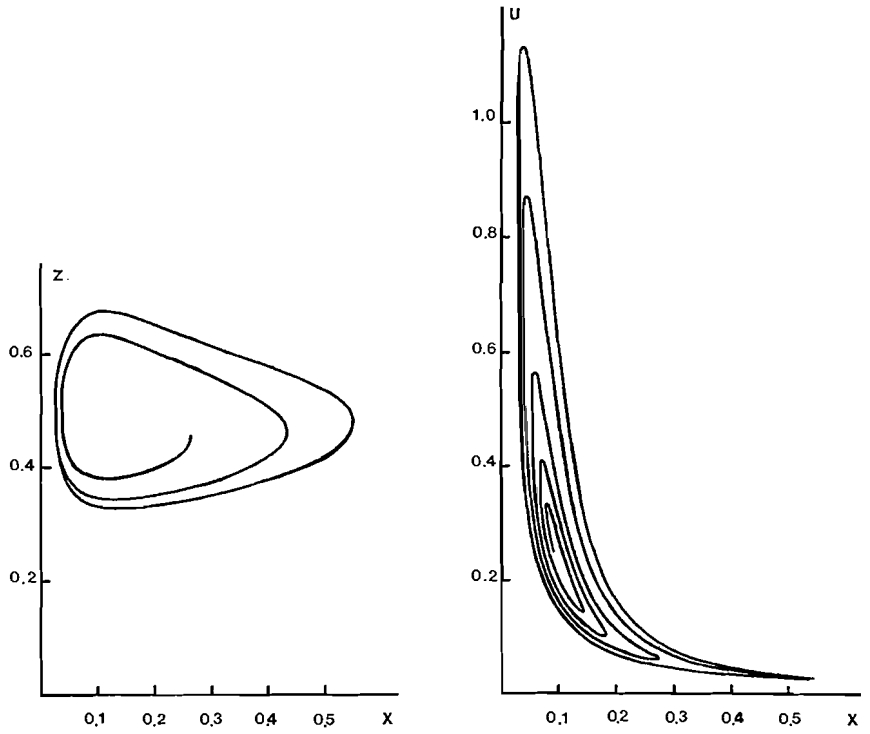

FIG. 5. Plans des phases correspondants à la fig. 4.

Nous avons du introduire le facteur $y/(y + \varepsilon)$ car sinon y tendait à devenir négatif. Cela résulte de l'ordre zéro admis pour le pas [6], ordre qui ne se maintient évidemment pas si y tend vers zéro. ε influence la position et la stabilité du point singulier mais cette influence peut être rendue négligeable en prenant ε suffisamment petit. Nous avons vérifié par le calcul analogique que pour $\varepsilon = 0.01$ la stabilité du point singulier correspond correctement aux résultats des calculs évoqués au paragraphe *2*. Lorsque ce point est instable on obtient, comme prévu, des oscillations entretenues dont un exemple est donné par les figs 4 et 5. Les valeurs de A et b correspondent à des ordres de grandeurs expérimentaux, celle de a_2 à l'idée que le pas [2] est réversible mais pas à l'équilibre, celles de B et c ne sont pas connues expérimentalement et ont été prises sans autre considération que l'instabilité du point singulier.

Le cas particulier étudié pouvant donner des oscillations il en est de même du cas général mais son étude qui devrait permettre de mieux reproduire les courbes expérimentales nécéssiterait la connaissance à priori de plusieurs constantes cinétiques ainsi que des moyens de calcul beaucoup plus puissants.

Conclusions

Sur base de nos résultats cinétiques antérieurs relatifs à la réaction bromate–céreux, nous proposons un nouveau modèle pour la réaction oscillante de Belousov. Après avoir montré intuitivement l'origine des oscillations nous avons étudié le système différentiel associé à notre modèle. Nous avons montré d'une part qu'il rend compte de la différence de comportement des solutions oscillantes en fin de réaction selon le rapport initial des concentrations du bromate et de l'acide malonique, d'autre part qu'il peut admettre des points singuliers instables. Face à la difficulté que présente l'étude de systèmes aussi complexes nous n'avons pas cherché à construire un modèle cinétique simplifié mais nous avons préféré étudier un cas particulier du système différentiel correspondant au modèle dans son intégralité. Le calcul analogique a montré que ce cas particulier peut admettre un cycle limite.

Les courbes cinétiques obtenues par le calcul

ne correspondent que qualitativement aux courbes expérimentales. Des essais d'ajustement quantitatifs nous sembleraient prématurés tant que l'on ne connait pas certaines constantes cinétiques ainsi que les lois de réduction du Ce(IV) par les acides maloniques et bromomaloniques simultanément.

Remerciements

Je remercie très vivement Monsieur le Professeur C. Herbo pour l'intérêt qu'il a porté à ce travail. Les nombreuses discussions que j'ai eues avec lui ont toujours été très fructueuses.

Received January 14, 1977

RICHARD M. NOYES and K. BAR-ELI. Can. J. Chem. **55**, 3156 (1977).

The preceding paper by Schmitz suggests a mechanism of the oscillating Belousov–Zhabotinsky reaction that differs significantly from the mechanism previously proposed by Field, Körös, and Noyes. The most important differences are associated with the mechanism assumed for the oxidation of cerium(III) by bromate. The alternative mechanisms for this oxidation are examined and compared with relevant experimental information on similar systems. We conclude the mechanism developed by Schmitz and associates is inconsistent with several observations and that it is doubtful it can be the correct interpretation of this reaction.

RICHARD M. NOYES et K. BAR-ELI. Can. J. Chem. **55**, 3156 (1977).

La communication précédente par Schmitz suggère un mécanisme pour la réaction oscillante de Belousov–Zhabotinsky qui diffère d'une façon importante du mécanisme proposé antérieurement par Field, Körös et Noyes. Les différences les plus importantes sont reliées au mécanisme présumé pour l'oxydation du cérium(III) par le bromate. On fait un examen des mécanismes alternatifs pour cette oxydation et on les compare avec les informations expérimentales disponibles pour des systèmes similaires. On conclut que le mécanisme développé par Schmitz et ses associés n'est pas en accord avec plusieurs observations et qu'il est peu probable qu'il puisse expliquer correctement cette réaction.

[Traduit par le journal]

Introduction

The Belousov–Zhabotinsky (2, 3) reaction is of interest because it is one of very few known oscillating chemical reactions taking place in homogeneous solution. Schmitz (4) has proposed a mechanism for this reaction that differs significantly from that previously proposed by Field *et al.* (5). Both mechanisms generate unstable steady states for certain combinations of rate constants, but they differ primarily in their explanation of the oxidation of cerium(III) by bromate ion. The purpose of this paper is to compare the two mechanistic proposals for this critical component of the oscillating system.

General Characteristics of Reaction

There have been several recent experimental studies of this reaction (6–10). It starts with an induction period of difficultly reproducible length during which initial traces of bromide ion are consumed and no cerium(III) is oxidized. If the initial bromide ion concentration is no more than about 1% that of bromate, the appropriate stoichiometry is that of equation [T1]. If more bromide is present initially, Br_2 will be produced in amount comparable to or greater than that of HOBr.

$$[T1] \qquad BrO_3^- + 2Br^- + 3H^+ \rightarrow 3HOBr$$

After the induction period is over, reaction with the stoichiometry of equation [T2] is suddenly initiated. Thermodynamic calculations confirm that this is the principal stoichiometry to be expected in systems containing a considerable excess of bromate ion. However, the final product should be mostly Br_2 when cerium(III) is in considerable stoichiometric excess. Nevertheless, Thompson (8) reports the final product is HOBr even under these conditions; the reasons the system does not react further must be kinetic rather than thermodynamic.

$$[T2] \qquad BrO_3^- + 4Ce^{3+} + 5H^+ \rightarrow HOBr + 4Ce^{4+} + 2H_2O$$

[1]This is paper No. 20 in the series "Oscillations in Chemical Systems"; for part 19 see ref. 1.

Assignment of Elementary Processes

Reactions [T1] and [T2] certainly do not take place in single steps. There have been two detailed efforts to devise a set of elementary processes generating the observed experimental facts (9, 11). They agree in ascribing significance to the three steps with [C] designations.

[C1] $HBrO_2 + Br^- + H^+ \rightleftarrows 2HOBr$

[C2] $HOBr + Br^- + H^+ \rightleftarrows Br_2 + H_2O$

[C3] $BrO_2\cdot + Ce^{3+} + H^+ \rightleftarrows HBrO_2 + Ce^{4+}$

The mechanism of Noyes *et al.* (11), hereafter designated NFT, includes the four other steps with [A] designations.

[A1] $BrO_3^- + Br^- + 2H^+ \rightleftarrows HBrO_2 + HOBr$

[A2] $BrO_3^- + HBrO_2 + H^+ \rightleftarrows 2BrO_2\cdot + H_2O$

[A3] $BrO_2\cdot + Ce^{4+} + H_2O \rightleftarrows BrO_3^- + Ce^{3+} + 2H^+$

[A4] $2HBrO_2 \rightleftarrows BrO_3^- + HOBr + H^+$

These seven elementary processes include only one species for each oxidation state of bromine and assume proton transfers to and from oxygen and bromine are so rapid that acid–base equilibria are maintained at all times. Four species contain one bromine atom in each odd oxidation number from -1 to $+5$, and steps [C1], [A1], and [A4] represent the only ways they could be interchanged by oxygen atom transfers. Steps [C2] and [A2] represent the ways even oxidation numbers 0 and $+4$ could be formed reversibly from the species with adjacent odd oxidation numbers. Cerium ions can only undergo one-equivalent changes, and steps [C3] and [A3] represent the only ways they could react with $BrO_2\cdot$ radicals. Step [A3] was originally (11) proposed to explain the dramatic slowing of the reaction long before the equilibrium of process [T2] is approached. It involves formation of a Br—O bond, while step [C3] is a simple electron transfer. The modeling calculations of Barkin *et al.* (10) subsequently demonstrated that step [A3] could be omitted entirely and that the slowing of reaction rate arose because the equilibrium constant for step [C3] is not much over 0.01 M^{-1}.

The alternative mechanism of Herbo *et al.* (9), hereafter designated HSV, omits the [A] steps and proposes three others with [B] designations.

[B1] $BrO_3^- + Br^- + 2H^+ \rightleftarrows Br_2O_2 + H_2O$

[B2] $Br_2O_2 + H_2O \rightleftarrows HBrO_2 + HOBr$

[B3] $HBrO_2 + Br_2O_2 \rightleftarrows 2BrO_2\cdot + Br^- + H^+$

All three steps involve the intermediate Br_2O_2, which is inferred from kinetic data without direct spectroscopic or other evidence. Two hydrolysis reactions are included for this species, and it is postulated that step [$-$B1] is much faster than [B2]. Step [B3], which produces $BrO_2\cdot$ radicals, is chemically unprecedented and contains three bromine atoms in the transition state. This high order in intermediate bromine oxidation states appears to be necessary if the HSV mechanism is to generate an unstable steady state in the Belousov–Zhabotinsky reaction (4).

General Comparison of Mechanisms

Both mechanisms can easily account for the stoichiometry of process [T1]. The NFT mechanism uses [A1] + [C1] with $HBrO_2$ the only intermediate species. The HSV mechanism replaces [A1] with [B1] + [B2] and considers Br_2O_2 another intermediate. The predictions of the two mechanisms are not significantly different during the induction period.

When the principal reaction commences, the NFT mechanism can generate the stoichiometry of process [T2] by combining three steps that treat $HBrO_2$ and $BrO_2\cdot$ as the only intermediates.

[A2] $\times$ 2 $2BrO_3^- + 2HBrO_2 + 2H^+ \rightarrow 4BrO_2\cdot + 2H_2O$

[C3] $\times$ 4 $4BrO_2\cdot + 4Ce^{3+} + 4H^+ \rightarrow 4HBrO_2 + 4Ce^{4+}$

[A4] $2HBrO_2 \rightarrow BrO_3^- + HOBr + H^+$

The HSV mechanism requires a combination of five steps to generate the same stoichiometry, and Br_2O_2, Br^-, and HOBr are also species that are both created and destroyed during the reaction.

[B1] $BrO_3^- + Br^- + 2H^+ \rightarrow Br_2O_2 + H_2O$

[B3] $\times$ 2 $2Br_2O_2 + 2HBrO_2 \rightarrow 4BrO_2\cdot + 2Br^- + 2H^+$

[C3] $\times$ 4 $4BrO_2\cdot + 4Ce^{3+} + 4H^+ \rightarrow 4HBrO_2 + 4Ce^{4+}$

[C1] $HBrO_2 + Br^- + H^+ \rightarrow 2HOBr$

[$-$B2] $HBrO_2 + HOBr \rightarrow Br_2O_2 + H_2O$

We can identify at least three ways in which the two mechanisms lead to different predictions that can be tested by means of experimental data presently available.

(*a*) The NFT mechanism regards HOBr as a product formed almost irreversibly in step [A4], while the HSV mechanism both forms this species in step [C1] and consumes it in step [−B2]. Therefore, the NFT mechanism predicts deliberate manipulation of [HOBr] should have no effect on the rate of oxidation of cerium(III), while the HSV mechanism predicts an effect.

(*b*) The NFT mechanism assumes that any Br^- initially present is destroyed by process [T1] during the induction period, and this species is at negligibly small concentration during all of the principal reaction. The HSV mechanism requires that Br^- is both created and destroyed at significant rates during most of the reaction. This requirement leads to predictions that can be tested.

(*c*) The NFT mechanism produces $BrO_2\cdot$ radicals by potentially reversible step [A2], and the HSV mechanism produces them by step [B3]. Information available on analogous systems permits definite conclusions about the relative plausibilities of these two mechanisms.

Detailed Comparison of Mechanisms

Effect of HOBr

We are not aware of any deliberate manipulations of [HOBr] during the oxidation of cerium(III), but Knight and Thompson (12) did examine effects on the analogous oxidation of neptunium(V) by bromate. They found that added HOBr shortened the induction period as would be predicted by both mechanisms. However, they found the rate of the principal reaction was not affected by addition of allyl alcohol, which is an effective scavenger for HOBr. This result is consistent with the predictions of the NFT mechanism but is inconsistent with the HSV predictions.

Effect of Br^-

Reaction [C2] has been studied kinetically by Eigen and Kustin (13). It is so rapid that equilibrium is established in much less than 1 s. If we accept the equilibrium constant used by Herbo *et al.* (9), then at all times we may assume

$$[Br^-] = 5.8 \times 10^{-9} \frac{[Br_2]}{[HOBr][H^+]}$$

As indicated above, the data of Thompson (8) in 1 *M* acid indicate that $[HOBr] \gg [Br_2]$ at least near the end of a reaction with cerium(III) in stoichiometric excess, and thermodynamic considerations suggest the inequality would be even more severe during the intermediate stages when BrO_3^- is still present in significant amount.

These restrictions create no difficulty for the NFT mechanism which considers $[Br^-]$ to be negligibly small during all of the principal reaction. However, the HSV mechanism predicts that Br^- is being produced at a rate equal to $\frac{1}{2}d[Ce^{4+}]/dt$. It is difficult to see how the inequality $[Br^-] \ll 6 \times 10^{-9}$ *M* can be maintained toward the end of the reaction unless steps [B1] and [C1] are much more rapid than is permissible even for diffusion control (14).

Mechanism of $BrO_2\cdot$ Formation

One of the greatest differences between the two mechanisms relates to the alternative steps [A2] and [B3] by which oxybromine radicals are proposed to be formed. We are not aware of any other chemical system for which a reaction like [B3] has been proposed. However, step [A2] is an exact analogue of a reaction that Taube and Dodgen (15) studied directly in the oxychlorine system. The thermodynamic estimates of Field *et al.* (5) indicate the equilibrium constant of step [A2] is not greatly different from that for the oxychlorine reaction (16), although Taube and Dodgen (15) do find the chlorine reaction is much slower than the analogous bromine one is predicted to be. An attempt to devise a mechanism for the oscillating iodate catalyzed decomposition of hydrogen peroxide (17) indicated the oxyiodine analogue of step [A2] had very similar rate and equilibrium parameters to [A2].

Further support for our rate estimates for [A2] is provided by the radiation chemical observations of Buxton and Dainton (18) on the reverse reaction. Their experiments were conducted in alkaline solution. However, if their interpretations may be extrapolated to the strongly acidic solutions employed for the oxidation of cerium(III), step [−B3] must have been much slower than step [−A2] at the very low bromide concentrations prevailing. The HSV mechanism regards step [B3] as reversible, and it then appears difficult to justify their ignoring of step [A2]. It also seems significant that Buxton and Dainton (18) found no effect of bromide ion on the rate of $BrO_2\cdot$ disproportionation even though step [B3] suggests that a large effect should have been observed.

The isotopic exchange studies of Betts and MacKenzie (19) provide still stronger evidence

for step [A2] of the NFT mechanism for radical formation. A small amount of tracer Br^- was added to an acidic solution prepared from Br_2 and BrO_3^-, and the rate of appearance of tracer in BrO_3^- was followed. The bromine species were not initially in equilibrium, and the ratio $[HOBr]/[Br^-]$ increased greatly over a period of days. During the same period, the rate at which BrO_3^- was gaining radioactivity changed by less than a factor of two. These observations seem to require that the rate-determining step for exchange of BrO_3^- and Br_2 does not involve either HOBr or Br^-; $HBrO_2$ is the only non-radical species left for consideration. It is the contention of Field *et al.* (5) that step [A2] of the NFT mechanism is also rate-determining for the isotopic exchange.

Further support for this interpretation is provided by the kinetic data of Betts and MacKenzie (19). They made a number of runs in which tracer was not added until the BrO_3^- and Br_2 had been in contact for 100 h. Although these systems had not yet attained equilibrium concentrations of HOBr, they had moved a considerable distance in that direction. Rates of exchange in those systems were proportional to $[BrO_3^-]^{1.7}[Br_2]^{0.3}$. If a single step were rate-determining for the exchange, and if all bromine species were in equilibrium, the rate of exchange would be proportional to $[BrO_3^-]^{\alpha}[Br_2]^{\beta}$ where $\alpha + 2\beta$ would equal the number of bromine atoms in the transition state and $5\alpha/(\alpha + 2\beta)$ would equal the average oxidation number of those bromines. The experimental data suggest a transition state with 2.3 bromine atoms having an average oxidation number of +3.7. Step [A2] has a transition state with 2 bromine atoms having an average oxidation number of +4 and predicts kinetics $[BrO_3^-]^{1.6}[Br_2]^{0.2}$. Step [B3] has 3 bromine atoms in a transition state having an average oxidation number of +2.33 and predicts kinetics $[BrO_3^-]^{1.4}[Br_2]^{0.8}$. The NFT prediction certainly comes much closer to fitting the experimental observations. No other step in the HSV mechanism has an average oxidation number greater than +2 for the average oxidation number of bromines in the transition state.

Summary

Overall stoichiometries like [T1] and [T2] can be established precisely if the necessary free energies are known. We can never determine with certainty the precise elementary processes by which a complicated chemical change is accomplished. It is difficult even to prove with absolute certainty that a particular mechanistic proposal is invalid. However, the accumulation of evidence can often generate a strong preference for one of two alternative mechanistic proposals. We believe such a situation applies to the present case.

The NFT (11) mechanism includes all of the possible oxygen atom transfer processes between bromine species with odd oxidation number. It includes the possible hydrolysis reactions of Br(0) and Br(IV); we have argued elsewhere (ref. 5, p. 8655) why reversible hydrolysis of Br(II) is also fast even though this process does not need to be included in the NFT mechanism. The possible reactions of cerium species with bromine dioxide free radicals are both considered, although we show (10) that only one contributes significantly. The proposed steps and rate constants for bromine reactions are also consistent with what is known about the chemistry of chlorine (15, 16) and of iodine (17), with independent studies of radiation chemistry in alkaline solution (18), and with the kinetics of isotopic exchange reactions between bromine and bromate (19). The resulting mechanism has been subjected to computer simulation (10) and found to be consistent with experimental information. We are not aware of any serious discrepancies with any known experimental facts. We therefore believe this mechanism can appropriately be applied with confidence to the still more complicated Belousov–Zhabotinsky reaction (5).

The HSV (9) mechanism omits oxygen transfer and hydrolysis steps like [A1], [A2], and [A4] for which there is considerable precedent, and it includes a peculiar [B3] step that differs from any we have seen proposed for an oxyhalogen system. This mechanism has not been subjected to computer simulation, but it predicts effects of [HOBr] manipulation different from those observed in an analogous system (12) and seems to require some bromide ion reactions to proceed at rates greater than would be permitted even for diffusion control (14). It also seems to us to be inconsistent with the results from radiation chemical (18) and isotopic exchange (19) studies. Unless these apparent inconsistencies can be explained, and unless the NFT mechanism can be proved inconsistent with some experimental fact, we believe a definite choice between the two

mechanistic proposals should strongly favor the NFT mechanism or some minor modification of it.

Substituent effects on the ^{13}C chemical shifts of monosubstituted twistanes

HELMUT BEIERBECK AND JOHN K. SAUNDERS
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 2, 1976

HELMUT BEIERBECK and JOHN K. SAUNDERS. Can. J. Chem. **55**, 3161 (1977).

The ^{13}C chemical shift data for some hydroxy, chloro, bromo, and oxo twistane derivatives are presented and compared to the shifts observed in corresponding adamantanes. The substituent effect at the α and β carbons is more pronounced in twistanes than in adamantanes. The substituent shift induced at an antiperiplanar γ carbon is shown to depend on the presence or absence of 1,3-diaxial hydrogen–hydrogen interactions between the substituted and γ carbons. If such an interaction is present the effect is of shielding whereas if it is absent, the effect is of deshielding. The deshielding effect appears to occur via a through bond interaction.

HELMUT BEIERBECK et JOHN K. SAUNDERS. Can. J. Chem. **55**, 3161 (1977).

Les déplacements chimiques du ^{13}C pour quelques hydroxy, chloro, bromo et oxo twistanes sont donnés et sont comparés aux déplacements chimiques observés dans les dérivés d'adamantane correspondants. L'effet d'un substituant sur les carbones α et β est plus grand dans les twistanes que dans les adamantanes. On démontre que le déplacement induit sur le carbone γ antiperiplanar, par un substituant, dépend de la présence ou de l'absence d'interactions hydrogène–hydrogène 1,3 diaxiales entre les hydrogènes sur le carbone substitué et le carbone γ. Si une telle interaction est présente, on observe un effet de blindage tandis que si elle est absente, le carbone γ est déblindé. Il semble que l'effet de déblindage soit dû à une interaction à travers les liaisons.

Substituent effects on ^{13}C chemical shifts have received a lot of attention since the earliest ^{13}C nmr studies (1). These studies have led to the development of empirical correlations between the substituent induced shift and the stereochemistry of the compound. Also such correlations can give insight into the fundamental interpretation of ^{13}C chemical shifts with respect to molecular and electronic structural characteristics. Molecular systems of well defined and rigid geometry provide good models for a study of the electronic effects on carbon shieldings. Adamantane is such a system, and thus the effect of substitution at either carbon 1 or 2 has been studied (2–4).

The difference in substituent induced shift at the α and β carbons between 1- and 2-substituted adamantanes is readily explained in terms of differences in *gauche* interactions (5). However, the effect at the γ carbon appears anomalous in that, for example, substitution of an OH at carbon 1 deshields the γ carbon by 2.4 ppm whereas substitution of an OH at carbon-2 results in shielding of both carbons by 6.7 and 1.2 ppm for the γ carbon *syn* and *anti* to the OH, respectively. For the carbon *syn*, the C_α—OH, C_β—C_γ bonds are in a *gauche* orientation, an orientation well known to give rise to shielding at the γ carbon, whereas for the carbon *anti*, the C_β—C_γ bond is antiperiplanar to the C—O bond, a relative orientation found for the γ carbon in 1-adamantanol.

Another class of compounds which have well defined geometry and which are relatively rigid are the twistane derivatives. However, the six membered rings in these compounds exist in a twist boat conformation in comparison with the chair conformation of adamantanes, hence the relative bond orientations are quite different in the two series of compounds. In this paper, we report the ^{13}Cmr data of a number of twistane derivatives and compare this data with that obtained in the corresponding adamantane derivatives.

Results and Discussion

The ^{13}C chemical shifts for twistane (**1**), 1-substituted twistanes (**2–4**), and 4-substituted twistanes (**5–7**) are given in Table 1 as are the data for the disubstituted adamantanes **8** and **9**. The resonances for **1** were readily assigned from the single-frequency, off-resonance decoupled (SFORD) spectrum and the relative intensities. For **2**, carbons 1, 2, 6, and 10 were assigned from the SFORD spectrum. The remaining resonances could be assigned as corresponding to either CH or CH_2 carbons but could not be assigned to a particular carbon. Consequently,

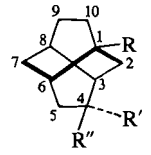
[e]Not observed.

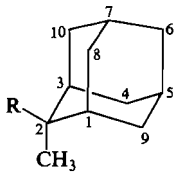
the effect of the addition of Pr(fod)$_3$ was used in order to complete the assignments. The Pr(fod)$_3$ induced shifts were treated using the McConnell equation as described previously (6). The calculated and observed induced shifts are given in Table 1. The observed resonances for **3** and **4** were assigned using the respective SFORD spectra and the recorded data for **2**. The spectra



1 R = R′ = R″ = H
2 R = OH R′ = R″ = H
3 R = Cl R′ = R″ = H
4 R = Br R′ = R″ = H
5 R = R″ = H R′ = OH
6 R = R′ = H R″ = OH
7 R = H R′ + R″ = O

for the 4-substituted twistanes were assigned using the corresponding SFORD spectrum and the Pr(fod)$_3$ induced shift data given in Table 1.

The spectrum for **8**, was assigned on the basis of relative intensities, the SFORD spectrum, and the Pr(fod)$_3$ induced shift data included in Table 1. The spectrum of **9** was assigned using



8 R = OH
9 R = Br

the relative intensities, the SFORD spectrum, and by comparison with the spectrum of **8**. Inspection of Table 1 indicates that the combination of SFORD spectra and Pr(fod)$_3$ induced shifts leads to relatively unambiguous assignments of all carbons with the possible exception of carbons 9 and 10 for compound **6**.

In Table 2 the chemical shift difference, Δδ, due to the introduction of each substituent for the twistane derivatives is compared to that observed in the corresponding adamantanes. The relative shift at the β carbon resulting from the introduction of the substituent depends on the dihedral angle between the C—X and C—H and/or C—C bonds (5). The γ carbons of the 1-twistane derivatives are deshielded, with the exception of C-5, by the introduction of a sub-

stituent, as are the γ carbons of 1-adamantanes although the magnitude is somewhat smaller in the case of the twistanes. In the adamantane compounds an approximative correlation between substituent induced shift at the γ carbon and σ* was observed (2) and thus it was concluded that the dominant factor causing the deshielding at this carbon was the through-bond interaction. If the transmission of this effect occurs by a hyperconjugative interaction (7) between the electrons of the C_β—C_γ bonds and the back lobe of the carbon sp^3 orbital of the C—X bond then this interaction will be a maximum when the C_β—C_γ and C_α—X bonds are *trans* antiperiplanar as is the case in adamantanes. The smaller shifts in twistanes are a consequence of the angle between the C_β—C_γ and C_α—X bonds differing from 180°. Although only a limited number of substituents have been studied, the same trend is apparent for both series of compounds i.e. bromine > chlorine > OH > H. Carbon 5 has a C—H bond in a pseudo 1,3-diaxial interaction with the C—X bond and will thus be shielded. For each substituent, the α shift is larger for twistanes than for adamantanes. This could also be a consequence, at least in part, of the lack of coplanarity between the C_β—C_γ and C_α—X bonds. Since the hyperconjugative effect which deshields the γ carbon will tend to shield the α carbon and, as mentioned above, this interaction will be a maximum when the C_β—C_γ and C_α—X bonds are coplanar.

The twistanols **5** and **6** exhibit both shielding and deshielding at the γ carbons whereas in 2-adamantanol both γ carbons are shielded. Recently, it has been suggested (8) that the ~5 ppm shielding of the γ carbon for C—X and C_β—C_γ in a *gauche* orientation is not a consequence of a steric interaction between the group X and a proton on the γ carbon but rather is due to the replacement of the hydrogen of the α carbon i.e.

[a]Negative values imply shielding.
[b]Adamantane values taken from ref. 3 with the exception of adamantan-2-one (2).

Thus the chemical shift will depend on the relative orientation of the C_α—H and C_γ—H bonds. Introduction of an electronegative substituent causes changes in valency angles of the substituted carbon and it is quite possible that the distance between the hydrogen on the α carbon and that on the γ carbon *anti* is increased upon substitution of X at the α carbon which would lead to a relative shielding of the γ carbon. The observed shift will then be a function of the through bond effect plus the effect due to a decrease in the 1,3-diaxial hydrogen–hydrogen interaction. In twistane, the two hydrogens of C-4 have pseudo 1,3-diaxial interactions with the hydrogens of carbons 2 and 8. Introduction of an OH at C-4 causes shielding of both of these carbons for both orientations of the OH group with the effect being more pronounced when the C—OH and C_β—C_γ bonds are in the pseudo *gauche* orientation. The third γ carbon, C-6, is in an orientation such that the angles between its C—H bond and the carbon–hydrogen bonds of C-4 are 90° or greater and thus introduction of an OH at C-4 results in deshielding.

The effect of introduction of an OH or Br on the chemical shift of the γ carbons in adamantane derivatives is given in Table 3. The γ carbon *syn* to the OH in **8** is shielded by 6.9 ppm relative to 2-methyladamantane (3) whereas the γ carbon *anti* is deshielded by 2.6 ppm. Thus the OH has a similar effect on the carbon *syn* to that observed in adamantan-2-ol. However, the effect on the carbon *anti* does not correlate with that observed in adamantan-2-ol, but rather to that found in adamantan-1-ol. The effect of the Br is similar in that the γ carbon *anti* is deshielded by 4.2 ppm which resembles the induced shift in 1-bromoadamantane. Thus, it appears that in order to observe an upfield shift of the γ carbon *anti*, the substituted carbon must bear a hydrogen. Eliel *et al.* (7) found that electronegative substituents on secondary or tertiary carbons shielded the γ carbon *anti* whereas Ayer *et al.* (9) observed deshielding at this carbon when the substituted carbon was quaternary.

The effect at the γ carbon (C-3) on substitution of a keto group in cyclohexane is a combination of two effects, namely a polar effect (either a through bond or a through space effect) which deshields, and the removal of one 1,3-diaxial hydrogen–hydrogen interaction which shields. This can be seen from the comparison

TABLE 3. Substituent induced shifts for adamantane[a] derivatives

Compound	γ Carbon	
	syn	*anti*
Adamantan-1-ol		2.4
Adamantan-2-ol	−6.7	−1.2
8	−6.9	2.6
1-Bromoadamantane		4.1
2-Bromoadamantane	−6.3	0.7
9	−5.8	4.2

[a]Shifts of mono substituted adamantanes taken from ref. 3.

of the chemical shifts recorded for 3,3,5-trimethylcyclohexanone (10) and 1,1,3-trimethylcyclohexane (11). For the former the quaternary carbon resonance appears at 35.1 ppm and the tertiary carbon at 29.5 ppm, whereas in the latter these carbons absorb at 31.4 and 28.9 ppm respectively. Thus the quaternary carbon is deshielded by 3.7 ppm whereas the tertiary carbon is only deshielded by 0.6 ppm. In **7**, the γ carbons (C-2 and 8) whose hydrogens had 1,3-diaxial interactions with the C-4 hydrogens in twistane, are shielded whereas the γ carbon (C-6), which did not have such an interaction, is deshielded. The results parallel those observed for OH substitution. The polar effect is probably, at least in part, a through bond effect and consequently will depend on the relative orientation of C—C and C=O bonds. Thus the magnitude of the observed shift caused by the introduction of the carbonyl group will depend on the severity of the replaced 1,3-diaxial interaction as well as the angle between the C—C and C=O bonds.

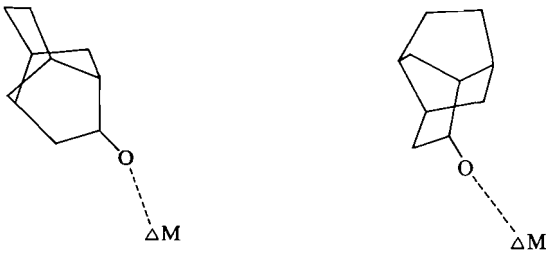
The effect of the OH group on the chemical shift of the δ carbon is of shielding, with the exception of C-7 in **5**. This is in the same direction as that observed in adamantane derivatives although, for the twistane, the numerical value is less due to lack of coplanarity between the C—X and C_β—C_γ bonds. The steric interaction between a substituent and the hydrogen of the δ carbon has been shown to deshield the δ carbon (12) which explains the downfield shift observed for C-7 in **5**. The substituent shifts for the δ carbons in **7** are somewhat larger and can in part be attributed to polar effects. Also, inclusion of an sp^2 carbon at C-4 changes the relative orientations of a number of C—H bonds and this will also influence the observed shift.

Conclusion

The shifts recorded at the γ carbons of the 1-substituted twistane derivatives agree in direction though not in magnitude to the corresponding 1-substituted adamantanes. This is interpreted as evidence for a through bond type mechanism since the substituent effect is a maximum where the C_α—X and C_β—C_γ bonds are *trans* antiperiplanar. The relatively larger α substituent effects in twistane are in agreement with this statement. The substituent shifts on γ carbons observed in 4-twistanols, 4-twistanone, and 2-adamantanols are shown to be a combination of field effects and conformational changes.

Experimental

All spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer operating in the Fourier transform mode. The compounds were analyzed as approximately 1 *M* $CDCl_3$ solutions with TMS used as internal reference. The experimental procedure for determining the effect of $Pr(fod)_3$ as well as the data analysis has been reported elsewhere (6). The calculated Pr—O internuclear distances varied between



2.8 and 3.5 Å. A typical position for the Pr is shown. The syntheses and structure proof of all twistane derivatives have been given elsewhere (13). Compound **8**, 2-methyladamantan-2-ol, was prepared by the reaction of CH_3Li on adamantanone (14). Compound **9** was prepared by reacting **8** with PBr_3/HBr (15).

Acknowledgement

We are very grateful to Professor Deslongchamps for the generous donation of all twistane derivatives and to Mr. Normand Pothier for the preparation of the adamantane derivatives. Financial support from the National Research Council of Canada is also gratefully acknowledged.

The comparative chemistry of ammine and methylamine complexes of rhodium(III) and cobalt(III)

THOMAS WILSON SWADDLE

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 12, 1977

THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 3166 (1977).

For the aquation of $(CH_3NH_2)_5RhCl^{2+}$, the first order rate coefficients are represented by $\Delta H_{aq}^* = 101.9$ kJ mol^{-1} and $\Delta S_{aq}^* = -50.2$ J K^{-1} mol^{-1} in 0.1 *M* $HClO_4$, while for base hydrolysis the rate is first order in $[(CH_3NH_2)_5RhCl^{2+}]$ and $[OH^-]$ at ionic strength 0.10 *M* and the rate coefficients (in M^{-1} s^{-1}) are represented by $\Delta H_{OH}^* = 108.6$ kJ mol^{-1} and $\Delta S_{OH}^* = 74.1$ J K^{-1} mol^{-1}. Acid dissociation constants are reported for $(RNH_2)_5MOH_2^{3+}$ (R = H or CH_3; M = Rh or Co), and these, combined with spectral data, show CH_3NH_2 to be a poorer electron donor than NH_3 in complexes of this type, contrary to expectations. The comparative kinetics of reactions of $(RNH_2)_5MCl^{2+}$ support the assignment of an I_a mechanism to aquation when M = Rh or Cr, I_d to aquation when M = Co, and D_{cb} for base hydrolysis in all these cases.

THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 3166 (1977).

Pour l'aquation de $(CH_3NH_2)_5RhCl^{2+}$, dans $HClO_4$ 0.1 *M*, les coefficients de vitesse du premier ordre sont représentés par $\Delta H_{aq}^* = 101.9$ kJ mol^{-1} et $\Delta S_{aq}^* = -50.2$ J K^{-1} mol^{-1}, et pour l'hydrolyse basique à force ionique de 0.10 *M* la vitesse est du premier ordre en $[(CH_3NH_2)_5RhCl^{2+}]$ et en $[OH^-]$ et les coefficients de vitesse (en M^{-1} s^{-1}) sont représentés par $\Delta H_{OH}^* = 108.6$ kJ mol^{-1} et $\Delta S_{OH}^* = 74.1$ J K^{-1} mol^{-1}. On rapporte les constantes de dissociation acide pour $(RNH_2)_5MOH_2^{3+}$ (R = H ou CH_3; M = Rh ou Co) et ces valeurs, combinées avec des données spectrales, montrent que le CH_3NH_2 est un plus mauvais donneur d'électron que le NH_3 dans des complexes de ce type et ceci contrairement aux anticipations. Les cinétiques comparées des réactions de $(RNH_2)_5MCl^{2+}$ sont en accord avec l'attribution d'un mécanisme I_a pour l'aquation quand M = Rh ou Cr, d'un mécanisme I_d pour l'aquation quand M = Co, et D_{cb} pour l'hydrolyse basique dans tous ces cas.

[Traduit par le journal]

Introduction

The hypothesis has been advanced (1, 2) that simple ligand substitution reactions of cationic octahedral complexes in solution occur by an associative interchange (I_a) mechanism for trivalent transition metals in general, with the important exception of cobalt(III), for which a dissociative interchange (I_d) mechanism evidently operates. The term 'simple' implies exclusion of special cases, notably conjugate-base solvolysis pathways in which a dissociative (D_{cb}) mechanism is considered to be generally applicable.

If this hypothesis is valid, then the effects of replacing R = H by R = CH_3 in $(RNH_2)_5MCl^{2+}$ (hereinafter called '*N*-methylation') on the rates of chloride aquation

[1] $(RNH_2)_5MCl^{2+} + H_2O \rightarrow (RNH_2)_5MOH_2^{3+} + Cl^-$

should be qualitatively different for M = Co relative to M = Cr, Rh, etc. Indeed the methylamine complex aquates 22 times more *rapidly* than the ammine for M = Co, but 33 times more *slowly* when M = Cr, at 298 K (3–5). In the simplest view, this can be attributed to the different roles of steric effects in the mechanistic dichotomy (1, 6–8), since it is known (9) that marked steric compression exists in both of these methylamine complexes, although there are fewer nonbonded contacts in the chromium one (as expected, since the ionic radius of Cr^{3+} is 61.5 pm as opposed to 52.5 pm for Co^{3+} (10)). We may therefore naively predict that $(CH_3NH_2)_5RhCl^{2+}$ should aquate more slowly than $(NH_3)_5RhCl^{2+}$, if the mechanism is indeed I_a, but that the rates should be more nearly equal than in the chromium(III) analogues, since the relatively large radius of Rh^{3+} (67 pm) (10) should reduce the number of nonbonded contacts in $(CH_3NH_2)_5MCl^{2+}$ still further.

On the basis of a common conjugate-base mechanism for the alkaline hydrolysis of $(RNH_2)_5MCl^{2+}$

[2] $(RNH_2)_5MCl^{2+} + OH^- \rightleftharpoons (RNH_2)_4M(NHR)Cl^+ + H_2O$

[3] $(RNH_2)_4M(NHR)Cl^+ + H_2O \rightarrow (RNH_2)_5MOH^{2+} + Cl^-$

one can similarly predict a marked steric acceleration of reaction 3 in all cases on *N*-methylation (6), but the decline in the number of nonbonded interactions in $(CH_3NH_2)_5MCl^{2+}$ on going from M = Co to Cr to Rh should reduce this effect rather sharply. Thus, if it can be shown that the effect of *N*-methylation on reaction 2 is not very much different for the various M, it can be predicted that the acceleration of base hydrolysis on *N*-methylation will fall in the sequence M = Co ≫ Cr > Rh.

The purpose of this study was to test these predictions experimentally, especially since Buchacek and Harris (11) have recently pointed out anomalies in the assignments of mechanism in octahedral rhodium(III) complexes. The predictions are based on the more obvious steric consequences of *N*-methylation, such as have been considered by many authors both recently (12, 13) and in the formative years of inorganic mechanistic studies (14). Consideration must be given, however, to possible indirect influences of *N*-methylation on reactivity such as through solvational and electronic effects, especially since the latter are of an unexpected kind in the complexes considered here.

Experimental

Materials

Chloropentaamminerhodium(III), aquopentaamminerhodium(III), and aquopentaamminecobalt(III) perchlorates were made as described previously (15, 16). Chloropentakis(methylamine)cobalt(III) chloride was made from dichlorotetrapyridinecobalt(III) chloride (17) by the method of Mitzner *et al.* (18), with minor variations in reagent quantities and reaction conditions between successive preparations.

Preparation of Chloropentakis(methylamine)rhodium(III) Perchlorate

Liquid methylamine (30 cm³) was obtained by adding the 40% aqueous solution dropwise to NaOH pellets with warming, drying the liberated gas over sodalime, and condensing it under reduced pressure at −78°C. To this liquid, 0.5 g $RhCl_3 \cdot 3H_2O$ (freshly prepared from Rh residues) was added, a little at a time, allowing the solid to dissolve after each addition. The red solution was allowed to evaporate, the yellow residue was dissolved in the minimum amount of hot dilute HCl, and the solution was filtered. On cooling, yellow crystals of $[Rh(NH_2CH_3)_5Cl]Cl_2$ (0.4 g) separated, and were converted to the perchlorate salt by dissolving them in 10 cm³ water at 65°C, adding about 8 cm³ 60% $HClO_4$, and cooling the solution to 0°C. The resulting pale yellow needles were filtered, washed with 2–3 cm³ ice-cold water, and dried in a vacuum desiccator over silica gel. *Anal.* calcd. for $[Rh(NH_2CH_3)_5Cl](ClO_4)_2$: C 12.2, H 5.1, N 14.2, Cl 21.6, Rh 20.9; found: C 12.3, H 5.2, N 14.1, Cl 21.5, Rh 20.9.

Preparation of Aquopentakis(methylamine)rhodium(III) Perchlorate

$[Rh(NH_2CH_3)_5Cl](ClO_4)_2$ (0.702 g) in 150 cm³ $HClO_4$ (0.01 *M*; *M* = mol dm^{-3}) was heated with $AgClO_4$ (0.305 g, a 3% excess) for 24 h at 95°C. The pale yellow solution was filtered, evaporated on the steam bath to about 15 cm³, and again filtered. The solution was treated with 5 cm³ 60% $HClO_4$, evaporated to 10 cm³, filtered, and kept overnight at 0°C. The resulting pale yellow crystals were filtered, washed quickly three times with ice-cold water, and dried under vacuum over fresh NaOH pellets. Yield, 0.36 g. *Anal.* calcd. for $[Rh(NH_2CH_3)_5OH_2](ClO_4)_3$: C 10.5, H 4.7, N 12.2, Cl 18.5 (formula weight 575); found: C 10.6, H 4.5, N 12.3, Cl 18.7 (formula weight by p*H* titration (see below) 580 ± 6).

Spectra

All spectrophotometric measurements were made using a freshly serviced Cary 15 spectrophotometer. The spectra of the pure compounds in acidic aqueous solution are listed in Table 1.

Kinetics

The kinetics of the aquation reactions were followed by thermostatting (±0.01°C) 10 cm³ aliquots of a solution of the rhodium(III) complex in $HClO_4$ in Pyrex ampoules in a darkened oil bath, quenching these to room temperature at appropriate times *t*, and measuring the optical density A_t of the solution at 200 nm. At this wavelength, the molar absorptivities ε of $Rh(NH_2CH_3)_5Cl^{2+}$, $Rh(NH_2CH_3)_5OH_2^{3+}$, $Rh(NH_3)_5Cl^{2+}$, and $Rh(NH_3)_5OH_2^{3+}$ in aqueous $HClO_4$ are 35 400, 18 000, 11 200, and 300 M^{-1} cm^{-1} respectively, while ε for Cl^- is negligible, and the final absorbance values A_∞ of the reaction mixtures after 10 half-lives were compared to these to show that the reactions being followed were indeed chloride aquations (reaction 1) and went to completion under the experimental conditions.

For the base hydrolysis reactions (reactions 2 and 3), accurately measured aliquots were pipetted from the thermostatted bulk reaction mixtures at appropriate intervals and quenched in a measured excess of 0.5 *M* $HClO_4$ at room temperature. The absorbances of the resulting solutions were measured at 200 nm, and again the final values A_∞ verified that the products were indeed $(RNH_2)_5RhOH^{2+}$ (identified in acid as the aquo complex).

All temperature measurements were made with calibrations traceable to NBS.

Acid Dissociation Constants of Aquo Complexes

For $Rh(NH_2CH_3)_5OH_2^{3+}$, $Rh(NH_3)_5OH_2^{3+}$, and $Co(NH_3)_5OH_2^{3+}$, aliquots of 0.0100 *M* solutions made from the solid perchlorates were thermostatted in a jacketted beaker and titrated with standardized 0.1 *M* NaOH solution from a microburette, while monitoring the p*H* with a Beckman 39502 combination electrode in conjunction with an Orion 801A potentiometer. This procedure gave both the acid equivalent weights of the complexes (which agreed with the theoretical values within the experimental uncertainty in all cases) and the pK_a

values at the ionic strength I of the midpoint of the titration curve.

This procedure was inapplicable to $Co(NH_2CH_3)_5OH_2^{3+}$, which was not obtained as a solid salt and which decomposed slowly with methylamine release in the course of a pH titration. Instead, solutions of $[Co(NH_2CH_3)_5Cl]Cl_2$ in dilute standard $HClO_4$ with the stoichiometric amount of $AgClO_4$ were kept at 22°C in the dark for 44 to 68 h, i.e., for times corresponding to over 99% chloride aquation even in the absence of the anticipated Ag^+ catalysis (3, 5). The solutions were then chilled to 0°C to ensure maximum precipitation of AgCl, filtered, and made to 100 cm^3 at 22°C such that $[HClO_4] = [(Co(NH_2CH_3)_5OH_2)(ClO_4)_3] = 0.0100\ M$. These freshly prepared solutions were used to obtain the spectrum of $Co(NH_2CH_3)_5OH_2^{3+}$, given in Table 1, which agrees well with that reported by Mitzner and Blankenburg (20). Aliquots of these solutions were placed in the darkened, thermostatted beaker as above but at a low temperature (2°C), and enough 0.1 M NaOH was added under thorough stirring to neutralize all the $HClO_4$ and precisely one-half of the aquo complex. The pH of the mixtures ($\equiv pK_a$ of the aquo complex) was then measured as above, arranging for the momentary pH meter reading immediately before immersion into the test solution to be within 1 pH unit of the anticipated pK_a value so as to expedite the attainment of a stable final reading without decomposition of the complex.

Results

Aquation of $Rh(NH_2R)_5Cl^{2+}$

Plots of ln $(A_t - A_\infty)$ vs. t were linear over at least 87% reaction (correlation coefficients $r^2 > 0.9994$), and the corresponding pseudo-first-order rate coefficients k_{aq} are collected in Table 2. For R = CH_3, standard errors in k_{aq} were typically $\pm 0.8\%$, and reproducibility was $\pm 1.8\%$. Precision was better than this for R = H because the final absorbances A_∞ were much smaller than for R = CH_3. The rate coefficients were the same in 0.01 M as in 0.10 M $HClO_4$, and over a twofold range of initial complex concentrations, within these limits of uncertainty.

The Eyring plot for R = CH_3 is linear ($r^2 = 0.9998$) and leads to $\Delta H_{aq}^* = 101.9 \pm 0.9$ kJ mol^{-1}, with $\Delta S_{aq}^* = -50.2 \pm 2.3$ J K^{-1} mol^{-1}. The data for R = H indicate $\Delta H_{aq}^* \sim 102$ kJ mol^{-1} and $\Delta S_{aq}^* \sim -44$ J K^{-1} mol^{-1}; the k_{aq} values agree well with those interpolated from the work of Poë *et al.* (22) and Lalor and Bushnell (23), and all these data taken together give $\Delta H_{aq}^* = 101.5 \pm 1.2$ kJ mol^{-1} and $\Delta S_{aq}^* = -45.6 \pm 3.4$ J K^{-1} mol^{-1} with $r^2 = 0.9992$ (the activation parameters calculated by Lalor and Bushnell are in error).

[b][Rh] = 6.34 × 10^{-5} M.

Base Hydrolysis of $Rh(NH_2R)_5Cl^{2+}$

Plots of ln $(A_t - A_\infty)$ vs. t were linear to at least 86% reaction, with r^2 always exceeding 0.995 for R = CH_3 and 0.999 for R = H. The corresponding pseudo-first-order rate coefficients k_{obs} were seen to be directly proportional to $[OH^-]$ at constant I, and accordingly Table 3 lists $k_{OH} = k_{obs}/[OH^-]$, together with the standard errors. The temperature dependence of k_{OH} gives $\Delta H_{OH}^* = 108.6 \pm 1.8$ kJ mol^{-1} and $\Delta S_{OH}^* = 74.1 \pm 6.1$ J K^{-1} mol^{-1} with $r^2 = 0.9995$ for $Rh(NH_2CH_3)_5Cl^{2+}$, and $\Delta H_{OH}^* = 114.8 \pm 0.7$ kJ mol^{-1} and $\Delta S_{OH}^* = 66.4 \pm 2.1$ J K^{-1} mol^{-1} with $r^2 = 0.99997$ for $Rh(NH_3)_5$-

Cl^{2+}, at $I = 0.100$ M. The latter parameters give $k_{OH} = 1.39 \times 10^{-3}$ M^{-1} s^{-1} for $Rh(NH_3)_5Cl^{2+}$ at 40.16°C, in excellent agreement with the value reported by Bushnell *et al.* (24) for this temperature and similar ionic strength.

Acid Dissociation Constants K_a of the Aquo Complexes

Values of pK_a (Table 4) obtained by the pH titration and the direct half-neutralization methods were equally reliable, according to experiments using $Co(NH_3)_5OH_2^{3+}$, were independent of variations in the mode of preparation of the complexes, and agreed well with literature values (22, 25, 26), allowing for ionic strength differences. The pH values of solutions of the pure solid salts were in good agreement with those calculated from the measured pK_a data.

Discussion

The *retardation* (×0.50 at 85°C) of the aquation of $(RNH_2)_5RhCl^{2+}$ on *N*-methylation, though modest, originates in ΔS_{aq}^* rather than ΔH_{aq}^* and so persists over the entire temperature range of interest. It is *opposite in direction* to the *acceleration* (×22 at 25°C) observed for the cobalt(III) analogues (3, 5, 6), and the simplest explanation is that the mechanism is I_a for M = Rh and I_d for M = Co, as previously contended (1, 2, 15). Steric effects can account for the consequences of the presumed mechanistic difference, and indeed the retardation is less striking for Rh than for Cr (3, 5), as expected on steric grounds. Steric factors in aliphatic substitution produce much larger effects than these, but organic S_N2 reactions involve attack remote from the replaced ligand with stereochemical inversion of the entire molecule, whereas octahedral sub-

stitution by an I_a process evidently involves flanking ('*cis*') attack with little disturbance of the ligands other than the one being replaced (1). Similarly, the large kinetic effects of steric decompression associated with organic S_N1 reactions, in which the geometry goes from tetrahedral to trigonal planar, may be matched in octahedral substitutions of the D type, in which the five-coordinate intermediate survives long enough to undergo major rearrangement (27), but will be less striking in I_d processes in which the configuration of the intermediate is less likely to change prior to resumption of six-coordination.

In the base hydrolysis of $Rh(NH_2R)_5Cl^{2+}$, we observe an *acceleration* (×29 at 35°C) on *N*-methylation. If a conjugate base mechanism (reactions 2 and 3) is operating, part of this acceleration could be due to an increased acidity of the N protons (reaction 2), but $Rh(NH_2CH_3)_5OH_2^{3+}$ is only 2.7 times more acidic than $Rh(NH_3)_5OH_2^{3+}$ (Table 4), so that an acceleration of about 10-fold still needs to be accounted for, if N-proton and O-proton acidity trends are at all similar. This acceleration contrasts with the retardation displayed in the aquation reactions of the same compounds, but is in accordance with the asssignment of a D_{cb} mechanism to base hydrolysis reactions in general, on the basis of steric acceleration of reaction 3. This argument applies much more forcefully when M = Co (6); $Co(NH_2CH_3)_5OH_2^{3+}$ is 6.3 times more acidic then $Co(NH_3)_5OH_2^{3+}$ (Table 4) but this still leaves an acceleration factor of about 2×10^3 to be attributed to *N*-methylation in reaction 3. The overall acceleration factors associated with *N*-methylation in base hydrolysis of $M(NH_2R)_5Cl^{2+}$ are 1.5×10^4, 225, and 29 for M = Co, Cr, and Rh respectively, as expected for a common D_{cb} mechanism, for which the steric acceleration of reaction 3 will decline with the decrease in the number and severity of the nonbonded interactions as the ionic radii of M^{3+} increase (9, 10).

While the above analysis explains the phenomena on the basis of steric effects alone, consideration must be given to the contributions of the rather unusual electronic effects revealed by Tables 1 and 4, and to solvational factors, even though these contributions will be similar for all the three M considered and hence do not seriously affect the foregoing conclusions. Table 1 shows that *N*-methylation in $(RNH_2)_5MCl^{2+}$ *decreases* the energy of the lowest spin-allowed ligand field band in every case, i.e., it decreases the ligand field strength of the nonreacting ligands, which in $(RNH_2)_5MCl^{2+}$ is a measure of σ electron release from N to M. This is surprising, since the methyl group is invariably electron releasing in organic molecules, yet Table 4 shows that the $(CH_3NH_2)_5MOH_2^{3+}$ are more *acidic* than the corresponding $(NH_3)_5MOH_2^{3+}$ even though CH_3NH_2 itself is 25 times more *basic* than NH_3 (28). Parris and Feiner (29) noted a similar spectroscopic effect in $M(NH_2R)_6^{3+}$, and attributed the anomaly to steric constraints on six-coordination when R = CH_3. The work of Foxman (9) suggests that the distortion of metal-to-ligand bond angles from 90° may account for the reduced effectiveness of N → M σ-electron donation in the methylamine complexes.

It is difficult to gauge the effect of reduced electron release from RNH_2 on the aquation rates of $(RNH_2)_5MCl^{2+}$. A lowered rate would be expected for an I_d process, on the basis of the lowered electron density at M, yet marked acceleration is observed when M = Co, where the I_d mechanism is almost certainly operative (1, 14); the steric effects discussed above are evidently much more important than these electronic factors. Furthermore, the replacement of NH_3 by H_2O in $(NH_3)_5CrCl^{2+}$ results in a decrease of over 3000 cm^{-1} in the wavenumber $\bar{\nu}_1$ of the first ligand field band and a 31-fold decrease in the chloride aquation rate (30), whereas replacement of NH_3 by CH_3NH_2 decreases $\bar{\nu}_1$ by only 410 cm^{-1} yet k_{aq} is reduced 33-fold. These observations also run counter to the expectation that increasing the ligand field should decrease the reaction rate of d^6 (spin-paired) or d^3 complexes (ref. 14, pp. 145–158). For M = Rh and Co, $\bar{\nu}_1$ decreases on *N*-methylation of $(NH_3)_5MCl^{2+}$ by amounts that are sufficiently small and similar (810 and 640 cm^{-1}, or 2.8 and 3.4%, respectively) to indicate that electronic effects cannot account for the differences in the kinetic consequences of *N*-methylation between M = Co, Rh, and Cr (compare ref. 14, p. 161).

Qualitatively, however, the spectroscopic data can be taken as evidence for a general electronic destabilization of $(RNH_2)_5MCl^{2+}$ through geometrical strain, leading to an expectation of labilization of the complexes in the order Co ≫ Cr > Rh, on *N*-methylation. Viewed in this way, the deactivation of the Cr and Rh complexes towards aquation becomes all the more significant.

Finally, solvational factors cannot account satisfactorily for the different kinetic consequences of *N*-methylation for M = Co, Cr, and Rh, since they will be rather similar in each case. Progress from R = CH_3 to R = C_2H_5, *n*-C_3H_7, etc. (the chief consequence of which will be desolvation) leads to modest stepwise *accelerations* of the aquations of $(RNH_2)_5MCl^{2+}$ for both Co and Cr (4–6), indicating that the *retardations* of aquation observed in *N*-methylation of $(NH_3)_5RhCl^{2+}$ and $(NH_3)_5CrCl^{2+}$ would be more striking if solvational factors could be allowed for. Again, this effect can be viewed as one of general labilization through destabilization of the complexes.

In summary, then, the kinetic phenomena observed in reactions 1–3 can be rationalized in terms of steric effects if aquation proceeds by an I_a mechanism for M = Rh or Cr but I_a for M = Co, and base hydrolysis by a D_{cb} process in all these cases.

Received February 3, 1977

A. B. P. LEVER, G. LONDON, and P. J. MCCARTHY. Can. J. Chem. **55**, 3172 (1977).

We have measured the polarized crystal spectra at 10 K of Ni(*s*-Et_2en)$_2X_2$, where X = Cl, Br, NCS, and H_2O (with Cl, Br, and I counterions) and *s*-Et_2en is *N,N'*-diethylethylenediamine, and of Ni(*s*-Me_2en)$_2X_2$, where X = NCS and NO_3, and *s*-Me_2en is *N,N'*-dimethylethylenediamine. Transition energies were calculated for D_{4h} symmetry using symmetry adapted functions and a normalized spherical harmonic Hamiltonian. When the differences between calculated and observed band positions are minimized, the ligand-field and angular overlap parameters listed in Table 2 are obtained. The criteria for the band assignments are discussed. The principal conclusions are: (*1*) The π interactions between Ni(II) and the axial ligands are small in contrast to tetragonal Cr(III) complexes. (*2*) Equatorial and axial parameters are relatively independent, in contrast to tetragonal Cu(II) complexes. (*3*) The more basic *s*-Et_2en exerts a stronger ligand field than *s*-Me_2en. (*4*) The σ-bonding strength of the axial ligands follows the spectrochemical series. (*5*) DQ for the axial ligands in the ethyl complexes is lower than anticipated, probably due to steric hindrance of the bulky ethyl groups. (*6*) B values are all near 850 cm^{-1}, except for an anomalously low value for Ni(*s*-Et_2en)$_2$(NCS)$_2$.

A. B. P. LEVER, G. LONDON et P. J. MCCARTHY. Can. J. Chem. **55**, 3172 (1977).

On a mesuré les spectres polarisés de cristaux à 10 K de Ni(*s*-Et_2en)$_2X_2$ où X = Cl, Br, NCS et H_2O (alors que Cl, Br et I agissent comme contrions) et *s*-Et_2en = *N,N'*-diéthyléthylènediamine et de Ni(*s*-Me_2en)$_2X_2$ où X = NCS et NO_3 et *s*-Me_2en = *N,N'*-diméthyléthylènediamine. On a calculé les énergies de transition pour la symétrie D_{4h} utilisant des fonctions adaptées pour la symétrie et un hamiltonian harmonique sphérique normalisé. Lorsque l'on minimise les différences entre les positions calculées et observées des bandes, on obtient les paramètres de champ de ligand et de recouvrement angulaire qui sont rapportés dans la tableau 2. On discute des critères pour l'attribution des bandes. Les principales conclusions sont: (*1*) Les interactions π entre le Ni(II) et des ligands axiaux sont plus petites que celles observées dans les complexes tétragonaux du Cr(III). (*2*) Les paramètres équatoriaux et axiaux sont relativement indépendants, ce qui est en opposition avec les observations effectuées avec les complexes tétragonaux du Cu(II). (*3*) Le groupe *s*-Et_2en qui est plus basique exerce un champ de ligand plus fort que celui exercé par le groupe *s*-Me_2en. (*4*) La force de liaison σ des ligands axiaux est en accord avec la série spectrochimique. (*5*) Les valeurs de DQ pour les ligands axiaux dans les complexes d'éthyle sont plus basses que celles anticipées et l'on attribue ce résultat à un empêchement stérique qui est probablement plus grand dans les groupes éthyles volumineux. (*6*) Les valeurs de B sont toutes près de 850 cm^{-1} excepté pour la valeur qui est basse d'une façon anormale pour Ni(*s*-Et_2en)$_2$(NCS)$_2$.

[Traduit par le journal]

The study of electronic spectra has played a dramatic role in our understanding of the nature of the metal–ligand bonds in coordination complexes. Much effort has been concentrated in studying complexes of high symmetry, generally containing only one kind of ligand. Numerous models exist to convert these data into chemical information. They range from simple crystal-field models through more sophisticated ligand-field approaches and various molecular orbital methods ranging from *ab initio* to semi-empirical (1). Most of these methods can adequately describe the behaviour of molecules of high symmetry, but generally are of less utility with molecules of lower symmetry, a direct consequence of the increase in the number of parameters required to describe such systems. However, since the number of observables also increases, generally, to a greater degree, this is not a serious drawback. Indeed, by using the extra

information contained within the spectrum of a low-symmetry complex much can be learned about how one metal–ligand bond interacts with another in the molecule. Such information is not generally available, at least from electronic spectra, because of some skepticism about the chemical significance of individual parameters in any given model, and because there has been little concentrated effort to obtain a large body of data particularly from closely related series of complexes. Moreover, the lack of any standardized approach to a study of low-symmetry systems makes it difficult to compare the results of one study with those of another (2).

We have recently introduced the normalized spherical harmonic (nsh) Hamiltonian approach as a means of standardizing spectroscopic analysis of low-symmetry systems (2–4). This method provides numerical values of *DQ*, *DS*, *DT*, *DM*, *DN*, etc., which have precise group theoretical significance and whose numerical values are independent of the choice of coordinate axes. Such a procedure standardizes the collection of data, but does not necessarily preclude its further analysis by means of other models, in particular the orbital angular overlap model (5 and references cited therein).

Useful information can only be derived satisfactorily from highly resolved electronic spectra, obtained preferably from polarized-light, single-crystal studies at cryogenic temperatures. While such studies are now routine, they are usually carried out on complexes of known structure (X ray), and thus tend to involve isolated individual complexes rather than closely related series.

We report here the polarized single-crystal spectra of the closely related series Ni(*s*-$Et_2en)_2X_2$ where X is Cl, Br, NCS, and H_2O (with Cl, Br, and I counterions) and *s*-Et_2en is *N*,*N*′-diethylethylenediamine. We also report the spectra of Ni(*s*-$Me_2en)_2X_2$ (X = NCS, NO_3) which contain *N*,*N*′-dimethylethylenediamine. In due course we will report data for complexes containing chloroacetate, NO_2, and NO_3 ligands, as well as those for several analogous cobalt(II) complexes. X-ray structures are not generally available for this series. If the spectral data are interpreted with care, however, useful chemical information can be derived. Publication of such spectra without X-ray data is not common (see, however, refs. 6, 7), but can nevertheless be exceedingly useful, and is certainly preferable to conventional solution or diffuse reflectance or transmittance spectra of solids.

Spectra are obtained by lining up extinction axes of the crystal parallel to the electric vector of the polarized light. Where the crystal morphology permits, spectra can be obtained along each of three orthogonal extinction axes. In general, for this series of compounds one expects that all or most of the spin-allowed bands will appear in every polarization, but not necessarily with the same intensity. The reasons for this are several: (*1*) The selection rules for D_{4h} symmetry do not strictly apply to the chromophores in this study, since the latter possess no true C_4. The rather small distortions from this symmetry could be a cause of finite intensity in bands which would be symmetry forbidden in D_{4h}. It is quite clear, however, from the observed spectra, that the designation of the split states with D_{4h} labels remains a rather good approximation. (*2*) Since the bands in the spectra studied here almost uniformly decrease in size upon cooling, vibronic mechanisms must contribute significantly to the intensity. When this situation obtains even bands which are symmetry forbidden could be vibronically allowed and appear in the spectra with significant intensity. (*3*) Since we have no information about the orientation of the chromophores, we cannot assume that their axes are collinear with the extinction axes. In this situation each of the observed polarizations will be a mixture of the spectra expected with light polarized along the three molecular axes. When one or more bands in the spectra are strongly polarized, the extinction axes may be assumed to be more nearly coincident with the molecular axes. In this case the selection rules may be used by induction (see Discussion).

In summary, we demonstrate below that unambiguous assignments can be made and useful chemical information obtained from spectra without the benefit of X-ray structural information.

Experimental

Preparation of the Compounds

The anhydrous complexes described here have been previously reported (8, 9). In growing the halo complexes from ethanol open to the atmosphere for a prolonged period, the hydrated versions were obtained. No problem of dehydration was experienced in obtaining electronic spectra at cryogenic temperatures even though the samples were evacuated in the Dewar assembly.

Analysis of the halo aquo complexes gave the following results: Ni(*s*-$Et_2en)_2(H_2O)_2 \cdot 2Cl \cdot 2H_2O$ requires Cl 16.3;

found Cl 16.1%. Ni(*s*-$Et_2en)_2(H_2O)_2 \cdot 2Br$ requires Br 32.8; found Br 32.5%. Ni(*s*-$Et_2en)_2(H_2O)_2 \cdot 2I$ requires I 43.7; found I 44.5%.

Spectral Measurements

The polarized absorption spectra of single crystals of all the compounds in this study were measured at room temperature (~295 K) and at approximately 10 K using an Air Products Displex cryogenic refrigerator. A Cary 14 spectrophotometer was employed, and the full range available (2500–185 nm) was scanned until complete absorption of light by the crystal occurred. The light was polarized by means of a pair of Glan-Thompson prisms, and spectra were recorded with the electric vector of the light parallel and perpendicular to an extinction axis of the crystal. The extinction axes are generally not coincident with any of the prominent crystal edges. Although we interpret the spectra in terms of D_{4h} symmetry, the chromophores have only an approximate C_4 axis, and so in principle three distinct spectra should be observable. In some cases we have obtained three distinct spectra, while in other cases the shape and size of the crystals permitted only two spectra. In all cases we are confident that we have observed all major features of the spectra. Tomlinson *et al.* (10) have measured the spectra of (Zn, Co)$(P\phi_3)_2I_2$ and of the corresponding bromide, the first along the *a*, *b*, *c* axes of the crystal, the second along the extinction axes. All the features appeared in each set, but in the former, the polarization of the bands is more complete, as expected. Similar measurements were made on $Ni(en)_2(NCS)_2$ by Bertini *et al.* (11). Again all major features could be seen both in the spectra taken along two of the crystal axes and in those taken along two extinction axes.

In calculating the band positions for the complexes, we have employed the symmetry adapted functions and a normalized spherical harmonic Hamiltonian for D_{4h} (2). A fitting program was used to minimize the differences between the calculated and observed positions for the spin-allowed bands.

Experimental Results

Structure of the Chromophores

In a previous study infrared spectra were used to demonstrate that the complexes under discussion here have a *trans* configuration (8). This conclusion was based on the close similarity of the finger-print region of the infrared spectra of each complex of a given amine, with each other, and with analogous copper complexes for which X-ray structural data had indicated a *trans* structure. Emphasis was also placed on the N—H stretching region and on the lack of splitting of the ν(C–N) mode of the thiocyanate complexes even at low temperature. A preliminary X-ray study of Ni(*s*-$Me_2en)_2(NO_3)_2$ (9) revealed that the molecule possesses a centre of symmetry and must therefore be *trans*. In this fashion we can conclude with confidence that the compounds in this study are all *trans*. As shown below, the electronic spectra of these complexes also confirm this assignment.

Criteria of Assignment

The splitting of the F and P terms of the nickel ion in a tetragonal field are shown in Fig. 1. Six spin-allowed transitions may be anticipated and in practice at least five are observed. The $^3A_{2g}$ component of the $^3T_{1g}$(P) term is rarely seen as a discrete band but may be observed as a shoulder. In addition, some spin-forbidden bands will appear and may be fitted.

In the absence of crystal structures and therefore the absence of an unambiguous use of selection rules, we have developed some criteria to aid in the assignment of these spectra. These are:

(*a*) Similarity to previous assignments. The spectra of tetragonal nickel complexes have been treated many times in the past (1, 2, 6, 12–14). Comparison of these new data with those previously reported often leads to a direct, essentially unequivocal assignment of the spectra. The transitions to the doubly degenerate ^3E_g levels are usually the most intense features. The highest energy *d–d* band near 28 kK may safely be assigned to the highest ^3E_g transition (from $^3T_{1g}$(P)), and the most intense feature near 17 kK to the second highest ^3E_g transition (from $^3T_{1g}$(F)). The $^3A_{2g}$ (from $^3T_{1g}$(F)) seems in these complexes usually to lie as a well-defined feature to lower energy of the latter *E* band. The $^3T_{2g}$ level generally splits to a greater degree than the other orbital triplets, and one of its components may lie at a sufficiently high energy to lead to some doubt as to the identity of the lowest energy $^3A_{2g}$. Spin–singlet transitions in this region often steal enough intensity from nearby spin-allowed bands (1) that these also cause some ambiguity in the assignment. In particular the $^1B_{1g}$ transition may lie very close to, and appear very similar to, the $^3B_{2g}$ transition, which may be a weak feature. The main peak near 9–11 kK is likely to be the lowest energy ^3E_g level (from $^3T_{2g}$).

The sense of the $^3T_{2g}$ splitting also provides information, in that tetragonal complexes with axial field weaker than equatorial field split $^3E_g < {}^3B_{2g}$, whereas the reverse is true for complexes whose axial field is stronger (12).

(*b*) In comparing data from two orthogonal polarizations, we observe that the energies of the ^3E_g transitions usually differ slightly, whereas transitions to orbital singlet states have essen-

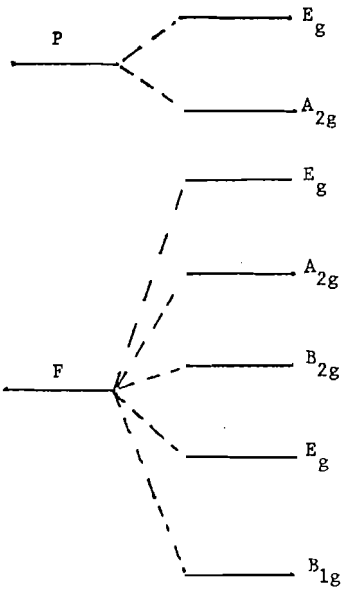

FIG. 1. Energy diagram for Ni^{2+} (d^8) in a tetragonal field.

tially the same energy in both polarizations. This may be due to some splitting of the E mode by lower symmetry and/or spin–orbit coupling. Whatever the mechanism, this observation provides a means of identifying transitions to E levels.

(*c*) Generally speaking, transitions dependent upon DQ increase significantly in energy upon cooling, whereas those independent of DQ are less temperature sensitive. This provides a mechanism for distinguishing spin-allowed transitions (always dependent upon DQ) from certain spin–singlet transitions.

(*d*) While selection rules cannot be used directly, we must require consistency in our assignments. In general *d–d* bands increase in intensity as their energy increases because they are closer to higher energy (uv) charge-transfer bands to which they are coupled. It would, therefore, be unreasonable to assign identical symmetry labels to two bands in the same polarization if the higher energy band were the weaker. Likewise, if a given band appears only in one polarization while another appears in two polarizations, it is unlikely that the two bands have the same symmetry label.

(*e*) There must be an acceptable fit between the observed energy levels and those calculated from the energy matrices (3). We are dealing basically with a four-parameter theory (DQ, DS, DT, and B). These four parameters should predict the six (or often only five) observed bands with a deviation in any given band of less than about 300 cm^{-1}. Often fits much better than this can be achieved. A good fit is not in itself an indicator of a correct assignment. However, the theory is now sufficiently well developed that even though vibrational and spin–orbit contributions are omitted, a really poor fit *is* an indicator of an incorrect assignment.

(*f*) The resulting parameters must make chemical sense. Thus, for example, it is well established that the crystal-field strength of the chloride ion is less than the crystal-field strength of the diamine. An assignment which failed to reproduce this would have to be rejected. However, one of the main purposes of this work is to gain further chemical insight into the nature of the metal–ligand bond. It is therefore to be hoped that some of the results will extend our chemical thinking and will not be rejected because they have not hitherto been observed.

Results for the Individual Compounds

The room temperature and 10 K spectra for the compounds used in this study are shown in Figs. 2–9. The band energies at 10 K, their probable assignments, and the parameters used in obtaining the best fits between observed and calculated energies are listed in Table 1. The root mean square deviations of the calculated from the observed energies are listed to give an indication of goodness of fit. Measurements of band areas for five compounds which show that the 18 and 28 kK bands are only 68 ± 10% and 50 ± 3% as intense at 10 K as they are at room temperature are indicative of vibronic coupling. The values for the 18 kK band vary between 57 and 88%, and so may involve different enabling vibrations in the different compounds. The value for the 28 kK band is quite constant, and seems to indicate a single enabling vibration, which on the basis of the coth law (1*b*) is calculated to be 225 ± 17 cm^{-1}. Many $Ni(diamine)_2X_2$ complexes have a fundamental vibration in this range (8). A band in the spectrum of $Cu(en)_2(SCN)_2$ at 230 cm^{-1} has been assigned to an N—Cu—N deformation mode (18). It is probably the N—Ni—N deformation which is the activating vibration for the 28 kK band in the nickel complexes.

[a]All data are in cm^{-1}; they represent the band peaks at 10 K. Bands in parentheses were not used in obtaining the best fit. The ground state of all compounds is $^3B_1$. Weak bands which are found in some spectra (see Figs. 2–9) above 30 kK are probably triplet–singlet transitions.
[b]$Ni(s\text{-}R_2en)_2X_2$; the aquo complexes are $[Ni(s\text{-}Et_2en)_2(H_2O)_2X_2]$. Et = ethyl; Me = methyl.
[c]Data are from ref. 11.
[d]A shoulder at 26.64 kK is probably due to triplet–singlet transitions; no reasonable parameters allow its assignment to the $^3B_1 \rightarrow {}^3A_2$ transition.
[e]Data are for room temperature; from ref. 23.
[f]The number of bands used in calculating the rms deviation is given in parentheses.
[g]The sign of DT follows the convention used in ref. 4; it is the opposite of that given earlier in refs. 2 and 3.

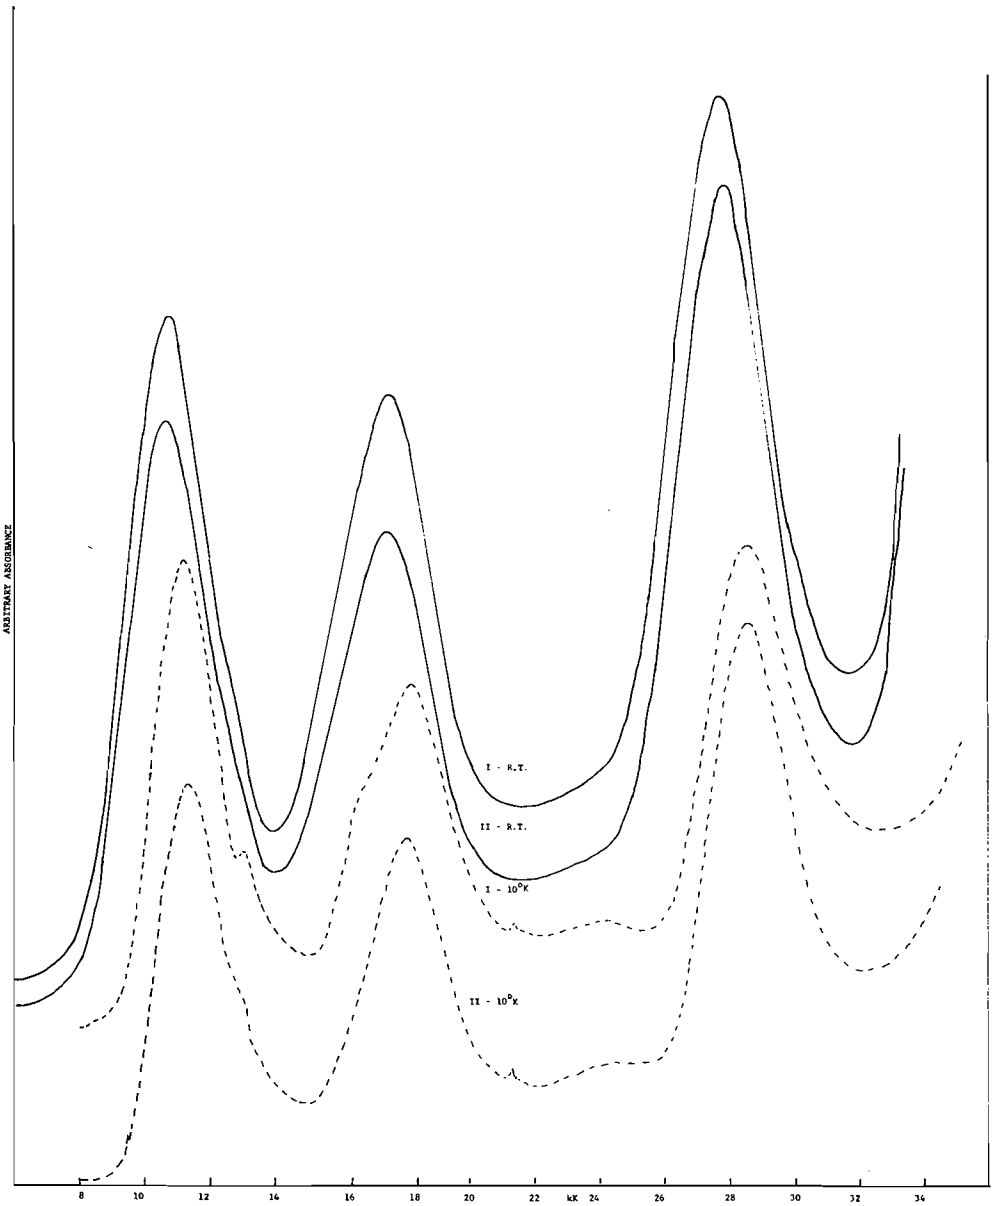

FIG. 2. Polarized crystal spectra of Ni(*s*-$Et_2en)_2(NCS)_2$. Polarization III is not shown; it is very similar to II, but also shows a weak band at 13 245 cm^{-1} and very weak absorptions at 34 150 and 34 560 cm^{-1}. The band positions in Table 1 are the averages of the three polarizations except that the value listed for $^3A_2$ (28 285 cm^{-1}) is the band maximum in III. The weak absorption at 21 340 cm^{-1} is a multiplet that contains up to six irregularly spaced bands. The Appendix contains a complete listing of the energies of all peaks and shoulders shown in Figs. 2–9.

been reported by Goodgame and Hitchman (15). The polarized spectra (Fig. 2) show little dichroism, and the spectroscopic details are very much like those of $Ni(en)_2(NCS)_2$ (11). The latter molecule has a *trans* configuration, and the NiN_6 departs from effective D_{4h} symmetry principally by the unequal N—Ni—N angles (82° and 98°) in the $Nien_2$ group. A similar structure may be assumed for the present compound.

The polarized spectra of three different crystals were recorded, and three distinct spectra were obtained, as was ascertained by the very different intensities of two sharp vibrational bands at 6464 and 6330 cm^{-1}. These have relative heights of 0.42 to 1, 1.56 to 1, and 37.5 to 1 in the three polarizations. The assignments of the triplet states agree completely with those made by Bertini *et al.* (11) for $Ni(en)_2(NCS)_2$. In addition, several spin-forbidden bands are observed. Of special interest is a group of weak bands starting at about 21 340 cm^{-1}. Similar bands with varying degrees of sharpness and complexity appear in the spectra of several of the compounds studied in this series. The bands are best ascribed to the $^3B_1 \rightarrow {}^1A_1$ spin-forbidden transition plus various associated vibronic bands.

(b) $Ni(s\text{-}Et_2en)_2Cl_2$

Because of the habit of the crystals of this complex, spectra along only two of the extinction axes were recorded (Fig. 3). The spectra in the two polarizations are very similar, the principal difference being in the intensities of the lower energy bands. At low temperature the band at ~17 kK shows a real difference of ~300 cm^{-1} between the two polarizations. The band at 8.6 kK also shows a difference of about 120 cm^{-1}, which may be beyond the limits of experimental error. As noted above, these splittings suggest the assignment of these bands to *E* states.

The spectra of this compound (as well as the others studied) show some features below 10 kK which from their intensity, position, and sharpness are readily assigned to overtones of the N—H and C—H stretching modes. In some cases the assignment is confirmed by the appearance of the band at an identical place in the spectra of the Co(II) analog (unpublished data).

(c) $Ni(s\text{-}Et_2en)_2Br_2$

The polarized spectra (Fig. 4) of this complex are quite similar to those of the analogous chloro compound, and again only two polarizations were recorded on the two crystals studied. The rapidly rising base line appears to be caused by light scattering due to the rather small crystals used in the study. Similar spectra on a third crystal at 77 K showed a more normal base line.

(d) The Halo–Aquo Complexes

Recrystallization of the halo complexes from aqueous ethanol or water yields crystals whose ir spectra and chemical analysis indicate the presence of water. The electronic spectra (Figs. 5–7) are similar to those of the anhydrous complexes with the bands in general shifted to higher energy, as expected if H_2O replaces a halogen in the coordination sphere. It is most probable that we have the *trans* diaquo complexes rather than complexes containing water and halogen bonded to the nickel. For example, substitution of bromine for chlorine in the anhydrous compounds causes *DS* to change significantly (−5072(Cl) to −6777(Br)). The change in *DS* for the analogous hydrated compounds is very much smaller. The iodo complex shows no low-lying charge-transfer absorption associated with coordinated iodine; so it cannot have iodide ions as ligands. It appears therefore that in all three compounds both halogens are replaced by H_2O in the coordination sphere. The different appearance of the three halo–aquo spectra and the rather significant differences in some band positions may then be attributed to variations in hydrogen bonding, and possibly to lattice effects due to the different sizes of the halo ions.

Both the bromo–aquo and iodo–aquo complexes show an absorption of moderate intensity ~36–38 kK. Attempts to assign this to one of the components of the third *d–d* band result in quite unacceptable parameters and fits of observed and calculated data. It may be a spin-forbidden band which shows rather large intensity because of its position as a shoulder on the charge-transfer rise. The chloro–aquo complex shows a similar band but it is poorly reproducible.

Two crystals of the chloro–aquo complex and two of the bromo–aquo complex were studied, and only two distinct spectra were observed in each case. A single robust crystal of the iodo–aquo complex was used to obtain three distinct spectra.

(e) $Ni(s\text{-}Me_2en)_2(NCS)_2$

The polarized spectra of three crystals were recorded and three distinct polarizations were obtained (Fig. 8). The band positions in the polarizations are quite similar except for the lowest *d–d* band where a difference of 860 cm^{-1} between two polarizations is seen.

(f) $Ni(s\text{-}Me_2en)_2(NO_3)_2$

The spectra of two crystals were recorded (Fig. 9). A unique feature of the spectra is the appearance at room temperature of a clear band

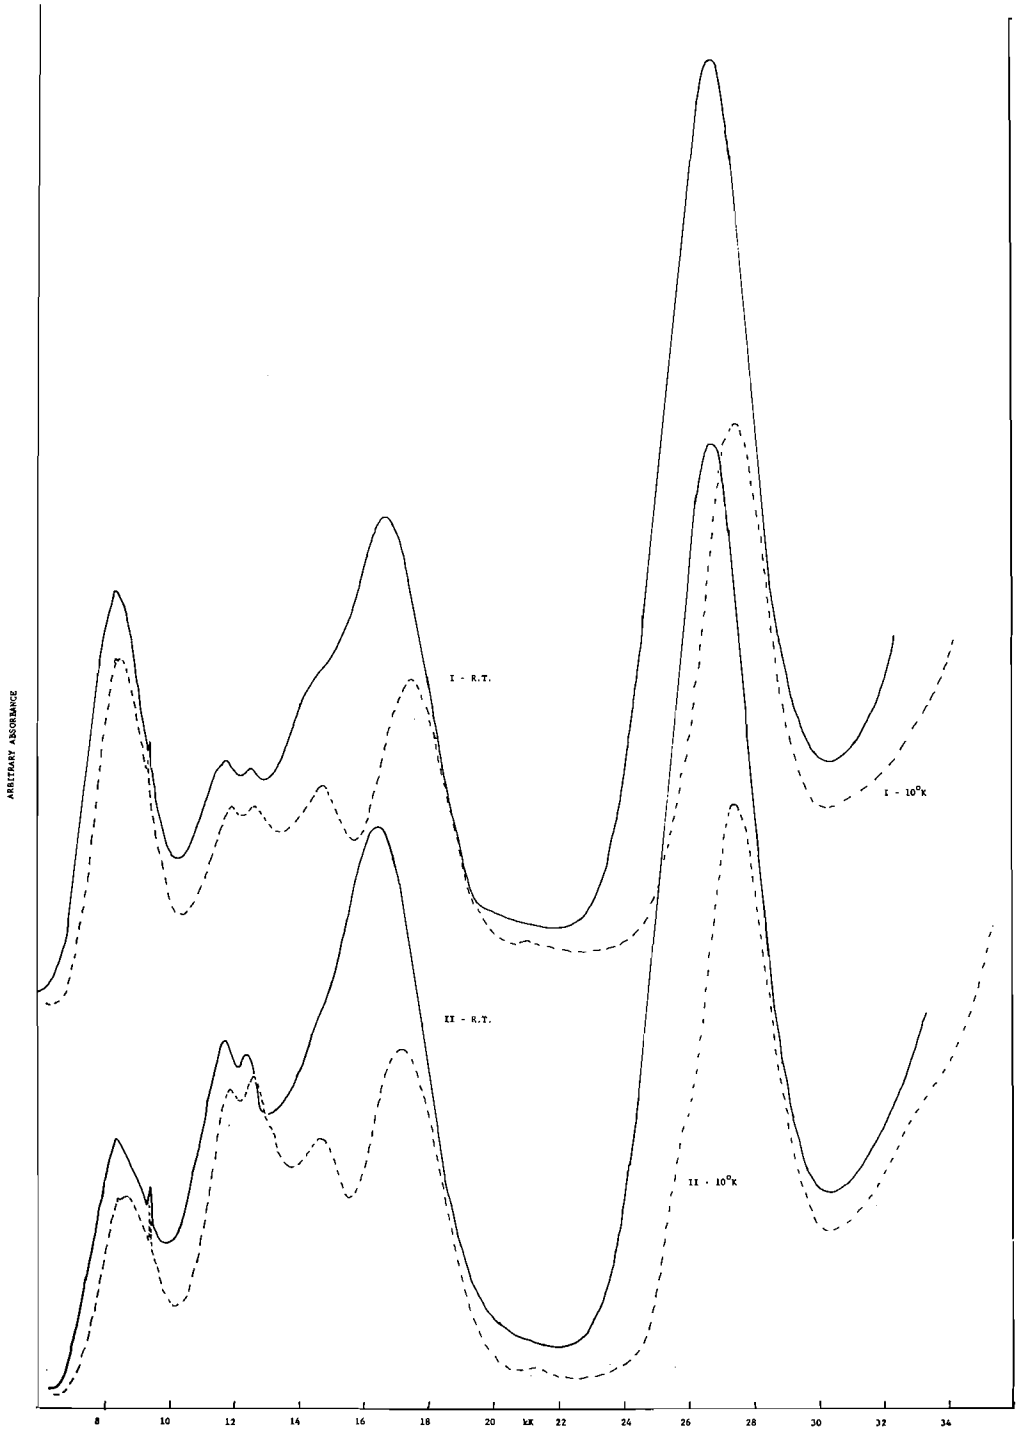

FIG. 3. Polarized crystal spectra of Ni(*s*-Et_2en)$_2Cl_2$. The bands at 8400 and 9470 cm^{-1} appear in the spectra of the analogous Co(II) complex, and so are probably ligand vibration second overtones. Stronger bands corresponding to the first overtones are found in the expected regions.

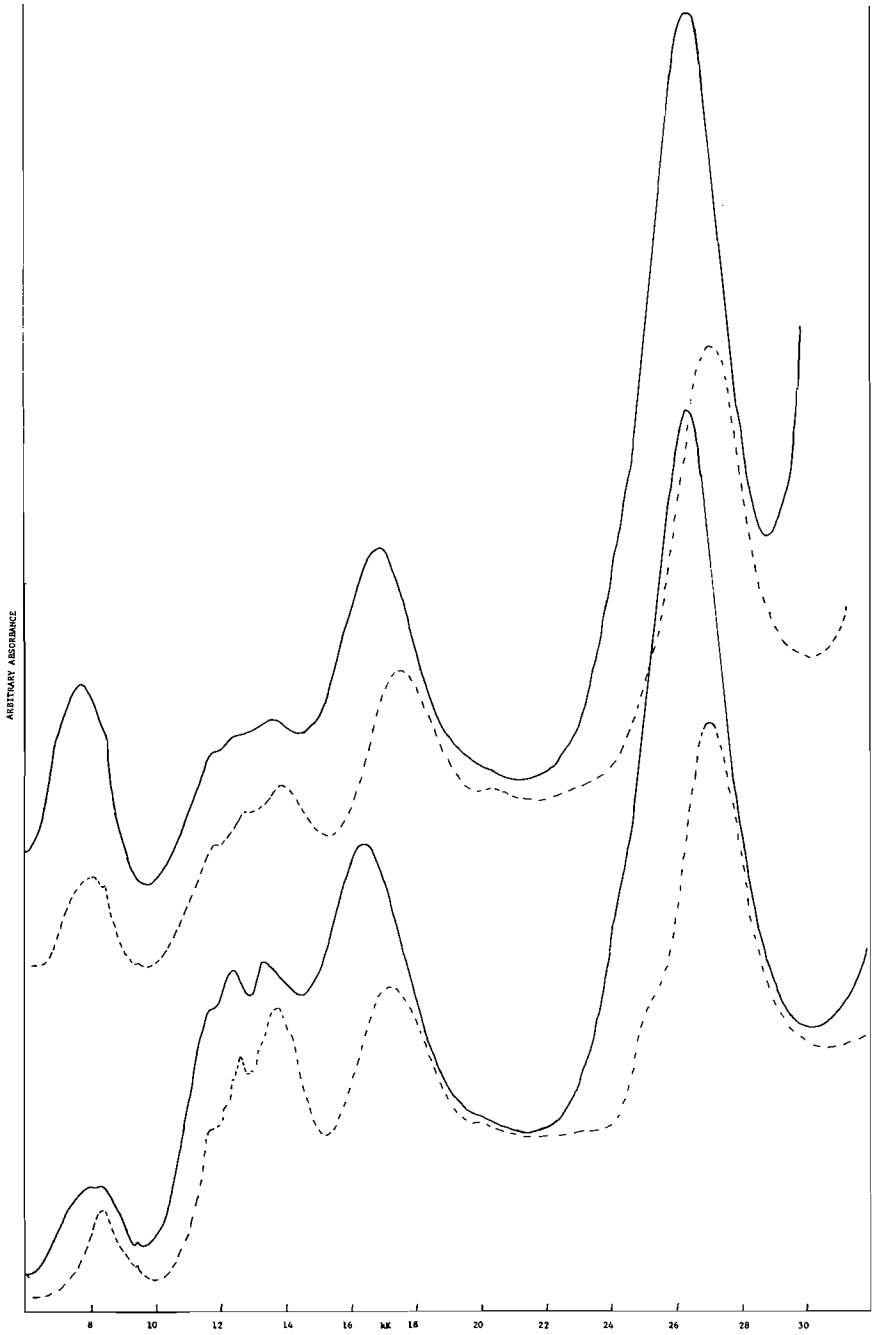

FIG. 4. Polarized crystal spectra of $Ni(s\text{-}Et_2en)_2Br_2$. The weak features at ca. 8.4 kK and 9.4 kK appear on other spectra also and are probably due to ligand vibrations.

in polarization I at 28.3 kK, which is reduced to a shoulder at 10 K. So the position of the third spin-allowed transition at 10 K is less certain for this compound.

Discussion

A complete listing of the experimental results (two or more sets of polarized data at room temperature and at 10 K) is given in the Ap-

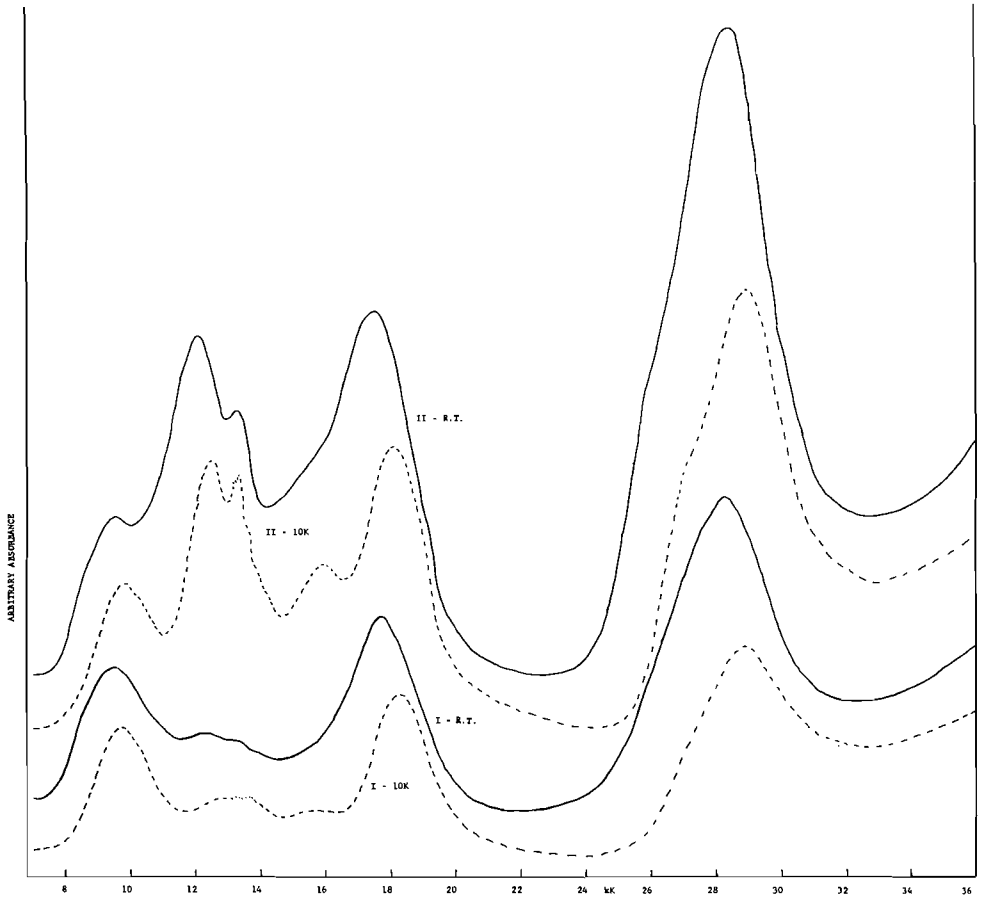

FIG. 5. Polarized crystal spectra of $Ni(s\text{-}Et_2en)_2(H_2O)_2^{2+} \cdot 2Cl^- \cdot 2H_2O$. The weak features at 10.4 kK (10 K) and 8.4 kK (room temperature and 10 K) are not shown in the spectra; they are probably ligand vibrations.

pendix. The energies cited in Table 1, used to derive the parameters shown in Table 2, are the average of the energies seen in each polarization at 10 K. In some cases several sets of data were obtained from different crystals. These data are included in the average; however, the Appendix cites data relating to the specific measurement shown in the appropriate figure.

In some cases there is doubt concerning the distinction between the transitions to $^1B_{1g}$ and $^3B_{2g}$, the alternate assignments both giving good fits. This need not be a serious cause of concern in that these two states are mixed together (1), and therefore the true parameter set is an average. The same general trends are observed using either set. Furthermore, since we are more interested in well-defined trends in parameters, the absolute values, in view of the approximations involved, are of less import. Since the upper band, in several spectra, has associated vibronic structure, and since the lower band often shows a greater shift to higher energy on cooling, we are assuming $^3B_{1g} < {}^1B_{1g}$ for all the complexes. Accordingly we list in Tables 1 and 2 only the energies and parameters based on this assignment.

As previously noted, we have neglected spin–orbit coupling and vibrational contributions to the energies. This is likely to introduce an error of up to $\pm 200\ cm^{-1}$ into the energies of the observed electronic transitions used to calculate the parameters. Since most of the orbital degeneracy has been removed in the energy levels of concern, first-order spin–orbit coupling should have little effect on the calculated energies. Second-order spin–orbit coupling will cause

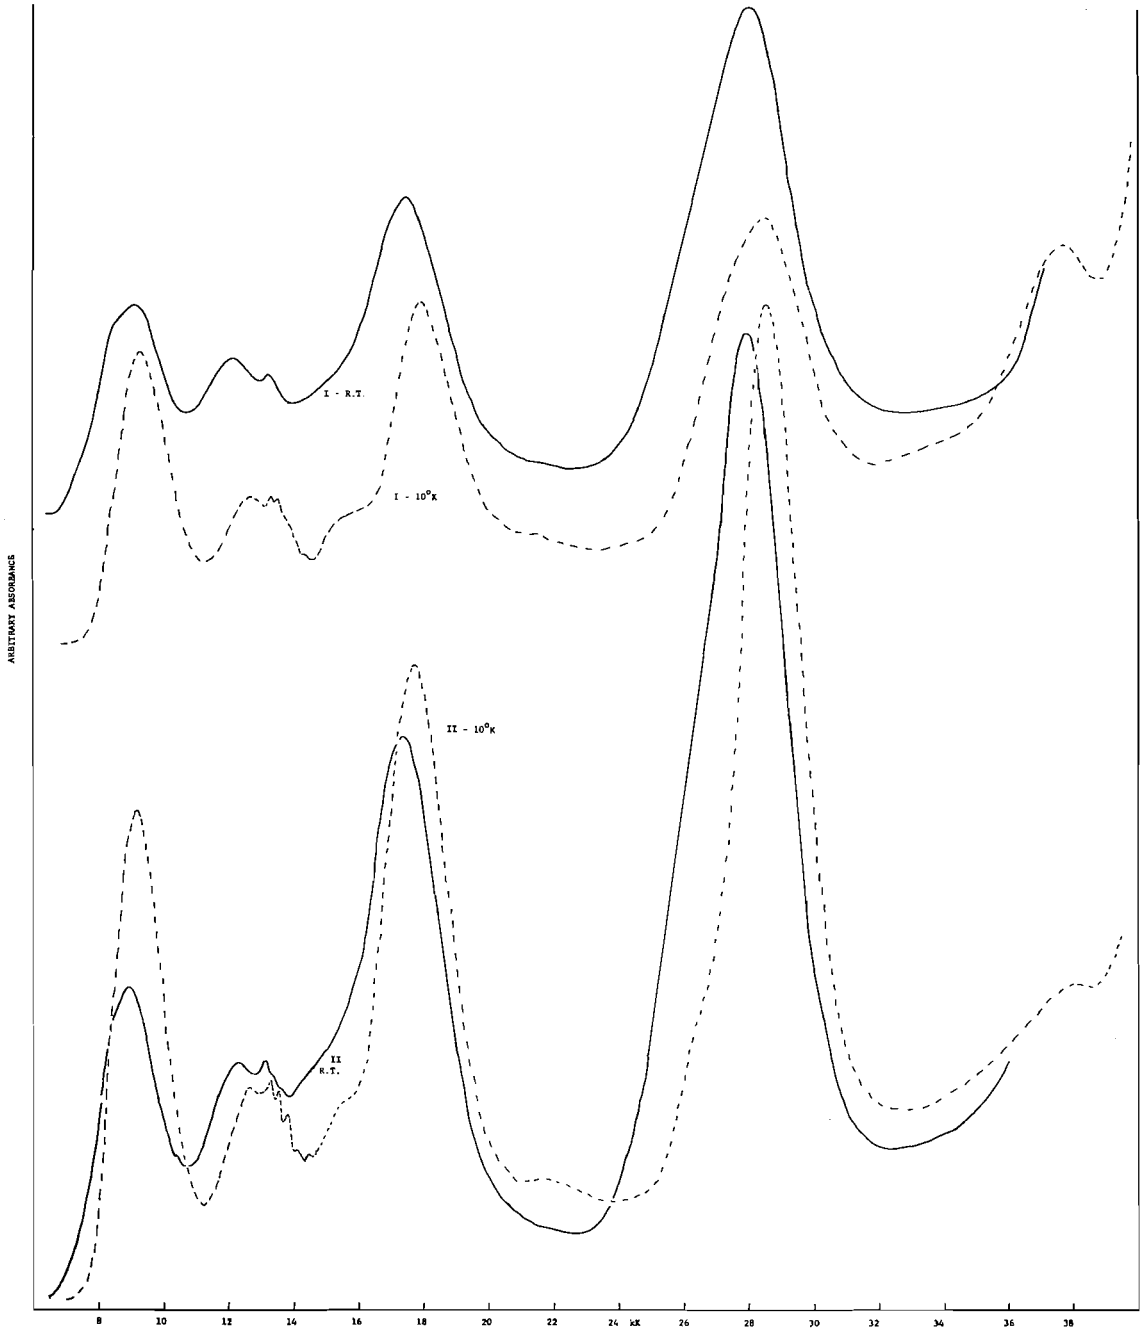

FIG. 6. Polarized crystal spectra of $Ni(s\text{-}Et_2en)_2(H_2O)_2^{2+}\cdot 2Br^-$. The 17.9 kK band (10 K) in polarization I shows some very weak structure beginning at ca. 16.9 kK which may be a progression in about 260 cm^{-1}. The bands at 8.4 kK (polarization I) and 10.4 kK (polarization II) appear to be ligand vibrations.

mixing, in particular, of the $^3B_{2g}$ and $^1B_{1g}$ levels alluded to previously, resulting in a small uncertainty in the value of DS (16).

Most bands can be measured with an accuracy of better than ± 100 cm^{-1} but larger errors may result for the broader bands and particularly the shoulders. Gaussian analysis of the 18 kK band for $Ni(s\text{-}Et_2en)_2(NCS)_2$ yields, however, band

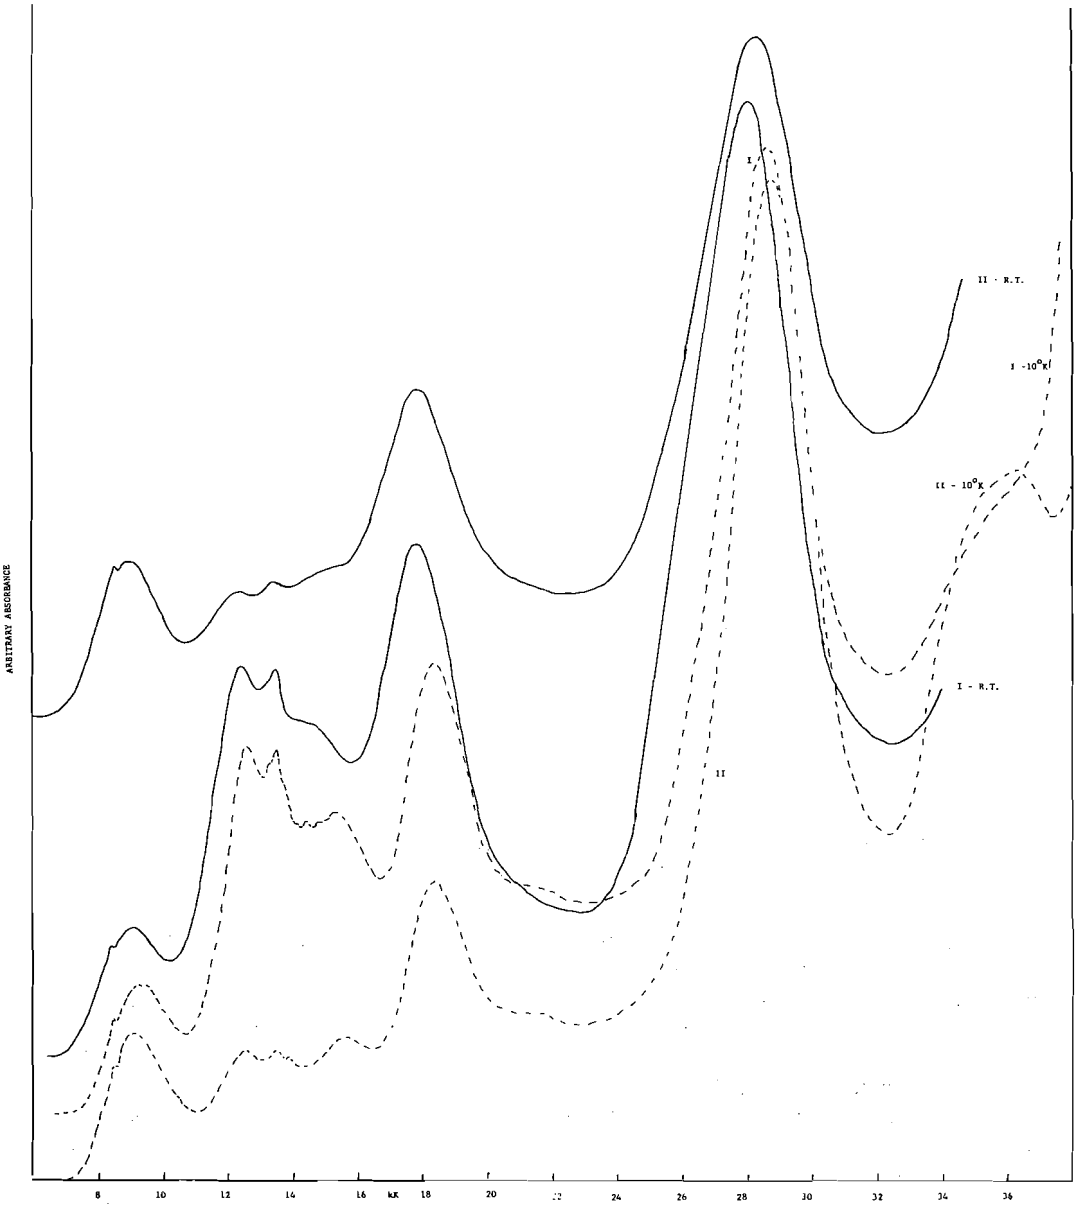

FIG. 7. Polarized crystal spectra of $Ni(s\text{-}Et_2en)_2(H_2O)_2^{2+} \cdot 2I^-$. Polarization III is not shown, since it is very similar to II. The positions listed in Table 1 are the averages of the three polarizations. The weak band at 8.4 kK (10 K, polarization I) consists of four closely spaced components, all probably ligand vibrations.

maxima not substantially different from those measured directly from the spectra. Trial calculations reveal that DS is most sensitive to these possible errors, the variations in DT and DQ being rather smaller. Thus, discussion of any trends in DS would be futile at this stage and must await a more complete analysis of the data.

For these reasons no attempt has been made to obtain a perfect fit to the observed energies, though with enough computer time this may be possible. Instead, a root mean square deviation of about 200 cm^{-1} or less is considered a thoroughly acceptable result. Once the spin-allowed transitions have been fitted, the positions of the

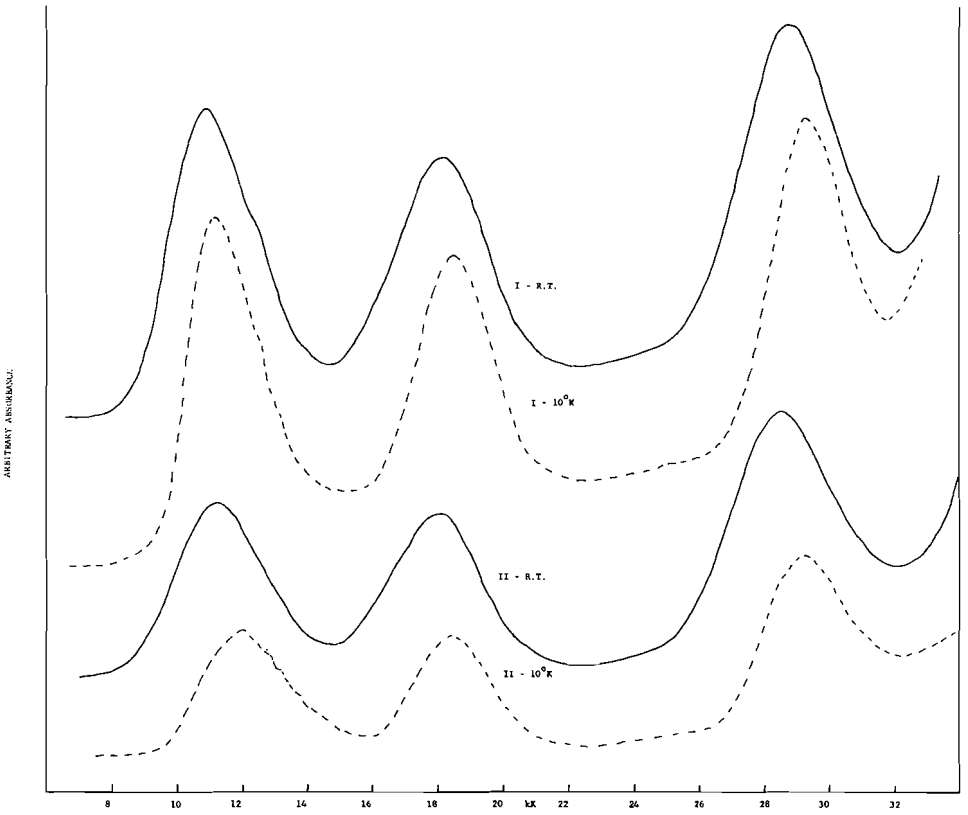

FIG. 8. Polarized crystal spectra of Ni(*s*-Me_2en)$_2$($NCS)_2$. Polarization III is not shown; it is very similar to II except that the 13.2 kK band is more clearly resolved in III. This band probably represents the transition to the $^1B_1$ state.

spin-forbidden transitions are computed and a value of C determined which will reproduce the dominant spin–singlet transitions observed in the spectra. These data are also shown in Table 1.

The orbital angular overlap parameters[1] e_{σ_N}' and e_{σ_Z}', which convey potentially the most chemical insight, are much less sensitive to the possible errors indicated above. Trends in these parameters are well defined and seem to make chemical sense. It has been pointed out that the angular overlap parameters refer only to the nonspherical part of the ligand field, and furthermore only to that part of it which is associated with bonding to the metal d orbitals (5). Thus they may possess chemical significance, yet not be very important with regard to total metal–ligand bond energy. For the complexes in this study, e_{π_N}' is assumed equal to zero. Values for the parameter e_{π_Z}' are for the most part close to zero. So it appears that π interactions between nickel(II) and the axial ligands are of relatively little importance, in contrast to tetragonal chromium(III) complexes, where this parameter can be quite large (17). This is explicable if the π interactions are largely ligand to metal π donation, since Cr(III) has a half-filled $t_{2g}(O_h)$ shell, whereas that of Ni(II) is full. Moreover, the higher positive charge of Cr(III) will cause greater ionic polarization of the ligand π pairs effectively increasing the magnitude of the e_{π_Z}' parameter.

The directional covalent contribution to the σ bond between the *s*-Et_2en ligand and the metal, as demonstrated by the magnitude of e_{σ_N}' (or

[1] e_σ' and e_π' represent respectively the nonspherical σ-antibonding and π-antibonding (or bonding) effects exerted on the metal d orbitals by interactions with the ligand orbitals (5). The additional subscript N refers to the four ammine nitrogens in the equatorial plane, while Z refers to the two axial ligands.

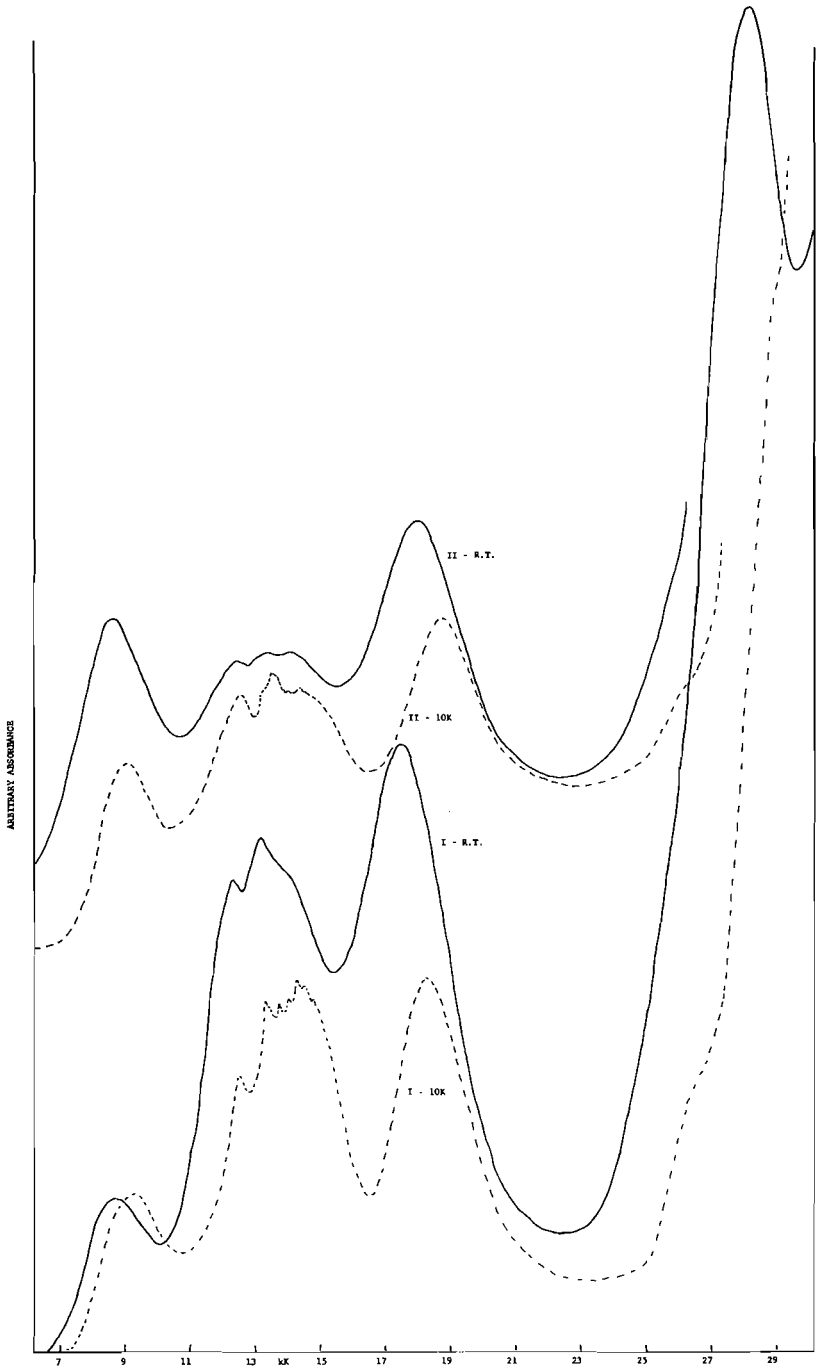

FIG. 9. Polarized crystal spectra of $Ni(s\text{-}Me_2en)_2(NO_3)_2$. A weak feature at ca. 8.4 kK in both polarizations and one at ca. 9.3 kK in II have been omitted. They probably represent ligand vibrations.

TABLE 2. Empirical parameter sets

	$R^a = H^c$ $X^a = NCS$	$R^a = Me$ $X^a = NCS$	$R^a = {}^d$ $X^a = NCS$	$R^a = Et$ $X^a = NCS$	$R^a = Et$ $X^a = Cl$	$R^a = Et$ $X^a = Br$	$R^a = Et$ $X^a = H_2O(Cl)$	$R^a = Et$ $X^a = H_2O(Br)$	$R^a = Et$ $X^a = H_2O(I)$	$R^a = Me$ $X^a = NO_3$
$d\sigma$	−1 111	−34	184	−923	−1 695	−2 058	−1 481	−1 647	−1 833	−2 350
$d\pi = (e_{\pi_Z}'(\text{axial}))^b$	−50	303	125	−42	−276	−644	−234	−140	−397	−925

[a]Ni(*s*-R_2en)$_2X_2$; the aquo complexes are [Ni(*s*-Et_2en)$_2$(H_2O)$_2$]X_2. Et = ethyl; Me = methyl. For the first three compounds all six triplet states were used to calculate the parameters; for the others the position of the upper $^3A_2$ was varied until a best fit was obtained. All values in cm^{-1}.
[b]e_{π_N}' (equatorial) is assumed equal to zero.
[c]Based on data of Bertini *et al.* (11).
[d]This compound is Ni(NH_3)$_4$(NCS)$_2$; based on room temperature data of Hare and Ballhausen (23).

DQ_{eq}), has an average value of 4132 cm^{-1} (or 34 087 for DQ_{eq}) in this series with rather small variation from one complex to another. This provides further support for the validity of the assignment made, and reflects the relative independence of the equatorial and axial parameters for these nickel complexes. This is in contrast to similar copper(II) complexes, in which the two parameters are quite dependent on one another (19). Gazo and Bersuker (20) describe this as the plasticity of the copper coordination sphere (see also ref. 24).

An infrared study of several Ni(diamine)$_2X_2$ compounds indicates that for a given X the ν(Ni–N) mode is higher for the *s*-Et_2en complex than for the *s*-Me_2en complex (9). This should be reflected by a larger DQ_{eq} for the former. We find DQ_{eq} to be about 9% greater for Ni(*s*-Et_2en)$_2$(NCS)$_2$ than for the corresponding Me complex. For the trichloroacetate complexes it is about 2% greater in the Et complex (unpublished data). While more data are needed in order to verify this as a general trend, the values correspond to what one would expect from the greater basicity of the *s*-Et_2en ligand. An earlier study (21) using data of much poorer quality led to the reverse conclusion. An apparent decrease in Dq for the *s*-Et_2en complexes was ascribed to increased steric hindrance. The importance of obtaining high quality data cannot be overemphasized.

The σ bonding strength of the axial ligand naturally depends upon the nature of this ligand. The parameter e_{σ_Z}' varies in the sequence:

[1] $$\begin{array}{lccccc} NCS \gg H_2O & > & Cl & > & Br & > NO_3 \\ 3536^2 & & 1979 & & 1712\ 1178 & 1064\ cm^{-1} \end{array}$$

certainly the anticipated order on the basis of the spectrochemical series. Recall that the crystal-field strength is related to the orbital angular overlap parameters by the relationship (3):

[2] $$(5/3)\sqrt{21}\,DQ = 10Dq = (3e_\sigma' - 4e_\pi')$$

The spectrochemical series reflects a relative order of DQ. Since in the case of nickel, the e_π' parameter is usually small, the spectrochemical series will also reflect the value of e_σ'.

In general, the axial field strengths are rather low. The conventional DQ values for an unhindered Ni(II)L_6 hypothetical complex would

[2]Average for the methyl and ethyl complexes.

be: 24.47 kK for L = H_2O, 19.58 for L = Cl, and 18.60 for L = Br (22). The calculated DQ values for these axial ligands (L) in the *s*-Et_2en complexes are: 17.81 to 20.73 kK for H_2O, 17.16 for Cl, and 16.80 for Br. The reduced values observed in these complexes may reliably be attributed to a weakened axial interaction as a consequence of steric hindrance by the *N*-ethyl groups. In the case of the thiocyanates shown in Table 2, the field strength of NCS in the less sterically hindered *s*-Me_2en complex is markedly greater than in the *s*-Et_2en complex. Curiously, however, the field strength of the NCS group in *trans*-Ni(en)$_2$(NCS)$_2$ is much smaller (Table 2). This is attributed by Bertini *et al.* (11) to a somewhat longer than normal Ni—NCS bond length. It is certainly not clear why *en* should behave so differently from its *N*-substituted derivatives in this respect. In this last complex the Ni—NCS bond is bent (140°) and this may be the reason for the low DQ value through decreased overlap. The equatorial field strength of this ethylenediamine complex is the same as that of the *s*-Me_2en complex.

In the sterically unhindered *trans*-Ni$(NH_3)_4$(NCS)$_2$ complex (23) the σ-bonding strength of ammonia is seen to be below that of the diamines whereas the thiocyanate has e_σ' and DQ values comparable to that of the *s*-Me_2en complex, where presumably steric hindrance is small, at least towards the sterically undemanding linear NCS group. It should be noted that these are room temperature spectral data, and so not directly comparable to the other data gathered at ~10 K.

The Racah B values do not vary a great deal, clustering with one important exception near 850 cm^{-1}. The exception is Ni(*s*-Et_2en)$_2$(NCS)$_2$ for which the low value of 690 cm^{-1} is observed. There can be no doubt that the value is correct in that the two highest energy bands in the spectrum (arising from the F and P terms) are closer together than in the other complexes considered. It is this fact which results in a decreased B value. The reason for the lower B value is by no means clear. The possibility of S bonding by the thiocyanate is absolutely ruled out both by the electronic and vibrational spectra.

This is the initial report of a series of papers describing the analysis of the spectra of both cobalt(II) and nickel(II) complexes of this general class. The cobalt data are, as expected, much more complicated. They can be fitted with parameters very similar to those reported here, but further supporting evidence, in particular magnetic circular dichroism data, are necessary to confirm the assignments. These cobalt data and those for other nickel(II) complexes will be reported in due course. At that time a more detailed analysis of the variation of the parameters as a function of both metal and stereochemistry will be attempted.

Appendix

Parameters

The various parameters are calculated from the following equations (4). Note change in sign of DT effective in our publications dating from 1976.

$$[3] \quad d\sigma = (6DS + \sqrt{15}\,DT)/28$$

$$[4] \quad d\pi = (3DS - 2\sqrt{5/3}\,DT)/14$$

$$[5] \quad DQ_{ax} = DQ + 2\sqrt{7/5}\,DT$$

$$[6] \quad DQ_{eq} = DQ - \sqrt{7/5}\,DT$$

$$[7] \quad e_{\sigma N}' = 5DQ_{eq}/9\sqrt{21} = 5/9(DQ/\sqrt{21} - DT/\sqrt{15})$$

$$[8] \quad e_{\sigma z}' = 4/3d\sigma + e_{\sigma N}' = \frac{1}{189} \times (5\sqrt{21}\,DQ + 54DS + 2\sqrt{15}\,DT)$$

$e_{\pi N}'$ is assumed to be zero; therefore $e_{\pi z}' = d\pi$.

The relationships with the conventional parameters are (2):

$$[9] \quad DQ = 6\sqrt{21}\,Dq - 3.5\sqrt{21}\,Dt$$

$$[10] \quad DT = -3.5\sqrt{15}\,Dt$$

$$[11] \quad DS = -7Ds$$

Experimental Energies

Listed here are the energies observed for all shoulders (sh) and peaks illustrated in Figs. 2–9. R.T.-I and R.T.-II are the two room temperature orthogonal polarizations, 10 K-I and 10 K-II, the corresponding data at 10 K. Sharp spikes are indicated by sp.

Studies on metal–acetylene complexes. VII. The molecular structure of bis(tricyclohexylphosphine)(hexafluorobut-2-yne)platinum(0)

JOHN F. RICHARDSON AND NICHOLAS C. PAYNE

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 21, 1977

JOHN F. RICHARDSON and NICHOLAS C. PAYNE. Can J. Chem. **55**, 3203 (1977).

The acetylene complex $Pt(P(cyclo\text{-}C_6H_{11})_3)_2(F_3CC{\equiv}CCF_3)$ crystallizes in the monoclinic space group $P2_1/c$ with four formula units in a cell of dimensions $a = 10.902(2)$, $b = 21.766(3)$, $c = 19.808(3)$ Å, and $\beta = 116.52(1)°$. Three-dimensional X-ray data were collected on a four circle automatic diffractometer using Cu radiation. The structure was solved by the heavy atom method, and refined by full-matrix least-squares methods on F. A conventional agreement factor of 0.062 was achieved, employing 6678 observations for which $I > 0$. The coordination geometry at the platinum atom is essentially planar, for the acetylene triple bond makes an angle of 6.5(5)° with the plane formed by the Pt and the two P atoms. The triple bond length is 1.260(10) Å. The acetylene adopts a *cis*-bent geometry, with a mean bend-back angle of 45.5(8)°. The ligand is considerably perturbed upon coordination to the Pt atom, as is evident from the $\Delta\nu(C{\equiv}C)$ value of 578 cm^{-1}.

JOHN F. RICHARDSON et NICHOLAS C. PAYNE. Can. J. Chem. **55**, 3203 (1977).

Le complexe acétylène $Pt(P(cyclo\text{-}C_6H_{11})_3)_2(F_3CC{\equiv}CCF_3)$ cristallise dans le groupe d'espace monoclinique $P2_1/c$ avec quatre unités dans la maille de dimensions $a = 10.902(2)$, $b = 21.766(3)$, $c = 19.808(3)$ Å et $\beta = 116.52(1)°$. On a recueilli les données de rayons-X en trois dimensions à l'aide d'un diffractomètre automatique à quatre cycles utilisant la radiation Cu. On a résolu la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice complète) autour de F. On a pu obtenir un facteur de R de 0.062 utilisant 6678 réflexions pour lesquelles $I > 0$. La géométrie de la coordination au niveau de l'atome de platine est essentiellement planaire puisque le lien triple de l'acétylène fait un angle de 6.5(5)° avec le plan formé par le platine et les deux atomes de phosphore. La longueur de la liaison triple est de 1.260(10) Å. L'acétylène adopte une géométrie *cis*-déformée avec un angle de déformation de 45.5(8)°. Le ligand est très perturbé par la coordination avec l'atome de platine et ceci est mis en évidence à l'aide d'une valeur de $\Delta\nu(C{\equiv}C)$ de 578 cm^{-1}.

[Traduit par le journal]

Introduction

The interaction between a metal atom and an acetylene molecule results in a π-bonded complex in which the acetylene ligand adopts a *cis*-bent geometry. The magnitude of the deviation from linearity may be determined from the bend-back angle. Such effects have been successfully explained by a modification of the Chatt–Dewar–Duncanson synergic bonding scheme (1, 2). The crystallographic studies completed to date suggest that, except in cases where the acetylene is cyclic, for example cyclohexyne or cycloheptyne (3), the maximum bend-back angle observed is around 40° (2). For example, a value of 39.9(5)° was found in the complex bis(triphenylphosphine)(hexafluorobut-2-yne)platinum(0) (2).

Thus the preparation and characterization (4) of the complex bis(tricyclohexylphosphine)-(hexafluorobut-2-yne)platinum(0) provided an opportunity to examine the geometry of the same acetylene ligand in the presence of phosphine ligands of greater basicity than triphenyl-

phosphine, and hence presumably greater electron-donating abilities (5, 6).

Further interest in the title compound is provided by the increased steric bulkiness of the tertiary phosphine ligand. In 1969 Tolman introduced the concept of a cone angle as a measure of the steric properties of a phosphine ligand (5). The value of 179(10)° given for tricyclohexylphosphine, later revised to 170(10)°, suggests that the acetylene complex should not exist. It was thus of interest to examine the interligand steric interactions with a view to determining the relative importance of the electronic and steric effects. The results of the study are presented herein.

Experimental

Colourless crystals of $Pt(P(C_6H_{11})_3)_2(F_3CC{\equiv}CCF_3)$ were kindly supplied by Attig and Clark (4). A preliminary photographic study using Weissenberg and precession techniques showed the crystals belonged to the monoclinic system. The systematic absences observed, l odd for $h0l$ and k odd for $0k0$, uniquely define the space group as $P2_1/c$, C_{2h}^5, No. 14 (7).

The crystal chosen for data collection was carefully measured with a microscope fitted with a filar eyepiece to permit an absorption correction. Approximate dimensions of 0.41 mm × 0.23 mm × 0.17 mm were observed. The crystal possessed nine faces, namely {010}, $(\bar{1}10)$, $(1\bar{1}0)$, $(\bar{1}\bar{1}0)$, (100), (001), and (011) as determined by optical goniometry. A fractured face was best approximated as $(10\bar{6})$. The crystal was mounted on a Picker FACS-1 diffractometer with the long dimension [100] offset from coincidence with the spindle axis by approximately 5°.

Unit cell dimensions were determined from a least-squares refinement[1] of the angular settings for 20 reflections centered using $CuK\alpha_1$ radiation. The crystal density, determined by the flotation method using carbon tetrachloride and n-hexane, was 1.46(1) g cm^{-3}. This is in good agreement with the density of 1.450 g cm^{-3} calculated assuming four molecules per unit cell. There are no crystallographic symmetry constraints imposed upon the molecule.

Crystal data and the conditions for data collection are summarized in Table 1. Intensity data were recorded over a period of 8 days giving a total of 7301 reflections. Of these 186 were standards, which were recorded every 150 reflections for the range $2.5° \leq 2\theta \leq 60°$, and then every 250 reflections up to the maximum 2θ of 125° as a check on the crystal quality and electronic stability. These were found to increase with time, the increase being relatively constant for each standard. This increase was attributed to an increase in crystal mosaicity, and a correction was therefore applied to the data. The intensity of the nth reflection, observed at I_0 was adjusted to I_n, where

$$I_n = I_0/(1.0 + n(3.789 \times 10^{-5}))$$

The raw data were then corrected for background and Lorentz-polarization effects, and standard deviations were assigned according to the expression

$$\sigma(I) = [T_C + \tfrac{1}{4}(t_c/t_b)^2(B_h + B_l) + (pI)^2]^{1/2}$$

where T_C is the integrated count over the scan range, measured in time t_c, B_h and B_l are background counts, each measured in times t_b. I, the corrected intensity, is given by $T_C - \frac{1}{2}(t_c/t_b)(B_h + B_l)$. A series of absorption correction trials using $\mu = 70.72$ cm^{-1} for $CuK\alpha$ radiation showed transmission factors varying from 0.185 to 0.321, so an absorption correction was applied. The analytical method of de Meulenaer and Tompa was used.[1] There were 5672 reflections regarded as observed ($I > 3\sigma(I)$) and used in the structure solution and preliminary refinement.

Structure Solution and Refinement

The positions of the Pt atom and the two P atoms were readily located from a three-dimensional Patterson synthesis. One cycle of full-matrix least-squares refinement on F, varying positional parameters and isotropic temperature factors, and minimizing the function $\sum w(|F_o| - |F_c|)^2$, led to the agreement factors

$$R_1 = \sum||F_o| - |F_c||/\sum|F_o| = 0.222$$

$$R_2 = (\sum(|F_o| - |F_c|)^2/\sum wF_o^2)^{1/2} = 0.308$$

The weight w is defined as $4F_o^2/\sigma^2(F_o^2)$.

The atomic scattering factors for neutral Pt, P, F, and C atoms were those of Cromer and Waber (8), while that of H was taken from Stewart *et al.* (9). Anomalous dispersion contributions to the scattering factor were included for Pt, P, and F atoms, and were taken from Cromer and Liberman (10).

The remaining 46 non-hydrogen atoms were located by means of a difference Fourier synthesis. Subsequent least-squares refinements were carried out with the Pt, P, and F atoms assigned anisotropic thermal parameters and the acetylene C atoms isotropic Debye factors. The cyclohexyl rings were treated as rigid groups, having the chair conformation with C—C bond lengths of 1.54 Å and C—C—C angles of 109.47° (11). Ten cycles of refinement gave agreement factors $R_1 = 0.048$ and $R_2 = 0.052$ (5672 observations, 190 variables).

[1]Computing was performed on the CDC Cyber 73-14 at the University of Western Ontario. Programs used include local modifications of: orientation matrix and cell refinement, a version of Hamilton's MODE1; absorption correction, AGNOST, as modified by Cahen and Ibers; Fourier syntheses, FORDAP, by Zalkin; least-squares refinements and structure factor calculations, a version of NUCLS, by Ibers; error calculations, ORFFE, by Busing, Martin, and Levy; and molecular illustrations, ORTEP, by Johnson.

TABLE 1. Summary of crystal data and conditions for data collection

$PtP_2F_6C_{40}H_{66}$	fw = 918.0
Crystal description	Colourless prisms
Cell constants	a = 10.902(2) Å, b = 21.766(3) Å, c = 19.808(3) Å, β = 116.52(1)°
Cell volume	4205.7 Å^3
Radiation	CuKα, Ni foil (0.018 mm thick) prefilter
Temperature	21°C
Mean ω scan width at half height	0.09°
Scan speed	2° min^{-1}
Stationary background count time	10 s at scan limits
Standard reflections	$\bar{1}00$, 020, 002, 100, $0\bar{2}0$
Take-off angle	1.4°
Crystal–counter distance	34 cm
Aperture size	5 × 5 mm

An analysis of the structure at this point revealed a probable disorder of one of the CF_3 groups, as indicated by C—F bond distances ranging from 1.203 to 1.362 Å and F—C—F bond angles from 87.1 to 116.8°. An examination of a difference Fourier synthesis indicated six F-atom sites. This disorder apparently occurs as a result of a 60° rotation of the group around the C—CF_3 bond. To account for this disorder a rigid group having D_{6h} symmetry and F—F nonbonded distances of 1.215 Å was refined with each F having a multiplicity of 0.5. Least-squares refinement of the group parameters proved successful, resulting in an acceptable model geometry and a slight increase in the agreement factors to $R_1 = 0.055$ and $R_2 = 0.057$ (5672 observations, 247 variables).

The positions of the 66 H atoms were calculated assuming a C—H distance of 1.00 Å, and sp^3 hybridization at the C atoms. All were found to correspond to regions of positive electron density (0.4–0.8 e Å^{-3}) in a difference Fourier synthesis. The H-atom contributions were henceforth included in structure factor calculations.

In the final stages of refinement the group constraints were lifted from the cyclohexyl substituents, and each C atom was allotted an isotropic thermal parameter. Idealized H-atom positions were recalculated. For the final cycle only the disordered hexagonal F entity was refined as a group with an overall group thermal parameter. The 36 cyclohexyl C atoms were allotted isotropic thermal parameters. Only unique data with $I > 0$ were used, and with 6678 observations and 247 variables, the refinement converged at $R_1 = 0.0624$ and $R_2 = 0.0631$. No parameter shifts other than those associated with the F6 group exceeded 0.14 of an estimated standard deviation, and a statistical analysis of R_2 in terms of $|F_o|$, indices, $\lambda^{-1} \sin\theta$, and the diffractometer setting angles χ and ϕ showed no unusual trends. The standard deviation on an observation of unit weight was 2.73 electrons. A final difference Fourier synthesis was calculated and showed no areas of significant positive electron density. The largest residual peak (1.85(18) e Å^{-3}) occurred at (−0.1279, 0.1212, 0.1662) and was associated with the F6 rigid group. No evidence was observed for secondary extinction.

The final positional and thermal parameters of the nongroup atoms are given in Table 2. The group parameters and the derived atom positional and isotropic thermal parameters for the F atoms in the F6 group are given in Table 3. Cyclohexyl H-atom parameters are given in Table 4 and final values of $10|F_o|$ and $10|F_c|$ in electrons are given in Table 5.[2]

Description of the Structure

The structure consists of discrete molecular units with the closest intermolecular distance of approach being 2.30 Å between cyclohexyl H atoms bonded to 4C5 and 5C6. Selected bond lengths and bond angles are given in Table 6. The inner coordination sphere of the Pt atom, showing the atom-labelling scheme and significant bond lengths and angles, is given in Fig. 1. A stereoview of the molecule is found in Fig. 2.

The coordination geometry around the Pt atom is essentially planar. A weighted least-squares plane was calculated using the Hamilton method[1] and results are shown in Table 7. The

dihedral angle between planes defined by the Pt, P(1), P(2) and Pt, C(1), C(2) indicates only a small deviation from planarity of 6.5(5)°.

The Pt—P distances of 2.301(2) and 2.309(2) Å may be considered statistically equivalent. The Pt—C distances to C(2) and C(3) of 2.047(7) and 2.045(8) Å respectively are also equivalent, and comparable to the values of 2.024(5) and 2.047(7) Å found in the triphenylphosphine complex (2). The two P atoms of the tricyclohexylphosphine ligands subtend an angle of 110.23(6)° at the Pt atom and the acetylene C atoms C(2) and C(3) form an angle of 35.9(3)° with the Pt atom. The angle of 36.1(2)° subtended in the triphenylphosphine complex by the acetylene ligand is comparable, but the P—Pt—P angle of 100.17(4)° is much less than that in the complex containing the bulkier tricyclohexylphosphine ligand.

The disorder of the CF_3 group bonded to C(3) renders comparisons of the CF_3 groups doubtful, but it should be noted that the ordered CF_3 group has dimensions comparable to those in the triphenylphosphine complex. Thus the mean

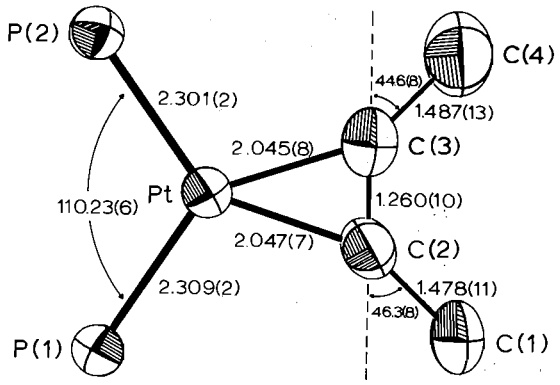

FIG. 1. Inner coordination sphere, showing the atom-labelling scheme and selected bond distances and angles.

C—F distance is 1.282(10) Å, and the mean F—C—F angle is 104.6(9)°. Mean values of 1.327(10) Å and 105.0(8)° respectively resulted from the refinement of the hexagonal F group. The mean P—C distance in the tricyclohexylphosphine ligands is 1.856(6) Å and the mean angle subtended by the cyclohexyl C1 atoms at the P atoms is 114.1(5)°. Within the C_6H_{11} rings a mean C—C bond length of 1.524(10) Å was observed, with an average C—C—C angle of 110.9(7)°.

Upon coordination to the Pt atom the $\nu(C{\equiv}C)$ is reduced by 578 cm^{-1}, an extent significantly greater than the value of 525 cm^{-1} observed for the triphenylphosphine complex (2). That the acetylene has been greatly perturbed upon coordination is shown by a mean bend-back angle of 45.5(8)°, also significantly larger than that found in the triphenylphosphine case (39.9(5)°). The acetylenic triple bond length

TABLE 7. Weighted least-squares plane

Atom	Distance from plane (Å)

of 1.260(10) Å is indistinguishable from the triphenylphosphine complex value of 1.255(9) Å, but significantly larger than the average value of 1.202(5) Å found in free acetylenes (12).

Discussion

Differences between the title compound and the triphenylphosphine complex are summarized in Table 8. As indicated, the relative basicities of the phosphine ligands were determined by two independent means. Thus Tolman (5) showed that in the complexes $Ni(CO)_3L$ the value of $\nu(C{\equiv}O)$ was a sensitive indicator of the ligand basicities. The infrared stretching frequency of the C≡O was found to decrease with increasing basicity of the ligand L, and thus tricyclohexyl-

Maximum	168	160

phosphine was considered a stronger electron donor than triphenylphosphine. Similarly, pK_a values determined by Trogler and Marzilli (6) show tricyclohexylphosphine to be the stronger base.

A greater basicity in the phosphine ligands is expected to cause a greater distortion in the acetylene due to increased back donation from the metal atom (1). An increase is indeed found, as the bend-back angle of the title compound is 5.6(8)° larger than that found in the triphenylphosphine analogue. The triple bond lengths do not indicate this as clearly, for the increase is 0.005(13) Å, a difference of only 0.4σ. However, a greater distortion of the bond is indicated by the larger reduction in the infrared stretching frequency ν(C≡C) which occurs for the acetylene in the title compound compared to that observed for the triphenylphosphine complex (4).

The greater distortion from linearity of the acetylene ligand might therefore be explained solely on the basis of electronic effects. However, it is apparent that steric considerations play a major role in this complex. That a symmetric cone angle is not applicable to the tricyclohexylphosphine ligand is evident from the disposition of the cyclohexyl groups in this complex. Thus cyclohexyl groups 'bracket' the CF_3 substituents on the acetylene ligand. The distances of approach noted are 2.325 Å (F(1)—2C1H1), 2.434 Å (F3—5C5H2), and 2.34 Å (F4—5C1H1) and steric constraints could be causing the large bend-back angle observed. In an analogous way the presence of the acetylenic triple bond within a small cyclic organic molecule (3) introduced steric constraints which resulted in bend-back angles of 52.7° and 41.3° respectively for the cyclohexyne and the cycloheptyne complexes. At present we cannot unambiguously attribute the magnitude of the bend-back angle observed in this complex to an electronic rather than a steric effect.

Modified cone angle calculations have also been performed, based upon the geometry of this complex.[3] In these calculations the conical symmetry has been removed, and maximum and minimum cone angle values determined for the phosphine ligand. The maximum value agrees well with Tolman's values, as is to be expected from the original hypothesis. The minimum values are more applicable to complexes of this type. It is apparent that the tricyclohexylphosphine ligand is significantly larger than triphenylphosphine, and thus sterically more demanding.

However, the phosphine interactions do not dictate the conformation of the complex. If the plane containing the Pt and the two P atoms is taken as a reference in each complex, then different ligand orientations are observed. In the triphenylphosphine complex, one phenyl ring on P(2) lies closest to the plane, while two rings on P(1) lie above and below the plane, 'bracketing' the ring on P(2). Such a conformation results in a relatively close approach between one CF_3 group and the third phenyl ring on P(1). By contrast, in the tricyclohexylphosphine complex, a cyclohexyl group on each phosphorus atom lies close to the reference plane, with a resulting unfavourable interligand interaction. The greater P—Pt—P angle (110.23(6)° for this study, compared to 100.17(4)° for the triphenylphosphine complex) could result from this interaction. Also the mean Pt—P distance is longer, being 5.4σ greater in the title complex. As a result of this close approach of the cyclohexyl groups to the reference plane, each CF_3 group is 'bracketed' by the two remaining cyclohexyl groups on each phosphorus atom. These observations would seem to indicate that the interactions between the CF_3 groups on the acetylene ligand and the phosphorus substituents are of major importance in the tricyclohexylphosphine complex. These interactions will of course affect the bend-back angles observed, and at present we are unable to distinguish conclusively between electronic and steric effects. Further studies are underway on complexes of hexafluorobut-2-yne with phos-

'Breaking' and formation of hydrogen bonds by proton donor anesthetics

RACHEL MASSUDA AND C. SANDORFY
Département de chimie, Université de Montréal, Montréal (Qué.), Canada H3C 2V1

Received March 21, 1977

RACHEL MASSUDA and C. SANDORFY. Can. J. Chem. **55**, 3211 (1977).

It has been shown previously that halofluorocarbons having anesthetic potency hinder the formation of hydrogen bonds (HB) of the N—H - - - N, O—H - - - O, N—H - - - O=C types and it has been suggested that this is linked to a competitive mechanism involving another type of association. Since some of the most potent and widely used fluorocarbon anesthetics contain a mobile hydrogen atom the question arises if in such molecules the competitive mechanism involves the formation of HB's with the anesthetic as the proton donor instead of, or in addition to, association due to the electron acceptor properties of the higher halogens as seems to be the case for those fluorocarbon anesthetics which contain no hydrogen. Chloroform, halothane, methoxyflurane, enflurane, and 4,5-dichloro-2,2-difluoro-1,3-dioxolane have been studied from this point of view with the result that both mechanisms appear to operate.

RACHEL MASSUDA et C. SANDORFY. Can. J. Chem. **55**, 3211 (1977).

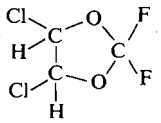
Nous avons montré antérieurement que les fluorocarbures contenant des halogènes supérieurs et ayant un pouvoir anesthésique entravent la formation des liaisons hydrogène (LH) de types N—H - - - N, O—H - - - O et N—H - - - O=C. Nous avons suggéré, en outre, que cela est dû à une association de type différent qui entre en compétition avec l'association par LH. Comme quelques uns des anesthésiques les plus puissants et les plus utilisés contiennent un hydrogène mobile, on peut se demander si cette association compétitive implique la formation d'une autre LH avec l'anesthésique comme donneur de proton, ou en plus des associations qui font intervenir les propriétés électron-accepteur des halogènes supérieurs, comme cela semble être le cas des fluorocarbures anesthésiques ne possédant pas d'atome d'hydrogène, ou les deux à la fois. Nous avons examiné le cas du chloroforme, de l'halothane, du méthoxyflurane, de l'enflurane et du dichloro-4,5 difluoro-2,2 dioxolanne-1,3 et nous concluons que les deux mécanismes contribuent à la dissociation des LH de types N—H - - - N, O—H - - - O et N—H - - - O=C par ces molécules anesthésiques.

Introduction

It has been observed in our laboratory through infrared spectroscopic measurements that fluorocarbon anesthetics containing higher halogens hinder the formation of ('break') hydrogen bonds of the N—H - - - N, O—H - - - O, and N—H - - - O=C type (1–3). Such hydrogen bonds (HB) are typical of the most frequently occurring HB's in the living organism. This effect can become very pronounced at low temperatures. While low temperatures normally favor association, in the presence of such halofluorocarbons the opposite is observed: a large relative decrease in the infrared intensities of the 'associated' NH or OH bands and an increase in the intensity of the 'free' band or bands due to less associated species. A qualitative correlation has been found between anesthetic potency and this HB 'breaking' property by Di Paolo and Sandorfy (2) who have shown by infrared spectroscopic measurements that, in general, halofluorocarbons known to have anesthetic potency are efficient HB breakers. The large changes observed at low temperatures made it easier to observe the smaller effects occurring at room temperature. Similar low temperature measurements have been carried out in the course of the work reported in the present paper.

In order to explain the hindering of HB formation by halofluorocarbon anesthetics it is natural to stipulate that there exists in these solutions a competitive mechanism of association which, under given circumstances, might be energetically favored over HB formation. This mechanism might be the formation of *another* hydrogen bond, charge transfer complex formation, Van der Waals interactions, or a combination of these. Many of the most potent anesthetics contain a mobile hydrogen atom as well as chlorine or bromine. In our previous work, the emphasis was laid on the role of the halogens. In this paper, we concentrate on the role of the mobile hydrogen atom. The following anesthetic compounds have been studied: chloroform $CHCl_3$, halothane $CF_3CHClBr$, enflurane

CF_2HOCF_2CHFCl, methoxyflurane CH_3OCF_2-$CHCl_2$, and 4,5-dichloro-2,2-difluoro-1,3-dioxolane henceforth abbreviated as DDD:



This latter compound has been recently prepared and proposed as an anesthetic by Denson *et al.* (4). Our aim has been to ascertain if a competitive formation of HB's of the C—H - - - N or C—H - - - O type takes place when these molecules are added to solutions of amines, amides, or alcohols which are engaged in HB's of the N—H - - - N, N—H - - - O=C, or O—H - - - O type.

Experimental

The solvents used were 1:1 mixtures of Freon-11 ($CFCl_3$) and methylcyclohexane (FM), or methylcyclohexane-d_{14}; the latter was needed for the investigation of the CH stretching bands. These solvents set to a glass at about −150°C; they are still glasses at liquid nitrogen temperature. The nondeuterated solvents were dried over P_2O_5 and distilled. Chloroform was washed several times with water, dried, and distilled. The other anesthetic compounds were high purity commercial products (Ayerst Laboratories for halothane, Abbott Laboratories for enflurane, and Pitman-Moore for methoxyflurane). The absence of any major impurity was verified by gas chromatography. The sample of 4,5-dichloro-2,2-difluoro-1,3-dioxolane (DDD) was supplied to us by D. D. Denson. All samples were stored over molecular sieves. The samples of amines, amides, and alcohols were all purified by distillation. The deuterated ones were obtained from Merck, Sharp and Dohme of Canada Ltd. and were used without purification. Halothane-*d* and methoxyflurane-d_1 were prepared by the method of Hine *et al.* (6). The disappearance of the CH bands was observed by infrared and nmr spectroscopy. The estimated yield was 97 and 89%, respectively. All preparations of solutions and the filling of cells were carried out in a dry box under nitrogen atmosphere.

The spectra were measured with a Perkin-Elmer model 621 infrared spectrophotometer at temperatures ranging from room to liquid nitrogen temperature. The low temperature cells were described previously (5).

The limits of error affecting the intensity measurements in these low temperature spectra are hard to estimate. Although every effort has been made to standardize the conditions of the cooling down procedure as much as possible the variations between repeated measurements remained nonnegligible. For this reason, we refrain from presenting quantitative results. However, we indicate the observed trends where they are clearly beyond possible experimental error. By 'intensity' we mean roughly estimated integrated intensities obtained by planimetering out the area under the bands taking approximate account of mutual overlapping between bands. A new series of works is underway in our laboratory using a nearly free-standing combination band with all spectra measured at room temperature.

Results

Our results indicate that HB formation takes place between our five anesthetic compounds and the amines, alcohols, and amides with the anesthetics as proton donors. The evidence is as follows.

Association with Amines

Figure 1*a* shows the NH stretching band for a 0.6 *M* solution of diethylamine in FM. The associated band which appears at 3268 cm^{-1} at 22°C increases in intensity on lowering the temperature and shifts to lower frequencies. At −180°C, a weak free NH band is still present at 3310 cm^{-1} and the much stronger associated band moves to 3224 cm^{-1}. Figure 1*b* shows the NH stretching band for a similar amine solution with 1.4 *M* chloroform added. It is observed that the growth of the associated band on lowering the temperature is much slower. At −150°C, for example, the free band is still more intense than the associated band indicating the much lesser extent of N—H - - - N association. Thus the HB 'breaking' property of chloroform appears clearly.

Similar observations have been made on chloroform-*d*, halothane, halothane-*d*, methoxyflurane, methoxyflurane-d_1, enflurane, and DDD. To illustrate these conditions in Fig. 2 the apparent molar extinction coefficient (computed with the initial room temperature concentration but corrected for changes in volume on lowering the temperature) has been plotted against temperature for the NH stretching band of diethylamine, first with no anesthetic present (curve *A*, concentration 0.61 *M*) and then for an equimolar (0.48 *M*) mixture of diethylamine and enflurane. At moderately low temperatures the difference is slight but from about −50°C it becomes rather sizeable. Similar plots have been obtained for the other four anesthetics.

The next step naturally consists of looking at the CH stretching band of chloroform and the other anesthetics. In order to avoid interference from the CH vibrations of diethylamine and from the methylcyclohexane component of the solvent (FM) we had to use $(CD_3)_2NH$ in a 1:1 mixture of $CFCl_3$ and methylcyclohexane-d_{14}. The associated CH stretching band appeared clearly in all cases between 2950 and 2900 cm^{-1}

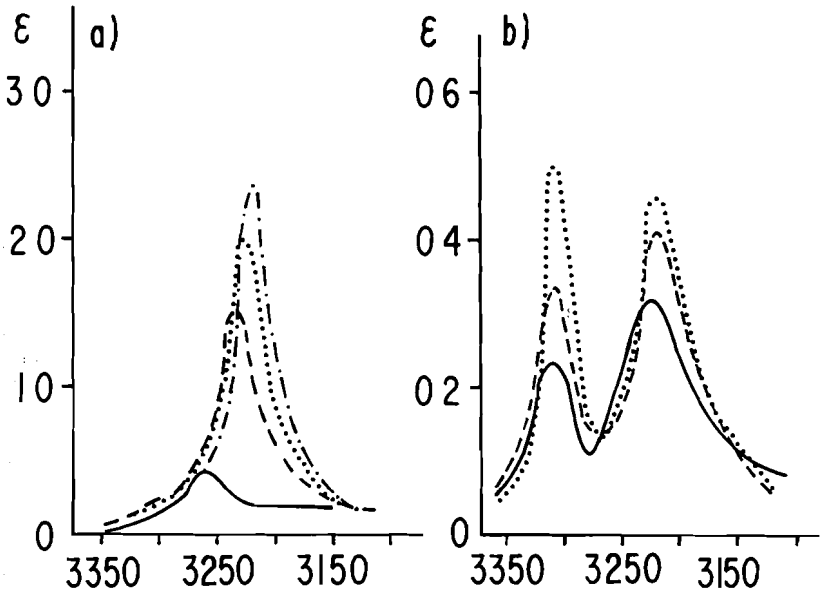


FIG. 1. (*a*) The infrared NH stretching band of a 0.6 *M* solution of diethylamine in a 1:1 mixture of $CFCl_3$ and methylcyclohexane (FM) at different temperatures. (*b*) The same with a 1.4 *M* $CHCl_3$ added to the solution. (Note the change of scale.) Apparent molar extinction coefficients (ℓ mol^{-1} cm^{-1}) against wave numbers in cm^{-1}. — −50°C; - - - −120°C; ··· −150°C; -·-·- −180°C.

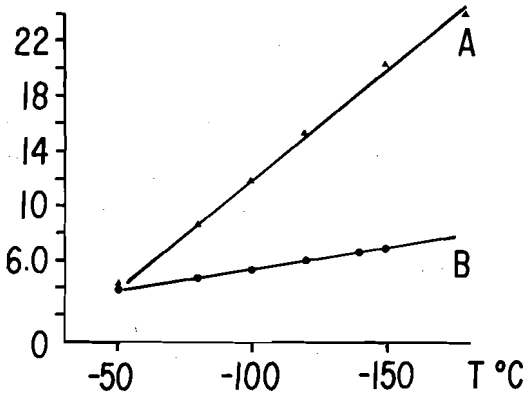

FIG. 2. Plot of the apparent molar extinction coefficient of the associated NH stretching band of diethylamine against temperature, from −50 to −180°C. Curve *A*: 0.61 *M* in FM, no anesthetic present. Curve *B*: equimolar mixture (0.48 *M*) of diethylamine and enflurane in FM.

(Table 1). The intensity of this band increases gradually for all our anesthetics with decreasing temperature and the band shifts to lower frequencies. For chloroform the intensity increased by a factor of six on lowering the temperature to −100°C and the band shifted to 2909 cm^{-1}. Enflurane which has two CH groups has also two free CH stretching bands, at 3023 and 2998 cm^{-1}. The latter is believed to correspond to the associated band at 2932 cm^{-1}. For methoxyflurane the presence of the methyl group gives rise to additional CH bands and we see four of these at 2960, 2910, and 2860 cm^{-1} while the band related to the tertiary CH group is at 3006 cm^{-1}. The increases in the intensity on lowering the temperature were in the order chloroform > halothane > methoxyflurane > enflurane > DDD. At the same time the intensity of the NH stretching band increased but much less than for diethylamine in solutions containing no anesthetics. This slowing down of the rate of increase was greatest for chloroform, > halothane > enflurane.

The first overtone of the CH bending mode is observed at 2398 and 2500 cm^{-1} for the free and associated species, respectively. The associated band increases in intensity, lowering the temperature as does the associated CH stretching band.

The free CD stretching band of $CDCl_3$ appears at 2250 cm^{-1}. In the presence of diethylamine an associated CD band appears at 2187 cm^{-1} at room temperature ($\Delta\nu$ = 63 cm^{-1}). The intensity of this band increases on lowering the temperature and it broadens on its low frequency side. Figure 3 shows the associated CD stretching band at different temperatures.

*N-methylacetamide: [a]2238 cm^{-1}; [b]2220 cm^{-1}; [c]2182 cm^{-1}; [d]2230 cm^{-1}.

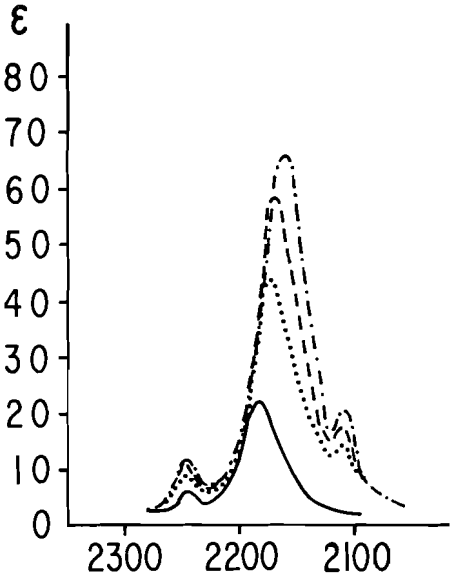

FIG. 3. The associated CD stretching band of $CDCl_3$ (0.88 *M*) at different temperatures in a solution of FM containing 0.50 *M* of diethylamine. Only the free band is seen in the absence of diethylamine. Apparent molar extinction coefficients against wave numbers. — −20°C; ··· −80°C; - - - −120°C; -·-·- −150°C.

The apparent increase in the intensity of the free band is largely due to overlap with the strong associated band. The weak band at the low frequency side of the associated band belongs probably to a more highly associated species (possibly a trimer) but we made no attempt to ascertain this.

Halothane-*d* exhibits two free CD stretching bands, at 2260 and 2218 cm^{-1}, respectively. The splitting is probably due to Fermi resonance. In the presence of diethylamine two additional bands appear, one at 2203, the other at 2150 cm^{-1} ($\Delta\nu$ = 57 and 68 cm^{-1}).

For methoxyflurane-d_1 the free CD band appears at 2245 cm^{-1}, the associated band at 2175 cm^{-1} ($\Delta\nu$ = 70 cm^{-1}). For both halothane-*d* and methoxyflurane-d_1 the associated band increases in intensity on lowering the temperature.

In all cases the increase in the intensity of the CH (or CD) bands was accompanied by the decrease of the NH bands showing that C—H - - - N and N—H - - - N HB formation compete with each other in these systems.

Association with Alcohols

In these studies we chose *tert*-butanol. In an FM solution its well known (composite) associated OH stretching band, centered at 3380 cm^{-1}, increases in intensity regularly with decreasing temperature. This increase is strongly reduced in the presence of chloroform or our other anesthetics (Fig. 4). At the same time the associated CH or CD band of the anesthetics appears and its intensity increases with decreasing temperature. In the presence of the anesthetics the *free* OH band is still seen at −20°C while it has disappeared in their absence.

The wave numbers of the free and associated CH bands are given in Table 1. The associated CD stretching band of $CDCl_3$ also increases in intensity on lowering the temperature, with a slight shift to lower frequencies (2230 cm^{-1} at −50°C and 2218 cm^{-1} at −180°C; its intensity

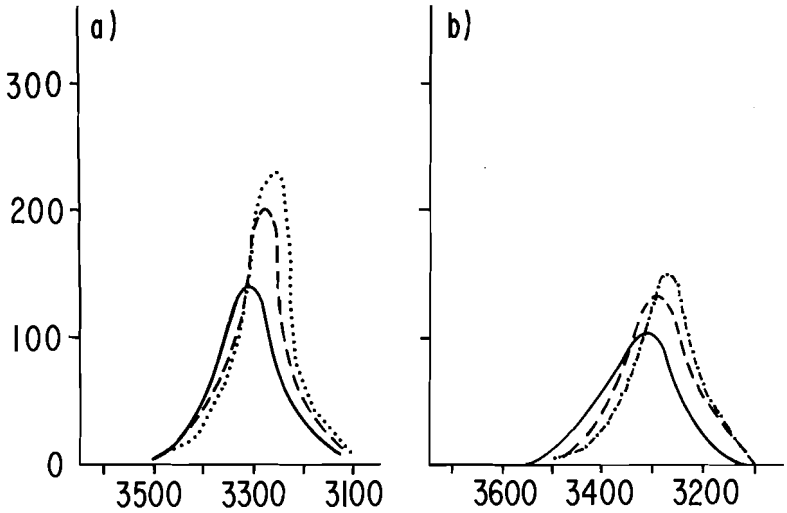

FIG. 4. (*a*) The infrared OH stretching band of *tert*-butanol in a 0.2 *M* solution in FM at different temperatures. (*b*) The same with 0.80 *M* $CDCl_3$ added to the solution. Apparent molar extinction coefficients against wave numbers. — −50°C; - - - −100°C; ··· −120°C; -·-·- −150°C.

increases about seven-fold). Deuterated halothane and methoxyflurane gave similar results. For deuterated halothane the associated CD stretching band is again split into two (2210 and 2182 cm^{-1}).

Association with Amides

The chosen amide, *N*-methylacetamide, presented us with some problems due to its insolubility in FM although the solubility increased in the presence of the anesthetics. This makes the determination of the concentrations more uncertain than in the previous case. We studied its association with chloroform-*d*, halothane-*d*, and methoxyflurane-d_1.

With $CDCl_3$ the free CD stretching band is at 2248 cm^{-1} (room temperature) (Table 1). On lowering the temperature, a slightly shifted associated band appears, first as a shoulder at 2238 cm^{-1}, then it increases in intensity and eventually becomes predominant. At room temperature the frequencies of free and associated NH stretching bands were measured as 3475 and 3312 cm^{-1} respectively. The latter shifted to 3268 cm^{-1} at −150°C. The first overtone of the bending band was measured as 3110 cm^{-1} at −20°C and shifted gradually to higher wave numbers on lowering the temperature. In general the CD bands were broader and less well defined for amides than for association with amines and alcohols.

With halothane-*d* again two free and two associated CD stretching bands are found but the lower free and the higher associated band coalesce into one broad band near 2220 cm^{-1}. The higher free band is at 2260 cm^{-1} and the lower associated band at 2182 cm^{-1}. The associated bands increase in intensity on lowering the temperature. With methoxyflurane the free CD stretching band is at 2248 and the associated one is at 2230 cm^{-1} and behaves similarly, but at −80°C precipitation occurred.

As in the case of amines and alcohols the increase in CH association is accompanied by a decrease in NH association. The intensity of the CD bands followed the order chloroform > halothane > methoxyflurane while the slowdown in the temperature increase of the N—H - - - O=C band followed the order chloroform > methoxyflurane > halothane.

We also studied a tertiary amide, *N*,*N*-dimethylacetamide and its deuterated analog against our five anesthetics. The wave numbers of the CH and CD stretching bands are included in Table 1. On lowering the temperature, the associated bands increase in intensity and shift to lower frequencies (Fig. 5) in a way similar to that observed for *N*-methylacetamide. The free and associated CD bands of $CDCl_3$ were mutually overlapped with an apparent maximum at 2245 cm^{-1}.

In all the cases discussed above, we checked our spectra for the self-association of our anesthetic molecules. Even at the lowest tempera-

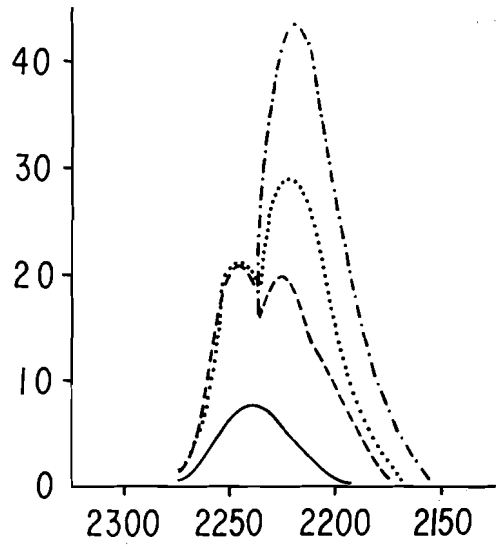

FIG. 5. The CD stretching band of methoxyflurane (0.28 *M*) associated with *N*,*N*-dimethylacetamide (0.25 *M*) at different temperatures in FM. Apparent molar extinction coefficients against wave numbers. — 25°C; - - - −10°C; ··· −80°C; -·-·- −120°C.

tures it caused only a slight broadening and intensification and a very slight shift of the free bands and no new bands due to self-association were ever found. In no case could it have interfered with the associations discussed above.

Discussion and Conclusions

It has been known for many years that the frequencies, intensities, and shapes of infrared absorption bands due to species associated by HB's are affected by solvent effects in addition to being affected by the formation of the HB itself (see, for example, refs. 7–11). The nature of these solvent effects has been investigated in the case of halogenated solvents by a number of different methods and various types of interactions, contact pair formation, charge transfer, 'electrostatic' interactions have been invoked (12–15).

The formation of HB's involving chloroform and similar molecules as proton donors was also established a long time ago (16–20), including, among many others, HB formation between chloroform and trimethylamine (21–25).

The investigation reported in this paper concerned five compounds widely used as anesthetics. Like the many fluorocarbons containing higher halogens which were studied previously in our laboratory, these compounds have been found to be potent hydrogen bond breakers. It has been shown that the remaining hydrogen atoms in these anesthetics do enter HB's. Brown and Chaloner (26) reported nmr evidence to the same effect.

The main point emerging from these observations is the following. Many of the fluorocarbon molecules which were studied by Di Paolo and Sandorfy (2, 3) do not contain hydrogen at all yet they are efficient HB breakers (CF_3Br, C_3F_7Br, $CF_2Br—CF_2Br$, and several fluoroiodides). Actually, when the work reported here was undertaken, we were wondering if chloroform's action is through proton donation or through interactions involving its chlorines or both. Combining the previous results of Di Paolo and Sandorfy and those presented in this paper leads to the conclusion that both mechanisms must be operating in halofluorocarbon anesthetics which contain a mobile hydrogen. The relative importance of the two is likely to vary from one anesthetic to the other. At the present stage, this cannot be assessed quantitatively because of the difficulties involved with the experimental techniques, but it seems that the mechanism by proton donation is the preponderant mechanism for chloroform while both mechanisms are important for halothane, methoxyflurane, enflurane, and DDD.

In a recent work, Martire *et al.* (14) applied nmr and gas chromatographic methods to investigate the thermodynamics of the association between chloroform and an ether, a thioether, and an amine. They found evidence to the effect that chloroform enters associations with these molecules both by forming HB's as a proton donor and by interacting with the chlorine atoms, although the latter interaction is probably not of the charge transfer type. This is entirely in line with the above interpretation of our results.

Although our work was done on model compounds the HB's they form are similar in type and energy to those which the living organism uses most. For this reason, we continue to believe that our observations do have relevance to the problem of the mechanism of anesthetic action.

Inhalation anesthetics are known to exert their action without undergoing chemical reactions (although they might be metabolized later) and recent theories of anesthesia (27, 28) concentrate on the perturbation of the permeability of the nerve cell membrane by the anesthetics. Since the permeability depends on the

conformation of the proteins and lipids which constitute the membrane and the right conformation is insured by intermolecular associations both within these macromolecules themselves and with the molecules forming their environment, the study of the possible perturbations of these intermolecular associations by anesthetics appears to be necessary and important for the elucidation of the mechanism of anesthesia.

We plan to present in subsequent publications the results of our efforts to obtain more quantitative relationships, our work done on systems representing in vivo conditions more closely as well as studies on anesthetics other than those of the fluorocarbon type.

Acknowledgements

Our thanks are due to Dr. K. C. Cole for helping us with his experience at the beginning of this work.

We are indebted to Dr. D. D. Denson for a highly stimulating conversation and for supplying us with samples of anesthetics including that of 4,5-dichloro-2,2-difluoro-1,3-dioxolane which he synthesized and to Dr. R. Denis from Hôpital Notre-Dame of Montreal for other anesthetics samples.

We thank the National Research Council of Canada and the Ministère de l'éducation du Québec for financial support.

Received March 8, 1977

ARLEN VISTE and DONALD E. IRISH. Can. J. Chem. **55**, 3218 (1977).

Raman and infrared spectra have been recorded for polycrystalline samples of $TlClO_3$, $TlBrO_3$, and $TlIO_3$ at room temperature. The vibrational spectra of these rhombohedral ($R3m$, C_{3v}^5) crystals are closely related to each other, and to single crystal Raman spectra of isomorphous $RbClO_3$ and $KBrO_3$ reported by others. Spectral assignments are made. The unimolecular unit cell yields no correlation field splitting, but lack of a center of inversion leads to TO/LO splitting of each active mode in these uniaxial piezoelectric crystals. Relationships between the thallium(I) halates and the NaN_3 and MXY_3 perovskite structures are considered.

ARLEN VISTE et DONALD E. IRISH. Can. J. Chem. **55**, 3218 (1977).

On a enregistré les spectres Raman et infrarouges d'échantillons polycristallins de $TlClO_3$, de $TlBrO_3$ et de $TlIO_3$ à température de la pièce. Les spectres vibrationnels de ces cristaux rhomboédriques ($R3m$, C_{3v}^5) se ressemblent beaucoup entre eux et ressemblent aussi aux spectres Raman de cristaux uniques de $RbClO_3$ et $KBrO_3$ isomorphes rapportés par d'autres. On effectue des attributions spectrales. La maille unitaire unimoléculaire ne fournit aucun couplage de corrélation de champ mais le fait qu'il lui manque un centre d'inversion conduit à une division TO/LO de chaque mode actif dans ces cristaux uniaxiaux piézoélectriques. On considère les relations entre les halates de thallium(I) et les structures perovskite de NaN_3 et de MXY_3.

[Traduit par le journal]

Introduction

Thallium halates, $TlXO_3$, with X = Cl, Br, or I, are isomorphous, each having the $KBrO_3$ structure, the space group $R3m$ (C_{3v}^5), and one formula unit per unit cell (1). Both $KBrO_3$ (2) and the isomorphous $RbClO_3$ (3–5) have been studied by single crystal Raman techniques. The present investigation concerns the observation and interpretation of the Raman and infrared spectra of polycrystalline thallium halates. These are structurally related, to various degrees, with NaN_3, space group $R\bar{3}m$ (D_{3d}^5), with linear azide ions rather than pyramidal halate (6) and with cubic perovskite, for which comparison is made by Wyckoff (1). Existing interpretations of the vibrational spectra of $KBrO_3$ (2), $RbClO_3$ (3–5), NaN_3 (7–9), and perovskite MXY_3 (10), have aided us in the present study.

Experimental

The thallium halates were prepared by simple precipitation from aqueous solution, as follows: $TlIO_3$ from $TlNO_3$ and KIO_3 solutions (11), $TlBrO_3$ from $TlNO_3$ and $KBrO_3$ (12), and $TlClO_3$ from $TlNO_3$ and $NaClO_3$ by an adaptation of the $TlBrO_3$ preparation (12) and solubility data (13). $TlClO_3$, the most soluble of the three (14), was recrystallized from water. The chemicals used in the preparations were $TlNO_3$, Laboratory BDH Reagent; KIO_3, Baker Analyzed Reagent 99.7%; $KBrO_3$, Fisher Certified Reagent; $NaClO_3$, Baker Analyzed Reagent.

Raman spectra, excited by the 514.5 nm or 488.0 nm line of a Coherent Radiation Model 52G argon ion laser, were recorded with a Jarrell-Ash 25–100 1.0-m double Czerny-Turner monochromator equipped with an SSR model 1105/1120 photon-counting system. Spectral slit widths of 2.4 or 1.2 cm^{-1} were used. Polycrystalline samples were generally in glass melting point capillaries. Low laser power was necessary with $TlIO_3$ and $TlBrO_3$ because of a tendency toward decomposition in the beam when at full power. $TlClO_3$ appeared to be more stable in this regard. A trace of NO_3^- impurity in the first $TlClO_3$ product, prior to recrystallization, was suggested by the appearance of a Raman line at about 1039 cm^{-1}; the strongest line of NO_3^- (ν_1) appears at 1042 cm^{-1} in pure $TlNO_3$ (15). This trace impurity was largely removed by recrystallization. Infrared spectra were also recorded, principally as Nujol mulls between AgCl or polyethylene windows, with the Perkin-Elmer 180 spectrophotometer. Except for shoulders and perhaps broad bands, the frequencies reported should be reliable to about ± 2 cm^{-1} for Raman and about ± 5 cm^{-1} for infrared spectra. All measurements were carried out at room temperature, $\simeq 22°C$.

Results and Discussion

Infrared and Raman data for $TlClO_3$, $TlBrO_3$, and $TlIO_3$ are presented in Tables 1 and 2. The

bands are identified by numbers which increase with increasing cm^{-1} for a given species; this scheme is identical to that used by Hwang and Solin (5) and thus facilitates comparison. Data for $RbClO_3$ (5) and $KBrO_3$ (2) are also tabulated. Photographs of Raman spectra of $TlXO_3$ (X = Cl, Br, I) are shown in Figs. 1–4; photographs of infrared spectra of these thallium halates, as Nujol mulls, are presented in Fig. 5. It is clear that the infrared spectra exhibit the distortion characteristic of strongly absorbing crystals and thus the frequencies of minimum transmission could differ from the frequencies of the TO modes. In fact, however, they agree closely with the Raman frequencies.

The free halate ion XO_3^-, of C_{3v} symmetry, has stretching modes ν_1 (A_1) and ν_3 (E), and bending modes ν_2 (A_1) and ν_4 (E). In solution, the Raman frequencies for ClO_3^-, BrO_3^-, and IO_3^- respectively are as follows (16): ν_2 (A_1), 610, 421, 390 cm^{-1}; ν_1 (A_1), 930, 806, 779 cm^{-1}; ν_4 (E), 479, 356, 330 cm^{-1}; ν_3 (E), 982, 836, 826 cm^{-1}. The irreducible representations of the point group, site group, and factor group are correlated in Table 3. There is one molecule of $TlXO_3$ per unit cell, and for the XO_3^- halate ion the point group of the free ion as well as the site group and the factor group are all C_{3v}. Similarly for the Tl^+ cation, C_{3v} is both the site group and the factor group. Thus, treatment by standard methods (10, 15, 17–20) indicates that correlation field splitting should not occur in this system.

Vibrational modes of a crystal which are infrared active are split into transverse and longitudinal components: TO/LO splitting (21). For a thallium halate $TlXO_3$, A_1 and E modes are active in both the infrared and the Raman spectra, prior to TO/LO splitting, whereas the A_2 mode is inactive. As a result, the number of bands in the Raman spectrum should be doubled by this TO/LO splitting (Table 3). However, for the thallium halates, as for $KBrO_3$ and $RbClO_3$ (5), even though infrared-active modes are subject to TO/LO splitting, in first approximation only the TO modes appear in the infrared spectrum (2, 5, 21). Table 3 indicates this. For directions of phonon propagation other than parallel or perpendicular to the C_3 or optic axis ($0° < \theta < 90°$), the phonon frequencies vary smoothly between their 0° and 90° limiting values (5, 20, 22). For such intermediate directions of phonon propagation, if short-range anisotropy forces

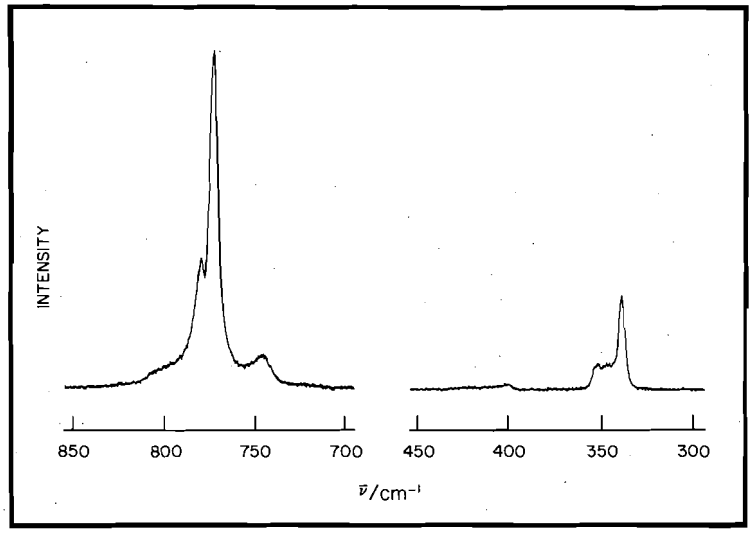

FIG. 2. Portions of Raman spectra of polycrystalline $TlBrO_3$, for the internal mode region.

(SRAF) predominate then the phonon may be idealized as having definite symmetry (A_1 or E) but mixed polarization (TO, LO), whereas if instead long-range electrostatic forces (LREF) predominate then the phonon may be idealized as of definite polarization (TO or LO) but mixed symmetry (A_1, E) (5, 23). The corresponding phonon dispersion curves of frequency vs. θ have been determined through single crystal Raman measurements for $RbClO_3$ by Hwang and Solin (5) and for $KBrO_3$ by Unger and Haussühl (2). As a further cautionary note, Hwang and Solin (5) have pointed out that in the general (real) case, strictly speaking "at oblique angles, each polar phonon mixes with every other polar phonon in the crystal".

In the present study, polycrystalline samples of the thallium halates have been observed because single crystals of suitable size and quality could not be grown. The relation of Raman spectra of

such polycrystalline substances to dispersion curves of single crystals has been discussed by Burns and Scott (22). The availability of single crystal phonon dispersion curves for $RbClO_3$ (5) and $KBrO_3$ (2) is valuable because they have provided model systems for comparison. For these two systems, the ordering of levels agrees except for the order and composition of the states associated with the $3A_1$ and $4E$ TO and LO modes (2, 5). Beyond the ordering of levels, one notes that only the $1E$(TO), $2E$(TO), $3E$(TO), and $4E$(TO) frequencies are independent of direction of phonon propagation (5). For the other phonon dispersion curves, one anticipates a tendency for the directions with large θ (approaching 90°) to appear more prominently in the spectrum than those with small θ, due in part to simple statistics since the random distri-

bution of orientation population varies as sin θ (22).

Using these considerations as helpful guides, the observed bands for the Raman and infrared spectra of $TlXO_3$ (X = Cl, Br, I) have been assigned, as summarized in Tables 1 and 2. The assignments are quite compatible with the ordering of levels in the isomorphous model compounds $RbClO_3$ (5) and $KBrO_3$ (2). The latter two systems differ in the order of the upper four levels. In $RbClO_3$, the order is given by $3A_1$(TO) < $3A_1$(LO) < $4E$(TO) < $4E$(LO), whereas in $KBrO_3$ $4E$(TO) < $3A_1$(TO) < $3A_1$(LO) < $4E$(LO). Unger and Haussühl (2) note that in the phonon dispersion curves, a symmetry selection rule prevents a quasi E [$4E$(TO) → $4E$(LO)] curve from crossing a quasi A_1 [$3A_1$(LO) → $3A_1$(TO)] curve. In consequence of this and the level ordering, in this region in $KBrO_3$ the curves may be described as quasi TO [$4E$(TO) → $3A_1$(TO)] and quasi LO [$3A_1$(LO) → $4E$(LO)], whereas in $RbClO_3$ the corresponding phonon dispersion curves are instead quasi $3A_1$[$3A_1$(LO) → $3A_1$(TO)] and quasi $4E$ [$4E$(TO) → $4E$(LO)] as the phonon direction θ varies from 0° to 90° (2, 5). Thus, for these four modes, it appears that there is dominance by LREF in $KBrO_3$ but by SRAF in $RbClO_3$ (2, 5).

In the case of the thallium halates, the $KBrO_3$ order of these upper four levels appears to hold at least for $TlIO_3$ and $TlBrO_3$, and probably for $TlClO_3$ as well. This conclusion is based on the following considerations. First, on the basis of the two alternative patterns of phonon dispersion curves (2, 5) and their relationship to the polycrystalline Raman spectrum (22), it is anticipated that the band intensities will be related as $3A_1(LO) < 3A_1(TO)$ and $4E(LO) < 4E(TO)$. Second, as noted earlier, to a first approximation the infrared spectrum is expected to display the TO rather than the LO component of each mode (2, 5, 21). Third, for ClO_3^- in $RbClO_3$ (5) as for the planar NO_3^- (15) the symmetric stretch ν_1 appears more intense in the Raman than the antisymmetric stretch ν_3, and similarily $3A_1(TO)$ will be more intense than $4E(TO)$ in $TlXO_3$ thallium halates.

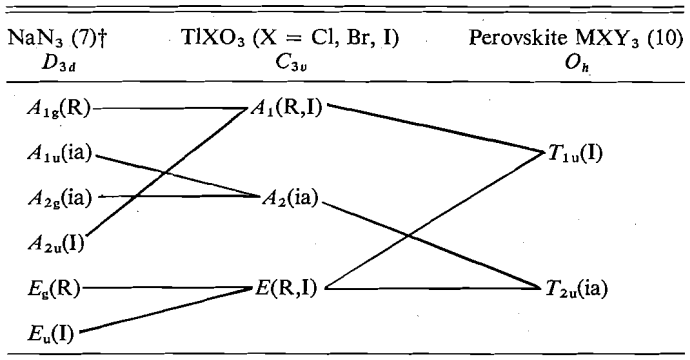
To illustrate the application of these interpretive principles, consider the case of $TlIO_3$. For the lower two bands in the ν_1, ν_3 region, the intensity of the 711 cm^{-1} Raman band is substantially less than that of the 740 cm^{-1} Raman band. This is compatible with the $KBrO_3$ order but not with the $RbClO_3$ order, since for the latter it would imply a greater intensity for $3A_1$-(LO) (as $\theta \rightarrow 0°$) than for $3A_1(TO)$ (as $\theta \rightarrow 90°$), which is unlikely. Similar arguments apply to $TlBrO_3$. The resulting $KBrO_3$ order of levels for $TlIO_3$ and $TlBrO_3$ also leads to a greater Raman intensity for $3A_1(TO)$ (ν_1) than for $4E(TO)$ (ν_3), a reasonable result. In going from $TlIO_3$ to $TlBrO_3$, the intensity of $4E(TO)$ and $4E(LO)$ fall off in comparison with that of $3A_1(TO)$ and $3A_1(LO)$. In addition the separation between $3A_1(TO)$ and $3A_1(LO)$ decreases from about 20 cm^{-1} to about 7 cm^{-1}. Apparently these trends continue, in going further to $TlClO_3$. The resulting spectrum (Fig. 1) is less clearcut in this region than that of $TlBrO_3$ (Fig. 2) or $TlIO_3$ (Fig. 3). However, it appears that $TlClO_3$, like $TlBrO_3$ and $TlIO_3$, conforms to the $KBrO_3$ level ordering in this ν_1, ν_3 region. The magnitude of the LO/TO splitting has been related to the square of the dipole derivative, $(\partial\mu/\partial Q)^2$, and thus a large separation of the components implies an intense infrared absorption (24–27). Although infrared band overlap is severe, the infrared intensities suggest that the splitting $4E(LO) - 4E(TO)$ should be greater than $3A_1(LO) - 3A_1(TO)$, as assigned.

The assignment of the levels arising from the other internal modes of XO_3^- (ν_2 and ν_4) is straightforward, since these occur reasonably well separated from other modes. However, the falling off in Raman intensity of these bending modes in $TlBrO_3$ and $TlIO_3$ in comparison with $TlClO_3$ is worth noting. The Raman intensities of $2A_1(TO)$ and $2A_1(LO)$ in particular drop to almost vanishingly small magnitudes.

The lattice modes of the $TlXO_3$ thallium halates are assigned in Table 2. The close relationships and smooth frequency trends for the lattice modes are clearly exhibited in the Raman spectra for the lattice mode region, displayed in Fig. 4. The order of levels utilized in the band assignments is as in $RbClO_3$ (5) and $KBrO_3$ (2). The approximate accidental degeneracy of $1A_1(TO)$ and $1E(TO)$ in $TlIO_3$ cited in Table 2 is inferred from the trend toward coalescence of these two bands observed in $TlClO_3$ and $TlBrO_3$. The missing $1A_1(LO)$ is expected to be of low intensity and probably a shoulder on the low frequency side of the $1E(LO)$ band, on the basis of the phonon dispersion curves of $RbClO_3$ (5) and $KBrO_3$ (2). However, the intensity of this missing $1A_1(LO)$ is apparently too low to confirm this expectation in the present case.

Comparison of frequencies within Table 2 indicates that the expected inverse dependence of frequencies of translatory modes on ionic mass is borne out. (Formula weights of the various ions are: Tl^+ 204.4, Rb^+ 85.5, K^+ 39.1, ClO_3^- 83.5, BrO_3^- 127.9, IO_3^- 174.9.) From Table 3 it follows that $1A_1(TO)$, $1A_1(LO)$, $1E(TO)$, and $1E(LO)$ are essentially translatory modes, and $2E(TO)$ and $2E(LO)$ are rotatory modes. There is a trend toward decreasing frequency for each of the translatory modes with increasing anion mass in the sequence $TlClO_3$, $TlBrO_3$, $TlIO_3$, and with increasing cation mass in the pairs $RbClO_3$, $TlClO_3$ and $KBrO_3$, $TlBrO_3$. The dependence on cation mass is considerably stronger for the translatory modes than for the rotatory modes, as seems reasonable. In connection with such mass comparisons, it is helpful that the cation radii are rather similar. For coordination numbers 12 and 8 respectively these are: Tl^+ 1.76, 1.60; Rb^+ 1.73, 1.60; K^+ 1.60, 1.51 Å (28). Moreover, in contrast to the translatory modes, the proposed rotatory modes $2E(TO)$ and $2E$-(LO) actually increase slightly in frequency in the series $TlClO_3$, $TlBrO_3$, $TlIO_3$ (Table 2). Such an increase would be quite out of character for a translatory mode. At first sight it also seems surprising for a rotatory mode, in view of the expected inverse dependence of rotatory

TABLE 4. Correlation diagrams*



*R = Raman active; I = infrared active; ia = inactive.
†NaN_3 has no modes of A_{1u} or A_{2g} symmetry.

mode frequency on XO_3^- anion moment of inertia, and in turn the involvement in this of the atomic weight of X for (R_x, R_y). However, it is pertinent to note that the Yatsimirskii thermochemical radii of the anions are ClO_3^- 2.00, BrO_3^- 1.91, IO_3^- 1.82 Å (29, 30), with the counterintuitive decrease in size due in part perhaps to differences in bond angles (31). Since the trends in atomic weight of X and Yatsimirskii thermochemical radii of XO_3^- tend to result in opposing influences on the rotatory mode frequencies, the slight increase in frequency from $TlClO_3$ to $TlIO_3$ does not appear to be unreasonable for the rotatory modes.

Bhagavantam and Venkatarayadu argue that among lattice modes, rotatory modes should normally tend to be more intense than translatory modes in the Raman spectrum (32). This appears to be the case in $RbClO_3$ for the $2E$(TO) mode in particular (5), and similarly for the Raman-active rotatory mode (E_g) of the planar NO_3^- ion in $LiNO_3$ and $NaNO_3$ (15). For $TlXO_3$ thallium halates, however, the rotatory mode Raman intensities do not seem to be as prominently enhanced. For example in $TlClO_3$ and $TlBrO_3$ the $2E$(TO) mode is considerably more intense than the translatory $1E$(LO), but roughly comparable to the translatory $1E$(TO) (Fig. 4). The significance of this more moderate Raman intensity of the rotatory modes in the $TlXO_3$ thallium halates is not clear. It may for example simply serve as a reminder that a conceptual distinction between translatory and rotatory lattice modes, while very useful, is not without its limitations (33). Since in our assignments the $1E$(TO) translatory mode and the $2E$(TO) rotatory mode in particular are of the same symmetry, some mixing of translatory and rotatory character is allowed by symmetry. It is conceivable that the admixture of a limited amount of rotatory character in the nominally translatory $1E$(TO) might appreciably enhance its intensity, along the lines of the observations.

Isotope splitting of vibrational bands by ^{35}Cl and ^{37}Cl has been observed in $RbClO_3$, with $2A_1$(TO) split by 4 cm^{-1} and $3A_1$(TO) split by 7 cm^{-1} (5). In $TlClO_3$, isotope splitting of $2A_1$-(TO) is indicated by the appearance of a shoulder on the low-frequency side of the band; the magnitude of the splitting is about 5 cm^{-1} (Fig. 1). Splitting of the $3A_1$(TO) band is not apparent, due perhaps to band overlap by $4E$(TO) and the quasi TO phonon dispersion curve connecting $4E$(TO) and $3A_1$(TO).

The $TlXO_3$ thallium halates are related to some extent to two other crystal types: NaN_3 (6, 8, 9) and perovskite MXY_3 (10).

NaN_3 (6, 7) belongs to space group $R\bar{3}m$ (D_{3d}^5). Placement of the Na^+ and N_3^- ions is similar to that of Tl^+ and XO_3^- in $TlXO_3$, with the C_∞ axis of N_3^- and the C_3 axis of XO_3^- aligned along the C_3 axis of the unit cell. However, NaN_3 has a center of inversion which is not present in $TlXO_3$. A correlation diagram relating the D_{3d} factor group of NaN_3 and the C_{3v} factor group of $TlXO_3$ is shown in Table 4. Since C_{3v} is a subgroup of D_{3d} and since both NaN_3 and $TlXO_3$ have one molecule per unit cell, the relationship between them is rather close. A thorough study of the lattice dynamics of NaN_3 has been carried out by Rafizadeh and coworkers (7), involving both theoretical calculation of dispersion curves within the Brillouin zone, and experimental neutron scattering with polycrystalline NaN_3. At $\boldsymbol{k} = 0$, in NaN_3 the rotatory E_g mode occurs at 122 cm^{-1}, below the translatory modes E_u(TO) and A_{3u}(TO) at about 175 cm^{-1} and E_u(LO) and A_{2u}(LO) at about 250

cm^{-1} (7). The formula weights of the ions are quite low (Na^+ 23.0, N_3^- 42.0) in comparison with Tl^+ and XO_3^-, and so the position of the translatory modes above the rotatory E_g in NaN_3 is not surprising. The A_{2u}(TO) and E_u(TO) translatory modes in NaN_3 are nearly accidentally degenerate (7), similar to the behavior of the corresponding $1A_1$(TO) and $1E$(TO) translatory modes in the $TlXO_3$ thallium halates (Table 2). The frequency of the rotatory E_g mode in NaN_3 is actually not greatly different from the $2E$(TO) rotatory component in $TlXO_3$ (Table 2); it is slightly lower, due perhaps to a somewhat larger moment of inertia for linear N_3^- than the corresponding moment of inertia of pyramidal XO_3^-.

Finally, consider the MXY_3 perovskite structure with space group $Pm3m$ (O_h^1) (10). Both perovskite MXY_3 and $TlXO_3$ have one molecule per unit cell. The C_{3v} factor group of $TlXO_3$ is a subgroup of the factor group O_h of the perovskite MXY_3, and the corresponding correlation diagram appears in Table 4. From one perspective the thallium halates $TlXO_3$ may be regarded as distorted perovskite structures (1, 32, 34), particularly in the case of the iodate. The relationship involves a trigonal distortion of the perovskite unit cell, together with a transition from an octahedral XO_6 unit to pyramidal XO_3 by the shortening of three X—O bonds and lengthening the other three. (An alternative C_{4v} distortion of the perovskite structure is also known in other systems (22).) The perovskite structure has only lattice modes, which (apart from acoustic modes) consist only of translatory modes: three T_{1u} and one T_{2u}, of which the T_{1u} are infrared active and the T_{2u} inactive; there are no Raman active modes. Trends in the $TlXO_3$ spectra from $TlClO_3$ to $TlIO_3$ appear to be compatible in part with a trend in the direction of the perovskite structure. Thus in the sequence $TlClO_3$, $TlBrO_3$, $TlIO_3$ the ν_2 and ν_4 bending modes [$2A_1$(TO), $2A_1$(LO), $3E$(TO), $3E$(LO)] are approaching one another and becoming markedly less intense, as if collapsing into the perovskite T_{1u} band. Similar movement of the TO and LO frequency components of $1A_1$ and $1E$ can be seen. The $2E$(TO) and $2E$(LO) modes would presumably coalesce with the inactive rotatory mode A_2, into the perovskite T_{2u} mode.

Conclusions

The Raman and infrared spectra of polycrystalline thallium halates $TlClO_3$, $TlBrO_3$, and $TlIO_3$ have been investigated, and the bands assigned. Although there is no correlation field coupling in these crystals, since there is only one molecule per unit cell, the existence of TO/LO splitting is important to the analysis of the spectrum. The band assignments are in accord with the Unger and Haussühl order of levels for $KBrO_3$ (2), though agreeing also in the majority of cases with the $RbClO_3$ order of levels found by Hwang and Solin (5). ^{35}Cl, ^{37}Cl isotope splitting was observed for the $2A_1$(TO) band of $TlClO_3$. Relationships between the results for the $TlXO_3$ thallium halates and the related systems NaN_3 and MXY_3 perovskite have been discussed.

Received March 31, 1977

JAMES P. KUTNEY, GORDON H. BOKELMAN, MASAHIRO ICHIKAWA, EDWIN JAHNGEN, ALUMMOOTTIL V. JOSHUA, PING-HUANG LIAO, and BRIAN R. WORTH. Can. J. Chem. **55**, 3227 (1977).

Detailed investigations involving the electrophilic attack of various reagents on the 3,4-double bond of catharanthine derivatives (e.g. **3**, R = O) furnished a series of novel derivatives of potential use in the syntheses of naturally occurring bisindole alkaloids. These studies include such reagents as peracid, osmium tetroxide, and positive iodine.

JAMES P. KUTNEY, GORDON H. BOKELMAN, MASAHIRO ICHIKAWA, EDWIN JAHNGEN, ALUMMOOTTIL V. JOSHUA, PING-HUANG LIAO et BRIAN R. WORTH. Can. J. Chem. **55**, 3227 (1977).

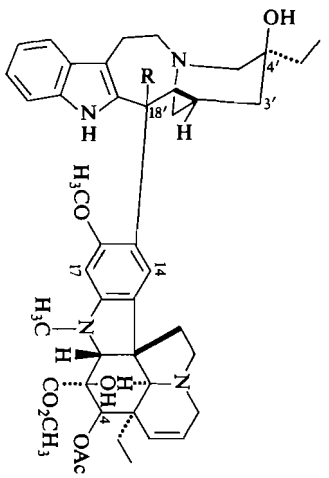
Des études détaillées impliquant l'attaque électrophile de divers réactifs sur la double liaison-3,4 de dérivés de la catharanthine (e.g. **3**, R = O), permettent d'obtenir une série de nouveaux dérivés susceptibles d'être utilisés pour la synthèse d'alcaloïdes bisindoles trouvés dans la nature. Ces études comportent des réactifs tels que les peracides, le tétroxyde d'osmium et de l'iode positif.

[Traduit par le journal]

The bisindole or 'dimeric' alkaloids of which vinblastine (VLB, **1**) may be cited as one of the best known members, are an important class of natural products (for a recent review see ref. 1). Vinblastine and vincristine (**1**, N—CH_3 replaced by N—CHO) are already well known as clinically important anti-tumor agents (2), while other members within this family exhibit considerable potential in this regard. A number of these alkaloids for example, leurosine (3–5), leurosidine (5), and vincadioline (6) differ in the nature of their oxygen functionality at the $C_{3'}$ and $C_{4'}$ positions of the indole unit (see **1**). Thus any research program directed at the synthesis of such bisindole alkaloids via coupling of appropriate indole and dihydroindole units (7–11) must consider, as one of its important phases, the preparation of requisite 3,4-oxygenated indole units. The results of such investigations form the subject of this publication.

Catharanthine (**2**), a major alkaloid in *Catharanthus roseus* G. Don (*Vinca rosea* L.) for which several total syntheses are now available (12, 13), was selected as the starting material in our experiments.

The high reactivity of the indole system and the basic nitrogen atom in **2** toward a variety of electrophilic reagents necessary for addition to the olefinic linkage dictated appropriate protection of these sites in **2**. An electron-withdrawing group present in the indole ring would be expected to reduce its reactivity while removal of the basic nitrogen, perhaps via lactam formation, seemed desirable to remove any undesirable interference at this site of the molecule.



1, R = $COOCH_3$

Reaction of catharanthine (**2**) with potassium hydride in anhydrous tetrahydrofuran at 0°C to form the indole anion and subsequent reaction of the latter with methyl chloroformate provided

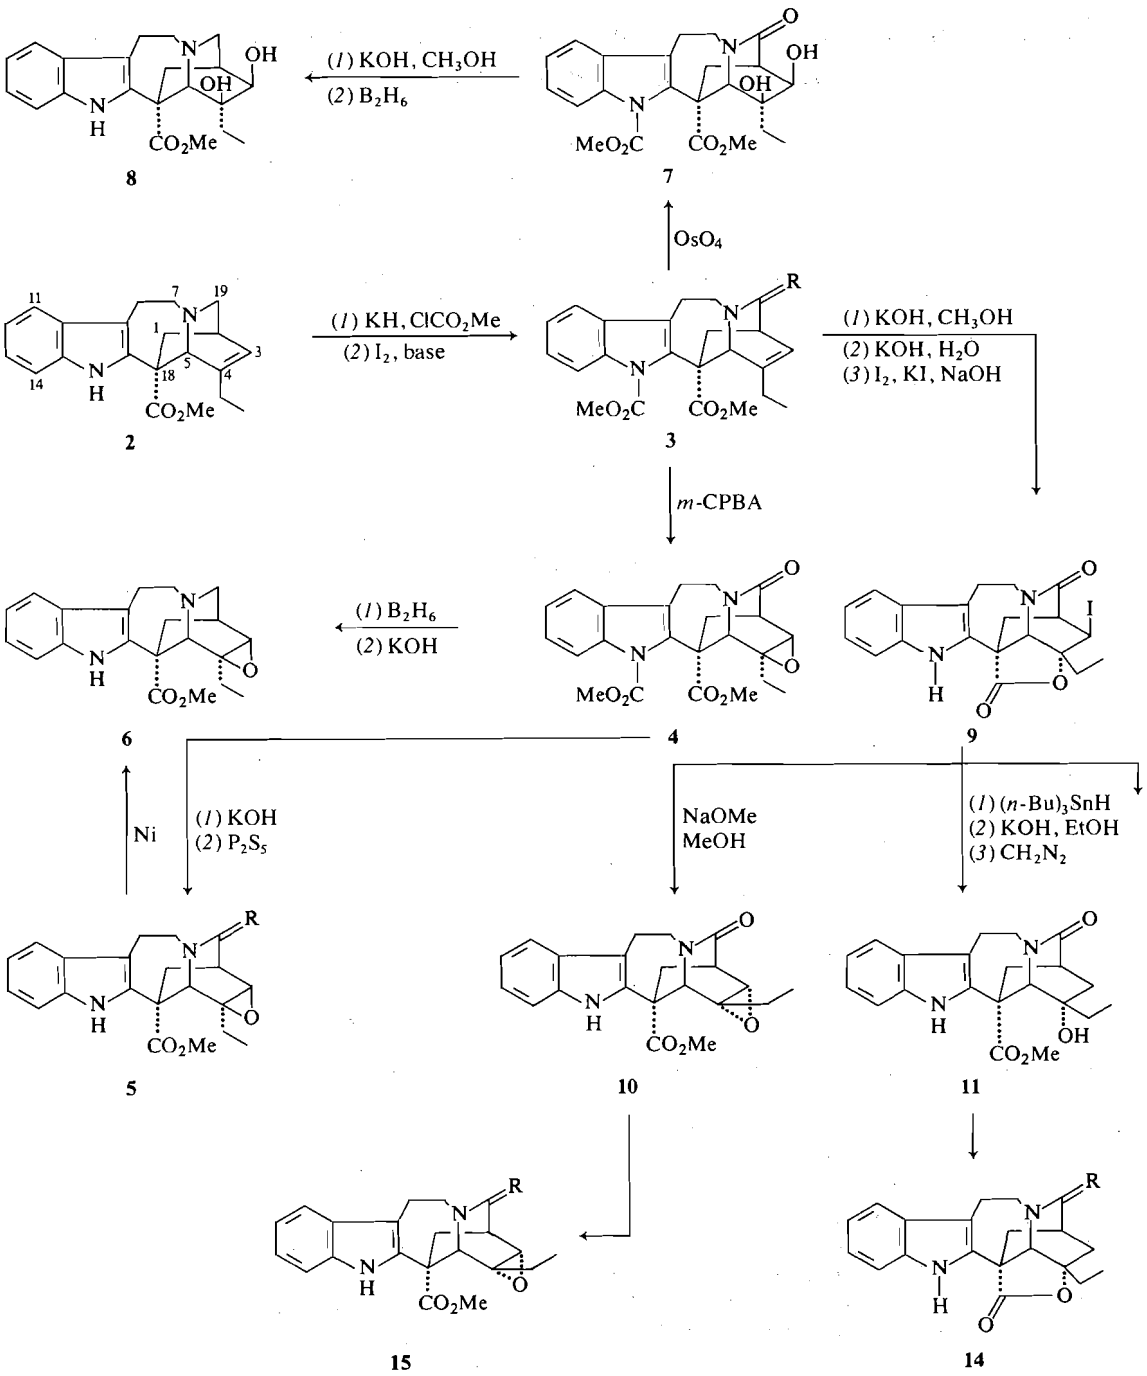

FIG. 1. The synthesis of a series of novel oxygenated catharanthine derivatives.

N_a-carbomethoxycatharanthine (**3**, R = H_2) in 91% yield. This intermediate, upon reaction with iodine in a basic medium (14) undergoes a facile conversion to the lactam **3** (R = O, 70% yield), (ir: 1735, 1670, 1650 cm^{-1}; nmr: δ 6.24 (m, 1H, olefinic), 3.95, 3.62 (2s, 2 × CO_2CH_3); ms: *m/e* 408 (M^+, $C_{23}H_{24}N_2O_5$)). As expected, this compound possessed the required properties for

further studies toward the synthesis of various novel oxygenated catharanthine derivatives. A summary of the various synthetic pathways is provided in Fig. 1.

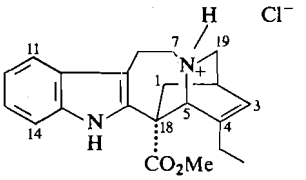
The alkaloid leurosine, already noted above, possesses an epoxy group at the 3′,4′ positions of the fundamental bisindole skeleton and it was essential to develop synthetic routes to the 3,4-epoxy catharanthine series so as to utilize such derivatives in the eventual synthesis of this bisindole alkaloid. Direct epoxidation of lactam **3** (R = O) with *m*-chloroperbenzoic acid (*m*-CPBA) in refluxing dichloromethane provided the crystalline epoxide **4** in 80% yield. Its characteristic spectral data (ir: 1720, 1665 cm^{-1}; nmr: δ 3.7 (s, 3H, C_{18}-CO_2CH_3), 3.98 (s, 3H, N-CO_2CH_3); ms: *m/e* 424 (M^+, $C_{23}H_{24}N_2O_6$), 285 (base peak)) left little doubt about the gross structure although the β-orientation assigned to the epoxide ring was established with certainty only after a comparison of this compound with the isomeric epoxide **10** prepared in an unambiguous manner (see later).

Removal of the lactam carbonyl in **4** (R = O) could be accomplished in two ways. Initial investigations involved reduction with diborane in tetrahydrofuran but the yields of the desired amine **6** were generally low (approximately 30%). Reductive opening of the epoxide ring became a serious side reaction in these studies. A preferable route involved the conversion of **4** to 3β,4β-epoxy-19-oxodihydrocatharanthine (**5**, R = O) by alkaline hydrolysis and reaction of the latter with phosphorus pentasulfide in refluxing benzene to provide the crystalline thiolactam **5** (R = S) in 73% yield (ir: 1730, 1480, 1455, 1440 cm^{-1}; nmr: δ 7.98 (bs, 1H, NH), 3.72 (s, 3H, C_{18}-CO_2CH_3); ms: *m/e* 382 (M^+, $C_{21}H_{22}N_2O_3S$), 227, 195). Raney Nickel desulfurization of **5** (R = S) provides 3β,4β-epoxydihydrocatharanthine (**6**).

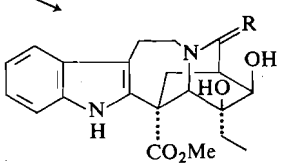
Vincadioline has been recently shown (6) to contain a vicinal diol system in the indole unit and consequently studies directed at the synthesis of 3,4-dihydroxy catharanthine derivatives were undertaken. For this purpose the intermediate **3** (R = O) was treated with osmium tetroxide in tetrahydrofuran at low temperature (−78°C) and the resultant product characterized as N_a-carbomethoxy-3β,4β-dihydroxy-19-oxodihydrocatharanthine **7** (ir: 3700–3150, 1735, and 1660 cm^{-1}; nmr: δ 4.87 and 4.28 (2bs, 2H, 2 × OH), 3.92 and 3.62 (2s, 6H, 2 × CO_2CH_3); ms: *m/e* 442 (M^+, $C_{23}H_{26}N_2O_7$, base peak), 410, 384, and 285). These spectral data do not allow unambiguous stereochemical assignment of the hydroxyl groups but since, as will be shown later, electrophilic attack at the double bond in **3** (R = O) by iodine (see iodolactone **9**) and peracid (see **4**) have occurred from the β face of the molecule, a similar assumption appears reasonable here. Molecular models of catharanthine or any of its derivatives carrying the double bond clearly reveal less hindrance, to attack at the β face.

A considerable amount of research was performed in developing conditions for removal of the indole protecting group and the lactam carbonyl in **7**. Alkaline hydrolysis of the indole ester group could be achieved in high yield (97%) but diborane removal of the lactam carbonyl group provided a relatively low yield (39%) of the desired 3β,4β-dihydroxydihydrocatharanthine **8** (ir: 3560–3400, 1720 cm^{-1}; nmr: δ 7.79 (bs, 1H, NH), 3.73 (m, 2H, C_3H and C_5H), 3.67 (s, 3H, CO_2CH_3); ms: *m/e* 370 (M^+, $C_{21}H_{26}N_2O_4$, base peak)).

An improved procedure for the preparation of the catharanthine glycol derivatives was obtained when catharanthine hydrochloride (**12**) was reacted at low temperature (0°C) with osmium tetroxide in tetrahydrofuran. Two products, the lactam diol **13** (R = O) and the diol **8** were obtained as the major and minor components, respectively.



12



13

It is clear from structure **1**, that vinblastine and vincristine both possess a tertiary hydroxyl group in the indole unit and the preparation of C_4-hydroxy derivatives of catharanthine would be required for eventual coupling with vindoline to provide these bisindole alkaloids. Experi-

ments directed to the synthesis of such intermediates were not only successful for this purpose but were important in terms of allowing stereochemical assignments to all of the novel oxygenated catharanthine derivatives shown in Fig. 1.

The above investigations have already demonstrated the facile electrophilic addition of peracids, for example, to the olefinic linkage in **3** (R = O). Consequently it was felt that the addition of 'positive' iodine should proceed equally well and the intermediate iodonium ion could undergo reaction with the C_{18} carboxyl function to provide an iodolactone (see **9**). The highly rigid bicyclic quinuclidine system present in **3** clearly demands a particular stereochemistry in the resultant lactone as shown in **9**. Further elaboration of such a system would impart definite stereochemistry to any functional groups at C_3 and C_4. Indeed this synthetic strategy has resulted in the successful syntheses of various catharanthine derivatives and an opportunity to interrelate their stereochemical differences.

Basic hydrolysis of the *N*-carbomethoxy group in **3** (R = O) provided 19-oxocatharanthine (**3**, R = O, N-CO_2CH_3 replaced by NH) in 74% yield (ir: 1740, 1668 cm^{-1}; nmr: δ 3.68 (s, 3H, C_{18}-CO_2CH_3); ms: *m/e* 350 (M^+, $C_{21}H_{22}N_2O_3$)). Further hydrolysis of the C_{18} ester group in the latter provides 19-oxocatharanthinic acid which, without purification, is subjected to reaction with potassium iodide and iodine in a basic medium. The product obtained, in overall 75% yield, is the desired iodolactone **9** (ir: 3435, 1770, 1690 cm^{-1}; nmr: δ 9.45 (bs, 1H, NH), 4.6 (dd, 1H, J = 3.5 and 1.5 Hz, CHI); ms: *m/e* 462 (M^+, $C_{20}H_{19}N_2O_3I$)). Clearly the successful formation of the iodolactone demands initial attack of iodine from the β face of the molecule and, in turn, the stereochemical assignments portrayed in **9**.

Deiodination of **9** with tri-*n*-butyltin hydride in tetrahydrofuran furnished the desired 4α-hydroxy-19-oxodihydrocatharanthinic acid lactone (**9**, I replaced by H) in 89% yield (ir: 1765, 1680 cm^{-1}; ms: *m/e* 366 (M^+ $C_{20}H_{20}N_2O_3$)). This intermediate provides a direct route to the required C_4-hydroxy dihydrocatharanthine series which, as noted above, could be employed in the eventual synthesis of vinblastine or vincristine.

Hydrolysis of 4α-hydroxy-19-oxodihydrocatharanthinic acid lactone under alkaline conditions and subsequent esterification of the resulting acid provided 4α-hydroxy-19-oxodihydrocatharanthine (**11**) in 54% yield (ir: 1725, 1635 cm^{-1}; nmr: δ 3.6 (s, 3H, CO_2CH_3), 1.85 (q, 2H, J = 7.5 Hz, CH_2CH_3), 1.15 (t, 3H, J = 7.5 Hz, CH_2CH_3). Thus the overall sequence, **3** → **9** → **11**, provides an effective method for the stereospecific introduction of an hydroxyl function at C_4 starting with the alkaloid, catharanthine.

The reductive removal of the lactam carbonyl in **11** appeared, in view of our previous success, to be a routine reaction. However contrary to expectation, reaction of **11** with diborane in the above-mentioned procedures provided instead, 4α-hydroxydihydrocatharanthinic acid lactone (**14**, R = H_2) as a crystalline product, mp 142–143°C (78% yield) (ir: 1750 cm^{-1}; ms: *m/e* 322 (M^+, $C_{20}H_{22}N_2O$)). Clearly the close proximity of the ester and hydroxyl groups in **11** have allowed a facile lactonization reaction to occur.

The lactone **14** was remarkably stable and showed no reaction even under rather drastic hydrolytic conditions (sodium methoxide in methanol or potassium hydroxide in refluxing aqueous ethanol).

It was hoped that lactone formation could be suppressed by converting **11** into its thiolactam derivative and then performing the desulfurization in the manner described earlier for the epoxide series. Unfortunately reaction of **11** with phosphorus pentasulfide under mild conditions (benzene, room temperature) provided the thiolactam lactone derivative **14** (R = S) again indicating the rapid lactonization reaction in this series. The structure of **14** (R = S) (ir: 1775, 1460 cm^{-1}; ms: *m/e* 352 (M^+, $C_{20}H_{20}N_2O_2S$)) was confirmed by reacting the lactone **9** (I replaced by H) under similar conditions with phosphorus pentasulfide whereupon the product isolated was shown to be identical with that obtained earlier.

The final series of reactions which were performed involved the synthesis of the 3α,4α-epoxy derivatives, which would be isomeric to the compounds derived from *m*-CPBA addition. The iodolactone **9** was an important starting material in these investigations. Reaction of **9** with sodium methoxide in methanol, at room temperature, provided 3α,4α-epoxy-19-oxodihydrocatharanthine **10** (79% yield) (ir: 1725, 1665 cm^{-1}; nmr: δ 8.17 (s, 1H, NH), 3.8 (s, 3H, $COOCH_3$); ms: *m/e* 366 (M^+, $C_{21}H_{22}N_2O_4$)). It is obvious that this conversion involves a methoxide-cata-

lyzed ring opening of the lactone with subsequent displacement of iodide ion by internal attack of the resultant alkoxide ion. Such a process demands α-orientation of the resulting epoxide and serves to substantiate the earlier statements concerning β attack of electrophilic reagents onto the olefinic linkage of catharanthine derivatives.

Removal of the lactam carbonyl group in **10** was accomplished via the thiolactam procedure already described. The final product, 3α,4α-epoxydihydrocatharanthine (**15**, R = H_2) was crystalline and revealed chromatographic as well as spectral characteristics which were clearly different from those of the isomeric epoxide **6**.

In conclusion, these investigations have provided a series of novel 3,4-oxygenated catharanthine derivatives which we hope will prove useful in the syntheses of various bisindole alkaloids. Some results in this direction are described in the accompanying publication (15).

After our studies in this area were completed and published in preliminary fashion, (17) an independent investigation by Ban and coworkers was published (16).

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometres (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin-Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers (cm^{-1}), calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were measured in deuterochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 intrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Thin layer chromatography (tlc) utilized Merck silica gel G (acc. to Stahl) containing 2% fluorescent indicator. For preparative layer chromatography (plc), plates (20 × 20 or 20 × 60 cm) of 1 mm thickness were used. Visualization was effected by viewing under ultraviolet light and/or by colour reaction with ceric sulphate spray reagent. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminum oxide 90 (neutral).

As a matter of routine, all reagents and solvents were recrystallized or distilled prior to use.

N_a-Carbomethoxycatharanthine (3, R = H_2)

A suspension of potassium hydride (KH), oil dispersion (0.6 ml, 24%, 2.0 mmol) in dry tetrahydrofuran (THF), (20 ml) was cooled to ca. −5°C under an atmosphere of nitrogen. Catharanthine **2** (500 mg, 1.35 mmol) in dry THF (2 ml) was added and the mixture stirred at −5°C for 1 h. Methyl chloroformate (190 mg, 2 mmol) was added and after 30 min, alumina (ca. 1 g of grade III) to quench excess KH. The mixture was filtered and the filtrate evaporated *in vacuo*. The oily product was triturated with hexane (3 × 15 ml) to remove the oil and yield *N_a-carbomethoxycatharanthine* (487 mg, 92%) as a white foam, homogeneous by tlc (silica gel; hexane–acetone, 3:2); uv: λ_{max} 293 (3.67), 281 (3.80), 263 (4.13), 226 (4.32); ir: ν_{max} 2950, 2850, 1730; ^{1}Hmr: δ 7.45 (1H, m, C_{14}-*H*), 7.35–7.2 (3H, m, aromatic protons), 5.70 (1H, m, C_3-*H*), 3.93 (3H, s, N-CO_2CH_3), 3.70 (3H, s, CO_2CH_3), 1.13 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 394 (M^+, base peak), 305, 188, 155, 121. High resolution molecular weight determination calcd. for $C_{23}H_{26}N_2O_4$: 394.463; found: 394.457. *Anal.* calcd. for $C_{23}H_{26}N_2O_4$: C 70.03, H 6.64, N 7.10; found: C 70.23, H 6.80, N 7.00.

N_a-Carbomethoxy-19-oxodihydrocatharanthine (3, R = O)

(*i*) Mercuric acetate (108 mg, 0.34 mmol) and EDTA disodium salt (125 mg, 0.34 mmol) were dissolved in 1% aqueous acetic acid (3 ml). A solution of **3** (R = H_2) (50 mg, 0.127 mmol) in dioxane (3 ml) was added and the mixture stirred for 24 h, diluted with water (20 ml), and extracted with ethyl acetate (2 × 20 ml). The organic phase was washed with 5% HCl solution (2 × 10 ml) then with saturated NaCl solution (2 × 10 ml), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was chromatographed on silica gel (ca. 10 g) to yield the *lactam* **3** (R = O) as a white foam (39.5 mg, 76%), mp 166–167°C; uv: λ_{max} 294 (3.90), 282 (3.95), 260 (4.33), 227 (4.51); ir: ν_{max} 2940, 2890, 1735, 1670, 1650; ^{1}Hmr: δ 6.24 (1H, m, C_3-*H*), 4.88 (1H, d, J = 1 Hz, C_5-*H*), 4.0 (1H, m, C_2-*H*), 1.92 (2H, m, —CH_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 408 (M^+), 285 (base peak), 286, 226, 168, 167. High resolution molecular weight determination calcd. for $C_{23}H_{24}N_2O_5$: 408.168; found: 408.171. *Anal.* calcd. for $C_{23}H_{24}N_2O_5$: C 67.63, H 5.92, N 6.86; found: C 67.56, H 5.93, N 6.73.

(*ii*) Sodium bicarbonate (680 mg, 8 mmol), water (40 ml), **3** (R = H_2) (110 mg, 0.28 mmol), and benzene (5 ml) were stirred vigorously at ambient temperature. A solution of iodine (354 mg, 1.4 mmol) in benzene (20 ml) was added and stirring continued for 1 h. Sodium bicarbonate (1 g) and sodium thiosulphate (500 mg) were added, the organic layer was separated and the aqueous phase washed with dichloromethane (3 × 20 ml). The extracts were combined, dried (Na_2SO_4), and evaporated *in vacuo*. Chromatography on silica gel afforded the *lactam* **3** (R = O) (81 mg, 71%), identical with that obtained above.

N_a-Carbomethoxy-3β,4β-epoxy-19-oxodihydrocatharanthine (4)

The *lactam* **3** (R = O) (816 mg, 2 mmol), purified *m*-CPBA (850 mg, 5 mmol), and 3-*tert*-butyl-4-hydroxy-5-methylphenylsulphide (ca. 10 mg) were stirred in refluxing 1,2-dichloroethane (50 ml) under an atmosphere of dry nitrogen for 5 h. The cooled solution was washed successively with saturated Na_2SO_3 solution and saturated $NaHCO_3$ solution, dried (Na_2SO_4), and filtered

through a small plug of Celite. Evaporation of the filtrate gave the *epoxide* **4** (677 mg, 80%); mp 234–236°C (acetone – petroleum ether (40–60°C)); uv: λ_{max} 294 (3.71), 285 (3.74), 282 (3.76), 267 (4.17), 259 (4.18), 232 (4.31), 227 (4.33); ir: ν_{max} 1720, 1665; ^{1}Hmr: δ 4.59 (1H, d, J = 1 Hz, C_5-*H*), 4.15 (1H, m, C_2-*H*), 3.98 (3H, s, N_a-CO_2CH_3), 3.72 (3H, s, CO_2CH_3), 1.4–2.2 (2H, m, —CH_2CH_3), 0.94 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 424 (M^+), 285 (base peak), 192 (metastable peak). *Anal.* calcd. for $C_{23}H_{24}N_2O_6$: C 65.08, H 5.70, N 6.60; found: C 65.14, H 5.80, N 6.56.

3β,4β-Epoxydihydrocatharanthine (6)

The *epoxide* **4** (42 mg, 0.1 mmol) in dry THF (2 ml) was treated with a solution of borane in THF (0.2 ml, 1 *M*, 0.2 mmol) in dry THF (2 ml). The solution was stirred at 0°C under an atmosphere of dry argon for 30 min, then at ambient temperature for 1 h. Acetone (0.5 ml) and triethylamine (2 ml) were added, followed by 1% methanolic KOH solution (1 ml). After 30 min the mixture was poured into dichloromethane (50 ml), washed with water, dried (Na_2SO_4), and evaporated *in vacuo*. Chromatography on silica gel afforded the *lactam* **5** (R = O) (11.4 mg, 31%) plus the *epoxide* **6** (5.3 mg, 15%); uv: λ_{max} 292 (3.91), 284 (3.96), 277 (3.93), 225 (4.66); ir: ν_{max} 3450, 1725; ^{1}Hmr: δ 7.60 (1H, bs, D_2O exchangeable, N-*H*), 4.18 (1H, s, C_5-*H*), 3.79 (3H, s, CO_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 352 (M^+, base peak), 323, 138. High resolution molecular weight determination calcd. for $C_{21}H_{24}N_2O_3$: 352.1787; found: 352.1790. *Anal.* calcd. for $C_{21}H_{24}N_2O_3$: C 71.57, H 6.86, N 7.95; found: C 71.52, H 6.77, N 7.75.

3β,4β-Epoxy-19-oxodihydrocatharanthine (5, R = O)

A solution of **4** (340 mg, 0.8 mmol) in 1% methanolic KOH (20 ml) was stirred at ambient temperature for 20 min, diluted with dichloromethane (30 ml), and filtered through a short plug of silica gel. Evaporation of the filtrate gave **5** (R = O), (300 mg, quantitative), mp 276–278°C dec. (acetone – petroleum ether (40–60°C)); uv: λ_{max} 292 (3.91), 283 (3.96), 275 (3.91), 222 (4.56); ir: ν_{max} 3460, 1725, 1665; ^{1}Hmr: δ 8.3 (1H, bs, D_2O exchangeable, N-*H*), 4.76 (1H, d, J = 1 Hz, C_5-*H*), 4.3 (1H, bm, C_2-*H*), 3.64 (3H, s, CO_2CH_3), 2.22 (6H, s, acetone), 1.4–2.2 (2H, bm, —CH_2CH_3), 0.97 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 366 (M^+, base peak), 228, 227, 214, 195, 168, 167, 154. *Anal.* calcd. for $C_{21}H_{22}N_2O_4 \cdot C_3H_6O$: C 67.91, H 6.65, N 6.60; found: C 67.63, H 6.46, N 6.77.

3β,4β-Epoxy-19-thionodihydrocatharanthine (5, R = S)

The *lactam* **5** (R = O) (366 mg, 1 mmol) and excess phosphorous pentasulphide (366 mg) were stirred in refluxing benzene (40 ml) under an atmosphere of dry nitrogen for 30 min. Water (5 ml) was added to the cooled mixture and stirring continued for 5 min. The mixture was diluted with dichloromethane (60 ml), washed with $NaHCO_3$ solution, dried (Na_2SO_4), and evaporated *in vacuo*. Recrystallization from methanol gave the *thiolactam* **5** (R = S) (278 mg, 73%), mp 259–260°C; uv: λ_{max} 291 (4.13), 279 (4.38), 272 (4.45), 222 (4.66); ir: ν_{max} 3450, 1730, 1480, 1455, 1440; ^{1}Hmr: δ 7.98 (1H, bs, D_2O exchangeable, N-*H*), 5.2 (1H, bm, C_2-*H*), 5.10 (1H, s, C_5-*H*), 3.72 (3H, s, CO_2CH_3), 1.4–2.2 (2H, bm, —CH_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 382 (M^+, base peak), 227, 195. *Anal.* calcd. for $C_{21}H_{22}N_2O_3S$: C 65.95, H 5.80, N 7.32, S 8.38; found: C 65.89, H 5.90, N 7.20, S 8.22.

3β,4β-Epoxydihydrocatharanthine (6)

The *thiolactam* **5** (R = S), (76 mg, 0.2 mmol) and a large excess of Raney Nickel (pre-washed with distilled water and ethanol) were stirred in ethanol (10 ml) at ambient temperature for 8 min. The mixture was diluted with dichloromethane (10 ml), filtered, and evaporated *in vacuo*. Chromatography on silica gel gave the *epoxide* **6** (37 mg, 53%), identical with that obtained above. A sample recrystallized from ether had mp 214–215°C.

N_a-Carbomethoxy-3β,4β-dihydroxy-19-oxodihydrocatharanthine (7)

The *lactam* **3** (R = O) (325 mg, 0.796 mmol) in dry THF (1.7 ml) and pyridine (3.25 ml) was treated at −78°C with osmium tetroxide (210 mg, 0.826 mmol) in dry THF (1.7 ml). After 2 h at −78°C, the mixture was diluted with ether (130 ml) and the resultant precipitate collected by filtration. This product was dissolved in dichloromethane, saturated with hydrogen sulphide, filtered, and evaporated *in vacuo*. Chromatography on silica gel afforded the *diol* **7** (201 mg, 57%) as an amorphous solid; uv: λ_{max} 294 (3.73), 285 (3.79), 282 (3.83), 261 (4.21), 228 (4.34); ir: ν_{max} 3700–3150, 3620, 1735, 1660; ^{1}Hmr: δ 4.87 (1H, bs, D_2O exchangeable, —O*H*), 4.50 (1H, s, C_5-*H*), 4.28 (1H, bs, D_2O exchangeable, —O*H*), 3.92 (3H, s, N_a-CO_2CH_3), 3.87 (1H, d, J = 2 Hz, C_3-*H*), 3.62 (3H, s, CO_2CH_3), 0.91 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 442 (M^+, base peak), 410, 384, 285, 100. High resolution molecular weight determination; calcd. for $C_{23}H_{26}N_2O_7$: 442.1739; found: 442.1693. *Anal.* calcd. for $C_{23}H_{26}N_2O_7$: C 62.43, H 5.92, N 6.33; found: C 62.19, H 6.00, N 6.47.

3β,4β-Dihydroxy-19-oxodihydrocatharanthine

The *diol* **7** (60 mg, 0.136 mmol) was stirred in 3 *N* methanolic KOH solution (3 ml) for 1 h. The mixture was diluted with water (15 ml) and extracted with dichloromethane (3 × 10 ml). The organic phase was dried (Na_2SO_4) and evaporated *in vacuo* to yield *3β,4β-dihydroxy-19-oxodihydrocatharanthine* (50.5 mg, 97%), mp 207–209°C dec. (acetone); uv: λ_{max} 292 (3.90), 284 (3.95), 278 (3.89), 222 (4.51); ir: ν_{max} 3540–3400, 3460, 1725, 1665; ^{1}Hmr: δ 8.02 (1H, bs, D_2O exchangeable, N-*H*), 4.62 (1H, s, C_5-*H*), 4.42 (1H, bs, D_2O exchangeable, —O*H*), 4.08 (1H, bs, D_2O exchangeable, —O*H*), 3.78 (1H, d, J = 3 Hz, C_3-*H*), 3.65 (3H, s, CO_2CH_3), 0.96 (3H, t, J = 6 Hz, —CH_2CH_3); ms: *m/e* 384 (M^+, base peak), 298, 228, 227, 215, 214, 195, 168, 167, 154, 143. High resolution molecular weight determination calcd. for $C_{21}H_{24}N_2O_5$: 384.1685; found: 384.1685. This compound decomposes during attempted removal of solvent. *Anal.* calcd. for $C_{21}H_{24}N_2O_5 \cdot \frac{1}{2}H_2O$: C 64.11, H 6.40, N 7.12; found: C 64.00, H 6.41, N 7.20.

3β,4β-Dihydroxydihydrocatharanthine (8)

3β,4β-Dihydroxy-19-oxodihydrocatharanthine (21.9 mg, 0.057 mmol) in dry THF (3.5 ml) was treated with a solution of borane in THF (0.29 ml, 1 *M*, 0.29 mmol) at ambient temperature under an atmosphere of dry argon for 2 h. The solution was diluted with dry acetone (1.5 ml), refluxed for 5 min, and evaporated *in vacuo*. The residue was stirred in 3 *N* HCl (10 ml) at ambient temperature for 30 min, the solution basified with NH_4OH to p*H* 9–10 and extracted with dichloromethane. The extract was dried (Na_2SO_4) and evaporated. Chromatography on silica gel gave **8** (8.2 mg, 39%) as a colourless oil; uv: λ_{max} 293 (3.77), 284 (3.81), 276 (3.77), 224 (4.44); ir: ν_{max} 3560–3400, 3460, 1720; ^{1}Hmr: δ 7.79 (1H, bs,

D_2O exchangeable, N-*H*), 3.73 (2H, m, C_3-*H* and C_5-*H*), 3.67 (3H, s, CO_2CH_3), 0.99 (3H, t, J = 7 Hz, $—CH_2CH_3$); ms: *m/e* 370 (M^+, base peak), 353, 313, 282, 228, 168, 165, 156, 100. High resolution molecular weight determination calcd. for $C_{21}H_{26}N_2O_4$: 370.1892; found: 370.1896.

3β,4β-Dihydroxy-19-oxodihydrocatharanthine

Osmium tetroxide (179 mg, 0.704 mmol) in dry THF (2 ml) was added to a slurry of catharanthine hydrochloride (150 mg, 0.403 mmol) in dry THF (5 ml) at −10°C under an atmosphere of argon. Dry pyridine (118 mg, 0.12 ml, 1.49 mmol) was added and the mixture stirred at ca. −10 to −5°C for 2 h. Hydrogen sulphide was bubbled through the cool mixture for 5 min. The mixture was diluted with ethyl acetate and washed with dilute NH_4OH solution. The aqueous phase was extracted with ethyl acetate, the extracts combined, dried (Na_2SO_4), and evaporated *in vacuo*. Chromatography on silica gel afforded: **8** (5.4 mg, 4%), catharanthine **2** (40 mg), and *3β,4β-dihydroxy-19-oxodihydrocatharanthine* (52 mg, 48%) identical with that obtained above.

19-Oxocatharanthine

Potassium hydroxide (3 *N*, 1 ml) was added to a solution of **3** (R = O) (300 mg, 0.735 mmol) in methanol (3 ml). The mixture was stirred at ambient temperature for 1 h, carefully neutralized with Amberlite IR-120 at ca. 0°C, filtered, and evaporated *in vacuo*. Trituration of the oily residue gave *19-oxocatharanthine* (234 mg, 91%), mp 231°C (methanol).

19-Oxocatharanthinic Acid

19-Oxocatharanthine (870 mg, 2.49 mmol) and 6 *N* KOH solution (5 ml) were heated in refluxing ethanol (15 ml) under an atmosphere of dry nitrogen for 6 h. The solution was cooled to 0°C, carefully neutralized with Amberlite IR-120, filtered, and evaporated *in vacuo* to give crude *19-oxocatharanthinic acid* (835 mg, quantitative), which was used, without further purification, in the next reaction.

4α-Hydroxy-3β-iodo-19-oxodihydrocatharanthinic Acid Lactone (9)

19-Oxocatharanthinic acid (101 mg, 0.3 mmol) was dissolved in the minimum required amount of 3 *N* NaOH solution and water (30 ml) added. Powdered iodine (305 mg, 1.2 mmol) and potassium iodide (75 mg, 0.45 mmol) were added and the mixture stirred in the dark, under an atmosphere of nitrogen for 24 h. Sodium thiosulphate (1 g) was added and the mixture extracted with dichloromethane (5 × 20 ml). The organic extract was dried (Na_2SO_4) and evaporated *in vacuo* to yield crude *iodolactone* **9** (135 mg, 97.5%). Purification by chromatography on silica gel gave **9** (75.5%) as an amorphous solid; uv: λ_{max} 288 (3.84), 280 (3.89), 272 (3.88), 222 (4.54); ir: ν_{max} 3435, 1770, 1690; ^{1}Hmr: δ 9.45 (1H, bs, D_2O exchangeable, N-*H*), 4.66 (1H, dd, J = 3.5, 1.5 Hz, C_3-α*H*), 4.45–4.70 (1H, m, C_2-*H*), 4.34 (1H, s, C_5-*H*), 2.22 (2H, m, $—CH_2CH_3$), 1.06 (3H, t, J = 7 Hz, $—CH_2CH_3$); ms: *m/e* 462 (M^+, base peak), 169, 168, 167, 128. High resolution molecular weight determination calcd. for $C_{20}H_{19}N_2O_3I$: 462.0440; found: 462.0462.

4α-Hydroxy-19-oxodihydrocatharanthinic Acid Lactone

The *iodolactone* **9** (615 mg, 1.33 mmol) and tri-*n*-butyltin hydride (744 mg, 2.66 mmol) were stirred in anhydrous THF (5 ml) under a nitrogen atmosphere for 72 h. Evaporation *in vacuo* and chromatography on silica gel gave *4α-hydroxy-19-oxodihydrocatharanthinic acid lactone* (400 mg, 90%) mp 196–196.5°C (dichloromethane–pentane); uv: λ_{max} 288 (3.86), 280 (3.91), 272 (3.89), 221 (4.65); ir: ν_{max} 3440, 1765, 1680; ^{1}Hmr: δ 9.56 (1H, bs, D_2O exchangeable, N-*H*), 4.40–4.65 (1H, bm, C_2-*H*), 4.20 (1H, s, C_5-*H*), 1.06 (3H, t, J = 7 Hz, $—CH_2CH_3$); ms: *m/e* 336 (M^+, base peak), 195, 168, 167. High resolution molecular weight determination calcd. for $C_{20}H_{20}N_2O_3$: 336.1474; found: 336.1471. *Anal.* calcd. for $C_{20}H_{20}N_2O_3$: C 71.40, H 6.00, N 8.33; found: C 71.23, H 6.25, N 8.03.

4α-Hydroxy-19-oxodihydrocatharanthine (11)

4α-Hydroxy-19-oxodihydrocatharanthinic acid lactone (33.6 mg, 0.1 mmol) and 6 *N* KOH solution (1 ml) were heated in refluxing ethanol (2 ml) under an atmosphere of nitrogen for 6 h. The solvents were removed *in vacuo* and the residue dissolved in water (2 ml). The solution was carefully neutralized at 0°C with oxalic acid, and extracted with dichloromethane (5 × 10 ml). The extract was dried (Na_2SO_4) and evaporated *in vacuo*. The residue was dissolved in anhydrous THF (2 ml) and treated with an excess of diazomethane in ether at 0°C for 30 min. Evaporation and trituration with chloroform–hexane (1:1) afforded **11** (20 mg, 55%), decomposes without melting above 200°C; uv: λ_{max} 291 (3.82), 282 (3.88), 275 (3.84), 221 (4.48); ir: ν_{max} 3400, 1725, 1635; ^{1}Hmr: δ (pyridine-d_5) 4.98 (1H, s, C_5-*H*), 4.6–4.9 (1H, m, C_2-*H*), 3.60 (3H, s, CO_2CH_3), 1.85 (2H, q, J = 7 Hz, $—CH_2CH_3$), 1.15 (3H, t, J = 7 Hz, $—CH_2CH_3$); ms: *m/e* 336 ($(M - CH_3OH)^+$, base peak), 195, 168, 167. High resolution molecular weight determination calcd. for $C_{20}H_{20}N_2O_3$: 336.1474; found: 336.1471. *Anal.* calcd. for $C_{21}H_{24}N_2O_4 \cdot 2H_2O$: C 62.38, H 6.93, N 6.93; found: C 62.74, H 6.65, N 6.86.

4α-Hydroxydihydrocatharanthinic Acid Lactone (14, R = H_2)

A solution of **11** (340 mg, 1.01 mmol) in anhydrous THF (25 ml) was treated with borane/THF solution (10 ml, excess). The solution was stirred at ambient temperature under an atmosphere of dry nitrogen for 4 h. Acetone (5 ml) was added and the solution refluxed for 5 min, triethylamine (5 ml) was added, and reflux continued for 1½ h. The solvents were removed *in vacuo* and the residue partitioned between dichloromethane (20 ml) and water (10 ml). The p*H* was adjusted to ca. 10 with 6 *N* NaOH and saturated NaCl solution (10 ml) added. The organic layer was separated and the aqueous layer extracted with dichloromethane (4 × 20 ml). The extract was dried (Na_2SO_4) and evaporated *in vacuo*. Chromatography on silica gel afforded the *lactone* **14** (R = H_2) (255 mg, 78%), mp 142–143°C (pentane); uv: λ_{max} 288 (3.77), 280 (3.80), 273 (3.77), 222 (4.47); ir: ν_{max} 3420, 1750; ^{1}Hmr: δ 9.60 (1H, bs, D_2O exchangeable, N-*H*), 3.54 (1H, s, C_5-*H*) 1.04 (3H, t, J = 7 Hz, $—CH_2CH_3$); ms: *m/e* 322 (M^+, base peak), 263, 130. High resolution molecular weight determination calcd. for $C_{20}H_{22}N_2O_2$: 322.1681; found: 322.1678. *Anal.* calcd. for $C_{20}H_{22}N_2O_2$: C 74.50, H 6.88, N 8.69; found: C 74.43, H 6.70, N 8.86.

4α-Hydroxy-19-thionodihydrocatharanthinic Acid Lactone (14, R = S)

(*i*) Phosphorous pentasulphide (10 mg, 0.045 mmol) was added to a suspension of **11** (5 mg, 0.0135 mmol) in dry benzene (1 ml). After 24 h at ambient temperature,

the mixture was filtered and the filtrate evaporated *in vacuo*. Chromatography on silica gel gave the *thiolactam* **14** (R = S), (3.9 mg, 82%) as an amorphous solid; uv: λ_{max} 288 (4.04), 278 (4.13), 272 (4.14), 219 (4.42); ir: ν_{max} 3420, 1775, 1460; ^{1}Hmr: δ 9.54 (1H, bs, D_2O exchangeable, N-*H*), 5.2–5.4 (1H, m, C_2-*H*), 4.43 (1H, s, C_5-*H*), 1.15 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 352 (M^+), 248, 195, 168, 167, 140. High resolution molecular weight determination calcd. for $C_{20}H_{20}N_2O_2S$: 352.1246; found: 352.1253.

(*ii*) Phosphorous pentasulphide (50 mg, 0.23 mmol) and *4α-hydroxy-19-oxodihydrocatharanthinic acid lactone* (26 mg, 0.077 mmol) were stirred in dry benzene (2 ml) for 24 h. Filtration, evaporation, and chromatography on silica gel gave **14** (R = S), (23 mg, 85%) identical with that obtained above.

3α,4α-Epoxy-19-oxodihydrocatharanthine (10)

The *iodolactone* **9** (35 mg, 0.075 mmol) was added to a solution of sodium methoxide in methanol (sodium metal ca. 2 mg in 3 ml of dry methanol). The solution was stirred at ambient temperature for 3 h, evaporated *in vacuo*, and the residue chromatographed on silica gel. Recrystallization from methanol gave the *epoxide* **10** (21 mg, 79%), mp 278–280°C; uv: λ_{max} 292 (3.92), 282 (4.02), 272 (3.99), 219 (4.60); ir: ν_{max} 3425, 1725, 1665; ^{1}Hmr: δ 8.17 (1H, bs, D_2O exchangeable, N-*H*), 4.82 (1H, s, C_5-*H*), 4.21–4.53 (1H, m, C_2-*H*), 3.80 (3H, s, CO_2CH_3), 1.02 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 366 (M^+, base peak), 308, 195, 164, 137. High resolution molecular weight determination calcd. for $C_{21}H_{22}N_2O_4$: 366.1579; found: 366.1586. *Anal.* calcd. for $C_{21}H_{22}N_2O_4 \cdot CH_3OH$: C 66.33, H 6.53, N 7.03; found: C 66.27, H 6.21, N 7.35.

3α,4α-Epoxy-19-thionodihydrocatharanthine (15, R = S)

The *epoxide* **10** (38 mg, 0.1 mmol) and phosphorous pentasulphide (44 mg, 0.2 mmol) were stirred in dry benzene (3 ml) for 4 h at ambient temperature. The mixture was filtered and the filtrate evaporated *in vacuo*. The residue was chromatographed on silica gel to yield starting material (8 mg) and the *thiolactam* **15** (R = S), (17 mg, 55%), mp 118–121°C (ethyl acetate – hexane); uv: λ_{max} 292 (4.13), 278 (4.36), 272 (4.38), 220 (4.59); ir: ν_{max} 3425, 1725, 1450, 1430; ^{1}Hmr: δ 8.17 (1H, bs, D_2O exchangeable, N-*H*), 5.09–5.40 (1H, m, C_2-*H*), 5.01 (1H, s, C_5-*H*), 3.82, (3H, s, CO_2CH_3), 1.02 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 382 (M^+ base peak), 227, 195, 178, 166, 149. High resolution molecular weight determination calcd. for $C_{21}H_{22}N_2O_3S$: 382.1331; found: 382.1341.

3α,4α-Epoxydihydrocatharanthine (15, R = H_2)

The thiolactam **15** (R = S) (40 mg) and excess Raney Nickel (pre-washed with distilled water and ethanol) were stirred in ethanol (5 ml) for 1.5 h. After filtration and evaporation *in vacuo*, the residue was chromatographed on silica gel to yield the *epoxide* **15** (R = H_2), (26 mg, 74%), mp 67–70°C (acetone–hexane); uv: λ_{max} 292 (4.02), 282 (4.19), 273 (4.08), 222 (4.61), ir: ν_{max} 3425, 1725; ^{1}Hmr: δ 8.04 (1H, bs, D_2O exchangeable, N-*H*), 3.91 (1H, s, C_5-*H*), 3.80 (3H, s, CO_2CH_3), 0.99 (3H, t, J = 7 Hz, —CH_2CH_3); ms: *m/e* 352 (M^+), 293 (base peak), 167, 166, 149, 138. High resolution molecular weight determination calcd. for $C_{21}H_{24}N_2O_3$: 352.1787; found: 352.1793. *Anal.* calcd. for $C_{21}H_{24}N_2O_3 \cdot \frac{1}{2}H_2O$: C 69.81, H 6.91, N 7.76; found: C 69.75, H 7.18, N 7.69.

JAMES P. KUTNEY, ALUMMOOTTIL V. JOSHUA, PING-HUANG LIAO, and BRIAN R. WORTH. Can. J. Chem. 55, 3235 (1977).

A detailed study involving the Polonovski-type coupling of vindoline (**2**) with several novel catharanthine derivatives is described. Coupling of vindoline (**2**) with the *N*-oxide intermediate of 3β,4β-epoxydihydrocatharanthine (**1**) provides a laboratory synthesis of the bisindole alkaloid leurosine (**3**, R = CO_2CH_3) and an unambiguous proof of the stereochemistry of the epoxide function in that alkaloid. The coupling of **2** with the *N*-oxides of 3α,4α-epoxydihydrocatharanthine (**4**) and 4α-hydroxydihydrocatharanthinic acid lactone (**6**) provide the rearranged bisindole products **5**, **7**, and **8**.

JAMES P. KUTNEY, ALUMMOOTTIL V. JOSHUA, PING-HUANG LIAO et BRIAN R. WORTH. Can. J. Chem. 55, 3235 (1977).

On décrit en détail l'étude impliquant un couplage du type Polonovski de la vindoline (**2**) avec quelques dérivés de la catharanthine. Le couplage de la vindoline (**2**) avec l'intermédiaire *N*-oxyde de l'époxy-3β,4β dihydrocatharanthine (**1**) permet de poursuivre la synthèse de la bis-indole leurosine (**3**, R = CO_2CH_3) et apporte une preuve très nette de la stéréochimie du pont époxyde dans l'alkaloïde. Le couplage de **2** avec les *N*-oxydes de l'époxy-3α,4α dihydrocatharanthine (**4**) et d'hydroxy-4α dihydrocatharanthinolactone (**6**) conduit aux bis-indoles réarrangées **5**, **7** et **8**.

[Traduit par le journal]

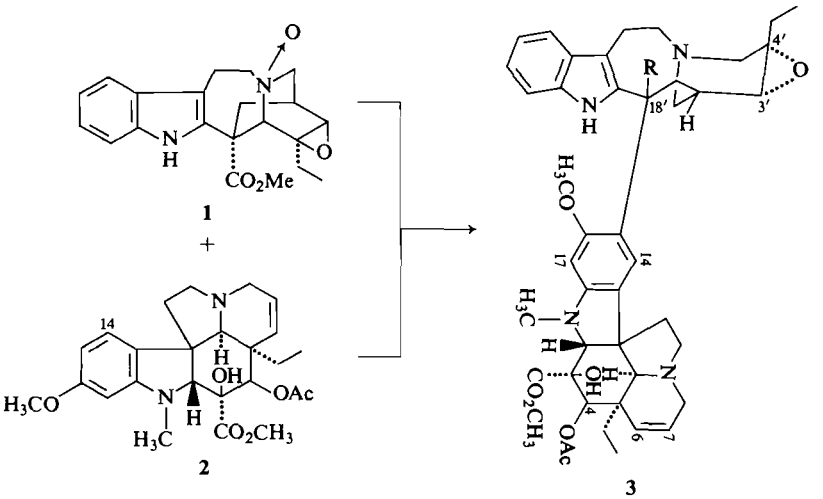
In the previous publication in this series (14) we presented a discussion of the experiments which provided a variety of novel oxygenated catharanthine derivatives. It was noted that such intermediates could prove valuable in the synthesis of various bisindole alkaloids and their derivatives. The present discussion exemplifies some of our studies in this direction.

The bisindole alkaloid leurosine (**3**, R = CO_2CH_3) was isolated some years ago and its structure has been investigated by several groups (1–3). These studies provided a structural assignment but the stereochemical assignment of the epoxide function remained unsettled. Analysis of proton magnetic resonance data provided a tentative assignment of a β orientation to this function (2) while more recent studies involving ^{13}C magnetic resonance and an acid-catalyzed rearrangement of leurosine assumed an α orientation (3). Since *N*-formyl leurosine (**3**, R = CO_2CH_3, N-CH_3 replaced by N-CHO) is presently in clinical studies in Hungary, it appeared particularly important to provide an unambiguous proof for the stereochemical orientation of the epoxide ring since this feature of the bisindole system may be important in terms of its antitumor activity. Consequently our initial studies with the oxygenated catharanthine derivatives (4, 14) were directed toward this objective. The two possible 3,4-epoxydihydrocatharanthine derivatives available from the previous studies (4, 14) were utilized in coupling experiments with vindoline (**2**) according to procedures developed independently in our laboratories (5, 6) and elsewhere (7, 8).

The *N*-oxide derivative of 3β,4β-epoxydihydrocatharanthine (**1**), prepared from the epoxide and *m*-chloroperbenzoic acid, was coupled with vindoline (**2**) in the presence of trifluoroacetic anhydride at −50°C (5, 6) to provide the alkaloid leurosine (**3**, R = CO_2CH_3) in 20% yield. This study not only provided a laboratory synthesis of this bisindole alkaloid but, most importantly, settled unambiguously the stereochemistry of the epoxide function at $C_{3'}$–$C_{4'}$ as shown in **3**. It is also of interest to note that, unlike the earlier studies involving the coupling of catharanthine derivatives lacking

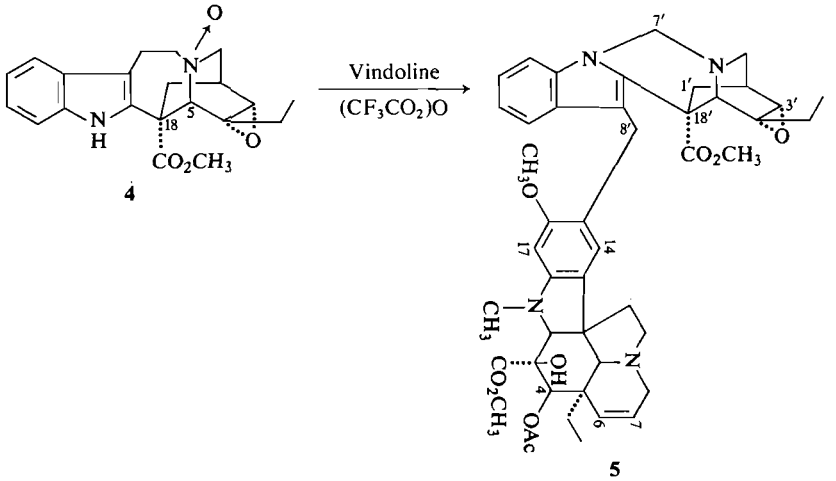
[1]Part X, see ref. 14.

[2]For preliminary reports on a portion of this work, see refs. 15 and 16.



oxygen functionality at the C_3–C_4 positions (5, 6), other bisindole products, particularly those bearing unnatural configuration at $C_{18'}$, are not isolated. The other byproducts obtained are monomeric in nature clearly arising from transformations of the catharanthine and indole systems.

It was now of particular interest to compare the results obtained when the isomeric 3α,4α-epoxide **4** was employed in the coupling studies. Indeed an unexpected result was obtained in that the only isolated bisindole product (51% yield) possessed spectral data which were not consistent with the 3′,4′-epileurosine structure which would be formed if normal fission of the C_{18}—C_5 bond in **4** had occurred. Careful analysis of the spectral data allowed the assignment of structure **5** to this product. The 'dimeric' nature of this compound was evident from the high resolution mass spectrum (*m/e* calcd. for $C_{46}H_{54}N_4O_9$: 806.409; found: 806.402) while the uv spectrum (λ_{max} 222, 255, 285, 292 nm) clearly revealed the presence of indole and dihydroindole units. The point of attachment of the indole unit at C_{15} of the vindoline ring system was readily ascertained from the ^{1}Hmr spectrum (singlets at δ 6.48 and 6.12 for the C_{14} and C_{17} protons, respectively). As in the previous studies (6, 9), this spectrum was highly informative, being essentially a summation of the appropriate signals for the indole and dihydroindole portions, and virtually on its own established the postulated structure **5**. Although the normal proton signals attributed to the vindoline unit were clearly evident in the ^{1}Hmr spectrum of **5**, several important differences in



the signal patterns for the indole unit were noted. The absence of the indole NH signal, so characteristic in all the previous bisindole products isolated previously (5, 6, 9) and in leurosine prepared above, was immediately noted and a new two-proton AB quartet centered at δ 5.02 (J = 11 Hz) never observed in any of the ^{1}Hmr spectra of the previously studied bisindole products, was noted. This quartet was attributed to the methylene group at C_7' in **5**, a product arising from a rearrangement of the *N*-oxide **4** prior to coupling with vindoline (see later).

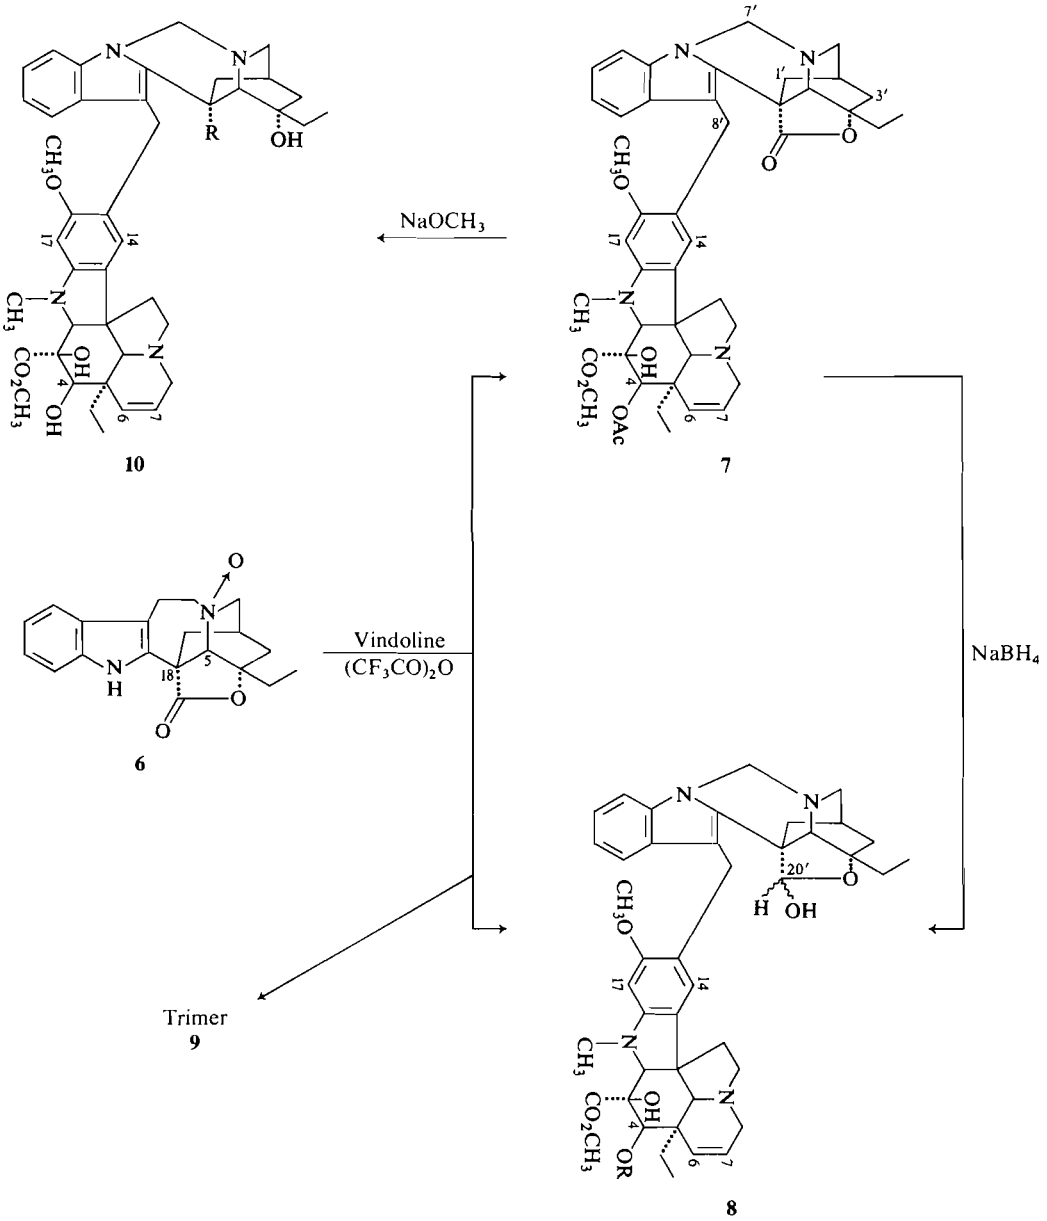
In a complementary series of investigations involving the coupling of the *N*-oxide intermediate of 4α-hydroxydihydrocatharanthinic acid lactone (**6**) (4, 14) with vindoline, a similar series of rearrangement products were isolated and characterized. Thus when **6** was coupled with vindoline in the presence of trifluoroacetic anhydride (methylene chloride, −50°C), three products resulting from the coupling of these units could be isolated. On the basis of careful spectroscopic analyses two of these products were assigned the bisindole structures **7** and **8** (R = $COCH_3$) while the third was a trimer resulting from the reaction of two vindoline units with an indole system.

The major component (62% yield) was assigned the bisindole structure **7** on the basis of the following spectral data. The molecular formula, $C_{45}H_{52}N_4O_8$ as determined by high resolution mass spectrometry (calcd: 776.388; found: 776.376), was consistent with the presence of an indole and dihydroindole unit and this was supported by the uv (λ_{max} 223, 250, 285, 292 nm) and ^{1}Hmr data. With respect to the latter, all the normal vindoline proton signals were evident in the spectrum but again the indole NH was absent and an AB quartet centered at δ 4.95 (2H, J = 12 Hz) could be assigned to the $C_{7'}$-methylene group. In this instance the ^{1}Hmr spectrum also revealed clearly a second new two-proton AB quartet (δ 4.43, J = 16 Hz) attributed to the methylene group ($C_{8'}$) linking the indole and dihydroindole units. The presence of the γ-lactone in **7** was clear from its ir spectrum (1775 cm^{-1}). Chemical experiments to substantiate the structural assignment are discussed later.

The second component (10% yield) differed from **7** in several respects. Its mass spectrum established a molecular formula, $C_{45}H_{54}N_4O_8$, (calcd.: 778.394; found: 778.394) which was two mass units higher than that of **7** while its ir spectrum indicated that the γ-lactone system was absent. The remaining spectral features were consistent with the structural assignment **8** (R = $COCH_3$) for this product. It was tempting to speculate that **8** (R = $COCH_3$) could arise via sodium borohydride reduction of the lactone carbonyl group since this reagent is employed prior to isolation of the coupling products from the reaction mixture. Indeed when **7** was exposed to such reduction (methanol, 0°C) lactol **8** (R = $COCH_3$) is obtained in 75% yield. The stereochemical assignment to the chiral center $C_{20'}$ in **8** remains an open question.

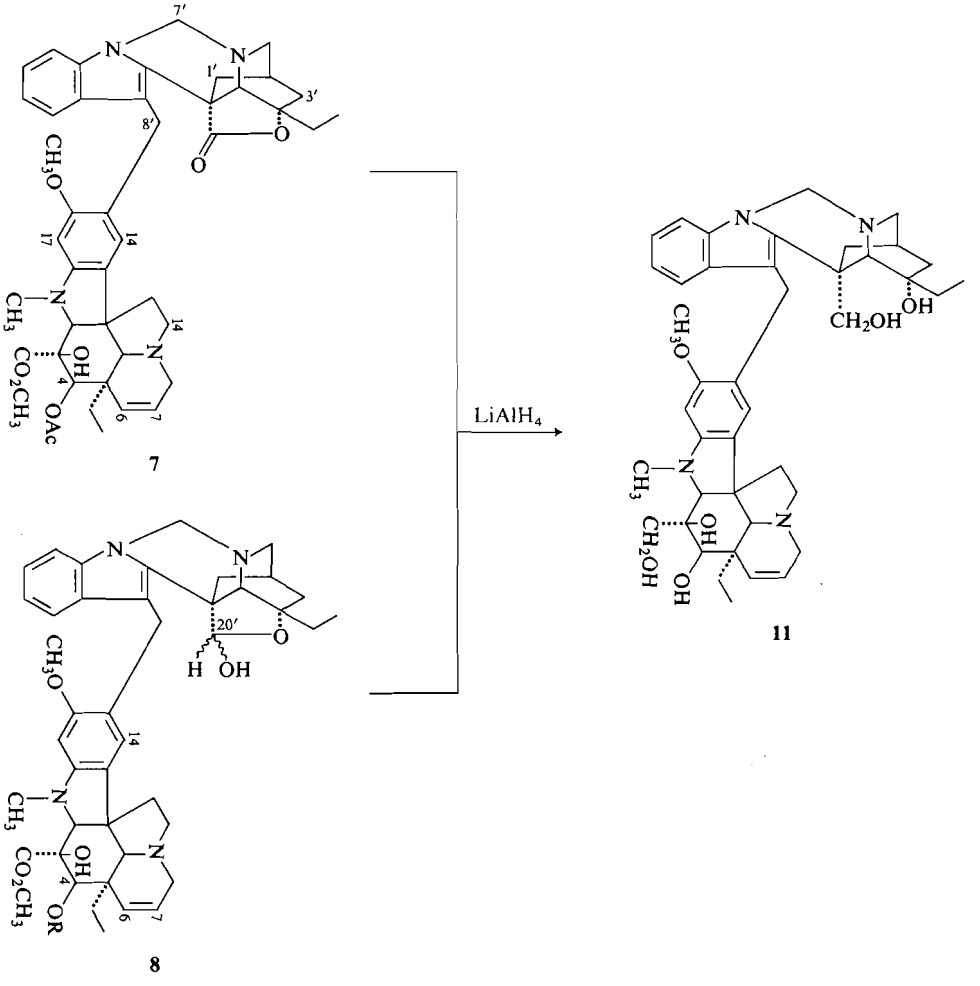
The third product (6% yield) obtained from the coupling of **6** with vindoline is a trimer corresponding to a structure derived from one indole unit and two vindoline units. The thermal lability of this compound in the mass spectrometer made it difficult to obtain the true molecular ion, but under carefully controlled conditions peaks in the desired mass range (*m/e* 1232 and 1234) corresponding to the molecular formulae $C_{70}H_{84}N_6O_{14}$ and $C_{70}H_{86}N_6O_{14}$, respectively, were observed. The ir spectrum of trimer **9** does not show the γ-lactone absorption at 1775 cm^{-1} observed in the spectrum of **7** but possesses a strong carbonyl absorption at 1740 cm^{-1}. In the uv spectrum, the absorption bands due to the dihydroindole chromophore (for example, 313 nm) were of significantly higher intensity than normally observed in spectra of the bisindole alkaloids. The ^{1}Hmr spectrum clearly revealed two vindoline units as evidenced by two sets of aromatic singlets (δ 6.82, 6.38, 6.08, 6.02), two N-CH_3 signals (δ 2.66, 2.64) and two methyl triplets (δ 0.28 and 0.0, J = 7 Hz) in addition to the proton signals for the indole unit. In summary the above data are insufficient to allow a definitive assignment of structure for trimer **9**.

The bisindole products **7** and **8** (R = $COCH_3$) were of more direct interest to this study so further experiments were conducted to substantiate the assignments made. For this purpose the lactone **7** was reacted with sodium methoxide (methanol, room temperature) and the product obtained in 77% yield was the hydroxyester **10** (R = CO_2CH_3) [ir: no γ-lactone absorption; ^{1}Hmr: δ 3.87, 3.84 (2s, 6H, OCH_3 and C_3-$COOCH_3$), 3.54 (s, 3H, $C_{18'}$-$COOCH_3$), no acetyl; ms: *m/e* calcd. for $C_{44}H_{54}N_4O_8$:



766.394; found: 766.399]. Under identical conditions, catharanthine lactone (4α-hydroxydihydrocatharanthinic acid lactone, **12**) is *not* converted to the corresponding hydroxyester thereby revealing a significant difference in reactivity of the lactone system when the rigid Iboga alkaloid skeleton is intact. Similarly lactol **8** (R = $COCH_3$) is stable to these conditions, the only reaction being hydrolysis of the acetate group to provide **8** (R = H).

The close relationship between **7** and **8** was confirmed when lithium aluminum hydride reduction of each compound provided the identical product. Thus when **7** or **8** (R = $COCH_3$) were reacted with $LiAlH_4$ in tetrahydrofuran at room temperature, the expected product **11** [ir: 3540, 3390 cm^{-1}, no carbonyl absorption; ^{1}Hmr δ 3.86 (s, 3H, OCH_3), 2.98 (s, 3H, NCH_3), no acetyl or carbomethoxy methyl signals; ms: *m/e* calcd. for $C_{42}H_{54}N_4O_6$: 710.404; found:



710.401) was isolated in 94% yield from the lactone **7** and 60% yield from the lactol **8** (R = $COCH_3$).

It was again of interest to compare the reactivity of catharanthine lactone (**12**) toward hydride reducing agents in order to evaluate the relative differences in reaction of this carbonyl system in the normal Iboga series with that of the rearranged system shown in **7**. For this purpose **12** was reacted under mild conditions with sodium borohydride and more severe conditions with lithium aluminum hydride. With the former reagent in methanol at room temperature, **12** was converted to the lactol **13** in 86% yield [ir: no carbonyl absorption; ms: *m/e* calcd. for $C_{20}H_{24}N_2O_2$: 324.184; found: 324.1844]. This product was a 1:1 mixture of the isomeric lactols as evidenced by the appropriate signals in the ^{1}Hmr spectrum. Thus two indole NH signals (δ 8.32, 7.99), two singlets (δ 5.29, 5.24) attributed to C_{20}-H, and two methyl triplets (δ 0.97, 0.94, $J = 7$ Hz) of essentially equal intensity were observed. This mixture was not separated into its pure components.

Somewhat surprisingly, the lactone **12** proceeded to the lactol **13** (77% yield) with lithium aluminum hydride even under rather severe conditions (refluxing tetrahydrofuran). These results portray, on the one hand, a similarity in reaction of the bisindole lactone **7** and **12** with borohydride (**7** → **8** and **12** → **13**) but a distinct difference with $LiAlH_4$ (compare **7** and **8** → **11** vs. **12** → **13**).

The isolation of the rearranged bisindole products **5**, **7**, and **8** was of considerable interest

since it portrayed the first instance in our extensive studies of the Polonovski-type coupling process (5, 6) where such substances had been observed as the predominant, if not exclusive, products. All previous coupling products were shown to arise from initial fragmentation of the C_{18}—C_5 bond in the *N*-oxide intermediate and subsequent reaction of this intermediate with the dihydroindole unit. The bisindole products **5**, **7**, and **8** clearly arise from fragmentation of the C_7—C_8 bond and subsequent reaction of the intermediate thus formed with vindoline as shown in the sequence **14** → **15** → **7**.

A comparison of the results in the isomeric epoxide series is particularly striking with the normal C_{18}—C_5 bond fragmentation process being predominant in the 3β,4β-epoxide (**1** → **3**) while with the 3α,4α-isomer only the alternative C_7—C_8 bond fragmentation is observed (**4** → **5**) under *identical* conditions of coupling. This latter fragmentation process has been recently observed in other laboratories (8, 10)[3] although there are differences in their experimental procedures when compared to ours.

It is interesting to note that in all of our studies thus far which are internally consistent in terms of the reaction conditions employed, the two examples which have led to the rearranged products are catharanthine derivatives containing C_3 and/or C_4 oxygen functionality in the α orientation as shown in **4** and **6**. Whether this pattern will continue in our future studies is of considerable importance since one of the obvious extensions of the Polonovski-type coupling to the synthesis of the clinical drugs vinblastine and vincristine would involve a

2

C_4α-oxygenated catharanthine derivative (11). Studies in this direction are presently underway.

It should be noted that the synthesis of leurosine, as reported herein, is less efficient than the first synthesis of this alkaloid reported earlier from these laboratories (12). Another low yielding synthesis of this alkaloid has been reported from another laboratory (13).

Experimental

All details concerning spectral measurements, chromatographic separations, etc. are provided in the accompanying publication (14).

Coupling of 3β,4β-Epoxydihydrocatharanthine-N-oxide (1) with Vindoline (2): Leurosine 3 (R = CO_2CH_3)

3β,4β-Epoxydihydrocatharanthine (34 mg, 0.1 mmol) and *m*-CPBA (19 mg, 0.11 mmol) were stirred in dichloromethane (1 ml) at −20°C for 20 min under an atmosphere of dry argon to form the *oxide* **1**. The solution was cooled to −50°C and vindoline **2** (50 mg, 0.11 mmol) followed by redistilled trifluoroacetic anhydride (60 µl, 0.5 mmol) were added. The mixture was stirred at −45 to −55°C for 4 h, quenched with excess $NaBH_4$ slurry in ethanol, and extracted with dichloromethane. The extracts were dried (Na_2SO_4) and evaporated *in vacuo*. Chromatography on silica gel afforded the previously described (6) isomers of 15-(2,2,2-trifluoro-1-hydroxyethyl)-vindoline, together with leurosine **3** (R = CO_2CH_3) (16 mg, 20%), identical with an authentic sample.

Coupling of 3α,4α-Epoxydihydrocatharanthine-N-oxide (4) with Vindoline (2): the Bisindole Product 5

3α,4α-Epoxydihydrocatharanthine (62 mg, 0.176 mmol) and *m*-CPBA (33 mg, 0.193 mmol) were stirred in dichloromethane (2 ml) at −20°C for 2 h under an atmosphere of dry argon to form the *oxide* **4**. The solution was cooled to −50°C and vindoline **2** (56 mg, 0.123 mmol) followed by redistilled trifluoroacetic anhydride (120 μl) were added. The mixture was stirred at ca. −50°C for 5 h, quenched with excess $NaBH_4$ slurry in ethanol, and extracted with dichloromethane. The extracts were dried (Na_2SO_4) and evaporated *in vacuo*. Chromatography on silica gel afforded an unidentified catharanthine derivative (14 mg), vindoline (14 mg), and the *bisindole* **5** (41 mg, 51%) as an amorphous solid; uv: λ_{max} 292 (4.61), 285 (4.52), 255 (4.05), 222 (3.91); ir: ν_{max} 1740; ^{1}Hmr: δ 6.80–7.41 (4H, m, aromatic protons), 6.48 (1H, s, C_{14}-*H*), 6.12 (1H, s, C_{17}-*H*), 5.78 (1H, dd, J = 10, 4 Hz, C_7-*H*), 5.39 (1H, s, C_4-*H*), 5.18 (1H, d, J = 10 Hz, C_6-*H*), 5.02 (2H, 2d, J = 11 Hz, $C_{7'}$-H_2), 3.95 (3H, s, -OCH_3), 3.81 (3H, s, -OCH_3), 3.62 (3H, s, -OCH_3), 2.02 (3H, s, -OCOCH_3), 0.98 (3H, t, J = 7 Hz, -CH_2CH_3), 0.09 (3H, t, J = 7 Hz, -CH_2CH_3); ms: *m/e* 806(M^+), 790, 737, 736, 731, 730, 718, 714, 684, 680, 658, 648, 647, 646, 645, 630, 624, 538, 351, 338, 282, 200, 188, 169, 149, and 135 (base peak). Coupling of 4α-Hydroxydihydrocatharanthinic Acid Lactone-N-oxide (6) with Vindoline (2): the Bisindole Products 7 and 8 and the Trimer 9

4α-Hydroxydihydrocatharanthinic acid lactone (100 mg, 0.31 mmol) and *m*-CPBA (56 mg, 0.325 mmol) were stirred in dichloromethane (3 ml) at −25°C under an atmosphere of dry nitrogen for 45 min. The solution was cooled to −50°C and vindoline **2** (100 mg, 0.219 mmol) followed by redistilled trifluoroacetic anhydride (216 μl) were added. The mixture was stirred at −50 to −60°C for 5 h, poured into a slurry of $NaBH_4$ (500 mg) in methanol (10 ml), shaken for 5 min, and extracted with dichloromethane. The combined extracts were dried (Na_2SO_4) and evaporated *in vacuo*. Chromatography on silica gel and crystallization from ethyl acetate – pentane afforded the following.

(*i*) *The bisindole lactone* **7**, mp 182–187°C (105 mg, 62%); uv: λ_{max} 292 (3.92), 285 (3.92), 250 (4.05), 223 (4.52), 211 (4.61); ir: ν_{max} 1775, 1740; ^{1}Hmr: δ 9.44 (1H, s, D_2O-exchangeable, -O*H*), 6.90–7.45 (4H, m, aromatic protons), 6.60 (1H, s, C_{14}-*H*), 6.09 (1H, s, C_{17}-*H*), 5.73 (1H, dd, J = 10, 4 Hz, C_7-*H*), 5.38 (1H, s, C_4-*H*), 5.13 (1H, d, J = 10 Hz, C_6-*H*), 4.95 (2H, 2d, J = 12 Hz, $C_{7'}$-H_2), 4.43 (2H, 2d, J = 16 Hz, $C_{8'}$-*H*), 3.83 (3H, s, -OCH_3), 3.73 (3H, s, CO_2CH_3), 2.62 (3H, s, N-CH_3), 2.00 (3H, s, -OCOCH_3), 1.03 (3H, t, J = 7 Hz, $C_{4'}$-CH_2CH_3), 0.10 (3H, t, J = 7 Hz, C_5-CH_2CH_3); ms: *m/e* 776(M^+), 717, 716, 702, 701, 700, 630, 629, 617, 616, 615, 509, 508, 494, 321, 323, 322, 309, 308, 296, 282, 269, 267, 263, 236, 235, 234, 222, 209, 202, 200, 188, 139, 135 (base peak), 122, 121. $NaBH_4$ Reduction of (7): the Lactol 8 (R = $COCH_3$)

A solution of **7** (20 mg) and trifluoroacetic anhydride (100 μl) in dichloromethane (2 ml) was added dropwise to $NaBH_4$ (50 mg) in methanol (2 ml) at 0°C. Excess $NaBH_4$ (50 mg) was added in two portions at 15 min intervals. The mixture was stirred at 0°C for 30 min, diluted with water (1 ml), saturated NaCl solution (5 ml), and extracted with dichloromethane. The combined extracts were dried (Na_2SO_4), and evaporated *in vacuo*. Chromatography on silica gel gave **7** (9.8 mg, 49%) and **8** (R = $COCH_3$) (7.7 mg, 38%) identical with that obtained above.

Reaction of (7) with NaOMe: the Hydroxyester 10

A solution of **7** (10 mg, 0.013 mmol) in anhydrous methanol (1 ml) was added to sodium methoxide in methanol (10 mg of sodium metal in 1 ml of anhydrous methanol) and the mixture stirred under an atmosphere of dry nitrogen for 20 h. The reaction mixture was cooled to 0°C, carefully neutralized with Amberlite IR-120, and filtered. The filtrate was evaporated *in vacuo*. Chromatography on silica gel and crystallization from ethyl acetate – methanol pentane afforded the *hydroxyester* **10** mp 170–177°C (7.6 mg, 77%); uv: λ_{max} 293 (4.03), 288 (4.00), 250 (4.13), 224 (4.59), 212 (4.68); ir: ν_{max} 3550, 1720; ^{1}Hmr: δ 6.8–7.25 (4H, m, aromatic protons), 6.47 (1H, s, C_{14}-*H*), 6.14 (1H, s, C_{17}-*H*), 5.62-5.86 (2H, m, C_7-*H*, C_6-*H*), 5.06 (2H, 2d, J = 12 Hz, $C_{7'}$-*H*), 3.87 (3H, s, -OCH_3), 3.84 (3H, s, -CO_2CH_3), 3.54 (3H, s, -CO_2CH_3), 2.73 (3H, s, -NCH_3), 0.96 (3H, t, J = 7 Hz, $C_{4'}$-CH_2CH_3), 0.42 (3H, t, J = 7 Hz, C_5-CH_2CH_3); ms: *m/e* 766(M^+), 735, 734, 702, 701, 700, 675, 674, 619, 618, 617, 615, 536, 509, 508, 495, 494, 481, 354, 321, 308, 297, 263, 248, 246, 240, 234, 202, 200, 188, 174, 172, 170, 154, 149, 135 (base peak), 122, 121, 108, 107. High resolution molecular weight determination calcd. for $C_{44}H_{54}N_4O_8$: 766.394; found: 766.399. *Anal.* calcd. for

$C_{44}H_{54}N_4O_8 \cdot CH_3OH$: C 67.66, H 7.27, N 7.01; found: C 67.80, H 7.30, N 6.66.

NaOMe Opening of the Lactol **8** *(R = $COCH_3$): the Lactol* **8** *(R = H)*

A solution of **8** (R = $COCH_3$) (8 mg) in anhydrous methanol (1 ml) was added to sodium methoxide (from 10 mg of sodium metal) in anhydrous methanol (1 ml) and the mixture stirred at ambient temperature under a nitrogen atmosphere for 17 h. Work-up, as described for the preparation of **10**, gave the *lactol* **8** (R = H), (5.8 mg, 77%); uv: λ_{max} 292 (3.89), 287 (3.88), 250 (4.014), 222 (4.40), 212 (4.45); ir: ν_{max} 3550, 3450, 1725; ^{1}Hmr: δ 6.9–7.4 (4H, m, aromatic protons), 6.72 (1H, s, C_{14}-*H*), 6.12 (1H, s, C_{17}-*H*), 5.76 (2H, m, C_7-*H*, C_6-*H*), 5.45 and 5.42 (1H, 2s, $C_{19'}$-*H*), 5.08 (1H, d, *J* = 12 Hz, $C_{7'}$-*H*), 4.99 (1H, d, *J* = 12 Hz, $C_{7'}$-*H*), 3.86 (3H, s, OCH_3), 3.84 (3H, s, OCH_3), 2.74 (3H, s, $-NCH_3$), 1.04 (3H, t, *J* = 7 Hz, $C_{4'}$-CH_2CH_3), 0.46 (3H, t, *J* = 7 Hz, C_5-CH_2CH_3); ms: *m/e* 736(M^+), 734, 703, 702, 701, 700, 677, 676, 674, 660, 620, 619, 618, 617, 538, 511, 510, 509, 508, 497, 495, 494, 393, 354, 337, 336, 321, 308, 277, 265, 263, 248, 240, 234, 202, 200, 195, 188, 168, 154, 149, 135 (base peak), 122, 121, 107. High resolution molecular weight determination calcd. for $C_{43}H_{52}N_4O_7$: 736.384; found: 736.388.

LAH Reduction of Lactone 7: the Pentahydroxy Bisindole **11**

Lithium aluminum hydride (30 mg) was added to a solution of the *lactone* 7 (20 mg) in anhydrous THF (1.5 ml). The mixture was stirred at ambient temperature for 18 h, treated with a few drops of water, and filtered. The filtrate was concentrated *in vacuo*, chromatographed on silica gel, and crystallized from ethyl acetate – pentane to afford **11**, mp 188–197°C (dec) (17 mg, 94%); uv: λ_{max} 294 (3.96), 288 (3.91), 250 (4.05), 226 (4.43), 213 (4.46); ir: ν_{max} 3540, 3390; ^{1}Hmr: δ 8.62 (1H, s, -O*H*), 6.8–7.4 (4H, m, aromatic protons), 6.48 (1H, s, C_{14}-*H*), 6.15 (1H, s, C_{17}-*H*), 5.75 (1H, dd, *J* = 10, 4 Hz, C_7-*H*), 5.56 (1H, d, *J* = 10 Hz, C_6-*H*), 5.04 (1H, d, *J* = 12 Hz, $C_{7'}$-*H*), 4.86 (1H, d, *J* = 12 Hz, $C_{7'}$-*H*), 3.86 (3H, s, $-OCH_3$), 2.98 (3H, s, $-NCH_3$), 0.96 (3H, t, *J* = 7 Hz, $C_{4'}$-CH_2CH_3), 0.38 (3H, t, *J* = 7 Hz, C_5-CH_2CH_3); ms: *m/e* 710(M^+), 709, 708, 692, 679, 677, 676, 675, 674, 662, 660, 658, 622, 621, 542, 541, 513, 512, 511, 498, 494, 429, 399, 398, 381, 380, 366, 365, 364, 363, 355, 354, 352, 325, 324, 312, 311, 297, 295, 294, 281, 278, 233, 229, 226, 223, 221, 210, 202, 200, 188, 169, 168, 167, 149 (base peak), 135, 124, 122, 115, 107. High resolution molecular weight determination calcd. for $C_{42}H_{54}N_4O_6$: 710.404; found: 710.401.

LAH Reduction of Lactol **8** *(R = $COCH_3$): the Pentahydroxy Bisindole* **11**

Reaction of **8** (R = $COCH_3$) (7 mg) with LAH (10 mg) as described above, gave **11** (3.8 mg, 60%) identical with that prepared earlier.

Reduction of 4α-Hydroxydihydrocatharanthinic Acid Lactone **12**: *the Lactol* **13**

(*a*) The *lactone* **12** (10 mg) was added to a solution of $NaBH_4$ (50 mg) in methanol (2 ml) at 0°C. Excess $NaBH_4$ (50 mg) was added in two portions at ca. 15 min intervals. The mixture was stirred at ambient temperature for 2 h. Work-up, as described above for the reduction of **7**, gave the *lactol* **13** (8.7 mg, 87%) as a mixture of diastereomers; uv: λ_{max} 283 (3.80), 280 (3.84), 274 (3.83), 222 (4.273); ir: ν_{max} 3550, 3425, 3340; ^{1}Hmr: δ 8.32 and 7.99 (1H, 2 bs, -N*H*), 6.9–7.6 (4H, m, aromatic protons), 5.29 and 5.24 (1H, 2s, C_{19}-*H*), 0.97 and 0.94 (3H, 2t, *J* = 7 Hz, $-CH_2CH_3$); ms: *m/e* 324 (M^+,base peak), 322, 307, 306, 278, 277, 263, 249, 236, 235, 234, 221, 209, 205, 204, 193, 184, 168, 167, 159, 154, 144, 141, 135, 130, 128, 122, 121, 115, 108, 105. High resolution molecular weight determination calcd. for $C_{20}H_{24}N_2O_2$: 324.184; found: 324.184.

(*b*) Lithium aluminum hydride (10 mg) was added to a solution of **12** (10 mg) in anhydrous THF (1.5 ml) and the mixture stirred at ambient temperature for 18 h. Work-up, as described above for the preparation of **11**, gave the *lactol* **13** (7.8 mg, 78%) identical with that described above.

Long-range proton–^{19}F spin–spin coupling interactions in phenyltrifluorosilane

WILLIAM J. E. PARR,[1] T. SCHAEFER, AND K. MARAT
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 14, 1977

WILLIAM J. E. PARR, T. SCHAEFER, and K. MARAT. Can. J. Chem. **55**, 3243 (1977).

Analysis of the proton magnetic resonance spectrum of phenyltrifluorosilane yields the spin–spin coupling constants between the fluorine nuclei and the protons. These are compared with the analogous long-range coupling constants in benzotrifluoride, toluene, and phenylsilane and are rationalized in terms of coupling mechanisms. The coupling over six bonds is assessed as a base point for the estimation of hindered rotation about the carbon–silicon bond.

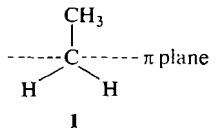
WILLIAM J. E. PARR, T. SCHAEFER et K. MARAT. Can. J. Chem. **55**, 3243 (1977).

L'analyse du spectre de résonance magnétique du proton du phényltrifluorosilane nous fournit les constantes de couplage spin–spin entre le noyau fluor et les protons. Celles-ci sont comparées à des constantes de couplage analogues à longue distance pour le trifluorobenzyle, le toluène et le phénylsilane et sont rationalisées en termes de mécanismes de couplage. Le couplage au delà de six liaisons est assigné comme référence pour l'estimation de la rotation empêchée autour du lien carbone–silicium.

[Traduit par le journal]

Introduction

The long-range spin–spin coupling constants between ring protons and protons or fluorine nuclei in the sidechain of benzene derivatives have been investigated in some detail (1–17). In addition to providing tests of theories of the transmission of spin state information, the couplings are often sensitive to the conformation of the molecule and have been employed in the empirical determination of free energy differences between conformational isomers (17, 18). It has also proved possible to extend their application to the derivation of twofold rotational barriers of magnitudes between about 0.2 and 2.2 kcal/mol (19, 20), such values being inaccessible to lineshape methods. For example, a careful comparison of the long-range coupling over six bonds, $^6J_p^{H,CH}$, in toluene and in phenylethane, combined with a hindered rotor treatment, yields a twofold barrier of 1.2 ± 0.1 kcal/mol to rotation about the C—CH_2 bond in the latter molecule in solution. In addition it is clear that **1** is the low-energy conformation (19).



1

It has also been seriously suggested (20, 21) that analogous couplings to fluorine nuclei on the sidechain, $^6J_p^{H,CF}$, are useful in finding small twofold internal barriers in $C_6H_5CHF_2$ and $C_6H_5CH_2F$.

An attempt to extend the approach to phenyl derivatives of the third row of the periodic table was partially successful when the barriers to rotation about the C_6H_5—Si bond were found for $C_6H_5SiH(CH_3)_2$ and $C_6H_5SiHCl_2$ and were estimated for $C_6H_5SiH_2Cl$ and $C_6H_5SiH_2CH_3$ (22).

All this work depends on having reliable values for couplings over six bonds to protons in the *para* position. These are now known for $C_6H_5CH_3$, $C_6H_5CF_3$, and $C_6H_5SiH_3$.

This paper reports the analysis of the proton magnetic resonance spectrum of $C_6H_5SiF_3$ and the determination of the long-range couplings from the ring protons to ^{19}F nuclei. The latter are compared with the analogous couplings in the three molecules above and are assessed for their possible use in the measurement of barriers to internal rotation. The magnitudes of the coupling constants are rationalized in terms of σ, σ–π, and direct (through-space) mechanisms.

Experimental

Antimony trifluoride (50 g, 0.28 mol) and tetramethylenesulphone (50 ml) were placed in a 250 ml flask equipped with a reflux condenser, dropping funnel, and thermometer. Phenyltrichlorosilane (14.1 g, 0.067 mol) was added from the dropping funnel at a rate such that the reaction temperature never exceeded 100°C. The phenyltrifluorosilane was distilled through a 15 cm

column, collecting the portion that boiled at 95–98°C. The yield was 10.7 g (98%).

Due to the air sensitivity of the phenyltrifluorosilane, it was necessary to prepare the sample under anhydrous conditions. C_6D_6, C_6F_6, and TMS were all dried for 24 h over a molecular sieve. Sufficient phenyltrifluorosilane for a 20 vol.% solution was condensed into a dried nmr tube from a bulb on the vacuum system. C_6D_6 and small quantities of C_6F_6 and TMS were condensed into the tube which was then flame sealed under dynamic vacuum.

The proton magnetic resonance spectrum was calibrated on a HA 100 spectrometer at 305 K. Calibration lines were placed at approximately 5 Hz intervals and the sweep and manual oscillator frequencies were recorded for each such line. The spectral dispersion was 1 Hz/cm, the sweep rate was 0.02 Hz/s, and the other instrumental parameters were adjusted to minimize distortion from saturation or filtering phenomena. The ^{19}F resonance spectrum was recorded in a similar way on a DA60I spectrometer at 301 K, employing C_6F_6 as an internal lock. The peak positions determined in this manner had rms deviations near 0.02 Hz.

Ab initio calculations at the STO-3G level of molecular orbital theory (23) employed a standard geometry (24) for the phenyl group, tetrahedral angles at silicon, and C—Si, Si—F bond lengths of 1.843 and 1.561 Å, respectively.

Results and Discussion

Spectral Analysis

The proton magnetic resonance spectrum was analyzed with the computer program LAME (25, 26). The spectral asymmetry was sufficient to establish the sign sequence given in Table 1. Figure 1 illustrates the sensitivity of the calculated spectrum to the sign of the small coupling, $^4J_o^{H,SiF_3}$. The *meta* and *para* proton peaks could only be fitted if $^5J_m^{H,SiF_3}$ and $^6J_p^{H,SiF_3}$ had opposite signs. The ^{19}F spectrum was consistent with a positive sign for $^5J_m^{H,SiF_3}$ and a negative sign for $^6J_p^{H,SiF_3}$. The sign sequence in Table 1 is firmly established. The standard deviations of 0.004 to 0.005 Hz (Table 1) in the long-range couplings suggest an accuracy of 0.02 Hz.

The Spectral Parameters within the Phenyl Group

The chemical shifts are no doubt influenced by the anisotropy of the benzene solvent molecules, but a comparison with the shifts for neat benzotrifluoride (8) is partially valid. It suggests that the CF_3 group withdraws slightly more charge from the ring than does the SiF_3 group. A similar conclusion follows from the ^{13}C chemical shifts (27).

In benzene, $^3J_o^{H,H}$, $^4J_m^{H,H}$, and $^5J_p^{H,H}$ are 7.54, 1.37, and 0.69 Hz, respectively (28). Comparison with the data in Table 1 indicates a very small perturbation of these values by the SiF_3 group. In fact, the sum of the six coupling constants in Table 1 is 19.86 Hz as compared to the 19.88 Hz for the corresponding sum in benzene. This sum is 20.65 Hz for $C_6H_5CF_3$.

Long-range Coupling Constants $^6J_p^{H,XH}$ and $^6J_p^{H,XF}$ (X = C or Si)

The sixfold barrier to internal rotation is 0.014 kcal/mol in toluene (29) and 0.010 kcal/mol in benzotrifluoride (30). Consequently their coupling constants in Table 1 represent averages over the essentially free rotation about the C—CH_3 and C—CF_3 bonds. The barrier to rotation about the C—SiH_3 bond in phenylsilane is 0.018 kcal/mol (31) and, on the assumption that it is no higher in phenyltrifluorosilane, the coupling constants for these two compounds in

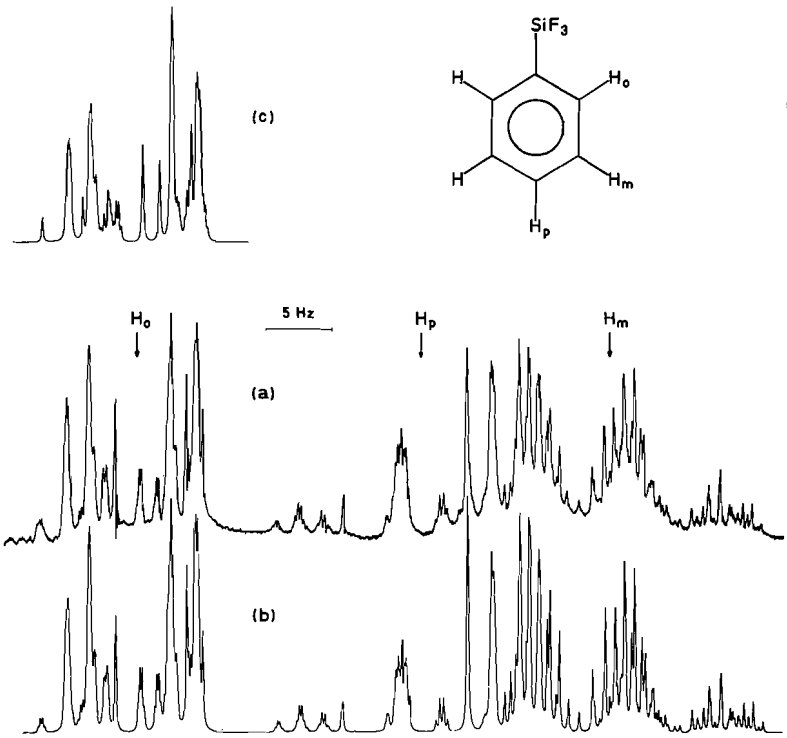

FIG. 1. The ring proton magnetic resonance spectrum at 100 MHz of a 20 vol.% solution of phenyltrifluorosilane in benzene-d_6 is shown in *a*. In *b* the spectrum calculated with the parameters in Table 1 is presented. The appearance of the calculated spectrum of the *ortho* protons, under conditions where $^4J_o^{H,SiF_3}$ is negative, is illustrated in *c*.

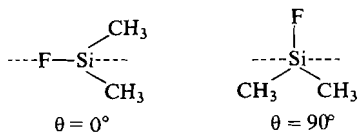
Table 1 may also be taken as averages over free rotation.

On the basis of INDO-MO-FPT calculations (7) and of measurements of $^6J_p^{CH_3,CH_3}$ (3, 4) it is apparent that $^6J_p^{H,CH_3}$ is proportional to $\sin^2\theta$, where θ is the angle by which a C—H bond of the methyl group twists out of the plane of the aromatic ring. The calculations agree quantitatively with the observed value of -0.62 Hz. This number is a base point in the derivation of barriers to internal rotation in α- and α,α-substituted toluene derivatives (19).

Similar calculations on $^6J_p^{H,CF_3}$ (32) also suggest a $\sin^2\theta$ dependence but predict a magnitude almost twice as large as the observed one of 0.64 Hz.

When the sidechain carbon atom is replaced by a silicon atom a σ–π hyperconjugative model suggests that the increased bond lengths may well reduce the overlap between the orbitals in the sidechain and the $p\pi$ orbitals in the phenyl group, thereby reducing the magnitude of the σ–π parameters. Indeed (see Table 1), $^6J_p^{H,SiH}$ is just over half as large in magnitude as $^6J_p^{H,CH}$. Similarly, $^6J_p^{H,SiF}$ is just under half as large in magnitude as $^6J_p^{H,CF}$.

$^6J_p^{H,SiF}$ is -0.28 Hz in $C_6H_5SiF_3$, so small a modulus that use of it as a base in determining barriers to rotation about the C—Si bond becomes relatively difficult for the following reasons. $^6J_{90}^{H,SiF}$ is -0.56 Hz. Now, for example, in $C_6H_5SiF(CH_3)_2$ it seems reasonable that the low-energy conformation is **2** and that the high-energy conformation is **3**. In **2**, $\sin^2\theta$ is zero. For free rotation, $\langle\sin^2\theta\rangle$ is 0.5 so that the observed $^6J_p^{H,SiF}$ would be -0.28 Hz. For a barrier lying between 0 and about 3 kcal/mol, $\langle\sin^2\theta\rangle$ would vary between 0.5 and 0.05. An error of 0.02 Hz in the measurements of $^6J_p^{H,SiF}$



in $C_6H_5SiF_3$ and of $C_6H_5SiF(CH_3)_2$ would introduce an error of about 20% into the determination of the barrier (33). Furthermore, small perturbations of ^6J by the substituents attached to silicon may introduce a further uncertainty into the barrier. It appears that the value of $^6J_p^{H,SiF}$ is near the limit at which significant deductions about conformational preferences and rotational barriers are still possible in compounds of formula $C_6H_5SiFX_2$.

$^5J_m^{H,XH}$ and $^5J_m^{H,XF}$ (X = C or Si)

The π electron contribution to $^5J_m^{H,CH_3}$ is 0.21 Hz (3, 4), leaving 0.15 Hz to the σ electron mechanism. The 0.20 Hz observed for $^5J_m^{H,SiH}$ can be attributed to reduced magnitudes of both coupling mechanisms. Clearly, both $^5J_m^{H,CF}$ and $^5J_m^{H,SiF}$ have a large σ component and, in view of their equality and of the relative magnitudes of the corresponding six-bond couplings, this component is larger in the silicon compound. INDO-MO-FPT calculations overestimate $^5J_m^{H,CH}$ and $^5J_m^{H,CF}$ (7, 32).

$^4J_o^{H,XH}$ and $^4J_o^{H,XF}$ (X = C or Si)

The magnitudes of $^4J_o^{H,CF_3}$ and $^4J_o^{H,CH_3}$ are equal (Table 1). According to INDO-MO-FPT calculations, the equality is coincidental. In addition to the σ–π and σ electron mechanisms common to both $^4J_o^{H,CH_3}$ and $^4J_o^{H,CF_3}$, the latter contains in addition a contribution from a direct interaction dependent on the proximity of the bonds carrying the coupled nuclei (7, 32).

The relatively small magnitude of $^4J_o^{H,SiH_3}$ can plausibly be attributed to a decrease in the magnitude of the σ–π mechanism (see $^6J_p^{H,CH_3}$) combined with a small positive σ electron contribution. The decrease in the former and the change in sign of the latter contributions relative to their role in determining $^4J_o^{H,CH_3}$ (7) could well be a consequence of the C—Si and Si—H bond lengths.

The positive sign of $^4J_o^{H,SiF_3}$ can be rationalized by assigning a lesser importance to the direct (through-space) mechanism which depends critically on the ^{19}F, ^1H internuclear distance (34), combined with a positive σ electron contribution which outweighs the expected negative σ–π mechanism (compare $^6J_p^{H,SiF_3}$).

STO-3G Calculations

These gave a barrier of 0.005 kcal/mol to rotation about the C—Si bond. Although such a small value is below the level of significance of these *ab initio* MO calculations (35), it is consistent with the very small barriers measured for the other three compounds.

Cupric ion binding by coal humic acids at p*H*'s 1–3

JOHN B. GREEN AND STANLEY E. MANAHAN[1]
Chemistry Department, University of Missouri-Columbia, Columbia, MO 65201, U.S.A.

Received October 25, 1976[2]

JOHN B. GREEN and STANLEY E. MANAHAN. Can. J. Chem. **55**, 3248 (1977).

The extent and mechanism of cupric ion binding by humic acid (HA) at low p*H*'s where the material was insoluble in aqueous media was investigated. It was shown that significant amounts of Cu(II) were bound by HA even at p*H*'s as low as 1.35. Two major types of HA–Cu^{2+} binding were observed. Binding which was accompanied by exchange of H^+ was more prevalent at high p*H*'s and $[Cu^{2+}]$. Nonexchange bonding occurred at all p*H*'s, but assumed greater importance at low p*H*'s. Since the pattern of Cu(II) uptake could not be interpreted in terms of basic ion exchange or surface adsorption theory, a new model was proposed which qualitatively explained the dependence of Cu(II) on p*H* and $[Cu^{2+}]$. The model assumed that the intermolecular bonding in flocculated HA was determined by the relative amounts of H^+ and Cu^{2+} available for forming bridging bonds between the HA molecules. The model suggested that at high concentrations of Cu(II) and/or high p*H*'s, the floc structure was such that the formation of copper bridge bonds was maximized.

JOHN B. GREEN et STANLEY E. MANAHAN. Can. J. Chem. **55**, 3248 (1977).

On a étudié l'étendue et le mécanisme de liaisons de l'ion cuprique par l'acide humique (AH) à de bas p*H* où les matériaux sont insolubles dans un milieu aqueux. On a pu montrer que des quantités importantes de Cu(II) sont liées en AH même à des p*H* aussi bas que 1.35. On a observé deux types majeurs de liaisons AH et Cu^{2+}. La liaison qui est accompagnée par un échange de H^+ est plus importante à des p*H* élevés et des concentrations de $[Cu^{2+}]$ élevées. La liaison sans échange se produit à tous les p*H*, mais elle est plus importante à des p*H* plus bas. Puisque l'on ne pouvait pas interpréter l'évolution de l'absorption de $[Cu^{2+}]$ en termes d'échange d'ions basiques ou de la théorie de l'adsorption par la surface, on propose un nouveau modèle qui explique qualitativement la relation entre le Cu(II) et le p*H* et la concentration en $[Cu^{2+}]$. Dans ce modèle, on fait l'hypothèse que la liaison intermoléculaire dans du AH floculé est déterminée par les quantités relatives de H^+ et de Cu^{2+} disponibles pour la formation de liens effectuant des ponts entre les molécules de AH. Le modèle suggère qu'à des concentrations élevées de Cu(II) et/ou des p*H* élevés, la structure flocculée est telle que la formation des liens pontés de cuivre est maximale.

Introduction

A large portion of the recent literature on humic acids (HA) extracted from soil, peat, and coal has been devoted to study of their metal ion binding properties (1, 2). However, practically all work has been at p*H* values where appreciable ionization of acidic functional groups on HA occurs. One mechanism of binding at the commonly studied p*H* range is thought to involve chelation by *ortho* phenolate and carboxylate groups on aromatic rings (1–5). This type of binding at acidic p*H*'s is unlikely, however, due to intense competition by hydrogen ion for very weakly acidic phenolate groups.

Two plausible mechanisms for interaction of HA and Cu(II) under acidic conditions are adsorption and ion exchange. A cation exchange reaction is usually symbolized in the following way for synthetic cation resins in hydrogen form:

$$[1] \qquad n\mathrm{HR} + \mathrm{M}^{n+}{}_{(aq)} = \mathrm{MR} + n\mathrm{H}^{+}{}_{(aq)}$$

HR and MR are resin-bound H^+ and M^{n+}.

The corresponding equilibrium quotient for [1] is, of course:

$$[2] \qquad K = \frac{[\mathrm{M}]_r[\mathrm{H}^+]_s{}^n}{[\mathrm{H}]_r{}^n[\mathrm{M}^{n+}]_s}$$

Davies *et al.* (5) referred to equations analogous to [1] and [2] in their work on retention of low levels of Cu(II) on HA. They found, however, that the quotient (K) varied with the extent of cupric ion saturation of HA. Also, Szalay (6) explained $UO_2{}^{2+}$ uptake by HA in terms of ion exchange.

Adsorption isotherms have also been used in conjunction with metal binding by HA precipitates. For example, sorption of Cu(II) (7) and

[1]Author to whom correspondence should be addressed.
[2]Revision received May 5, 1977.

Cd(II) (8) reportedly follows the well-known Langmuir equation. Log–log plots corresponding to the Freundlich isotherm were used to describe Ga^{3+} sorption on peat and HA (9). Titanium's interactions with peat have been interpreted in terms of an adsorption model (10). Adsorption isotherms have also been used to describe binding of organic molecules to HA. For example, adsorption to linuron (a herbicide) is best represented by a Freundlich isotherm (11). Hayword and Trapnell (12) describe adsorption isotherms in detail, hence they need not be discussed here.

Both ion exchange and adsorption equations were tested by the authors using Cu(II)–HA equilibration data taken in acidic media. Neither was found to be satisfactory.

Experimental

The HA's used in these experiments were prepared from Illinois No. 6 coal by oxidation with nitric acid followed by extraction with NaOH (13). The different batches were designated by their date of preparation and were stored in plastic bottles under slightly alkaline conditions. The HA's were characterized with regard to their gravimetric concentration (mg dry weight/ml) using a straightforward technique (14). Also, the hydrogen exchange capacity was determined by potentiometric titration; and the Cu(II) exchange capacity was determined by adding excess $CuSO_4$ at p*H* 5.0, filtering off the copper humate, and titrating an aliquot of the filtrate with EDTA (14). Prior to equilibration with Cu^{2+} at low p*H*, the p*H*-dependent solubility behavior of each HA was determined to ensure that the equilibration experiments would be performed at p*H*'s where the HA was insoluble.

I. Procedure for the Determination of the Precipitation pH

A series of tared 15 cm^3 centrifuge tubes was filled with 8.00 ml of sodium humate (NaHA) from a single batch. The p*H*'s of the humate solutions were adjusted to p*H* values between 8 and 2 at 0.3–0.5 p*H* intervals with HCl and NaOH allowing 15 min equilibration time. The adjusted solutions were centrifuged for 0.5 h and the liquid decanted. The entire collection of tubes was vacuum dried and weighed. A plot of mg dry solid vs. p*H* described the solubility behavior of the given batch of HA.

II. Procedures for Cu(II) Binding at Low pH's

A. Equilibration of HA and Cu(II) at Low pH's

The equilibration experiments were carried out in the following manner. Two millilitres of NaHA was pipetted into each of several vials. Various amounts of standard copper solutions were measured into the vials in order to obtain the desired concentrations of Cu(II). Deionized water was added to make the total volume of 10 ml. Then, the entire series of solutions was adjusted to within 0.02 units of the desired p*H* with small additions of HCl or NaOH. The samples were analyzed for soluble Cu after standing overnight by centrifuging, removing an aliquot of the clear liquid, diluting if necessary, followed by atomic absorption analysis. In a few samples (especially at low concentrations of Cu^{2+} and at p*H* 3), incomplete HA precipitation after centrifugation was observed. In those cases, approximately 0.05 g of NaCl solid was added, the solution stirred, and recentrifuged. Usually, the sample would precipitate out quantitatively after this treatment. If incomplete precipitation was still obtained, the sample was discarded.

B. Measurement of the pH Drop Upon Addition of $CuSO_4$

In order to determine if H^+ was released upon the uptake of Cu^{2+} by insoluble HA, the following procedure was followed. Five millilitres of NaHA stock was pipetted into a centrifuge tube and acidified. The solution was centrifuged and washed once. HCl and/or NaOH plus deionized water was added for p*H* adjustment and dilution, and the HA solid in the centrifuge tube was shaken vigorously until it was in suspension. The suspension was diluted to 10 ml, transferred to a beaker, and the p*H* was measured precisely. Twenty-five millilitres of standard $CuSO_4$ was added, and the new p*H* measured. Attainment of a steady p*H* was achieved in a few seconds, although this did not necessarily imply that equilibrium was reached in such a short time. After at least 1 h of equilibration, the contents of the beaker were then gravity filtered through medium porosity paper. An aliquot of the filtrate was titrated for Cu(II) using EDTA and Murexide indicator after a procedure by Flaschka (15). At the end of each series of experiments, the p*H* of the $CuSO_4$ standard solution was measured precisely. The p*H* expected on the basis of dilution of the HA with 25.00 ml of $CuSO_4$ of known p*H* assuming no interaction between Cu^{2+} and HA was calculated and compared with the observed p*H*. The hydrogen ion released (Δmmol H^+) through Cu^{2+} uptake was calculated from that p*H* difference. The cupric ion bound by the HA (Δmmol Cu^{2+}) was calculated from the initial concentration of $CuSO_4$ and the EDTA titration results. A comparison of Δmmol H^+ and Δmmol Cu^{2+} enabled determination of the extent of H^+ exchanged for Cu^{2+} bound by HA.

Results

I. pH-dependent Solubility Behavior

Figure 1 shows a typical solubility curve for coal HA's. The exact range of precipitation for a given preparation was observed to vary with the concentration of HA and the concentrations of cations present. The very narrow p*H* range between onset and completion of precipitation shown in Fig. 1 is typical of coal HA's.

II. Analytical Data

The analytical data for two different batches of HA appear in Table 1. The near equivalence of the mmol titratable H^+ and mmol Cu(II) bound at p*H* 5 for both HA's tends to support the *ortho* carboxylate–phenolate binding model mentioned in the Introduction. It should be noted, however, that Cu(II) uptake at p*H* 5 was considerably higher than at p*H*'s 1–3, and that considerable ionization of carboxylate groups on HA occurred at p*H* 5. Hence, caution is warranted in drawing analogies between Cu(II)

binding under the acidic conditions studied here, and at p*H*'s where HA is soluble.

III. Results of Equilibration Experiments

The insoluble HA was observed to bind significant amounts of Cu(II). This binding depended on the initial concentration of Cu(II) to a large extent and on p*H* to a smaller extent. In general, linear least-squares regression of log (mg Cu^{2+} absorbed) vs. log ($[Cu^{2+}]_0$) ($[Cu^{2+}]_0 = [Cu^{2+}]$ before absorption of Cu^{2+} by HA) yielded significantly smaller slope standard deviations than any other method of plotting the data. For example, Fig. 2 is linear within 2.02% over four orders of magnitude of $[Cu^{2+}]_0$ (0.1–700 ppm). Figures 3 and 4 show the same data plotted on linear axes. Other methods of plotting the data included attempts at fitting the Freundlich and Langmuir equations to the data, and fitting equations analogous to [1] and [2] in the Introduction. Langmuir plots were nonlinear even over small concentration ranges. Ion exchange equilibrium quotients (see [2]) were also not constant over small Cu(II) concentration ranges. The failure of ion exchange quotients is especially obvious in the relatively small p*H* dependence of Cu^{2+} uptake, as seen in Table 2. For example, eq. 2 predicts that the ratio of bound to free Cu(II) should increase 100-fold as the p*H* is raised 1 unit. However, inspection of Table 2 reveals that the ratio changes only about a factor of 4 as the p*H* increases from 1.37 to 3.00. It should be noted that the term $[H^+]_r''$ in [2] did not change significantly under conditions employed in taking data for Table 2. In other words, the H^+ exchanged from HA by 1–10 ppm Cu(II) solutions was small compared to the total H^+ capacity. Table 3 summarizes slopes and intercepts of log (mg Cu^{2+} adsorbed) vs. log $[Cu^{2+}]_0$ plots and Freundlich isotherm plots. The relative standard deviations in Table 3 show the superiority of the empirical log–log relation over the Freundlich relation for all data sets.

amount of Cu^{2+} bound occurred throughout the p*H* range studied. (Variation was larger for some other HA's studied, but was never greater than a factor of 3 over three orders of magnitude of hydrogen ion concentration.) However, the considerable increase in the mmol H^+ exchanged as the initial p*H* increased shows that the Cu(II) binding mechanism approached an ion exchange type at p*H* 3 and above.

Discussion

The results clearly indicate that two major types of Cu(II) binding occur under acidic conditions: (*1*) binding where at least one proton is exchanged and (*2*) binding where no protons are exchanged. The relative importance of each type appears to be p*H* dependent. For example, Table 4 shows fairly consistent amounts of Cu(II) bound between p*H* 1.84 and 3.06, but shows considerable increase in hydrogen ion exchange with increasing p*H*. In addition, the overall increase in amount of Cu(II) bound with increasing p*H* (Table 2) tends to substantiate the idea of greater hydrogen ion exchange with increasing p*H*.

On the other hand, considerable evidence exists for Cu(II) binding without exchange throughout the p*H* range studied. For example, Table 4 shows the amount of Cu(II) bound to be always in

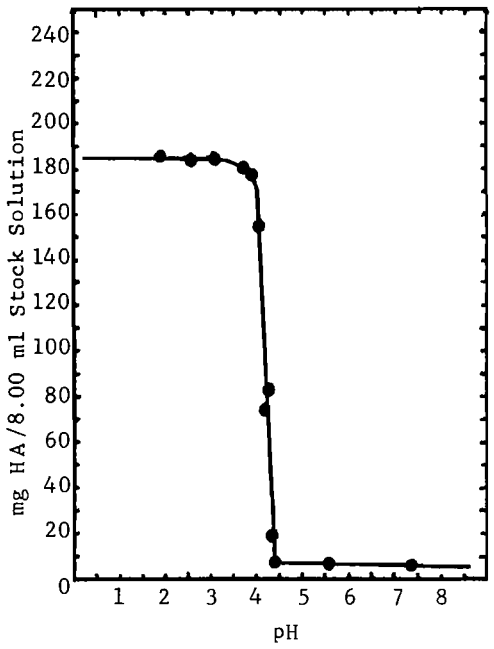

FIG. 1. Solubility vs. pH curve for HA prepared 5/30/74.

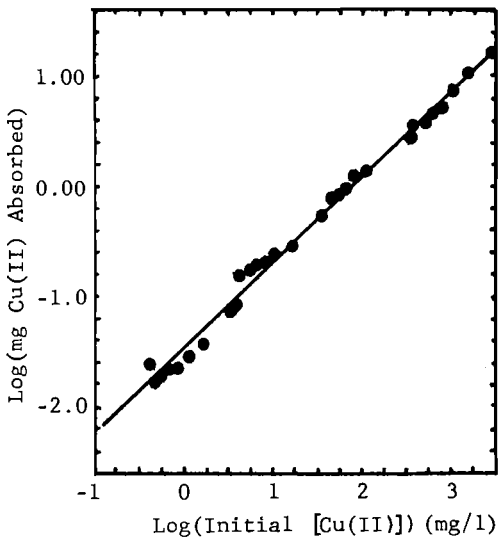

FIG. 2. Log–log plot of mg Cu(II) bound by HA vs. initial concentration of Cu(II) (HA prepared 5/24/74, pH = 2.00 ± 0.02).

excess of H^+ exchanged, especially at lower pH values. Also, the consistency of y intercepts obtained from the empirical least-squares fits (Table 3) indicates that nearly the same amount of Cu(II) would be bound at any pH value from 1–3 from a 1 ppm Cu(II) solution. (This conclusion follows from the fact that y intercept = log (mg Cu^{2+} absorbed) when $[Cu(II)]_0$ = 1 ppm.) Such a pH-independent uptake of Cu(II) would, of course, indicate a nonexchange mode of binding.

Since both exchange and nonexchange binding occur simultaneously, it is not surprising that neither ion exchange nor surface adsorption theory alone adequately account for the pattern

of Cu(II) uptake by HA. And, although the empirical equation described in the Results section fits the data within 2% except in one case (see Table 3), it unfortunately yields no direct clues to the mechanism(s) of the HA–Cu(II) interaction. However, the fact that the Cu(II) bound by HA can be related to the initial concentration of Cu(II) present does suggest at least one model which is consistent with that fact plus the observations mentioned above.

I. Proposed Binding Model

The fact that HA can be precipitated by adding hydrogen ion or other cations indicates that they are important links in the intermolecular bonding resulting in HA flocculation. The importance of hydrogen bonding in HA structure has been widely recognized (1, 16, 17), but the similar influence of metal cations has only recently become apparent in the literature. For example, substantial molecular size increases with increasing hydrogen ion (18, 19) and/or other cation (20) concentrations indicate their intermolecular bridging function. Formation of metal ion linked molecules is also consistent with recent complexation studies (21, 22). Thus, it appears that if aggregation occurs beyond a given point for HA, flocculation is induced and a solid HA results. Intuitively, the concentration and chemical properties of a given cation should determine the extent to which it participates in intermolecular bonding between flocculated HA molecules. For example, calcium ion is much more effective than magnesium or sodium ions in flocculating HA (23). The concentration dependence for intermolecular bonding by a given ion is suggested by the following example. Addition of excess cupric ion to NaHA at p*H* 5 causes precipitation of Cu(II)–humate; and evidence such as Table 1 indicates that most hydrogen ions are displaced from HA by Cu(II). However, addition of excess Cu(II) to NaHA at p*H* 4.5 (assuming that the HA is soluble at that p*H*) also causes precipitation of HA; yet the Cu(II) bound is less than that at p*H* 5.0.[3] Assuming that approximately the same number of bridge bonds are formed in each case, the obvious conclusion is that the p*H* 4.5 precipitate is a mixed hydrogen–copper linked floc.

Given the above points, one can postulate that the same process is operable in the p*H* range 1–3. Hence, the pattern of Cu(II) binding observed can be explained in terms of Cu(II) and H^+ competition for intra- and for intermolecular bonding in the HA solid. At low p*H*'s and low [Cu(II)], hydrogen bonding is the dominant form of bonding. Cu(II) incorporated in HA under these conditions is largely without ion exchange and thus is most likely to be at sites where hydrogen bonding does not occur. At higher p*H*'s and [Cu(II)], it appears that Cu(II) replaces hydrogen bonding at many sites as evidenced by the observed increase in H^+ exchange and Cu(II) uptake under those conditions. Incorporation of Cu(II) may involve changes in floc structure, which is suggested by the stair-step pattern evident in Figs. 3 and 4. That is, Cu(II) uptake levels off until sufficient amounts are present to cause a shift in floc structure, which allows for increased Cu(II) absorption. Thus, the empirical relation between the Cu(II) bound by HA and the initial concentration (amount) of Cu(II) present can be explained in terms of HA forming a solid structure which best utilizes available H^+ and Cu^{2+} for bonding.

The observed deviation of Cu(II) uptake from that predicted by ion exchange theory is consistent with the above model. For example, if the hydrogen on a carboxylate group is bonded to another polar group on the same or another HA molecule, two bonds must be broken in order for the Cu(II) ion exchange to occur. Because of its increased size and charge, the incorporation of Cu(II) in place of H^+ may also necessitate a shift in HA structure. Finally, a multiple intra- or intermolecular Cu(II) bond may form in place of the hydrogen bond, along with the added possibility of HA bonding with Cu(II)'s waters of hydration or other coordinated ligands. Thus, such a complicated exchange would not be expected to follow a simple ion exchange quotient (eq. 2). In light of the model, deviation from surface adsorption theory is not surprising since incorporation of Cu(II) is not a surface type of phenomenon. Surface chemistry concepts such as 'adsorbed monolayer,' etc. do not apply.

The last feature of the model is the question of anion incorporation into the HA floc to maintain the electrical neutrality of the precipitate. Since all evidence indicates that on the average at most one proton is exchanged for each Cu^{2+} incorporated into HA, anions must accompany the bound copper. Chloride ion was present in all samples, and thus was probably incorporated

[3]Typical values are 0.0426 (p*H* 4.93) and 0.0353 (p*H* 4.34) mmol Cu(II) bound/ml HA.

into the floc. Bergseth *et al.* (24) have shown that $SrCl^+$ instead of Sr^{2+} was bound by humus, hence it seems reasonable that $CuCl^+$ was also bound.

II. Comparison of Findings with Previous Work

The 'binding model' presented here incorporates the concepts of ion exchange and adsorption, but goes beyond both in that cupric ion is assumed to be an integral part of the HA structure. The findings presented here are consistent with some previous work, yet contradict other papers. For example, Davies *et al.* (5) also found that ion exchange quotients were not constant in their work with Cu(II) and HA, but explained the variation in terms of different functional groups on HA having different affinities for Cu(II). From this work, it appears that variation of Cu^{2+} binding by HA would be more p*H* dependent than actually observed if variation was simply due to interaction with carboxylate groups with different acidities, for example. Guy *et al.* (7) observed no Cu^{2+} binding in the p*H* range studied here; this may be due to differences in HA's used in the two works. Porphyrin rings in HA have also been implicated in the binding of small amounts of Cu(II) (25). The importance (or existence) of such in our HA preparations is unknown; however, infrared spectra of the coal HA's indicate that most of the N is in the form of nitro groups. Participation of nitro groups in hydrogen and metal ion bonding is likely, but as yet unconfirmed.

Nuclear magnetic resonance studies of the solution chemistry of metal complexes. XIV. The aqueous chemistry of trimethyllead(IV) and its carboxylic acid complexes

T. L. SAYER, S. BACKS, C. A. EVANS, E. K. MILLAR, AND D. L. RABENSTEIN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 14, 1977

T. L. SAYER, S. BACKS, C. A. EVANS, E. K. MILLAR, and D. L. RABENSTEIN. Can. J. Chem. **55**, 3255 (1977).

The aqueous solution chemistry of the trimethyllead(IV) species and the trimethyllead(IV) complexes of six carboxylic acids of pK_a values ranging from 2.75 to 4.95 has been investigated by proton magnetic resonance spectroscopy. Equilibrium constants for the reaction of $(CH_3)_3Pb^+$ with hydroxide ion to form $(CH_3)_3PbOH$ and $((CH_3)_3Pb)_2OH^+$, and the formation constants of the carboxylic acid complexes were determined from the pH dependence of the chemical shift of the methyl protons of trimethyllead. The formation constants of the complexes increase as the pK_a of the ligand increases. The lead-207–proton coupling constant was found to be insensitive to complexation.

T. L. SAYER, S. BACKS, C. A. EVANS, E. K. MILLAR et D. L. RABENSTEIN. Can. J. Chem. **55**, 3255 (1977).

On a étudié par résonance magnétique du proton la chimie aqueuse des solutions d'espèces triméthylplomb(IV) et de complexes triméthylplomb(IV) de six acides carboxyliques de pK_a se situant de 2.75 à 4.95. Les constantes d'équilibre pour la réaction de l'espèce $(CH_3)_3Pb^+$ avec l'ion hydroxyde pour former $(CH_3)_3PbOH$ et $((CH_3)_3Pb)_2OH^+$ ainsi que les constantes de formation des complexes d'acid carboxylique ont été déterminées à partir de la dépendance du pH du déplacement chimique des protons méthyliques du triméthylplomb. Les constantes de formation des complexes augmentent à mesure que croit la valeur des pK_a. Il apparaît que la constante de couplage proton–plomb-207 soit insensible à la complexation.

[Traduit par le journal]

Introduction

Inhalation or absorption of tetraalkyllead compounds results in the presence of lead in the fluids and tissues of the body, primarily as dissolved trialkyllead salts (1). Also, recent research by Wong, Chau, and Luxon (2) has revealed the methylation of certain organic and inorganic lead compounds by microorganisms in lake sediments. Although the organometallic chemistry of the trialkyllead compounds has been the subject of much study (3–6), their aqueous solution chemistry and coordination chemistry have not been characterized. In response to the need for such information, we have initiated a program directed towards characterizing the aqueous solution chemistry of trimethyllead and its complexes. For example, chelation therapy, a common form of treatment for inorganic lead poisoning (7), has thus far proven to be rather ineffective in the treatment of organic lead poisoning because of the lack of an effective chelating agent for organic lead salts (1).

In this paper, results are presented which provide the first characterization of the aqueous solution species and equilibria of $(CH_3)_3Pb^+$ and of the coordination chemistry of $(CH_3)_3Pb^+$ with carboxylic acid ligands.[1] The equilibrium constants for the acid–base equilibria of $(CH_3)_3Pb^+$ and the formation constants of the carboxylic acid complexes were determined by proton magnetic resonance spectroscopy. ^1H nmr is a direct method for studying the solution chemistry of $(CH_3)_3Pb^+$ and its complexes; the chemical shift of the methyl protons of $(CH_3)_3Pb^+$, the coupling constant for spin–spin coupling between ^{207}Pb ($I = \frac{1}{2}$, natural abundance = 21.1%) and the protons of the methyl group, and the chemical shift of the ligand protons all provide information about the complexes at the molecular level. The type of detailed information ^1H nmr can provide about the binding of organometallic ions by polydentate biological ligands is illustrated by the study of the binding of methylmercury by glutathione (8).

[1]For simplicity, waters of hydration are omitted from the formula throughout this paper. Hydrated $(CH_3)_3Pb^+$ is assumed to be trigonal bipyramidal with water molecules in the axial positions.

Experimental

Chemicals

The carboxylic acids were of the highest grade commercially available and were used without further purification. Sodium formate was used as the source of formate ligand. The trimethyllead – acetic acid studies were carried out using trimethyllead acetate (Alfa Inorganics) as the source of both $(CH_3)_3Pb^+$ and acetate.

Trimethyllead acetate was the only water soluble form of trimethyllead commercially available and was converted to a stock solution of trimethyllead perchlorate prior to use in the acid–base and complexation studies. An initial attempt to extract $(CH_3)_3PbOH$ from benzene, using a method developed for triethyllead chloride (9), yielded only an insoluble, gelatinous mass of unknown composition. Ion exchange has been used to remove acetate from methylmercuric hydroxide solutions (10), and a similar method was developed for the conversion of $(CH_3)_3PbO_2CCH_3$ to trimethyllead perchlorate.

A solution of trimethyllead acetate ($\sim 0.25\ M$) was passed two or three times through a column containing anion exchange resin (Dowex 2 × 8) in the hydroxide form. The column was regenerated between passes with 1 *M* NaOH. The ^1H nmr spectrum, at high amplitude, of an aliquot was then checked to ensure the absence of acetate (in basic solution the resonance of the methyl protons of acetate is located approximately 0.67 ppm downfield from the *tert*-butyl resonance of tertiary butanol and is detectable at concentration levels of $\gtrsim 0.001\ M$). The solution was filtered twice through Nalgene filter units, 0.2 μm pore, and then neutralized with concentrated perchloric acid (to p*H* ~ 5) and stored in the dark. Before use, this solution was standardized as described below.

pH Measurements

All p*H* measurements were made at 25 ± 1°C using an Orion Model 701 digital p*H* meter equipped with a standard glass electrode – porous ceramic junction electrode pair. Initially a saturated calomel reference electrode was used; to avoid precipitation of $KClO_4$ in the liquid junction, electrical contact between the solution and the reference electrode was made in a salt bridge containing 4.0 *M* NaCl solution. In later experiments, Na_2SO_4 was used as the reference solution in a Ag/AgCl electrode. The p*H* meter was calibrated using Fisher certified standard solutions of p*H* 4.01, 7.00, and 10.00.

^1H Nuclear Magnetic Resonance Measurements

^1H nmr spectra were obtained on a Varian A-60-D high resolution spectrometer at a probe temperature of 25 ± 1°C. Spectra were recorded at sweep rates of 0.1 Hz s^{-1}. Reported results are the average of 2–3 scans. Chemical shifts were measured relative to the *tert*-butyl resonance of *tert*-butanol (TBA) or the central resonance of the tetramethylammonium (TMA) cation, but are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulphonic acid (DSS). Positive shifts correspond to resonances of protons less shielded than the methyl protons of DSS. The *tert*-butyl resonance of TBA is 1.243 ppm downfield from the methyl resonance of DSS; the central triplet of the methyl resonance of TMA is 3.175 ppm downfield from DSS.

Solution Preparation

(i) ^1H Nuclear Magnetic Resonance Studies

Solutions for the ^1H nmr studies were prepared from an aliquot of stock $(CH_3)_3PbClO_4$ solution and the appropriate amount of sodium perchlorate and/or carboxylic acid. All solutions were prepared using doubly distilled water.

For the studies of the acid–base chemistry of trimethyllead, the initial sample was taken at a p*H* no higher than 5. Samples were taken approximately every 0.3 p*H* unit to a maximum p*H* between 11 and 12. The ionic strength was kept constant at 0.3 *M* with $NaClO_4$.

The initial p*H* of the $(CH_3)_3Pb^+$ – carboxylic acid solutions was reduced to a value about 3.0 p*H* units below the pK_a of the acid in order to obtain the chemical shift of the fully protonated acid and of the free $(CH_3)_3Pb^+$ ion. For acids with a pK_a below 3.75, a minimum p*H* of 0.75 was used. Samples were taken every 0.3 of a p*H* unit to a p*H* value 3.0 p*H* units above the pK_a of the acid and then every p*H* unit to a maximum p*H* of 11.00.

All p*H* adjustments were made with concentrated $HClO_4$ or carbonate-free NaOH solution. The temperature was maintained at 25 ± 1°C using a water bath.

(ii) Standardization of Trimethyllead Stock Solutions

The ion exchanged $(CH_3)_3Pb^+$ stock solutions were standardized by potentiometric titration using a glass electrode. The titrations were carried out using carbonate-free NaOH and the ionic strength was controlled using $NaClO_4$. To ensure complete neutralization of all the $(CH_3)_3PbOH$ present in solution, the initial p*H* was reduced to a value between 2 and 3 using concentrated $HClO_4$. The solution is thus a mixture of a strong acid ($HClO_4$) and a weak acid ($(CH_3)_3Pb^+$) and the titration yields two inflection points. Titration of the added perchloric acid yields a sharp inflection point at p*H* 5 and the $(CH_3)_3Pb^+$ an inflection point at p*H* 10.5. The exact position of the $(CH_3)_3Pb^+$ endpoint was determined using a second derivative plot of the titration curve (11). The titration with base converts the trimethyllead from $(CH_3)_3Pb^+$ to $(CH_3)_3PbOH$, so that the amount of NaOH added between the first and second endpoints provides the concentration of trimethyllead in the stock solution.

The potentiometric method was verified by determining the trimethyllead concentration of several stock solutions using both atomic absorption spectroscopy, and EDTA titration of aliquots following conversion to Pb^{2+}.

The atomic absorption measurements were made at the 282.3 nm line using a Perkin-Elmer 290-B atomic absorption spectrophotometer. A working curve was prepared using $Pb(NO_3)_2$ and a 0.1 *M* solution of the disodium salt of ethylenediaminetetraacetic acid was used as a common matrix. Standard solutions were prepared containing 10–40 μg/ml of lead and an aliquot of the trimethyllead stock solution was diluted to yield a solution of approximately 20–30 μg/ml of lead. Although the atomic absorption results tended to be slightly higher than the trimethyllead concentrations obtained by potentiometry, the agreement is sufficient to support the potentiometric standardization.

Further confirmation of the validity of potentiometric titrations as a convenient and rapid method of standardiz-

ing the $(CH_3)_3PbClO_4$ stock solutions was obtained from EDTA titrations of the $Pb(NO_3)_2$ solutions resulting from digestion of portions of the stock solution with aqua regia. Aliquots (typically 5.00 ml) of the stock solution were digested with aqua regia (15 ml) and then with nitric acid to remove chloride which causes separation of $PbCl_2$. The solution was adjusted to about neutral with solid sodium hydroxide, and the aliquots titrated with standard EDTA, using hexamine and xylenol orange indicator (12).

Results and Discussion

The Stability of Trimethyllead in Aqueous Solution

The stability of the carbon–lead bonds towards hydrolysis has been considered to establish that the trimethyllead moiety is stable on the time scale of these experiments. Acidic, neutral, and alkaline solutions of trimethyllead were tested periodically for the presence of Pb(II) using chemical spot tests. Sodium rhodizonate was used as detailed by Feigl and Anger (13), and is sensitive to inorganic lead at concentrations greater than approximately 10^{-4} *M*. The results, after 7 months of monitoring, indicate that the concentration of inorganic lead is not greater than 10^{-4} *M* in solutions at neutral or alkaline p*H* and is approximately 10^{-3} *M* in solutions at p*H* 1.0 and 2.0.

The Acid–Base Chemistry of Trimethyllead

The acid–base chemistry of trimethyllead has been characterized by fitting of proton magnetic resonance data to various acid–base models. The chemical shift of the methyl protons is given by the position of the central resonance and the lead–proton coupling constant by the separation of the satellite lines. A typical spectrum is shown in Fig. 1. Both of these quantities are p*H* dependent; the variation of the chemical shift as a function of p*H* is shown by the bottom curve in Fig. 2, and the variation of the coupling constant in Fig. 3. This p*H* dependence is caused by formation of hydroxyl complexes as the p*H* of an acidic solution is increased above ca. p*H* 6. There is no evidence for the addition of more than one hydroxide ion per trimethyllead cation up to p*H* 12, at which point essentially all of the trimethyllead has been converted to $(CH_3)_3PbOH$.

Of various models tested, the best fit was obtained with the model described by eqs. 1–4,

[1] $$(CH_3)_3Pb^+ + OH^- \rightleftarrows (CH_3)_3PbOH$$

[2] $$K_1 = \frac{[(CH_3)_3PbOH]}{[(CH_3)_3Pb^+]a_{OH^-}}$$

[3] $$(CH_3)_3Pb^+ + (CH_3)_3PbOH \rightleftarrows ((CH_3)_3Pb)_2OH^+$$

[4] $$K_2 = \frac{[((CH_3)_3Pb)_2OH^+]}{[(CH_3)_3Pb^+][(CH_3)_3PbOH]}$$

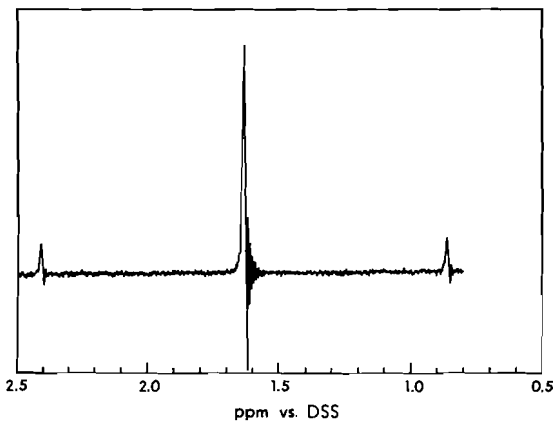

FIG. 1. ^1H nmr spectrum of the methyl groups of trimethyllead in 0.140 *M* solution at approximately neutral p*H*.

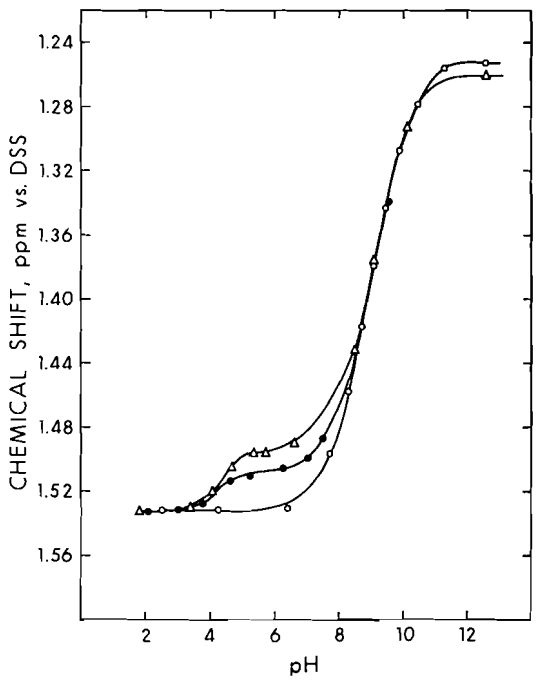

FIG. 2. p*H* dependence of the methyl protons of trimethyllead in a 0.140 *M* aqueous solution (open circles), in an aqueous solution containing 0.153 *M* trimethyllead and 0.071 *M* pivalic acid (closed circles), and in an aqueous solution containing 0.102 *M* trimethyllead and 0.093 *M* pivalic acid (triangles).

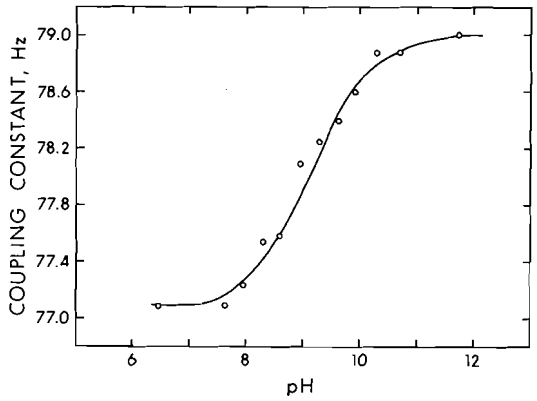

FIG. 3. pH dependence of the lead-207 – proton coupling constant in a 0.140 M aqueous solution.

where K_1 and K_2 are the formation constants for the mononuclear and dinuclear hydroxyl complexes, respectively, and a_{OH^-} represents the activity of hydroxide ion.

K_1 and K_2 were evaluated from chemical shift data of the type shown in Fig. 2. Since the exchange of the trimethyllead moiety between its various solution forms is fast on the nmr scale, the observed chemical shift (or coupling constant), δ_{obs}, is an average of the chemical shifts of the various molecular forms present in solution, weighted proportionally to their individual populations. For the system described by eqs. 1–4

$$[5] \qquad \delta_{obs} = P_a\delta_a + P_b\delta_b + P_c\delta_c$$

where a, b, and c refer to the species $(CH_3)_3Pb^+$, $(CH_3)_3PbOH$, and $((CH_3)_3Pb)_2OH^+$ respectively, P refers to the fraction of the total trimethyllead present in each of the forms, and δ is the chemical shift of that form. The fractions are defined as

$$[6] \qquad P_a = [(CH_3)_3Pb^+]/TMLT$$

$$[7] \qquad P_b = [(CH_3)_3PbOH]/TMLT$$

$$[8] \qquad P_c = 2[((CH_3)_3Pb)_2OH^+]/TMLT$$

where TMLT represents the total concentration of trimethyllead. Manipulation of these equations leads to an expression for δ_{obs}, viz.

$$[9] \qquad \delta_{obs} = P_a\delta_a + K_1a_{OH}P_a\delta_b + 2K_1K_2a_{OH}P_a^2\delta_c$$

where

$$[10] \qquad P_a = \frac{(-(1 + K_1a_{OH}) + [(1 + K_1a_{OH})^2 + 8K_1K_2a_{OH}(TMLT)]^{1/2})}{4K_1K_2a_{OH}(TMLT)}$$

K_1, K_2, and δ_c were evaluated from chemical shift data, over the pH range 0.5–13.0 and trimethyllead concentrations in the range 5×10^{-3} M to 2×10^{-1} M, using the nonlinear least-squares fitting program described by Dye and Nicely (14). δ_a and δ_b were measured directly on solutions sufficiently acidic and alkaline, respectively. The values obtained are $K_1 = 7.34\ (\pm 0.1) \times 10^4\ M^{-1}$ and $K_2 = 3.12\ (\pm 0.1) \times 10^1\ M^{-1}$, where the uncertainties are linear estimates of the standard deviation. The ionic strength was 0.3 M. The chemical shifts of the species are 1.535 ($(CH_3)_3Pb^+$), 1.253 ($(CH_3)_3PbOH$), and 1.327 ppm ($((CH_3)_3Pb)_2OH^+$), quoted from DSS.

Attempts to fit the observed chemical shift data to models involving either the species $((CH_3)_3Pb)_2O$ or $((CH_3)_3PbOH)_2$ in addition to $(CH_3)_3Pb^+$ and $(CH_3)_3PbOH$ gave poor fits. The model giving the best fit is analogous to that for methylmercury (10, 15, 16) and in view of the low value estimated for the formation constant of the oxonium species, $(CH_3Hg)_3O^+$ (16), such a species is not considered in the present system.

Because of the unsymmetrical nature of eq. 3, the importance of $((CH_3)_3Pb)_2OH^+$ is dependent on the total concentration of trimethyllead. The species distribution, calculated using the above values of K_1 and K_2 and a trimethyllead concentration of 0.100 M is shown in Fig. 4. At 0.005 M the maximum fractional concentration of trimethyllead as $((CH_3)_3Pb)_2OH^+$ is 0.07.

Carboxylic Acid Complexes of Trimethyllead

The formation constants have been derived for binding of trimethyllead by the carboxylate group of carboxylic acids with a range of acid dissociation constants. The results are listed in Table 1. Representative chemical shift data for the trimethyllead protons in the presence of a carboxylic acid are shown in Fig. 2, in this case for the trimethyllead – pivalic acid system. Qualitatively the effect of complexation can be observed as the upfield displacement of the trimethyllead resonance in the pH region below

TABLE 1. Acid ionization constants and formation constants of the trimethyllead and the methylmercury complexes of selected carboxylic acids, and the trimethyllead chemical shifts of their trimethyllead complexes

Carboxylic acid	pK_a[a]	$\delta_{Complex}$[c]	Log K_f[a,b,e] $(CH_3)_3Pb^+$	Log K_f[a,b,d] CH_3Hg^+
Pivalic	4.95	1.436	1.22	3.53
Propionic	4.80	1.449	1.08	3.37
Acetic	4.65	1.450	0.97	3.16
Formic	3.55	1.492	0.86	2.65

[e]Standard deviation 0.05, except for formic acid, 0.1.

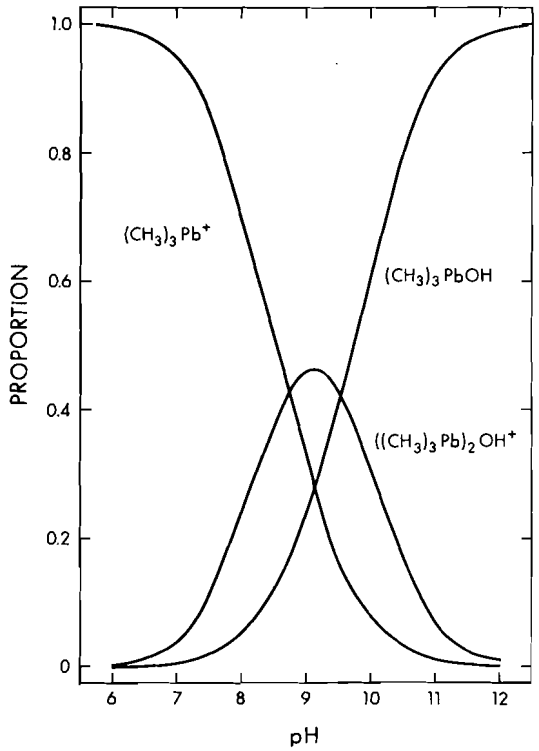

FIG. 4. pH dependence of the trimethyllead species distribution in a 0.100 M aqueous solution calculated using K_1 and K_2 as in the text.

pH 7 when the solution contains a carboxylic acid. Above pH 7 the hydroxide ion competes effectively with the carboxylate ligand for trimethyllead and by a pH of 11 the great majority of the trimethyllead is present as a hydroxide complex. The small plateau in the 1:1 plot at approximately pH 6 indicates that complexation by the pivalic acid has reached its greatest extent (43% of the trimethyllead is as the pivalate complex) in this pH region.

The formation constant of the trimethyllead–carboxylate complex is defined by eqs. 11 and 12:

[11] $$(CH_3)_3Pb^+ + RCO_2^- \rightleftarrows (CH_3)_3PbO_2CR$$

[12] $$K_f = \frac{[(CH_3)_3PbO_2CR]}{[(CH_3)_3Pb^+][RCO_2^-]}$$

Exchange of the trimethyllead moiety among the various species in solution is fast on the nmr time scale and thus the formation constant and chemical shift of the complex were determined by procedures similar to those outlined previously for the trimethyllead hydroxide equilibria.

The upper curves in Fig. 2 are described by the equation

[13] $$\delta_{obs} = P_a\delta_a + P_b\delta_b + P_c\delta_c + P_d\delta_d$$

where P_d and δ_d represent respectively the fractional concentration of trimethyllead complexed by carboxylate and the chemical shift of the trimethyllead protons of this complex, and other symbols are as defined in connection with eq. 5. In this case, the polynomial in P_a is a cubic in which the coefficients are expressions in K_1, K_2, K_a, and K_f; this was solved by an iterative method (SSP Library Subroutines, DRTMI). Values for P_b, P_c, and P_d were then calculated using modified versions of eqs. 2, 4, and 12, yielding the values for K_f and $\delta_{complex}$ listed in Table 1. The distribution of trimethyllead among the various species is shown as a function of pH in Fig. 5 for the trimethyllead – pivalic acid system.

There are no formation constants for trimethyllead complexes available for comparison

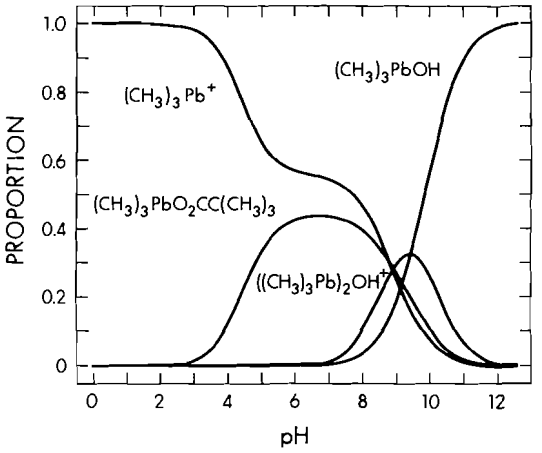

FIG. 5. pH dependence of the trimethyllead species distribution in an aqueous solution containing 0.102 M trimethyllead and 0.093 M pivalic acid.

with the results in Table 1. Comparison is made in the table with the previously reported formation constants for the methylmercury complexes of the same carboxylic acids, which are consistently larger than those for trimethyllead by a factor of approximately 10^2 (10). The logarithms of the formation constants of Pb^{2+} with formate and acetate, respectively, are reported as being 0.85 and 2.33 (17); that for formate is close to the value reported here for the trimethyllead complex.

By analogy to methylmercury (8, 10), it was expected that the ^{207}Pb–^1H coupling constant would be sensitive to complex formation. However, the coupling-constant data presented in Fig. 3 for hydroxyl complexes and the even smaller changes in $J_{^{207}Pb-^1H}$ observed for the carboxylic acid complexes indicates that the lead-207 proton coupling constant is not sensitive to the complexation of trimethyllead by the ligands studied. Any changes in the hybridization of lead, due to complexation, which involve the bond angles at the lead atom should be reflected in changes in $J_{^{207}Pb-^1H}$ (18). Shier and Drago (18) have shown, however, that $J_{^{207}Pb-^1H}$ changes from 77.5 Hz for $(CH_3)_3PbBF_4$ in water to 85.0 for $(CH_3)_3PbClO_4$ in hexamethylphosphoramide and that the change is not solely dependent upon any apparent geometrical change in the planar $(CH_3)_3Pb^+$ ion. Raman spectroscopy studies (19) have indicated that $(CH_3)_3Pb^+$ is planar in aqueous solutions of perchlorate salt. It is possible, then, that complex formation with the carboxylic acids studied does not bring about any significant change in the geometrical configuration or in the hybridization of the lead ion in trimethyllead.

^{13}C chemical shifts in medium ring and macrocyclic ketolactones

JASWANT R. MAHAJAN AND HUGO C. ARAÚJO
Universidade de Brasília, Dept. de Química, 70.000 Brasília, DF. Brasil

Received March 28, 1977

JASWANT R. MAHAJAN and HUGO C. ARAÚJO. Can. J. Chem. **55**, 3261 (1977).

Natural abundance ^{13}C Ft nmr spectra of four different series of title compounds have been examined. Unambiguous chemical shift assignments could be made for all the carbons of the 11-membered *cis*-3,3-dimethyl-5-keto-6-alkyl-8-decenolides. In the rest of the 9- to 16-membered ketolactones, unique as well as logical assignments have been made using the standard ^{13}C chemical shift rules. In the case of two benzo- and naphthoketolactone series examined, the available shielding parameters for the substituted benzenes were employed with success to the naphthalene series for the assignment of aromatic carbons.

JASWANT R. MAHAJAN et HUGO C. ARAÚJO. Can. J. Chem. **55**, 3261 (1977).

On a examiné les spectres rmn en tf du ^{13}C en abondance naturelle de quatre séries différentes de composés mentionnés dans le titre. On a pu faire l'attribution non-ambigue des déplacements chimiques de tous les carbones des diméthyl-3,3 céto-5 alkyl-6 décen-8 olides-*cis* à onze chaînons. Dans le cas des cétolactones possédant de 9 à 16 chaînons, on a pu faire des attributions aussi précises que logiques en faisant appel aux règlements standards de déplacements chimiques du ^{13}C. Dans le cas de deux séries de benzo- et naphtocétolactones qui ont été examinées, on a utilisé avec un certain succès les paramètres de blindage disponibles pour les benzènes substitués afin de faire l'attribution des carbones aromatiques en série naphthalénique.
[Traduit par le journal]

We have recently reported the synthesis of several medium ring and macrocyclic ketolactones **2**, **4**, **6**, **9** by the intramolecular reverse Dieckmann reaction of 2,2-dialkyl-1,3-cyclohexanediones (1) as well as by the oxidative procedures (2, 3), as shown in Scheme 1. These ketolactones are related to some of the macrolide antibiotics (4, 5). Recently, ^{13}C nmr spectral studies have been reported for some of the 14- and 16-membered macrolides (6, 7). It seemed likely that ^{13}C spectral examination of our synthetic polyfunctional large ring lactones would be valuable in the spectral interpretation of the more complex natural products. We now report the results of this study.

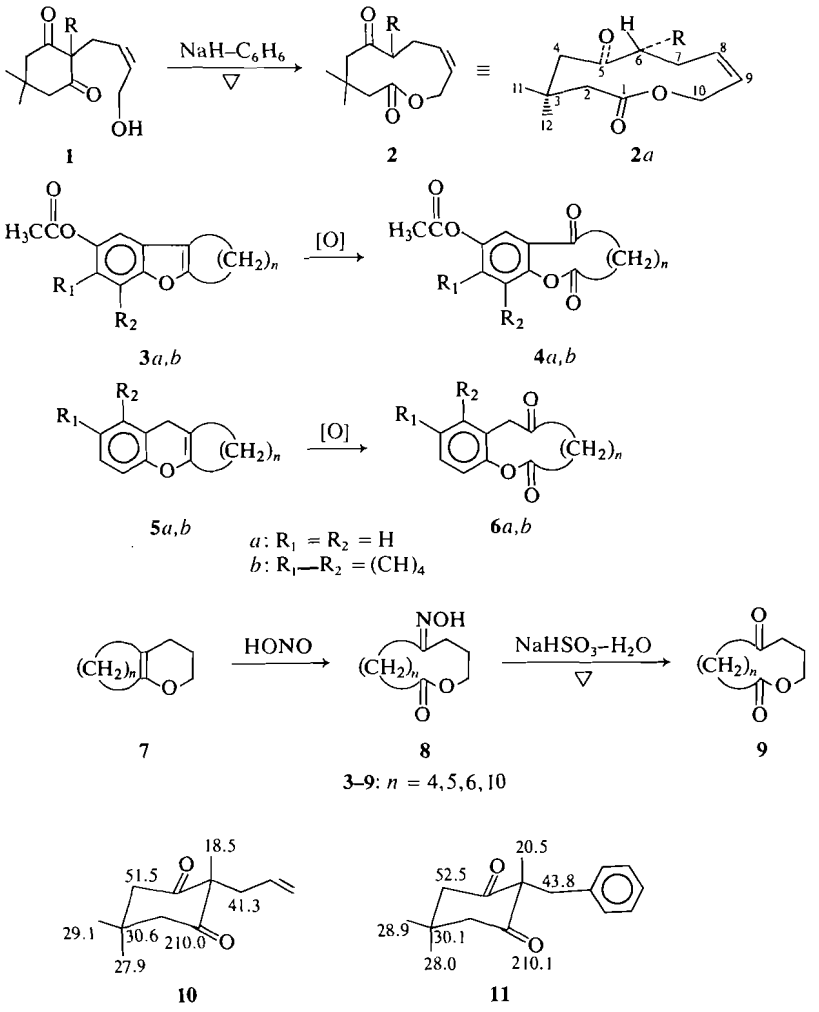
The proton noise decoupled as well as the single-frequency off-resonance decoupled (SFORD) natural abundance ^{13}C Ft nmr spectra of 0.3–1.0 *M* solutions of the ketolactone in $CDCl_3$, containing 10% TMS (v/v), were recorded on a Varian CFT-20 (20 MHz) spectrometer using standard parameters, with pulse width of 30–37.5° (8–10 μs) and aquisition time of 0.75–0.91 s, without any pulse delay. The line positions and intensities were obtained relative to internal TMS. The reported values (δ ppm) have been rounded to the nearest first decimal place for simplicity.

Results and Discussion

cis-3,3-Dimethyl-5-keto-6-alkyl-8-decenolides (2; R = CH_3, CH_2—CH=CH_2, $CH_2C_6H_5$)

The ^{13}C chemical shifts of the carbon atoms of three ketolactones examined in this series, including those of the substituent at C-6, could be unambiguously assigned on the basis of chemical shift rules (8), aided by the lower relative intensity of the quaternary carbon atom and further confirmed by the observed multiplicity in the SFORD spectra. These assignments, along with the SFORD results, are recorded in Table 1.

A close examination of Table 1 reveals that all the functionalities in these 11-membered ketolactones, except for the diversely substituted C-6, show constant chemical shifts and appear around the expected values. For instance, the observed chemical shifts for the carbonyl and lactonic carbons in these compounds, ~210.5 and 171.5 ppm, respectively, compare very favorably with the corresponding chemical shifts of 2-methylcyclohexanone (210.3) (8*a*), cycloundecanone (211.1) (8*b*) and medium to large ring lactones (172.2 ppm) (8*c*). Similarly, the C-6 substituent is expected to occupy a quasi equatorial position in the more stable conformation, e.g. **2***a*. Accordingly, the C-6 methyl group appearing at 16.8 ppm compares favorably with that of 2-methyl-



SCHEME 1

cyclohexanone at 13.8 ppm, (8*d*), bearing in mind that the 11-membered ring is more flexible than the 6-membered one. It indicates that the C-6 substituent is occupying a quasi equatorial position, partially eclipsed by the carbonyl group (9), as depicted in the chair-boat-boat conformation **2***a*. Moreover, this chemical shift of 16.8 ppm compares very favorably with that of the similarly situated methyl group at C-8 of the 14-membered (6) as well as the 16-membered (7) macrolides: erythromycin A 16.2, erythromycin B 15.6, magnamycin A 17.1, magnamycin B 17.3, tylosin 17.4, and cirramycin A 17.5 ppm, despite the greater functional complexity of these molecules.

In the case of 14-membered macrolides (erythromycins A, B) ^{1}H and ^{13}C nmr studies have suggested the presence of a single conformation in the solution of these compounds, with the ring atoms occupying cyclohexane-like positions (6). In the case at hand, a stable conformation could be represented by **2***a* and would lead to non-equivalent axial and equatorial methyl groups at C-3. The observed chemical shifts for these two methyl groups, in the three lactones, are very close to one another and are separated by only 1.1–1.5 ppm. Usually, the geminal axial and equatorial methyl groups in a frozen conformation are expected to appear about 8 ppm apart. For example, the axial and equatorial methyl groups of 1,1,3-trimethylcyclohexane appear at 25.5 and 34.3 ppm, respectively (8*e*). Similarly, the corresponding values in the case of 3,3,5-trimethylcyclohexanol are 25.7 and 33.1 ppm

(10). The small difference (1.1–1.5 ppm) between the two methyl groups in the present case could probably arise due to two factors: (*a*) the absence of hydrogen atoms at the γ-positions, which has thus eliminated the major cause of lowering the chemical shift of the axial methyl group (8*f*); and (*b*) the presence of chirality at C-6, in a conformationally equilibrating system. This reasoning is supported by examining the ^{13}C spectra of several conformationally mobile 2,2-dialkyl-5,5-dimethyl-1,3-cyclohexanediones.[1] It has been found that while the 5,5-dimethyl groups become equivalent (~28.5 ppm) in compounds bearing two identical substituents at C-2, they are separated by a small difference (~1 ppm) in the compounds bearing a chiral carbon atom. For example, the chemical shifts for the C-5′ methyls in 2-methyl-2-allyldimedone **10** and 2-methyl-2-benzyldimedone **11** are 27.9, 29.1 ppm and 28.0, 28.9 ppm, respectively. A few more chemical shifts relevant to the present case are shown along with the structures **10** and **11**.

*4-Acetoxybenzo- and 4-Acetoxynaphthoketolactones **4a,b** (Table 2)*

The ketonic, lactonic, and the acetate carbonyls as well as the methylenes adjacent to the ketone (C-α) and lactone (C-α′) carbonyls could be easily assigned due to their unambiguous and well-separated chemical shifts. The acetate methyl was distinguished from the other upfield signals as a quartet in the SFORD spectra, which also confirmed all the quaternary carbons which had been assigned on the basis of their lower relative intensities in the noise-decoupled spectra. Although there is as yet no unequivocal way of assigning all the carbons in a large cycloalkanone (9, 11) or a large-ring lactone, we have attempted to assign the remaining methylenes in the present investigation guided by the following two main arguments. Firstly, the known β-effect of a ketone (1 ppm) is smaller than that of the ester carbonyl (3 ppm), while their γ-effects are equal (−2 ppm) (12*a*); the shielding effect of the carbonyl at the γ-position (−2 ppm) cannot override the increased substitution effect at that position. Secondly, the chemical shift should increase from the β- to the γ-position, from each functional group, while the δ- and ε-carbons are expected to show a slight successive decrease and increase, in their respective values. Although relevant bifunctional model compounds have not yet been examined, the observed trends in the

dibasic acids are consistent with this reasoning (8*g*). This leads to the prediction of slightly lower chemical shifts for the methylenes on the ketonic side (C-β to C-ε) than those on the lactonic side (C-β′ to C-ε′). The observed chemical shifts can thus be assigned in a self consistent way for all the polymethylenic ketolactones reported in Tables 2–4.

It is interesting to note that the highest observed chemical shifts for the aliphatic methylenes in these compounds (Tables 2–4) are very close to those in the 10- to 16-membered cycloalkanes. This could lead to an alternative way of assigning the γ–ε methylenes, assuming a decreasing shielding effect of each functional group along the chain. Thus the highest chemical shift, among the γ to ε methylenes, would be assigned to the farthest position from the functional group (C-ε and C-ε′) and the decreasing trend followed to the γ-position. These alternative assignments are illustrated only for the ketolactone **4***b* ($n = 10$), in Table 2.

The aromatic carbons of both the benzene and naphthalene series could be assigned on the basis of proton noise-decoupled and SFORD spectra, aided by the calculated values. As the required shielding parameters for substituted naphthalenes are not available (13),[2] the values reported for OAc and COC_2H_5 for the substituted benzenes (8*h*) were also used for the naphthoketolactones. The base values used for α, β, and junction carbons in the naphthalene series were 128.3, 126.1, and 133.9 ppm, respectively. The substituent was counted as *para* or *meta* to a

[2]For the ^{13}C spectra of some substituted naphthalenes (OH, OCH_3, CH_3, F, CN, and NO_2) see ref. 13 and references cited therein. We thank the referees for bringing this report to our notice.

position in the unsubstituted part of the naphthalene molecule (C-5 to C-8), depending on whether it was conjugated or not to that position. It is gratifying to note a close correspondence between the calculated and observed chemical shifts for both the series (Table 2).

*Benzo- and Naphthoketolactones **6a,b** (Table 3)*

All the assignments in these compounds were also made on the basis established in the preceding series. The chemical shifts of benzenic and naphthalenic carbons were calculated using the available data for the closely resembling substituents, OAc and CH_3, as compiled by Wehrli and Wirthlin (12*b*). In this case, the recommended value of 128.5 ppm was used for benzene, instead of 128.7 ppm employed by Stothers (8*h*). The base values used for C-1, C-2, and C-9 of the naphthalene system were the same as in the previous case: 128.3, 126.1, and 133.9 ppm, respectively. An examination of the aromatic carbons in Table 3 reveals that, but for C-1 and C-2, there is a remarkable agreement between the calculated and observed chemical shifts. The lower observed values for C-1 and C-2 are undoubtedly, in part, due to the shielding influence of the ketonic carbonyl, which has not been taken into account, while 1,8-*peri* interactions may also contribute to the excessive shielding of the C-1 in the naphthalene series. Moreover, it is well known that the additive relationship does not work very well when the substituents are *ortho* to each other.

*Ketolactones **9** and their Corresponding Oximes **8** (Table 4)*

In these compounds, apart from the unique assignments for the carbonyl functions and the two methylenes adjacent to the lactonic carbonyl and the oxygen atom, the β-carbon in the three

[b]Δ = (Chemical shift of ketone — chemical shift of oxime).

carbon chain was unambiguously assigned the highest field value, because it carries the least number of substituents among the methylenes β to the functional groups. The most difficult choice was between the two methylenes adjacent to the ketone carbonyl. However, as the three carbon chain remains constant while successive methylenes are added to the other side of the ring, one would expect comparatively constant chemical shift for the α-methylene in this chain. Thus the higher chemical shifts varying over 1.2 ppm only (40.7–41.9 ppm) were allotted to this carbon (C-α), while the upfield values (38.6–40.4 ppm) ranging over 1.8 ppm were assigned to the other methylene (C-α′). Although these assignments are arbitrary, the chemical shift comparison with the corresponding oximes (described below) seems to support them. The rest of the methylenes (γ,γ′ to ε,ε′) were assigned on arguments already elaborated in the previous two series.

In the ketoximes the α-methylenes *syn* to the oxime OH are known to be upfield by about 14–16 ppm, while the α-methylene *anti* to this hydroxyl should be shielded by only 8–10 ppm, as compared with the corresponding ketone (11). So the observed chemical shifts for the α-methylenes of the oximinolactones **8** (n = 4, 5, 6, 10) were allotted to fit the expected trend. An examination of Table 4 shows that the observed shieldings in these oximes indeed correspond very nicely to the expected values.

The shielding parameters at the β-carbons in oximes are not well defined and can be either positive or negative (11). So the rest of the methylenes were assigned to afford the closest fit to that of the corresponding ketolactone.

In conclusion, we may point out that molecular models reveal that the 9- to 16-membered ketolactones examined in the present study are conformationally very flexible molecules. It is

noteworthy that although subtle conformational changes causing slight variations in the chemical shift of certain carbons are evident in Tables 1–4, for the most part these compounds show remarkably constant values for the respective series.

Acknowledgments

Tricyclic aromatic hydrocarbons. III. Isomerically pure *meta*-bis-annelated benzenes: a simple synthesis

M. ELAINE ISABELLE, DARRYL H. LAKE,[1] AND ROBERT H. WIGHTMAN[2]

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received March 21, 1977

M. ELAINE ISABELLE, DARRYL H. LAKE, and ROBERT H. WIGHTMAN. Can. J. Chem. **55**, 3268 (1977).

A short, general synthetic sequence has been developed, involving cycloaddition and a new decarboxylation/aromatization step, to prepare isomerically pure *meta*-bis-annelated benzenes. Some new bis annelated benzoic acids were isolated as by-products. Examples of a new decarboxylation of (annelated) benzoic acids catalyzed by Pd/C are reported.

M. ELAINE ISABELLE, DARRYL H. LAKE et ROBERT H. WIGHTMAN. Can J. Chem. **55**, 3268 (1977).

On a développé une séquence synthétique générale et courte impliquant une cycloaddition et une nouvelle étape de décarboxylation/aromatisation afin de préparer des benzènes *méta*-bis accolés isomériquement purs. Des nouveaux acides benzoïques bis accolés sont isolés comme sous-produits. On rapporte aussi des exemples d'une nouvelle décarboxylation d'acides benzoïques (accolés) qui est catalysée par le Pd/C.

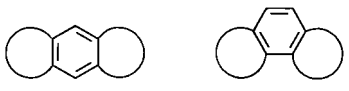
[Traduit par le journal]

Introduction

Tricyclic hydrocarbons in which a central benzene ring has been fused to two saturated carbocyclic rings have been prepared for their contribution to bonding studies (1–3), as rearrangement products of macrocyclic annulenes (4) or as intermediates in the synthesis of analogues with extended unsaturation (5, 6). The two most commonly encountered configurations involving two annelations on the benzene ring are the so-called *para-* or 'linear' (**1**) and *meta-* or 'angular' (**2**) isomers, neither of which has a generally applicable synthetic approach.

Previous synthetic attempts to obtain compounds of type **2** have been rather cumbersome (7, 8), specific for one type of saturated ring (9, 10) or complicated by the presence of the corresponding linear isomer (**1**) (11, 12). One recently published approach seems best suited to *meta* annelations of small (4- or 5-membered) rings (13).

In this paper we wish to outline a four step synthetic sequence (Scheme 1) which can produce isomerically pure 'angular' hydrocarbons (**2**) with various combinations of ring sizes. We have tested ring sizes from 5–8 carbons and believe the method to be quite general. It also nicely complements the aforementioned approach for small ring compounds (13).



1 **2**

Results and Discussion

The General Sequence

As outlined in Scheme 1 the most direct approach to the carbocyclic skeleton corresponding to 'angular' compounds of type **2** would appear to proceed via some Diels–Alder cycloadduct, e.g. **5** or **6**, derivable from bicyclic dienes (**4**). The dienes can be obtained directly by dehydration of the corresponding diols (**3**) using phosphorus oxychloride/pyridine to avoid rearrangements (14, 15). The diols **3** are now available from the cyclanones in excellent yield by employing the titanium tetrachloride modification of the pinacol reduction as recently reported by Corey *et al.* (16). Bicyclic dienes **4** are known to react readily with a variety of dieneophiles (15, 17, 18) but it is the efficient conversion of these cycloadducts to hydrocarbons such as **2** that has presented the synthetic problem.

We have been unable to obtain practically useful conversions of the anhydrides **6** or the corresponding diacids to unsaturated hydro-

carbon products employing traditional decarboxylation reagents such as lead tetraacetate (19), electrolysis (20), or bis(triphenylphosphine)-nickel dicarbonyl (21). Similarly neither halodecarboxylation of the acids **5** with lead tetraacetate/lithium chloride (22) plus base-promoted elimination nor Diels–Alder reactions of the dienes **4** with ethylene (22) followed by dehydrogenation produced **2** in acceptable yields.

In an earlier publication we had observed that the Diels–Alder anhydride **6** could be directly converted into the corresponding 'angular' hydrocarbon **2** by pyrolytic (~350°C) decarboxylation/dehydrogenation in the presence of an excess of 10% palladium-on-carbon (11). At the time the large amounts of Pd/C seemed to preclude this method as practical for the preparative synthesis of these hydrocarbons. We now find that the monocarboxylic acids **5**, obtained from Diels–Alder addition of the dienes **4** with acrylic acid (**5***a* (18*a*), **5***b* (18*b*), **5***d* (18*c*), **5***a* and **5***b* (18*d*)), on pyrolytic decomposition with small amounts of 10% Pd/C lead directly to the isomerically pure *meta*-bis-annelated benzenes **2**. Absence of any 'linear' isomers (**1**) can be readily verified by ^{13}Cmr (23). Furthermore either of these catalytic aromatizations, i.e. of **5** or **6**, can be effected with catalyst which has been 'recovered' by simply filtering and drying in an oven at 110°C. This now makes the method economically feasible for preparative scale runs.

Reaction Parameters

A representative list of specific reaction conditions are included in Tables 1 and 2 to indicate the variations in yield of **2** (and **7**) which can be encountered by altering such parameters as substrate structure, activity (source) of catalyst, ratio of reactants, and time or temperature of reaction. However, several points should be noted.

(*a*) We have found the activity of the catalyst drops significantly during storage on the laboratory shelf interspersed with frequent usage. A brief period of heating, e.g. 110°C for 24–48 h or 300°C for 30 min, appears to rejuvenate the catalyst or suffice for recycling.

(*b*) All cyclohexane rings were completely dehydrogenated in the process, i.e. **5***b* or **6***b* produced only phenanthrene.

(*c*) An interesting variation on the method is the formation of the tetracyclic hydrocarbon **10** from diacid **9** in 25% yield via the sequence outlined in Scheme 2. In contrast the corresponding dianhydride produced no **10** on pyrolysis with 10% Pd/C and only 6% of **10** on heating with phosphorus pentoxide (24).

The above example emphasizes the conclusion that the acids **5** generally afford better conversions to **2** than the corresponding anhydrides **6**. Such 'aromatizations' have been noted before on similar types of anhydrides (ref. 17, p. 455) but we believe this to be the first report of

TABLE 1. Typical 'aromatizations' of Diels–Alder acids **5**

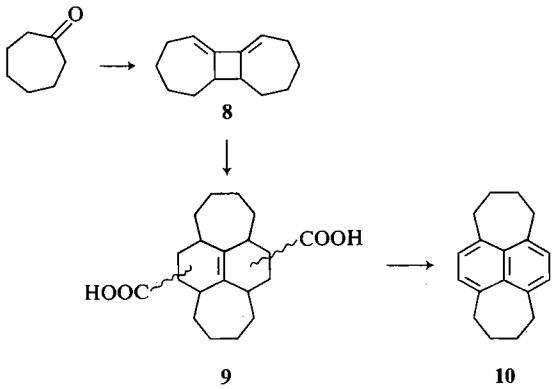
such a process occurring directly from the cyclohexene carboxylic acids **5** with Pd/C. Additionally we report the first examples of the Pd/C catalyzed decarboxylation of aromatic acids (e.g. **7***a*,*d*,*e*). The method could be considered a viable alternate to traditional methods for aromatic decarboxylations (25) and somewhat resembles the reported Pd/C catalyzed decarboxylations of aromatic aldehydes (26). Thus the formation of **2** from **5** may well involve initial dehydrogenation to **7** followed by decarboxylation.



8 **9** **10**

SCHEME 2

Experimental

Melting points were obtained on a Buchi SMP-20 melting range apparatus. Infrared spectra (ν_{max} in cm^{-1}) were recorded on a Perkin-Elmer 237B spectrophotometer. Ultraviolet spectra (λ_{max} in nm (ε)) were obtained in 95% EtOH on a Perkin-Elmer–Coleman-124 spectrophotometer. ^{13}Cmr data were obtained on a Varian XL-100 (100 MHz) instrument and proton nmr spectra were recorded on a Varian T-60 (60 MHz) instrument; all values are recorded in ppm (δ) with reference to TMS. All nmr spectra were taken in $CDCl_3$ with 1% TMS. Band shape is indicated by s(singlet), d(doublet), t(triplet), m(multiplet), b(broad). Thin layer chromatography was performed using silica gel G (0.25 mm layers) on glass plates (Merck). Petroleum ether with boiling range 30–60°C was used exclusively. Microanalyses were obtained from Organic Microanalyses, Montreal, Canada, and Spang Microanalytical Laboratory, Ann Arbor, USA.

Preparation of Diols 3a–e

A typical procedure modified from the method of Corey *et al.* (16) is as follows. Magnesium turnings (24.3 g, 1.0 mol) were amalgamated and treated with $TiCl_4$ (42.7 g, 24.8 ml, 0.225 mol) at 0°C in dry THF under a nitrogen atmosphere. To this mixture at −10°C was slowly added a solution of cyclopentanone (21.0 g, 0.25 mol) and cycloheptanone (28.0 g, 0.25 mol) in THF then the cooling bath was removed and the temperature rose to 42°C over a period of 30 min, then dropped. The usual work-up produced a viscous oil (47.5 g) which contained only the diols (**3***a*, **3***c*, and **3***d*) as indicated by tlc. Such mixtures cannot be separated by conventional column chromatography (11, 14); however, the short, wide column (35 cm × 10 cm diameter) technique (27) using silica gel H (1000 g, Merck, particle size 10–40 × 10^{-6} m) and ethyl acetate – benzene (3:7 v/v) produced **3***a* (1.8 g, mp 107–109°C), **3***c* (6.3 g, mp 62–63°C), and **3***d* (4.0 g, mp 76–77°C) from 15.0 g of the crude mixed diols. Similarly **3***a*, **3***b*, **3***d*, and **3***e* could be prepared in yields ≥85% from the corresponding ketones and the crude product used directly for preparation of the dienes.

TABLE 2. Typical 'aromatizations' of Diels–Alder anhydrides **6**

Substrate/weight (mg)	Weight of 10% Pd/C (mg)	Temp. (°C)/Time (min)	Yield of **2** (%)
6*a*/200	400	350/30	30
6*a*/200	400	400/15	22
6*a*/200	67	350/30	7
6*b*/200	400	390/30	74 (phenanthrene)
6*c*/500	900	350/20	52
6*d*/200	400 (recycled)	350/30	68
6*d*/200	400	315/30	47
6*d*/200	100	350/30	54
6*e*/200	400	350/30	26
6*e*/200	400	400/15	20
6*e*/200	67	350/30	13

Preparation of Bicyclic Dienes 4a–e

Essentially the method of Greidinger and Ginsberg (15) was followed involving heating the diols with freshly distilled phosphorus oxychloride and dry pyridine. Reaction times of 2–4 h and a temperature of 90°C were found to be sufficient. Yields of the dienes (**4**) were 80–95% and as before (11, 15) the crude dienes were found to be of sufficient purity for direct use in the ensuing Diels–Alder reactions.

Preparation of Tricyclic Acids 5a–e

Following the procedure of Christol *et al.* (18) diene **4***e* (5.7 g, 0.026 mol) and acrylic acid (1.87 g, 0.026 mol) in refluxing benzene for 9 h produced unreacted diene **4***e* (1.63 g), mp 41°C, and **5***e* (4.89 g, 90% when corrected for recovered diene), mp 125°C; ir 3300–2600, 1700 (-COOH); ^{1}Hmr 11.31 (1H, bs, COOH) 2.90–1.90 (7H, bm, allylic H's), 1.90–1.00 (22H, m, all other H's). *Anal.* calcd. for $C_{19}H_{30}O_2$: C 78.57, H 10.41; found: C 78.72, H 10.30.

We have found that extended reflux times (up to 30 h) or temperatures (e.g. refluxing toluene) may be required depending on the reactivity of the dienes. Thus the following acids were prepared (mp, corrected yield, (lit.) mp): **5***a* (118–122°C, 87%, (18*a*) 128°C), **5***b* (172–176°C, 90%, (18*b*) 185°C), **5***d* (80–92°C, 92%, (18*c*), 75–90°C), and **5***c* (72%, presumably as a mixture of the two regioisomers which were not separated). The acids **5** were crystallized from petroleum ether.

Preparation of Tricyclic Anhydrides 6a–e

Again the method of Greidinger and Ginsberg (15) was employed, namely heating the dienes **4** with maleic anhydride for 2–5 h depending on the reactivity of each individual diene. Yields of anhydrides (**6**) were ≥ 85% and all compounds agreed by mp with previously reported values (11, 15).

Preparation of Hydrocarbons 2a–e and Benzoic Acids 7a–e

For specific conditions of time, temperature, and amounts, see Tables 1 and 2.

The acid **5** or anhydride **6** was intimately mixed with a certain amount of 10% Pd/C and this mixture placed in a glass tube (~50 cm × 0.10 cm diameter) open at one end. This tube was placed vertically in a preheated (usually 350–400°C) furnace (25 cm × 8 cm diameter) for a short period of time. The tube was removed, allowed to cool, and the contents rinsed out with CH_2Cl_2. The catalyst was filtered (to be oven dried at 110°C and reused), the filtrate stripped of solvent, and the crude product either separated into acidic and neutral fractions or adsorbed directly onto a short column of silica gel. The hydrocarbon **2** was eluted with petroleum ether and easily identified by ^{1}Hmr and ^{13}Cmr (23). The major by-product from **5** at lower temperatures proved to be the benzoic acid **7** which could be eluted from the column with benzene–ether (19:1 v/v). These acids were crystallized from petroleum ether and characterized as follows.

7*a*: mp 203–204°C; lit. mp 202–204°C (28); ir: 3300–2700, 1680 (aryl COOH); uv: 244 (14 833), 290 (3 300); ^{1}Hmr, 11.00 (1H, bs, COOH), 7.64 (1H, s, ArH), 2.95 (8H, m, benzylic H), 1.53 (4H, m, other H). *Anal.* calcd. for $C_{13}H_{14}O_2$: C 77.19, H 6.98; found: C 77.20, H 6.94.

7*d*: mp 141°C; ir: 330–2700, 1680 (aryl COOH); uv: 245 (2466), 288 (304); ^{1}Hmr: 11.50 (1H, bs, COOH), 7.63 (1H, s, ArH), 3.00 (8H, m, benzylic H), 1.70 (12H, m, other H). *Anal.* calcd. for $C_{17}H_{22}O_2$: C 79.02, H 8.59; found: C 79.30, H 8.58.

7*e*: mp 151°C; ir: 3300–2800, 1680 (aryl COOH); uv: 244 (8375), 298 (1175); ^{1}Hmr: 11.13 (1H, bs, COOH), 7.64 (1H, s, ArH), 2.95 (8H, m, benzylic H), 1.53 (16H, m, other H). *Anal.* calcd. for $C_{19}H_{26}O_2$: C 79.67, H 9.16; found: C 79.86, H 9.30.

Preparation of Tetracyclic Hydrocarbon 10

Tricyclic diene **8** (8.0 g, 0.022 mol) (24), acrylic acid (3.4 g, 0.061 mol), and hydroquinone (0.1 g) in dry benzene (50 ml) were heated at reflux under a nitrogen atmosphere for 54 h. After the benzene was removed and the residue triturated with petroleum ether to remove any unreacted diene, there remained an amorphous glass (10.0 g) which could not be induced to crystallize but appeared to be diacid **9** (perhaps a mixture of regioisomers) on the basis of the following spectral data; ir: 3300–2600, 1720 (COOH); nmr: 10.65 (2H, bs, COOH), 3.10–2.40 (6H, m, H α to C=C and C=O), 2.4–1.0 (16H, m, other H). When this crude diacid **9** was subjected to the usual decomposition in the presence of 10% Pd/C, the hydrocarbon **10** mp 140–142°C, lit. mp 143°C (24), could be isolated in 25% yield after chromatography on alumina (Woelm, neutral, activity I). In preparation for the reaction a concentrated solution of **9**

in CH_2Cl_2 was added to the catalyst in the reaction tube and the solvent then carefully evaporated. Specific conditions are outlined in Table 1.

Acknowledgments

We acknowledge with thanks the National Research Council of Canada which provided the operating grants to finance much of this work. Mr. David Laycock prepared the diene **8** and diacid **9**. The continued assistance of Mr. G. K. Diedrich is much appreciated. ^{13}Cmr were obtained through Dr. G. W. Buchanan, Carleton University.

Sterically hindered aromatic compounds. VII. Deoxygenation of 2,5-di-*tert*-butyl- and 2,4,6-tri-*tert*-butylnitrosobenzene

L. Ross C. Barclay, Prabhaker G. Khazanie, Kenneth A. H. Adams, and Elaine Reid

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received February 2, 1977

L. Ross C. Barclay, Prabhaker G. Khazanie, Kenneth A. H. Adams, and Elaine Reid. Can. J. Chem. **55**, 3273 (1977).

Deoxygenation of 2,5-di-*tert*-butylnitrosobenzene (**1**) by triethylphosphite gave a complex mixture containing 2,5-di-*tert*-butylaniline, 2,5,2′,5′-tetra-*tert*-butylazobenzene, *N*-(2,5-di-*tert*-butylphenyl)-α-*tert*-butyl-α-2-(5-*tert*-butylpyridyl)nitrone, and diethyl *N*-(2,5-di-*tert*-butylphenyl)phosphoramidate. In contrast deoxygenation of 2,4,6-tri-*tert*-butylnitrosobenzene (**2**) yielded mainly 3,3-dimethyl-5,7-di-*tert*-butyl-2,3-dihydroindole (80%), together with small amounts of 2,4,6-tri-*tert*-butylaniline and a product of side chain rearrangement, 2-(2-methyl-3-propenyl)-4,6-di-*tert*-butylaniline. Reaction pathways involving nitrenoid intermediates account for the various products. The different types of products from **1** and **2** are explained in terms of differential steric and conformational effects.

L. Ross C. Barclay, Prabhaker G. Khazanie, Kenneth A. H. Adams et Elaine Reid. Can. J. Chem. **55**, 3273 (1977).

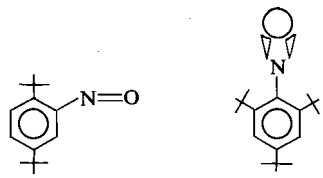
La déoxygénation du di-*tert*-butyl-2,5 nitrosobenzène (**1**) par la triéthylphosphite donne un mélange complexe de di-*tert*-butyl-2,5 aniline, tétra-*tert*-butyl-2,5,2′,5′ azobenzène, *N*-(di-*tert*-butyl-2,5 phényl)-α *tert*-butyl-α (*tert*-butyl-5 pyridyl)-2 nitrone et *N*-(di-*tert*-butyl-2,5 phényl) phosphoramidate de diéthyle. Par contre, la déoxygénation du tri-*tert*-butyl-2,4,6 nitrosobenzène (**2**) conduit principalement au diméthyl-3,3 di-*tert*-butyl-5,7 dihydro-2,3 indole (80%), avec un faible pourcentage de tri-*tert*-butyl-2,4,6 aniline contenant un produit de réarrangement de la chaîne latérale, le (méthyl-2 propényl-3)-2 di-*tert*-butyl-4,6 aniline. Les sentiers réactionnels impliquant des intermédiaires nitrénoïde sont responsables des composés divers. Les différents type de produit obtenus à partir de **1** et **2** sont expliqués en terme d'environnement stérique et d'effets conformationnels.

[Traduit par le journal]

Introduction

Deoxygenation of aromatic nitro and nitroso compounds by tervalent phosphorus reagents results in reactions indicative of the presence of nitrenes as discrete intermediates. The generation and reactions of aryl nitrenes have been reviewed (1–5). They are of continuing interest in the synthesis of heterocyclic compounds (3, 6–8), and the detailed nature of the intermediates involved in reactions, such as cyclizations of 2-azidobiphenyl to carbazole, is still an interesting question (9).

Ortho tert-butyl groups are known to affect the lifetimes of various types of radicals (10, 11) in aromatic compounds. As part of our continuing study of steric influences on reactions and reactive intermediates, we have examined the steric effect of one and of two *ortho tert*-butyls on the reactions of aryl nitrenes derived from 2,5-di-*tert*-butylnitrosobenzene (**1**) and 2,4,6-tri-*tert*-butylnitrosobenzene (**2**) by triethyl phosphite deoxygenation. These conveniently exist as the monomers and preferentially with the nitroso group in the coplanar *anti* (**1**) and out-of-plane (**2**) conformations shown (12).

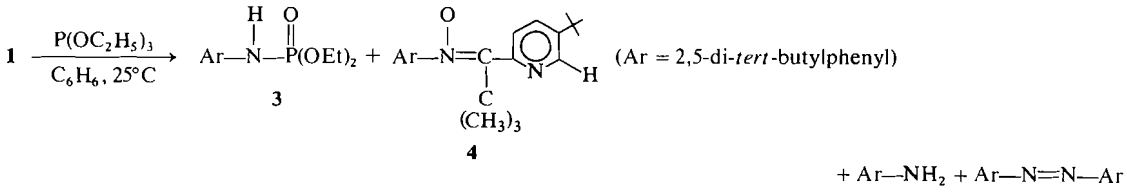


Results and Discussion

(a) Deoxygenations of 1 and 2. Analysis of Products

Deoxygenation of **1** yielded four identifiable products as illustrated in Scheme 1 and Table 1.

The major product, diethyl *N*-(2,5-di-*tert*-butylphenyl)phosphoramidate (**3**) (35%) was identified from its spectroscopic properties and hydrolysis to the known amine (**5**). The structure of the rearrangement product, the pyridine derivative or nitrone (**4**) (29%) was determined from its analytical and spectroscopic proper-



SCHEME 1

ties.[1] The elemental and mass spectroscopic data agreed with the formula $C_{28}H_{42}N_2O$. A peak at *m/e* 407 is assigned to $M - CH_3$, one at *m/e* 406 to $M -$ oxygen, and the base peak at *m/e* 365 to $M -$ *tert*-C_4H_9. The structure assigned to **4** is based mainly on its nmr spectrum, especially the low field portion of the aromatic absorption. In addition to a multiplet at 7.64 δ (5-hydrogens), a weakly coupled peak at 8.70 δ (doublet, $J \simeq 1$ Hz) is attributed to the α-H of a 2,5-disubstituted pyridine ring.

Deoxygenation of **2** with triethyl phosphite required elevated temperature and longer reaction times. However, the product mixture was not so complex as in the reduction of **1** (compare Scheme 2 and Table 2), in that reduction of **2** gave a high yield of 3,3-dimethyl-5,7-di-*tert*-butyl-2,3-dihydroindole (**7**). The cyclic amine **7** was identified by its spectroscopic properties and by preparing it through hydride reduction of 5,7-di-*tert*-butyl-3,3-dimethyloxindole (**10**), a known photolysis product from 2,4,6-tri-*tert*-butylnitrobenzene (13).

The rearranged unsaturated amine **8** is an unexpected product from the reduction of **7**. Its infrared spectrum indicated a primary amine. The structure assigned is based mainly on the nmr spectrum, especially the bands for the rearranged side chain, $Ar—CH_2—\overset{CH_2}{\overset{\|}{C}}—CH_3$ (see Experimental). The broad nature of these bands is presumably due to weak allylic coupling.

TABLE 1. Deoxygenation products of 2,5-di-*tert*-butylnitrosobenzene (**1**) by triethyl phosphite

Compound	Isolated yields[a]

4	31–29[b]
5	11–13
6	3

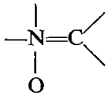
[a]The percent yields actually isolated from two separate runs by column and tlc.
[b]The yield of 4 was increased to 70% from a run using direct nmr observations.

(b) Proposed Reaction Pathways

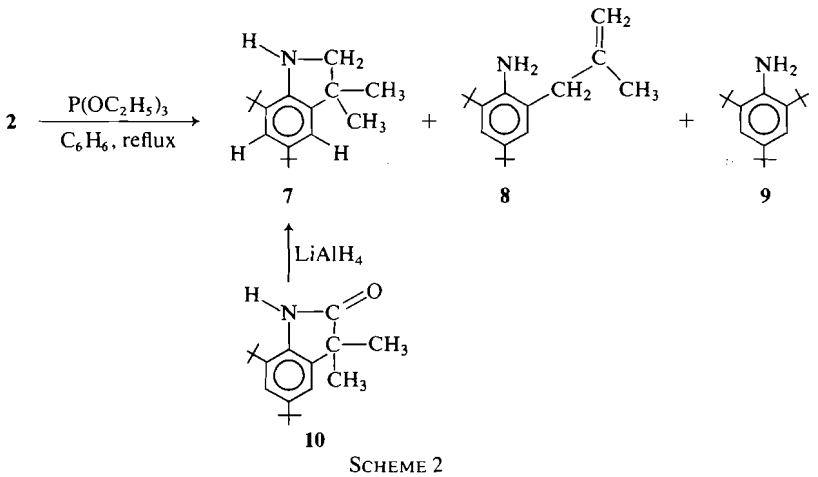
A pathway (Scheme 3) for deoxygenation of 2,5-di-*tert*-butylnitrosobenzene through the dipolar intermediate **11** (14) should account both for products arising directly from an aryl nitrene (e.g., **3**, **5**, and **6**) and also for products of molecular rearrangement and recombination (e.g., the nitrone **4**). The amine **5** and the azo compound **6** would form from the aryl nitrene **13** by hydrogen abstraction and dimerization respectively. There is also precedent for the reaction of aryl nitrenes with triethyl phosphite to form a phosphoramidate via an *N*-aryl phosphorimidate intermediate (15); in our case for the sequence **13** → **14** → **3**.

Several suggestions have been made for the reaction pathway to account for intermolecular reactions and rearrangements of aryl nitrenes leading to pyridine derivatives (16–19). Phenylnitrene and 2-pyridylcarbene are known to interconvert, at least in the gas phase (19), and one could formulate nitrone formation as simply a combination of a 2-pyridylcarbene with a nitroso compound (i.e., in this case **18** and **1**). The exclusive formation of isomer **4** is an interesting example of the directional specificity of the rearrangement. This presumably occurs by preferential ring expansion involving migration of the *unsubstituted* carbon *ortho* to the electron deficient nitrogen. This kind of specificity has been observed before in the triethyl phosphite deoxygenation of *o*-methylnitrosobenzene (16), in the photochemical deoxygenation of aromatic nitro-compounds in triethyl

[1]Unlike a similar aryl nitrone containing an α-methyl substituent (16), nitrone **4** failed to undergo acid-catalyzed hydrolysis. The α-*tert*-butyl group of **4** evidently results in steric hindrance to nucleophilic attack at the



group.



SCHEME 2

TABLE 2. Deoxygenation products of 2,4,6-tri-*tert*-butylnitrosobenzene (**2**) by triethyl phosphite

Compound	Relative yield[a]	Isolated yield[b]

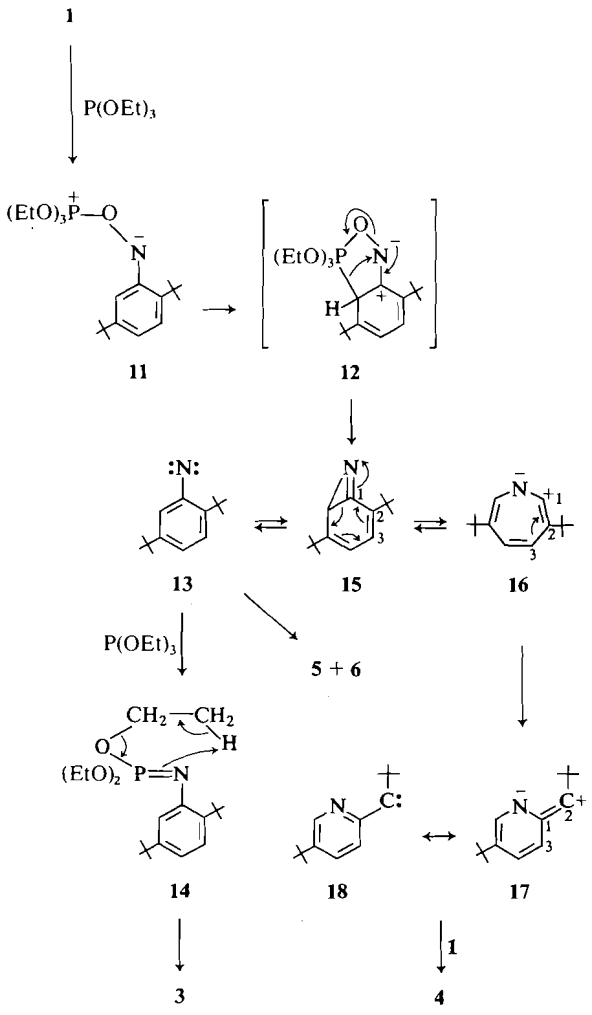
phosphite (17), and in the photolysis of *ortho*-substituted aryl azides in diethylamine (20).

The specificity in the present deoxygenation–rearrangement of **1** may be explained on the basis of conformational or steric control. The preferred *anti* conformation for **1** is presumably retained in the more bulky dipolar intermediate (**11**). We speculate that the preferential bonding at the *ortho* site on the same side of the benzene ring as the leaving group ($(EtO)_3P{=}O$) may be a result of polarization of the *ortho* position by the electrophilic phosphorus in **11**. This could be formulated in terms of a cyclic intermediate such as **12** which could preferentially form the azirine (**15**). Alternatively **15** could be the preferred azirine simply due to steric inhibition of attack of the nitrene centre at the *tert*-butylated site-2. The rearrangement can be formulated as proceeding via ring expansion of **15** in the direction indicated leading to **16** then **17** (or **18**). Reaction of the aryl nitroso compound with the latter would yield the nitrone **4**. This pathway has the advantage of accommodating both the directional specificity and the required C-1 to C-3 shift (17).

The major product (**7**) from deoxygenation of 2,4,6-tri-*tert*-butylnitrosobenzene (**2**) resulted from reductive cyclization into an *o-tert*-butyl group. The marked difference in behaviour of **1** and **2** can be attributed to differential conformational or steric effects. The dipolar intermediate from **2** is expected to retain the out-of-plane conformation (Scheme 4, **19**). This would inhibit the coplanar conformation of the charged leaving group which may be preferred for the rearrangement of the aromatic ring, as suggested above for the deoxygenation–rearrangement of **1**. Alternatively, and more simply, the different products from **2** could be a result of steric inhibition of attack of the nitrene (**20**) at *both tert*-butylated *ortho* positions coupled with steric hindrance to intermolecular reactions, such as dimerization and reaction with triethyl phosphite. As a result, cyclization into a methyl group of an *o-tert*-butyl leading to **7** in high yield is the predominant reaction. Such cyclizations can be formulated via insertion involving an initial singlet nitrene or through hydrogen abstraction by triplet nitrene followed by radical coupling (2, 4). The latter is the suggested route to account for the cyclization yielding **7** because a radical intermediate[2] can also account for the interesting side product (**8**), where an *o-tert*-butyl group has undergone skeletal rearrangement (**21** → **22** → **8**) *leading to a nonconjugated*

[2]NOTE ADDED IN PROOF: The esr spectrum measured directly on the deoxygenation reaction of **2** showed a very persistent 1:1:1 triplet ($a_N \simeq 10.0$ G) with unresolved fine structure. This is probably due to an anilino radical of the type Ar—N̈—OR (Ar = 2,4,6-tri-*tert*-butylphenyl) formed by spin trapping of radical intermediates by unreacted **2** (see Terabe and Konaka (22)).



SCHEME 3

double bond in the side chain. This result provides an interesting contrast to results of Sundberg (16) who found a selectivity in H-abstracting for *ortho* alkyl aryl nitrenes derived from *o*-azidopropylbenzene pyrolysis and from triethyl phosphite reduction of *ortho* propyl or butylnitrobenzene. The formation of only the nonconjugated alkene in those cases was an argument against any mechanism involving a radical or carbonium ion at the β and γ carbon. That particular concerted pathway is not open for the intermediate **20** since it lacks a γ carbon. The formation of the nonconjugated double bond in **8** may be a result of kinetic control in elimination of hydrogen in the rearrangement **21** → **22**. Alternatively the second hydrogen atom might be abstracted from the γ position as illustrated in **23**, although the latter involves a relative unfavourable seven-membered cyclic transition state.

It is of interest to note that the nitro compounds, 2,5-di-*tert*-butylnitrobenzene and 2,4,6-tri-*tert*-butylnitrobenzene, failed to undergo triethylphosphite deoxygenations, even on prolonged treatment at elevated temperatures.

Experimental

The nmr spectra were recorded on a Varian A-60 nmr spectrometer using carbon tetrachloride solvent containing tetramethylsilane as an internal reference. The ir spectra were recorded on a Perkin-Elmer model 467 grating infrared spectrophotometer using potassium bromide pellets for solids and films for liquids. Mass spectra were determined on a Varian MAT-111 GC/MS system using a direct probe. Gas–liquid chromatography (glc) analysis were determined on a F & M model 500 gas chromatograph equipped with a dual column attachment, using 8 ft × 14 in. columns packed with 20% Carbowax on Chromosorb P and helium flow rate of 60 ml/min at 175°C. Thin layer chromatographic (tlc) preparative separations were carried out on plates (20 × 20 cm × 0.5 mm thick) prepared from Woelm Silica Gel F with 10% calcium sulfate binder added. Melting points were determined on a hot stage equipped with a microscope and are uncorrected. Elemental analyses were determined by Alfred Bernhardt, West Germany.

(a) Deoxygenation Procedure

The deoxygenations were carried out in dry benzene under a nitrogen atmosphere. The solutions were prepared from 2–3 mmol of the nitroso compound (**1** or **2**) (21) and excess (20–30 mmol) triethyl phosphite (Aldrich Chemical Co.) in 15–25 ml of benzene. It was convenient to follow the progress of the reductions by measuring the decrease in the visible absorbance readings at 790 nm for **1** and 750 nm for **2**. The reduction of **1** was complete in approximately 11 h at room temperature. The reduction of **2** did not appear to take place at room temperature but was complete after 20 h at the reflux temperature of benzene.

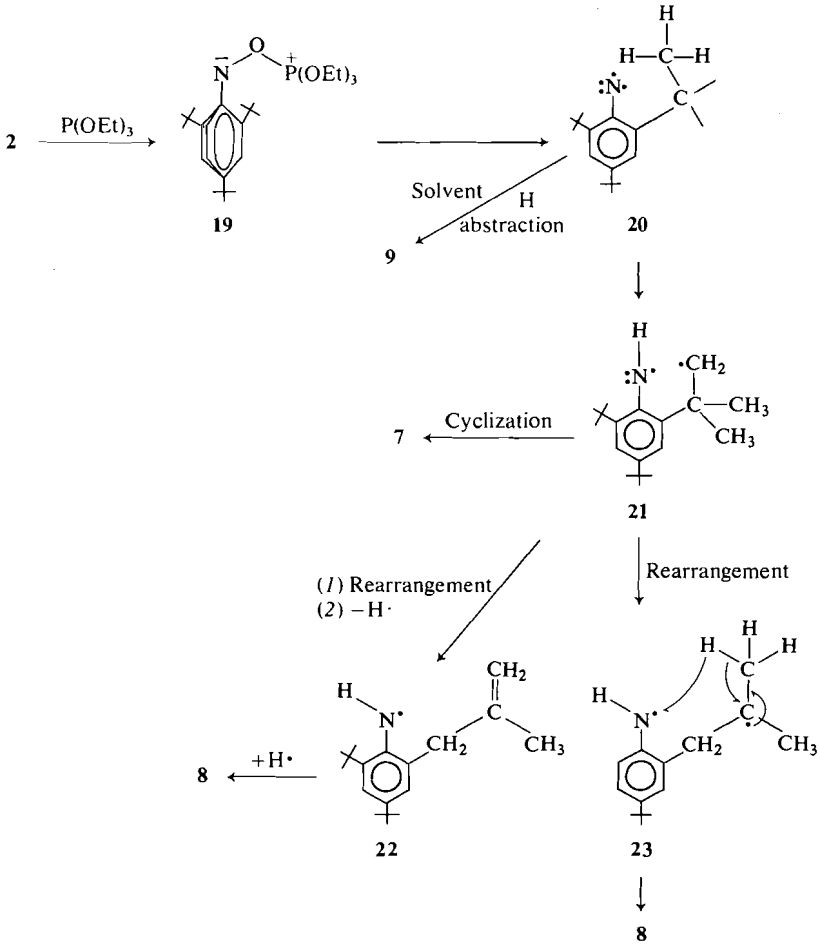
The relative ease of reduction of **1** and **2** was also followed by direct nmr observations of the aromatic proton region using equimolar solutions of the nitroso compound and triethyl phosphite in carbon tetrachloride. Under these conditions, the reduction of **1** was complete in 6 h. In contrast, the reduction of **2** was only ⅓ complete after 1 week.

The reaction mixtures were worked up by first evaporating the solvent and excess triethyl phosphite under reduced pressure. The residues were dissolved in ethyl ether, washed with water, the ether extract dried over anhydrous calcium chloride, and the ether evaporated. The crudes obtained were analyzed by chromatographic methods as described below.

(b) Product Analysis

(1) Deoxygenation Products from 2,5-Di-tert-butylnitrosobenzene (1)

The crude product from reduction of **1** (0.657 g) was



SCHEME 4

found to be a complex mixture by tlc analysis. It was dissolved in petroleum ether (bp 30–60°C) and separated into various fractions by column chromatography on a 2.5 × 28 cm column of neutral alumina as outlined in Table 3. Pure compounds were isolated by further separation of the column chromatograph fractions by means of preparative tlc.

2,5,2',5'-Tetra-tert-butylazobenzene (6)—The azo compound (**6**) was purified by preparative tlc using cyclohexane solvent. The compound separated as a narrow orange-red band by rapid elution near the solvent front. Sublimation *in vacuo* gave orange crystals, mp 227°C. The nmr spectrum showed a singlet at 1.38 (18H, 2 *tert*-butyls) and 1.64 (18H, 2 *tert*-butyls) and multiplets at 7.61 (4H, aryl) and 7.94 δ (2H, aryl). The mass spectrum showed a molecular ion peak at *m/e* 406 expected. *Anal.* calcd. for $C_{28}H_{42}N_2$: C 82.70, H 10.41, N 6.89; found: C 82.59, H 10.30, N 6.95.

N-(2,5-Di-tert-butylphenyl)-α-tert-butyl-α-2-(5-tert-butylpyridyl)nitrone (4)—Fractions 4–6 from the column chromatography (Table 3) yielded 305 mg of crystalline material. This material was chromatographed on five preparative tlc plates using benzene as the developer. There resulted two well-separated bands. The first band (near the solvent front) yielded, on extraction with ethyl ether, 197 mg (31%) of near colorless crystalline material identified as the nitrone (**4**). The analytical sample was obtained by sublimation *in vacuo* and gave a mp 189°C. The nmr spectrum showed four singlets of equal intensity at 1.39, 1.41, 1.47, and 1.53 δ (36H, three aryl *tert*-butyls and *tert*-butyl in $(CH_3)_3C-\overset{|}{\underset{|}{C}}=N-O$), a multiplet at 7.53–7.78 (5H, three hydrogens on benzenoid ring plus hydrogens 3,4 of pyridine ring), and a doublet at 8.70 ($J \simeq 1$ Hz, 1H, α-pyridyl hydrogen).

The mass spectrum showed a molecular ion peak at *m/e* 422 and an accurate mass measurement indicated the formula $C_{28}H_{42}N_2O$ (calcd. mass 422.3297; found 422.3288). *Anal.* calcd.: C 79.59, H 10.02, N 6.63; found: C 79.62, 79.47, H 9.96, 9.86, N 6.63, 6.56.

The nitrone (**4**) was recovered unreacted from an attempted hydrolysis by treatment in boiling ethanol–hydrochloric acid for 2 days.

The second band from the above tlc separation yielded 66 mg (11%) of 2,5-di-*tert*-butylaniline identified by a mixture melting point and comparison of its nmr spectrum with an authentic sample.

Diethyl N-(2,5-Di-tert-butylphenyl)phosphoramidate

TABLE 3. Column chromatography of deoxygenation products from 2,5-di-*tert*-butylnitrosobenzene (**1**)

Fraction	Solvent (ml)[a]	Yield (mg)	Identity of products[b]
1	PE (20)	44	Di-*tert*-butylazobenzene (**6**)
2, 3	PE (20)	19	Unidentified mixture
4–6	PE–bnz (80)	305	Di-*tert*-butylaniline (**5**), nitrone (**4**)
7–8	bnz (80)	7	Unidentified polymeric
9–14	bnz (300)	311	Phosphoramidate (**3**), traces of TEP

[a]PE = petroleum ether (bp 30–60°C), bnz = benzene.
[b]Products were further separated and purified by preparative tlc.

(3)—Fractions 9–14 from the column chromatography (Table 3) contained 311 mg (31%) of the crude phosphoramidate (**3**). It was separated from traces of a colored (violet) impurity by preparative tlc on four plates using 20% ethyl ether in benzene as developer. The ester **3** developed very slowly and was readily separated in this way. It was isolated as a colorless, thick, oily material. The nmr spectrum showed a singlet at 1.32 superimposed on a triplet between 1.47–1.22 (J in Hz) (15H, a *tert*-butyl and two CH_3-[s] of the CH_3CH_2O- groups), a singlet at 1.50 (9H, a *tert*-butyl), a multiplet at 3.9–4.5 (4H, $J = 7$ Hz, two -CH_2-[s] of CH_3CH_2O- groups), a doublet, exchangeable with D_2O at 5.28 (1H, —N—H), and an abc type of multiplet at 7.2–7.7 δ (3H, $J_{ab} = 9$ Hz, $J_{bc} = 2$ Hz, aryl). The ir spectrum showed a band at 3480 cm^{-1} attributed to N—H. A strong band at 1250 cm^{-1} is assigned to P=O and very strong absorption at 970–1060 to P—O—ethyl. The mass spectrum showed a molecular ion peak at *m/e* 341 as expected. *Anal.* calcd. for $C_{18}H_{32}NPO_3$: C 63.32, H 9.45, N 4.10, P 9.07; found: C 63.13, H 9.44, N 4.15, P. 8.99.

A sample (39 mg) of the phosphoramidate (**3**) was hydrolyzed by refluxing in a mixture of ethanol (10 ml) and concentrated hydrochloric acid (5 ml) for 2 days. The alcohol was distilled, the solution neutralized with sodium carbonate and the product extracted with ether. There was obtained 19 mg (81%) of 2,5-di-*tert*-butylaniline, identified by its nmr spectrum and melting point.

The deoxygenation of **1** with triethylphosphite was repeated in order to test the reproducibility of the rather complex reaction. The work-up and separation of products by a combination of column chromatography and tlc was carried out in a similar manner to the first run. The yields of the main products from this second run were azo compound **6** 3%, nitrone **4** 29%, amine **5** 13%, and the phosphoramidate **3** 35%. These results are in reasonably good agreement with those described above. When an equimolar mixture of **1** and triethylphosphite was used as described in the direct nmr observation, the yield of **4** (tlc) was increased to 70%.

(2) Deoxygenation Products from 2,4,6-Tri-tert-butylnitrosobenzene (2)

The crude product from reduction of **2** (0.550 g) was separated into three main bands by preparative tlc using benzene as developer. The first band gave 37 mg (6.9%) of 2,4,6-tri-*tert*-butylaniline (**9**) identified by its ir and nmr spectra. The second band yielded the major product, a colorless solid material (482 mg, 90%) which was shown by the nmr spectrum to be a mixture of the two amines **7** (*mainly*) and **8** described below. This mixture was separated on preparative tlc plates prepared from acid-treated silica gel. For this purpose, the plates were prepared from a slurry of the silica gel and binder in 1:1 ethanol–acetone containing 5% concentrated hydrochloric acid. The minor component (**8**) (48 mg, 9%) of this mixture eluted first with benzene followed by the major reaction product (**7**, 424 mg, 79%).

This deoxygenation of nitroso compound **2** was repeated in order to determine more precisely the percent composition of the products by glc. The compounds eluted from the column in the order **7**, **9**, and **8** and in the relative yields of 81.3%, 7.3%, and 11.4% respectively.

3,3-Dimethyl-5,7-di-tert-butyl-2,3-dihydroindole (7)—The major product **7** from the deoxygenation of **2** was sublimed *in vacuo* for analysis. It was a colorless crystalline compound, mp 105–106°C. The nmr and ir spectra established this compound to be identical to **7** obtained earlier (13) from hydride reduction of 5,7-di-*tert*-butyl-3,3-dimethyloxindole. It gave a parent mass at *m/e* 259 as expected. *Anal.* calcd. for $C_{18}H_{29}N$: C 83.33, H 11.26, N 5.40; found: C 83.52, 83.48, H 11.27, 11.25, N 5.20, 5.16.

2-(2-Methyl-3-propyl)-4,6-di-tert-butylaniline (8)—The amine **8** from the deoxygenation was isolated as an oil and distilled *in vacuo* for analysis. The nmr spectrum showed sharp singlets at 1.32 and 1.47 (9H each, *tert*-butyls), a broad singlet at 1.78 (3H, methyl of $CH_2{=}C(CH_3)$—), a broad singlet at 3.37 (2H, benzylic methylene of $Ar{-}CH_2{-}C(CH_2){-}CH_3$), two broad singlets at 4.92–5.00 (2H, nonequivalent olefinic H[s] of $>C{=}CH_2$), a singlet at 3.80 (2H exchangeable, -NH_2), and doublets at 7.11 and 7.37 δ ($J \simeq 3$ Hz) (1H each, *meta* aryl hydrogens). The ir spectrum showed bands at 3520 and 3420 cm^{-1} attributed to N—H stretching absorption of a primary amine and a band at 3090 cm^{-1} to the C—H stretching absorption of the $>C{=}CH_2$ group. The mass spectrum showed a parent mass at *m/e* 259 as expected. *Anal.* calcd. for $C_{18}H_{29}N$: C 83.01, H 11.22, N 5.38; found: C 83.21, H 11.09, N 5.53.

Synthesis of enantiomers of sulcatol

HERMANN R. SCHULER[1] AND KEITH N. SLESSOR

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received February 22, 1977

HERMANN R. SCHULER and KEITH N. SLESSOR. Can. J. Chem. **55**, 3280 (1977).

The synthesis of *R*-(−)- and *S*-(+)-6-methylhept-5-en-2-ol (sulcatol) is reported from commercially available carbohydrate precursors. The synthesis of the *R*-(−) enantiomer utilizes the four hydroxy function of 2-deoxy-D-ribose as a preformed precursor of the chiral secondary alcohol centre. The five hydroxy group of L-fucose provides the basis for a similar synthesis of the *S*(+) enantiomer. These isomers are to be used to test the aggregation response of *Gnathotricus sulcatus*, a northwestern American timber pest.

HERMANN R. SCHULER et KEITH N. SLESSOR. Can. J. Chem. **55**, 3280 (1977).

On rapporte la synthèse des *R*-(−)- et *S*-(+)-méthyl-6 heptène-5 ols-2 (sulcatol) à partir de précurseurs carbohydrates disponibles commercialement. La synthèse de l'énantiomère *R*-(−) utilise la fonction hydroxyle quatre du déoxy-2 D-ribose comme des précurseurs préformés du centre alcoolique secondaire chiral. Le groupe hydroxyle cinq du L-fucose fournissent la base pour une synthèse similaire de l'énantiomère *S*(+). Ces isomères seront utilisés pour déterminer une réponse d'agrégation de *Gnathotricus sulcatus*, un insecte des bois du nord ouest de l'Amérique.

[Traduit par le journal]

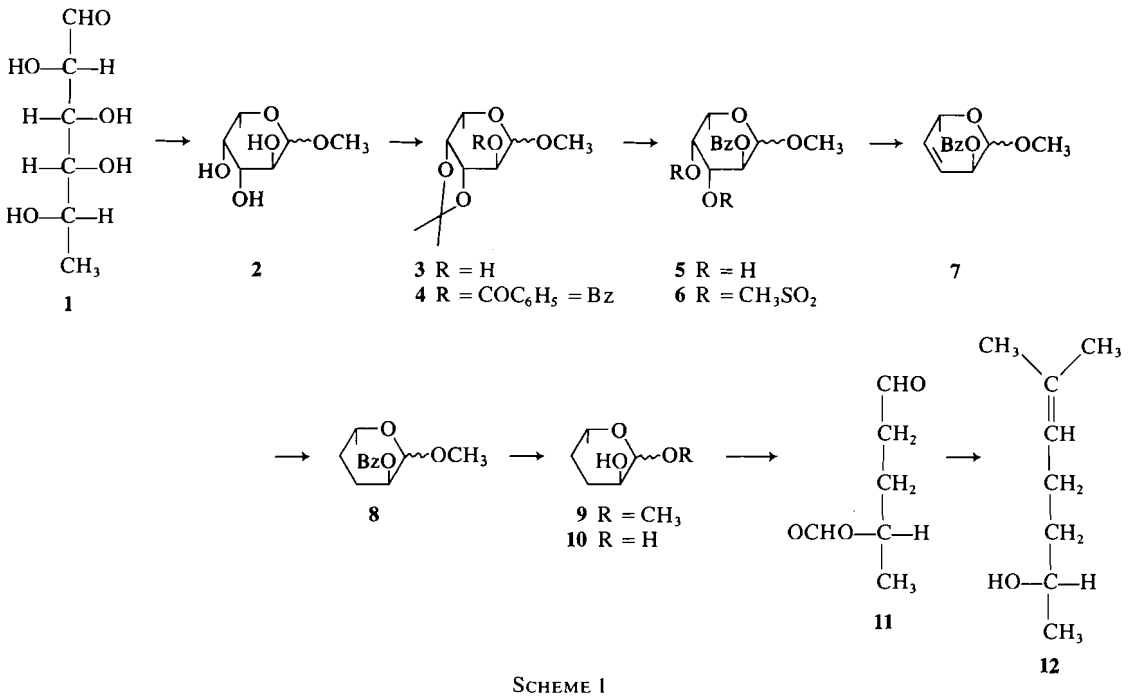
The ambrosia beetle, *Gnathotricus sulcatus*, a widely occurring timber pest in western North America, has been found to possess an aggregation pheromone (1), identified as 6-methylhept-5-en-2-ol (sulcatol). Furthermore, it was shown to consist of a 65:35 mixture of the (*S*)-(+) and the (*R*)-(−) enantiomers (2). This finding was rather unexpected as racemic sulcatol, which can be readily obtained by borohydride reduction of 6-methylhept-5-en-2-one, produced a beetle response comparable to the 65:35 mixture. Thus the question arose whether one or both enantiomers are needed to trigger an aggregation response by the beetle.

To investigate this question, pure enantiomers of sulcatol were required. Initially attempts were made to resolve racemic sulcatol by counter current distribution of diastereoisomeric sulcatol esters of 2,3:4,6-di-*O*-isopropylidene-L-*xylo*-hexulofuranosonic acid (3, 4). Although resolution was possible using this method, its quantitative aspects were unfavorable and led us to look for an alternative approach. We decided to design synthetic routes which utilize as starting materials compounds already containing the stereochemical requirements of the desired isomeric products. Sugars seemed well suited for this approach as their absolute configuration and optical purity are well established.

In the course of our synthetic work we learned of another preparation of the isomers of sulcatol by Mori (5), whose approach was similar as it uses optically active precursors, namely the two enantiomers of glutamic acid. Both of these enantiomers were subjected to the same reaction sequence leading to the two enantiomers of sulcatol. Initial studies, using Mori's enantiomers, gave evidence that *G. sulcatus* would not respond to either pure enantiomer, only to a mixture of the isomers. To our knowledge this is the first report (6) of a synergistic response to optical isomers. To further study this response, more pheromone was necessary, preferably from a different route to establish the weak, but possibly real response of the *S*(+) isomer.

In this paper we wish to describe the synthesis of the two pure enantiomers of sulcatol by two different routes starting from two different sugar precursors, namely L-fucose **1** and 2-deoxy-D-ribose **13** which are both commercially available. In **1**, the centre C-5 with its (*S*)-configuration was intended to become the chiral centre C-2 in (*S*)-sulcatol **12**. Great care was taken to maintain this configuration throughout the reaction sequence by keeping the C-5 oxygen of **1** fixed in a pyranose ring and by working under basic or very weakly acidic reaction conditions.

[1]Present address: Halifax Laboratory, Fisheries and Marine Service, Department of the Environment, P.O. Box 429, Halifax, N.S. B3J 2R3.



SCHEME I

The obvious transformations to be carried out on the sugar moiety were the removal of the hydroxy functions and the introduction of a double bond and a methyl branch. The latter two changes appeared to be most easily effected by a Wittig reaction. This gave the framework for the conversion of **1** to **12** as shown in reaction Scheme 1.

L-Fucose was converted to the methyl α,β-pyranoside **2** (7). As for the products of the subsequent reactions no attempts were made to isolate pure anomers. Treatment of **2** with acetone and zinc chloride led to the 3,4-*O*-isopropylidene derivative **3** which was then benzoylated to **4**. Hydrolysis with 50% aqueous acetic acid removed the isopropylidene group to give methyl 2-*O*-benzoyl-α,β-L-fucopyranoside **5**. Mesylation yielded the 3,4-di-*O*-mesyl derivative **6** which was used to introduce 3,4-unsaturation by the Tipson–Cohen method (8). Refluxing a mixture of **6**, sodium iodide, and zinc dust in dimethylformamide for 1 h thus gave the unsaturated derivative **7** in a yield of 52%. Catalytic reduction furnished the saturated compound **8**. The benzoyl group was then removed by reaction with methanolic potassium hydroxide to produce **9**. This was followed by hydrolysis to the pyranose **10**, which was carried out with a cation exchange resin, Dowex 50[H^+], as catalyst. Subsequent oxidation with sodium periodate afforded 2,3,5-trideoxy-4-*O*-formyl-L-*glycero*-pentose **11**. In the final step, **11** was treated with isopropylidenetriphenylphosphorane in THF. The product of this Wittig reaction was purified by column chromatography and distillation. Dextrorotatory (*S*)-sulcatol **12** was thereby obtained in a yield of 57%. The overall yield from **1** amounted to 13%.

The same sequence of reactions can be followed in order to synthesize (*R*)-sulcatol starting from D-fucose. However, the fact that D-fucose is not as readily available as its L-enantiomer led us to search for another starting material and an alternative synthetic route. Our choice of 2-deoxy-D-ribose **13** as such a precursor rested upon its availability and its synthetic potential. The centre C-4 in **13** with its (*R*)-configuration, its oxy and methyl functions appeared appropriate for becoming the chiral C-2 centre in (*R*)-sulcatol **19**. Furthermore, the aldehyde function of **13** seemed to allow the necessary elongation and modification to the sulcatol skeleton via a Wittig reaction. Another change to be brought about on the route from 2-deoxy-D-ribose to (*R*)-sulcatol was the removal of the two hydroxy groups attached to C-3 and C-5 of the sugar precursor. Primary hydroxy groups such as the one attached to C-5 can be readily removed by the

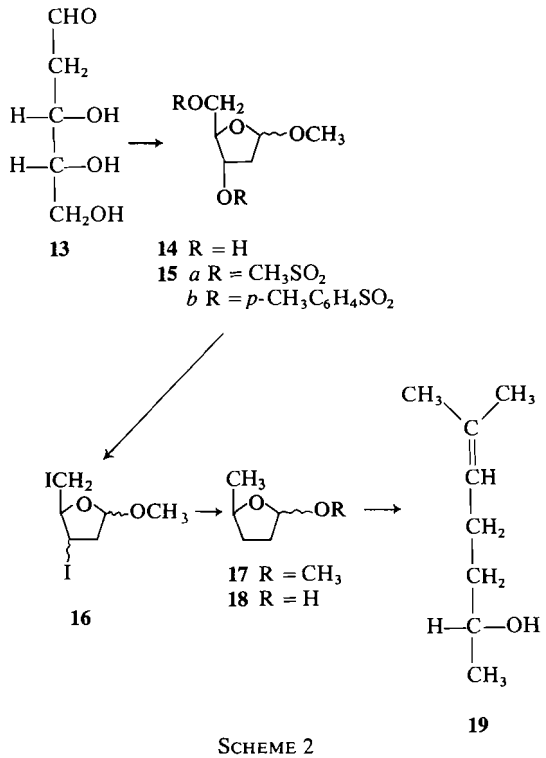
following method which has been widely used in carbohydrate chemistry for the preparation of deoxy sugars (9, 10):

$$R—OH \rightarrow R—OSO_2R' \rightarrow R—X \rightarrow R—H$$

$$R' = CH_3 \text{ or } p\text{-}CH_3C_6H_4$$

The hydroxy function to be removed is converted into a sulfonyloxy group which serves as leaving group in the subsequent substitution by halogen. Reductive dehalogenation then furnishes the deoxy compound. The displacement of a secondary sulfonyloxy group has in most cases proved to be rather difficult, if not impossible. However, there are reports describing the successful removal of the secondary hydroxy group bound to C-3 of 2-deoxy-D-ribose forming the glycone part in thymidine and other nucleosides (11, 12). This gave encouragement for our synthetic approach outlined in Scheme 2.

As in the synthesis of (*S*)-sulcatol, it was of utmost importance to retain the configuration at the carbon which was to become the chiral centre in (*R*)-sulcatol. This was again achieved by forming and maintaining a glycoside ring throughout the synthesis. 2-Deoxy-D-ribose **13** was first refluxed in 0.01% methanolic hydrogen chloride to furnish the methyl α,β-furanoside **14** (13). In view of the intermediacy of product **18**, it did not appear necessary to separate the anomeric mixture obtained. Similarly no attempts were made in the following steps to obtain pure anomers and therefore optical rotations were not determined. Reaction of **14** with an excess of methylsulfonyl chloride yielded syrupy dimesylate **15***a*. Treatment of **15***a* with sodium iodide in DMF at 70°C resulted in the effective displacement of the primary methylsulfonyloxy group at C-5 within 5 h. In contrast, the substitution of the secondary sulfonyloxy function at C-3 proceeded much more slowly and was still incomplete after 5 days at this temperature. Higher temperatures did not so much accelerate the formation of the diiodide **16** but promoted discoloration and gradual decomposition of the reaction mixture. So, even at 70°C, undesirable side reactions became noticeable from the 5th day onwards, and it was necessary at this point to isolate the diiodide from the reaction mixture and subject the unreacted 5-deoxy-5-iodo-3-mesylate to further reaction with sodium iodide. A 51% yield of diiodide was thus obtained after two recycling steps. Earlier attempts to prepare the diiodide via the ditosyl analogue of **15***a* were



13 **14** R = H
15 *a* R = CH_3SO_2
b R = *p*-$CH_3C_6H_4SO_2$
16 **17** R = CH_3
18 R = H
19

SCHEME 2

even less successful. This was mainly due to the thermal instability of the ditosylate **15***b*. After twofold recrystallization from petroleum and chloroform, **15***b* could be obtained as a white crystalline solid with a melting point of 88°C. In pure form it decomposed shortly after melting. Likewise, heating of **15***b* with sodium iodide and dimethylformamide at 60°C resulted in extensive charring before any sizeable amount of diiodide **16** could be detected.

Hydrogenolysis of **16** using a Raney nickel (W-7) catalyst in methanolic potassium hydroxide furnished the volatile methyl 2,3,5-trideoxy-α,β-D-*glycero*-pentofuranoside **17**. This was hydrolyzed in the presence of a cation exchange resin catalyst, Dowex 50[H^+]. Serious difficulties were encountered in the isolation of the hydrolysis product **18** as this hemiacetal was found to be soluble not only in various organic solvents but also in water and, moreover, appeared to be rather unstable. These solubility characteristics as well as the instability had already been pointed out in the case of the optically inactive 4-hydroxypentanal (14). The crude hemiacetal **18**, which was recovered in a 52% yield, was therefore used in the following step without further

purification. Treatment with isopropylidenephosphorane in THF produced the (*R*)-sulcatol **19** which was purified by column chromatography and distillation. The yield of laevorotatory (*R*)-sulcatol was 30% in this Wittig reaction and 5% overall from 2-deoxy-D-ribose.

The purity of our sulcatol products was examined by glc and found to be greater than 99% for both the (*R*)- and the (*S*)-isomers. The spectroscopic characteristics were in good agreement with the data reported for natural sulcatol (2). The optical rotations $[\alpha]_D^{20}$ for ethanolic solutions of our (*R*)- and (*S*)-sulcatol were $-13.9°$ and $+14.0°$, respectively. They differ somewhat from Mori's determinations of $-14.5°$ and $+14.4°$ (5). It should be pointed out that the absolute rotation values do not differ significantly for our stereoisomers which, in contrast to the ones prepared by Mori, have been synthesized from chemically different precursors and by different routes.

In order to assess the optical purity we reacted both sulcatol isomers with (*R*)-(+)-α-methoxy-α-trifluoromethylphenylacetyl chloride (15). The nmr spectra (60 MHz) of the two diastereomeric esters (**20***a* and **20***b*) exhibited significant differences which are in line with the correlation of configuration and nmr shifts for diastereomeric MTPA esters derived by Dale and Mosher (16). The methyl group attached to the chiral centre of the sulcatol appeared as doublets at δ 1.35 and 1.25 for the (*S*,*R*)- and the (*R*,*R*)-MTPA esters, respectively.

Both MTPA esters appeared free of any cross contamination by the alternate diastereoisomer, thus proving the optical purity of our two sulcatol enantiomers. Since the (*R*,*R*)- and (*S*,*S*)- like the (*R*,*S*)- and (*S*,*R*)-MTPA esters are enantiomers having identical nmr spectra, a comparison is possible between the above-mentioned methyl absorptions and the corresponding shifts in (*S*)-MTPA esters of (*S*)- and (*R*)-sulcatol prepared by Mori (5). This shows good agreement between our results and Mori's values of δ 1.34 and 1.23 for his (*R*,*S*)- and (*S*,*S*)-MTPA esters. Our shift values are also in accord with the recently published results of the nmr study (100 MHz) which established the enantiomeric composition of natural sulcatol (17). In the (*R*)-MTPA ester of (*S*)-sulcatol, the C-1 methyl signal appeared at δ 1.33 whereas the corresponding absorption for the diastereomeric ester of (*R*)-sulcatol was found at δ 1.26.

Preliminary results of the biological testing of our sulcatol isomers in the laboratory as well as in the field seem to corroborate our purity assessment. The biological work will be published elsewhere.

Experimental

All solvents were dried and distilled before use. Silica gel G, E. Merck, type 60, was used for tlc. The following solvent systems were employed: A: ethyl acetate – ethanol, 10:1; B: toluene – diethyl ether, 1:2; C: petroleum (boiling ranges 30–60°C) – diethyl ether, 2:3; D: petroleum – diethyl ether, 7:3; E: butanone–water, 9:1. Spots were visualized by spraying with aqueous sulfuric acid (10%). Column chromatography was performed using Silica gel powder, 60–200 mesh. Symbols like PE10 stand for a 90:10 (vol) mixture of petroleum (boiling range 30–60°C) and diethyl ether.

All nmr spectra, unless stated otherwise, were recorded at 60 MHz on a Varian A-56/60A. All shift values are given in ppm downfield from TMS (δ = 0). Coupling constants (*J*) are given in Hz. Mass spectra were recorded on a Hitachi–Perkin-Elmer RMU-6E spectrometer using an ionization potential of 80 eV. Optical rotations were determined on a Perkin-Elmer P22 spectropolarimeter.

L-Fucose and 2-deoxy-D-ribose were commercially obtained from Sigma Chemical Company.

Methyl α,β-L-Fucopyranoside **2**

L-Fucose (**1**, 7.60 g, 46.3 mmol) was dissolved in methanolic hydrochloric acid (0.5 *M*, 150 ml) and stirred under reflux. The course of the reaction was followed by tlc (solvent A) which showed the disappearance of **1** (R_f 0.14) and the appearance of the product (R_f 0.21) and traces with R_f values of 0.27 and 0.40. After 1.5 h, the acid was neutralized with methanolic sodium methoxide (2.4 *M*, 30 ml). The precipitate was filtered and the filtrate was evaporated. The solid residue was triturated with dry acetone. Filtration and removal of acetone gave a white solid (8.82 g) which was used in the following step without further purification.

Methyl 3,4-O-Isopropylidene-α,β-L-fucopyranoside **3**

A solution of zinc chloride (8.82 g) and concentrated phosphoric acid (0.05 ml) in dry acetone (80 ml) was added with stirring to a suspension of crude product **2** (8.82 g) in dry acetone (80 ml). After a few minutes an only slightly turbid solution was obtained. Stirring at room temperature was continued for 1.5 h. Then tlc (A) indicated complete conversion to a product of R_f 0.56 with two minor components corresponding with R_f values of 0.27 and 0.40. The reaction solution was neutralized by stirring in sodium methoxide (7.0 g) and was filtered. The filtrate was evaporated. The residue was taken up in aqueous ammonia (1 *M*, 100 ml) and extracted with chloroform (5 × 50 ml). The chloroform layers were washed with water (3 × 40 ml), combined, and dried over anhydrous magnesium sulphate. Filtration and evaporation yielded a viscous liquid (10.0 g) which was pure by tlc giving a single spot (R_f 0.56). Spectral data: nmr: δ 1.26–1.54 (m, 9H), 3.2 (bs, 1H), 3.46 and 3.55 (two s, total of 3H), 3.7–4.2 (m, 4H), 4.73 (d, J = 3.5, 1H), ms: *m/e* 203($M - CH_3$, 21), 187($M - OCH_3$, 5), 143(5), 129(16), 101(69), 100(74), 99(71), 87(53), 85(50), 83(35), 71(74), 59(90), 42($C(CH_3)_2$, 100).

Methyl 2-O-Benzoyl-3,4-O-isopropylidene-α,β-L-fucopyranoside **4**

Benzoyl chloride (8.39 g, 59.7 mmol) was run into a stirred and ice cooled solution of **3** (10.0 g, 45.9 mmol) in dry pyridine (130 ml) over a period of 1 h. After stirring at room temperature for 1 h, the reaction mixture was concentrated *in vacuo* and partitioned between aqueous sodium hydroxide (1 *M*, 70 ml) and chloroform (3 × 100 ml). The chloroform extracts, after washing with brine and drying over anhydrous magnesium sulphate, yielded a viscous liquid (14.2 g, 95% from **1**). It had no ir absorption for O—H and ran on tlc (B) as two spots with R_f values of 0.76 and 0.79. Spectral data: nmr: δ 1.36–1.63 (m, 9H), 3.37 and 3.48 (two s, total of 3H), 3.9–4.6 (m, 3H), 4.92–5.4 (m, 2H), 7.2–7.7 (m, 3H), 7.95–8.25 (m, 2H); ms: *m/e* 307($M - CH_3$, 11), 291($M - OCH_3$, 2), 205(10), 200($M - C_6H_5COOH$, 17), 185(200 − CH_3, 7), 156(8), 147(17), 122(22), 105(C_6H_5CO, 100), 100(44), 99(61), 86(35), 85(63), 84(48), 83(72), 77(C_6H_5, 49).

The two compounds (**4***a* and **4***b*) corresponding with the two tlc spots (R_f 0.79 and 0.76) could be separated by chromatography through silica gel column eluting with PE 15. In contrast to their mass spectra, their nmr spectra exhibited significant differences indicating that **4***a* and **4***b* were anomers: **4***a* (R_f 0.79): δ 1.37 (s, 3H), 1.42 (d, J = 7, 3H), 1.57 (s, 3H), 3.37 (s, 3H), 4.92–5.28 (m, J_1 = 7, J_2 = 3.5, 2H); **4***b* (R_f 0.76): δ 1.36 (s, 3H), 1.47 (d, J = 7, 3H), 1.63 (s, 3H), 3.47 (s, 3H), 5.16 (d, J = 7, 1H), 5.29 (d, J = 7, 1H).

Methyl 2-O-Benzoyl-α,β-L-fucopyranoside **5**

A solution of **4** (14.2 g) in aqueous acetic acid (50%, 150 ml) was stirred for 1 h at 70°C. Evaporation and repeated coevaporation with toluene left a white solid residue (11.91 g). The product gave two major spots (R_f 0.14 and 0.23) on tlc (C) along with traces of **4** (R_f 0.71 and 0.82). The nmr spectrum indicated the anomeric nature of product **5**: δ 1.32 and 1.37 (two d, J = 6.5, total of 3H), 3.36 and 3.47 (two s, total of 3H), 3.63–4.52 (m, 3H), 5.05, 5.28, and 5.45 (three d, J = 4, 2H), 7.18–7.68 (m, 3H), and 8.00–8.18 (m, 2H).

Methyl 2-O-Benzoyl-3,4-di-O-(methylsulfonyl)-α,β-L-fucopyranoside **6**

A solution of crude product **5** (11.91 g) in dry pyridine (125 ml) was cooled in ice and methanesulphonyl chloride (11.91 g) was slowly added. The reaction mixture was stirred at room temperature overnight. After evaporation aqueous sodium hydroxide (1 *M*, 50 ml) was added to the residue. Extraction with petroleum (bp 30–60°C, 2 × 70 ml) removed the small amount of **4** carried over by the preceding reaction as well as traces of other by-products. Chloroform (4 × 70 ml) extracted a viscous brown liquid which was decolorized by treatment with charcoal. The product (19.2 g) had the same mobility on tlc (C) as the starting material **5** but showed no O—H absorption in the ir. The nmr spectrum indicated a mixture of two anomers in equal amounts. This was confirmed by comparison of the spectra obtained for compounds **6***a* and **6***b* which had been derived separately from **4***a* and **4***b*: **6***a*: δ 1.38 (d, J = 6.5, 3H), 3.02 (s, 3H), 3.21 (s, 3H), 3.40 (s, 3H), 4.18 (m, J = 6.5, 1H), 5.12 (m, 2H), 5.37 (m, 2H), 7.40–7.65 and 8.00–8.26 (two m, total of 5H); **6***b*: δ 1.43 (d, J = 6.5, 3H), 2.98 (s, 3H), 3.23 (s, 3H), 3.50 (s, 3H), 4.62 (d, J = 7, 1H), 5.13 and 5.35 (two m, total of 4H), 7.40–7.65 and 8.00–8.26 (two m, total of 5H); ms: *m/e* 315 ($M - C_6H_5CO$, H_2O; 3), 299($M - C_6H_5COO$, H_2O, 1), 283(1), 238(1), 226(6), 199(15), 122(C_6H_5COOH, 32), 105(C_6H_5CO, 100), 77(C_6H_5, 69).

Methyl 2-O-Benzoyl-3,4,6-trideoxy-α,β-L-erythro-hex-3-enopyranoside **7**

Product **6** (19.0 g, 43.4 mmol) in DMF (150 ml) was added to a hot solution of sodium iodide (90 g) in DMF (450 ml). Zinc powder (35 g) was added and the mixture was refluxed for 1 h. Removal of the solvent was followed by addition of water (200 ml) and extraction with chloroform (4 × 200 ml). The chloroform layers were washed with aqueous sodium thiosulphate (ca. 2 *M*, 200 ml) and brine (200 ml) and evaporated to yield a brown liquid (11.0 g). It was shown by tlc (D) to consist of several components corresponding with R_f values of 0.63, 0.52, 0.23, 0.12, and 0.02. The main component with R_f 0.63 (5.58 g, 22.5 mmol, 52%) was eluted from a silica gel column with PE 10. Its anomeric nature was again evident from its nmr spectrum: δ 1.28 and 1.33 (two d, J = 7, total of 3H), 3.47 and 3.52 (two s, total of 3H), 4.38 (m, J = 7, 1H), 4.72 (d, J = 5) and 5.18 (d, J = 3.5) (both 4.72 and 5.18 corresponding with 1H in total), 5.50 (m, 1H), 5.82 (m, 2H), 7.32–7.62 and 7.98–8.22 (two m, total of 5H); ms: *m/e* 248(M, 1), 217($M - OCH_3$, 7), 188($M - CHOOCH_3$, 47), 143(8), 127(7), 105(C_6H_5CO, 100), 77(C_6H_5, 71).

Methyl 2-O-Benzoyl-3,4,6-trideoxy-α,β-L-erythrohexopyranoside **8**

A Parr hydrogenator was used to hydrogenate **7** (5.51 g, 22.2 mmol) dissolved in methanol (75 ml) with Pd (10% on charcoal, 0.30 g) as a catalyst. An atmosphere of hydrogen (ca. 70 psi) was maintained at room temperature for 12 h. Filtration and evaporation left the product (5.39 g, 21.6 mmol, 97%) which on tlc (D) gave two spots with R_f values of 0.62 and 0.71 apparently being an anomeric mixture. Spectral data: nmr: δ 1.18 and 1.28 (two d, J = 7, total of 3H), 1.43–2.32 (4H), 3.43 and 3.50 (two s, total of 3H), 3.58–4.10 (m, 1H), 4.45 and 5.12 (two m, total of 1H), 7.17–7.55 and 7.60–8.30 (two m, total of 5H); ms: *m/e* 249(M − H, 1), 219($M - OCH_3$, 18), 190($M - CHOOCH_3$, 20), 165(20), 162(22), 148(10), 134(14), 128($M - C_6H_5COOH$, 48), 105(C_6H_5CO, 100), 77(C_6H_5, 68).

Methyl 3,4,6-Trideoxy-α,β-L-erythrohexopyranoside **9**

A solution of **8** (5.33 g, 21.3 mmol) in methanolic potassium hydroxide (0.5 *M*, 150 ml) was refluxed for 1 h. The solution was cooled and neutralized with methanolic hydrogen chloride (ca. 1 *M*). Filtration and evaporation left a residue which was taken up in water (100 ml). Extraction with chloroform (5 × 100 ml) yielded a crude product (3.78 g) which contained some methyl benzoate as indicated by its smell. Methyl benzoate was eluted from a silica gel column by PE 2, whereas PE 10 was used to elute product **9** (2.14 g, 14.7 mmol, 69%). The product **9**, an anomeric mixture, appeared on tlc (D) as a double spot with R_f values of 0.09 and 0.16. The ir spectrum had a strong O—H peak but no carbonyl absorption as had the ester **8**. Spectral data: nmr: δ 1.13 and 1.21 (two d, J = 6, total of 3H), 1.35–1.92 (m, 4H), 2.69 (bs, 1H), 3.42 and 3.51 (two s, total of 3H), 3.60–3.99 (m, 1H),

4.07 (d, J = 7) and 4.61 (d, J = 3.5) (both 4.07 and 4.61 corresponding with a total of 1H); ms: *m/e* 146(M, 2), 144(3), 115(M − OCH_3, 27), 104(M − C_3H_6, 80), 97(6), 75(41), 61($CHOHOCH_3$, 100), 57(41), 44(CH_3CHO, 78).

2,3,5-Trideoxy-4-O-formyl-L-glyceropentose ***11***

A mixture of **9** (2.10 g, 14.4 mmol), distilled water (50 ml), and Dowex 50[H^+] (prepared from 10 g of resin) was stirred and heated to 60°C. After 3 h, tlc (C) showed the conversion of **9** (R_f 0.34) to product **10** (R_f 0.10) to be complete. The resin was filtered off and washed with distilled water (50 ml). This washing solution was used to dissolve sodium periodate (3.39 g, 15.8 mmol) for the subsequent oxidation. The solution containing the hydrolysis product **10** was cooled to 0°C and mixed with the ice cooled solution of sodium periodate. The oxidation appeared to be complete after 10 min as indicated by a single spot (R_f 0.44) on tlc (C). In order to remove the excess sodium periodate, the reaction mixture was run through an anion exchange column (25 ml) of Dowex 1 X-4[Cl^-] which was then washed with distilled water (50 ml). The aqueous solution was extracted with chloroform (5 × 70 ml). The combined chloroform extracts were dried over anhydrous magnesium sulphate, filtered, and evaporated at atmospheric pressure. The liquid product (1.46 g) had a smell reminiscent of an aldehyde. As indicated by its nmr spectrum it consisted of compound **11** (1.32 g, 10.2 mmol, 71%) and a small amount of chloroform (0.14 g). For the use in the subsequent Wittig reaction, the contaminating chloroform was removed by repeated coevaporation with THF. Spectral data: nmr: δ 1.30 (d, J = 6.5, 3H), 1.72–2.15 (m, 2H), 2.38–2.73 (m, J_1 = 6, J_2 = 1.5, 2H), 5.09 (sextet, J = 6, 1H), 8.05 (s, 1H), 9.80 (t, J = 1.5, 1H); ms: *m/e* 129(M − H, 1), 101(M − CHO, 7), 84(M − CHOOH, 56), 72(37), 71(36), 69(36), 67(13), 56(C_4H_8, 100), 45(CHO_2, 78), 29(CHO, 69); ir: 1720 cm^{-1} (s) and 1185 cm^{-1} (vs).

(S)-(+)-6-Methylhept-5-en-2-ol [(S)-(+)-Sulcatol, ***12****]*

Care was taken to exclude moisture and to maintain an atmosphere of dry nitrogen throughout the following Wittig reaction. To a suspension of isopropyltriphenylphosphonium iodide ((18) 15.1 g, 35 mmol) in dry THF (60 ml) was slowly added a solution of *n*-butyllithium in hexane (2.1 M, 16.7 ml, 35 mmol). The resulting red-brown solution of the ylide was stirred at room temperature for 0.5 h and then cooled in an ice bath. A solution of **11** (1.30 g, 10 mmol) in dry THF (7.5 ml) was slowly added with stirring. After 1 h, the excess ylide was quenched by addition of ice (60 g). The product was extracted with petroleum (bp 30–60°C, 3 × 100 ml). The extracts were washed with water (50 ml), combined and dried over anhydrous sodium sulphate. Filtration and evaporation gave a crude product (5.5 g) which tlc (D) showed to consist of several components with R_f values of 0.04, 0.23, 0.34, 0.39, 0.69, 0.76, and 0.82. The tlc spot of racemic sulcatol coincided with the component with R_f 0.34. The product was purified by eluting from a silica gel column. PE 2.5 and PE 5 were used to elute the components with R_f values larger than 0.34. (*S*)-Sulcatol (1.09 g), eluted with PE 10, was subjected to vacuum distillation (29 Torr, bath temperature 120–130°C) to give a clear, colorless liquid (0.73 g, 5.7 mmol, 57%); $[\alpha]_D^{32}$ +13.20°, $[\alpha]_D^{20}$ +13.96° (*c* 4.56, EtOH); nmr; δ 1.19 (d, J = 6.5, 3H), 1.35–1.75 (m, J = 7, 2H), 1.65 (s, 3H), 1.72 (d, J = 1.3, 3H), 2.09 (q, J = 7, 2H), 2.53 (bs, 1H), 3.80 (sextet, J = 6.5, 1H), 5.17 (m, J_1 = 7, J_2 = 1.3, 1H); ms: *m/e* 128(M, 14), 113(M − CH_3, 4), 110(M − H_2O, 29), 95(110 − CH_3, 100), 85(27), 83(M − CH_3CHOH, 10), 81(12), 71(26), 69(CH_2CH=$C(CH_3)_2$, 58), 67(30), 55(CH=$C(CH_3)_2$, 36), 43(33), 42($C(CH_3)_2$, 36). Gas–liquid chromatography (column: 5% Carbowax 20 M on Chromosorb G70/80, 12 ft × ⅛ in; 150°C; carrier gas, He 40 ml/min): *Rt* 5.7 min, 99%; impurity *Rt* 2.3 min, 1%. *Anal.* calcd. for $C_8H_{16}O$: C 74.94, H 12.58; found: C 74.78, H 12.63.

Methyl 2-Deoxy-α,β-D-ribofuranoside ***14***

A solution of 2-deoxy-D-ribose (**13**, 11.6 g, 87.6 mmol) in methanolic hydrogen chloride (0.01 M, 250 ml) was stirred at room temperature. Monitoring by tlc (E) showed the conversion of **13** (R_f 0.26) to a single product with R_f 0.40 to be complete after 0.5 h. This solution was neutralized by addition of methanolic sodium methoxide (0.5 M). Evaporation gave a syrup which was taken up in dry acetone. A white precipitate formed and was filtered off. The filtrate was evaporated and coevaporated (2×) with dry pyridine to give **14** (12.5 g).

Methyl 2-Deoxy-3,5-di-O-(methylsulfonyl)-α,β-D-ribofuranoside ***15a***

Product **14** (12.5 g) was dissolved in dry pyridine (150 ml) and cooled in an ice bath. A solution of methanesulfonyl chloride (24.0 g, 210 mmol, ca. 25% excess) in dry pyridine (50 ml) was slowly added. The reaction mixture was stirred at room temperature for 15 h. The salt formed was filtered off and washed with pyridine (50 ml). The filtrate and washing solution were combined and evaporated. After addition of aqueous sodium hydroxide (1 M, 100 ml), the product was extracted with chloroform (4 × 100 ml). The chloroform layers were washed with water (2 × 50 ml), combined, and decolorized with charcoal. Removal of chloroform gave product **15***a* (24.6 g, 80.9 mmol, 92% from **13**) which on tlc (B) ran as a double spot with R_f values of 0.17 and 0.19. There was no O—H absorption in the ir spectrum but two strong peaks at 1350 and 1180 cm^{-1}. Spectral data: nmr: δ 2.23–2.55 (m, 2H), 3.10 (s, 6H), 3.37 and 3.39 (two s, total of 3H), 4.33–4.48 (m, 3H), 5.07–5.28 (m, 2H); ms: *m/e* 304(M, 1), 273(M − OCH_3, 2), 209(M − OSO_2CH_3, 7), 195(M − $CH_2OSO_2CH_3$, 34), 149(15), 117(13), 113(11), 111(13), 109(11), 99(100), 87(70), 81(83), 79(98), 71(43), 59(57), 52(55).

Methyl 2,3,5-Trideoxy-3,5-diiodo-α,β-D-glyceropentofuranoside ***16***

Compound **15***a* (24.3 g, 80 mmol) in DMF (40 ml) was added to a solution of sodium iodide (75 g) in DMF (300 ml). The reaction mixture was kept stirred and heated to 70°C. Higher temperatures caused the gradual decomposition of the starting material and of the products formed. Frequent checking by tlc revealed that all starting material had reacted within the first 5 h. The product appeared on tlc (B) as a double spot with R_f values of 0.48 and 0.53. It was accompanied by a component (R_f 0.80) whose concentration increased up to the fifth day when the reaction mixture started to turn dark brown. At this point the solvent was removed and water (300 ml) was added. The product was extracted with petroleum (bp 30–60°C) followed by chloroform (3 ×

200 ml). The organic layers were washed with aqueous sodium thiosulphate (5%, 2 × 100 ml) and brine (50 ml). The combined chloroform extracts yielded a crude product (14.0 g) which consisted mainly of the component B with R_f values 0.48 and 0.53 and of small amounts of more polar by-products. The petroleum extracts (13.1 g) contained the component A (R_f 0.80) as well as component B. These were separated by percolation through a column of silica gel (200 g). PE 15 eluted the component A (6.0 g) being the pure diiodide **16**. Component B (6.4 g, methyl 5-deoxy-5-iodo-3-*O*-(methylsulfonyl)-α,β-D-ribofuranoside) was eluted with PE 50. It was combined with the chloroform extract for further reaction with sodium iodide which was carried out and worked-up as described above giving another 5.8 g of diiodide. A second repetition of the reaction and extraction cycle made a further contribution (3.4 g) to the total of 15.2 g of **16** (41.0 mmol, 51%). Attempts to improve this yield by further recycling failed as charring occurred.

Component A, i.e. **16**, had the following spectral features: nmr: δ 2.23–2.68 (m, 2H), 3.23–3.57 (m, 2H), 3.40 (s, 3H), 3.75–3.95 (m, 1H), 4.03–4.38 (m, 1H), 4.95–5.18 (m, 1H); ms: *m/e* 368(*M*, 15), 337(*M* − OCH_3, 6), 241(*M* − I, 7), 227(*M* − CH_2I, 89), 209(241 − CH_3OH, 13), 181(100), 128(15), 127(13), 114(11), 113(9), 100(94), 71(51), 59(66).

Component B, nmr: δ 2.21–2.60 (m, 2H), 3.10 (s, 3H), 3.27–3.48 (m, 2H), 3.40 (s, 3H), 4.00–4.60 (m, 1H), 5.05–5.17 (m, 2H); ms: *m/e* 336(*M*, 5), 305(*M* − OCH_3, 2), 240(*M* − $HOSO_2CH_3$, 18), 227(6), 209(*M* − I, 72), 195(*M* − CH_2I, 16), 181(15), 179(31), 166(84), 149(39), 139(8), 128(3), 127(5), 113(62), 99(71), 87(100), 82(50), 81(34), 79(56), 71(57), 59(82).

Methyl 2,3,5-Trideoxy-α,β-D-glyceropentofuranoside ***17***

The catalytic hydrogenation of **16** to **17** was carried out in a Parr hydrogenator. A mixture of **16** (14.9 g, 40.5 mmol) and Raney Nickel (W-7) (freshly prepared from 10 g NiAl alloy) in methanolic potassium hydroxide (1.0 *M*, 85 ml) was vigorously shaken at room temperature in a hydrogen atmosphere of 70 psi. After 14 h, the mixture was filtered. Most of the solvent was removed by slow distillation through a Vigreaux column (12 cm) at atmospheric pressure. The residue was then partitioned between water (25 ml) and petroleum (bp 30–60°C, 4 × 50 ml). Evaporation of the petroleum left product **17** (3.16 g, 27.2 mmol, 67%) which ran on tlc (D) as a single spot R_f 0.52). Spectral data: nmr: δ 1.23 and 1.31 (two d, *J* = 6, total of 3H), 1.67–2.20 (m, 4H), 3.33 (s, 3H), 2.52 (sextet, *J* = 6, 1H), 2.93–3.09 (m, 1H).

2,3,5-Trideoxy-α,β-D-glyceropentofuranose ***18***

A mixture of product **17** (3.10 g, 26.7 mmol), water (40 ml), and Dowex 50[H^+] (from 15 g resin) was stirred at 50°C. The hydrolysis was monitored by tlc (D) which after 1 h showed complete conversion of **17** to a product consisting of a major component with R_f 0.11 and small amounts of by-products (R_f 0.15 and 0.18). The resin was then filtered off and the filtrate extracted with ether (6 × 75 ml). The ether extracts yielded the crude product **18** (1.40 g). Earlier attempts to purify product **18** by column chromatography had proved unsuccessful due to its instability. The crude product **18** was therefore employed in the subsequent Wittig reaction.

(R)-(−)-6-Methylhept-5-en-2-ol, (R)-(−)-Sulcatol, ***19***

Isopropyltriphenylphosphonium iodide (17.8 g, 41.1 mmol) was suspended in dry THF (80 ml) and reacted with *n*-butyllithium in hexane (2.1 *M*, 19.6 ml, 41.1 mmol). After stirring for 0.5 h, the red-brown ylide solution was cooled in an ice bath. Crude compound **18** (1.4 g) in THF (5 ml) was slowly added. After 1.5 h, the excess ylide was destroyed by addition of ice (100 g). Extraction with petroleum (bp 30–60°C, 6 × 100 ml) yielded a crude product consisting of several components (R_f 0.10, 0.34, 0.43, 0.53, 0.68, 0.75, and 0.81) as indicated by tlc (D). The product was purified by column chromatography (silica gel). The components with R_f values larger than 0.34 were eluted with PE 1, 2.5, and 4.0, whereas PE 7.5 was used to elute (*R*)-sulcatol (0.71 g, R_f 0.34). Vacuum distillation (29 Torr, bath temperature 130°C) gave colorless clear (*R*)-sulcatol (0.524 g, 4.1 mmol, 15.4%) from **17**. $[\alpha]_D^{20}$ −13.89°, $[\alpha]_D^{32}$ −13.24° (*c* 4.76, EtOH). Gas–liquid chromatography (for operating conditions see preparation of (*S*)-sulcatol **12**) *Rt* 5.7 min, impurity less than 1%, *Rt* 9.2 min. The nmr, ms, and ir data were essentially the same as for (*S*)-sulcatol. *Anal.* calcd. for $C_8H_{16}O$: C 74.94, H 12.58; found: C 74.97, H 12.48.

(R)-(+)-α-Methoxy-α-trifluoromethylphenylacetates of Sulcatol (S)-Sulcatol-(R)-MTPA Ester ***20a***

(*S*)-Sulcatol **12**, (32 mg, 0.25 mmol) dissolved in carbon tetrachloride (0.7 ml) was added to a solution of (*R*)-MTPA chloride (15) (65.6 mg, 0.26 mmol) in dry pyridine (0.7 ml). The mixture was stirred for 12 h, added to dilute aqueous hydrochloric acid (0.5 *M*, 10 ml) and extracted with chloroform (3 × 10 ml). The chloroform extracts were washed with saturated aqueous sodium bicarbonate followed by water. The product obtained after drying and removal of the solvent was purified by preparative tlc (PE 40) to give **20***a* (81.7 mg, 0.24 mmol, 96%). Spectral data: nmr: δ 1.35 (d, *J* = 6, 3H), 1.54 (s, 3H), 1.68 (s, 3H), 1.54–2.21 (m, 4H), 3.58 (t, *J* = 1, 3H), 4.86–5.37 (m, 2H), 7.21–7.73 (m, 5H); ms: *m/e* 262(*M* − C_6H_{10}, 11), 232(*M* − C_8H_{16}, 18), 189($C_9H_8F_3O$, 100), 139(22), 127($C_8H_{15}O$, 23), 119(32), 110(C_8H_{14}, 49), 105(41), 95(C_7H_{11}, 37), 69(C_5H_9, 39).

(R)-Sulcatol-(R)-MTPA Ester ***20b***

The conversion of (*R*)-sulcatol **19** to the (*R*, *R*)-MTPA ester **20***b* was carried out in the same way. The mass spectrum of **20***b* did not differ significantly from that of **20***a*. However, distinction of the two diastereomeric esters was possible on the basis of their nmr spectra. The nmr spectrum of **20***b* contains the following features: δ 1.25 (d, *J* = 6.5, 3H), 1.58 (s, 3H), 1.69 (s, 3H), 1.58–2.33 (m, 4H), 3.57 (t, *J* = 1, 3H), 4.85–5.37 (m, 2H), 7.22–7.75 (m, 5H).

No sign of cross contamination could be detected in the nmr spectrum of either diastereoisomer.

Radiation chemistry of acetylene at high intensity: the initial product distributions[1]

C. WILLIS, R. A. BACK, AND R. H. MORRIS[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received May 18, 1977

C. WILLIS, R. A. BACK, and R. H. MORRIS. Can. J. Chem. **55**, 3288 (1977).

The distribution of products observed in the radiation chemistry of acetylene at high dose rate is dramatically different from that observed at low dose rate. The dominant products observed at high dose rate are vinyl acetylene and diacetylene with C_3 to C_9 compounds having smaller but significant yields. At low dose rate benzene and cuprene are the exclusive products. The difference in product distribution is attributed to the suppression of secondary attack on products at high dose rate so that the observed distribution approximates more closely the 'zero dose' or 'initial' distribution.

C. WILLIS, R. A. BACK et R. H. MORRIS. Can. J. Chem. **55**, 3288 (1977).

La répartition des produits observés dans la chimie du rayonnement de l'acétylène à grande intensité est très différente de celle observée à faible intensité. Les principaux produits observés à grande intensité sont le butène-3 yne-1 et le butadiyne-1,3, des composés en C_3 jusqu'à C_9 ayant des rendements plus faibles mais importants. A faible intensité, les seuls produits formés sont le benzène et le cuprène. La différence dans la répartition des produits est attribuée à l'absence, à grande intensité, d'une attaque secondaire sur les produits formés. Il en résulte que la répartition observée est plus proche de la répartition de "l'intensité zéro" ou "initiale".

[Traduit par le journal]

Introduction

The radiation-induced polymerization of acetylene has been a subject of study almost since it was first recognized that ionizing radiation could induce chemical change (1). Several groups have shown that at conventional low dose rate, about 10^{16} eV g^{-1} s^{-1}, two major products are formed, benzene and an acetylenic polymer loosely called cuprene, with a yield of disappearance of acetylene, $G(-C_2H_2)$, of between 50 and 100 molecules per 100 eV of energy absorbed (2). Trace amounts of vinyl acetylene, diacetylene, and butadiene, have been observed but with very small yields (3, 4).

It has been difficult to suggest a reasonable mechanism for the radiation chemistry of acetylene and indeed it is uncertain whether the predominant processes are ionic, involve free radicals, or are more comparable to those occurring in the thermal pyrolysis where it is thought that polymerization takes place via a triplet biradical species (5).

We decided to investigate the radiation chemistry of acetylene at very high dose rates in an attempt to map out the general features of the system. The high dose rate should reduce the length of both ionic and free radical chains, which have bimolecular termination steps, but should have a lesser effect on biradical chains, which have predominantly unimolecular termination steps. Furthermore, the short lifetime of ions and free radicals at high dose rates should also tend to reduce consumption of primary products by secondary attack by these species.

Experimental

The source of radiation was a Febetron 706. This gives short (~3 ns) pulses of approximately 600 keV electrons at high currents (~10 000 A) which correspond to a dose rate of the order of 10^{28} eV g^{-1} s^{-1}. Samples were irradiated in a cylindrical aluminum cell, 5 cm long and 4 cm in diameter. The front face of the cell had a 2.5 cm diameter electron window which had been machined down to a thickness of approximately 0.025 cm. The dose per pulse averaged over the cell volume was about 0.1 Mrad which was determined by irradiating CO_2 in the cell and assuming $G(CO) = 7.8$ (6). The cell was also fitted with a thermal syphon so that the gas could be circulated through a U-trap. In some experiments this trap was held at dry-ice temperature to maintain a low partial pressure of the higher molecular weight products. No differences were noted in the product distribution between experiments with the low temperature trap and experiments where the trap was at room temperature.

Products were analyzed by gas chromatography with flame ionization detection. The irradiated sample was condensed in the U-trap in the thermal syphon which was then used as part of the injection system of the gas

[2]NRCC Summer Student 1975. Present address: Chemistry Department, University of British Columbia, Vancouver, B.C.

chromatograph. Because of the large number of peaks observed a mass spectrometer was interfaced with the chromatograph so that part of the exit flow was injected directly into the mass spectrometer. Peaks were identified from standard tables of mass spectra. Two different column packings were used. Poropak Q, programmed between 80 and 160°C, was used for C_3–C_6 species and Durapak OPN/Poracil C, programmed between 30 and 120°C, was used to separate C_4–C_9 species. Stainless steel column tubing was used to avoid the possibility that copper tubing might distort the observations by acetylenic reactions.

Acetylene (Matheson, C.P. Grade) was passed through a trap at dry-ice temperature followed by a U-tube, packed with activated charcoal and also held at dry-ice temperature. These remove all traces of acetone contamination. The final purification stage involved several bulb-to-bulb distillations using alternately liquid nitrogen and dry-ice temperatures (3).

Results

Yield of Disappearance of Acetylene, $G(-C_2H_2)$

We attempted to measure the yield for disappearance of acetylene by the change in pressure. The aluminum cell was connected directly to a high precision quartz spiral gauge (Texas Instruments) and the average temperature of the cell was monitored by an array of 10 iron–constantin thermocouples taped to the cell body. This should have allowed measurement of pressure differences of about 20 μm. Unfortunately pressure changes were dominated by small geometry changes associated with flexing of the thin electron window of the cell and this allowed only measurement of an upper limit of $G(-C_2H_2) \leq 50$ for the disappearance of acetylene.

Products Observed

Table 1 gives a summary of the gas chromatograph peaks and their probable assignments as determined by mass spectrometry. Although compounds having up to six carbon atoms were assigned with reasonable certainty, above this it became increasingly difficult to determine more than a carbon count. The yields given in Table 1 are taken relative to benzene on the basis of peak areas assuming that relative sensitivities depend only on the number of carbon atoms in the species.

Effect of Pressure and Dose

The yields of benzene obtained for different acetylene pressures and for different numbers of irradiation pulses are given in Table 2. There is no apparent dependence on either pressure or dose within the rather large experimental scatter. A similar behaviour was observed for all C_6 products where again the yields appear to be independent of irradiation dose over the range 10–90 pulses.

Yield of Polymer

Only qualitative observations on polymer formation were made. In a series of experiments acetylene was irradiated in glass cells of a similar size and shape to the aluminum cell and a He–Ne laser beam was shone through the cell. About 2 s after a single irradiation pulse scintillations were observed, and the beam became clearly visible. Despite this evidence for light-scattering particles, we did not observe settling out of a cuprene-like polymer even after more than a hundred pulses. In fact, only a slight blooming of the glass thermal syphon trap on the aluminum cell was noted after more than a thousand pulses had been used to irradiate different samples of acetylene at atmospheric pressure. This is in direct contrast to the low dose rate behaviour where cuprene is seen to settle out after a dose of a few megarads.

Discussion

In an earlier paper (7) a four stage mechanism for the low dose rate radiation chemistry of acetylene was presented. This was: (*i*) *A primary polymerization* of acetylene to form polyunsaturated hydrocarbons with molecular weights in the C_4 to C_{20} range. (*ii*) *A secondary polymerization* of the polyenes initially formed. (*iii*) *A physical condensation* of the polyenes formed by primary and secondary polymerization. (*iv*) *Rapid and extensive polymerization and cross-linking in the liquid polyene droplets*, induced by radiation and leading to the final intractable cuprene product.

The present results lend some support to this mechanism. The observation that the yield per pulse was independent of the number of pulses for all of the products examined implies that no secondary reactions of these products were occurring. Thus the second stage of the mechanism is suppressed and we are seeing the products from the first stage alone, the primary polymerization. This is to be expected at high dose rate since the lifetimes of ions, atoms, and radicals will be greatly reduced because of their high concentrations and consequent fast second order combination reactions. The average ion lifetime in the present experiments is estimated to be of the order of 3×10^{-8} s which will limit even the

TABLE 1. Yields of observed products in acetylene radiolysis

Carbon number	Formula	Probable structure	Relative yield	Yield (*G*-units)	Yield as acetylene loss	Total for group

primary polymerization of the acetylene substrate to only a few steps. Product concentrations were always much less than 1% of that of acetylene so that secondary ionic polymerization of products, stage 2 in the low intensity mechanism, was quite negligible. At typical gamma ray dose rates, on the other hand, ion lifetimes would be 10–100 ms and the kinetic chain length in both primary and secondary polymerization would be much longer.

Very similar arguments apply to free-radical polymerization reactions which are also probably operative in acetylene radiolysis. A polymerization propagated by biradicals, however, might still be efficient at high dose rate if termination were first order (e.g. by ring closure, isomerization to a stable molecule, or by internal conversion of a triplet state) rather than second order. Biradical polymerization reactions initiated by the triplet state have been postulated in

TABLE 2. Yield of benzene as a function of pressure and dose

760	30	0.27
760	100	0.34
Average yield = 0.31 ± 0.10		

the pyrolysis of acetylene (5) and are not unlikely in the radiolysis, but the independence of the product yields on dose indicates again that reaction with products was negligible. It is possible that triplet–triplet annihilation becomes an important loss process which reduces the biradical lifetime at high intensity.

In low intensity radiolysis of acetylene benzene was the only volatile product of any importance. This was confirmed in the present work by a few experiments in which acetylene was irradiated with gamma rays, which showed that even at the lowest conversions, only negligible traces of other products were detectable with the same analytical techniques used in the Febetron experiments. It was suggested previously that benzene was the only volatile product not because it was the only one formed but because it is relatively unreactive towards secondary polymerization. The present results support this suggestion as it seems probable that many of the volatile polyunsaturated products observed in the present study were also transient intermediates in the low intensity radiolysis. It should be noted, however, that the distribution of the primary products was probably quite different in the two systems, as the primary polymerization may have been much attenuated at high intensity as noted earlier.

The average yield of benzene, G(benzene) = 0.31 ± 0.10, is very much smaller than the value of 5 ± 1 observed at low dose rate, perhaps reflecting the reduced extent of primary polymerization. Many reaction sequences were apparently limited to a single step, yielding C_4 products, which at low dose rate might have proceeded further to yield benzene or higher products. Both the product distribution and the G-value of about 4.4 for the total of all the volatile products observed demonstrate the absence of long chain reactions.

It is difficult to account quantitatively for the products observed although some generalizations can be offered. Table 3 shows the main ion–molecule sequences which will occur following the initial generation of primary species. The yields are derived from the W-value of 24 eV per ion pair (8) and mass spectral abundances (9). The various reaction sequences were identified by Derwish *et al.* (9) using high pressure mass spectrometry. Although the rates of the first stage reactions are reasonably well known, with values of the order of 3×10^{-10} cm^3 molecule^{-1} s^{-1}, the rates of subsequent stages are much less certain although it is apparent that the reaction rates decrease as polymerization proceeds. For ion lifetimes with respect to charge neutralization of approximately 3×10^{-8} s it seems very doubtful that any primary ions or those produced in the first stage took part in neutralization which probably involved ions of C_6 and higher carbon numbers. What is clear from the suggested reaction sequence is that the ions all tend to be less hydrogenated than the substrate, an effect which will be enhanced since neutralization will tend to decrease rather than increase the hydrogen content. The yields of species predicted from the data given in Table 3 are very much larger than were observed and either our yield measurements are very wrong or the majority of products formed by ion–molecule sequences are not being detected.

Similar problems are encountered with a quantitative accounting for products from neutral processes. The ion–molecule sequence given in Table 3 will generate a yield of H-atoms in excess of 6 G-units and presumably more are formed by dissociative excitation processes,

$$C_2H_2 \rightsquigarrow C_2H + H$$

A series of workers have investigated the reactions of H-atoms with acetylene and suggest that the main ultimate products are benzene and polymer (see, for example, ref. 10). Quantitative rate data are not available, but simple arguments suggest that yields of these products are much lower than expected from the estimated yield of H-atoms. Again, if chain reactions are involved, they may be minimized at the high dose rates employed, accounting for the low yields.

*Yields are given in parentheses.

The production of vinyl acetylene and diacetylene can most easily be attributed to reactions of excited states,

$$C_2H_2^* + C_2H_2 \rightarrow C_4H_4 \text{ and } C_4H_2 + H_2$$

but it is difficult to assess the possible contribution from other sources. Reaction of triplet $C_2H_2^*$ formed by cadmium photosensitization (11) yielded only benzene and vinyl acetylene. The mercury-photosensitized decomposition, which can form both free radicals and the triplet state (12) gave benzene, vinyl acetylene, H_2, C_2H_4, diacetylene, cyclooctatetrene, and polymer (13). Direct photolysis (14, 15) which would proceed through the singlet $C_2H_2^*$ and probably free radicals gave relatively large amounts of diacetylene. It is clear that a variety of concurrent processes could be and probably are operating in the high-intensity radiolysis and there is no difficulty in writing plausible sequences of addition, combination, and abstraction reactions of free radicals and excited molecules leading to the products observed.

There is about a 20% deficit of hydrogen in the observed products which probably lies beyond the errors in analysis. Low limits can be put on the yields of H_2 and CH_4 as the irradiated samples were totally condensible in liquid nitrogen and ethane and ethylene were not detected by gas chromatography. One possible explanation of the hydrogen deficit is the dehydrogenation of some unstable polyunsaturated compounds in the heated inlet of the gas chromatograph, a process previously observed with vinyl acetylene, and it must be recognized that some of the highly unsaturated compounds reported (e.g. C_6H_2, C_4H_2) may not be entirely true primary products of the radiolysis. However, it is also possible that hydrogen-rich higher hydrocarbons, undetected by our analysis, could account for the deficit.

Finally, despite our conclusions that at high dose rate secondary polymerization is virtually eliminated and primary polymerization much attenuated, physical condensation, probably of liquid droplets, was observed within a couple of seconds after a single pulse of radiation. These droplets persisted for several hours, suspended in the gas, only detectable by their scattering of a laser beam. We have not been successful in further characterizing this high molecular weight fraction. It probably accounts for the product deficit noted in conjunction with the ion–molecule chemistry and with the H-atom chemistry. It can be shown on the basis of simple vapor pressure arguments that the molecular weight of these condensing species must be above C_{12}, and they were not observed by our analytical procedure.

The crystal structure of bis(diethylamino)dithiaboretane, a compound with a four-membered alternating boron–sulfur ring

G. W. BUSHNELL AND G. A. RIVETT

Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 19, 1977

G. W. BUSHNELL and G. A. RIVETT. Can. J. Chem. **55**, 3294 (1977).

The crystal structure of bis(diethylamino)dithiaboretane, $C_8H_{20}B_2N_2S_2$, is determined by single crystal X-ray diffraction and refined to $R = 0.120$, $R_w = 0.091$ for 373 independent reflections. The tetragonal cell dimensions are $a = 10.396(3)$, $c = 25.589(7)$. The space group is $P_{4_12_12}$ (No. 92) or its enantiomorph (No. 96); $D_m = 1.08(8)$, $D_c = 1.10$ g cm^{-3}; $n = 8$. The asymmetric unit is one half of a pair of molecules. Both molecules have approximate symmetry 222 with one of these symmetry elements being a crystallographic axis. The latter passes through all the B and N atoms of molecule 1, and is perpendicular to the B,S ring of molecule 2. The four-membered B,S rings are planar. The nitrogen coordination is trigonal, planar, and set at $<10°$ to the ring planes within each molecule. The mean bond lengths are: B—S = 1.84(4), B—N = 1.38(5) Å, and the mean bond angles: S—B—S = 105(3)°, B—S—B = 76(2)°. The results suggest single B—S and double exocyclic BN bonds.

G. W. BUSHNELL et G. A. RIVETT. Can. J. Chem. **55**, 3294 (1977).

La structure cristalline du bis(diéthylamino)dithiaborétane, $C_8H_{20}B_2N_2S_2$, est déterminée à l'aide d'un seul cristal par diffraction aux rayons X et affinée à $R = 0.120$, $R_w = 0.091$ pour 373 réflections indépendantes. Les dimensions de la cellule tétragonale sont $a = 10.396(3)$, $c = 25.589(7)$. Le groupe spatial est $P_{4_12_12}$ (No. 92) ou son énantiomorphe (No. 96); $D_m = 1.08(8)$, $D_c = 1.10$ g cm^{-3}; $n = 8$. L'unité asymétrique est la moitié de la paire de molécules. Les deux molécules ont une symétrie approximative de 222 dont l'un des éléments de symétrie est un axe cristallographique. Cet axe passe par tous les atomes B et N de la molécule 1 et est perpendiculaire au cycle B,S de la molécule 2. Les cycles B,S à quatre chaînons sont planaires. La coordination de l'atome d'azote est trigonale, planaire et fait un angle de 10° avec les plans des cycles à l'intérieur de chaque molécule. La longueur moyenne des liaisons principales ainsi que les angles formés entre ces liaisons sont: B—S = 1.84(4), B—N = 1.38(5) Å, S—B—S = 105(3)°, B—S—B = 76(2)°. Les résultats suggèrent une simple liaison B—S et une double liaison BN exocyclique.

[Traduit par le journal]

Introduction

The dithiaboretane ring system has been known for many years, but no X-ray structure determination has been done. In 1966, Forstner and Muetterties (1) reported a synthesis of bis-(diethylamino)dithiaboretane, **1**, by the reaction of H_2S with triethylamine borane. The crystal structure of **1** was undertaken to confirm the structure and investigate the geometry and bonding of the four-membered ring system.

Preparation

The literature method (1) yielded $(Et_2NBS)_3$, $(m/e)_{max} = 347$ in the mass spectrum. To obtain **1**, conditions were modified as follows: molar ratio H_2S: $Et_3NBH_3 = 4.3$, reaction time = 24 h at 175°C, sublimation temperature = 75°C, yield 50%. Identification was by mass, infrared, and proton magnetic resonance spectra. Crystals were obtained by cooling a solution in *n*-pentane. A dry box was used for all manipulations, as the compound is unstable in air.

Experimental Crystallography

The crystal data are shown in Table 1. Compound **1** formed tetragonal tablets showing the faces {110},{001}.

A large single crystal was measured and weighed to obtain the density. Smaller crystals were wedged into Lindemann tubes and sealed in with black wax. Over 40 crystals were mounted, of which 4 were single crystals. Three of these were used for photography, while the best crystal with dimensions 0.4 × 0.4 × 0.1 mm (shortest dimension along C) was used on the diffractometer. The crystals were mounted with the 1,1,0 planes approximately parallel to the axes of the Lindemann tube and the goniometer head. The space group $P_{4_12_12}$ (No. 92) is enantiomorphous with $P_{4_32_12}$ (No. 96) and no attempt to distinguish between these alternatives was made. The unit cell was refined by least-squares using diffractometer measurements at $\pm 2\theta$ for 28 reflections. A C-centred tetragonal cell was used for the intensity measurements only, which were done on a manual Picker 4-circle diffractometer using Zr-filtered Mo radiation ($\lambda = 0.71069$ Å). All reflections in one octant up to $2\theta = 30°$

TABLE 1. Crystal data for bis(diethylamino)dithiaboretane

System	Tetragonal
Space group	$P_{4_12_12}$, No. 92 (or $P_{4_32_12}$, No. 96)
Molecular weight	230.01 g mol^{-1}
Cell dimensions	$a = 10.396 \pm 0.003$ Å $b = 10.396 \pm 0.003$ Å $c = 25.589 \pm 0.007$ Å $\alpha = \beta = \gamma = 90.00°$
Cell volume	2765 × 10^{-24} cm^3
Density (measured)	1.08 ± 0.08 g cm^{-3}
Density (calculated)	1.10 g cm^{-3}
Molecules per cell	8
Absorption coefficient (MoK$_\alpha$)	3.43 cm^{-1}

were measured. Scans were in the $\theta/2\theta$ mode for 1 min, at 2° in 2θ min^{-1}. Background measurements were for 30 s at each extremity of the scan. Reflection 8,0,0 which was measured hourly as the standard reflection, had an intensity of 45 200 counts initially, falling to 9600 counts at the end of the data collection 59 h later. In the X-ray beam the material lost crystallinity in 2–5 days by a process which seemed to start where the crystal touched the glass. The crystal orientation was checked frequently and adjustments were necessary. Lorentz and polarization factors were applied and the intensities were corrected for crystal deterioration using the current intensity of the standard reflection. The indices were transformed to correspond to the primitive unit cell. As the Laue symmetry was 4/*mmm*, pairs of equivalent reflections were averaged. Four pairs of reflections showed differences in $|F_o|$ greater than 5% and were rejected. The final data set contained 373 reflections.

Structure Determination

The structure was solved by conventional Patterson and Fourier methods. All atomic scattering curves were from the *International Tables for X-Ray Crystallography* (2) with the atoms assumed to be uncharged. The programs used were supplied by Penfold (3). The refinement minimized $w(|F_o| - |F_c|)^2$ by full matrix least squares initially with unit weights. In the final stages of refinement, through analysis of $w\Delta^2$, a weighting scheme $w = (25/|F_o|)^2$ was employed. No significant shifts in positional or thermal parameters were observed. The final agreement factors were $R = 0.120$, $R_w = 0.091$ for all reflections and $R = 0.109$, $R_w = 0.088$ when those reflections for which $I < \sigma(I)$ were omitted. The final difference synthesis, with a maximum of 0.38 e Å^{-3} and $\sigma(\rho) = 0.18$ e Å^{-3}, gave no evidence of misplaced atoms. The structure factor table has been deposited.[1] The fractional atomic coordinates and isotropic temperature factors are given in Table 2.

Results

One unit cell and its contents are shown in Fig. 1 with the atoms of the asymmetric unit labelled. For descriptive purposes, consider the twofold rotation axes in space group $P_{4_12_12}$ lying diagonally in the planes $Z = 0$, $Z = \frac{1}{4}$, $Z = \frac{1}{2}$, and $Z = \frac{3}{4}$. A pair of molecules occurs at each Z level, and the asymmetric unit is one-half of such a pair. In one molecule the twofold axis passes through the atoms NBBN and in the other molecule this same axis is perpendicular to the plane of the four-membered ring and passes through its centre. The symmetry of both molecules is approximately 222. All intramolecular S–S vectors are at a small angle (< 10°) to the c axis. The bond lengths and angles are given in Table 3 and the mean planes in Table 4. Assuming the covalent radii for B, N, and S to be 0.85, 0.70, and 1.04 Å, respectively, the single bond length for B—N is 1.55 Å, and B—S 1.89 Å.

A suitable reference compound for the single B—S bond is $(BrBS)_3$ (4) B—S = 1.74–1.88 (3). A double bond length of 1.5994(4) for B=S has been measured by microwave spectroscopy on thioborine H—B=S (5). The mean bond length of 1.84(4) in compound **1** indicates single bonding.

Single B—N bonds have been observed in many compounds, a good example being cyclotriborazane (6) B—N = 1.576(2) Å corrected for thermal motion. In borazine (7), where multiple bonding is expected, BN = 1.4355(21) Å. The microwave spectrum (8) of aminodifluoroborane $F_2B{=}NH_2$, shows that the molecule is planar and gives 1.402(24) Å for B=N. The BN lengths for compound **1** indicate double bonding.

Table 4 shows the planarity of the four-membered rings and of the nitrogen atom coordination. Where $\chi^2 = 0$, crystallographic symmetry ensures perfect planarity. The nitrogen planes are rotated by ±9.4° from the ring plane in the case of the molecule containing S1. In the molecule containing S2, the ring plane is only 2.9° from the nitrogen plane. Near-coplanarity of the ring plane and the nitrogen coordination plane is necessary for N—B π-bonding. The B octet is thus completed by $p\pi$–$p\pi$-bonding between first row elements, rather than by B—S π-bonding.

The mean angles are 76(2)° for BSB and 105(3)°

4	S2, B3, S2′, B3′	5.9
5	C5, C7, N3, B3	1.8

*Angles between planes 1,2 = 9.4°; 1,3 = −9.4°; 4,5 = −2.9°. $\chi^2 = \sum_i (p_i^2/[\sigma_i(p)^2])$, where p_i = the perpendicular distance of the atom (i) from the mean plane.

for SBS and seem to be strained equally and by approximately 15° from 90° and 120°. The bond angles at the nitrogen atoms are very close to 120°.

Conclusion

The structure proposed by Forstner and Muetterties (1) is confirmed. The accuracy of the structure is limited by experimental difficulties but the molecular geometry and the bond lengths taken in conjunction suggest double bonding in the exocyclic BN bonds and single bonding in the ring.

Acknowledgments

Arguments based on ^{13}C and ^{1}H nmr spectroscopy are presented to elucidate the structures of 3,4,5- and 4,5,6-trichloroguaiacol, 12- and 14-monochlorodehydroabietic acid, and 12,14-dichlorodehydroabietic acid. These compounds were recently isolated and tentatively identified as major components toxic to fish in kraft mill caustic extraction effluents.

A. N. THAKORE et A. C. OEHLSCHLAGER. Can. J. Chem. **55**, 3298 (1977).

On présente une discussion basée sur la spectroscopie rmn du carbone ^{13}C et du proton ^{1}H afin d'éclaircir la structure des composés suivants: les trichloro-3,4,5 et -4,5,6 guaiacols, les acides monochloro-12 et -14 déhydroabiétiques et l'acide dichloro-12,14 déhydrobiétique. Ces composés ont été récemment isolés des eaux s'écoulant d'une usine de pâte et papier et identifiés comme étant les produits toxiques majeures responsables de l'empoisonnement des poissons.
[Traduit par le journal]

Introduction

In a typical pulping process, the unbleached pulp becomes fully bleached in five or six sequential stages designated CEHDED, where C is chlorination, E is caustic extraction, H is hypochlorite, and D is chlorine dioxide. Effluents produced by washing the pulp after each stage are combined into acid and caustic streams before being sewered. In the present work the elucidation of the structures of chlorinated compounds previously isolated from the caustic stream and found to be responsible for a major part of the effluent toxicity to fish (1) are presented. The compounds discussed were isolated from the caustic effluent by the fractionation procedure outlined in Fig. 1 and explained in detail in previous reports (1). Toxicity of the effluent was traced during the fractionation by 96 h bioassays with juvenile rainbow trout as previously described (1). Since exact structures of several of the compounds isolated have not been reported in the literature we wish to present arguments based on ^{13}C and ^{1}H nmr spectral data which lead to structural assignments.

Results and Discussion

Column and thin layer chromatographic fractionation of the acidic portion of the effluent (Fig. 1) yielded two apparently fish-toxic compounds (**1** and **2**, never isolated from the same sample of effluent) mass spectral analysis of which showed each had a molecular ion peak *m/e* 226, together with $(M^+ + 2)$ and $(M^+ + 4)$ peaks, in the ratio of 3:3:1. Methylation of these effluent derived toxicants (**1** and **2**) with diazomethane gave the same dimethoxy derivative (**3**, $M^+ = 240$), which had methoxyl resonances at δ 3.93 and a downfield signal due to an aromatic proton at δ 6.88. The proton magnetic resonance spectrum of the least polar isomer (**1**) contained signals due to one methoxyl group (δ 3.92), one exchangeable hydrogen (δ 5.90), and one aromatic hydrogen (δ 6.88), whereas the more polar isomer (**2**) gave resonances at δ 5.08 (D_2O exchangeable), and δ 7.05 (aromatic), and a methoxyl signal at δ 3.92. On this evidence effluent derived **1** and **2** were believed to be trichloroguaiacol isomers.

Controlled chlorination of guaiacol gave only one crystalline trichloroguaiacol which was identical by mass and nmr spectroscopy to **1** isolated from caustic effluent. Methylation of the synthesized trichloroguaiacol gave a veratrol derivative that was identical to **3**. Attempts to synthesize **2** by chlorination of guaiacol failed.

An additional toxic constituent isolated from

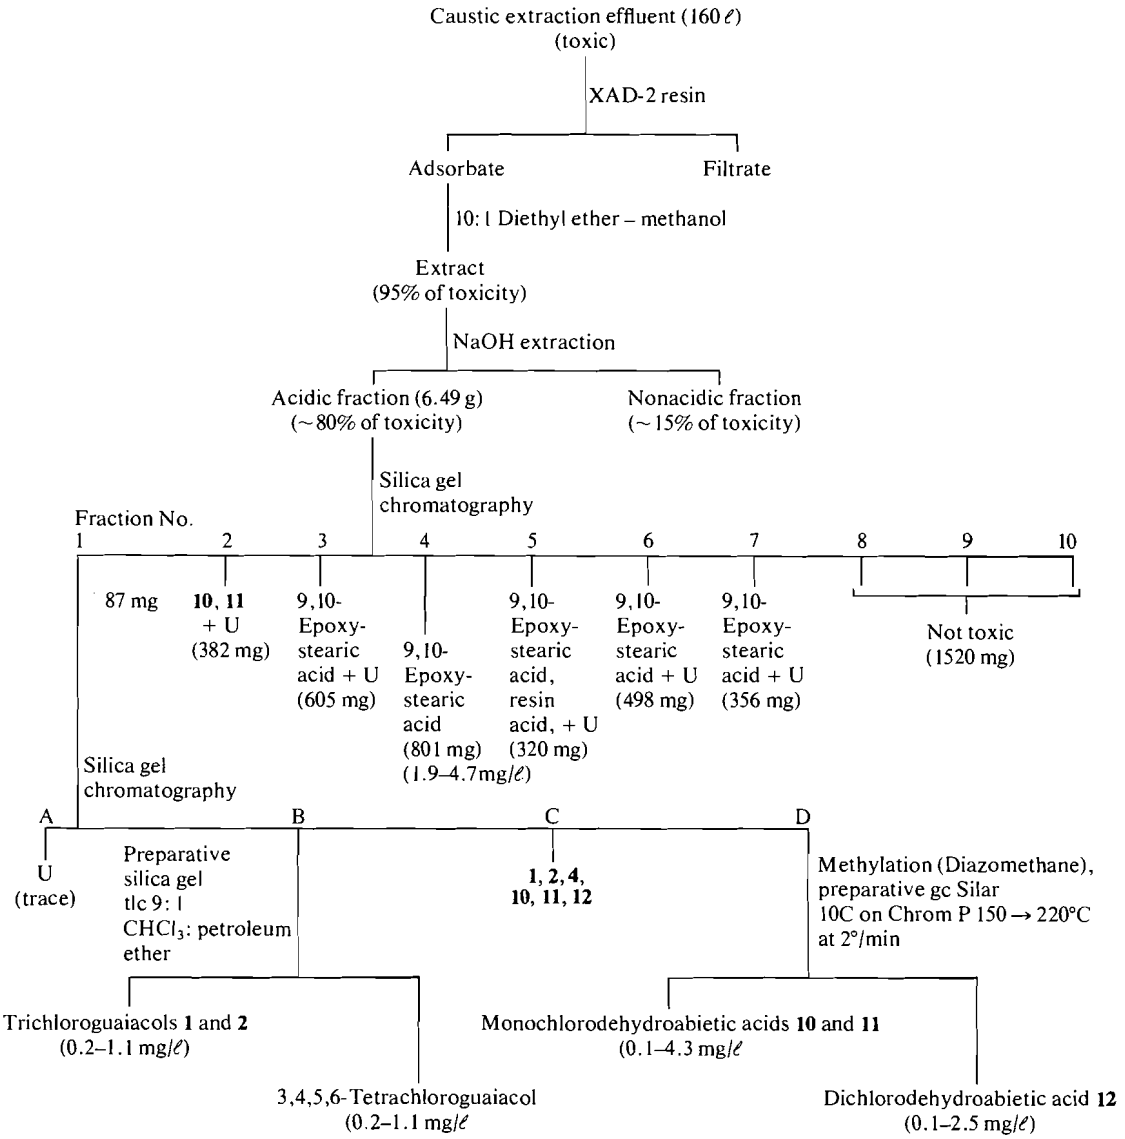

FIG. 1. Fractionation scheme for caustic extraction effluent and calculated concentrations of toxicants (1). U = unidentified constituents.

the same fraction of effluent as **1** and **2** was found by mass spectroscopic analysis to have a molecular weight of 260 with a M^+:(M^+ + 2):(M^+ + 4):(M^+ + 6) peak ratio of 1:1.3:0.6:0.1 indicating the presence of four chlorines. The proton magnetic resonance spectrum of this compound (**4**) contained signals due to one exchangeable hydrogen (δ 6.00) and one methoxyl group (δ 3.97). On the basis of the above data it was considered likely that **4** was tetrachloroguaiacol. Chlorination of guaiacol under vigorous conditions according to the method of Sarkanen and Dence (3) yielded a tetrachloroguaiacol, which was identical to **4** on the basis of nmr and mass spectroscopic analysis and by mixture melting point. Methylation of both the synthetic and isolated tetrachloroguaiacol **4** gave the same veratrole derivative **5** (M^+ = 274).

Structure determination of trichloroguaiacols **1** and **2** involved comparison of the ^1H and ^{13}C magnetic resonance spectra of **1**–**5**, guaiacol **6**, and veratrole **7**. A priori four trichloroguaiacol

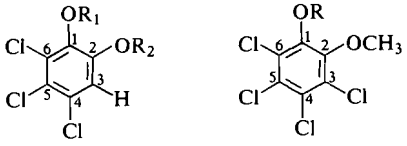
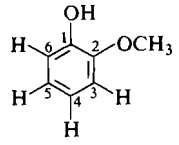
†Shifts reported in ppm relative to tetramethylsilane.

isomers **1**, **2**, **8**, **9** are possible. Although it is known (4) that substitution patterns influence the ^1H chemical shift of aromatic bound methoxyls, no significant differences were observed in the chemical shifts of the methoxyls of **1**, **3**, and **4** which would allow us to deduce the substitution patterns in **1** and **3**. However, examination of the ^{13}C magnetic resonance spectra of **1**–**7** revealed correlations in the chemical shifts of the methoxyl carbons as reported in Table 1.

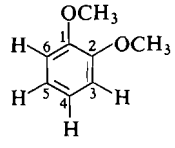


1 $R_1 = H, R_2 = CH_3$
2 $R_1 = CH_3, R_2 = H$
3 $R_1 = R_2 = CH_3$

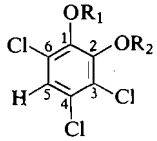
4 R = H
5 R = CH_3



6



7



8 $R_1 = H; R_2 = CH_3$
9 $R_1 = CH_3; R_2 = H$

The data show that in tetrachloroguaiacol **4** and tetrachloroveratrole **5** the methoxyl carbons are deshielded relative to their nonchlorinated analogs (**6** and **7** respectively). This observation is analogous to that of Stothers *et al.* (5) who observed a downfield chemical shift of aromatic alkoxyl carbon resonances upon di-*ortho* substitution. The methoxyl carbon resonance of **1** does not indicate this deshielding effect whereas one of the methoxyl resonances in its methylated derivative **3** is deshielded. From these observations one can deduce that **1** possesses an aromatic hydrogen adjacent to its methoxyl and a chlorine adjacent to its hydroxyl. This uniquely defines the structure of **1**.

The carbon resonance attributable to the methoxyl of **2** is deshielded compared to **1**, guaiacol **6**, or veratrole **7**. This suggests that a chlorine is situated adjacent to the methoxyl of **2**. Since treatment of **2** with diazomethane yields a chlorinated veratrole identical with **3** (derived from **1**) compound **2** is uniquely defined.

The assignment of the aromatic ^{13}C resonances for **1**–**7** given in Table 1 are based on internal comparisons within the series and not on calculation, which for *ortho* substituted aromatics gives approximate results at best (6).

Since several unsuccessful attempts were made to synthesize **2** by chlorination of guaiacol it is considered unlikely that **2** is produced by direct chlorination of guaiacol during pulp bleaching. A more likely route for formation of **2** is considered to be dealkylation of chlorinated alkyl guaiacols present in the pulp slurry during the bleaching stage. The present experimental results indicate that a likely route for formation of **1** is chlorination of guaiacol during the first bleaching stage.

As shown in Fig. 1 silica gel chromatography of the acidic fraction of caustic extraction effluent yielded fractions containing both mono- (**10** and **11**) and dichlorodehydroabietic (**12**) acids. Methylation (diazomethane) of the fraction containing the chlorinated resin acids followed by preparative glpc facilitated separation of the mono- from dichloro derivatives. Gas–liquid partition chromatography also revealed that the methyl monochlorodehydroabietate was a separable 2:1 mixture of two isomers.

Controlled chlorination of dehydroabietic acid gave a 2:1 mixture of two crystalline monochlorodehydroabietic acids. Methylation of this mixture with diazomethane gave a mixture of methyl monochlorodehydroabietates which by nmr and gc/ms was identical to the mixture of **10** and **11** isolated from caustic extraction effluent.

Chlorination of dehydroabietic acid with excess chlorine gave only one dichlorodehydroabietic acid which was identical to **12** by mixture melting point, nmr, and mass spectroscopic analysis. Methylation of both synthetic and effluent derived **12** gave methyl esters that were identical when examined by gc/ms. The structures of **10** and **11** as well as that of the methyl dichlorodehydroabietate **12** were determined by comparison of their ^{1}H nmr spectra with those of dehydroabietic acid **13** and trichlorodehydroabietic acid **14**. The latter derivative was prepared by halogenation of **13** with an excess of chlorine. Integration of the aromatic region in the ^{1}H nmr spectra of **10–14** indicated that chlorination of **13** (to produce **10**, **11**, **12**, and **14**) occurred exclusively in the aromatic ring.

Examination of data in Table 2 indicates significant deshielding (δ 1.22 → δ 1.52) of the C-10 methyl in **14** (compared to the C-10 methyl of dehydroabietic acid, **13**) due to the chlorine atom at C-11. The observation that this deshielding does not occur in the dichloro derivative, **12**, uniquely defines the position of chlorine atoms to be C-12 and C-14. Structures can be assigned to the monochlorodehydroabietic acid isomers on the basis of the above deductions and the observation that the aromatic resonances of the methyl ester of one monochloro isomer appear as a two hydrogen singlet (δ 7.14) and the corresponding resonances in the other occur as two single hydrogen singlets (δ 7.03, 6.89). These latter signals cannot be due to two *ortho* hydrogens (no coupling observed) hence they must be due to two *para* hydrogens. The isomer yielding the methyl ester with aromatic resonances at δ 7.03 and δ 6.89 must therefore be **11**. The sequence of chlorination of dehydroabietic acid in the kraft mill bleach plant and in the laboratory synthesis can therefore be deduced as shown in Scheme 1.

TABLE 2. ^{1}H nmr chemical shifts* of methyl groups in dehydroabietic acid and its chlorinated derivatives

Compound No.	C_4-CH_3	C_{10}-CH_3	$C_{15}(CH_3)_2$†
10	1.28	1.22	1.24
11	1.28	1.22	1.26
12	1.28	1.22	1.41
13	1.28	1.22	1.23
14	1.32	1.52	1.41

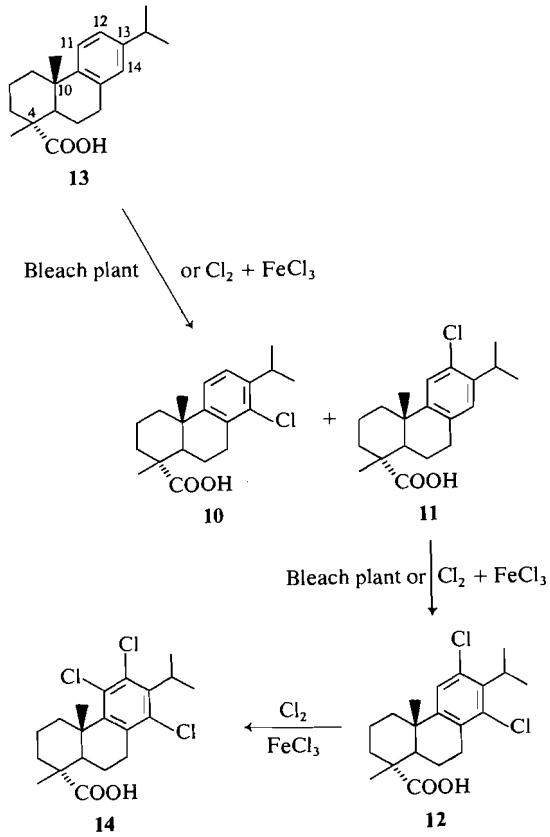

SCHEME 1

Experimental

General

Gas–liquid partition chromatography (glpc) was carried out on a Perkin-Elmer Model 881 instrument fitted with dual flame ionization detectors. Stainless steel (ss) columns (6 ft × ⅛ in.) were used containing 10% (w/w) Silar-10C on 100–120 mesh Gas Chrom P.

Gas chromatography – mass spectrometry was carried out using a 10% Silar-10C column in a Varian Associates Model 1400 Aerograph GC connected via a glass interface to a Hitachi Perkin-Elmer RMU-GE mass spectrometer.

Proton nuclear magnetic resonance (^{1}H nmr) spectra were obtained on a Varian A 56/60 spectrometer in deuteriochloroform solution using tetramethylsilane (TMS) as an internal standard. ^{13}C magnetic resonance spectra (^{13}C nmr) were taken at 25.2 MHz on a Varian XL-100

Fourier transform spectrometer. Chemical shifts for ^{13}C nmr spectra are in ppm downfield from TMS. In deuteriochloroform solution $\delta(TMS) = \delta(CDCl_3) + 77.6$ ppm.

Melting points (mp) were measured on a Kofler hot stage apparatus.

Synthesis of Toxicants

Guaiacol **6** was purchased from MCB Chemicals. Pure dehydroabietic acid **11** was isolated from a commercial preparation of dehydrogenated wood resin according to the method described by Halbrook and Lawrence (2). Methylations were carried out on guaiacol and dehydroabietic acid derivatives with diazomethane (in ether) which was generated by base treatment of *N*-nitroso-*N*-methyl urea.

4,5,6-Trichloroguaiacol 1

Trichloroguaiacol **1** isolated from caustic extraction effluent (1) had mp 105–107°C. A melting point of 107–108°C is given (7) for one trichloroguaiacol isomer generated on methylation of 3,4,5-trichlorocatechol.

An authentic sample was obtained by treating guaiacol (0.1 mol) with chlorine (0.3 mol) in acetic acid (500 ml) at room temperature for 1 h. The product was isolated by concentration of the reaction mixture *in vacuo* and crystallization three times from petroleum ether to give 4,5,6-trichloroguaiacol (**1**, yield 30%); mp 105–107°C; ^1H nmr δ 6.88 (1H, s, aromatic), 5.90 (1H, s, D_2O exchangeable hydrogen), and 3.92 (3H, s, OCH_3); ms *m/e* 226 (M^+), 228 ($M^+ + 2$), 230 ($M^+ + 4$), ratio 3:3:1 for M^+, ($M^+ + 2$), ($M^+ + 4$) peaks. Mixture melting point of **1** from both sources was undepressed.

3,4,5-Trichloroguaiacol 2

Trichloroguaiacol **2** isolated from caustic extraction effluent had mp 127–128°C. A melting point of 127–128°C is reported (7) for one trichloroguaiacol isomer generated on methylation of 3,4,5-trichlorocatechol; ^1H nmr δ 7.05 (1H, s, aromatic), 5.08 (1H, s, D_2O exchangeable), and 3.92 (3H, s, OCH_3); ms *m/e* 226 (M^+), 228 ($M^+ + 2$), 230 ($M^+ + 4$) (ratio 3:3:1), 211, 183, 147, 113.

4,5,6-Trichloroveratrole 3

Synthesization by methylation with diazomethane (75% yield) of **1** and **2** isolated from caustic extraction effluent gave **3**; mp 68–69°C (lit. (7) mp 68–69°C); ^1H nmr δ 6.88 (1H, s, aromatic) and 3.93 (3H, s, OCH_3); ms *m/e* 240 (M^+, base peak), 242 ($M^+ + 2$), 244 ($M^+ + 4$), 225, 162, 197, 147.

Methylation of **1** synthesized from guaiacol gave a crystalline veratrol, mp 68–69°C; nmr and ms identical to the veratrol derived above from **1** and **2**.

3,4,5,6-Tetrachloroguaiacol 4

Guaiacol (0.01 mol) was reacted with chlorine (0.04 mol) in 50 ml of acetic acid. After 1 h the solvent was removed *in vacuo* and the crude product was crystallized once from $MeOH–H_2O$ and twice from petroleum ether to yield 32% of **4**. Mixture melting point of this sample and that of material isolated from caustic extraction effluent was undepressed; mp 119–120°C (lit. (3) mp 119–121°C); ^1H nmr δ 6.00 (1H, s, D_2O exchangeable), 3.97 (3H, s, OCH_3); ms *m/e* 260 (M^+), 262 ($M^+ + 2$), 264 ($M^+ + 4$), 266 ($M^+ + 6$) (ratio 1:1.3; 0.6:0.1), 246 (base peak), 244, 219, 183.

Tetrachloroguaiacol **4**, isolated from the effluent had the same spectroscopic characteristics as synthetic **4**.

3,4,5,6-Tetrachloroveratrole 5

Methylation of **4** with diazomethane gave **5** (yield 70%); nmr δ 3.97 (3H, s, OCH_3); ms *m/e* 274 (M^+, base peak), 276 ($M^+ + 2$), 278 ($M^+ + 4$), 206, 261, 218.

Monochlorodehydroabietic Acids

The monochlorodehydroabietic acids were obtained from effluent as a 2:1 mixture of **10** and **11** (1). The same 2:1 mixture was generated upon chlorination (0.24 g) of dehydroabietic acid (1.00 g) and a crystal (~5 mg) of $FeCl_3$ in carbon tetrachloride for 1 h at room temperature with the exclusion of light. The solvent was removed *in vacuo* and the crude product was treated with 2-amino-2-methyl-1-propanol. The resulting salt was crystallized three times from acetone. Acid hydrolysis of the salt gave monochlorohydroabietic acids (0.4 g) as a 2:1 mixture of **10** and **11** (yield 36%) revealed by gas chromatography–mass spectrometry of the methyl esters. The methyl esters of the isolated compounds were separated by preparative glpc.

The methyl ester of the major isomer **10** (shorter retention time) had the following spectral characteristics: ^1H nmr near Cl δ 7.14 (2H, s, aromatic), 3.70 (3H, s, CO_2CH_3), 1.28 (3H, s, C_4CH_3), 1.23 (6H, d, $J = 7$ Hz, $C(CH_3)_2$), 1.20 (3H, s, $C_{10}CH_3$); ms *m/e* 273 (base peak), 275, 348 (M^+), 333, 207, 181, 350 ($M^+ + 2$); mass measurement, M^+ calcd. for $C_{21}H_{29}O_2Cl$: 348.193; found: 348.184.

The spectroscopic characteristics of the methyl ester of **11** were ^1H nmr δ 7.03 (1H, s, aromatic), 6.89 (1H, s, aromatic), 3.70 (3H, s, CO_2CH_3), 1.28 (3H, s, C_4CH_3), 1.23 (6H, d, $J = 7$ Hz, $C(CH_3)_2$), 1.20 (3H, s, $C_{10}CH_3$); ms *m/e* 273 (base peak), 275, 219, 348 (M^+), 221, 207, 181, 165, 333. M^+ calcd. for $C_{21}H_{29}O_2Cl$: 348.193; found: 348.184.

12,14-Dichlorodehydroabietic Acid 12

This compound was isolated from caustic extraction effluent (1) and also synthesized by addition of chlorine (0.7 g), dissolved in CCl_4, to a solution of dehydroabietic acid (1.5 g) and $FeCl_3$ (~5 mg) in CCl_4 at 20°C for 1 h in the dark. The mixture was worked up according to the procedure described for monochlorodehydroabietic acid to give 0.6 g of dichlorodehydroabietic acid (yield 33%); both isolated and synthesized samples had identical spectroscopic properties; nmr δ 7.14 (1H, s, aromatic), 1.41 (6H, d, $J = 7$ Hz, $C_{15}(CH_3)_2$), 1.27 (3H, s, C_4-CH_3), 1.20 (3H, s, C_{10}-CH_3); spectral details of the methyl ester were ^1H nmr δ 7.18 (1H, s, aromatic), 3.68 (3H, s, CO_2CH_3), 1.41 (6H, d, $J = 7$ Hz, $C(CH_3)_2$), 1.27 (3H, s, C_4, CH_3), 1.20 (3H, s, $C_{10}CH_3$); ms *m/e* 307 (base peak), 309, 382 (M^+), 241, 308; mass measurement, M^+ calcd. for $C_{21}H_{28}O_2Cl_2$: 382.146; found: 382.144.

11,12,14-Trichlorodehydroabietic Acid 14

This compound was obtained by addition of chlorine (0.8 g) and ~5 mg of $FeCl_3$ to a solution of dehydroabietic acid (1 g) in CCl_4 at 20°C for 1 h in the dark. After the usual work-up procedure, trichlorodehydroabietic acid (0.66 g) was obtained; nmr δ 1.52 (1H, s, C_{10}-CH_3), 1.41 (6H, d, $J = 7$ Hz, $C_{15}(CH_3)_2$, 1.32 (1H, s, C_4-CH_3). Spectral details for the methyl ester were ^1H nmr δ 3.70 (3H, s, $COOCH_3$), 1.52 (3H, s, $C_{10}CH_3$), 1.41 (6H, d, $J = 7$ Hz, $C(CH_3)_2$), 1.32 (3H, s, C_4CH_3); ms *m/e* 341 (base peak) 343, 345, 416 (M^+), 418 ($M^+ + 2$), 420 ($M^+ + 4$).

^{13}C nuclear magnetic resonance spectra of the spirobenzylisoquinoline alkaloids and related model compounds

DONALD W. HUGHES, BALA C. NALLIAH, HERBERT L. HOLLAND,[1] AND DAVID B. MACLEAN

McMaster University, Department of Chemistry, Hamilton, Ont., Canada L8S 4M1

Received March 2, 1977

DONALD W. HUGHES, BALA C. NALLIAH, HERBERT L. HOLLAND, and DAVID B. MACLEAN. Can. J. Chem. **55**, 3304 (1977).

The natural abundance ^{13}C nuclear magnetic resonance spectra of a number of spirobenzylisoquinoline alkaloids and related model compounds have been recorded. The carbon resonances of the alkaloids were assigned by comparison with the spectra of other isoquinoline alkaloids and with those of the model compounds. It has been shown that ^{13}C nmr spectroscopy may be used to differentiate between diastereomers in this series.

DONALD W. HUGHES, BALA C. NALLIAH, HERBERT L. HOLLAND et DAVID B. MACLEAN. Can. J. Chem. **55**, 3304 (1977).

On a enregistré par résonance magnétique nucléaire ^{13}C les spectres de plusieurs alkaloïdes spirobenzylisoquinoléiques ainsi que d'autres composés de structure analogue. Par comparaison avec d'autres spectres d'alkaloïdes isoquinoléiques et de composés analogues, on assigne les valeurs trouvées à chaque carbone des alkaloïdes. On a montré que la spectroscopie rmn ^{13}C peut être utilisée pour différencier entre diastéréoisomères dans ces séries.

[Traduit par le journal]

Several classes of isoquinoline alkaloids have been examined recently by ^{13}C nuclear magnetic resonance spectroscopy. In a recent review (1) Wenkert has reported spectra of a simple benzylisoquinoline, several tetrahydroprotoberberines, several aporphines, the pavine alkaloid argemonine, and cularine. Other reports have appeared on the protoberberines (2, 3), the phthalideisoquinolines (2), and the protopines (4). We report here on our investigation of the spirobenzylisoquinoline system in which we have examined several model systems, some synthetic analogues, and alkaloids of this family.

We have made use of what are now standard techniques in ^{13}C magnetic resonance spectroscopy. The spectra of all compounds were recorded using broad band decoupling, and where applicable the off-resonance technique was used to determine the substitution at carbon. In some cases the alternately pulsed or gated decoupling method (5–7) was employed. Deuterium labelling and selective proton decoupling have also been used to make unequivocal assignments of several carbon resonances. Reference is made to model systems in which the assignments are already secure and in other appropriate cases calculated chemical shifts of model systems have been used.

The spirobenzylisoquinoline alkaloids are a relatively small group of alkaloids within the isoquinoline family. Their structure and chemistry are the subject of several recent reviews (8, 9). Ochotensimine **1***a* was the first member of this family to be investigated and it and ochotensine (8, 9) are the only alkaloids that carry an exocyclic methylene on the spiro ring. More common are the alkaloids that are oxygenated in the five-membered ring and carry the oxygens in the form of carbonyl, hydroxy, or acetoxy groups on one or both of carbons 8 and 13. The structures of alkaloids of this group and synthetic analogues used in this study are shown as the formulas **1***a*–**1***j* in Fig. 3.

The appropriately substituted 1,2,3,4-tetrahydroisoquinolines and indanes serve as models for rings A and B, and rings C and D, respectively, of the spiro alkaloids. A discussion of the ^{13}C spectra of the former has already appeared (2) and the information is used here in making assignments in rings A and B in this series. Several indane derivatives have been prepared in this study and their spectra have been recorded and interpreted to aid in the assignment of the ^{13}C resonances in rings C and D of the spiro compounds.

[1]Present address: Department of Chemistry, Brock University, St. Catharines, Ontario.

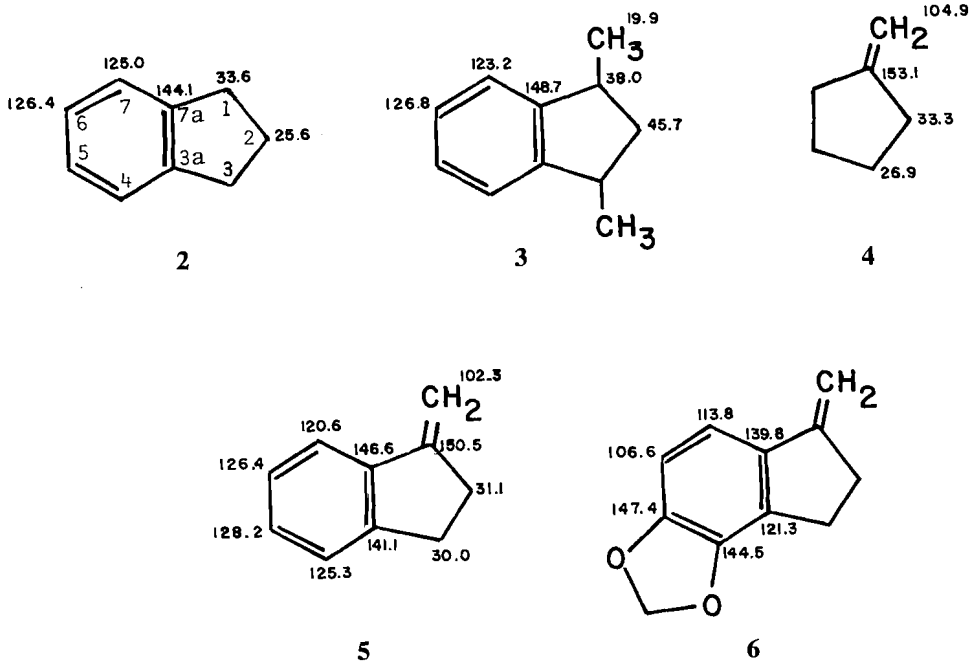

FIG. 1. ^{13}C resonances of indanes **2**–**6**.

The spectra of indane **2** and of 1,3-dimethylindane **3** have been published (10, 11), and the indane assignments recently verified (12). By using the indane spectra and the already reported spectrum of methylenecyclopentane **4** (13) as models, we assigned the spectrum of 1-methyleneindane **5** as shown in Fig. 1. Of the two substituted aromatic carbons, C-7*a* has been assigned at lower field because of β substitution at C-1. Of the four signals associated with unsubstituted aromatic carbons that at 120.6 was assigned to C-7 because of the γ-steric effect of the C-1 substituent. While the signal at 125.3 could not be unambiguously differentiated from that at 126.4, it was assigned to C-4 since this carbon is in an environment analogous to that in indane. Of the two remaining signals, that at lower field is tentatively assigned to C-5 because it is *para* to the double bond system. The aromatic spectrum of 4,5-methylenedioxy-1-methyleneindane **6** was then calculated using the substituent parameters already derived for a methylenedioxy group (2) and it served as model for rings C and D of ochotensimine.

The spectrum of 1-indanone **7***a* and several derivatives were examined to serve as models for the alkaloids bearing a carbonyl group in ring C (Table 1). In the case of indanone itself assignments were made initially by comparison with the spectrum of phthalide (2) and verified by examination of the spectrum of 6-deuterio-1-indanone **7***b*. In the latter the signal at 127.1 had virtually disappeared so that the assignment at C-6 was secure. Carbon 5 follows from consideration of the substituent effect for a carbonyl group on a *para* carbon. The remaining positions C-4 and C-7 were determined from the gated decoupled spectrum since deuterium substitution at C-6 removes the 7.0 Hz *meta* coupling between C-4 and the C-6 hydrogen. With the spectrum of 1-indanone established it was a simple matter to assign the resonances in the substituted 1-indanones **8** and **9** by making use of the substituent parameters for *o*-dimethoxy and methylenedioxy groups (2). The calculated chemical shifts show a resonable agreement with observed values except for the expected deviation at C-3*a* in the dimethoxy compound (2). The assignments of the protonated aromatic carbons were verified in all cases by selective proton decoupling.

Another series of models, the 1,3-indandiones, was also studied. No 1,3-diones have yet been found in nature among the spiro alkaloids but since the diols and the hydroxyketones are well known they may be present but undetected. The diones have been prepared, however, as

TABLE 1. ^{13}C chemical shifts of indanones and indandiones **7-12**

 **12**	200.8	73.5	200.8	141.5	123.8	136.4	136.4	123.8	141.5				136.3	127.5	129.0	128.8	31.6

intermediates in several synthetic approaches to the spiro alkaloids (8, 9) and their spectra are also reported here. The compounds examined are also shown in Tables 1 and 2. In two of them the complete skeleton of the spiro alkaloids is present.

The spectra of the 1,3-indandiones **10**, **11**, and **12** were used in the interpretation of the spectra of the spiro compounds **13** and **14**. Assignment of the resonances of **10** was made without difficulty because of the molecular symmetry of the system and by taking into account the substituent effects of the two carbonyl groups. As C-2 becomes more substituted in going from **10** to **12**, its chemical shift moves downfield as expected. Substitution at C-2 also deshields the carbonyl carbons but has very little influence on the aromatic carbons of the indandione system.

In the spiro compounds, **13** and **14**, the indandione part of the molecule retains its symmetry and chemical shifts are observed which are similar to the models **10**, **11**, and **12**. The resonances of the ring A carbons are very similar to those found in other tetrahydroisoquinolines (2). The assignments made for C-4*a* and C-14*a* are based on the argument that C-14*a* has a greater number of β substituents. In the proton spectrum of **14** the hydrogen at C-1 is shielded relative to that at C-4 (14) and it was through selective proton decoupling that the resonances of these carbon atoms were established. The major difference between **13** and **14** lies in the chemical shifts of C-6 and C-14, both of which are deshielded as expected in the *N*-methyl relative to the N–H compound. Calculations, using the β equatorial methyl parameter derived from methylcyclohexane (11, 15), work well for C-6 but because of the highly substituted nature of C-14 there was a deviation between the observed and calculated chemical shift.

We turn now to (+)-ochotensimine **1***a* (Fig. 3) which is distinguished from the other alkaloids of the series examined here by the presence of an exocyclic methylene at C-13. The assignments (Table 3) in rings A and B were made by comparison with the spectrum of **15** (2) (Fig. 2). Carbons 1, 2, 3, 4, and 4*a* are not greatly different from the model and the assignments of C-1 and C-4 were differentiated from C-11 and C-12 by selective proton decoupling. Since carbons 2 and 3 are separated by only 0.2 ppm unambiguous assignments could not be made. C-14*a* and C-12*a* cannot be differentiated but it is noteworthy that relative to the model C-14*a* has shifted considerably downfield. This shift is attributed to greater substitution at C-14 in **1***a* relative to **15**.

FIG. 3. Structures of the spirobenzylisoquinoline alkaloids **1***a*–**1***j*. (The absolute stereochemistry is not implied in this figure.)

In ring B the changes between **15** and **1***a* are as follows: C-14, +14.3; C-6, −4.9; C-5, +0.3; N—CH_3, −7.0. The shielding of both C-6 and the *N*-methyl group may be attributed to the combined γ-gauche effect of both C-8 and C-13. Creation of the spiro ring junction at C-14 causes a significant deshielding in a manner analogous to that observed for the spiro carbon in spiro[4.5]decan-1-one **16** (16) relative to cyclohexane.

Chemical shift assignments for rings C and D were determined with the aid of the model compounds **5** and **6**, already discussed. The chemical shifts assigned to **6** served as a guide in assigning the substituted aromatic carbons of ring D. Selective proton decoupling was used to differentiate between C-11 and C-12. The exocyclic methylene of ring C was identified in a gated decoupling experiment. This resonance appears at 106.7 with $^1J\,^{13}C\,^1H = 160.6$ Hz.

The synthetic spiro ketone **1***b* was examined as a model for the sibiricine type alkaloids where we have examined three diastereomeric pairs, the compounds **1***c* and **1***d*, sibiricine **1***e* (17) and corydaine **1***f* (18), and raddeanone **1***g* (19) and yenhusomidine **1***h* (20), all of established stereochemistry (Fig. 3 and Table 3). The resonances of the carbon atoms of rings A and B of **1***b* were assigned through comparison with other benzylisoquinoline alkaloids that carry methylenedioxy substitution in ring A, e.g. hydrastine and berberine (2). The resonances of C-1 and C-4 were confirmed through selective proton decoupling. The fact that C-1 and C-4 are not equivalent as they are in ochotensimine may be a reflection of the difference in anisotropic shielding between the exocyclic methylene in **1***a* and the carbonyl in **1***b*. C-4*a* and C-14*a* follow the same trend observed in **1***a* but C-14*a* is less deshielded.

The chemical shifts of the aliphatic carbons of **1***b* are virtually identical with those of **1***a*. The indanone **8** serves as an excellent model for the carbons of rings C and D of **1***b*; however, one cannot differentiate between C-8*a* and C-9 because of their similar resonances.

Alkaloids of the sibiricine group differ from **1***b* by the presence of a hydroxy function at C-8

TABLE 3. ^{13}C chemical shifts of the spirobenzylisoquinoline alkaloids

	Compound									
Carbon	**1***a*	**1***b*	**1***c*	**1***d*	**1***e*	**1***f*	**1***g*	**1***h*	**1***i*	**1***j*

*These assignments may be reversed.

and may exist in diastereomeric forms. The chemical shift assignments for the synthetic compounds **1***c* and **1***d* follow directly from the model **1***b*. The ring D assignments for the pairs **1***e* and **1***f* and **1***g* and **1***h* were made by selective proton decoupling and by comparison with chemical shifts calculated for 4,5-methylenedioxy-1-indanone: C-3*a*, 135.2; C-4, 145.8; C-5, 153.6; C-6, 107.3; C-7, 116.6; C-7*a*, 130.2.

In **1***c*, C-8 and C-14 show the expected downfield shifts relative to **1***b* because of the α- and β-OH substituent effects, respectively. The carbonyl group is shielded by −4.0 ppm. In **1***d* there are a number of significant changes relative to its diastereomer. Hydrogen bonding between the hydroxy group and the nitrogen (18) causes slight conformational and electronic changes in the system resulting in a deshielding of C-8, C-6, and the *N*-methyl. At the same time C-14 is appreciably shielded. Differences of similar sign and magnitude are also observed between sibiricine (**1***e*) and corydaine (**1***f*) and raddeanone (**1***g*) and yenhusomidine (**1***h*). It is apparent then that ^{13}C nmr may be used to differentiate between diastereomers in this series of compounds.

Ochrobirine **1***i* and yenhusomine **1***j* (20) carry hydroxy groups in each of C-8 and C-13 and they represent another structural variation. We wished to determine if ^{13}C nmr could differentiate between C-8 and C-13 in these compounds and be used to assign the configuration of the hydroxy groups.

The data presented in Table 3 show that a number of significant chemical shift changes occur when corydaine **1***f* is transformed to ochrobirine **1***i*. Upon replacement of the carbonyl function by hydroxy, the aromatic carbon C-1 is deshielded by 3.9 ppm relative to corydaine while C-12 is shielded by −3.5 ppm. Examination of the aliphatic carbons of **1***i* indicates a distinct difference between C-8 and C-13. Selective proton decoupling was used to resolve these assignments since in the ^1H nmr spectrum of **1***i*, C-8 and C-13 hydrogens appear at 4.88 and 5.42 ppm, respectively (8). Although C-8 is shielded relative to that in corydaine **1***f*, C-8 is still downfield from the corresponding carbon in sibiricine (**1***e*) which indicates a retention of the corydaine relative configuration.

Of the ring B carbons of ochrobirine **1***i*, only C-14 has undergone a downfield shift whereas

C-5, C-6, and the *N*-methyl are shielded by −6.7, −2.6, and −4.0 ppm respectively, relative to corydaine **1***f*. The γ steric effect of the sp^3 centre at C-13 accounts for the shielding of C-6 and the *N*-methyl. Examination of molecular models demonstrates that the C-13 hydrogen and both the *N*-methyl and pseudo-axial C-6 hydrogen are quite sterically crowded when ring B adopts a half-chair conformation. Distortion of the B ring half-chair to a slightly more flattened conformation partially relieves these steric interactions while maintaining the internal hydrogen bond. This conformational change may contribute to the upfield shift of C-5.

Yenhusomine **1***j* is a *trans* diol like ochrobirine with the hydroxy at C-8 hydrogen bonded to nitrogen. The changes that occur in going from yenhusomidine **1***h* to yenhusomine exactly parallel those that take place in the corydaine to ochrobirine transformation. Unfortunately the *cis* diols were not available for examination. It is apparent that ^{13}C nmr is of value in the assignment of both gross structure and relative stereochemistry of the spirobenzylisoquinoline alkaloids.

Experimental

Apparatus, Methods, and Materials

Natural abundance ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WH-90 Fourier transform spectrometer at 22.62 MHz and a temperature of +35.0°C. Samples were 0.16 *M* to 0.41 *M* in $CDCl_3$; TMS was used as an internal reference. Field/frequency locking was provided by the deuterium signal of $CDCl_3$.

^1H nuclear magnetic resonance spectra were obtained on either a Varian HA-100 or a Varian EM-390 spectrometer in the frequency sweep mode. $CDCl_3$ and TMS were again used as solvent and internal reference, respectively.

Mass spectra were determined on a C.E.C. 21-110B mass spectrometer at an ionizing voltage of 80 eV and a source temperature of 200–250°C. Melting points were determined on a Kofler hot stage and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer 337 spectrometer. Thin layer chromatography was performed either on silica gel ($F\text{-}60_{254}$) or alumina. 1-Indanone and 1,3-indandione were obtained commercially. All other compounds were synthesized in this laboratory by standard procedures or isolated from natural sources: 1-methyleneindane **5** (21), 4,5-dimethoxy-1-indanone **8** (22), 6,7-methylenedioxy-1-indanone **9** (23), 2-phenyl-1,3-indandione **11** (24), 2-methylamino-2-phenyl-1,3-indandione **12** (25), spiro diones **13** and **14** (14), spiro ketone **1***b* (26), (±)-sibiricine **1***e* (27), (±)-corydaine **1***f* (27), (±)-raddeanone **1***g* (27), (±)-yenhusomidine **1***h* (27), (±)-ochrobirine **1***i* (27), (±)-yenhusomine **1***j* (27), (+)-ochotensimine **1***a* (28).

6-Deuterio-1-indanone

6-Amino-1-indanone (29) was diazotized and converted to its diazonium fluoborate (30). The solid fluoborate (210 mg) was added with vigorous stirring in portions to 4 ml of hypophosphorous acid-d_3 (4 ml) at −5 to 0°C. Stirring of the mixture was continued for 15 min after addition was complete and the mixture was allowed to stand in a refrigerator for 48 h before work-up. D_2O (10 ml) was added to the reaction mixture and the mixture was extracted with chloroform, the extract dried and evaporated, and the residue purified by tlc on alumina using $CHCl_3$ as eluent. The 6-deuterio-1-indanone (40 mg, 35%) so obtained gave the following analysis by mass spectrometry: d_0 31%; d_1 69%; ^1H nmr δ 2.75 (2H, m, CH_2CO), 3.21 (2H, m, benzylic CH_2), 7.62 (3H, m, aromatic H's).

Acknowledgments

We thank Mr. B. Sayer for his assistance in recording the ^{13}C spectra and the National Research Council of Canada for financial support.

Competitive adsorption of urea and Et_4NBr at the electrode/electrolyte interface

FRANK M. KIMMERLE AND HUGUES MÉNARD

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 9, 1976[1]

FRANK M. KIMMERLE and HUGUES MÉNARD. Can. J. Chem. **55**, 3312 (1977).

The simultaneous adsorption of urea and tetraethylammonium bromide has been investigated in ternary solutions varying in composition from 10^{-3} to 1 mol ℓ^{-1}. The adsorption of urea at the electrode/electrolyte interface can be described at low surface coverage by a Langmuir isotherm taking into account the surface unoccupied by the ionic components of the Et_4NBr salt. At high surface coverage, perturbation of Γ_{urea} by the simultaneous adsorption of the electrolyte is explained in terms of the lateral attractive forces previously observed in concentrated bulk solutions.

FRANK M. KIMMERLE et HUGUES MÉNARD. Can. J. Chem. **55**, 3312 (1977).

Nous avons étudié l'adsorption simultanée de l'urée et du bromure de tétraéthylammonium à l'interface électrode/électrolyte dans des solutions ternaires de composition variant de 10^{-3} à 1 mol ℓ^{-1}. L'adsorption de l'urée à l'interface électrode/électrolyte suit, à faible recouvrement de surface, l'isotherme de Langmuir en tenant compte de la surface non occupée par les composants ioniques du sel Et_4NBr. A recouvrement élevé, la perturbation du terme $\Gamma_{urée}$ par l'adsorption simultanée de l'électrolyte, est expliquée par des forces d'attraction latérales antérieurement observées en solutions concentrées.

Introduction

The interfacial region separates two regions: one which can be described by the bulk electrolyte properties, the other by the bulk electrode properties. While the anisotropic distribution of cations and anions in this 'electrical double layer region' may depend to a large degree on the electron charge density on the metal surface, the distribution of solvent molecules and neutral solutes can be expected to strongly reflect the bulk electrolyte properties. Knowledge of the bulk thermodynamic properties is thus essential for the study of the structure of the interfacial region; not only in order to calculate correctly the thermodynamic parameters of the interfacial region, but also in order to postulate models of the anisotropic structure in agreement with this experimentally accessible thermodynamic data.

The thermodynamics of aqueous urea solutions have been reviewed by Stokes (1), the thermodynamics of aqueous tetraalkylammonium solutions by Wen and Hung (2), and recently the ternary aqueous – urea – tetraalkylammonium bromide solutions have been examined by a number of workers (3–5). Schrier *et al.* (5) have succinctly summarized the Friedman cosphere model (6) as it applies to these results. Within slightly different frameworks, e.g. that of Desnoyers and Jolicoeur (7), or that of Parker (8), it is also taken for granted that urea salt solutions have less structure than pure water. Furthermore, it is admitted that entropy considerations are largely responsible for the negative free energy of transfer of R_4NBr to a more highly concentrated urea solution as well as the spontaneous transfer of urea to a R_4NBr solution.

The adsorption of Et_4NBr at the mercury/aqueous electrolyte interface has been studied by Verdier *et al.* (9), Piro *et al.* (10), and Ménard and Kimmerle (11). Piro *et al.* interpreted the adsorption over a range of 0.04 C m^{-2} at high negative potentials in terms of specific cation adsorption and postulated monolayer coverage by the cations ($r + \sim 4$ Å) in contact with each other. Just as Sarma and Ahluwalia (12) contend that the quaternary ammonium salts behave as soluble hydrocarbons with respect to the free energy of transfer, we have contended that Et_4NBr behaves in the interfacial region quite unlike the ionic alkali salts whose anionic and cationic attributes can be readily identified. Therefore, we have insisted (11) that Br^- and R_4N^+ ions are not adsorbed as separated entities and that one might treat instead the adsorption of an entity 'R_4NBr'.

[1]Revision received May 25, 1977.

The adsorption of urea had received little attention until Parsons *et al.* (13) recently undertook an experimental and theoretical study of the adsorption of urea from aqueous 1.0 *M* KNO_3 solutions. Although they neglected the activity coefficients of urea and employed instead the concentration terms in their data analysis, some very useful information was obtained. Weak lateral interactions of the adsorbed urea molecules and a Langmuir fit corresponding to a molecular area at saturation coverage of 24 $Å^2$ were reported. It was suggested that adsorbed urea molecules displace about three water molecules and that the urea is most strongly adsorbed at an electrode charge $q_M = +0.08$ C m^{-2} in a configuration with its dipole at a small angle to the surface. They also suggested that the nitrate ion modifies substantially the neighbouring water structure but in their numerical calculations did not explicitly consider interactions between the solvent shell of urea and the nitrate ion at the interface or in solution. The interpretation of the simultaneous adsorption of urea and Et_4NBr presents two challenges. (*i*) It is necessary to take into account the variation of activity coefficients of urea with varying salt concentration and vice versa. (*ii*) It is necessary to use a simple model of the interfacial region which will allow for the competitive adsorption. The first condition has only recently been examined for a ternary solution by Nakadomari *et al.* (14) who arranged to keep the activity of a Na_2SO_4 base electrolyte constant while varying the concentration of the 2-butanol solute. We chose to vary the concentrations of both the salt and neutral solute and to calculate both Γ_{urea} and Γ_{Et_4NBr} by use of the appropriate relationship (viz. eq. 4 *b* and *c* below). In order to meet condition (*ii*) the results presented here will emphasize the solution compositions where Γ_{urea} predominates, i.e., high urea and low Et_4NBr concentrations. We will extrapolate these results to Et_4NBr concentrations where the ionic population of the interfacial region is given by electrostatic considerations only. We will thus distinguish between three different types of phenomena in the interfacial region: (1) The adsorption of urea molecules on the electrode surface. (2) The attraction of Et_4NBr into the interfacial region. (3) The interaction between adsorbed urea molecules and adsorbed ionic components of the electrolyte.

Theory

A general electrocapillary equation for an ideally polarized electrode at constant pressure and temperature, where the indicator electrode is reversible with respect to the anion of a uni-univalent electrolyte can be written as:

$$[1]\quad d\gamma = -q_M\,dE^- - \Gamma_{1,h}\,d\mu_1 - \Gamma_{2,h}{}^+\,d\mu_2$$

where the subscripts 1 and 2 refer to the neutral and the ionic solute, respectively. The relative surface excess parameters can be given in terms of the mole fractions X_{urea}, X_{Et_4NBr}, X_{H_2O} and the experimentally inaccessible absolute surface excess, e.g.

$$[2]\quad \Gamma_{1,h} = \Gamma_{urea} - \frac{X_{urea}}{X_{H_2O}}\Gamma_{H_2O}$$

and

$$[3]\quad \Gamma_{2,h}{}^+ = \Gamma_{Et_4N^+} - \frac{X_{Et_4NBr}}{X_{H_2O}}\Gamma_{H_2O}$$

Differentiating [1] with respect to the activity of one solute at constant activity of the second solute will immediately yield the relative surface excess values: e.g.

$$[4a]\quad -(\partial\gamma/\partial\mu_1)_{E^-,\mu_2} = \Gamma_{1,h}$$

and

$$[5a]\quad -(\partial\gamma/\partial\mu_2)_{E^-,\mu_1} = \Gamma_{2,h}{}^+$$

This approach used by Nakadomari *et al.* (14) is very inconvenient to realize experimentally if both $\Gamma_{1,h}$ and $\Gamma_{2,h}{}^+$ are sought but it could be used with surface tension values interpolated from data obtained at fixed concentrations. Differentiating [1] with respect to the activity of one solute at constant molarity or molality of the second solute will yield two terms:

$$[4b]\quad -\left(\frac{\partial\gamma}{\partial\mu_1}\right)_{E^-,c_2\text{ or }m_2} = \Gamma_1' = \Gamma_{1,h} + \Gamma_{2,h}{}^+\left(\frac{\partial\mu_2}{\partial\mu_1}\right)_{c_2\text{ or }m_2}$$

and

$$[5b]\quad -\left(\frac{\partial\gamma}{\partial\mu_2}\right)_{E^-,c_1\text{ or }m_1} = \Gamma_2' = \Gamma_{2,h}{}^+ + \Gamma_{1,h}\left(\frac{\partial\mu_1}{\partial\mu_2}\right)_{c_1\text{ or }m_1}$$

where Γ_1' and Γ_2' are apparent surface excess values. Differentiating [1] with respect to the logarithm of the concentration will yield terms involving the activity coefficients f_1 and $f_{\pm,2}$.

$$[4c] \quad -\left(\frac{\partial\gamma}{RT\,\partial \ln c_1}\right)_{E^-,c_2} = \Gamma_{1,h} \times \left(1 + \frac{\partial \ln f_1}{\partial \ln c_1}\right)_{c_2} + 2\Gamma_{2,h}{}^{+}\left(\frac{\partial \ln f_{\pm,2}}{\partial \ln c_1}\right)_{c_2}$$

and

$$[5c] \quad -\left(\frac{\partial\gamma}{2RT\,\partial \ln c_2}\right)_{E^-,c_1} = \Gamma_{2,h}{}^{+} \times \left(1 + \frac{\partial \ln f_{\pm,2}}{\partial \ln c_2}\right)_{c_1} + \Gamma_{1,h}\left(\frac{\partial \ln f_1}{2\,\partial \ln c_2}\right)_{c_1}$$

The latter approach has frequently been used in the past but all terms involving the activity coefficients have generally been neglected.

Activity coefficients can be calculated from potentiometric results, although isopiestic results lead to unequivocal interpretations and are to be preferred (5), particularly if solute 1 may be thought to influence one ion of the solute 2 differently than its counterion. Such data were not available for aqueous urea Et_4NBr solutions, although Wen and Chen (3) have calculated the activity coefficients of the ternary solutions of urea, Me_4NBr, or Bu_4NBr. Interpolation from these systems is necessary in order to estimate μ_{Et_4NBr} at varying urea concentrations and μ_{urea} at varying Et_4NBr concentrations. Furthermore, it is necessary to estimate the derivative of the activity coefficients of one solute at fixed concentration with respect to concentration of the second solute.

As can be expected, the activity corrections given by the second terms on the right-hand side of [4*b*] and [5*b*] become important at high solute concentrations. Increasing the urea concentration depresses the activity of Et_4NBr and vice versa. $(\partial\mu_2/\partial\mu_1)_{c_2 \text{ or } m_2}$ and $(\partial\mu_1/\partial\mu_2)_{c_1 \text{ or } m_1}$ are therefore both negative quantities. For ternary solutions involving strong salting out (e.g. the butanol solutions (14)) the opposite trends are observed. Neglecting these changes in bulk solution activity and retaining only the first term of [4*c*] or [5*c*] would lead to erroneous high Γ values for solutions having less structure than bulk water and to erroneous low Γ values for ternary solutions having greater structure.

Experimental

The surface tension values were calculated from drop-time measurements using the computational techniques and instrumentation described previously (11).

Solutions were used within 24 h of preparation from water twice distilled from alkaline permanganate, Et_4NBr (Eastman Kodak Co.) recrystallized twice from ethanol, and urea (Baker Chem. Co.). We recorded drop-time for eight concentrations of urea varying from 0.005 to 2 *M* and for nine concentrations of Et_4NBr varying from 0.0025 to 1 *M* over 1.4 V intervals. Eighty-one different solution compositions were thus investigated in order to determine simultaneously the surface excess of the ionic species $\Gamma_{Et_4N^+}$ and Γ_{Br^-} and the surface excess of the neutral molecule, Γ_{urea}. Electrode potentials, E^-, were calculated with respect to a reversible Br^- electrode and verified by measuring the potential difference between a saturated calomel and a specific Br^- electrode (Orion 94-35A) in the urea–Et_4NBr solutions. All experiments were carried out at 25.0 ± 0.05°C.

Results and Discussion

Interpolation of Activity Coefficients

Wen and Chen (3) have shown that the molal activity coefficient of the nonelectrolyte γ_1 and the mean molal activity coefficient of the electrolyte $\gamma_{\pm,2}$ in a ternary system urea – tetraalkylammonium bromide – water may be expressed as a function of the concentration of the nonelectrolyte m_1 and the electrolyte m_2. Schrier *et al.* (5) used a somewhat simpler expression:

$$[6] \quad \log \gamma_1/\gamma_1{}^0 = -m_2\{g_{12}{}^{(0)} + \tfrac{2}{3}g_{12}{}^{(1)}\, m_2{}^{1/2} + g_{12}{}^{(2)}\, m_1\}$$

to express γ_1 in terms of the activity coefficient in the binary solution, $\gamma_1{}^0$, and a correction term, the right-hand side of [6]. Although $\log \gamma_1/\gamma_1{}^0$ and also $\log \gamma_{\pm,2}/\gamma_{\pm,2}{}^0$ differ somewhat with the nature of the electrolyte, as illustrated in Fig. 1,

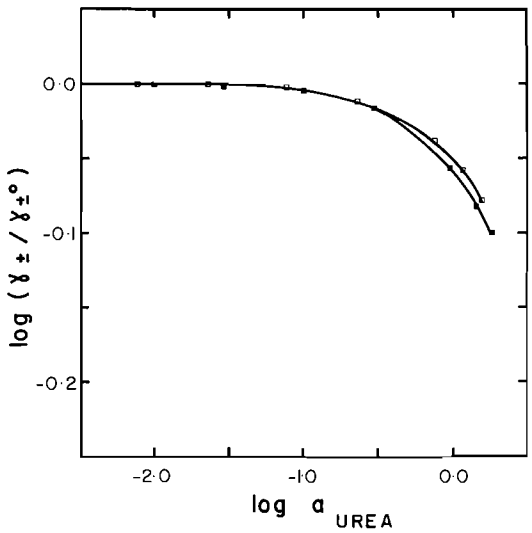

FIG. 1. Mean molal activity coefficient of Et_4NBr vs. activity of urea in a ternary Et_4NBr–urea–H_2O solution: ■ 0.01 *M* Et_4NBr, □ 1.0 *M* Et_4NBr.

for $(\log \gamma_{\pm,2}/\gamma_{\pm,2}{}^0)$ in Me_4NBr and Bu_4NBr solutions, this variation is surprisingly small. The correction terms become appreciably large for $m_1 > 0.1$ *m* and vary slightly more as a function of urea concentration at low electrolyte concentrations. The difference in the behaviour of the two salts becomes more apparent at high urea concentrations. Similarly, the differences in the behaviour of the urea molecule in Me_4NBr or Bu_4NBr solutions become somewhat more appreciable at high electrolyte concentrations. Since these correction terms reflect the effects of the interactions between the nonelectrolyte and electrolyte solutes it is to be expected that the chemical nature of the species would manifest itself when three or more solute particules are likely to interact.

Nevertheless, even at the highest concentrations employed, 2 *m* urea and 1 *m* R_4NBr, the differences in the correction terms for Me_4NBr and Bu_4NBr, Fig. 1, are less than 0.08 units. We therefore suggest that

$$[7]\quad (\ln \gamma_{\pm,2}/\gamma_{\pm,2}{}^0)_{Et_4NBr} = \tfrac{1}{2}\{(\ln \gamma_{\pm,2}/\gamma_{\pm,2}{}^0)_{Me_4NBr} + (\ln \gamma_{\pm,2}/\gamma_{\pm,2}{}^0)_{Bu_4NBr}\}$$

and

$$[8]\quad (\ln \gamma_1/\gamma_1{}^0)_{Et_4NBr} = \tfrac{1}{2}\{(\ln \gamma_1/\gamma_1{}^0)_{Me_4NBr} + (\ln \gamma_1/\gamma_1{}^0)_{Bu_4NBr}\}$$

constitute approximations for the activity coefficients in the ternary system Et_4NBr–urea–water to within 0.04 units. When $\gamma_{urea}{}^0$ and the right-hand sides of [7] and [8] are calculated from the data of Wen and Chen (3), and $\gamma^0{}_{\pm,Et_4NBr}$ taken from the work of Lindenbaum and Boyd (15), γ_{urea} and $\gamma_{\pm,Et_4NBr}$ are likely to be correct to within 1% for all but the most concentrated solutions examined.

Calculation of Relative Surface Excess Values

In order to verify that adsorption equilibrium had been attained within less than 5 s, we re-examined by the droptime technique the urea – 1 *M* KNO_3 solutions recently studied by Parsons *et al.* (13). The surface pressure curves as calculated from droptime data are in agreement with those calculated from differential capacitance data as are the surface excess results up to a concentration of 2 *M* in urea.

Typical electrocapillary results in Et_4NBr solutions containing up to 2 *M* urea are not remarkably different from those containing no urea. The influence of electrolyte concentration on the electrocapillary curves at varying urea concentrations is much more remarkable. At the lower Et_4NBr concentrations, 0.01 *M* Et_4NBr, the series of curves resemble that found for 1.0 *M* KNO_3. At higher concentrations, 0.1 *M* Et_4NBr, the family of curves has shrunk and at 1.0 *M* Et_4NBr the curves at different urea concentrations become practically indistinguishable. The surface pressure curves for the adsorption of urea are congruent with respect to charge in 1 *M* KNO_3 and in Et_4NBr at the concentrations below 0.01 *M*. Above these concentrations, charge congruency is not observed and the surface pressure values have considerably diminished.

This behaviour is even more clearly illustrated in Fig. 2 by the variation of Γ_{urea,H_2O} with surface charge. Whereas in Fig. 2*a* at 0.01 *M* Et_4NBr, the adsorption of urea tends toward a maximum at $q_M = +0.08\ C\ m^{-2}$ and resembles that found for 1.0 *M* KNO_3 solutions, no maximum is attained in Fig. 2*b* at 0.1 *M* Et_4NBr. At intermediate and high Et_4NBr concentrations, Γ_{urea,H_2O} is depressed considerably showing little charge dependency, Fig. 2*c*. Both the incongruency of the surface pressure curves, and the variation of charge dependence illustrated in Fig. 2*b* indicate strong lateral interactions involving adsorbed urea molecules. These interactions evidently also involve the adsorbed ionic species. It is generally accepted that adsorbed solute molecules replace adsorbed water molecules and that adsorbed ions replace adsorbed water molecules or at least influence their orientation. The free surface area open for this competition thus diminishes if the fractional surface coverage, θ_{urea}, or the surface excess of ionic components increase.

As indicated, apparent and relative surface excess values differ by the term $\Gamma_{2,h}{}^+ (\partial\mu_2/\partial\mu_1)$. In Fig. 3, Γ' at 0.1 *M* Et_4NBr is given to illustrate this point. The apparent values are consistently lower and in error by as much as 50% at negative charges with respect to the true values, Fig. 2*b*. At yet higher Et_4NBr concentrations this difference is even more important. In the past, calculations of apparent surface excess values have been made using the solute concentration instead of the solute activity in [2]. Since a_{solute} is normally less than [solute] even smaller values of apparent surface excess values would be obtained if such an erroneous data treatment were adopted here.

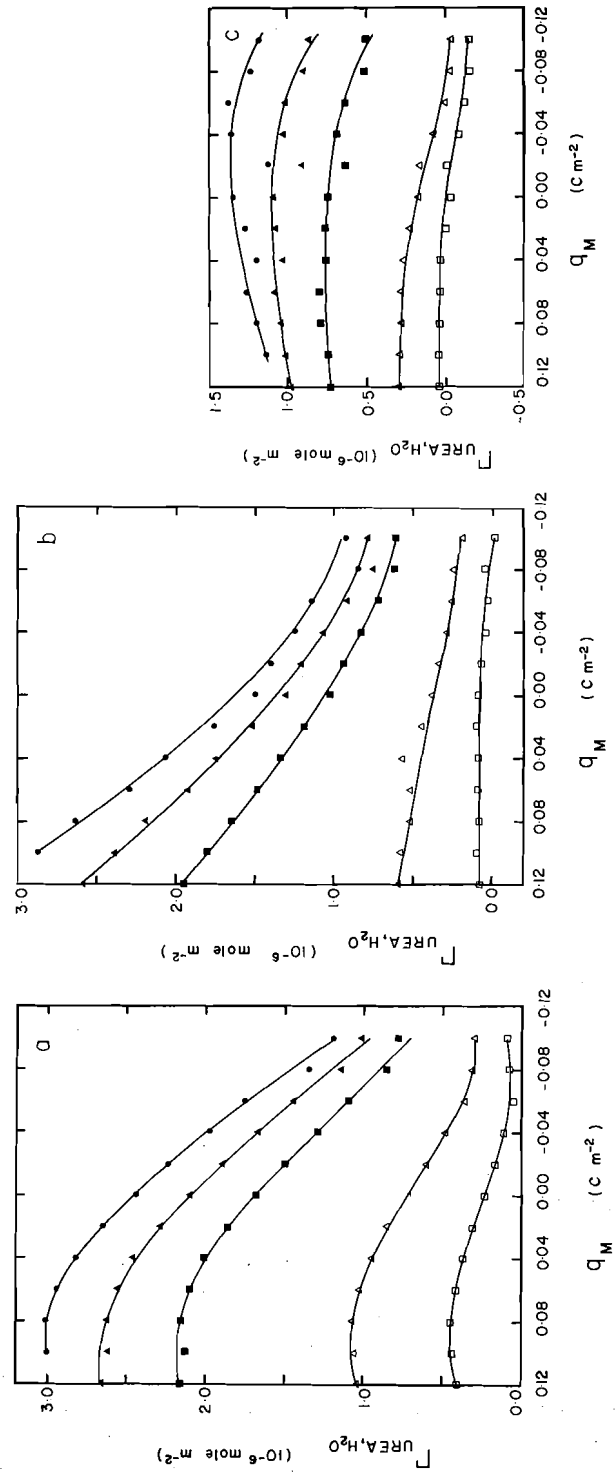

FIG. 2. (*a*) Surface excess Γ_{urea,H_2O} vs. surface charge at 0.01 *M* Et_4NBr: □ 0.1 *M*, △ 0.3 *M*, ■ 1.0 *M*, ▲ 1.5 *M*, ● 2.0 *M* urea. (*b*) Surface excess Γ_{urea,H_2O} vs. surface charge at 0.1 *M* Et_4NBr. Scale and symbols as in Fig. 2*a*. (*c*) Surface excess Γ_{urea,H_2O} vs. surface charge at 1.0 *M* Et_4NBr. Scale and symbols as in Fig. 2*a*.

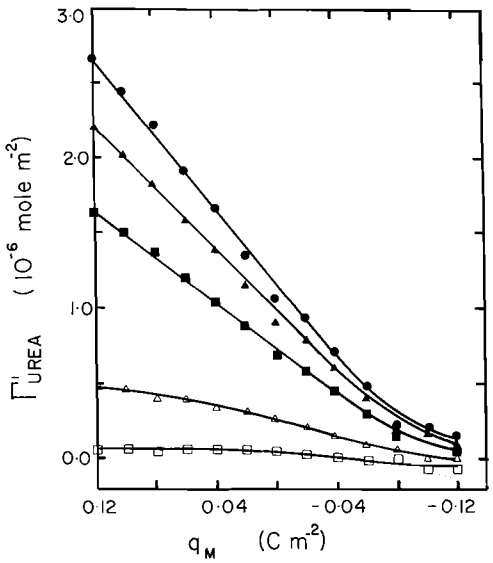

FIG. 3. Apparent surface excess Γ_{urea}' vs. surface charge at 0.1 *M* Et_4NBr. Scale and symbols as in Fig. 2*a*.

It cannot be denied that the injudicious treatment of thermodynamic data can lead to erroneous results difficult to interpret in terms of simple microscopic models. We should therefore view with caution any explanation of double layer phenomena in ternary systems unless it is established that the activity corrections have been applied or that they are indeed of negligible magnitude.

The ternary system urea–R_4NX–water reflects the behaviour of two binary systems: urea–water and R_4NX–water. Whereas the adsorption of R_4NX at different electrode charges can be studied, the system urea–water cannot be investigated directly without an electrolyte. However, extrapolating the surface excess value Γ_{urea,H_2O} to low electrolyte concentrations should yield results corresponding to the binary urea–water system. Thus

$$[9] \qquad \lim_{a_2 \to 0} \{\Gamma_{1,h}\} = \Gamma_{1,h} \quad (a_2 = 0)$$

However, plotting $\Gamma_{1,h}$ as a function of a_2 does not permit a linear extrapolation and involves highly curved regions at low Et_4NBr concentrations. Indeed, it would be surprising if the surface activity of urea varied linearly with the bulk Et_4NBr electrolyte activity. It is more useful to carry out the extrapolation with respect to the Et_4NBr population of the interfacial region itself.

It is possible (11) to divide the ionic surface excess $\Gamma_{2,h}^{+}$ into electrostatic and nonelectrostatic contributions:

$$[10] \qquad \Gamma_{2,h}^{+} = \Gamma_2^{+}\ \text{Electrostatic} + \Gamma_2^{\Delta}$$

where

$$\Gamma_2^{+}\ \text{Electrostatic} = A\ [\exp -(\sinh^{-1}(q_M/2A)) - 1]$$

and

$$A = (RT\varepsilon c/2\pi)^{1/2}$$

Extrapolating the surface excess Γ_{urea,H_2O} to a double layer composition where anions and cations are found only in the Outer Helmholtz region, i.e., where $\Gamma^{\Delta}_{Et_4NBr} = 0$, was carried out as in Fig. 4. The extrapolation is fairly linear, and the intercepts

$$[11] \qquad \lim_{\Gamma_2^{\Delta} \to 0} \{\Gamma_{1,h}\} = \Gamma_{1,h}^{0} \quad (\Gamma_2^{\Delta} = 0)$$

It now becomes possible to plot the isotherms for the adsorption of urea at different electrode charges without needing to consider the nature of the electrolyte. Such a plot is given in Fig. 5.

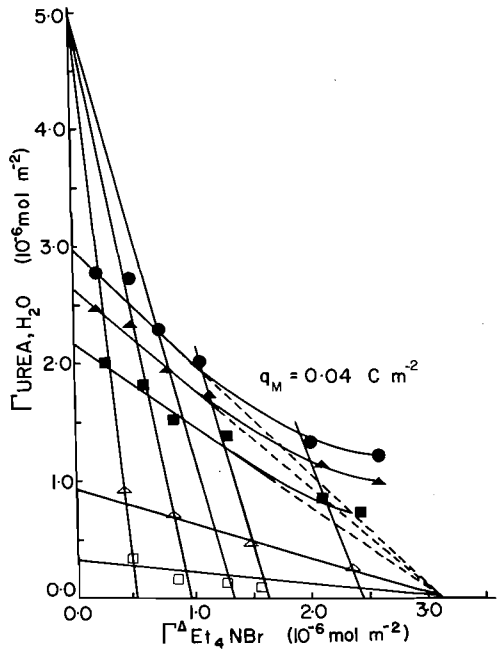

FIG. 4. Surface excess Γ_{urea,H_2O} vs. surface excess $\Gamma^{\Delta}_{Et_4NBr}$ at $q_M = 0.04$ C m^{-2} at fixed urea concentrations: □ 0.1 *M*, △ 0.3 *M*, ■ 1.0 *M*, ▲ 1.5 *M*, ● 2.0 *M* urea and at fixed Et_4NBr concentrations (left to right) 0.005, 0.01, 0.025, 0.05, 0.1, 0.5, 1.0 *M* Et_4NBr (10^{-6} mol m^{-2}) vs. (10^{-6} mol m^{-2}).

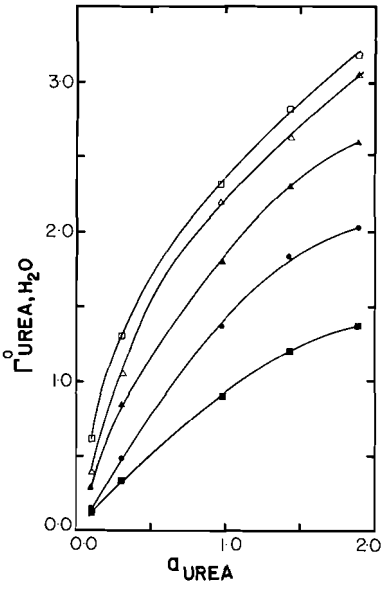

FIG. 5. Surface excess Γ^{o}_{urea,H_2O} extrapolated to $a_{Et_4NBr} = 0$ vs. activity of urea: $q_M = 0.08$, 0.04, 0.0, −0.04, −0.08 C m^{-2}.

Although different adsorption isotherms have been used (16) the Langmuir isotherm and variations thereof describe adequately the adsorption of simple molecules at the electrode/electrolyte interface. For the adsorption of a neutral solute (1) we may write:

$$[12] \quad \beta_1 a_1 = \theta_1/1 - \theta_1, \quad \theta_1 = \Gamma_1/\Gamma_{1\,max}$$

where $\beta_1 = \exp -(\Delta\bar{G}_1^{o}/RT) \exp -(g_1/RT)$ and where $\Delta\bar{G}_1^{o}$ is the free energy of adsorption of solute 1 and g_1 is a function of electrode charge, and where $\Gamma_{1\,max}$ is the surface excess corresponding to monolayer coverage.

Although we recognize that the Langmuir isotherm is unlikely to describe adequately the adsorption of the ionic components of an electrolyte, it is useful to employ this mathematical framework in order to describe the competitive adsorption of two solutes. For the simultaneous adsorption of two solutes (1) and (2) we may suppose that:

$$[13] \quad \beta_1' a_1 = \frac{\theta_1}{1 - \theta_1 - \theta_2}$$

where

$$\beta_2' = \beta_1 \exp -(\Delta\bar{G}_{1,2}/RT)$$

and where $\Delta\bar{G}_{1,2}$ refers to the lateral interaction energy between two adsorbed solutes (1) and (2).

The surface coverage θ_1 will diminish when θ_2 or $\beta_2' a_2$ becomes appreciably large, even in the absence of intersolute interactions. Since the surface activity of urea is considerably less than that of the tetraalkylammonium salt, θ_{urea} is expected to diminish by the simultaneous adsorption of the electrolyte.

The free energy terms β_1 and β_2 are normally charge dependent variables. The variation with charge of θ_1 will therefore be influenced by the variation of θ_2. If $\Delta\bar{G}_{1,2} = 0$, θ_1 should decrease most appreciably at those values of q_M where θ_2 becomes most significant because of increased competition for the space occupied by adsorbed water molecules. If $\Delta\bar{G}_{1,2} < 0$, the adsorption of the more weakly adsorbed species, here species (1), will be somewhat enhanced, particularly so at charges where solute (2) is strongly adsorbed.

We hesitate to identify θ_2 in the case of electrolytes although we recognize that the accepted mathematical treatment separates the ions into 'specifically' or 'contact' adsorbed and electrostatically adsorbed species. Different assumptions concerning the relative strength of the specific adsorption of the cation and anion will lead to different anion and cation profiles as a function of the distance from the electrode (17). At $q_M = 0$, the use of $\Gamma^{\Delta}_{Et_4NBr}$, the quantity of Et_4NBr adsorbed beyond that predicted from electrostatic behaviour, does not in itself presume any particular concentration profile. The use of $\theta_2 = \Gamma_2^{\Delta}/\Gamma_{2\,max}^{\Delta}$ in a Langmuir type isotherm does however presume adsorption of anion–cation pairs on the electrode surface. We shall examine the results for the ternary urea–Et_4NBr–water system to see to what degree this simplification is justified. A Langmuir type isotherm, [12], was imposed on the data given in Fig. 6 by a least-squares fit, varying $\Gamma_{1\,max}$ from 4×10^{-6} to 6×10^{-6} mol m^{-2} to obtain a concentration independent value of β_1. The results plotted in Fig. 6 indicate clearly, in agreement with Parson's conclusions (13), that little interaction exists between adsorbed urea molecules. We find $\Gamma_{max}^{urea} = 4.96 \times 10^{-6}$ mol m^{-2}, significantly less than that calculated by Parsons by neglecting activity coefficients in 1 M KNO_3. Our value in infinitely dilute electrolyte would allow full rotational freedom for the adsorbed molecule. In the absence of nonelectrostatic adsorption of Et_4NBr, the adsorption of urea follows a relatively simple pattern with a free energy of adsorption symmetrical about $q_M^{max} = +0.08$ C m^{-2}. A parabolic charge dependence was ob-

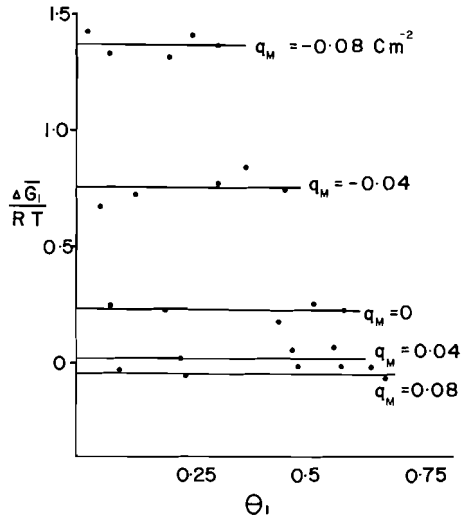

FIG. 6. Free energy of adsorption of urea vs. θ_{urea}. Calculated for $\Gamma_{max}^{urea} = 4.96 \times 10^{-6}$ mol m^{-2}: q_M = 0.08, 0.04, 0.0, −0.04, −0.08 C m^{-2}.

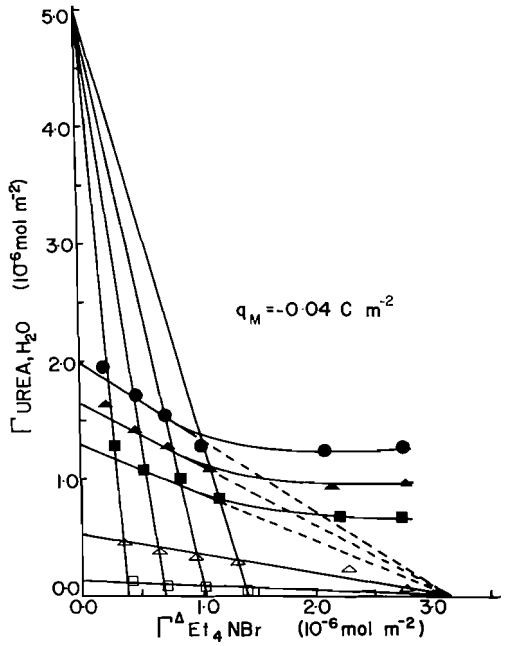

FIG. 7. Surface excess Γ_{urea,H_2O} vs. surface excess $\Gamma^{\Delta}_{Et_4NBr}$ at $q_M = -0.04$ C m^{-2}. Symbols as in Fig. 4.

served with $g_1/RT \propto -(q - q_{max})^2$, as expected if urea replaces absorbed water molecules.

Equation 12 constitutes a satisfactory description of the binary system. We can now examine Figs. 4 and 7 to see to what extent [13] describes the ternary system.

At any given urea activity a linear relationship exists between Γ_{urea,H_2O} and $\Gamma^{\Delta}_{Et_4NBr}$ at low Et_4NBr concentrations. Similarly, at any given salt activity a quasi-linear relationship is found, although the variations of $\Gamma^{\Delta}_{Et_4NBr}$ are slight and of the same magnitude as the experimental uncertainty. Extrapolation of $\Gamma^{\Delta}_{Et_4NBr}$ to $\Gamma_{urea} = 0$ yields values unaffected by the presence of adsorbed urea molecules and identical to those observed in binary solutions. Extrapolation of Γ_{urea,H_2O} to $\Gamma^{\Delta}_{Et_4NBr} = 0$ yields Γ^{0}_{urea,H_2O} whose numerical value is thought to be relatively little influenced by the chemial nature of the quaternary ammonium salts.

The intercepts Γ^{0}_{urea,H_2O} ($\Gamma^{\Delta} = 0$) at values of q_M from $q_M = +0.08$ to -0.08 C m^{-2} were used to establish an unique value of Γ_{max}^{urea} as indicated above. An attempt to evaluate Γ_{max}^{Δ} from a Langmuir isotherm at different values of q_M was not successful. Obviously the Langmuir model which supposes monolayer coverage and absence of lateral interactions is inadequate to describe the adsorption of an electrolyte. The value $\Gamma^{\Delta}_{max} = 3.15 \times 10^{-6}$ mol m^{-2} obtained by linear extrapolation of data such as in Figs. 4 and 7 is nevertheless in good agreement with that calculated from the theoretical model of the surface occupied by the voluminous cation (18).

From these two values, Γ_{max}^{urea} and Γ_{max}^{Δ}, obtained in 'binary' solutions, we can calculate θ_1 and θ_2 and evaluate [13] in the ternary solutions. Competition for the number of sites available is probably the underlying cause for the linear portions in Figs. 4 and 7. At low surface coverage $\Delta\bar{G}_{1,2} \simeq 0$ and little lateral interaction between adsorbed urea and adsorbed Et_4NBr is evident. Thus $(\theta_1 + \theta_2)$ remain relatively constant provided that a_1 or a_2 is held fixed. At high surface coverage θ_2, and fixed activity a_1, the lateral interaction term $\exp -(\Delta\bar{G}_{1,2}/RT)$ (eq. 13) is responsible for attracting increased amounts of species (1). Similarly, at high surface coverage θ_1, and fixed activity a_2, more species (2) are attracted than would be predicted if no lateral interactions existed. Again, the overwhelming surface activity of Et_4NBr vs. urea is such that the lateral urea–Et_4NBr interactions have a more prominent effect (at all surface charges) on the adsorption of urea than on the adsorption of Et_4NBr.

Interactions between adsorbed urea molecules are minimal, perhaps because appreciably large surface coverages were not attained, $\theta_{urea} < 0.6$. The perturbation due to adsorbed ionic components of Et_4NBr can be rationalized in a

manner analogous to the free energy of transfer of urea from a binary aqueous solution to a ternary Et_4NBr–urea–water solution. The overlap of a structure breaking type II_{sb} cosphere (5) of the Br^- ion with that of urea will lead to a relaxation of unstructures water to bulk water and a concomitant loss of enthalpy and entropy. In homogeneous solution this overlap leads to negative values of the free energy. In homogeneous solution a similar contribution due to the Et_4N^+ is thought to be minor. At the interface the analogous overlap of the hydration shells could also be responsible for the negative value of $\Delta\bar{G}_{1,2}$. For any given $\Gamma^{\Delta}_{Et_4NBr}$, this effect is relatively charge independent (viz. Figs. 4 and 7) and is consistent with the underlying assumption for the adsorption of Et_4NBr, namely that both anion and cation are found in the Inner Helmholtz Layer.

Conclusions

For ternary systems, surface excess values, Γ_{1,H_2O}, obtained at fixed concentration of species (2) should be calculated according to [4] and [5]. Neglect of the activity corrections would lead to erroneous results for urea–Et_4NBr–H_2O solutions. Since Et_4NBr is much more readily adsorbed than urea at the mercury/electrolyte interface, it competes most successfully for vacant sites and displaces adsorbed urea molecules at all but the highest concentrations and for $q_M \gg 0$. At high surface coverage, lateral attractive forces between adsorbed urea and Br^- species are probably due to overlap of hydration cospheres similar to that found in concentrated ternary solutions.

Arrhenius parameters for the reactions of $O(^3P)$ atoms with several aldehydes and the trend in aldehydic C—H bond dissociation energies[1]

D. L. SINGLETON, R. S. IRWIN, AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received March 23, 1977

D. L. SINGLETON, R. S. IRWIN, and R. J. CVETANOVIĆ. Can. J. Chem, **55**, 3321 (1977).

The phase-shift technique has been used to determine the temperature dependence of the reaction of ground state oxygen atoms with several aldehydes. Oxygen atoms were generated by modulated photosensitized decomposition of nitrous oxide and were monitored by the chemiluminescence from their reaction with nitric oxide. The Arrhenius expressions determined over the temperature interval 298–472 K are: k_1(acetaldehyde) = $(7.21 \pm 1.49) \times 10^9 \exp(-1960 \pm 153/RT)$; k_1(propionaldehyde) = $(7.78 \pm 0.75) \times 10^9 \exp(-1727 \pm 66/RT)$; k_1(butyraldehyde) = $(9.99 \pm 0.56) \times 10^9 \exp(-1702 \pm 40/RT)$; k_1(isobutyraldehyde) = $(7.92 \pm 1.02) \times 10^9 \exp(-1445 \pm 91/RT)$, where the units are ℓ mol^{-1} s^{-1} and cal mol^{-1}. The indicated uncertainties are one standard deviation. After small corrections were made for the potential abstraction of alkyl hydrogens, the activation energies of aldehydic hydrogen abstraction were used to estimate the aldehydic C—H bond dissociation energies, D(RCO—H). The trend of slightly decreasing values of D(RCO—H) thus obtained for the sequence H_2CO, CH_3CHO, C_2H_5CHO, n-C_3H_7CHO, i-C_3H_7CHO was also indicated by the aldehydic C—H stretching frequencies.

La technique de déphasage est utilisée afin de déterminer l'effet de la température sur la réaction de l'oxygène atomique à l'état fondamental avec plusieurs aldéhydes. Les atomes d'oxygène sont formés par décomposition photosensibilisée de l'oxyde nitreux. Ces atomes sont ensuite mesurés par chemiluminescence résultant de leur réaction avec l'oxyde nitrique. Les expressions d'Arrhénius déterminées pour l'écart de température 298–472 K sont: k_1(acétaldéhyde) = $(7.21 \pm 1.49) \times 10^9 \exp(-1960 \pm 153/RT)$; k_1(propionaldéhyde) = $(7.78 \pm 0.75) \times 10^9 \exp(-1727 \pm 66/RT)$; k_1(butyraldéhyde) = $(9.99 \pm 0.56) \times 10^9 \exp(-1702 \pm 40/RT)$; k_1(isobutyraldéhyde) = $(7.92 \pm 1.02) \times 10^9 \exp(-1445 \pm 91/RT)$, avec les unités exprimées en ℓ mol^{-1} s^{-1} et cal mol^{-1}. Les incertitudes indiquées correspondent à l'écart type. Après avoir fait les corrections pour l'abstraction possible des hydrogènes d'un groupe alkyle, les énergies d'activation de l'abstraction d'un hydrogène aldéhydique sont utilisée afin d'évaluer les énergies de dissociation du lien carbone hydrogène D(RCO—H). La tendance qu'ont les valeurs à décroître légèrement dans la série H_2CO, CH_3CHO, C_2H_5CHO, n-C_3H_7CHO, i-C_3H_7CHO est indiquée aussi par les fréquences d'élongation du lien C—H.

[Traduit par le journal]

Introduction

The reactions of ground state oxygen atoms with aldehydes occur in the initiating stages of photochemical smog and in the combustion of aldehydes. In the primary step for the reaction of $O(^3P)$ with acetaldehyde at 298 K, reactive acetyl and hydroxyl radicals are formed by abstraction of hydrogen from the aldehydic group (1, 2). An analogous mechanism should occur for the other aldehydes, and has indeed been shown to occur for the simplest member of the series, formaldehyde (3–5).

Kinetically obtained thermochemical data for various aldehydes indicate that the bond dissociation energies of the aldehydic hydrogen are about the same, within 1 or 2 kcal mol^{-1} (6). However, the reported rate constants and Arrhenius parameters for the $O(^3P)$ + aldehyde reactions are significantly different for the simpler aldehydes and do not appear to follow a consistent trend. The preferred room temperature rate constant for formaldehyde has recently been given as 0.9×10^8, and for acetaldehyde, 3.1×10^8 ℓ mol^{-1} s^{-1} (7). Nearly identical values of 1.4 and 1.5×10^8 have been reported for propionaldehyde (8) and butyraldehyde (9). Activation energies of 2.6, 2.3, and 3.8 kcal mol^{-1} have been reported for formaldehyde (10), acetaldehyde (11), and propionaldehyde (8).

[1]NRCC No. 16096.

Almost all the available values of the rate constants for the reactions of $O(^3P)$ with aldehydes have been determined by the discharge-flow technique. It is desirable to verify the values of these rate constants by an independent technique in order to establish the actual sequence of reactivity and the trends in the values of the Arrhenius parameters.

The modulated chemiluminescence ('phase-shift') technique has been used previously in this laboratory to determine rate constants and Arrhenius parameters for the addition of $O(^3P)$ atoms to several olefins (12). The rate constants determined with this technique were precise, and the agreement with the flash photolysis–resonance fluorescence results and the competitive (product analysis) results was generally very good. In the present work we use the modulated chemiluminescence technique to determine the temperature dependence of the rate constants for the abstraction reactions of $O(^3P)$ with acetaldehyde, propionaldehyde, butyraldehyde, and isobutyraldehyde. Estimates of the aldehydic C—H bond dissociation energies are made, based on correlations with (*1*) the activation energies for abstraction by $O(^3P)$ and (*2*) the aldehydic C—H stretching frequencies.

Experimental

Details of the experimental technique have been given previously (13–15). Ground state oxygen atoms are generated by modulated mercury photosensitized decomposition of nitrous oxide in a flowing mixture of Hg, N_2O, NO, and aldehyde. The $O(^3P)$ atoms react with both nitric oxide and aldehyde.

[1] $$O(^3P) + RCHO \rightarrow OH + RCO$$

[2] $$O(^3P) + NO + M \rightarrow NO_2 + M$$

The reaction with NO produces the well known NO_2 chemiluminescence, the intensity of which is also modulated. The phase difference between the 254 nm light, which initiates the reaction sequence, and the chemiluminescence is the primary measurement and is related to the rate constants k_1 and k_2 for reactions 1 and 2,

$$\frac{2\pi\nu}{\tan\phi} = k_1[RCHO] + k_2[NO][M]$$

where ϕ is the phase shift and ν is the modulation frequency. The phase shift is measured with photomultipliers and a lock-in amplifier.

The flow rate of N_2O was determined by a frequently calibrated rotameter. The flow rates of NO and the aldehydes were determined by calibrated capillaries. The pressure drops across the capillaries were measured with a DC-704 silicone oil manometer in the case of nitric oxide, and with an electronic pressure transducer (Dynisco DPT 85-2 or Decker 306) in the case of the aldehydes. Flows of the aldehydes were controlled by stainless steel bellows sealed needle valves. Teflon stopcocks with which the aldehydes came in contact were provided with ethylene propylene rubber O-rings.

At each of the experimental temperatures between 298–472 K, the following conditions were used. The modulation frequency was usually varied by a factor of two within the range 1500–8000 Hz. Experiments were done at both 30 and 60 Torr, except for butyraldehyde and isobutyraldehyde for which experiments were done only at 30 Torr because of difficulties associated with their lower volatilities. The NO concentration was 5 to 10% of the N_2O concentration, and the aldehyde concentration was varied from about 1–10% of the N_2O concentration.

The rate of absorption of 254 nm radiation, less than 1×10^{12} quanta cm^{-3} s^{-1}, was determined by gas chromatographic analysis of the products of the reaction: $O(^3P)$ + 1-butene.

All the aldehydes were obtained from Eastman Organic Chemicals, except isobutyraldehyde which was obtained from Anachemia. The aldehydes were distilled into a storage reservoir with care being taken always to maintain the aldehydes above their melting points to reduce polymerization. Gas chromatographic analysis on β,β′-thiodipropionitrile and β,β′-thiodipropionitrile + squalane capillary columns gave the following detectable impurity levels: acetaldehyde, <0.01%; propionaldehyde, 0.09% (0.05% as butyraldehyde); butyraldehyde, 0.01% (as isobutyraldehyde); isobutyraldehyde, 0.01%. Nitrous oxide and nitric oxide were obtained from Matheson. The nitric oxide was passed through Linde 13X molecular sieve to remove traces of NO_2.

Results

In the present experiments, an emission signal could be detected when only Hg, N_2O, and aldehyde were irradiated with the modulated low pressure mercury lamp. The intensity of the emission signal was proportional to the aldehyde concentration. A Corning 2-61 filter effectively blocked the extraneous emission, and transmitted the longer wavelength portion of the NO_2 chemiluminescence. The measured chemiluminescence intensity was decreased by about a factor of 2.5, relative to the intensity detected with the previously used 3-70 filter. This caused a corresponding decrease in the signal to noise ratio. It was estimated that the extraneous emission signal contributed less than 5% error to the measurement of tan ϕ. The error approached this value for only three points; usually it was much less.

The extraneous emission proved to be fluorescence from the aldehydes excited by absorption of the 313 nm line from the modulated low pressure mercury lamp. The spectrum of the

[b]Values were calculated from the Arrhenius expression, determined for k_2 in mixtures of Hg, N_2O, and NO, reported in ref. 15.

emission from irradiated isobutyraldehyde + mercury, determined with a Bausch and Lomb monochromator and EMI 9558 photomultiplier, extended from 364 nm to beyond 500 nm with a maximum at about 418 nm. Also, the extraneous emission was eliminated when the 313 nm line was removed by placing an interference filter (center wavelength ~254 nm) between the Hg lamp and the reaction cell. The emission spectrum is similar to the reported fluorescence spectrum of acetaldehyde excited at 313 nm (16). However, in the present work, emission is detected at even longer wavelengths, (using Corning filters in place of the monochromator) up to about 600 nm, for all four aldehydes. This probably reflects somewhat greater sensitivity in the present experiments.

Rate constants of reactions 1 and 2 were obtained from plots of $2\pi\nu$/[aldehyde]tan ϕ vs. [NO][M]/[aldehyde]. The intercepts of linear least-squares lines through the points gave the values of k_1, and the slopes gave the values of k_2. The plots for the four aldehydes are given in Fig. 1 for $T = 298$ K. The slopes of the plots are the same, as they should be, and are within 4% of the value of k_2 determined previously in the absence of aldehyde. Also, the precision of the points indicates that the rate constants, k_1, of the four aldehydes are significantly different.

Several points were obtained for isobutyraldehyde at 298 K with a 254 nm interference filter placed in front of the reaction cell to block the 313 nm light in order to eliminate fluorescence of the aldehyde. In these additional experiments, the Corning 2-61 filter in front of the photomultiplier monitoring the chemiluminescence was replaced by a 3-70 filter. As shown in Fig. 1, elimination of the 313 nm line had no significant effect on the results.

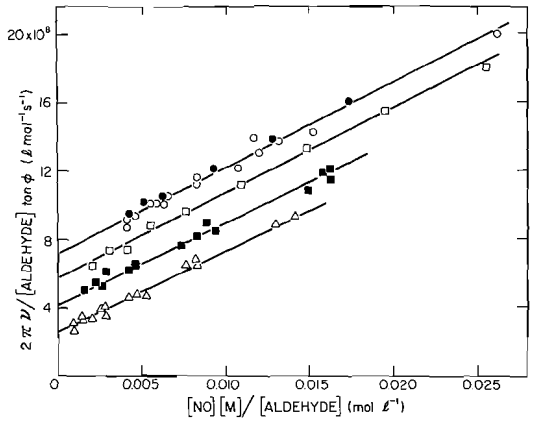

FIG. 1. Plots of $2\pi\nu$/[aldehyde] tan ϕ vs. [NO][M]/[aldehyde] for the reactions of $O(^3P)$ atoms with aldehydes at 298 K. △ Acetaldehyde; ■ propionaldehyde; □ butyraldehyde; ○ isobutyraldehyde; ● isobutyraldehyde with a 253.7 nm interference filter between the lamp and the reaction cell.

The rate constants, k_1, determined for the aldehydes at four temperatures are listed in Table 1. Also listed are values of k_2 determined from the slopes of plots similar to those in Fig. 1. With one exception (acetaldehyde at 339 K) the values of k_2 are in good agreement with the values of k_2 determined previously in the absence of aldehyde. (The Arrhenius parameters for acetaldehyde would be altered only slightly if the value of k_1 at 339 K were excluded.)

The rate constants, k_1, are plotted in Arrhenius form in Fig. 2. The points can be adequately represented by the Arrhenius equation. The least-squares Arrhenius parameters are given in Table 2.

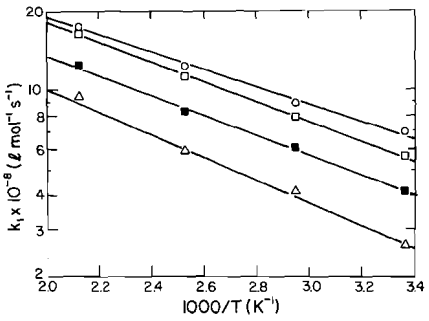

FIG. 2. Arrhenius plots of the reactions of $O(^3P)$ atoms with aldehydes. △ Acetaldehyde; ■ propionaldehyde; □ butyraldehyde; ○ isobutyraldehyde.

On the basis of a previously suggested generalized reaction scheme (14), it is estimated that less than 0.5% of the oxygen atom consumption in the presence of the aldehydes was by secondary reactions with primary reaction products. Less than 0.1% of the aldehydes were consumed by oxygen atoms, as estimated from the rate of oxygen atom production and the residence time of the aldehydes in the reaction cell.

Discussion

Comparison of the Rate Constants with Literature Values

A comparison of the present results with other reported values of k_1 is made in Table 2. The agreement among all the reported values for acetaldehyde is good. The value of Cadle and Powers (11) at 476 K is about 25% larger than the present value at 472 K, and their room temperature value is within 5%. The value determined by Cvetanović (1) for acetaldehyde, measured relative to ethylene, is also in good agreement, as is the value by Mack and Thrush (17).

The present Arrhenius expression for propionaldehyde differs considerably from that reported by Cadle and Allen (8), who used the same technique as was used by Cadle and Powers (11) with acetaldehyde. They determined the

rate constants from the initial $O(^3P)$ decay rate in a discharge flow system, using the chemiluminescence from reaction 2 to monitor the $O(^3P)$ concentration. At higher temperatures their values are in reasonable agreement with the present values (the Arrhenius lines intersect at 433 K), but at room temperature their value is only $\frac{1}{3}$ of the present value. It is not clear why such a discrepancy occurs, but it may not be significant when the scatter in the experimental values is taken into account.

There is apparently only one previously reported value of k_1 for butyraldehyde. Jaffe and Wan (9) reported a value, which is $\frac{1}{4}$ the present value, in a study of the photochemical reaction of NO_2 with butyraldehyde. The value of k_1 was obtained from the quantum yield for NO_2 loss as a function of [aldehyde]/[NO_2]. Within the experimental error, the results of Jaffe and Wan for acetaldehyde and butyraldehyde suggested that both aldehydes react with similar rates in the photochemical reactions with NO_2, implying similar values of k_1. However, these are indirect determinations of k_1, and various complicating factors may be involved.

Allowances for Abstraction of H Atoms from the Alkyl Groups

At room temperature the mechanism of the $O(^3P)$ + acetaldehyde reaction involves abstraction of the aldehydic hydrogen atom. There is no evidence of other reactive paths, such as abstraction of hydrogen from the methyl group (1, 2). However, abstraction of hydrogen from the alkyl group of the aldehydes will become more significant (*1*) as the C—H bonds become weaker on going from primary to secondary to tertiary, (*2*) as the temperature increases, and (*3*) as the number of alkyl C—H bonds increases.

It is possible to estimate the contributions to the observed rate constants made by alkyl hydrogen abstraction by assuming that the rate constants for abstraction (per C—H bond) from primary, secondary, and tertiary C—H bonds in the compounds C_2H_6, n-C_4H_{10}, and $(CH_3)_2CHCH(CH_3)_2$, respectively, as reported in ref. 18, are transferable to the alkyl groups in the aldehydes. The percentages estimated in this way for abstraction from the alkyl group relative to the total observed rate at 298 and 472 K are: acetaldehyde 0.1, 1.4; propionaldehyde 1.8, 12; butyraldehyde 2.6, 18; isobutyraldehyde 0.9, 4.2. These estimates show that abstraction from the alkyl groups probably becomes significant at the higher temperatures used in the present work as the number of alkyl $\rangle CH_2$ groups increases.

TABLE 3. Estimated[a] Arrhenius parameters for the reaction $O(^3P)$ + RCHO → OH + RCO[b]

Aldehyde	$A \times 10^{-9}$ (ℓ mol^{-1} s^{-1})	E (cal mol^{-1})
CH_3CHO	7.00±1.40	1941±148
CH_3CH_2CHO	5.67±0.51	1543± 62
$CH_3(CH_2)_2CHO$	6.23±0.13	1428± 15
$(CH_3)_2CHCHO$	7.18±0.87	1390± 86

[a]The estimated rate of H abstraction from the alkyl group is subtracted from the total measured rate.
[b]The indicated uncertainties are one standard deviation.

Rate constants corresponding to abstraction of the aldehydic hydrogen by $O(^3P)$ are estimated by substracting from the observed rates the calculated rates of abstraction of hydrogen atoms from the alkyl groups. The Arrhenius parameters for abstraction of the aldehydic hydrogen were evaluated from these 'corrected' rate constants. The least-squares values of the Arrhenius parameters, obtained using the statistical weights of the observed rate constants, are given in Table 3. The pre-exponential factors are the same, within about one standard deviation, for the four aldehydes, and are comparable to values, per C—H bond, for the $O(^3P)$ + alkane reactions (18). The Arrhenius activation energies are significantly lower (by 1 to 8 kcal mol^{-1}) than the activation energies for the $O(^3P)$ + alkane reactions, consistent with the weaker aldehydic C—H bond. There is a trend of decreasing activation energies in the series acetaldehyde–propionaldehyde–butyraldehyde–isobutyraldehyde. A question of considerable interest is whether this trend signifies that there is a corresponding trend in the bond dissociation energies of the aldehydic hydrogen, D(RCO—H),[2] for the four aldehydes.

Thermochemical Values of D(RCO—H)

The aldehydic C—H bond dissociation energies reported for formaldehyde, acetaldehyde, and propionaldehyde are very similar. Some recent values, in kcal mol^{-1}, are: CH_2O 88.5 (19), 87 (20), 76 (21); CH_3CHO 87.7 (22), 87 (20), 87.3 (21); CH_3CH_2CHO 87.4 (23). To our knowledge there are no values reported for the

[2]The bond dissociation energies in this paper refer to D^o_{298} values.

butyraldehydes. All of the values except Fletcher and Pilcher's value (19) for formaldehyde are based on kinetic data (i.e., differences in activation energies for various forward and reverse reactions). Within the experimental errors of about 1 or 2 kcal mol^{-1}, the bond dissociation energies are the same. The thermochemical data are not sufficiently precise to ascribe the small variation in activation energies in Table 3 to changes in D(RCO—H). Thus it is necessary to examine other physical properties of the aldehydes that might provide a more precise relative ordering of D(RCO—H).

Estimates of D(RCO—H) from the Trend in the Arrhenius Activation Energies

In a review of reactions of $O(^3P)$ atoms with hydrocarbons, Huie and Herron (18) correlated C—H bond dissociation energies with the activation energies for $O(^3P)$ abstraction reactions. Although the correlation is not necessarily linear, as they discussed, we have used their plot to estimate D(RCO—H) for the aldehydes in the present study and also for formaldehyde, for which the temperature dependence of the rate constant of reaction with $O(^3P)$ has been reported (10) as $3.7 \times 10^9 \exp(-2.4 \text{ kcal mol}^{-1}/RT)$ ℓ mol^{-1} s^{-1}. Values of D(RCO—H) were calculated from the line in Huie and Herron's plot of D vs. E using the values of E in Table 3 and Cadle's activation energy for H_2CO. The values D(RCO—H) thus obtained are given in Table 4 under the 'E vs. D' heading. The most significant decreases in D(RCO—H) occur going from formaldehyde to acetaldehyde (1.5 kcal mol^{-1}) to propionaldehyde (1.3 kcal mol^{-1}), but there is little further change on going to the butyraldehydes.

Because the correlation of bond energy with activation energy is not necessarily linear, and because the 'corrections' for abstraction from the alkyl portion of the aldehydes are estimates, the above correlation must be made advisedly. However, in support of this correlation, C—H stretching frequencies also indicate a similar trend in D(RCO—H).

Estimates of D(RCO—H) from the Trend in the Aldehydic C—H Stretching Frequencies

The stretching frequencies of C—H bonds have been correlated recently with the bond dissociation energies for a variety of molecules (24). We arbitrarily use the line drawn by McKean *et al.* (24) connecting the data for HCN and CH, and estimate D(RCO—H) for each aldehyde using the C—H stretching frequencies in Table 4. The trend in the D(RCO—H) values obtained from the stretching frequencies is similar to the trend obtained from the activation energy correlation, and in fact, the absolute values are in fairly good agreement, as shown in Table 4. However, only the relative values are sought, and the values are therefore normalized to $D(CH_3CO—H) = 87.3$ kcal mol^{-1}, the mean of the values in refs. 20–22. The trend in D(RCO—H) is perhaps shown more convincingly by comparing these normalized values, which are enclosed in parentheses in Table 4. It is interesting to note that Bernstein (27), in an earlier correlation of C—H stretching frequencies, predicted values of 88 and 85 kcal mol^{-1} for D(RCO—H) for formaldehyde and acetaldehyde, respectively.

Discussion of the Trend in D(RCO—H)

It should be emphasized that the trend in D(RCO—H) values suggested by the present work and by the C—H stretching frequencies is relatively small, and is within the uncertainties in the thermochemical results based on kinetic techniques such as iodine atom reactions. The near constancy of the aldehydic hydrogen bond dissociation energies has been discussed by Solly and Benson (28). Within the precision of the thermochemical data available, they concluded that there was no effect of alkyl group substitution of the magnitude exhibited by CH_3—H (104 kcal mol^{-1}) and C_2H_5—H (98 kcal mol^{-1}). It would be interesting to compare the aldehydes with the isoelectronic series $RC(=CH_2)$—H, but unfortunately there does not appear to be much thermochemical data on vinylic hydrogen dissociation energies.

The difference of $\sim$20 kcal mol^{-1} in the dissociation energies of the vinylic ($\sim$108 kcal mol^{-1} in C_2H_4) and the analogous aldehydic C—H bonds is very striking. The potential electronic interactions which may affect the strength of the aldehydic C—H bonds and the stability of the radicals formed after removal of H have been discussed (28–30). The fact that the C—H stretching frequencies are low, and that they predict fairly well the observed values of D(RCO—H), would seem to indicate that the bond weakening factors are operative in the

TABLE 4. Estimates of the aldehydic C—H bond dissociation energies, D(RCO—H), from the correlations E vs. D and ν vs. D, i.e., of activation energies, E, and of vibrational frequencies, ν, with the C—H bond dissociation energies, D

Aldehyde	E[b] (kcal/mol)	ν (cm^{-1})	D(RCO—H) from correlations[a]: E vs. D (kcal/mol)	ν vs. D (kcal/mol)
Formaldehyde	2.4[c]	2812[d]	87.6 (88.8)	87.7 (91.0)
Acetaldehyde	1.94	2770[e]	86.1 (87.3)	84.1 (87.3)
Propionaldehyde	1.54	2758[e]	84.8 (86.0)	83.1 (86.3)
Butyraldehyde	1.43	2757[e]	84.5 (85.7)	83.0 (86.2)
Isobutyraldehyde	1.39	2750[e]	84.3 (85.5)	82.4 (85.5)

[a]The values in the parentheses are normalized taking $D(CH_3CO—H) = 87.3$ kcal mol^{-1}, i.e., the mean of the values quoted in refs. 20–22.
[b]The activation energies have been corrected for the potential contribution of alkyl hydrogen abstraction.

aldehyde, and not solely through stabilization (28) of the radical, because the stretching frequencies are expected to be sensitive to properties of the aldehyde rather than to the separated radical and H atom. This is exemplified by comparing benzaldehyde and toluene. For the former, the aldehydic C—H stretch (average) is the same as that in acetaldehyde, 2770 cm^{-1} (24), as is the bond dissociation energy, 86.9 kcal mol^{-1} (28). Benzyl radical, on the other hand, exhibits about 15 kcal mol^{-1} stabilization. The value of $D(C_6H_5CH_2—H)$ that would be predicted by the C—H stretching frequency is 99.9 kcal mol^{-1} (24), whereas the observed value is only 85 kcal mol^{-1} (20).

Metal-ion oxidations in solution. Part XVIII.[1] Characterization, rates, and mechanism of formation of the intermediates in the oxidation of thiols by chromium(VI)

ALEXANDER McAULEY[2] AND M. ADEGBOYEGA OLATUNJI[3]

Department of Chemistry, University of Glasgow, Glasgow G12 8QQ, Scotland, and Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 7, 1977

ALEXANDER McAULEY and M. ADEGBOYEGA OLATUNJI. Can. J. Chem. **55**, 3328 (1977).

The stopped-flow technique has been used to study the reactions of $[HCrO_4^-]$ and penicillamine, glutathione and β-mercaptoethylamine (RSH) in perchlorate media, $[H^+] = 0.02$–0.100 M, $I = 1.00$ M over the temperature range 10–30°C. The transient orange species formed as intermediates are 1:1 chromate esters,

$$RSH + [(HO)CrO_3]^- \overset{K_1}{\rightleftharpoons} [(RS)CrO_3]^- + H_2O$$

with $\lambda_{max} \sim 420$–430 nm and $K_1 \sim 700$ (DL-penicillamine) to 1440 M^{-1} (glutathione) at $T = 25$°C. Thermodynamic parameters for complex formation have been derived from initial absorbance data and the evidence for sulphur bonding is discussed. Kinetics of the reactions conform to the rate law

$$d[Complex]/dt = (k_f + k_f^{H^+}[H^+])[HCrO_4^-][RSH]$$

Activation enthalpies lie in the range 6–10 kcal/mol but ΔS^* values vary considerably possibly reflecting solvation effects. The rate constants $k_f^{H^+}$ are several orders of magnitude lower than those found for this parameter in other reactions of this type. The complex formation mechanisms are discussed and the possibility of some associative character in the present reactions is considered.

ALEXANDER McAULEY et M. ADEGBOYEGA OLATUNJI. Can. J. Chem. **55**, 3328 (1977).

On a employé la technique du "flux stoppé" pour étudier les réactions de $[HCrO_4^-]$ avec la penicillamine, le glutathion et la β-mercaptoethylamine en milieu perchlorique, $[H^+] = 0.02$–0.100 M, $I = 1.00$ M, entre 10–30°C. Les espèces transitoires de couleur orange ont été identifiées comme étant des esters chromiques 1:1 ($\lambda_{max} \sim 420$–430 nm),

$$RSH + [(HO)CrO_3]^- \overset{K_1}{\rightleftharpoons} [(RS)CrO_3]^- + H_2O$$

avec $K_1 = 700$ M^{-1} (DL-penicillamine) jusqu'à 1440 M^{-1} (glutathion) à 25°C. Les paramètres thermodynamiques pour la formation de ces complexes ont été obtenus à partir des mesures d'absorption initiale. On suggère un liaison soufre–metal pour ces espèces. Les vitesses de ces reactions obéissent à l'expression

$$d[complexe]/dt = (k_f + k_f^{H^+}[H^+])[HCrO_4^-][RSH]$$

Les enthalpies d'activation se situent entre 6–10 kcal mol^{-1}, mais les valeurs de ΔS^* présentent une grande variation reflètant probablement des effets de solvatation.

Les constantes de vitesse $k_f^{H^+}$ sont plus petites, par plusieurs ordres de magnitude, que celles mesurées pour d'autres réactions comparables. Les mécanismes de formation d'un complexe intermédiaire sont discutés, ainsi que la possibilité d'un caractère associatif pour les réactions présentées.

Whilst oxygen-bonded chromate esters are well characterized (2–4), having been identified as intermediates in the oxidation of organic substrates by chromium(VI), much less is known of the corresponding sulphur-bonded complexes. Recent kinetic studies using rapid reaction techniques (5–9) have demonstrated the existence of these transient species, but they are very much more susceptible to oxidation than the O-bonded analogues. Also, the formation constants and spectra of the oxygen- and thioesters show marked differences, e.g. in the reaction with acid thiosulphate (7, 8), a complex is formed with $HCrO_4^-$ with an equilibrium constant of $\sim 10^4$

M^{-1} compared with $\sim 4\ M^{-1}$ for the bisulphate system (10). The red shift of about 30 nm of the charge-transfer band in the near uv ($\lambda = 350$ nm) has been interpreted as evidence for an S-bonded intermediate. Changes in the absorption maxima of this magnitude have also been observed with thiocyanate (11) and thioureas (12) whilst the displacement is even greater (to 420 nm) for cysteine (6). In all cases, however, the extinction coefficients are ~ 1.2–$1.4 \times 10^3\ M^{-1}\ cm^{-1}$, substantially in excess of that for the hydrogen chromate ion or the O-bonded esters. In view of the need for more information on these systems and of the importance of the sulphydryl group in electron-transport processes an extension of these studies into more biologically important substrates was undertaken.

Experimental

DL-Penicillamine (puriss), glutathione, and β-mercaptoethylamine hydrochloride (Koch Light) were used without further purification. Potassium dichromate (Analar grade) was used for kinetic runs, the sodium salt (BDH Reagent) being used where concentrations were such as to have caused precipitation of potassium perchlorate. Perchloric acid (A.R.) and sodium perchlorate (Fluka, puriss) were used to maintain a constant ionic strength of 1.00 M at varying hydrogen ion concentrations. Stock solutions of perchloric acid were analysed by titration against weighed quantities of sodium tetraborate.

Kinetic Studies

The complex formation reactions of glutathione and β-mercaptoethylamine were investigated using the stopped-flow apparatus described previously (13). Oscilloscope displays of transmission curves were photographed using a Polaroid camera and by comparison with a known reference voltage, the optical density of any point on the trace could be calculated using a Nova 1200 computer. The slower reaction with penicillamine was monitored using a hand driven (two jet glass mixer) stopped-flow system which utilized a Unicam SP800 spectrophotometer both as monochromatic light source and detection system (6). Experiments were carried out using a 1 cm flow-through cell, the dead time being 0.30 ± 0.05 s. For the formation reactions conditions were carefully chosen such that a state of equilibrium was reached prior to the subsequent redox reactions.

Results and Discussion

Interpretation of the kinetic data is strongly dependent on a detailed knowledge of the reactant species. The concentration of chromium(VI) was such that the predominant species was $HCrO_4^-$ throughout the acidity range used (4, 5). For the thiols, the pK_a values corresponding to the loss of a proton from —SH and $\overset{+}{N}H_3$ are >8 (14, 15). The carboxyl group pK values, on the other hand, are much lower, 2.44 for penicillamine and 2.1 and 3.5 for glutathione (14, 16). Under the conditions used in these investigations ($[H^+] = 0.04$–$0.10\ M$), the carboxylic acid is the predominant species although a small proportion of zwitterion is also present. Attempts were made to determine the effects of these proton equilibria on the actual concentration of hydrogen ions present. This was achieved by measuring the pH's of various solutions of the ligand prepared under conditions identical to those used for kinetic runs. Using a calibration curve derived from measurements of accurate dilutions of perchloric acid (0.01–0.10 M) at $I = 1.0\ M$, the pH's of mixed solutions at the start and completion of reaction were compared with those of the ligand alone. Representative data are presented in Table 1 where it is seen that no differences were observed. Interestingly, no trend was observed between the lowest and highest ligand concentrations at constant $[H^+]$. Hence, although a small proportion of deprotonated carboxylate may be formed the effective concentration of hydrogen ion is the initial value $[H^+]_0$.

In all the kinetic measurements carried out for the determination of the formation rate constants, the initial absorbance ($t = 0$) was found to be identical with that of chromium(VI) containing no ligand. By measuring the optical

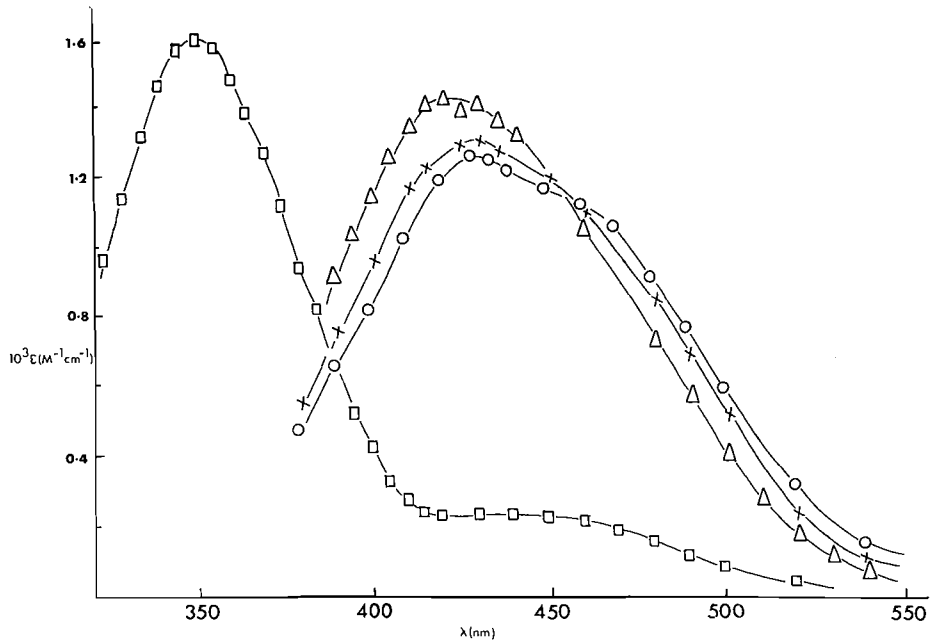

FIG. 1. Spectra of intermediate complexes. □, $HOCrO_3^-$; ○, Cr(VI)–glutathione ester; △, Cr(VI)–β-mercaptoethylamine ester; ×, Cr(VI)–penicillamine ester.

density changes, ΔOD, at various wavelengths under normal reaction conditions it was possible to compile the spectra of these complexes. In all cases λ_{max} was found to be 420–430 nm as is shown in Fig. 1. Kinetic and equilibrium measurements were carried out at this wavelength. Repeated spectroscopic scans of the relatively slowly reacting mixtures of Cr(VI) and penicillamine show an absorbance decrease at $\lambda = 350$, an increase at $\lambda \sim 420$, and an initial isobestic point at 390 nm.

In the acid concentration range 0.02–0.10 *M* the formation of the intermediate was sufficiently rapid compared with the subsequent decay that an equilibrium condition was achieved. Since $HCrO_4^-$ is generally considered to form only 1:1 complexes under the conditions employed in this study, eq. 1 may be derived where [RSH] is the

$$[1] \quad \frac{[Cr(VI)]_0[RSH]}{\Delta OD} = \frac{[RSH]}{\Delta\varepsilon \cdot l} + \frac{1}{K\Delta \cdot l}$$

ligand concentration and *K* the equilibrium constant. Plots of $[Cr(VI)]_0[RSH]/\Delta OD$ against [RSH] showed good linearity at all temperatures studied (Fig. 2). The absence of any variation of intercept with $[H^+]_0$ is an indication of little or no net uptake of protons on complex formation. In addition the linearity supports the assumption of only a monoester being formed.

Equilibrium data are presented in Table 2 where the associated thermodynamic parameters for complex formation are also reported. The magnitude of the formation constants when compared with the oxygen-bonded esters provides evidence for the Cr–S linkage in these systems (8). Also, the similarity of the spectroscopic and thermodynamic parameters of the α-aminocarboxylic acids and mercaptoethylamine suggests that there is little influence of oxygen as a donor atom in a possible chelate. In these systems where the amino group is protonated, any chelation via the nitrogen atom would require a preliminary deprotonation. In the oxidation of the hydrazinium ion, $\overset{+}{N}H_3NH_2$, there is evidence (17) for a very weakly bonded Cr(VI)–N complex ($K_f = 3 \pm 0.3\ M^{-1}$). Again the significant difference between this value and that of $\sim 10^3\ M^{-1}$ observed in the present case would argue in favour of the Cr–S linkage as contributing to the heat and entropy effects. If, in fact, the site of attack by the metal is the sulphydryl group it would appear that the equilibrium constants for the (carboxylate) protonated and anionic forms of the ligand with Cr(VI) are iden-

tical to within the limits of experimental error in this study.

The formation kinetics were measured in conditions of excess of the ligands. Plots of log $(OD_{max} - OD_t)$ against time showed good linearity to greater than 80% of reaction. Pseudo-first-order rate constants, k_{obs}, were derived from the slopes of such plots and representative data at 25°C are presented for each ligand in Table 3. Plots of k_{obs} as a function of $[ligand]_0$ at constant $[H^+]_0$ were linear with positive intercepts. If the total ligand concentration is $[RSH]_0$ the various reactions contributing to the complex formation may be formulated as in eqs. 2 and 3.

$$[2]\qquad HCrO_4^- + RSH \underset{k_b}{\overset{k_f}{\rightleftharpoons}} RSCrO_3^- + H_2O$$

$$[3]\qquad HCrO_4^- + RSH + H^+ \underset{k_b^{H^+}}{\overset{k_f^{H^+}}{\rightleftharpoons}} RSCrO_3^- + H_2O + H^+$$

On the basis of this scheme, [4] may readily be derived

$$[4]\qquad k_{obs} = \{k_f^{H^+}[RSH]_0 + k_b^{H^+}\}[H^+]_0 + k_f[RSH]_0 + k_b$$

Rearrangement of [4] leads to an expression of the form

$$[5]\qquad k_{obs} = \alpha[RSH]_0 + \beta$$

where

$$\alpha = (k_f + k_f^{H^+}[H^+]_0) \text{ and } \beta = (k_b + k_b^{H^+}[H^+]_0)$$

On plotting the slope (α) and intercepts (β) derived from [5] against $[H^+]_0$ good straight lines were obtained (Figs. 3, 4) from which the rate constants $k_f^{H^+}$, k_f, and $k_b^{H^+}$ were derived. In all cases the constant k_b was too small to be determined with any certainty and was taken to be negligible. Overall rate constants are shown in Table 4 where thermodynamic parameters for the principal (hydrogen-ion dependent) pathway are also presented.

Several interesting conclusions derive from the data and from the observed hydrogen-ion dependence which differs from many other reactions of this type (e.g. for the reaction with $(H_3N)_5$-$CoOH_2^{3+}$ the expression corresponding to the α above is of the form (18, 19) $k_f + k_f^1[H]_0^{-1}$ and may be interpreted in terms of the prior dissociation of a proton before the attack on the $HOCrO_3^-$ unit). In previous studies one reaction pathway has been observed (9) involving the rate law

$$[6] \qquad R = k_f^{H^+}[H^+][L^-][HOCrO_3^-]$$

and the constancy of the $k_f^{H^+}$ ($\sim 5 \times 10^5$ M^{-2} s^{-1}) has led to the suggestion that a weak L–$Cr(OH)O_3$ species is formed which reacts with H^+ to liberate water. An alternative postulate has been advanced by Haim (20) who reasoned that since the pathway is proton dependent the H^+ must be incorporated prior to the rate-determining step and so protonation of the $HCrO_4^-$ would be the first step with rate of loss of water as rate determining.

In the present study the $k_f^{H^+}$ values for substitution on $HCrO_4^-$ are all $\sim 10^3$–10^4 lower than the values obtained previously. The similarity of the rate for mercaptoethylamine with those of the aminocarboxylic acids is significant. In these systems either formation of the Cr—S bond or dissociation of the S—H bond is rate determining. Protonation occurs prior to the slow step and coordination of the sulphur is either rate determining or occurs before it. Following the mechanism preferred by Haim (20), water loss, which is not rate determining in this reaction, takes place with a specific rate of $\sim 5 \times 10^5$ s^{-1} as the equilibrium constant for $[(H_2O)CrO_3]$ is almost certainly less than unity. If protonation at sulphur is diffusion controlled (21) and the strength of the S—H bond is unaffected by a weak Cr---S linkage, then the rate of dissociation may be estimated from the dissociation constant of the thiol group.

$$RSH \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} RS^- + H^+$$

$$K_a' = k_d/k_{-d} \quad k_d \sim 10^{10}K_a'$$

Since $K_a' \sim 10^{-7}$–10^{-8} (14, 22), values of k_d obtained in this way are of the order of 10^2–10^3 s^{-1}. The mechanism of reaction may then be written as

$$HOCrO_3^- + H^+ \rightleftharpoons (H_2O)CrO_3$$

$$RSH + (H_2O)CrO_3 \rightleftharpoons R\text{—}\underset{\vdots\atop H}{\overset{OH_2\atop\vdots}{S}}\cdots CrO_3$$

where the water loss is more rapid than proton dissociation which is the final step. The activation energies for the systems studied so far all fall within the range 6–10 kcal/mol. The entro-

pies of activation differ markedly, however, and may reflect differing degrees of solvation, a result not altogether surprising considering the differences in the nature of the substrates.

Desolvation of the transition state may be approximated to a melting process. This process with the attendant change in geometry has a marked influence on $\Delta S^{\neq}$ and $\Delta H^{\neq}$ and the effects work in opposition to one another (23). The free energy of solvation is considered to contribute only a fraction of the rate. Differences in $T\Delta S^{\neq}$ which roughly parallel differences in $\Delta H^{\neq}$ thus confirm the solvational effects in this study.

The hydrogen-ion independent pathway, k_f, is detectable only in the reactions of penicillamine and mercaptoethylamine, the values being of the same order of magnitude (~ 1–$2\ M^{-1}\ s^{-1}$) as that of cysteine (6). Values of k_f tend to vary with the acidity of the H—L bond and an inter-

nal proton transfer governs the rate of water elimination. More data are required, however, before too much credence can be attributed to these values.

Metal-ion oxidations in solution. Part XIX.[1] Redox pathways in the oxidation of penicillamine and glutathione by chromium(VI)

ALEXANDER McAULEY[2] AND M. ADEGBOYEGA OLATUNJI[3]

Department of Chemistry, The University of Glasgow, Glasgow G12 8QQ, Scotland, and Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 7, 1977

ALEXANDER McAULEY and M. ADEGBOYEGA OLATUNJI. Can. J. Chem. **55**, 3335 (1977).

Three moles of penicillamine or glutathione are required to reduce chromium(VI) to chromium(III). The kinetics and mechanism of the redox reaction have been studied using the stopped-flow method. The reaction proceeds via the formation of a transient intermediate (K_1) which decomposes either in a proton-catalyzed pathway or by reaction with a second mole of thiol. The rate law

$$-\mathrm{d[Cr(VI)]}/\mathrm{d}t = \frac{K_1[\mathrm{RSH}](k_a[\mathrm{H}^+]^n + k_2[\mathrm{RSH}])[\mathrm{Cr(VI)}]}{1 + K_1[\mathrm{RSH}]}$$

where $n = 1$ for penicillamine and 2 for glutathione has been shown to hold over a range of thiol and hydrogen-ion concentrations. At 25°C $k_2 = 14.3 \pm 1.0\ M^{-1}\ s^{-1}$ for penicillamine ($\Delta H^{\ddagger} = 9 \pm 2$ kcal mol^{-1}, $\Delta S^{\ddagger} = -33 \pm 6$ cal K^{-1} mol^{-1}) and $12.1 \pm 0.4\ M^{-1}\ s^{-1}$ for glutathione ($\Delta H^{\ddagger} = 7 \pm 2$ kcal mol^{-1}, $\Delta S^{\ddagger} = -40 \pm 5$ cal K^{-1} mol^{-1}). Several chromium(III) products have been identified by ion-exchange methods. The significance of the second-order pathways in these reactions is discussed.

ALEXANDER McAULEY et M. ADEGBOYEGA OLATUNJI. Can. J. Chem. **55**, 3335 (1977).

La penicillamine ou le glutathion présent dans un rapport 3:1 réduit le chrome(VI) en chrome(III). La cinétique et le mécanisme de ces réactions d'oxydo-réduction ont été étudiés au moyen d'un appareil de "flux-stoppé". Le mécanisme de ces réactions implique la formation d'un complexe intermédiaire (K_1) qui peut, soit se décomposer selon une voie catalysée par les protons, soit réagir avec une deuxième mole de thiol. La vitesse de la réaction obéit à l'expression

$$-\mathrm{d[Cr(VI)]}/\mathrm{d}t = \frac{K_1[\mathrm{RSH}](k_a[\mathrm{H}^+]^n + k_2[\mathrm{RSH}])[\mathrm{Cr(VI)}]}{1 + K_1[\mathrm{RSH}]}$$

dans laquelle $n = 1$ pour la penicillamine et $n = 2$ pour le glutathion. Cette expression est valable pour une variété de concentrations de thiol et de [H$^+$]. A 25°C, $k_2 = 14.3 \pm 1.0\ M^{-1}\ s^{-1}$ pour penicillamine ($\Delta H^{\ddagger} = 9 \pm 2$ kcal mol^{-1}, $\Delta S^{\ddagger} = -33 \pm 6$ cal K^{-1} mol^{-1}) et $12.1 \pm 0.4\ M^{-1}\ s^{-1}$ pour le glutathion ($\Delta H^{\ddagger} = 7 \pm 2$ kcal mol^{-1}, $\Delta S^{\ddagger} = -40 \pm 5$ cal K^{-1} mol^{-1}). Plusieurs complexes du chrome(III) ont été identifiés au moyen de colonnes échangeuses d'ions. On discute de l'implication d'un terme du second ordre en thiol pour ces réactions.

The oxidation of nonmetallic substrates by both metal ions and oxy-anions is often accomplished by way of inner-sphere complexes (2–5), presumably since they provide a low energy pathway for electron transfer. The ability of $HCrO_4^-$ to form esters with electron pair donors, particularly those with —OH groups, is already well established (6) and an increasing amount of data is now being provided on the corresponding thiol complexes. For these transient sulphur-bonded esters the formation constants are significantly higher than the oxygen-bonded species (7–10). Most metal-ion oxidants require only a one-electron transfer to attain a lower stable oxidation state; chromium(VI), however, requires three electrons for this purpose and only in a relatively small number of instances has a simultaneous three-electron transfer been reported (11). In other cases both one- and two-electron redox reaction pathways are important. Identification of the final products which usually include various inert Cr(III) complexes yields information on the elementary steps which take place after the transition state (12).

The oxidation of thiols to disulphides is an

important biological process and the role of metal ions in the reactions of penicillamine, glutathione, and β-mercaptoethylamine (RSH) is of significance in view of the nature of electron-transport enzymes which often incorporate sulphydryl groups of this type. The reactions of penicillamine with heavy metal ions have been extensively studied and characteristic reductive chelate formation with Cu(II), Fe(III), etc. has been observed (13). Few data are available for the Cr(VI) reactions. One reference (14) to the reaction at pH 7 has described the characterization of a 1:3 Cr(III)–penicillamine complex. The significance of this study was related to the effectiveness of various chelating agents for the removal of chromium bound to haemoglobin. The present investigation deals with the kinetics and mechanism of the redox processes involving these systems in the context of the reaction of intermediate S-bonded esters characterized previously (1).

Experimental

Details of the preparation and purification of reagents are available elsewhere (1). Kinetic studies were carried out using stopped-flow spectrometers described previously (10, 15) over a temperature range 12–30°C with the thiol ligand in excess. The redox reactions were in all cases at least a factor of 10 slower than the formation of the intermediate complexes and pseudo-first-order rate constants were derived from plots showing linearity to greater than 90%. Data were reproducible to ±2%.

Stoichiometry

Attempts to determine the stoichiometries of the overall redox reactions by spectrophotometric titration were unsuccessful as has been observed in the corresponding reaction with thiosulphate (16). For this reason and because it was considered desirable to measure the stoichiometry under conditions related directly to the kinetic data, acidimetric titration of the sulphydryl group was used (17). In this analysis, 50 ml of 0.2 M thiol was mixed with 25 ml of 4×10^{-2} M chromium(VI) and the requisite volumes of $NaClO_4$ and $HClO_4$ to give $[H^+] = 0.10$ M and $I = 1.0$ M on dilution of the mixture to 100 ml. After completion of the reaction a 50 ml sample of this mixture was used to charge a Dowex 50W × 8, 100–200 mesh cation-exchange column. Rinsing first with water, then with 0.10 M $HClO_4$, and finally a solution containing 0.10 M $HClO_4$ and 1.0 M $NaClO_4$ until the first coloured complex had reached the lower part of the resin ensured the removal of all excess free ligand. The fraction collected was analyzed as outlined (17).

Products

After the excess ligand had been removed, continued elution with various $HClO_4$–$NaClO_4$ mixtures resulted in a separation of the Cr(III) complexes. In order to minimize aquation, the ion-exchange column was maintained at 0°C during the separation procedure. The chromium content was determined by bromine oxidation in basic media with spectrophotometric measurement of the resulting $[CrO_4]^{2-}$ ($\varepsilon = 4814\ M^{-1}\ cm^{-1}$ at $\lambda = 372$ nm) (18).

Results and Discussion

The electron-transfer reactions of the penicillamine and glutathione systems were studied. Under the experimental conditions used, the redox reactions involving β-mercaptoethylamine were found to be very slow. In order to simplify the kinetics, a sufficient excess of the thiol was present so that no $[HCrO_4^-]$ was present in the redox step. Representative rate data at various $[H^+]$ and [RSH] at 25°C are presented in Table 1. Degassing the reactant solutions had no effect on the reaction rates. Also, no difference was observed in experiments where 0.0416 M Mn(II) was present.

Plots of k_{obs} as a function of $[RSH]_0$ yielded straight lines with positive intercepts. The gradients of these lines were acid independent although in each case the thiol-independent pathway showed a dependence on $[H^+]$.

For the reaction of penicillamine, the data are consistent with the rate scheme

$$[1]\quad RSH + [HOCrO_3^-] \overset{K_1}{\rightleftharpoons} [RSCrO_3^-] + H_2O$$

$$[2]\quad [RSCrO_3^-] + H^+ \overset{k_1}{\rightarrow} Cr(V)$$

$$[3]\quad [RSCrO_3^-] + RSH \overset{k_2}{\rightarrow} Cr(IV)$$

The rate law [4] may thus be derived.

$$[4]\quad \frac{-d[Cr(VI)]_{tot}}{dt} = \frac{K_1[RSH](k_1[H^+] + k_2[RSH])[Cr(VI)]_{tot}}{1 + K_1[RSH]}$$

Rearrangement of the observed rate constant (k_{obs}) in [4] yields the expression

$$[5]\quad \alpha = k_{obs}(1 + K_1[RSH])/K_1[RSH] = k_1[H^+] + k_2[RSH]$$

From a knowledge of the equilibrium constants at the various temperatures (1), plots of α against [RSH] were made (Fig. 1) from which the rate constant k_2 was derived directly from the gradients. The thiol-independent rate constant was derived from a plot of intercepts (I) of such plots against $[H^+]$ (Fig. 2). In the reaction of penicillamine only one proton is required in the one-electron reduction to Cr(V) (eq. 2).

[a]Third-order rate constant, units $M^{-2}\,s^{-1}$.

Individual rate constants and thermodynamic parameters are presented in Table 2. It is known that the reduction from Cr(VI) to Cr(V) is often accompanied by proton dependences (6) (usually two are required) and it is probable that the penicillamine itself provides one of the protons required for reduction. Why the same process does not take place with the glutathione is not certain at present but it may be that conformational changes in the tripeptide require an external rather than an internal proton transfer for reduction to take place.

The reaction mechanisms for [2], [3], and [6] may be discussed in terms of single and multiple electron-transfer reactions. In steps 2 and 6 the rate-determining step is envisaged as the first of three consecutive one-electron transfers which have been well documented previously (6). Second-order ligand dependences (k_2 pathway) have been encountered in a number of systems, some of which involve sulphur centres. In Table 3 are listed the activation parameters for such reactions involving essentially similar processes with negligible dissociative character. In these systems the expansion of the chromium coordination sphere from four to six may be important. For sulphur-containing one-electron substrates, such as those under consideration,

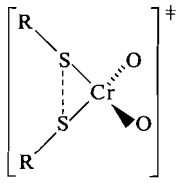
cysteine, thiourea, and thiocyanate (19), routes corresponding to such terms may also provide a low energy pathway for the formation of a disulphide via a 'template' reaction with a transition state of the form



Such a system would be formally similar to chromyl chloride CrO_2Cl_2 but the differences in electronegativities of the halide and sulphur atoms are probably responsible for the differing stabilities. A similar incipient RS—SR bond formation has been observed (20) in the redox reactions of iron(III)–thiolate complexes in which a rate-determining dimerization involving the formation of a Fe_2S_2 four-centre electron-transfer transition state is observed rather than the unimolecular decomposition of the complex to yield Fe(II) and the RS$^{\bullet}$ radical. The fact that a two-electron transfer to Cr(IV) is possible thus facilitates disulphide formation.

The lack of an effect of Mn(II) on the reaction rate is similar to that observed in reactions with other thiols (10, 21) and with iodide (21). This transition metal ion has been used successfully as a trapping agent for Cr(IV) thus rendering impossible reaction of a second Cr(VI) species with either chromium(IV) or the radical produced if the latter reacts with another substrate molecule. Thus participation of a second mole of complex [$RSCrO_3^-$] in the reduction of Cr(IV) to Cr(III) complexes is eliminated and support is lent to the view that it is the ligand which is involved in this (rapid) step.

The results obtained by the acidimetric titration method are consistent with a ligand–chromium(VI) ratio of $(3.0 \pm 0.1):1$ in the reactions involving penicillamine and glutathione, consistent with the overall reaction

$$n\mathrm{H}^+ + 2[\mathrm{HCrO_4}]^- + 6\mathrm{RSH} \rightarrow 2\mathrm{Cr(III)} + 3\mathrm{RS{-}SR}$$

The thiol acts as a one-equivalent reductant under conditions of excess ligand. In spectrophotometric titrations solutions having Cr(VI) in excess were found to undergo further reaction, presumably overoxidation of the thiol to sulphoxide or sulphone.

Using the conditions referred to in the Experimental section, ion-exchange procedures indicated several complexes as products in the reaction of each thiol. With penicillamine, the first complex to be eluted was purple in colour. Comparison of elution rates with those of known complex ions showed the species to be doubly charged and containing about 60% of the total chromium. The second species had a more intense purple colour and could not be eluted even under extreme conditions of eluant concentration (2 *M* $HClO_4$ – 4 *M* $NaClO_4$). The complex did appear to aquate on prolonged elution to yield $[Cr(H_2O)_6]^{3+}$. This latter species is presumably a dimeric 4+ charged ion which could have resulted from the parallel reaction of $Cr_2O_7^{2-}$ which was present in the original solution. The results are similar to those obtained for cysteine where it was concluded (10) that the monomeric complex ion has cysteine coordinated to the chromium(III) centre via an α-aminocarboxyl binding site. Product mixtures from the glutathione reactions yielded three species, $Cr(H_2O)_6^{3+}$ ~ 50%, a green second complex (containing about 40% of the total chromium) also +3 in charge, and approximately 10% of the dimeric complex which was difficult to isolate. Although the presence of sulphur in the green species was confirmed by $BaSO_4$ precipitation after oxidation of the complex the low concentrations involved prevented an accurate determination of the Cr–S ratio. It is of interest to note that similar products were identified in the reaction of β-mercaptoethylamine with 78% of the aquo complex, ~20% of the green monomeric ion with little trace of the dimer. The fact that green chromium(III) complexes are observed as products in the oxidation of thioureas (21) is consistent with a postulate of nitrogen coordination in these species. It may be that (1)

in the case of the glutathione only the amine groups are accessible for binding to the metal centre.

Oxidations of thiols by chromium(VI) appear to be a route to chromium(III) species with coordinated disulphides. Before the mechanism of such reactions can be established with certainty more work is required on the nature of the radical intermediates and of the concentrations of chromium(V) generated. Flow esr will be of use in this regard and such studies are in progress.

Chemistry of chelocardin II[1]: chemical modifications at $C_{2''}$ and C_{12a}

DANIEL T. W. CHU, STUART N. HUCKIN, AND EDITH BERNSTEIN
Abbott Laboratories, Limited, P.O. Box 6150, Montreal, P.Q., Canada H3C 3K6

Received February 24, 1977

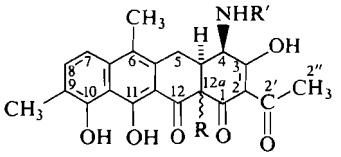
DANIEL T. W. CHU, STUART N. HUCKIN, and EDITH BERNSTEIN. Can. J. Chem. **55**, 3341 (1977).

A selective reduction of chelocardin has been developed leading to 12a-deoxychelocardin which retains much of the antibacterial potency of the parent antibiotic, unlike the analogous reduction of tetracycline. Reaction of an *N*-protected chelocardin with amide acetals leads exclusively to products in which the condensation has occurred at the methyl group of the acyl side chain.

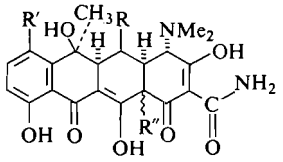
DANIEL T. W. CHU, STUART N. HUCKIN et EDITH BERNSTEIN. Can. J. Chem. **55**, 3341 (1977).

On a réalisé une réduction sélective de la chelocardine qui a donné la 12a-deoxychelocardine. Ce dernier retient en grande partie l'activité antibiotique de la chelocardine, contrairement à la réduction similaire de la tetracycline. La réaction des chelocardines *N*-bloquées avec certains amidoacétals a donné des composés dont la condensation s'est produite uniquement sur le groupe méthylique de l'acétyle.

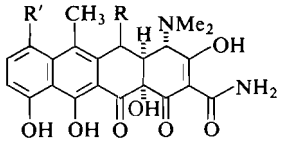
Chelocardin, a broad spectrum antibiotic that was first described in 1962 (1) and subsequently shown to be **1** (2), bears a marked structural resemblance to the tetracycline (**2**) and specifically to the anhydrotetracycline (**3**).



1 R = α-OH, R′ = H
5 R = α-OH, R′ = $CO_2CH_2C_6H_5$
6 R = H, R′ = $CO_2CH_2C_6H_5$
7 R = H, R′ = H·HBr



2 R′ = R = H, R″ = α-OH tetracycline
2 R′ = H, R = OH, R″ = α-OH oxytetracycline
2 R′ = Cl, R = H, R″ = α-OH chlorotetracycline
4 R′ = R = H, R″ = H



3 R′ = R = H anhydrotetracycline
3 R′ = H, R = OH anhydrooxytetracycline
3 R′ = Cl, R = H anhydrochlorotetracycline

[1]For Part I of this series, see ref. 12.

Since the discovery of the tetracycline class of antibiotics in 1948 (3) much effort has been expended to elucidate the structure–activity relationship of this class of compounds and considerable progress toward this end has been made (for a review of the structure–activity relationship see ref. 4*a*; for a more recent but less comprehensive review, see ref. 4*b*). However, during the course of our studies in the chemical modification of chelocardin, it became increasingly apparent that this body of literature concerning the tetracycline structure–activity relationship did not apply to chelocardin despite their structural similarities.

This divergence was first noted when the structure of chelocardin was elucidated (3) in that all of the modifications of the tetracycline ring system toward chelocardin are individually correlated with a decrease in antibiotic activity. For example, 2-acetyl-2-decarboxamidotetracycline possesses (depending upon the species of bacteria) between 6 and 15% of the activity of tetracycline (5), anhydrotetracycline has only slight antibacterial activity (6), 4-epitetracycline has only slight antibacterial activity in vitro (6), whereas the introduction of a methyl group at C_9 in deoxycycline gives an analogue with less than 10% of the parent antibiotic's antibacterial activity (7).

We now wish to report our chemical investigation on the modifications of chelocardin at C_{12a} and $C_{2''}$. It appears that there is a further difference between chelocardin and tetracyclines, namely the retention of antibacterial activity

upon removal of the 12a-hydroxyl function of chelocardin.

Modification at C_{12a}

12a-Deoxytetracycline (**4**) has been prepared by hydrogenolysis of O^{12a}-formyltetracycline (8) and by direct reduction of tetracycline with zinc and aqueous ammonia (9). Chelocardin, without protection of the amine functionality, would not withstand prolonged basic treatment. Even with the amine converted to the benzyl urethane, strong base causes epimerization at C_4 of chelocardin derivatives. However, it was found that treatment of *N*-carbobenzoxychelocardin (**5**) with zinc under acidic conditions gave a mixture of products, the major of which was characterized as the desired *N*-carbobenzoxy-12a-deoxychelocardin (**6**).

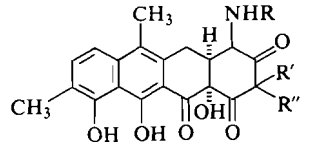
The removal of the hydroxyl functionality from the 12a position in both chelocardin and tetracycline permits the two, normally isolated, π-systems to interact, and this is reflected in the appearance of a new absorption band in the uv spectrum of **6** at 382 nm (cf. the additional band at 378 nm in the uv spectrum of anhydro-12a-deoxytetracycline (8) compared to anhydrotetracycline (10)). Further evidence for the assignment of the reduction products as **6** is the presence in its Hmr spectrum of two additional resonances; one at δ 4.0 ppm, assignable to the C_{12a}-hydrogen, and one in the enol region (δ 15–17 ppm) which together account for one proton (indicating that **6** in chloroform solution exists as a mixture of keto and enol forms). The ^{13}C nmr of the product is also compatible with reduction at the 12a position showing substantial shifts in the resonances previously assigned to C_{12}, C_{12a}, C_{4a}, and C_1.[2]

The carbobenzoxy group could be easily removed from **6** by treatment with hydrobromic acid in acetic acid to give 12a-deoxychelocardin as its hydrobromide salt (**7**) which could be purified more readily than **6**. Whereas reduction of the 12a-hydroxyl group of tetracycline reduces the antibacterial properties substantially (**4** is reported to possess only 2% of the activity of tetracycline toward *Staphylococcus aureus* (8)), 12a-deoxychelocardin possesses comparable efficacy toward Gram-positive bacteria as chelocardin and shows about one quarter of the latter's activity toward Gram-negative bacteria.

[2]R. S. Egan, R. S. Stanaszek, E. Bernstein, D. T. W. Chu, and S. N. Huckin, manuscript in preparation.

Modification at $C_{2''}$

Modification of the acyl side chain was initially achieved by substitution at the carbonyl group of the acyl side chain to give hydrazones (11*a*,*b*) and anils (11*c*), but subsequent indirect attempts at this modification via reacylation of 2-deacetylchelocardin (**8**) (12) have not been promising (19, 12).



8 R = H, R′ = R″ = H

9 R = $CO_2CH_2C_6H_5$, R′, R″ = 
Direct reaction at the 2″ methyl group appeared to be chemically infeasible, as the enolization of the tricarbonyl system occurs initially with loss of the proton at C_2.[3] Subsequent enolization occurs by loss of the C_4 proton as evidenced by the epimerization of the amino groups in a wide variety of chelocardin derivatives under moderately basic conditions (for example see preparation of **9**). Modification of the tricarbonyl system by formation of the enamine at $C_{2'}$, to give **9**, also failed to allow reaction at $C_{2''}$, either directly or formally via acylation–deacylation at C_2. Compound **9** being a vinylogous imide was inert to the usual enamine alkylation and acylation conditions[4] and the presence of the other acidic groups in chelocardin precluded the preparation of the carbanion at $C_{2''}$ (14).

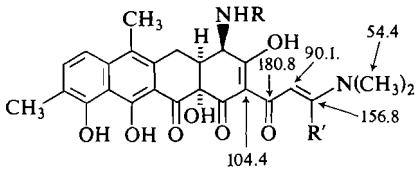
It is well known that *N*,*N*-disubstituted amide acetals (e.g. 1,1-dimethoxy-*N*,*N*-dimethylmethylamine **10**) undergo condensation with acid groups, such as a methyl ketone giving in this instance enamino-ketone (15). Although chelocardin contains several acidic groups with which a highly reactive compound such as **10** might react,[5] it was hoped that conditions which favored reaction at the 2″ methyl group could be

[3]However, no indication of reaction at C_2 was observed in a variety of acylations of chelocardin and derivatives even under forcing conditions (12).

[4]Vinylogous amides are somewhat deactivated (13) toward alkylation and acylation compared to enamines, **9** having two carbonyl groups in conjugation with the enamine can be expected to be even less reactive.

[5]For example, *trans* ketalization could occur involving the phenolic groups or the 12*a* hydroxyl and C_1 enol of chelocardin. For a review of amide acetals see ref. 20.

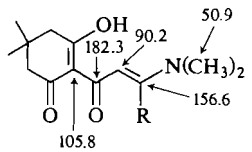
found. Accordingly, *N*-carbobenzoxychelocardin (**5**) was treated with an excess of **10** in refluxing benzene and tlcs taken after only 5 min reaction time indicated the complete conversion to a more polar product, subsequently shown to be the desired compound **11***a*.



11*a* R = $CO_2CH_2C_6H_5$ and R′ = H
11*b* R = $CO_2CH_2C_6H_5$ and R′ = CH_3
11*c* R = H·HBr and R′ = H
11*d* R = H·HBr and R′ = CH_3
(^{13}C nmr data refer to **11***a* only)

Reaction at $C_{2''}$ was indicated by the presence in the Hmr spectrum of the product of a pair of doublets at δ 6.67 and δ 8.02 (J = 11 Hz) characteristic of *trans* vicinal vinylic protons and by the absence of the signals analogous to those assigned to the 2″ methyl group of *N*-carbobenzoxychelocardin. Compounds **11** possess a new band in their uv spectra at ca. 377 nm, and the model compounds **12**, derived from 2-acetyldimedone and the corresponding amide acetal, exhibit similar uv spectra.

The structure of **11***a* is further confirmed by its ^{13}C nmr spectrum which shows a striking parallel to that of **12***a* in that the corresponding carbon resonances for the side chain in both compounds are almost coincident. The relevant ^{13}C nmr data in ppm downfield, from internal TMS for **11***a* and **12***a*, are shown in their structures.

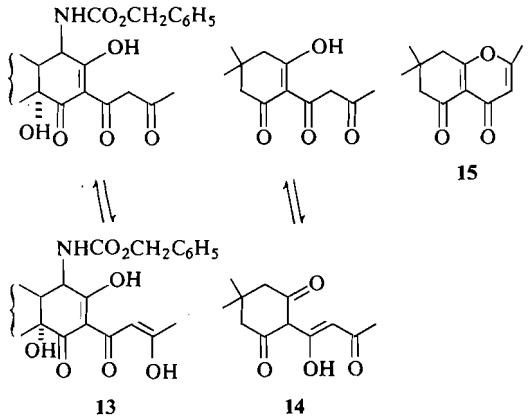


12*a* R = H
12*b* R = CH_3
(^{13}C nmr data refer to compound **12***a* only)

All attempts to hydrolyze the enamine moiety of the side chain in the formamide condensation products **11***a*, **11***c*, and **12***a* to produce the corresponding β-aldehydoketones failed. However, the corresponding ketamine compounds **11***b* and **12***b* derived from the dimethyl acetal of dimethylacetamide could be hydrolyzed to the corresponding carbonyl compounds **13** and **14**, by aqueous sodium carbonate.

Hydrolysis of compound **12***b* was very facile, even occurring during attempted purification by column chromatography on silica. If acidic hydrolysis conditions were employed, cyclization to the pyrone **15** occurred. Attempts to obtain the corresponding cyclization of **13** under similar conditions were not successful.

Unfortunately, the extension of conjugation of the 2′ carbonyl group away from the 1 and 3 carbonyls alters the electronic environment of the tricarbonyl system sufficiently that most of the antibacterial activity of chelocardin is lost and the nitrogen deprotected compounds **11***c* and **11***d* have only weak inhibitory effects on Gram-positive bacteria and are ineffective against Gram-negative bacteria at concentrations up to 100 μg/ml.



Experimental

The Hmr spectra were recorded on a Varian Associates EM-360 spectrometer in $CDCl_3$ solutions, resonance positions were reported using the δ scale relative to internal tetramethylsilane. The abbreviations used in reporting the signals are: s, singlet; d, doublet; m, multiplet, and b, broad. The mass spectra were recorded on an AEI MS-902 double focussing mass spectrometer. The uv spectra were recorded on a Unicam SP800A spectrometer in 0.1 *N* methanolic HCl solutions. Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. The ^{13}C nmr spectra were recorded on a Varian Associates XL-100-15/TT-100 spectrometer system in DMSO; resonance positions are given in ppm relative to internal tetramethylsilane.

Preparation of N-Carbobenzoxychelocardin (5)

Chelocardin hydrochloride (10 g, 0.022 mol) and benzyl chloroformate (20 ml) were dissolved in a mixture of tetrahydrofuran (300 ml) and water (60 ml), and a solution of sodium bicarbonate (15 g) in water (250 ml) was added, with vigorous stirring, over 15 min. The mixture was acidified with concentrated hydrochloric acid to p*H* 2.0 and the organic layer was separated and concentrated

to approximately 50 ml, before being dissolved in chloroform (250 ml). The chloroform solution was washed with saturated brine (2 × 30 ml) and dried over anhydrous sodium sulfate. Evaporation at reduced pressure gave 10.7 g (88%) of yellow amorphous solid which was essentially pure *N*-carbobenzoxychelocardin. Recrystallization from glacial acetic acid (6 ml/g) gave crystalline material, mp 206–211°C; Hmr δ 2.22 (s, 3H, C_9—CH_3), 2.30 (s, 3H, C_6—CH_3), 2.56 (s, 1.4H, $C_{2'}$—CH_3), 2.62 (s, 1.6H, $C_{2'}$—CH_3), 3.0–3.6 (m, 3H, C_5—H_2 and C_{4a}—*H*), 5.03 (m, 1H, —N*H*), 5.17 (m, 2H, —O—CH_2—C_6H_5), 6.05 (m, 1H, —C_4—*H*), 7.0–7.6 (m, 7H, C_7—*H*, C_8—*H*, and C_6H_5), 9.85 (s, 1H, C_{10}—O*H*), 15.1 (bs, 1H, C_{11}—O*H*), 18.1 (vbs, 1H, ring A enol —O*H*); uv λ_{max} 226, 275, and 435 nm; ms *m/e* 545 $M^{+}\cdot$. *Anal.* calcd. for $C_{30}H_{27}NO_9$: C 66.06, H 4.99, N 2.57; found: C 65.78, H 5.29, N 2.55.

*N-Carbobenzoxy-12a-deoxychelocardin (**6**)*

Zinc dust was activated by vigorous agitation with 1 *N* hydrochloric acid (10 ml/g), rapidly filtered, washed with water (3 × 25 ml/g) and acetone (2 × 10 ml/g), and dried under high vacuum.

N-Carbobenzoxychelocardin **5** (10 g, 18.2 mmol) was dissolved in glacial acetic acid (500 ml) and freshly activated zinc dust (30 g, 0.46 g-atom) added. The mixture was stirred at ambient temperature for 18 h and filtered. The filtrate was diluted with water (250 ml) and the resulting precipitate collected by filtration. The precipitate was dissolved in chloroform (500 ml) and the solution was washed with saturated brine (3 × 100 ml), dried over anhydrous sodium sulfate, and evaporated at reduced pressure to give 7.3 g (74%) of crude **6** as a red solid. Purification of **6** was achieved by chromatography on Sephadex LH20 using chloroform as eluent to give an amorphous solid having a melting point of 175–183°C; uv λ_{max} 226, 275, 382, and 445 nm; Hmr ($CDCl_3$) δ 2.27 (s, 6H, C_6—CH_3 and C_9—CH_3), 2.60 (s, 3H, $C_{2'}$—CH_3), 2.9–3.4 (m, 3H, C_5—H_2 and C_{4a}—*H*), 4.0 (d, 0.5H, C_{12a}—*H*), 4.6 (m, 1H, N—*H*), 5.17 (s, 2H, —O—CH_2—C_6H_5), 6.1 (m, 1H, C_4—*H*), 7.0–7.6 (m, 7H, C_7—*H*, C_8—*H* and C_6H_5), 10.1 (s, 0.5H, C_{10}—O*H*), 10.2 (s, 0.5H, C_{10}—O*H*), 15.1 (s, 0.5H, C_{11}—O*H*), 16.1 (s, 0.5H, C_{11}—O*H* or C_{12}—O*H*), 16.3 (s, 0.5H, C_{11}—O*H* or C_{12}—O*H*), 17.7 (bs, 0.5H, ring A enol O*H*) and 18.1 (bs, 0.5H, ring A enol O*H*); ^{13}C nmr (DMSO-d_6) δ 197.2 (s, C_3), 193.6 (s, C_2—*C*=O), 185.7 (s, C_{12}), 174.5 (s, C_1), 160.4 (s, C_{11}), 156.6 (s, N—CO_2), 154.5 (s, C_{10}), 137.0 (s, C_{6a}), 136.4 (s, C_1 of C_6H_5), 133.5 (d, C_8), 129.6 (s, C_{11a}), 128.2 (d, C_2 and C_6 of C_6H_5), 127.7 (d, C_4 of C_6H_5), 127.5 (d, C_3 and C_5 of C_6H_5), 119.8 (s, C_{5a}), 118.4 (s, C_9), 114.3 (d, C_7), 112.0 (s, C_2), 108.1 (s, C_6), 105.8 (s, C_{10a}), 99.6 (s, C_{12a}), 65.6 (t, OCH_2), 58.6 (d, C_4), 31.9 (d, C_{4a}), 29.0 (t, C_5), 25.6 (q, CO—CH_3), 15.1 (q, C_6—CH_3), 13.7 (q, C_9—CH_3); ms: *m/e* 529 $M^{+}\cdot$. *Anal.* calcd. for $C_{30}H_{27}NO_8$: C 68.04, H 5.14, N 2.64; found: C 68.75, H 5.43, N 2.63.

*12a-Deoxychelocardin Hydrobromide (**7**)*

Crude *N*-carbobenzoxy-12a-deoxychelocardin (5 g) was dissolved in hydrobromic acid (30% solution in glacial acetic acid, 75 ml) and the solution stirred for 5 min. The solution was poured into ether (500 ml) and the resulting precipitate collected by filtration and dried under high vacuum. The solid was dissolved in methanol (27 ml) and after 0.5 h, filtered. The filtrate was diluted to 50 ml with methanol and charcoal (2 g) added. The resulting suspension was stirred for 1 h, filtered, and concentrated to approximately 20 ml. Addition of ethanol (30 ml) and evaporation under reduced pressure gave 2.2 g (45%) of semicrystalline 7, mp 232–236°C (dec.); uv λ_{max} 225, 275, and 440 nm; Hmr (DMSO-d_6) δ 2.17 (s, 6H, C_6—CH_3 and C_9—CH_3), 2.67 (s, 3H, CO—CH_3), 3.0–3.5 (m, 3H, C_5—2*H* and C_{4a}—*H*), 5.0 (m, 1H, C_4—*H*), 7.0–7.5 (q, 2H, C_7—*H* and C_8—*H*), 9.0 (bs, 3H, —NH_3), 10.0 (bs, 1H, C_{10}—O*H*), 16.3 (bs, 1H, C_{11}—O*H*); ms *m/e* 395 $M^{+}\cdot$. *Anal.* calcd. for $C_{22}H_{22}NO_6Br$: C 55.47, H 4.65, N 2.94, Br 16.78; found: C 55.85, H 4.88, N 3.02, Br 16.45.

*2'-Pyrrolidine Enamine of N-Carbobenzoxychelocardin (**9**)*

Pyrrolidine (35 µl, 0.42 mmol) was added to a solution of *N*-carbobenzoxychelocardin (200 mg, 0.37 mmol) in benzene (10 ml) and the mixture was refluxed for 10 min. After cooling to room temperature, the mixture was poured into a large excess of hexane (~75 ml) and the resulting precipitate was filtered off, washed with a little hexane, and dried under high vacuum to give 210 mg (96%) of **9** as a mixture of epimers at C_4. Hmr δ 2.0 (m, 4H, pyrrolidine β-H), 2.26 (s, 3H, $C_{2'}$—CH_3), 2.40 (s, 3H, C_9—CH_3), 2.47 (s, 3H, C_6—CH_3), 3.0–3.9 (m, 7H, C_{4a}—*H* and C_5—H_2 and pyrrolidine α-*H*), 4.2 (m, 0.6H, N—*H*), 4.6 (m, 0.4H, N—*H*), 5.1 (d, 2H, —O$CH_2C_6H_5$), 5.5 (d, 0.4H, β-C_4—*H*), 6.05 (d, 0.6H, α-C_4—*H*) and 7.0–7.7 (m, 7H, C_7—*H*, C_8—*H*, and C_6H_5); high resolution mass spectrum calcd. for $C_{34}H_{34}N_2O_8$: *m/e* 598.2315; found: *m/e* 598.2357.

*N-Carbobenzoxy-2''-dimethylaminomethylene-chelocardin (**11a**)*

Dimethylformamide dimethyl acetal (70 µl, 0.65 mmol) was added to a refluxing solution of carbobenzoxychelocardin (100 mg, 0.18 mmol) in benzene (5 ml) and reflux was continued for 5 min. The mixture was cooled, washed with water (2 × 2 ml), dried by percolation through a small amount of anhydrous sodium sulfate, and poured into a large excess of hexane (40 ml). The resulting precipitate was collected by filtration, washed with a small quantity of ice-cold hexane, and dried under high vacuum to give 104 mg (95%) of pure **11***a*; Hmr δ 2.20 (s, 3H, C_9—CH_3), 2.30 (s, 3H, C_8—CH_3), 2.93 (s, 3H, N—CH_3), 3.13 (s, 3H, N—CH_3), 3.2–3.5 (m, 3H, C_{4a}—*H*, C_5—H_2), 4.2 (m, 1H, N—*H*), 5.20 (s, 2H, —O—CH_2—C_6H_5), 6.0 (d, 1H, C_4—*H*), 6.67 (d, J = 11 Hz, 1H, *H*C=CH—N—$(CH_3)_2$), 7.37 (m, 7H, C_7—*H*, C_8—*H*, and C_6H_5), 8.02 (d, J = 11 Hz, 1H, CO—CH=C*H*), 10 (bs, 1H, C_{10}—O*H*); uv λ_{max} 223, 271, 377, and 430 nm; high resolution mass spectrum calcd. for $C_{33}H_{30}N_2O_8$(**11***a*–H_2O): *m/e* 582.2002; found: *m/e* 582.2004. The relevant ^{13}C nmr data are given in the text.

*N-Carbobenzoxy-2''-(1-dimethylaminoethylidene)-chelocardin (**11b**)*

Dimethyl acetamide dimethyl acetal (100 µl, 0.65 mmol) was added to a refluxing solution of carbobenzoxychelocardin (100 mg, 0.18 mmol) in benzene (5 ml) and reflux was continued for 8 min. The mixture was cooled and poured into a large excess of hexane (40 ml). The resulting precipitate was collected by filtration, washed with a small quantity of ice-cold hexane, and dried under high vacuum to give 100 mg (98%) of pure **11***b*; Hmr δ 2.17 (s, 3H, C_9—CH_3), 2.23 (s, 3H, C_6—CH_3), 2.43 (s, 3H, C=C—CH_3), 2.83 (s, 3H,

N—CH_3), 2.90 (s, 3H, N—CH_3), 3.2 (m, 3H, C_5—H_2 and C_{4a}—H), 4.9 (m, 1H, N—H), 5.2 (s, 2H, —O—CH_2—C_6H_5), 6.03 (m, 1H, C_4—H), 6.87 (s, 1H, CH=C), 7.33 (m, 7H, C_7—H, C_8—H and C_6H_5); uv λ_{max} 225, 271, 377, and 420 nm; high resolution mass spectrum calcd. for $C_{33}H_{32}NO_9$(**11***b*–CH_2NO): *m/e* 570.2128; found: *m/e* 570.2139.

*2''-Acetyl-N-carbobenzoxychelocardin (**13**)*

A solution of sodium carbonate (40 mg) in water (4 ml) was added to **11***b* (100 mg, 0.16 mmol) dissolved in THF (20 ml) and the resulting mixture was stirred at room temperature for 2 h. The mixture was acidified to p*H* 2.0 with 1 *N* hydrochloric acid and the THF removed by evaporation under reduced pressure. The aqueous suspension was extracted with chloroform (2 × 15 ml) and the extract dried over sodium sulfate and concentrated to about 5 ml before being poured into hexane (30 ml). The resulting precipitate was collected by filtration and dried under high vacuum to give 76 mg (81%) of **13**; Hmr δ 2.05 (s, 1.5H, CH_3—C(OH)=C), 2.12 (s, 1.5H, CH_3—C=O), 2.30 (s, 3H, C_9—CH_3), 2.35 (s, 3H, C_6—CH_3), 3.1 (m, 3H, C_5—H_2 and C_{4a}—OH), 4.05 (s, 1.5H, CO—CH_2—CO), 5.2 (s, 2H, —OCH_2—C_6H_5), 5.4 (m, 1H, N—H), 5.9 (d, 1H, C_4—H), 6.8 (s, 0.5H, CO—CH=COH), 7.3 (m, 7H, C_7—H, C_8—H, and C_6H_5), 9.9 (bs, 0.5H, C_{10}—OH), 10.3 (bs, 0.5H, C_{10}—OH), 14.8 (bs, 0.5H, C_{11}—OH) and 15.4 (bs, 0.5H, C_{11}—OH); uv λ_{max} 228, 272, and 425 nm; high resolution mass spectrum calcd. for $C_{32}H_{29}NO_{10}$: *m/e* 587.1791; found: *m/e* 587.1820.

*5,5-Dimethyl-2-(3-dimethylaminopropenoyl)-1,3-cyclohexanedione (**12***a*)*

Dimethylformamide dimethyl acetal (0.24 ml, 1.75 mmol) was added to a solution of 2-acetyl dimedone (16) (100 mg, 0.55 mmol) in benzene (10 ml) and the solution was quickly heated to reflux which was maintained for 2 min. The solution was concentrated to ca. 2 ml under reduced pressure and chromatographed on a silica gel (25 g) column using chloroform – ethyl acetate (9:1) as eluent. The first component eluted from the column was **12***a* 98 mg (75%), mp 121–122°C; Hmr δ 1.03 (s, 6H, C_5—$(CH_3)_2$), 2.32 (s, 2H, C=C(OH)—CH_2), 2.40 (s, 2H, —CO—CH_2), 2.97 (s, 3H, N—CH_3), 3.17 (s, 3H, N—CH_3), 6.77 (d, J = 12 Hz, 1H, CO—CH=CH), 7.93 (d, J = 12 Hz, CO—CH=CH), 18.7 (s, 1H, C=C—OH); uv λ_{max} 270 and 370 nm; ms *m/e* 237 M^+·; *Anal.* calcd. for $C_{13}H_{19}NO_3$: C 65.80, H 8.07, N 5.90; found: C 66.05, H 8.34, N 5.72.

*5,5-Dimethyl-2-(3-dimethylamino-2-butenoyl)-1,3-cyclohexanedione (**12***b*)*

Dimethylacetamide dimethyl acetal (0.25 ml, 1.6 mmol) was added to a refluxing solution of 2-acetyldimedone (16) (100 mg, 0.55 mmol) in benzene (10 ml) and reflux was maintained for 10 min. The solution was cooled and concentrated, under reduced pressure to ca. 1 ml. The mixture was purified by preparative thin layer chromatography on a 20 × 20 cm silica gel plate (Quantagram PQIF 1000) using chloroform – ethyl acetate (9:1) as eluent. The band, visualized under uv light, at R_f 0.35 was removed and extracted with ethyl acetate. Upon concentration of this ethyl acetate solution, the product **12***b* crystallized yielding 94 mg (68%) of pure product, mp 132–134°C; Hmr δ 1.05 (s, 6H, C_5—$(CH_3)_2$), 2.39 (s, 2H, CH_2—C—(OH)=C), 2.57 (s, 2H, CH_2—C=O), 3.17 (s, 6H, N—$(CH_3)_2$), 7.05 (s, 1H, C=CH), 13.4 (bs, 1H, C=C—OH); uv λ_{max} 265 and 371 nm; high resolution mass spectrum calcd. for $C_{14}H_{21}NO_3$: *m/e* 251.1521; found: *m/e* 251.1530.

*Hydrolysis of (**12***b*)*

(*a*) *Basic Hydrolysis*

A solution of sodium carbonate (50 mg) in water (2 ml) was added to a solution of **12***b* (60 mg, 0.24 mmol) in THF (10 ml) and the mixture was stirred at room temperature for 2 h. The THF was removed by evaporation under reduced pressure and the aqueous residue extracted with chloroform (2 × 30 ml). Concentration of the dried (sodium sulfate) extract gave 42 mg (85%) of pale yellow crystals of 5,5-dimethyl-2-(1,3-dioxobutyl)-1,3-cyclohexanedione (**14**), mp 59–60°C (lit. (17) mp 60–61°C). The Hmr of **14** was essentially the same as the previously reported (17) differing only in the proportion of enol form present.

(*b*) *Acidic Hydrolysis*

Aqueous hydrochloric acid (5 ml, 1 *N*) was added to a solution of **12***b* (160 mg, 0.63 mmol) in THF (25 ml) and the mixture stirred at room temperature overnight. The THF was evaporated under reduced pressure and the aqueous residue extracted with chloroform (2 × 30 ml). Concentration of the dried (Na_2SO_4) extract gave 110 mg (84%) of colourless crystals identified as 7,8-dihydro-2,7,7-trimethyl-4H-1-benzopyran-4,5-(6H)-dione (**15**); mp 118–120°C (lit. (17) 121–122°C; lit. (18) 207–208°C) which exhibited an identical Hmr to that previously reported (17).

Acknowledgments

We thank G. Nettleship and Ms. S. Mueller of Abbott Laboratories for Hmr and mass spectra, respectively, and R. S. Egan and Ms. R. S. Stanaszek for the ^{13}C nmr spectra, and the staff of the microanalytical department of Abbott Laboratories for elemental analyses. We also thank D. L. Garmaise for his interest and encouragement throughout the course of this work.

Benzannelated annulenes. II.[1] The synthesis of *trans*-12*b*,12*c*-dimethyl-12*b*,12*c*-dihydrobenzo(e)pyrene. An indication of the exceptional aromaticity of the 15,16-dimethyldihydropyrene[2] system

REGINALD H. MITCHELL[3] AND JOSEPH SHUE-HEN YAN

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 22, 1977

REGINALD H. MITCHELL and JOSEPH SHUE-HEN YAN. Can. J. Chem. **55**, 3347 (1977).

The synthesis of *trans*-12*b*,12*c*-dimethyl-12*b*,12*c*-dihydrobenzo(e)pyrene **4**, in 10 steps from *o*-dibromobenzene and 2,6-dichlorotoluene utilizing a Wittig rearrangement – Hofmann elimination sequence on the benzothiacyclophane **6** is described. The diatropicity of **4** is compared to the parent *trans*-10*b*,10*c*-dimethyl-10*b*,10*c*-dihydropyrene **1**, and to other benzannelated annulenes.

REGINALD H. MITCHELL et JOSEPH SHUE-HEN YAN. Can. J. Chem. **55**, 3347 (1977).

On décrit la synthèse comportant 10 étapes du diméthyl-12*b*,12*c* dihydro-12*b*,12*c* benzo(e)pyrène *trans* **4** à partir du *o*-dibromobenzène et dichloro-2,6 toluène en utilisant une séquence comportant un réarrangement de Wittig et une élimination d'Hofmann sur le benzothiacyclophane **6**. La diatropicité de **4** est comparée à une molécule analogue le diméthyl-10*b*,10*c* dihydro-10*b*,10*c* pyrène *trans* **1** et à d'autres annulènes benzannelés.

[Traduit par le journal]

Like benzene, *trans*-15,16-dimethyl-15,16-dihydropyrene **1** has both a $(4n + 2)$–π electron periphery and two identical Kekulé structures and, moreover, since models indicate the macro-ring of **1** to be nearly planar, it could reasonably be expected to be aromatic. The synthesis of **1** by Boekelheide and Phillips (2) confirmed this point, and in its ^{1}H nmr spectrum, **1** showed its internal methyl protons to be exceptionally shielded at τ 14.25 by the strong diamagnetic ring current. A more recent (3) synthesis of **1**, utilizes the ready conversion of [2,2]metacyclophane-1,9-diene **2** into the thermodynamically (4) more stable photoisomer **1**. In this conversion, the delocalization of the electrons in both the benzene rings has to be interrupted in order to achieve conjugation in the macro-ring of **1**. In light of the fact that many tri and higher benzannelated annulenes have been known for a considerable number of years (see, for example, ref. 5) and none of them show any detectable delocalization in the macro-ring at the expense of the benzene rings, we thought it worthwhile to prepare the tribenzo compound **3** to determine whether it is possible to partially disrupt three benzene rings to form the macrocyclic system **4** which can be considered to be a benzannelated derivative of **1**.

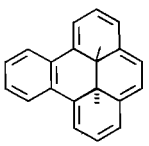
3 **4**

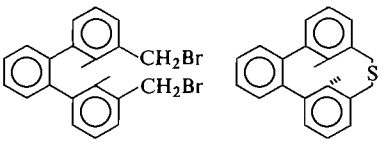


[1]For part I, see ref. 1.

[2]Chemical Abstract name is now *trans*-10*b*,10*c*-dimethyl-10*b*,10*c*-dihydropyrene.

[3]To whom correspondence should be addressed.

The synthesis of **3** required the dibromide **5**, which we prepared (mp 129–130°C)[4] in six steps[5] from *o*-dibromobenzene and 2,6-dichlorotoluene. Treatment of **5** under high dilution conditions (3) with sodium sulphide gave ca. 40% of the *anti*-thiacyclophane **6**, mp 201–202°C (along with a nearly equal amount of *syn*-isomer, mp 251–253°C). Separation was readily accomplished by chromatography on silica gel, the *anti*-cyclophane **6** being eluted first. *Anti*-**6** was readily distinguishable from *syn*-**6** by its ^{1}H nmr spectrum in which the shielded internal methyl protons appear at τ 9.1, whereas in *syn*-**6** they are in the normal toluene region (τ 7.9). Application of our Wittig rearrangement – Hofmann elimination sequence (6) to **6** then gave an 80% overall yield (from **6**) of the deep purple hydrocarbon **4**, mp 137–138°C, no detectable amount of the photoisomer **3** being present. The presence of a strong diamagnetic ring current in **4** was clearly evident from its ^{1}H nmr spectrum in which the internal methyl protons were strongly shielded at τ 11.85 and the external protons strongly deshielded at τ 1.0–3.6. The position of the internal methyl protons of **4** indicates[6] that



5 **6**

[4]The structure of all new compounds was fully supported by mass and nmr spectral data, and elemental analyses.

[5]Reaction of Mg with 2,6-dichlorotoluene in dry THF yielded the mono-Grignard reagent which on addition of *o*-dibromobenzene and 0.1 mol% $Ni(acac)_2$ gave 60% of 3,3″-dichloro-2,2″-dimethyl-*o*-terphenyl which was then converted through the dinitrile, dialdehyde, dialcohol to the dibromide **5** in 59% yield using the same reagent sequence (3) as for 2,6-bis(bromomethyl)toluene.

[6]This assumes that shielding is proportional to ring current. Calculated by comparison to a nonaromatic cyclic model, where methyl protons in a similar environment are at τ 9.0 (2).

4 sustains about 55% of the ring current of **1**. This is much greater than for benzo[14]annulene itself (7) or benzodidehydro[14]annulene (8), and must reflect on the considerably greater aromaticity of the rigid dihydropyrene nucleus of **1** than that of [14]annulene. Indeed **4** must be a contender for sustaining the largest ring current of any monobenzoannulene yet reported.[7]

This together with the fact that to disrupt the delocalization of each benzene ring of **3** may cost up to 36 kcal/mol (9) must point to the exceptional aromatic stability of the dihydropyrene system. We have not yet succeeded in converting *syn*-**6** into the corresponding *syn*-isomer of **4**.

Photochemistry of oxalate esters as a route to free radicals. Decay routes of crowded free radicals[1]

SIDDIK IÇLI,[2] VINCENT J. NOWLAN, PARVIZ M. RAHIMI, CHACKO THANKACHAN, AND THOMAS T. TIDWELL

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 14, 1977

SIDDIK IÇLI, VINCENT J. NOWLAN, PARVIZ M. RAHIMI, CHACKO THANKACHAN, and THOMAS T. TIDWELL. Can. J. Chem. **55**, 3349 (1977).

Photolysis of suitable oxalate esters leads to alkyl radicals which in the case of di- and tri-*tert*-butylmethyl abstract hydrogen and for triisopropylmethyl-d_{18} gives an esr spectrum consistent with the 'cogwheel' conformation for this species.

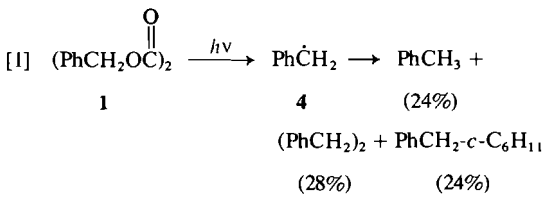
SIDDIK IÇLI, VINCENT J. NOWLAN, PARVIZ M. RAHIMI, CHACKO THANKACHAN et THOMAS T. TIDWELL. Can. J. Chem. **55**, 3349 (1977).

La photolyse d'oxalates appropriés conduit à des radicaux alkyles qui, dans le cas des di-, et tri-*tert*-butylméthyles, enlevent un hydrogène, et du tri-isopropylméthyle-d_{18}, présentent un spectre rpe compatible avec une conformation "roue dentée".

[Traduit par le journal]

Oxalate esters have been used to prepare free radicals by pyrolysis (1) and reduction (2), but although the photochemistry of esters has been a topic of intense recent interest (3), only scattered reports of oxalate photolysis have appeared (4). Oxalate esters have an attractive potential stoichiometry for photolysis to give only radicals and carbon dioxide, and absorb light at lower energies than ordinary esters (λ_{max} ethyl oxalate = 244 nm).

We now have found that photolysis of the oxalates **1–3** in cyclohexane with a medium pressure Hg lamp through quartz gave the products shown in eqs. 1–3 which implicate the radicals **4–6** as intermediates.[3] The esr spectrum of **6** was also observed during the photolysis (5). Oxalates with reactive β-hydrogens such as *tert*-butyl and cumyl gave mostly photoelimination (3*a*) to alkenes.



[1] $(PhCH_2OC(=O))_2 \xrightarrow{h\nu} PhC\dot{H}_2 \longrightarrow PhCH_3 + (PhCH_2)_2 + PhCH_2\text{-}c\text{-}C_6H_{11}$

[2] $(t\text{-}Bu_2CHOC(=O))_2 \xrightarrow{h\nu} t\text{-}Bu_2\dot{C}H \longrightarrow t\text{-}Bu_2CH_2$ (16%)

2 5

[3] $(t\text{-}Bu_3COC(=O))_2 \xrightarrow{h\nu} t\text{-}Bu_3\dot{C} \longrightarrow t\text{-}Bu_3CH$ (38%)

3 6

The isolation of t-Bu_2CH_2 and t-Bu_3CH from the corresponding radicals establishes hydrogen abstraction as an important decay route for these long lived radicals (6[4]). This point has been unsettled (5), and the current results suggest these radicals may be very much longer lived in the absence of abstractable hydrogens.

i-$Pr_3C\cdot$ $Me_2C{=}C{-}i$-Pr_2

7 8

A well resolved esr spectrum of **7** (7) was observed on photolysis of the oxalate, but interestingly the only volatile product observed was **8** (91% by vpc). This product may arise partly from photoelimination but studies of **7** from the perester (7) show that it can also arise from disproportionation reactions of **7** with cyclohexyl radicals. A sample of **7** fully deuterated in the methyl groups was prepared (eq. 4). Irradiation gave **7**-d_{18} whose esr spectrum in cyclopropane

was a simple quartet (Fig. 1). The a_H^β values were found to vary with temperature as previously suggested in our interpretation of the spectrum of the undeuterated material (7). This is consistent with a planar geometry for the radical (Fig. 2), with small a_H^β values arising from the methine C—H bonds being orthogonal to the p orbital carrying the unpaired spin. The increase in a_H^β with temperature would arise from an increased amplitude of the torsional vibrations of the C—C bonds from the sp^2 carbon. The esr spectrum of undeuterated **7** is not fully resolved due to the γ splittings.

Thus this procedure provides improved routes to radicals such as **5**–**7** and the theoretically interesting tri-*tert*-butylmethane (6), and also resolves the questions as to the decay routes of **5** and **6** and the structure of **7**.

Solvated electrons and the effect of coordination on the optical spectra of alkali metal cation – electron pairs in ethers[1]

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, FRED CHARLES SOPCHYSHYN, AND RON CATTERALL[2]

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received April 28, 1977

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, FRED CHARLES SOPCHYSHYN, and RON CATTERALL. Can. J. Chem. **55**, 3356 (1977).

Pulse radiolysis of tetrahydrofuran (THF), dimethoxyethane (DME), diglyme (DG), and triglyme (TG), results in the formation of solvated electrons, e_s^-, with optical band maxima $\lambda_{max} \geq 1840$ nm. In the presence of alkali metal salts transient optical bands are observed with λ_{max} at ~ 900 and ≥ 1600 nm. The latter bands are assigned to the formation of 'monomeric' species of stoichiometry M considered to be 'tight' and 'loose' ion-pairs, respectively. The proportion of 'loose' ion-pairs increases with decreasing temperature and increasing coordination of the solvent in the order THF $\ll$ DME $<$ DG $<$ TG. These results demonstrate a good correlation with established electron spin resonance data in alkali metal solutions and substantiate the coexistence of at least two 'monomeric' species in DME and the glymes.

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, FRED CHARLES SOPCHYSHYN et RON CATTERALL. Can. J. Chem. **55**, 3356 (1977).

La radiolyse par impulsion du tétrahydrofuranne (THF), diméthoxyéthane (DME), diglyme (DG) et triglyme (TG) conduit à la formation d'électrons solvatés e_s^- ayant des bandes optiques de maxima $\lambda_{max} \geq 1840$ nm. En présence de sels de métaux alkalins on observe des bandes optiques transitoires ayant des λ_{max} à ~ 900 et ≥ 1600 nm. Ces dernières bandes sont attribuées à la formation d'espèces "monomères" de stoechiométrie M que l'on considère comme étant respectivement des ions-pairés "près" et "loin". La proportion d'ions-pairés "loin" croît avec la diminution de la température et l'augmentation des sites de coordination du solvant: THF $\ll$ DME $<$ DG $<$ TG. Ces résultats démontrent une bonne corrélation avec les données établies par résonance de spin électronique en solutions de métaux alkalins et justifient la coexistence d'au moins deux espèces "monomères" dans le DME et les glymes.

[Traduit par le journal]

Introduction

The nature of the blue solutions of alkali metals in ethers has aroused considerable interest since their original discovery in 1957 (1, 2). Optical (3), electron spin resonance (esr) (4, 5), conductivity (6), flash photolysis (7–9), and pulse radiolysis (10–12) techniques have now clearly established the contribution of solvated electrons, e_s^-, cation–electron aggregates (M^+, e_s^-), and alkali metal anions M^- to the chemistry of such solutions.

Nevertheless, considerable controversy revolves around the precise identity of the (M^+, e_s^-) species. Pulse radiolysis of alkali metal salts in several amines and tetrahydrofuran (THF) (13) has established the formation of transient optical bands of stoichiometry M, resulting from the reaction of the cation M^+, with e_s^-.

[1] $$e_s^- + M^+ \rightarrow (M^+, e_s^-) \text{ or } M$$

Such bands exhibit a distinct blue shift from that of e_s^- observed in the same solvent. The magnitude of this shift shows a clear correlation with the percent atomic character, deduced from the esr hyperfine splitting constants, A_{iso}, for the corresponding 'monomeric' M species produced in alkali metal solutions (14–16). The value of A_{iso} is markedly temperature dependent and two different models have been proposed to explain this behaviour. In a static or continuum model, a single species is proposed whose structure is temperature dependent while a dynamic or multistate model envisages a temperature-

[1]AECL No. 5886.

[2]Visiting scientist, May–September 1976. Permanent address: Chemistry Department, University of Salford, Salford M54WT, England.

dependent equilibrium between two (or more) species of the same stoichiometry whose structures are relatively insensitive to temperature (17–23).

The observation of a single optical absorption band, and its correlation with esr (16), would appear to contradict the multistate theory. However, in progressing along the series THF, dimethoxyethane (DME), and the polyglycoldimethyl ethers (glymes), evidence was obtained for the existence of two distinct optical bands resulting from the reaction of e_s^- with Na^+ (24). Glymes have the general formula $CH_3O[CH_2CH_2O]_nCH_3$ and for $n = 1$, 2, and 3 correspond to DME, diglyme (DG), and triglyme (TG), respectively. In this series the chelating or cation solvating ability is well established (25) and increases markedly in the order THF < DME < DG < TG. This paper expands our preliminary account (24), compares our results with esr, and presents our conclusions with respect to the influence of solvent structure on the nature of (M^+, e_s^-).

Experimental

Details of the pulse radiolysis equipment, flow systems, and general techniques have been discussed elsewhere (26, 27). In this work all experiments were conducted using a 1.0 cm cell and 0.3 μs pulses of 2.25 MeV electrons. Solution preparation and purification of THF were as described previously (12). DME (Eastman) and the glymes (Matheson, Coleman and Bell, and Aldrich Chemicals) were purified by refluxing over calcium hydride in an inert atmosphere followed by fractional distillation. The middle fractions were degassed and allowed to stand over Na/K alloy until a stable blue color was obtained. This solution was then cooled and decanted, under vacuum, from the alloy and the ethers subsequently redistilled into the appropriate flow system. Sodium and potassium tetraphenylboron salts were used to give solutions of the alkali metal cations (12).

Results and Discussion

Solvated Electrons

Figure 1 shows the optical absorption spectra of e_s^- observed at 21°C immediately after the pulse in pure DME, DG, and TG. In each case there is good agreement with the normalized spectra (solid lines) observed previously having band maxima of 2050, 1915, and 1840 nm, respectively (10). As in other work (11, 28, 29) both the yield, $G_{e_s^-}$ molecules per 100 eV, and extinction coefficient ε_{max} at the band maximum, were determined by comparison with $G\varepsilon$ (anion) in the presence of $\leq 5 \times 10^{-4}$ M biphenyl (B) as an electron scavenger. Assuming $\varepsilon_{B^-} = 4 \times 10^4\ M^{-1}\ cm^{-1}$ at 410 nm (29) yields were calculated from linear plots of optical density against the energy absorbed per pulse for doses $\leq 1 \times 10^{20}$ eV ℓ^{-1}. On this basis we obtain $G_{e_s^-} = 0.40 \pm 0.03$ and $\varepsilon_{max} = 3.8 \pm 0.3 \times 10^4\ M^{-1}\ cm^{-1}$ for each ether. Again this is in good agreement with previous work in DME and THF where $\varepsilon_{max} = 3.4 \pm 0.7$ (10) and 4.0 ± 0.8 or $5.0 \pm 0.5 \times 10^4\ M^{-1}\ cm^{-1}$, respectively (10, 12).

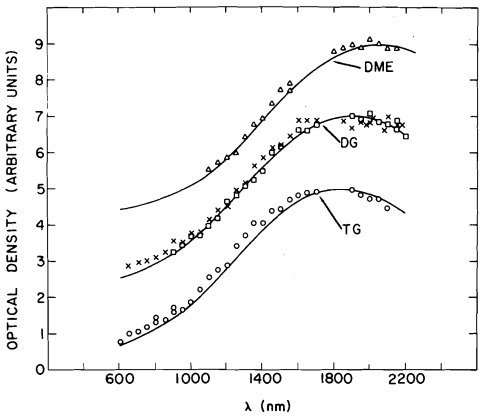

FIG. 1. Optical absorption spectra of e_s^- in ethers at 21°C. The solid lines represent the normalized spectra obtained previously (10). The DG and DME spectra are successively displaced vertically by two units for clarity in presentation.

With increasing temperature the absorption maxima shift toward lower energies with temperature coefficients of -17 ± 2, -19 ± 3, and $-20 \pm 3\ cm^{-1}\ deg^{-1}$ from −50, −64, and −40°C to 21°C for DME (mp −58°C), DG (mp −64°C), and TG (mp −45°C), respectively. At temperatures close to the melting point (mp) where the band maxima are more clearly resolved the corresponding widths at half height, $\Delta\nu_{1/2}$, are found to be ~5200, 5500, and 5900 cm^{-1}. Using the approximation $f \sim 4.32 \times 10^{-9}\ \varepsilon_{max} \times \Delta\nu_{1/2}$ (30), and substituting the appropriate values from above the oscillator strengths, f, of the e_s^- absorption bands are estimated as 0.85, 0.90, and 0.97, respectively.

Solvated Electron – Cation Aggregates

Optical Spectra

Figure 2 shows the optical spectra observed at the end of the pulse in DG solutions containing 7.2×10^{-4} and 9×10^{-3} M sodium tetraphenylboron ($NaB\phi_4$). The dotted line shows

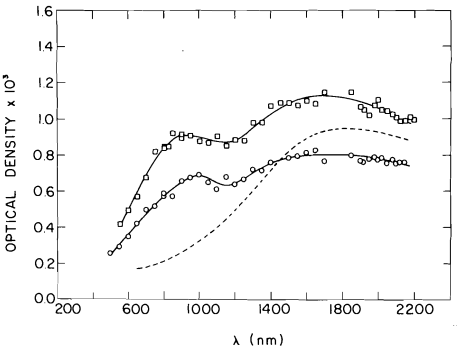

FIG. 2. Transient optical spectra observed immediately after the pulse in DG at 21°C. Dotted line, e_s^-; ○ and □ solutions containing 7.2×10^{-4} *M* and 9×10^{-3} *M* $NaB\phi_4$, respectively. Doses/pulse were $\sim 1 \times 10^{20}$ eV ℓ^{-1} with the optical densities normalized to a dose of 4.1×10^{18} eV ℓ^{-1}.

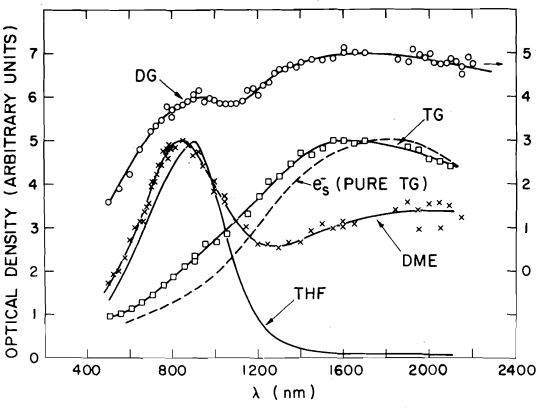

FIG. 3. Transient optical spectra observed immediately after the pulse in $\sim 10^{-2}$ *M* $NaB\phi_4$ solutions in THF, DME, DG, and TG. For THF and DME the spectra are normalized to a peak height of five units for the 900 and 850 nm band maxima, respectively. In DG and TG the spectra are normalized with respect to the 1600 nm band with the ordinate for the DG spectrum displaced two units (right hand scale). The dotted line shows the spectrum of e_s^- in TG.

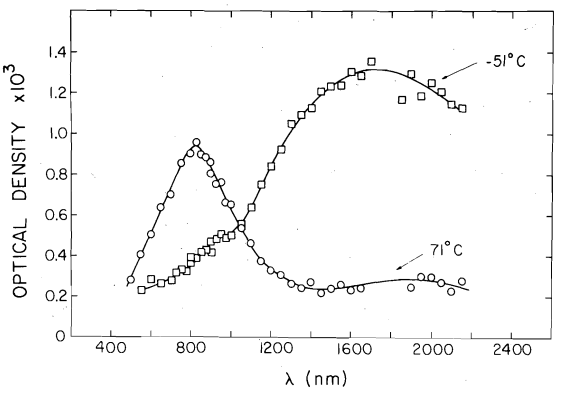

FIG. 4. Transient optical spectra observed immediately after the pulse as a function of temperature in $\sim 10^{-2}$ *M* $NaB\phi_4$ solutions in DME. Optical densities correspond to a dose of 2.66×10^{18} eV ℓ^{-1} at 71°C and 2.96×10^{18} eV ℓ^{-1} at −51°C. Typical doses/pulse were $\sim 6 \times 10^{19}$ eV ℓ^{-1}.

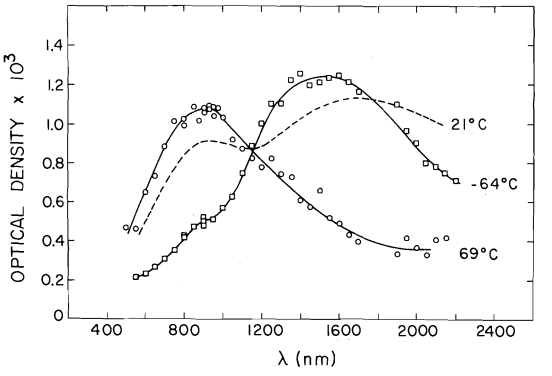

FIG. 5. Transient optical spectra observed immediately after the pulse as a function of temperature in $\sim 10^{-2}$ *M* $NaB\phi_4$ in DG. Optical densities correspond to doses of 2.3, 4.1, and 3.61×10^{18} eV ℓ^{-1} at −64, 21, and 69°C, respectively. Doses/pulse ranged from 0.7 to 1.0×10^{20} eV ℓ^{-1}.

the spectrum of e_s^- in DG from Fig. 1. Figure 3 shows the corresponding normalized spectra obtained in $\sim 10^{-2}$ *M* $NaB\phi_4$ solutions in DME and TG together with those observed in DG and THF for comparison. Similar spectra are obtained in solutions containing $NaAlH_4$. Figures 4, 5, and 6 show the effect of temperature on the DME, DG, and TG spectra presented in Fig. 3. Corresponding temperature studies from 21 to −17°C in THF gave no change in the spectrum. Figure 7 shows the optical spectrum observed at the end of the pulse in $\sim 10^{-2}$ *M* $KB\phi_4$ solutions in THF, DG, and DME along with the spectrum of e_s^- in DG for comparison.

The spectra, extinction coefficients, and oscillator strengths for e_s^- are in good agreement with previous work (10) and require no further comment. The blue shifts in band maxima with decreasing temperature are also typical of e_s^- in other systems (31).

With the addition of $NaB\phi_4$ the optical bands show a progression from a single peak at 900 nm in THF, through a composite spectrum in DME and DG with peaks at ~900 and ≥1600

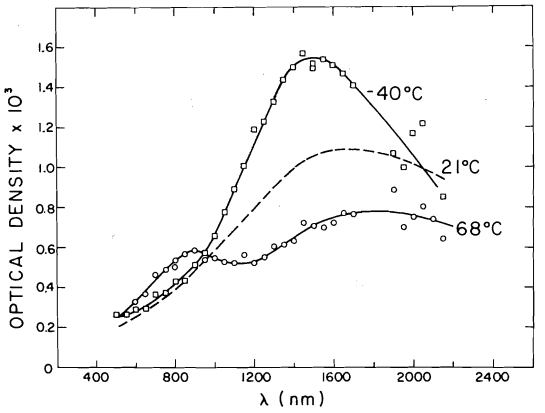

FIG. 6. Transient optical spectra observed immediately after the pulse as a function of temperature in $\sim 10^{-2}$ *M* $NaB\phi_4$ in TG. Optical densities correspond to doses of 3.24, 4.20, and 2.95 $\times$ 10^{18} eV ℓ^{-1} at -40, 21, and 68°C, respectively. Doses/pulse ranged from 0.6 to 1.0 $\times$ 10^{20} eV ℓ^{-1}.

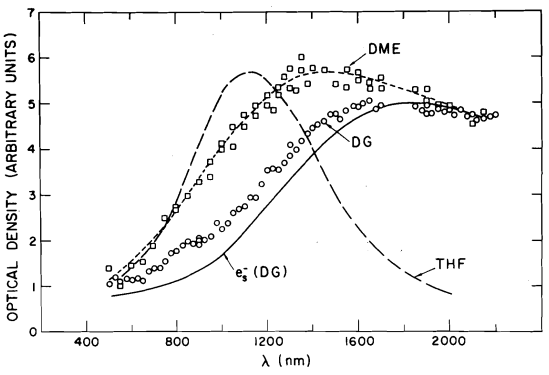

FIG. 7. Transient optical spectra observed immediately after the pulse in $\sim 10^{-2}$ *M* $KB\phi_4$ solutions in THF, DME, and DG. The dashed line shown for DME represents a calculated composite spectrum containing 25% of the THF species and 75% of the DG species (see text).

nm, until finally only the latter band is observed in TG. It can be seen in Figs. 2, 3, and 7 that although small, there is in the presence of $NaB\phi_4$ or $KB\phi_4$, a distinct blue shift in the long wavelength maximum from that of the corresponding e_s^- band in the same solvent.

In THF it is well established that [2] produces the 900 nm band with a second order rate constant $k_2 = 7.9 \times 10^{11}\ M^{-1}\ s^{-1}$ (10, 12)

[2] $$e_s^- + Na^+ \rightarrow (Na^+, e_s^-)$$

Because of spectral overlap it is not possible to measure the corresponding rate constants in DG, DME, or TG. However, changes in spectra such as depicted in Figs. 2 and 3 are observed immediately after the pulse at concentrations of $\sim 10^{-4}$ *M* $NaB\phi_4$. Since, as in THF (32, 33), it is likely that $NaB\phi_4$ is only weakly dissociated this indicates that the corresponding values of k_2 are $\geq 5 \times 10^{10}\ M^{-1}\ s^{-1}$.

On the basis of the optical–esr correlation (15, 16) we propose that in these ethers the 900 nm (r band) corresponds to the formation of a 'tight' ion-pair structure, whereas the 1600 nm (ir band) relates to a 'loose' ion-pair aggregate. By 'tight' we envisage a structure which allows a significant degree of interaction between e_s^- and the outer *s*-orbital of M^+ resulting in an appreciable atomic character of $\geq 30\%$ as found in THF (4). By 'loose' we imply a greater degree of solvent separation between M^+ and e_s^- resulting in less hyperfine interaction and an atomic character ≤ 2–5%. In both DME and DG (and THF) we suggest that the 'tight' aggregates represent coordination of M^+ with a single oxygen lone-pair whereas the ir bands reflect cation solvation by coordination with more than one site. In the latter case the glyme effectively shields the outer *s*-orbital of the cation from overlap with the e_s^-. These two types of aggregates we designate as $(M^+, e_s^-)_{tight}$ and $(M^+, e_s^-)_{loose}$, analogous to the well established ion-pair concepts in organic anion systems (34).[3]

From spectra such as shown in Fig. 2 it is apparent that the relative intensities of the r and ir bands remain the same over a 25-fold range of $NaB\phi_4$ concentration. This indicates that any contribution from e_s^- to the overall optical spectrum must be very small and a rapid equilibrium, predominantly in favour of 'loose' and 'tight' ion pairs, is established during the pulse.

[3] $$M^+ + e_s^- \rightleftarrows (M^+, e_s^-)_{loose} \rightleftharpoons (M^+, e_s^-)_{tight}$$

Such an interpretation is in accord with esr multistate models which require the existence of two or more distinct cation–electron aggregates in equilibrium (19).

In $KB\phi_4$ in THF, DG, and DME solutions (Fig. 7) only a single broad absorption band is observed. This again is consistent with the esr–optical correlation (16) in that the corresponding

[3]After submission of our original manuscript essentially the same description for the M species in alkali metal solutions appeared elsewhere (35).

potassium 'tight' ion-pair is expected to be red shifted by ~200 nm from that observed in $NaB\phi_4$ solutions. The lack of any obvious shoulder at ~1100 nm suggests that the equilibria in [3] lie more in favour of the 'loose' structure potassium solutions than for sodium. For example in DME the dashed line in Fig. 7 corresponds to a composite spectrum containing 25% of the 'tight' structure, as observed in THF, and 75% of the 'loose' structure observed in DG. For the corresponding sodium species at 21°C we estimate the fraction of 'tight' ion-pairs to be ~50% (see below).

In general the percent atomic character observed in alkali metal solutions for a given solvent increases in the order Na < K < Rb < Cs (16). The above observation is therefore not necessarily inconsistent with this trend since the expected increase in atomic character for K may compensate for the relative difference in equilibria from Na to K.

Another well established feature of the esr spectra is the marked temperature dependence of the metal hyperfine splitting constants, A_{iso} (3, 4). Increasing the temperature increases A_{iso} (and hence the percent atomic character) and vice versa. For organic anions and ethereal solvents the formation of loose ion-pairs is usually exothermic and is determined by the coulombic interaction between anion and cation in the tight and loose configurations and by the solvation energy of the two ion-pairs (25). In general the exothermicity and degree of solvent separation increases in the more polar solvents. Therefore, as suggested previously (36), a decrease in temperature is not inconsistent with a shift of [3] to the left. It can be seen from Figs. 4–6 that a clear shift in the optical spectrum corresponding to the formation of $(M^+, e_s^-)_{loose}$ is observed at low temperatures and vice versa at high temperatures. It is difficult to make precise quantitative comparisons with esr because of the corrections for spectral overlap and the uncertainty in relating esr data for potassium solutions with optical spectra for the corresponding sodium species. However, relative contributions of the 'tight' and 'loose' species can be estimated provided the extinction coefficients are known. The latter were estimated by comparison of the appropriate $G\varepsilon$ values obtained in $\sim 10^{-2}$ M $NaB\phi_4$ solutions with the corresponding values for B^- produced via [4] (12).

TABLE 1. Molar extinction coefficients for the tight and loose ion-pair species in ethers

		ε_{max} (M^{-1} cm^{-1}) ($\times 10^{-4}$)	
Solvent	Cation	Tight	Loose
THF*	Na^+	2.4 ± 0.2	
	K^+	2.9 ± 0.2	
	Cs^+	2.5 ± 0.2	
DME	Na^+	2.7 ± 0.4	2.9 ± 0.4
	K^+		2.8 ± 0.4
DG	Na^+	2.4 ± 0.4	2.4 ± 0.4
	K^+		2.4 ± 0.4
TG	Na^+	2.2 ± 0.4	2.4 ± 0.4

*See refs. 10 and 12.

[4] $$(Na^+, e_s^-) + B \rightarrow (Na^+, B^-)$$

For DME, DG, and TG at 21°C we find $G(B^-) = G(Na^+, e_s^-)_{tight} + G(Na^+, e_s^-)_{loose} = 0.9 \pm 0.1$. For DME this value was independent of temperature from −50 to 70°C. At −50°C only the ir band is observed from which we deduce $\varepsilon_{loose} = 2.9 \pm 0.3 \times 10^4$ M^{-1} cm^{-1}. However, at 71°C the r band predominates. Assuming the contribution of the r band to the ir band maximum to be negligible, and taking the above ε_{loose} to calculate the fraction of 'loose' ion-pairs, we then estimate $\varepsilon_{tight} = 2.7 \pm 0.3 \times 10^4$ M^{-1} cm^{-1}. This value is corrected for the overlap due to the ir band. At intermediate temperatures corrections for spectral overlap are more significant but adopting the same technique we obtain values in good agreement with the above. A similar procedure was utilized for DG and TG. However, at temperatures close to the mp the yield is approximately twice that observed at 21°C, presumably due to the enhanced escape probability of e_s^- from the spur (37). The appropriate extinction coefficients in each of the ethers are summarized in Table 1.

Utilizing the fraction tight/(tight + loose) and taking $A_{iso}(r) = 30$ G (by comparison with THF) and $A_{iso}(ir) = 0.3$ G as representative of splitting constants for the 'tight' and 'loose' ion-pairs in this series of ethers we can, since [3] is established in ≤0.3 μs, estimate the observed esr parameters from the weighted average of each form (38). These values are summarized in Table 2. Although the comparison is not exact the trend, particularly in DME, is remarkably good. We believe this adds further weight to the esr models in which the observed A_{iso} is thought to

TABLE 2. Optical ratio of tight and loose ion-pairs as a function of temperature for sodium species in ethers

Solvent	Temperature (°C)	Tight (Tight + Loose)	A_{iso} (G)* Calc.	Expt.
DME	−51	0.04	1.5	
	−20	0.11	3.6	0.0
	21	0.54	16.3	12.5
	71	0.75	22.5	28.5

arise from a rapidly fluctuating hyperfine interaction between two discretely different solvated cation – electron aggregates.

In contrast it is interesting to note that in THF no shift or change in the (Na^+, e_s^-) spectrum was observed from 21 to −17°C. However, esr studies in potassium solutions show a decrease in A_{iso} over this temperature range of ~5 G (4), indicative of a looser structure. Since both the e_s^- and Na^- shift to the blue with decreasing temperature the relative position of the (Na^+, e_s^-) band is therefore closer to that of e_s^- and consequently we would predict a lower A_{iso} and a somewhat looser structure. This observation would imply a somewhat enhanced degree of cation-solvation with decreasing temperature compatible with the static model. For the multistate model to apply one might also consider an equilibrium between two slightly different 'tight' species (21) rather than a distinct contribution from a 'loose' species characteristic of the glymes.

This situation would also seem to apply in the glymes as a lower order effect in that there appears to be no shift in the position of the corresponding r band maxima with change in temperature. Furthermore, for the ir band, blue shifts of ~4, 7, and 9 cm^{-1} deg^{-1} observed in Figs. 4–6 for DME, DG, and TG, respectively, are significantly less than observed for e_s^- (this work) or M^- in the same solvents (31). Again this can be interpreted in favour of a slightly looser structure for the ir species. We suggest therefore that a combination of both the static and dynamic models are applicable in these systems either one of which can predominate according to the nature of the solvent. Such a conclusion is analogous to that suggested previously in the interpretation of esr spectra for organic radical anions (38).

Reaction Kinetics

No detailed kinetic studies of the subsequent ion-pair decay processes were investigated since the bulk of the decay probably occurs by reaction with other radiolytically produced radicals (12). However, in each case for solutions containing ~10^{-2} *M* $NaB\phi_4$ or $KB\phi_4$ and doses per pulse of ~1×10^{20} eV ℓ^{-1}, the decay at wavelengths ≥1150 nm is complete with ~10 μs. At lower wavelengths the absorption initially decays at the same rate but is then followed by a slow build up which reaches its maximum intensity some 30 μs after the pulse. The spectrum observed on this time scale peaks at 900 nm, reaches a maximum intensity ~30% of that observed initially at 2000 nm, and decays completely after ~500 μs. This additional absorption is not produced in $NaAlH_4$ solutions. A weak absorption observed ~7 μs after the pulse in $NaB\phi_4$ solutions peaks at ~700 nm and is undoubtedly due to Na^- (13).

We have been unable to identify the intermediate long-lived absorption at 900 nm but the available evidence indicates that this results from a reaction involving the tetraphenylboron anion.

Comparisons with Flash Photolysis

In an earlier study on the flash photolysis of Na^- in DG at −60°C (8, 39) the immediate formation of an ir band, with a maximum at 1600 nm, was followed by the slow (t_{max} = 0.1 s) formation of an intense absorption peaking at 830 nm and the subsequent regeneration of Na^-. Similar results were observed in DME containing NaCl dissolved in potassium solutions. These observations were attributed to the formation of e_s^- (ir band) and (Na^+, e_s^-) as precursors of Na^-.

Comparing this work with our pulse radiolysis results it is clear that at low temperatures the ir band observed by flash photolysis is consistent with the formation of $(Na^+, e_s^-)_{loose}$ or e_s^-. However, the 830 nm band cannot be identified with $(Na^+, e_s^-)_{tight}$ since the latter is absent, or is seen only as a minor component, at low tem-

peratures. Furthermore the pulse radiolysis results (see earlier) show that the formation of the ion-pair in [2] is diffusion controlled whereas the flash photolysis interpretation indicates the contrary (8, 39). Further experiments are in progress in an attempt to rationalize these puzzling discrepancies.

Non-chelating Solvents

In the non-chelating amine solvents such as methylamine MA (40), ethylamine EA (25), and isopropylamine IPA (14) only a single optical band attributed to ion-pair formation is observed. In MA we would consider such ion-pairs to be of a 'loose' type which, with decreasing solvent polarity, become progressively tighter in the order MA < EA < IPA (16, 35). In this respect one cannot refer to distinct 'tight' and 'loose' entities but must instead consider a continuous range of ion-pair species. Likewise in THF/EA mixtures the species varies between the 'tight' and the 'loose' as a function of solvent composition suggesting again a successive replacement of solvent molecules and the formation of an intermediate type of ion-pair consistent with the static model (15). For a dynamic equilibrium to be applicable it would seem that any two species would have to be structurally very similar but necessarily intermediate in character to our conception of 'tight' and 'loose' pairs in the pure solvents. Practically, this situation is impossible to distinguish from the static model.

In contrast mixtures containing a chelating solvent such as in THF/DG solutions[4] clearly show a change in the proportion of 'tight' and 'loose' species with increasing DG and are qualitatively, at least, consistent with the dynamic model.

Volumes and heat capacities of some amino acids in water at 25°C

JAGDISH C. AHLUWALIA,[1] CLAUDE OSTIGUY, GERALD PERRON, AND JACQUES E. DESNOYERS[2]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received April 13, 1977

JAGDISH C. AHLUWALIA, CLAUDE OSTIGUY, GERALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **55**, 3364 (1977).

The apparent molal volumes and heat capacities of nine amino acids were measured in water at 25°C with a flow densimeter and a flow microcalorimeter. It is shown that the poor additivity of the standard partial molal quantities of amino acids in water are attributable to the ionization of the two groups NH_2 and COOH. The hydration of these ionic groups interfere with each other when they are separated by less than three carbon atoms.

JAGDISH C. AHLUWALIA, CLAUDE OSTIGUY, GERALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **55**, 3364 (1977).

Les volumes et capacités calorifiques molaires apparents de neuf acides aminés ont été mesurés dans l'eau à 25°C avec un densimètre et un microcalorimètre dynamiques. On peut démontrer que la pauvre additivité de groupe que l'on observe avec les acides aminés peut être attribuée à l'ionisation des deux groups NH_2 et COOH. L'hydratation de ces groupes se gêne lorsqu'ils sont séparés par moins de trois atomes de carbone.

Introduction

In recent years there has been a large effort to accumulate thermodynamic data on model organic molecules in water with the aim of devising simple additivity schemes for the prediction of the properties of biochemical systems. Volumes and heat capacities have drawn particular attention, since their standard partial molal quantities readily lead themselves to such an analysis.

Nichols *et al.* (1) have proposed a very simple group additivity scheme which predicts surprisingly well the standard partial molal heat capacities $\bar{C}_p^0$ of aliphatic nonionic solutes in water. However, parallel work by Spink and Wadsö (2) and by Prasad and Ahluwalia (3) shows that the additivity is far from being as good with amino acids. As a check of the reliability of the data by the integral heat method used by Prasad and Ahluwalia, concurrent measurements were made on nine amino acids with the flow microcalorimetric technique. The purpose of this paper is to report these heat capacities and the accompanying standard partial molal volumes $\bar{V}^0$. As it will be shown, the present data on $\bar{C}_p^0$ and $\bar{V}^0$ support the interpretation of Cabani *et al.* (4) that the poor additivity with amino acids is related to the ionization of the NH_2 and COOH groups.

Experimental

The flow microcalorimeter (5, 6) and flow densimeter (7) used in this study have been described elsewhere. Essentially heat capacities per unit volume and densities of the solution were measured relative to pure water and from these differences the apparent molal quantities ϕ_C and ϕ_V were calculated.

The amino acids studied were the following: DL-α-alanine (Fisher Scientific), DL-β-alanine (BDH chemicals, 99%), DL-α-aminobutyric acid (Sigma Chemical Co.), L-leucine (Anachemia Chemicals Company), DL-norleucine (Sigma Chemical Co), DL-β-amino-*n*-butyric acid (Sigma Chemical Co.), DL-γ-amino-*n*-butyric acid (Sigma Chemical Co., 99%), DL-5-amino-*n*-valeric acid (Aldrich Chemical), and DL-6-amino-*n*-caproic acid (Sigma Chemical Co.). The amino acids were not purified but dried under vacuum for 48 h. The solutions were prepared by weight with distilled deionized water (Continental Deionizer).

Results

For each amino acids about 8 to 15 data points were taken for m above 0.02 mol kg^{-1}, the highest concentration depending on the solu-

bility.[3] In general the amino acids show little concentration dependence. The standard partial molal quantities, $\bar{C}_p^0$ and $\bar{V}^0$, and slopes, A_C and A_V, derived by least-squares analysis of the equations

$$[1] \qquad \phi_C = \bar{C}_p^0 + A_C m$$

$$[2] \qquad \phi_V = \bar{V}^0 - A_V m$$

are summarized in Table 1.

The heat capacities for DL-α-alanine are compared with other data in Table 2. Most results agree inside the experimental uncertainty of each technique. The agreement with the other amino acids is also good in most cases where literature values were available (see refs. 2–4 for a survey of $\bar{C}_p^0$ values). In addition to the uncertainties attached to a different technique, some errors probably result from the impurities of the amino acids. Impurities of 1% can probably cause uncertainties of 5 to 10 $J\ K^{-1}\ mol^{-1}$. Most of the amino acids used were guaranteed to 99% and attempts to determine by chromatography the extent of residual impurities failed.

The volumes of α-alanine, β-alanine, and 6-amino caproic acid are also compared with those of other authors in Table 3. The agreement is quite good with α-alanine and β-alanine but less so with β-alanine. Here again the disagreement

might be reflecting more the purity of the samples than the precision of the techniques.

Discussion

A comparison of the present $\bar{C}_p^0$ with those of the literature (2–4) shows that the CH_2 contribution of the α-amino acids are similar to those of other homologous *n*-alkyl solutes but are significantly different with ω-amino acids. To find the origin of this difference, $\bar{C}_p^0$ of the amino acids were calculated from the additivity scheme of Nichols *et al.* (1). The difference between the experimental and predicted values are about -40 to -50 J K^{-1} mol^{-1} for the α-amino acids, -90 to -100 for the β-amino acids and -140 to -170 for the γ and higher amino acids. Cabani *et al.* (4) have recently shown that the change in heat capacity for the reaction

[3] $\quad RCOOH + RNH_2 \rightarrow RCOO^- + RNH_3^+$

is between -160 to -170 J K^{-1} mol^{-1}. Therefore, the present observations suggest that the amino acids when the amino group is separated from the carboxylate group by more than two carbons, act as two independent ions. When the groups are closer together the hydration of the groups interfere with each other and the experimental $\bar{C}_p^0$ are intermediate to those for fully ionized and unionized amino acids. This interpretation is essentially the same as that offered by Cabani *et al.* (4).

The same reasoning can be applied to volumes. From the work of Jolicoeur and Lacroix (13), Høiland and Vikingstad (14), and Cabani *et al.* (15), the group contribution to $\bar{V}^0$ in cm^3 mol^{-1} for neutral molecules in water at 25°C are: CH_3, 26.4; COOH, 25.8; CH_2, 16.0; NH_2, 15.3; CH, 6.5; OH, 12.2. Here the mean differences between measured and predicted $\bar{V}^0$ for α, β, and higher amino acids are -13, -14, and -17 cm^3 mol^{-1}. The change in volume for reaction 3 can be estimated from the data of King (16), Cabani *et al.* (16), Palma and Morel (17), and Desnoyers and Arel (18) to be about -18 cm^3 mol^{-1}. This ΔV for different alkyl groups is not as constant as ΔC_p since the values for CH_2 near ionic groups are usually different from 16.0 cm^3 mol^{-1} (19). Still, the difference between the measured and predicted $\bar{V}^0$ can be largely attributed to the ionization of the amino acids: the effect is complete if the groups are far apart and partial if they are close together. This effect is less spectacular with $\bar{V}^0$ than with $\bar{C}_p^0$ since the hydration contribution to $\bar{V}^0$ is mostly electrostatic while that to $\bar{C}_p^0$ is mostly structural in origin. The interference between the hydration cospheres of the two ionic groups will thus be more important with $\bar{C}_p^0$ since the structural hydration effects are of longer range than the electrostatic ones. This higher sensitivity for $\bar{C}_p^0$ results from the fact that it is a second derivative with respect to free energies while $\bar{V}^0$ is a first derivative.

Heat capacities, volumes, and expansibilities of sodium phenyl carboxylates in water

CLAUDE OSTIGUY, JAGDISH C. AHLUWALIA,[1] GERALD PERRON, AND JACQUES E. DESNOYERS[2]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received April 13, 1977

CLAUDE OSTIGUY, JAGDISH AHLUWALIA, GERALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **55**, 3368 (1977).

The heat capacities per unit volume at 25°C and densities from 10 to 55°C of sodium phenyl carboxylates were measured with a flow microcalorimeter and a flow densimeter. The apparent molal heat capacities and volumes were used to derive standard partial molal heat capacities $\bar{C}_p^0$, volumes $\bar{V}^0$, and expansibilities $\bar{E}^0$. The CH_2 contribution to $\bar{V}^0$ is the same as that usually observed for aliphatic solutes but the contribution to $\bar{C}_p^0$ and $\bar{E}^0$ is not constant and significantly different. No simple explanation can be offered for this anomaly.

CLAUDE OSTIGUY, JAGDISH C. AHLUWALIA, GERALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **55**, 3368 (1977).

Les capacités calorifiques par unité de volume à 25°C et les masses volumiques de 10 à 55°C des phenyl carboxylates de sodium ont été mesurées avec un microcalorimètre dynamique et un densimètre dynamique. Les capacités calorifiques et volumes molaires apparents ont été utilisés pour calculer les valeurs molaires partielles standard pour les capacités calorifiques $\bar{C}_p^0$, les volumes $\bar{V}^0$ et les expansibilités $\bar{E}^0$. La contribution de chaque CH_2 à $\bar{V}^0$ est essentiellement la même que celle des solutés aliphatiques mais la contribution à $\bar{C}_p^0$ et $\bar{E}^0$ n'est pas constante et est très différente. Aucune explication simple n'a pu être proposée pour expliquer ces anomalies.

Introduction

There is much interest in the group additivity of organic molecules in water. In particular Nichols *et al.* (1) have shown that a very simple group additivity scheme can predict the standard partial molal heat capacities, $\bar{C}_p^0$, of many aliphatic nonionic molecules in water with a precision which is often comparable with the experimental uncertainty. Similarly, the work of Yalkowsky and Zografi (2), Jolicoeur and Lacroix (3), Høiland and Vikingstad (4), and Cabani *et al.* (5) indicates that reasonably good additivity schemes can be devised for standard partial molal volumes, $\bar{V}^0$, although the presence of charged groups can have a significant contribution on the adjacent groups (6). Cabani *et al.* (7) have also been accumulating data on standard partial molal expansibilities, $\bar{E}^0$, from which it will eventually be possible to obtain group additivity contributions.

Recent work in our laboratory (8) has shown that it is also possible to get an excellent additivity scheme of $\bar{C}_p^0$ and $\bar{V}^0$ of aromatic molecules in water. These group contributions are fairly similar to those of aliphatic molecules for $\bar{V}^0$ but significantly different with $\bar{C}_p^0$. Also, Nichols and Wadsö (9) found that the methylene contribution to $\bar{C}_p^0$ of homologous aromatic alcohols and amines are different from the normal aliphatic compounds. Similar differences, although less important, were also observed with diol (1).

In an attempt to find the origin of this lack of additivity of homologous aromatic solutes in water we determined $\bar{C}_p^0$, $\bar{V}^0$, and $\bar{E}^0$ of a series of aromatic carboxylate salts.

Experimental

The flow microcalorimeter (10, 11) and flow densimeter (12) used in this study have been described elsewhere. The expansibilities were obtained from the temperature dependence of the volumes, $\bar{E}^0 = d\bar{V}^0/dT$. All acids except phenyl pentanoic acid (Ash Stevens) were purchased from J. T. Baker Chemicals. The salts were prepared by neutralization of the acids in water followed by dry evaporation. The salts were then recrystallized in ethanol adding acetone to initiate the crystallization.

All solutions were prepared by weight with deionized distilled water (Continental Deionizer). The temperature was measured to 0.01°C with a Hewlett-Packard Quartz Thermometer, calibrated at the factory.

Results

The apparent molal volumes ϕ_V and heat capacities ϕ_C are obtained from the relative change in heat capacities per unit volume (11) and from the change in densities (12) in the usual way. The standard values, $\phi_Y^\theta = \bar{Y}^\theta$, are then obtained from a least-squares analysis with the general equation

$$[1] \qquad \phi_Y = \bar{Y}^\theta + A_Y m^{1/2} + B_Y m$$

where A_Y is the limiting slope of the Debye–Hückel law and has been given elsewhere (13) for ϕ_V and ϕ_C. About 8 to 12 data points were measured for each system.[3] The parameters $\bar{V}^\theta$, $\bar{C}_p^\theta$, B_V, and B_C are given in Table 1. The expansibilities obtained from the differences $\Delta\bar{V}^\theta/\Delta T$ are given in Table 2. It became apparent that the data for sodium phenyl propanoate were definitely out of line. A new sample was therefore purified and $\bar{V}^\theta$ was remeasured at 25°C. The anomalies with $\bar{V}^\theta$ and $\bar{C}_p^\theta$ then disappeared. The temperature dependence of $\bar{V}^\theta$ was not repeated however, and it will be apparent later on that the derived $\bar{E}^\theta$ are too large for this salt.

[3]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 2. Standard partial molal expansibilities $\bar{E}^\theta$ (cm^3 K^{-1} mol^{-1}) of sodium phenyl carboxylates in water at 25 and 40°C

Solute	At 25°C	At 40°C
ϕCOONa	0.170	0.122
ϕCH_2COONa	0.180	0.129
$\phi(CH_2)_2COONa$	0.219	0.180
$\phi(CH_3)_3COONa$	0.209	0.163

Discussion

The values of $\bar{C}_p^\theta$, $\bar{V}^\theta$, and $\bar{E}^\theta$ at 25°C are plotted against the number of methylene groups of the homologous sodium phenyl carboxylates in Fig. 1. The $\bar{C}_p^\theta$ of phenylamines and alcohols (9) are also given for comparison. The expected slope from the CH_2 contribution of aliphatic solutes in water, 90 J K^{-1} mol^{-1} (1), 16.0 cm^3 mol^{-1} (4), and 0.023 cm^3 K^{-1} mol^{-1} (7) are also given in Fig. 1. With $\bar{V}^\theta$ the predicted and experimental slopes coincide. Only sodium benzoate falls slightly out of line as with aliphatic carboxylates (6). On the other hand the CH_2 contribution to $\bar{C}_p^\theta$ is not constant and is approaching the expected value only when there are more than 4 carbon atoms in the chain. The alcohols and amines also show a smaller contribution per CH_2 but here the deviation from the expected slope is much smaller. In the case

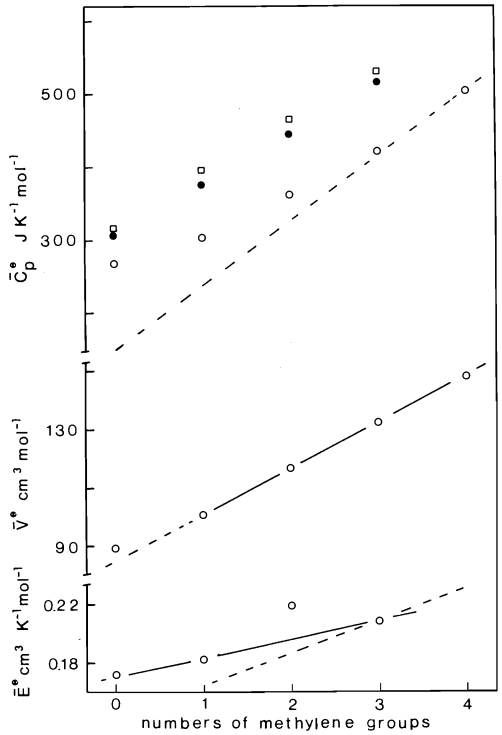

FIG. 1. Dependence of standard partial molal functions of aromatic solutes in water at 25°C on the number of methylene groups: ○, $\phi(CH_2)_nCOONa$; □, $\phi(CH_2)OH$; ●, $\phi(CH_2)_nNH_2$.

of $\bar{E}^\theta$ the carboxylates seem to fall on a straight line if we assume that the value of sodium phenyl propanoate is erroneous (see Results), and this experimental slope is, as with $\bar{C}_p{}^\theta$, significantly lower than the expected one for aliphatic solutes.

The interaction between the two groups increases significantly as the number of CH_2 groups between $NH_2{}^+$ and COO^- decreases. These interactions have a large effect on $\bar{C}_p{}^\theta$ but a smaller one on $\bar{V}^\theta$. By analogy with the amino acids it would seem that there are some interactions between the phenyl group and the ionic or polar end groups. These relatively weak interactions mostly affect second derivative functions, such as $\bar{C}_p{}^\theta$ and $\bar{E}^\theta$, implying that they are very temperature dependent or related to some shift in equilibrium with temperature. The exact nature of these interactions is still unknown.

^{13}C and $^{33,34}S$ isotope effects on the vapor pressure of liquid carbon disulfide

GÁBOR JANCSÓ[1] AND W. ALEXANDER VAN HOOK
Chemistry Department, University of Tennessee, Knoxville, TN 37916, U.S.A.
Received February 25, 1977

GÁBOR JANCSÓ and W. ALEXANDER VAN HOOK. Can. J. Chem. **55**, 3371 (1977).

Prompted by the experimental investigation of Betts and Buchannon a thorough analysis of CS_2 vapor pressure isotope effects has been made in the context of the theory of isotope effects in condensed phases and the available spectroscopic information. The agreement between the calculated and experimental results is satisfactory. The calculated results may be empirically described by the equations

$$\ln (P_{^{12}C^{32}S_2}/P_{^{13}C^{32}S_2}) = \frac{-0.529}{T} + 0.00035$$

and

$$\ln (P_{^{12}C^{32}S^{32}S}/P_{^{12}C^{32}S^{34}S}) = \frac{0.185}{T} - 0.00040$$

The analysis indicates that the principal contribution to the ^{13}C isotope effect is due to the shift on condensation of the asymmetric stretching frequency $\Delta\nu_3$, and quantitatively corroborates the theoretical conclusion reached earlier by Akopyan, Girin, and Bakshiev and others of the magnitude of the dielectric correction for this band. The ^{34}S effects are principally determined by the hindered rotation and translation in the liquid and the shift in the symmetric stretching motion $\Delta\nu_1$.

GÁBOR JANCSÓ et W. ALEXANDER VAN HOOK. Can. J. Chem. **55**, 3371 (1977).

A la lumière des résultats expérimentaux obtenus par Betts et Buchannon, on a fait une analyse complète des effets isotopiques de la pression de vapeur du CS_2 en tenant compte de la théorie des effets isotopiques en phase condensées et des informations spectroscopiques disponibles. Les valeurs calculées sont en bon accord avec les résultats expérimentaux. Les résultats calculés peuvent être empiriquement décrits par les équations;

$$\ln (P_{^{12}C^{32}S_2}/P_{^{13}C^{32}S_2}) = \frac{-0.529}{T} + 0.00035$$

et

$$\ln (P_{^{12}C^{32}S^{32}S}/P_{^{12}C^{32}S^{34}S}) = \frac{0.185}{T} - 0.00040$$

L'analyse indique que la contribution principale à l'effet isotopique ^{13}C est due au déplacement sur la condensation de la fréquence assymétrique d'élongation $\Delta\nu_3$ et confirme entièrement la conclusion théorique postulée antérieurement par Akopyan, Girin et Bakshiev puis d'autres, sur l'ampleur de la correction diélectrique de cette bande. Les effets du ^{34}S sont déterminés principalement par la rotation et la translation empêchée dans le liquide et par le déplacement dans le mouvement d'élongation symétrique $\Delta\nu_1$.

[Traduit par le journal]

Introduction

The theory of isotope effects on the properties of condensed phases as formulated in 1961 by Bigeleisen (1) has been successfully applied in the quantitative interpretation of the vapor pressure isotope effect (vpies) of a large number of different molecules. The literature in this field has been critically analyzed by Jancsó and Van Hook (2) who conclude (in agreement with previous authors (1, 3–6)) that the measurement of the vpie is a useful tool for determining the effects of molecular structure and the influence of intermolecular forces on the motions of molecules in condensed phases. The appearance of new data on a simple molecular system is therefore of considerable interest, because in such a case the spectroscopic parameters are often defined to relatively high precision, and the data can be used in a straightforward test of the theory. The recently reported measurements of Betts and Buchannon (7) therefore attracted our interest

[1]Permanent address: Central Research Institute for Physics, Hungarian Academy of Sciences, Budapest.

for this reason, and also because of their claim that the measured $^{13}C/^{12}C$ and $^{34}S/^{32}S$ effects were independent of the temperature over the range -20 to $+60°C$. This was puzzling for theoretical reasons. Earlier workers have also noted the inverse carbon isotope effect in this system but there is no other mention in the literature of sulfur isotope studies or of the temperature dependencies of the effects (2).

Background

The vapor pressure ratio between two isotopic isomers of a given molecule has been related to the reduced partition function ratio of the molecules by Bigeleisen (1). Following Jancsó and Van Hook (2) we write

$$[1]\quad \ln\frac{P'}{P} = \ln\left(\frac{f_c}{f_g}\right) + (RT)^{-1}(P'V' - PV) - (B_0P + \tfrac{1}{2}C_0P^2)' + (B_0P + \tfrac{1}{2}C_0P^2) - (RT)^{-1}\int_V^{V'} P'\,dV$$

The logarithmic vapor pressure ratio, $\ln(P'/P)$ (the prime denotes the lighter isotope), is given by the difference in quantum effects for the condensed and gaseous states (the first term) and correction terms which account for the difference between the Helmholtz and Gibbs free energies for the condensed phase (second term), gas imperfection (term 3), and the difference in the condensed phase molar volumes of the isotopic isomers. We have estimated the correction terms from available data on the virial coefficient (8) and molar volume (9) (neglecting the isotope effects on these parameters) and find them negligible in comparison with the experimental error (7). The reduced partition function ratio is then well approximated by the vapor pressure ratio. Following Stern *et al.* (3) we have elected to make a calculation in the harmonic approximation obtaining for a working equation,

$$[2]\quad \frac{f_c}{f_g} = \prod_{\text{int}}^{3n-5}\left[\frac{(u_i/u_i')_c \exp((u_i' - u_i)_c/2)}{(u_i/u_i')_g \exp((u_i' - u_i)_g/2)}\right] \times \left[\frac{(1-\exp(-u_i')_c)/(1-\exp(-u_i)_c)}{(1-\exp(-u_i')_g)/(1-\exp(-u_i)_g)}\right] \times \prod_{\text{ext}}^{5}\frac{u}{u'}\left[\exp\left(\frac{u'-u}{2}\right)\right]\left[\frac{1-\exp(-u')}{1-\exp(-u)}\right]$$

where $u_i = h\nu_i/kT$. In the derivation of eq. 2 a harmonic cell model has been assumed where the average condensed phase n-atom molecule is assigned $3n$ degrees of freedom. Of these, the $3n-5$ internal modes are treated in a fashion analogous to that used in the gas phase and the remaining hindered translations and rotations are assumed to be subject to harmonic restoring forces. In the calculation of the condensed phase frequencies due account is to be taken of terms which couple the internal and external motions of the molecules. These are often isotope dependent and give rise to interesting effects. In the presentation of eq. 2 we have not written the small correction which accounts for the effect of nonclassical rotation in the gas phase. We have, however, calculated this correction and found it to be negligible within the experimental precision of the results discussed in this paper.

In the next section of the paper, which describes the results of the calculation, our approach will be to present isotope independent force constant matrices which reproduce the spectroscopically observed frequencies in the gas and liquid phases. These will then be employed to calculate frequencies and isotopic frequency shifts in both phases which are then substituted into eq. 2 to obtain the calculated vapor pressure ratios.

It is clear for such a simple molecule as CS_2 the approach outlined above can be refined so that a calculation which takes account of anharmonic corrections in both phases can be made. However, the additional complexity and the marked increase in the number of parameters (as well as the additional labor) is not warranted, either by the precision of the presently available spectroscopic data, or by the precision of the vapor pressure results.

Analysis

A selection of spectroscopic data for the condensed and vapor phases of CS_2 is presented in Table 1. We note that the data are unusually complete and can be used to define effective harmonic gas and liquid force fields in a relatively unequivocal fashion. In the gas phase the recently reported high precision measurements of Smith and Overend (10) are in excellent agreement with the best of the earlier work. They have been used to define the gas phase force field reported in Table 2. In the liquid phase we have selected

the results of Ribnikar and Puzić (11) thereby obtaining the set of experimental internal frequency shifts on condensation reported in the second part of Table 1. The observed shifts in the asymmetric stretching frequency, ν_3, and the bending mode, ν_2, are in general agreement among the different laboratories (Table 1) but Ribnikar's value for ν_1 lies 2 ± 1 cm^{-1} below values reported by other workers. We are inclined, however, to accept his value as it is based on a thorough study of the entire ir spectrum of the liquid, including the assignment of many overtone and combination bands, and a complete anharmonic analysis. In the Raman spectrum the band around 650–660 consists of an overlapped doublet including the fundamental and a satellite assigned to the (11′0), (030) ← (01′0) transition which has tended to complicate the assignment. Some authors (12–14) have reported the shifts on condensation in ν_1 for $^{34}S^{12}C^{32}S$ variously at 2.3, 3.5, and 7.2 cm^{-1} and this also indicates the difficulty of the assignment problem. (For CS_2 the phase frequency shift of this internal mode is much larger than is its isotope dependence, so to first order $\Delta\nu \cong \Delta\nu'$.) We note that the shift calculated from

Ribnikar's assignment, $\Delta\nu = 5.2$ cm^{-1}, is certainly good to ± 2 cm^{-1} (i.e. even if the alternative assignment is accepted), and most probably is good to better than ± 1 cm^{-1}. The other two phase frequency shifts $\Delta\nu_2 = 5.5$ and $\Delta\nu_3 = 27.1$ cm^{-1} we also estimate as good to better than ± 1 cm^{-1}. All shifts are to the red on condensation.

We now turn attention to the hindered external translational and rotational modes. The 70 cm^{-1} frequency observed in the liquid (15–18) has been assigned to the doubly degenerate libration. The 70 cm^{-1} frequency has been observed in the solid phase at liquid nitrogen temperature blue shifted to the region between 73 and 85 cm^{-1} where the librational assignment is much more certain (19–21). The magnitude of the red shift observed on melting and lattice expansion is reasonable. The assignment is further substantiated by the ir high pressure studies of Bradley *et al.* (17) who found that by applying pressure to the liquid at room temperature the 70 cm^{-1} peak shifted to a value of 85–90 cm^{-1} in the solid at 12–13 kbar.

The liquid frequency observed at 52 cm^{-1} (21) near the melting point has been assigned to the triply degenerate hindered translation. Although the authors (21) did not discuss the origin of this band we note that in the solid at 77 K these frequencies are observed at 66 cm^{-1} (15, 22) and have been assigned to the translational modes. By employing the known volume expansion on melting (23) together with a reasonable estimate of the Grüneisen constant using the method of Slater (24) and Mizushima (25) we calculate a liquid frequency of about 45 cm^{-1} (300 K) which is in fair agreement with the observed band at 52 cm^{-1}. We conclude that the assignment is reasonable. In any event the details of the results are not very sensitive to the choice of the translational frequency.

The gas phase frequencies and phase frequency shifts as assigned above have allowed the definition of gas and liquid force fields which are presented in Table 2. The phase frequency shifts as calculated for $^{12}C^{32}S_2$ from these force fields have already been presented at the bottom of Table 1. For the asymmetric stretching motion, ν_3, an important correction must be applied to the spectroscopic data. This is discussed in detail in the material on $^{13}C/^{12}C$ which follows.

The $^{13}C/^{12}C$ Effect

The interpretation of the carbon isotope vpie is considerably simplified by virtue of the symmetry of the molecule. Since the carbon is located at the center of mass there is no isotope shift on the symmetric stretch, ν_1, nor is there any isotope effect on the moments of inertia and the librational frequencies. The observed effect is therefore due to a combination of the triply degenerate translations and the isotope dependencies of the phase frequency shifts in the doubly degenerate bending motion and the single asymmetric stretch. The isotope dependence of the translational and bending modes is small and cannot begin to explain the magnitude of the unusually large inverse vpie for this isomer. The value of the phase frequency shift, $\Delta\nu_3$, required to fit the experimental data at -14.8°C (where the experimental scatter is at its minimum) is 13.09 cm^{-1}. This compares to the experimentally observed shift of 27 cm^{-1} which is independent of temperature (26). However, it is now well established that the observed shift must be corrected for dielectric effects which take account of the difference between the mean field and the effective field of the light wave acting on the molecule in the condensed phase. This point has been discussed in considerable detail by Akopyan *et al.* (27), Lefranc *et al.* (28), and Clifford and Crawford (29). The correction is only important for very intense bands such as the

one under discussion. The value of the corrected shift (i.e. that portion due to the effect of intermolecular forces on the motion) has been variously estimated as 10–15 cm^{-1} (27), 8 cm^{-1} (Onsager correction following ref. 30), and 15 cm^{-1} (Lorentz correction following ref. 30). The value of 13 cm^{-1} obtained from the vpie measurements via the present interpretation is comfortably in the middle of these theoretical estimates. The result is one of useful precision (± 2 cm^{-1} if the error in the vpie at -14°C can be taken as $\pm 1 \times 10^{-4}$ (7) and the uncertainties in the frequency phase shifts are those discussed above). It can be usefully employed to test theories of the spectroscopic corrections to the contours of very intense bands (43).

The $^{34}S/^{32}S$ Effect

The vpie, $R_{34} = P_{^{12}C^{32}S_2}/P_{^{12}C^{32}S^{34}S}$, is now defined in terms of the parameters developed above. The rotational and translational contributions predominate for this isomer and determine the sign of the positive (normal) effect.

Results

The results of the calculation are plotted in Fig. 1 where they are compared with the data points reported by Betts and Buchannon (7). The temperature dependence of the calculated effects is evident and in our opinion the calculations are in satisfactory agreement with the experimental data. The calculated results can be satisfactorily described by the relations $\ln(P_{12}/P_{13}) = -0.529/T + 0.00035$ and $\ln R_{34} = 0.185/T - 0.00040$. These equations are purely empirical and should not be used to extrapolate the results outside the temperature limits of the calculation. We have not reported fits to the more commonly employed approximation, $\ln R = A/T^2 + B/T$ because the frequency distribution of the CS_2 molecule is such that this relation is not a good approximation to the complete eq. 2 in the liquid temperature range. We have also calculated the vpies for other isotopic isomers of CS_2 and find (as expected) that the results are reasonably well described by the law of the geometric mean (certainly well within the precision of the data under discussion). Thus, for example, $(\ln R_{34}/\ln R_{33}) - 2.0 \cong 0.06$.

Discussion

The vpies of the isotopic isomers of CS_2 are

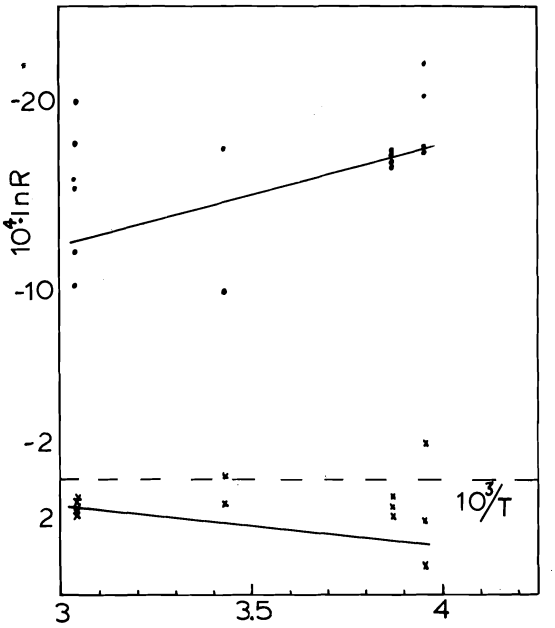

FIG. 1. Vapor pressure isotope effects of CS_2. Upper line $R = (P_{^{12}C^{32}S_2}/P_{^{13}C^{32}S_2})$ (calculated). Lower line $R = (P_{^{12}C^{32}S_2}/P_{^{34}S^{12}C^{32}S})$ (calculated). The data points are from ref. 7.

amenable to interpretation with the theory of isotope effects in condensed phases as applied in the harmonic approximation. Both carbon and sulfur effects show decided temperature dependences in accord with experiment. The large inverse carbon isotope effect is due principally to the red shift in the very intense asymmetric stretching frequency near 1535 cm^{-1}. Its magnitude offers confirmation of the theoretical conclusion that only about half of the observed spectroscopic shift is due to the influence of intermolecular forces on this motion. Our calculated value of the carbon vpie is in good agreement with the earlier estimate of Baertschi and Kuhn (31) of the inverse contribution to this effect, -1.6×10^{-3}, made from other (but related) considerations.

Earlier in a qualitative interpretation Betts and Buchannon (7) leaned heavily on comparisons between the CO_2 and CS_2 systems. Isotope effects in CO_2 have been recently reinterpreted by Bikladi *et al.* (32) using the same kind of approach as that employed here. Most of their attention was focused on vpies in the solid, but the liquid phase effects were also considered. Certainly comparisons between the two mole-

cules are pertinent and interesting but it must be emphasized that important differences between the molecules exist. These markedly influence the choice of parameters and the nature of the results. First, and most importantly, the spectroscopic information on the liquid phase is much more nearly complete for CS_2 than for CO_2. The phase frequency shift of the CO_2, and additionally the intensity change, is also smaller, so dielectric effect corrections are not as important. The ^{13}C vpie is therefore much larger for CS_2 than CO_2. The difference in intensity changes in the ν_3 band has been correlated with the difference in the crystal structure of the two solids (39) and it has been further indicated that the intermolecular forces in the liquid and the 'liquid structure' of the materials are different in kind (38), due to the same effect. The sulfur or oxygen effects are relatively independent of the asymmetric stretching motion and are predominantly determined by the hindered rotation and translational modes. Comparisons between the two materials for these effects are therefore more useful.

Studies on metal hydroxy compounds. XV. Electrical conductivity measurements on Cd(OH)Cl, Cu(OH)Cl, and PbOHCl

MAHADEVA NATARAJAN AND ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received April 28, 1977

MAHADEVA NATARAJAN and ETALO A. SECCO. Can. J. Chem. **55**, 3377 (1977).

The electrical conductivity dependence on temperature measurements for three metal basic chlorides are reported. The conductivity results yield energy values which are interpreted in terms of active solid state processes leading up to, and including, the decomposition step.

MAHADEVA NATARAJAN et ETALO A. SECCO. Can. J. Chem. **55**, 3377 (1977).

On étudie la dépendance de la conductivité électrique sur les mesures de la température pour trois chlorures de métaux basiques. Les résultats obtenus pour la conductivité, nous amène à des valeurs d'énergie qui sont interprétées en termes de processus actifs de l'état solide se rapprochant et incluant l'étape de décomposition.

[Traduit par le journal]

Introduction

Thermal decomposition of a metal hydroxyhalide usually occurs via dehydroxylation (1, 2). The dehydroxylation step was speculated to be effected by (*i*) OH abstraction by a mobile H or (*ii*) H abstraction by a mobile OH (3). Since these species are expected to be electrically charged it was thought that electrical conductivity data on hydroxyhalide compounds might lead to a better understanding of the decomposition reaction.

Electrical conductivity, by its nature, can be more sensitive, than gravimetry, to the elementary or microscopic solid state effects. Therefore, conductivity has the added potential of providing a more detailed preview of the solid state processes leading up to the decomposition step. On the other hand, in the region of active decomposition conductivity data can be less reliable in view of the measurement's susceptibility to composite or masking effects arising from product presence.

This report contains electrical conductivity measurements done on three hydroxychlorides, viz. CuOHCl, CdOHCl, PbOHCl, selected as representative members of hydroxyhalide compounds which undergo first-order, second-order, and diffusion rate decomposition kinetics, respectively. The chloride derivatives were chosen on the probable basis of a constant overall anion conductivity.

[1]To whom correspondence should be addressed.

Experimental

All hydroxyhalides were prepared by the procedures already described (1–3); each compound was identified by its characteristic thermal analysis trace and X-ray diffraction pattern.

Electrical conductivity measurements were done on compressed polycrystalline discs held between Pt plates in a stainless steel conductivity cell (4) using Gr-1608A Impedance bridge; disc measurements were recorded both in ambient air and flowing N_2 (2SCFH). The normal heating rate was 20°C h^{-1} but lower heating rates were maintained as the cell temperature approached the region of active decomposition.

Results and Discussion

Plots of the logarithm of conductivity σ vs. $1/T$ K for CuOHCl, CdOHCl, and PbOHCl are presented in Figs. 1, 2, and 3, respectively. The activation energy values determined from the regional slopes on each plot are tabulated in Table 1; the activation energy E_a for each decomposition reaction obtained from gravimetric kinetic data is also included for comparison. Although the conductivity results obtained in air atmosphere are assumed to be valid, our discussion will be restricted to N_2 atmosphere conductivity results in view of their consistent nature and in the expectation that meaningful comparisons or correlations can be made with the gravimetric kinetic results.

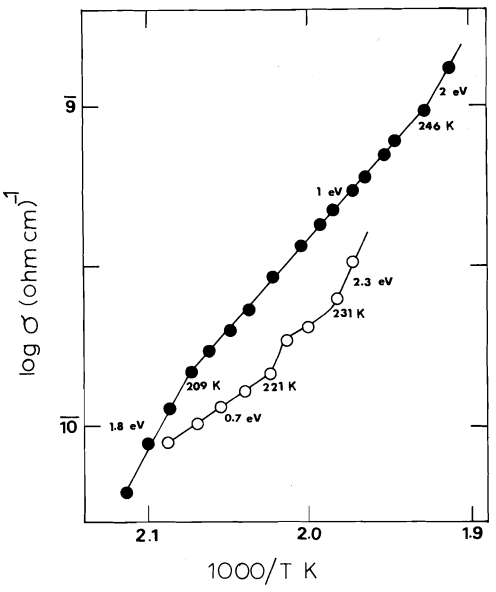

FIG. 1. Logarithm of conductivity, σ, vs. $10^3/T$ K for Cu(OH)Cl in air ○, and in N_2 ●.

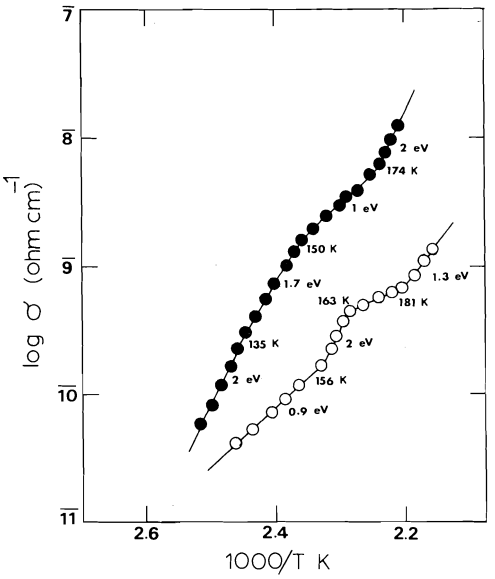

FIG. 3. Logarithm of conductivity, σ, vs. $10^3/T$ K for Pb(OH)Cl in air ○, and in N_2 ●.

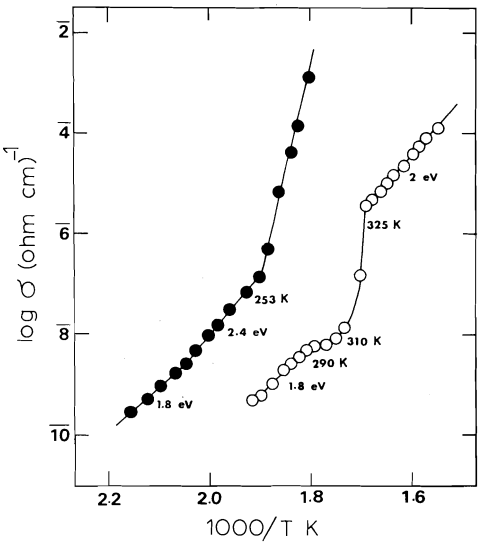

FIG. 2. Logarithm of conductivity, σ, vs. $10^3/T$ K for Cd(OH)Cl in air ○, and in N_2 ●.

The conductivity plots of Table 1 reveal (*i*) $\sigma_{N_2} > \sigma_{air}$; (*ii*) $\sigma_{(CuOHCl)} \approx \sigma_{(CdOHCl)} < \sigma_{(PbOHCl)}$ at ~200°C; (*iii*) common low temperature $E_1 = 43 \pm 2$ kcal; (*iv*) CuOHCl energies pass through minimum to attain E_3 in agreement with its E_a, PbOHCl energies drop to E_3 consistent with its E_a, and E values for CdOHCl jump to E_3 much higher than its E_a.

The common E_1 value is attributed to the migration energy of OH^- species in some form of complexes (5, 6). These complexes are expected to break up at higher temperatures accompanied in the absence of secondary effects, by lower energies as in CuOHCl and PbOHCl. The E_3 values consistent with their E_a values, viz. PbOHCl and CuOHCl, suggest active decomposition whereas E_2 represents the stage prior to the onset of decomposition. The agreement between E_2 for CdOHCl and its E_a suggests decomposition to be active under these conditions and the high E_3 value results from the high conductivity contribution by the product CdO.

The suggested condition of H^+ mobility governing first-order rate kinetics in the decomposition of hydroxyhalides requires σ(CuOHCl) to be much greater than σ(PbOHCl). The conductivity data do not support this condition. The initial fundamental step in a solid state decomposition reaction is most likely a nucleation process. The observed overall rate kinetics and activation energy is eventually determined by the specific boundary condition, if any, imposed on the reaction relative to the nucleation process. The first-order rate can be interpreted in terms of

TABLE 1. Regional energies (kcal) from conductivity vs. temperature data (°C)

Compound	Medium	E_1	E_2	E_3	E_a	Rate
CuOHCl	N_2	42(190–210)	23(210–245)	46(>246)	41.0(230–280)	First order
	Air	16(200–220)	—	53(>231)		
PbOHCl	N_2	46(120–135)	39(135–150)	23(150–175)	20.0(150–200)	Diffusion
	Air	21(125–155)	46(155–165)	30(>180)		
CdOHCl	N_2	42(175–220)	55(215–255)	~110(>255)	54.3(300–350)	Second order
	Air	42(250–310)	~110(310–325)	46(>325)		

a limiting case of the A–E type equation, $-\ln(1-\alpha) = (kt)^n$, with the boundary condition $n = 1$. This condition implies a collapse of the interface between the product and reactant phases leaving isolated blocks of solid with each molecule possessing equal probability for reaction.

In summary, the conductivity measurements provided more details regarding the solid state processes leading up to the decomposition stage and a basis for the interpretation of first-order rate in hydroxyhalide compounds.

Strong amide–halothane hydrogen-bonding observed by nuclear magnetic resonance

JOHN M. BROWN AND PENNY A. CHALONER
Dyson Perrins Laboratory, South Parks Road, Oxford, England OX1 3QY

Received May 10, 1977

JOHN M. BROWN and PENNY A. CHALONER. Can. J. Chem. **55**, 3380 (1977).

The widely-used halothane anaesthetic $CF_3CHBrCl$ exhibits a proton magnetic resonance signal in CCl_4 solution which is strongly deshielded by addition of *N*-methylpyrrolidone. This is interpreted as a hydrogen-bonding interaction with halothane C—H as donor and carbonyl as acceptor. From the temperature dependence of the halothane C—H proton chemical shift in the presence of varying concentrations of *N*-methylpyrrolidone, thermodynamic parameters $\Delta H_0 = -4.7$ kcal mol^{-1} and $\Delta S_0 = -14$ cal mol^{-1} deg^{-1} were obtained. The carbon magnetic resonance spectrum of the two components in CCl_4 shows deshielding of the carbonyl carbon at higher concentrations of $CF_3CHBrCl$. The halocarbons (1-*H*)undecafluorobicycloheptane and (1-*H*,4-*H*)decafluorobicycloheptane show similar H-bonding behaviour which is comparable with that exhibited by $CHCl_3$.

These results are discussed in relation to their possible relevance to the mechanism of action of halocarbon anaesthetics.

JOHN M. BROWN et PENNY A. CHALONER. Can. J. Chem. **55**, 3380 (1977).

L'halothane anesthésique grandement utilisé $CF_3CHBrCl$ présente un signal dans son spectre rmn, enregistré dans le CCl_4, qui est fortement déblindé par addition de *N*-méthylpyrrolidone. Ceci est expliqué par une interaction hydrogène-lié avec le C—H de l'halothane comme donneur et le carbonyle comme accepteur. A partir de l'effet de la température sur le déplacement chimique du proton C—H en présence de différentes concentrations de *N*-méthylpyrrolidone on obtient les paramètres thermodynamiques suivants: $\Delta H_0 = -4.7$ kcal mol^{-1} et $\Delta S_0 = -14$ cal mol^{-1} deg^{-1}. Le spectre de résonance magnétique nucléaire du carbone des deux composés en solution dans le CCl_4 montre un déblindage du carbone du groupe carbonyle à fortes concentrations en $CF_3CHBrCl$. Les hydrocarbures halogénés (1-*H*) undécafluorobicycloheptane et (1-*H*,4-*H*) décafluorobicycloheptane présentent un comportement similaire H-lié, ce qui est comparable avec celui observé pour le $CHCl_3$.

Ces résultats sont discutés en fonction d'un rapprochement possible avec le mécanisme d'action des hydrocarbures halogénés anesthésiques.

[Traduit par le journal]

Introduction

The mechanism and site of action of inhalant anaesthetics have been the subject of much discussion (1), without evidence of any general agreement. Anaesthetic potency correlates more satisfactorily with lipid solubility than with other physicochemical properties (2) although there is some suggestion that a "polar factor" may also be important (3). Anaesthesia can be reversed by high pressures of inert gases (4) which corroborates the idea that dissolution of the anaesthetic in a lipid membrane, or its interaction with the hydrophobic region of a nerve protein causes a local volume expansion and neurotransmitter inhibition. Attempts to simulate these effects in simple systems have proved equivocal. One group of workers suggest that halothanes at a concentration of 0.16 m*M* or 0.32 m*M* increase the order parameter *S* determined by esr, in palmitoyllauryllecithin vesicles containing ketostearate-derived spin-labels, but cause a decrease at 9.3 m*M* (5). The effect on membrane fluidity in these and related experiments is slight, leading to criticism of the membrane-expansion model. A more specific role may be inferred from the effect of anaesthetic fluoroethers on the crab neuromuscular junction (6) which preferentially block the action of glutamate receptor sites, whereas convulsants of related structure act at γ-aminobutyrate receptors.

In view of the long-standing emphasis on the solubility characteristics of inhalant anaesthetics, and a chemically non-specific mechanism of

interaction, some recent findings are of particular interest. The effect of $CF_3CHBrCl$ on the nmr spectrum of haemoglobin has been studied in detail, and the major perturbation involves a small number of histidine H-2 resonances on residues remote from the site of oxygenation, together with (unassigned) hydrophobic resonances (7). Sandorfy (8) has shown that a variety of halocarbons, both fluorocarbon anaesthetics and others, perturb intermolecular hydrogen-bonding in amides, phenols, and amines. The dominant role is assigned to donor-acceptor complex formation between the halocarbon and addend, there being a correlation between hydrogen-bond breaking potency as observed by infrared spectroscopy and the lowest lone-pair ionisation potential of the halocarbon. Whilst this must be important in several cases (e.g., CF_3I, CF_2BrCF_2I) it seemed to us that many others might be better explained by competitive hydrogen-bonding by the C—H bond of the halocarbon. More recent infrared studies by Sandorfy (9) support this idea, and in the present paper we demonstrate the existence of strong hydrogen-bonds between $CF_3CHBrCl$ and *N*-methylpyrrolidone by nmr spectroscopy.

Experimental

Chloroform was purified before use by passage through a short column of Laporte type 'H' chromatographic alumina, and carbon tetrachloride was freshly distilled. Trifluorochlorobromomethane was a gift from the Department of Pharmacology, Oxford University and fluorobicycloheptanes were donated by Dr. R. Stephens of Birmingham University. The purity of all samples was checked by nmr.

^1H nmr spectra were obtained on a Perkin-Elmer R32 spectrometer equipped with variable temperature accessory which was calibrated with a standard methanol sample. Solutions were prepared by addition of aliquots of neat acceptor to standard solutions of donor in carbon tetrachloride. Frequencies are recorded in ppm downfield from an internal tetramethylsilane lock. The shift parameter (Δ) and binding constants K for a given system were calculated by the iterative procedure of Higuchi (10) using a Hewlett-Packard 91 desk calculator. Carbon magnetic resonance spectra were recorded on a Bruker WH-90 instrument with a D_2O external lock. Frequencies are recorded in ppm downfield from tetramethylsilane.

Results and Discussion

1,1,1-Trifluorobromochloroethane/N-methylpyrrolidone

The ^1H nmr spectrum of **1** in carbon tetrachloride shows a quartet, $J_{H-F} = 5.2$ Hz, at 5.75 ppm. The position is slightly temperature dependent, there being a shift to lower field of 0.03 ppm between 35 and −20°C. Addition of portions of **2** to standard solutions of **1** produces a substantial downfield shift, and Fig. 1 shows a series of runs at different concentrations of **2** and various temperatures between 35 and −20°C. Under these conditions complex formation is incomplete, and an iterative procedure was employed to derive Δ, defined as the chemical shift difference between **1** and the 1:1 association complex, and the complexation equilibrium constant K. The thermodynamics of complexation were derived from a standard Arrhenius plot incorporating data from runs at five different temperatures (Fig. 2).

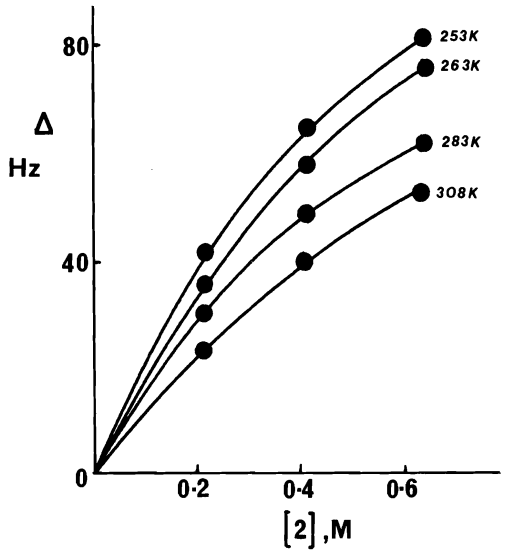

FIG. 1. Chemical shift changes induced by addition of **2** to solutions of **1** (0.38 *M* in CCl_4).

The ^{13}C nmr spectrum of **2** (1.1 *M* in CCl_4) has absorbances at 178.9 (*C*=O), 54.9 (CH_2—N), 36.1 (CH_2—CO), 35.3 (CH_3—N), and 23.9 (CH_2—CH_2—CH_2) ppm. Addition of portions of **1** to the solution causes downfield shifts of the carbonyl carbon resonance of up to 1 ppm at 2 *M* addend, without affecting other resonances by more than 0.15 ppm (Fig. 3). The C-1 carbon of **1** (127.0 ppm, $J_{C-F} = 278$ Hz) is slightly deshielded in mixed solutions but the C-2 carbon (55.8 ppm, $J_{C-F} = 41$ Hz) is more substantially affected.

Taken together, this evidence strongly suggests that hydrogen-bonding is the major interaction leading to complexation. The data may

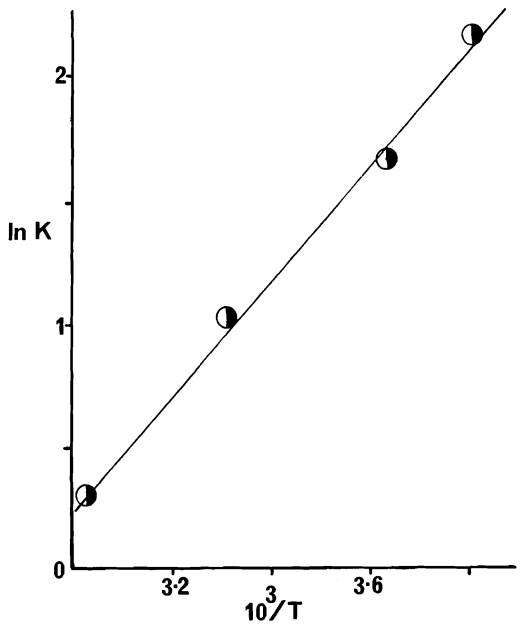

FIG. 2. Arrhenius plot and least-squares line correlating complexation data for mixtures of **1** and **2** in CCl_4.

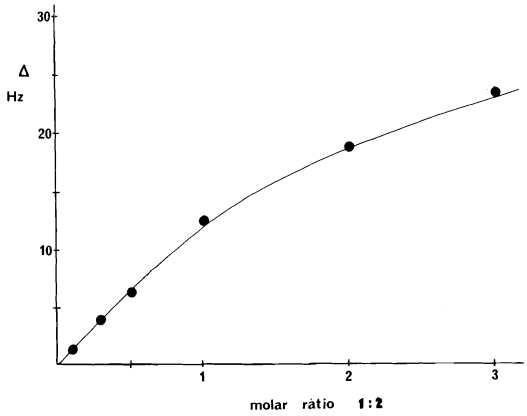

FIG. 3. Concentration dependence of the ^{13}C nmr carbonyl chemical shift of **2** in mixtures of **1** and **2** in CCl_4.

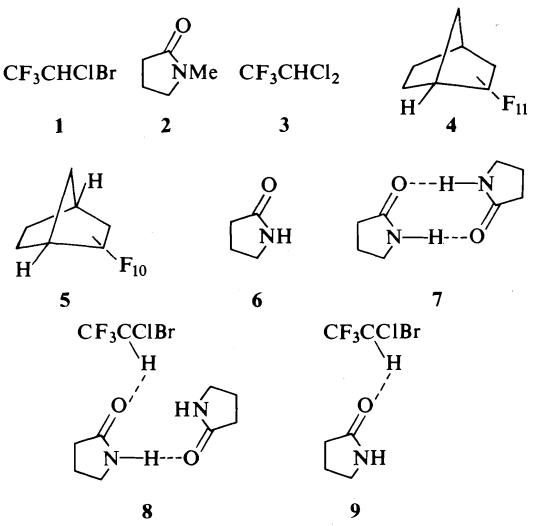
be compared with more extensive studies on hydrogen-bonding by chloroform to a variety of carbonyl compounds (11). For example, recent work on mixtures of chloroform and **2** (12), studied by ^1H nmr in cyclohexane, gave $\Delta H_0 = -3.99$ kcal mol^{-1} and $\Delta S_0 = -10.9$ cal mol^{-1} deg^{-1}, which may be compared with our values for **1** and **2** of $\Delta H_0 = -4.7$ kcal mol^{-1} and $\Delta S_0 = -14$ cal mol^{-1} deg^{-1}. Miller found the limiting chemical shift for complexation of chloroform and **2**, Δ, to be 84 Hz at 28°C as compared with our value of Δ = 132 Hz for **1** and **2** in CCl_4 at 35°C. Insofar as this parameter reflects changes in charge-density at the hydrogen-bonding proton, it provides a measure of the tightness of the hydrogen-bond.



These results demonstrate that halothane **1** hydrogen-bonds strongly to a typical model tertiary amide. It would clearly be useful to correlate the hydrogen-bonding ability of this and other halothane anaesthetics with some readily measurable molecular property. Allen (13*a*), in a recent theoretical study of hydrogen-bonding, found that donor reactivity correlated well with the C—H bond dipole moment μ_{A-H}.[1] This is, however, difficult to evaluate in unsymmetrical organic molecules. Nevertheless, the electrostatic properties it represents may be reflected in the acidity of that C—H bond provided that the carbanion is charge-localized and of similar geometry to the hydrocarbon. It is particularly interesting that the pK_a's of **1**, **3**, and chloroform in cyclohexylamine (14) are 24.0, 24.4, and 24.4, respectively, that pentafluorobenzene, which has significant anaesthetic properties (15), has a pK_a of 24.2, and that **4** and **5** are extremely powerful anaesthetics (16), and have pK_a's of 20.5 and 22.3. Less acidic fluorocarbons (CF_3H, pK_a, 30.5; CF_3CF_2H, pK_a 28.2) are much less potent anaesthetics than **1** (1).

[1]Compare more recent theoretical studies of hydrogen-bonding (13*b*,*c*).

1,1,1-Trifluorobromochloromethane/pyrrolidone

It was of interest to determine whether hydrogen-bonding of **1** to a secondary amide might compete with inter-amide association (17) in CCl_4 solution. ^1H nmr measurements were carried out with mixtures of **1** and **6** as before, and the data treated to give $\Delta H_0 = -2.2$ kcal mol^{-1} and $\Delta S_0 = -6.5$ cal deg^{-1} mol^{-1} for hydrogen-bonding association. This may be compared with literature values (17) of $\Delta H_0 = -6.73$ kcal mol^{-1} and $\Delta S_0 = -13.1$ cal mol^{-1} deg^{-1} for self-association of **6**.

Amide dimers in solution may have a doubly hydrogen-bonding structure **7** (17), and our data do not distinguish between structures **8** and **9** for the halothane complex. They do, however, demonstrate that the hydrogen-bond between **1** and **6** is qualitatively similar in strength to a single inter-amide hydrogen-bond, one of the strongest known between organic molecules.

Fluorobicycloheptanes/N-Methylpyrrolidone

The polyfluorinated bicyclic compounds **4** and **5** are both highly acidic (14) and potent anaesthetics (16) and it was of interest to determine their C—H donor properties. Unlike **1** the chemical shift of the C—H in **4** is strongly temperature dependent, implying considerable self-association. Quantitative temperature dependence studies were therefore not attempted, but we have established that considerable deshielding of the C—H resonance in **4**, which is a complex multiplet centred at 3.50 ppm (0.26 *M*, CCl_4) occurs on addition of portions of **2**. The complexation chemical shift, Δ, is 122 Hz and $K = 1.9\ M^{-1}$ at 35°C. Similar results were obtained with **5**, showing that both of these fluorocarbons are capable of forming strong hydrogen bonds to amides.

Overall, these results suggest that halothane anaesthetics such as **1** may operate in vivo by a mechanism involving hydrogen-bonding, which may augment the more generally accepted role of lipid solubility (1).

Acknowledgments

We thank I.B.M. for a Fellowship (to P.A.C.), Dr. R. Stephens for samples of **4** and **5**, and Professor C. Sandorfy for communicating his later results to us, and for an exchange of manuscripts.

An electron impact study of the two isomeric tricarbonylchromium complexes of *N*-benzylideneaniline

EBERHARD W. NEUSE

Abteilung für Organische Chemie der Universität Ulm, D-7900 Ulm, Federal Republic of Germany[1]

Received January 4, 1977

EBERHARD W. NEUSE. Can. J. Chem. **55**, 3384 (1977).

Under electron impact, the two isomers resulting from tricarbonylchromium complexation of *N*-benzylideneaniline decarbonylate completely before the chromium-ring bond is broken and the azomethine ligand undergoes further fragmentation. The loss of two CO molecules is favored over the competitive process involving elimination of a single CO molecule, especially at high ionizing voltage. In both cases the highly stable benzylideneanilinechromium cations decompose primarily through fission of the metal-ring bond, although additional fragmentation pathways of minor importance are also observed. The decay patterns of the benzylideneaniline ligand cation are identical in the spectra of both complexes and very nearly coincide with that shown by benzylideneaniline itself under the same conditions of electron impact.

EBERHARD W. NEUSE. Can. J. Chem. **55**, 3384 (1977).

Sous impact électronique, les deux isomères provenant de la complexation du tricarbonylchrome avec le *N*-benzylidèneaniline se décarbonylent complètement avant que le lien chrome-cycle soit brisé et le ligand azométhine subisse des fragmentations subséquentes. La perte de deux molécules de CO est favorisée par rapport au processus compétitif impliquant l'élimination d'une seule molécule de CO spécialement à des hauts voltages d'ionisation. Dans chaque cas, les cations benzylidèneanilinechromes très stables se décomposent en premier lieu par la fission du lien métal-cycle, quoique des chemins additionnels de fragmentation d'importances mineures ont aussi pu être observés. Les patrons de décomposition du cation ligand-benzylidèneaniline sont identiques dans chacun des spectres des deux complexes et coincident presque complètement avec celui présenté par le benzylidèneaniline lui-même dans les mêmes conditions d'impact électronique.

[Traduit par le journal]

Introduction

The synthesis of mono- and bis(π-tricarbonylchromium) complexes of *N*-benzylideneaniline was first reported by Mostardini *et al.* (1), and their spectroscopic behavior was investigated more recently (2). In the following, we examine the fragmentation under electron impact of the two isomeric mono-complexes, (1,2,3,4,5,6-hexahapto-benzylideneaniline)tricarbonylchromium, **1**, and (1′,2′,3′,4′,5′,6′-hexahapto-benzylideneaniline)tricarbonylchromium, **2**.

Results and Discussion

(1,2,3,4,5,6-η⁶-Benzylideneaniline)tricarbonylchromium (1)

The mass spectral fragmentation characteristics of arenetricarbonylchromium complexes (3) depend primarily on the relative strength of the bonds between the chromium atom and the various ligands, as well as on the type and inherent stability of the arene ligand involved. Two factors deserve attention here: (*i*) fission of the Cr—CO bonds entails the elimination of carbon monoxide molecules as uncharged, stable entities, and (*ii*) the metal-to-

[1]Permanent address: Department of Chemistry, University of the Witwatersrand, Johannesburg, Republic of South Africa.

carbonyl backdonation as a contributor to Cr—CO bonding, brought about by the pronounced π^* acceptor properties of carbon monoxide, is appreciably reduced on ionization, because the electron removed, stemming from a high-energy chromium *d* orbital with predominant metal character (4), leaves a cation characterized by an effectively lowered metal *d* electron population involved in the backbonding.[2] Both factors combine to cause Cr—CO dissociation energies in the various metal carbonyl ions to be lower than the Cr–arene dissociation energy and thus generally render carbon monoxide elimination a facile and preferred process. We find this trend confirmed in the 70 eV mass spectrum of complex **1**: initial degradation proceeds through carbon monoxide loss, and no other parent ion fragmentation steps, such as C_{ring}—C, C_{ring}—N, or C═N fission, are indicated in the spectrum. As a result, both the parent ion, $P^{+\cdot}$ (*m/e* 317), and the carbonyl-containing fragment ions are less abundant than the carbonyl-free *m/e* 233, the benzylideneanilinechromium cation.

The successive removal of CO ligands from metalpolycarbonyl ions entails a concomitant increase in the dissociation energies of the remaining M—CO bonds in the product ions (3, 8). In the fragmentation of **1**, simple stability arguments should, therefore, predict an increase in peak intensity as one follows the cascade sequence $P^{+\cdot}$(*m/e* 317) → $[P - CO]^{+\cdot}$(*m/e* 289) → $[P - 2CO]^{+\cdot}$(*m/e* 261) → $[P - 3CO]^{+\cdot}$(*m/e* 233). At low ionizing voltages this is seemingly the case, relative intensities at 15 eV increasing in the order 18 (*m/e* 317), 20 (*m/e* 289), 58 (*m/e* 261), 100 (*m/e* 233). At 70 eV, however, a different pattern obtains; while the order of increasing yields still holds for the ions *m/e* 317, 261, and 233 (and, similarly so, for their doubly charged counterparts), the peak at *m/e* 289 is drastically attenuated (*m/e* 289 to *m/e* 261 abundance ratio, 0.14). This suggests that, at the higher ionizing voltage, the parent ion prefers to convert directly to *m/e* 261 through the expulsion of two CO molecules, either concertedly or in a fast consecutive two-step process, and indeed we find the process *m/e* 317 → *m/e* 261 + 2CO unambiguously confirmed as a metastable transition. Although this process requires a higher activation energy than does the reaction *m/e* 317 → *m/e* 289 + CO (otherwise, the *m/e* 289 to *m/e* 261 ratio should decrease, rather than increase as the ionizing voltage is lowered to the more selective 15 eV level), it must proceed with a higher frequency factor in order to account for its absolute predominance at both voltage limits. Within the framework of quasi-equilibrium theory (9–11), the relationship between the unimolecular rate constant of decomposition, $k(E)$, and the total internal energy, E, imparted to the ion by the applied ionizing voltage can be expressed in simplified form by eq. 1, in which ν represents a frequency factor, E_0 is

$$k(E) = \nu((E - E_0)/E)^{s-1} \qquad [1]$$

the energy of activation of the decay process, and *s* indicates the effective number of weakly coupled harmonic oscillators (i.e. vibrational modes) operating in the molecule.[3] The relationship has been used extensively, notably by Williams (11, 15) and Shapiro (16, 17) with their collaborators, in the analysis of concurrent decomposition mechanisms under electron impact. With the aid of eq. 1, the trend of rate constants in two competitive parent ion decompositions can be depicted schematically (ref. 14, Chapt. 8, 18–20) by diagrams of the type shown in Fig. 1, in which log $k(E)$ is plotted against E

[2]While it is recognized (5, 6) that ionization will generally lead to immediate electronic reorganization, which is unaffected by the site of the original electron removal, the resultant charge distribution in the product cation must be consistent with the tendency for the lower-lying electronic states to be more highly populated at a given internal energy (in comparison with higher-lying states) because of the greater number of vibrational quanta present and concomitantly greater vibrational degeneracy (7). The increased population and enhanced vibrational energy of the lower-lying electronic states both combine to render further fragmentation more probable from these lower states than from the higher-lying ones. The lower-lying states, however, are precisely those characterized by reduced occupancy of the high-energy antibonding π^* orbitals of the Cr—CO bond system. Abandoning the concept (now somewhat outdated (6)) of charge localization and concomitant selective bond fission does, therefore, not invalidate the argument presented.

[3]For large molecules, the number of oscillators is given by $3n - 6$ (n = number of atoms). The effective number of modes is usually taken as one-half to one-third (one-fifth near threshold) of that value (11, 12). The more rigorous Rice–Ramsperger–Kassel–Marcus formulation (13) employs an exact enumeration of states and is, therefore, sometimes preferred (ref. 14, Chapt. 8) over the simple quasi-equilibrium theory formulation of eq. 1 and modified forms. Qualitatively, however, both theories lead to the same conclusions presented in the text.

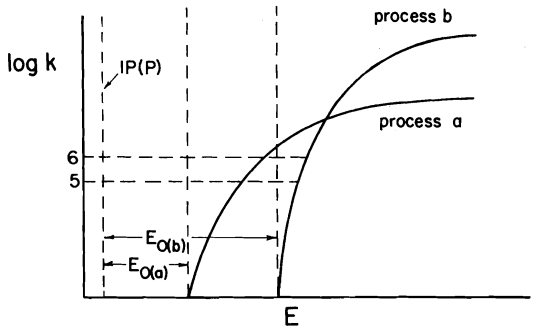

FIG. 1. Log k vs. E curves (schematic) for two competitive, unimolecular parent-ion degradation reactions.

for both reactions. In such systems of competing decay steps, in which ΔE_0, the difference in activation energy between the two reactions, determines their relative rates at low E, while $\Delta\nu$ becomes the controlling factor at high E (16), process b (high ν, E_0) passes through a relatively loose activated complex (ref. 14, Chapt. 8, 18) and so generally represents a direct bond cleavage. Process a (low ν, E_0), on the other hand, passing through a tighter (and perhaps anchimerically assisted) transition state, tends to involve a rearrangement (ref. 14, Chapt. 8, 16–19). The observed energy dependence of the reactions m/e 317 → m/e 289 and m/e 317 → m/e 261 suggests these two processes to be congruent with the depicted model, the former reaction being represented by a, and the latter by b. (Appearance potential measurements for the two daughter ions, not feasible with our present spectrometer set-up, will be necessary to confirm the implicit assumptions.) It appears, therefore, that the loss of two carbon monoxide molecules proceeds by direct breaking of Cr—CO bonds, whereas the competing expulsion of a single monoxide molecule proceeds through a transition state with a reduced number of active rotational modes as exemplified in a structure comprising pentacovalent chromium through coordinate bonding interaction with the C=N system. This question requires further study.

The benzylideneanilinechromium cation, m/e 233, is the most stable intermediate in the overall decay pattern of **1** and so, if one excepts $Cr^{+\cdot}$ as the highly abundant terminal fragmentation product ion, represents the base peak in the m/e 50–317 range, reflecting the higher arene–chromium bond dissociation energy (2.4 eV in benzenechromium cation (21)) relative to the various M—CO dissociation energies associated with the preceding CO expulsion steps (1.2–2.0 eV in benzenetricarbonylchromium decarbonylation (21)). The subsequent decay processes are straightforward. Arene–chromium bond fission, as the principal path, leads to chromium cation and probably also (albeit not associated with a detectable m^*) to benzylideneaniline cation.[4] Loss of chromium hydride, supported by the increased intensity ratio of m/e 180 to m/e 181 (1.03) in the spectrum of **1** relative to that of benzylideneaniline (0.88), and elimination of benzene (subsequent to a hydrogen migration) with generation of m/e 155 both represent low-abundance steps. The benzene elimination path is paralleled by the even less significant transition m/e 233 → m/e 78 involving loss of benzonitrile-chromium,[5] the benzene ion peak intensity being only moderately enhanced relative to the corresponding peak in the benzylideneaniline spectrum (measured against m/e 181 in both cases). Further fragmentations of m/e 155 give rise to $Cr^{+\cdot}$ and to $CrCN^+$, in the latter case through rearrangement and ejection of phenyl free radical (allowed by the even-electron rule). The transition m/e 155 → m/e 77, the species eliminated being neutral CrCN,[6] is suggested by the observation of a metastable peak, whose abundance, however, is too low to permit an unambiguous assignment. Should this latter reaction indeed occur, it would represent the only observed

[4]We are grateful to one of the referees for suggesting the possibility of benzylideneaniline cation formation through loss of neutral $Cr(CO)_n$ from $RCr(CO)_n^{+\cdot}$ (R = benzylideneaniline). In view of the prominence of m/e 181, this proposal appears quite valid, although we were unable to find corroboration by metastable peaks.

[5]Although the m^* associated with m/e 233 → m/e 78 also holds for m/e 317 → m/e 91 (C=N fission), we neglect this latter transition on energetic grounds; indeed, we were unable to detect metastable peaks for the corresponding C=N fission steps in m/e 289, 261, or 233, all of which should be energetically more amenable to such fission than the parent ion, and even in the uncomplexed benzylideneaniline the incidence of azomethine double bond fission is remarkably low (22).

[6]There is precedence in the literature for the generation of ions of the type CrX^+ by the reaction: $CrC_6H_5X^{+\cdot} \rightarrow CrX^+ + C_6H_5\cdot$, provided only that X represents a substituent of higher electronegativity (21). The analogous process in which the positive charge remains with the ring ligand, whereas a neutral species CrX departs, is feasible in cases where the resultant organic cation exhibits high stability (23).

metastable transition originating from Cr-containing fragment ions that would contribute directly to the phenyl cation[7] peak; the latter, only moderately intensified relative to its *m/e* 77 counterpart in the benzylideneaniline spectrum, appears to derive most of its intensity from fragmentations of the azomethine cation, although a minor additional contribution from *m/e* 233 decomposition by a rapid (and therefore not necessarily metastable) direct bond cleavage cannot be discounted.

The phenylchromium cation, manifested by a peak of low abundance at *m/e* 129, is probably (no *m**) formed in part by C_{ring}—C bond cleavage in *m/e* 233. Yet the principal mode of formation, substantiated by a relative ion yield increase with rising source pressure, involves phenyl radical capture by $Cr^{+}\cdot$. The phenylchromium ion decays through fission of the C—Cr bond and so contributes to the ion yield of *m/e* 52. The spectrum shows a peak of low intensity at *m/e* 80, identified as $[CrCO]^{+}\cdot$ by an accurate mass number determination. The peak's observed intensity increase at higher source pressure or inlet temperature suggests $[CrCO]^{+}\cdot$ formation to be due to an ion–molecule reaction involving CO capture by $Cr^{+}\cdot$.

In addition to the fragment ion peaks discussed in the foregoing, which are derived from chromium-containing species, the spectrum in the lower mass-number range extending up to *m/e* 181 shows the typical fragmentation pattern of benzylideneaniline (22, 25) as verified by comparison with the mass spectrum of this compound recorded separately under identical conditions. Additionally, the characteristic $[C_4H_3]^{+}$ peak at *m/e* 51 (through expulsion of acetylene from phenyl cation) should be mentioned, as should the low-intensity peaks at *m/e* 63, 64, 78, and 89. The ion of *m/e* 63 most probably is a fragment of *m/e* 77 (expulsion of methylene); a contribution may reasonably be ascribed to $[C_7H_5]^{+} \rightarrow [C_5H_3]^{+} + HC{\equiv}CH$. Loss of HCN from the ion of *m/e* 91 (identified as $[C_6H_5N]^{+}\cdot$ by accurate mass number determination) accounts for *m/e* 64. The benzene cation peak, *m/e* 78, derives most of its intensity from the fragmentation *m/e* 181 → *m/e* 78 + 103. (The minor transition *m/e* 233 → *m/e* 78 was mentioned above.)

[7]Both $[C_6H_5]^{+}$ and $[C_6H_6]^{+}\cdot$, although for convenience designated here as phenyl and benzene cations, respectively, may well possess non-cyclic isomer structures (24).

We expected a contribution from the reaction *m/e* 77 + H· → *m/e* 78; however, the injection of D_2O into the ionization chamber failed to produce a significant peak at *m/e* 79, suggesting hydrogen capture by the phenyl cation to be a negligible process. The benzene cation undergoes further breakdown in a straightforward manner through elimination of acetylene. No reasonable mode of formation of the ion of *m/e* 89 is apparent from the spectrum. Although the ion could result from *m/e* 181 by a hydrogen migration, followed by azomethine bond cleavage, the involved rearrangement should provide kinetic conditions conducive to the appearance of a metastable peak; this, however, was not observed.

In the previous papers (22, 25) the generation of *m/e* 77 in the fragmentation of benzylideneaniline was accounted for in terms of loss of $C_7H_6N\cdot$ from *m/e* 181 (*m** reported at *m/e* 32.8). However, we find the metastable peak more accurately at *m/e* 32.9, reflecting the transition *m/e* 180 → *m/e* 77, and this step in fact appears more plausible than *m/e* 181 → *m/e* 77 on energetic grounds. The species expelled from *m/e* 180 represents a stable molecular entity (benzonitrile), which on account of its high IP shows little tendency to accept the positive charge. In contrast, the species $C_7H_6N\cdot$ that would be ejected in the corresponding fragmentation of *m/e* 181 represents a free radical of low stability; hence, the preferred path originating from *m/e* 181 clearly comprises the formation of the highly stabilized even-electron cation $[C_7H_6N]^{+}$ (*m/e* 104) as indeed observed, and the elimination of the $C_7H_6N\cdot$ free radical is likely to constitute at best a competitive process of very low abundance.

(1′,2′,3′,4′,5′,6′-η⁶-Benzylideneaniline)tricarbonylchromium (2)

The mass spectrum of **2**, as would be expected, closely resembles that of isomer **1**, showing the *m/e* 317 parent ion and fragmentation peaks at all the positions cited in the foregoing section. The peaks and their relative abundances are juxtaposed in Table 1 to their counterparts derived from **1**, and the overall fragmentation patterns proposed for both compounds are depicted in Fig. 2. Table 2 lists the metastable transitions observed; it is seen that, with few exceptions, the respective *m** signals appear at virtually identical positions. On comparison of

TABLE 1. Significant peaks in the mass spectra of complexes **1** and **2**[a]

[h]Contains contribution by $[C_4H_4]^{+\cdot}$.

the spectra of **1** and **2**, several features deserve comment as detailed.

(*1*) The breakdown pattern from *m/e* 181 down to *m/e* 50 is about the same, which is, of course, in accord with the common ion intermediate role of the benzylideneaniline cation and needs no further discussion.

(*2*) Resulting from differences in both stability and ionization potential, the abundance of the parent ion in relation to the carbonyl-free complex ion (*m/e* 233) is distinctly lower in **1** than in **2**. The stability of **1**, in terms of resistance to the primary steps involving Cr—CO bond fission, is probably lower than that of **2** because of increased backbonding from Cr to ring ligand (and accordingly reduced Cr—CO backdonation), brought about by the lower charge density on the complexed ring of **1** (mildly electron-withdrawing —CH=N—Ph substituent (2)) as compared to the situation in **2** (weakly electron-donating —N=CH—Ph substituent (2)). In contrast, **1** can be expected to possess the higher IP[8] for the very same reason of electron withdrawal by the substituent on the complexed ring in this compound. Lower stability and higher ionization potential both will combine to render $P^{+\cdot}$ of **1** the less abundant one (ref. 14, pp. 35, 36) of the two parent ions.

(*3*) The decarbonylation pattern of **2** differs from that of **1** insofar as the $[P - 2CO]^{+\cdot}$ species is of noticeably lower relative intensity than the isomer ion derived from **1**, and the $[P - CO]^{+\cdot}$ daughter ion peak is effectively absent (<0.5%) in the spectrum at 70 eV, becoming significant only as the electron beam energy is lowered (2.9% at 20 eV, 6.0% at 15 eV). This indicates

[8]Accordingly, by plotting IP (by electron impact (26)) against k_{CO}, the carbonyl stretching force constant (from ν_{CO} (27)), for 12 representative arenetricarbonylchromium complexes as previously done by Müller (26), we obtain a least-squares fit, from which for **1** ($k = 15.000 \times 10^5$ dyn cm^{-1} (2, 27)) and **2** ($k = 14.867$ dyn cm^{-1} (2, 27)), respectively, IP values of 7.38 and 7.26 eV can be derived.

[f]Tail at *m/e* 44.6–44.7 vw.

that the velocity curve for the transition *m/e* 317 → *m/e* 289 (Fig. 1) is even shallower, and approaches a lower limiting value of $k(E)$, in the decarbonylation of **2** than holds for the analogous step in the decarbonylation of **1**. For **2**, hence, the monodecarbonylation step is associated with a lower frequency factor, and thus passes through a tighter transition state, than in the case of **1**. Anchimeric assistance by the proximate N donor atom in a suitably adapted transition-state geometry, resulting in further rotational restrictions, may be responsible for this trend.

(*4*) The *m/e* 181 to *m/e* 233 ion yield ratio is higher, and so indicates a more favored Cr–ring bond cleavage, in *m/e* 233 (**2**) than in *m/e* 233 (**1**). This is not what one would expect on the basis of stability considerations: in the former ion, the more powerful π donating effect exerted by the complexed ring, brought about by the electron-releasing —N=CH—Ph substituent, should result in a stronger Cr–ring bond and, thus, in a correspondingly reduced relative *m/e* 181 ion yield. Possibly, competitive degradation reactions, at the expense of Cr–ring bond fission, are faster in the *m/e* 233 ion stemming from **1** than in the isomer derived from **2**. It can be argued, for example, that the higher stability of the benzonitrilechromium ion (possibly further stabilized by rearrangement to the *N*-substituted tropylium isomer) arising from *m/e* 233(**1**) decomposition, as compared to the isonitrile-type isomer resulting from degradation of *m/e* 233(**2**), should render benzene expulsion from *m/e* 233 a relatively more favorable process in the fragmentation sequence of **1**, and indeed the slightly enhanced abundance of *m/e* 155(**1**) relative to 155(**2**) corroborates this proposition. However, in view of the possibility of isomerizations at the more advanced stages of fragmentation, the difference in abundances is not significant enough to permit any rationalizations, which

must await the availability of appearance potential data on all fragment ions involved.

Experimental

Compounds

Complexes **1** and **2**, obtained from precomplexed starting materials (1), were further purified by repeated recrystallization from dry, deoxygenated heptane under rigorously controlled anhydrous conditions in the dark; **1**, mp 106.5–107.5°C; **2**, mp 109–110°C (sealed). Failure to observe these precautions resulted in samples giving noticeably variant mass spectra. *N*-Benzylideneaniline (28) was recrystallized from dry methanol (moisture protection); mp 50.5–52°C.

Instrumental Conditions

Mass spectra of **1**, **2**, and *N*-benzylideneaniline were obtained on a Varian Mat CH5 single-focusing mass spectrometer operating at 15–70 eV ionizing voltage, 3 kV (nominal) accelerating voltage, 6×10^{-6} Torr source ion gauge pressure, and 150°C source temperature. Unless specifically stated otherwise, information was retrieved from the 70 eV spectra. Samples were admitted through a direct inlet system. Within the probe temperature range of 60–80°C no temperature sensitivity of relative peak intensities was observed; probe temperatures were therefore maintained at 71 ± 1°C. At this level, satisfactory intensities were obtained without the risk of thermal decomposition. Peaks and relative intensities are recorded in Table 1 for both **1** and **2**; for each compound, the abundance values represent averages of 24 scans taken on 12 samples individually prepared and admitted (i.e. two scans per sample), with normal bake-out procedures interposed between successive sample applications. Metastable peaks were recorded at the Inorganic Chemistry Laboratory, Technical University, Munich, with the aid of an Atlas-CH4 mass spectrometer equipped with a TO 4 ion source; ionizing voltage, 50 eV; probe temperature, 75 ± 2°C. The peaks are listed in Table 2.

Acknowledgments

This work was supported by the South African Atomic Energy Board, and a stimulating discussion with Dr. S. Gordon of that organization is gratefully acknowledged. Thanks are due to Mrs. M. Stein for her patient experimental assistance, and to Professor J. Müller, now at the Technical University of Berlin, for his invaluable help in obtaining spectra on the Atlas instrument under conditions conducive to the observation of metastable transitions. The kind hospitality extended by Professor H. A. Brune during the author's stay in Ulm, where the final preparation of the manuscript was done, is deeply appreciated.

Organic electrode processes: generalized reduction mechanisms[1]

PHILIP J. ELVING

The University of Michigan, Ann Arbor, MI 48109, U.S.A.

Received February 28, 1977

PHILIP J. ELVING. Can. J. Chem. **55**, 3392 (1977).

Prototype formulations are considered for the reaction pathways commonly encountered for the electrolytic reduction of organic compounds in aqueous and nonaqueous media on the basis that the essential feature is severance of a chemical bond which requires transfer into the reaction site of one or two electrons; multiple electron processes result from instability at the applied potential of initially produced species or their chemically altered products. To obtain electrical neutrality, uptake of electrons may have to be accompanied by that of a cation, generally a proton. Pertinent factors in the path followed in the overall electrode process may include a sequence of free radical or radical anion going to dimeric or carbanion species (depending on the relative rates of chemical and charge-transfer steps), possible interaction of intermediate products with their progenitors, proton donor activities, medium properties (e.g in respect to rates of chemical reactions accompanying charge-transfer and control of the chemical states of reactants and intermediates), stereochemical factors inherent in reactant and intermediate species, and chemical interaction with the electrode material. Application of the general mechanistic considerations are illustrated by various types of electrolytic reductions: aromatic hydrocarbon, nitrogen heterocycle, carbon–halogen bond, ketone carbonyl group, and beta halogenated and/or unsaturated acids.

PHILIP J. ELVING. Can. J. Chem. **55**, 3392 (1977).

Des formules modèles sont considérées pour des chemins réactionnels souvent rencontrés dans la réduction électrolytique de composés organiques en milieu aqueux et non aqueux. On se base sur le fait que la rupture du lien chimique exige le transfert d'un ou deux électrons au site réactionnel. Les processus multi-électroniques résultent de l'instabilité au potentiel appliqué des espèces initialement produites ou de leurs produits transformés. Afin d'obtenir une neutralité électrique, le transfert d'un électron doit être accompagné par celui d'un cation, généralement un proton. Les facteurs appropriés dans ce chemin réactionnel suivi, tout au long du processus prenant place aux électrodes, peut impliquer: (*a*) la séquence d'un radical libre ou d'un radical anionique donnant des dimères ou carbanions (dépendant des vitesses relatives des étapes chimiques et celles de transfert de charge); (*b*) l'interaction possible des intermédiaires avec les produits initiaux, (*c*) des activités proton-donneur; (*d*) des propriétés de milieu (i.e. par rapport aux réactions chimiques accompagnant le transfert de charge ainsi que du contrôle des états chimiques des réactifs et intermédiaires); (*e*) des facteurs stéréochimiques propres aux réactifs et intermédiaires; (*f*) l'interaction chimique avec l'électrode. L'application des considérations mécanistiques générales est illustrée par différents types de réduction électrolytique, un hydrocarbure aromatique, un hétérocycle contenant un atome d'azote, un lien carbone–halogène, le groupe carbonyle d'une cétone et des acides bêta-halogénés ou insaturés.

[Traduit par le journal]

Introduction

The prototype formulation for the half-cell reaction mechanism for the electrolytic reduction of an organic compound, can be expressed in its simplest form as

$$[1] \qquad Ox + ne^- = Red$$

Although the stoichiometric form of eq. 1 is usually quite simple, involving small integral ratios of oxidized and reduced forms with perhaps the addition for reactions in aqueous media of hydrogen ions and/or water, and in nonaqueous media of proton donors and/or acceptors, the actual course of the reaction is often quite complex since it is heterogeneous in nature, involving electron transfer between a solution species (or its adsorbed or otherwise altered form) and the electrode, and occurring in the interfacial region between bulk solution and bulk electrode.

In 1961, Elving and Pullman (1) discussed three general approaches to the description of organic electrode reaction pathways: (*a*) the *chemical* reaction mechanism as stated in terms

[1]Presented at the International Conference on Modern Electrochemical Techniques for Investigating Chemical Systems, Carleton University, Ottawa, Canada, July 13–16, 1976.

of the species involved, following the format usually used in describing organic reaction mechanisms in homogeneous solution; (*b*) the *electrochemical* reaction mechanism, which involves a more detailed analysis of the physical situation at the solution–electrode interface; (*c*) the *energetic* reaction mechanism, in which a more precise (if possible) mathematical statement is attempted. This sequence was considered to be a logical development in the elucidation of a mechanism and its interrelations with the factors involved.

Since 1961, much work has been done on the elucidation of organic electrode reaction paths with extensive examination of the behavior of free radical and other intermediate species as well as of the roles of adsorption and kinetics in guiding the overall reaction in one direction in preference to another. The magnitude of the available literature and the complexity of effects involved can be seen from the compendia by Baizer (2), Tomilov *et al.* (3), and Mann and Barnes (4), two Faraday Society Discussions (5, 6), and the discussions on basic concepts in organic electrochemical reaction paths by Cauquis (ref. 7, pp. 13–91) and methods for such reaction elucidation by Cauquis (ref. 7, pp. 93–154) and by Fleischmann and Pletcher (8).

The present discussion, consequently, attempts to bring prototype formulations for the general reductive mechanism up to date by explicating possible alternate paths, particularly as these may cast light on reactive configurations at the solution–electrode interface and on the interplay of thermodynamic and kinetic effects. Stress is placed on the 'chemical reaction mechanism'. To conserve space, correlations of proposed mechanistic schemes with theoretical calculations, e.g. of the HMO type (cf. refs. 9 or 10), will not be explored. Similarly, correlation of reaction schemes with heterogeneous rate constants for electron-transfer (charge-transfer) steps will be largely omitted due, in this instance, to the paucity of $k_{s,h}$ data for organic compounds.

The discussion is largely focussed on data obtained by polarography, derived technics (e.g. cyclic voltammetry and ac polarography), and related approaches (e.g. controlled electrode potential electrolysis). Frequently, solutions of products prepared by the latter approach have been examined and products identified by diverse electrochemical, spectrophotometric, chemical, and enzymatic means; often, periodic examination of the test solution during electrolysis provides helpful information.

Basic Mechanistic Considerations

Because an electrochemical reaction is a heterogeneous process, a completely satisfactory mechanistic description must await a detailed understanding of phenomena in the electrical double layer and the immediately surrounding solvent region, e.g. ref. 11. Meanwhile, elucidation of a mechanism for an organic electrode reaction optimumly includes specification of (*a*) state of the compound in solution and on approaching the interface, (*b*) redox reaction sites in the molecule, (*c*) adsorption sites (and evaluation of adsorption in relation to electron-transfer), (*d*) the sequence of charge-transfer and coupled chemical steps, and (*e*) kinetic and energetic parameters for these steps. Where possible, the effects should be specified of variation in experimental conditions which may alter, for example, nature of the electroactive and intermediate species and extent of participation of other solution species, and attempts should be made to describe possible structures for the transition states involved, including orientation of the compound relative to the electrode when electron transfer occurs.

These goals are often approached with many descriptions stating in more or less detail the sequence of steps including the presence of accompanying chemical reactions, the reversibility of electron-transfer processes, the roles of free radical and other short- and long-lived intermediate species, the product ratio if more than one product is formed, the extent and manner of adsorption and orientation of reactant and products at the interface, and any changes produced at the electrode surface, e.g. film formation.

A limiting factor is the ability of the experimental technics used to discriminate between the various steps in the electrode process, and to follow these steps adequately, i.e., the relative time scales of reaction sequence and experimental approach. An obvious example is the increasing amount of information available from cyclic voltammetry as the potential scan rate (dE/dt) is increased; variation in initial and reversal potentials, and nonsymmetrical and repeated scanning may further amplify the information obtainable.

Bond Rupture

Electrolytic reduction of both organic and inorganic species involves the net transfer of electrons from electrode to electroactive species; an essential difference is that in inorganic reductions 'normal' largely covalent chemical bonds are only apt to be broken in cases where the electroactive element is present as an oxygenated species or has a lesser coordination number in the reduced than in the oxidized state. In contrast, the fundamental process in an electrolytic organic reduction is a change in the structure of a functional group due to bond rupture, which requires only one electron to produce a free radical species; addition of a second electron completes rupture of the bond. Accordingly, from the mechanistic viewpoint, only one-electron (1e) or two-electron (2e) processes need to be considered; apparent multiple electron processes result from the instability at the potential of its formation of the initially produced species, perhaps following an intermediate chemical reaction, and, consequently, its immediate further reduction, i.e., multiple electron processes are due to combinations (simultaneous and/or successive) of 1e and/or 2e processes. Polarographic waves, for example, may also overlap due to a succession of electrode processes at only small potential separation from each other, e.g. behavior of nicotinamide in alkaline solution (12).

It is reasonable to assume on the basis of the evidence accumulated on the mechanisms of homogeneous and heterogeneous (including electrode) reactions, both inorganic and organic, that the occurrence of an electrode reaction involving the actual simultaneous transfer of more than two electrons is likely to be small. Indeed, a question might be raised as to whether observed simultaneous 2e transfer processes are not actually two 1e processes which follow each other, for example, within less than either the lifetime of an intermediate species or the time of a single molecular vibration (cf. suggestion by Jacq, Cavalier, and Bloch (13)). Since the previous argument often is a nonoperational one and since dimers indicating the presence of 1e processes are found, we may safely assume that a simultaneous 2e process is the rapid succession of the 1e reactions represented in Fig. 1 with the proviso that electrons may follow each other so rapidly that the transition state

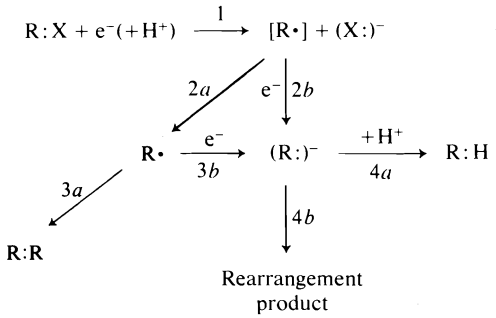

FIG. 1. Generalized chemical reaction mechanism (discussed in the text). If R and X were connected by multiple bonds, the initial reaction product may be [Ṙ—X—Z] (from ref. 1).

effectively represents a combination of the electroactive species and two electrons.

General Mechanism

Based on the previous discussion, a general mechanistic pattern for organic reductions (Fig. 1) can be proposed, which permits rationalization of the course of such processes and of variation in mechanism with experimental conditions or between members of a homologous series (cf. ref. 1). The pattern assumes a reaction site, R—X, where R may be a reactive carbon center (or another atom, e.g. nitrogen, oxygen, or sulfur), X another carbon, oxygen, nitrogen, halogen, or other atom, and the bond an electron pair; there may be more than one bond between R and X, e.g. C=N in a heterocyclic ring. (In the subsequent discussion and equations, H^+ or (H^+) represents a proton source, e.g. HA; hydrogen, hydroxide ions, and water are not usually shown except where necessary to indicate final establishment of an electrically balanced species.)

In the primary charge-transfer reaction, which is generally potential-determining, a single electron enters the reaction site to form presumably an activated complex, which can dissociate to a free radical precursor and an anionic species (step 1); if a multiple bond was originally present between R and X, a radical anion could be formed. The exact nature of species will be modified by the extent of participation of protons, solvent molecules, other solution constituents, and the electrode surface (participation of these species in subsequent steps is not explicitly indicated but may be involved), e.g. H^+ can participate by chemical polarization of the R—X bond through formation of an H—X

bond; H^+ is the most common third participant in the initial step, although another Lewis acid may act similarly.

The free radical precursor can either immediately (or after rapid chemical rearrangement) accept a second electron to form a carbanion (step 2*b*) or can exist as a discrete free radical (step 2*a*), which eventually either dimerizes (step 3*a*) or is reduced at more negative potential to the equivalent of a carbanion (step 3*b*). The charge on the carbanion, formed by either path, is usually neutralized either by acceptance of a Lewis acid, e.g. H^+ derived from a solution species (step 4*a*), or by electronic rearrangement (step 4*b*) with the charge being transferred to another part of the molecule where it can be suitably handled, e.g. elimination of an atom or group from an atom adjacent to the original reactive site with consequent formation of a double bond between this atom and that of the reactive site.

Completion of the initial electron addition (and perhaps displacement of the X moiety) by step 2*a* or 2*b*, depends on which route requires the less activation energy, i.e., on the difference in free energies of the transition states. Chemical reactions such as protonation, dimerization, rearrangement and elimination, which precede, accompany and/or follow charge-transfer, often play significant roles in the overall process, as has been noted and will be subsequently discussed.

Effect of the Medium

The effects of solution composition and experimental conditions on electrochemical behavior have been abundantly discussed, e.g. refs. 2–4 and 14–19, typically in respect to interaction of solvent and background electrolyte components with participants in the electrode process.

The principal effect of the medium is generally related to the sensitivity of the mechanistic pathways to proton availability. Thus, pyrimidine and nicotinamide are each initially reduced in a 1e process to the neutral free radical in acidic aqueous solution and to the radical anion in aprotic media; however, their behavior in aqueous solution differs markedly as the p*H* is increased, e.g. pyrimidine undergoes an initial 2e reduction by p*H* 6 and a 4e reduction by p*H* 9, whereas nicotinamide undergoes an initial 1e reduction up to p*H* 12. Furthermore, many initial 1e reactions in aprotic media may (in the presence of sufficient proton activity) become overall multiple electron reactions, e.g. reduction of aromatic hydrocarbons (2e reactions), nitro groups (4e or 6e reactions), and purines (2e, 4e, or 6e reactions).

Hydrogen ion can affect the reduction mechanism by (*a*) direct interaction with the chemical system and electrons at the reaction site, e.g. via polarization of the bond to be ruptured, (*b*) control of the nature of chemical participants in various steps via, for instance, acid–base equilibria, (*c*) effect on species behavior at the electrode in terms of adsorption and/or steric phenomena, and (*d*) alteration of relative reaction rates for electrochemical and chemical reactions.

Among the specific effects seen are the fusing of consecutive electron-transfer steps, the splitting of multiple electron-transfer steps, and the removal or formation of reduction sites such as double bonds as a result of tautomeric shifts and intramolecular chemical reactions, e.g. deamination and dehydration.

As previously noted, in many subsequent equations, H^+ can represent hydrogen ion furnished by dissociation of a sufficiently strong acid (e.g. $HClO_4$) or a slightly dissociated proton donor, e.g. H_2O. The latter is frequently the case in nonaqueous media, where reaction, for example, of an anion or radical anion, R^-, with a proton donor, HA, is likely to follow the course,

$$[2] \qquad R^- + HA \rightleftharpoons [R\text{---}H\text{---}A]^- \rightleftharpoons RH + A^-$$

Multiple bond reductions frequently involve an additional reactant, e.g., a solution component, Z, such as hydrogen ion,

$$[3] \qquad R{=}X + e + Z = [\dot{R}{-}X{-}Z]$$

Succeeding reactions of the intermediate species can still be depicted by the equations of Fig. 1.

Referring, then, to Fig. 1, the p*H*-dependence of organic electrolytic reductions is commonly associated with step 1; there are few well-defined examples of steps 2 and 3 being p*H*-dependent. For example, in the reduction of nitrogen heterocycles or ketones, where two polarographic waves are observed with wave I being due to formation of a free radical and II to its reduction, wave I may be p*H*-dependent but wave II rarely is. The p*H*-dependence of wave I may then be associated with hydrogen ion being involved in

formation of the energy-determining activated complex or transition state, regardless of whether hydrogen ion is involved in the final stoichiometry of the first step (eq. 3) or not. This does not necessarily mean that every first reaction step representable by eq. 3 is p*H*-dependent. The importance of H^+ in determining the state of the electroactive species and, consequently, the energy of the reaction is considerable in many situations, e.g. those involving acid–anion and keto–enol systems. For example, $E_{1/2}$ for the 2-bromoalkanoic acids is p*H*-dependent in the p*H* region where the shift from anion to more readily reduced acid form is appreciable; the fundamental carbon–bromine bond fission process is p*H*-independent throughout the p*H* range involved.

The argument is general, since other solution components may also affect the reactive species, e.g. the effect of ammonia and amines on carbonyl group reductions. An analogous argument concerns the effect of ion pair formation between, for example, a carbanion or other anion and a metallic cation.

An important reason for examining compounds in nonaqueous media has to do with their nonreducibility in aqueous media (20). If nonavailability of potential range is the cause, the use of solvents such as *N*,*N*-dimethylformamide (DMF), acetonitrile (AN), and dimethylsulfoxide (DMSO) provides at least a limited answer as the available potential range is a volt or more greater than in aqueous alkaline medium.

Reversibility and Characteristic Potentials

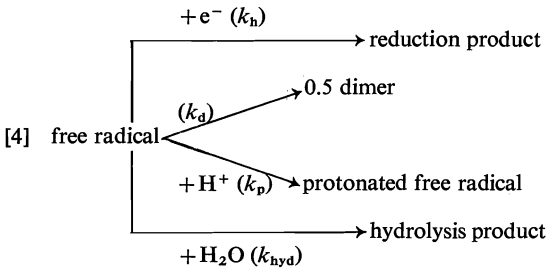
The energy level at which an electrode process occurs is indicated by a potential characteristic of the faradaic reaction, e.g. the half-wave potential, $E_{1/2}$, which (for a thermodynamically reversible redox half-reaction system) corresponds to the formal potential, E_c^0, for the specified experimental conditions, corrected for diffusion coefficient differences. For an irreversible system, $E_{1/2}$ corresponds to the formal potential plus terms involving the diffusion coefficient ratio, the activation energy for the electron-transfer, certain experimental conditions, and, at times, rate constants for chemical steps in the overall electrode process (cf. refs. 16, 18, 19, 21, and 22) for a summary of the nature of $E_{1/2}$ and related potentials, and the factors which enter into their measured values.

It is important to characterize the kinetics of both heterogeneous electron-transfer and homogeneous chemical reaction steps in the overall electrode process, since irreversible redox behavior may be shown, for example, by electrode processes involving either slow electron-transfer or rapid electron-transfer coupled to a subsequent (follow-up) rapid but irreversible chemical reaction; such a distinction is crucial for proper mechanistic evaluation. In the case of the compounds to be discussed, irreversibility is often associated with follow-up chemical reactions. In order to apply various approaches for calculating the rates of chemical reactions coupled to an electron-transfer reaction, it is essential to know that the latter is reversible, e.g. that the standard formal heterogeneous rate constant, $k_{s,h}$, is 0.1 cm s^{-1} or greater.

Signs of the potentials for the half-reactions discussed are determined by their being formulated as reductions with the usual thermodynamic conventions. Numerical potential values for aqueous media are based on comparison with the saturated calomel electrode (sce). Where possible, potentials for processes in nonaqueous media are also given vs. aqueous sce and, consequently, include liquid junction potentials of unknown magnitude.

Kinetics as a Factor in Electrode Reaction Mechanisms

If a compound can be transformed by different reactions into different products, the relative amounts of the products formed will be proportional to the relative rate constants (k). Thus, a free radical (or radical anion) can undergo a variety of reactions with the products formed being dependent on the relative rates, which are affected by medium composition and applied potential:



Enough studies have been made, for example, on electrode processes involving nitrogen hetero-

cyclic compounds of the pyridine, pyrimidine, and purine types to allow reasonable estimates to be made of rate constants and reaction sequences (22–24), e.g. $k_{s,h}$ for the initial 1e and 2e reductions seems to exceed 0.1 cm s^{-1}; the free radical reduction rate seems to be comparable. In any event, reduction of a free radical is rapid if the potential is sufficiently negative; as would be expected, it is more difficult to reduce an anionic free radical, $\dot{R}^-$, than the corresponding neutral radical, $\dot{R}H$. Dimerization rate constants (k_d) for anion radicals in nonaqueous media are about 10^4 or 10^5 M^{-1} s^{-1} and for neutral free radicals in aqueous or nonaqueous media are about 10^6 or 10^7.

Protonation rates of anionic species are quite rapid (25); those of neutral species are often slower but still rapid. The effective rate depends on the proton donor activity, e.g. whether it is water, a slightly ion-paired Brønsted acid, or a slightly dissociated acid. The protonation rate constant for pyrimidine anion radical by residual water (k_{hyd}) in AN is about 7 M^{-1} s^{-1}. Pseudo first order protonation rate constants at pH 3–5 for pyrimidine, cytosine, and purine carbanions are about 10^4 s^{-1}; those for adenine species are about an order of magnitude more rapid.

Thus, if a free radical can dimerize or hydrolyze, dimerization will predominate unless solution conditions increase the hydrolysis rate by several orders of magnitude. The dimer, once formed, may itself hydrolyze but the rate would, again, be much less than that of dimerization.

Chemical reactions, other than dimerization and protonation, are generally relatively slower. Pseudo first order rate constants for the acid-catalyzed hydrolytic decomposition of the dihydropyridine nucleotides in aqueous solution are about 10^{-3} s^{-1} at pH 4 and 10^{-5} s^{-1} at pH 7 (26). The deamination rate constant of reduced cytosine is about 10 s^{-1}; that of reduced adenine is much less (27, 28). Consequently, deamination to produce a species reducible at the potential of its formation is a factor in the reduction of cytosine at the dme but not in that of adenine.

The multitude of theoretically possible reaction paths is well exemplified for the case of the reaction,

$$[5] \qquad R + 2H^+ + 2e^- = RH_2$$

by Fig. 2, which scheme was originally proposed by Jacq (29) and has been discussed by Kastening

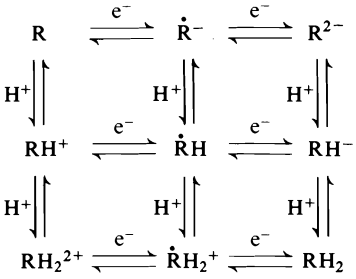


FIG. 2. Generalized scheme of theoretically possible reaction paths for a two-electron, two-proton reduction, i.e., $R + 2e + 2H^+ = RH_2$. Based on Jacq's formulation (29) (cf. ref. 7, pp. 13–91, and ref. 30).

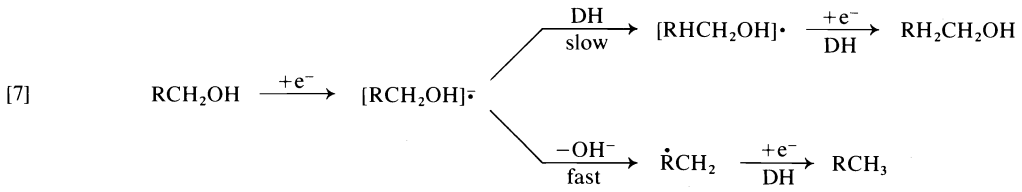
(30) and Cauquis (ref. 7, pp. 13–91). In Fig. 2, horizontal reactions involve electron transfer; vertical reactions hydrogen ion transfer. The left column represents the original electroactive species in various states of protonation; the center column similarly represents the free radical species; the right column represents the fully reduced (2e process) product. It is apparent that the course of the reaction in an actual situation (for example, double bond reduction) will be critically dependent on the electron activity (i.e., the potential), the pK_a magnitudes for the various acid–base equilibria, the H^+ activity, and the relative rates of the various charge-transfer and chemical reactions involved. (Some subsequently discussed reaction paths, e.g. that for aromatic hydrocarbons (Fig. 4), involve a portion of the general scheme of Fig. 2.)

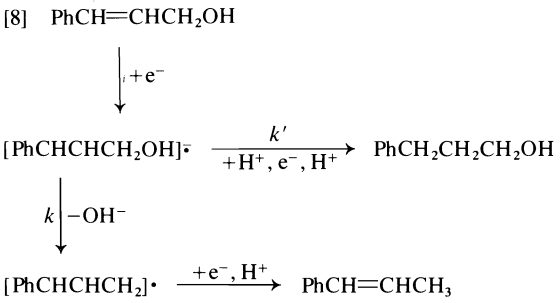
Such rates must be taken into account when considering possible alternate reaction paths. The variety of factors, which can effect rate and rate constants, have been amply considered in the literature. For example, due to the easier reducibility of the protonated member (conjugate acid) of a conjugate acid–base pair, the conversion of base to acid by a fairly rapid protonation will affect the observed polarographic pattern (25):

$$[6] \qquad RH^+ \rightleftharpoons R + H^+$$

An example of the effect of rates on the products obtained is provided by Mairanovsky's comparison (31) of two studies (32, 33) on the electrolytic reduction of carbon–oxygen bonds in unsaturated alcohols and related compounds. One paper (32) cited the mechanism as being



where DH represents a proton donor. The mechanism described in the other paper (33) was considered to be identical:



where $k \gg k'$. Mairanovsky *et al.* (32) pointed out that change in direction of the overall process to favor alcohol (ether) or hydrocarbon formation by variation in proton donor content (and the resulting effect on kinetics) has been used for selective syntheses.

Electrode Oriented Reaction Mechanisms

Since the electrode reaction locus is the solution–electrode interface, the structure of the electrical double layer is important in electrochemical kinetics and, therefore, in the potentials of many organic electrode reactions because of its influence, *inter alia*, on the effective potential difference which favors the electrochemical reaction and on the effective concentration of the electroactive species (34).

Furthermore, in many instances, adsorption of reactant, intermediate, and/or product is an important factor. A preferred orientation of the organic species in the interphase may often be necessary before electron transfer occurs; the energy for such a process woud be apt to vary similarly to that for an adsorption process. Many investigators have considered the energy of adsorption, if involved, to be negligible compared to the other energies acting, although adsorption energy has been suggested as the possibly significant factor in the variation of $E_{1/2}$ for an aliphatic homologous series (35).

Attempts to define the physical path for the overall electrode reaction usually lead to a more detailed geometric description, as is subsequently illustrated by considering those for two fundamentally different types of electrochemical bond rupture: (*a*) sigma bond breaking in single bond systems as in carbon–halogen bond fission and (*b*) pi bond rupture in multiple bond systems as in ketone carbonyl reduction. The geometrical treatment outlined is essentially descriptive but does help to define kinetic and energetic factors which must be considered.

Reduction of aromatic hydrocarbons, carbon–carbon double bonds in C_4 dibasic acids, and carbon–nitrogen double bonds will also be used to illustrate mechanistic generalities.

Digital Simulation of Reaction Mechanisms

In recent years, there has been increasing activity in the use of computer digital simulation studies, using ranges of reaction rate constants for the various reactions which may be involved if experimental rate constant data are not available, to generate the experimental results that would be expected for a particular investigative technic for postulated electrode reaction mechanisms. The general approaches involved have been described by Feldberg (36) and others, e.g. Bard and collaborators in papers in the *Journal of the Electrochemical Society* from 1970 to the present. In Feldberg's words,

"The simulation approach to problem solving no doubt tends to abort the search for an analytical solution. It can, however, greatly facilitate this search by providing the correct quantitative relationships and by indicating valid approximations (e.g., steady-state approximations)."

"Accessibility to the quantitative aspects of any system would seem to be greatly advantageous to the experimentalist. Paradoxically, he may actually find his task more difficult because of the variety of theoretical mechanisms that may seemingly describe a given experimental system. The mechanistic subtleties will take on added importance; a significant decrease

in the radius of Frost's "ring" will require utmost effort in development, selection, and application of *experimental* techniques."

Father–Son Reactions

Since mother–daughter reaction is a well established designation for a sequence in which the product of an initial reaction becomes a reactant in a second reaction, the term, father–son reaction, will be used to describe the situation where the principal product of a reaction reacts with the original reactant, e.g.

[9] $$R + \text{reagent} = R'$$

[10] $$R' + R = \text{products}$$

where the reagent may be an electron. (The term, father–son reaction, is obviously based on the frequently discussed conflict which arises from competition between father and son with the offspring (here, for example, a radical anion) attacking its immediate progenitor (here, the parent compound). An alternative term would obviously be the "Oedipus reaction".)

Reactions of this general type are not infrequently encountered (or, at the least, postulated) in connection with the electrochemistry of inorganic and organic species, e.g. the reverse disproportionation sequence such as the following:

[11] $$R + 2e^- = R^{2-}$$

[12] $$R^{2-} + R = 2R^-$$

For example, the following reaction sequence has been invoked to explain the presence of coupled products (dimers) on electrolysis of halides, R—X, where SH represents the solvent or a solution species:

[13] $$R\text{—}X + e^- = \begin{bmatrix} \delta^+ & \delta^- \\ R & \text{---} X \end{bmatrix}^-$$

[14] $$\begin{bmatrix} \delta^+ & \delta^- \\ R & \text{---} X \end{bmatrix}^- + e^- \xrightarrow{\text{rapid}} R^- + X^-$$

[15] $$R^- + SH = R\text{—}H + S^-$$

[16] $$R^- + R\text{—}X = \dot{R} + \dot{R} + X^-$$

[17] $$2\dot{R} = R\text{—}R$$

[18] $$\dot{R} + SH = RH + \dot{S}$$

In electrochemical studies of heterocyclic nitrogen bases in nonaqueous media, we have encountered a number of cases where a compound, RH, can serve as a proton source for neutralization of the radical anion, which it forms on 1e reduction, i.e.

[19] $$RH + e^- = \dot{R}H^-$$

[20] $$\dot{R}H^- + RH = \dot{R}H_2 + R^-$$

Since such father–son reactions may account for many situations, where, for example, polarographic wave heights and coulometric faradaic *n* values are less than expected for a 1e process, the mechanistic paths possibly involved will be considered. The patterns seen with some pyrimidines, e.g. 2-hydroxypyrimidine, in nonaqueous medium are illustrated in Fig. 3; dme polarographic waves and hmde cyclic voltammetric peaks are designated by a Roman number with addendum c indicating a cathodic faradaic reaction and a an anodic reaction.[2]

2-Hydroxypyrimidine (2-HP) is reversibly reduced (1e process; Ic) to a radical anion, whose dimerization is slower than its attack (it is a strong base) on unreduced pyrimidine to abstract a proton, producing the neutral free radical, which dimerizes much more rapidly than the radical anion, and the anion of 2-HP. (The radical anion of pyrimidine itself dimerizes in AN at about 0.1 of the rate of the neutral free radical produced in water (37, 38).) The 2-HP anion is involved in a Hg(I)–Hg(0) couple (IVa–IVc).

On addition of strong base (hydroxide ion) to a 2-HP solution, all of the 2-HP is converted to the anion and the only electrochemical activity seen is that due to the mercury couple (IVa–IVc).

On strong acid addition, the protonated pyrimidine formed is more easily reduced (IIc) than the neutral pyrimidine (Ic); the current (IIc) considerably exceeds that for the neutral pyrimidine; the couple ascribed to the pyrimidine anion – mercury reaction (IVa–IVc) is not seen. The neutral free radical can dimerize or, when the proton/pyrimidine ratio exceeds 1, can be protonated and reduced in an ECE reaction.

Addition of a weak acid apparently causes formation of an adduct as a result of hydrogen bridging between acid anion and pyrimidine reduction site, since reduction is facilitated (IIIc); the free radical produced can dimerize or can hydrogen-bond another molecule of acid to form an adduct reducible to a dihydropyrimidine within the available potential range. The

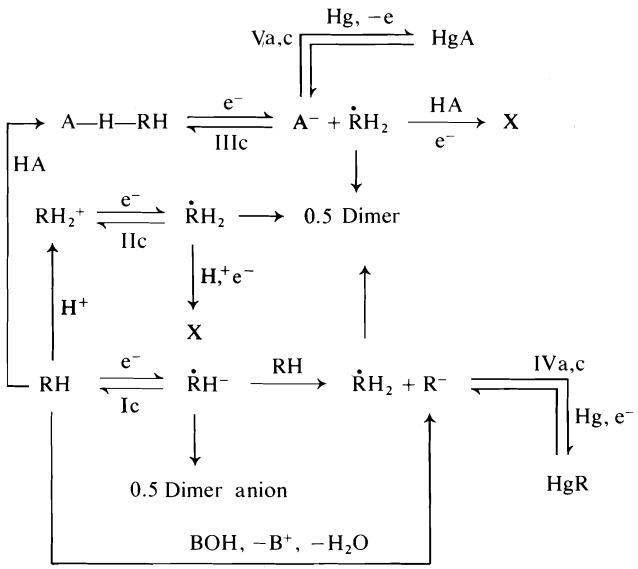

FIG. 3. Pattern for a 'father–son' reaction sequence and accompanying reactions in nonaqueous media in absence of added acid or base and on addition of a strong base (BOH), of a strong acid (H^+), and of a weak acid (HA). In the case of 2-hydroxypyrimidine in DMSO (0.1 *M* TEAP), the approximate potentials (dme polarography and hmde cyclic voltammetry) are as follows (vs. aqueous sce): Ic, −1.7 V; IIc, −0.8 V (HCl; $HClO_4$); IIIc, −1.2 to −1.3 V (benzoic and chloroacetic acids); IVa–IVc, −0.2 V; Va–Vc, 0.2 to −0.1 V.

acid anion can be involved in a Hg(I)–Hg(0) couple (Va–Vc) at a potential characteristic for the acid used; the mercury–pyrimidine anion couple (IVa–IVc) occurs at a potential characteristic of the pyrimidine.

Reduction of Aromatic Hydrocarbons

Much of our mechanistic conception of how the electrochemical reduction of hydrocarbons (largely, aromatic) occurs (39–42) is due to Hoytink. The relationships between redox potentials, ionization potentials, electron affinities, and solvation energies of alternant aromatic hydrocarbons for the initial 1e reduction or oxidation in aprotic media have recently been well reviewed by Parker (43) on the basis of the pioneering approach of Hoytink and van Schooten (44).

In nonaqueous media (commonly necessary to obtain the desired potential range), reduction generally proceeds through two successive 1e additions, producing two waves:

[21] $$R + e^- = \dot{R}^-$$

[22] $$\dot{R}^- + e^- = \ddot{R}^{2-}$$

Proton donor addition increases the wave I height with a corresponding decrease in wave II; in presence of excess donor, most aromatic hydrocarbons show a single 2e wave. The mechanism is usually considered to be

[23] $$R + e^- = \dot{R}^-$$

[24] $$\dot{R}^- + H^+ = \acute{R}H$$

[25] $$\dot{R}H + e^- = \ddot{R}H^-$$

Since protonated $\dot{R}H$ has a higher electron affinity than R itself, it is reduced at the same potential as R, resulting in a typical ECE process. Anion $\ddot{R}H^-$ can be protonated by an available proton source. A possible reaction is reduction of the free radical $\dot{R}H$ by the radical anion $\dot{R}^-$, which is the homogeneous equivalent of heterogeneous reaction [25] (45–47):

[26] $$\dot{R}H + \dot{R}^- = \ddot{R}H^- + R$$

The radical anion may disproportionate,

[27] $$2\dot{R}^- = R + \ddot{R}^{2-}$$

followed by protonation of the dianion (48, 49).

Based on extensive studies of electrochemical aromatic hydrocarbon reduction (due, at least in part, to the ready application of HMO theory to these compounds and the resulting feasibility of comparing experimentally measured and theoretically calculated ease of reduction for

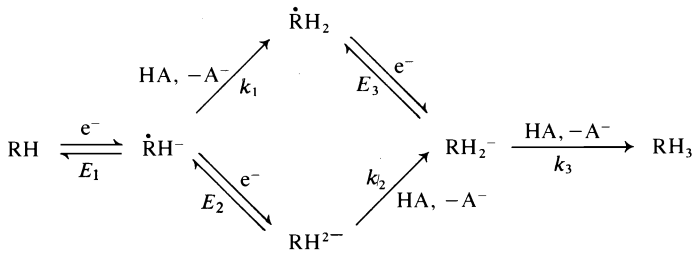

FIG. 4. Alternative patterns for reduction of aromatic hydrocarbons and other organic compounds containing unsaturated double bonds. Modelled after reaction sequences given in refs. 50 and 51. RH represents the parent compound; HA represents a potential proton donor.

compound sequences), the interrelated equilibria and reactions involved in aromatic hydrocarbon reduction (as well as for other highly conjugated compounds such as aromatic ketones and amines) have been frequently summarized in general schemes; Fig. 4 is a composite of those by Janata *et al.* (50) and Fry and Reed (51) (the parent hydrocarbon is represented as RH to indicate its availability as a proton donor).

As Janata *et al.* (50) and Fry and Reed (51) point out, Fig. 4 illustrates the major influence of proton availability on the courses of reaction. In media of high proton donor concentration (EtOH; aqueous organic solvent; added donor such as phenol), initially formed $\dot{R}H^-$ radicals will be rapidly protonated. Since E_3 for reduction of $\dot{R}H_2$ is generally less negative than E_1 for reduction of the parent RH, $\dot{R}H_2$ will be reduced as formed (ECE process). In media of low proton availability (aprotic solvent; alkaline aqueous solution), the lifetime of radical anion $\dot{R}H^-$ is sufficiently long that 1e reduction to a dianion is observed at more negative potential E_2 on dme polarography as well as on hmde cyclic voltammetry; the dianion can abstract protons from the medium. The importance of the relative magnitudes of the rate constants, k_i, for the various protonation steps is discussed in the references cited (50, 51) (cf. Jacq's general formulation (29), (Fig. 2), and the provocative study by Wightman *et al.* (52) of the protonation kinetics and mechanism of the 2e quinone reduction, which parallels that for aromatic hydrocarbons in aprotic media).

Dietz (39) has reviewed possible mechanistic paths (chemical and electrochemical) for the electrogenerated anions and dianions.

Carbon–Halogen Bond Fission

The voluminous data on reduction of organic halogen-containing compounds in aqueous and nonaqueous media have been interpreted from a variety of viewpoints, e.g. refs. 53–55; ref. 4, pp. 201–244. Any attempt to force all of the data into a strict ionic or free-radical mechanism leads to a formulation of limited utility because of the essentially dual nature of the process (cf. subsequent discussion of the dibromosuccinic acids).

In electrochemical carbon–halogen (C—X) bond fission, the carbon to which the halogen is attached can be considered as an electrophilic reaction center, on which nucleophilic displacement occurs with electrons from the electrode acting as displacing agent. As the compound diffuses towards the electrode, the C—X bond or dipole is increasingly oriented, finally approaching in a direction normal to the electrode plane with the halogen as the more negative portion of the C—X bond oriented away from the electrode. In immediate vicinity of the electrode, electrostatic repulsion causes elongation of the C—X bond; a state is finally reached where the attractive forces between carbon and electrode, and between carbon and halogen are in balance; this may be considered as the transition state since movement of carbon towards the halogen tends to reform the C—X bond, whereas movement towards the electrode results in the forces between carbon and halogen being insufficient to retain the halogen, which separates as the negative halide ion since the electron pair constituting the C—X bond has been driven even closer to it during the process described. Departure of the halogen with the electron pair makes the carbon even more electropositive and an electron (or two) will flow to it from the electrode to form a free radical (or carbanion); the free radical normally rapidly adds a second electron to form a carbanion, which then neutralizes its charge by abstracting a proton from a solution or interfacial region

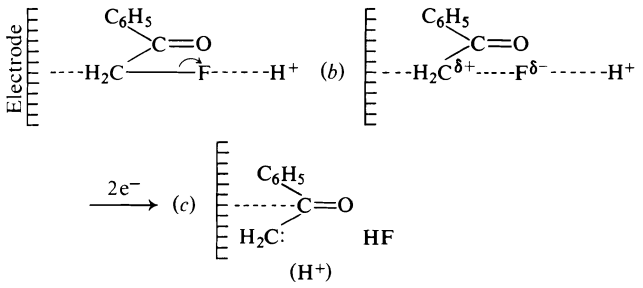

FIG. 5. Reaction path for the fission of the carbon–fluorine bond in phenacyl fluoride at a mercury electrode. The approach of the phenacyl fluoride to, and its orientation at, the electrode is represented by (*a*); polarization and subsequent reduction of the bond are represented by (*b*) and (*c*), respectively (from ref. 56).

species, or by electronic rearrangement and expulsion of an anion (cf. subsequent discussion of vicinal dihalides).

Final products of the 2e C—X fission are normally halide ion and an organic compound in which hydrogen has replaced halogen. In the case of compounds with halogens on adjacent carbons, $R_1R_2CX—R_3R_4CX$, the products of the initial 2e reaction are the halide ions and a more unsaturated species, $R_1R_2C{=}CR_3R_4$.

Since proton acquisition is not part of the rate-determining step in the C—X bond fission, it is clear why the process per se is normally p*H*-independent. The effect of p*H* on carbon–fluorine bond fission in aqueous solution further illuminates the process (56). $E_{1/2}$ for C—F fission is p*H*-independent above p*H* 6, but shows a sigmoidal dependence below p*H* 6. This is due to H^+ being able to assist the electrode in polarization of the C—F bond by H—F bonding in the transition state (Fig. 5). With decreasing H^+ concentration, the effect decreases and the fission becomes p*H*-independent. The marked tendency for ion pairing between fluoride and hydrogen ions is evident from the aqueous pK_a for hydrofluoric acid ($HF = H^+ + F^-$) of 3.17.

Sease (57) and Lambert and co-workers (58, 59) discuss whether electrochemical reduction of bridgehead bromides proceeds through back-side attack on carbon, as described, or through front-side attack on bromine. Alternate mechanisms involving, for example, attack by an electron from the electrode surface in a direction perpendicular to the C—X bond (9), have also been proposed (cf. pp. 885–891 of ref. 60 for a succinct summary).

Ketone Reduction

In aqueous acidic solution, aromatic ketones exhibit a p*H*-dependent 1e wave I and a p*H*-independent 1e wave II; these merge at about p*H* 6 to form a single p*H*-dependent wave III; the latter reaches 2e magnitude at about p*H* 9 and then decreases with increasing p*H* to near 1e magnitude; a more negative wave IV appears above p*H* 9 (61, 62). (In the case of some aromatic alkyl ketones, waves II and/or IV are obscured by background discharge.)

The proposed mechanism postulates (*a*) formation of a free radical as the fundamental process, (*b*) modification of this process with change in p*H*, i.e., anion radical formation in the alkaline region, and (*c*) possible reduction of the radical before dimerization occurs.

The process producing wave I can be explained as follows (Fig. 6) (61): (*a*) As the ketone diffuses into the field of the electrode, the latter initiates polarization of the carbonyl group. (*b*) Simultaneously, the carbonyl oxygen attracts neighboring protons, favoring increased polarization (the negligible effect of ionic strength indicates that little, if any, of the diffusing material is charged before it enters the electrode field). (*c*) The ketone, under influence of both proton and field completes diffusion (now supplemented by electromigration) into the interphase and acquires an electron. These steps are continuous and involve a transition state in which, as an electron is transferred to the carbonyl carbon, a proton is simultaneously bonded to the carbonyl oxygen.

The free radical produced dimerizes until a potential is reached at which it is reducible; it can then dimerize or be reduced; the latter reduction (wave II) is p*H*-independent.

The p*H*-dependency seen in the alkaline region, even though lessened, indicates continued proton participation in the potential-determining step. Since the decreased H^+ concentration

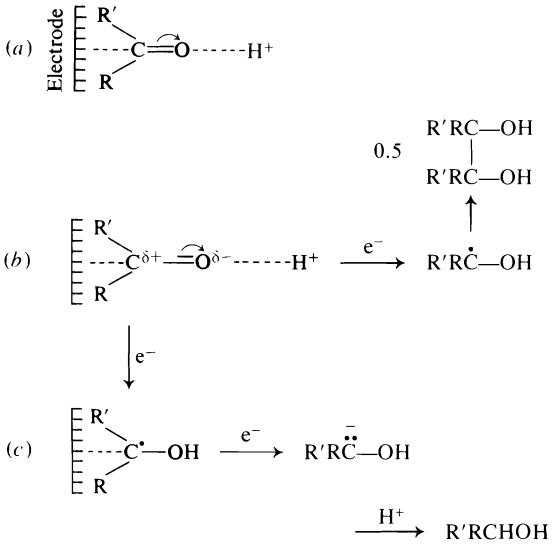

FIG. 6. Electrochemical reduction of a ketone in acidic, neutral, and slightly alkaline media: (*a*) initial diffusion–polarization process; (*b*) formation of the carbinol free radical (wave I); (*c*) reduction of the carbinol free radical (wave II) and subsequent acquisition of a proton. In neutral and slightly alkaline media, the combined sequence of electron-transfer steps represented by (*b*) and (*c*) produces the combined wave (from ref. 61).

greatly diminishes the probability of forming an O—H bond simultaneously with electron transfer, increasing amounts of carbinolate radical anion are formed (Fig. 7*b*). The latter, which is more difficultly reducible than the neutral radical, dimerizes until its reduction potential is reached. The needed additional energy for its reduction arises from the coulombic repulsion between it and the electrode, and from the electron having to enter an area of increased electron density. If the carbinolate radical anion is at the electrode when it acquires a proton, the resulting radical will be reduced to carbinol, thereby contributing to the wave III magnitude. Conversely, if the radical anion has diffused away from the electrode, the carbinol free radical subsequently formed will not be reduced but will dimerize.

Formation of the radical anion decreases the magnitude of wave III above p*H* 9, while its reduction produces wave IV. Since reduction of the carbinol free radical is unaffected by p*H*, the wave III height increases to a maximum at about p*H* 9 even though free radical formation becomes more difficult with increasing p*H*.

Electrochemical reduction of benzophenone in aprotic medium (63) supports the mechanism outlined. The benzophenone is reduced in successive 1e steps, first to the radical anion and then to the benzhydrol dianion. Proton addition causes the second 1e step to merge with the first since the neutral free radical is reduced at the potential of initial benzophenone reduction.

Further formulations of reduction paths for the carbonyl group are given by Zuman *et al.* (64) and Feoktistov and Lund (65).

Significance of pH-Dependence of $E_{1/2}$

Based on the foregoing discussion, a p*H*-dependent potential for an electrochemical bond fission may be due to H^+ aiding the electrode in polarization of the bond to be broken, i.e., a concerted push–pull attack on that bond by both electrode and H^+ (or proton donor). Thus, as shown in Figs. 6 and 7, the p*H*-dependence of carbonyl group reduction is ascribable to a transition species analogous for that described for C—F bond fission (Fig. 5):

[28] 
All multiple bond reductions in neutral organic compounds in aqueous or partially aqueous solutions are likely to be p*H*-dependent in the region of appreciable H^+ activity. Unfortunately, reduction of some types of multiple bonds (such as those of the phenyl-substituted olefins) occur at such negative potentials that, in solutions of appreciable H^+ activity, H^+ would be reduced at less negative potential than the multiple bond. However, $E_{1/2}$ for some such compounds in nonaqueous media is shifted to more positive potential on addition of a proton source with often an increased current flow due to the change from a 1e to a multielectron process. Thus, on proton donor addition, the 1e wave shown by purine, adenine, and other 6-substituted purines in nonaqueous media generally shifts positively and grows in magnitude to that expected for a 4e process (two 2e waves for purine itself and 6-methylpurine) (20).

Effect of Substitution: Reduction of Nitrogen Heterocycles

The alteration of reaction path by substitution can be illustrated by the electrochemical reduction of azabenzene ring systems, e.g., the three classes of nitrogen heterocycles: pyridines in the form of nicotinamides; pyrimidines; purines

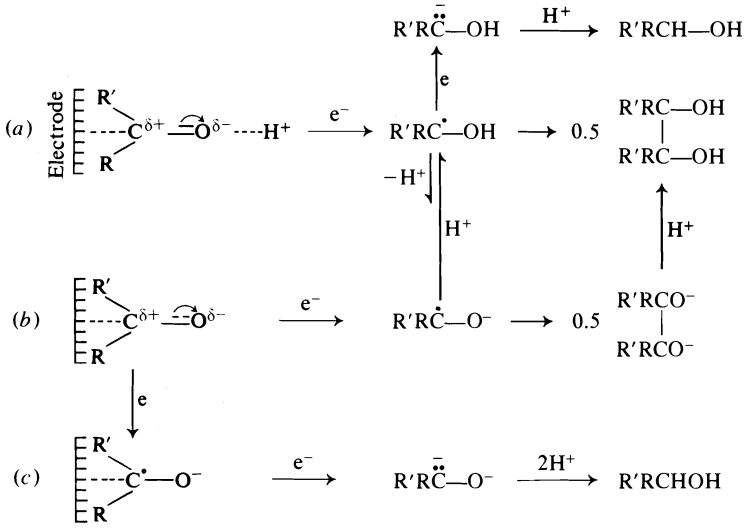

FIG. 7. Electrochemical reduction of a ketone in alkaline media (above p*H* 9): (*a*) and (*b*) processes producing the combined wave; (*c*) reduction of carbinolate radical anion (wave III); the steps shown should be considered as continuous. The position of the equilibrium between carbinol free radical (*a*) and its anion (*b*) is dependent on p*H* (from ref. 61).

(cf. refs. 24 and 66 for a review of the electrochemistry of these compounds). A general reduction path can be schematically formulated as follows, where RN represents an electroactive nitrogen heterocycle:

$$[29] \quad RN + e^- = \dot{R}N^- = \text{product(s)}$$

$$[30] \quad RN + ne^- + mH^+ = \text{product(s)}$$

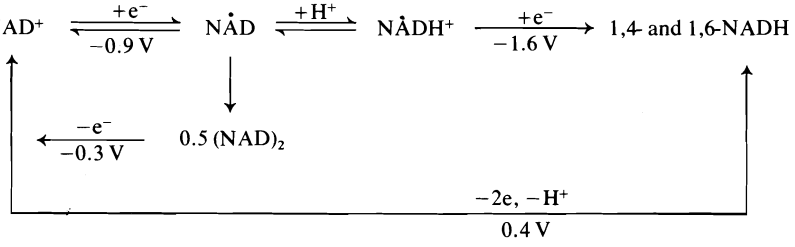
$$[35] \quad RN_{ads} + ne^- + mH^+ = \text{product(s)}$$

$$[36] \quad \text{product} + \text{electrode} = \text{product}_{ads}$$

Equations 29 and 30 refer to the initial and overall electron-transfer processes; eq. 35 refers to reduction of an adsorbed reactant (eq. 33), which may associate in the adsorbed state (eq. 34). Adsorption of product is indicated by eq. 36. Possible association of reactant, e.g. formation of a complementary purine–pyrimidine pair, is accounted for by eqs. 31 and 32; the associated species may then be the reactant of eqs. 29, 30, and 33. In proton-containing media, the electroactive reactant may be protonated RN or corresponding species. Complications may be introduced in nonaqueous media by father–son reactions (cf. supra).

The polarographic and allied chemical behavior of the 1-substituted nicotinamides and the equivalent protonated nicotinamides in aqueous media is exemplified by that of NAD^+ (nicotinamide adenine dinucleotide), which can be summarized as follows (approximate potentials are shown) (67):



Reduction occurs in the cationic pyridinium ring. The first 1e reduction is p*H*-independent. The free radical rapidly dimerizes, largely to the 4,4′ isomer, reflecting the transition from the 6,6′ isomer in the case of nicotinamide itself to the 4,4′ form as the substituent on the pyridinium nitrogen increases in size. At more negative potential, NAD^+ is reduced to a dihydropyridine via 1e reduction of the free radical; the dimer is not reduced at this potential. The free radical reduction must be preceded by a protonation, e.g. in nonaqueous media in absence of a suitable proton donor, a second charge transfer is not seen. The dimer can be oxidized to NAD^+ at a potential considerably more positive than that for the initial reduction; NADH is oxidized to NAD^+ at still more positive potential in a nearly p*H*-independent process.

Reduction of Pyrimidine

Electrochemical reduction of the pyrimidine (1,3-diazine) ring differs markedly from that of the nicotinamide (3-carbamoylpyridine or 3-carbamoyl-1-azine) ring, which, within the available potential range, shows at most two separate 1e steps, which fuse only in rather alkaline aqueous medium. Pyrimidine, however, can be reduced in a series of 1e, 2e, and 4e steps depending on proton availability.

In aqueous media, pyrimidine exhibits five cathodic waves over the p*H* range (38, 68, 69) (Fig. 8). In acid solution, only p*H*-dependent 1e wave I is seen. At about p*H* 3, nearly p*H*-independent 1e wave emerges from background discharge. Because of the difference in p*H*-dependence, waves I and II merge at about p*H* 5 to form p*H*-dependent 2e wave III. Near p*H* 7, p*H*-independent 2e wave IV emerges from background and, due to the differing p*H*-dependencies, merges at about p*H* 9 with wave III to form p*H*-dependent 4e wave V. This wave pattern can be readily explained on the basis of the general electrode reaction mechanism (Fig. 1), as indicated in Fig. 9, which also shows the relation between reaction paths in protic and aprotic media.

Wave I results from 1e reduction of the 3,4 N=C bond with simultaneous (or prior) acquisition of a proton at N(3) to form a free radical, which may dimerize to 4,4′-bipyrimidine or be reduced (1e process) at more negative

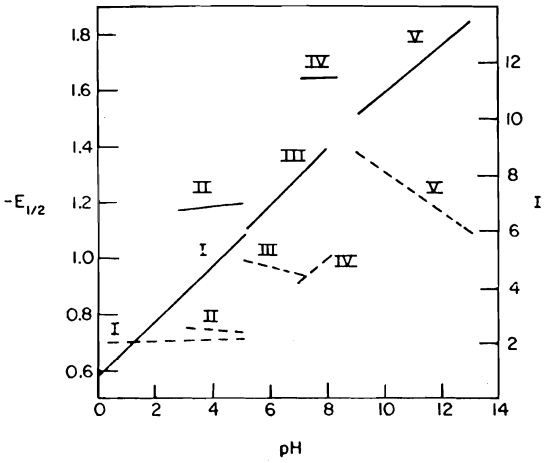


FIG. 8. Variation with p*H* of half-wave potentials ($E_{1/2}$; solid lines) and diffusion current constants (*I*; dashed lines) for pyrimidine. Roman numerals refer to the waves (cf. text).

potential (wave II) to a carbanion, which then acquires a proton to form 3,4-dihydropyrimidine. Wave III results when the potential necessary to transfer the first electron into the 3,4 N=C bond becomes, as a result of decreasing proton activity, more negative than that required to reduce the free radical. Wave IV results from a probably stepwise 2e reduction at still more negative potential of the 1,2 N=C bond in the dihydropyrimidine to form a tetrahydropyrimidine. When the energy necessary to transfer the first electron into the 3,4 N=C bond exceeds that necessary for a similar addition to the 1,2 N=C bond, wave V (4e process) results as an example of the cascading effect mentioned in connection with the general mechanism, i.e., separate faradaic processes may merge into a single wave due to the instability of the various products at the potential required to introduce the first electron.

Reduction of Substituted Pyrimidines

Substitution may alter the prototype pyrimidine reduction path, e.g. the initially produced free radical or a chemically altered form of it may be unstable at the potential of its formation and, consequently, would be immediately reduced to produce a 2e wave.

Tautomeric shifts due to substituents having divalent oxygen singly bonded to carbon, e.g. C—O—H, may result in migration of double bonds out of the ring to form less readily re-

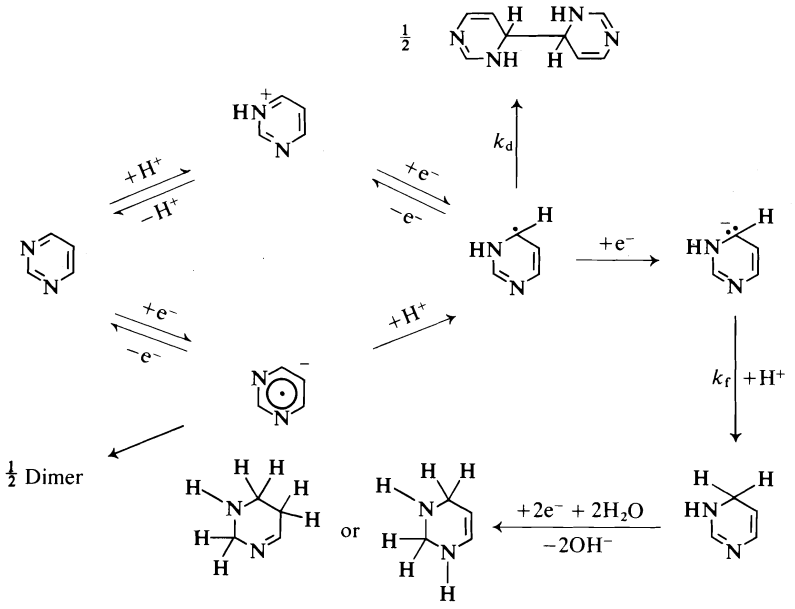

FIG. 9. Interpretation of the electrochemical behavior observed for pyrimidine in aqueous media. The lower reaction sequence involving electron addition to unprotonated pyrimidine is that in aprotic media. The reactions involved in the reduction of the 1,2 N=C bond are analogous to those indicated for the 3,4 N=C bond reduction (from ref. 38).

ducible external double bonds, thus limiting the extent of reduction or making it more difficult. Two commonly occurring nucleic acid pyrimidines, uracil (2,4-dihydroxypyrimidine) and thymine (2,4-dihydroxy-5-methylpyrimidine), are not reducible in aqueous media but are reduced in nonaqueous media at very negative potential.[3]

Chemical reactions such as deamination or hydrolysis, which follow electron-transfer, may generate electroactive species, e.g. reduction of 4-aminopyrimidines hydrogenates the 3,4 N=C bond to produce a *gem* diamine on C(4); resulting deamination regenerates the 3,4 N=C bond, which is reduced as formed since presence of the C(4) amino group made reduction of the original 3,4 N=C bond more difficult.

Effects may be compounded. Presence of a hydroxyl group on C(2) removes the 1,2 N=C bond, facilitates 3,4 N=C bond reduction, and increases markedly the dimerization rate of the initially produced free radical; its presence also seems to accelerate deamination of a C(4) diamine. Thus, 2-hydroxypyrimidine undergoes only a 1e reduction over the entire p*H* range to produce a bipyrimidine.

The result of such substitution effects is evident in the reduction path observed for cytosine, which is the most important pyrimidine occurring in nucleic acids.

Reduction Path: Cytosine

At p*H* 3.7–5.7, cytosine (4-amino-2-hydroxypyrimidine) gives a well defined dme reduction wave (27, 28, 68). Cyclic voltammetric and ac polarographic data support at the least a CECCEC process.

The proposed mechanism (Fig. 10) for the overall 3e process involves reduction of the protonated 3,4 N=C bond in cytosine (Cy) to a carbanion, protonation of the latter, deamination of the resulting *gem* diamine to 2-hydroxypyrimidine (2-HP), protonation of the latter followed immediately by a 1e reduction, and dimerization of the resulting free radical:

$$[38] \quad Cy + H^+ \underset{}{\overset{{}_1k_p}{\rightleftharpoons}} CyH^+$$

$$[39] \quad CyH^+ + 2e^- \overset{{}_1k_{s,h}}{\rightleftharpoons} CyH^-$$

$$[40] \quad CyH^- + H^+ \xrightarrow{{}_2k_p} CyH_2$$

$$[41] \quad CyH_2 \xrightarrow{k_{da}} 2\text{-HP} + NH_3$$

[3]T. E. Cummings and P. J. Elving, unpublished results.

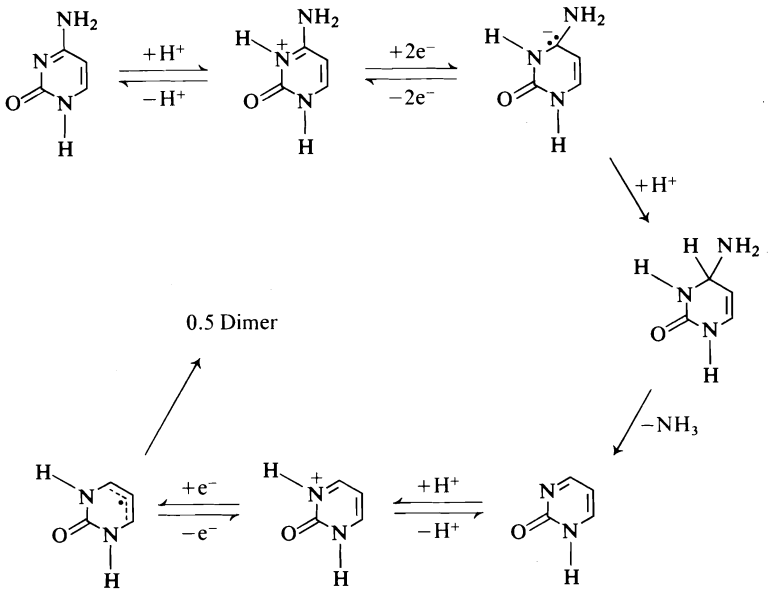

FIG. 10. Proposed reaction pathway for the reduction of cytosine in aqueous media (from ref. 27).

[42] $$2\text{-HP} + H^+ \underset{}{\overset{{}_3k_p}{\rightleftharpoons}} 2\text{-HPH}^+$$

[43] $$2\text{-HPH}^+ + e^- \underset{}{\overset{{}_2k_{s,h}}{\rightleftharpoons}} 2\text{-H}\dot{\text{P}}\text{H}$$

[44] $$2\ 2\text{-H}\dot{\text{P}}\text{H} \xrightarrow{k_d} (2\text{-HPH})_2$$

where k_p, k_{da}, and k_d are rate constants for homogeneous chemical reactions involving protonation, deamination, and dimerization, respectively. Protonation reactions 38 and 42 are very rapid and do not affect the equilibria of the other reactions. Deamination is somewhat slow on the time scale involved in dme polarography but occurs completely on prolonged electrolysis.

Structural Effects on Mechanistic Paths

The influence of structure on electrode mechanisms can be illustrated by phenomena observed on reduction of carbon–halogen (C—X) bonds and C_4 dibasic acids. The stereochemistry of organic electrode processes has been reviewed by Eberson and Horner (62).

Steric Effects and Steric Hindrance

Little or no steric hindrance is evident to electron transfer from electrode to carbon center in C—X fission, e.g. contrary to behavior of such groups to OH^- attack, a C—Br bond is more readily broken electrochemically in a tribromomethyl group than in a dibromomethyl and more readily in the latter than in monobromomethyl. However, steric effects may be manifest through adsorption or orientation of the molecule at the interface relative to the distance between electrode and reactive center (35), and possible interference with electrode-compound overlap by the bulk of the compound, e.g. due to side chains on the reactive center.

In reduction of the 2-bromoalkanoic acids, the shift of $E_{1/2}$ in the alkaline region to more negative values than expected for acids having ethyl or larger groups on the same carbon as the halogen was ascribed to the tendency towards stable ring formation in compounds having chains of at least six members with terminal atoms differing in electronegativity (35, 70, 71).

Steric Control of Products

Control of product structure by external conditions is indicated by the effect of p*H* on reduction of *meso-* and *racemic*-α,α′-dibromosuccinic acids (72).

Although some maleic acid production might be expected in the p*H* range where each acid exists as the monoanion, as a result of the *cis* configuration being maintained during reduction due to chelation between undissociated carboxyl group hydrogen and carboxylate group oxygen, polarographic and macroscale re-

ductions of the *meso* acid and the diethyl esters do not yield any detectable maleate species; the sole product formed in the single 2e wave is fumerate. However, the *racemic* acid yields a varying amount of maleic acid in the p*H* range of 1–7 with a maximum yield (70%) at p*H* 4; the remainder of the product is fumaric acid. These results can be explained in terms of a hydrogen bonding whose strength is influenced by p*H* and steric factors irrespective of the mechanistic route proposed.

Examination of molecular models of the *meso* and *racemic* acids (both carboxyl groups undissociated; one group ionized; both groups ionized) and consideration of other pertinent factors indicate that, of the six species, in only one (singly ionized *racemic* acid) do the charge and steric factors combine energetically to favor cyclic hydrogen bond formation. The stability of this cyclic form is supported by the fact that steric factors alone tend to keep both *meso*- and *rac*-2,3-dibromobutane (73) in the *trans* position. This, coupled with the added energy of interaction between hydroxyl hydrogen and carboxylate ion, should lead to a relatively stable configuration.

In reduction of the *meso* acid over the whole p*H* range and of the *racemic* acid in the intermediate p*H* range, step 2*b* (Fig. 1) is followed by step 4*b* since the conformation of the molecules is such that the two Br atoms are essentially *trans* and coplanar so that, as an electron pair is added to one C atom as its Br departs as a bromide ion, rearward displacement of the second Br atom as a bromide ion and formation of the C=C double bond can occur simultaneously due to electronic rearrangement, i.e., the electron pair on the original reactive center shifts towards the adjacent more positive C which still has a halogen attached to it. Such an action would have a relatively low activation energy.

The preferred configuration for the *racemic* acid at high p*H* and probably also at low p*H*, however, has the Br atoms constrained in a *cis* position and single step rearward elimination is not possible. In such a situation, a reaction involving step 2*a* is postulated; a planar free radical is formed and the second electron is so added that the remaining Br can be displaced at the same time (rotation of the sigma bond joining the two carbon centers in the anion produced on the second electron addition would help give the thermodynamically favored fumerate product).

Stereospecific Reduction

Dibromomaleic and dibromofumaric acids are quantitatively reduced (2e process) to acetylenedicarboxylic acid (ADCA) (Fig. 11); their diesters behave similarly (74). Between p*H* 0.4 and 3, ADCA is reduced in a 3e process to *rac*-α,α′-dimethylsuccinic acid; its monoester yields diethyl *rac*-α,α′-dimethylsuccinate in a 3e process; however, its diethyl ester is reduced to diethyl fumarate (2e process). The stereospecificity of these reductions is due to structural factors inherent in the compounds involved and not to interaction between them and the electrode.

The ADCA reduction mechanism is moderately complex (Fig. 11). Addition of two H^+ (one is formally the lost carboxyl group hydrogen) and one electron converts ADCA to fulgenic acid (enclosed in square in the figure) with loss of CO_2. The nature of the activated state is uncertain; however, comparison of acid, monoester and diester behavior shows that the second carboxyl group plays no direct role in the decarboxylation. A possible path would be addition of one e and one H^+ to form the free radical, HOOC—Ċ=CH—COOH, which could then decarboxylate as such structures often do to yield HOOC—Ċ—CH_2, whose dimerization would produce fulgenic acid. Reduction of the latter produces dimethylmaleic acid which, in turn, is specifically reduced to *rac*-α-α′-dimethylsuccinic acid. This mechanism indicates why the monoester with one unprotected carboxyl group also forms the *rac*-succinate, whereas the diester, both of whose carboxyl groups are esterified, goes to the fumarate.

The reduction of dimethylmaleic and dimethylfumaric acids by single 2e waves to *rac*- and *meso*-α,α′-dimethylsuccinic acids, respectively (Fig. 11), is direct evidence that reduction of the double bonds at the electrode proceeds through *trans* hydrogen addition. Evidence excluding certain intermediates, as indicated in Fig. 11, is discussed in the original paper (74).

The effects of structure and rates on electrode reaction stereochemistry are further indicated by polarographic and macroscale electrolysis of the monobromo C_4 dibasic acids and their esters (75), although in this case interaction with the electrode may be a significant factor. Be-

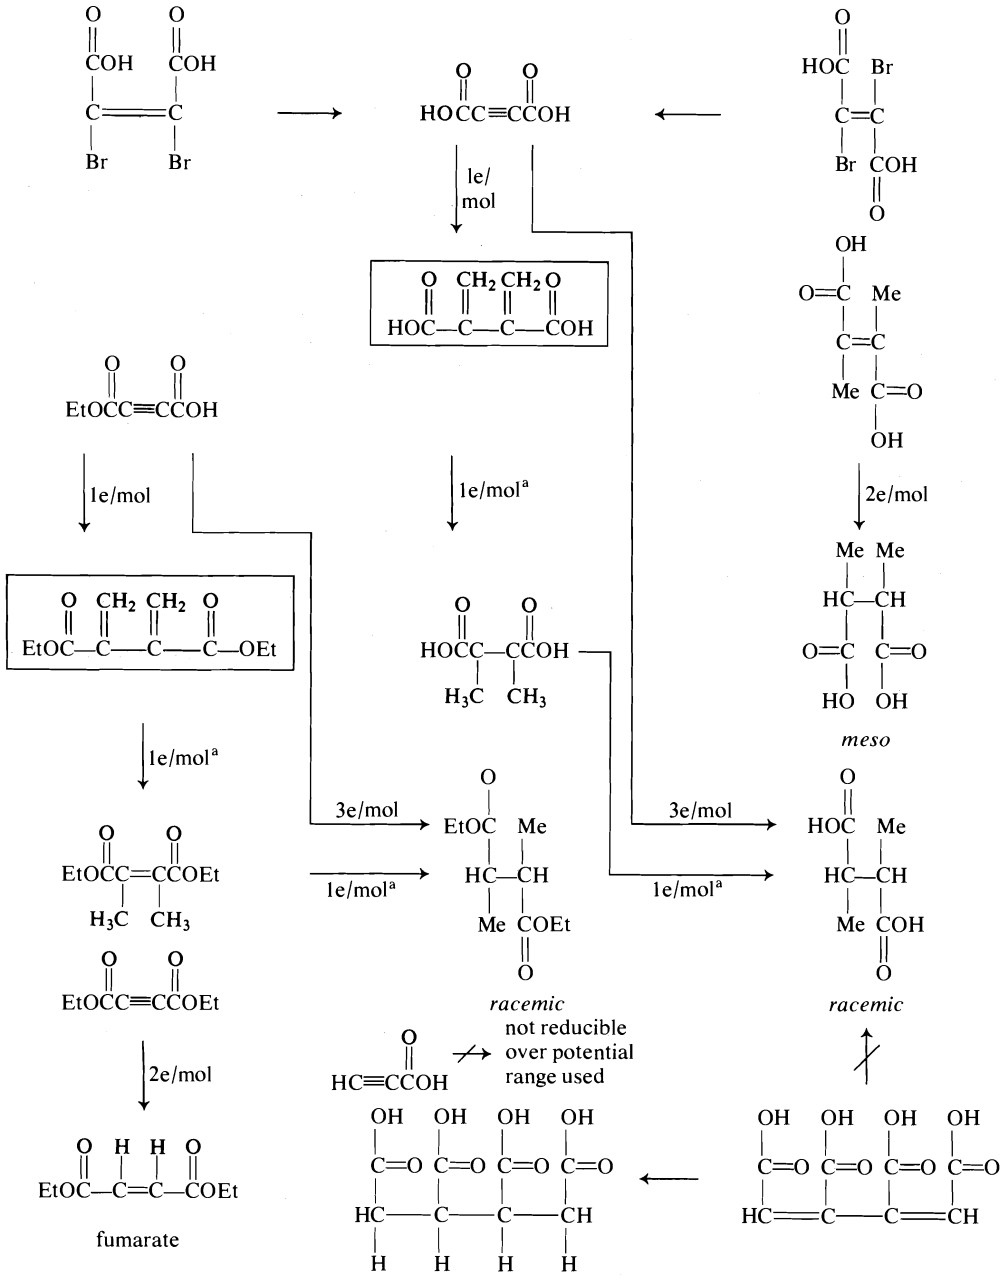

FIG. 11. Interrelation and proposed mechanisms for the electrochemical reduction of acetylenedicarboxylic acid (ADCA) and related compounds. Compounds enclosed in rectangles are postulated intermediates. The superscript a indicates that the electron transfer shown is calculated on the basis of the constituent (ADCA) acid or ester. A crossed arrow indicates that the reaction does not proceed under normal polarographic conditions (from ref. 74).

tween p*H* 0.5 and 10.5, the diethyl esters of monobromomaleic acid (MBMA) and monobromofumaric acid (MBFA) are quantitatively reduced (2e process) to diethyl fumerate (C—Br bond fission occurs before C=C bond reduction); MBFA is reduced (2e process) to fumaric acid. MBMA, however, is reduced to maleic and fumaric acids, and a dimer, butadiene-

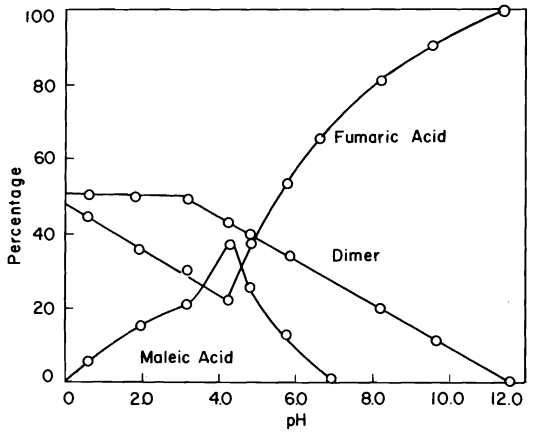

FIG. 12. Variation with p*H* of relative amounts of reduction products of monobromomaleic acid produced on coulometric (macro scale) electrolysis (from ref. 75).

1,2,3,4-tetracarboxylic acid; the relative amounts of these products are dependent on p*H* (Fig. 12), but the maleic–fumaric ratio at any p*H* is the same as that found on reduction of *rac*-α,α′-dibromosuccinic acid (cf. supra).

The mechanism outlined in Fig. 13 was proposed to explain the product observed (the structures drawn are meant not to define rigidly the structures but to aid the discussion). Electron addition to MBMA (I) liberates a bromide ion and forms a radical (II). The latter can dimerize to IV or add a second electron to form III, which is the intermediate common to the dibromosuccinic acid reduction. During the formation and/or existence of II or III, rotation can occur to form the *trans* product as obtained from the unionized, doubly ionized and ester species. With the singly ionized form, an intramolecular hydrogen bond between the carboxyl groups hinders rotation.

The same general mechanism can be applied to MBFA reduction, whose intermediate structures, however, are stable to rotation. Single-bonded intermediates II and III exist for an extremely short time and, if the species has no great need to rotate, the reaction will proceed and refreeze to the original structure without rotation. The energy diagrams for species II and

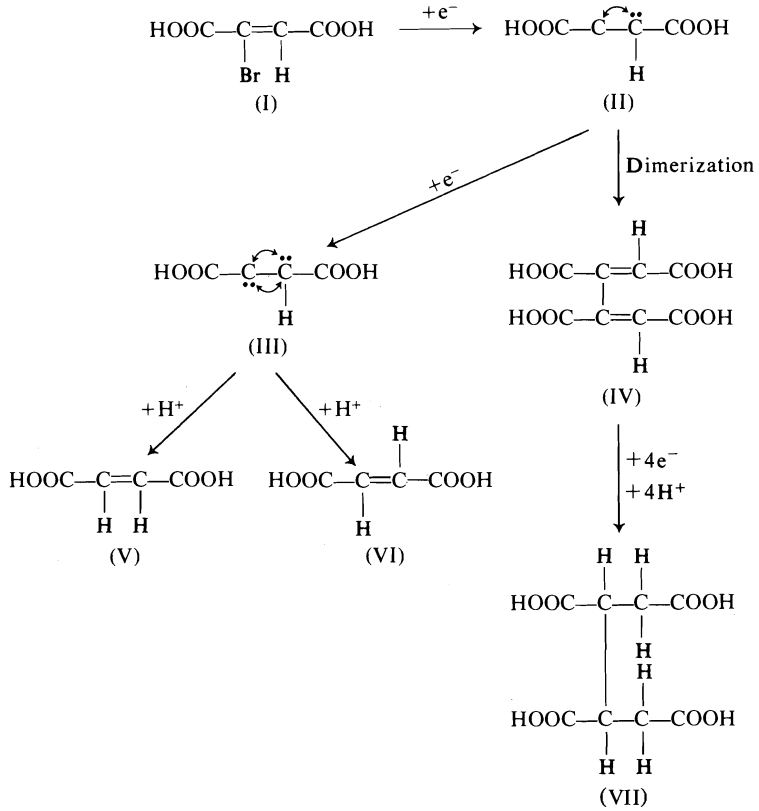

FIG. 13. Reaction mechanism proposed for electrochemical reduction of monobromomaleic and monobromofumaric acids (from ref. 75).

III with regard to orientation show one energy minimum for the ionized, double ionized, and ester species of both acids, corresponding to a *trans* conformation, and two minima for the singly ionized species, corresponding to *trans* and *cis* (hydrogen bound species) configurations. An energy barrier exists between the latter forms, so that, interconversion to the *cis* structure requires time and energy, which the reaction makes unavailable.

As to why only MBMA reduction yields a dimer, intermediate structure II can undergo two opposing reactions, whose rates, in the case of the *cis* form, are nearly equal up to p*H* 3 (Fig. 12). The double bond in maleic acid reacts with mercury while that in fumaric acid does not (76); the effect of this reaction and that of a free radical with mercury (77) will be to stabilize the *cis* form of intermediate II, thus slowing its reaction to III and resulting in a large free radical concentration at the interface. These effects enhance dimerization with the *cis* form.

Since dimer production is strong, if not conclusive, evidence for the existence in the course of a reaction of a free radical intermediate, formation of a dimeric product on MBMA reduction offers the strongest experimental support for electrochemical carbon–halogen bond fission in aqueous media proceeding, at least in part, through a free radical intermediate.

A potentially important approach is that of asymmetric reduction as a result of addition of suitable chemical reagents to the solutions being electrolyzed (78) or covalent attachment of such reagents to the electrode surface (79). Thus, addition of alkaloids has been found to induce optical activity in some electrolytic reductions, e.g. of acetyl pyridines at a mercury electrode. Recent studies are listed in ref. 78.

Vibrational analysis of alkyl bromides. II. Secondary bromides

G. A. CROWDER AND MAURICE IWUNZE

Department of Chemistry, West Texas State University, Canyon, TX 79016, U.S.A.

Received March 30, 1977

G. A. CROWDER and MAURICE IWUNZE. Can. J. Chem. **55**, 3413 (1977).

Infrared and Raman spectra were obtained for 2-bromopentane, 3-bromopentane, 2-bromohexane, and 3-bromohexane. Vibrational assignments were made for several conformers of each compound with the aid of normal coordinate calculations. A 48 parameter modified valence force field was obtained that fit 221 frequencies of three conformers of 2-bromopentane, 4 conformers of 3-bromopentane, and 1 conformer of 2-bromobutane with an average error of 4.1 cm^{-1}. This force field was transferred to the bromohexanes, with good results.

G. A. CROWDER et MAURICE IWUNZE. Can. J. Chem. **55**, 3413 (1977).

On a obtenu les spectres infrarouge et Raman des composés suivants: bromo-2 pentane, bromo-3 pentane, bromo-2 hexane et bromo-3 hexane. L'attribution des vibrations est déterminée pour plusieurs conformères de ces composés grâce à des calculs de coordonnées normales. Un champ modifié de force de valence est obtenu et celui-ci comporte 48 paramètres, lequel s'adapte à 221 fréquences pour trois conformères du bromo-2 pentane, quatre conformères du bromo-3 pentane et un conformère du bromo-2 butane avec une erreur moyenne de 4.1 cm^{-1}. Ce champ de force appliqué aux bromohexanes donne de bons résultats.

[Traduit par le journal]

Introduction

Infrared spectra have been reported for 2-bromopentane and 3-bromopentane only in the 400–800 cm^{-1} region by Gates, Mooney, and Willis (1). Carbon–bromine stretching bands were assigned to four conformers of 2-bromopentane and five conformers of 3-bromopentane. These authors made analogous assignments for 2-chloro- and 2-iodopentane and 3-chloro- and 3-iodopentane, which included assignment of bands to the C—X stretch of a '*cis* X—H' conformer of 2-halopentane and the S_{CC} conformer of 3-halopentane. These bands have been interpreted by other authors as being due to the other conformers present for the chloro- (2) and iodo- (3) pentanes, rather than to the *cis* X—H and S_{CC} conformers.

Since the previous study (1) included only the 400–800 cm^{-1} region of the infrared spectra and did not include any Raman data, infrared and Raman spectra have been obtained in this laboratory in order to make vibrational assignments and to learn more about the conformational behavior of these compounds. Normal coordinate calculations were made for three conformers of 2-bromopentane and for four conformers of 3-bromopentane to aid in making vibrational assignments and identifying conformations and to develop a force field that will be useful for interpretations of the spectra of other secondary bromides.

No spectra have been published for 2-bromohexane or 3-bromohexane, so infrared and Raman spectra have been obtained for these two compounds and vibrational assignments were made with the aid of normal coordinate calculations that utilized the force constants obtained from the bromopentanes. The first paper of this series presented results for a series of primary bromides (4).

Experimental

Infrared spectra were obtained with a Beckman IR12 spectrophotometer, and Raman spectra were obtained with a Beckman Model 700 spectrometer equipped with a Coherent Radiation Model 54 argon laser. The 488.0 nm line was used. The samples were obtained from K & K Laboratories or Aldrich Chemicals, and were used without further purification. Gas chromatographic analysis showed no appreciable amounts of impurity.

Calculations

Normal coordinate calculations were made with a PDP-10 computer and utilized programs written by Schachtschneider (5, 6) for calculation of the **G**-matrix (GMAT), solution of the vibrational secular equation (VSEC), and for the least-squares refinement of designated force constants to fit the calculated to the observed frequencies (FPERT). These references should be consulted for details of the calculations, treatment of the redundancy problem, etc. The molecular parameters used were C—C = 1.54

Å, C—H = 1.09 Å, C—Br = 1.94 Å, and all angles were assumed to be tetrahedral.

Results and Discussion

Normal Coordinate Calculations for 2-Bromobutane

In order to obtain force constants to use initially for the bromopentanes, calculations were first made for the three conformers of 2-bromobutane, i.e., S_{HH}, $S_{HH'}$, and S_{CH}. A 48 parameter modified valence force field was used, with initial values being taken from the secondary iodides (3), except for the C—Br stretch force constant, which was taken from the force field of 2-bromobutane developed by Benedetti and Cecchi (7).

The band assignments made by Benedetti and Cecchi were used in our initial calculations. Seventeen force constants were refined by the least-squares program, and 69 frequencies of the three conformers were fitted with an average error of 5.4 cm^{-1}, as compared with an average error of 6.75 cm^{-1} obtained by Benedetti and Cecchi (7). The present calculations resulted in a change of only two of the band assignments given by those authors, both for the S_{CH} conformer. We have assigned the 1360 and 1120 cm^{-1} bands to this conformer, rather than those observed at 1346 and 1145 cm^{-1}. Our calculated values are 1363 and 1118 cm^{-1}, whereas the calculated values of Benedetti and Cecchi are 1345 and 1143 cm^{-1}. The difference between the present results for this compound and those of Benedetti and Cecchi are not significant enough to warrant listing our results here.

2-Bromopentane and 3-Bromopentane

Liquid-state ir and Raman spectra of 2-bromopentane were obtained with salt plates. Solid-state spectra were obtained by cooling a liquid film held between salt plates, in hopes that some simplification from the liquid-state spectrum would be observed, as a result of the disappearance of some of the conformers upon crystallization. However, crystallization did not take place, even with annealing for 1 h. Gates *et al.* (1) also reported only the amorphous solid. The solid-state spectrum is essentially identical to that for the liquid. There were, however, two bands observed in the solid-state spectrum that were not present in the spectra of the liquid.

As an aid in assigning the observed bands to the appropriate conformers, normal coordinate calculations were made for the S_{HH}, $S_{HH'}$, and S_{CH} conformers of 2-bromopentane (carbons 2, 3, 4, and 5 are coplanar in all three conformers) and for the S_{HH}, $S_{HH'}$, S_{CH}, and $S_{CH'}$ conformers of 3-bromopentane. Initially, zero-order calculations were made for the three conformers of 2-bromopentane and for the S_{HH}, $S_{HH'}$, S_{CH}, and $S_{CH'}$ conformers of 3-bromopentane. Initial calculations were made for the three conformers of 2-bromopentane, using the values of the force constants that had been obtained for 2-bromobutane. Band assignments were made by comparison of the observed and calculated wave numbers, and then a least-squares refinement was made to simultaneously fit the frequencies of the three conformers of 2-bromobutane and the three conformers of 2-bromopentane. Fifteen force constants were adjusted and 144 wave numbers of the six conformers were fit with an average error of 5.5 cm^{-1}.

The next step in the development of the force field was to make preliminary calculations for the four conformers of 3-bromopentane, using the force constants that were determined as described in the preceding paragraph. Again, band assignments were made by comparison of observed and calculated wave numbers. Our computer facility was limited to inclusion of eight molecules in the FPERT program, and several combinations of eight of the ten conformers of the butane and two pentanes were used, with essentially the same results for the conformers common to all the calculations. In the final computer run reported here, 16 force constants were refined to provide the best fit for 221 wave numbers below 1500 cm^{-1} of the 3 conformers of 2-bromopentane, the 4 conformers of 3-bromopentane, and the S_{HH} conformer of 2-bromobutane. The average difference between observed and calculated wave numbers for the 221 values was 4.1 cm^{-1}. The calculated wave numbers are available on request from the authors, and the force constants are given in Table 2. Comparison of the values of the force constants listed in Table 2 with those obtained for secondary iodides (3) shows 30 values used for both bromides and iodides and several others that are quite close. Of course, quite a few of those iodide values were transferred from a hydrocarbon force field.

The calculated wave numbers strongly support the presence of the three conformers of 2-bromo-

pentane for which calculations were made. There are seven observed bands assigned solely to the S_{HH} conformer (1340, 1150, 1071, 928, 536, 420, and 181 cm^{-1}), four bands assigned to the $S_{HH'}$ (1135, 578, 512, and 314 cm^{-1}), and two bands assigned to the S_{CH} (743 and 616 cm^{-1}). Several other bands were assigned to different pairs of conformers, i.e., S_{HH} and $S_{HH'}$; S_{HH} and S_{CH};

[a]Stretching constants are in units of mdyn/Å; stretch–bend constants are in units of mdyn/rad; bending constants are in units of mdyn Å/(rad)^2.
[b]Force constants for which no standard error is given were constrained to the transferred values.

$S_{HH'}$ and S_{CH}. The assignment of the C—Br stretch bands by Gates *et al.* (1) to these three conformers was confirmed. However, these authors assigned the band they observed at 515 cm^{-1} to the C—Br stretch of a '*cis* X—H' conformer, whereas our calculations indicate assignment of this band to the $S_{HH'}$ conformer. The potential energy distribution shows this band to be due to a mixture of skeletal bending and C—Br stretching modes. This interpretation is identical to that for 2-iodopentane (3).

Table 1 lists several observed bands that were unassigned to the three conformers for which calculations were made. This probably indicates the presence of one or more additional conformers.

The S_{HH}, $S_{HH'}$, and S_{CH} conformers of 2-bromopentane are interconverted by internal rotation about the C_2—C_3 bond. Rotation about the C_3—C_4 bond leads to additional conformers, two of which are shown in Fig. 1. These seem to be the conformers most likely to be present, in addition to the three already discussed. In an effort to determine if these two conformers are present, normal coordinate calculations were made for them, using the force constants given in Table 2. These calculated wave numbers are available from the authors. Comparison of the calculated values with the observed values given in Table 1 shows that the conformer shown in Fig. 1*a* can account for the band observed at 490 cm^{-1}, and the other calculated values are in good agreement with observed values. None of the bands previously unassigned can be unambiguously assigned to the conformer shown in Fig. 1*b*, and there is therefore no evidence to indicate the presence of this conformer, although this conformer seems as probable as that of Fig. 1*a*. There are still four unassigned bands listed in Table 1, and at least two of these can be explained as summation bands. No further attempt was made to try to determine the source of these bands.

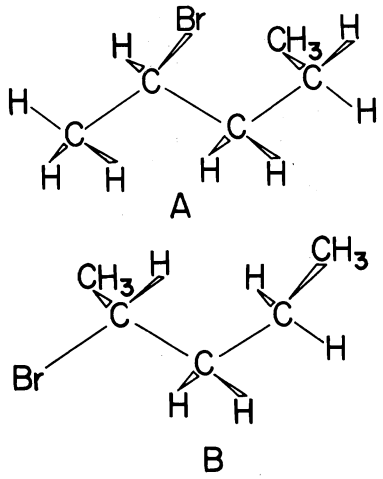

FIG. 1. Additional conformers of 2-bromopentane for which calculations were made.

Gates *et al.* (1) show the liquid-state infrared spectrum and list the observed bands of 3-bromopentane only for the 425–700 cm^{-1} region. The liquid-state infrared and Raman spectra of this compound were obtained in this laboratory. Solid-state infrared spectra were also obtained for this compound, but crystallization did not take place. The solid obtained by Gates was also amorphous.

Evidence has been given for the presence of four conformers of 3-chloropentane (8) and 3-iodopentane (3), and the present results indicate the same behavior for 3-bromopentane. There are seven bands assigned solely to the S_{HH} conformer (1254, 1151, 1082, 1068, 532, and 415 cm^{-1}), three bands to the $S_{HH'}$ (597, 374, and 265 cm^{-1}), six bands to the S_{CH} (1123, 870, 604, 450, 359, and 294 cm^{-1}), and three to the $S_{CH'}$ (616, 520, and 278 cm^{-1}).

Gates *et al.* assigned the band they observed

[a]The existence of these bands is uncertain.

at 491 cm^{-1} to the S_{CC} conformer. Moore and Krimm (8) found no evidence for the presence of S_{CC} 3-chloropentane, nor was any evidence found for the presence of S_{CC} 3-iodopentane (3), as would be expected from steric considerations. Therefore, calculations were not made for the S_{CC} conformer of 3-bromopentane. Calculation shows that the 491 cm^{-1} band is due to both S_{HH} and $S_{HH'}$ conformers.

In order to conserve space, the potential

energy distributions will not be given here, but they are available from the authors.

2-Bromohexane and 3-Bromohexane

Liquid and solid-state infrared spectra and liquid-state Raman spectra for these compounds were obtained, and the observed wave numbers are listed in Table 3. The solid-state spectra for these compounds were due to all conformers and aided in the analysis only by the presence of some bands that were not resolved in the liquid-state spectra.

In order to make vibrational assignments, preliminary normal coordinate calculations were made for both compounds, using the force constant values given in Table 2. For 2-bromohexane, calculations were made only for the three conformers that differ by rotation about the C_2—C_3 bond, so the C_2 through C_6 carbons are all coplanar. The calculated wave numbers indicate five bands due solely to the S_{HH} conformer (1312, 1066, 900, 540, and 475 cm^{-1}), five bands to the $S_{HH'}$ (981, 579, 508, 402, and 347 cm^{-1}), and five bands to the S_{CH} (1260, 915, 791, 614, and 455 cm^{-1}). Not all of these band assignments are unambiguous, however. For example, the band observed at 540 cm^{-1} can be confidently assigned to the S_{HH} conformer and not to the other two, but the calculated value of 1316 cm^{-1} for the S_{HH} could be due to either the 1310 or 1326 cm^{-1} observed band. Nevertheless, we believe these results justify the conclusion that all three of these conformers are present. There are several unassigned bands listed in Table 3, which probably indicates the presence of additional conformers. However, the number of conformers possible from internal rotation about the other C—C bonds is relatively large and no attempt was made to identify additional conformers.

There are nine possible conformers of 3-bromohexane that differ in the *trans–trans* environment of the bromine atom as a result of rotation about the C_2—C_3 and C_3—C_4 bonds, and calculations were made for all but the S_{CC} and $S_{H'H'}$. The calculated wave numbers for this compound are available from the authors. There are only two observed bands assigned solely to one conformer (1310 and 483 cm^{-1}); but this is not surprising because major overlapping of bands is expected when seven conformers are involved. However, there are several bands assigned to only two or three conformers (1346, 1325, 1240, 1232, 1148, 1066, 1047, 1001, 911, 903, 889, 590, 508, 430, 398, 352, and 245 cm^{-1}).

Torsional Modes

Only the CH_3—CHI torsion was included in the calculations of the secondary iodides (3) because observed torsional frequencies were available only for 2-iodopropane and it was thought that neglect of the other torsions would not affect the calculations appreciably. Therefore, all torsions except CH_3—CHBr were neglected in the initial calculations of the secondary bromides. During the time this work was in progress, calculations were completed for a series of *n*-alkyl bromides that showed the necessity of including the torsional coordinates in order to fit certain low frequencies (4). Therefore, calculations were repeated for the secondary bromides, including all torsional coordinates.

Comparison of the calculations that included the torsional coordinates with those that excluded them shows only minor differences. However, the overall average error was lowered by 0.5 cm^{-1}. The major effect involves the lowest-frequency CH_2 rocking frequency of 2-bromopentane and 2-bromohexane. The calculated wave number was 20–30 cm^{-1} too low for all conformers of these two compounds, and could not be increased by the least-squares program. Inclusion of the other torsions increased the calculated wave numbers of this mode in all conformers. Examination of the Jacobian matrix showed that force constant H_τ has a very large effect on this frequency.

Semi-empirical non-adiabatic potential energy curves for hydrogen, deuterium, and their molecule-ions

MARY KURIYAN AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received February 17, 1977

MARY KURIYAN and HUW O. PRITCHARD. Can. J. Chem. **55**, 3420 (1977).

Effective non-adiabatic potential curves were constructed for the ground states of the deuterium molecule and of the hydrogen and deuterium molecule-ions by scaling our empirical non-adiabatic coupling correction for hydrogen according to the approximate rules given by Bunker. These effective potentials were refined by the techniques we have described previously, and were then used to generate the rotation–vibration energy-level spectra for H_2^+ and D_2^+; tables of these energy levels, which we consider to be the best available at the present time, are presented.

MARY KURIYAN et HUW O. PRITCHARD. Can. J. Chem. **55**, 3420 (1977).

Des courbes effectives de potentiel non-adiabatique sont construites pour les états fondamentaux de la molécule de deutérium et des ions-moléculaires d'hydrogène et de deutérium en calibrant notre correction du couplage empirique non-adiabatique pour l'hydrogène selon les règles approximatives rapportées par Bunker. Les potentiels effectifs sont affinés par les techniques décrites précédemment. Pour chacun de ces ions-moléculaires H_2^+ et D_2^+, ces calculs engendrent une série de niveaux d'énergie de rotation–vibration. On présente plusieurs tables des niveaux d'énergie que l'on considère les mieux réalisées jusqu'à maintenant.

[Traduit par le journal]

We have recently used an RKR-like procedure to invert the rotation–vibration energy-level spectrum of H_2 to an accuracy approaching ± 0.1 cm^{-1} (1). This procedure made use of the best available theoretical adiabatic potential $V(R)$ tabulated by Bishop and Shih (2) as the starting approximation, and an effective correction function $\Delta V(R)$ was deduced which would

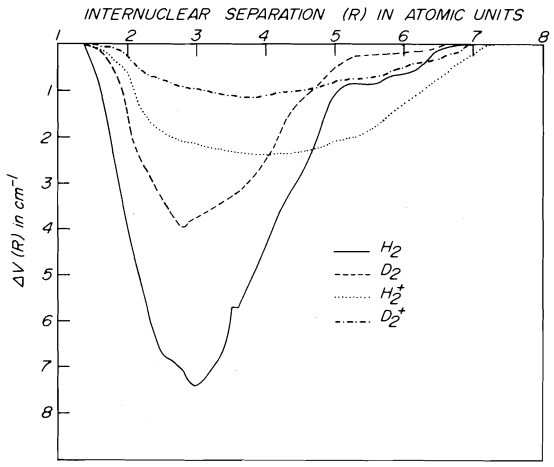

FIG. 1. Effective corrections required for H_2^+, D_2^+, H_2, and D_2 in order to make the best available adiabatic potential curves for these molecules yield the known energy-level spectra. For use in future computations, the corrections are also listed in Table 1.

regenerate the experimental energy-level spectrum for all J. It is widely believed (see ref. 1) that the inability of the function $V(R)$ to generate the known energy-level spectrum of H_2 arises from the neglect of non-adiabatic effects, and if this is so, our effective correction term $\Delta V(R)$ represents an approximate way of incorporating the non-adiabatic coupling. However, as Bunker has shown (3), the non-adiabatic effects at small internuclear separation should be about four times as large for H_2 as they are for H_2^+, and consequently the addition of $0.25\Delta V(R)_{H_2}$ to the exact adiabatic potential curve for H_2^+ (4) should give a good representation of the energy-level spectrum for the hydrogen molecule-ion. The known spectrum consists principally[1] of some experimental observations by Herzberg and Jungen (5) for most members of the group

[1]Six quasibound levels for H_2^+ and five for D_2^+ have also been observed (14), but their accuracy is not such that they are suitable as calibration points in our energy-level inversion scheme.

of states $0 \leq v \leq 3$, $0 \leq J \leq 4$, and the non-adiabatic calculations by Bishop (6) for $0 \leq v \leq 11$, $J = 0$.

It should be noted at the outset that no single potential can reproduce exactly all the rotation–vibration levels reported by Herzberg and Jungen (5), and irregularities somewhat larger than the estimated uncertainties ($\pm 0.2\ cm^{-1}$) are apparent. However, there is no guarantee that a single potential curve will be able to regenerate all the known levels, since it may be necessary to construct one effective potential curve for each vibrational state: this would represent an inherent limit in our effective potential method, but although the associated errors are not known at this time, they are certainly small (2, 7).

Figure 1 shows the effective correction to the known adiabatic potential (4) required to produce the best fit to the experimental data (5) and an exact fit to the theoretical data (6) for H_2^+. In the region of $2 \leq R \leq 3a_0$, the required correction is roughly one quarter of that required for H_2, as predicted by Bunker (3), but it becomes progressively larger relative to the H_2 correction term as the internuclear separation increases: this manifests itself in the calculation in that the first guess of $0.25\Delta V(R)_{H_2}$ for the correction term reproduces quite well the low-lying states of H_2^+, but not the higher ones; however, having established the magnitude of the correction term at small R, it is a simple matter to generate the whole correction function by the method we described previously (1).

Again, following from the earlier work of Bunker (8), we may argue that to a first order of approximation the effective corrections for D_2 and D_2^+ will be respectively about one half of those appropriate to H_2 and H_2^+ (cf. also the results of Bishop and Shih (2)). These correction functions are also shown in Fig. 1, and it can be seen that for both pairs a factor of two is remarkably close to the truth. The data fitted in these two cases are as follows: for D_2, the experimental values of Bredohl and Herzberg (9) for $0 \leq v \leq 21$, $0 \leq J \leq 9$; for D_2^+, the non-adiabatic theoretical results of Bishop (6) for $0 \leq v \leq 11$, $J = 0$, and of Hunter and Pritchard (10) for $0 \leq v \leq 3$, $0 \leq J \leq 2$. It is worth remembering here that for HD^+, a more complicated theoretical problem than either H_2^+ or D_2^+, non-adiabatic calculations (10, 11) are in virtually exact agreement with experiment (12).

In general, the correction functions shown in

Fig. 1, when applied to the existing adiabatic potentials, will reproduce the known bound-state energy levels to within about $\pm 0.2\ cm^{-1}$. We may draw two conclusions from this observation. (*i*) That the correspondence of the effective correction terms shown in Fig. 1 with the relative magnitudes expected from Bunker's analyses (3, 8) identifies these correction terms more positively than ever with non-adiabatic coupling effects. (*ii*) That in the absence of costly and time-consuming non-adiabatic calculations for about 1400 individual states of H_2^+ and D_2^+, the best energy-level spectra available at the present time are those derived using these effective correction potentials. Hence, the complete energy-level spectra for these two species are reproduced in Tables 2 and 3. Comparison with an earlier tabulation of these energy levels (13) based on *adiabatic* internuclear potentials shows that the inclusion of non-adiabatic effects lowers most states of H_2^+ by some $1–3\ cm^{-1}$, with the lowerings for D_2^+ being somewhat less.[2] It should also be noted that we have not included resonance widths for the quasi-bound states in the present tables, for two reasons. (*i*) It is not clear to us that our effective potential method, although yielding good answers for the energies of the levels, need represent the tunnelling properties at all well. (*ii*) The tunnelling lifetimes are *very sensitive indeed* to small changes in the assumed potential, and the level widths quoted previously (13) change by as much as a factor of four when the effective potential is used instead of the adiabatic one; hence, numerical values of resonance widths can only have qualitative significance at the present time.

[2]Throughout these calculations 1 au = 219 474.72 cm^{-1}, but the present tables use a slightly different value for the mass of the deuteron viz. $M_D = 3673.17 m_e$ (15) from that used previously (13). Missing from the table for H_2^+ is an entry corresponding to $v=19$, $J=0$, which has been reported by other workers (16, 17); we searched extensively for an eigenvalue corresponding to such a state, both in this work and previously (13), but our potential does not support such a state. Also, we have omitted from the present tables a few of the topmost quasi-bound levels whose positions are rather difficult to locate and consequently cannot be quoted with the accuracy claimed.

Mécanisme d'apparition de la coloration jaunâtre dans les poudres de sulfate stanneux[1]

G. VERVILLE

Division Sources d'énergie électrique, Centre de recherches pour la Défense, Ottawa, Ont., Canada K1A 0Z4

Reçu le 13 janvier 1977

G. VERVILLE. Can. J. Chem. **55**, 3425 (1977).

Une étude spectrophotométrique des poudres de sulfate stanneux nous a permis de définir le mécanisme d'apparition de la coloration jaunâtre dans ces poudres. La formation des complexes de transfert de charge 1Sn(II)–4Sn(IV) dans le film d'eau adsorbée et acidifiée entourant certains grains de sulfate stanneux est à la base du mécanisme proposé. Ces complexes sont formés par fixation d'ions $Sn^{2+}\cdot xH_2O$ ou $SnHSO_4^+$ à la surface des colloïdes $Sn(OH)_4\cdot xH_2O$ obtenus par oxydation et hydrolyse du sulfate stanneux.

G. VERVILLE. Can. J. Chem. **55**, 3425 (1977).

A spectrophotometric study of stannous sulphate powders has enabled the mechanism of the yellow coloration of these powders to be defined. It is shown that the yellow coloration results from the formation of charge transfer complexes of the type 1Sn(II)–4Sn(IV) in a film of adsorbed and acidified water which surrounds some stannous sulphate particles. The charge transfer complexes are formed by the adsorption of $Sn^{2+}\cdot xH_2O$ or $SnHSO_4^+$ ions onto the surface of colloidal $Sn(OH)_4\cdot xH_2O$ that is formed by the oxidation and hydrolysis of the stannous sulphate.

Introduction

Les poudres de sulfate stanneux se présentent sous forme de cristaux aciculaires incolores qui laissés au repos en présence d'air se colorent en jaune avec le temps. Donaldson et Moser (1) attribuent cette coloration à l'apparition progressive de composés stanniques dans les poudres de sulfate stanneux. D'après ces auteurs, lorsque les premiers signes de coloration apparaissent, les échantillons contiennent plus de 2% de composés stanniques.

Mis à part le sulfure stannique, à notre connaissance il n'existe pas de composés stanniques purs ayant une coloration jaune en soi et à première vue, la présence de composés stanniques ne semble pas constituer une condition suffisante pour donner aux poudres leur aspect jaunâtre. Nous avons donc entrepris une étude spectrophotométrique des poudres et celle-ci nous a permis de préciser les résultats antérieurs et de définir le mécanisme d'apparition de la coloration jaunâtre dans les poudres de sulfate stanneux.

Mode opératoire

Les poudres de sulfate stanneux sont obtenues de diverses sources dans le commerce. Après réception, les poudres sont mélangées et broyées dans un mortier pendant 5 min. Les poudres sont ensuite analysées par spectrométrie de masse (spectre d'étincelles) afin de déceler les impuretés métalliques et la concentration en étain (stanneux, stannique, totale) est déterminée.

A la suite de ces analyses, les spectres de réflectance uv–visible des poudres sont enregistrés sur un spectrophotomètre SAFAS 1700 à l'aide d'un accessoire de réflectance diffuse $_{45}R^\circ$ où les poudres sont placées en vrac dans le compartiment échantillon et de l'oxyde de magnésium en poudre dans le compartiment référence. Les études dans le domaine infra-rouge sont effectuées sur un appareil Perkin-Elmer 137, par pastillage dans le bromure de potassium.

Résultats

Les analyses par spectrométrie de masse n'ont pas permis de déceler de différence fondamentale au niveau des impuretés métalliques, par conséquent la coloration jaunâtre n'apparait pas liée à la présence d'impuretés métalliques dans les poudres.

Par contre, nous avons enregistré des écarts importants, entre les poudres, dans la concentration en composés stanniques et stanneux. Dans la majorité des cas, les poudres ayant une concentration supérieure à 2% en composés stanniques présentaient déjà un aspect jaunâtre lors de la réception. Les analyses des poudres par réflectance diffuse nous ont permis d'établir la raison de ce critère de 2%. La fig. 1 montre les spectres de réflectance diffuse uv–visible d'une poudre blanche, courbe *a*, et d'une poudre

[1]Travail effectué à l'Ecole Nationale Supérieure d'Electrochimie et d'Electrométallurgie de Grenoble lors du travail de thèse de l'auteur.

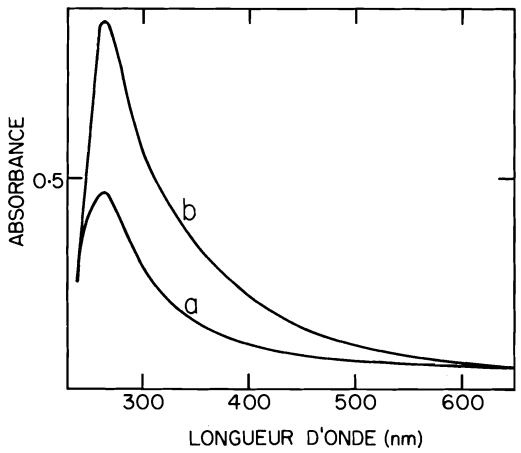

FIG. 1. Spectres de réflectance diffuse de poudres $SnSO_4$. *a*, Poudre blanche, 1.8% d'étain stannique; *b*, poudre jaunâtre, 2.8% d'étain stannique.

jaunâtre, courbe *b*. Ces poudres contiennent respectivement 1.8 et 2.8% d'étain stannique. Les spectres présentent la même allure générale et sont caractérisés par une bande d'absorption dans l'ultra-violet qui se prolonge vers le visible. Bien que très ressemblant, le spectre de la poudre jaunâtre se distingue du spectre de la poudre blanche par une absorption beaucoup plus intense dans l'uv et le proche uv. Il apparait que la coloration jaunâtre est due à un seuil continu d'absorption entre 400 et 600 nm et que la différence d'absorbance entre 400 et 600 nm détermine l'absence ou la présence de la coloration jaunâtre dans les poudres. Par exemple, sur le spectre *a*, la différence d'absorbance entre 400 et 600 nm est trop faible pour être perçu par un oeil de sensibilité moyenne, et par conséquent la poudre apparait blanche (un oeil d'une sensibilité supérieure pourrait éventuellement détecter des signes de coloration sur cette poudre). Aux concentrations supérieures à 2% en étain stannique, la différence d'absorbance entre 400 et 600 nm devient suffisamment importante pour permettre à l'oeil de percevoir la coloration jaunâtre qui devient de plus en plus intense à mesure que la concentration en étain stannique augmente dans les poudres. Cette observation a pu être reliée à une augmentation de la différence d'absorbance entre 400 et 600 nm et au déplacement progressif du seuil d'absorption vers les grandes longueurs d'onde.

Les résultats antérieurs sont donc bien confirmés et la coloration apparait bien liée à la présence d'étain stannique dans les poudres. Cependant, comme Donaldson et Moser (1), nous avons constaté que l'apparition de la coloration jaunâtre au cours du temps, sur les poudres initialement blanches, n'était pas uniforme. Les premiers signes visibles de coloration apparaissent souvent sur les parois des contenants. Nous avons recueilli et analysé les grains provenant de ces zones jaunâtres. Certains échantillons ont présenté des concentrations de l'ordre de 30–40% en étain stannique. A la suite de ces constatations nous avons été amené à considérer l'humidité atmosphérique comme un élément essentiel dans le processus d'obtention de la coloration jaunâtre.

Influence de l'humidité atmosphérique

Les échantillons jaunâtres contenant 30–40% d'étain stannique sont placés dans un four à 200°C pendant 24 h. Les échantillons perdent leur coloration et sont ensuite remis à la température ambiante sous l'atmosphère du laboratoire. Les poudres redeviennent progressivement jaunâtres en adsorbant de l'eau qui est mise en évidence par spectrophotométrie infra-rouge (ir). Les spectres ir ont également révélé la présence de groupements hydroxyles liés à l'étain stannique (doublet entre 3500 et 3600 cm^{-1}) (2, 3) et la présence du groupement HSO_4^- (bande située à 2900 cm^{-1}) dans ces échantillons.

Après un séjour prolongé à l'air libre les échantillons se transforment en boue dont le p*H* est inférieur à zéro. Ceci est révélateur d'une hydrolyse d'ions qui conduit à la formation d'ions H_3O^+. Quel que soit le degré de transformation de ces poudres, la diffraction des rayons X ne révèle que la présence de sulfate stanneux. Les composés stanniques résultant de l'oxydation se trouvent donc à l'état colloïdal.

Mécanisme d'apparition de la coloration

L'ensemble de ces constatations nous amène à proposer, pour l'apparition de la coloration, trois étapes principales:

1. Oxydation de Sn^{2+} en Sn^{4+} à la surface de certains grains de poudre

Cette étape est nécessaire mais non suffisante.

2. Formation d'un film d'eau adsorbée sur ces grains

Les Sn^{4+} à la surface des grains jouent le rôle d'acide de Lewis et l'adsorption de la vapeur d'eau se fait préférentiellement sur ces sites. Les $Sn^{4+}\cdot xH_2O$ isolés sur la surface servent ensuite de germes à la formation d'un film d'eau qui

entoure finalement les grains qui commencent alors à s'agglomérer entre eux. Le film formé est le siège de la prochaine étape conduisant à la coloration jaunâtre.

3. Formation des colloïdes $Sn(OH)_4 \cdot xH_2O$ et des ions $Sn^{2+} \cdot xH_2O$ et $SnHSO_4^+$ dans le film: apparition de la coloration

Le film d'eau étant formé, les ions $Sn^{4+} \cdot xH_2O$ et Sn^{2+} à la surface des grains se dissolvent dans le film. La poursuite de l'hydrolyse des ions stanniques conduit principalement à la formation des colloïdes $Sn(OH)_4 \cdot xH_2O$ (4) qui ont été mis en évidence par spectrophotométrie infra-rouge alors que l'hydrolyse des ions stanneux conduit à la formation des ions $SnOH^+$, $Sn_2(OH)_2^{2+}$, $Sn_3(OH)_4^{2+}$ (5). Cette hydrolyse augmente l'acidité du film d'eau adsorbée. Lorsque l'acidité devient suffisante les ions $Sn^{2+} \cdot xH_2O$ et $SnHSO_4^+$ prédominent sur les autres ions stanneux (6). La présence simultanée de composés stanneux et des colloïdes stanniques dans le film d'eau acidifiée conduit à la formation des complexes de transfert de charge 1Sn(II)–4Sn(IV) déjà étudiés dans les mélanges de solutions stanneuses et stanniques par Paul *et al.* (7) et Feldstein *et al.* (8). Ces complexes sont caractérisés, comme l'illustre les spectres de la fig. 2 par une absorption intense dans l'uv qui s'étend parfois jusqu'au visible pour conférer aux mélanges une coloration jaunâtre. Durant nos travaux (9) nous avons confirmé les résultats de ces auteurs et nous avons montré que les complexes 1Sn(II)–4Sn(IV) sont observés chaque fois que l'on met en présence des colloïdes stanniques et des complexes stanneux du type $Sn^{2+} \cdot xH_2O$ ou SnX^+ où X représente les anions usuels à l'exception de F^-.

Une vérification du mécanisme proposé nous est fournie par la mise en solution des poudres de sulfate stanneux contaminées; la fig. 3 présente les spectres d'absorption uv–visible de trois solutions $SnSO_4$ 30 g/ℓ, en milieu H_2SO_4 10% V. Ces spectres ont été réalisés immédiatement après la dissolution des poudres qui contenaient respectivement 0.8, 1.5 et 2.6% d'impuretés stanniques. On constate que l'absorption se présente sous la forme d'un seuil qui

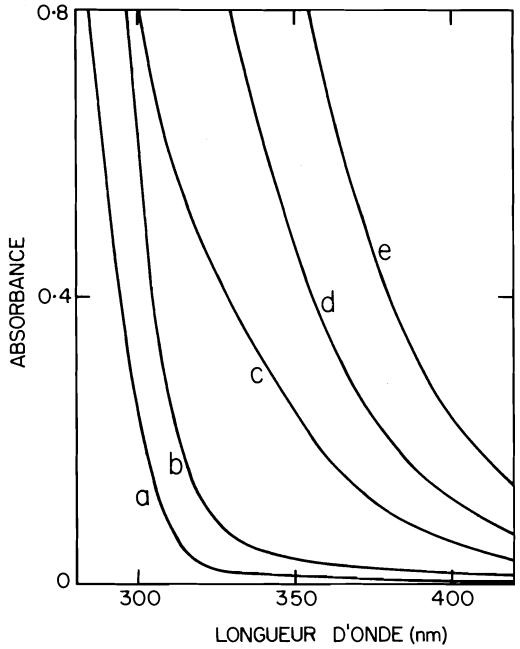

FIG. 2. Spectres d'absorption uv–visible d'une solution stanneuse, d'une solution stannique et de leurs mélanges en milieu HCl, pH = 0.6. *a*, Solution stanneuse fraichement préparée ($SnCl_2 \cdot 2H_2O$, 5×10^{-3} *M*); *b*, solution stannique vieillie pendant 24 h ($SnCl_4 \cdot 5H_2O$, 5×10^{-3} *M*); *c*, mélange équimolaire, 2.5×10^{-3} *M* Sn total; *d*, mélange équimolaire, 5.0×10^{-3} *M* Sn total; *e*, mélange équimolaire, 1.0×10^{-2} *M* Sn total.

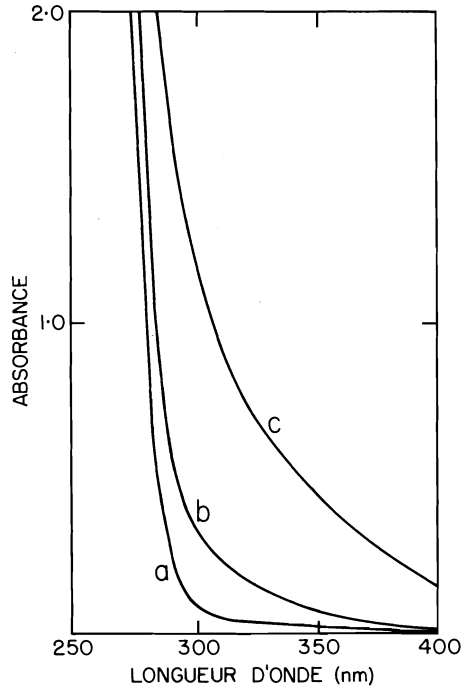

FIG. 3. Spectres d'absorption uv–visible de solutions $SnSO_4$ 30 g/ℓ, H_2SO_4 10%. *a*, Poudre contenant 0.8% d'étain stannique; *b*, poudre contenant 1.5% d'étain stannique; *c*, poudre contenant 2.6% d'étain stannique.

se déplace vers le visible lorsque la concentration en impuretés stanniques augmente. L'allure de ces spectres dans le proche uv est à comparer avec l'allure des spectres des solutions jaunâtres résultant des mélanges des solutions stanneuses et des solutions contenant des colloïdes stanniques de la fig. 2 et avec l'allure des spectres des poudres de la fig. 1. La dissolution du sulfate contenant 2.6% d'impuretés stanniques a entraîné l'apparition immédiate de la coloration jaunâtre de la solution (spectre *c*).

Conclusion

La coloration qui apparait progressivement sur les poudres blanches de sulfate stanneux est attribuable à la formation de complexes de transfert de charge 1Sn(II)–4Sn(IV) dans le film d'eau adsorbée et acidifiée entourant certains grains. Ces complexes sont formés par la fixation d'ions $Sn^{2+}\cdot xH_2O$ ou $SnHSO_4^+$ à la surface des colloïdes $Sn(OH)_4\cdot xH_2O$ obtenus par oxydation et hydrolyse du sulfate stanneux. Le mécanisme proposé rend compte des résultats observés et met bien en évidence le rôle de l'oxydation et de l'humidité dans l'obtention de la coloration; pour qu'apparaisse cette coloration les conditions d'obtention des constituants du complexe de transfert de charge doivent être respectées, c'est-à-dire que $Sn(OH)_4\cdot xH_2O$ d'une part et $Sn^{2+}\cdot xH_2O$ ou $SnHSO_4^+$ d'autre part puissent exister. Ainsi en chauffant à 200°C une poudre jaunâtre, celle-ci contient toujours les colloïdes stanniques mais la disparition du film d'eau adsorbée entraine la disparition des complexes stanneux et cause la disparition de la coloration. La dissolution en milieu acide de cette poudre, entraine l'apparition immédiate de la coloration jaunâtre de la solution.

Dans un cadre plus général, nous pensons que la coloration jaunâtre rapportée dans les poudres des composés stanneux et stanniques autres que les sulfures pourrait être due à une seule et même cause, c'est-à-dire à la présence des complexes de transfert de charge dans ces poudres.

A detailed assignment of the O–H stretching bands of ice I[1]

E. WHALLEY

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received March 15, 1977

E. WHALLEY. Can. J. Chem. **55**, 3429 (1977).

A detailed assignment of the infrared and Raman O–H stretching bands of disordered ice Ih and Ic is proposed. It is based on the assumptions that the spectra of disordered ice Ic are closely related to those of ordered ice Ic, and that the spectra of the as yet unrealized ordered ice Ic can be predicted from the spectra of ice VIII. The supposed similarity between the spectra of ordered and disordered ice Ic is justified by the observed similarity of the spectra of ice VIII and VII, which are respectively ordered and disordered forms of the same structure and are closely related to ordered and disordered ice Ic. The assignment takes into account the intermolecular coupling, which is particularly strong for the ν_1 vibrations but weak for the ν_3, and the TO–LO splitting, particularly of the ν_3 vibrations, which is shown to be required by the high infrared intensity. The infrared and Raman bands of amorphous ice have been assigned by analogy with the assignments of ice I.

E. WHALLEY. Can. J. Chem. **55**, 3429 (1977).

On propose une attribution détaillée des bandes d'élongation O–H en ir et en Raman des glaces désordonnées Ih et Ic. Cette attribution est basée sur l'hypothèse que le spectre de la glace désordonnée Ic ressemble beaucoup à celle de la glace ordonnée Ic et que le spectre qui n'a pas encore été obtenu pour la glace ordonnée Ic peut être prédit à partir du spectre de la glace VIII. Les similarités supposées entre les spectres des glaces Ic ordonnée et désordonnée sont justifiées par la similarité observée dans les spectres des glaces VIII et VII qui sont respectivement les formes ordonnées et désordonnées de la même structure et sont très reliées aux glaces Ic ordonnée et désordonnée. L'attribution rend compte du couplage intermoléculaire, qui est particulièrement fort pour les vibrations ν_1 mais faible pour ν_3, et le dédoublement TO–LO, en particulier des vibrations ν_3, qu'on démontre être nécessaire par conséquence de la grande intensité du spectre infrarouge. On a attribué les bandes infrarouges et Raman de la glace amorphe par analogie avec les attributions de la glace I.

[Traduit par le journal]

1. Introduction

The detailed origin of vibrational bands in crystalline solids can usually be determined by using techniques such as the infrared or Raman intensities and polarizations, transferability of force constants, normal coordinate calculations, etc. These techniques can be applied because there is always a high symmetry (even if it is only the translational symmetry) which restricts the number of spectroscopically active bands to a countable number. The vibrational bands of solids with a high degree of disorder cannot be so easily assigned in detail because 10^{24} or more vibrations per mole are actually observed, and because polarization does not provide much information.

The spectra in the 3-μm region in ice are undoubtedly due to the O–H stretching vibrations, but in spite of many discussions, little real progress has been made in assigning them in detail, as is described in Section 2. Many of the assignments are based on *ad hoc* assumptions that cannot be justified by appeal to other evidence. One reason for this lack of progress is that nearly all discussions have concentrated on the vibrations of a single water molecule, and have ignored the strong intermolecular coupling. To understand the spectrum of ice in detail, it must be approached from the point of view of solid-state spectroscopy, not isolated-molecule spectroscopy. A start has already been made in this program (1), and the strong O–H stretching Raman band at 3083 cm^{-1} at 100 K has been firmly assigned to intermolecularly coupled ν_1 vibrations moving in phase with one another, and it has been shown (2) that at least 25 molecules take part in each vibration.

The purpose of this paper is to propose a detailed assignment based on the following assumptions.

1. The spectra of ice Ic are closely related to the spectra of orientationally ordered ice Ic.

[1]NRCC No. 16037.

2. The spectra of ordered ice Ic can be predicted by analogy with the spectra (3–5) of ice VIII (6–8), whose crystal is made (9, 10) of two interpenetrating ice Ic structures oriented antiparallel to one another.

3. The spectra of ice Ih can be assigned by direct analogy with the spectra of ice Ic, with which they are identical within experimental uncertainty.

2. Previous Assignments

The vibrational spectrum of ice has probably been studied more than the spectrum of any other crystal, but its interpretation is still in a primitive state and the purpose of this section is to review the progress that has been made so far as an introduction to the proposals of this paper. A number of papers that report experimental measurements without an interpretation have been omitted; the earlier ones are reviewed by Ockman (11).

The absorption of ice in the 3-μm region has been known for many years (12, 13) but it was not until 1940 that films thin enough to show the structure were examined (14), and the peak at 3256 cm^{-1} at −9°C was identified. Typical spectra are reproduced in Fig. 1 in the 5th and 7th frame from the top.

Ice was studied (15, 16) in the very early days of Raman spectroscopy, and three bands were observed near 3200 cm^{-1}. They have been assigned in many ways. Rao (15, 17, 18) thought they were due to the water monomer, dimer, and trimer, which had been supposed to occur by W. Sutherland (19). G.B.B.M. Sutherland (20) dismissed the trimer but assigned the strong low-frequency peak to the dimer, and the two higher frequency peaks to Fermi resonance between the stretching and the overtone of the bending vibrations. Sutherland was influenced by Dennison's (21) (correct) finding of a hexagonal unit cell and proposal that it was a hexagonal close packed arrangement of dimers. Although the proposal is not entirely incorrect, Bragg (22) soon showed that the correct configuration allowed no unique choice of dimers, and this was later fully confirmed by Barnes (23). Rao (17) and Cross *et al.* (24) introduced a distinction between the symmetric ν_1 and asymmetric ν_3 stretching vibrations in discussing the spectrum of ice, and Ellis (25) had discussed the spectrum of the liquid in these terms several years earlier, before in fact the symmetric stretching had been identified in the vapor (26). However, Rao (17) interpreted the spectrum in terms of polymers and Cross *et al.* (24) made their interpretation in terms of differently hydrogen-bonded water molecules although it had been known (22, 23, 27) for some years that the water molecules are crystallographically equivalent. This interpretation has been revived (28) recently, but with no greater cogency. Venkatesh *et al.* (29)[2] have made a related suggestion that the 3370-cm^{-1} Raman band of amorphous ice is due to ν_1 of molecules with bent hydrogen bonds. There appear to be no arguments that strongly support this assignment, but there are two strong arguments against it. The first is that ice Ih and Ic (30) have a similar band which probably has the same origin, but have only one kind of hydrogen bond. The second is that the resolution proposed by the authors assigns about 30% of the Raman intensity to the bent hydrogen bonds, whereas the supposed contribution of the bent hydrogen bonds to the uncoupled O–H stretching band is only 12% of the band.

Fox and Martin (14) assigned the strongest Raman band to ν_1 and the strongest infrared band to ν_3. The only significant improvements on this assignment are the recognition (31) of the fact that intermolecular coupling is responsible for a large part of the breadth of the band and that disorder would result in broadened bands, and specifically (32) that all 10^{24} or so normal vibrations are infrared and Raman active, and a more precise assignment (1) of the low-frequency Raman band to the ν_1 vibrations that are intermolecularly coupled in phase with one another.

Hornig *et al.* (31) dismissed assignments based on different coordinations, and suggested that the three principal infrared bands were, in order of increasing frequency, $2\nu_2$, ν_3, and ν_1. The strongest Raman band was identified as $2\nu_2$, an impossible assignment as the stronger component of a Fermi doublet is principally the fundamental, and they were apparently unaware of Sutherland's (20) different assignment of $2\nu_2$. Ockman (11) reversed this assignment of ν_1 and $2\nu_2$ to the Raman bands, and this reversal was accepted by Haas and Hornig (33), and by many later workers (34, 35).

Val'kov and Maslenkova (36) assigned the

[2]Since this paper was submitted Dr. Rice has told me that this suggestion is withdrawn in a paper accepted by Chem. Phys. Lett.

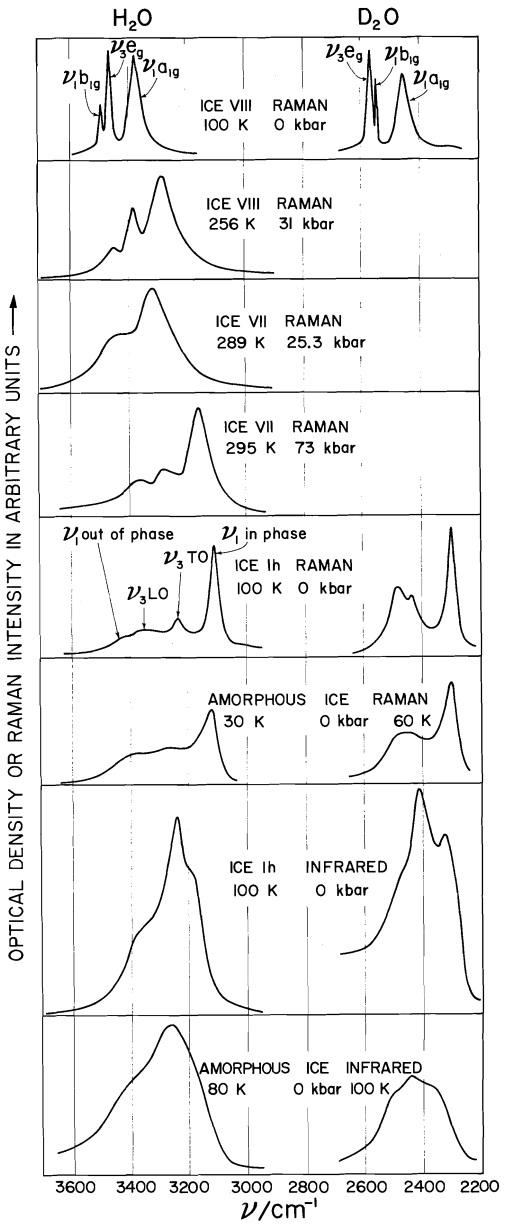

FIG. 1. Infrared and Raman spectra in the O–H stretching region of ice VIII (Raman only), VII (Raman only), Ih, and amorphous ice under various conditions as indicated.

3323- and 3400-cm^{-1} Raman bands to combinations of 3083-cm^{-1} and the 230- and 310-cm^{-1} lattice vibrations respectively. Ockman (11) suggested other combinations, and Hardin and Harvey (37) accepted that the 3340-cm^{-1} infrared band is a combination. But the bands seem too strong for this, and the corresponding difference bands are not observed in the Raman even at 0°C (11). White (38), Miller (39), Maisch (40), and Ockman (41) were the first to take account of coupling between water molecules, although the work was never fully published, and although the work was important in contributing to our general understanding, it did not lead to any significant advance in the assignment of the spectra. Maisch (40), Ockman (41), and Ockman and Sutherland (42) took specific account for the first time of the orientational disorder which had been known for nearly 20 years (43, 44*a*)[3] and calculated the Raman (40) and infrared (41, 42) polarizations. Bertie and Whalley (32) argued that because of the strong intermolecular coupling and the lack of selection rules caused by the disorder, the number of peaks and shoulders could not be predicted from the vibrations of an uncoupled water molecule, and that there was no strong evidence that $2\nu_2$ contributed significantly. These points were made again later (45), and it was emphasized that the observed absorption or scattering intensity is the density of vibrational states multiplied by an absorption or a scattering intensity function. Venkatesh *et al.* (29) found no evidence for $2\nu_2$ in the Raman spectrum of amorphous ice. Little further progress was made until Wong and Whalley (1) assigned the 3083-cm^{-1} Raman band to the particular group of ν_1 in-phase vibrations in which the molecules move in phase with one another.

A theoretical investigation by Shawyer and Dean (46) showed that the orientational disorder ensured that the vibrations were much more localized than in a perfect crystal, but used too little intermolecular coupling and so obtained too narrow ν_1 and ν_3 bands. The calculated degree of localization is therefore unreliable. Recently (2), a lower limit of about 25 molecules to the extent of the coupling has been obtained from the width of the strong Raman band.

Gurikov (47) assigned the 3210-cm^{-1} infrared band to the vibrations of O—H bonds parallel to the *c* axis and the 3450-cm^{-1} band to the vibrations of bonds inclined to the *c* axis. Mikhailov and Zolotarev (48) described a more elaborate assignment based on the same distinction between the bonds. There are two strong reasons for not accepting this assignment. The first is that the infrared spectrum of dilute

[3]See ref. 44*b* for a summary.

solutions of HDO (32, 33, 37) are not consistent with two significantly different kinds of O—H bond, and the ratio (49, 50) of the unit cell edges is only 0.3% from the ideal value for perfect tetrahedral coordination. The second is that all the bonds in ice Ic are crystallographically identical, but nevertheless its infrared (32, 37)[4] and Raman spectra (30) are identical with the spectra of ice Ih within experimental error.

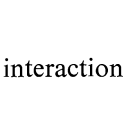
The present state of knowledge can be summarized by saying that the strong Raman band is due to ν_1 vibrations (14) in which the molecules are vibrating largely in phase with one another (1), and the strong infrared band is due to ν_3 vibrations (14) in which the molecules are vibrating largely in a phase correlated with their orientation (1).

3. Spectra of Ice VIII and VII

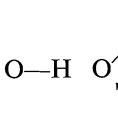
3.1. Ice VIII

Ice VIII forms a tetragonal crystal consisting of two interpenetrating ice Ic structures, one with the axes of its water molecules parallel to the *c* axis, and the other with the axes antiparallel to the *c* axis (9, 10). The primitive cell contains four translationally inequivalent molecules, which are illustrated in Fig. 2. The crystal space group is $I4_1/amd$, D_{4h}^{19} and the water molecules are on sites of symmetry C_{2v}. Consequently the ν_1 (symmetric stretching) and ν_3 (antisymmetric stretching) motions do not couple with each other at the center of the Brillouin zone. The ν_1 vibrations of the individual molecules couple to form Raman-active A_{1g} and B_{1g} vibrations, an infrared-active A_{2u} vibration, and an inactive B_{2u} vibration. The ν_3 vibrations form a Raman-active E_g and an infrared-active E_u vibration (3).

The Raman spectra of H_2O and D_2O ice VIII (3) at 100 K and zero pressure are shown in Fig. 1, and the bands are labelled by their form and species. The spectrum agrees well with an earlier spectrum (51) using mercury excitation. The infrared spectrum has not been reported; there should be two bands in this region, $\nu_1 a_{2u}$ and $\nu_3 e_u$. $\nu_3 e_g$ should be close in frequency to $\nu_3 e_u$ for the following reason. If the coupling between molecules in the same substructure of ice Ic can be described by a coupling constant between two O—H bonds that are hydrogen bonded together, as in O—H---O—H, the contribution to the potential energy of the interaction



is zero because in the ν_3 vibration one O—H expands and the other contracts. For a similar reason the coupling between the near-neighbor nonbonded molecules



is zero. Consequently, $\nu_3 e_g$ and $\nu_3 e_u$ have approximately the same frequency, and that frequency is approximately the same as that of a water molecule uncoupled from the rest of the crystal (3).

This conclusion can be stated more formally in terms of group theory. Each ice Ic substructure belongs to the space group $I4_1md$, C_{4v}^{11}, and molecules 1 and 2 are related by the operation $\pm C_4$ and a *z*-axis translation. The character of $\pm C_4$ for the *E* species is zero, and consequently if coupling of the ν_3 vibrations with translational and rotational motions is neglected, the two

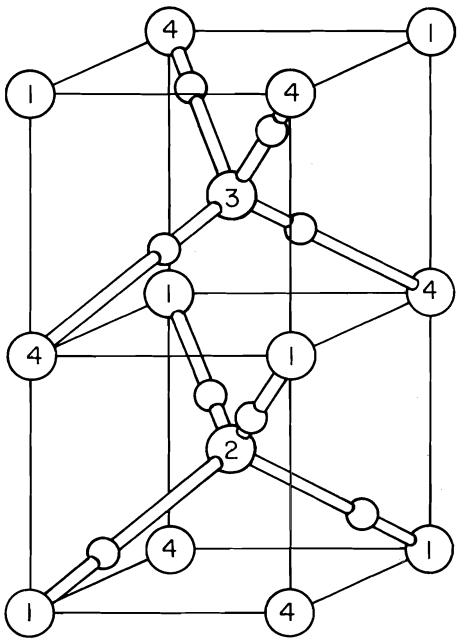


FIG. 2. The relationship between the four molecules in the primitive unit cell of ice VIII. Molecules 1 and 2 form an ice Ic structure with its dipole moment upwards, and molecules 3 and 4 form one with its dipole moment downwards.

[4]Hardin and Harvey (37) relied on making cubic ice by warming amorphous ice, and did not verify independently that ice Ic was formed.

components of the $\nu_3 e$ normal coordinate can be considered as the ν_3 vibration of molecule 1 and the ν_3 vibration of molecule 2. The ν_3 vibrations are therefore coupled only between molecules having their planes parallel to one another, i.e. only between second, fourth, etc. neighbors.

In D_2O ice VIII, the weak $\nu_1 b_{1g}$ band is at a lower frequency than the medium $\nu_3 e_g$, whereas in H_2O ice VIII it is at a higher frequency. The separation between them in H_2O ice VIII is 29.8 cm^{-1} at ~100 K and zero pressure. The hydrogen–deuterium isotope ratios for the ν_1 and ν_3 vibrations are respectively 1.365 and 1.342 (3), which are close to the values in the vapor (52), and arise from the different reduced masses. The effect of these ratios is to change $\nu_1 b_{1g}$–$\nu_3 e_g$ from 29.8 cm^{-1} in H_2O to -20.7 cm^{-1} in D_2O. At 103 kbar and 118 K the intermolecular coupling has increased so much that the $\nu_1 a_{1g}$ band of H_2O has decreased to ~3030 cm^{-1} (as read from Fig. 1 of ref. 4) or about 53 cm^{-1} below the corresponding ice Ih band at zero pressure, and the distance between the $\nu_1 a_{1g}$ and $\nu_1 b_{1g}$ bands is ~400 cm^{-1}, which is comparable to the breadth of the ice Ih band. At the same time, the separation of $\nu_1 b_{1g}$ and $\nu_3 e_g$ has increased to 185 cm^{-1}, and it is very unlikely that the isotope effect can reverse the order. In fact, if the isotope ratios that occur at 100 K and zero pressure (3) occur at 103 kbar, which seems likely as at zero pressure they are only 0.4% below the value in the vapor, the frequencies are ~2454 and ~2358 cm^{-1}, a separation of 95 cm^{-1}. In Section 4, the Raman spectrum of ice VIII will be used to assign the Raman spectrum of ice Ic. A reversal of order is unlikely to occur in ice Ic, where the intermolecular coupling is of comparable magnitude to that in ice VIII at 103 kbar and 118 K, but the two bands may be much closer together in D_2O than in H_2O.

Away from the zone center, the $\nu_1 a_{2u}$ and $\nu_3 e_u$ vibrations should be split by the long-range electric field arising from the transition moments of the molecules. The $\nu_1 a_{2u}$ vibrations propagating along the z direction, which are longitudinal optic (LO) vibrations, should be raised in frequency by the long-range field, while the $\nu_1 a_{2u}$ vibrations propagating along the x,y directions, which are transverse optic (TO) vibrations, would not be affected. The degeneracy of the $\nu_3 e_u$ vibrations is split by a similar process. The ratio of the two frequencies is given by the generalized Lyddane–Sachs–Teller relation (53)

$$\frac{\nu_1 a_{2u}\mathrm{LO}}{\nu_1 a_{2u}\mathrm{TO}} = \frac{n_{0z}}{n_{\infty z}}$$

$$\frac{\nu_3 e_g\mathrm{LO}}{\nu_3 e_g\mathrm{TO}} = \frac{n_{0x}}{n_{\infty x}}$$

where n_0 and n_∞ are the limiting low-frequency and high-frequency refractive indices of the infrared band, and subscripts x and z indicate the x and z principal values.

The change of refractive index across the O–H stretching bands of ice VIII is not known, but the contribution of all the infrared bands is. The mean permittivity at 10 kHz extrapolated to 100 K and 22 kbar, which is $\frac{1}{3}(2n_{0x}^2 + n_{0y}^2)$, is 4.32 (8). The effect of pressure is not known; increasing the pressure will increase the permittivity by increasing the density and probably the infrared absorption intensity, and decreasing some frequencies, and will decrease it by increasing some frequencies. It will be neglected. The mean permittivity at visible frequencies is 2.59, calculated assuming that the electronic polarizability of the water molecule is the same in ice I and ice VIII (8). The change of the mean refractive index across the infrared bands is (8) therefore 0.47 which is the same as the corresponding value for ice I (54). Because nothing further is known, it seems not too unreasonable to assume that the O–H stretching region contributes the same proportion of the infrared contribution to the refractive index in ice I and ice VIII. Then the change of the mean refractive index across the O–H stretching bands in ice VIII is (54) about 0.0308.

The ν_1 band contributes to the z component of the refractive index and the ν_3 band to the x and y components, which are equal. We have then

$$[1] \quad 2(n_{0x} - n_{\infty x}) + (n_{0z} - n_{\infty z}) = 0.0924$$

The contribution of a band to the change of refractive index across it is proportional to the Kramers–Kronig integral $\int K\nu^{-2}\,d\nu$ across it. If the changes of dipole moment when the two O—H bonds stretch independently are at the tetrahedral angle to one another, the integrated intensity of the ν_1 band is a half that of the ν_3 band. If the difference of the frequencies is ignored, as they must be at present because they are not known, then because of the Kramers–

Kronig integral,

$$[2] \qquad n_{0x} - n_{\infty x} = 2(n_{0z} - n_{\infty z})$$

From eqs. 1 and 2

$$[3] \qquad \begin{aligned} n_{0x} - n_{\infty x} &= 0.037 \\ n_{0z} - n_{\infty z} &= 0.019 \end{aligned}$$

As the optical birefringence of ice VIII is not known, it will be neglected. We then find

$$[4] \qquad \begin{aligned} \frac{\nu_1 a_{2u}\mathrm{LO}}{\nu_1 a_{2u}\mathrm{TO}} &= 1.012 \\ \frac{\nu_3 e_u\mathrm{LO}}{\nu_3 e_u\mathrm{TO}} &= 1.023 \end{aligned}$$

There is in the Raman spectrum of ice VIII (3) an unreported weak band at $\sim 3524\ \mathrm{cm}^{-1}$ in H_2O and $\sim 2625\ \mathrm{cm}^{-1}$ in D_2O. If these are the $\nu_3 e_u$LO vibrations, the corresponding TO vibrations are at 3445 and 2566 cm^{-1} respectively. These frequencies are 2 and 3 cm^{-1} respectively below the $\nu_3 e_g$ vibrations. The e_u vibrations should be similar in frequency to the e_g because the first-neighbor intermolecular coupling of the ν_3 vibrations should be small (3), as was shown earlier. The e_u vibrations should of course be Raman inactive, and if this assignment is correct they must be activated by some as yet unrecognized disorder. In any case, it seems likely that they are close to the $\nu_3 e_u$LO frequencies because $\nu_3 e_u$ and $\nu_3 e_g$ are close and eq. 4 holds. The assignments are summarized in Table 1.

3.2. Ice VII

The Raman spectra of ice VIII at 31 kbar and −17.4°C and of ice VII at 25 kbar and 16.1°C according to Hawke *et al.* (5)[5] are also shown in Fig. 1. The spectrum of ice VIII is broadened from that at ~100 K, no doubt because of thermal excitations, and $\nu_1 a_{1g}$ is displaced downwards in frequency from 3358.8 cm^{-1} to ~3277 cm^{-1}, $\nu_1 b_{1g}$ from 3477.4 cm^{-1} to ~3436 cm^{-1}, and $\nu_3 e_g$ from 3447.6 to ~3368 cm^{-1}. No doubt the decrease of frequency due to increased pressure dominates the increase due to increased temperature. Bands corresponding to $\nu_3 e_u$LO cannot be clearly identified because of overlap, but there is a high-frequency tail at ~3460 cm^{-1} that might be caused partly by LO vibrations.

When ice VII is formed, the spectrum, which is shown in Fig. 1 at 25 kbar and ~292 K retains[6] its character except that the bands broaden enough to cause the two higher frequency peaks to merge, and the frequencies of all the peaks increase by about 30 cm^{-1}. At 73 kbar (4), all the bands shift to lower frequency and the lower the frequency the more the shift, no doubt for reasons similar to those causing a related temperature effect in ice I (1). Because of this, the two higher frequency peaks again separate.

The orientational disorder that is produced (6–8) when ice VIII is converted to ice VII destroys all the selection rules that limit the spectrum of the crystal, and all vibrations become active. The normal vibrations can no longer be characterized by wave vectors, and they presumably become more localized. They do not shift much in frequency so they do not become localized enough to seriously reduce the effect of the intermolecular coupling on the frequency. It has been concluded (2) that in ice Ih more than about 25 molecules take part in the ν_1 in-phase stretching vibrations, and perhaps the increase in frequency and band width from ice VIII to VII is partly due to a reduced extent of intermolecular correlation.

The similarity of the spectra of ice VII and VIII indicates that the vibrations of ice VII retain a good deal of the ν_1 or ν_3 character that they had in ice VIII. The 3130-cm^{-1} band (at 73 kbar) is therefore due largely to coupled ν_1 oscillations with the molecules moving nearly in phase; the 3350-cm^{-1} band is due largely to ν_1 oscillations in which neighboring molecules move out of phase; and the 3260-cm^{-1} band is due largely to ν_3 oscillations whose frequencies are expected to be little influenced by intermolecular coupling, as was argued above. This assignment is summarized in Table 2.

The similarity of the Raman spectra of ice VIII and VII suggests that the Raman spectra of orientationally ordered and disordered ice Ic should also be similar to one another. Therefore, a detailed assignment of disordered ice Ic can be based on an assignment of ordered ice Ic. By an extension of this argument, it seems likely that the spectra of orientationally ordered and disordered ice Ih are also closely related to one another. This argument will be pursued in Section 4.

[5]The frequencies were read from a photocopy of the original of ref. 5, Fig. 6.

[6]Similar spectra are reported at this pressure and 295 K in ref. 4 and 289 K in ref. 5.

TABLE 1. Summary of assignments of the O–H stretching Raman bands of ice VIII

Vibrational form and species	ν/cm^{-1}			
	H_2O			D_2O
	0 kbar, 100 K	31 kbar, 256 K	103 kbar, 118 K	0 kbar, 100 K
$\nu_1 a_{1g}$	3358.8[a]	3277[d]	3030[e]	2462.7[a]
$\nu_1 b_{1g}$	3477.4[a]	3436[d]	3350[e]	2548.0[a]
$\nu_3 e_g$	3447.6[a]	3368[d]	3165[e]	2568.7[a]
$\nu_3 e_u$TO	3445[b]	3382[b]	—	2566[b]

[e]From Fig. 4 of Holzapfel *et al.* (4).

4. Ice Ic and Ih

The Raman spectrum of ice VII is very similar to that of ice Ih and Ic. This is shown in Fig. 1 for ice VII and Ih, and the Raman spectra of ice Ih and Ic are identical to one another within present accuracy in both the Raman (30) and the infrared (32, 37).[4] However, the mercury-excited Raman (30) spectrum did not contain the bands at 3420 (1) and 2515 cm^{-1} (1) in H_2O and D_2O respectively, so it can only be inferred that they are present in ice Ic. The similarity of the structures of ice VII and Ic suggests that the bands of ice Ic can be assigned by analogy with the bands of ice VII. The assignment of ice Ih can then be made by analogy with ice Ic.

4.1. Ordered Ice Ic

Before discussing the actual disordered ice Ic it is worth discussing the hypothetical ordered structure in which the molecular dipoles are parallel to one another. The unit cell is represented by molecules 1 and 2 (or alternatively 3 and 4) in Fig. 2. It is tetragonal and belongs to space group $I4_1md$, C_{4v}^{11} with two molecules in the primitive cell and four in the conventional body-centered cell. It forms one of the interpenetrating substructures of ice VIII, the other being the same structure with its polarity reversed. The molecular site symmetry is C_{2v}, so that the ν_1 and ν_3 vibrations do not couple at the center of the Brillouin zone.

TABLE 2. Assignment of O–H stretching bands of ice VII

ν/cm^{-1}[a]		
25 kbar, 16°C	73 kbar, 22°C	Assignment
~3305	3130 s	ν_1 in-phase
~3400[b]	3260 m	ν_3
~3450[b]	3350 w	ν_1 out-of-phase

[a]From Fig. 6 of Holzapfel *et al.* (4).
[b]These bands are not resolved.

The ν_1 vibrations are split by intermolecular correlation into a $\nu_1 a_1$ and a $\nu_1 b_1$ vibration, and ν_3 forms a degenerate $\nu_3 e$ vibration. Each of these is of course split into a gerade and an ungerade vibration when two such structures are combined to form ice VIII (3) and the corresponding gerade vibrations are active in the Raman spectrum. All the vibrations of ordered ice Ic are active in the Raman, and $\nu_1 a_1$ and $\nu_3 e$ but not $\nu_1 b_1$ are active in the infrared.

The effective charge for the stretching of an O—H bond is (54, 58) 4.0 D $Å^{-1}$ or about 0.8 of an electronic charge, and the direction is uncertain. The zone-center vibrations of ordered ice Ic then split, as one moves from the zone center, into a TO branch whose frequency is little changed from the zone center, and an LO branch, whose frequency is increased by the long-range electric field generated by the vibration. Both the a_1 and the e vibrations have a finite infrared activity and so generate a TO–LO splitting.

The change of refractive index across the O–H stretching vibrations of disordered ice Ih is 0.0308 (54). It will be assumed that the same change of refractive index occurs in disordered ice Ic, whose infrared (32, 37) and Raman (30) spectra are identical within present experimental error with that of ice Ih, and in ordered ice Ih and Ic, which have not yet been prepared.

If the dipole-moment changes caused by stretching the two O—H bonds in ice I are at the

tetrahedral angle to one another, the integrated infrared intensities of the ν_1 and ν_3 bands are the ratio 1 to 2. This implies that the change of refractive index across the $\nu_1 a_1$ band is 0.019 and across the $\nu_3 e$ band is 0.037, where the difference in frequencies has been neglected. The optical refractive index of ice Ih is nearly isotropic, and hence that of ordered ice Ic will be assumed to be so. Then

$$\frac{\nu_1 a_1\text{LO}}{\nu_1 a_1\text{TO}} = 1.015 \qquad \frac{\nu_3 e\text{LO}}{\nu_3 e\text{TO}} = 1.028 \qquad [5]$$

The $\nu_1 a_1$ vibration of ordered ice Ic will surely have a frequency similar to that of the strong Raman band of disordered ice Ih, which is due to ν_1 in-phase vibrations (1). It is therefore at 3083 cm^{-1}. The $\nu_3 e$ is surely the second peak, at 3209 cm^{-1}. It almost coincides with the infrared maximum at 3220 cm^{-1}, as it should because ν_3 is much stronger than ν_1 in the infrared. The $\nu_1 b_1$ frequency can be estimated as follows. Holzapfel *et al.* (4) have plotted the $\nu_1 a_{1g}$, $\nu_1 b_{1g}$, and $\nu_3 e_g$ frequencies of ice VIII against the O--O bond length. When $\nu_1 a_{1g}$ is at 3083 cm^{-1}, $\nu_1 b_{1g}$ is at 3390 cm^{-1} and $\nu_3 e_g$ is at 3210 cm^{-1}. In ordered ice Ic, it is expected therefore that when $\nu_1 a_1$TO is at 3083 cm^{-1} and $\nu_3 e$TO at 3209 cm^{-1}, then $\nu_1 b_1$ would be about 3390 cm^{-1}. From eq. 5 $\nu_1 a_1$LO is predicted to be at 3129 cm^{-1} and $\nu_3 e$LO at 3299 cm^{-1}. These bands and the corresponding bands for D_2O and the methods of obtaining them are listed in Table 3.

TABLE 3. Predicted infrared and Raman bands of ordered ice Ic in space group $I4_1md$, C_{4v}^{11}

Form and species	Optical activity	ν/cm^{-1} H_2O	ν/cm^{-1} D_2O	Isotope ratio
$\nu_1 a_1$TO	R, ir	3083[a]	2295[a]	1.343[a]
$\nu_1 a_1$LO	R, ir	3129[b]	2329[b]	1.343
$\nu_1 b_1$	R	3390[c]	2524[d]	(1.343)[e]
$\nu_3 e$TO	R, ir	3209[a]	2429[a]	1.321
$\nu_3 e$LO	R, ir	3299[b]	2497[b]	1.321

[a]By analogy with ice Ih (1) and ice VIII (3, 4).
[b]Calculated from eq. 5.
[c]By analogy with ice VIII (3, 4).
[d]Calculated from the frequency for H_2O and the quoted isotope ratio.
[e]Assumed the same as for $\nu_1 a_1$TO.

4.2. *Disordered Ice Ic*

The similarity between the spectra of ice VII and VIII suggests that the spectra of disordered and ordered ice Ic will be similar and that the bands of disordered ice Ic can be assigned by analogy with those of ordered ice Ic.

It is important to be clear about what is meant by an assignment of the bands of a highly disordered material; it is not quite the same as the assignment of a perfect crystal. Of course, all the 1.2×10^{24} O–H stretching vibrations per mole of ice are optically active, and so the bands are usually broader than the bands of the crystal. The spectrum is the density of states at each frequency multiplied by a mean intensity function at that frequency. The identification attempted in this paper is a description of the kinds of vibration that dominate the absorption or scattering at a particular frequency and that give rise to recognizable features. No doubt other vibrations overlap in frequency with the recognized features and also contribute to the spectrum and no doubt there is some coupling between ν_1 and ν_3 vibrations, at least in some regions. To identify these more precisely is both an experimental and theoretical problem for the future.

The observed infrared and Raman frequencies of ice Ih and Ic are summarized in Table 4 along with their assignments. The basis of the assignments is as follows.

There seems little doubt that the 3083-cm^{-1} band is due to coupled ν_1 vibrations moving in phase, and corresponds to the $\nu_1 a_1$TO vibration of ordered ice Ic. The corresponding band in ice Ih has already been assigned to these motions (1). The TO–LO splitting is predicted to be only 46 cm^{-1}, and the LO band may be hidden in the high-frequency end of the 3083-cm^{-1} band. The ν_1 in-phase infrared band has its maximum at 3150 cm^{-1}, which is 67 cm^{-1} higher than the Raman maximum. In ordered ice Ic they would coincide. The difference of frequency is no doubt due to the different rules for adding the polarizability-derivative scalars, which determine the Raman intensity, and the dipole-moment-derivative vectors, which determine the infrared intensity. In the vibrations having the maximum infrared intensity, the molecules vibrate in phases that are as much as possible correlated with their orientations, whereas the maximum Raman intensity occurs when the molecules are all in phase (1). The intermolecular coupling constant is negative (33), so the maximum infrared intensity should be somewhat higher than the maximum Raman intensity.

TABLE 4. Assignment of the O–H stretching infrared and Raman bands of ice I

	ν/cm^{-1}[a]					
	H_2O		D_2O		Isotope ratio	
Vibration	Raman[b]	Infrared[c]	Raman[b]	Infrared[c]	Raman	Infrared
ν_1 in-phase[d]	3083	3150	2295	2332	1.343	1.349
ν_3TO	3209	3220	2427	2425	1.322	1.328
ν_3LO	3323	3380	2502[e]	2485	1.343[f]	1.360
ν_1 out-of-phase[d]	3420[g]		2547[g]		1.322[f]	

[a]Frequencies are at 100 K.
[b]From Wong and Whalley (1). References to earlier work are given in that paper.
[c]Many authors have observed these bands. The frequencies quoted are from Bertie and Whalley (32). The 3150-, 3380-, and 2485-cm^{-1} bands are shoulders and the characteristic frequency is to some extent arbitrary.
[d]The adjectives 'in-phase' and 'out-of-phase' mean that the molecules are moving, by and large, in phase and out of phase respectively with their immediate neighbors.
[e]Calculated frequencies using the quoted isotope ratios. They are not experimentally resolved and the Raman maximum is at 2482 cm^{-1}.
[f]Assumed isotope ratios.
[g]Not observed in ice Ic, probably because it is too weak for the technique used, as is the corresponding band of ice Ih.

The strongest infrared band is at 3220 cm^{-1} and undoubtedly corresponds to the $\nu_3 e$ band of ice Ic. The ν_3 vibrations probably occupy a much narrower band than the ν_1 except for the TO–LO splitting, as was shown in Section 3. Accordingly, the 3209-cm^{-1} Raman band is assigned to the same vibration. The difference between the infrared and Raman bands is 11 cm^{-1}, about $\frac{1}{6}$ of the difference between the infrared and Raman ν_1 in-phase bands. This is as expected if the ν_3 vibrational band is much narrower than the ν_1. Because the Raman peak corresponds to vibrations that are nearly in phase it will be taken as the ν_3TO band. The corresponding LO band is therefore predicted to be at 3299 cm^{-1}. There is a weak Raman peak at 3323 cm^{-1} which is therefore identified with ν_3LO. The ν_1 out-of-phase band, corresponding to $\nu_1 b_1$ of ordered ice Ic, should be weak in the Raman spectrum and is assigned to the 3420-cm^{-1} Raman band. A frequency of 3390 cm^{-1} was predicted earlier in this section for ordered ice Ic by analogy with the spectrum of ice VIII. In the infrared spectrum, only a single high-frequency shoulder at 3380 cm^{-1} can be identified with overlapping ν_3LO and ν_1 out-of-phase bands. These assignments are summarized in Table 4.

For a model of ordered ice Ic which includes only nearest-neighbor coupling, the mean of the $\nu_1 a_1$ and $\nu_1 b_1$ frequencies would be the frequency of an uncoupled ν_1 vibration. If this is also true for disordered ice I, as it should be, at least approximately, the uncoupled ν_1 frequency would be 3252 cm^{-1}. The uncoupled O–H stretching frequency is 3273 cm^{-1} (32, 37, 59), which is 22 cm^{-1} higher. In the vapor the corresponding bands differ by 50 cm^{-1}. This difference may be due to a smaller ν_1–ν_3 splitting in the crystal than in the vapor or to the vibrations that contribute to the ν_1 in-phase and out-of-phase bands not having near neighbors moving precisely in phase or out of phase respectively, or to a combination of both. Fifer and Schiffer (60) have shown that the ν_1–ν_3 splitting of water molecules in several metal chloride hydrates is significantly smaller than in the vapor. While the hydrogen bonding in these salts may not be exactly comparable to that in ice I, the observation is consistent with the proposed assignment of ice I.

Longitudinal optic vibrations have occasionally been identified in the past in disordered materials. Fournier *et al.* (61) have identified what appears to be an LO band in the Raman spectrum of liquid carbon tetrafluoride, Devlin *et al.* (62, 63) have identified LO bands in the Raman and attenuated total reflection spectra of orientationally disordered and molten nitrate salts, and Galeener and Lucovsky (64) have identified LO bands in the Raman spectra of vitreous silica and germania. A TO–LO splitting also appears to occur in the translational infrared and Raman spectra of ice I (65). The occurrence of TO–LO splitting in disordered materials appears to be now well established. It presumably means that at least some of the normal vibrations are coupled over significant distances.

The assignment of D_2O follows similar arguments except that the ν_3LO and ν_1 out-of-phase bands appear to overlap, and so their frequencies were calculated from the H_2O

frequencies using the isotope ratios obtained for the ν_3TO and ν_1 in-phase bands respectively. The frequencies are summarized in Table 4.

4.3. Ice Ih

Ice Ih has four molecules in a hexagonal cell. It can be considered as being made from two hexagonal puckered sheets stacked one on top of the other, and two molecules from each sheet make a unit cell. Each sheet has only one ordered arrangement of the protons having two molecules in the repeating unit, and it is shown by either the upper or lower pairs of either Fig. 3*a* or 3*b*. Two equivalent arrangements can be made by rotating the sheet $\pm 2\pi/3$ about a vertical axis through any oxygen atom. Two ordered arrangements of ice Ih in the four-molecule unit can be made by stacking equivalent sheets on top of one another, puckered in the right way, or by alternately stacking rotationally equivalent but not identical sheets. The first gives a C_{2v} structure in space group $Pmc2_1$, C_{2v}^2 shown in Fig. 3*a*, and the second a C_1 structure in space group Pl, C_1 shown in Fig. 3*b*.

In the C_{2v} structure, the molecules are all on sites of C_s symmetry. Two have the plane perpendicular to the molecular plane, so that ν_1 and ν_3 do not couple for these molecules at the zone center. The other two have the plane in the molecular plane, and so symmetry does not forbid the coupling of ν_1 and ν_3.

Both structures have eight Raman-active vibrations, four ν_1 and four ν_3, which may of course couple. The ν_1 in-phase vibration will be particularly strong, and no doubt corresponds to the 3083-cm^{-1} band of ice Ih and Ic. The ν_3 vibrations will be only slightly coupled intermolecularly, and all are active in the Raman. They no doubt correspond to the 3209-cm^{-1} band. Only three ν_3 infrared bands of the C_{2v} structure are allowed, that belonging to the A_2 species being infrared inactive. Hence, a small difference in the infrared and Raman ν_3 frequencies, which is experimentally about 11 cm^{-1}, can be understood. The TO–LO splitting will occur, much as in ice Ic, and the 3323-cm^{-1} Raman band is assigned to ν_3LO. The ν_1 out-of-phase Raman band, which would belong to the A_1 species in C_{2v} ice, no doubt corresponds to the 3420-cm^{-1} band.

It seems likely therefore that this discussion provides an approximation to the assignment of the infrared and Raman bands of ice Ih, and that the assignment in Table 4 applies to disordered ice Ih as well as to Ic. The caveat incorporated into Section 4.2 should of course be kept in mind.

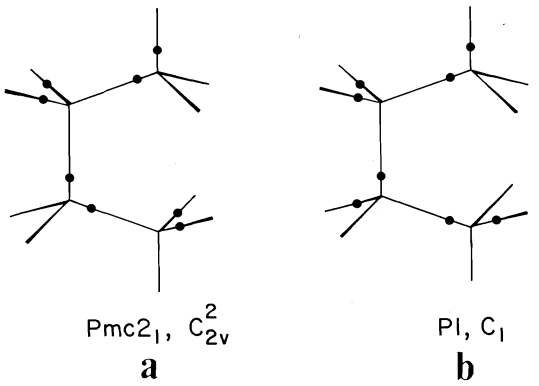

FIG. 3. The two ordered arrangements of the water molecules in the four-molecule unit cell of ice Ih and their symmetry species.

Although ice Ih (43, 44) and Ic appear[7] to be fully disordered within the restrictions of the ice rules, there is still a good deal of order. If there were no correlation of the orientations of neighboring molecules, the mean value of the reduced scalar product $(\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)/\mu^2$ of the dipole moments of near-neighbor molecules 1 and 2 would be zero, and if it were fully ordered it would be 1. As the orientations are fully disordered within experimental uncertainty and within the limits of the ice rules, the product is $\frac{1}{3}$. Perhaps this large amount of local order is partly responsible for the visibility of particularly the Raman bands of ice I.

5. Amorphous Ice

The infrared (31, 32, 37, 68, 69) and Raman (29, 35, 70) spectra of amorphous ice have been investigated several times, and typical spectra are reproduced in Fig. 1. The infrared H_2O and D_2O spectra are from Buontempo (68) and Bertie and Whalley (32) respectively, and the Raman spectra are from Venkatesh *et al.* (29). The spectra of others are in substantial agreement. They are all similar to the spectra of ice Ih, the main differences being an increase in frequency, due no doubt to the distortion of the hydrogen bonds and an increased band width. The increase in band width is partly due to the variable distortion of the bonds, which causes a variation of the frequencies of the O–H oscilla-

[7]The similarity of the low-frequency permittivities of ice Ih and Ic (67) shows this.

TABLE 5. Assignment of the infrared and Raman bands of amorphous ice

	ν/cm^{-1}[a]					
	H_2O		D_2O		Isotope effect	
Vibration	Raman[b]	Infrared[c]	Raman[b]	Infrared	Raman	Infrared
ν_1 in-phase	3116	3191	2318		1.344	1.377
ν_3TO	3220	3253	3281	2436	1.352	1.366
ν_3LO	3372	3367	2483	2499	1.358	1.347
ν_1 out-of-phase	3483		2530		1.377	

[a]Frequencies are at ~100 K.
[b]As resolved using Gaussian line shapes by Venkatesh *et al.* (29). The frequencies are somewhat arbitrary because the band is a product of a density of states and an intensity, and there is no reason to assume it is a sum of a limited number of Gaussian bands.
[c]Frequencies taken from Hardin and Harvey (37). The spectra of D_2O (32) and H_2O (68) agree.

tors (32), and perhaps to a decrease in the extent of the intermolecular coupling, so that small variations of the extent from vibration to vibration will cause a variation of frequency. It appears (2) that the frequency of the in-phase ν_1 vibrations that dominate the low-frequency Raman peak at 3108 cm^{-1} at 30 K is not significantly broadened from its width in ice Ih by a decrease of coupling, but it is not known whether the other bands behave similarly.

The similarity of the crystalline and amorphous bands strongly suggests that they have similar causes. Consequently they can be assigned by analogy with the assignments of ice I, as given in Table 5.

6. Ice VI

The Raman spectrum of ice VI (5) at 14 kbar and 292 K resembles the spectrum of ice I, but the bands are broader, and are more like the bands of amorphous ice. Their centers are at ~3180, 3310, and 3400 cm^{-1}, and there may be a significant band at ~3500 cm^{-1}. At atmospheric pressure and 77 K the strong Raman band is (51) at 3204 cm^{-1} in H_2O and 2370 cm^{-1} in D_2O. By analogy with ice I, the bands can be assigned to ν_1 in-phase, ν_3(TO), and ν_1 out-of-phase mixed with ν_3(LO), in order of increasing frequency.

7. Discussion

It appears that a fairly detailed justifiable assignment of a quite complicated spectrum of a highly disordered material has been achieved, perhaps for the first time. The most likely avenue for further progress on ice is lattice dynamical calculations on ordered and eventually, but with much more difficulty, on disordered ice. Two calculations have been published, one (71) on the C_{2v} ordered ice in the four-molecule cell and one (46) on disordered ice. Both, however, used too little intermolecular O–H coupling, and so result in two too narrow and nonoverlapping bands of ν_1 and ν_3 vibrations.

One of the conclusions from this work is that the spectra of disordered phases are frequently closely related to the spectra of the corresponding crystalline phases, and in the O–H stretching region in ice I there appears to be almost a one-to-one correspondence. The correspondence extends even to the longitudinal vibrations, whose frequencies in the crystal are raised above the frequencies of the corresponding transverse vibrations by the long-range electric field in a well understood way (55). Their existence in disordered phases is less well understood.[8] When a crystal is disordered, the integrated infrared intensity of its strong bands is not markedly changed. The transition-moment coupling that causes the TO–LO splitting in the crystal is therefore still present with about the same magnitude. It will cause a long-range coupling of the atomic motions, and so also of course will the short-range forces which will also cause a finite range of coupling of the motions (46, 57, 66). The vibrational spectra of models of disordered solids resemble in general features the spectra of models of the corresponding crystals (46, 57, 66) and it appears that for most of the vibrations "the localization, although somewhat higher than for a crystalline solid, is by no means intense" (57). If this is so, it seems likely that many of the vibrations will have a significant plane-wave component of finite extent and can be approximately characterized by a local wave

[8]See the comments of E. Galeener appended to the paper by Galeener and Lucovsky (56).

vector. There will be vibrations in which the polarization is mainly parallel or respectively perpendicular to the wave vector, and so there will be local LO and TO vibrations having approximately the same separation as in the crystal.

It appears therefore that the appearance of LO vibrations in highly disordered solids can be understood, at least on a qualitative and somewhat intuitive level.

8. Summary

The arguments and conclusions of this paper can be summarized as follows.

1. The O–H stretching bands of ice are strongly coupled and can only be understood in detail from the point of view of solid-state spectroscopy, not from single-molecule spectroscopy.

2. Ice VIII is composed of two interpenetrating ordered ice Ic structures. Its experimental Raman and predicted infrared spectra have been used to predict the Raman and infrared spectra of ordered ice Ic.

3. Ice VII is an orientationally disordered ice VIII whose Raman spectrum has similar features to that of ice VIII. An assignment of the ice VII bands follows from the assignment of the ice VIII bands.

4. The similarity of the spectra and assignments of ice VIII and VII suggests that there will be a corresponding similarity in the spectra and assignments of ordered and disordered ice Ic. This allows the bands of disordered ice Ic to be assigned in some detail.

5. The infrared and Raman spectra of ice Ih and Ic are indistinguishable at present accuracy, and so the ice Ih bands can be assigned by analogy with the ice Ic bands.

6. The high infrared intensity of the O–H stretching bands of ice requires that there shall be strong TO–LO splitting of the bands of ordered ice Ic, particularly of the $\nu_3 e$ band. The bands in ordered ice Ih should be split in a similar way. A band that can be considered to be derived from the $\nu_3 e$(LO) band of ordered ice has been identified in the Raman and infrared spectra. The ν_1 bands should also show LO–TO splitting, perhaps by a smaller amount, but their effects have not been observed. The assignments are summarized in Table 4.

7. The corresponding bands in amorphous ice and ice VI have been assigned by analogy with the assignment for ice Ih and Ic.

J. P. QUAEGEBEUR, B. PERLY, G. SURPATEANU et A. LABLACHE-COMBIER. Can. J. Chem. **55**, 3442 (1977).

L'analyse des spectres de rpe de la pyridine *N*-oxyde soumise au rayonnement γ, en matrice vitreuse méthanolique à 77 K montre la présence d'un mélange de radicaux 2 et 4-azacyclohexadienyles *N*-oxydes (respectivement **1** et **2**), formés par addition de l'espèce primaire hydroxyméthyle sur le cycle pyridinique. La détermination de la structure des différents radicaux a été facilitée par l'utilisation de pyridines *N*-oxydes substituées.

J. P. QUAEGEBEUR, B. PERLY, G. SURPATEANU, and A. LABLACHE-COMBIER. Can. J. Chem. **55**, 3442 (1977).

The analysis of esr spectra derived from γ irradiated pyridine *N*-oxide in a methanolic vitreous matrix at 77 K shows the presence of a mixture of 2- and 4-azacyclohexadienyl *N*-oxide radicals (respectively **1** and **2**) formed by the addition of the hydroxymethyl primary species to the pyridine ring. The structure of the different radicals was determined by comparison with spectra derived from several substituted pyridine *N*-oxides.

Introduction

Les radicaux libres dérivés des composés hétérocycliques azotés, générés aussi bien sous rayonnement γ que par photolyse ont fait l'objet de nombreux travaux (par ex. réf. 1). Dans le cadre de l'étude des effets des radiations sur la pyridine et ses dérivés, nous nous proposons d'examiner les espèces radicalaires formées à partir de la pyridine *N*-oxyde (py *N*-O), dans le but de mettre en évidence l'influence du groupement *N*-oxyde sur la réactivité du cycle pyridinique. La radiolyse à 77 K de ce composé en matrice méthanolique vitreuse donne naissance aux espèces primaires $\cdot CH_2OH$ lesquelles, par addition sur les molécules de soluté engendrent un nouveau radical dont le spectre de rpe semble différent de ceux obtenus à partir de la pyridine.

Afin d'identifier ce nouveau radical et d'élucider le mécanisme de sa formation, des études complémentaires effectuées sur différentes py *N*-O deutérées sélectivement ou méthylées ont été effectuées et ont permis de mettre en évidence la non sélectivité de l'addition du groupement hydroxyméthyle sur le cycle pyridinique.

Mode expérimental

Les expériences de rpe ont été effectuées à l'aide d'un spectromètre Varian V 4502, en bande **X**, avec une fréquence de modulation de 100 kHz. Les échantillons dégazés et scellés sous vide ont été irradiés à 77 K à l'aide d'une source ^{60}Co de 10 kCi (doses de 1 à 2 Mrad). Les spectres ont été enregistrés à 90 K après réchauffement des échantillons vers 115 K, afin de faire disparaître les radicaux provenant de la matrice.

La dideutéro-3,5 pyridine *N*-oxyde ($^2H_2$-3,5 py *N*-O) a été préparée par oxydation de la $^2H_2$-3,5 pyridine (dont la synthèse a été décrite dans la référence 1*c*) par l'acide peracétique suivant la méthode mentionnée dans la réf. 2. La lutidine-3,5 *N*-oxyde a été préparée à partir de la 3,5 lutidine de la même façon. La 2,6 dideutero pyridine *N*-oxyde ($^2H_2$-2,6 py *N*-O) a été synthétisée suivant la méthode décrite par Hershenson et Bauer (3). La pureté isotopique de ces composés a été vérifiée par spectroscopie rmn à 60 MHz (Jeol C 60 HL) ou 250 MHz (Cameca TSN 250). Les autres dérivés méthylés de la pyridine *N*-oxyde, provenant de chez Aldrich, ont été utilisés sans purification préalable.

Identification des spectres de résonance paramagnétique électronique

A 77 K, les signaux de rpe obtenus sous irradiation γ de la py *N*-O en concentration 0.3 *M* en matrice vitreuse CH_3OH (ou CD_3OD) sont attribués exclusivement aux radicaux issus du solvant, c'est à dire $\cdot CH_2OH$ et $\cdot CD_2OD$

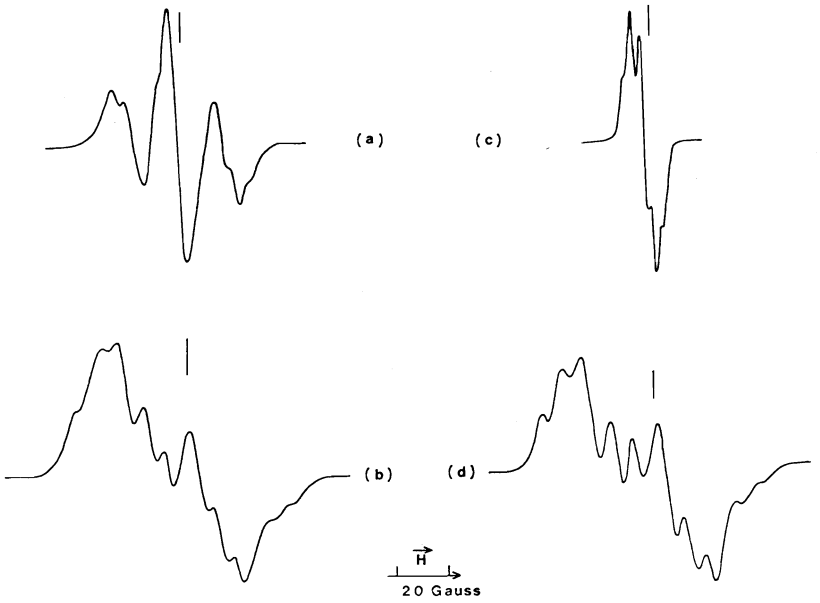

FIG. 1. Spectres rpe après irradiation à 77 K de la py *N*-O en matrice CH_3OH (spectres de gauche) et CD_3OD (spectres de droite). (*a*) et (*c*): respectivement des radicaux $\cdot CH_2OH$ et $\cdot CD_2OD$ (enregistrés à 90 K avant réchauffement de l'échantillon). (*b*) et (*d*): enregistrés à 90 K après réchauffement vers 115 K. Trait vertical: $g = 2.0028$.

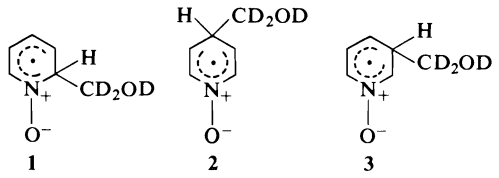
respectivement. Lors du réchauffement de l'échantillon de 90 à 115 K, nous assistons à une décroissance progressive de ce signal puis ensuite à l'apparition d'un nouveau signal (fig. 1) avec conservation du paramagnétisme. Cette dernière constatation, ainsi que l'allure générale du spectre dont la structure hyperfine principale se compose d'un doublet partiellement structuré nous permettent d'envisager une espèce radicalaire différente de celles obtenues à partir de la pyridine dans diverses conditions (1*b*, *c* et *d*).

Par ailleurs, la deutération de la matrice ne se manifeste que par une diminution légère de la largeur de raie, sans modification notable du spectre de rpe (fig. 1), ce qui nous permet de supposer que le radical obtenu dans ces conditions provient d'une addition du groupement $\cdot CH_2OH$ (ou $\cdot CD_2OD$) sur le cycle pyridinique et peut être assimilé à un radical du type aza-cyclohexadiényle substitué.[1] Trois espèces radicalaires peuvent être envisagées, selon que l'addition de $\cdot CD_2OD$ se fait en position 2, 4 ou 3 par rapport à l'azote (numérotation cf. tableau 2).

[1]Le groupement hydroxyméthyle ne contribuant pas au spectre, CD_3OD a été utilisé comme solvant dans les expériences suivantes.

L'attribution du spectre provenant de la py *N*-O a été effectuée par comparaison avec ceux issus de différents dérivés deutérés ou



méthylés. Les différentes constantes de couplage ont été déduites des largeurs totales et des seconds moments des spectres de rpe (4), dont l'analyse a été décrite précédemment (5). La validité des attributions a été vérifiée par calcul INDO des densités de spin. La simulation des spectres a été effectuée d'après le programme de Lefebvre et Maruani (6), en tenant compte de l'anisotropie du couplage des protons σ et du tenseur **g**. Les différents paramètres ont été légèrement modifiés jusqu'à obtenir un accord satisfaisant entre les spectres calculés et expérimentaux.

Compte tenu de la délocalisation partielle de la densité de spin sur l'atome d'oxygène, conduisant à un paramètre de couplage spin–orbite important, nous avons déterminé les composantes principales $g_{\parallel}$ et $g_{\perp}$ du tenseur **g**.

En supposant que ce dernier est à symétrie axiale, $g_{\|}$ est donné par la position moyenne des deux raies extrêmes du spectre et sera pris comme la composante la plus petite, perpendiculaire au plan du cycle ($g_{\|} = g_{xx}$) (7). Les composantes $g_{\perp}$ ne pouvant être déterminées directement à partir du spectre, nous avons calculé la valeur isotrope g_{iso} de **g** à partir du premier moment mesuré par rapport à H_0:

$$[1] \qquad M_1 = -H_0(g_{iso}/g_0 - 1)$$

où $H_0 = 3320$ G et g_0 la valeur correspondante de **g** étant égale à 2.0028.

La valeur moyenne de M_1 étant (-4.41 ± 0.20) G, il s'en suit $g_{iso} = 2.0055 \pm 0.0004$; par suite comme $g_{\|} = 2.0028$, $g_{\perp} = \frac{1}{2}(3g_{iso} - g_{\|}) = 2.0068 \pm 0.0004$. La contribution au second moment de l'anisotropie du tenseur **g** est alors égale à (6):

$$[2] \quad \langle \Delta H^2 \rangle_g = (H_0{}^2/5)\{\varepsilon_{xx}{}^2 + \varepsilon_{yy}{}^2 + \varepsilon_{zz}{}^2 + \tfrac{2}{3}(\varepsilon_{xx}\varepsilon_{yy} + \varepsilon_{yy}\varepsilon_{zz} + \varepsilon_{zz}\varepsilon_{xx})\}$$

avec $\varepsilon_{uu} = g_{uu}/g_0 - 1$ ($u = x$, y ou z) et g_{uu} étant la composante principale de **g** suivant l'axe u soit

$$\langle \Delta H^2 \rangle_g \simeq (20 \pm 4)\ \mathrm{G}^2$$

Ces valeurs principales du tenseur **g** sont voisines de celles des radicaux nitroxydes pour lesquels $g_{\|} = g_{xx} \simeq 2.0030$ et $g_{iso} \simeq 2.0060$. Différents calculs INDO effectués sur les formes **1**, **2** et **3** (tableau 2) font apparaitre tout d'abord que l'addition de $\cdot CD_2OD$ en position 3 par rapport à l'azote conduirait à un spectre de rpe dont la largeur totale serait voisine de 95 G et le second moment M_2 supérieur à 440 G^2, valeurs incompatibles avec les résultats expérimentaux.

Le choix entre les espèces **1** et **2** semble plus difficile: en particulier les densités de spin voisines dans les deux cas (cf. tableau 2) fourniraient des spectres de rpe identiques, hypothèse vérifiée ultérieurement lors de la simulation des spectres. Nous envisagerons dans un premier temps, l'existence d'une espèce radicalaire du type **1**.

Les constantes de couplage $a^H{}_3$ et $a^H{}_5$ sont déterminées par la comparaison des largeurs totales et seconds moments de la py *N*-O et de son dérivé deutéré en 3 et 5 ($^2H_2$-3,5 py *N*-O) (tableau 1). En supposant que les densités de spin portées par les carbones C_3 et C_5 sont pratiquement égales,

$$\Delta(\Delta H) = (86 - 75)\ \mathrm{G} = 2(a^H{}_3 - 2 \times a^D{}_3)$$

soit, comme $a^D \sim 0.154a^H$,

$$|a_3| \sim |a_5| \sim (8 \pm 0.5)\ \mathrm{G}$$

Des valeurs du même ordre sont retrouvées en comparant les résultats expérimentaux de la py *N*-O et de la diméthyl-3,5 py *N*-O. Dans ce cas la largeur totale est augmentée de:

$$[3] \qquad \Delta(\Delta H) = 2(3 \times a^H{}_{CH_3} - a^H{}_3)$$

En supposant d'autre part que la substitution des protons par les groupements méthyles ne modifie pas de manière appréciable la répartition des densités de spin, le second moment est accru de:

$$[4] \quad \Delta(M_2) = 2\left\{-\frac{3.5}{12}(a^H{}_3)^2 + \tfrac{3}{4}(a^H{}_{CH_3})^2\right\}$$

si

$$\rho_3 = a^H{}_3/Q^H{}_{\alpha 3} = a^H{}_{CH_3}/Q^H{}_{CH_3}$$

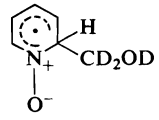
avec $Q^H{}_{\alpha} = -23$ G et $Q^H{}_{CH_3} = 28$ G, nous en déduisons

$$|a_3| \sim |a_5| \sim (7.0 \pm 0.5)\ \mathrm{G}$$

$$|\rho^{\pi}{}_3| \sim |\rho^{\pi}{}_5| \sim (0.30 \pm 0.02)$$

Les spectres expérimentaux provenant des 2 et 4 picolines *N*-oxydes étant sensiblement identiques (fig. 3) et leurs caractéristiques voisines de celles de la py *N*-O, les constantes de couplages $a^H{}_4$ et $a^H{}_2$ (ou $a^H{}_6$), dans l'hypothèse des espèces du type **1** ou **2**, sont du même ordre de grandeur et inférieures à la largeur de raie σ: $|a_2| \sim |a_4| < 2$ G.

Il est alors possible, dans le cas du radical



1

d'estimer approximativement la densité de spin $\rho_N{}^{\pi}$ ainsi que la constante de couplage isotrope $a^H{}_2$, à partir de ΔH et M_2. En incluant $a^H{}_4$ et

TABLEAU 1. Largeurs totales (ΔH) et seconds moments (M_2) des spectres de rpe des radicaux azacyclohexadienyles *N*-oxydes (matrice CD_3OD)

Composé	ΔH/G	M_2/G²*

*Mesurés par rapport à $g = 2.0028$ à $T = 90$ K après réchauffement de l'échantillon à 115 K.

TABLEAU 2. Densités de spin et constantes de couplage données par calcul INDO des radicaux azacyclohexadienyles *N*-oxydes

Radical	Position	Densités de spin Π	Constantes de couplage (G) INDO*	Valeurs expérimentales	Valeurs optimisées pour la simulation des spectres
 **1**	1	0.340	$a_N = 9.23$	$\begin{cases} A_{N\parallel} = 18.7 \\ A_{N\perp} = 3.3 \end{cases}$	$\begin{cases} A_{N\parallel} = 20 \\ A_{N\perp} = 3.5 \end{cases}$
	2	—	$a^H_{iso} = 24.8$	$a^H_{iso} = 27.4$	$a^H_{iso} = 27.5$
	3	0.240	$a^H = -6.94$	$\lvert a^H\rvert = 8.0 \pm 0.5$	$a^H = -8$
	4	−0.164	$a^H = 4.35$	$a^H < 2$	$a^H = 1.2$
	5	0.236	$a^H = -6.35$	$\lvert a^H\rvert = 8.0 \pm 0.5$	$a^H = -7.2$
	6	−0.252	$a^H = 5.96$	$a^H < 2$	$a^H = 1.5$
	7	0.468			$\begin{cases} g_\parallel = 2.0028 \\ g_\perp = 2.0064 \end{cases}$
 **2**	1	0.285	$a_N = 6.47$		$\begin{cases} A_{N\parallel} = 20 \\ A_{N\perp} = 3.5 \end{cases}$
	2,6	−0.178	$a^H = 4.32$		$a^H = 1.5$
	3,5	0.214	$a^H = -6.27$		$a^H = -7.5$
	4	—	$a^H_{iso} = 21.7$		$a^H_{iso} = 27.5$
	7	0.520			$\begin{cases} g_\parallel = 2.0028 \\ g_\perp = 2.0064 \end{cases}$
 **3**	1	−0.204	$a_N = -6$		
	2	0.573	$a^H = -14.7$		
	3	—	$a^H_{iso} = 44.8$		
	4	0.428	$a^H = -11.7$		
	5	−0.201	$a^H = 6.09$		
	6	0.44	$a^H = -11.1$		
	7	−0.31			

*Les valeurs des distances interatomiques et des angles de liaison utilisées dans ces calculs sont données dans la réf. 8, en supposant la liaison N—O située dans le plan du cycle et l'angle θ (cf. texte) égal à 50°.

a^H_6 dans la largeur de raie σ,

[5] $$\Delta H - \sigma - a^H_3 - a^H_5 = 2A_{N\parallel} + a^H_2$$

soit

$$2A_{N\parallel} + a^H_2 \sim 65 \text{ G}$$

De même, la contribution des couplages hyperfins au second moment étant (4):

$$M_2 - \langle \Delta H^2 \rangle_g - \sigma^2/4 = \langle \Delta H^2 \rangle_{hf} = \tfrac{1}{3} \sum_i \sum_u n_i S_i A_{ui}^2$$

il s'en suit:

[6] $$(2/9)(A_{N\parallel}^2 + 2A_{N\perp}^2) + (1/4)(a^H_2)^2 \sim 278 \text{ G}^2$$

Les valeurs principales du tenseur de couplage de l'azote sont reliées à ρ_N^Π par:

[7] $$A_{N\parallel} = a_N + 2B \sim 62\rho_N^\Pi$$

[8] $$A_{N\perp} = a_N - B \sim 11\rho_N^\Pi$$

Dans ces expressions, dans la limite des incertitudes expérimentales, nous avons négligé la contribution $S^N\rho_N^\Pi$ de l'orbitale 1*s* de l'azote ainsi que l'interaction entre les noyaux N et O, si bien que

$$a_N \sim Q_N^N \rho_N^\Pi$$

Le couplage isotrope a^H_2 est relié aux densités de spin ρ_3^Π et ρ_N^Π portées par les atomes adjacents, par la relation (9):

[9] $$a^H_2 = Q(\rho_3^{1/2} + \rho_N^{1/2}) \cos^2 \theta$$

où $Q = (58 + 55)/2 = 56.5$ G et θ est l'angle que fait le plan $(C_3C_2H_2)$ ou (NC_2H_2) avec l'axe de l'orbitale de l'e^- non apparié, en admettant que la liaison N—O se trouve dans le plan du cycle.[2]

La substitution de [7], [8] et [9] dans [5] et [6] nous fournit ainsi $|\rho_N| \sim 0.303$ et $\theta \sim 50°$.

Dans l'hypothèse du radical **2** et en supposant que ρ_N reste du même ordre (cf. calcul INDO du tableau 2), nous obtenons $\theta = 51°$.

La validité de nos résultats est confirmée par simulation des spectres de rpe des radicaux

[2]Nous avons démontré, par calcul INDO que la distribution de densités de spin et l'énergie électronique totale n'étaient que faiblement affectées par l'inclinaison $\alpha (0 < \alpha < 20°)$ du groupement N—O par rapport au plan du cycle.

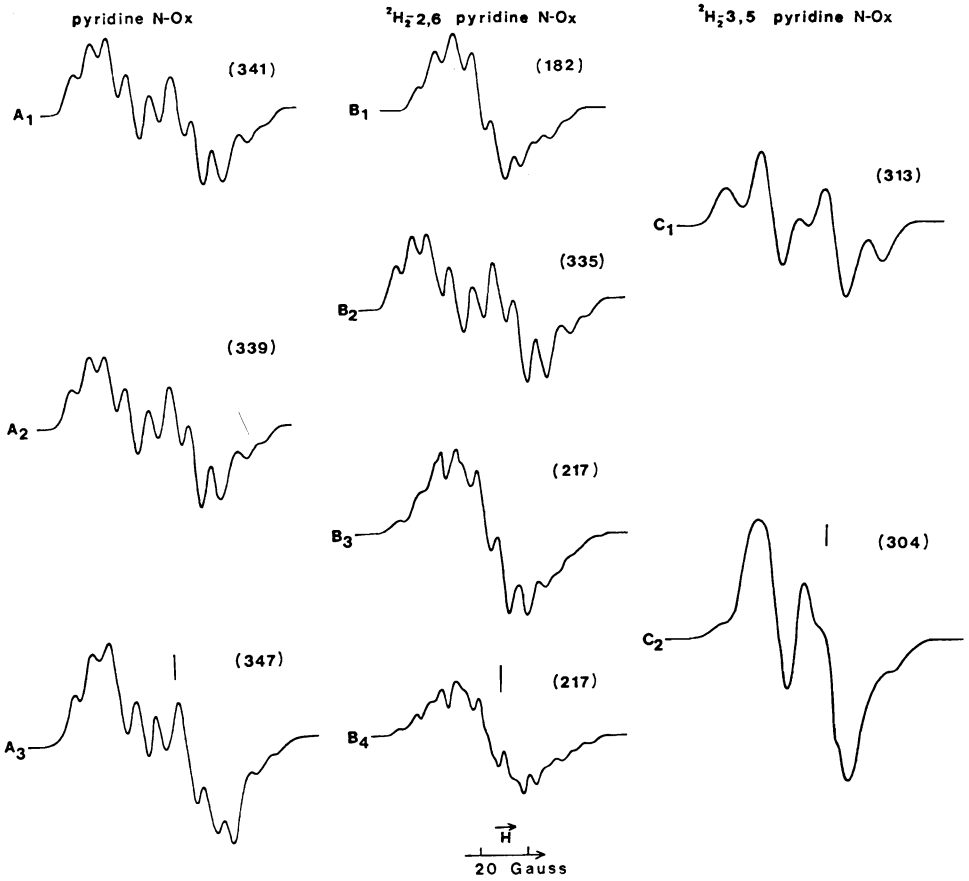

FIG. 2. Spectres rpe expérimentaux et calculés des radicaux azacyclohexadiényles *N*-oxydes (matrice: CD_3OD). A_3, B_4 et C_2: spectres expérimentaux. A_1 et A_2: spectres calculés correspondant aux espèces **1** et **2** respectivement (cf. tableau 2). B_1 et B_2: spectres calculés correspondant aux radicaux **4** et **5**. B_3 résulte de la superposition de B_1 et B_2 dans les proportions respectives 2:1. C_1: spectre calculé correspondant au radical **1**. Entre parenthèses figurent les seconds moments. Trait vertical: $g = 2.0028$.

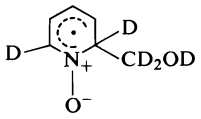
1 et **2** (figs 2 et 3), pour lesquels les paramètres optimisés figurent dans le tableau 2. Il apparait ainsi que les spectres calculés des radicaux **1** et **2** sont pratiquement semblables de sorte que nous ne pouvons conclure à la présence préférentielle de l'une ou de l'autre espèce. Le cas de la $^2H_2$-2,6 py *N*-O permet de lever cette ambiguité. En admettant l'existence de la seule espèce **4** formée dans ces conditions,



4

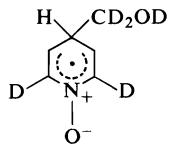
la largeur et le second moment théoriques, calculés à partir des caractéristiques $\langle \Delta H \rangle_{\text{py } N\text{-O}}$ et $\langle M_2 \rangle_{\text{py } N\text{-O}}$ du spectre de py *N*-O sont respectivement égales à:

$$\langle \Delta H \rangle = \langle \Delta H \rangle_{\text{py } N\text{-O}} - a^{\text{H}}{}_2 + 2a^{\text{D}}{}_2 = 66 \text{ G}$$

et

$$\langle M_2 \rangle = \langle M_2 \rangle_{\text{py } N\text{-O}} - \tfrac{1}{4}(a^{\text{H}}{}_2)^2 + \tfrac{2}{3}(a^{\text{D}}{}_2)^2 = 163 \text{ G}^2$$

De la même façon, les caractéristiques du spectre de rpe d'un radical du type **5**



5

seraient voisines de 84 G et 335 G^2 respectivement. Ces valeurs théoriques des seconds moments ne sont pas compatibles avec M_2 expérimental = 217 G^2. De plus les spectres

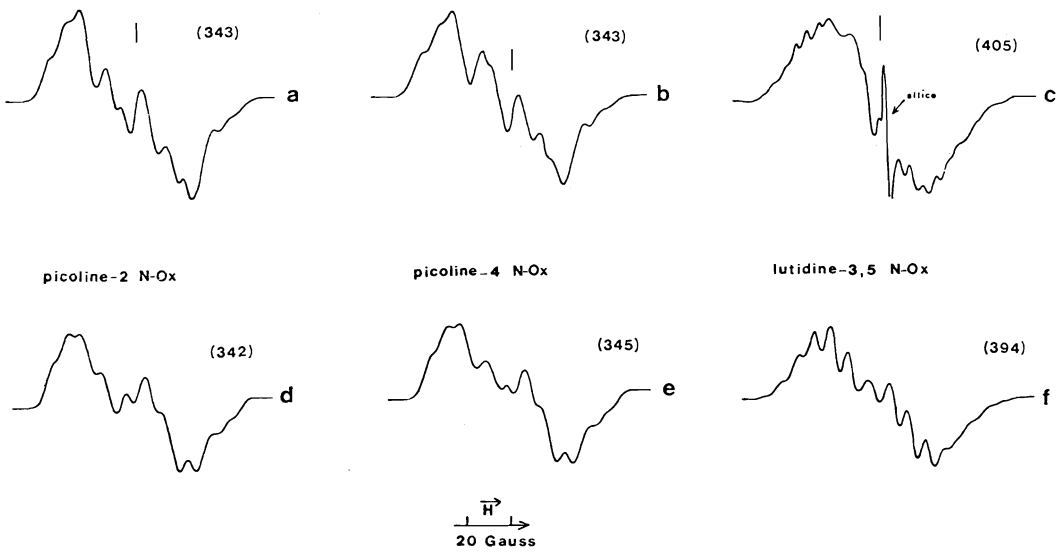


FIG. 3. Spectres rpe expérimentaux (ligne du haut) et calculés (ligne du bas) des radicaux dérivés des méthyl pyridines *N*-oxydes, avec leurs seconds moments correspondants. (*a*): Radicaux **1** et **2**; (*b*): radical **1**; (*c*): radicaux **1** et **2**. Trait vertical: $g = 2.0028$.

calculés pour les formes **4** et **5** ne correspondent pas précisément au spectre expérimental obtenu à partir de la $^2H_2$-2,6 py *N*-O (fig. 2). En supposant alors que l'addition du groupe hydroxyméthyle se fasse sur les positions 2 (ou 6) et 4, nous aurons un mélange des radicaux **4** et **5** dans les proportions respectives 2:1.

Ce rapport est effectivement celui obtenu en appliquant la règle d'additivité des seconds moments:

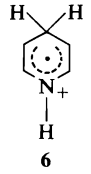
$$M_{2\text{exp}} = x(M_2)_{(5)} + (1 - x)(M_2)_{(4)}$$

soit

$$x \sim 0.31$$

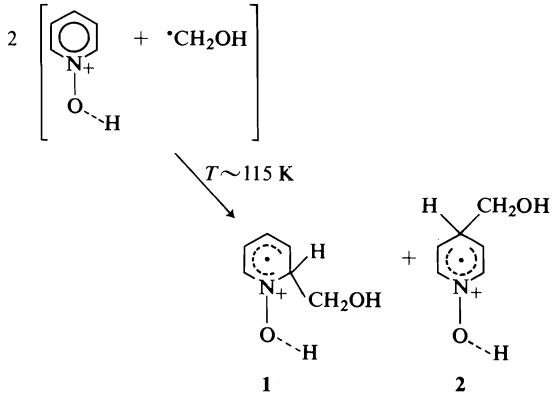
Une vérification supplémentaire de notre hypothèse est apportée par la comparaison entre le spectre expérimental provenant de la $^2H_2$-2,6 py *N*-O et celui obtenu par addition des spectres calculés des radicaux **4** et **5** dans ces proportions relatives (fig. 2).

Il devient alors possible, compte tenu des données rassemblées pour les différents radicaux étudiés, d'attribuer avec plus de certitude les spectres de rpe obtenus. En particulier dans le cas de la py *N*-O et de ses dérivés 3–5 disubstitués, et 2–6 dideutéré nous obtenons les deux espèces correspondantes **1** et **2** dans les proportions 2:1, alors que l'addition de $^{\cdot}CD_2OD$ se fait préférentiellement en position 2 (ou 6) dans la methyl-4 py *N*-O, et en position 4 dans le cas de la methyl-2 py *N*-O (fig. 3). Ce résultat est différent de ceux obtenus par Symons et coll. (1*a*) lors de la radiolyse de l'ion pyridinium. Dans ce dernier cas l'addition de H sur le cycle se faisait exclusivement en position 4 pour donner naissance au radical 4-azacyclohexadienyle **6.**



6

Dans le cas de la py *N*-O, la non sélectivité de la réaction serait induite par le groupe *N*-oxyde lequel favoriserait l'attaque sur les positions 2 et 4 de densités électroniques faibles. Ceci suggère que le groupement hydroxyméthyle piégé dans la matrice possède un caractère nucléophile faible:



1 **2**

Conclusion

Bien qu'un accord satisfaisant entre les spectres expérimentaux et ceux calculés ait nécessité l'introduction d'une anisotropie du tenseur **g** dont la détermination des composantes principales reste assez approximative, les résultats obtenus par simulation des spectres de rpe et par la méthode des moments confirment notre hypothèse concernant l'existence d'un mélange de deux radicaux. Cependant nous n'avons pu détecter ces radicaux lors de l'irradiation uv en phase liquide et à température ambiante d'une solution 10^{-3} *M* de py *N*-O dans CH_3OH + 1% H_2O_2, selon la méthode de Livingston et Zeldes (10) à cause de la durée de vie trop courte de l'espèce primaire $\cdot CH_2OH$ ou parce que la transformation des espèces **1** et **2** en une molécule stable diamagnétique est beaucoup plus rapide que celle de la formation des radicaux.

Remerciements

Les auteurs tiennent à remercier le Dr. Chachaty du CEN/SACLAY pour ses suggestions et ses remarques qui nous ont été très utiles.

Ligand substitution kinetics of nickel(II) ion in *N,N*-dimethylformamide

PRAPHULLA KUMAR CHATTOPADHYAY AND BYRON KRATOCHVIL

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 20, 1977

PRAPHULLA KUMAR CHATTOPADHYAY and BYRON KRATOCHVIL. Can. J. Chem. **55**, 3449 (1977).

Rate constants and activation parameters for formation of the monocomplexes of Ni(II) ion with several mono-, bi-, and terdentate ligands in *N,N*-dimethylformamide were obtained by stopped-flow spectrophotometry. The gross features of substitution for all the ligands studied could be accommodated within the structure of an I_d-type mechanism. 4-Phenylpyridine behaves most 'normally', and 1,10-phenanthroline stabilized most strongly outer-sphere complex formation with Ni(II). Comparison of these data with previously reported work by other authors for substitution at Ni(II) in acetonitrile with the same ligands indicates that in dimethylformamide pyridine-type ligands generally affect the stability of metal–ligand outer-sphere complexes less dramatically than in acetonitrile. Hammett correlation is observed for 1,10-phenanthroline and its 5- and 5,6-substituted derivatives. The slope of the Hammett correlation plot in dimethylformamide is in the order of -0.2, about half the value of -0.4 reported previously in acetonitrile by other authors. This indicates that the stability of the metal–ligand outer-sphere complex is affected more greatly by small differences in the electronic nature of the coordinating substituted 1,10-phenanthrolines in acetonitrile than it is in dimethylformamide.

PRAPHULLA KUMAR CHATTOPADHYAY et BYRON KRATOCHVIL. Can. J. Chem. **55**, 3449 (1977).

On obtient, par spectrophotométrie à flux stoppé, les constantes de vitesse et les paramètres d'activation pour la formation de monocomplexes d'ion Ni(II) avec plusieurs ligands mono-, bi- et terdentate dans la *N,N*-diméthylformamide. Les traits caractéristiques de la substitution pour tous les ligands étudiés peuvent être assimilés à l'intérieur d'un mécanisme de type I_d. La phényl-4 pyridine se comporte le plus souvent 'normalement' et la phénanthroline-1,10 stabilise plus fortement la formation d'un complexe à sphère extérieure avec le Ni(II). La comparaison de ces valeurs avec celles rapportées antérieurement par d'autres auteurs pour la substitution au site Ni(II) dans l'acétonitrile avec les mêmes ligands indique que pour les ligands de types pyridine dans la diméthylformamide, la stabilité des complexes métal–ligand aux sphères extérieures est moins affectée que dans l'acétonitrile. On observe une corrélation d'Hammett pour la phénanthroline-1,10 et ses dérivés 5- et 5,6-substitués. La pente de la courbe pour la corrélation d'Hammett dans la diméthylformamide est de l'ordre de -0.2 correspondant à environ la moitié de la valeur -0.4 rapportée antérieurement par d'autres auteurs pour l'acétonitrile. Ces résultats indiquent que la stabilité des complexes métal–ligand aux sphères extérieures est affectée plus grandement par de petites différences dans la nature électronique des phénanthrolines substituées si la coordination se produit dans l'acétonitrile que si elle se produit dans la diméthylformamide.

[Traduit par le journal]

Introduction

N,N-Dimethylformamide is an important dipolar aprotic solvent frequently used as a reaction medium for inorganic and organic reactions because of its ability to solvate both metal ions and nonpolar organic compounds. In recent years considerable data have been collected on metal–ligand equilibria and reaction rates in a variety of solvents, especially between nickel(II) and amines, and it has been found that a dissociative-interchange (I_d) type mechanism (1) fits the rate data for the reaction of nickel(II) with simple mono-dentate ligands in water (2), methanol (3), ethanol (4), acetonitrile (5), and propylene carbonate (6). Little data are available in dimethylformamide, however, and the mechanism of substitution at nickel(II) in this solvent has not yet been determined. Bennetto and Caldin have investigated the nickel(II)–bipyridine system (7*a*), and Hoffman and co-workers have made preliminary measurements on rates of reaction between nickel(II) and thiocyanate, chloride, trifluoroacetate, and *p*-toluenesulfonate ions (7*b*). The nickel(II)–isoquinoline reaction has also been investigated (7*c*).

For an I_d mechanism the pathways for

reaction between nickel(II) and a monodentate ligand L can be represented by

$$[1] \qquad NiS_6 + L \underset{\longleftarrow}{\overset{K_{12}}{\rightleftharpoons}} \underset{I}{NiS_6, L} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{II}{NiS_5L, S}$$

in which the rate-determining step for the formation of the inner-sphere complex (process II, forward rate constant k_{23}) is preceded by rapid formation of an outer-sphere complex (process I, equilibrium formation constant K_{12}). In eq. 1 S stands for a solvent molecule and charges on the metal ion and ligand have been omitted for convenience.

For a 'normal' type of substitution (5*b*), when $K_{12}[L] \ll 1$, the second order rate constant k_f for formation of the inner-sphere complex is given by

$$[2] \qquad k_f = K_{12}k_{23}$$

As discussed before, for a 'normal' reaction the quantity R, given by

$$[3] \qquad R = (4/3)k_{23}/k_{ex} = (4/3)k_f/(k_{ex}K_{12})$$

should be close to unity (7*c*). Here k_{ex} and K_{12} have their usual significance (8). For normal substitution with a neutral monodentate ligand the enthalpy of activation for formation ($\Delta H_f^{\ddagger}$) of the complex is expected to be close to the corresponding quantity for solvent exchange ($\Delta H_{ex}^{\ddagger}$) for a given metal–ligand system in the same solvent.

Investigations of ligand substitution reactions at nickel(II) in solution have led to the identification of several specific rate-determining effects. These include (*a*) a solvent-dependent steric requirement exhibited by multidentate ligands during chelation, (*b*) a solvent-dependent rotational barrier to the proper orientation in space of coordinating ligand atoms during chelation, and (*c*) stabilization of metal–ligand outer-sphere complexes by π orbital or electrostatic interactions between the incoming ligand and polarized solvent molecules in the first coordinating sphere of the metal ion. All these effects influence the rate of substitution at nickel(II), especially in dipolar aprotic solvents such as acetonitrile and dimethylsulfoxide (5).

Of the solvents studied thus far, acetonitrile is the one in which nickel–ligand outer-sphere complexes are most influenced by variations in electronic character of the entering ligands (5*a*). Similar outer-sphere stabilization is absent in water, and has not been reported in any other dipolar aprotic solvent, although with phenanthroline there may be some stabilization in poor donor solvents such as propylene carbonate or sulfolane (9).[1] The specific property of acetonitrile that causes the stability of the metal–ligand outer-sphere complex to be so sensitive to the electronic character of the ligand has not been identified. Dimethylformamide and acetonitrile have similar dipole moments but differ considerably in size and in donor properties towards metal ions, acetonitrile being a weaker Lewis base toward nickel(II) than dimethylformamide. Hence a study of substitution at nickel(II) in dimethylformamide with ligands of varying electronic and steric properties could aid in improving understanding of the specific properties of the solvent that contribute to the stability of metal–ligand outer-sphere complexes, and will help establish the gross features of the mechanism of substitution at nickel(II) in dimethylformamide.

Experimental

Solvent

N,N-dimethylformamide (Fisher, Certified ACS) was purified as described before (7*c*). Purified solvent was used within 24 h after the final purification step.

Reagents

4-Phenylpyridine (Aldrich, mp 69–73°C) was recrystallized from ethanol. 2,2′-Bipyridine (G. F. Smith, mp 70°C), 2,2′,2″-terpyridine (G. F. Smith, Reagent Quality, mp 68–69°C), 1,10-phenanthroline monohydrate (B.D.H., mp 98°C), 5x-1,10-phenanthroline monohydrate (x = chloro, nitro, methyl) (G. F. Smith, Reagent Quality), and 5,6-dimethyl-1,10-phenanthroline (J. T. Baker, Baker Grade) were used as received. Nickel was used as $Ni(ClO_4)_2 \cdot H_2O$; the method of preparation of the salt was described previously (5*b*). Concentrations of nickel(II) solutions were determined by EDTA titration with murexide indicator after dilution with water and buffering at p*H* 10 with ammonia–ammonium chloride.

Procedure

Kinetic measurements were made with a stopped-flow spectrophotometer (Durrum Instrument Co., Model D-110). Descriptions of the instrument, along with modifications for better temperature control, were given previously (7*c*, 10). All other instruments and techniques used were as described before (7*c*).

Kinetic measurements for formation rate constants were made under pseudo-first-order conditions, the ratio of nickel(II) to ligand being held in the range of 10 to 100 throughout. All ligand and metal ion solutions were used within 4 to 6 h of preparation. Measurements were made

[1]Confer both ref. 9 and J. F. Coetzee, private communication.

TABLE 1. Rate constants for formation of the monocomplexes of pyridine-type ligands with nickel(II) in dimethylformamide at various temperatures

Ligand	Rate constant (k_f) × 10^{-3} (ℓ mol^{-1} s^{-1})			
	15°C	25°C	35°C	45°C
4-Phenylpyridine	0.968	2.00	[a]	
Bipyridine	0.227	0.564	1.09_0	2.25
Terpyridine	0.135	0.300	0.578	1.13_2
Phenanthroline	1.62_5	3.28	6.46	1.23
5-Chlorophenanthroline	1.06_7	2.39	4.61	9.33
5-Nitrophenanthroline	0.677	1.59	3.11	5.95
5-Methylphenanthroline	1.81_0	3.51	6.60	1.34
5,6-Dimethylphenanthroline	1.82_8	4.00	7.83	1.44

[a]Additional values: 0.409 at 4.75°C, 1.46_9 at 20°C, and 3.27 at 30°C.

at wavelengths where the complex absorbed more strongly than the reactants: 277 nm for 4-phenylpyridine, 335 nm for 2,2′,2″-terpyridine, 308 nm for 2,2′-bipyridine, and 272 nm for 1,10-phenanthroline and the substituted 1,10-phenanthrolines. Reaction rates were calculated from the rate of change of absorbance of the reaction solutions with time. All other experimental procedures were as described before (*7c*).

Results

The rate constants for substitution of the ligands studied at nickel(II) are presented in Table 1. Under the experimental conditions used, only 1:1 complexes are expected. A pseudo-first-order rate plot with terpyridine as the ligand is shown in Fig. 1. Except for 4-phenylpyridine and bipyridine, plots for all the ligands studied pass near the origin. This indicates that the equilibrium constants for formation of the nickel(II) monocomplexes are all relatively large; on the basis of the experimental uncertainty in the pseudo-first-order rate constants we estimate formation constants greater than 3×10^4 at 25°C for all the systems studied. In Table 2 rate constants and associated activation parameters for substitution of the above ligands at nickel(II) are compared with those for solvent exchange (11).

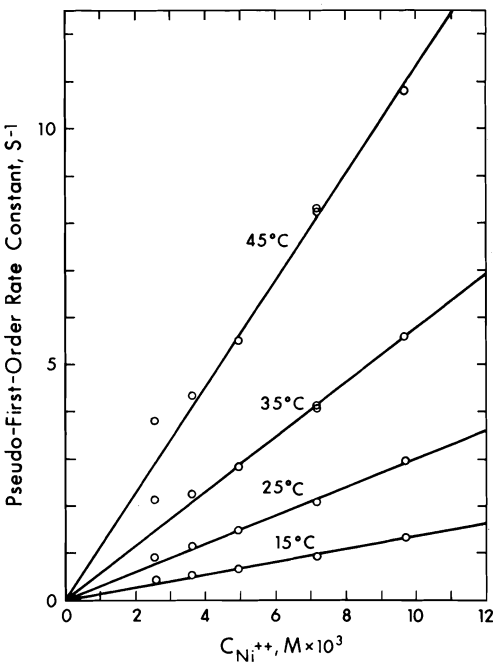

FIG. 1. Pseudo-first-order rate constants for formation of the monocomplex of nickel(II) with terpyridine as a function of nickel(II) concentration in dimethylformamide. $C_L = 2.52 \times 10^{-5}$ *M*.

Discussion

Pseudo-first-order Rate Constants

In a simple pseudo-first-order kinetic plot, the intercept is equal, in theory, to the dissociation rate constant for the reaction. This was found previously to hold for the nickel(II)–isoquinoline complex in dimethylsulfoxide (8). Intercepts that do not correspond to k_d have been observed in some solvents, however (*7a*). This may result from the presence of substances that affect the rate of reaction. Thus, traces of amine-type impurities in the solvent that can form stable complexes with nickel(II) can increase the magnitude of the real intercept owing to simultaneous formation of ternary complexes. This was observed in earlier work on the nickel(II)–isoquinoline system in dimethylformamide, where the value of 19.5 for k_b obtained from the intercept of pseudo-first-order plots agreed only approximately with the value of 26.5 obtained from K_{eq} and k_f measurements (8). A parallel but better-behaved system exists in dimethylsulfoxide, where intercepts of pseudo-first-order

TABLE 2. Rate constants at 25°C and associated activation parameters for formation of the monocomplexes of pyridine-type ligands with nickel(II) in dimethylformamide

Ligand	$k_f \times 10^{-3}$ (ℓ mol^{-1} s^{-1})	R	$\Delta H_f^{\ddagger}$ (kcal mol^{-1})	$\Delta S_f^{\ddagger}$ (eu)
Dimethylformamide[a]	3.8	—	15.0	+8
Isoquinoline[b]	2.42	0.98	12.4±0.4	−2±1

[a]Data from ref. 11.
[b]Data from ref. 7c.

plots for formation of the 4-phenylpyridine and isoquinoline complexes of nickel(II) both agree with directly measured k_b values (8, 12). Since both complexes are of comparable stability in dimethylsulfoxide (K_{eq} = 35.8 and 31.3) it seems likely that the reaction of 4-phenylpyridine with nickel(II) in dimethylformamide has an equilibrium constant of about the same size as that of isoquinoline, and that an intercept value for k_b at 25°C on the order of 15 may be reasonable.

In general, however, dissociation rate constants should be determined either directly or calculated from directly measured overall equilibrium constants and formation rate constants rather than being obtained from the intercepts of pseudo-first-order kinetic plots for formation of the complex. Thus the intercepts observed with 2,2′-bipyridine in this work cannot be assumed to give correct values for k_d, especially since Bennetto and Caldin did not observe a positive intercept for this system in dimethylformamide (*7a*). Our values for the formation rate constant of this complex as measured from the slopes of the pseudo-first-order plots, and for the activation enthalpy for the formation of the complex, agree with their results within 1%. The discrepancy in intercept may be due to the presence in our solvent of a constant trace amount of a complexing impurity such as dimethylamine, a hydrolysis product of dimethylformamide. The concentration of bipyridine being on the order of 10^{-5} *M*, a concentration of dimethylamine in the solvent as low as 10^{-4} *M* would be likely to increase the pseudo-first-order rate constant with different concentrations of nickel(II) by a constant amount, and thereby cause a shift in the pseudo-first-order plots (13). Of the systems studied in this work, the one involving nickel(II) and terpyridine is most effected by the addition of low concentrations of dimethylamine. For example, the pseudo-first-order rate constant for the reaction between nickel(II) at 2.5 × 10^{-3} *M* and terpyridine at 2.5 × 10^{-5} *M* was doubled by the addition of about 5 × 10^{-4} *M* dimethylamine. The presence of traces of a complexing impurity is further indicated by the deviation from linearity of the points in Fig. 1 at nickel(II) concentrations below about 3 × 10^{-3} *M*. Therefore, we suspect the presence of a contaminant, probably dimethylamine, in the range of 10^{-5} to 10^{-6} *M* in our solvent; however, values for formation rate constants obtained from the slopes of pseudo-first-order plots using data measured at higher concentrations of nickel(II) are considered to be accurate within ±2 to ±3%.

Formation Rate Constants

From the k_f and R values listed in Table 2 it appears that the reaction with nickel(II) of 4-phenylpyridine, like isoquinoline, is 'normal' in dimethylformamide, and that an I_d type of reaction mechanism is involved. Recently Coetzee and co-workers reported that the reaction of 4-phenylpyridine with nickel(II) is normal in propylene carbonate, 2-propanol, and isobutyronitrile (6). Analysis of the values of R listed in Table 2 shows that the same conclusion can be applied to all the ligands studied in this work.

Terpyridine reacts more slowly with nickel(II) in dimethylformamide than does bipyridine, while 1,10-phenanthroline reacts more rapidly. This order is the same as that observed in all the nonaqueous solvents studied. Chattopadhyay and Coetzee (5) explained this order in acetonitrile by considering the thermodynamic parameters associated with the reactions. As in

acetonitrile, in dimethylformamide also the rings of bipyridine and terpyridine may experience some solvent-hindrance to attainment of the *cis* position during formation of the outer-sphere complex, while the rigid phenanthroline ligand is not affected.[1]

Enthalpy of Activation ($\Delta H_f^{\ddagger}$)

The variation in $\Delta H_f^{\ddagger}$ found for the ligands studied in this work is relatively small. Despite this, some significance can be attached to the differences because the formation rate constants vary by over an order of magnitude for the same set of ligands, and because the experimental uncertainty in $\Delta H_f^{\ddagger}$ values is smaller relative to the spread of results for the ligands studied. The observed $\Delta H_f^{\ddagger}$ values can be related to $\Delta H_{ex}^{\ddagger}$ for solvent exchange at nickel(II) in dimethylformamide by considering (*a*) the effect of the ligand on the stability of the metal–ligand outer-sphere complex, and (*b*) the steric effect exhibited by the ligand molecule. In this discussion it is assumed that the stability of the metal–ligand outer-sphere complex increases with an increase in the number of pyridine nitrogens and benzene rings in the ligand, and that benzene rings fused to pyridine rings have a greater stabilizing effect on the metal–ligand outer-sphere complex than do those connected by a carbon–carbon bond. On this basis the value of $\Delta H_f^{\ddagger}$ for 4-phenylpyridine is expected to be closest to $\Delta H_{ex}^{\ddagger}$; this is indeed observed (Table 2). The values of $\Delta H_f^{\ddagger}$ for bipyridine, isoquinoline, and phenanthroline would be expected to be lower than for 4-phenylpyridine in the order given; this is in agreement with experimental results for all but bipyridine. As mentioned above, bipyridine may be hindered by solvent interaction from ready attainment of the *cis* configuration necessary for chelation with nickel(II). The energy required to overcome this rotational barrier is compensated for by the extra stabilization of the metal–ligand outer-sphere complex provided by the additional pyridine nitrogen. The difference between the $\Delta H_f^{\ddagger}$ values for bipyridine and 4-phenylpyridine depends on the magnitude of the two opposing effects; since that for bipyridine is only 0.4 kcal lower than the corresponding quantity for 4-phenylpyridine, and about at the level of experimental uncertainty, we conclude that the two opposing effects for bipyridine are either about equal in magnitude or the stabilizing effect is slightly stronger than the steric effect.

In the solid state the rings of bipyridine are coplanar, with the nitrogen atoms in the *trans* position (14); this conformation is likely in solution also. For chelation with nickel(II) the two nitrogens must rotate from the *trans* to the *cis* position. The energy required for this rotation being small, it can be concluded that the decrease in $\Delta H_f^{\ddagger}$ due to extra stabilization of the metal–ligand outer-sphere complex by the additional pyridine nitrogen atom in bipyridine, as compared to 4-phenylpyridine, is also small. This may explain why $\Delta H_f^{\ddagger}$ for the reaction of nickel(II) with 4-phenylpyridine is only 1.4 kcal lower than $\Delta H_{ex}^{\ddagger}$ for solvent exchange and why 4-phenylpyridine follows a 'normal' I_d-type mechanism. Similarly, comparison of $\Delta H_f^{\ddagger}$ for the reaction of terpyridine with that of 4-phenylpyridine can be rationalized by assuming that in dimethylformamide the extra stabilizing effect on the metal–ligand outer-sphere complex of the additional two pyridine nitrogen atoms is greater than the energy required to put all the terpyridine nitrogen atoms in the *cis* position for chelation with nickel(II). We conclude that of the ligands studied in this work 5-methylphenanthroline has the strongest influence on the stability of the metal–ligand outer-sphere complex. 1,10-Phenanthroline and its 5-methyl derivative behave similarly; the difference in $\Delta H_f^{\ddagger}$ values is within experimental uncertainty.

Hammett Correlation

In dimethylformamide pyridine-type ligands generally affect the stability of metal–ligand outer-sphere complexes less dramatically than in acetonitrile. This is demonstrated in Fig. 2, in which the slope of Hammett plots for reactions of nickel(II) with substituted 1,10-phenanthro-

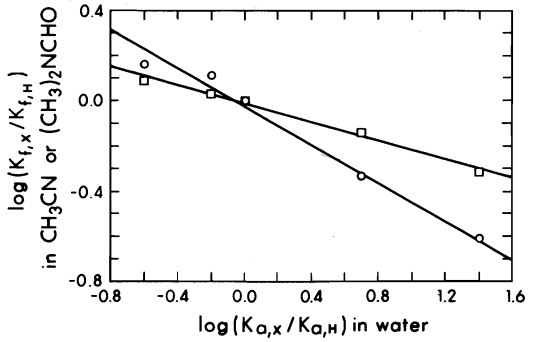

FIG. 2. Hammett correlation plots for reaction of substituted phenanthrolines with nickel(II) in acetonitrile (circles, slope = −0.40) and in dimethylformamide (squares, slope = −0.20).

lines in dimethylformamide are compared with previous results in acetonitrile by Chattopadhyay and Coetzee (5*a*).

The Hammett correlation shown is based on relative pK_a values of the ligands in water (15). The correlation in any solvent preferably should be based on relative pK_a values of the ligand in that solvent. It has been reported that a virtually constant difference exists between pK_a values in acetonitrile and water for a series of closely-related bases (16). Therefore the use of relative pK_a values in water for Hammett correlation in dimethylformamide should be feasible.

The different reaction rates observed in dimethylformamide for substitution at nickel(II) with 5- and 5,6-substituted 1,10-phenanthrolines may be the result of different electronic effects of the substituent groups on the stabilities of the metal–ligand outer-sphere complexes. A similar trend in rates was observed in acetonitrile (5*a*). The nature of the reaction mechanism in both cases is I_d rather than I_a. Slopes of Hammett correlations in the order of -0.4 ± 0.03 in acetonitrile and -0.2 ± 0.01 in dimethylformamide indicate that the metal–ligand outer-sphere complexes are more susceptible to the electronic nature of substituent groups on the parent phenanthroline in acetonitrile than in dimethylformamide.

Acetonitrile coordinates to nickel(II) through the nitrogen atom in the cyanide group, while dimethylformamide coordinates through the oxygen atom in the amide group, but the dipole moments of 3.92 and 3.86 D at 25°C are similar (17). Dimethylformamide is more bulky and exerts more steric hindrance to the approach of an incoming ligand to a dimethylformamide-solvated metal cation than does acetonitrile. Also, Gutmann donor numbers of 26.8 for dimethylformamide and 14.1 for acetonitrile (18) indicate that dimethylformamide is a much stronger Lewis base toward nickel(II) than acetonitrile. If the stability of the metal–ligand outer-sphere complex is mainly dependent on the intensity of π orbital or simple electrostatic interaction between the incoming ligand and a polarized solvent molecule in the inner sphere of the central cation, then from consideration of the molecular size and dipole moments of dimethylformamide and acetonitrile it is predicted that the outer-sphere complex with the phenanthrolines will be stabilized more in acetonitrile than in dimethylformamide. Comparisons of $\Delta H_f^{\ddagger}$ and $\Delta H_{ex}^{\ddagger}$ values in Table 2 with earlier results in acetonitrile (5*a*) show this to be the case. Similarly, the solvent donicity values suggest that stability of the outer-sphere phenanthroline complex is influenced by variation of 5- and 5,6-substitution more in acetonitrile than it is in dimethylformamide. This also is substantiated by the greater slope of the Hammet correlation plot for acetonitrile in Fig. 2.

In summary, we conclude that pathways for ligand substitution reactions between nickel(II) and the mono-, bi- and terdentate ligands studied so far in dimethylformamide can be accommodated within the framework of an I_d-type mechanism if effects of possible fine interactions between solvent and solute are considered. Of the ligands studied 4-phenylpyridine shows least interaction with dimethylformamide, whether the dimethylformamide is considered as bulk solvent or as polarized individual solvent molecules in the inner sphere of nickel(II). Consequently its reaction with nickel(II) in this solvent appears to be guided most 'normally' by an I_d-type mechanism. As was previously observed in acetonitrile, in dimethylformamide also 1,10-phenanthroline among all the ligands studied stabilizes most strongly the outer-sphere complex in reaction with nickel(II), but this influence on stabilization of the outer-sphere complex is less significant in dimethylformamide than in acetonitrile. Also, the stability of the metal–ligand outer-sphere complex is affected more greatly by small differences in the electronic nature of the coordinating substituted 1,10-phenanthrolines in acetonitrile than it is in dimethylformamide.

ROGER N. RENAUD, JOHN W. BOVENKAMP, ROBERT R. FRASER, and JEAN-LOUIS A. ROUSTAN. Can. J. Chem. **55**, 3456 (1977).

The conformational properties of seven 5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctenes bearing substituents at C-6 have been studied using variable temperature proton nmr spectroscopy. The position of the equilibrium between boat-chair (BC) and twist-boat (TB) conformers has been measured in several solvents. In contrast to the unsubstituted dibenzocyclooctene, appreciable amounts of TB conformer are present when C-6 is substituted by alkyl, hydroxy, or cyano substituents. Measurements at different temperatures showed the TB form to possess the greater entropy. Barriers to the BC → TB interconversion were determined by coalescence studies, using both approximate and complete line shape methods. Barriers ranged from 10.1 kcal/mol for the 6-keto derivative to 16.7 kcal/mol for the 6-hydroxy-6-methyl derivative.

ROGER N. RENAUD, JOHN W. BOVENKAMP, ROBERT R. FRASER et JEAN-LOUIS A. ROUSTAN. Can. J. Chem. **55**, 3456 (1977).

On étudie, par résonance magnétique du proton (rmn) et variant la température, les propriétés conformationnelles de sept tétrahydro-5,6,7,12 dibenzo[*a*,*d*]cyclooctènes ayant des substituants en C-6. La position de l'équilibre entre les conformères chaise-bateau (CB) et bateau-croisé (BC) est mesurée dans plusieurs solvants. Contrairement au dibenzocyclooctène non substitué, une quantité appréciable de conformères (BC) est présente lorsque le C-6 est substitué par un groupe alkyle, hydroxy ou cyano. Les mesures à différentes températures montrent que la forme BC possède une plus grande entropie. Les barrières d'interconversion CB → BC sont déterminées par des études de coalescence en utilisant les méthodes approximatives et complètes basées sur la forme des courbes. Les barrières s'étalent de 10.1 kcal/mol pour le dérivé céto-6 à 16.7 kcal/mol pour le dérivé hydroxy-6 méthyl-6.

[Traduit par le journal]

In the past few years the dibenzocycloocta-1,4-diene[3] ring system **1***a* has attracted considerable interest regarding its conformational properties. The first evidence on this topic came from a ^{1}H nmr study of compounds related to **1***a*, specifically the azocines **2***a–f* (1, 2). Subsequently studies on a variety of other heterocyclic analogs **3***a–l* were reported (3) and, most recently, the conformational properties of the hydrocarbon **1***a* itself have been described (4). The parent compound, 1,4-cyclooctadiene, has been the subject of analysis by ^{13}C and ^{1}H techniques (5) as well as by strain energy or force field calculations (5, 6). In this paper we wish to describe the elucidation of the conformational properties of a series of dibenzocyclooctadiene derivatives **1***b–h* (7) by the use of ^{1}H nmr techniques.

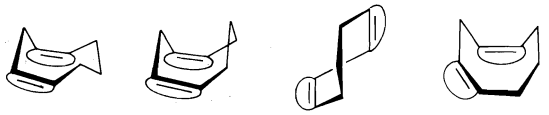
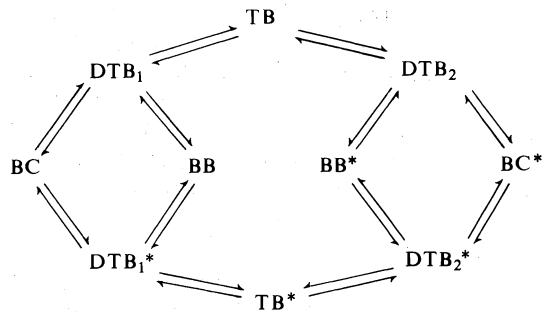
Initial proton studies of the azocine series, **2**, established the presence of two conformational isomers having comparable energies (1, 2). Depending upon the substituent at nitrogen either the boat-chair (BC) or the twist-boat (TB) conformer predominated in the equilibrating mixture. Barriers to this interconversion were found to be of the order of 15–17.5 kcal/mol. In a recent paper by Gellatly *et al.* (3) the relative energies of the various conformers of **2***a* as well as the possible pathways to their interconversion were computed using force-field calculations. The values they obtained for the enthalpy difference between BC and TB conformers was 1.2 kcal/mol (BC more stable) in fair agreement with the experimental value for ΔH of 3.2 kcal/mol (1). Two additional results of the calculations are pertinent in relation to the general properties of the ring system **2**. Calculations for a number of boat-like geometries indicated that of three possible conformers, a boat (BB) having C_s symmetry, a twist-boat (TB) having C_2 symmetry, and an asymmetric distorted twist-boat (DTB), the boat (BB) was of higher energy than either of the others.[4,5] The geometries of these conformers are depicted in Fig. 1. Calculations were also performed on three possible transition states for the BC → TB interconversion. One of these, involving rotation about the C-4 to C-5 and C-5 to C-6 bonds of the BC form, was of much lower energy than the other two. The activation energy of 18.3 kcal/mol calculated for the BC → TB process is in remarkably good agreement with the experimentally derived value of 17.0 kcal/mol.[6] On the basis of these calculations we need consider only one transition state, with the result that the interconversion pathways available to **1***a–h* can be represented as shown in Scheme 1.



BC(C_s) BB(C_s) TB(C_2) DTB(C_1)

FIG. 1. Possible low energy conformations of 5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctene with their symmetry classification.



SCHEME 1. Allowed conformational interconversions for 5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctene. The species designated by an asterisk are mirror images of those lacking an asterisk. Subscripts are used to differentiate DTB_1 from DTB_2 since, although the two forms represent the same enantiomer, they can in principle be differentiated by the proton shifts at C-5 and C-7.

A. Criteria for Assignment of Conformation

Several parameters diagnostic of either the TB or BC conformation have been employed in our earlier studies of the azocines (1, 2). The same criteria to be applied to compounds **1***b–h* are summarized as follows.

i. The flexibility of the TB conformer gives it a greater entropy than the rigid BC conformer (e.g. ΔS = 7 eu for **2***a* (1)).

ii. The geminal coupling constant between the

[4]This nomenclature has been adopted to coincide with that employed by Anet (5) for 1,4-cyclooctadiene. It differs from that of Gellatly *et al.* (3) which uses C rather than BC and Boat rather than DTB.

[5]The small energy differences between the DTB and TB forms suggest that the more stable conformer may well differ for various members of series **1** and **2**. In the absence of definitive evidence on relative stabilities we will arbitrarily refer to any twist-boat conformer as TB.

[6]Previously $\Delta G^{\ddagger}_{211}$ (TB → BC) has been measured as 15.3 kcal/mol, ΔS_{eq} as −7 eu, and ΔH^0 as 3.2 kcal/mol. If we make the assumption that $S^{\ddagger}$ = 0, then $\Delta S^{\ddagger}$ = −7 eu, and thus $\Delta H^{\ddagger}$(TB → BC) = 13.8 kcal/mol. To obtain the BC → TB barrier one must then add ΔH^0 = 3.2 kcal/mol giving $\Delta H^{\ddagger}$(BC → TB) = 17.0 kcal/mol.

protons at C-12 is much more positive for the BC (−12 to −14 Hz) than for the TB (−19 Hz) conformation, as was anticipated on the basis of the previous known effect of a benzene ring (8).

iii. Two of the vicinal coupling constants between protons at C-5 and C-6 will be close to zero in the BC conformer only. This results from the fact that in the BC conformer the dihedral angles for two pairs of vicinal protons are approximately 90°.

iv. The BC conformer will normally give rise to two sets of nonequivalent methylene proton absorptions whereas the TB conformer, whenever the equilibration process (TB $\rightleftharpoons$ TB*) is rapid, will give rise to two singlets (except when C-6 bears two different substituents).

B. Criteria for Assignment of Configuration at C-6

In the derivatives **1***d–h* two BC conformers are possible, one in which the bond to the substituent at C-6 is essentially in the plane of either benzene ring (which will be referred to as the pseudoequatorial position), the other having the substituent oriented downwards from this plane (a pseudoaxial orientation). Distinction between these conformers can be made in two ways.

i. As was observed in the azocines, there should be a marked difference in chemical shift between a pseudoaxial and pseudoequatorial substituent. The shift of the pseudoaxial substituent to higher field by 0.6–0.8 ppm is attributable to the ring currents of the two benzene rings (9).

ii. Examination of a Dreiding model of the rigid BC conformer indicates the dihedral angles to be 90° and 150° between the protons at C-5 and the pseudoaxial proton at C-6. When the C-6 proton is pseudoequatorial the angles are 90° and 30°. From the extensive studies on the Karplus relation it is clear that the protons oriented at 150° to one another will exhibit a larger vicinal splitting than those oriented 30° to one another.[7] Thus of two BC conformers, that with pseudoequatorial substituent (pseudoaxial proton) will exhibit the larger vicinal splitting.

Determination of Barrier Heights from Variable Temperature Nuclear Magnetic Resonance Data

The measurement of free energies of activation for the interconversion of conformers has been accomplished for compounds **1***b*, *c*, *e*, *f*, *g*, and *h*. In each case the free energy has been calculated from the standard expression (10, 11) for coalescence of an AB system. For compounds **1***b* and *c* the coalescence of an AB pattern to a singlet was complicated by the presence of about 10% of the TB conformer whose singlet coalesced at the same time. However, it has been demonstrated by a comparison of a complete line shape (cls) analysis with the simple AB coalescence that the only effect of the second conformer is to cause unequal line widths of the A and B signals. Its presence in minor amounts does not affect the accuracy of determination of the coalescence temperature (3).

For compounds **1***e*, *f*, and *g* the coalescence being monitored involved two singlets of not quite equal intensities (the most unequal ratio was 2:1 (CH_{3a} vs. CH_{3e}). It has been shown previously by Raban and Carlson (12) that in such cases, treatment of the system by the simple two-site equation for equal populations still gives the same resultant $\Delta G^{\ddagger}$ as that obtained by cls analysis. For compound **1***h* measurement of the TB $\rightleftarrows$ TB* interconversion involved straightforward analysis of the AB coalescence of two protons at C-5 and C-7. To obtain the BC $\rightleftarrows$ BC* barrier the coalescence of two approximately equal intensity singlets[8] for the BC and TB absorptions at C-5 and C-7 was observed. To convert the derived barrier TB $\rightleftarrows$ BC into BC $\rightleftarrows$ BC* one simply adds $RT \ln 2$ to correct for the fact that for the equilibrium involved, BC $\rightleftarrows$ TB $\rightleftarrows$ BC*, the BC $\rightleftarrows$ BC* process is half as fast (probable) as the BC $\rightleftarrows$ TB process.

For compound **1***h*, a complete line shape analysis was carried out for comparison with the results obtained by use of the two-site approximation.

One additional method of measuring the TB $\rightleftarrows$ BC process was used with **1***d*. This method, previously used by us (1) to study **2***a* measured the rate of equilibration of a sample of **1***d* containing excess TB conformer (at −72°C) produced by plunging a heated sample into liquid N_2 before transferring to the nmr probe for monitoring. Similar 'T-jump' techniques have recently been elegantly exploited (13) to obtain observable concentrations of the boat conformation of cyclohexane.

The basic nmr spectral parameters, equilib-

[7]While application of the Karplus relation to stereochemical problems must be made with caution, as was discussed extensively by Jackman and Sternhell (9, p. 280), there is general agreement that the right hand side ($90° < \theta \leq 180°$) gives rise to larger coupling constants.

[8]The BC absorption of the C-5,7 protons appeared as a singlet in toluene but as an AB pattern in $CDCl_3$.

rium concentrations of conformers and barriers to interconversion, are presented in Tables 1–4. Distinctive aspects of these spectral studies will be best considered individually.

5,6,7,12-Tetrahydrodibenzo[a,d]cyclooctene-6,6-d_2, 1a-d_2

The analysis of the ^{1}H nmr spectrum of **1***a* at several temperatures has been described by Elhadi *et al.* (4). They conclude that the molecule exists in the BC conformation in equilibrium with 2% of a TB conformer. Our results of examination of the spectra of **1***a*-6,6-d_2 in several solvents lead us to essentially the same conclusion.

The dideuteroderivative of **1***a* was used to study the coalescence of both methylene quartets by variable temperature. The barrier to interconversion BC ⇄ BC* was found to be 15.1 kcal/mol at 36.5°C, in good agreement with both the recent experimental (15.2) and calculated (15.2) values reported by Elhadi *et al.* (4). Since the presence of 2% of a TB conformer was indicated by their studies of line shapes, we attempted to observe weak peaks ascribable to the TB form in the simplified spectrum of **1***a*-d_2. No peaks due to a second conformer could be detected.

5,6,7,12-Tetrahydrodibenzo[a,d]cycloocten-6-one, 1b

The presence of two singlet methylene absorptions in the nmr spectrum of **1***b* indicates either a TB conformer or a mobile equilibrium between BC and TB conformers. As the temperature is lowered the two singlets broaden and diverge to several overlapping multiplets (in a 1:1:1 mixture of acetone-d_6, CS_2, and $CDCl_3$). From a study of 5,5,7,7-tetradeutero **1***b* in this solvent mixture over the temperature range −107 to −50°C the barrier to interconversion of BC conformers was found to be 10.1 kcal/mol. At −107°C the BC to TB ratio was 10:1. The absorption of the C-12 protons of the BC conformer appeared as an AB quartet while the TB absorption was a singlet. When the spectrum of **1***b*-d_4 was measured in toluene-d_8–CS_2(1:1) at the same temperature the ratio of conformers changed to 1:1 again appearing as a quartet and a singlet. Comparison of this latter spectrum with that of **1***b* (undeuterated) allowed the identification of an AB quartet and a singlet due to the protons at C-5,7. All shifts and coupling constants thereby obtained are given in Table 2. An interesting value was found for the geminal coupling constant between the methylenes adjacent to the carbonyl group of the BC conformer. This coupling constant is 3 Hz more positive than the value for ^2J at C-5 in the hydrocarbon **1***a*. This increment to ^2J, caused by replacing a CH_2 group with a C=O oriented orthogonal to the antisymmetric MO of the CH_2 group (14), is in perfect agreement with the value predicted from the empirical relation of Montecalvo and St-Jacques (15).

6-Methylene-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene, 1c

The spectrum of **1***c* at room temperature showed three sharp singlets for the three types of methylene groups at δ 3.65 (C-5,7), 4.06 (C-12), and 5.0 (vinyl). At −65°C the protons at C-12 and those at C-5,7 appeared as AB quartets while the olefinic protons remained as a singlet. The nonequivalence of the C-12 protons indicates a BC conformer. A small amount of TB conformer (5%) is also present as indicated by a second singlet peak in the *exo* methylene region (δ 5.11). The barrier to the BC ⇄ BC* interconversion was found to be 13.1 kcal/mol.

It is interesting to note that the difference in the BC ⇄ BC* barrier for the ketone versus the *exo* methylene derivative is 3.0 kcal/mol, reminiscent of the difference between cyclohexanone (ΔG^+ = 4.0 kcal/mol (16)) and methylene cyclohexane (ΔG^+ = 8.4 kcal/mol (17)).

6-Methyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene, 1d

The spectrum of this compound shows a

*Chemical shifts are in δ units, coupling constants in Hz. Coupling constants without subscripts represent geminal interactions which are negative in sign (ref. 9, p. 270).

similarity to its nitrogen analog, **2***a*, in the methyl region, having three distinct methyl absorptions representing TB, BC_e and BC_a conformers in a ratio of 8:42:50. The identification of the methyl signal of weakest intensity as a TB absorption follows from the observation of its increase in intensity from 3% of total methyl absorption at −73°C to 8% at −30°C, indicative of its greater entropy (+4 eu) than either of the more intense signals whose ratio stays constant. Furthermore the coupling constants for the methylene protons at C-12 of the two most abundant conformers confirm their identity as BC conformers. The assignment of an equatorial configuration to the methyl group of the weaker BC doublet rests on both the chemical shift and vicinal coupling constant criteria mentioned earlier.

All temperature dependent spectra were run using the 6,12,12-trideutero derivative. The barrier to interconversion, $BC_e \rightarrow BC_a$ was determined to be 15.9 kcal/mol at 55°C, the coalescence temperature of the two methyl singlets. Using the quenching technique the TB → BC barrier was found to be 14.2 kcal/mol from the rate of equilibration of the TB signal. The rate constant for this process represents the TB → BC_e and TB → BC_a transformations. Thus the TB → BC_a rate constant will be half as large giving $\Delta G^{\ddagger}$ (TB → BC_a) = 14.5 kcal/mol at −72°C. A comparison with $\Delta G^{\ddagger}$ (BC_a → TB) = 15.5 kcal/mol at 55°C reveals a good agreement between the two methods. If one assumes $\Delta S^{\ddagger} = 0$, and $\Delta S_{eq} = 4$ eu then $\Delta G^{\ddagger}$ (TB → BC_a) can be calculated to be 15.0 kcal/mol at 55°C. These two barriers, having a common transition state, should differ by ΔG_{eq} for TB ⇄ BC_a which is 0.5 kcal/mol at 55°C, consistent with the experimental values.

Methyl 5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene-6-carboxylate, 1e

The methyl ester **1***e* gives rise to a simple ^1H spectrum at −20°C which shows a dominant conformer to be present accompanied by 7% of a second isomer. The major component can be identified as the BC conformer from both the chemical shift and the coupling constant data. The pseudoequatorial orientation of the carbomethoxy group of the BC form is indicated by the 10 Hz vicinal coupling constant involving the methine proton at C-6. The second isomer can be assigned to the TB conformation. A sample of 6,12,12-trideuterated ester clearly showed a small singlet for the protons at C-5 and 7 (δ 2.86) whose intensity diminished as the temperature was lowered (i.e. it has greater entropy than the BC form).

6-Hydroxy-6-methyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene, 1f

The tertiary alcohol, **1***f*, gives rise to a ^1H spectrum which is considerably broadened by

*Unequal singlets coalescence.
†Equal singlets coalescence.

interconversions between the various conformers at 0°C or above. At −40°C the spectrum shows three sharp methyl singlets indicating the presence of three conformers comprising 50, 16, and 34% of the total and representing the BC_e, TB, and BC_a conformers, respectively, whose assignments followed from the customary applications of criteria *A*, *i* and *ii*, and *B*, *i*. A measurement of the coalescence of the two more intense singlets at 68°C indicates the barrier to interconversion of boat chairs to be 16.7 kcal/mol. The increase in this barrier over that of the parent (15.2) is quite consistent with the additional eclipsing of both the CH_3 and OH substituents with their vicinal protons in the transition state.

6-Hydroxymethyl-6-methyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene, 1g

From the nmr spectrum, the primary alcohol **1***g* at −18°C was found to exist in the three conformations BC_e (methyl equatorial), BC_a, and TB in the ratio 34:6:60, assignable on the basis of criteria *A*, *i* and *ii*. The barrier to interconversion of the two BC conformers was found to be the same as for **1***f*, as one would expect for two compounds, each having two substituents of similar size at C-6.

6,6-Dicyano-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene, 1h

The conformational properties of **1***h* differ significantly in several ways from the other members of the series. In $CDCl_3$ at −30°C, the proton spectrum of **1***h* shows the presence of a BC conformer (59%) represented by two AB quartets in the methylene region and a TB conformer (41%) whose methylene absorptions are a singlet (C-12 protons) and an AB quartet (protons at C-5 and C-7). As the temperature is raised to −3°C the quartet for the C-5,7 protons of the TB conformers broadens and coalesces, indicating the conformational process which averages the proton environments to have $\Delta G^{\ddagger}$ = 13.4 kcal/mol. This process, already observed by us in the structurally similar quaternary methiodide of the azocine **2***a*, was termed a

racemization process, i.e. TB ⇄ TB*. One distinctive property of **1***h*, as indicated by the data in Table 1, is that its conformational equilibrium is less influenced by temperature than was **1***d*. That the entropy difference between BC and TB conformers is smaller in **1***h* by 2 eu is consistent with the presence of two cyano groups restricting the mobility of the twist-boat. Interestingly this BC ⇄ TB equilibrium is surprisingly sensitive to solvent. At 27°C, the ratio [TB]/[BC] is unity in both $CDCl_3$ and toluene-d_8, whereas in acetone it is 0.2.

The barrier to the TB ⇄ BC interconversion for **1***h* was determined in several solvents. In toluene-d_8, a $\Delta G^{\ddagger}$ of 16.5 kcal/mol was obtained by observing the coalescence T_c = 59°C of the singlet for C-5,7 for the TB conformer with the equally intense absorption of the C-5,7 protons of the BC form which in this solvent appears as a singlet. At the same time the singlet (TB) and the AB quartet (BC) representing the C-12 protons also coalesced (T_c = 59°C). This latter coalescence was subjected to a complete line shape analysis (18) which yielded a value for $\Delta G^{\ddagger}$ of 16.4 kcal/mol.

In $CDCl_3$, observation of coalescence of the AB quartet (BC) and the singlet (TB) due to the protons at C-5 and C-7 indicates a $\Delta G^{\ddagger}$ of 16.3 kcal/mol. Thus for **1***h*, the effect of solvent on the BC → TB barrier is negligible.

The similarity in the geminal coupling constants for the methylene protons at C-5 and C-7 in the BC (−14.6 Hz) and TB (−14.1 Hz) conformers gives some indication of the geometry of the TB conformer of **1***h*. Recently we have shown that the hyperconjugative effect of a phenyl substituent on the geminal coupling constant of an attached methylene group varies from 0–5.5 Hz (19). Specifically the coupling constant is 5.5 Hz more negative when the π orbitals of the ring and a line drawn through the two protons are parallel (projected angle ϕ = 0°) rather than perpendicular (ϕ = 90°). Since MO theory predicts the effect to be proportional to $\cos^2\phi$, the hyperconjugative shift can be expressed as $\Delta J = 5.5\cos^2\phi$. Dreiding models show that the projected angle ϕ for **1***h* is 75° in the BC, 85° in the dissymmetric TB form and 0° in the symmetric BB. Models indicate that the DTB conformer produced from the symmetrical TB form by a 30° rotation about the C-5 to C-6 bond has the projected angle changed to 75°. Any further rotation would lead to a projected angle sufficiently smaller to cause a difference of greater than 0.5 Hz in the geminal coupling constants of the TB and BC conformers. Thus for **1***h* at least, the conformation of the twist-boat is either the symmetric TB or a DTB in which the change from the TB form is not great.

Experimental

All nmr spectra were recorded on a Varian HA-100 spectrometer, using simultaneous deuterium spin-decoupling by means of an SD-100 decoupler for those measurements involving deuterated derivatives. All coupling constants were determined with an accuracy of ±0.2 Hz. At temperatures other than ambient, the probe temperature was measured before and after recording the spectra by means of a copper–constantan thermocouple inserted into a nonspinning sample tube containing solvent. Such measurements are thought to be accurate to better than ±1°C. Spectra near the coalescence temperature were recorded at sweep widths of 250 Hz using a sweep time of 0.25 Hz/s. Care was taken to avoid saturation. The $\Delta\nu$'s used in calculating $\Delta G^{\ddagger}$ were determined over the range 213–263 K. No significant temperature dependences were encountered. Spectral calculations using the complete line shape program of Kleier and Binsch (18) were carried out on an IBM 360/65 computer.

The preparation of all the compounds except **1***b*-d_4 and **1***f* used in this study has been published elsewhere (7).

5,6,7,12-Tetrahydrodibenzo[a,d]cycloocten-6-one-5,5,7,7-d_4

The 5,5,7,7-tetradeuterio ketone **1***b* was obtained by the exchange of **1***b* with a DCl – D_3PO_3 – D_2O–dioxane solution according to the method of Seible and Gäumannl (20). No peaks for the C-5 and C-7 protons were seen in the ^{1}H nmr.

6-Hydroxy-6-methyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene ***1f***

Using the procedure of Cope and Fenton (21), the ketone **1***b* was reacted with methylmagnesium iodide in dry ether to give a quantitative yield of the alcohol **1***f*. An analytical sample was obtained by passing the crude oil through silica gel and distilling it at an air bath temperature of 100°C (0.01 Torr) using a Späth bulb apparatus to give a colorless viscous oil. *Anal.* calcd. for $C_{17}H_{18}O$: C 85.67, H 7.61; found: C 85.46, H 7.43.

Studies of a model of hydrogen recombination

NEIL S. SNIDER

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received March 24, 1977

NEIL S. SNIDER. Can. J. Chem. **55**, 3464 (1977).

A Morse oscillator model for recombination of hydrogen and its isotopes was investigated computationally. The model is very similar to one recently studied by Pritchard and co-workers. The aims of the study were the test of certain approximations and the determination of the range of validity of the model. It was found that at low temperatures the steady state approximation is an increasingly accurate and increasingly convenient approximation. A way of estimating the error arising from this approximation was proposed. Other approximations which were tested gave unsatisfactory results. The rate constant vs. temperature curve for the model does not agree well with the experimental curve for hydrogen in argon except insofar as it reproduces the observed levelling-off at high temperatures. For the model this result may be ascribed to increasing relative rates for multiquantum transitions among the levels of the diatom. The model does give the experimentally observed ratios of the rate constants for H- and D-atom recombination. This result indicates that the important factor in determining the isotope ratio is the effect of mass change on the density of states rather than its effect on the collision dynamics.

NEIL S. SNIDER. Can. J. Chem. **55**, 3464 (1977).

On a étudié, à l'aide d'un calculateur, la recombinaison de l'hydrogène et de ses isotopes en prenant comme modèle l'oscillateur de Morse. Le modèle est très proche de celui récemment étudié par Pritchard et ses collaborateurs. Le but de cette étude est de vérifier certaines approximations et de déterminer la zone où le modèle est valable. Il apparaît qu'à basse température l'approximation de l'état stationnaire est de plus en plus exacte et convenable. On propose une méthode d'évaluation de l'erreur sur cette approximation. Plusieurs autres approximations n'ont pas donné de bons résultats. La courbe de la constante de vitesse vs. la température pour ce modèle ne correspondent pas bien à la courbe expérimentale pour l'hydrogène dans l'argon. On peut utiliser cette courbe en autant qu'elle reproduit le palier observé à haute température. Le résultat obtenu pour ce modèle peut être attribué à l'accroissement des vitesses relatives de transitions multiquantiques parmi les niveaux du diatome. D'ailleurs, le modèle reproduit les rapports qui sont observés expérimentalement pour les constantes de vitesse pour la combinaison des atomes H et D. Ce résultat suggère que le phénomène majeur dans la détermination du rapport isotopique est l'effet de la variation de masse sur la densité des états plutôt que son effet sur la dynamique des collisions.

[Traduit par le journal]

Introduction

It has been understood for some time (1) that a theoretical description of thermal dissociation of diatomic molecules A_2 in the presence of a diluent gas M,

$$A_2 \underset{}{\overset{M}{\rightleftharpoons}} 2A$$

entails the solution of a set of N coupled linear differential equations,

$$[1] \qquad \frac{dn_i}{dt} = \sum_{\substack{j=1 \\ \neq i}}^{N} k_{ij}n_j - \sum_{\substack{j=1 \\ \neq i}}^{N+1} k_{ji}n_i$$

where n_i is the concentration of A_2 in level i, N is the number of levels of A_2, level $N + 1$ corresponds to atoms, and k_{ji} is the frequency of transitions to j from i. The k_{ji}'s are directly proportional to n_M, the concentration of the diluent. The solution of [1] is characterized by the eigenvalues of κ, the matrix of coefficients of the n_i's. The dissociation rate constant k_d is related to λ_1, the smallest (in magnitude) of these eigenvalues,

$$k_d = -\lambda_1/n_M$$

The rate constant for recombination k_r is k_d divided by K, the equilibrium constant for dissociation.

Computation of the eigenvalues of κ is a straightforward task, but it is a lengthy one if N is large. Hence, approximation methods are normally employed to find λ_1. It has been known for some time (2) that the steady state approximation is useful here. A further simplification can be effected by approximate conversion of [1] to an equivalent diffusion (Fokker–Planck) equation (3). Recently still another approxima-

tion has been proposed (4) wherein the distribution of level populations is assumed to have a plausible functional form which is characterized by two parameters. The best values of the parameters for a given case are found by the variational method. The accuracy of the steady state approximation for k_d and k_r has been discussed at some length (4–6). Less attention has been paid to the accuracies of the second (3, 4) and the third (4) of the just mentioned approximations.

In this article are presented computational tests of these approximations for a model similar to one which has been assumed for H_2 dissociation in helium (7). The k_{ij}'s are given by

$$[2]\quad k_{ij}(\tilde{T}, \Delta_{ij}) = \tau^{-1}[1 - \exp(-49.6\Delta_{i,i-1})] \exp[-49.6\Delta_{ij} + (617 + 223 \ln \tilde{T})\Delta_{ij}^2] \quad \text{for } 0 < \Delta_{ij} < 0.157,\ 1 \le i \le N$$

$$= \tau^{-1} \exp[-49.6\Delta_{ij} + (617 + 223 \ln \tilde{T})\Delta_{ij}^2] \quad \text{for } 0 < \Delta_{ij} < 0.157,\ i = N + 1$$

$$= k_{ij}(\tilde{T}, 0.157) \exp[-67.2(\Delta_{ij} - 0.157)] \quad \text{for } \Delta_{ij} > 0.157$$

$$= k_{ji}(\tilde{T}, \Delta_{ji}) \exp(\Delta_{ij}/\tilde{T}) \quad \text{for } \Delta_{ij} < 0$$

where $\tilde{T}$ is kT/D_e, D_e is the depth of the potential well for the ground electronic state of H_2, $\Delta_{ij}D_e$ is the difference between the energies ε_i and ε_j of the levels i and j, and τ is the average time between collisions. The model, as characterized by [2], applies just to transitions between vibrational levels of the molecule. A simple generalization which takes account of rotation is introduced later in this article. This model differs from the one treated in ref. 7 in two ways: the Morse oscillator formula[1] is used for the ε_i's,

$$[3]\quad \varepsilon_i = -D_e[1 - s(i - \tfrac{1}{2})]^2$$

and a factor

$$1 - \exp(-49.6\Delta_{i,i-1})$$

is included (admittedly arbitrarily) to prevent the total rate of transitions out of closely spaced levels from becoming anomalously large.

None of the aforementioned approximations has yet been tested on a model of the type just described. Such a study is warranted since the model, hereafter referred to as the Morse oscillator model, has some realistic features.

The present article has as its other goal the test of the model itself as a predictor of isotope effect and temperature dependence for H- and D-atom recombination rate constants. The effect on rate constants of a change in level density has been examined for the Morse oscillator model (8) and for the so-called separable exponential model (4). In both studies the preexponential factor of k_d was found to increase with increasing level density, but it is not evident that the cause of the increase is the same in both cases. The present article attempts to clarify this point and to answer the related question of whether or not changes in level density alone can account for experimentally observed isotope effects.

Finally, it has been argued (9) that much of the temperature dependence of k_r is due to a simple factor which accounts for the rotation of A_2. It is therefore of interest to treat a simple generalization of the Morse oscillator model which includes rotation. In the present article such a treatment is carried out, and comparison is made between the temperature dependence of k_r for the model and the observed temperature dependence of k_r for H_2 in argon.

Tests of Approximations

The equations which underlie the various approximations to be tested have been presented in ref. 4. They are briefly summarized here to provide an immediate frame of reference. In the steady state approximation the time derivatives in [1] are set equal to 0 for all i greater than 1. The resulting equations can be cast in the form of $N - 1$ linear algebraic equations for N unknown δ_i's given by

$$\delta_i = (x_i/x_{i,e}) - 1$$

[1]Equation 3 differs slightly from the standard Morse oscillator energy level expression because the levels are numbered from 1 to N rather than from 0 to $N - 1$ as is usually the case. The parameter s in terms of the potential parameters a and D_e and the reduced mass μ is equal to $a\hbar/(2\mu D_e)^{1/2}$.

where x_i is the fraction of molecules in level i, and $x_{i,e}$ is the fraction of molecules which level i would contain if a Boltzmann distribution were maintained. For the Morse oscillator model $x_{i,e}$ is given by

$$[4a] \quad x_{i,e} = q_v^{-1} \exp[-s(2 - si)(i - 1)/\tilde{T}]$$

$$[4b] \quad q_v = \sum_{i=1}^{N} \exp[-s(2 - si)(i - 1)/\tilde{T}]$$

The aforementioned equations for the δ_i's are as follows:

$$[5] \quad \sum_{i=1}^{N} R_{ji}(\delta_{j,s} - \delta_{i,s}) - R_{N+1,i}(1 + \delta_{i,s}) = 0 \qquad \text{for } 2 \le i \le N$$

where R_{ji} is given by

$$R_{ji} = k_{ji}x_{i,e} = k_{ij}x_{j,e} = R_{ij}$$

The additional subscript s is appended to the δ_i's in [5] to indicate that they are the steady state approximations to these quantities. The dissociation rate constant is given by

$$k_{d,s} = \sum_{i=1}^{N} R_{N+1,i}(1 + \delta_{i,s})$$

In the computations reported here $\delta_{i,s}$ was set equal to zero for all i less than m where m is an appropriate integer greater than 1. Equations 5 for i equal to and greater than m were then solved for the remaining δ_i's. A subroutine based on the square root method (10) was employed in the solution of the equations.

For the approximately equivalent stepladder model the R_{ij}'s, call them R^*_{ij}, are given by

$$R^*_{ij} = R^*_{ji} = \sum_{k=1}^{N} \frac{(k - i + 1)(k - i)}{2} R_{ki} \qquad \text{for } j = i + 1$$

$$= 0 \qquad \text{for } j > i + 1$$

The dissociation rate constant, call it $k_{d,1}$, is given by

$$k_{d,1} = \left(\sum_{i=1}^{N} R_{N+1,i} \sum_{j=i}^{N} \frac{1}{R^*_{i+1,i}}\right)\left(\sum_{j=1}^{N} \frac{1}{R^*_{i+1,i}}\right)^{-1}$$

This approximation is the simplest of the three to carry through computationally.

In the final approximation considered, δ_i is taken to have the form

$$[6] \quad \delta_i = -\sigma(\rho - 1 + \sigma)^{-1} \rho^{-(N-i)}$$

where ρ and σ are variational parameters. The best values of ρ and σ, denoted below by subscript zeros, are given by

$$[7a] \quad a'(\rho_0)b(\rho_0) = a(\rho_0)b'(\rho_0)$$

$$[7b] \quad \sigma_0 = (\rho_0 - 1)a(\rho_0)/[a(\rho_0) - b(\rho_0)]$$

provided that ρ_0 differs sufficiently from 1. The primes in [7a] denote differentiation with respect to ρ, and the functions a and b are given by

$$[7c] \quad a(\rho) = \sum_{i=1}^{N} \left[\sum_{j=i+1}^{N} R_{ij}(\rho^{j-i} - 1)^2 + R_{N+1,i}\right]\rho^{-2(N-i)}$$

$$[7d] \quad b(\rho) = \sum_{i=1}^{N} R_{N+1,i}\rho^{-(N-i)}$$

The dissociation rate constant in this approximation is denoted $k_{d,v}$ and is given by

$$k_{d,v}n_M = k_{d,e}n_M - b^2(\rho_0)/a(\rho_0)$$

where $k_{d,e}$ is the rate constant which applies if the level populations maintain a Boltzmann distribution,

$$k_{d,e}n_M = \sum_{i=1}^{N} R_{N+1,i}$$

The basic approximation here is [6]. This equation is suggested by results for the separable exponential model (4), a model which reproduces the important features (although perhaps not the details) of many models of dissociation and recombination of diatomic molecules.

Calculations were carried out on a Burroughs B-6700. In finding the eigenvalues of κ, the matrix was first symmetrized by a standard similarity transformation (1). The symmetrized matrix was then tridiagonalized using the library subroutine TRED1, and the eigenvalues of the tridiagonalized matrix were found using the library subroutine RATQR. Because of technical difficulties, eigenvalues were only obtained for temperatures 3000 K and above. However, as will be shown, there is good reason to take the steady state approximation to be essentially exact below 3000 K.

For H_2 a value of s equal to 0.0575 was chosen. This gives the best fit to the known spacings of the low-lying vibrational levels of this molecule. There is probably no really suitable criterion for choosing a most appropriate value of s. The results of this study indicate that the Morse oscillator expression for the energy levels is

probably inadequate in any case. For T greater than 7000 K [2] gives a range of Δ_{ij} for which k_{ij} increases with increasing Δ_{ij}. It was considered best to terminate this study at a temperature well short of that at which the model develops this unphysical feature. The temperature 5000 K was chosen.

In Table 1 exact and approximate results are compared. Said results are expressed in terms of the dimensionless preexponential factor p given by

$$p = \tau k_d n_M \exp(D/kT)$$

where D is the dissociation energy. As before, subscripts s, l, v refer to steady state, equivalent stepladder, and variational approximations, respectively. The steady state approximation is clearly the most reliable of the three approximations. As mentioned above, $\delta_{i,s}$ was set equal to zero for all i less than some m. Results accurate to three or more significant figures were obtained provided ε_m was $-8kT$ or less relative to the dissociation energy. The variational method, although it gives somewhat better values of p at the highest temperatures, gives values of δ_N at 3000 and 5000 K which are less than -1. This result has the physically absurd implication that level N has a negative population. The variational approximation is also unsatisfactory in that eqs. 7 are difficult to solve computationally because of spurious roots.

It has been shown (4–6) that the fractional error f in the steady state approximation is of the same order as λ_1/λ_2, the ratio of the first two eigenvalues of κ,

$$f \equiv |k_d - k_{d,s}|/k_d \approx \lambda_1/\lambda_2$$

The present calculations confirm this assertion, as is shown by Table 2. At 5000 K, f is about a factor of four larger than λ_1/λ_2. It has been argued (1) that $-\lambda_2$ is τ_v^{-1}, the reciprocal of the vibrational relaxation time. For the harmonic oscillator model τ_v is given by (11)

$$\tau_v = q_v/k_{12}$$

Values of $-\lambda_2\tau$ and $k_{12}\tau/q_v$ for the Morse oscillator model are given in Table 2. As found previously (7), the latter quantity is larger, but by less than a factor of two. Since $k_{d,s}n_M$ is very close to $-\lambda_1$, a rough estimate of the error in the steady state approximation is given by

$$f \approx k_{d,s}n_M q_v/k_{12}$$

Since k_d increases much more rapidly with T than does k_{12}, the steady state approximation is sufficiently accurate below a certain temperature. As is seen from Table 1, that temperature is about 3000 K for the model under investigation.

Rate Constants and Distribution Functions

Vibrational Levels Only

In Table 3 are shown values of p for the various values of s considered.[2] In descending order, these values of s are meant to correspond to H_2, D_2, T_2, and a hypothetical isotope of H_2 with a molecular weight of 10. Decreasing s implies increasing N as indicated in the table. An increase in N always produces an increase in p. This result is in agreement with earlier findings (8).

In order to better understand this result, the variation of r with s was considered where r is the factor by which the rate constant is reduced due to deviations from a Boltzmann distribution,

$$[8] \qquad r \equiv k_d/k_{d,e} = p/p_e$$

Figure 1 shows logarithmic plots of r vs. T for H_2, T_2, and the hypothetical isotope. In all three cases the curves level off at the temperature extremes. As s decreases, the rate of change of r with T decreases so that r increases with increasing s at low temperatures but decreases with increasing s at high temperatures. From [8] and Table 3 it is seen that p_e must decrease with increasing s at low temperatures. It was found

[2]In what follows, p is taken to be equal to p_s.

TABLE 3. Preexponential factors at two temperatures for Morse oscillator models with different level spacings

T (K)	s	N	p
77	0.0575	17	1.229

5000	0.0332	30	0.143
5000	0.0257	39	0.167

that p_e decreases with increasing s at all temperatures.[3]

Figure 2 shows curves of ln $(-\delta_i)$ vs. ε_i/kT at 3000 K for the three cases discussed above.[4] The curves coincide near the dissociation limit, but for the underlying levels the population at given ε_i is closer to being in a Boltzmann distribution at smaller s. Nevertheless, even for the case with the smallest s, deviations from a Boltzmann distribution are already as high as 50% for a few of the levels which are more than kT below the dissociation limit. Similar results were found at the other temperatures investigated.

In Fig. 3 are shown plots of contributions to the rate from the individual levels as a function of level energy. Curves are shown only for T_2 because they are very similar for the other isotopes. The contributions are expressed in terms of p_i which is given by

$$[9] \qquad p_i = \tau R_{N+1,i}(1 + \delta_i) \exp(D/kT)$$

As can be seen from [2], $k_{N+1,i}$ increases monotonically with ε_i at the temperatures in question. However, because of the drastic depletion of the uppermost levels, p_i goes through a maximum. Also of note is that the maximum is broader at the higher temperature.

These results enable one to account for the variation of r with temperature for the various values of s. At low temperatures most of the dissociation comes from levels in the energy range for which δ_i at given ε_i is the same for all the isotopes. The pattern of levels and the variation of $k_{N+1,i}$ with ε_i are such that a decrease in s produces a decrease in r. At high temperatures this effect is offset by the relatively greater contribution to the rate from levels for which the populations come closer to maintaining a Boltzmann distribution at the smaller values of s. Since this contribution is decisive at the higher temperatures, r increases with decreasing s.

[3]The values of p_e and r for D_2 are out of step with these trends. However, D_2 can be regarded as the exception which proves the rule because the Nth level in this case is exceedingly close to the dissociation limit.

[4]As will be seen later, this representation of the δ's was chosen in order to facilitate comparison with predictions of the separable exponential model.

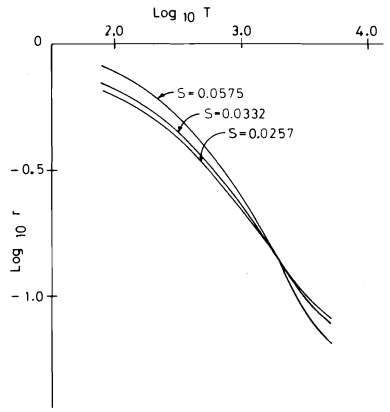

FIG. 1. Rate reduction due to non-Boltzmann distribution as a function of temperature for Morse oscillator models with different level spacings.

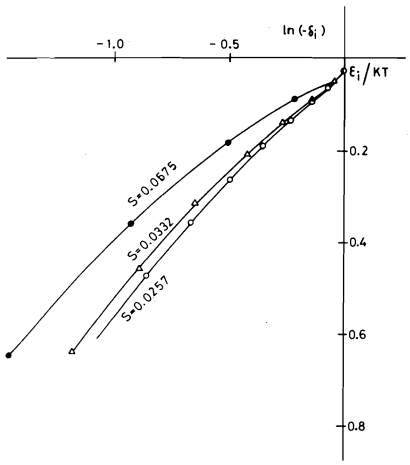

FIG. 2. Semilog plot of fractional deviation of level populations from a Boltzmann distribution as a function of level energy at 3000 K for Morse oscillator models with different level spacings.

A Rotational–Vibrational Model

In order to make meaningful comparisons with experiment, one must generalize the Morse oscillator model to account for rotation. It is also necessary to assume an explicit expression for τ^{-1}. The simplest assumption in the latter case is based on hard sphere collision theory,

$$[10] \qquad \tau^{-1} = \sigma(8kT/\pi\mu)^{1/2} n_M$$

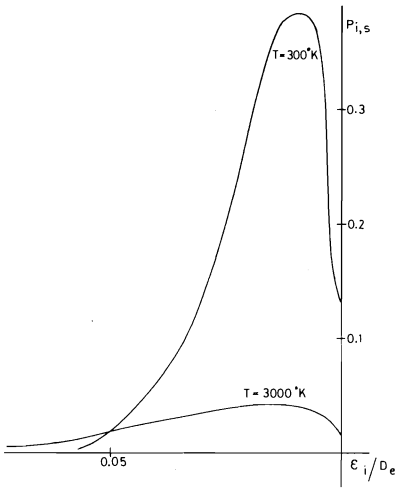

FIG. 3. Contributions to the rate from individual levels as a function of level energy for the Morse oscillator model of T_2 at 300 K and at 3000 K.

where σ is the hard sphere collision cross section (not to be confused with the σ of [6] and [7]) and μ is the reduced mass of the A_2–M pair.

Let L be the angular momentum of A_2 and let $P_{N+1,i}(L)$ be given by

$$P_{N+1,i}(L) = \tau k_{N+1,i}(L)$$

where $k_{N+1,i}(L)$ is the rate constant for dissociation of A_2 with angular momentum L and vibrational quantum number i. The dissociation rate constant $k_{d,e}$ is a thermal average of $k_{N+1,i}(L)$,

$$[11] \quad k_{d,e} = (\tau q_{INT})^{-1} \exp(-D/kT) \times \int_0^{L_m} \sum_{i=1}^{N(L)} P_{N+1,i}(L) \exp\{-[\epsilon_i(L) + \epsilon_b(L)]/kT\} \frac{L\,dL}{\hbar^2}$$

where q_{INT} is the partition function for the rotational–vibrational degrees of freedom of A_2, L_m is the maximum angular momentum which a bound A_2 may possess, $\epsilon_i(L)$ is the energy of level iL relative to the top of the centrifugal barrier, $N(L)$ is the number of vibrational levels for given L, and $\epsilon_b(L)$ is the height of the centrifugal barrier relative to the dissociation energy at $L = 0$. Strictly speaking, the integral over L in [11] should be a sum over the allowed values of the angular momentum quantum number. However, for the model assumed, the discrepancy between sum and integral is small even at the lowest temperature considered.

The recombination rate constant $k_{r,e}$ is related to $k_{d,e}$ by a factor K^{-1}. With K^{-1} written in terms of molecular parameters, this relation takes the form

$$k_{r,e} = k_{d,e} R_g q_{INT} \left(\frac{h^2}{\pi m_A kT}\right)^{3/2} \exp(D/kT)$$

where m_A is the mass of A and R_g is the ratio of the electronic degeneracy of the ground state of A_2 to the square of the electronic degeneracy of the ground state of A. Substitution of [10] and [11] for τ and $k_{d,e}$ and multiplication by r gives the following equation for k_r:

$$[12] \quad k_r = R_g \frac{2\sigma h^3}{\pi^2 m_A{}^2 D_e \tilde{T}} \left(\frac{m_M + 2m_A}{m_M}\right)^{1/2} r \times \int_0^{L_m} \sum_{i=1}^{N(L)} P_{N+1,i}(L) \exp\{-[\epsilon_i(L) + \epsilon_b(L)]/kT\} \frac{L\,dL}{\hbar^2}$$

The right-hand side of [12] really only contains a factor of Planck's constant to the first power since only the vibrational degree of freedom of A_2 is being regarded as quantum mechanical. For most diatomic molecules one likely can, to a good approximation, treat this degree of freedom classically as well.

Equation 12 is based on a reasonably realistic model for atom recombination, but further approximations are necessary in order to obtain numerical results. First, $\epsilon_i(L)$ and $P_{N+1,i}$ are taken to be independent of L so that the sum and the integral in [12] become separable. Next, ϵ_b is taken to have the form

$$[13] \quad \epsilon_b = D_e(X/X^*)^n$$

where X^* and n are constants. The variable X is related to L by

$$X = L^2/2\mu_{A-A} r_e{}^2 D_e$$

where μ_{A-A} is the reduced mass of A_2 and r_e is its equilibrium internuclear separation. This approximation for ϵ_b may be fairly good since [13] has been found (5) to provide an accurate representation of the angular momentum dependence of ϵ_b for the potential of the rotating Morse oscillator,

$$D_e[\exp[-2a(r - r_e)] - 2\exp[-a(r - r_e)] + Xr_e{}^2/r^2]$$

With the two just mentioned approximations, [11] becomes

$$[14]\quad k_r = \frac{R_g \sigma h^3 X^*}{n\pi^2 m_A{}^2 k\Theta_r}\left(\frac{m_M + 2m_A}{m_M}\right)^{1/2} \times \tilde{T}^{(1/n)-1}\gamma\left(n^{-1}, \frac{\varepsilon_c}{kT}\right) r \times \sum_i P_{N+1,i} \exp(-\varepsilon_i/kT)$$

where Θ_r is the rotational temperature of A_2, $\gamma(n^{-1}, \varepsilon_c/kT)$ is the incomplete gamma function, and ε_c is $\varepsilon_b(L_m)$. The factor

$$\frac{h^2 X^*}{n\pi m_A k\Theta_r}\tilde{T}^{(1/n)-1}\gamma\left(n^{-1}, \frac{\varepsilon_c}{kT}\right)$$

can be regarded as a rotational equilibrium constant. It corresponds to the formation of metastable A_2 at the top of the rotational barrier. The decrease with temperature can be ascribed to the slow increase of the thermally averaged ε_b relative to that of the average energy associated with orbital motion of the unbound atoms. The contribution of this effect to the temperature fall-off of k_r has recently been emphasized (9).

For the Morse potential used in the previous section one obtains values of 9.21 and 1.46 for X^* and n, respectively. The potential has a minimum only for X less than 2.26, which in conjunction with [13] implies that ε_c equals $0.136D_e$. Equation 13 with these specific values of the parameters gives for H_2

$$[15]\quad \int_0^{L_m} \exp[-\varepsilon_b(L)/kT]\frac{L\,dL}{\hbar^2} = 1837\tilde{T}^{0.685}\gamma(0.685, 0.136/\tilde{T})$$

For D_2 the result is exactly twice as large. At a temperature of 77 K the right-hand side of [15] is smaller by about 4% than the corresponding quantum mechanical sum. Furthermore, the ratio of ortho and para contributions to the sum is almost exactly 3:1. Therefore, this model predicts no significant para enrichment of H_2 due to recombination at 77 K, a result which agrees with experiment (12).

For r times the sum of the $P_{N+1,i}$'s, one may take pq_v where p is given by the computations reported in the previous sections, and q_v is readily computed from [4*b*]. As shown by Fig. 1, r decreases with T, albeit more slowly at the highest temperatures considered. The factor $p_c q_v$ increases with temperature, which may be the most unrealistic feature of the model. The hard sphere collision cross section σ in [14] is treated here as an adjustable parameter. Assuming for it a not unreasonable value of 10 Å^2, one obtains for hydrogen

$$[16]\quad k_{r,H} = (5.4 \times 10^8)\,\tilde{T}^{-0.315}\gamma(0.685, 0.136/\tilde{T}) \times q_v p\ \ell^2\ \text{mol}^{-2}\ \text{s}^{-1}$$

For deuterium the factor $m_A{}^2\,\Theta_r$ in the denominator of [14] is twice as large as it is for hydrogen. Thus the isotopic ratio is given by

$$[17]\quad k_{r,H}/k_{r,D} = 2(q_v p)_H/(q_v p)_D$$

The factor of two more than outweighs the larger $q_v p$ values for deuterium.

Figure 4 shows a logarithmic plot of [16] along with the most recent experimental values (13–15) of k_r for H_2 in argon. The graph of [16] is seen to level off at the extremes of temperature, a reflection of the levelling-off of r. Agreement with experiment is not very good. The experi-

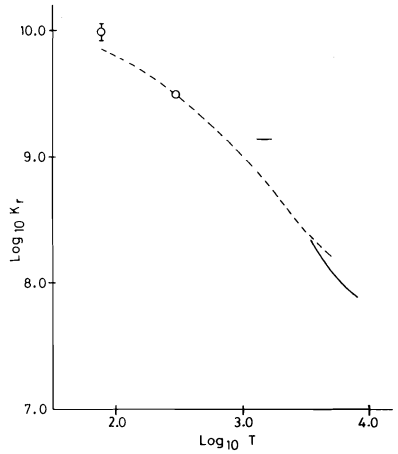

FIG. 4. Recombination rate constant as a function of temperature for H_2 in Ar. Dashed line was calculated from [16], circles represent data of ref. 13, and solid lines represent data of refs. 14 and 15.

mental curve does level off at the highest temperatures. However, it does not level off at low temperatures, and there appears to be a shoulder between 1000 and 2000 K. It is of some significance that the modified phase space theory (16) does predict these latter two features of the experimental curve.

In Table 4 values of the isotope ratio calculated from [17] are compared with values obtained from experiment. Here the agreement is good.

Discussion

Comparison with the Separable Exponential Model

The separable exponential model (4) is defined by the equations

$$[18]\quad R_{ij} = \tau^{-1}(1 - e^{-\theta})^2 \exp[\beta(N - i)\theta - \alpha(N - j)\theta - N\theta] \quad \text{for } j < i < N + 1$$
$$= \tau^{-1}(1 - e^{-\theta})^2(e^{\beta\theta} - 1)^{-1} \exp[\beta(N - i)\theta - \alpha(N - j)\theta - N\theta] \quad \text{for } i = N + 1$$
$$= R_{ji} \quad \text{for } j > i$$

The model is characterized by parameters α, β, and θ. The parameter θ is a measure of the level spacing and is of greatest interest in the present discussion. In ref. 4 it was shown that the steady state approximation gives for this model

$$[19]\quad \delta_i = -(e^{\alpha\theta} - 1)(e^{\beta\theta} - 1)^{-1} e^{(\beta-\alpha)\varepsilon_i}$$

$$[20]\quad p = (1 - e^{-\theta})^2(e^{\beta\theta} - 1)^{-3}(1 - e^{-\alpha\theta})^{-1}(e^{\beta\theta} - e^{\alpha\theta})(e^{\beta\theta} - e^{-\alpha\theta})$$

$$[21]\quad r = 1 - \sinh^2(\tfrac{1}{2}\alpha\theta)\sinh^{-2}(\tfrac{1}{2}\beta\theta)$$

where ε_i is $-(N - i)\theta$.

The monotonic increase of p with decreasing s for the Morse oscillator model has been ascribed to network effects (17). The monotonic increase of p with decreasing θ for the separable exponential model cannot be explained in this way (4). The present study goes beyond ref. 17 by showing which independent paths are important for bringing about the increase, namely those which lead directly to the dissociated state. Increase of the number of these paths increases p_e, and p is thereby increased even at low temperatures where r decreases markedly with increasing s.[5]

As mentioned above, the increase of r with decreasing s for the Morse oscillator model at high temperatures is apparently due to differences in the variation of δ_i with ε_i for the different values of s. From Fig. 2 one would surmise that the curves of $\ln(-\delta_i)$ vs. ε_i converge to a continuum ($s \to 0$) limit and that this limit is approached more rapidly for ε_i's near the dissociation energy. From [19] one sees that the continuum limit of the $\ln(-\delta_i)$ vs. ε_i curves for the separable exponential model is approached at the same rate for all ε_i. Furthermore, the curves approach this limit from below whereas the corresponding curves for the Morse oscillator model appear to approach their continuum limit from above. These differences between the $\ln(-\delta_i)$ vs. ε_i curves for the Morse oscillator model and those for the separable exponential model can be explained on the basis of the variable level spacings for the former model. Simply because the levels for the Morse oscillator approach a continuum most rapidly near the dissociation limit, it would seem reasonable that δ_i should approach its continuum value most rapidly here as well. The downward concavity of the $\ln(-\delta_i)$ vs. ε_i curves for the Morse oscillator model can also be ascribed to the variation in level spacing since a greater number of levels per energy interval of given size is almost certain to imply less tendency for any one of them to be replenished. Thus the populations of the lower, less densely packed levels come closer to being in a Boltzmann distribution than would be expected on the basis of a linear extrapolation from the higher levels. Finally, since the relatively high depletions of the uppermost levels account for the maxima in the p_i vs. ε_i curves for the Morse oscillator model, this effect can be ultimately traced back to the variation of level spacing with ε_i.

[5]For the separable exponential model as well it is the increase of p_e with decreasing θ that is decisive, but here the increase can be ascribed only in part to network effects.

Comparisons with Experiment and with other Theories

As already mentioned, the modified phase space theory (16) gives a k_r vs. T curve more nearly in agreement with the experimental curve for H_2 in Ar than does the cruder theory discussed here. However, it has been pointed out (7) that the Morse oscillator model is really intended to describe H-atom recombination in He at high temperatures. No experimental data are available for this case, but the differences between He and Ar as third bodies are probably not large. Mass effects appear not to be important (18), and the effects of attractive forces are important only at low temperatures. One sees from Fig. 4 that the Morse oscillator model does come closest to representing the experimental variation of k_r with T at high temperatures. What is notable about this variation is the levelling-off of the curves as T increases. In the case of the model this levelling-off is a consequence of the levelling-off of r. The levelling-off of r is probably due to the increase with T of the probabilities of multiquantum transitions. Such an increase would slow the decrease of r in two ways: by evening out the reactivities of the various levels and by causing the reactive levels to be more easily replenished.

The failure of the Morse oscillator model to reproduce the low temperature portion of the k_r vs. T curve is most likely a consequence of the neglect of atom – third body attraction. As can be seen from the results of ref. 16, the prediction of the modified phase space theory as to the rapidity of the fall-off of k_r with T at low temperatures is quite sensitive to the assumed depth of the H–M potential well. The absence of a shoulder on the curve for the model in the intermediate temperature range may be due to a decline of r with T which is too gradual. Calculations, the results of which were not presented here, show that a relative widening of the level spacings near the dissociation limit results in a more abrupt fall-off of r with T. It is known (19) that [3] gives energy levels near the dissociation limit which are more closely spaced than those actually observed for H_2. It may be that the k_r vs. T curve for a model with level spacings somewhere between those of a harmonic oscillator and those of a Morse oscillator would exhibit the observed shoulder. Such an explanation of the shoulder would be, nevertheless, ambiguous. The modified phase space theory of ref. 16 is also based on a Morse oscillator model, and it does predict the shoulder.

Conclusions

The present study of the Morse oscillator model of hydrogen dissociation and recombination has two parts: a test of approximations to the smallest eigenvalue λ_1 of the matrix κ for the model and an analysis of rate constants and level populations for the model in the light of experimental and of other theoretical results. It was found that the steady state approximation gives a highly accurate result for λ_1 provided that T is sufficiently low. A rough estimate of the error due to the steady state approximation is given by

$$k_{d,s}n_M q_v/k_{12}$$

This ratio increases rapidly with temperature, but it does not become appreciable compared to one until temperatures such as are only occasionally investigated experimentally. The steady state approximation reduces the problem of calculating the rate constant and the level populations to one of solving a system of simultaneous linear algebraic equations. The number of equations which must be solved to get an accurate result decreases as T decreases. No satisfactory further simplification of the calculations was found. Conversion to an approximately equivalent stepladder model led to inaccurate results.

Transformation to an equivalent separable exponential model by means of the variational principle was also found to lead to inaccurate results. The failure of this approximation is elucidated by comparing curves of $\ln(-\delta_i)$ vs. ε_i for the two models. For the Morse oscillator model the curves are concave downward over most of the range of ε_i whereas they are linear for the separable exponential model. This difference can be ultimately related to the decrease in level spacing with increase in ε_i for the Morse oscillator model.

The recombination rate constant for the Morse oscillator model decreases as T increases. The decrease is due in part to the decrease of the rotational equilibrium constant for the formation of metastable A_2. The rest of the decrease is due to the fall-off of r. The temperature variation of k_r with T for the model does not agree well with that observed for H-atom recombination in argon. It seems fairly certain that neglect of atom – third body attraction is partly to blame for this discrepancy. The use of a rather unrealistic energy level expression may also be partly to blame.

The model best reproduces the observed variation of k_r with T at high temperatures where a levelling-off of both curves is found. For the model this levelling-off is due to increase with T of the relative rates of multiquantum transitions. The model also reproduces the experimentally observed ratios of the rate constants for H-atom and D-atom recombination. Phase space factors for degrees of freedom other than vibration of A_2 give a ratio of $k_{r,H}$ to $k_{r,D}$ equal to 2. The effect of increasing the vibrational level density is to reduce this ratio to values not much greater than one, which agrees with experiment. Apparently the effect which requires special consideration in predictions of $k_{r,H}/k_{r,D}$ is the effect of the change in the spacing of vibrational levels.

The ion equilibria $R_1H + R_2^- = R_1^- + R_2H$ involving nitroalkanes and compounds with known gas phase acidity were measured at 500 K with a pulsed high pressure mass spectrometer. The resulting $\Delta G^0 = -RT \ln K$ combined with calculated ΔS^0 values lead to the corresponding ΔH changes. The enthalpy changes are used for the evaluation of the difference between the bond dissociation energy and the electron affinity D(R—H) − EA(R). The values obtained are: CH_3NO_2 44.0, $CH_3CH_2NO_2$ 43.7, $(CH_3)_2CHNO_2$ 43.0 kcal/mol. D(R—H) − EA(R) is a measure of the gas phase acidity. The nearly equal gas phase acidities of the nitroalkanes above are due to a decrease of D(R—H) and to a decrease of EA(R) with methyl substitution. In aqueous solution the acidities are known to increase substantially for the above nitroalkane order. Decrease of EA with methyl substitution indicates that there will be more charge localization on the O atoms in R^- with methyl substitution. This leads to better H bonding and solvation of R^- in protic solvents. This explains the higher acidity of the methyl substituted nitroalkanes in aqueous solution. The acidities in DMSO are closer to those in the gas phase since DMSO is not so sensitive to the charge distribution in R^-.

J. B. CUMMING, T. F. MAGNERA et P. KEBARLE. Can. J. Chem. **55**, 3474 (1977).

L'équilibre ionique $R_1H + R_2^- = R_1^- + R_2H$ impliquant des nitroalkanes et des composés d'acidité connue en phase gazeuse sont mesurés à 500 K avec un spectromètre de masse à haute pression impulsive. L'expression $\Delta G^0 = -RT \ln K$ résultante, combinée avec les valeurs calculées du ΔS^0 conduisent aux valeurs ΔH correspondantes. Les changements d'enthalpie sont utilisés pour évaluer la différence entre l'énergie de dissociation d'une liaison et l'affinité électronique D(R—H) − EA(R). Les valeurs obtenues sont: CH_3NO_2 44.0, $CH_3CH_2NO_2$ 43.7, $(CH_3)_2CHNO_2$ 43.0 kcal/mol. La différence D(R—H) − EA(R) est une mesure de l'acidité des composés en phase gazeuse. Cette similarité des valeurs de l'acidité, en phase gazeuse des nitroalkanes ci-dessus, est due à une diminution des termes D(R—H) et EA(R) avec la substitution par un groupe méthyle. Par contre, pour la même séquence que ci-dessus, on note une augmentation de l'acidité de ces nitroalkanes en solution aqueuse. La diminution du terme EA avec la substitution par un groupe méthyle indique qu'il y a une localisation de charge plus grande sur les atomes d'oxygène O dans R^- avec la substitution par un groupe méthyle. Ceci nous amène à un meilleur établissement de la liaison H et une meilleure solvatation du radical R^- dans les solvants protiques. Ceci explique l'acidité plus grande des nitroalkanes méthyl-substitués en solution aqueuse. Les acidités dans le DMSO sont proches de celles obtenues en phase gazeuse puisque le DMSO n'est pas aussi sensible à la distribution de charge dans R^-.

[Traduit par le journal]

Introduction

Recently we reported gas phase acidities of a large variety of carbon acids RH obtained from measurements of the gas phase proton transfer equilibria 1 and 2 (1).

$$[1] \qquad R_1H + R_2^- = R_1^- + R_2H$$

$$[2] \qquad RH + Cl^- = R^- + HCl$$

The proton transfer process 2 relates the acidities to that of a common standard HCl. The previous measurements included only one nitro compound, p-NO_2 toluene. The anion of p-NO_2 toluene is highly delocalized and therefore not essentially different from the other highly delocalized anions reported in that work. The nitroalkanes, whose acidities are reported in the present work, are of special interest for several reasons. They are similar to the carbonyl carbon acids for which recently gas phase acidities (1, 2) and electron affinities (3) have become available. Therefore comparisons between the alkyl substituent effects prove to be quite fruitful even in the absence of electron affinities and bond dissociation energies for the nitro compounds. The nitroalkanes undergo measurable acid dissociation in aqueous solution so that acidity constants for that medium are available (4).

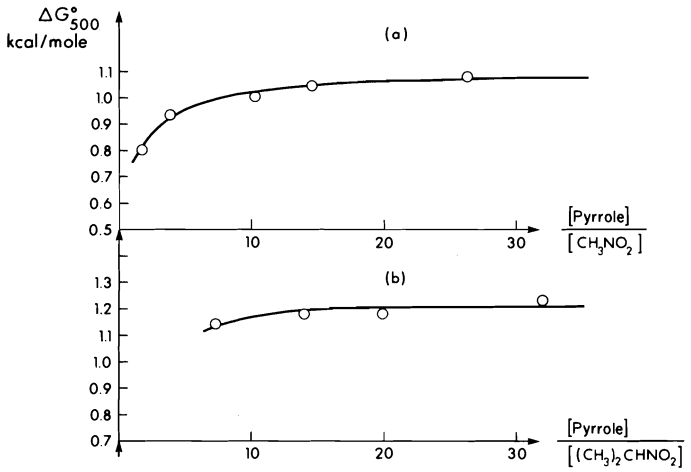

FIG. 1. Dependence of $\Delta G_1^0 = RT \ln K_1$ for proton transfer reaction involving nitroalkane and reference acid pyrrole. (*a*) $CH_2NO_2^- + PyH = CH_3NO_2 + Py^-$. (*b*) $(CH_3)_2CNO_2^- + PyH = (CH_3)_2CHNO_2 + Py^-$. Because of reaction producing NO_2^- (see text) consistent equilibrium constants could be obtained only for large [pyrrole]/[nitroalkane] ratios.

Acidity measurements in the important aprotic solvent DMSO have also been determined (5). Therefore comparisons between the acidities in the dilute gas phase, water, and DMSO are possible and, as will be seen, prove very informative.

Experimental

The measurements of the proton transfer equilibria 1 were made in a high pressure mass spectrometer (6) using procedures very similar to those described earlier (1). A gas mixture containing the buffer gas methane at 1–4 Torr, R_1H and R_2H generally in the 1–100 mTorr range, and NF_3 at ~20 mTorr was passed in slow flow through the ion source. Fluoride ions are formed by the dissociative electron capture: $e^- + NF_3 = F^- + NF_2$. The ions R^- result from the proton transfer: $F^- + RH = HF + R^-$. This reaction removes all the fluoride ions, since HF is a much weaker acid than RH. Pulsing of the electron beam permits one to follow the temporal change of R_1^- and R_2^-. In normal measurements, after a kinetic stage of some 50 μs, the concentration ratio R_1^-/R_2^- becomes constant, which indicates the achievement of equilibrium 1.

Some difficulties were encountered with the nitro compounds. For all nitroalkanes RH, the major ion observed was not R^- but NO_2^-. This ion was present directly after the electron pulse and continued to grow slowly in intensity at the expense of the R^- ions. Low pressure mass spectrometric studies (7) have shown that NO_2^- is produced directly by dissociative electron capture $e^- + C_nH_{2n+1}NO_2 = NO_2^- + C_nH_{2n+1}$. While this reaction might be responsible for the NO_2^- observed at the beginning of the pulse, the growth of NO_2^- with time after the pulse must be due to some ion molecule reaction. One possibility is the occurrence of nucleophilic displacement reactions of the type: $CH_2NO_2^- + CH_3NO_2 = CH_3CH_2NO_2 + NO_2^-$. Another possibility is proton transfer from HNO_2 i.e. $CH_2NO_2^- + HNO_2 = CH_3NO_2 + NO_2^-$, where the HNO_2 is either a minor impurity present in the nitroalkanes or a product of some reaction occurring in the ion source. Since HNO_2 is a much stronger acid, HNO_2 present at 10^{-4} Torr i.e. less than 0.1% of RH will still be able to convert half of the R^- to RH in ~1 ms.

It was found that equilibrium 'constants' K_1 obtained at longer reaction times where the anion ratio had become constant were not always independent of the neutral acid ratio used. Constant values of K_1 could be obtained only if the concentration of the nitroalkane RH was much lower than the concentration of the reference acid (pyrrole). This situation is illustrated by the results shown in Fig. 1. $\Delta G_1^0 = RT \ln K_1$ is seen initially to increase with the [pyrrole]/[nitroalkane] ratio but the value becomes constant for a ratio larger than ~10. This behaviour may be a result of the side reactions producing NO_2^-, which were mentioned above. The following scheme written for nitromethane AH and pyrrole PyH may be considered:

$$[3] \qquad PyH + A^- \underset{k_r}{\overset{k_f}{\rightleftarrows}} Py^- + AH$$

$$[4] \qquad Py^- + AH \xrightarrow{k_{s1}} NO_2^- + \text{neutrals}$$

$$[5] \qquad A^- + AH \xrightarrow{k_{s2}} NO_2^- + \text{neutrals}$$

The possible neutrals being $PyCH_3$ and $C_2H_5NO_2$ respectively if the side reactions are nucleophilic substitution processes. The results shown in Fig. 1*a* were measured for long reaction times where $[A^-]/[Py^-] =$ constant. For this condition to hold: $d[A^-]/dt = d[Py^-]/dt$. Expressing the rates in terms of the concentrations and the rate constants one obtains, after rearranging

[6] $$Q = \frac{2k_f}{2k_r + k_{s1}} + \frac{k_{s2}}{2k_r + k_{s1}} \frac{[AH]}{[PyH]}$$

where,

$$Q = \frac{[AH][Py^-]}{[PyH][A^-]}$$

Q is the equilibrium quotient for the proton transfer reaction 3.

A replot of the data used in Fig. 1*a* is shown in Fig. 2, where Q is plotted vs. the concentration ratio [AH]/[PyH]. An (approximately) straight line is obtained, which shows that the experimental results are consistent with the mechanism [3]–[5]. The slope of the straight line obtained is 0.2 while the intercept with the Q axis is ~0.325. This leads to the expressions:

$$Q = 2k_f/(2k_r + k_{s1}) = 0.325$$

and,

$$k_{s2}/(2k_r + k_{s1}) = 0.2$$

Evidently Q will be close to the equilibrium constant K for [3], only if $2k_r > k_{s1}$. Unfortunately quantitative measurements of the rate constants were not made; however qualitative examinations of the concentration changes of the ions before the ion ratio $[A^-]/[Py^-]$ becomes constant did indicate that k_r, which corresponds to the exothermic direction of equilibrium 3, is considerably larger than $k_{s1} + k_{s2}$. The equilibrium constant therefore should be equal to 0.325 the same value as that obtained by the extrapolation in Fig. 1*a*. An additional reason for confidence in the results is the thermodynamic consistency of the data presented in Fig. 3. The results of Fig. 3 are considered in the next section.

It should be pointed out that an equation of the same form as [6] will be obtained if the side reactions 4 and 5 involved not AH directly but some impurity like HNO_2 whose concentration is proportional to that of AH.

Results and Discussion

The free energy changes for reaction 1, $\Delta G_1^0(500) = RT \ln K$ for $T = 500$ K, are shown in Fig. 3. The determinations include, for the ion equilibria,

$$R_1H + R_2^- = R_1^- + R_2H$$

$$RH + Cl^- = R^- + HCl$$

some multiple thermodynamic cycles which are

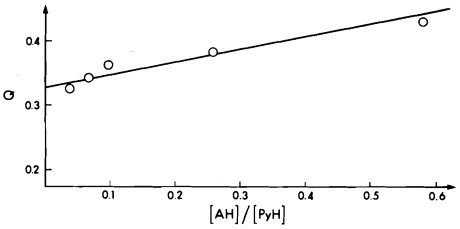

FIG. 2. Replot of data from Fig. 1*a* as a test of eq. 6. $Q = [AH][Py^-]/[PyH][A^-]$ is the equilibrium coefficient of reaction: $PyH + A^- = Py^- + AH$, slope of line equals 0.2 and intercept of Q axis equals 0.325.

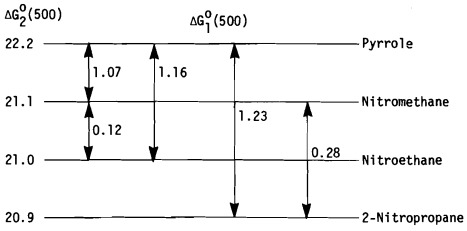

FIG. 3. Summary of gas acidity measurements. Numbers beside double arrows represent directly measured $\Delta G_1^0(500) = -RT \ln K_1$ for reaction 1: $R_1H + R_2^- + R_2H$ measured at 500 K. R_1H is the compound on the upper end of the double arrow. $\Delta G_2^0(500)$, given in column on the left are values for reaction 2: $RH + Cl^- = R^- + HCl$, relating present acidities to the primary standard HCl.

consistent to 0.1 kcal/mol. The $\Delta G_2^0(500)$, also shown in Fig. 3, relate the acidities to the primary standard HCl. They were obtained from ΔG_1^0 and the ΔG_2^0 for pyrrole which was determined in separate measurements (1, 9).

From ΔG_2^0, ΔH_2^0 can be evaluated by using calculated ΔS_2^0 values. Since $\Delta H_2^0 = D(R—H) - EA(R) - D(H—Cl) + EA(Cl)$, it is possible to evaluate $D(R—H) - EA(R)$ by using the known $D(H—Cl) - EA(Cl) = 20$ kcal mol (8). The entropy change in reaction 2 was evaluated (9) by considering the appearance of two rotational degrees of freedom in the change $Cl^- \rightarrow HCl$ and the conversion of an internal rotation to a restricted rotation in the change $C_nH_{2n+1}NO_2 \rightarrow C_nH_{2n}NO_2^-$. Symmetry number changes were considered also. The barrier to internal rotation around the C—N bond arises because of the formation of a partial double bond in the anion. The corresponding structures for the nitromethane anion are shown in **1**.

1 
A full account of entropy calculations for reactions 2 involving all measurements done in our laboratory is given elsewhere (9). The calculated (9) $T\Delta S_2^0$ are approximately 2.2 kcal/mol (at 500 K) for the nitroalkanes. Since they don't change much for the three nitroalkanes studied, they do not have a significant effect on the relative acidities. However, this correction improves the accuracy of the absolute $D - EA$ results. The $D - EA$ values for the nitroalkanes are shown in Table 1.

A key to the changes of gas phase acidities of the nitroalkanes can be obtained by comparison

with the acidities of the carbonyl compounds also shown in Table 1.

Recent determinations of the photodetachment thresholds of the enolate ions R^- by Zimmerman, Reed, and Brauman (3) have provided electron affinities for the enolate radicals R. With these data the D(R—H) − EA(R) obtained from gas phase acidity measurements (2) can be separated into substituent effects on EA(R) and on D(R—H) for the carbonyl compounds. Examining the pairs $HCOCH_2$—H, $HCOCH(CH_3)$—H and CH_3COCH_2—H, $CH_3COCH(CH_3)$—H (Table 1), we notice that methyl substitution on the carbon carrying the acidic hydrogen lowers the electron affinity of R by 2.8 and 2 kcal/mol and the bond energies D(R—H) are lowered by 3.4 and 3.8 kcal/mol, respectively. Since electron affinity and bond energy have opposite effects on the acid dissociation energy, the net result is a very small increase of acidity with methyl substitution. The bond energy change with methyl substitution is the familiar decrease which occurs from a primary to a secondary C—H bond. Since for the nitroalkanes CH_3NO_2, $C_2H_5NO_2$, and i-$C_3H_7NO_2$ we have again a change from primary to secondary and to tertiary C—H bonds one may certainly expect that decreases of D(R—H) of some 3–4 kcal/mol will be occurring with each methyl that is introduced. Since the measured D − EA values change (decrease) by much smaller amounts the electron affinities must be decreasing with methyl substitution. It is interesting to note that $D(CH_3CH_2$—H) = 98 and $D(CH_3CH(CH_3)$—H) = 94.5 kcal/mol (10) are very close to $D(CH_3COCH_2$—H) ≈ 97 and $D(CH_3COCH(CH_3)$—H ≈ 93 kcal/mol (Table 1). The lack of change when CH_3 is replaced by the electron withdrawing group CH_3CO makes it plausible to assume that the R—H bond energies in the nitromethanes might also be approximately equal to the bond energies of the primary, secondary, and tertiary C—H in the alkanes. Using $D((CH_3)_3C$—H) = 91.5 kcal/mol (10) and the values 97 and 93 kcal/mol for primary and secondary C—H given above one obtains the approximate values for EA(R) of the nitroalkanes given in Table 1.

It is interesting to compare the three substituted 'methanes' $(CN)CH_3$, $(CH_3CO)CH_3$, and $(NO_2)CH_3$ (Table 1). The D − EA values are 58.7, 56.4, and 44 kcal/mol, an acidity order observed previously in the more qualitative measurements by Bohme (11). The lack of a reliable $D(NO_2CH_2$—H) is unfortunate, but the available data indicate that the observed acidity change is determined by increases in the electron affinities: 34.8, 40.6, and ~53 kcal/mol. The bond energies also increase in this order but the changes are much smaller.

A comparison between the nitroalkane acidities in the dilute gas phase, in aqueous solution, and in DMSO can be made on the basis of the data shown in Table 2. This is best done by considering the experimental ΔG data for proton transfer in the gas phase, water, and DMSO since these do not involve corrections for symmetry number as do the D − EA data. While the acidity in the gas

TABLE 2. Acidities in the dilute gas phase, in water, and in DMSO

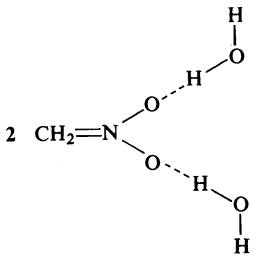
phase experiences practically no increase with methyl substitution to the carbon carrying the acidic hydrogen, in water a substantial increase of acidity is observed. Generally alkyl substitution decreases the aqueous acidity relative to that in the gas phase so that, at a first glance, the results for the nitroalkanes appear surprising. However there is a good explanation for these observations. As noted earlier methyl substitution decreases the electron affinity EA(R). Therefore it may be assumed that methyl relative to H has a charge localization effect in the anion, i.e. the partial negative charge on the oxygen atoms increases in the order $CH_2NO_2^-$ < $CH_3CHNO_2^-$ < $(CH_3)_2CNO_2^-$. This means that the first and the few subsequent strong hydrogen bonds with HOH molecules, which will occur to the oxygen atoms as in structure **2**, will be stronger for the more highly methyl substituted anions.



Therefore the solvation of the methyl substituted anions will be more favorable. The favorable solvation effect will partially offset the unfavorable decrease of electron affinity and a substantial increase of acidity will result from the decreasing bond energies R—H.

In DMSO the situation is quite different. As pointed out earlier (12), the behavior of aprotic solvents like acetonitrile and DMSO toward anions can be explained on the basis of the electric dipole charge distribution in the solvent molecules. Since the positive charge in aprotic dipolar molecules is distributed diffusely over bulky hydrocarbon groups, the centre of the positive pole of the dipole is relatively inaccessible to the negative ion. The strength of the interaction of the first few solvent molecules with the negative ion is therefore less sensitive to increase of ionic radius or delocalization of negative charge from a small functional group. Therefore, the solvation of the nitro anions in DMSO will not increase appreciably with charge localization on the O atoms upon methyl substitution and consequently the relative DMSO acidities will follow approximately the gas phase acidities.

Acknowledgments

Financial support by the National Research Council of Canada is gratefully acknowledged. Encouragement for us to undertake the above measurements came from Prof. F. G. Bordwell who also provided us with a pure sample of $2NO_2$–propane.

Microwave spectrum of *trans*-1-methoxy-1,3-butadiene

R. KEWLEY AND S. C. DASS[1]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received May 4, 1977

R. KEWLEY and S. C. DASS. Can. J. Chem. **55**, 3480 (1977).

The microwave spectra of two conformers of 1-methoxy-1,3-butadiene have been studied in the 18 to 40 GHz region. One conformer is the s-*trans* conformer of *trans*-1-methoxy-1,3-butadiene. The other is most likely the corresponding s-*cis* conformer. The rotational constants for the ground vibrational state are (in MHz) s-*trans*: $A = 24\,524(16)$; $B = 1336.51(1)$; $C = 1277.76(1)$; s-*cis*: $A = 12\,642.73(23)$; $B = 1607.61(1)$; and $C = 1439.64(1)$. The centrifugal distortion parameters D_{JK} and D_J have also been determined for each conformer.

For the s-*trans* conformer two series of torsional satellites have been found which are assigned as O—CH torsion with frequency 60(20) cm^{-1} and =C—C= torsion, frequency 80(30) cm^{-1}. For the s-*cis* conformer one series of satellites has been observed, which has been assigned to =C—C= torsion, of frequency 103(30) cm^{-1}.

R. KEWLEY et S. C. DASS. Can. J. Chem. **55**, 3480 (1977).

On a enregistré les spectres microondes de deux conformères du méthoxy-1 butadiène-1,3 dans la région de 18 à 40 GHz. L'un d'eux est le conformère s-*trans* du méthoxy-1 butadiène-1,3 *trans*. L'autre est vraisemblablement le conformère s-*cis* correspondant. Les constantes de rotation pour l'état vibratoire fondamental sont (en MHz) pour le s-*trans*: $A = 24\,524(16)$; $B = 1336.51(1)$; $C = 1277.76(1)$; et pour le s-*cis*: $A = 12\,642.73(23)$; $B = 1607.61(1)$; $C = 1439.64(1)$. Les paramètres de distorsion centrifuge D_{JK} et D_J sont aussi déterminés pour chaque conformère.

On a trouvé pour le conformère s-*trans* deux séries de satellites de torsion auxquelles sont assignées la torsion O—CH de fréquence 60(20) cm^{-1} et la torsion =C—C= de fréquence 80 (30) cm^{-1}. Pour le conformère s-*cis*, on observe une série de satellites à laquelle on attribut la torsion =C—C= de fréquence 103(30) cm^{-1}.

[Traduit par le journal]

Introduction

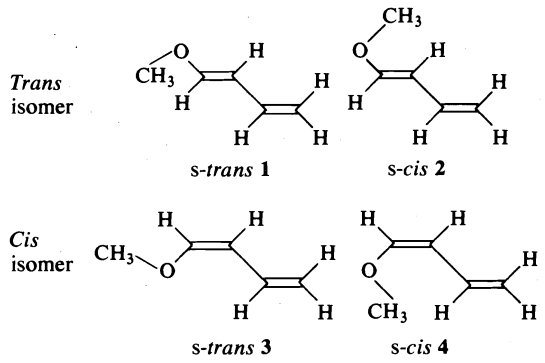
Recently a number of straight chain methoxy compounds have been studied by microwave spectroscopy. These include methyl ethyl ether (1), chloromethyl ether (2, 3), bromomethyl ether (3), methyl propargyl ether (4), methoxyacetonitrile (5), and 3-methoxypropionitrile (6).

Less work has been done on fairly small molecules of the type in which a methoxy oxygen is attached directly to an unsaturated carbon atom. The only conformer of methoxyethyne, $CH_3OC{\equiv}CH$, is planar except for two of the methyl hydrogens (7) and in methyl formate, $HCOOCH_3$, the O—CH_3 and C=O bonds are *cis* to one another (8). Of all the molecules investigated previously the one which has the greatest structural similarity to 1-methoxy-1,3-butadiene is methyl vinyl ether, $CH_3OCH{=}CH_2$. The conformer observed in the microwave study of this molecule (9) is the one which is structurally analogous to methyl formate, having the CH_3—O bond *cis* to C=C. The gas phase infrared spectrum of methyl vinyl ether (10) also showed the *cis* conformer to be predominant with about 12% *trans* conformer also present. In an infrared study of the molecules $CH_3OCH{=}CHCH_3$ and $CH_3OCH{=}CHC_2H_5$ Owen and co-workers (11) concluded that in the geometric isomer in which the CH_3O and CH_3 (or C_2H_5) are *trans* to one another the situation is like that in methyl vinyl ether, i.e. the conformer with an s-*cis* CH_3O predominates and there is also a less abundant s-*trans* CH_3O conformer. The other isomer, which has CH_3O and CH_3 (or C_2H_5) *cis*, is considered to have a slightly nonplanar s-*trans* structure (11).

The *cis* and *trans* isomers of 1-methoxy-1,3-butadiene have been the subjects of an nmr solution investigation by Diez and Rico (12).

In their study the *trans* and *cis* isomers were synthesized separately, the *cis* by hydrogenation of *cis*-$CH_3OCH{=}CH{-}C{\equiv}CH$ and the *trans* by treatment of crotonaldehyde, $CH_3CH{=}CH{-}CHO$, with methanol. The analysis of the nmr coupling constants data led to the conclusions

[1]Present address: Microwave Technology, 7512 Bath Road, Mississauga, Ont., Canada L4T 1L2.



that the preferred conformation of the *trans* isomer is planar s-*cis* (conformer **2**) and that the *cis* isomer has the s-*trans* conformer **3** as its preferred configuration. The corresponding conclusion was reached, by dipole moment studies, for the related molecule 1-methoxy-but-1-ene-3-yne (13).

Because of the relative lack of microwave data on unsaturated methoxy compounds and because of the possibility of comparing the results with those found in a liquid medium by nmr it was considered to be of interest to use the microwave rotational spectrum of 1-methoxy-1,3-butadiene as a means of studying the conformational situation in the vapor state.

Experimental

Three samples of 1-methoxy-1,3-butadiene (technical grade), consisting of 88–95 of the *trans* isomer[2], were purchased on separate occasions from the Aldrich Chemical Company. Even a sample from a freshly opened vial gave strong microwave absorption lines due to *trans*-crotonaldehyde, for which the *a*-type $J = 5 \leftarrow 4$, $6 \leftarrow 5$, $7 \leftarrow 6$, $8 \leftarrow 7$, and $9 \leftarrow 8$ transitions fall within the frequency region studied (14). Although the presence of this strong spectrum caused some initial confusion its overlap with that of the molecule under study was not a serious difficulty, so that it was possible to use the commercial samples throughout without further purification. A few weak lines of methanol were also noticed in the 15–30 GHz region.

The initial work in the 18–26.5 GHz region was carried out at Queen's University using a Hughes-Wilson 100 kHz Stark-modulated spectrometer (15) at both room and dry ice temperatures. Samples pressures between 100 and 200 mTorr and Stark voltages in the range 100 to 2000 V cm^{-1} were used. Later work, in the 26.5 to 40 GHz region, was done using a Hewlett-Packard model 8460A MMR spectrometer in the laboratory of Professor R. F. Curl at Rice University, Houston, TX. All the measurements on this instrument were made at room temperature with pressures of 20–60 mTorr and Stark voltages of 800–2000 V cm^{-1}. The accuracy of the frequency measurements is 0.1 MHz or better. All computations were carried out in double precision arithmetic on the Queen's University Burroughs 6700 computer.

Rotational Spectrum

Prediction and Assignments, Ground Vibrational State

As an aid to the initial assignment the rotational constants and spectra were predicted for conformers **1–4**, see Introduction, using structural parameters taken from refs. 5 and 16. The resulting values of $B + C$ and the asymmetry parameter κ are given in Table 1.

It was considered unnecessary to include in these predictions isomers in which the carbon–carbon double bonds are s-*cis* since Carreira[3], in a Raman study, found the s-*cis* configuration of 1,3-butadiene to be 873 cm^{-1} higher in energy than the s-*trans* form.

For conformers **1–4** estimates were also made of the μ_a and μ_b dipole moment components and were based on the observed magnitude and direction of the dipole moment of methyl vinyl ether (9). The estimated values of (μ_a, μ_b) were (in D): **1** (0.07, 0.96); **2** (0.65, 0.72); **3** (0.51, 0.83); **4** (0.95, 0.16).

The *a*-type $J = 9 \leftarrow 8$ and $10 \leftarrow 9$ transitions of conformer **1** were identified on a scan of the 22–26.5 GHz region. The $J = 12 \leftarrow 11$ and $14 \leftarrow 13$ transitions were then examined in detail using the Hewlett-Packard instrument. Only in these transitions was it found possible to make a detailed assignment of the high K_{-1} components. This is because the value of the centrifugal distortion parameter D_{JK} is such as to largely nullify the asymmetry shifts for lines with smaller K_{-1} values. This results in considerable overlapping of lines that would be well resolved for a rigid rotor. Once a satisfactory high K_{-1} assignment had been achieved the $K_{-1} = 1$ lines were identified by using the $(B + C)$, $(A - \frac{1}{2}(B + C))b_p^2$, D_J, and D_{JK} values from the high K_{-1} fit together with the condition that the out-of-plane hydrogen coordinate, c_H, is expected to be close to 0.89 Å. The value in methyl vinyl ether is 0.889 Å (9) and similar values are found in other methoxy compounds (5, 6). In addition a further check on the $K_{-1} = 1$ assignment was made by comparing the resulting A, B, and C values with those obtained from the assumed structure; see also below. The $K_{-1} = 1$ lines

however were weak and difficult to assign as Stark lobes were not observed. The assigned transitions of conformer **1** are given in Table 2 and the derived constants in Table 4. The constants given were obtained using the program DLSQF which fits the observed transition frequencies to the asymmetric rotor constants $(A + C)/2$, $(A - C)/2$, and κ and the centrifugal distortion constants D_{JK} and D_J of a slightly asymmetric rotor. Since this program does not yield directly the standard errors in the rotational constants A, B, and C a second fit was carried out as a check and to obtain consistent standard errors. In this fit multiple linear regression was carried out using the known derivatives of the line frequencies with respect to D_{JK} and D_J and the derivatives with respect to A, B, and C, calculated using the rigid rotor frequency prediction program ROTSPE with the values from the DLSQF fit as the initial ones. The second fit gave essentially the same constants as the first. In both fits the centrifugal distortion constant D_K was set equal to zero. Some use was also made of the program CDANAL (written by Dr. W. H. Kirchoff and modified by Dr. R. S. Lowe) for predicting unobserved lines. However, this program was not used in the final fit as for this type of molecule, with very slight asymmetry, a constrained value of τ''_{aaaa} has to be used giving rather dubious values for the other τ coefficients. The absence of observed *b*-type lines for conformer **1**, in spite of the relatively large μ_b component, is due to the large uncertainties (over 100 MHz) attached to the prediction of such lines from the CDANAL program. Also only a few widely spaced *b*-type transitions would be expected to lie in the region studied.

The initial scan also revealed a group of lines near 24.4 GHz which was assignable as the *a*-type $J = 8 \leftarrow 7$ transition of a second conformer. Vibrational satellites are much less in evidence for this conformer. This may be seen on the trace shown in Fig. 1. Work at higher frequencies led to detailed assignments for the $J = 9 \leftarrow 8$,

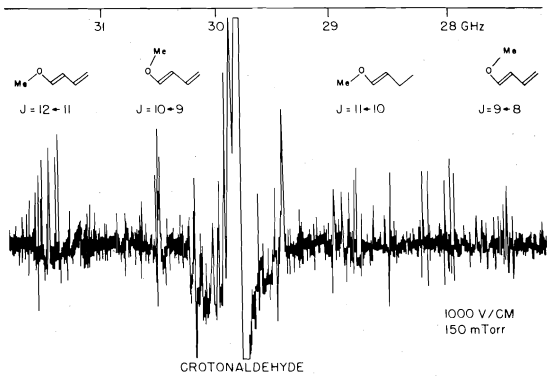

FIG. 1. A trace of the spectrum of *trans*-1-methoxy-1,3-butadiene in the 27 to 32 GHz region, showing the vibrational satellite patterns of the s-*trans* and s-*cis* conformers and the strong absorption due to the presence of crotonaldehyde impurity.

10 ← 9, 11 ← 10, and 12 ← 11 transitions. In the case of this conformer the $K_{-1} = 1$ lines were quite easy to assign from an accurate prediction based on the frequencies of the remaining K_{-1} components, no assumptions concerning the value of c_H being needed. The CDANAL program was used to predict a few *b*-type transition frequencies. This allowed an improvement in the accuracy of the *A* rotational constant to be brought about. The observed frequencies and derived constants for this conformer are given in Tables 3 and 4. In the DLSQF fit for this conformer D_K was again set equal to zero because of the small number of *b*-type lines measured and their weak dependence of their frequencies upon D_K.

On the basis of the $B + C$ of 3047.25 MHz and κ value of −0.970 it would not be possible to assign this second conformer unequivocally as conformer **2** or conformer **3**. However it would be surprising to find no observable spectrum from the s-*cis* form of the *trans* isomer when the s-*trans* form has already been detected, since the similar molecule methyl vinyl ether is mainly in the s-*cis* form (9). An additional point is that the two s-*trans* isomers (**1** and **3**), in which the methoxy group is situated rather similarly in each case, might be expected to have rather similar vibrational satellite patterns, mainly as regards intensity, but this is not what is observed; see Fig. 1.

Abundance of Conformers

Because of the rather large *J* values involved in the observed transitions of both conformers and because the spectra are not very intense it has not proved possible to obtain any Stark shift measurements. This makes it difficult to make meaningful estimates of the relative abundances of the conformers **1** and **2**. The small estimated μ_a (0.07 D) for the s-*trans* form is particularly susceptible to large uncertainty. By comparing the intensity of the s-*trans* peak at 36 602.30 MHz, which is assigned as a superposition of the $K_{-1} = 4$, 7, and 8 components of the $J = 14 \leftarrow 13$ transition, with that of the s-*cis* peak at 36 607.27 MHz, assigned as $J = 12 \leftarrow 11$, $K_{-1} = 4$, the intensity ratio was determined as

$$[1] \quad \frac{\text{s-}trans\ (J = 14 \leftarrow 13\ (K_{-1} = 4, 7, 8))}{\text{s-}cis\ (J = 12 \leftarrow 11\ (K_{-1} = 4))} = 1.6$$

The deduction of the relative proportion of the

two conformers from this ratio is, unfortunately, so highly dependent on the assumptions made in estimating μ_a (s-*trans*) that it is not considered meaningful to quote a precise figure. About all that can be said is that the s-*trans* form is probably between about 50 and 98% in abundance (corresponding to an energy difference E(s-*cis*) − E(s-*trans*) in the range 0 to 8 kJ mol^{-1}). Comparing this result with that of the nmr study (12) indicates that, for the *trans* isomer, the proportion of the s-*trans* conformer increases on going from the liquid solution phase (in TMS) to the vapor phase.

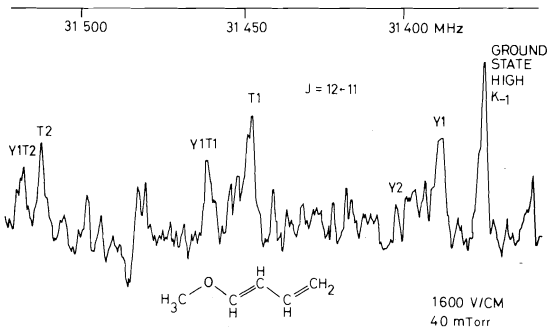

FIG. 2. A trace of a portion of the $J = 12 \leftarrow 11$ transition of the s-*trans* conformer showing some of the torsional satellites.

Vibrational Satellites

In addition to the ground vibrational state spectrum the s-*trans* conformer exhibits two series of vibrational satellites to higher frequency; see Fig. 2. For one series four successive excited states are easily observable. These are designated $T1$–$T4$. Relative intensity measurements on the high K_{-1} bunches in the $J = 11 \leftarrow 10$, $12 \leftarrow 11$, and $14 \leftarrow 13$ transitions yielded a vibrational frequency of 60 ± 20 cm^{-1} for the T series. Two excited states of the second (Y) vibrational motion were assigned and a vibrational frequency of 80 ± 30 cm^{-1} obtained from intensities. The B^* values for these states are given in Table 5 together with the values for two states in which both vibrations are excited. The B^* values for the T series fit the equation (for $T = 1$–4)

$$[2] \quad B_T^* = 2611.01 + (6.865)(T + \tfrac{1}{2}) - (0.350)(T + \tfrac{1}{2})^2$$

indicating a fairly harmonic potential. The T and Y vibrational satellites clearly must be those due to progressive excitation of the torsional motions about the O—CH and =C—C= bonds. The lower frequency (60 cm^{-1}) may be assigned to the O—CH torsion. This is comparable with the O—CH_2 torsional frequencies in methoxyacetonitrile, CH_3OCH_2CN and 3-methoxypropionitrile, $CH_3OCH_2CH_2CN$, which are, re-

spectively, 74 ± 32 and 90 ± 17 cm^{-1} (5, 6). These molecules are not exactly analogous to the present one. In methyl vinyl ether the lowest vibration frequency of the molecule, at 219 ± 20 cm^{-1}, was assigned to the O—CH torsional mode (9). However for a molecule of this type in the s-*cis* conformation interaction between the methyl hydrogens and the nearby CH hydrogen should restrict the torsional motion, giving it a relatively high frequency. In s-*trans trans*-1-methoxy-1,3-butadiene the methyl group is situated further away from the closest CH hydrogen and the O—CH torsion is evidently less restricted.

The other frequency (80 cm^{-1}) is assigned to torsion about the =C—C= bond. The frequency is surprisingly low compared to the corresponding one in unsubstituted 1,3-butadiene, of 162 cm^{-1},[3] even though a lower frequency would be expected because of increased mass in the present case.

The only vibrational satellites observed for the s-*cis* conformer were the first and second excited states of a vibration for which the satellites are to the low frequency side of the ground state transition; see Table 6. The intensities yield a frequency of 102 ± 30 cm^{-1}. These excited states ($Y1$ and $Y2$) are assigned as due to =C—C= torsion on account of the proximity in frequency to the value of 80 cm^{-1} for the s-*trans* conformer and also because of the absence of any such low frequency modes in methyl vinyl ether.

For neither of the two observed conformers has an assignment been made of a satellite due to methyl torsion. Possibly this is due to the fact that in a relatively long-chain molecule the

[a]The relative intensity of a vibrational satellite is in each case given with respect to the corresponding ground state peak.

excitation of methyl torsion does not cause enough change in the rotational constants to shift the satellite clear of the corresponding ground state transition. This is more likely to be a cause in the s-*trans* conformer, with its bunched high K_{-1} lines, than in the s-*cis*. If the barrier to internal rotation were 3820 cal mol^{-1} in the s-*cis* conformer, as it is in the structurally similar s-*cis* methyl vinyl ether, then using the equation

$$[3] \qquad V_3 = (8/9)\,\pi^2\,\nu^2\,I_r$$

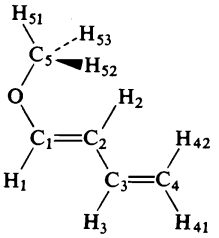
together with an assumed methyl top moment of inertia $I_\alpha = 3.123$ amu Å^2 and a resulting I_r of 3.088 amu Å^2, calculated from the assumed structure, a value of ν of 256 cm^{-1} is estimated for the frequency of the methyl torsion mode. A similar calculation for the s-*trans* conformer predicts a frequency of 268 cm^{-1}. With a lower assumed barrier of 3000 cal mol^{-1} a value of 237 cm^{-1} is obtained. The barrier is likely to be less in the s-*trans* conformer due to a smaller interaction between the CH_3 group and the nearest CH hydrogen. These considerations serve to confirm that the vibrational satellites already assigned (T and Y for s-*trans*, Y for s-*cis*) are not due to methyl torsion.

Structure Calculations

On the basis of the observed rotational constants of the two conformers estimates have been made of the CCO and COC bond angles in each.

Since the constants are more accurate for the s-*cis* conformer an assumed structure for it was

first set up using data from the molecule methyl formate (8) to established the C—O—CH_3 parameters and from *trans*-1,3-pentadiene for the remainder of the structure (16). This initial structure was



All C—H distances = 1.09 Å, HC_5H angles all 110.67°, $C_1C_2 = C_3C_4 = 1.337$ Å, all HC_5O angles equal, $C_2C_3 = 1.476$ Å, $C_1O = 1.334$ Å, $OC_5 = 1.437$ Å, $\angle H_{41}C_4C_3 = 121.5°$, $\angle H_{42}C_4C_3 = \angle H_1C_1C_2 = 120.5°$, $\angle C_4C_3H_3 = 119°$, $\angle C_2C_3C_4 = 122.9°$, $\angle H_2C_2C_3 = 118.1°$, $\angle H_2C_2C_1 = 119°$, $\angle C_2C_1O = 124.5°$, $\angle C_1OC_5 = 114.8°$.

When the C_2C_1O and C_1OC_5 angles were varied, holding the other parameters constant, a fit to the observed P_a and P_b planar moments of the s-*cis* conformer was achieved at $\angle C_2C_1O = 131.0°$ and $\angle C_1OC_5 = 114.3°$. The increased value of the first angle possibly indicates the effect of the repulsion between H_2 and the methyl group. When 131.0° and 114.3° were used as starting angles for the s-*trans* conformer and these angles were then varied, with other parameters fixed, the P_a and P_b planar moments of the s-*trans* conformer were reproduced when $\angle C_2C_1O = 123.5°$ and $\angle C_1OC_5 = 114.1°$. This appears to be a reasonable result and can be taken as additional confirmation of the correctness of the observed rotational constant of the s-*trans* conformer.

The P_c planar moments for the two conformers, which were kept fixed in the above calculations, are related to the observed moments of inertia and out-of-plane hydrogen coordinates by

$$[4] \quad P_c = (1/2)(I_a + I_b - I_c) = 2m_H c_H^2$$

The values of $I_a + I_b - I_c$ from Table 4 give a c_H coordinate of 0.894 ± 0.003 Å for the s-*trans* conformer and one of 0.904 ± 0.001 Å for the s-*cis* conformer. These values may be compared with that for the c_H coordinate in methyl vinyl ether (9), which is 0.889 Å, and with the values in *trans*- and *cis*-1,3-pentadiene (16) which are respectively 0.900 and 0.905 Å.

Preparation and Mössbauer spectra of organotin(IV) compounds containing the $CH_3(C_6H_5)Sn(IV)$ moiety

T. K. SHAM, J. S. TSE, V. WELLINGTON, AND G. M. BANCROFT

Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 3, 1977

T. K. SHAM, J. S. TSE, V. WELLINGTON, and G. M. BANCROFT. Can. J. Chem. **55**, 3487 (1977).

The synthesis and Mössbauer spectra of 16 organotin compounds of the type $MePhSnX_2$ (X = F, Cl), $[Et_4N]MePhSnCl_3$, $MePhSnCl_2L_2$ (L = oxygen and nitrogen neutral donor ligands), and $MePhSnL_2'$ (L' = acetylacetonates and 8-hydroxyquinolate) are reported. The Mössbauer quadrupole splittings (qs) are used to assign the structures of the complexes. The $MePhSnX_2$ (X = F, Cl) compounds have similar structures to their Me_2Sn analogues, while the six-coordinate complexes show a greater structural similarity to their Ph_2Sn analogues. Thus $MePhSnF_2$ is a highly associated structure like Me_2SnF_2 with a six-coordinate Sn atom; while the $MePhSnL_2'$ complexes have the *cis* structure like their Ph_2Sn analogues. The structures of the six-coordinate organotin complexes are rationalized using steric calculations and the known bonding properties of the ligands. The quadrupole splittings and centre shifts (cs) are also used to suggest variations in ligand bonding properties, and to discuss variations in C—Sn—C angles from the MePhSn complexes to their Ph_2Sn analogues.

T. K. SHAM, J. S. TSE, V. WELLINGTON et G. M. BANCROFT. Can. J. Chem. **55**, 3487 (1977).

On présente la synthèse et les spectres Mössbauer de 16 composés organostanniques de types $MePhSnX_2$ (X = F, Cl), $[Et_4N]MePhSnCl_3$, $MePhSnCl_2L_2$ (L = ligand neutre ayant un oxygène ou azote donneur), et $MePhSnL_2'$ (L' = acétylacétonate et hydroxy-8 quinolate). Les dédoublements quadrupolaires (dq) tirés des spectres Mössbauer sont utilisés pour déterminer la structure des complexes. Les composés $MePhSnX_2$ (X = F, Cl) ont une structure similaire à leurs analogues Me_2Sn alors que les complexes hexacoordonnés montrent une plus grande similarité structurale à leurs analogues Ph_2Sn. Le composé $MePhSnF_2$ a une structure très associée comme Me_2SnF_2 et possède un atome Sn hexacoordonné; tandis que les complexes $MePhSnL_2'$ possèdent une structure *cis* comme leurs analogues Ph_2Sn. Les structures des complexes organostanniques hexacoordonnés sont rationalisées en faisant appel à des calculations stériques et des propriétés liantes déjà connues pour ces ligands. Les dédoublements quadrupolaires ainsi que le centre des déplacements (cd) sont aussi utilisés pour expliquer les variations des propriétés liantes du ligand et de discuter les variations des angles C—Sn—C lorsqu'on passe des complexes MePhSn à leurs analogues Ph_2Sn.

[Traduit par le journal]

Introduction

The stereochemistry of diorganotin compounds has been a subject of recent interest (1–3). The variable C—Sn—C angle in Me_2Sn compounds has been rationalized using ligand–ligand repulsion calculations (2), and the Mössbauer quadrupole splittings (qs) are useful for estimating this angle (1, 3). However, the stereochemical preference of *trans* and *cis* configurations in six-coordinate dimethyl and diphenyl compounds is not clearly understood. Accumulated X-ray structures (1, 3, 4) of dimethyl tin compounds indicate that with the exception of $Me_2Sn(oxin)_2$ (5) [oxin = anion of 8-hydroxyquinoline] and $Me_2Sn(ONHCOMe_2)$ (6), all the six-coordinate dimethyl tin compounds have the *trans* or distorted *trans* configurations. By contrast, Mössbauer data (7, 8) strongly suggest that all the diphenyl compounds with chelating ligands have the *cis* configuration. This *trans–cis* difference is manifested in the study of diorganotin acetylacetonates (8). All the dimethyl tin acetylacetonates are *trans*, whereas all the corresponding diphenyl compounds are *cis*. It is also interesting that while Me_2SnF_2 (9) is six coordinate with a linear Me—Sn—Me group and Me_2SnCl_2 (10) forms an associated compound, Ph_2SnCl_2 (11) is a monomer in the solid state.

The above differences in Me_2Sn and Ph_2Sn compounds make structural studies of MePhSn-(IV) compounds very desirable, but only a few MePhSn compounds have been previously prepared (12, 13), and the ^{119}Sn Mössbauer spectra of only two compounds have been recorded (13). The previous preparations of

[a]The $MePhSn(AcAc)_2$ and $MePhSn(BzAc)_2$ compounds could not be prepared analytically pure (see text). Abbreviations used stand for: py = pyridine; bypy = 1,1′-bipyridine; phen = 1,10-phenanthroline; dmso = Me_2SO; HMPA = $(Me_2N)_3PO$; bipyo = 2,2′bipyridine *N*′,*N*-dioxide; opo = methylenebis (diphenylphosphine oxide); diphoso = ethylenebis (diphenylphosphine oxide); BzBz = anion of dibenzoylmethane; oxin = anion of 8-hydroxyquinoline; AcAc = anion of acetylacetone; BzAc = anion of benzoylmethane.

MePhSn compounds, and the very similar bonding properties of Me and Ph from Mössbauer partial quadrupole splittings (pqs) (8, 14–18), strongly suggested that a large number of MePhSn compounds could be prepared. In this study, we report the preparation and Mössbauer parameters of 16 compounds of the type $MePhSnX_2$ (X = F, Cl), $[Et_4N]$ $MePhSnCl_3$, $MePhSnCl_2L_2$ (L = nitrogen or oxygen donor), and $MePhSnL_2'$ (L′ = anion of acetylacetonates and 8-hydroxyquinoline). The structures of these compounds are assigned using the ^{119}Sn Mössbauer quadrupole splittings. Our results show that the stereochemical behaviour of MePhSn(IV) and Ph_2Sn(IV) units are similar in six-coordinate Sn(IV) compounds, and that the relatively bulky phenyl group plays an important stereochemical role in both types of complexes.

Experimental

All the reagents are commercially available or prepared with well established techniques (16). The starting material, $MePhSnCl_2$, was prepared by reacting Me_4Sn with $PhSnCl_3$ as described by Kuivila *et al.* (12). Reactions (13, 16) described previously in preparing analogous Me_2Sn(IV) and Ph_2Sn(IV) compounds were used with slight modification. All the compounds appear to be air stable although most of them were prepared under a dry N_2 atmosphere. Yields are always excellent (>90%) except in the cases of $MePhSnL_2'$ compounds (L_2' = acetylacetonates) where oily products make the separation of the pure product difficult (L_2' = AcAc, BzAc). We were, however, able to crystallize $MePhSn(BzBz)_2$ as light yellow needles.

The new compounds were characterized by spectroscopic techniques (ir, nmr, and Mössbauer), melting points, and elemental analyses (Table 1). Typical preparative procedures are as follows:

(*i*) $[Et_4N]$ $[MePhSnCl_3]$: $MePhSnCl_2$ (0.27 g) was dissolved in a minimum amount of ethyl alcohol. Dried tetraethylammonium chloride (0.17 g) was added to the solution. Crystallization of the product was obtained after the solvent was evaporated under reduced pressure. Recrystallization was from alcohol. The yield was quantitative.

(*ii*) $MePhSn(oxin)_2$: $MePhSnCl_2$ (0.56 g) was dissolved in a minimum amount of alcohol. 8-Hydroxylquinoline (0.58 g) was added, and the solution was neutralized with aqueous ammonia. The yellow precipitate was collected through suction filtration. Yield ~90%.

(*iii*) $MePhSn(BzBz)_2$: TlBzBz (0.64 g) was dissolved in 20 ml of benzene. $PhMeSnCl_2$ (0.21 g) was added, and the solution was stirred under nitrogen for an hour. The TlCl was filtered off, and the excess solvent was evaporated under vacuum. The oily residue was dissolved in hexane, and the yellow crystals of $MePhSn(BzBz)_2$ were collected.

Mössbauer spectra were recorded at 110 K for all the compounds. A 10 mCi $BaSnO_3$ source was used for ^{119}Sn spectra. The spectrometer was calibrated using a 99.99% Fe foil. All the spectra were fitted to Lorentzian line shapes using methods described previously (8, 19). The magnetic spectrum of $MePhSn(BzBz)_2$ (Fig. 1) was obtained at the PCMU Harwell.

Nuclear magnetic resonance spectra of MePhSn(IV) compounds, with sufficient solubility in organic solvents, were obtained using T60 and HA 100 spectrometers. The chemical shifts and coupling constants are given in Table 2. Infrared spectra were obtained using a Perkin-Elmer 621 spectrometer.

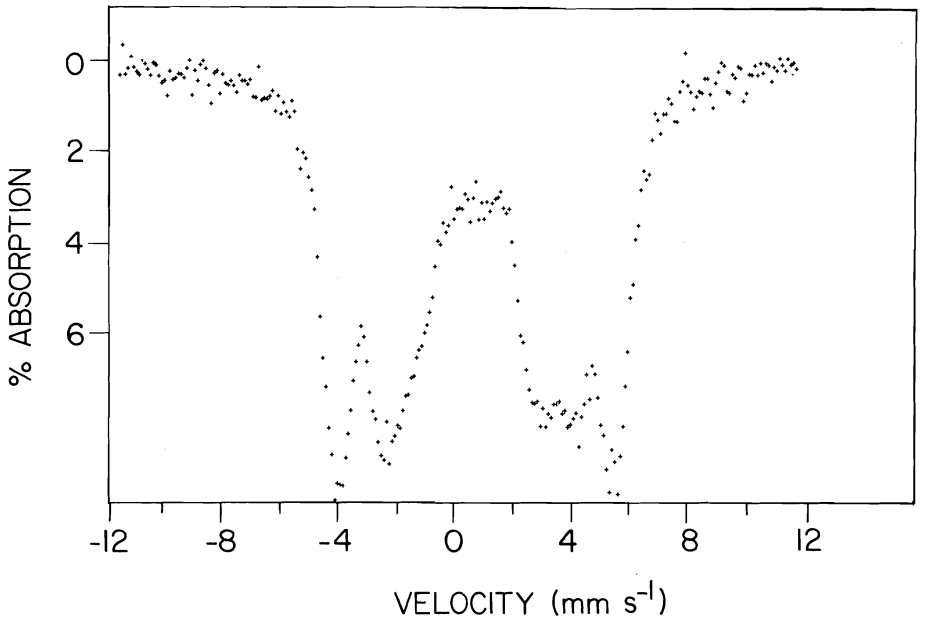

FIG. 1. ^{119}Sn Mössbauer spectrum of *cis*-MePhSn(BzBz)$_2$ taken at 4 K in a magnetic field of 6 T.

Results and Discussion

(*1*) *Chemistry*

The compounds reported in this study were prepared using the following well documented reactions (16):

[1] $MePhSnCl_2 + L_2 \rightarrow MePhSnCl_2L_2$

where L = neutral nitrogen or oxygen ligands.

[2] $MePhSnCl_2 + 2TlL' \rightarrow MePhSnL_2 + 2TlCl$

where L′ = AcAc, BzAc, BzBz.

[3] $MePhSnCl_2 + 2H\ oxin \rightarrow MePhSn(oxin)_2 + 2HCl$

[4] $MePhSnCl_2 + Et_4NCl \rightarrow [Et_4N]\,[MePhSnCl_3]$

These reactions yield the desired products readily except in eq. 2 where reactions between $MePhSnCl_2$ and the thallium salts seem to be less smooth than those reported previously for Me_2SnCl_2 and Ph_2SnCl_2 (8, 17). Oily products always result from reaction 2. We had difficulty in isolating the $MePhSn(AcAc)_2$ and $MePhSn(BzAc)_2$ from the oily substance. The Mössbauer spectra of these two compounds are however very good, and indicate no visible Sn impurity.

(*2*) *Structure and Bonding from Mössbauer Spectra*

(*a*) *Structure from Quadrupole Splittings*

The Mössbauer parameters for the MePhSn compounds are given in Tables 3 and 4 along with those for the corresponding Me_2Sn and Ph_2Sn compounds. It is immediately apparent that all the $MePhSnCl_2L_2$ adducts have qs values in the 4 mm s^{-1} range, while the $MePhSnL_2'$ compounds (L′ = AcAc, BzAc, BzBz, and oxin) have qs values in the 2 mm s^{-1} range. As discussed previously (18, 19), these results strongly indicate that all the $MePhSnCl_2L_2$ compounds have *trans*-C—Sn—C structures whereas the $MePhSnL_2'$ compounds have *cis* structures.

The *cis* structure occurring in the $MePhSnL_2'$ compounds is particularly interesting, since the analogous compounds Me_2SnL_2' and Ph_2SnL_2' have the *trans* and *cis* configurations respectively. These configurations are consistent with the

donor properties of Me and Ph, and our steric calculations (20) based on the ligand–ligand repulsion arguments introduced by Kepert (2) and steric angle calculations introduced by Zahrobsky (21). For any $RR'SnL_2'$ structure (R,R′ = Me or Ph), the *cis* structure is always favoured sterically (2, 20), with the *cis* preference increasing in the order $Me_2SnL_2' < MePhSnL_2' < Ph_2SnL_2'$. The *trans* configurations in Me_2SnL_2' (L′ = AcAc, BzAc, BzBz) can be attributed to the small differences in the *cis–trans* repulsive energies (20), and the electronic effect of the two methyl groups. Since the methyl group is a very good donor, and tends to acquire most of the tin 5*s* character (Bent's rule (22)), a linear C—Sn—C structure results. If the methyl group(s) is (are) replaced by a poorer σ donor (e.g. chloride or phenyl), the *cis*-structure becomes more favourable for both steric and electronic reasons. The *cis*-Ph_2Sn (8, 18) and Cl_2Sn (23, 24) structures are consistent with this argument. Our calculations (20) indicate that the C—Sn—C angle in MePhSn compounds should be smaller than those in the analogous Ph_2Sn compounds. Consistent with these steric calculations, the qs and cs for the MePhSn acetylacetonates are smaller than those for the analogous Ph_2Sn compounds (Table 4, and see next section for discussion).

The qs values for $MePhSnF_2$ and $MePhSnCl_2$ show that the former compound has an associated six-coordinate Me_2SnF_2 structure (9); while the latter compound has a very weakly associated structure intermediate between the

weakly associated Me_2SnCl_2 (10) structure and the unassociated Ph_2SnCl_2 (11) structure.

(*b*) *Application of Partial Quadrupole Splitting Values in the MePhSn(IV) System*

The quadrupole splittings for the MePhSn complexes can be used once again to test the validity of the additive model (7, 19, 25). It is immediately apparent from additive model expressions (7, 19, 25) that the qs for a *trans*-MePhSn compound (C—Sn—C angle = 180°) should be midway between the qs values for the analogous *trans*-MeSn and *trans*-Ph_2Sn analogues. The results in Table 3 show that most of the MePhSn compounds have qs midway between the two analogues. The exceptions (e.g. $RR'SnCl_2$(opo) and $RR'SnCl_2$(diphoso) in Table 3) may be due to the different degrees of distortion of the C—Sn—C moiety between the three types of organotin complexes.

Using the pqs values in refs. 8, 14, and 15, the calculated qs for the *trans* compounds are compared with the observed values in Table 5. The agreement is generally good, although the calculated qs values are larger (with one exception) than the observed qs. This trend has already been observed in the corresponding $Me_2SnCl_2L_2$ and $Ph_2SnCl_2L_2$ systems studied previously (15). This trend is due either to a distortion of the C—Sn—C bond angle, or to a slight change of bonding properties of the ligands from $R_2SnL_4^{2+}$ compounds to the $R_2SnCl_2L_2$ compounds.

It is also interesting to compare the qs values of the *trans*-$RPhSnCl_2$ phen compounds (R = Me, Ph, and $Mn(CO)_5$, with qs = 3.74, 3.37, and 3.25 mm s^{-1}, respectively (26)). This trend is entirely consistent with the pqs values derived for these ligands (26), and confirms the σ donor series, Me > Ph > $Mn(CO)_5$.

Considering the *cis* compounds (Tables 4 and 5), it is apparent that the MePhSn compounds have smaller qs values than their Ph_2Sn analogues. Also, the calculated *cis*-MePhSn |qs| are in good agreement with the observed Ph_2Sn qs values (8). Because $(pqs)_{Me} > (pqs)_{Ph}$, the smaller MePhSn qs are perhaps surprising. However, the trend is consistent with the repulsion calculations described above: the C—Sn—C bond angle in the MePhSn compounds is closer to 90° than in the Ph_2Sn analogues, and a smaller qs results (1).

We had hoped that the proposed smaller C—Sn—C angle in the MePhSn compounds would lead to the first negative *cis*-^{119}Sn qs (27), but the observed sign for *cis*-$MePhSn(BzBz)_2$ is still positive ($\eta \simeq 0.5$). This result, combined with recent ^{121}Sb Mössbauer results[1] and our steric calculations (20), shows that the chelates are important in determining the C—Sn—C angle and/or contribute substantially to the electric field gradient themselves. X-ray determinations of *cis*-Ph_2Sn and *cis*-MePhSn compounds are now needed.

[1]A negative ^{121}Sb qs has been observed in *cis*-Ph_2SbCl_2(oxin) (28) which has only one chelating ligand. The C—Sb—C angle is thus probably less than 109.5° (27).

(*c*) *Centre Shifts and Bonding*

Centre shift (cs) values (Table 3) show that all the *trans*-MePhSn compounds have similar cs values ($\sim$1.3 mm s^{-1}) to the Me_2Sn and Ph_2Sn compounds. The general order of cs (Me_2Sn > MePhSn > Ph_2Sn) is consistent with the pqs values for Me and Ph, which show that Me is a better donor than Ph and/or that the Me C—Sn bond has a higher *s* character than the Ph C—Sn bond. These similar cs values also indicate that the bonding properties of Me and Ph (and thus the C—Sn—C angle) do not vary substantially from the *trans*-MePhSn compounds to their Me_2Sn and Ph_2Sn analogues.

The *cis*-$MePhSnL_2'$ complexes (like other *cis*-R_2Sn compounds) have considerably lower cs values than their *trans*-Me_2Sn analogues, due to the lower Sn 5*s* character in the Sn—C bonds in the *cis* position (7, 8, 25). The nmr coupling constant $^2J_{CH_3-^{119}Sn}$ of *cis*-$MePhSn(BzBz)_2$ (83 Hz) compared with the *trans*-$Me_2Sn(BzBz)_2$ value (97.2 Hz) is entirely consistent with these differences in cs and *s* character arguments (16).

From the above *trans*-R_2Sn cs values and the known donor properties of Me and Ph, it is perhaps surprising that the cs values for *cis*-$MePhSnL_2'$ (L' = AcAc, BzAc, BzBz) are consistently *smaller* than those for the corresponding Ph_2Sn compounds (Table 4). This trend can be readily rationalized if the C—Sn—C bond angle in the MePhSn compounds is smaller than that in their Ph_2Sn analogues, as previously suggested by the steric calculations and the qs values. The Sn 5*s* character in the Sn—C bonds in the MePhSn compounds would be smaller than in the Ph_2Sn compounds, and a lower cs for the MePhSn compounds would result. If our conclusions are correct, the MePhSn compounds violate Bent's rule. Thus, the Me—Sn bond in MePhSn compounds does not have a higher Sn 5*s* character than the Ph—Sn bond in Ph_2Sn compounds. Ligand–ligand repulsion effectively forces this situation (20).

The relative cs (and qs) values for the *cis*-$R_2Sn(oxin)_2$ (R = Me, Ph) are consistent with the above argument. The chelate ligand oxin has a substantially smaller bite than the AcAc ligands, and ligand–ligand repulsion will not be as important for the oxin compounds. Due to the normal electronic effect of the Me group to maximize Sn 5*s* density in its C—Sn bond, the C—Sn—C bond angle probably increases in the order Ph_2Sn < MePhSn < Me_2Sn in the oxin compounds. The normal trend in cs (and qs) for the oxin compounds is thus not surprising.

Finally, it is interesting (and puzzling) that the cs of the four-coordinate Sn(IV) compounds (such as $MePhSnCl_2$) have substantially larger cs values than the six-coordinate complexes. Similar trends have been observed previously (7, 25). This trend is not expected on *s* character arguments, which are supported by proton and ^{13}C nmr results (16, 29). Thus, the *s* character in R—Sn bonds in tetrahedral structures (sp^3 hybridized Sn) should be less than in R—Sn bonds in *trans*-R_2SnL_2' structures (*sp* hybridized Sn for the C—Sn bonds). Also, the bond lengths in four coordinate Me—Sn compounds are, if anything, larger than those in six coordinate Me—Sn compounds. Thus, there is no evidence that the R groups in tetrahedral compounds are better donors than in octahedral compounds. On both hybridization and bond length criteria, we would expect the tetrahedral compounds to have a *smaller* cs than the octahedral compounds.

Comparison of the charge distributions and barriers to ring inversion of protonated eucarvone and its boron trihalide adducts[1]

RONALD F. CHILDS[2] AND YEE-CHEE HOR
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 6, 1977

RONALD F. CHILDS and YEE-CHEE HOR. Can. J. Chem. **55**, 3495 (1977).

The protonation and formation of the boron trifluoride, trichloride, and tribromide adducts of eucarvone, **1**, are described. Examination of the nmr and uv spectra of these systems showed that in each case the proton or Lewis acid was bonded to the carbonyl oxygen of **1**. From the various ^{13}C chemical shifts of the Lewis acid adducts of **1**, it is concluded that there is significantly less positive charge induced on the dienylic part of these molecules than is found with protonated **1**. All of these cationic systems undergo a ring inversion process, the barriers of which are about 1 kcal/mol greater than that reported for the comparable inversion of **1**.

RONALD F. CHILDS et YEE-CHEE HOR. Can. J. Chem. **55**, 3495 (1977).

On décrit la protonation ainsi que l'addition du trifluorure, trichlorure et tribromure de bore sur l'eucarvone **1**. L'examen des spectres rmn et uv de ces systèmes montre que, dans chaque cas, le proton ou acide de Lewis est lié à l'oxygène du groupe carbonyle de l'eucarvone **1**. En se basant sur les différents déplacements chimiques du ^{13}C obtenus pour les adduits des acides de Lewis sur **1**, il apparaît que la charge positive induite sur la partie diénylique de ces molécules est plus petite que celle observée pour la forme protonée de **1**. Tous ces systèmes cationiques subissent une inversion de cycle, les barrières d'énergie étant environ 1 kcal/mol plus grande que celles rapportées pour une inversion comparable de **1**.

[Traduit par le journal]

In the following paper we present the results of our investigation into the effect on the photochemistry of eucarvone on its complexation with various boron trihalides (1). There are numerous reports of the protonation of aldehydes and ketones and the spectroscopic characterization of the resulting hydroxy substituted carbocations (2). Well defined complexes of carbonyl compounds and boron trifluoride have also been known for a long time (3, 4) and recently there has been a spate of publications defining their spectral properties (5–7). In contrast, comparatively few complexes of ketones and boron trichloride or tribromide have been described (4, 7–9). Before the excited state behaviour of the complexed or protonated cycloheptadienones can be examined, it is necessary to establish their ground state properties and this question is addressed in this paper. In particular, the different effects of complexation and protonation on the charge distribution and conformational mobility of eucarvone are examined.

Results and Discussion

Dissolution of eucarvone, **1**, in FSO_3H at $-78°C$ gave a clear yellow solution which exhibited nmr spectra (Tables 1 and 2) which

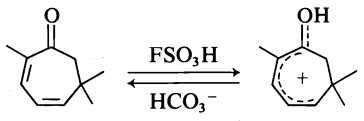
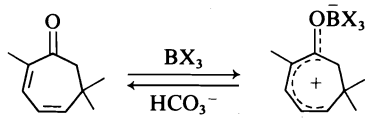
*22.63 MHz spectra using tetramethylsilane (δ 0.00) as internal standard for **1** and **6**, $CDCl_3$ (δ 77.2) for **3**, **4**, and **5**, and CD_2Cl_2 (δ 53.6) for **7**. External dimethylsulfoxide-d_6 (δ 39.6) was used as a standard for **2**. Carbon resonances were assigned on the basis of gated and selective proton decoupling.

were completely consistent with the formation of the hydroxydienyl cation **2**. For example, the downfield shifts of the various proton resonances of **1** on protonation are very comparable to those found in protonation of 6,6-disubstituted-cyclohexa-2,4-dienones (10). At temperatures above −60°C, no signal attributable to an OH resonance could be detected in FSO_3H solutions of **2**; however on cooling the samples to −90°C a singlet at δ 12.02 was observed. This signal, which is in a typical position for an OH resonance of a protonated enone (11), broadened and appeared to average with the solvent peak when the acid solution was warmed to −60°C. No change in the ^{1}Hmr spectrum of **2** occurred when FSO_3H solutions of this cation were kept at room temperature for several hours. Neutralization of the acid solution of **2** led to the recovery of **1** in 90–95% yield.



1 **2**

Eucarvone was reacted with the boron trihalides, BX_3 (X = F, Cl, and Br), by condensing the appropriate Lewis acid into a $CDCl_3$ or CH_2Cl_2 solution of **1**. The spectroscopic properties of the resulting yellow solutions indicated that the various boron trihalides had in each case formed a complex with **1**.



1 **3** X = F
4 X = Cl
5 X = Br

As is shown in Tables 1 and 2, the nmr spectral changes associated with the protonation of **1** or its reaction with the three boron trihalides are very similar. There are some differences in the magnitude of the shifts involved but the overall pattern of changes is the same in each case, indicating that the Lewis acids have coordinated with the carbonyl oxygen of **1** to give **3**, **4** and **5**.

The similarity of the structures of **2**, **3**, **4**, and **5** is also demonstrated in their uv spectra. The

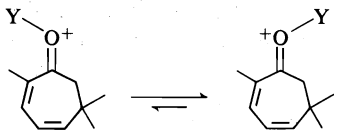
absorption maximum of **1** is red shifted by about the same amount on either the protonation or complexation of eucarvone (Table 3). Shifts of this magnitude of what would appear to be a π,π* band, are consistent with either coordination (12) or protonation (13) of the carbonyl oxygen.

Dilute solutions of **2**, **3**, and **4** were stable at temperatures below 0°C for long periods of time and could be reacted with bicarbonate to regenerate **1** in high yield. The complexes slowly decomposed on standing at room temperature for a few hours (14). This decomposition was more rapid when BBr_3 was used as the Lewis acid or when the concentrations of the complexes were increased beyond 0.1 *M*.

Charge Distribution

There has been considerable discussion over the question of the charge distribution in protonated aldehydes and ketones (2, 11, 15). In this present case, however, the issue is not only one of how the positive charge is distributed but how this distribution is affected by change of the group attached to the oxygen from a proton to a Lewis acid.

Examination of the chemical shift data presented in Tables 1 and 2 indicates that it is the C_1, C_3, C_5, and C_7 carbon resonances and the C_3, C_4, C_5, and C_7 proton resonances which are most affected by protonation or complexation of eucarvone. Apart from the C_1 and C_7 carbon and C_7 proton resonances, the changes in chemical shifts observed on complexation of **1** are smaller than those found on its protonation (Table 4). As the carbon–oxygen bond in these cationic systems will still have some double bond character, formally a proton or Lewis acid bonded to the oxygen of **1** could take a position which is either *cis* or *trans* with respect to C_7. It is known that a proton (11) or Lewis acid (6) normally adopts the sterically least hindered position which in this case is *cis* to C_7. The large deshielding effects observed with the C_7 proton and carbon resonances of **3**, **4**, and **5** as compared to **2** most probably result from the anisotropy of the adjacent boron trihalide group.



Y = H or $\bar{B}X_3$

Carbons C_3, C_4, and C_5 are well removed from any anisotropic effects of the Lewis acid groupings and the change in chemical shifts of these carbon resonances should reflect the fraction of positive charge induced on the dienylic part of the system by reaction with a proton or a Lewis acid. The downfield shifts observed for these carbons on complexation of **1** (Table 4) are in general only some 70% as large as those found on its protonation. Thus significantly less charge is induced at these carbons when a boron

trihalide rather than a proton is coordinated to the carbonyl oxygen of eucarvone.

The charge distribution in these Lewis acid adducts should also vary as a function of the boron trihalide used. It is anticipated that positive charge should be increasingly located on the dienylic portion of the molecule as the halogens bonded to the boron are changed from fluorine to chlorine to bromine (7, 9, 16). Examining the chemical shifts of the C_3, C_4, and C_5 carbon resonances of **3**, **4**, and **5** (Table 2), it can be seen that this is indeed the case for **5** as compared to **3** or **4**. The resonances of the C_3, C_4, and C_5 carbons of **5** occur at significantly lower field than those of the comparable carbons of **3** and **4**. There would appear, however, to be little difference in the charge distributions of **3** and **4**. It is not clear at this stage whether this is a general feature of boron trichloride and fluoride complexes of enones, or specific to the eucarvone complexes.

While the fraction of the positive charge residing on the dienylic portion of **2**, **3**, **4**, and **5** varies, the distribution of the charge between the various sp^2 hybridized carbons of these systems would appear to be much the same. Cornelis and Laszlo (17) have pointed out that the changes in the nmr spectrum of **1** as it is protonated closely parallel those observed on the protonation of cyclohexa-2,4-dienones. As the cyclohexadienones and protonated cyclohexadienones are planar species this would strongly suggest that the dienylic portions of **2**, **3**, **4**, and **5** are also close to being planar.

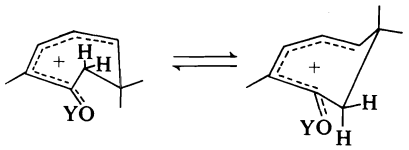
Included in Table 2 are details of the ^{13}C nmr spectra of cyclohepta-2,4-dienone, **6**, and protonated cyclohepta-2,4-dienone, **7** (18). As is shown in Table 4, the magnitude of the shifts observed of both the ^1H and ^{13}C resonances of **6** on its protonation are very similar to those observed on the protonation of **1**, indicating that the charge distribution in these systems is not affected to any great degree by the methyl substituents on eucarvone.

Ring Inversion

Despite the apparent simplicity of the room temperature nmr spectra of eucarvone, the seven-membered ring of this molecule is not planar. Cuthbertson and MacNicol (19) have shown that by cooling a sample of eucarvone to −130°C, it is possible to sufficiently slow a ring inversion process for the C_6 methyl proton resonances to appear as two singlets and C_7 methylene proton signals to occur as an AB quartet in its ^1Hmr spectrum. The barrier to this ring inversion was found to be 8.3 kcal/mol.

The ^1Hmr spectra of **2**, **3**, **4**, and **5** each exhibited a similar temperature dependence to that described by Cuthbertson and MacNicol for **1**. For example at −106°C the C_6 methyl signals of **3** appeared as two singlets at 1.13 and 1.34 δ and the C_7 protons as an AB quartet at 3.31 and 4.02 δ (J = 16.8 Hz). Apart from some general line broadening, the rest of the resonances of **3** were unchanged on cooling the sample to −106°C. On warming the solution, the *gem* dimethyl and methylene proton resonances reverted to singlets. The resolution of the ^1Hmr spectra of **2**, **3**, **4**, and **5** at temperatures below −100°C were not sufficient to warrant a full line shape analysis of these systems. The coalescence temperatures and low temperature limiting separation of the *gem* dimethyl group resonances of compounds **2** to **5** were obtained and are given in Table 5.

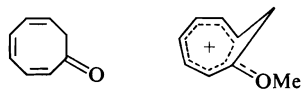
In view of the similarity in the temperature dependence of the ^{1}Hmr spectra of **1** and **2** to **5**, it would appear that a ring inversion process is occurring with these latter systems similar to that suggested for **1** itself. To confirm this and completely eliminate the possibility of involvement of any exchange or isomerization reactions involving the groups coordinated to the oxygen, the variable temperature ^{13}C nmr spectrum of **3** was examined. It was found that the resonance attributed to the C_6 methyl carbons of **3**, a sharp singlet at temperatures above -40°C, broadened at low temperatures and below -80°C, two singlets at 33.1 and 20.1 ppm were observed for these methyl carbons. No changes in any of the other carbon resonances were detected as the temperature was varied. The temperature dependencies described above of both the ^{13}C and ^{1}H nmr spectra of these cationic systems are thus fully consistent with a ring inversion process which interconverts the two C_6 methyl groups and also the C_7 methylene protons on the seven-membered ring.



Y = H or $\bar{B}X_3$

It is interesting to compare the barriers to this ring inversion of the seven-membered ring of eucarvone and its complexed and protonated forms. The barrier to inversion of **1** ($\Delta G^{\ddagger}$ = 8.3 kcal/mol) is somewhat less than that found for **2** ($\Delta G^{\ddagger}$ = 9.1 kcal/mol). An examination of models suggests that ring inversion is helped if the five sp^2 hybridized carbons of these systems are allowed to be twisted somewhat away from a planar configuration. The higher energy barrier found for **2**, compared to **1**, is consistent with this view as conjugation, which would be more important with **2**, would be diminished as the dienylic portion of the molecule is twisted. However, the magnitude of the difference in the barrier to inversion of **1** and **2** and the similarity of the barriers of **2**, **3**, **4**, and **5** would indicate that conjugation is by no means completely lost in the transition state of this inversion process.

In conclusion, it is instructive to note that the conversion of cyclic unsaturated ketones to their corresponding cationic forms can, in some cases, have very large effects on the conformational mobility of the ring. Thus the barriers to ring inversion of cyclooctatrienone, 8, (E_a = 11.9 kcal/mol) (20) and the corresponding methoxy cation, **9**, ($\Delta G^{\ddagger}$ = 19.6 kcal/mol) (21) are considerably different. In this case, however, the conversion of the trienone to the cationic system involves the formation of a cyclically delocalized system, for **9** has been shown to be homoaromatic. The difference in the barriers to inversion of **8** and **9** in this case reflects the importance of homoaromaticity in a charged versus a neutral system.



8 **9**

Experimental

Materials

Eucarvone was prepared from carvone by the procedure of Corey and Burke (22). FSO_3H was doubly distilled through a 12 in. glass column and stored in glass ampoules. CH_2Cl_2 was purified by the procedure of Jones and Wood (23). The boron trihalides, $CHCl_2F$, and SO_2ClF were all distilled on a vacuum line before use.

Protonation of Eucarvone

Protonations were carried out by slowly adding precooled FSO_3H (0.5 ml) to a dry nmr tube which contained **1** (ca. 20 mg) and which was kept in a dry-ice – acetone bath. Solution was achieved by agitating the sample with a quartz rod.

Formation of Complexes

Eucarvone (10–15 mg) was weighed into a dry nmr tube which was attached to a high vacuum line. The tube was cooled with liquid N_2 and the appropriate solvent distilled in. The sample was warmed to room temperature to allow **1** to dissolve, cooled again, and a known amount of the appropriate boron trihalide distilled over. The sample tube was sealed under vacuum and allowed to warm to -78°C.

For the uv measurements, a similar procedure was adopted except that a 200 ml reaction flask fitted with a side arm leading to a 2 mm quartz cuvette was used. The complexes were prepared in the 200 ml flask and after completion of the reaction some of the solution was transferred into the cuvette which was then sealed under vacuum. All these operations were carried out at low temperatures.

Quenching Procedure

The solution of protonated or complexed **1** was added dropwise to a stirred suspension of $NaHCO_3$ (5 g for **2**; 0.5 g for **3**, **4**, or **5**) in ether (25 ml) at -78°C. Upon warming to 0°C ice water (5 ml) was added, and the mixture stirred and filtered under suction. The organic layer was washed with saturated brine solution and dried

($MgSO_4$). The products were recovered by careful evaporation of the solvent at atmospheric pressure through a 6 in. Vigreux column and analyzed by glpc. (Varian Aerograph 204 using a 10 ft × $\frac{1}{8}$ in. column packed with 20% Carbowax 2000 M on Chromosorb W) and ^{1}Hmr. In each case only **1** was detected and recoveries were in the 90–95% range.

Spectroscopic Procedures

^{1}Hmr spectra were obtained on Varian HA-100 and A-60 spectrometers and both ^{1}H and ^{13}C nmr spectra on a Bruker WH 90 instrument. All three instruments were fitted with variable temperature probes, the probe temperature being measured with a copper–constantan thermocouple mounted at the appropriate depth in a nonspinning nmr tube. The rate constants for ring inversion at the coalescence temperature were obtained by using the equation $k = \pi\nu_{AB}/\sqrt{2}$. Ultraviolet spectra were obtained with a Cary 14 spectrometer.

Photoisomerization of the boron trihalide complexes of eucarvone[1]

RONALD F. CHILDS[2] AND YEE-CHEE HOR
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 6, 1977

RONALD F. CHILDS and YEE-CHEE HOR. Can. J. Chem. **55**, 3501 (1977).

The photoisomerization of the BF_3, BCl_3 and BBr_3 complexes of eucarvone (2,6,6-trimethylcyclohepta-2,4-dienone), **1**, have been examined. Irradiation of these zwitterions at low temperature gave, after subsequent recovery of decomplexed materials, 3,7,7-trimethylbicyclo-[4.1.0]hept-2-en-4-one, **2**, 2-methyl-5-isopropylphenol, **3**, 2-methyl-6-isopropylphenol, **4**, dehydrocamphor, **5**, and carvone, **6**. In the case of **1**·BF_3 and **1**·BCl_3 the initial photoproducts were shown to be the complexes of **2**, **3**, **4**, and **5**. The complexes of **6** were shown to arise from a secondary photoisomerization of **2**·BX_3. It was not possible to establish the primary product distribution, obtained from **1**·BBr_3 as further photoisomerization of **2**·BBr_3 occurred even at very low degrees of conversion. The mechanisms and synthetic utility of these reactions is discussed.

RONALD F. CHILDS et YEE-CHEE HOR. Can. J. Chem. **55**, 3501 (1977).

On examine la photoisomérisation des complexes BF_3, BCl_3 et BBr_3 de l'eucarvone (triméthyl-2,6,6 cycloheptadiène-2,4 one), **1**. L'irradiation de ces ions hermaphrodites à basse température conduit, après récupération des substances décomplexées, au triméthyl-3,7,7 bicyclo [4.1.0]heptène-2 one-4, **2**, méthyl-2 isopropyl-5 phénol, **3**, méthyl-2 isopropyl-6 phénol, **4**, déshydrocamphre, **5**, et à la carvone, **6**. Dans le cas des espèces **1**·BF_3 et **1**·BCl_3 on a montré que les produits initiaux de photolyse sont les complexes de **2**, **3**, **4** et **5**. Les complexes de **6** proviennent d'une seconde photoisomérisation de **2**·BX_3. Il n'a pas été possible de déterminer la distribution des produits primaires obtenu à partir de **1**·BBr_3 étant donné qu'une photoisomérisation plus poussée de **2**·BBr_3 a lieu même à très bas degré de conversion. On discute des mécanismes et des avantages synthétiques de ces réactions.

[Traduit par le journal]

In preceding papers we have examined the interrelationship of the photochemistry of neutral and protonated ketones (1–3). It is apparent from these and related studies (4–6) that protonation represents a method of exerting considerable control over the excited states reached and products obtained in the photoisomerization of a carbonyl compound. However, several problems stand in the way of the effective utilization of protonation as a general technique for the regulation of a photoreaction.

One of the major difficulties rests in the use of a strong acid such as FSO_3H to effect the complete protonation of a carbonyl compound. While the transfer of a ketone into such an acid is usually straightforward and the photochemical transformations are remarkably clean and free from intermolecular side reactions, the subsequent recovery of the products from the acid solution can be troublesome. On a small scale, substrates may readily be recovered in high yield on quenching the acid solutions with an appropriate base. However, in our experience the yields of recovered materials drop significantly as the scale of the reaction is increased.

Coordination of the carbonyl oxygen of a ketone with a Lewis acid induces changes in its ground state properties similar to those encountered on protonation (7). As the regeneration of a ketone from a Lewis acid complex is generally facile, the question arises whether a Lewis acid might not be used in a similar manner to a proton to modify the photochemistry of a ketone. Photochemically induced reactions of certain complexes of carbonyl compounds have been previously reported (8, 9). However, it would appear that no systematic study of their behaviour has been made. To this end we have examined the photoisomerizations of the boron trihalide adducts of eucarvone, **1**, a ketone for which the effects of protonation have been previously investigated (1). The boron halide complexes were selected for this study on the basis of their ready availability, ease of manipulation, and solubility characteristics as well as

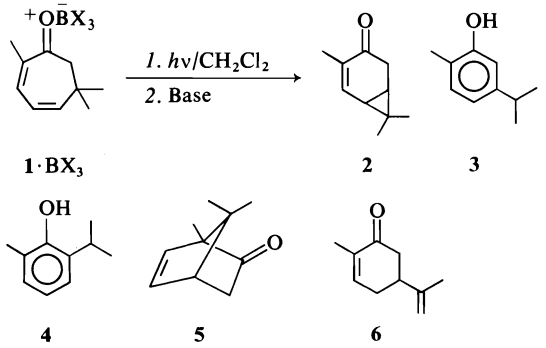
[1]The chemistry of cycloheptadienones, Part X.
[2]Author to whom correspondence should be addressed.

the possibility that the nature of the photoisomerizations could change as an increasingly heavy atom is introduced into the system on going from BF_3 to BBr_3.

Results

Product Characterization

Irradiation of a CH_2Cl_2 solution of **1**·BCl_3 (λ_{max} = 389 nm (7)) at −90°C with light of wavelength greater than 370 nm caused it to isomerize to give a series of products. The low temperature ^{1}Hmr spectrum of the resulting solution was too complex to be readily interpretable and accordingly the products were recovered by quenching the solution with an ether–bicarbonate slurry. Five major components were found to be present by glpc and these were collected and shown to be **2**, **3**, **4**, **5** and **6**.[3] Samples of **2** and **5** were available from the photoisomerizations of protonated (1) and neutral eucarvone (6, 10), while **3** and **6** were both obtained commercially. In each case the glpc retention time and spectroscopic properties of the authentic material were identical to those of the corresponding compound isolated from the photoisomerization.



The ir, mass, and nmr spectra of the remaining compound were entirely consistent with the structure shown as **4**. A sample of **4** was prepared by the procedure of Sowa *et al.* (11) and found to be identical in every respect to the material obtained in the photoreaction. 2-Methyl-4-isopropylphenol, **7**, prepared by the method of Carpenter and Easter (12), had different spectral and glpc properties from any of the above products. The phenol **7** could have been detected as a photoproduct if it had been formed in greater than 1% yield.

The photoisomerizations of **1**·BF_3 and **1**·BBr_3 were examined in a similar manner to that outlined above for **1**·BCl_3. In each case the same five products were formed.

Quantitative product analyses were carried out on each of these systems and the results are given in Table 1. The yields of the recovered material were generally high (>94%) and the compositions were reproducible.

These photoisomerizations were also examined in a nonchlorinated solvent medium. Difluoroethane was eventually found to be a suitable solvent for the three complexes at low temperatures. The same products were formed in CH_3CHF_2 as were found in CH_2Cl_2 and details of the product compositions are given in Table 1.[4]

Product Stability

The composition of the photoproducts obtained on irradiation of **1**·BF_3 and **1**·BCl_3 was found to be a function of the degree of conversion of the initial complex. This was particularly noticeable with **1**·BCl_3, entries 4 and 5, Table 1, where **6**, a major product in the latter stages of the photoisomerization, could not be detected when the reaction was only taken to 4% completion. It would seem that **6** is arising from a secondary photochemical or thermal reaction of one of the photoproducts, most likely, in fact, **2**·BX_3. Accordingly, the individual photoproducts and several related potential products were reacted with BX_3 and the stability of the resulting complexes examined.

The bicyclic compound **2** was reacted with BCl_3 in CH_2Cl_2 at −90°C to give **2**·BCl_3. The ^{1}Hmr spectrum of this complex was very similar to that of protonated **2** (1) (Table 2) and **2** was recovered in high yield on treatment of the solution with base. While **2**·BCl_3 was stable at −90°C, it underwent a slow decomposition when kept at −78°C. No products could be recovered on quenching the CH_2Cl_2 solution after this decomposition had occurred. The reaction of **2** with BF_3 and BBr_3 proceeded in a comparable manner to give **2**·BF_3 and **2**·BBr_3. Both of these complexes were stable at −90°C and gave back the starting ketone when treated with base.

[3]Other minor products (each much less than 1%) were detected by glpc. These were not characterized.

[4]There appeared to be a slow thermal reaction of BBr_3 with CH_3CHF_2 which resulted in the formation of a yellow solid. This reaction was not investigated further.

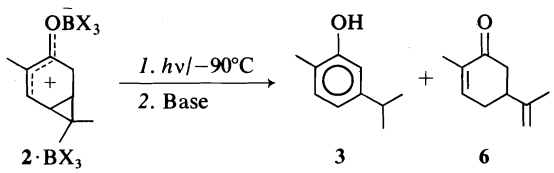
TABLE 2. ^{1}Hmr spectra of various BCl_3 complexes in CH_2Cl_2*

Compound	Chemical shifts (ppm) H_1	H_2	H_3	H_4	H_5	H_6	H_7	Other
$2 \cdot BCl_3$	1.30	8.07	—	—	3.52	2.00	—	0.88, 1.47, 1.88 (Me)
$6 \cdot BCl_3$	—	—	7.81	2.78	2.78	2.78	—	1.69, 1.88 (Me), 4.81 (=CH_2)
$9 \cdot BCl_3$	—	6.67	6.67	3.68	—	1.67 1.60	—	0.92, 1.10, 1.24 (Me)
$10 \cdot BCl_3$	—	—	7.63	8.60	3.34	—	2.25 1.76	0.90, 1.40, 1.42 (Me)
$8 \cdot BCl_3$	—	—	7.3	—	7.3	7.3	—	2.31, 4.52 (Me), 1.17 (Me_2C), 2.89 ($CHMe_2$)

*All spectra recorded at −50°C apart from that of $2 \cdot BCl_3$ which was obtained at −90°C.

The complexes of **2** were found to be photolabile under the conditions used in the irradiations of $1 \cdot BX_3$. Two products were formed in each case and these were identified after quenching the solutions as **3** and **6** (Table 1, entries 10–12). Qualitatively it was found that the relative efficiencies of the photoisomerization of the three complexes of **2** were quite different. Thus while $2 \cdot BF_3$ and $2 \cdot BCl_3$ each reacted about a factor of two more slowly than $1 \cdot BF_3$ or $1 \cdot BCl_3$, respectively, when irradiated under comparable conditions, $2 \cdot BBr_3$ photoisomerized some four times more rapidly than $1 \cdot BBr_3$. A mixture of $1 \cdot BBr_3$ and $2 \cdot BBr_3$ in a ratio 2.5:1 in CH_2Cl_2 was irradiated at −90°C for the time normally taken to achieve a 5–10% photoconversion of $1 \cdot BBr_3$. After quenching the solution the ratio of **1**:**2** was found to be 20:1, indicating that competitive photoisomerization of $2 \cdot BBr_3$ is significant even in the early stages of the rearrangement of $1 \cdot BBr_3$. It is clear that for $1 \cdot BF_3$ and $1 \cdot BCl_3$ and quite possibly also for $1 \cdot BBr_3$, that the complexes of **6** are not initial photoproducts but are produced in secondary photoreactions of $2 \cdot BX_3$. While complexes of **3** are also produced in this subsequent photoisomerization, it would seem that they are also produced directly from $1 \cdot BX_3$.



$2 \cdot BX_3$ **3** **6**

TABLE 3. ^{1}Hmr spectra of protonated phenols*

Phenol	Site of protonation	Chemical shifts (ppm) C_2Me	C_3H	C_4H	C_5H	C_6H	$CHMe_2$
3	C_4	2.25	8.10	4.13	—	7.15	1.35d

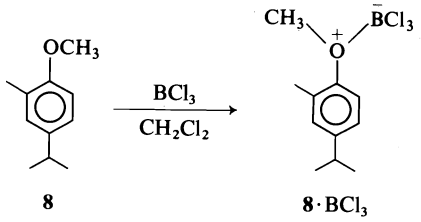
7	C_6	2.33	8.4	—	7.21	4.32d	1.30d
7	O	2.37	7.2	—	7.2	7.2	1.30d

*In FSO_3H at $-50°C$; d = doublet, m = multiplet.

Reaction of **6** with BCl_3 in CH_2Cl_2 at $-78°C$ resulted in the formation of the corresponding complex **6**·BCl_3. The ^{1}Hmr spectrum of **6**·BCl_3 was entirely consistent with its assigned structure (Table 2) and **6** was recovered in good yield on reacting the solution with ether–HCO_3^- slurry. The complex was found to be stable at $-20°C$ for long periods of time and to be photochemically stable under the conditions used in the photoisomerization of **1**·BCl_3.



8 **8**·BCl_3

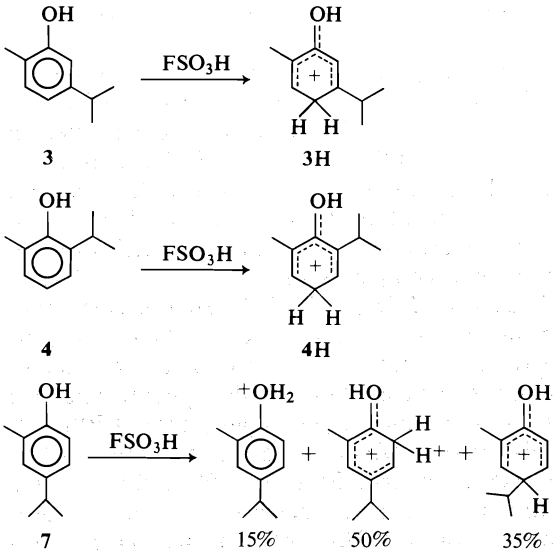
The phenols **3**, **4**, and **7** gave solutions with rather ill-defined ^{1}Hmr spectra when reacted with BCl_3 in CH_2Cl_2. This is in contrast, for example, with the reaction of the anisole **8** with BCl_3 which results in the formation of **8**·BCl_3 (Table 2).

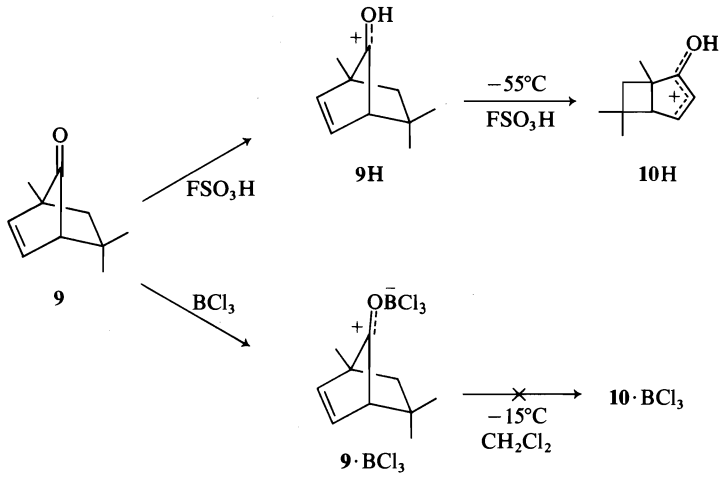
The presence of a resonance at ca. δ 1.3 in the ^{1}Hmr spectra of solutions of these phenols and BCl_3 which was absent when the O-deuterated phenols were used, suggested that HCl was being formed in these reactions. Solutions of anhydrous HCl and BCl_3 in CH_2Cl_2 at low temperatures exhibited a signal in a comparable position. Phenols are known to react with BCl_3 to give mixtures of phenoxyboron halides and triaryl borates together with HCl (13) and it would appear that similar reactions take place between **3**, **4** and **7** and BCl_3. The phenols were recovered unchanged on reaction of these solutions with base.

It would seem likely from a mechanistic consideration, *vide infra*, that complexes of the keto tautomers of phenols **3** and **4** are obtained in the photoisomerization of **1**·BCl_3. As it was not possible to form this type of complex directly, the protonation of **3**, **4**, and **7** was examined in order to see if migration of the isopropyl groups would occur in these systems.

The cation **3H**, formed on protonation of **3** in FSO_3H, is known to be stable below 0°C (1). Dissolution of **4** in FSO_3H gave a cation with a ^{1}Hmr spectrum (Table 3) completely consistent with protonation in the *para* position, while **7** gave, as would be expected on the basis of the protonation of 2,4-dimethylphenol (14), a mixture of carbocations. No isopropyl group migrations could be detected in any of these systems at temperatures up to $-20°C$.

Unlike the photoisomerizations of **1H**, none of the 7-norbornenone **9** could be detected as a product of **1**·BX_3. To ensure that complexes of **9** would be stable under the reaction conditions,





$9 \cdot BCl_3$ was prepared. This complex (^{1}Hmr spectral data in Table 2) was found to be thermally stable up to at least −15°C and unchanged when irradiated under the same conditions as used with $1 \cdot BCl_3$ The thermal stability of $9 \cdot BCl_3$ is in marked contrast with that of the corresponding protonated material which isomerized to give **10**H in FSO_3H −55°C (1).

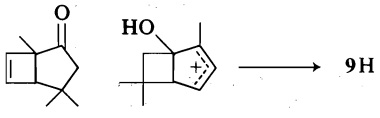
Discussion

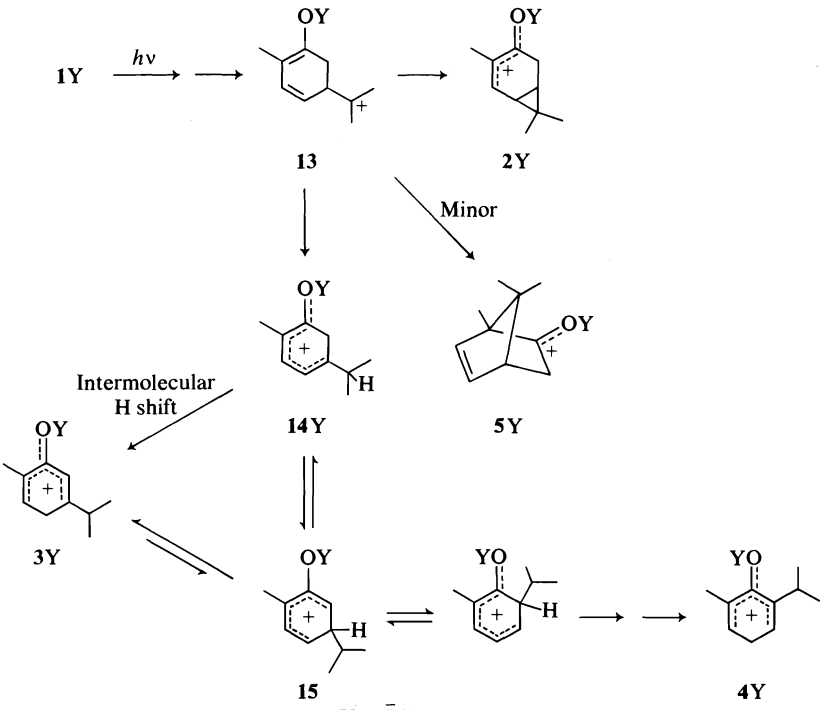
It is clear from the results presented above that the boron trihalide complexes of **1** predominantly undergo isomerization reactions on irradiation. In each case, apart from small manipulative losses, the yields of recovered materials are essentially quantitive and can be accounted for, after quenching, entirely in terms of isomers of **1**. It should be noted, however, that the wavelength of the incident light was such that only the complexed dienone chromophore and not any free boron halide could be excited (15). BCl_3 and BBr_3 are known to undergo dissociation on direct irradiation and this can lead to the occurrence of substitution reactions with hydrocarbon solvents (16). No such substitution reactions would appear to be occurring during the photoisomerizations of $1 \cdot BX_3$ nor were they observed by Griffith and Hart (8) on irradiation of the BF_3 complex of 2,4,6,6-tetramethylcyclohexa-2, 4-dienone, a system with a similar chromophore.

The profound effect of protonation on the photoisomerizations of eucarvone has largely been attributed to the reversal in the relative energies of the n,π^* and π,π^* states attendant upon protonation (1, 6). The uv spectra of $1 \cdot BX_3$ and **1**H are very similar (7) and it is again likely that the lowest energy transition in $1 \cdot BX_3$ is of π,π^* character.

It is interesting to compare the photoproducts obtained on irradiation of protonated eucarvone, **1**H, with those formed from $1 \cdot BX_3$. In each case **2** and **3** are the major products obtained on neutralization of the acid solutions and no materials corresponding to 1,4,4-trimethylbicyclo-[3.2.0]hept-6-en-2-one, **11**, are formed. The bicyclic ketone **11** is the predominant material obtained on irradiation of eucarvone itself in a wide variety of solvents, including CH_2Cl_2, Table 1, entry 13 (17). While the major products obtained on irradiation of $1 \cdot BX_3$ and **1**H are the same, they differ in that **4** ($4 \cdot BX_3$) and a trace of **5** ($5 \cdot BX_3$) are produced in the Lewis acid cases whereas **9**H is obtained from **1**H.

At first sight it is attractive to consider that the production of **4** or **9** in the complexed or protonated eucarvone photoisomerization respectively are somehow linked, especially as they are both formed in about the same yield. However, such a possibility is very unlikely. The control experiments described earlier showed that the products **4** and **9** do not interconvert when either protonated or complexed with BCl_3. It has also been shown by trapping experiments (1) that the precursor to **9**H is the bicyclic cation **12** and it is





Y = $\bar{B}X_3$ or H

SCHEME 1

very difficult to conceive how an analogous species, differing only in the replacement of the OH group by an $O\bar{B}Cl_3$ group, could rearrange to give **4**·BCl_3.

The formation of the major photoproducts in both the complexed and protonated cases can be understood in terms of the intermediacy of the same type of carbocation. As is shown in Scheme 1, an intermediate such as **13** could, by bonding the positive centre to either C_4 or C_2, yield derivatives of **2** and **5** respectively, the latter process only occurring to a minor extent with **13**·BX_3 and not being detectable with **13**H. Alternatively, a 1,2 hydride shift would in each case convert **13** to **14**. While **14** would yield **3** on reaction with base, it is known that **14** rearranges in FSO_3H to give the more stable, isomeric cation **3**H (1). This thermodynamic preference for the formation of the cross conjugated dienone derivative should still be maintained in the corresponding Lewis acid complexes.[5]

[5]While the same relative order of stability is expected between the protonated and BX_3 complexed forms of **3**, **14**, and **15**, the exact positions of the various equilibria will be dependent on the nature of the group coordinated to the oxygen atom (18).

One possible difference between these protonated and complexed systems which might account for the formation of **4**·BX_3 in the latter case involves the mechanism of this hydride shift. In FSO_3H, the rearrangement of **14**H to **3**H most probably occurs via an intermolecular hydride shift (14, 19). On the other hand, if the isomerization of **14**·BX_3 were to proceed by successive intramolecular hydride shifts, **15** would be involved as an intermediate. This zwitterion could undergo subsequent hydride or isopropyl group migrations, the latter possibility eventually leading to **4**·BX_3. It is somewhat surprising that if **4**·BX_3 is indeed formed by such a route, there is no concurrent migration of the isopropyl group to the C_4 position (3, 5).

It has been suggested that the formation of **9**H from protonated eucarvone involves a triplet, π,π^* state, whereas the other photoproducts, **2**H and **3**H are derived from a singlet π,π^* state (1). With these complexes, an increasingly heavy atom is introduced into the zwitterions as the Lewis acid is changed from BF_3 to BCl_3 to BBr_3. It might well have been expected that the rates of intersystem crossing between the singlet and triplet states of **1**·BX_3 would be dependent on the halogen atom present. If such an effect is

operative, it is not apparent in terms of the photoproducts obtained from these complexes. Even in CH_3CHF_2, a solvent comprised solely of light atoms, there are no different photoproducts obtained from **1**·BBr_3 as are formed from **1**·BF_3 and no evidence for the formation of **9**·BX_3.

Overall it is apparent that a Lewis acid and a proton exert a comparable modifying effect on the direction of photoisomerization of a carbonyl compound. In view of the very large differences in the polarity of the halocarbon solvents used with the Lewis acid complexes and the FSO_3H employed in the photoisomerizations of **1**H, it is remarkable how similar the initial product distributions are in these two systems. In the case of eucarvone, the thermal and photochemical lability of the complexes of **2** strictly limits the synthetic utility of using a Lewis acid to direct the course of the photoisomerization. This extreme lability of **2**·BX_3 is unexpected in view of the known properties of **2**H and the stability of the boron halide complexes of the other related ketones. It is likely that the difficulties encountered are specific to the eucarvone system and that they do not detract from the general usage of a Lewis acid to direct the course of the photoisomerization of a carbonyl compound.

Experimental

General

^{1}H nmr spectra were recorded on Varian HA-100 and A-60 spectrometers equipped with variable temperature probes. The probe temperature was measured with a copper–constantan thermocouple mounted at the appropriate depth in a nonspinning sample tube. Chemical shifts of neutral materials are referred to internal tetramethylsilane and those of the complexes and protonated compounds are referred to internal CH_2Cl_2 taken as 5.30 δ. Infrared spectra were obtained with a Perkin-Elmer Model 337 grating spectrometer. A Nicolet 1080 Mini-Computer using the Nuclear Resonance Spectrum Calculation Programme (NMRCAL NIC-80/S-7117-D) was used to simulate the ^{1}Hmr spectrum of **4** and obtain the coupling constants of the ring protons. Varian Aerograph 204 (analytical) and Aerograph A-90-P3 (preparative) gas chromatographs were used with He as a carrier gas. The columns employed were: A, 10 ft × $\frac{1}{8}$ in., 20% Carbowax 2000 M on Chromosorb W; B, 10 ft × $\frac{1}{4}$ in., 15% SE 30 on Chromosorb W; C, 13 ft × $\frac{1}{4}$ in., 20% Carbowax 2000 M on Chromosorb W.

Materials

The purification of solvents, formation of the various complexes and protonation of the phenols were carried out as outlined in the previous paper (7).

2-Methyl-6-isopropylphenol, 4

2-Methyl-6-isopropylphenol was prepared by the method of Sowa *et al.* (11) and purified by preparative glpc, column C; ^{1}H nmr (CCl_4) δ 6.92 (1, H-3), 6.67 (1, H-4), 6.82 (1, H-5), $J_{3,4}$ = 7.74 Hz, $J_{4,5}$ = 7.54 Hz, $J_{3,5}$ = 1.66 Hz, 4.24 (s, 1, OH), 3.14 (h, 1, $CH(CH_3)_2$), 2.20 (s, 3, 2-CH_3), 1.15 (d, J = 7 Hz, 6, $C(CH_3)_2$).

2-Methyl-4-isopropylphenol, 7

This phenol was prepared by standard procedures (12); ^{1}H nmr (CCl_4) δ 6.82 (d, $J_{3,5}$ = 2.1 Hz, 1, H_3), 6.80 (q, $J_{3,5}$ = 2.1 Hz, $J_{5,6}$ = 7.8 Hz, 1, H-5), 6.52 (d, $J_{5,6}$ = 7.8 Hz, 1, H-6), 4.46 (s, 1, OH), 2.75 (h, 1, $CH(CH_3)_2$), 2.17 (s, 3, 2-CH_3), 1.16 (d, J = 7 Hz, 6, $C(CH_3)_2$).

Photochemical Procedures

A Phillips SP 500 W lamp was used in conjunction with the apparatus previously described (20). A Corning Glass filter #3850 was used in all irradiations and this cut off light with wavelength less than 370 nm. The temperature of the sample was maintained at −90°C during the course of the photoisomerizations, the temperature being monitored by a glass encased copper–constantan thermocouple inserted into the solution.

Following completion of the photoreaction the products were recovered by the addition directly to the sample tube of 2 ml of a cold (−90°C) slurry of $NaHCO_3$ (0.5 g) in ether (25 ml). The sample tube was agitated with a glass rod during this addition. The quenched solution was quickly transferred into the remaining ether–$NaHCO_3$ mixture and allowed to warm to 0°C. Ice water (5 ml) was added to the ether slurry, the mixture swirled and filtered under suction. The organic layer was washed with brine until neutral (litmus) and dried ($MgSO_4$). The solution was concentrated by careful evaporation of the solvent at atmospheric pressure through a 6 in Vigreux column and subjected to glpc analysis.

Large scale photoisomerizations of **1**·BCl_3 (prepared from 200 mg of **1**) in CH_2Cl_2 (2 ml) required some 4–5 h of irradiation and after quenching the solution, the products were collected by preparative glpc using column B. The products obtained were identified as **2**, **3**, **4**, **5** and **6** on the basis of the comparison of their ir and ^{1}Hmr spectra with those of authentic samples.

The product distributions (Table 1) were obtained with samples containing the appropriate complex (formed from ca. 15 mg of **1**) in CH_2Cl_2 or CH_3CHF_2 (0.5 ml). Following recovery of the products, a weighed amount of cycloheptanone was added and the percent recovery and product compositions determined by analytical glpc, column A. The areas of the peaks were found by triangulation or by cutting and weighing. Detector response curves were established in the usual manner.

Tricarbonylferrole iron tricarbonyl derivatives: formation from thiophenes and iron atoms in a CO atmosphere and fluxional behaviour

TRISTRAM CHIVERS[1] AND PETER L. TIMMS[2]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 13, 1977

TRISTRAM CHIVERS and PETER L. TIMMS. Can. J. Chem. **55**, 3509 (1977).

Co-condensation of metal atoms (Cr, Fe) with thiophenes  (R = R′ = H, Me; R = H, R′ = Me) at −196°C leads to desulphurization of the thiophene. Warm-up of the iron–thiophene co-condensate in a CO atmosphere produces derivatives of tricarbonylferrole iron tricarbonyl, $C_4H_2RR'Fe_2(CO)_6$. ^{13}C nmr studies of these complexes show that the tricarbonyl ferrole unit is static from −95°C to +60°C, while the π-$Fe(CO)_3$ group exhibits fluxional behaviour. Addition of dienes or Me_3P in hexane to the iron–thiophene co-condensate at −196°C yields thermally unstable red solutions on melting.

TRISTRAM CHIVERS et PETER L. TIMMS. Can. J. Chem. **55**, 3509 (1977).

La co-condensation d'atomes de métaux (Cr, Fe) avec les thiophènes  (R = R′ = H, Me; R = H, R′ = Me) à −196°C, conduit à la désulfuration de ces derniers. Le réchauffement du composé co-condensé thiophène–fer dans un atmosphère de CO, conduit aux dérivés du tricarbonyle tricarbonylferrole–fer $C_4H_2RR'Fe_2(CO)_6$. Les études par rmn du ^{13}C de ces complexes montre que la partie tricarbonylferrole est statique de −95°C à +60°C, alors que le groupe π-$Fe(CO)_3$ présente un comportement variable. L'addition de dienes ou du Me_3P dans l'hexane au composé co-condensé thiophène–fer à −196°C, conduit par fusion à des solutions rouges, thermiquement instables.

[Traduit par le journal]

Introduction

Since the first report of a π-complex of thiophene with a transition metal, viz. $(C_4H_8S)Fe(CO)_3$ (1, 2), numerous studies of related complexes have appeared (3–5) and corresponding cationic manganese complexes have been prepared(6). Bis(tetramethylthiophene)$Fe^{2+}(PF_6^-)_2$ has recently been isolated (7), but no neutral bis(thiophene)metal complexes are known although electrochemical reduction of this salt suggested the possibility of isolating bis(tetramethylthiophene)iron(0).

The direct synthesis of bis(arene)metal complexes from arenes and metal vapours at −196°C (8) is a versatile route to such complexes (9), and this approach has recently been extended to the synthesis of bis(2,6-dimethylpyridine)chromium (10). We describe here parallel investigations of the reactions of thiophenes with iron or chromium vapours at −196°C (for a preliminary communication see ref. 11), carried out as a possible source of bis(thiophene)metal(0) complexes.

Experimental

Apparatus and Techniques

Evaporation and low temperature co-condensation reactions of Fe and Cr were carried out in a glass apparatus previously described (12) and in a prototype of the commercially available Kontes metal atom reactor. Metals were evaporated from alumina-coated molybdenum wire crucibles at 25–30 A and 5–6 V. Solvents were dried, freshly distilled, and de-aerated before use.

The following instruments were used to obtain spectroscopic data: Perkin-Elmer 457 (ir spectra), Atlas CH5 (mass spectra), Varian HA100 (^1H nmr spectra), Bruker WH90 (^{13}C nmr spectra) operating in the pulsed Fourier transform mode at 22.63 MHz. The latter instrument is equipped with a Nicolet B-NC 12 data system. The ^{13}C chemical shifts were measured relative to tetramethylsilane as internal standard. Tris(acetylacetonato)chromium(III) (ca. 0.05 *M*) was added to each nmr sample to reduce T_1 relaxation times, and the spectra were recorded at various temperatures in the range −95°C to +60°C. The thiophenes were commercially available samples (Aldrich) and were used without further purification.

Iron, Thiophenes, and Carbon Monoxide

The typical reaction procedure is described here for 2,5-dimethylthiophene. Analogous products were ob-

tained from thiophene and 2-methylthiophene (see Discussion).

Iron (1.0 g, 18 mmol) was vaporized and condensed at −196°C with 2,5-dimethylthiophene vapour (20 g, 179 mmol) in 2 h. After addition of the thiophene, the reaction flask was allowed to slowly warm up under nitrogen. A deep purple-plum solution was observed when the co-condensate melted. The solution retained this colour up to ca. −20°C, whereupon it gradually became colourless with deposition of Fe metal. When the co-condensate was allowed to warm up under CO (½ atm), the solution remained purple up to ca. −30°C when CO uptake occurred and the solution became red-brown. Excess of thiophene was removed by vacuum transfer, and the residue was extracted with benzene (150 ml). The solution was filtered by forcing it under a pressure of N_2 through a stainless steel tube (1 mm diameter) with filter paper attached to one end. Benzene was removed from the clear red-brown filtrate by vacuum transfer to give a brown oil which was purified by chromatography on alumina using *n*-hexane. Orange crystals of tricarbonyl-2,5-dimethylferrole – iron tricarbonyl (mp 45°C) were obtained after solvent removal under vacuum. The yield was 91 mg or ca. 5% (allowing for 40% loss of the metal evaporated). *Anal.* calcd. for $C_{12}H_8Fe_2O_6$: C 40.0, H 2.24; found: C 39.9, H 2.35. The mass spectrum showed a molecular ion (M^+) at *m/e* 360 (59) together with major peaks at 332 (22), 304 (34), 276 (29), 248 (100), 220 (54), 192 (47) corresponding to the stepwise loss of six CO's from M^+. The infrared spectrum of the product was identical to that of an authentic sample prepared from $Fe_3(CO)_{12}$ and 2,5-dimethylthiophene by the literature procedure (13, 14).

The benzene-insoluble residue was washed several times with benzene, dried under vacuum, and ground up in a mortar before analyzing for sulphur. Values in the range 11–17% S were obtained for several residues resulting from the reactions with different thiophenes.

Vapour and liquid phase ir spectra and ^1H nmr spectra of the recovered volatiles provided no evidence for volatile products other than the recovered thiophene, with the exception of ir bands at 2970 (m) (aliphatic C—H) and 911 (m) cm^{-1} in the vapour phase ir spectrum of the volatiles from the reaction with thiophene.

Chromium, Thiophene, and Carbon Monoxide

Chromium (1.5 g, 29 mmol) was vaporized and condensed at −196°C with thiophene (12 g, 143 mmol) during 1.5 h. The co-condensates were allowed to melt under a nitrogen atmosphere to give a yellow-brown solution which became colourless at room temperature (15).[3] Excess of thiophene was removed in vacuo and the dark-green solid residue was washed with hexane and benzene, dried under vacuum (25°C; 10^{-2} Torr), and analyzed for sulphur. Found S = 13.5%. The ir spectrum (Nujol) showed no bands (other than Nujol) in the 2000–600 cm^{-1} region.

In a separate experiment the chromium-2,5-dimethylthiophene co-condensate was allowed to warm up under a CO atmosphere (0.5 atm). The solution was orange-brown on melting but colourless at room temperature. Excess of thiophene was removed under vacuum to give a pale-yellow solid (on the sides of the reaction flask), insoluble in benzene and involatile at 50°C/10^{-2} Torr. This solid became green in air and showed no bands in the 2000–600 cm^{-1} region of the ir spectrum. After drying under vacuum, the sulphur content of this solid was 11.4%. Infrared spectra of the volatile products (vapour phase and liquid film) showed no peaks other than those attributable to 2,5-dimethylthiophene.

Synthesis of Tricarbonylferrole Iron Tricarbonyl Derivatives from Iron Carbonyls

For comparison with the products from the iron atom – thiophene–CO reactions and for spectral measurements, tricarbonylferrole iron tricarbonyl and the 2-methyl, 3-methyl, and 2,5-dimethyl derivatives were prepared from the appropriate thiophene and $Fe(CO)_5$ or $Fe_3(CO)_{12}$ according to the literature procedures (13, 14). The 2-methyl and 3-methyl compounds were obtained as orange oils, after chromatography on alumina, and their ir and mass spectra were entirely consistent with the spectra expected for tricarbonylferrole iron tricarbonyl derivatives.

Results and Discussion

Co-condensation Reactions

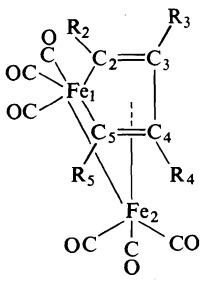
The co-condensation of Cr atoms with thiophenes at −196°C produces yellow-brown solutions on melting which become colourless at room temperature. Analysis of the solid residues for sulphur, after removal of excess of thiophene, gave values in the range 10–13.5%, demonstrating that desulphurization of the thiophene had occurred. There was no evidence for the formation of a thermally stable organometallic product.

Similarly the co-condensation of Fe atoms with thiophene, 2-methyl- or 3-methyl-, or 2,5-dimethylthiophene at −196°C gives a plum-coloured matrix which retains its colour on melting up to ca. −20°C but becomes colourless at room temperature. After removal of excess ligand, the solid residues gave values in the range 11–17% for sulphur. When the iron–thiophene co-condensate was allowed to warm up in an atmosphere of CO, orange-brown crystals of **1** or **4** were isolated in low yield. The compounds **2** and **3** were obtained as orange oils.

Nature of the Iron–Thiophene Co-condensate

The isolation of the organometallic complexes **1**–**4** confirms that thiophenes are desulphurized after co-condensation with iron vapour at −196°C. It has previously been observed that tricarbonylferrole derivatives are formed via desulphurization of thiophenes by iron car-

[3]The reaction of thiophene with chromium atoms has been reported to give a dark, involatile product insoluble in the common organic solvents, but no details were given.



1 $R_2 = R_3 = R_4 = R_5 = H$
2 $R_2 = CH_3$; $R_3 = R_4 = R_5 = H$
3 $R_3 = CH_3$; $R_2 = R_4 = R_5 = H$
4 $R_2 = R_5 = CH_3$; $R_3 = R_4 = H$
5 $R_2 = R_5 = t$-Bu; $R_3 = R_4 = H$

bonyls (13). In the metal atom reactions, it is necessary to decide whether desulphurization occurs immediately on co-condensation or on warm-up of an unstable (thiophene)$_2$metal complex, which may involve σ- or π-coordination of thiophene to iron (16[4], 17[5]) or a combination of both.

The following observations and experiments indicate that the former pathway predominates. (*a*) Whereas the thermal stability of (arene)$_2$Fe complexes increases markedly with alkyl substitution on the arene ligand, the thermal stability of the plum-coloured Fe–thiophene co-condensates appears to be independent of alkyl substitution on the thiophene. (*b*) Addition of cyclopentadiene to an Fe–benzene co-condensate at −196°C produces ferrocene in 40% yield (8), but no ferrocene is obtained when an Fe–thiophene co-condensate is treated in a similar manner. (*c*) No (thiophene)Cr(CO)$_3$ was obtained from warm-up of the Cr–thiophene co-condensate in a CO atmosphere.

We therefore pursued the possibility that the Fe–thiophene co-condensate contained ferroles e.g.  which might be trapped by the addition of suitable ligands, e.g. dienes, Me_3P (18).[6] When trimethylphosphine (20% solution in *n*-hexane) was added to an Fe–2,5-dimethylthiophene co-condensate at −196°C, a bright-red solution was observed on melting. At 0°C the red colour was much less evident, and the solution became orange-yellow with deposition of some black solid at 20°C. No derivatives of the type described by Rathke and Muetterties (18) could be isolated. Similarly, the addition of dienes, e.g. butadiene, 1,5-cyclooctadiene to Fe–thiophene co-condensates at −196°C gave, on melting, red solutions which were unstable above ca. −20°C. Thus the exact nature of the species responsible for the plum colour of the Fe–thiophene co-condensate remains uncertain.

Tricarbonylferrole Derivatives: ^1H Nuclear Magnetic Resonance Spectra

The ^1H nmr spectra and crystal structure of $C_4H_4Fe_2(CO)_6$ have been reported recently (14). The spectrum was analyzed as an AA′XX′ system and chemical shifts of 6.2 and 6.8 ppm, respectively, were assigned to the pairs of protons $H_{2,5}$ and $H_{3,4}$ (the subscripts refer to the carbon atoms to which the hydrogens are attached in **1**). The coupling constants are indicated in Table 1 together with our data for the tricarbonylferrole derivatives **2**–**4** which suggest that the chemical shift assignments reported for **1** (14) should be reversed. For the 2,5-dimethyl derivative, **4**, two singlets are observed at 5.82 ppm and 2.30 ppm and these can readily be assigned to ferrole protons and methyl substituents respectively. The ^1H nmr spectrum of the ferrole protons of the 2-methyl derivative, **2**, is that of an AMX system. In addition to the signal for the methyl group, three equally intense signals are observed at 6.66, 6.18, and 5.94 ppm, which appear as two doublet of doublets and a triplet, respectively. The triplet clearly arises accidentally as a result of two approximately equal couplings to non-equivalent protons as expected for H_3 on the basis of coupling constants reported for **1**. The assignment of the other two signals to H_4 or H_5 is, at this stage, ambiguous. The ^1H nmr spectrum of the 3-methyl derivative, **3**, showed two doublets at 6.84 and 6.37 ppm, respectively, and a doublet of doublets at 6.14 ppm, in addition to the signal for the methyl substituent. From the data for compound **1** in Table 1, the larger doublet (6.84 ppm) is assigned to H_5 and the smaller doublet (6.37 ppm) to H_2. Thus the signal at 6.14 ppm must be due to H_4, which

[4]The detection of CrS^+ in the mass spectrum of $(C_4H_8S)Cr(CO)_3$ suggests that σ-bonding of sulphur to chromium is important in the $C_4H_8SCr^+$ ion.

[5]The σ-bonded thiophene complex, (2-methyl,5-diethylborylthiophene)chromium pentacarbonyl has recently been described.

[6]The novel iron heterocycle  has recently been isolated and is described as a blue, highly volatile solid of high thermal reactivity. It was purified by vacuum sublimation at 40°C.

[b]Data from ref. 14.

shows two couplings of ca. 5.2 and 2.7 Hz, as expected. The high field signal therefore corresponds to the ferrole proton remote from the iron atom, and this assignment together with the chemical shift (5.82 ppm) of the ferrole protons in **4** suggests that the signals at 6.66 and 6.18 ppm in **2** can be assigned to H_5 and H_4, respectively. We, therefore, propose that the reported assignments for the ferrole protons in **1** should be reversed, i.e. $\delta_{H_2} = \delta_{H_5} = 6.8$ ppm and $\delta_{H_3} = \delta_{H_4} = 6.2$ ppm. Thus the chemical shifts of the protons (H_2, H_5) nearest to iron in tricarbonylferrole derivatives are consistently to high field of the chemical shift for the remote protons (H_3, H_4).

^{13}C *Nuclear Magnetic Resonance Spectra and Fluxional Behaviour*

The crystal structure of **1** shows that one of the CO groups of the π-bonded $Fe(CO)_3$ unit forms a highly unsymmetrical bridge to the other iron atom (Fe_1) (14). This structural feature has been observed in a number of other (19–21), but not all (22), tricarbonylferrole iron tricarbonyl derivatives. The static structure suggests, therefore, that such molecules should exhibit four carbonyl resonances with relative areas of 2:2:1:1. A number of recent ^{13}C nmr studies have shown, however, that in solution the π-$Fe(CO)_3$ group is stereochemically nonrigid. For example, the 3 carbonyl resonances of this group in the tricarbonylferrole derivative ($R_2 = R_4 = CH_3$; $R_3 = R_5 = C{\equiv}CCH_3$) remain magnetically equivalent down to −78°C (23). Similarly, the derivative in which $R_2 = R_5 = Ph$; $R_3 = R_4 = H$ shows an unchanged ^{13}C nmr spectrum over the temperature range −125°C to +95°C (21), although other authors (24)[7] report significant broadening at −75°C. It was suggested that the area 3 resonance was due either to a coincidental overlap of two signals or to a very low energy fluxional process (21). Resolution of the ^{13}C signals of the π-$Fe(CO)_3$ group has been reported for compound **5** ($R_2 = R_5 = t$-Bu) (24). At −100°C two signals (intensities 2:1) were observed at 214.1 and 222.2 ppm. This result suggests that a fluxional process is indeed responsible for the apparent equivalence of carbonyl groups on Fe_2 at higher temperatures, and that the steric bulk of the *tert*-butyl group results in a higher activation energy for rotation of the π-$Fe(CO)_3$ group in **5** compared to other tricarbonylferrole derivatives.

Our ^{13}C nmr data for compounds **2–4** are compared with the literature data for **1** (21) and **5** (25) in Table 2. Methyl substitution results in a deshielding of the ferrole ring carbon signals by 20–25 ppm. A similar deshielding is observed for phenyl (21) and *tert*-butyl substituents (25). Compounds **2–4** show three sharp resonances at room temperature with relative intensities 3:1:2. The area 3 resonance was not significantly broadened down to −95°C suggesting that the exchange of the CO groups on Fe_2 via rotation of the $Fe(CO)_3$ unit has a lower activation energy for compounds **2–4** compared with **5**. There was no evidence for exchange between carbonyls on Fe_1 and Fe_2 at higher temperatures (+60°C, see also ref. 21) and, thus, in solution the two $Fe(CO)_3$ groups in these complexes behave independently despite the observation of a *semi-bridging* CO in the solid state structure (*vide supra*). The loss of the plane of symmetry which bisects C_3–C_4 results in distinct signals for C_3 and C_4 in **2** and for C_2 and C_5 in **3**. For the same reason the equatorial CO's on Fe_1 are no longer equivalent in **2** and **3**, although separate signals could only be resolved for **2**.

It is instructive to compare these results with the extensive studies of the fluxional behaviour

[7]This paper also reports some ^{13}C nmr data for various methylsubstituted tricarbonylferrole iron tricarbonyls, including **4**, but they were not obtained as pure samples, and thus the carbonyl carbon signals were not resolved.

of (η-diene)$Fe(CO)_3$ derivatives carried out by Kruczynski and Takats (25) who found a marked dependence of the rate of carbonyl scrambling on the nature of the diene. For nonconjugated dienes, e.g. cycloocta-1,5-diene, no evidence for line broadening was observed even at the lowest accessible temperatures (−130°C), whereas for conjugated 1,3-dienes, e.g. butadiene, the activation barrier was sufficiently large to be observable by nmr. This difference was attributed to significant contributions from six-coordinate structures (B) in the case of conjugated dienes and the relative unimportance of such contributions in complexes with nonconjugated dienes.

Our results suggest that, in contrast to the general accepted bonding description for butadiene iron tricarbonyl (25, 26) back-bonding between filled metal *d* orbitals and the LUMO (π_3*) of the diene is an unimportant component of the ligand–metal bonding in tricarbonylferrole iron tricarbonyl derivatives. For the tricarbonylferrole ligand there is good evidence from X-ray structural data for multiple bonding in the Fe—C bonds of the ferrole ring (14).Thus these bonds are 1.94–1.95 Å compared to 2.08–2.12 Å expected for the sum of the covalent radii of iron and carbon. Such multiple bonding can arise via interaction of d_{xz} and d_{yz} on Fe_1 with π_3* of butadiene. This electron donation would greatly diminish contributions to π_3* from the π-bonded $Fe(CO)_3$ group and hence six-coordinate structures would be less important in the bonding of tricarbonylferrole $Fe(CO)_3$ complexes compared to $C_4H_6Fe(CO)_3$. This conclusion is in accord with the observed low activation energies for carbonyl exchange in ferrole complexes and provides further support for the arguments used by Kruczynski and Takats to explain the dynamic behaviour of (diene)$Fe(CO)_3$ compounds (25).

Homogeneous catalysis of deuterium transfer by potassium hydroxide and potassium methoxide D_2–H_2O and D_2–CH_3OH exchange[1]

GRAEME G. STRATHDEE, DAVID M. GARNER, AND RUSSELL M. GIVEN

Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received February 25, 1977

GRAEME G. STRATHDEE, DAVID M. GARNER, and RUSSELL M. GIVEN. Can. J. Chem. **55**, 3515 (1977).

The kinetics and mechanism of exchange of deuterium between D_2 and water and between D_2 and methanol, catalyzed respectively by concentrated potassium hydroxide and potassium methoxide, has been studied between 348 and 398 K. In the D_2–KOH–H_2O case, the transfer of deuterium was found to be controlled by the rate of activation of the D_2 molecule by OH^-. Rapid exchange of D^+ with the aqueous solution followed. From the D_2–$KOCH_3$–CH_3OH studies, it was concluded that deuterium exchange depended upon the rates of both D_2 activation by methoxide and interaction of the solvent with the transition, or encounter, complex. The dependence of second-order rate constants on solvent activity for both systems was determined by normalization of the exchange reaction rates to unit reagent activity. Analysis of the kinetic isotope effects for each system suggested that their increase with base concentration or temperature was due to solvation effects.

GRAEME G. STRATHDEE, DAVID M. GARNER et RUSSELL M. GIVEN. Can. J. Chem. **55**, 3515 (1977).

On étudie entre 348 K et 398 K les cinétiques et le mécanisme d'échange du deutérium entre D_2 et l'eau puis entre D_2 et le méthanol, catalysé respectivement par des solutions concentrées d'hydroxyde de potassium et de méthylate de potassium. Dans le cas D_2–KOH–H_2O, le transfert du deutérium semble être contrôlé par la vitesse d'activation de la molécule D_2 par l'ion OH^-. Un échange rapide de l'ion D^+ avec la solution aqueuse s'en suit. A partir des études faites sur D_2–$KOCH_3$–CH_3OH, on en déduit que l'échange du deutérium dépend de la vitesse d'activation de D_2 par le méthylate et de la vitesse d'interaction du solvant avec le complexe de transition ou rencontre. La dépendance des constantes de vitesse du second ordre sur l'activité du solvant pour les deux systèmes est déterminée par normalisation des vitesses d'échange par unité d'activité du réactif. L'analyse des effets isotopiques cinétiques pour chaque système suggère que leur augmentation avec la concentration en base ou la température est due à des effets de solvatation.

[Traduit par le journal]

Introduction

Strong bases such as alkali metal hydroxides (1–6), alkoxides (4), amides (7, 8), and alkylamides (9–11) are effective homogeneous catalysts for the exchange of deuterium between D_2 and their corresponding protic solvents. The general pattern of reactivity of these catalyst systems is well known: the nitrogen bases are substantially better for the D_2-exchange application than are the oxygen bases and alkyl substitution of the amide anion, NH_2^-, yields higher specific rate constants for this proton transfer process. The present research has dealt mainly with the relative activity of aqueous KOH with respect to methanolic $KOCH_3$ and has allowed us to make a better comparison of the performance of these oxygen bases with that of KNH_2 in ammonia or $KNHCH_3$ in methylamine.

We have also investigated in detail the mechanism of deuterium transfer from D_2 to the protic solvent. The solution properties were nonideal because of the high electrolyte concentrations. To enable us to analyze the data at unit activity of the reagents we have evaluated the activities of the solutes and solvent in both the D_2–KOH–H_2O and D_2–$KOCH_3$–CH_3OH systems. Our kinetic studies have shown that in these solutions where the proportion of 'free' solvent is small, the manner in which the solvent participates in the proton transfer process may be defined. The mechanism which we propose to explain our results requires that D—D bond-breaking and solvation steps are of comparable importance in determining the overall rate of the exchange reaction. In this respect our con-

[1]Issued as AECL No. 5871.

clusions differ from that of Ritchie and King (12) who have argued that solvation is of greater importance.

It was also our intent to investigate why the oxygen bases promote D_2 exchange at rates which are unattractive from the chemical processing standpoint. Solutions of these catalysts are thermally stable and easily handled and are therefore of interest because of potential application for heavy water production, for example, in a bithermal hydrogen–water system. By describing the mechanism of proton transfer we hoped to assess if chemical modification of the system would lead to enhancement of rates of exchange.

Experiment

Purifications

Deuterium gas was C.P. grade (Matheson) and was used as received or was evolved from uranium deuteride (UD_3) at 723 K. The UD_3 was formed by reaction of commercial D_2 with uranium metal turnings at 600 K. No difference between exchange rates was found using D_2 from these sources. Water was distilled and deionized. Methanol was percolated through a bed of Linde 4A molecular sieves and distilled under dry nitrogen.

Preparations

Hydroxide solutions were made gravimetrically with reagent grade KOH. Alkoxide solutions were prepared by dissolution of the alkali metal in freshly distilled methanol. The metal was handled in a nitrogen filled glove box. The solution concentrations were determined by acid titration.

Procedures

The transfer of deuterium from D_2 gas to the protic solvents was followed by sampling the gas phase of a stirred two-phase reactor and by analyzing the gas for D_2, HD, and H_2 mass spectrometrically. The exchange reactions were run in either a 116 cm^3 Pyrex glass cell or in a glass-lined 248 cm^3 stainless steel autoclave, depending upon the total pressure at the operating temperature. The gas space – solution volume ratio was 7.7 in each case. Stirring speeds were always above 25 Hz to maintain satisfactory dispersion of the gas in the solution. Reaction rates were independent of agitation speed under those conditions. Constant temperatures were obtained by circulating a hydrocarbon oil from a thermoregulated bath through fluid-jackets around the reaction cells.

In other experiments, solubilities of H_2 in methanol and in alkali metal methoxide solutions in methanol were measured by gas chromatography using our dissolved gas stripping technique (13). The solutions were saturated with H_2 at known pressure and temperature. Liquid samples were withdrawn into a 1 cm^3 sampling valve loop, and were injected into a 10 cm^3 stripping cell held at room temperature. Sampling valves and all lines were heated to avoid precipitation of methoxides from the concentrated solutions. The partial pressure of H_2 in the autoclave was readjusted after each sampling step.

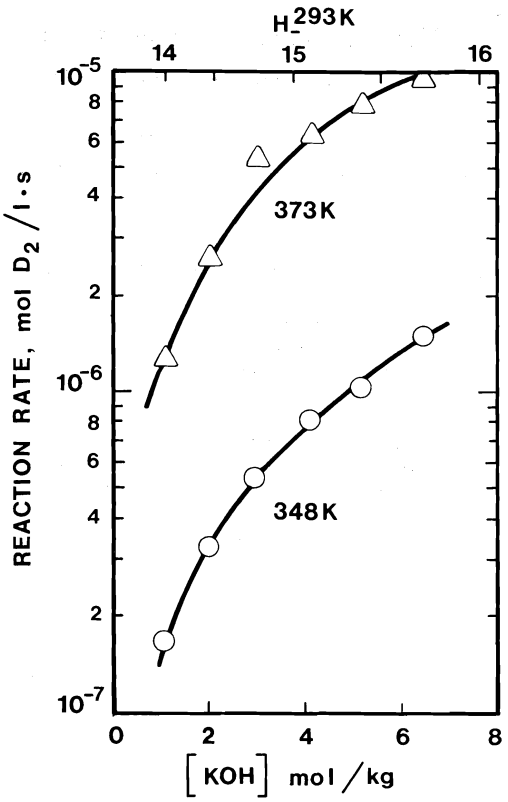

FIG. 1. Rate of D_2–H_2O exchange catalyzed by KOH.

Results

In this section, D_2 exchange rate, physical property, and kinetic isotope effect data are presented for both the D_2–KOH–H_2O and D_2–$KOCH_3$–CH_3OH cases. Our method of calculation of rate constants is considered in the section on Treatment of Data. The two systems are compared in the Discussion.

Deuterium Exchange Rates

D_2–KOH–H_2O

The rates of exchange of D_2 with water catalyzed by KOH at 348 and 373 K are shown in Fig. 1 as a function of KOH molality. The rates were calculated as described later in the section on Treatment of Data. These rates are essentially the same as those quoted by Flournoy and Wilmarth (3) and by Schindewolf (4). A plot of log exchange against log base concentration showed that the apparent reaction orders in hydroxide were greater than unity, although in dilute solution Wilmarth and co-workers have

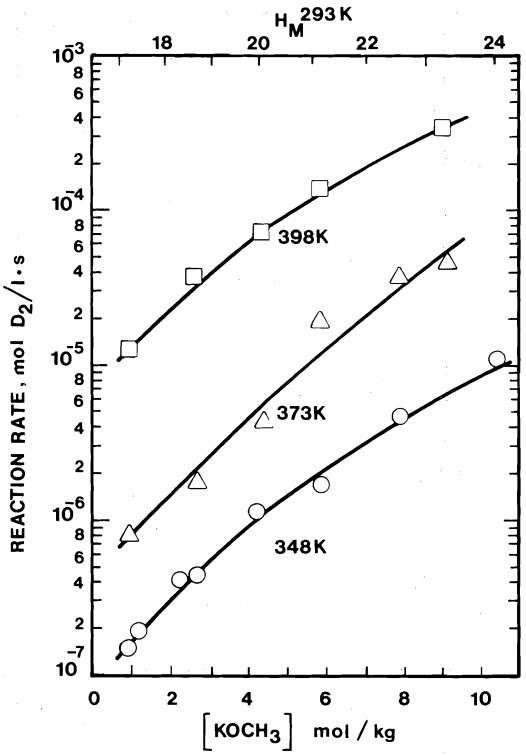

FIG. 2. Rate of D_2–CH_3OH exchange catalyzed by $KOCH_3$.

shown that the rate law for deuterium transfer contains first-order terms in hydroxide and D_2 (2). The remainder of this paper deals with the factors which contribute to the form of these results.

For reference purposes, the H_- basicity scale at 293 K for these aqueous KOH solutions (14) has been included on the upper abscissa of Fig. 1. It is noteworthy that for a unit increase in H_- (factor of 10 in basicity) there is approximately a 5-fold increase in D_2 reaction rate. This topic is also considered later in the Discussion.

D_2–$KOCH_3$–CH_3OH

In Fig. 2, the D_2 exchange rate data for the D_2–$KOCH_3$–CH_3OH system are presented for 348, 373, and 398 K as a function of base concentration. The absolute rates are very similar to those reported for the D_2–KOH–H_2O case, although there is somewhat less curvature on this logarithmic plot at high concentrations. The apparent order of the exchange reaction in $KOCH_3$ at 373 K, obtained from a plot of log (rate) against log [$KOCH_3$], increased from 1 at low concentration to about 3 above 4 mol/kg. The H_M basicity scale for these solutions determined at 20°C (15*a*) is shown as the upper scale of Fig. 2. As was the case with the D_2–KOH–H_2O system, the exchange rates increased by approximately a factor of 5 per unit of H_M.

Activities and Activity Coefficients

Our results for each system will be discussed in this order: activity coefficients for dissolved H_2, activity of the solvent, activity coefficient of the solute base. For the D_2–KOH–H_2O ternary mixture, data were available in the literature. For the D_2–$KOCH_3$–CH_3OH solutions, our new data were employed to derive the appropriate functions. In each case the mean activity coefficient for the catalyst was calculated from solvent vapour pressure data by integration of the Gibbs-Duhem equation as discussed below. All activity coefficients for D_2 and KOH were unsymmetrically normalized (16) and refer to the standard state of infinitely dilute base. The subscripts 1, 2, and 3 refer to the solvent, D_2, and base respectively.

D_2–KOH–H_2O

Shoor, Walker, and Gubbins (17) have reported activity coefficients for H_2 in water at temperatures up to 373 K, and their results have been used to calculate the activity of D_2 in our aqueous solutions. It is probable that D_2 is slightly more soluble than H_2 in aqueous KOH (5, 18) but in the absence of specific data we have employed results for H_2. The activity coefficient for H_2 does not vary with temperature between 298 and 373 K (17) and for a given KOH molality c, it is given by $\gamma_2^* = 10^{0.129c}$ as shown in Fig. 3.

The activity of water was calculated from the ratio of the vapour pressure of the aqueous KOH solution to that of pure water at the temperature of interest using the data of Anisimov (19). The activity of water for a given KOH mole fraction x_3 was essentially independent of temperature. The activity coefficients were calculated using the usual relation $\gamma_1 = a_1/x_1$ and are summarized in Fig. 3 for 373 K.

To calculate the activity coefficients for KOH from the activity of the solvent we employed the integral form of the Gibbs-Duhem equation:

$$[1] \quad \log \gamma_3^* = -\int_{\gamma_1=1}^{\gamma_1=\gamma_1} (x_1/x_3)\, d \log \gamma_1$$

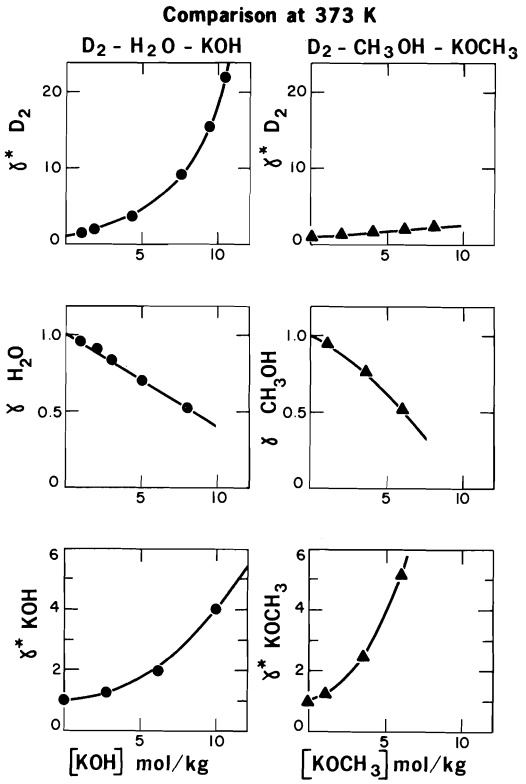

FIG. 3. Comparison of activity coefficients for D_2, the solvent, and the base for each exchange reaction mixture at 373 K. In the text, the subscripts 1–3 refer to solvent, D_2, and base respectively.

It was assumed that the resultant binary solution activity coefficients could be used for our three-component system calculations because the mole fraction of D_2 was exceedingly low. The right-hand side of eq. 1 was made explicit in x_1 by differentiation of $\log \gamma_1 = \log a_1 - \log x_1$:

$$[2] \qquad d \log \gamma_1 = [f'(x_1) - x_1^{-1}]\, dx_1$$

in which $f'(x_1)$ was the first derivative of the computer-fit polynomial $\log a_1 = f(x_1)$. Also, we made the approximation $x_3^{-1} = (1 - x_1)^{-1}$ and expanded that as a binomial series in x_1. Since $f(x_1)$ for the KOH–H_2O system using Anisimov's data for 373 K was:

$$[3] \quad \log a_1 = -10.6216 + 20.6578x_1 - 10.0365x_1^2$$

eq. 1 became:

$$[4] \quad \log \gamma_3^* = 4.0144x_1^5 - 0.1463x_1^4 + 0.0500x_1^3 - 10.1115x_1^2 + 0.434x_1 + 13.791$$

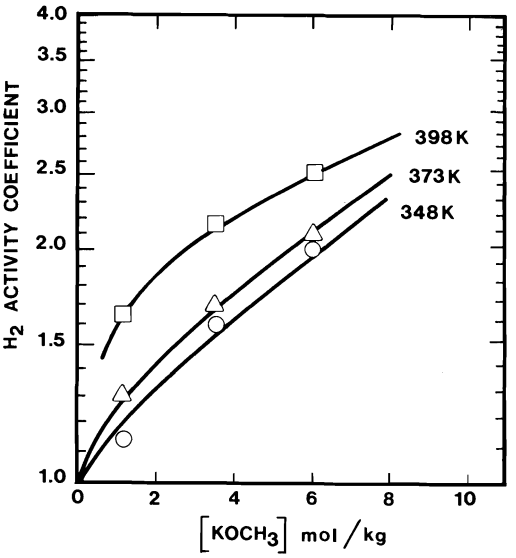

FIG. 4. Dependence of activity coefficients for H_2 in methanol on $KOCH_3$ concentration.

between the integration limits of $x_1 = 1$ to $x_1 = x_1$. These equations are valid up to a KOH molality of 8 mol/kg. The values for γ_3^* plotted in Fig. 3 apply to both 348 and 373 K since [4] holds at each temperature. Activity coefficients calculated in this way are similar to those tabulated by Robinson and Stokes for aqueous KOH up to 6 kmol/m^3 (6.55 mol/kg) at 298 K (20).

D_2–$KOCH_3$–CH_3OH

Solubilities of H_2 in methanolic $KOCH_3$ were measured by the solution purging method described in the Experiment section. The resultant data were treated in the same way as those of Shoor *et al.* (17) for the aqueous KOH system. The effect of $KOCH_3$ concentration c_3 on H_2 solubility was slight, and our results are summarized in Fig. 4 as a plot of activity coefficient γ_2^* values for H_2 in each catalyst solution at each temperature. Presumably, dissolution of H_2 is less affected by $KOCH_3$ concentration in methanol than by KOH in water because the free energy of cavity formation for the small H_2 molecule is much less in the methanolic system. The greater molar volume of methanol compared with water is consistent with the lesser dependence of γ_2^* on c_3 in the methanolic case.

The vapour pressures of methanolic $KOCH_3$ solutions were measured and used to calculate solvent activities and activity coefficients.

Activities, $a_1 = P/P_0$ where P and P_0 are the solution and pure solvent vapour pressures respectively, were found to be independent of temperature and the correlation given by [8] held between 348 and 398 K.

Potassium methoxide activity coefficients were calculated from those of the solvent by using [1] and [2] in which:

$$[5] \quad \log a_1 = f(x_1) = -7.6312 + 14.0291x_1 - 6.3919x_1^2$$

This gave

$$[6] \quad \log \gamma_3^* = 2.5568x_1^5 - 0.3113x_1^4 - 0.2704x_1^3 - 6.7975x_1^2 + 0.4340x_1 + 4.3884$$

which holds up to 10 mol/kg $KOCH_3$ in methanol. The results for 373 K are shown in Fig. 3 together with those for aqueous KOH.

The greater dependence of γ_3^* for $KOCH_3$ in methanol compared to KOH in water was due mainly to the higher molecular weight of $KOCH_3$. For a given molal concentration, the former solution contained fewer moles of solvent than did the latter. This relative reduction of available solvent in the $KOCH_3$ solutions resulted in the greater sensitivity of γ_3^* to $KOCH_3$ concentration.

Kinetic Isotope Effects

We have defined the kinetic isotope effect (kie) to be the ratio of the best first-order rate constants, $2k_{HD}/k_{D_2}$, calculated by the procedure discussed later in the section on Treatment of Data. The factor of 2 is a statistical correction for the fact that although either end of the HD molecule can react, only removal of the D by base can be observed. The standard deviation on the calculated kie was usually much less than 10% of the value, particularly at large overall conversion of D_2 to yield the products HD and H_2.

D_2–KOH–H_2O

At both 348 and 373 K the kie was found to be greater than 1, as expected for a normal HD:D_2 kie. As illustrated in Fig. 5, at 348 K the kie was independent of KOH concentration, but at 373 K a significant increase of kie was found. Our kie data are similar to those of Schindewolf (4), who reported a kie of 1.42 ± 0.06 for D_2–H_2O exchange catalyzed by NaOH at 388 K, although the kie was independent of base concentration.

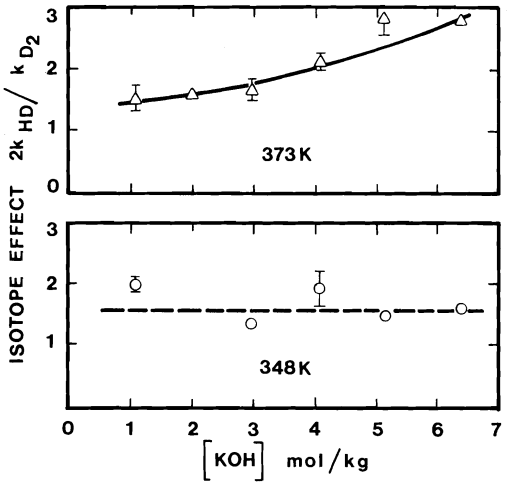

Fig. 5. Variation in the kinetic isotope effect for D_2–H_2O exchange with KOH concentration at 348 and 373 K.

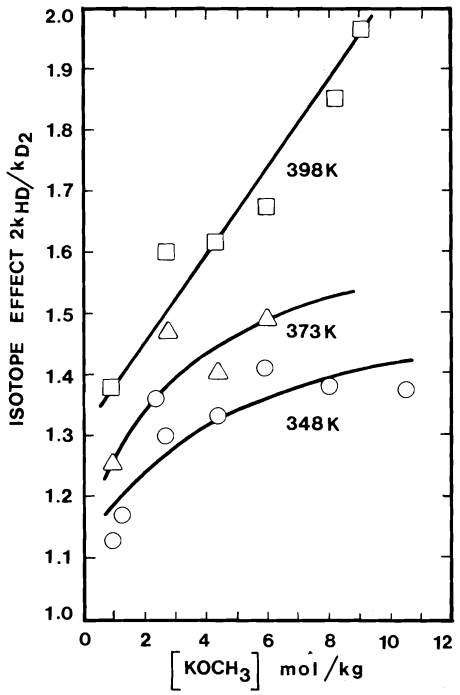

FIG. 6. Variation in the kinetic isotope effect for D_2–CH_3OH exchange with $KOCH_3$ concentration between 348 and 393 K.

D_2–$KOCH_3$–CH_3OH

The kie's for this system increased with base concentration at each temperature we selected. The scatter in the results at 348 and 373 K was primarily due to the low total conversion of D_2 for cases where the D_2 exchange rates were

slow. The trend of each set of data in Fig. 6 is clear. We believe these observations are due to a transition in the mode of solvent participation in the component steps of the deuterium transfer mechanism. This topic is dealt with in the Discussion.

Treatment of Data

Calculation of Exchange Rates

In-solution rates of exchange of D_2 to yield HD were calculated from the change of D_2 in the gas phase with the equation:

$$[7] \quad -\mathrm{d}[D_2]/\mathrm{d}t = \ln [(n_0 - n_e)/(n_t - n_e)]\, A/t$$

where n_0, n_t, and n_e represent the mol% D_2 at time $t = 0$, t, and at equilibrium, respectively. A is the total gas-to-liquid mole/volume ratio in moles D_2 per litre of solution at 293 K. The reaction rates which we quote at elevated temperature T_2 are high by an amount equal to the ratio of specific volumes of the electrolyte solutions at T_2 compared to 293 K. Densities of the methanolic solutions at high temperatures were unavailable. We were, thus, unable to correct solution volumes to T_2. It was necessary to treat our data in this manner because H_2 solubilities were measured on a volumetric basis. The resultant error in the D_2 exchange rates given below was small and less than the experimental error.

In each D_2 experiment, the sequential conversion of both D_2 to HD (k_{D_2}) and of HD to H_2 (k_{HD}) by reaction with the protic solvent were accurately first-order.

$$[8] \quad D_2 + ROH \xrightarrow{k_{D_2}} HD + ROD$$

$$[9] \quad HD + ROH \xrightarrow{k_{D_2}} H_2 + ROD$$

Back reactions were ignored because ROD was always less than 1 mol% of the ROH. To calculate apparent kinetic isotope effects, kie = $2k_{HD}/k_{D_2}$, an iterative curve-fitting technique was employed in which the computer program minimized the standard deviation between the observed and calculated HD yield and gave the best values for k_{HD} and k_{D_2}. Provision was made for the possibility that initial concentrations of HD and H_2 (in the feed D_2) might be significant. This procedure was necessary when overall D_2 conversions were low, e.g., 10–35% (21).

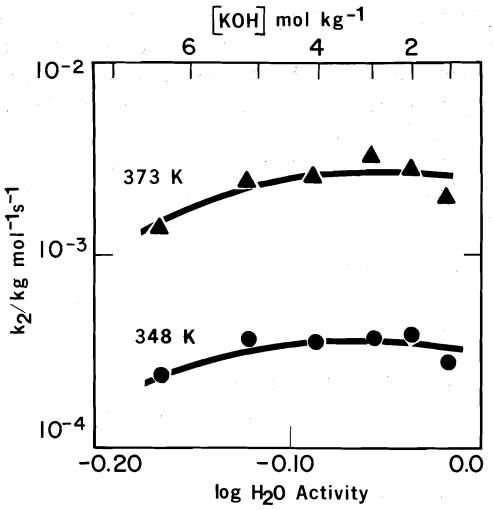

FIG. 7. Second-order rate constants for D_2–H_2O exchange catalyzed by KOH.

Rate Constants for D_2 Exchange

Wilmarth and co-workers (2) and Lin (22) have demonstrated the rate law for deuterium exchange with dilute aqueous KOH (less than 1 kmol/m^3) to be:

$$[10] \quad -\mathrm{d}[D_2]/\mathrm{d}t = k_2[D_2][KOH]$$

We have assumed that the deuterium transfer mechanism was the same as in dilute solution, that is the reaction order in D_2 and base remained unity in concentrated alkali. A corresponding equation was considered to hold for $KOCH_3$ in methanol. Accordingly, we have calculated second-order rate constants (identified by the subscript 2) for both systems in this way:

$$[11] \quad k_2 = \mathrm{Rate}/(a_2 a_3) = \mathrm{Rate}/(\gamma_2{}^*\gamma_3{}^*[D_2][K\beta])$$

where K refers to the potassium cation, and β to the anion OH^- or $OCH_3{}^-$ of the corresponding solvent.

The results are presented in Fig. 7 for D_2–KOH–H_2O and in Fig. 8 for D_2–$KOCH_3$–CH_3OH. All numerical values have also been summarized in Tables 1 and 2.[2] In each figure the logarithm of the rate constant k_2 is plotted against the logarithm of the solvent activity. The

[2]Copies are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

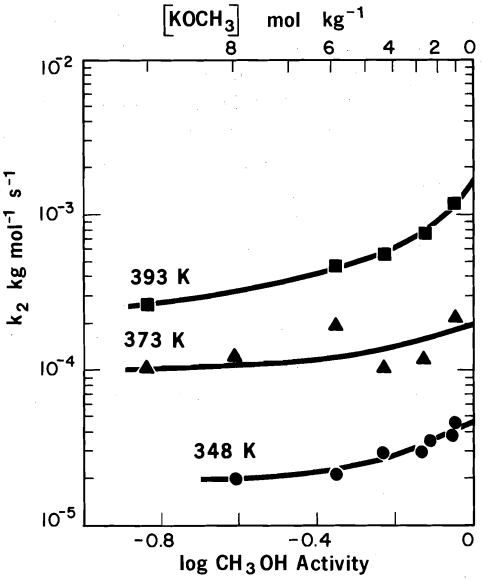

FIG. 8. Second-order rate constants for D_2–CH_3OH exchange catalyzed by $KOCH_3$.

corresponding base concentration is indicated on the upper abscissa in each figure.

In the aqueous system, k_2 appears to exhibit a slight maximum at about 3 mol/kg of KOH at both 348 and 373 K, although additional data below 2 mol/kg would be required to confirm that trend. The cumulative error associated with the evaluation of k_2 was approximately 10%; therefore assignment of significance to that trend requires caution. The reaction mechanism which we propose in the Discussion considers k_2 to be essentially independent of KOH concentration below about 5 mol/kg. At that point, the molar ratio of solvent:solute is 6.25, which is somewhat less than the sum of solvation numbers of 3 for hydroxide plus 4 for K^+ (23, 24).

In Fig. 8, k_2 initially decreases with decreasing methanol activity, that is, with increasing $KOCH_3$ concentration at each temperature. Above about 6 mol/kg $KOCH_3$, k_2 is only slightly dependent upon solvent activity. This unexpected result suggested that the solvent plays an important part in determining the overall rate of the D_2 exchange reaction and also that there was no increase in the intrinsic reactivity of $KOCH_3$ upon reduction of solvent molecules available for stabilization of $KOCH_3$. In the following section we present a mechanism which explains the dependence of k_2 on methanol activity in the D_2–$KOCH_3$–CH_3OH system and the independence of k_2 from water activity in the D_2–KOH–H_2O case.

Activation Energy

An apparent activation energy at infinite dilution of the base may be calculated from the limiting values

$$\lim_{a_3 \to 0} k_2$$

taken from Figs. 7 and 8. Our results for the D_2–KOH–H_2O system do not extend to sufficiently low concentrations of base to permit satisfactory extrapolation. That uncertainty, plus the limited data and cumulative error in evaluation of the two k_2 values at 75 and 100°C as described above, suggests that the activation energy for the D_2–KOH–H_2O case falls within the range 88 $\pm$ 20 kJ/mol. The studies of Wilmarth and coworkers (2) of the temperature dependence of para-hydrogen conversion or of Schindewolf (4) of HD exchange yielded comparable activation energies of about 100 kJ/mol.

The values of k_2 taken from Fig. 8 for the D_2–$KOCH_3$–CH_3OH system are more reliable, and an activation energy of 81 $\pm$ 5 kJ/mol was obtained.

Discussion

Review of Base-catalyzed Activation of D_2

This discussion of the mechanism of base-catalyzed D_2 exchange is essentially a consideration of the nature of an unidentified unstable intermediate. A brief review of this topic is necessary.

In the early work of Wilmarth and his colleagues (2), attack of OH^- on D_2 to yield an intermediate deuteride anion was thought to be the most probable rate-determining process (reaction 12):

[12] $$D_2 + OH^- \rightarrow D^- + HDO$$

which was followed by the rapid abstraction of a proton from water and regeneration of the base:

[13] $$D^- + H_2O \rightarrow HD + OH^-$$

It was also recognized that the exchange rate data could not be employed to distinguish between this reaction sequence and the concerted proton transfer process (reaction 14):

[14] $$D_2 + OH^- \rightarrow HD + OD^-$$

whereby D^+ transfer occurred smoothly via a multicentered intermediate. One argument against the former scheme rests on the inability of these aqueous KOH solutions containing H_2 to catalyze reductions of unsaturated organics or hydride-transfer reactions (4).[3] However, the former mechanism, which requires rate-controlling cleavage of the D—D bond, can account for the relatively high activation energy of the exchange reaction of about 100 kJ/mol. Note also that [13] specifically requires discharge of the D^- anion by water.

The calculations of Ritchie and King (12) on the gas phase reaction:

[15] $$H^- + H_2O \rightarrow HOHH^-$$

which showed the $HOHH^-$ species to be slightly stabilized with respect to the reactants, caused Ritchie to speculate that the rate-determining step in the D_2 exchange sequence was the loss of one molecule of solvation from the primary solvation shell of the OH^- anion prior to rapid attack of D_2. In that scheme, the high energy of activation was attributed to the enthalpy of solvation of OH^- by 1 mol of water. The structure of the intermediate encounter complex in that mechanism was considered to be similar to that of the product in [15].

Catalytically Active Species in Concentrated Solution

In eqs. 16 and 17 which follow, the anionic species OH^- and CH_3O^- have been considered to be catalytically active. Ion-pair formation is probably an important process in each base system. However, the limited data available in the literature do not allow us to treat that topic quantitatively. Under our experimental conditions, KOH was likely highly dissociated in water (26, 27) and the dominant catalyst species was $OH^-(H_2O)_3$ (23). Evidence from other proton-transfer reactions at carbon centers has suggested that the ion pair K^+OH^- does not promote rapid deuterium exchange (26).

Information on $KOCH_3$ in methanol (27) also favours ion-pair formation, although Barthel, Wachter, and Knerr (28) reported an association constant of zero based on conductometric studies on dilute $KOCH_3$ at 298 K. Jones has concluded from a review of the kinetic studies of proton transfer that ion-pairing of alkoxides is significant in concentrated solution (26). Our own unpublished data on D_2–methanol exchange have shown that $NaOCH_3$ and $KOCH_3$ possess identical reactivities which are about an order of magnitude greater than that of $LiOCH_3$ at a given base concentration and temperature. That suggests that ion-pairing of $KOCH_3$ is incomplete. The anion CH_3O^- is probably the species which activates D_2, firstly, because of its close relationship to OH^- and, secondly, because k_2 falls off at high $KOCH_3$ concentration where ion-pairing is greater (cf. Fig. 8). If $KOCH_3$ were a superior catalyst to CH_3O^-, k_2 would be expected to increase in that region.

Exchange Reaction Mechanism

In the mechanism which we present below, two points are noteworthy, (*i*) the exact structure of the intermediate need not be specified, but (*ii*) the stage at which solvent participation is essential must be identified to account particularly for the form of the D_2–$KOCH_3$–CH_3OH data presented in Fig. 8. The simple reaction sequence which we favour is as follows:

[16] $$D_2 + \beta^- \underset{k_{-16}}{\overset{k_{16}}{\rightleftharpoons}} D_2\beta^-$$

[17] $$D_2\beta^- + n\mathrm{S} \xrightarrow{k_{17}} \mathrm{HD} + \beta^- + (n-1)\mathrm{S} + \mathrm{S}\text{-}d_1$$

We consider that the initial equilibrium of D_2 with the solvated base β^- occurs with no net change in solvation and that is followed by decay of the intermediate $D_2\beta^-$ to yield products by reaction with n mol of solvent. The symbols β^- and S refer to the solvated base anion and solvent respectively, and S-d_1 denotes monodeuterated solvent.

If we consider the species $D_2\beta^-$ to be present in a low, steady-state concentration, the rate of exchange of D_2 may be written as:

[18] $$-\mathrm{d}[D_2]/\mathrm{d}t = \left(\frac{k_{16}k_{17}a_1{}^n}{k_{-16} + k_{17}a_1{}^n}\right)\gamma_2{}^*\gamma_3{}^*[D_2]\,[\beta^-]$$

where the subscripts 2 and 3 refer to D_2 and β^- as previously defined. For the case in which the terms in the denominator $k_{-16} + k_{17}a_1{}^n$ are of similar magnitude, this expression can be used to explain the decrease in k_2 of eq. 11 with decrease in solvent activity in the D_2–$KOCH_3$–

[3]The hydride-transfer mechanism is a plausible one for the D_2–$KOCH_3$–CH_3OH system (25).

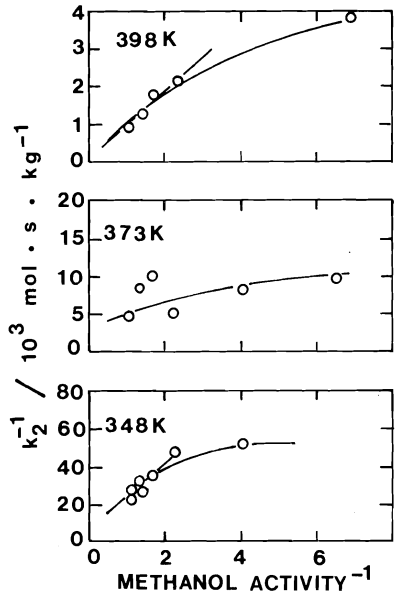

FIG. 9. Variation of k_2^{-1} with a_1^{-1} for D_2–$KOCH_3$–CH_3OH system.

CH_3OH system (cf. Fig. 8).[4] Equation 18 can also account for the independence of k_2 from water activity in the D_2–KOH–H_2O case (cf. Fig. 7) if $k_{17}a_1^n \gg k_{-16}$ since k_{16} alone would account for the observed D_2 exchange rate.

We may test the validity of this mechanism by transforming eq. 18 to give:

$$[19] \quad \frac{a_2a_3}{\text{Rate}} = \frac{1}{k_2} = \left(\frac{k_{-16}}{k_{16}k_{17}}\right)\frac{1}{a_1^n} + \frac{1}{k_{16}}$$

For the D_2–methanol exchange, k_2^{-1} and a_1^{-n} can be linearly correlated reasonably well up to 7 mol/kg $KOCH_3$ for $n = 1$ as shown in Fig. 9 at 348, 373, and 398 K. Above that concentration the solvent:solute molar ratio is less than 4.5 and our mechanism appears to become unsatisfactory with respect to the constraint that $n = 1$. Note that our results plotted in Fig. 8 as log k_2 against log a_1 also suggest that n (=d log k_2/d log a_1) decreases from 1 at $a_1 = 1$ to apparent fractional values at high $KOCH_3$ concentrations. That behaviour was expected as the amount of 'free' solvent became negligible.

The two-step mechanism which we have presented (eqs. 16 and 17) accounts for the fall-off in k_2 with decrease of the solvent activity. Alternative models such as that in which D_2 activation by β^- is rate-controlling, or that described by Ritchie (12, 29) in which loss of one molecule of solvent from β^- precedes attack upon D_2, cannot explain the form of our D_2–$KOCH_3$–CH_3OH data of Fig. 8. Those two mechanisms cannot, however, be rejected for the D_2–KOH–H_2O case because the slight dependence of k_2 on water activity up to 5 mol/kg KOH does not allow identification of the best option. Experiments at higher KOH concentrations may show the hydroxide and methoxide behaviour to be similar.

To review, we conclude that in both strongly basic media, the activation of D_2 by β^- is generally the rate-determining process but in concentrated solutions reaction of an unstable complex involving transfer of D^+ to the solvent may be of comparable magnitude.

Kinetic Isotope Effects

Three topics will be considered: (*i*) the magnitude of the kie's, and the effect of (*ii*) base concentration, and (*iii*) temperature on the experimental values (cf. Figs. 5 and 6). Two points must be clarified: firstly, because we quote the kie as a ratio of two pseudo-first-order rate constants, each of which is affected equally by reagent activities to a first approximation, then that ratio should be independent of those variables; secondly, we consider that dual exchange of D_2 to yield H_2 without transfer of the intermediate product HD to the gas phase is improbable for the reasons cited in the following text. The effect of such an event would be to yield an abnormally high kie compared to that calculated assuming the sequential first-order conversion $D_2 \rightarrow HD \rightarrow H_2$.

The kie's for both systems were always above 1 and are normal in that HD, with the higher zero-point energy, reacted more rapidly than D_2. This is consistent with our assignment of the rate-controlling process in the D_2–KOH–H_2O system to be D_2 bond cleavage (reaction 16 forward) and in the D_2–$KOCH_3$–CH_3OH case to be that plus solvation of the encounter-complex intermediate (reaction 17).

The effect of base concentration and temperature on the kie requires a more tentative interpretation. Recall that in the aqueous system, rate constant k_2 was independent of, but the kie increased with, KOH activity (i.e., reduction of solvent activity). Alteration of the relative

[4]Note that k_2 is equal to the bracketed rate constant in eq. 18.

solvation of ground and encounter-complex species during the overall proton-transfer process must therefore favour HD over D_2 exchange. We suggest that an increase in the entropy of activation of DH compared to D_2 occurs with KOH concentration. Furthermore, to account for the increase in kie with temperature at a given KOH molality it is necessary that the activation energy for HD must exceed that for D_2, which is contrary to the usual sequence (30). Since the difference in the zero point energies between HD and D_2 is approximately given by the difference between their fundamental stretching modes of 3632 and 2993 cm^{-1}, respectively (31), it is necessary that the ground-state difference of 639 cm^{-1} be exceeded by 450 $\pm$ 110 cm^{-1} for the corresponding encounter complexes to account for our observed dependence of kie on temperature. An explanation of the constraints thus placed on the activation entropy and enthalpy may lie in the marked reduction of 'free' solvent with increased electrolyte concentration.

Our data do not justify more detailed speculation upon the chemical bonding interactions which control the observed kie's. However, in principle it may be argued that reorientation of the H-bonded solvent structure surrounding an intermediate of the type proposed by Ritchie and King (12) could result in appropriate changes in the relative energetics of the different isotopically substituted species.

The comments above have been restricted to the D_2–KOH–H_2O system but are also applicable to the D_2–$KOCH_3$–CH_3OH case. In the latter, however, the interpretation of kie results must include the fact that the experimental constant k_2 is a function of k_{16}, k_{17}, and methanol activity. If the kie for k_{17} is less than that for k_{16}, the above discussion is directly applicable.

Reactivity of KOH and $KOCH_3$ and Basicity Scales

The acidity function approach has been applied to the investigation of the participation of the solvent in proton-transfer reactions by several workers. Rochester (15*b*) and Boyd (32) have each reviewed this subject. It is the purpose of this section to consider the manner in which D_2 exchange rates for each system vary with the corresponding basicity scales.

First-order rate constants for D_2–H_2O exchange, $k_1 = -(1/[D_2])(d[D_2]/dt)$ plotted against H_- values for aqueous KOH at 298 K (15) are shown in Fig. 10. Since temperature will mainly affect the K_w term in this definition of H_- (15*c*),

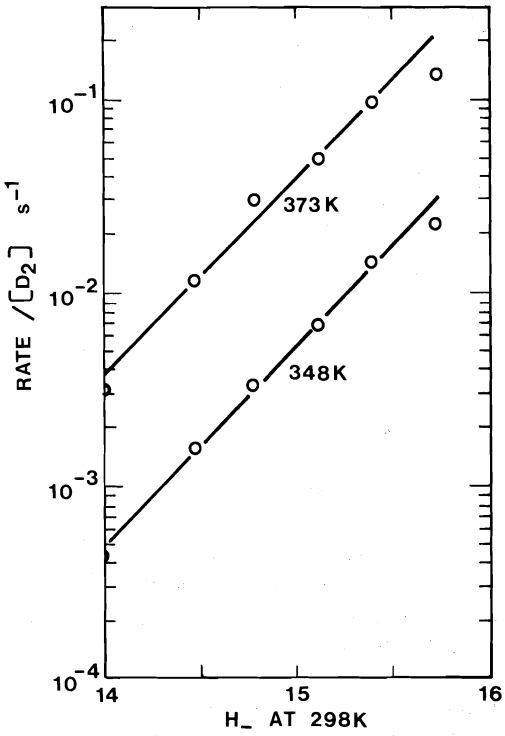

FIG. 10. Dependence of the first-order rate constant for D_2–H_2O exchange on H_-.

[20] $$H_- = pK_w + \log [OH^-] - \log a_w + \log (\gamma_{SH}{}^*\gamma_{OH^-}/\gamma_S)$$

where the subscript w refers to water, SH to the indicator acid, and S to its anion. It is reasonable to correlate our rate data at 348 and 373 K with H_- (298 K).

The slopes of the two straight lines for the D_2–KOH–H_2O system were 0.97 and 0.98 at 348 and 373 K, respectively. This direct dependence of k_1 on H_- supports our conclusion that activation of D_2 is the rate-controlling process in aqueous solution (15*b*). Our attempts to evaluate the difference between solvation of species in the ground and transition states by the methods of Yagil and Anbar and co-workers (23, 33), Rochester (34), and others (15) (i.e., from plots of our log k_2 data against logarithm of water

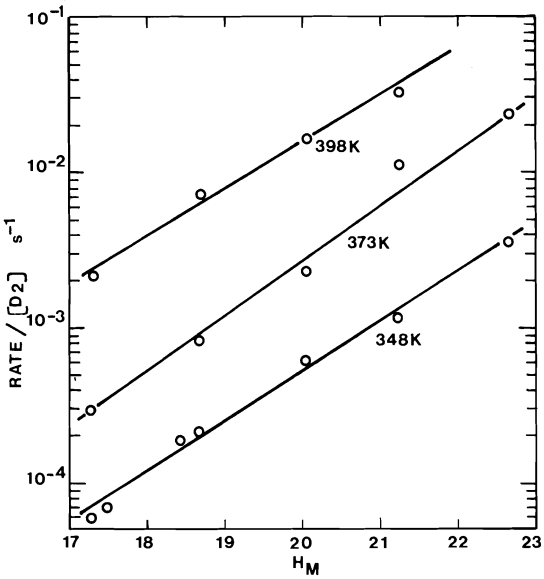

FIG. 11. Dependence of the first-order rate constant for D_2–CH_3OH exchange on H_M.

concentration or activity) yielded spuriously high results. We attributed that to the invalidity of the usual approximation, that the activity coefficient ratio term (in our case $\gamma_2^*\gamma_3^*/\gamma_{DDOH^-}$) was unity, mainly because of the extensive salting-out of D_2 (17).

The slopes of the three straight lines given in Fig. 11 for the D_2–$KOCH_3$–CH_3OH case were as follows: 348 K, 0.32; 373 K, 0.35; 398 K, 0.30. These values are smaller than those found for other correlations between rate constants for proton-transfer reactions at carbon acids and H_M (15). Perhaps our slopes are low because our D_2 exchange mechanism has shown the first-order rate constant employed here to be complex:

$$[21] \quad \text{Rate}/[D_2] = \frac{k_{14}k_{15}a_1\gamma_2^*\gamma_3^*[K\beta]}{k_{-14} + k_{15}a_1}$$

All parameters in [21] are functions of H_M except for $[\beta^-]$, therefore unequivocal identification of the origin of the slight dependence of Rate/$[D_2]$ on H_M cannot be made. The basicity scale approach is therefore of limited utility for detailed analysis of the deuterium exchange mechanism in this system.

The crystal structure of bis(ethyldiazoacetate) mercury(II) $Hg(CN_2CO_2C_2H_5)_2$

R. A. SMITH, M. TORRES, AND O. P. STRAUSZ

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 19, 1977

R. A. SMITH, M. TORRES, and O. P. STRAUSZ. Can. J. Chem. **55**, 3527 (1977).

Bis(ethyldiazoacetate) mercury(II) is orthorhombic with the following unit cell data at 20°C: *Fdd*2, $a = 19.810(8)$, $b = 14.387(5)$, $c = 9.015(2)$ Å, $V = 2569.3$ Å^3, $\rho_o = 2.17(2)$, $\rho_c = 2.21$, $Z = 8$ (MoK_{α_1}, $\lambda = 0.70930$ Å). The structure was solved by heavy atom methods and refined to $R = 2.2\%$ for 706 reflections. The molecule has a 2-fold axis of symmetry and all thermal parameters are large in the direction of this axis; diffuse scattering was observed in the rotation photograph taken about this axis. As expected the diazoacetate portion is planar.

R. A. SMITH, M. TORRES et O. P. STRAUSZ. Can. J. Chem. **55**, 3527 (1977).

Le bis-éthyldiazoacétate de mercure(II) cristallise dans le système orthorhombique avec des valeurs de maille suivantes à 20°C: *Fdd*2, $a = 19.810(8)$, $b = 14.387(5)$, $c = 9.015(2)$ Å, $V = 2569.3$ Å^3, $\rho_o = 2.17(2)$, $\rho_c = 2.21$, $Z = 8$ (MoK_{α_1}, $\lambda = 0.70930$ Å). La structure est résolue par la méthode des atomes lourds et affinée à $R = 2.2\%$ pour 706 réflections. La molécule possède un axe de symétrie d'ordre 2 et tous les paramètres thermiques sont élevés en direction de cet axe; une diffraction est observée sur un cliché lorsqu'on fait une rotation autour de cet axe. Conformément aux prévisions, la partie diazoacétate est planaire.

Introduction

Bis(ethyldiazoacetate) mercury(II), $Hg(CN_2CO_2C_2H_5)_2$, (I), was synthesized by Buchner in the past century (1). Together with its analog bis(methyldiazoacetate) mercury(II) it remained the only known representative of a metal α-diazo structure until the last decade. Since then a large number of molecules with the same generic structure has been synthesized (2). The crystal structure of these molecules, with the exception of *tert*-butyl ethyldiazoacetate mercury(II) (3), has not been determined and for this reason we have currently undertaken a systematic X-ray diffraction study to elucidate the crystal structure and molecular geometry of the known diazomercurial compounds.

Some of these diazomercurials, in particular (I), have been employed as a photolytic source of carbynes (4) in the liquid phase and a knowledge of the molecular geometry may be helpful in the elucidation of the primary photochemical step.

Experimental

$C_8H_{10}HgN_4O_4$ fw = 426.70

*Fdd*2, $a = 19.810(8)$, $b = 14.387(5)$, $c = 9.015(2)$ Å, $V = 2569.3$ Å^3, $\rho_o = 2.17(2)$, $\rho_c = 2.21$, $Z = 8$ (MoK_{α_1}, $\lambda = 0.70930$ Å; 20°C).

The crystals were yellow prisms with all faces of the form {1,1,1}. Rotation photographs were taken about each axis and that about c showed very weak diffuse scattering corresponding to $hk\frac{1}{2}$ only. Mercury exhibits large anomalous dispersion with MoK_α radiation and unless these effects are correctly allowed for, large errors in bond distances are possible in polar space groups (5). Therefore, intensities of both hkl and $hk\bar{l}$ were collected and used in refinement. A very regular crystal with all faces 0.0067 cm from the center was selected, mounted about a, and placed on a Picker FACS-1 diffractometer. Twelve highangle reflections were carefully centered and accurate cell constants were derived. (MoK_{α_1} radiation, no monochromator.)

Data sets hkl and $hk\bar{l}$ with $0 \leq 2\theta \leq 45°$ were collected (MoK_α radiation, graphite (002) monochromator) by the coupled $\theta/2\theta$ scan method. A scan width of 2° was employed, the scan rate was 2° min^{-1} and background counts were accumulated for 20 s either side of the scan. Decomposition was monitored by measurement of standards every 100 reflections. A total of 844 reflections were measured and corrected for Lorentz-polarisation, decomposition, and absorption (μ, $MoK_\alpha = 122$ cm^{-1}) (6). The data were reduced to $|F|$, $\sigma(F)$, and $\sigma(I)$ using a p value of 0.06 (7). Using an acceptance criterion $I \geq 3\sigma(I)$ 706 reflections had significant intensity and of these only 40 had no net contribution from the Hg atom.

The Hg is required to occupy a position 0,0,z and in view of the polar nature of the space group it was assigned coordinates 0,0,0. The mercury was allowed anisotropic thermal parameters and anomalous dispersion corrections were applied to a refinement of this atom to the 666 reflections of the data sets $h, k, l, = 2n + 1$ and $h + k + l = 4n$ only. This model refined to $R = 8.0\%$ and a difference Fourier map was then calculated. The procedure outlined above led to false site symmetry, 222, that expected for the centrosymmetric case. The inclusion of anomalous dispersion had greatly favoured one

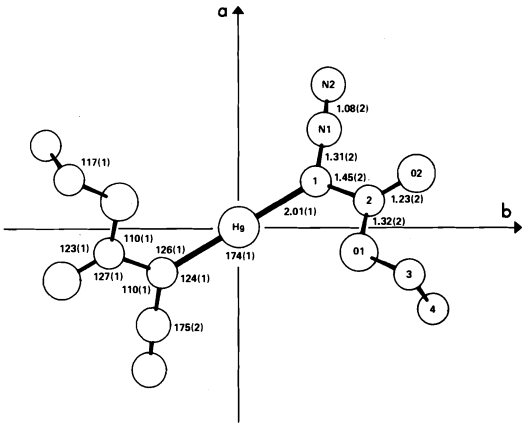

FIG. 1. A schematic representation of $Hg(CN_2CO_2C_2H_5)_2$ showing the atom numbering scheme and important bond angles, distances, and associated standard deviations.

logical set of 8 atoms and with anisotropic vibration allowed for all atoms R was reduced to 2.3% for all 706 reflections of the general data set. Structure factors were taken from Cromer and Mann (8). A weight of $4F^2/\sigma^2(F^2)$ was applied to every reflection. The model with $z = -z$ would not refine below 7% and the thermal parameters of several atoms reached absurd proportions at R of 7.4%. The first model can thus be taken as the correct one (9). The secondary extinction parameter was refined after examination of the data indicated such a problem (10), the refined value was $4.1(6) \times 10^{-7}$ and the final R value was 2.2%. The R value for all 844 measured reflections was 3.2%. A final difference Fourier map contained peaks of the order 1.25 e Å^{-3} and consequently no attempt was made to determine the H atom coordinates.

Results and Discussion

The atomic numbering scheme and important bond angles and distances are given in the schematic representation in Fig. 1. Final atom parameters are given in Table 1 and the Table of Structure Factors has been placed in the Depository of Unpublished Data.[1]

The thermal parameter U_{33} is large for all atoms and is expected in a polar space group in view of the weak diffuse scattering from a doubled polar axis. A slight disorder in the z coordinate of the mercury atom is possible, the fixing of the z value at 0 for all Hg atoms would give a ghost molecule slightly displaced in z from the chosen molecule and lead to large U_{33} values for all atoms during refinement compensating for the unexplained electron density. All 7 atoms of the $HgCN_2CO_2$ portion of the molecule lie within 0.03 Å of the mean plane, and the shape and dimensions of the diazo moiety are similar to those found in (II). The standard deviations in (II) were large because of problems associated with severe decomposition; however the Hg—C distance in this case, 2.01(1) Å, is significantly shorter than that observed in (II), 2.12(2) Å. The strength of the Hg—C bond to the carbon atom of the diazoacetate moiety and that of the C—N bond in compounds of the form R—Hg—$CN_2CO_2C_2H_5$ are of great interest, in view of the changes in photolysis products as a function of R and the proven formation of carbethoxymethyne during these reactions (4).

A detailed discussion of the structural implications of various bond strengths in these systems would require further data on diazomercurials and on the compound ethyldiazoacetate, the latter requiring a low temperature

[1]The Structure Factor Table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

study. Other members of the diazomercurial series are currently under investigation.

Thermochemical measurement of the ligand field splitting energies for hexaammine complexes of Mn(II), Fe(II), and Zn(II)[1]

M. BADRI AND J. W. S. JAMIESON[2]

Department of Chemistry, Universiti Pertanian Malaysia, Serdang, Selangor, Malaysia

Received September 8, 1976

M. BADRI and J. W. S. JAMIESON. Can. J. Chem. **55**, 3530 (1977).

Various lower ammines and high-energy modifications of lower ammines of the sulphates of Mn(II), Fe(II), and Zn(II) have been prepared and their heats of solution have been measured. For each of these ammine systems, the maximum difference in heat of solution, expressed in kcal/mol of heptaammine, has been found to be of the right order of magnitude to be regarded as the ligand field splitting energy for the hexaammine complex of the metal ion.

M. BADRI et J. W. S. JAMIESON. Can. J. Chem. **55**, 3530 (1977).

On a préparé et mesuré les chaleurs de solutions de diverses ammines de bas poids moléculaires et de diverses modifications riches en énergie d'ammines de bas poids moléculaires de sulphates de Mn(II), Fe(II) et Zn(II). Pour chacun de ces systèmes ammines, on a trouvé que la différence maximum dans la chaleur de solution exprimée en kcal/mol d'heptaammine est du bon ordre de grandeur pour l'énergie de dissociation du champ de ligand pour le complexe hexaammine de l'ion métallique.

[Traduit par le journal]

Introduction

The maximum differences in heat of solution between the normal crystalline lower hydrates and the high-energy modifications of the lower hydrates of manganese(II) sulphate, iron(II) sulphate, cobalt(II) sulphate, and nickel(II) sulphate, when expressed in kcal/mol of each heptahydrate, have been observed (1) to be equivalent to the ligand field splitting energies of the corresponding hexaaquo metal(II) ions. Further experimental verification of the validity of this thermochemical method for the measurement of ligand field splitting energies, which had previously been obtainable only from rather complex interpretation of observed spectra, has recently been provided (2) by the results of studies with the ammine complexes of cobalt(II) sulphate and nickel(II) sulphate. Thus it has been shown that the maximum differences in heat of solution between the normal crystalline lower ammines and the high-energy modifications of the lower ammines of these salts, when expressed as kcal/mol of each heptaamine, are equivalent to the ligand field splitting energies of the hexaamine metal(II) ions.

Experimental

The anhydrous manganese(II) sulphate, iron(II) sulphate, and zinc(II) sulphate were prepared by heating their respective hydrates at suitable temperatures which were experimentally determined using thermogravimetric analysis (TGA) and differential thermal analysis (DTA). Thus $MnSO_4 \cdot H_2O$ (Merck and Co. Ltd.) and $ZnSO_4 \cdot 7H_2O$ (J. T. Baker 'analyzed' reagent) were heated gradually to 265°C in an oven and kept at that temperature for a period of two days. Anhydrous $FeSO_4$, from the Fisher Scientific Company, was found to contain some water which was removed by heating the salt *in vacuo* at 170°C.

The anhydrous salts were finely powdered and samples of about 3 g were taken for reaction with anhydrous ammonia (supplied by Matheson of Canada, Ltd.) in the manner previously described for the preparation of the ammine complexes of nickel(II) sulphate and cobalt(II) sulphate (2–7). Since the hexaammines are unstable at room temperature, each sample prepared was analyzed for ammonia content. These samples were stored in an atmosphere of ammonia in sealed tubes.

The lower ammines were prepared by heating the hexaammines of the metal(II) sulphates in an oven or *in vacuo* at various temperatures. They were kept in sealed glass tubes to ensure that no reactions with water vapour from the air would take place. Such reactions may produce mixed ligand complexes and these would have different heats of solution depending on the amount of water absorbed.

Integral heats of solution were measured as previously described (1). To ensure complete solubility, the ammines of zinc(II) sulphate were dissolved in 0.75 *M* NH_4OH solution and the ammines of manganese(II) sulphate and iron(II) sulphate were dissolved in 1 *M* HCl solution.

[1]The experimental work was done while the authors were at Dalhousie University, Halifax, N.S., Canada.

[2]Present address: Kars, Ont., Canada.

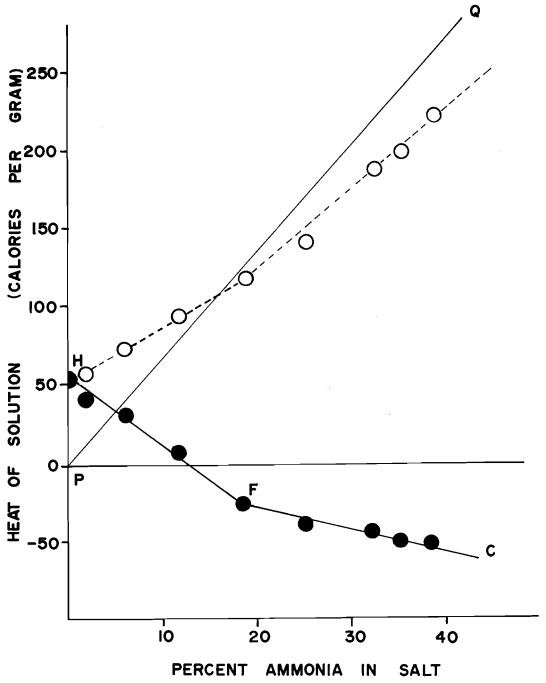

FIG. 1. Heats of solution for various ammines of $MnSO_4$ in 1 *M* aqueous HCl. ○, uncorrected; ●, corrected.

Results

For the ammine complexes of manganese(II) sulphate and iron(II) sulphate the heats of solution were found to increase with increasing ammonia content. Such results for some of the ammine complexes of manganese(II) sulphate are shown by the open circles in Fig. 1. This increase seems to disagree with the previous observations of the heats of solution for the ammine complexes of cobalt(II) sulphate and nickel(II) sulphate as well as the aquo complexes. In the case of the latter, the heat of solution decreases as the percent ligand increases. Thus it appears that all the ammonia in the ammine complexes of manganese(II) sulphate and iron(II) sulphate has been neutralized by hydrochloric acid. The heat of neutralization has been represented in Fig. 1 by the straight line *PQ* passing through the origin having a slope of 7.10 cal/1% ammonia. The lines *HF* and *FC* in Fig. 1 denote the differences between the heats of solution measured and the heats of neutralization of the ammonia, thus giving normal linear relations as have been observed for other systems. Values corrected in this way (Tables 1 and 2) have been plotted in Fig. 2 for the ammine complexes of manganese(II) sulphate and in Fig. 3 for the ammine complexes of iron(II) sulphate.

Manganese(II) Sulphate

Using the method of least squares, the heat of solution data of Fig. 2 for the ammine complexes of manganese(II) sulphate can be expressed as

$$y_{BC} = -1.32x - 2.36$$

$$y_{FH} = -4.17x + 52.4$$

and

$$y_{IK} = -4.15x + 90.6$$

Extrapolation of the line *BC* gives the heat of solution of $[Mn(NH_3)_6]^{2+}SO_4^{2-}\cdot NH_3$ (with 44.11% ammonia) as −60.5 cal/g and that of $MnSO_4\cdot NH_3$ (with 10.13% ammonia) as −15.7 cal/g. The line *CE* has been drawn through the

point *C* for $MnSO_4 \cdot 7NH_3$, the species which would probably contain the hexaammine-manganese(II) ion, with a slope equal to that of the line *IK*. Thus it is possible to estimate the heat of solution for the high-energy modification of $MnSO_4 \cdot NH_3$ at the point *D* as 80.5 cal/g. The maximum energy of transition *DB* is therefore 96.2 cal/g of monoammine, or 26.0 kcal/mol of heptaamine, which is equivalent to 9.10×10^3 cm^{-1}.

Iron(II) Sulphate

To prevent oxidation of iron(II) the normal lower ammines of iron(II) sulphate were prepared by heating higher ammines in a nitrogen atmosphere.

Using the method of least squares, the heat of solution data of Fig. 3 for various ammine complexes of iron(II) sulphate can be expressed by the linear relations

$$y_{BC} = -1.22x - 24.0$$

$$y_{FH} = -4.57x + 38.1$$

TABLE 3. Heats of solution for various ammines of zinc(II) sulphate

% Ammonia in sample	Heat of solution (cal/g)	Method of preparation

25.21	17.4	Vacuum at 22°C

and

$$y_{IK} = -4.59x + 82.5$$

Extrapolation of the line *BC* gives the heat of solution of $[Fe(NH_3)_6]^{2+}SO_4^{2-}\cdot NH_3$ (with 43.96% ammonia) as −77.4 cal/g and that of $FeSO_4\cdot NH_3$ (with 10.08% ammonia) as −36.2 cal/g. The line *CE* has been drawn through the point *C* for $FeSO_4\cdot 7NH_3$, the species which would probably contain the hexaammineiron(II) ion, with a slope equal to that of the line *IK*. Thus the heat of solution of the high-energy modification of the monoammine at point *D* is estimated as 78.3 cal/g, and the maximum energy of transition *DB* is therefore 114.5 cal/g of monoammine, or 31.0 kcal/mol of hepta-ammine, which is equivalent to 1.09×10^4 cm^{-1}.

Zinc(II) Sulphate

The heat of solution data for the ammine complexes of zinc(II) sulphate (Table 3, Fig. 4) have been similarly treated. The relations are:

$$y_{AB} = -7.32x + 127$$

$$y_{BC} = -3.74x + 88.2$$

and

$$y_{FH} = -7.32x + 201$$

The heat of solution for $Zn(NH_3)_6SO_4\cdot NH_3$ (with 42.76% ammonia) was estimated as

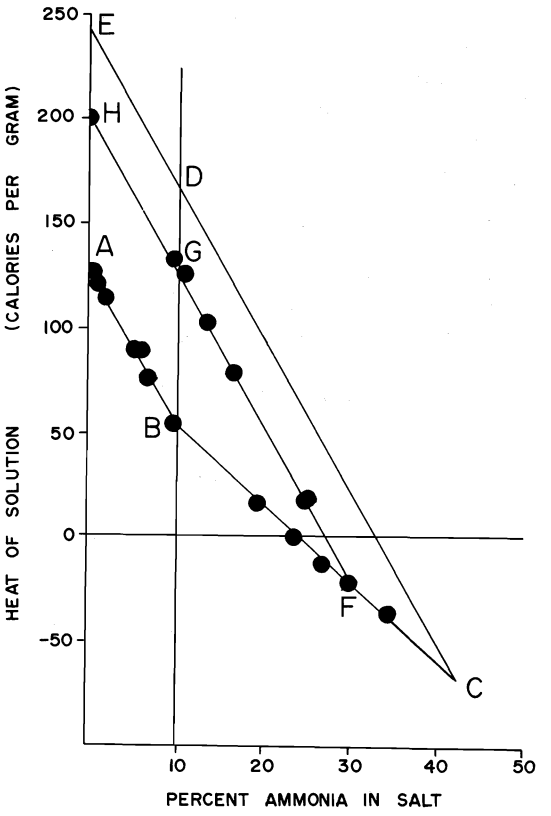

FIG. 4. Heats of solution for various ammines of $ZnSO_4$.

−71.6 cal/g and that for $ZnSO_4\cdot NH_3$ as 52.5 cal/g. Using the slope of the line *FH*, the line *CE* has been drawn having the equation

$$y_{CE} = -7.32x + 240$$

which gave the heat of solution for the mono-ammine at *D* as 170 cal/g. The maximum heat of transition is 117.5 cal/g or 32.9 kcal/mol of heptaammine which is equivalent to 11.5×10^3 cm^{-1}.

Discussion

Unfortunately no spectroscopic values have been given for the ligand field splitting energies of the hexaammines of manganese(II), iron(II), and zinc(II). Therefore the values now obtained for these complexes cannot be compared with the spectroscopic values as has been done for the hydrates and the hexaammines of cobalt(II) and nickel(II) (1, 2).

In aqueous ammonia the ammines of manganese(II) and iron(II) are hydrolyzed to their

hydroxides which precipitate as black solids. These salts dissolve readily in 1 *M* aqueous hydrochloric acid. This could be due to marked lability of ammonia ligands which allow reactions such as

[1] $[M(NH_3)_6]^{2+} + 6L \rightarrow [ML_6]^{2+} + 6NH_3$

where L could be either H_2O or Cl^- in solution. The ammonia released could then undergo hydrolysis to produce the hydroxide ions which in turn could react with the complex $[ML_6]^{2+}$ to form the black hydroxide observed.

In the presence of excess hydrogen ions, the net reaction can be written as

[2] $[M(NH_3)_6]^{2+} + 6H^+ + 6L \rightarrow [ML_6]^{2+} + 6NH_4^+$

From the heat of solution data, *e.g.*, Fig. 1 for the ammines of manganese(II) sulphate, it is apparent that all the ammonia ligands in the heat of solution samples have been replaced by water molecules or chloride ions, and therefore it is necessary to subtract the heat of neutralization of ammonia from the heat of solution of every sample except the anhydrous salt. The quantity to be subtracted, 7.10 cal/1% ammonia content, is obtained from thermochemical data (8) for the equation

$$NH_{3(aq)} + HCl_{(aq)} \rightarrow NH_4Cl_{(aq)}$$

[3] $$\Delta H^0 = 12.09 \text{ kcal/mol}$$

It is probably due to this that no attempt has been made to measure ligand field splitting energies spectroscopically for the hexaammines of maganese(II) and iron(II), since the hexaammines (or any lower ammine) do not exist in aqueous solution. It is, of course, impossible to measure the ligand field splitting energies for zinc(II) complexes spectroscopically since all the 3*d*-orbitals are filled so that no absorption spectra due to the *d–d* transitions could be observed.

However, the values obtained both by the present calorimetric technique and the spectroscopic method for other complexes of the metal ions may be used for the purpose of comparison. From the spectrochemical series it is known that the ligand field splitting energies due to H_2O, NH_3, and ethylenediamine (en) are in the order

$$H_2O < NH_3 < en$$

The values (9–15) for those ligands and various cations under consideration are reproduced in Table 4 and Fig. 5 together with the values found for the hexaammines of mangenese(II), iron(II), and zinc(II). It seems that they all are of the same order of magnitude; thus giving confidence in the present method. For the reason discussed above, it is unfortunate that no ligand field splitting energy for the tris(ethylenediamine) zinc(II) has yet been given. However, the ligand field splitting energy obtained for hexaaquozinc(II) (10) appears to suggest that the present assignment of $10Dq$ for hexaamminezinc(II) is correct.

DENNIS D. TANNER, TAMEICHI OCHIAI, JEFF ROWE, TONY PAĊE, HIDEKI TAKIGUCHI, and PETER W. SAMAL. Can. J. Chem. **55**, 3536 (1977).

A general method for the evaluation of the kinetics of the solution phase bromination of alkanes and substituted alkanes is presented. The model used considers reversible transfer reactions of the radicals formed with both hydrogen bromide and hydrogen tribromide. Cage reversal of the geminate radical – hydrogen bromide pair and reversal with hydrogen tribromide are used to rationalize the differences observed between the vapor and solution phase kinetics. The method is applied to the bromination of 1-chlorobutane.

DENNIS D. TANNER, TAMEICHI OCHIAI, JEFF ROWE, TONY PAĊE, HIDEKI TAKIGUCHI et PETER W. SAMAL. Can. J. Chem. **55**, 3536 (1977).

On présente une méthode générale d'évaluation de la cinétique pour la bromation en solution d'alkanes substitués et non substitués. Le modèle utilisé tient compte des réactions réversibles de transfert des radicaux formés avec le bromure et le tribromure d'hydrogène. L'inversion en cage de l'ensemble, radical géminé et bromure d'hydrogène, et l'inversion avec le tribromure d'hydrogène sont utilisées pour rationaliser les différences observées entre la cinétique en solution et en phase vapeur. La méthode est appliquée à la bromation du chloro-1 butane.
[Traduit par le journal]

Introduction

The detailed mechanism of the liquid phase photobromination of alkanes and substituted alkanes has been a topic of both theoretical and synthetic concern. Recently several new details of the mechanism have been reported which make possible a clearer understanding of the reaction (2, 3). The more detailed pathway suggested for the reaction is presented in Scheme 1.

Cage reversal (the reverse of A), the reaction of the caged geminate radical – hydrogen bromide pair, was found to be a reaction which is competitive with diffusion of the radical from the solvent cage, reaction B. The cage reversal reaction was deemed to be competitive with diffusion since k_{-a} is a rate constant whose magnitude is near the diffusion controlled limit and the concentration of the species in the individual cage can be approximated as their bulk concentrations.[8] It was suggested that in the bromination of a substrate which can yield

$$\text{[A]}\quad RH + Br^{\bullet} \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} (R^{\bullet} + HBr)^{cage}$$

$$\text{[B]}\quad (R^{\bullet} + HBr)^{cage} \xrightarrow{k_d} R^{\bullet}$$

$$\text{[C]}\quad R^{\bullet} + HBr \xrightarrow{k_{-a}} RH + Br$$

$$\text{[D]}\quad R^{\bullet} + HBr_3 \xrightarrow{k'_{-a}} RH + Br_3^{\bullet}$$

$$\text{[E]}\quad R^{\bullet} + Br_2 \xrightarrow{k_t} RBr + Br.$$

[8]For a discussion of this assumption for reactions involving cage recombination reactions see ref. 8.

isomeric products, the variation of the rates of reversal of the isomeric radicals, when competing with diffusion, could lead to a differentiation in the proportion of each radical that escaped from the cage and ultimately formed products (3). In solution the relative rates of transfer, with bromine and with hydrogen bromide, of the radicals free of the solvent cage were found to be dependent upon the concentration of bromine and hydrogen bromide. The rate of transfer with hydrogen relative to bromine was found to be increased at higher concentration of transfer agents since a new species HBr_3, was found to react with an organic radical at a faster rate (k'_{-a}) than hydrogen bromide itself.

$$HBr + Br_2 \rightleftharpoons HBr_3$$

$$R^{\cdot} + HBr_3 \xrightarrow[k'_{-a}]{} RH + {}^{\cdot}Br_3$$

No information was available concerning the possibility that the species hydrogen tribromide could, likewise, act as a bromine atom donor. If this were so, however, the measured value, k'_{-a}/k_{-a}, would be even larger than reported. The possibility also existed that hydrogen abstraction in solution could take place by, the presumably more selective and less reactive species, $Br_3^{\cdot}$. Although this process would complicate the kinetic expression used to evaluate the relative rates of product formation for reactions carried out in solution, the values of the relative rates of abstraction used to evaluate the kinetics were obtained from vapor phase studies where this complication is not important. Both of these processes are not further considered in the development of this model although they can conceivably occur.

The liquid phase bromination of 1-chlorobutane has been previously studied and the product distribution obtained from the reaction has been rationalized on the basis of both the polar effects of the electronegative substituent and the strength of each carbon hydrogen bond that is broken in the abstraction process.[9]

A study of the kinetics of the bromination of perdeuterio-1-chlorobutane in the vapor phase allowed the determinations of the relative rates of abstraction of hydrogen in each position of 1-chlorobutane and the relative rates of transfer with bromine and hydrogen bromide of the isomeric set of radicals formed from the abstraction reaction (1). When the bromination was carried out in the vapor phase, to low conversion, and at high concentrations of molecular bromine, neither the cage reactions nor the transfer reactions with HBr_3 were present as competing processes.

In this publication we would like to report a study of the kinetics of the liquid phase photobromination of 1-chlorobutane which takes into account all of the details established previously, reactions A–E. The report details a general method which can be applied to evaluate the solution phase kinetics of bromination of substrates which yield isomeric mixtures of bromination products.

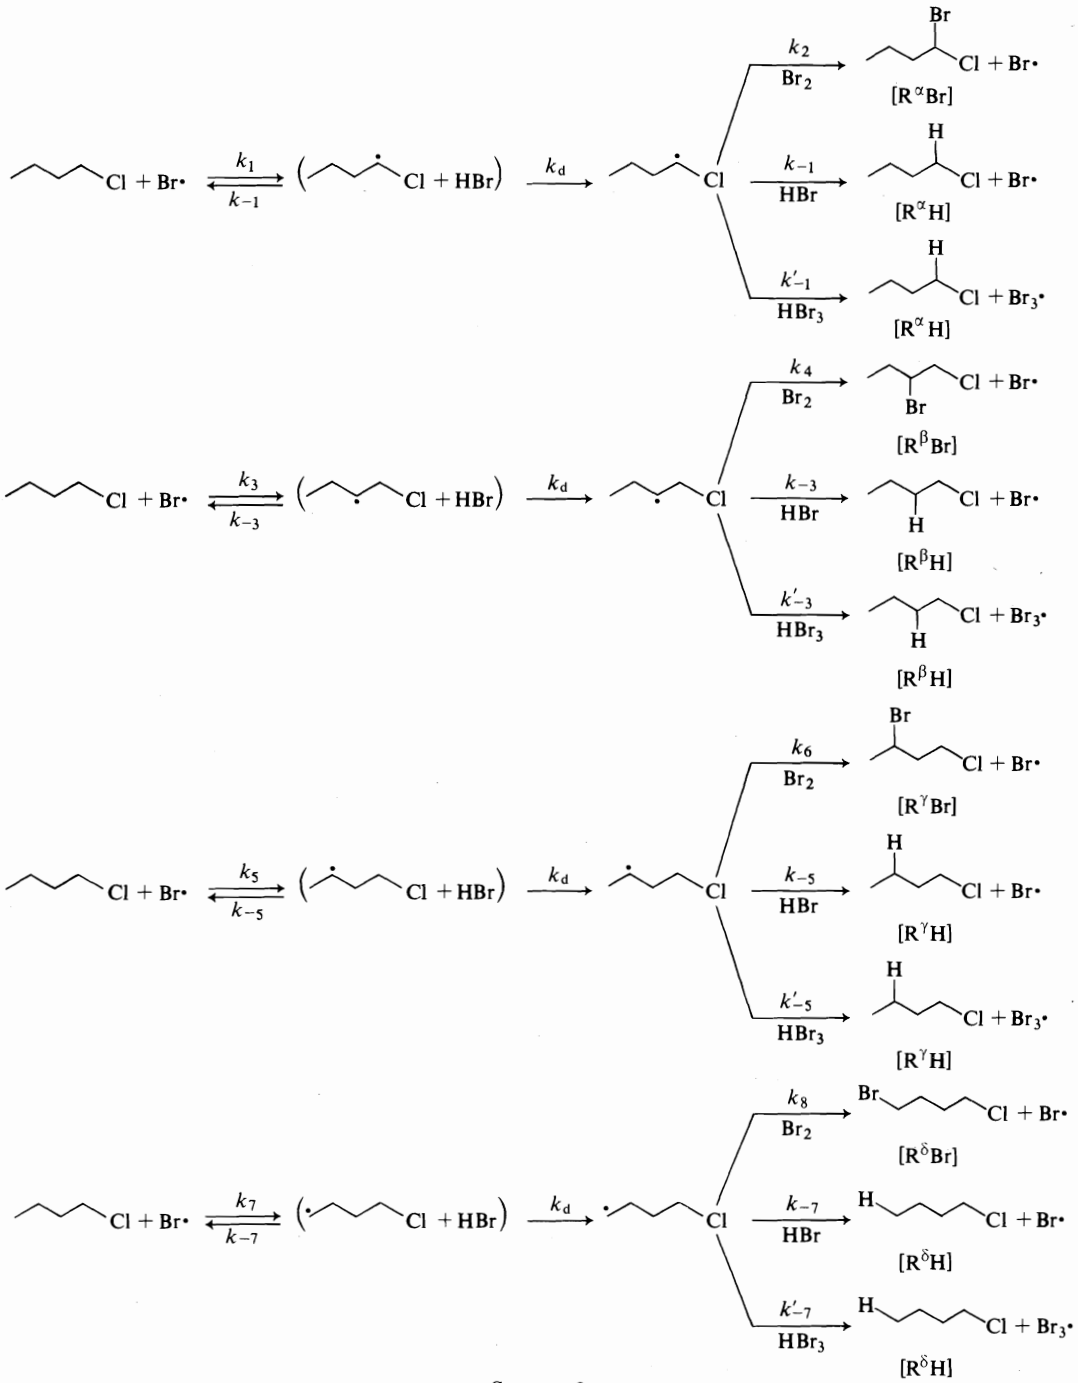
Discussion and Results

The simplest mechanism for the solution phase bromination of a molecule which yields isomeric radicals on hydrogen abstraction can be exemplified by the bromination of 1-chlorobutane (see Scheme 2). The relative rates of the appearance of any two products can be derived, using this mechanism (i.e. $(d[R^{\alpha}Br]/dt)/(d[R^{\gamma}Br]/dt)$, [1]; $(d[R^{\beta}Br]/dt)/(d[R^{\gamma}Br]/dt$, [2]).

$$[1]\quad \frac{d[R^{\alpha}Br]/dt}{d[R^{\gamma}Br]/dt} = \left(\frac{k_2}{k_{-1}}\right)\left(\frac{k_{-5}}{k_6}\right)\left(\frac{k_1}{k_5}\right)\left(\frac{k_{-5}[HBr]^c + k_d}{k_{-1}[HBr]^c + k_d}\right) \times \left(\frac{(k_6/k_{-5})[Br_2] + [HBr] + (k'_{-5}/k_{-5})[HBr_3]}{(k_2/k_{-1})[Br_2] + [HBr] + (k'_{-1}/k_{-1})[HBr_3]}\right)$$

$$[2]\quad \frac{d[R^{\beta}Br]/dt}{d[R^{\gamma}Br]/dt} = \left(\frac{k_4}{k_{-3}}\right)\left(\frac{k_{-5}}{k_6}\right)\left(\frac{k_3}{k_5}\right)\left(\frac{k_{-5}[HBr]^c + k_d}{k_{-3}[HBr]^c + k_d}\right) \times \left(\frac{(k_6/k_{-5})[Br_2] + [HBr] + (k'_{-5}/k_{-5})[HBr_3]}{(k_4/k_{-3})[Br_2] + [HBr] + (k'_{-3}/k_{-3})[HBr_3]}\right)$$

[9]For reference on the bromination of 1-chlorobutane see ref. 1 and the references quoted therein.



SCHEME 2

Equations 1 and 2 were derived using a steady state approximation for the concentrations of both 'free' and caged radicals and by assuming that k_d, the specific rate constant for diffusion, was the same for all of the 1-chlorobutyl radicals involved. If the reaction is carried out with high concentrations of bromine and hydrogen bromide, to low conversion, where the concentra-

tions of bromine and hydrogen bromide are relatively constant, then [1] and [2] can be integrated.

The relative rates of transfer, other than cage transfer, can be evaluated at each position in the molecule by a study of the relative rate of product formation (R^iH and R^iBr) for each position of perdeuterio-1-chlorobutane. The expression takes the form of [3] (α-position), [4] (β-position), and [5] (γ-position), and each expression may in turn be integrated when the reaction is carried out to low conversion using high concentrations of bromine and hydrogen bromide.

$$[3]\quad \frac{d[R^\alpha H]/dt}{d[R^\alpha Br]/dt} = \frac{[HBr] + k'_{-1}/k_{-1}[HBr_3]}{k_2/k_{-1}[Br_2]}$$

$$[4]\quad \frac{d[R^\beta H]/dt}{d[R^\beta Br]/dt} = \frac{[HBr] + k'_{-3}/k_{-3}[HBr_3]}{k_4/k_{-3}[Br_2]}$$

$$[5]\quad \frac{d[R^\gamma H]/dt}{d[R^\gamma Br]/dt} = \frac{[HBr] + k'_{-5}/k_{-5}[HBr_3]}{k_6/k_{-5}[Br_2]}$$

By a combination of the integrated forms of [3], [5], and [1] or [4], [5], and [2], two expressions ([6] and [7]) can be obtained that will allow an experimental evaluation of the effect of cage reversal on the ratio of products formed.

$$[6]\quad C_\gamma^{\ \alpha} = \left(\frac{k^D_{-1}(DBr)^c + k_d}{k^D_{-5}(DBr)^c + k_d}\right) = (k_1/k_5)\left(\frac{\Delta[R^\gamma H] + [R^\gamma Br]}{\Delta[R^\alpha H] + [R^\alpha Br]}\right)$$

$$[7]\quad C_\gamma^{\ \beta} = \left(\frac{k^D_{-3}[DBr]^c + k_d}{k^D_{-5}[DBr]^c + k_d}\right) = (k_3/k_5)\left(\frac{\Delta[R^\gamma H] + [R^\gamma Br]}{\Delta[R^\beta H] + [R^\beta Br]}\right)$$

The effect of cage reversal, $C_j^{\ i}$, may be evaluated from the results of the bromination of perdeuterio-1-chlorobutane if one invokes the assumption proposed by Mayo (4) that there will be negligible solvent effects on the relative rates of competitive free radical reactions of the same kinetic order. If one makes the substitution $(k_1/k_5)^{vapor} \simeq (k_1/k_5)^{solution}$ then [6] and [7] may be evaluated using the vapor phase values previously reported (ΔR^iH is the change from the initial to the final concentration of protium at each position i and $[DBr]^c$ is the cage concentration of deuterium bromide).

TABLE 1. Photobromination of perdeuterio-1-chlorobutane in Freon 113 (23.0°C)

	Concentration (mol/ℓ × 10^3)		
	Run 1	Run 2	Run 3
Reactants[a]

$[R^\gamma H]$	1.163	0.778	0.953
$[R^\delta H]$	1.292	0.853	1.199
$[R^\alpha Br]$	0.440	0.355	0.259
$[R^\beta Br]$	0.482	0.392	0.288
$[R^\gamma Br]$	0.699	0.573	0.318
$[R^\delta Br]^c$	0.000	0.000	0.000

[a][RD(H)] refers to the concentration of perdeuterio-1-chlorobutane, and $[R^iH]$ is the average concentration of the residual protium at position i.

[b]The values for $[R^iH]$ at the end of the reaction were calculated as: $[R^iH]^f + 1/2([R^iH]^0 + [R^iH]^f)([RDH]^0 - [RDH]^f/[RDH]^0)$, in order to correct for the small amount of protiated material that has undergone reaction.

[c]Not detected by glpc.

The photobrominations of perdeuterio-1-chlorobutane were carried out at 23°C in Freon 113 solution. The reactions were carried out to low conversion where multiple exchange reactions (H for H or D for D) will be negligible and where the concentration of bromine or the initially added hydrogen bromide were not appreciably changed during the reaction. The reaction mixture after photolysis was freed from excess bromine and hydrogen bromide and the yields of the bromination products were determined by glpc analysis. The analysis showed the presence of only the perdeuterated analogs of 1-bromo-1-chlorobutane, 2-bromo-1-chlorobutane, 3-bromo-1-chlorobutane, and the unbrominated substrate. A material balance of >97% for each of the brominated materials was obtained (in control experiments) using this analytical procedure (1). The unbrominated substrate was collected by preparative glpc and the change in the relative amount of incorporated protium at each position (see Table 1) was determined from a comparison of the ^1H 100 MHz nmr spectrum of the residual protium in the (Merck, Sharp and Dohme, 98.3 at.% D) starting perdeuterio-1-chlorobutane and the

TABLE 2. Relative kinetic values calculated for 1-chlorobutyl radicals[a]

I. Relative rates of transfer of 1-chlorobutyl radicals with Br_2 and HBr (vapor phase, 23°C)[b]
(α-position) $k_2/k_{-1} = 65.5 \pm 7.9$
(β-position) $k_4/k_{-3} = 15.6 \pm 3.0$
(γ-position) $k_6/k_{-5} = 8.1 \pm 0.5$

II. Relative rates of transfer of 1-chlorobutyl radicals with HBr_3 and HBr (Freon 113, 23.0°C)
(α-position) $k'_{-1}/k_{-1} = 57.6 \pm 1.2$

$C_\gamma^\alpha = 0.73 \pm 0.01$
$C_\gamma^\beta = 0.89 \pm 0.04$
$C_\gamma^\gamma = (1.00)$

[a]Errors quoted are based on the reproducibility between kinetic determinations.
[b]Data taken from ref. 1.

spectrum of the recovered unbrominated substrate. The total amount of protium in the starting material and the recovered substrate was determined by mass spectrometry. The concentrations, conditions, and values obtained for the kinetic analysis are listed in Table 1.

The ratio of rate constants for the abstraction of a deuterium atom from perdeuterio-1-chlorobutane in the α-, β-, and γ-positions can be equated to the same ratio of rate constants in the undeuterated substrate if the assumption is made that analogous ratios of rate constants for the two substrates are the same, eq. 8.

$$[8] \qquad k^H{}_i/k^H{}_j = k^D{}_i/k^D{}_j$$

From the data in Table 1, using the integrated forms of [3], [4], and [5], and the vapor phase relative rate data for transfer of each radical with bromine and hydrogen bromide (see Table 2) the ratio of transfer rates with HBr_3 vs. HBr could be calculated for each position in the molecule. The value of $[HBr_3]$ could be obtained from the equilibrium constant, $K = 2.8 \pm 0.3$ (23°C), determined by the nmr method previously described (2). Although the experimental error is large the value of k'_{-5}/k_{-5} listed in Table 2 is quite similar to the analogous value reported for perdeuteriocyclohexyl radicals, $k'_{-i}/k_{-i} = 22 \pm 7$ (32°C) (2). The similarity of these values was expected for structurally and energetically similar secondary radicals.

The effect of cage reversal, C_γ^i, as was expected, follows the same trend as that observed for the relative rate of transfer with bromine compared with hydrogen bromide (1). As the radical center involved was further removed from the electron withdrawing chlorine substituent the ratio of transfer rates for the three secondary radicals decreased in the order, $k_2/k_{-1} > k_4/k_{-3} > k_6/k_{-5}$. This change in relative rates was rationalized on the basis of a polar deactivation to transfer with hydrogen bromide which falls off as the distance from the electronegative substituent was increased, while the transfer with molecular bromine was little affected. The cage reversal effect is the result of a competition between diffusion and the reversal of the isomeric radicals formed with deuterium bromide, and since from the above reasoning $k^D{}_{-1} < k^D{}_{-3} < k^D{}_{-5}$, then it follows that cage reversal, C_γ^i, should increase as observed from C_γ^α to C_γ^γ (see Table 2).[10]

In the absence of external reversal [1] (or [2]) reduces to an expression [9] (or [10]) which can be integrated to obtain the predicted ratios of products obtained for the bromination of the natural protiated material.

$$[9] \qquad \frac{d(R^\alpha Br)/dt}{d(R^\gamma Br)/dt} = \left(\frac{k_1}{k_5}\right)\left(\frac{k_{-5}[HBr]^c + k_d}{k_{-1}[HBr]^c + k_d}\right)$$

$$[10] \qquad \frac{d[R^\beta Br]/dt}{d[R^\gamma Br]/dt} = \left(\frac{k_3}{k_5}\right)\left(\frac{k_{-5}[HBr]^c + k_d}{k_{-3}[HBr]^c + k_d}\right)$$

When the bromination of 1-chlorobutane was carried out to low conversion (see Table 3, reactions 1–8) under conditions where the reversal reaction was negligible the ratio of products found agreed reasonably well with the values predicted using [9] and [10] (Table 4, entries 1 and 2). The agreement between the observed and calculated values of the product ratios lends support to the assumption made, that the vapor phase values of the relative rate constants may be substituted into the kinetic expression for the solution phase reactions, and the cage reversal expression C_γ^i, evaluated using the data obtained from the bromination of the perdeuterated substrate, can equally well be used to predict the products obtained from the natural protiated substrate.

[10]Using [6] the cage reversal effect at the δ-position, C_γ^δ, was found to have a value of 0.56, rather than one closer to unity, as expected. This result may be due to the large error in the calculated value, since $[R^\delta Br]$ and $[R^\delta H]$ are both rather small.

[c]Taken from Table 3, reactions 9–12.
[d]Taken from ref. 1.

We have previously suggested that the values obtained for the relative rates of bromination of several pairs of substrates in solvent liquid bromine (10–18 M) could be rationalized on the basis of competitive abstraction reactions which proceeded to products without internal (cage) or external return (5). In support of this suggestion that cage return can be interfered with by carrying out the brominations in very high concentrations of bromine it has been recently demonstrated that the deuterium isotope effect for the bromination of cyclohexane and perdeuteriocyclohexane, in the absence of external reversal, gave the same value, k_{RH}/k_{RD}, in the vapor phase and in solution (10–18 M liquid bromine) (3). The brominations of 1-chlorobutane in liquid bromine (reactions 9–12, Table 3), likewise, show the same product distribution as the vapor phase reactions of perdeuterio-1-chlorobutane and of 1-chlorobutane carried out under irreversible conditions, low conversion in the presence of excess bromine (see Table 4, compare entries 3 and 4 or 5). The coincidence of the product distributions obtained from these experiments in the vapor phase and in solution further substantiates the concept of cage scavenging of an alkyl radical by liquid bromine, and serves as a further example of the importance of considering differential cage reversal of isomeric radicals in solution phase brominations. The conclusions reached in the vapor phase study (1), that hydrogen abstraction and its reversal are both deactivated by the polar influence of the substituent, and that the effect

falls off as the distance of the substituent from the C—H bond involved increases, are consistent with the results of this study. The conclusion previously reached (1) that there is no evidence for anchimeric assistance by a neighboring chlorine atom during hydrogen abstraction is further enforced.

Experimental

Materials

1-Chlorobutane was washed with concentrated sulfuric acid, water, 10% aqueous sodium carbonate solution, and water, dried over calcium chloride, and distilled twice through a 1 ft Vigreaux column. The middle fraction was collected, bp 72.5–73.5°C (708 mm). Commercial perdeuterio-1-chlorobutane (Merck, Sharp and Dohme of Canada Ltd.) was used without further purification: glpc analysis showed it to be 99.5% pure. Analysis by mass spectroscopy showed it to contain 98.3 at.% D, while nmr analysis, using 1,1-diphenylethene as internal standard, showed it to be 98.0 at.% D.

Molecular bromine (Raylo Chemicals Ltd.) was washed with concentrated sulfuric acid and distilled, bp 56.7°C (700 mm). Hydrogen bromide (Matheson) was distilled prior to use.

Freon 113 (Matheson) and Freon 112 (PCR) were distilled from phosphorus pentoxide through a 1 ft Vigreaux column, bp 45.5°C and 88.0°C (700 mm), respectively.

1,1-Diphenylethene (Eastman Organic Chemicals) was distilled under reduced pressure, bp 133.5–133.8°C (7.6 mm), n_D^{20} 1.6088 (lit. (6) bp 139°C (11 mm), n_D^{20} 1.6085); nmr spectroscopy and glpc analysis showed it to have no detectable impurities.

Photobromination of Perdeuterio-1-chlorobutane with Excess Bromine and Excess Hydrogen Bromide

A Freon 113 solution of hydrogen bromide was allowed to equilibrate in a water bath maintained at 23.0 ± 0.1°C. The solution was protected from the atmosphere by a mercury bubbler. Perdeuterio-1-chlorobutane, bromine, and Freon 112 (internal standard) were added in the absence of light, and the concentrations of bromine and hydrogen bromide were determined by iodometric titration (7). The solution was irradiated (2 × 200 W incandescent lamps) until 4–10% of the perdeuterio-1-chlorobutane had reacted. The reaction mixture was washed with ice-cold, 5% aqueous sodium bisulfite solution and with water. It was dried over anhydrous sodium sulfate, and then analyzed by glpc (10 ft × ¼ in. 10% UCON 50 LB 550X on Chromosorb P AW, glass column) for the remaining perdeuterio-1-chlorobutane and products (1). The solution was concentrated by distillation on a 24 in. Teflon spinning band column and the unbrominated perdeuterio-1-chlorobutane was collected by preparative glpc. The protium content was then determined (using nmr and mass spectroscopy) as previously described (1).

Equilibrium Constant Measurements

Solutions of hydrogen bromide and bromine in Freon 113 (1% in TMS) were prepared in 4 mm id nmr tubes as previously reported (1). The tubes were allowed to equilibrate to the probe temperature, 23.0 ± 0.2°C, and the nmr spectrum was obtained. All line positions were measured in Hertz relative to TMS by counting the difference between the lock and sweep oscillator frequencies using a Varian HA 100 spectrometer. Reproducibility of the measurement was better than 0.2 Hz. The equilibrium constant was determined as described in our previous paper (1). The results are given in Table 5.

Photobromination of 1-Chlorobutane

Aliquots of Freon 113 solutions of 1-chlorobutane, bromine, and Freon 112 (internal standard) were placed in Pyrex tubes. The tubes were degassed three times by the freeze–thaw method and sealed. They were placed in a water bath, equilibrated in the absence of light for 10 min, and then irradiated until 1–10% of the 1-chlorobutane had been brominated. The tubes were opened, the excess bromine destroyed with aqueous sodium bisulfite solution, and the organic layer washed with water and dried (Na_2SO_4). It was then analyzed by glpc (10 ft × ¼ in. 10% UCON 50 LB 500X on Chromosorb P AW, glass column).

Ultrasonic velocities for deuterium oxide – water mixtures at 298.15 K[1,2]

OSAMU KIYOHARA,[3] CARL J. HALPIN, AND GEORGE C. BENSON
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 12, 1977

OSAMU KIYOHARA, CARL J. HALPIN, and GEORGE C. BENSON. Can. J. Chem. **55**, 3544 (1977).

Ultrasonic velocities in deuterium oxide – water mixtures were measured at 298.15 K and 1 atm pressure using the pulse-echo-overlap method in a successive dilution mixing cell. On a mole fraction basis, the velocities show negative deviations from linearity. Excess adiabatic compressibilities derived from the results are almost zero or slightly negative.

OSAMU KIYOHARA, CARL J. HALPIN et GEORGE C. BENSON. Can. J. Chem. **55**, 3544 (1977).

On mesure les vitesses ultrasonores dans des mélanges oxide de deutérium – eau à 298.15 K sous 1 atm de pression en utilisant le recouvrement impulsion-écho dans une cellule à mélange par dilution successive. En se basant sur la fraction molaire, les vitesses montrent des écarts negatifs à la linéarité. Les compressibilités adiabatiques d'excès dérivées à partir des résultats sont presque nuls ou légèrement négatifs.

[Traduit par le journal]

Introduction

In spite of the physical similarity between water and deuterium oxide, the difference of the velocities of ultrasound in these liquids is relatively large, ~ 98 m s^{-1} at 298 K. There have been several previous ultrasonic studies of deuterium oxide – water mixtures (1–4). Mathieson and Conway (3) found that a plot of ultrasonic velocity against mole fraction showed a small but significant curvature away from the composition axis. Gupta *et al.* (4) reported that the speed of sound varies linearly with volume fraction.

Our ultrasonic velocity measurements were undertaken as part of an on-going study of the thermodynamic properties of deuterium oxide – water mixtures. To avoid the exchange of deuterium oxide with atmospheric water vapor, a new mixing cell was designed in which the mixing could be carried out in the absence of any vapor space.

Experimental

Component Liquids

The deuterium oxide was Merck, Sharp and Dohme reagent with a specified minimum isotopic purity of 99.7 at.% D. An Anton Paar densimeter (5) was used to determine its density (1.10420 g cm^{-3} at 298.15 K) just before making the ultrasonic measurements. Assuming the only impurity to be H_2O, the mole fraction of D_2O in our sample was estimated to be 0.9976, based on a value of 1.104449 g cm^{-3} (6) for the density of pure D_2O at 298.15 K.

The water was distilled and deionized. Both component liquids were partially degassed prior to their use in the ultrasonic measurements.

Measurements of Ultrasonic Velocity

Ultrasonic velocities were determined by the pulse-echo-overlap method (7, 8) in which the time interval is measured between a pair of echoes of an ultrasonic wave travelling between a transducer and reflector. For the present work the rf generator was operated at 3 MHz. Details of our equipment have been described previously (9); only the mixing cell was new.

Ultrasonic Cell

A schematic drawing of the cell is shown in Fig. 1, and structural details are given in the legend. The whole unit is securely mounted on a brass frame which can be immersed in a thermostated water bath. The cell was designed to allow successive additions of one component to a known mass of the other component in the absence of any vapor space. The body of the cell is a Pyrex cylinder with a small U-shaped side chamber. The bottom is closed by a transducer–reflector assembly, the top by a movable plunger. The total inner volume when the plunger is withdrawn to its highest position is about 120 cm^3.

The transducer (Panametrics Type 5070 VIP) is mounted in a brass holder. In our previous cell (9), the face of the transducer was gold plated to protect it from the action of the liquid in the cell. It was found that this coating deteriorated with exposure to a variety of solvents. In the new cell direct contact between the transducer and the cell liquid is avoided by coupling through a double transition layer resonator (10). The latter consists of a thin layer of epoxy resin mixed with tungsten powder which couples the transducer to a piece of brass shim

stock (thickness 0.025 mm) (see Fig. 1 insert). The transducer and reflector are connected by a rigid framework which also supports the pivot of the magnetic stirrer. Four screws are provided for adjusting the parallelism between the transducer and reflector faces.

The plunger sealing the upper end of the cell is moved by a threaded rod. Thus the volume of the cell can be increased during the addition of the feed component, and the level of mercury in the capillary part of the side chamber can be altered to maintain a constant pressure within the cell.

The mercury also keeps the two components separate before mixing. The feed component is delivered by a calibrated piston displacement burette (11). The liquid flows through Teflon and stainless steel tubing and is injected into the mercury. The magnetic stirrer is activated by a rotating magnet outside the cell. It has four blades with long narrow brass arms attached and provides quick mixing of the liquid above and below the reflector.

Loading and Operating Procedure

After the cell is cleaned, the plunger is set just above the connection to the side chamber. Mercury (~ 3 cm^3) is placed in the U-tube and one of the component liquids (~ 40 cm^3) is introduced through the filling port from a weighing burette. All weighings are corrected to *vacuo*. The filling port Y is temporarily closed with an auxiliary stopper to prevent evaporation while the piston burette is loaded with the other component. The burette is operated to expel all air bubbles from it and the attached feed tubes (X and A′). The end of tube X is dipped into a dish containing mercury and the burette motor is reversed briefly, sucking a small amount of mercury into X before the motor is stopped. The filling port is then opened and the level of liquid in the cell is raised to the top of the side chamber by readjusting the plunger. The feed tube, still sealed by mercury, is inserted and the cell is closed without any vapor space by the Teflon stopper.

The loaded cell is immersed in a water bath operated at 298.15 $\pm$ 0.01 K and controlled to better than $\pm$0.003 K during a run. The temperature is monitored by a quartz crystal thermometer. After thermal equilibrium is reached, the mercury level in the feed tube is set close to a reference mark on the tube X by operating the piston burette, and the mercury levels in the two arms of the U-tube are set at the same height by readjusting the plunger.

After measuring the ultrasonic velocity of the liquid in the cell, the feed component is slowly added by the piston burette. At the same time the plunger is gradually raised to increase the inner volume of the cell. A balance is achieved by keeping the level of the mercury in the capillary nearly constant. The amount of the component added is obtained from the difference of the readings of the counter coupled to the piston burette. A small correction is subtracted from the first addition to allow for the mercury initially present in the feed tube. The imprecision of the composition of the mixture is estimated to be less than 0.02%.

Calibration of the distance between the transducer and reflector was based on the value of the ultrasonic velocity for pure water (1496.687 m s^{-1} at 298.15 K) reported by Del Grosso and Mader (12). The relative error of velocities measured with our equipment is estimated to be less than 0.2 m s^{-1}.

Measurements on Aqueous NaCl Solutions

Results of very accurate ultrasonic velocity measurements are avilable for aqueous NaCl solutions (13–15). Although the mercury and brass in the present cell make it rather unsuitable for measurements of this type, a few test runs were carried out. An aqueous NaCl solution of known concentration (~ 3 *m*) was prepared by mass from Anachemia reagent which had been dried in an oven at 338 K. This solution was successively added to the cell which was originally filled with water. Velocity measurements were made as rapidly as possible but changes in the appearance of the mercury indicated that some reaction

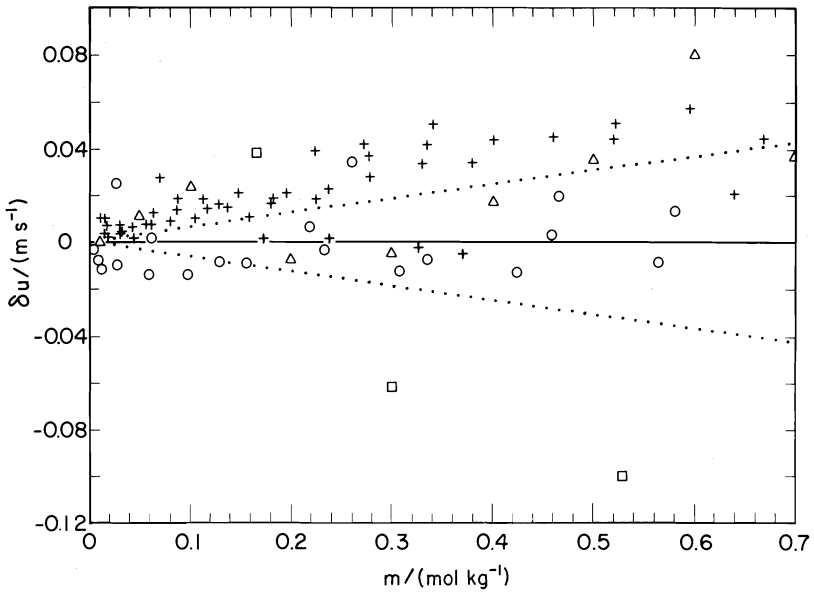

FIG. 2. Deviation plot for ultrasonic velocities, u, at 298.15 K in aqueous NaCl solutions with molality m. Plot shows deviations from eq. 1. $\delta u = u - u_0 - m(64.804 - 4.679m^{1/2})$. Experimental results: ○, present work; +, Sakurai *et al.* (13); □, Gucker *et al.* (14); Δ, Millero *et al.* (15). Dotted lines represent deviations of ±0.1%.

was occurring within the cell. The results obtained for $m < 0.7$ are represented by

$$[1] \quad (u - u_0)/(\text{m s}^{-1}) = m(64.804 - 4.679m^{1/2})$$

where u and u_0 (1496.687 m s^{-1}) are the velocities for a solution of molality m and for water respectively. The standard deviation of the representation is 0.014 m s^{-1}.

Our results, compared in Fig. 2 with values from the literature (13–15), are in close agreement with those of Sakurai *et al.* (13) and of Millero *et al.* (15). The apparent molal adiabatic compressibility $\phi_{K_S}{}^0$ of NaCl in water at infinite dilution, calculated from our velocity results using the limiting value of the apparent molal volume of NaCl (16) is −50.2 cm^3 mol^{-1} GPa^{-1} at 298.15 K. This agrees reasonably well with values reported by other workers: −50.45 (13), −52.88 (14), −50.5 (15, 17), −49.8 (18), and −50.8 (19).

Results and Discussion

Ultrasonic velocities, u, measured at 298.15 K in $D_2O(1) + H_2O(2)$ mixtures with various mole fractions x_1 of D_2O are listed in Table 1. These results were obtained in two independent dilution runs starting with H_2O, and with D_2O, in the cell. The smooth overlap of the results in the central part of the mole fraction range provides a good check on the consistency of the dilution technique. Extrapolation of the results for D_2O-rich mixtures leads to a value of u = 1398.74 m s^{-1} at $x_1 = 1$. This agrees well with the value 1398.6 m s^{-1} obtained by Yosioka (1) using the optical method. Other published values for u/(m s^{-1}) in pure D_2O at 298.15 K are: 1403.31 (4) and 1401 (20), interferometer method; 1402 (21) and 1399.24 (22), pulse method; ~1396 (3), sing-around method.

The deviation of the ultrasonic velocity in a mixture from additivity on a mole fraction basis is

$$[2] \quad \Delta u = u - \sum x_i u_i{}^0$$

where $u_i{}^0$ is the velocity in pure component i. Our results for the present system are represented by the polynomial expression

$$[3] \quad \Delta u/(\text{m s}^{-1}) = x_1x_2[-8.047 - 0.137(x_2 - x_1) + 0.171(x_2 - x_1)^2]$$

with a standard deviation σ = 0.007 m s^{-1}. A comparison of our results with values taken from the literature (1, 4) is given in Fig. 3. Our results are in close agreement with those of Yosioka (1). We find that Δu is negative over the whole mole fraction range, and this behavioral pattern is qualitatively unchanged if volume fractions are used in place of mole fractions in eq. 2. This is in contrast to the findings of Gupta

et al. (4) who reported that the speed of sound varied linearly with volume fraction.

Adiabatic compressibilities, κ_s, were calculated from the ultrasonic velocities using the relation

$$[4] \quad \kappa_s = [u^2 \sum M_i x_i/(V^E + \sum x_i V_i^0)]^{-1}$$

where M_i and V_i^0 are the molecular mass and molar volume of component i, and V^E is the molar excess volume of the mixture. Estimates of V^E for $D_2O + H_2O$ mixtures were based on the work of Bottomley and Scott (23). Results for κ_s are given in Table 1. Also included in Table 1 are values of the excess adiabatic compressibility defined by

$$[5] \quad \kappa_s^E = \kappa_s - \kappa_s^{id}$$

where κ_s^{id} is the adiabatic compressibility of an ideal mixture of the components at the same temperature and pressure. Previously we approximated κ_s^{id} by a volume fraction average of the adiabatic compressibilities $\kappa^0_{s,i}$ for the pure components (9). However in the present work we used the exact expression (24)

$$[6] \quad \kappa_s^{id} = \sum \phi_i^0 \gamma_i^0 \kappa^0_{s,i} \times (\sum x_i (C^0_{p,i}/\gamma_i^0)/\sum x_i C^0_{p,i})$$

where

$$[7] \quad \phi_i^0 = x_i V_i^0 / \sum x_i V_i^0$$

and

$$[8] \quad \gamma_i^0 = 1 + T V_i^0 (\alpha^0_{p,i})^2/(\kappa^0_{s,i} C^0_{p,i})$$

In eq. 8, T is the temperature, and $C^0_{p,i}$ and $\alpha^0_{p,i}$ are the isobaric molar heat capacity and thermal expansibility for pure component i. Numerical values of C_p/(J K^{-1} mol^{-1}) equal to 84.68 (25) and 75.297 (26), and of $10^3\alpha_p$/K^{-1} equal to 0.1918 (27) and 0.2572 (26) were adopted for D_2O and H_2O respectively.

Although our results for κ_s^E are only slightly larger than the estimated imprecision of κ_s ($\sim$0.02 TPa^{-1}), it appears that the adiabatic compressibilities of $D_2O + H_2O$ mixtures display small negative deviations from ideal behavior, and that the variation of these with mole fraction is somewhat asymmetric. Our value of $\kappa^0_{s,1}$ for pure D_2O corresponds to an isothermal compressibility $\kappa^0_{T,1}(=\gamma_1^0 \kappa^0_{s,1})$ of 465.13 TPa^{-1}, in excellent agreement with 465.3 TPa^{-1} (27) and 465.2 TPa^{-1} (28) obtained from direct PVT measurements by Millero and co-workers.

NOTE ADDED IN PROOF: Since the submission or our manuscript, correspondence with Dr. J. G. Mathieson has revealed that the ultrasonic velocities in ref. 3 should be increased by about 0.24% to allow for a change in calibration constant. The corrected value for D_2O, 1399.2 m s^{-1}, is thus much closer to our result than indicated in our text. We are indebted to Dr. Mathieson for sending us a copy of the primary data. It also appears from this that there is excellent agreement between our values of Δu for $D_2O + H_2O$ mixtures and the results of Mathieson and Conway.

Mixed valence properties of a pyrazine bridged ruthenium–iron complex

HENRIQUE E. TOMA AND PAULO S. SANTOS

Instituto de Química, Universidade de São Paulo, Caixa Postal 20780, São Paulo, Brazil

Received March 14, 1977

HENRIQUE E. TOMA and PAULO S. SANTOS. Can. J. Chem. **55**, 3549 (1977).

A study is presented on the chemistry of the binuclear complex $[(CN)_5FepzRu(NH_3)_5]^n$ ($n = 0$ for the II–III complex and $n = -1$ for the II–II complex, pz = pyrazine) in solid state and in aqueous solution. Evidence for a mixed valence transition for the II–III complex was observed in the near infrared region. Based on infrared and resonance Raman spectra, a trapped-valence or class II formulation was proposed for the complex. Cyclic voltammetry indicated the occurrence of two reversible waves at 0.48 V and 0.72 V vs. NHE, which were assigned to the oxidation of the ruthenium(II) and iron(II) centers, respectively.

HENRIQUE E. TOMA et PAULO S. SANTOS. Can. J. Chem. **55**, 3549 (1977).

On présente l'étude de la chimie du complexe binucléaire $[(CN)_5FepzRu(NH_3)_5]^n$ ($n = 0$ pour le complexe II–III et $n = -1$ pour le complexe II–II, pz = pyrazine) dans l'état solide et en solution aqueuse. On a observé dans la région proche-infrarouge, l'existence d'une transition de valence mixte pour le complexe II–III. En se basant sur les spectres infrarouge et Raman, on propose pour le complexe, une valence piégée ou une formulation de classe II. Des mesures polarographiques cycliques nous indiquent la présence de deux ondes réversibles à 0.48 V et 0.72 V vs. NHE, lesquelles sont attribuées respectivement à l'oxydation des sites ruthénium(II) et fer(II).

[Traduit par le journal]

Introduction

Binuclear complexes of ruthenium ammines have been much studied over the last 6 years (1–5) since the mixed valence complex $[(NH_3)_5RupzRu(NH_3)_5]^{5+}$ was first described by Creutz and Taube (1, 2). Similar studies involving cyanoferrate complexes have also appeared in the literature (6–8). In the present work we report some properties of the binuclear complex $[(CN)_5FepzRu(NH_3)_5]^n$ ($n = 0, -1$, pz = pyrazine) in solid state and in aqueous solution.

Experimental

Materials

$[Ru(NH_3)_5pz](ClO_4)_2$ was prepared as described by Anson and co-workers (9). The *p*-toluenesulfonate salt was also prepared as described (9) but using silver *p*-toluenesulfonate instead of silver trifluoroacetate to remove the chloride ions from the starting materials. $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ was prepared from sodium nitroprusside according to the conventional procedure (10). The purity of these complexes was checked spectrophotometrically and by microanalysis.

The dark red II–II ($n = -1$) complex can be easily prepared in aqueous solution by mixing equimolar solutions of the pentaammine(pyrazine)ruthenium(II) complex and of the aquopentacyanoferrate(II) ion (10–14) under argon atmosphere. The 1:1 composition of the complex in solution was demonstrated using Job's method. The II–II complex was isolated as the sodium salt $Na[Fe(CN)_5pzRu(NH_3)_5]\cdot 3H_2O$ according to the following procedure: 0.12 g (0.2 mmol) of $[Ru(NH_3)_5pz](C_7H_7SO_3)_2\cdot 3H_2O$ was dissolved in ca. 50 ml of water, and mixed with 10 ml of aqueous solution containing 0.065 g (0.2 mmol) of $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ under argon atmosphere. After 20 min, the dark-violet solution was treated with argon saturated ethanol to precipitate the binuclear complex. *Anal.* calcd. for $Na[Fe(CN)_5pzRu(NH_3)_5]\cdot 3H_2O$: C 20.42, N 31.75, H 4.7; found: C 20.2, N 31.5, H 5.5.

The II–III complex was prepared in a similar way of the II–II analog, except that aqueous bromine (10^{-2} *M*) was added in nearly stoichiometric amounts to the final solution to oxidize the binuclear complex. The II–III complex is neutral and practically insoluble in water, precipitating immediately after the addition of aqueous bromine. *Anal.* calcd. for $[Fe(CN)_5pzRu(NH_3)_5]\cdot 5H_2O$: C 19.93, N 31.00, H 5.3; found: C 20.0, N 31.3, H 4.9.

Spectra

Near infrared and visible spectra were measured on a Cary 14 spectrophotometer in aqueous solution or in KBr pellets. Infrared spectra were recorded on either a Perkin-Elmer 337 or 180 spectrophotometer. A Jarrel-Ash, Model 25-300 spectrometer was used for the Raman measurements with argon ion laser excitation at 5145 Å, and a spinning cell to prevent or minimize the decomposition of the sample.

Studies in Solution

The kinetics of formation and dissociation of the II–II binuclear complex were investigated with a Durrum D-110 stopped-flow spectrophotometer equipped with a Kel-F flow system, or with a Cary 14 spectrophotometer in the conventional way. Pseudo-first-order behavior was observed during at least three half lives. For the cyclic voltammetry measurements, a PAR system consisting of a Model 173 Potentiostat and a Model 175 Universal

Programmer was employed. Platinum wires were used as auxiliary and working electrodes, with saturated calomel as the reference electrode.

Results and Discussion

The II–II binuclear complex is rapidly formed when solutions containing the aquopentacyanoferrate(II) ion and the pentaammine(pyrazine)-ruthenium(II) complex are mixed.

$$Fe(CN)_5H_2O^{3-} + pzRu(NH_3)_5^{2+} = (CN)_5FepzRu(NH_3)_5^{-}$$

The reaction can be monitored at 520 nm, the maximum wavelength for the visible absorption band of the product, with the stopped-flow apparatus. Using always freshly prepared solutions of the aquopentacyanoferrate(II) ion (3×10^{-5} *M* to 2×10^{-4} *M*) the specific rate of the formation reaction was $3.1 \pm 0.1 \times 10^3$ M^{-1} s^{-1}, at 25°C, $\mu = 0.10$ *M* (lithium perchlorate), and p*H* 4.5 (acetate buffer, 10^{-2} *M*), under argon atmosphere. The rates decrease with the ionic strength (e.g., for $\mu = 0.015$ *M* and 0.20 *M*, $k_2 = 1.60 \times 10^4$ and 1.58×10^3 M^{-1} s^{-1}, respectively), suggesting a S_N1, dissociative ion-pair mechanism (15).

The complex dissociates very slowly in aqueous solution, in the presence of ligands such as dimethyl sulfoxide. This ligand reacts with the aquopentacyanoferrate(II) ion to form the stable and inert pentacyano(dimethylsulfoxide)-ferrate(II) complex (16), driving to completion the dissociation of the binuclear complex. As expected for a limiting S_N1 dissociative mechanism (11–14), the rates were independent of the concentration of dimethyl sulfoxide (0.05 *M* – 0.5 *M*). For $\mu = 0.20$, 0.10, and 0.015 *M* (lithium perchlorate), at 25°C, the specific rates were 6.5×10^{-4}, 6.9×10^{-4}, and 8.1×10^{-4} s^{-1}, respectively. From the rates of formation and dissociation of the binuclear complex, the equilibrium constants were calculated to be 2.4×10^7, 4.5×10^6, and 1.9×10^6 M^{-1}, at 25°C and $\mu = 0.015$, 0.10, and 0.20 *M*, respectively.

The electronic spectra of KBr pellets of the II–II and II–III complexes, in the visible and near infrared region are shown in Fig. 1. As in the system described by Creutz and Taube (1, 2), combination of the filled Ru and Fe d_π orbitals with the vacant pyrazine π^* orbital of appropriate symmetry would result in a set of three π–MO orbitals, ψ_b, ψ_n, ψ_a, having respectively a bonding, nonbonding, and antibonding character. The band centered at 19.1 kK for the II–II and II–III complexes can be assigned to the transition from the occupied, nonbonding (metal) orbitals to the antibonding (ligand) orbitals. For the II–III complex, the new band appearing at 7.5 kK could be assigned to the ψ_b–ψ_n transition, or using a valence trapped description, to a metal(II)-to-metal(III) transition. A comparison of the absorption spectra of the binuclear Ru–pz–Ru, Fe–pz–Fe, and Ru–pz–Fe complexes can be seen in Table 1.

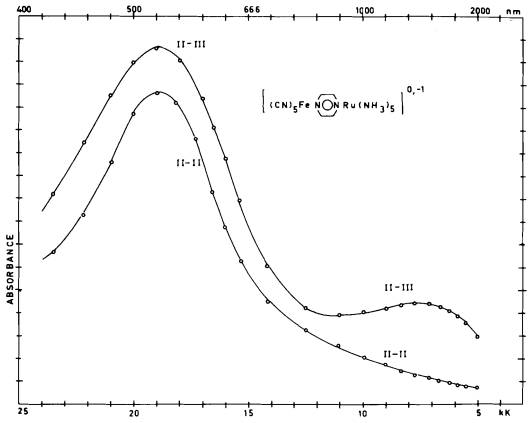

FIG. 1. Absorption spectra of the II–II and II–III binuclear complexes, in KBr pellets.

The absorption bands of the mononuclear and binuclear cyanoferrates occur systematically at higher energies than those of the corresponding ammine complexes. The hypsochromic shift of the visible band of the cyanoferrates from 19.8 to 21.8 kK contrast with the bathochromic shift from 18.3 to 17.7 kK, for the binuclear ruthenium ammines, when the II–II complexes are oxidized to the II–III mixed valence species. It is therefore remarkable that the visible absorption band of the Ru–pz–Fe complex is not shifted in the oxidation process, but remains at an intermediate position with respect to those for the Fe–pz–Ru and Ru–pz–Ru complexes. A similar behavior is shown by the intervalence transitions in the near infrared region.

In an attempt to identify the nature of the donor and acceptor centers in the asymmetric mixed valence complex, $(NH_3)_5RupzFe(CN)_5$, the infrared and Raman spectra were recorded and compared to those for the original II–II complex. This can be seen in Table 2.

The wavelength of the exciting radiation from

the argon laser (5145 Å) practically coincides with the maximum of the visible absorption band of the complexes. This is especially convenient for the purposes of investigating the occurrence of resonance Raman phenomena (17–19) which can be very useful in the assignment of the vibrational spectra. Analogously to a recent work (5) with the binuclear Ru–pz–Ru complex, we have observed that the enhancement of the Raman bands is associated exclusively with the pyrazine ligand, the MNH_3 and MCN groups being practically undetectable in the presence of the enhanced bands.

Since the resonance effect is related to the excited electronic state of the molecule (17–19), the enhancement of the pyrazine bands can be taken as evidence for its involvement in the electronic excitation responsible for the absorption in the visible region. The enhancement has been observed essentially with the totally symmetric vibrations of pyrazine. According to Albrecht and Hutley (18) this may be the case of a typical vibrational interaction with a single excited electronic state. When two or more electronic states are involved in the excitation process, vibronic mixing should enhance any symmetry mode which is contained in the direct product of the representations of the two electronic states.

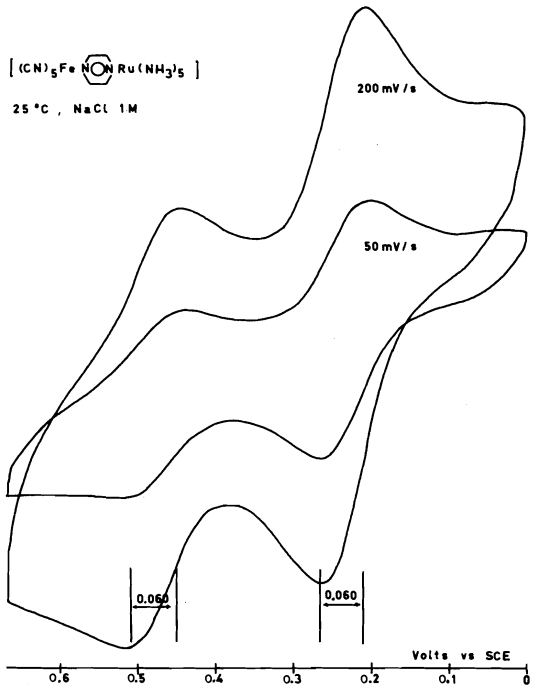

FIG. 2. Cyclic voltammograms of the binuclear complex $[(CN)_5FepzRu(NH_3)_5]^n$ in aqueous solution.

Comparison of the data collected in Table 2 shows that except for the NH_3 bands, the spectra of the II–II and II–III complexes are very nearly the same. This is an important observation if we are interested in the problem of valence delocalization in the system.

It is currently known (21) that the frequencies associated to the vibrations of the CN and NH_3 groups depend on the nature and charge of the metal ions to which they are coordinated. The symmetric deformation and rocking vibrational modes of the coordinated NH_3 group occur at frequencies which usually increase with the oxidation state and electronegativity of the central ion in the complex (22). For ruthenium hexaammines in the oxidation states II and III, they occur at 1220 and 769 cm^{-1} (23) and 1316–1362 and 788 cm^{-1} (24), respectively. Therefore, the observed shifts from 1280 and 770 cm^{-1} in the II–II complex to 1310 and 800 cm^{-1} in the II–III complex are consistent with the oxidation of the ruthenium(II) center.

The similar cyanide stretching frequencies, in the range of 2080–2040 cm^{-1}, for the II–II and II–III species, are characteristic of cyanoferrate(II) complexes (21, 25). In the case of cyanoferrate(III) complexes they are usually observed in the 2100–2150 cm^{-1} region. We therefore conclude that the complex II–III belongs to a valence trapped, or a class II type of system (26, 27) in which the oxidized center is mainly localized on the ruthenium ammine moiety.

Cyclic voltammetry waves for the binuclear complex, recorded at 25°C, $\mu = 1.0\ M$ in NaCl, at several sweep rates, are shown in Fig. 2.

The two reversible waves with $E_{1/2}$ of 0.48 and 0.72 V vs. NHE were ascribed to the oxidation of the ruthenium(II) and iron(II) centers, respectively. They can be compared to 0.37 and 0.76 V for the analogous binuclear ruthenium ammine complex (2).

Without additional information, the choice of the oxidized center could represent a real challenge in the present system. The oxidation potentials of the mononuclear $Ru(NH_3)_5L^{n+}$ and $Fe(CN)_5L^{m-}$ complexes (28, 29) do not necessarily constitute a criterium, since they are very sensitive to substituent effects on the ligand L, as well as to the nature of the metal–ligand bond. For example, the oxidation potentials for

the ruthenium ammine complexes of pyridine, pyrazine, *N*-methyl pyrazinium, and dimethyl sulfoxide are −0.35, −0.49, −0.89, and −1.0 V, in comparison to −0.47, −0.55, −0.78, and −0.89 V, respectively, for the analogous pentacyanoferrate(II) complexes.

These ligands were ordered according to their π-acceptor affinities (29) to show that the oxidation potentials of the ruthenium ammines decrease more rapidly in comparison to those for the cyanoferrates, becoming nearly the same at the proximity of ligands such as pyrazine. Therefore, in the case of the binuclear complexes here reported, the prediction of the oxidized center will depend on the knowledge of the relative stabilities of the Ru(III)–pz–Fe(II) and Ru(II)–pz–Fe(III) species, which can not be estimated from the properties of each moiety, isolately.

NOTE ADDED IN PROOF: The spectra of the mixed valence complex have been measured only for the solid, since it is not stable in aqueous solution. We would like to acknowledge Dr. Albert Haim for calling our attention to the possibility of decomposition even in the solid, which we neglected in the tentative assignment of the electronic and vibrational spectra.

Matrix dependence of the electron spin resonance spectra of the $(CH_3)_3N^{\ddagger}$ radical trapped in different single crystals

J. P. MICHAUT AND J. RONCIN

Laboratoire de Résonance Electronique et Ionique (associé au CNRS), Université de Paris-Sud, Centre d'Orsay, 91405 Orsay, Cedex, France

Received April 18, 1977

J. P. MICHAUT and J. RONCIN. Can. J. Chem. **55**, 3554 (1977).

Nitrogen and proton coupling tensors have been measured for the $(CH_3)_3N^{\ddagger}$ radical trapped in five different single crystal matrices. As all isotropic coupling constants are the same within experimental error (a_N = 21.2 G, a_H = 28.4 G), no measurable crystal field effect is found. In these solids the motions of the radical depend on the dimension of the trapping cage and the motions of the surrounding molecules.

J. P. MICHAUT et J. RONCIN. Can. J. Chem. **55**, 3554 (1977).

Les tenseurs de couplage de l'azote et des protons ont été mesurés pour le radical $(CH_3)_3N^{\ddagger}$ piégé dans cinq matrices monocristallines. Pour ces cinq matrices les constantes de couplage isotrope sont semblables aux erreurs expérimentales près (a_N = 21.2 G, a_H = 28.4 G). Ceci indique que le champ cristallin a un effet négligeable sur la structure du radical. Les mouvements qui animent ce radical dépendent de la matrice de piègeage premièrement par la dimension de la cage de piègeage, deuxièmement par les mouvements des molécules voisines.

Introduction

Several studies (1, 2) have pointed out the influence of the polarity of the trapping matrix on the structure of some Si, Sn, Ge, or P centered free radicals: variations from 10–25% of the central atom spin densities are observed when replacing a nonpolar matrix by a polar one. It is known also that the matrix strongly influences the motion of the trapped radicals. It is for these two reasons that we have studied the temperature dependence of the coupling tensors of the radical $N^{\ddagger}(CH_3)_3$ trapped in five different matrices. We have chosen this radical firstly because the isotropic nitrogen coupling constants quoted in the literature seem to be very matrix sensitive (from 18.0 G (3) up to 22.6 G (4)) and secondly, because from its high degree of symmetry it is expected that it may have various kinds of reorientational motions in these solids.

Experimental

All the single crystals, except betaine hydrochloride, were grown from saturated alcoholic solutions by slow cooling. The betaine hydrochloride single crystals come from saturated aqueous solutions. Due to their highly hygroscopic character all the methylammonium salts were manipulated in a dry box. The crystal habits are hexagonal plates for betaine hydrochloride, rectangular plates for betaine, and square plates for betaine monohydrate. The methylammonium salts also give plates but with a tendency to twinning.[1] All crystals have been irradiated in a ^{60}Co source (doses of about 10^{20} eV/g). The esr spectra were recorded on a JEOL ME 1X spectrometer.

Results

1. Betaine Hydrochloride

Two magnetically unequivalent trapping sites are present in this matrix. The principal values of N and H coupling tensors are given in Table 1. They are quite different from the values reported in a previous study on this compound (4). However, the isotropic couplings agree quite well within experimental error with the value determined in the liquid phase (5) (a_N = 20.55 G, a_H = 28.56 G). We found no temperature dependence of the couplings between 77 and 293 K. As expected from the symmetry of the radical the nitrogen coupling tensor is cylindrical within the limits of experimental error. The direction cosines of the largest principal value of this tensor give the direction of the free electron π orbital axis of the radical. The angle between these directions for the two radical sites is about 30°, a value which corresponds approximately to that of the angle between the N—CH_2 bonds of the undamaged molecules in the crystals (35°)

[1]We are greatly indebted to Mister Jean Godard, Laboratoire de Physique cristalline Orsay, for the growth of a tetramethylammonium chloride single crystal.

TABLE 1. Coupling of nitrogen and proton in the five different matrices

Sample	Nitrogen			Proton		
	Total coupling tensor	Isotropic coupling	Dipolar coupling tensor	Total coupling tensor	Isotropic coupling	Dipolar coupling tensor
Betaine hydrochloride	49.40		28.20	27.00		−0.90
	6.80	21.20	−14.40	28.40	27.90	0.50
	7.30		−13.90	28.40		0.50
Betaine monohydrate	47.60		26.50	27.50		−1.10
	8.90	21.10	−12.20	29.30	28.60	0.70
	6.80		−14.30	29.10		0.50
Betaine (168 K)	50.80		29.50	27.10		−1.10
	7.90	21.30	−13.40	28.70	28.20	0.50
	5.30		−16.00	28.70		0.50
Trimethylammonium chloride (100 K)	53.80		28.90	22.40		−1.30
	11.40	24.90	−13.50	24.30	23.70	0.60
	9.40		−15.50	24.30		0.60
Trimethylammonium chloride (293 K)	48.10		26.40	23.80		−1.20
	7.00	21.70	−14.70	25.50	25.00	0.50
	10.00		−11.70	25.70		0.70
Tetramethylammonium chloride	13.60		−7.50	29.30		0.40
	25.00	21.10	3.90	28.70	28.90	−0.20
	24.60		3.50	28.70		−0.20

(6). The H coupling tensor is also cylindrical and the direction of its smallest principal value is parallel to that of the largest principal value of the nitrogen coupling tensor. This fact, together with the equivalence of the coupling tensors of all the nine protons and the very low values of the dipolar part of the H tensors, indicates that the $N^{\pm}\dot{}(CH_3)_3$ radical undergoes two types of motion in this matrix: a reorientation of the CH_3 groups around the N—C bonds and another reorientation of the whole radical around its C_{3v} symmetry axis. The frequencies of these motions are certainly higher than 10^8–10^9 even at 77 K.

2. Betaine Monohydrate

In that matrix too, two magnetically unequivalent sites for the radical in the crystal are present. The measured N and H coupling tensors are given in Table 1. The angle between the orbital directions in the two sites is about 20°. Here also no temperature dependence of the coupling was found between 77 K and room temperature.

The behaviour of $N^{\pm}\dot{}(CH_3)_3$ in matrices I and II is very similar, However, in betaine monohydrate the values of the nitrogen dipolar coupling tensors are smaller. This difference may arise from a small librational oscillation of the C_{3v} symmetry axis of the radical around its mean direction in the crystal.

3. Betaine

Figure 1 shows a spectrum of the $N^{\pm}\dot{}(CH_3)_3$ radical trapped in a room temperature γ-irradiated single crystal of betaine. In this matrix there is only one trapping site. The nitrogen and proton coupling tensors principal values measured at 168 K are given in Table 1. These couplings are not temperature dependent between 77 and 168 K. Above 168 K all the couplings continuously and reversibly decrease and at 345 K the $N^{\pm}\dot{}(CH_3)_3$ radical disappears. Since all the couplings decrease by the same amount (about 9% between 168 K and 345 K as seen in Table 2), these variations are certainly due to a reduction of the π spin density in the $2p$ orbital of this planar radical. The origin of this decrease of spin density is not yet understood.

Figure 1 shows that a second radical is produced during the irradiation of betaine. Its spectrum consists of two broad lines arising from a very anisotropic interaction of the free electron with an α proton and some other nuclei which

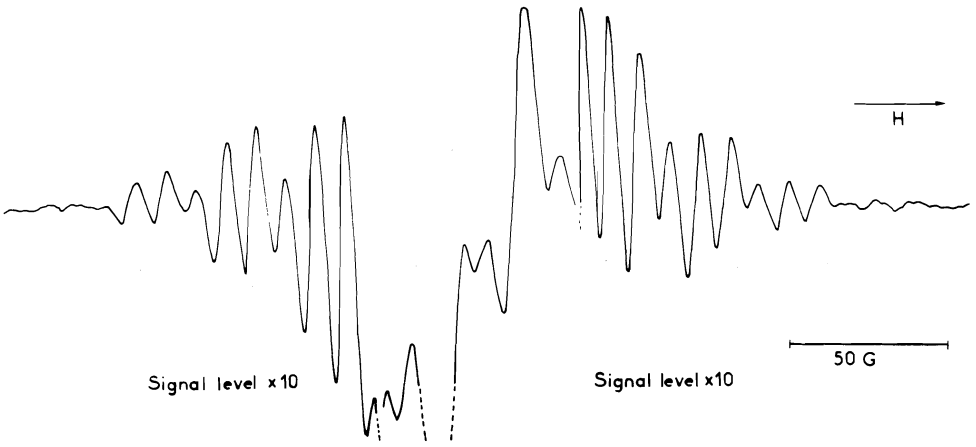

FIG. 1. Electron spin resonance spectrum of $(CH_3)_3N^{\ddagger}$ radical trapped in betaine single crystal. Spectra obtained for matrices 1–2 and 4 are quite similar to this one.

TABLE 2. Temperature variation of the coupling in the betaine matrix

	Nitrogen			Proton		
T (K)	Total coupling tensor	Isotropic coupling	Dipolar coupling tensor	Total coupling tensor	Isotropic coupling	Dipolar coupling tensor
168	50.80		29.50	27.10		−1.10
	7.90	21.30	−13.40	28.65	28.20	0.45
	5.30		−16.00	28.75		0.55
232	50.20		29.20	26.95		−1.05
	7.70	21.00	−13.30	28.50	28.00	0.50
	5.10		−15.90	28.60		0.60
293	48.90		28.30	26.30		−1.00
	5.40	20.60	−15.20	27.80	27.30	0.50
	7.60		−13.00	27.70		0.40
330	47.60		27.60	25.70		−0.20
	6.60	20.00	13.40	26.90	26.50	0.40
	5.80		14.20	26.90		0.40
345	45.40		26.90	25.10		−0.60
	5.50	19.50	−14.00	26.10	25.70	0.40
	6.60		−12.90	25.90		0.20

gives unresolved couplings. On the basis of the great similarity (Table 3) of the coupling tensor of this proton to that found by Ghosh and Whiffen (7) for the proton of the radical $N^+H_3\dot{C}HCOO^-$ trapped in irradiated glycine we tentatively attribute this spectrum to the $N^+(CH_3)_3\dot{C}HCOO^-$ radical.

4. Trimethylammonium Chloride

In this matrix $N^{\ddagger}(CH_3)_3$ has only one trapping site. The couplings are temperature dependent. The values of N and H coupling tensors measured at 100 K and 393 K are given in Table 1. The low temperature values are quite different from those obtained in other crystals. The isotropic nitrogen coupling is larger and the isotropic proton coupling is smaller than those found in the betaines while the dipolar tensors are the same. All these observations may be accounted for in the following way. When the $N^{\ddagger}(CH_3)_3$ radical is formed by γ irradiation of trimethylammonium chloride crystal it is not in its equilibrium planar configuration. A slightly pyramidal structure of the radical in the crystal may account for the 3.5 G increase of the isotropic nitrogen coupling constant which corresponds to a variation of the CNC angle from 120° to around 119.5° at 100 K. This deviation

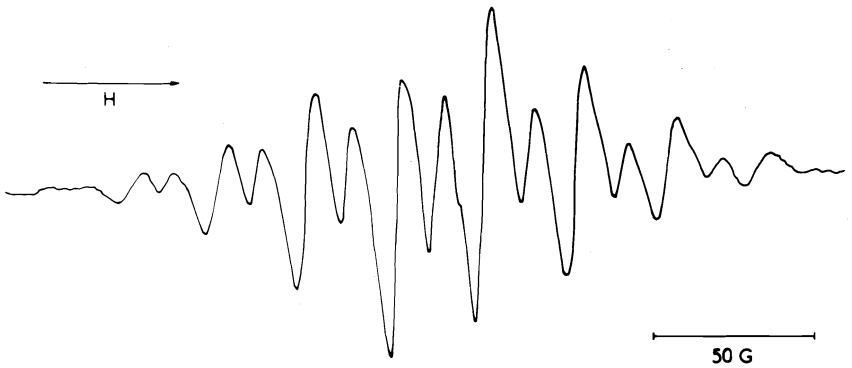

FIG. 2. Electron spin resonance spectrum of $(CH_3)_3N\dot{+}$ radical trapped in tetramethylammonium chloride single crystal.

TABLE 3. Comparison of the couplings of the alleged additional radical $N^+(CH_3)_3\dot{C}HCOO^-$ in betaine and the couplings of the $N^+H_3\dot{C}HCOO^-$ radical in glycine

Radical	Total coupling tensor	Isotropic coupling	Dipolar coupling tensor
$N^+(CH_3)_3\dot{C}HCOO^-$	−34.80		−10.60
in betaine	−22.10	−24.20	+2.10
	−15.60		+8.60
$N^+H_3\dot{C}HCOO^-$	−35.20		−11.50
in glycine	−22.00	−23.70	+1.70
	−13.90		+9.80

from the equilibrium configuration may result from a balance between the intramolecular electronic interactions which tend to give to the radical a planar configuration and the intermolecular repulsion interactions which tend to keep the pyramidal structure of the parent molecule. Then the variations of isotropic couplings (decrease for nitrogen, increase for proton) as temperature increases is due to a thermal expansion of the matrix. However, one difficulty still remains. The hypothesis of steric hindrance seems to be in contradiction with the existence of fast reorientational motions of the radical in the crystal as shown by the values of the dipolar coupling tensors. In fact this contradiction is only apparent because, even at low temperature, the trimethylammonium chloride molecules undergo fast intra- and intermolecular motions in the crystal so that the radical may be carried as if in a set of gear wheels. This explanation also supposes that the deformation energy of the radical is small.

5. Tetramethylammonium Chloride

Figure 2 shows a spectrum of the $N\dot{+}(CH_3)_3$ radical trapped in a room temperature γ-irradiated tetramethylammonium chloride single crystal. No site splitting is observed above the transition temperature of the matrix (185 K) and the couplings are not temperature dependent between 185 K and room temperature. From Table 1, it can be seen that the values of the nitrogen and proton isotropic couplings are in good agreement with those found in the other matrices but they are different from those reported in a previous study on the same compound (a_N = 18 G, a_H = 26.7 G) (3).

The dipolar parts of the couplings in this matrix are very different both in magnitude and in sign from those obtained in the betaines and in trimethylammonium chloride. This indicates a difference in the motion of $N\dot{+}(CH_3)_3$ in this matrix which is probably an additional motion of the radical reducing the parallel values of the tensor from the mean values of these couplings in the betaines ($b_N\| = 27.7$ G, $b_H\| = -1.1$ G) to $b_N\| = -7.5$ G and $b_H\| = 0.38$ G. This motion may be either free rotation or jumping reorientation between at least three equivalent positions in the crystal. In both cases the motion has to occur around an axis making an angle of about 23° with the C_{3v} symmetry axis of the radical. Then the parallel coupling becomes

$$2B \sin^2 (23) - B \cos^2 (23) = -7.5$$

where $2B$ is the mean parallel value of the nitrogen dipolar coupling for the $N^+(CH_3)_3$ radical in the matrices studied in this paper (28.3 G).

Conclusion

The measured N and H isotropic coupling constants of the $N\dot{+}(CH_3)_3$ radical are the same within experimental error in all the matrices studied. The only exception is the trimethylam-

monium chloride crystal but it seems that, in this case, steric hindrances may explain the observed distorted structure. Furthermore, the mean values of these couplings in the solid matrices studied (a_N = 21.2 G and a_H = 28.4 G) are in very good agreement with isotropic couplings found in the liquid phase (a_N = 20.55 G and a_H = 28.56 G) (5). This shows that the crystal field has a negligible effect on the structure of the radical, its only effect being to allow or inhibit some kinds of motion of the trapped radical. These motions depend on the dimensions of the trapping cage and also on the motions of the surrounding molecules. A good example is given by the tetramethylammonium chloride matrix. In this crystal the spectrum of $N^{\dagger}\bullet(CH_3)_3$ is well resolved only above 185 K, the transition temperature of the matrix, when the reorientations of the $N^{+}(CH_3)_3$ ions are allowed (4). From the crystal structure (8) it may be shown that even at these temperatures the cage is not large enough to allow the motion seen by esr so that a cooperative motion of the radical with the surrounding molecules has to be invoked to explain the nitrogen and proton couplings.

Kinetics of ligand exchange between a uranium(IV) β-diketonate and free β-diketone

G. FOLCHER, N. KELLER, C. KIENER, AND J. PARIS

CEN-Saclay, Division de Chimie, S.E.P.C.P., B.P. nº 2–91190 Gif-sur-Yvette

Received March 1, 1977

G. FOLCHER, N. KELLER, C. KIENER, and J. PARIS. Can. J. Chem. **55**, 3559 (1977).

The intermolecular ligand exchange kinetics between a uranium(IV) β-diketonate and free β-diketone were studied by ^{1}H nmr as a function of temperature and concentration. The reaction was found to be of first order in both chelate and free ligand. The results suggest that the exchange mechanism involves a ninth coordination site in the uranium(IV) chelate.

G. FOLCHER, N. KELLER, C. KIENER et J. PARIS. Can. J. Chem. **55**, 3559 (1977).

La cinétique d'échange intermoléculaire du ligand entre une β-dicétonate d'uranium(IV) et la β-dicétone libre a été étudiée par rmn du proton en fonction de la température et de la concentration. On montre que la cinétique est du premier ordre par rapport aux deux espèces en échange. Les résultats suggèrent que le mécanisme d'échange implique un neuvième site de coordination dans la chélation de l'uranium(IV).

The kinetics of intermolecular ligand exchange in coordination compounds of uranium(IV) is little known. Johnson and Larsen (1) have measured oxalate exchange lifetimes by using C^{14}-labeled oxalate in tetraoxalatometallates of zirconium(IV), hafnium(IV), and uranium(IV). In the case where uranium(IV) β-diketonates form adducts with a variety of Lewis bases, we have noticed (2) that the base exchange rate is rapid on an nmr time scale. The same holds for the ligand exchange rate between free amino acids and the corresponding uranium(IV) complexes in aqueous solutions (3). By contrast the coordinated proton lifetime in the aquo-ion of uranium(IV) lies between 10 ms and 1 s (4).

Intermolecular ligand exchanges in metal β-diketonate complexes have been followed by nmr spectroscopy: quadrivalent (5, 6), trivalent (6, 7), and divalent (8) compounds have been studied.

The present paper describes the kinetics of intermolecular ligand exchange between a uranium(IV) paramagnetic complex and free ligand in solution. The exchange rates have been followed by high-resolution nmr techniques and have been studied as a function of temperature and concentration (9, 10).

Experimental Section

The $U(fod)_4$ (1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl octane-4,6 dione) is prepared as follows: an aqueous solution of UCl_4 (0.5 *M*) and HCl (1 *N*) is mixed with one Hfod (Pierce Chemicals) equivalent and stirred. Within a few minutes, a solid compound forms. It is filtered, washed with a little petroleum ether, dried, and sublimated at 250°C in a water cooled apparatus under 10^{-2} Torr. The product is reasonably pure (*Anal.* calcd.: U 16.8, C 33.8; found: U 16.8, C 33.6; mp 165°C). The nmr spectra are obtained with a 60 MHz Varian NV-14 spectrometer fitted with a variable temperature probe.

Results

The ^{1}H nmr spectrum of $U(fod)_4$ in solution displays two resonance signals. The first one is assigned to the 36 protons of the four *tert*-butyl groups shifted 5.5 ppm upfield from the corresponding Hfod signal. The second signal is assigned to the four methylene protons. We have chosen to investigate ligand exchange between $U(fod)_4$ and Hfod, by following the variations of the strong *tert*-butyl signals.

Figure 1*A* displays the experimental ^{1}H nmr spectra between 30 and 100°C in deuterated toluene and for concentrations of $[U(fod)_4] = 0.046\ M$ and $[Hfod]_{enol} = 0.238\ M$. In the low temperature range ($T \lesssim 40$°C), the *tert*-butyl proton resonances are separated and remain approximately Lorentzian. As temperature is increased, the two signals collapse at about 100°C.

This behaviour can be explained in terms of ligand exchange between the acid form and the bound form by the following reaction:

$$[1] \qquad U(fod)_4 + Hfod^* \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} U(fod)_3(fod^*) + Hfod$$

In the slow exchange limit, the bound ligand

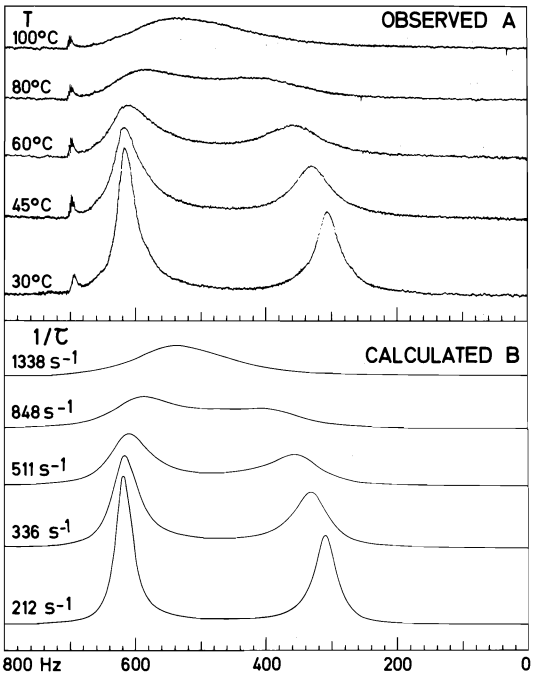

FIG. 1. Proton resonance signals of the (*tert*-butyl) groups in a toluene-d_8 solution of U(fod)$_4$ and Hfod, as a function of temperature, [U(fod)$_4$] = 0.046 *M*, [Hfod] = 0.238 *M*. *A*, experimental spectra; *B*, calculated spectra.

lifetime τ_{UL_4} is given by:

$$[2] \quad \frac{1}{\tau_{UL_4}} = \frac{1}{[UL_4]}\frac{d[UL_4]}{dt} = \frac{1}{T'_{2UL_4}} - \frac{1}{T_{2UL_4}}$$

Transverse relaxation times are obtained from the linewidths observed in the high resolution nmr spectra. T_{2UL_4} stands for the transverse relaxation time of the complex in absence of exchange. The corresponding linewidth $(\Pi T_{2UL_4})^{-1}$ does not vary significantly with temperature and is roughly equal to 1 Hz. The free ligand lifetime τ_{HL} is obtained from an equation analogous to [2].

The exchange reaction rate can be described by the following equation:

$$[3] \quad \frac{4d[UL_4]}{dt} = \frac{d[HL]_{enol}}{dt} = k[UL_4]^m[HL]_{enol}{}^n$$

The kinetic law is first order in UL_4 and HL (Fig. 2).

Temperature Dependence

In the higher temperature range ($T > 40°C$) the condition $1 \lesssim 2\Pi\tau\Delta\nu$ is realized. $\Delta\nu$ is the chemical shift difference between the protons in the free and coordinated sites and $\tau^{-1} =$

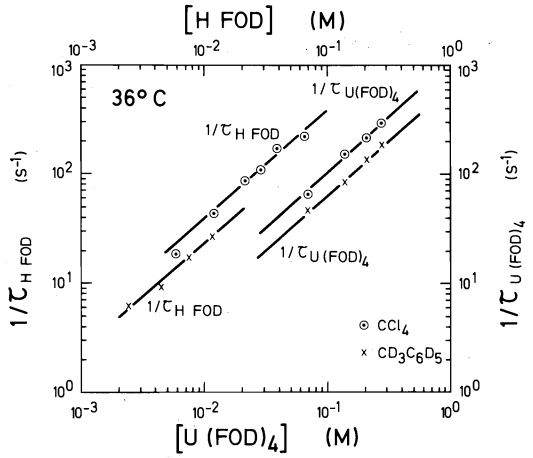

FIG. 2. Log $(\tau_{U(fod)_4}{}^{-1})$ vs. log [Hfod]$_{enol}$ and log $(\tau_{Hfod}{}^{-1})$ vs. log [U(fod)$_4$] at 36°C, ⊙ CCl_4 and × toluene-d_8.

$\tau^{-1}{}_{HL_4} + \tau^{-1}{}_{HL}$ is the ligand exchange rate. The absorption band shapes are calculated under the assumption that the exchange model between two unequally populated sites (11) is applicable. These are fitted to the experimental band shapes. The parameters involved in the fit are temperature dependent: i.e. the exchange time τ and the chemical shift of the bond ligand which is mainly paramagnetic. This paramagnetic contribution varies similarly to the magnetic susceptibility and follows a Curie Law in this temperature range. The best fit for the lineshapes is obtained using the following equation yielding the exchange time:

$$[4] \quad \tau\,(s) = \frac{2365 \times 10^{-7}}{T\,(K)} \exp\left(\frac{5238}{RT\,(K)}\right)$$

There is good agreement between the calculated lineshapes and the experimental spectra (Fig. 1 *A*, *B*). The free energy of activation can be calculated from the value of the rate constant k according to Eyring's equation:

$$[5] \quad k = \frac{\kappa k_B T}{h} \exp -\left(\frac{\Delta G^{\ddagger}}{RT}\right)$$

where the symbols have their usual meanings and by making the assumption that the transmission coefficient κ is equal to 1 (12). The exchange rate is given by:

$$[6] \quad \frac{1}{\tau} = \frac{1}{\tau_{UL_4}} + \frac{1}{\tau_{HL}} = k\left(\frac{[HL]_{enol}}{4} + [UL_4]\right)$$

Hence, the enthalpy and the entropy of activation can both be calculated: $\Delta H^{\ddagger} = 5.2$ kcal/mol and $\Delta S^{\ddagger} = 26$ eu.

Base Dependence

As one equivalent of DMSO is added to a CCl_4 or toluene-d_8 solution of $U(fod)_4$ containing also free Hfod, the bound and free ligand resonances become much narrower. Their linewidths are again of the same order of magnitude (1 Hz) as in the absence of exchange. Simultaneously, we observe an important upfield shift of the DMSO proton signals resulting from the DMSO molecule bounding onto the $U(fod)_4$ chelate (2). The same results have been obtained with strong bases like HMPA, DMF. Therefore the strong bases hinder ligand exchange by forming adducts with the chelates.

Discussion

The crystal structures of several uranium(IV) β-diketonates have been determined by X-ray crystallography (13, 14). The uranium(IV) atom is coordinated to eight oxygen atoms according to a square antiprismatic or dodecahedral arrangement. Besides, a recent study (2) shows that uranium(IV) β-diketonates form adducts with Lewis bases with a possible nine-coordination configuration. The absence of ligand exchange in the presence of a Lewis base suggests that the base occupies the ninth coordination site which is then no longer available. We propose here an exchange mechanism where a free β-diketone (in an enolic form) binds with an UL_4 chelate. From this adduct, the enolic proton escapes along with another ligand L (Fig. 3). Our mechanism differs from that proposed by Adams and Larsen (5) and assumed by Glass and Tobias (6) and also by Tanner, Tuck, and Wells (7). Their mechanism, which appears to apply to the transition metals and tin(II) (8), includes a first step involving the breaking of one metal–oxygen bond which consequently lowers the coordination number. In our case, the breaking of one bond leads to a 7 coordinated uranium which is not likely, while the 9 coordinance is more favorable. Adams and Larsen (5) have reported a faster ligand exchange for thorium(IV) than for zirconium(IV) and hafnium(IV) chelates. The exchange rate for a uranium(IV) chelate is found to be similar to that of the corresponding thorium(IV) chelate. A possible explanation of this behaviour is the existence of an accessible ninth coordination site which confers to the actinide complexes a greater lability as compared to transition metal complexes.

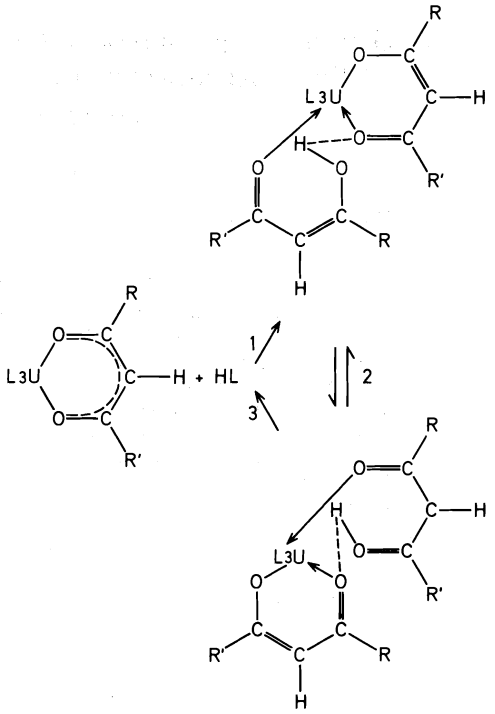

FIG. 3. Exchange mechanism where L represents a β-diketone ligand.

Cyclization of glycol monoesters to give hemiorthoesters: a test of the thermochemical method for determining free energies of tetrahedral intermediates

J. Peter Guthrie[1]

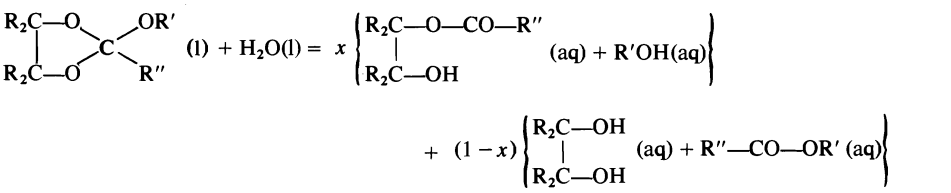
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 9, 1976[2]

J. Peter Guthrie. Can. J. Chem. **55**, 3562 (1977).

From calorimetric heat of formation data, free energies of cyclization (to the hemiorthoester) for the following glycol monoesters have been calculated: ethylene glycol monoformate, +7.54; ethylene glycol monoacetate, +10.72; pinacol monoformate, +3.21; ethylene glycol monotrifluoroacetate, +2.83; pinacol monotrifluoroacetate, −3.38. The latter two results are shown to be in satisfactory agreement with experimental results. This investigation represents a further test of the thermochemical method for calculating free energies of tetrahedral intermediates in acyl transfer reactions which was reported earlier.

In the course of this work, various thermochemical quantities were determined. Heats of reaction for the process:

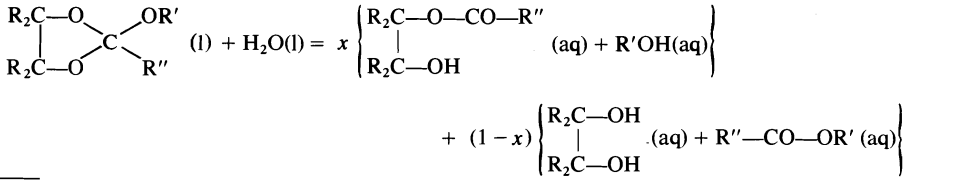


have been measured for three compounds: **1**, R = H, R′ = CH_3, R″ = H; $x = 0.92$, $\Delta H_{obs} = -7.13 \pm 0.60$ kcal/mol; **2**, R = H, R′ = CH_3, R″ = CH_3; $x = 0.98$, $\Delta H_{obs} = -10.11 \pm 0.40$ kcal/mol; **9**, R = CH_3, R′ = C_2H_5, R″ = H; $x = 0.98$, $\Delta H_{obs} = -4.76 \pm 0.19$ kcal/mol. From these may be obtained heats of formation of the liquids: **1**, −126.01 ± 0.94; **2**, −137.25 ± 0.87; **9**, −173.87 ± 2.09 kcal/mol. For some related esters, heats of hydrolysis were measured, leading to the following heats of formation of the liquids: *tert*-butyl formate, −117.85 ± 0.80; *tert*-butyl trifluoroacetate, −271.28 ± 1.14; pinacol monoformate, −175.02 ± 2.12 kcal/mol. Heats of hydrolysis were measured for methoxyethyl formate and acetate, but in the absence of a reliable value for the heat of formation of methoxyethanol, do not lead to calorimetric heats of formation. Equilibrium constants for formation of the monoesters of ethylene glycol with formic, acetic, and trifluoroacetic acids were measured (nmr analysis of equilibrated solutions) and lead to free energies of hydrolysis of −2.34, −1.65, and −2.75 kcal/mol respectively.

J. Peter Guthrie. Can. J. Chem. **55**, 3562 (1977).

On calcule, à partir des enthalpies de formation, obtenues par calorimétrie, les énergies libres de cyclisation (pour former l'hémiorthoester) des monoesters de glycol suivants: le monoformiate d'éthylène glycol, +7.54; le monoacétate d'éthylène glycol, +10.72; le monoformiate de pinacol, +3.21; le monotrifluoroacétate d'éthylène glycol, +2.83; le monotrifluoroacétate de pinacol, −3.38. Ces deux derniers résultats sont en bon accord avec les résultats expérimentaux. Cette étude représente un autre essai de la méthode thermochimique pour le calcul des énergies libres des intermédiaires tétrahédriques dans les réactions de transfert de groupes acyle rapportée antérieurement.

Dans ce travail, plusieurs entités thermochimiques sont déterminées. Les chaleurs de réaction pour le processus suivant:



---

[1]Alfred P. Sloan Fellow, 1975–1977.

[2]Revision received May 5, 1977.

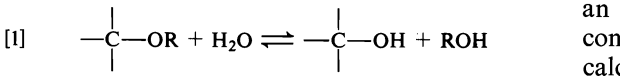
sont mesurées pour trois composés: **1**, R = H, R′ = CH_3, R″ = H; $x = 0.92$, $\Delta H_{obs} = -7.13 \pm 0.60$ kcal/mol; **2**, R = H, R′ = CH_3, R″ = CH_3; $x = 0.98$, $\Delta H_{obs} = -10.11 \pm 0.40$ kcal/mol; **9**, R = CH_3, R′ = C_2H_5, R″ = H; $x = 0.98$, $\Delta H_{obs} = -4.76 \pm 0.19$ kcal/mol. De ces données, on peut obtenir les chaleurs de formation des liquides; **1**, -126.01 ± 0.94; **2**, -137.25 ± 0.87; **9**, -173.87 ± 2.09 kcal/mol. A partir des mesures des chaleurs d'hydrolyse de quelques esters analogues, on obtient les chaleurs de formation suivantes des liquides: formiate de *tert*-butyle, -117.85 ± 0.80; trifluoroacétate de *tert*-butyle, -271.28 ± 1.14; monoformiate de pinacol, -175.02 ± 2.12 kcal/mol. Les chaleurs d'hydrolyse sont obtenues pour le formiate et l'acétate de méthoxyéthyle; n'ayant pas une bonne valeur de chaleur de formation du méthoxyéthanol, il n'est pas possible de calculer les chaleurs de formation calorimétriques. Les constantes d'équilibre de formation des monoesters d'éthylène glycol par les acides formique, acétique et trifluoroacétique sont mesurées (analyse rmn des solutions équilibrées), puis on en déduit les énergies libres d'hydrolyse qui sont respectivement de -2.34, -1.65 et -2.75 kcal/mol.

[Traduit par le journal]

Introduction

The vast majority of acyl transfer reactions proceed by way of tetrahedral intermediates (1), although other mechanisms intervene for some special situations (2). These intermediates are normally much too unstable to be detected, although stable analogs are known in the form of orthoesters and related compounds (3). In some cyclic or polycyclic compounds species analogous to the tetrahedral intermediates in ester hydrolyses, i.e. orthoacid diesters or hemiorthoesters, are thermodynamically favored relative to the ordinary ester plus alcohol (4, 5). There have been to date only two cases where the equilibrium constant for formation of a neutral tetrahedral species has been directly measured (4, 5), and one for formation of an anionic species (6, 7).

Recently, a method has been developed for evaluating the free energies of formation of tetrahedral intermediates (7–10), starting with the free energies of formation of the orthoester analogs. The basis of this method is that the dependence of the (symmetry corrected) free energy change for process [1] upon steric and electronic factors can be evaluated for alcohols,



[1]

carbonyl hydrates, and hemiacetals from experimental data, and then (with a small extrapolation) applied to orthoesters. All available data for free energies of formation of ethers and alcohols and for equilibrium constants for hemiacetal and acetal formation involving methanol or ethanol and carbonyl compounds could be fitted to a straight line relating ΔG^0 to $\Sigma\sigma^*$, once steric and symmetry factors were allowed for (10).

This procedure has been applied to esters (7, 8), and amides (9), and gave results which were intuitively reasonable. Having a method for evaluating the equilibrium constant for addition to acyl groups should prove very useful in mechanistic analysis since it permits calculation of all the microscopic rate constants in favorable cases, whereas the best that can be done without the equilibrium constant for formation of the tetrahedral intermediate is to evaluate the rate constant for addition and the partitioning ratio. Indeed, the method has already been employed in this way (11). Although the basis of the method appears sound, it does involve an extrapolation, so that it seems desirable to test it as thoroughly as possible.

The first such test involved the addition of methanol to methyl trifluoroacetate (7). The equilibrium constant for addition of methoxide ion, in methanol, to methyl trifluoroacetate to give the anionic addition compound is readily measurable. Unfortunately, a direct test of the thermochemical approach was not possible, since the hydrolysis of trimethyl orthotrifluoroacetate was too slow to permit measurement of the heat of hydrolysis (7). In the absence of a heat of combustion for this orthoester, only an indirect test was possible. The equilibrium constants for addition of water to the acids, calculated using equilibrium constants for [1], and starting from the free energies of formation of trimethyl orthoacetate and trimethyl orthoformate, and the equilibrium constant for addition of methanol to methyl trifluoroacetate, showed a linear dependence upon σ^* with a slope similar to, but somewhat larger than, the slope which was observed for addition of water to the analogous carbonyl compounds (8).

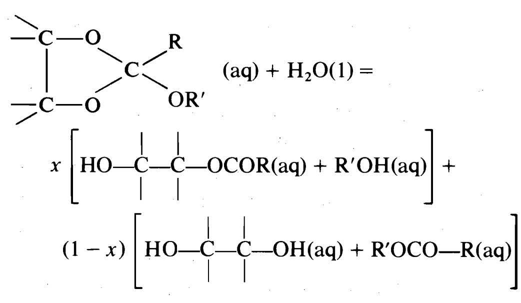
This paper reports another test of the method, employing it to calculate the equilibrium constants for cyclization of glycol monoesters to

hemiorthoesters. Hine *et al.* (5) found that pinacol monotrifluoroacetate (and monotrichloroacetate) was partially or predominantly (depending upon the solvent) present as the hemiorthoester. For the monoesters of ethylene glycol the presence of the hemiorthoester could be demonstrated by trapping experiments, although it could not be detected spectroscopically (5). A direct application of the thermochemical method is not practical, since the heats of hydrolysis of the appropriate orthoesters are not measurable for technical reasons (7). Accordingly, an indirect test has been carried out, by determining the heats of formation, and hence the free energies of formation of analogous orthoformates and acetates, and then calculating the desired free energies of formation of the orthotrifluoroacetates by methods based upon the assumption of group additivity. From these values, equilibrium constants for the cyclization reactions could be deduced; these will be seen to be in satisfactory agreement with the experimental values.

Results

Calorimetric heats of reaction and solution determined in this work are found in Table 1. For the cyclic orthoesters, it was necessary to determine the stoichiometry of the reaction, expressed as x, the fraction of hydrolysis leading to the glycol monoester. Nuclear magnetic resonance analysis of product solutions permitted the determination of the product ratio; the final heat of formation of the orthoester is relatively insensitive to experimental errors in the stoichiometry. In order to calculate the heat of formation of the orthoester from the heat of reaction [2], it is also necessary to have heats of

[2]



formation for the products. Literature values are available for methanol, ethanol, methyl formate, ethyl formate, methyl acetate, ethylene glycol, methoxyethanol, and pinacol (see Table 2; for the latter two, see also the Discussion section). The heat of formation in aqueous solution of pinacol monoformate could be calculated from the heats of hydrolysis and solution measured in this work. Although the monoformate and monoacetate of ethylene glycol are known compounds (12), it seemed likely that they would be difficult to obtain free of the diester and glycol (13). Accordingly, the heats of formation have been calculated on the assumption that the heat of hydrolysis for reaction [3] is independent of

$$[3]\quad R{-}O{-}CH_2{-}CH_2{-}O{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}R'(aq) + H_2O(l) = ROCH_2CH_2OH(aq) + HO\overset{\overset{\displaystyle O}{\|}}{C}{-}R'(aq)$$

whether R is H or CH_3, using heats of reaction and solution for methoxyethyl formate and acetate determined in this work. The heats of formation of the orthoesters are found in Table 2. Entropy values were calculated by standard estimation procedures. Where possible, free energies of transfer from gas to aqueous solution were calculated from solubility and vapor pressure data. For those compounds which were excessively water soluble (methoxyethyl acetate, methoxyethyl formate, 2-methoxydioxolane, 2-methoxy-2-methyldioxolane), free energies of transfer were calculated by the group equivalent method of Hine and Mookerjee (14).

Equilibrium constants for the formation of the ethylene glycol monoesters of acetic, formic, and trifluoroacetic acids were determined by nmr analyses of solutions containing the acid, the glycol, and (except in the case of trifluoroacetic acid) 0.1 N HCl as a catalyst. The ester signal was integrated relative to the signal from the acid, or, when very little ester was present, the ^{13}C satellite of the signal from the acid. In some cases it was necessary to shift the pH to 7 after equilibrium had been established in order to get adequate separation of the ester and acid signals, since the acid and not the ester undergoes titration and consequently the resonance position shifts. The results of these experiments are found in Table 3. Free energies of formation of the esters were calculated from these results and the free energies of formation of the other reactants, and are found in Table 2. The free energy of formation (in aqueous solution) of pinacol monoformate is more difficult to obtain, since the equilibrium is quite far on the side of hydrolysis. For neither pinacol nor pinacol monoformate could the free energy of transfer

be determined by the simple method involving solubilities and vapor pressures, since pinacol forms a hexahydrate on contact with water and solubility and vapor pressure do not therefore refer to the same species, and pinacol monoformate is miscible with water. Two methods were used to calculate the free energy of pinacol monoformate. In the first, free energies of transfer were calculated by methods based upon the assumption of group additivity. From the known free energy of transfer of ethylene glycol, and the group contributions for $CH_2(C)(O)$, $CH_3(C)$, and $C(C)_3(O)$ a free energy of transfer for pinacol could be calculated. For pinacol monoformate, a

[a]In aqueous solution: standard state for water is the pure liquid with unit activity.
[b]Calculated from the free energy of formation data in Table 2.

value for the free energy of transfer was calculated from the group contributions reported by Hine and Mookerjee, with the inclusion of the 'distant polar interaction' which they report for ethylene glycol. This is equivalent to the assumption that in both ethylene glycol and pinacol monoformate an intramolecular hydrogen bond is present in the gas phase. In the second method, the assumption was made that the free energy of hydrolysis of pinacol monoformate was the same as for *tert*-butyl formate. This assumption involves the subsidiary assumption that the second hydroxyl in pinacol does not affect the stability of the ester in a strongly hydrogen bonding solvent such as water. The agreement between the two methods is good (see Table 4). The free energy of formation (in aqueous solution) for pinacol monotrifluoroacetate was calculated using the assumption that the free energy of hydrolysis for this ester was the same as for *tert*-butyl trifluoroacetate. The latter value was calculated from the heat of hydrolysis determined in this work.

The free energies of formation for **3** and **11** were calculated from those for **1** and **2**, and **10** respectively. The free energy of formation of **10** was calculated from that for **9** making the assumption that the free energy change for

$CF_3C(OCH_3)_3$	−231.00(1.30)		−233.34(2.75)[c]	−2.34[d]

[a]In aqueous solution at 25°C; kcal mol^{-1}.
[b]$\Delta\Delta G_f^0 = \Delta G_f^0$ dioxolane − ΔG_f^0 orthoester.
[c]Calculated using the appropriate value for $\Delta\Delta G$.
[d]Assumed.

reaction [4] was zero. Advantage was taken of the small, and within experimental error constant, magnitude of the difference in free energy of formation of **1** and trimethyl orthoformate, or **2** and trimethyl orthoacetate (see Table 5). The corresponding quantity for the trifluoroacetates was also assumed to be constant. This assumption is equivalent to the assumption of group additivity; the particular method employed has the advantage of using a small difference in free energies of formation. Similarly the free energy of formation of **11** was calculated making the assumption that the difference in free energies of formation of **11** and trimethyl orthotrifluoroacetate was the same as that for **10** and trimethyl orthoformate.

[4]  (aq) + MeOH(aq) =

 (aq) + EtOH(aq)

Finally, the free energies of formation of **4**, **5**, **6**, **12**, and **13** were calculated from those for **1**, **2**, **3**, **9**, and **11** by the methods previously described (10).

Thermodynamic data for all the compounds discussed in this paper are found in Table 2. Further details of the calculation procedure are to be found in the Experimental.

In principle, all of the group equivalents (and most of the steric interaction corrections) necessary to calculate $\Delta H_f^0(g)$, $S^0(g)$, and ΔG_t for the compounds considered in this paper are available, either from the tabulations in Benson (17, 18) and Hine (14), or from other work. In order to test the predictive power of these methods, and also as a check on the calorimetric determinations, values were calculated for many of the compounds in Table 2. In the case of hydroxy compounds, no correction to $\Delta H_f^0(g)$ was made for hydrogen bond formation (since the heat of hydrogen bond formation in the gas phase is unknown), and therefore the 'distant polar interactions' correction to ΔG_t was that for

RO—C—C—OR and not for HO—C—C—OH (14). The values so calculated are also found in Table 2. The agreement is quite satisfactory, and indicates that the group contributions approximation is quite satisfactory for these compounds, provided that adequate corrections can be made for steric interactions. In the case of the pinacol orthoesters and monoesters, the magnitudes of the steric corrections necessary were not obvious, and experimental measurements were obligatory.

Equilibrium constants for the cyclization reactions are found in Table 6, which compares the thermochemical and experimental values. Despite the fact that the thermochemical values were necessarily calculated in a rather roundabout way the agreement is satisfactory.

Discussion

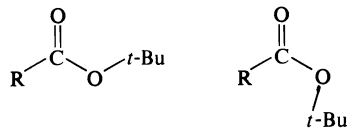
Thermochemical Quantities

Several of the heat of formation values upon which this work is based are less reliable than would be desired: the values for methoxyethanol and pinacol are old (pre 1930 (15)), and could be in error by several kilocalories (although the pinacol value is consistent with values calculated by the group additivity scheme, the value for methoxyethanol is in disagreement by 14 kcal/mol, whether the calculated value is estimated directly or indirectly, starting with an estimated value for methoxyethyl formate, and using the experimental value for the heat of hydrolysis). Although this introduces a systematic error of unknown magnitude into the enthalpies and free energies of formation of each series of esters and orthoesters, it does not affect the relative values within each series, nor the absolute values of the free energy changes for the cyclization reactions.

Steric Interactions

Several of the compounds studied in this work are subject to significant crowding; for these compounds comparison of the observed free energies of formation with those calculated by the group additivity method permits an evaluation of the magnitude of this interaction (subject to possible systematic errors resulting from the uncertainty in the heat of formation of pinacol).[3]

For *tert*-butyl formate, the observed strain is 2.53 ± 2.13 kcal/mol; for *tert*-butyl trifluoroacetate the observed strain is 3.39 ± 2.72 kcal/mol. These values are indistinguishable within experimental error, and therefore it seems probable that both esters adopt the same conformation, **14**, with the carbonyl eclipsing the



14 **15**

tert-butyl group rather than **15**, since the latter conformation would show a significant increase in crowding when R changes from H to CF_3.[4]

For pinacol the observed strain is 2.13 ± 2.85 kcal/mol; for pinacol monoformate the strain is higher, 6.95 ± 3.07 kcal/mol; the strain in **9** is only 2.07 ± 2.92 kcal/mol, which is within experimental error the same as for pinacol. Cyclization of pinacol monoformate to the orthoester apparently provides considerable relief of strain.

Free Energies of Cyclization

In Table 6 are summarized the thermochemically derived free energies of cyclization which were the object of this investigation, as well as the experimental values of Hine *et al.* (5) which permit a test of the thermochemical approach.

In calculating the probable errors for Table 6, it was necessary to perform a complete error analysis to determine the terms which actually contributed to the uncertainty in the change in free energy for cyclization. The uncertainties in free energy of formation in Table 2 are not independent quantities for related orthoesters and glycol monoesters. Consequently the uncertainties reported are in some cases significantly smaller than would be obtained directly from Table 2.

For the monoformates and monoacetates of ethylene glycol, the free energies of cyclization are quite unfavorable (and in fact are only about 3 kcal/mol more favorable than for the analogous intermolecular reaction of methanol with the methyl esters (7)), so that these reactions

[3]The effect of alkyl substituents upon the ease of ring formation (the *gem*-dialkyl effect) has been shown to result from both enthalpic and entropic contributions (44) for the case of six-membered rings. The 'strain energies' evaluated in this section will likewise contain both enthalpic and entropic contributions.

[4]Esters normally adopt the *s-trans* (*Z*) conformation **14** (45), but for *tert*-butyl esters it seemed quite possible that there might be a shift to the *E* conformation **15**, particularly in the case of the formate. This appears not to have happened.

TABLE 6. Free energies of cyclization for glycol monoesters

[a]In kcal mol^{-1}.
[b]Calculated using pK_a values estimated (by methods described in ref. 8) as 14.4(1.0) for $HOCH_2CH_2OCOCF_3$ and 8.8(1.0) for **6**.
[c]Reference 5; although no equilibrium constant could be measured for cyclization of $HOCH_2CH_2OCOCF_3$ or its anion, it was demonstrated that some **6** was present in neutral solutions, and that extensive cyclization occurred in basic solutions.

are essentially unobservable by any direct method. Pinacol monoformate shows a much greater tendency to cyclize, although the equilibrium is still sufficiently unfavorable that the noncyclic form predominates overwhelmingly, and is the only species observable in the nmr spectrum. Comparison of Tables 6 and 7 shows that the greater tendency for pinacol monoformate to cyclize, relative to ethylene glycol monoformate, may be attributed to relief of steric compression involving the methyl groups of pinacol. It would be of interest to see if molecular mechanics calculations predict an effect of this magnitude, but unfortunately no calculation for the appropriate tetramethyl cyclopentane appears to have been done.

Ethylene glycol monotrifluoroacetate shows the expected (7) increase in cyclization tendency resulting from the electron withdrawing acyl substituent, but the equilibrium is still unfavorable for the neutral compound. The thermochemical prediction is in accord with experiment, since Hine *et al.* (5) report that none of the cyclic form could be detected, although enough of this rather acidic hydroxyl compound was present to be trapped by diazomethane. Using pK_a values estimated using ρ^*–σ^* correlations (7), the free energy of cyclization of the anion of ethylene glycol monotrifluoroacetate can be estimated as -4.82 ± 2.80 kcal/mol, which is consistent with the observation that addition of this ester to a solution of sodium 2-hydroxyethoxide in ethylene glycol leads to rapid formation of a less basic species, presumed to be the conjugate base of **6**, followed by a slower decomposition (5).

When both of the effects which favor cyclization (electron withdrawing acyl substituent and steric compression by methyl substituents) operate together, as in pinacol monotrifluoro-

TABLE 7. Strain energy for crowded compounds

Compound	ΔG_f^0(aq)[a] Ideal	ΔG_f^0(aq)[a] Experimental	$\Delta\Delta G_f^0$(aq)[a]

[a]In kcal mol^{-1}; no corrections for *gauche* interactions.
[b]Difference in strain between pinacol monoformate and pinacol.
[c]Calculated including a correction for ring strain (ref. 16), but no corrections for steric interactions.

acetate, the cyclization of the neutral ester becomes favored. The calculated value of -3.38 ± 2.75 kcal/mol, aqueous solution, is in satisfactory agreement with the observed value of -1.75 kcal/mol in dioxane or acetonitrile.[5]

The results in Table 6 show that predictions based upon the thermochemical method developed in this laboratory for calculating the free energies of formation of tetrahedral intermediates are in satisfactory agreement with the available data for cyclization of glycol monoesters, and provide a means to calculate the equilibrium constant for cyclization in cases where direct measurement is impossible. The results in this paper constitute a further test of the method, which demonstrably had led to valid results in those cases where comparison with experiment has been possible, and therefore may be assumed to be a reliable guide when no other source of information is available, as is the case for almost all tetrahedral intermediates in acyl transfer reactions.

Furthermore, the results in Table 2 show that the free energies of formation of the orthoesters could be calculated quite successfully by the group additivity methods of Benson and coworkers (17, 18) and Hine and Mookerjee (14) in the absence of severe steric interactions. For many classes of organic compounds calculations by these methods deserve to be considered competitive with experiment as sources of thermodynamic information. Calculations of this sort coupled with extrathermodynamic relations of the sort used to obtain free energies of formation of tetrahedral intermediates from free energies of formation of orthoesters (7–10) are potentially a very powerful source of information otherwise unobtainable concerning the energetics of reaction intermediates. It is the thesis of this paper that these calculational methods deserve to be included in the standard armamentarium of the physical organic chemist engaged in studying the mechanisms of reactions in solution.

[5]Although an experimental value for the free energy of cyclization for pinacol monotrifluoroacetate in aqueous solution would be extremely desirable, it is likely to be extremely difficult to measure, if it is ever possible, because of the rapid and irreversible hydrolysis of trifluoroacetate esters (28). The solvent effect has been attributed (5) to the need for a hydrogen bond accepting solvent to stabilize the cyclic hemiorthoester, which cannot form an intramolecular hydrogen bond as can the acyclic tautomer. However, the well known insensitivity of hydrogen bond strength to acceptor basicity (46), which is borne out by the identity of equilibrium constants in dioxane and acetonitrile, despite the very different basicities of the solvents, suggests that the equilibrium constant in water will be very similar to that in acetonitrile.

Experimental

Materials

Ethylene glycol, methoxyethanol, triethyl orthoformate, trimethyl orthoformate, trifluoroacetic acid, and *tert*-butyl alcohol were reagent grade chemicals, redistilled before use if necessary. Pinacol was freed of water by azeotropic distillation with benzene and recrystallized from benzene – petroleum ether and then pentane; mp 41.5–44°C; lit. (19) mp 42.5–44.5°C.

Methoxyethyl formate was prepared by the method of van Es and Stevens (20) for alkyl formates; bp 126.5–128.5°C; lit. (21*a*) bp 131°C. Methoxyethyl acetate was

prepared from methoxyethanol and acetic anhydride; bp 64–66°C (12 Torr); lit. (21*b*) bp 144°C. **1** and **2** were prepared by exchange reactions from the trimethyl orthoester and ethylene glycol (21*c*); bp (**1**) 126–129°C; lit. (21*b*) 129.5°C; (**2**) 129°C; lit. (22) 132–134°C. **9** was prepared from triethyl orthoformate and pinacol by the method of Crank and Eastwood (23); bp 78–80°C (12 Torr); lit. (23) bp 72–75°C (17 Torr); 168–172°C. **7** was prepared from **9** by partial hydrolysis (23); **9** was dissolved in 0.001 *N* HCl, allowed to stand a few minutes, neutralized with bicarbonate, and extracted repeatedly with ether; bp 80–82.5°C (12 Torr); lit. (24) bp 84–85°C (18 Torr). *Tert*-Butyl formate was prepared by the method of Stevens and van Es (20, 25); bp 82°C, lit. (25) bp 83°C. *tert*-Butyl acetate was prepared by the method of Hauser *et al.* (26); bp 96°C; lit. (26) bp 97°C. *tert*-Butyl trifluoroacetate was prepared by the method of Bourne *et al.* (27); bp 84.5°C; lit. (27) bp 85–86°C. All compounds were checked for purity by nmr spectroscopy.

Methods

Heats of reaction and solution were measured using a simple Dewar calorimeter of the kind previously described (9). Solubilities were measured as previously described (7), by nmr analysis of equilibrated samples, integrating relative to suitable internal standards. In this way were measured the following solubilities in water at 25 ± 2°C: **1**, ca. 3 *M*; **2**, ca. 2 *M*; *tert*-butyl formate, 0.30 ± 0.3 *M*; *tert*-butyl acetate, 0.043 ± 0.004 *M*; **9**, 0.104 ± 0.001 *M*; methoxyethyl formate and acetate were miscible with water as was **7**. Since *tert*-butyl trifluoroacetate hydrolyzes rapidly (28), its solubility was estimated from that of *tert*-butyl acetate using the relationship between solubility and hydrophobicity (measured by Hansch π values (29)) (30) and the π values for CH_3 and CF_3 bound to carbonyl groups (31).

The stoichiometry of the hydrolysis of **1**, **2**, or **9** was determined by nmr analysis of a solution obtained from 100 μl of the orthoester in 1.0 ml of 0.001 *N* HCl. A lower concentration of HCl than in the calorimetric measurements was used to slow the hydrolysis of the esters which are the immediate products of hydrolysis from the orthoesters. Error analysis shows that the final results are insensitive to errors in the stoichiometry.

Equilibrium constants for ester formation were determined by dissolving weighed amounts of acid and alcohol, with 1 ml of 1 *N* HCl in a known total volume (made to 10 ml with water). After standing overnight at room temperature (24 ± 1°C), the solutions were analyzed by nmr. If the acid and ester peaks were not resolved, a portion of the equilibrium solution was titrated to p*H* 7 (p*H* meter) using saturated aqueous Na_3PO_4. Ionization of the carboxylic acid caused a chemical shift sufficient for easy resolution of the ester and 'acid' peaks.

For this work, the literature value of the heat of formation of solid pinacol was used. The heat of vaporization was estimated from the available boiling point data (bp 173°C at 762 Torr, bp 85°C at 21 Torr) by fitting to the Antoine equation

$$\log p = A - B/(t + C)$$

with $C = 230$. Empirically this equation has been found to correlate vapor pressure data for a wide range of compounds remarkably well (16). The heat of vaporization of the liquid was then calculated from the derivative of this equation; the value so obtained was 14.08 kcal/mol. The heat of melting was estimated by assuming that the entropy of melting is the same as that for *tert*-butyl alcohol, i.e. 5.32 eu (15). Then from the melting point (41°C), the heat of melting is 1.67 kcal/mol, and the heat of sublimation is 15.75 kcal/mol. For methoxyethanol, the heat of formation employed for calculations was that derived from the heat of hydrolysis of methoxyethyl formate, starting with the heat of formation of the ester estimated by the group additivity method.

Calculations

Vapor pressures were calculated from the normal boiling point using heats of vaporization estimated using the Wadsö equation (32), and an average value of -12 cal deg^{-1} mol^{-1} for the heat capacity of vaporization (33). When the only available boiling point was at reduced pressure, the normal boiling point was estimated by iterative solution of the equation obtained by substituting the Wadsö equation into the integrated equation for ln *p* as a function of *T*.[6]

Free energies of transfer were calculated from vapor pressure and solubility data as previously described (8).

Entropy Values

Wherever possible, entropy values were taken from standard compilations (15, 34); where no literature values were available, the entropies were estimated by accepted procedures, using, in order of preference, the methods of substitution (15), starting with the analogous hydrocarbon (for **1**), the method of group contributions (18) (for methoxyethanol, **2**, *tert*-butyl formate, methoxyethyl acetate, pinacol, pinacol monoformate, and **9**), and the method of atomic contributions (17) (for *tert*-butyl trifluoroacetate).

ZAHID AMJAD, JOHN G. CHAMBERS, and ALEXANDER MCAULEY. Can. J. Chem. **55**, 3575 (1977).

The oxidation of 2-mercaptosuccinic (thiomalic) acid (HRSH) by thallium(III) proceeds via an inner sphere mechanism. Spectrophotometric and kinetic evidence are provided for the formation of a sulphur-bonded thallium(III) intermediate. The data are consistent with the reaction scheme

$$TlOH^{2+} + HRSH \underset{}{\overset{K_2}{\rightleftharpoons}} [TlSRH]^{2+} \xrightarrow{k_2} Tl(II) + HRS^{\cdot}$$

in which the complex decomposes via a one-electron intramolecular transfer $k_2 = 3.8 \times 10^{-4}$ s^{-1} at 25°C, with $K_2 = 1650\ M^{-1}$. The enthalpy of activation $\Delta H_2^{\ddagger}$ for the redox reaction (11.8 ± 1.2 kcal/mol) is considerably smaller than for other systems of this type and reflects the greater ease of reaction. Comparison is made of possible one- and two-electron transfer pathways.

ZAHID AMJAD, JOHN G. CHAMBERS et ALEXANDER MCAULEY. Can. J. Chem. **55**, 3575 (1977).

L'oxydation de l'acide mercapto-2 succinique (thiomalique) (HRSH) par le thallium(III) procède selon un mécanisme "sphère interne". Les résultats des mesures spectrophotométriques et cinétiques sont en faveur de la formation d'un complexe intermédiaire présentant une liaison soufre–thallium(III). Ces résultats sont en accord avec le schéma réactionnel suivant:

$$TlOH^{2+} + HRSH \underset{}{\overset{K_2}{\rightleftharpoons}} [TlSRH]^{2+} \xrightarrow{k_2} Tl(II) + HRS^{\cdot}$$

dans lequel le complexe intermédiaire se décompose par transfert intramoléculaire d'un électron ($k_2 = 3.8 \times 10^4\ s^{-1}$ et $K_2 = 1650\ M^{-1}$ à 25°C). L'enthalpie d'activation $\Delta H_2^{\ddagger}$ pour la réaction d'oxydation–réduction (11.8 ± 1.2 kcal mol^{-1}) est considérablement plus petite que pour d'autres systèmes du même genre et reflète une plus grande réactivité. On fait une comparaison entre la possibilité d'un processus par transfert d'un ou de deux électrons.

[Traduit par le journal]

Thallium(III) has recently been used as a mild oxidant in the reactions of a variety of organic compounds (2, 3). Most of these oxidations have been carried out in acetate media owing to solubility problems associated with more polar media. In some instances, nitrate, sulphate, and chloride salts have been investigated in aqueous solutions but difficulties in interpretation arise from the presence of several reactant Tl(III) complexes (4). The situation is somewhat clearer in perchloric acid media where there is less tendency for complexation between Tl^{3+} and ClO_4^- to occur.

Recently, the stopped-flow technique has been used to investigate the oxidation of catechol and other 1,2- and 1,4-dihydroxybenzenes (5–7). In these reactions there is no spectroscopic or kinetic evidence for any precursor complex formation prior to the electron transfer step except in the case of the adrenaline oxidation (7) where kinetic parameters are suggestive of the existence of an intermediate. Spectrophotometric evidence for complex formation in Tl(III) oxidations of this type was first provided by Halvarson and Halpern (8) in the reaction with formic acid. Kinetic analysis of the reaction with phosphorous acid (9) is also consistent with an initial preequilibrium.

The oxidation of sulphur-containing substrates by various metal ions has been the subject of

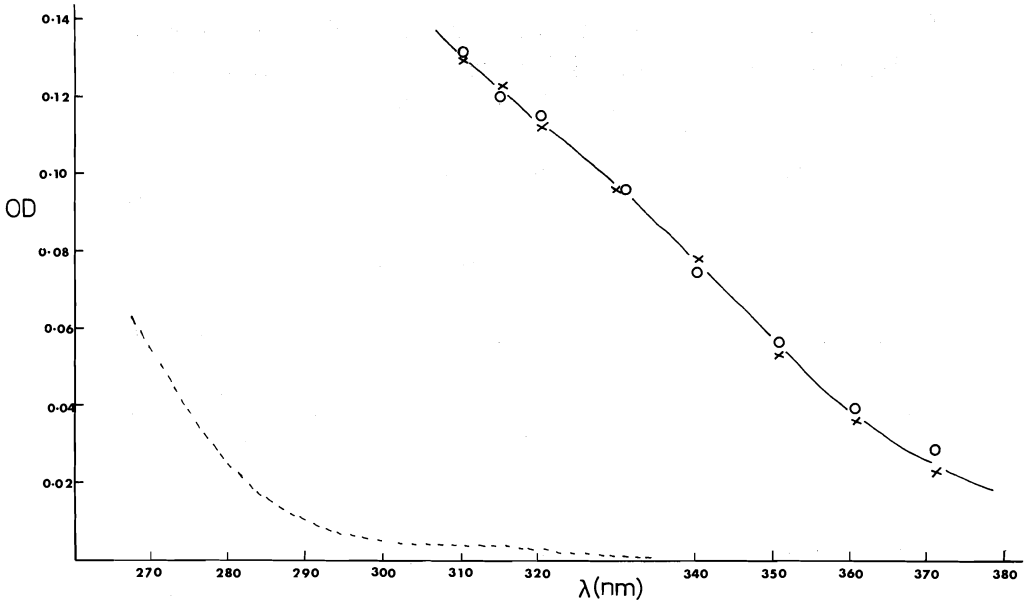

FIG. 1. Spectrum of Tl(III)–thiomalic acid intermediate. $T = 25°C$; $[H^+] = 1.00\ M$; $I = 2.00\ M$. (○) $[Tl(III)] = 3 \times 10^{-4}\ M$, [thiomalic acid] $= 3 \times 10^{-4}\ M$; (×) $[Tl(III)] = 3 \times 10^{-4}\ M$, [thiomalic acid] $= 3 \times 10^{-3}\ M$; (-) $[Tl(III)] = 3 \times 10^{-4}\ M$.

numerous investigations and in many instances (e.g. with Fe(III) (10), V(V) (11), Cr(VI) (12)) intermediates have been characterized from initial absorbance changes. There are, however, no data available on the reactions of thallium(III) with thiols and it is of interest to examine whether Tl(III)–sulphur bonded complexes have any significant thermodynamic stability in aqueous media. In the present study, the reaction with thiomalic acid (2-mercaptosuccinic acid) has been investigated at various ligand and hydrogen ion concentrations using stopped-flow and conventional methods.

Experimental

Thallium(III) perchlorate was prepared by dissolution of Tl_2O_3 (Koch-Light 99.99% pure) in 5–7 M $HClO_4$ at 60–70°C over a period of 6–8 h. An alternative approach was also used where after reaction of Tl_2CO_3 with excess $HClO_4$, the washed acidified slurry of thallium(I) perchlorate was electro-oxidized at room temperature until all the metal ion was dissolved. The thallium(III) concentration was determined by dilution of a known volume of the stock to yield a solution less than 0.5 M in $HClO_4$. Addition of 2% KI was followed by titration against sodium thiosulphate. The end point was marked by the change from dirty blue to the clear yellow of the precipitate of thallium(I) iodide. The thallium(I) content of the stock was determined following addition of HCl by titration with potassium iodate with chloroform as indicator. The analytical hydrogen ion concentration was determined by dilution, reaction with H_2O_2 to reduce the metal ion and after cooling, titration with standard base, due account being taken of the protons liberated in the peroxide reduction. Freshly prepared $Tl(ClO_4)_3$ solution (ca. 0.225 M Tl^{3+} in 6.39 M $HClO_4$) was found to contain less than 0.1% Tl(I) and storage at ~5°C in a dark bottle showed a content of <0.3% after 3 months.

Thiomalic acid (Evans Chemetics or Koch-Light (pure)) was used. In some instances material re-crystallized from ethanol was also reacted. The preparation and standardization of sodium perchlorate, lithium perchlorate, and perchloric acid have been described previously (10).

The product disulphide was identified spectroscopically. Whereas the thiol shows only a broad band in the range 200–230 nm, the disulphide exhibits a peak at 215 nm. On reacting solutions of Tl(III) and thiol in 0.5 M $HClO_4$ the spectrum produced was identical to that obtained on treatment of a solution of the thiol with hydrogen peroxide which is known to yield the disulphide.

Kinetic Measurements

The reactions were investigated in an excess of thiomalic acid in order to maintain the disulphide as product and to minimize any overoxidation which has been observed previously in reactions of this type (13). A modified two-jet mixer stopped-flow system incorporated into a Unicam SP800 spectrophotometer was used for most kinetic runs although at low temperatures either a SP800 or Cary 17 spectrometer with thermostatted cell holder was used to monitor the absorbance changes directly. In a typical experiment, reactant solutions were prepared immediately prior to use. Comparison of optical densities at $\lambda = 280$ nm of 'blank' solutions in which Tl(III) was diluted with acid perchlorate solution with those where thiomalic acid was present indicated the formation of a complex within the time of mixing. Data derived under

differing sets of conditions are presented as the spectrum of the intermediate in Fig. 1. In previous reactions where complexes have been identified it has been possible, in some instances where the equilibrium constant is low, to evaluate *K* from the initial absorbance changes (10). Attempts to derive this information by this method were unsuccessful probably owing to a fairly high formation constant with consequent virtual total complexing of the metal present (*vide infra*). The subsequent redox reactions were monitored at $\lambda = 290$–350 nm. The [H⁺] range studied was 0.25–1.00 *M* at a total ionic strength of 2.00 *M*. All experiments were conducted in the presence of air which was shown to have no detectable effect on the observed rate constants Reactions carried out under nitrogen with solutions previously de-gassed yielded the observed rate constants to within experimental error (Table 1). Although air sensitivity has been found for the Np(VI) oxidation of thiols, this has not been shown to be the case for the corresponding cerium(IV) oxidations (14).

Results and Discussion

The stoichiometry of the reaction was determined by spectrophotometric titration of the unreacted thiomalic acid present in the mixture (14). Typical reaction conditions were [Tl(III)] = 5–12 $\times 10^{-5}$ *M*, [thiol] = 5.2×10^{-4} *M*,

$[H^+] = 1.2\ M$ and three evaluations yielded a ratio of 2.1 ± 0.3 mol of thiomalic acid (HRSH) reacting per mole of metal ion, consistent with the reaction

[1] $Tl(III) + 2HRSH \rightarrow Tl(I) + HRSSRH + 2H^+$

The overall kinetics may be adequately represented by the following reaction scheme

[2] $$Tl^{3+} + H_2O \underset{}{\overset{K_h}{\rightleftharpoons}} TlOH^{2+} + H^+$$

[3] $$Tl^{3+} + HRSH \overset{K_1}{\rightleftharpoons} [TlHRSH]^{3+}$$

[4] $$TlOH^{2+} + HRSH \overset{K_2}{\rightleftharpoons} [TlSRH]^{2+} + H_2O$$

[5] $$[TlHRSH]^{3+} \overset{K_3}{\rightleftharpoons} [TlSRH]^{2+} + H^+$$

[6] $$[TlHRSH]^{3+} \xrightarrow{k_1} Tl(II) + HRS^{\cdot} + H^+$$

[7] $$[TlSRH]^{2+} \xrightarrow{k_2} Tl(II) + HRS^{\cdot}$$

[8] $$[Tl(II)] + HRSH \xrightarrow{k_3} Tl(I) + HRS^{\cdot} + H^+$$

[9] $$2HRS^{\cdot} \xrightarrow{k_4} HRSSRH$$

Further hydrolysed species of Tl(III) and the proton-dissociated carboxylate anion form of the ligand are also possible reactants but at the hydrogen ion concentrations used, the amounts of such species present in solution would be very low.

Providing the protolytic reactions are fast, and the electron transfer sufficiently slow such that $k_3, k_4 \gg k_1, k_2$ then in an excess of substrate the decrease of Tl(III) may be described as

[10] $$\frac{-d[Tl(III)]_{tot}}{dt} = k_1[TlHRSH]^{3+} + k_2[TlSRH]^{2+}$$

and using the above scheme, the observed rate constant, k_{obs}, may be expressed in the form

[11] $$k_{obs}^{-1} = \frac{([H^+] + K_h)}{(k_1K_1[H^+] + k_2K_2K_h)[HRSH]} + \frac{K_1[H^+] + K_2K_h}{(k_1K_1[H^+] + k_2K_2K_h)}$$

Kinetic runs showed good linearity of first order plots to 80–90% reaction. Measured values at various $[H^+]$ and [HRSH] are presented in Table 1.

The inverse hydrogen ion dependence may be correlated with the hydrolytic equilibrium of Tl_{aq}^{3+} and using a hydrolysis constant $K_h = 0.073\ M$ (15), the aquated metal ion Tl_{aq}^{3+} is present, under the experimental conditions used, to the extent of 78–94%. An alternative origin of the effect may derive from equilibrium 5 where $K_1K_3 = K_2K_h$. It is impossible to distinguish kinetically between reaction combinations [2] and [4], and [3] and [5] as to the route for formation of $[TlSRH]^{2+}$. An equilibrium similar to [5] has been favoured, however, in the oxidation of H_2O_2 (16) and hypophosphorous acid (9).

According to [11] at constant $[H^+]$, plots of k_{obs}^{-1} against $[HRSH]^{-1}$ should be linear and this is observed. Using the slope (S) and intercept (I) values derived (Table 1) the following equations may be evaluated

[12] $$\frac{([H^+] + K_h)}{S} = k_1K_1[H^+] + k_2K_2K_h$$

and

[13] $$\frac{([H^+] + K_h)}{S} I = K_1[H^+] + K_2K_h$$

In order to calculate the rate and equilibrium parameters, accurate values for K_h are required. There appears to be little dependence of this equilibrium constant on ionic strength (15, 17, 18) and the data used in this study are extrapolated from those at various temperatures (17) at 1.00 M. Evaluation of the left-hand side of eq. 13 showed the values to be independent of $[H^+]$ (Table 2). It would thus appear that only one complex, namely $[TlSRH]^{2+}$, predominates in

the rate determining redox step. The spectrum shown in Fig. 1 probably closely approximates that of a Tl(III)—S bonded complex. The value at 25°C of the equilibrium constant for the reaction

$$Tl^{3+} + HRSH \rightleftharpoons [TlSRH]^{2+} + H^+$$

may be computed to be 129 ± 8.

Modification of eq. 11 to exclude terms involving k_1 and K_1, which are negligible under the experimental conditions, thus allows for the evaluation of the redox rate constant k_2. Values at various temperatures together with associated thermodynamic data are presented in Table 3. The associated activation enthalpy is 11.8 ± 1.2 kcal/mol. This value is substantially lower than that for reaction of the oxygen bonded complexes: 26.0 (formic acid) (8), and 27.8 kcal/mol (oxalic acid) (19) respectively. This may be the result of a greater degree of electron delocalization in the Tl—S bond compared with that in Tl—O.

Unfortunately there are few data available with which to make comparisons. Also, the reaction is too slow to allow for detection of radical intermediates of this substrate. With the one-electron oxidants Fe(III) (20) and Cu(II) (21) a rate determining dimerisation provides a low-energy pathway for electron transfer via a four-centre M_2S_2 system which yields disulphide without radical formation. In cases where two-electron transfer reactions have been encountered (e.g. Cr(VI) + cysteine (12) or thioureas (22)) 2 mol of thiol are generally incorporated in the transition state. Since there is no evidence for any second-order kinetic term in reductant (and little change in the uv spectrum in the presence of a 10-fold excess of mercaptosuccinic acid confirms the absence of significant build-up of 1:2 complexes, see Fig. 1) it may be assumed that the rate determining reaction is a one-electron transfer to Tl(II) and the organic radical. Tl(II) has been shown recently to be a powerful oxidant (23) and a rapid second reaction to produce Tl(I) with formation of another RS$^{\bullet}$ species would be consistent with the observed stoichiometry. It is considered unlikely that thallium(III) is a sufficiently strong oxidant to undergo a two-electron reaction to give RS^+ which could react with a second mole of thiol to yield the disulphide. More data are required on reactions of this type especially to enable comparisons to be made of Tl(III)—O and Tl(III)—S bond types. Attempts are currently underway to measure the reaction rates of the initial complex formation in order to provide much needed detail on the reactivity of Tl(III) aquo-ions.

ZAHID AMJAD, JEAN-CLAUDE BRODOVITCH, and ALEXANDER MCAULEY. Can. J. Chem. **55**, 3581 (1977).

The mechanisms of oxidation of the three di-hydroxy substrates in the title reactions have been investigated in acid media [$HClO_4$] = 0.04–1.00 *M*, at an ionic strength of 1.0 *M* [$LiClO_4$] over the temperature range 5–35°C using the stopped-flow method. In contrast to the reactions of hydroquinone (k_2(25°C) = 1.43×10^4 M^{-1} s^{-1}, $\Delta H^{\ddagger} = 3.6 \pm 0.4$ kcal mol^{-1}, $\Delta S^{\ddagger} = -34 \pm 8$ cal deg^{-1} mol^{-1}) and catechol (k_2(25°C) = 9.5×10^2 M^{-1} s^{-1}, $\Delta H^{\ddagger} = 5.9 \pm 0.9$ kcal mol^{-1}, $\Delta S^{\ddagger} = 27 \pm 8$ cal deg^{-1} mol^{-1}) where no hydrogen ion dependence is observed over the range studied, the rate variations of oxidation of ascorbic acid (H_2A) are consistent with two reactions involving H_2A ($k_5 = 77.4$ M^{-1} s^{-1}, $\Delta H^{\ddagger} = 4.5 \pm 0.6$ kcal mol^{-1}, $\Delta S^{\ddagger} = -35 \pm 5$ cal deg^{-1} mol^{-1}) and HA^- ($k_6 = 2.41 \times 10^5$ M^{-1} s^{-1}, $\Delta H^{\ddagger} = 2.0 \pm 1$ kcal mol^{-1}, $\Delta S^{\ddagger} = -17 \pm 6$ cal deg^{-1} mol^{-1}). The dissociation constant of ascorbic acid has been redetermined over the temperature range studied. Solvation effects are considered important in these outer-sphere systems, which may be discussed in terms of the Marcus relationship. Comparisons with related reactions are discussed.

ZAHID AMJAD, JEAN-CLAUDE BRODOVITCH et ALEXANDER MCAULEY. Can. J. Chem. **55**, 3581 (1977).

On étudie par la méthode du flux stoppé les mécanismes d'oxydation des trois substrats dihydroxylés figurant dans le titre, en milieu acide [$HClO_4$] = 0.04–1.00 *M*, pour une force ionique de 1.0 *M* [$LiClO_4$] et dans un écart de température de 5–35°C. En comparaison avec les réactions de l'hydroquinone (k_2(25°C) = 1.43×10^4 M^{-1} s^{-1}, $\Delta H^{\ddagger} = 3.6 \pm 0.4$ kcal mol^{-1}, $\Delta S^{\ddagger} = -34 \pm 8$ cal deg^{-1} mol^{-1}) et du catéchol (k_2(25°C) = 9.5×10^2 M^{-1} s^{-1}, $\Delta H^{\ddagger} = 5.9 \pm 0.9$ kcal mol^{-1}, $\Delta S^{\ddagger} = 27 \pm 8$ cal deg^{-1} mol^{-1}) ou il n'y a pas de dépendance avec l'acidité du milieu dans l'écart étudié, les variations de la vitesse d'oxydation de l'acide ascorbique (H_2A) sont en accord avec les deux réactions impliquant les espèces H_2A ($k_5 = 77.4$ M^{-1} s^{-1}, $\Delta H^{\ddagger} = 4.5 \pm 0.6$ kcal mol^{-1}, $\Delta S^{\ddagger} = -35 \pm 5$ cal deg^{-1} mol^{-1}) et HA^- ($k_6 = 2.41 \times 10^5$ M^{-1} s^{-1}, $\Delta H^{\ddagger} = 2.0 \pm 1$ kcal mol^{-1}, $\Delta S^{\ddagger} = -17 \pm 6$ cal deg^{-1} mol^{-1}). La constante de dissociation de l'acide ascorbique est recalculée pour les conditions expérimentales indiquées ci-dessus. Les effets de solvatation semblent être importants pour ces systèmes à sphères extérieures lesquels peuvent être interprétés selon la théorie de Marcus. Une comparaison avec d'autres réactions similaires est présentée.

[Traduit par le journal]

Although the 12-heteropoly-acids and their salts were first described in 1933 (2), relatively little is known of the mechanism of their reactions in solution. The 12-tungstocobaltate(II) $[Co(II)O_4 \cdot W_{12}O_{36}]^{6-}$ and 12-tungstocobaltate-(III) $[Co(III)O_4 \cdot W_{12}O_{36}]^{5-}$ ions, hereafter described as [Co(II)] and [Co(III)], have been shown (3, 4) to be examples of complexes in which both the oxidized and reduced forms of the metal are located within CoO_4 tetrahedra. Indeed, in the case of the cobalt(III) complex it is one of the few instances of this metal ion in a tervalent state in a tetrahedral site. Unlike many octahedral cobalt(III) complexes the metal centre in the tungstocobaltiate ion is reduced reversibly. Brubaker and Rasmussen (5) have described the kinetics of the electron exchange between [Co(II)] and [Co(III)] using ^{60}Co tracer techniques. From the structure and stability of these anions it appears that the tungstate groups are substitutionally inert and species of this type

[1]For Part XX, see ref. 1.
[2]Present address: The University of Victoria, Victoria, B.C., Canada V8W 2Y2.

represent ideal complexes for the study of outer-sphere electron transfer in solution.

In many studies of the oxidation of ligands by metal ions the possibility exists for transient complex formation. Intermediate cobalt(III) species have been identified in several instances (6–8). In the present study, using [Co(III)], such interactions between oxidant and reductant would be expected to be weak and this enables the investigation of other factors in electron transfer reactions of this type.

The oxidation of L-ascorbic acid has been studied using a variety of reagents and conditions. An intermediate complex has been identified with vanadium(V) (9), the redox decomposition involving the formation of an ascorbate radical rather than a two-electron transfer to the diketone. Similar radical formation has also been established in the reactions with iron(III)–EDTA complexes (10) and hexacyanoferrate(III) (11). In a recent study (12) the rates of oxidation of ascorbic acid by tris(1,10-phenanthroline)iron(III) and its derivatives have been discussed in terms of free energy changes using the Marcus theory (13). The reaction of benzene 1,2- and 1,4-diols by hexaquo-cobalt(III) (14) may also involve some outer-sphere character. In the case of hydroquinone particularly, there is conflicting evidence as to the reaction mechanism. Davies (15) has suggested, from a comparison of reactivity of several substrates, that an outer-sphere process is operative but this conflicts with the data of Wells (16). Later investigations (14) support the former suggestion with no evidence for any reaction intermediates. Studies with the heteropolyacid system may help to resolve this problem and for this reason the investigations were extended to include both hydroquinone and catechol.

Experimental

Potassium 12-tungstocobaltiate was prepared by the method of Baker and McCutcheon (3) either from the 12-tungstodicobaltoate by oxidation with persulphate or by electrolysis of the 12-tungstocobaltoate complex. The uv-visible spectrum was monitored and it was found that no changes in absorbance were evident over the hydrogen ion concentration range $pH \sim 5.5$–0. At 388 nm, $\varepsilon = 1150 \pm 5\ M^{-1}\ cm^{-1}$.

Stock solutions of L-ascorbic acid (Hopkin and Williams) and hydroquinone (B.D.H. reagent) and catechol (Fisher, resublimed) were prepared prior to use. Details of preparation and standardisation of other solutions have been published previously (17).

Stoichiometry

Spectrophotometric titrations were used to determine reaction stoichiometries. Spectra of solutions containing various concentrations of organic substrate ($0.7–15 \times 10^{-4}\ M$) at a constant oxidant concentration in the range $1.0–4.5 \times 10^{-4}\ M$ at $[H^+] \sim 0.5\ M$ (ascorbic acid), $[H^+] = 0.04\ M$ (catechol and hydroquinone) were measured after reaction had occurred.

Dissociation Constants

In the hydrogen ion concentration ranges used ($[H^+] = 0.04–1.00\ M$) any proton dissociation of the phenol groups was considered to be negligible ($pK > 6$) (18). Ascorbic acid, however, is known to act as a monobasic acid and since data are few (11, 19) on the value for the dissociation constant at the ionic strength used in this study and over a range of temperatures, it was decided to measure this value precisely. Since the kinetic data (*vide infra*) are insensitive to Cl^- ions, solutions were prepared using this anion since better reproducibility was obtained in glass electrode measurements when compared to perchlorate solutions. Accurate dilutions of $[H^+] \sim (4.00 \times 10^{-4} - 5.00 \times 10^{-2}\ M)$ were made in 1.00 M LiCl solutions and a reference slope derived from measurements using a glass electrode/saturated calomel system. Hydrogen ion concentrations of ascorbic acid solutions in acid/base titrations were thus obtained directly. The concentration quotient $K_a = [H^+][HA^-]/[H_2A]$ was measured (reproducibility $\pm 6\%$) over the temperature range 3.8–35.0°C.

Kinetic Measurements

The reactions were studied either at 388 nm (decrease of [Co(III)]) or 625 nm (formation of [Co(III]) under conditions of excess reductant. The latter wavelength was used specifically in the reaction with catechol where there was evidence for a slower secondary process (interpreted as hydrolysis of the ketonic product) which interfered with infinity readings. Measurements were made using the stopped-flow apparatus described previously (20) and a modified Applied Photophysics instrument. The hydrogen concentration range employed was $[H^+] = 0.04–1.00\ M$ at a total ionic strength of 1.00 M ($LiClO_4$). The presence of a sufficient excess of reductant ensured pseudo-first order reaction conditions and plots were linear to at least 85–90% reaction. In the case of catechol, however, interference from the secondary reaction was noted at higher temperatures. Replicate measurements agreed to $\pm 3\%$. Studies were carried out in the presence of air which was found to have no detectable effect on the observed rate constant.

Results and Discussion

(*a*) *Stoichiometry*

In all three systems studied, the spectrophotometric titrations showed oxidant–reductant ratios of $(2.01 \pm 0.02):1$ (ascorbic acid), $(2.00 \pm 0.03):1$ (hydroquinone), and $(2.09 \pm 0.05):1$ (catechol). The overall reaction may thus be written in the form

[1] $2[Co(III)] + R(OH)_2 \longrightarrow 2[Co(II)] + R(=O)_2 + 2H^+$

where  represents the dihydroxy substrate.

(b) Dissociation Constant of Ascorbic Acid

The data from acid–base titrations using the known $[H^+]$ of each solution were treated in the manner suggested by Speakman (21). The data at several temperatures are presented in Table 1 where there is seen to be only a small variation in K_a over the range studied. Determinations in both chloride and nitrate media indicate that the values derived in the present study are slightly higher at lower temperatures than those obtained recently (12). The agreement at room temperature and above, however, is excellent. Dissociation constants are known to vary markedly with temperature over wide ranges and for many systems the values pass through a minimum at or near room temperature (22). The position of this minimum is dependent on solvation and electrostatic effects. In the present conditions ($I = 1.0\ M$), however, over the temperature range studied, the best representation of all the available data is of a linear relationship between pK_a and temperature. This line was used in the interpolations to yield the dissociation constants at the appropriate temperatures.

(c) Kinetics and Mechanism

The linearity of first order plots confirmed the reaction order as unity with respect to the oxidant and data over a wide range of reductant concentrations established a first order dependence. Data at 25°C are presented in Fig. 1 for the systems studied. The rate law may thus be expressed in the form (H_2L = reductant)

$$-d[Co(III)]/dt = 2k_2[Co(III)][H_2L]$$

TABLE 1. Dissociation constant[a] for ascorbic acid at various temperatures, $I = 1.00\ M$ LiCl, or $1.0\ M$ $NaNO_3$

[c]Reference 12, $NaClO_4$ solutions.

The second order rate constants k_2 were found to be independent of wavelength of investigation, [Co(II)], oxygen, and added chloride ion. Extinction coefficients obtained by extrapolation to $t = 0$ were identical to those obtained in the absence of reductant. Values for k_2 for hydroquinone and catechol showed no variation with $[H^+]$ over a 25-fold concentration range and rate constants are presented in Table 2. The data are thus consistent with the reaction scheme

$$[2]\quad [Co(III)] + H_2L \xrightarrow{k_2} [Co(II)] + H^+ + HL^\cdot$$

$$[3]\quad [Co(III)] + HL^\cdot \xrightarrow{\text{fast}} [Co(II)] + L + H^+$$

The reaction with ascorbic acid, however, showed a marked hydrogen ion dependence on the rate. In this case the data may be represented by the scheme

$$[4]\quad H_2L \xrightarrow{K_a} HL^- + H^+$$

$$[5]\quad [Co(III)] + H_2L \xrightarrow{k_5} [Co(II)] + H^+ + HL^\cdot$$

$$[6]\quad [Co(III)] + HL^- \xrightarrow{k_6} [Co(II)] + HL^\cdot$$

$$[7]\quad Co(III) + HL^\cdot \xrightarrow{\text{fast}} [Co(II)] + L + H^+$$

where H_2L and HL^- represent the protonated and dissociated forms of ascorbic acid. Assuming the pre-equilibrium to be rapidly established, and allowing for the overall stoichiometry, the reaction rate may be written as

$$[8]\quad -d[Co(III)]/dt = \frac{2\{k_5 + k_6K_a/[H^+]\}[Co(III)][H_2L]_t}{(1 + K_a/[H^+])}$$

TABLE 2. Second order rate constants for reactions of [Co(III)] with hydroquinone and catechol, $I = 1.0\ M$ $LiClO_4$, $[H^+] = 0.04\ M$, $[Co(III)] = 1\text{–}3 \times 10^{-4}\ M$

where $[H_2L]_t = [H_2L] + [HL^-]$. Under the experimental conditions used, $[H^+]$ = 0.04–1.00 M, $K_a/[H^+] \ll 1$ (Table 1), the second order rate constants may be expressed in the form

$$[9] \quad \frac{k_{obs}}{2[H_2L]} = k_2 = (k_5 + k_6K_a/[H^+])$$

Treatment of the data (Table 3) according to eq. 9 yielded straight lines at all temperatures studied, with slopes and intercepts equal to k_2K_a and k_1 respectively. The rate constants for the various reactions studied are presented in Table 4. Since there is no change in the nature of the oxidant over the hydrogen ion concentration range studied (confirmed both spectroscopically and by a lack of any $[H^+]$ dependence in the reactions of the benzene diols) it is possible to assign the reaction pathways unambiguously. It is of interest to note that although the oxidant carries a large negative charge, the anionic form

of the ascorbic acid in fact is substantially more reactive than the undissociated substrate. Second order rate constants for reaction 6 were calculated using the K_a values interpolated at the appropriate temperatures. The increased reactivity of the ascorbate anion has been observed previously in the reactions with anionic iron(III) chelates (23) (Table 5) where unlike the present study there is no evidence for any pathway corresponding to k_5. An analysis of the data presented in the paper by Mushran and coworkers (11) indicates (Fig. 2 of ref. 11) that a hydrogen ion dependence similar to that observed with the cobalt complex is shown in the reaction with hexacyanoferrate(III). Also, interestingly, the ratio of k_6/k_5 rate constants in the $Fe(CN)_6^{3-}$ system is $\sim 1.25 \times 10^3$ which is not too markedly different from the corresponding ratio of 3.1×10^3 observed in the present study. For the reaction with HA^-, however, the rate constants obtained are very much ($\sim 10^6$) lower than those derived for the reaction of the cationic $Fe(phen)_3^{3+}$ oxidants (12). This may reflect the importance of electrostatic parameters in these reactions.

The activation parameters for the various reactions investigated are very similar and possibly indicate common reaction features, especially for the three dihydroxy species, hydroquinone, catechol, and undissociated ascorbic acid. It is interesting to note that the more rapid reaction of the ascorbate ion is associated with the only species among those studied here for which no proton solvation is required.

An attempt was made to interpret these data using the LFER proposed by Marcus (13) as applied by Pelizzetti and Mentasti (12). For an outer-sphere transition complex, one would expect the activation to be given by the expression

$$[10]\quad \Delta G^*_{12} = w_r + \frac{\lambda_{12}}{4} + \frac{\Delta G^{\phi\prime}_{12}}{4} + \frac{(\Delta G^{\phi\prime}_{12})^2}{4\lambda_{12}}$$

where $\lambda_{12} = 2(\Delta G^*_{11} - w_{11} + \Delta G^*_{22} - w_{22})$, and $\Delta G^{\phi\prime}_{12} = \Delta G^{\phi}_{12} + w_p - w_r$. The terms ΔG^*_{11} and ΔG^*_{22} represent the free energies of activation of the self-exchange reaction and ΔG^{ϕ}_{12} the standard free energy of the reaction. The different work terms, w_{11}, w_{22}, w_p, w_r, required to bring the reactants and products together are considered to provide only a small contribution at this ionic strength and were neglected (24).

Equation 10 is usually written in the form

$$[11]\quad \Delta G^*_{12} - \frac{\lambda_{12}}{4} - \frac{\Delta G^{\phi}_{12}}{4\lambda_{12}} = \tfrac{1}{2}\,\Delta G^{\phi}_{12}$$

A plot of the left-hand side of eq. 11 against ΔG^{ϕ}_{12} should have a slope of $\frac{1}{2}$ and zero intercept.

All the parameters required for such a plot were either available (5, 12, 24) or could be inferred. For the Co(III)/Co(II) self-exchange

reaction the value $\Delta G^*_{11} = 15.36$ kcal/mol was obtained by extrapolating to 1.0 M ionic strength the data of Rasmussen and Brubaker (5). The corresponding parameter $\Delta G^*_{22} = 6.5$ kcal/mol for the $H_2L/HL^\bullet$ couples was assumed to be constant for all the dihydroxy forms of the reductants (24). For the ascorbate ion the value $\Delta G^*_{22} = 4$ kcal/mol for $HA^-/HA^\bullet$ was used (12). The ΔG^*_{12} values were obtained from the experimental activation parameters. The redox potentials were identical to those quoted previously (24), except for that of the couple $H_2A/HA^\bullet$. In this case by extrapolating from a plot of log k_2 against E^0 for the three dihydroxy substrates under investigation the value $E^0 = 1.31$ V for $H_2A/HA^\cdot$ was determined.

Table 6 includes the values of the terms involved in eq. 11. When plotted these data gave a slope of 0.34 ± 0.07 and an intercept of -0.56 ± 0.6 kcal/mol. Considering the relative scarcity of data and the precision with which all the various parameters are known, these results show at least a good qualitative agreement with the theory. More definitive statements must await written data using the same oxidant but with different reducing species encompassing a wide range of E_0 values.

Nonexistence of the alleged isobindone. The aldol–retroaldol reaction of 1,3-indandione

ALFRED TAURINS
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received April 4, 1977

ALFRED TAURINS. Can. J. Chem. **55**, 3587 (1977).

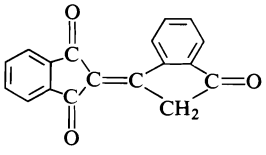
The existence of the alleged isobindone has been disproved. The compound, mp 330°C, formed as a byproduct in the aldol–retroaldol condensation reaction of 1,3-indandione is not isobindone but 1-(1,3-indandionyl-2)-3-(1,3-indandionyliden-2)indene. The compound, mp 337°C, formed from bindone in pyridine solution has the composition $C_{36}H_{18}O_5$.

ALFRED TAURINS. Can. J. Chem. **55**, 3587 (1977).

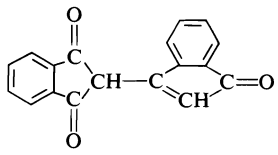
On réfute l'existence de la soi-disante isobindone. Le composé qui fond à 330°C et qui se forme comme produit secondaire dans la condensation aldolique–rétroaldolique de l'indandione-1,3, n'est pas l'isobindone mais le (indandione-1,3 yl-2)-1 (indandione-1,3 ylidène-2)-3 indène. Le composé formé à partir de la bindone en solution pyridinique, et qui a un point de fusion de 337°C, possède la composition $C_{36}H_{18}O_5$.

[Traduit par le journal]

In 1931, Fischer and Wanag (1) claimed that bindone (**1**) possessed an isomer, 'isobindone', of structure **2**. They studied the transformation of bindone to 'isobindone' and a reverse reaction under various conditions and considered these processes as isomerization (1, 2). Thirty years later an ir and uv investigation (3) did not provide support for the structure **2**; however, no further work on this subject appeared.



1



2

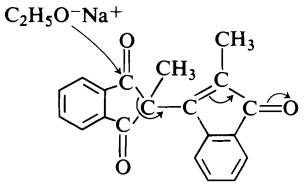
Despite the closely related structural formulas for bindone (**1**) and isobindone (**2**) there are striking differences in their chemical and physical properties indicating the inadequacy of the structure **2**.

Bindone; mp 210°C. Soluble in hot glacial acetic acid. Aqueous sodium hydroxide forms a violet solution of the Na-salt of **1**. Ultraviolet spectrum of the Na-salt of **1**: $\lambda_{max}(H_2O)$ 305, 355.5, 525 nm (log ε 1.58, 1.17, 1.38) (3). Dry K_2CO_3 in hot toluene forms a dark green K-salt of isobindone (2).

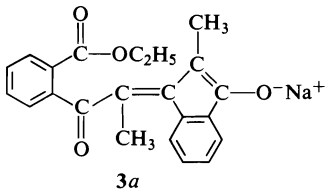
'*Isobindone*'; mp 330°C. Insoluble in hot glacial acetic acid. Methanolic 0.5% sodium methoxide forms a dark-green solution of the Na-salt of 'isobindone'. Ultraviolet spectrum of the Na-salt: $\lambda_{max}(CH_3OH)$ 420, 655 nm (log ε 1.45, 1.05) (3). Hot aqueous sodium hydroxide (0.1 *N*) forms a violet solution of the Na-salt of bindone.

Comparison of the spectral properties of the salts of bindone and 'isobindone' (see above) leads to the conclusion that the latter has a more extended chromophore and, in order to accommodate the more extended chromophore, it is likely to be a larger molecule.

An additional sign of the inadequacy of formula **2** for 'isobindone' is the existence of 2,2′-dimethylisobindone (**3**) (4) (systematic name: 2,2′-dimethyl-2,3′-biindenyl-1,1′,3(2H)-trione). Both formulas **2** and **3** possess the same basic



3



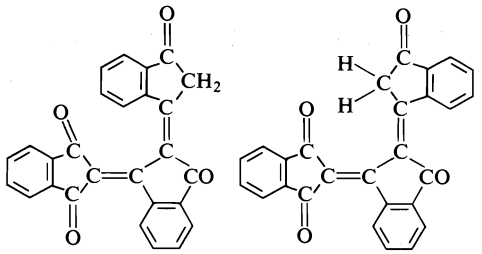
3a

structure. The only difference between them is that the structure **2** has hydrogens on C-2 and C-2′ while in **3** the same carbon atoms carry methyl groups. Therefore, one could expect that if 'isobindone' had the structure **2**, its physical properties should be similar to those of compound **3**. However, that is not the case, since compound **3** is volatile *in vacuo* and has mp 198°C (4), significantly lower than the mp of 'isobindone' (see above).

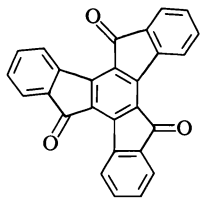
Despite the fact that compound **3** has no —CH_2CO— groups, and consequently cannot enolize, it very easily forms a blue solution with ethanolic sodium ethoxide (4). Therefore, we postulate that the reaction involves the ring opening (**3** → **3***a*).

Reinvestigation of the alleged 'isobindone' showed definitely that it has the formula $C_{27}H_{14}O_4$, formed by the aldol condensation of three molecules of 1,3-indandione. The proof was provided by elemental analysis and mass spectrometry. *Anal.* calcd. for $C_{27}H_{14}O_4$ (mw 402.41): C 80.6, H 3.5; found: C 80.7, H 3.8. Mass spectra for $C_{27}H_{14}O_4$: *m/e* 402 (M^+), 374 ($M^+ - CO$), 358 ($M^+ - CO - O$; HR $C_{26}H_{14}O_2$), 346 ($M^+ - 2CO$), 329 ($M^+ - 2CO - OH$; HR $C_{25}H_{13}O$), 289 ($M^+ - 4CO - H$; HR $C_{23}H_{13}$); ms for bindone, $C_{18}H_{10}O_3$ (mw 274.28): *m/e* 274 (M^+), 246 ($M^+ - CO$), 219 ($M^+ - 2CO + H$; HR $C_{16}H_{10}O$), 189 ($M^+ - 3CO - 1H$; HR $C_{15}H_9$), 163 (HR $C_{13}H_7$), 114 (HR C_9H_6).

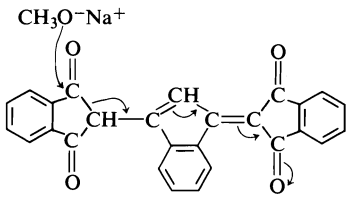
In order to obtain compound $C_{27}H_{14}O_4$ in the pure state, it is essential to crystallize it from a low boiling solvent, like chloroform, but not from nitrobenzene as suggested by Fischer and Wanag (1). In boiling nitrobenzene the compound undergoes a chemical change resulting in blackening of the solution from which only a part of the solute of varying composition can be recovered. Fischer and Wanag (1) claimed that they established the composition of 'isobindone' by elemental analysis and cryoscopic mw determination in phenol (mw found: 246, 265; calcd. for $C_{18}H_{10}O_3$: 275). Obviously, their samples were not the right ones, and their oversight arose from the fact that they did not recognize the true nature of the transformation: bindone ⇄ 'isobindone' as being an aldol–retroaldol reaction which occurred also during the crystallization of the sample from nitrobenzene and mw determination in phenol.



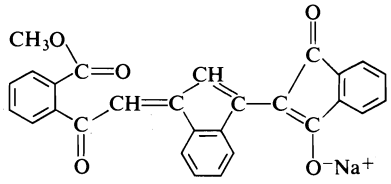
4 **5**



6

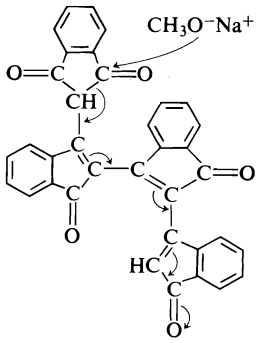


7

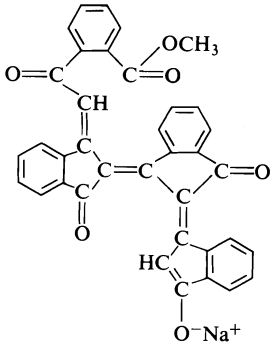


8

For compound $C_{27}H_{14}O_4$ (mp 330°C) structures **4** and **5** must be excluded on steric grounds and, therefore, the most probable structure could correspond to 1-[1,3-indandionyl-2]-3-[1,3-indandionyliden-2]indene (**7**). Examination of space-filling molecular models for bindone and compound $C_{27}H_{14}O_4$, containing two or three 1,3-indandionyl units, respectively, shows that the molecules cannot be planar at the C=C bonds due to interference of a C=O group with a hydrogen atom on the neighboring benzene



9



ring. The twist of the double bond could be ~30° resulting in decrease of the overlapping of π-electrons and the decrease in the double-bond character. The structure **4** is the most crowded while the structure **5** could lead to the formation of truxenquinone (**6**). It is believed that the reaction of compound **7** with 0.5% methanolic sodium methoxide is not based on enolate formation, but is analogous to the reaction of compound **3** forming a dark-green salt (**8**) by the ring opening and increasing the number of conjugated double bonds.

In conclusion, the name 'isobindone' must be removed from the literature.

The condensation product of bindone (**1**) in pyridine solution which has been described either as $C_{45}H_{24}O_7$ (5) or $C_{27}H_{14}O_4$ (1), actually is $C_{36}H_{18}O_5$. It melts at 337°C and is slowly soluble in 1.5% methanolic sodium methoxide solution with a dark-blue color. For this compound the structure **9** is proposed possessing single bonds between the indandionyl units. These bonds allow the existence of a non-planar structure. The incorrect results by the previous workers have been apparently obtained by crystallizing the compound **9** from nitrobenzene. In this work, compound **9** was obtained in pure state by precipitating it from the solution in sodium methoxide with dilute HCl, washing with water and methanol, and drying. *Anal.* calcd. for $C_{36}H_{18}O_5$ (mw 530.54): C 81.5, H 3.4; found: C 81.5, H 3.7; ms: *m/e* 530 (M^+), 513 ($M^+ - OH$), 502 ($M^+ - CO$), 485 ($M^+ - CO - OH$), 474 ($M^+ - 2CO$), 460 ($M^+ - 2CO - CH_2$), 460 ($M^+ - C_6H_4(CO)_2$) + 2H. Ultraviolet visible spectrum of the Na-salt of **9**: $\lambda_{max}(CH_3OH)$ 283, 312, 345, 378, 538, 605, 625 nm (log ε 4.39, 4.29, 4.13, 4.06, 4.07, 4.13, 4.12).

Influence de la coordination du thallium sur la cinétique de décomposition du composé d'oxythallation: C_6H_5—$CH(OCH_3)$—$CH_2Tl(OAc)_2$

LOUISE NADON ET MIKLOS ZADOR
Département de chimie, Université de Montréal, C.P. 6210, Montréal (Qué.), Canada H3C 3V1

Reçu le 17 février 1977

LOUISE NADON et MIKLOS ZADOR. Can. J. Chem. **55**, 3590 (1977).

L'influence de la coordination du thallium sur la vitesse de décomposition du composé d'oxythallation C_6H_5—$CH(OCH_3)$—CH_2TlX_2($R'TlX_2$) a été étudiée en milieu eau–méthanol. En présence de faibles concentrations d'ions Cl^-, la vitesse de décomposition oxydante diminue à cause de la formation d'espèces $R'TlCl^+$ et $R'TlClOH$, ces deux dernières étant moins réactives que l'espèce $R'Tl^{2+}$. A haute concentration en ions Cl^-, il y a formation d'espèces $R'TlCl_2$ ou $R'TlCl_3^-$; on observe alors la décomposition en réactifs de départ, soit le styrène et le Tl(III), similairement observée pour les organomercuriques.

Le mécanisme des réactions est discuté en termes de changement du caractère électrophile du thallium dû à la coordination par le ligand.

LOUISE NADON and MIKLOS ZADOR. Can. J. Chem. **55**, 3590 (1977).

The effect of coordination of thallium was studied on the rate of decomposition in methanol–water of the product of oxythallation, C_6H_5—$CH(OCH_3)$—CH_2TlX_2($R'TlX_2$). At low Cl^- ion concentrations, the rate of the oxidative decomposition decreased because of the formation of $R'TlCl^+$ and $R'TlClOH$, both of which are less reactive than $R'Tl^{2+}$. At high Cl^- ion concentration, $R'TlCl_2$ or $R'TlCl_3^-$ are formed and a decomposition to the starting materials, namely styrene and Tl(III), was observed; this is analogous to the behaviour of organomercurials.

The mechanism of the reactions is discussed in terms of the electrophilic character of thallium effected by the coordination by ligand.

[Journal translation]

Introduction

Le mécanisme de décomposition d'organothalliques du type $R_1R_2C(OR_3)$—CH_2TlX_2 ($R'TlX_2$) présente un intérêt particulier étant donné que ces composés se forment comme intermédiaires dans l'oxydation d'oléfines par les sels thalliques (1).

Les études précédentes ont permis de montrer que les principales formes réactives sont $R'Tl^{2+}$ et $R'TlOH^+$ et que la réactivité de $R'Tl^{2+}$ est beaucoup plus grande que celle de $R'TlOH^+$ (2, 3).

Dans ce travail on présente les résultats d'une étude de l'influence de quelques ligands sur la vitesse de décomposition de C_6H_5—$CH(OCH_3)$—$CH_2Tl(OAc)_2$.

Partie expérimentale

Réactifs et produits

La méthode de synthèse de C_6H_5—$CH(OCH_3)$—$CH_2Tl(OAc)_2$ ainsi que l'analyse des produits d'oxydation ont été décrites précédemment (2). Les réactifs utilisés sont de qualité analytique.

Méthodes cinétiques

Les réactions sont suivies par la mesure de la variation de l'absorbance. La méthode expérimentale a été décrite auparavant (2). Les résultats de flux stoppé sont traités par un système d'acquisition et de traitement de données de notre construction (4). Les constantes de vitesse sont obtenues directement par un programme de régression approprié à l'aide d'une calculatrice programmable Tektronix 31. Les constantes de vitesse sont, en général, les moyennes de cinq expériences et la reproductibilité des résultats est d'environ ±5%.

Résultats et discussion

La décomposition oxydative de l'organothallique $R'Tl(OAc)_2$ se fait d'après l'éq. 1.

$$[1]\quad C_6H_5—CH(OCH_3)—CH_2Tl(OAc)_2 \xrightarrow{ROH} C_6H_5—CH_2—CH(OCH_3)(OR) + Tl^+ + OAc^- + HOAc$$

Elle implique la migration du groupe phényle et conduit à un acétal ou un aldéhyde suivant la nature de R (2).

En solution eau–méthanol (75% v/v – 25% v/v) il a été montré (2) qu'à des $pH < 5$ et à des concentrations en $R'Tl(OAc)_2 \leq 10^{-3}$ M, celui-ci se dissocie et les espèces dominantes en solution sont reliées par l'équilibre 2.

$$[2]\quad R'TlOH^+ + H^+ \overset{K_1}{\rightleftharpoons} R'Tl^{2+} + H_2O$$

L'acidité influence cet équilibre et, partant, la nature et la concentration des espèces éventuelles se formant en présence de ligands.

Influence de faibles concentrations en ions Cl^-

En l'absence d'acide fort ajouté ($pH \simeq 5.0$) l'addition d'ions Cl^- entraîne la diminution de la vitesse de réaction, comme l'indiquent les résultats du tableau 1. Ceci est attribué, en se basant sur les connaissances acquises sur l'affinité du Tl^{3+} pour les halogénures, à la formation d'espèces telles $R'TlCl_n^{2-n}$, moins réactives que $R'Tl^{2+}$. Les résultats indiquent que, pour un rapport $[R'Tl]/[Cl^-] = 1$ la vitesse ne diminue que d'un facteur de 0.7 et qu'il faut la présence de grands excès de Cl^- pour avoir une diminution de vitesse appréciable.

A une acidité plus élevée où l'équilibre 2 est plus déplacé vers la formation de $R'Tl^{2+}$, l'influence des ions chlorure est plus prononcée (voir tableau 2).

TABLEAU 1. Influence des ions Cl^- en absence d'acide fort*

$[Cl^-]$ (M)	$10^4 \times k_{exp}$ (s^{-1})	$10^4 \times k_{calc}$ (s^{-1})
—	17.8	19.5
2.0×10^{-4}	17.2	18.2
4.0×10^{-4}	15.8	16.9

1.5×10^{-3}	11.0	12.2
2.0×10^{-3}	11.1	10.8
4.0×10^{-3}	7.9	7.6
6.0×10^{-3}	6.5	6.0
8.0×10^{-3}	6.1	5.0
1.0×10^{-2}	5.3	4.4
5.0×10^{-2}	2.3	2.0

*$T = 25°C$; $[R'Tl(OAc)_2] = 1.0 \times 10^{-3}$ M; $[H^+] = 1.7 \times 10^{-5}$ M; solvant: H_2O–CH_3OH 75%–25% (v/v); $\mu = 0.5$ M.

TABLEAU 2. Influence des ions Cl^- en présence de $HClO_4$*

$[Cl^-]$ (M)	$10^2 \times k_{exp}$ (s^{-1})	$10^2 \times k_{calc}$ (s^{-1})
—	29	32
1.0×10^{-5}	24	26
3.0×10^{-5}	19	18
5.0×10^{-5}	14	13
1.0×10^{-4}	5.6	7.0
1.5×10^{-4}	4.5	4.7
2.0×10^{-4}	3.1	3.5
1.0×10^{-2}	0.12	0.10

*$T = 25°C$; $[R'Tl(OAc)_2] = 2.5 \times 10^{-5}$ M; $[H^+] = 0.025$ M; solvant: H_2O–CH_3OH 75%–25% (v/v); $\mu = 0.5$ M.

Pour interpréter l'ensemble des résultats il a fallu tenir compte des équilibres 3 et 4.

$$[3] \qquad R'Tl^{2+} + Cl^- \overset{K_2}{\rightleftharpoons} R'TlCl^+$$

$$[4] \qquad R'TlOH^+ + Cl^- \overset{K_3}{\rightleftharpoons} R'TlClOH$$

La vitesse de réaction est donnée par l'éq. 5.

$$[5] \quad V = k_{exp}[R'Tl]_{total} = k_1[R'Tl^{2+}] + k_2[R'TlOH^+] + k_3[R'TlCl^+]$$

Ces hypothèses conduisent à l'éq. 6.

$$[6] \quad k_{exp} = \frac{k_1K_1[H^+] + k_2 + k_3K_1K_2[H^+][Cl^-]}{1 + K_1[H^+] + K_1K_2[H^+][Cl^-] + K_3[Cl^-]}$$

La détermination des paramètres de l'éq. 6 a été faite par une méthode d'itération en utilisant, en première approximation les valeurs de K_1, k_1 et k_2 obtenues précédemment (2).

Le calcul des concentrations des diverses expèces à l'équilibre a été fait en admettant des valeurs de K_2 et K_3 raisonnables compte tenu de l'affinité de Tl^{3+} pour l'ion Cl^-. L'affinement des résultats consiste à optimiser les valeurs de K_2, K_3 et k_3. Les valeurs suivantes des paramètres ont été obtenues: $k_1 = 0.36$ s^{-1}, $k_2 = 1.5 \times 10^{-4}$ s^{-1}, $k_3 = 3.0 \times 10^{-4}$ s^{-1}, $K_1 = 300$ M^{-1}, $K_2 = 5 \times 10^4$ M^{-1} et $K_3 = 300$ M^{-1}.

La constante de vitesse calculée à l'aide de ces paramètres est en accord satisfaisant avec les résultats obtenus aux deux acidités (tableaux 1 et 2).

Les valeurs des paramètres indiquent que la coordination de $R'Tl^{2+}$ par le Cl^- entraîne une diminution des réactivité ($k_1/k_3 = 1200$) du même ordre que la coordination par OH^- ($k_1/k_2 = 2400$). Les deux ligands entraînement donc une diminution similaire du caractère électrophile du Tl, et du carbone adjacent ce qui rend la migration du groupe phényle lors de la rupture hétérolytique du lien C—Tl, moins favorisée.

La constante d'équilibre de formation de $R'TlCl^+$, K_3 est d'au plus un ordre de grandeur inférieure à la constante similaire du Tl(III) ($TlCl^{2+} + Cl^+ \rightleftharpoons TlCl^{2+}$, $K_{1,2} = 1.5 \times 10^5$ M^{-1} (5)); ceci montre que le thallium conserve son affinité pour ce ligand dans l'organothallique.

Il y a une espèce 1:2, R'TlOHCl, qui intervient dans l'interprétation des résultats. Sa concentration est relativement importante à

p$H \sim 5.0$, ce qui est dû au fait que $R'TlOH^+$ est l'espèce qui domine, par rapport à $R'Tl^{2+}$, dans ces conditions. Sa contribution à la vitesse n'est pas significative mais elle pourrait l'être à p$H > 5$; toutefois, il y a alors formation d'un précipité, ce qui rend l'étude impossible. A acidité plus élevée ($>10^{-2}$ M) sa concentration devient négligeable.

L'hypothèse impliquant la formation d'une autre espèce 1:2, $R'TlCl_2$, n'améliore pas de façon significative l'accord entre résultats expérimentaux et calculés.

Influence des hautes concentrations en ions Cl^-

A hautes concentrations en ions chlorures (≥ 0.1 M) et à acidité plus élevée (≥ 0.1 M) un phénomène nouveau apparaît. En effet, au lieu de la diminution habituelle d'absorbance, on observe une augmentation. L'étude de la nature des produits a permis de montrer que dans ce cas l'organothallique se décompose pour redonner les réactifs de départ:

$$C_6H_5—CH(OCH_3)—CH_2TlX_2 \rightarrow C_6H_5CH=CH_2 + Tl(III) + CH_3OH$$

Dans ces conditions il n'y a pas de disparition de thallium d'état d'oxydation 3+, tel que montré par le dosage iodométrique, dans lequel l'organothallique se comporte comme le Tl(III) (voir plus loin). L'analyse chromatographique en fin de réaction, correspondant à l'arrêt de la variation de l'absorbance, indique que le styrène s'est regénéré quantitativement à l'exclusion des produits d'oxydation habituels.

Il apparaît donc, que dans le schéma habituel de l'oxydation thallique:

$$[7] \qquad Tl(III) + \text{oléfine} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{organothallique}$$

$$[8] \qquad \text{organothallique} \xrightarrow{k_2} \text{produits d'oxydation}$$

l'étape correspondante au retour vers les réactifs de départ (k_{-1}) devient prépondérante.[1] En tenant compte de l'ensemble des résultats, on peut expliquer ce phénomène (au point de vue dynamique) comme suit. (*i*) L'augmentation de la concentration en Cl^- entraîne la formation d'espèces telles $R'TlCl_2$, $R'TlCl_3^-$. (*ii*) L'électronégativité du thallium ainsi coordiné est nettement diminuée; ceci cause une diminution de la polarisation du lien C—Tl et la diminution ou même la disparition du caractère électrophile du carbone lié au thallium. (*iii*) La rupture hétérolytique du lien C—Tl pour conduire aux produits d'oxydation est empêchée ou du moins drastiquement ralentie. (*iv*) En même temps, l'attaque électrophille par H^+ est favorisée et le retour vers les réactifs de départ est accéléré.

Au point de vue thermodynamique l'explication est également assez cohérente avec les connaissances acquises. Pour Tl^{3+} l'équilibre 7 est déplacé complètement vers la droite. Toutefois, en présence de 0.1 M en ion Cl^-, la concentration du Tl^{3+} libre est d'environ 10^{-12}% de celle du Tl(III) total, compte tenu des constantes de stabilité des complexes avec Cl^- (5) ce qui explique le renversement de la situation.

La réaction de décomposition en réactifs de départ est d'ordre un en organothallique. La constante k_{-1} varie linéairement avec la concentration en H^+, mais elle est indépendante de la concentration en Cl^- (voir fig. 1).

Ces résultats sont compatibles avec le méca-

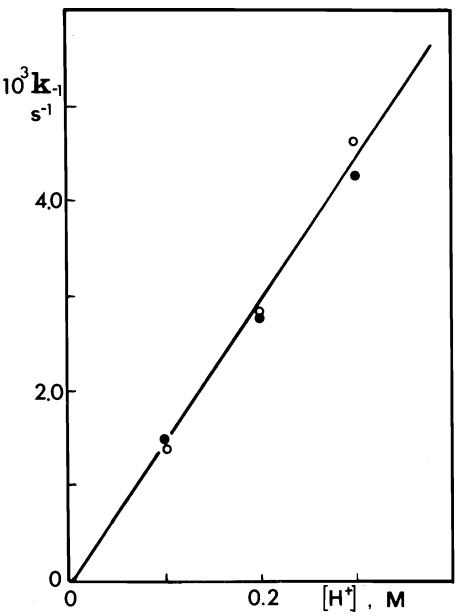

FIG. 1. Décomposition de l'organothallique en réactifs de départ. $T = 25°C$; $[R'Tl(OAc)_2] = 2.5 \times 10^{-5}$ M; solvant: H_2O–CH_3OH 75%–25% (v/v); $\mu = 0.5$ M. ○, $[Cl^-] = 0.1$ M; ●, $[Cl^-] = 0.5$ M.

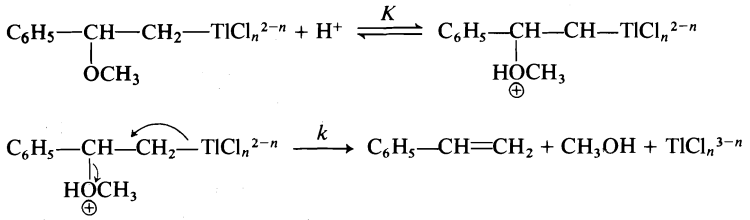
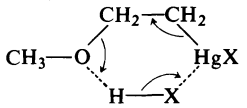
[1]A des concentrations en H^+ et en Cl^- inférieures à 0.1 M les étapes 7 et 8 interviennent simultanément, leur importance et vitesse relatives dépendant des conditions.

nisme suivant:



avec $k_{-1} = kK[H^+]$ et $kK = 1.5 \times 10^{-2} M^{-1} s^{-1}$ à 25°C

Dans le cas de la décomposition des organomercuriques dans le méthanol un mécanisme légèrement différent a été proposé; il implique une attaque concertée par un acide halogéné, HX (6):



Dans notre cas l'ion Cl^- coordine le métal avant l'attaque de H^+, et son rôle consiste à rendre le thallium moins électrophile. Le fait que la vitesse de réaction soit indépendante de la concentration en Cl^- (0.1 *M* à 0.5 *M*) indique[2] que la coordination ne change pas dans ce domaine ou, si elle change (e.g. $R'TlCl_2 + Cl^- \rightleftharpoons R'TlCl_3^-$), ce changement n'a pas d'influence appréciable sur la vitesse de décomposition. A cause de la gamme de concentration limitée, il n'est pas possible d'avoir plus d'information sur la nature exacte des expèces.

Il est à remarquer que l'influence des ions Cl^- observée dans ce cas est très différente de celle observée dans la décomposition des diacetoxyalkylthallium (e.g. $CH_3Tl(OAc)_2$). Cette réaction est accélérée par les ions Cl^- (7). Ceci est expliqué en admettant que Cl^- agit comme réactif nucléophile dans l'attaque S_N2 sur le carbone portant le thallium (8). Ce changement du mécanisme d'intervention des ions Cl^- montre l'importance de la participation ou la migration des groupes en position β (H, alkyle, aryle, OH, OR, OOCR) lors de la rupture du lien C—Tl dans le cas des composés d'oxythallation.

[2]A acidité constante, l'augmentation de la concentration en Cl^- entraîne l'augmentation de la très faible quantité de HCl non-dissocié Il ne semble donc pas que le mécanisme concerté puisse avoir une contribution majeure.

L'influence d'ions I^- et de l'éthylènediamine

La décomposition de l'organothallique en présence d'ions I^- se fait d'après l'éq. 9.

[9] $C_6H_5—CH(OCH_3)—CH_2Tl^{2+} + 3I^- \rightarrow C_6H_5—CH=CH_2 + CH_3OH + TlI + I_2$

La quantité de I_2 formé correspond à la quantité de[3] RTl^{2+} et le styrène est régénéré quantitativement, à l'exclusion de tout produit d'oxydation.

La cinétique de cette réaction rapide n'a pas pu être étudiée par flux stoppé, dû aux problèmes causés par la précipitation de TlI. Par analogie au cas des ions Cl^-, il est logique d'admettre qu'il y a d'abord coordination conduisant à $R'TlI_n^{2-n}$, qui se décompose ensuite par le mécanisme discuté plus haut. Dans ce cas, l'équilibre 7 est déplacé vers la formation du styrène à cause de la réduction du Tl(III) formé par I^-.

Nous avons voulu étudier l'influence de divers ligands azotés. Deux limitations ont été rencontrées, soit l'absorption par les bases aux longueurs d'onde utilisées et, l'influence faible (e.g. NH_3) due à la protonation des bases en milieu acide.

A pH = 5.0, l'influence de l'éthylènediamine (en) a été étudiée. Dans ce cas on observe encore une diminution de la vitesse de décomposition oxydative (voir fig. 2). Ceci est attribué à la coordination du thallium entraînant une baisse importante de la réactivité.

Le Tl(III) forme divers complexes avec l'éthylènediamine (9). En solution aqueuse on admet la formation d'un complexe 1:1 d'après l'équation: $Tl(OH)_2^+ + en \rightleftharpoons Tl(OH)_2 \cdot en^+$, avec une constante de $1 \times 10^{13} M^{-1}$ (10). Par

[3]Cette réaction peut être utilisée pour le dosage de l'organothallique par iodométrie.

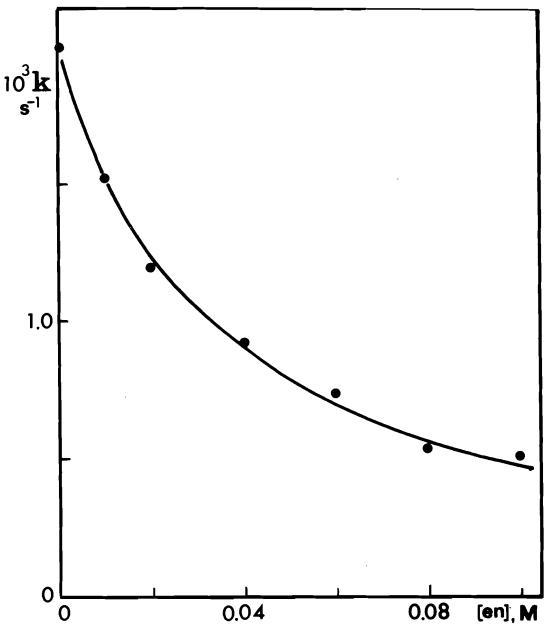


FIG. 2. Influence de l'éthylènediamine. $T = 25°C$; $[R'Tl(OAc)_2] = 1.0 \times 10^{-3}$ M; $[H^+] = 1.7 \times 10^{-5}$ M; solvant: H_2O–CH_3OH 75%–25% (v/v); $\mu = 0.5$ M. Courbe calculée; points expérimentaux.

analogie, il est probable que dans notre cas il s'agisse de la formation de $R'TlOH{\cdot}en^+$.

L'interprétation des résultats, en admettant que le complexe formé n'a pas de contribution à la vitesse[4], conduit à un accord satisfaisant entre résultats expérimentaux (points) et la courbe calculée de la fig. 2, d'après l'éq. 10.

$$[10] \quad k_{exp} = \frac{k_1 K_1[H^+] + k_2}{1 + K_1[H^+] + K_{en}[en]_{total}}$$

On obtient une constante de formation apparente[5] de $K_{en} = 30$ M^{-1}. En utilisant les valeurs de pK_a de l'éthylènediamine dans l'eau ($pK_{a_1} = 7.5$, $pK_{a_2} = 10.8$) on peut estimer la valeur de la constante d'équilibre pour la réaction: $R'TlOH^+ + en \rightleftharpoons R'TlOH{\cdot}en^+$ à $\sim 10^{10}$ M^{-1}.

La stabilité de $R'TlOH{\cdot}en^+$ est donc d'un facteur d'environ 10^3 inférieure à celle de $Tl(OH)_2{\cdot}en^+$. Ceci permet de comprendre les résultats à une acidité plus élevée ($[H^+] = 0.025$ M à l'équilibre); dans ces conditions, Tl(III) est complexé significativement (10), malgré la faible concentration de l'éthylènediamine non-protonée, mais RTlOH ne l'est plus et on n'observe pas d'effet mesurable sur la vitesse.

Conclusion

L'étude de la cinétique de formation du composé d'oxythallation a déjà permis de montrer que la coordination du Tl^{3+} par l'ion Cl^- entraîne une baisse de sa réactivité (11). Les résultats présents montrent, que la vitesse de décomposition oxydative de l'organothallique formé dépend, de façon encore plus marquée, de la coordination du thallium dans $R'Tl^{2+}$. De plus, dans ce composé, l'affinité du Tl pour divers ligands (OH^-, Cl^-, éthylènediamine) est comparable à celle de Tl^{3+}.

La réactivité de $R'Tl^{2+}$ est beaucoup plus grande que celle de $R'TlOH^+$ et $R'TlCl^+$, tandis que celle de R'TlOHCl n'est pas mesurable dans les conditions expérimentales. La diminution du caractère électrophile du Tl entraîne la polarisation moindre du lien C—Tl et la migration du groupe phényle est défavorisée.

La formation d'espèces, telles $R'TlCl_2$ ou $R'TlCl_3^-$ amplifie encore ce phénomène et la vitesse de décomposition oxydative devient négligeable. Par contre, elle favorise l'attaque électrophile par H^+ sur le groupe méthoxy, conduisant de façon semblable aux cas des organomercuriques à la décomposition de l'organothallique pour régénérer le styrène et le Tl(III).

En conclusion, l'influence des ligands affecte de façon déterminante la vitesse relative des étapes de l'oxydation thallique et l'ensemble doit être considéré lorsqu'on interprète les résultats obtenus pour des sels thalliques différents.

Consecutive reactions in the thermal decomposition of phenylalkyldiazirines

MICHAEL T. H. LIU AND BARRY M. JENNINGS

Department of Chemistry, University of Prince Edward Island, Charlottetown, P.E.I., Canada C1A 4P3

Received May 5, 1977

MICHAEL T. H. LIU and BARRY M. JENNINGS. Can. J. Chem. **55**, 3596 (1977).

The thermal decomposition of phenyl-*n*-butyldiazirine and of phenylmethyldiazirine in DMSO and in HOAc have been investigated over the temperature range 80–130°C. The intermediate diazo compounds, 1-phenyl-1-diazopentane and 1-phenyldiazoethane respectively have been detected and isolated. The decomposition of phenyl-*n*-butyldiazirine and the subsequent decomposition of its product, 1-phenyl-1-diazopentane, are an illustration of consecutive reactions. The kinetic parameters for the isomerization and decomposition reactions have been determined. The isomerization of phenylmethyldiazirine to 1-phenyldiazoethane is first order and probably unimolecular but the kinetics for the subsequent reactions of 1-phenyldiazoethane are complicated by several competing rate processes.

MICHAEL T. H. LIU et BARRY M. JENNINGS. Can. J. Chem. **55**, 3596 (1977).

On étudie la décomposition thermique entre 80 et 130°C du phényl-3 *n*-butyl-3 diazirine et du phényl-3 méthyl-3 diazirine dans le DMSO et l'acide acétique. Les composés diazo intermédiaires sont respectivement le phényl-1 diazo-1 pentane et le phényl-1 diazo-1 éthane. Ces derniers ont été détectés et isolés. La décomposition du phényl-3 *n*-butyl-3 diazirine et la décomposition ultérieure de son intermédiaire le phényl-1 diazo-1 pentane sont un bon exemple de réactions successives. On détermine les paramètres cinétiques pour les réactions d'isomérisation et de décomposition. L'isomérisation du phényl-3 méthyl-3 diazirine en phényl-1 diazo-1 éthane est d'ordre 1 et probablement unimoléculaire, mais les cinétiques des réactions ultérieures du phényl-1 diazo-1 éthane sont compliquées par plusieurs processus qui entrent en compétition.

[Traduit par le journal]

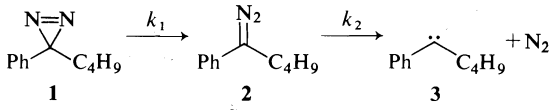
Introduction

The intermediacy of diazomethane in the decomposition of diazirine has been the subject of discussion for many years (1–3). While there is sufficient evidence for the diazomethane intermediate in the photolysis of diazirine (4), its presence in the thermal decomposition has only been implicated, and no diazomethane intermediate has ever been isolated from a diazirine pyrolysis experiment (5–8). In one report (9), the attempted synthesis of 3,3-diphenyldiazirine resulted in the formation of diphenyldiazomethane; however, the precursory existence of diazirine was never verified. Only in the case of 3-methyl-3-vinyldiazirine has the linear diazo isomer been observed (8) as its subsequent reaction product, 3-methylpyrazole. We have recently reported (10) the formation of 1-phenyl-1-diazopentane (**2**) as evidence for diazo intermediate in the thermolysis of phenyl-*n*-butyldiazirine (**1**). In this paper, we wish to report the complete kinetic data for the thermal decomposition of **1** and **2** as well as the data for the decomposition of phenylmethyldiazirine (**4**). Comparisons will be made in relation to the existing data for the thermal decomposition of methylvinyldiazirine and of various chlorodiazirines.

Results and Discussion

1. Decomposition of Phenyl-n-butyldiazirine (1)

The thermal decomposition of **1** in DMSO solutions (0.1 *M*) at 100°C gave nitrogen, *cis*- and *trans*-1-phenyl-1-pentenes (ratio *cis*:*trans* = 1:5) along with a small amount (<5%) of valerophenone. No azine was found. The formation of valerophenone was due to the oxidation of **2** by DMSO and the olefins were the rearrangement products of carbene **3**. When the reaction was followed by uv or ir spectroscopy, an intermediate species was observed to form rapidly and subsequently diminish, uv_{max} at 520 nm (low ε) and ir at 4.90 μ are consistent with this intermediate being assigned as 1-phenyl-1-diazopentane, **2**. The isolation of **2** was possible by interruption of the reaction after 1 h followed by extraction with petroleum ether. Compound **2** appears to be very stable, as the red petroleum ether solution remained unchanged at room temperature for several days. The above results serve to support a stepwise mechanism for the decomposition of the diazirine as in



1 2 3

SCHEME 1

Scheme 1. The rates of decomposition of **1** in DMSO were studied over the temperature range 80–130°C by measuring the disappearance of its uv_{max} at 371 nm (k_1) and by measuring the evolved nitrogen during the decomposition (k_2). The first-order rate constants, k_1 and k_2, are presented in Table 1. The determination of k_2 in DMSO by the N_2 evolution method requires elaboration. The first-order plot from N_2 measurements does not give a straight line; in fact, there is a slight curvature (convex) during the first 20–30 min of the reaction. This curvature is due to the build-up of the diazo compound. After such time, N_2 evolution begins to approximate first-order behavior and it is in this portion of the graph that k_2 was taken. In order to confirm the value of k_2, we have synthesized 1-phenyl-1-diazopentane from a separate experiment, and its N_2 evolution in DMSO was measured. The first-order rate constants determined in this manner were within 3% of the values reported in Table 1. That the two measurements in DMSO solvent differ by a factor of 3 suggests that in fact two different rates are being measured; k_1 can therefore be taken as the rate of isomerization of **1** to **2**, while k_2 may be regarded as the rate of decomposition of **2** giving nitrogen and **3**. The assignment of k_1 and k_2 above finds further support in their measurement in acetic acid (Table 1). It is well established that diazirine decomposition is unaffected by acid (1) while the decomposition of diazomethanes is acid catalyzed (11). Thus in this case, the isomerization of **1** to **2** would be the rate determining step in the overall reaction and k_2 would be expected to equal k_1, which is the experimental observation. The data in Table 1 gave excellent Arrhenius plots from which equations 1 and 2 were obtained by least-squares analysis. R is taken as

*All k_1 values were determined by uv and k_2 values by N_2 measurements.

[1] $k_1 = 10^{13.26\pm0.05} \exp((-28\,080 \pm 90)/RT)\ s^{-1}$

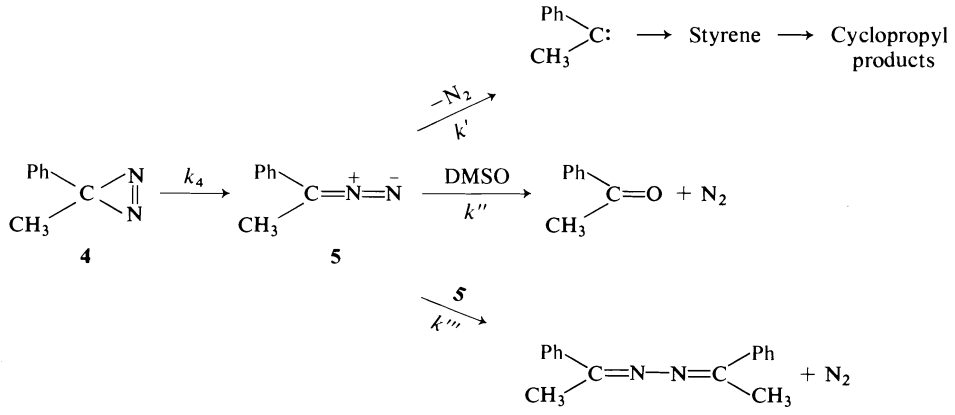
[2] $k_2 = 10^{12.03\pm0.54} \exp((-26\,810 \pm 950)/RT)\ s^{-1}$

1.987 cal mol^{-1} K^{-1} throughout this text. The errors quoted are standard deviations. The Arrhenius parameters for k_1 are in good agreement with reported values for decomposition of other diazirines (7). The parameters for k_2 compare well with those for the decomposition of diethyl diazosuccinate (11) (E = 27.31 kcal/mol, log A = 11.77) and for the decomposition of diphenyldiazomethane (12) (E = 27.9 kcal/mol, log A = 13.25).

Now the question arises whether the concerted elimination of N_2 from **1** to give carbene **3** can be completely ruled out. In order to answer this question and also to test the consistency of the rate constants (k_1 and k_2) assignment, the following experiments have been carried out. For a consecutive reaction of the type $A \xrightarrow{k_1} B \xrightarrow{k_2} C$, the concentration of B is given by [3] (13).

[3] $[B] = [A]_0 \frac{k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t})$

Thus by knowing the initial concentration of **1** and the values of k_1 and k_2 at the temperature of the experiment, the concentration of **2** can be determined at any time t. The concentration of **2** at a time t was determined by withdrawing an aliquot of reaction mixture and running it into a large excess of acetic acid to convert **2** to the ester, 1-phenyl-1-pentyl acetate. This mixture was then worked up in the usual manner and analyzed by vpc. When observed m mole ester vs. calculated m mole ester are plotted, a straight line with a slope of 0.90 is obtained. This indicates that 90% of the calculated amount of **2** is being accounted for in the measured ester. Owing to the number of manipulations required in the experimental procedure and analysis, a value for



SCHEME 2

the experimental error of ±5–10% does not seem unreasonable. Hence, it is suggested that all diazirine **1** decomposes via the diazo isomer **2**.

2. Decomposition of Phenylmethyldiazirine (4)

Schmitz and Ohme (14) reported that the thermal decomposition of phenylmethyldiazirine **4** in nitrobenzene gave styrene. This is to be contrasted with Overberger and Anselme's results (15) for which they reported that the thermal decomposition of 1-phenyl-diazoethane **5** gave acetophenone azine as the only product. In our present work, the thermal decomposition of **4** in DMSO (0.1 *M*) gave the following products: styrene 10–15%, cyclopropyl products (carbene + styrene) 15%, acetophenone 45%, and acetophenone azine 10–15%. In addition, 1-phenyldiazoethane (**5**) has been isolated as evidence for a diazo intermediate during the decomposition of phenylmethyldiazirine (**4**). The decomposition pathways are summarized in Scheme 2. Further experimentation (16) shows that in the decomposition of diazirine **4**, the formation of **5** is not affected by the nature of the solvent, but its subsequent decomposition to stable products is dependent on solvent polarity and concentration. A separate study in the mechanism of azine formation (17) clearly indicates that azine could not be formed by the attack of carbene on **5**. It is interesting to note that the absence of azine formation in the decomposition of phenyl-*n*-butyldiazirine could well be explained in terms of a steric effect. It is because of this steric effect that the decomposition of **1** is truly an example of consecutive reactions. In the decomposition of **4**, the kinetics are complicated by the presence of several other competing reactions in the decomposition of **5**. However, the isomerization of **4** to **5** is still first order and probably unimolecular. Thus, rate constants in DMSO for the isomerization reaction were determined by uv spectroscopy and are listed in Table 2. The data gave a good Arrhenius plot from which [4] was obtained by least-squares analysis. When N_2

$$[4] \quad k_4 = 10^{13.45\pm0.46} \exp((-28\,500 \pm 790)/RT)\ s^{-1}$$

kinetics were attempted in DMSO, great curvature was evident in the first-order plots, thus confirming the complexity of the reaction. Since the rate of nitrogen formation is

$$[5] \quad V_{N_2} = k'[\mathbf{5}] + k''[\mathbf{5}][\text{DMSO}] + k'''[\mathbf{5}]^2$$

the order of the reaction should, in fact, be between first and second order in **5**. When **4** is decomposed in HOAc, the diazo compound **5** will immediately be removed by HOAc as the ester; hence, the rate constant obtained by uv measurements should be equal to the one obtained by N_2 measurement. This was observed experimentally. The activation energies for the thermal decomposition of the diazirines **1** and

TABLE 2. Rate constants for the thermal decomposition of phenylmethyldiazirine (k_4)

Solvent	T(°C)	$k_4 \times 10^4$(s^{-1})	Method
DMSO	83.6	0.98±0.02	uv
	92.1	2.70±0.04	uv
	99.6	6.44±0.05	uv
	108.6	14.40±0.31	uv

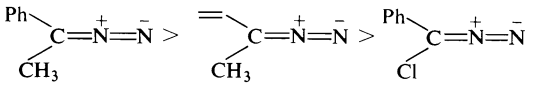
	99.6	4.79±0.03	N_2

4 as well as that of chlorophenyldiazirine (7*c*) in DMSO solvent are about 28 kcal/mol. It would appear that the energy of activation depends only on the presence of the phenyl ring. However, the relative rate for k(chlorophenyldiazirine)/k(**1** or **4**) at 100°C is approximately equal to 6.

Our earlier work (7*b*, *d*, *e*) on the thermal decomposition of chlorodiazirines suggests that the decomposition of diazirine occurs by a two-step mechanism. We have also inferred that the intermediate is similar to diazomethane in structure and the extent of polarization in this intermediate would depend on the substituent present in the diazirine ring (7*b*, *e*). Perhaps the most striking example for a polarized transition state is the 3-chloro-3-*p*-methoxyphenyldiazirine in which the positive charge on the carbon of the diazo group is stabilized by the *p*-methoxyphenyl substituent (7*b*). In the decomposition of **1**, the two measurements (by uv and N_2) in DMSO differ by a factor of 3, but in the decomposition of chlorophenyldiazirine in the same solvent, the rate constants obtained by either method are equal (7*c*). This implies that the chlorophenyldiazomethane intermediate decomposes rapidly as soon as it is formed. However, we are certain that there is a definite lifetime for the chlorophenyldiazomethane intermediate but the duration is too short to be detectable by conventional techniques. Several chlorodiazomethanes are also known to be unstable (18, 19).

In conclusion, all diazirines will isomerize (k_i) to the corresponding diazo intermediate with similar rate constants (hence similar E and A) since all reactions involve the ring opening process. However, the rate constants (k_d) for the subsequent reaction of the diazo intermediates differ in many powers of 10. In the case of phenyl-*n*-butyldiazirine, a value of 0.33 was obtained for k_d/k_i and in the case of methylvinyldiazirine (7*d*, 8, 20), a value of approximately 70 was found for k_d/k_i. It is reasonable to assume a value of $>10^3$ in the case of chlorophenyldiazirine. It is to be noted that the diazirines, which we have chosen in the above discussion, are all stable compounds (chlorophenyldiazirine has the least kinetic and thermodynamic stability) and they can be kept in the refrigerator (0°C) for several weeks without decomposition. Such stability is not observed for the corresponding diazo compounds. The indicated order of stability is as follows:



Experimental

The ir and nmr spectra were obtained with Perkin-Elmer Model 257 and Varian Associates, T60 instruments respectively. The chemical shifts are given in τ scale together with splitting pattern, relative integrated areas, and assignments. The uv spectra were measured with a Unicam SP 800 spectrophotometer and mass spectra with a Hitachi-Perkin-Elmer model RMS-4 spectrometer. The vpc analyses were carried out using a Perkin-Elmer model F 11 equipped with a hydrogen flame detector; the peak areas were integrated by a ball and disc integrator.

1. Synthesis of n-Butylphenylketimine

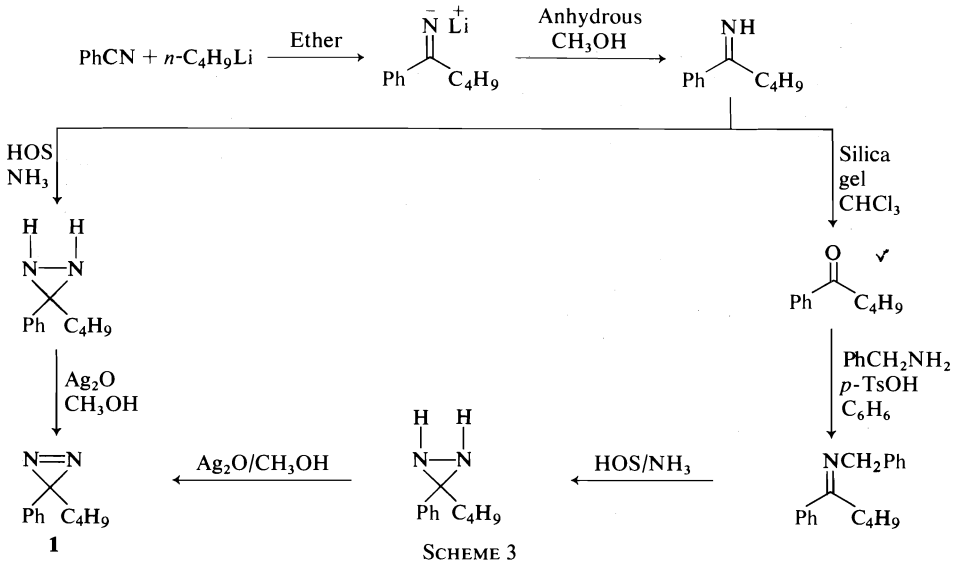
To a 1 ℓ, 3 neck flask equipped with magnetic stirrer, dropping funnel, and condenser was added 100 ml of anhydrous ether and 100 ml (0.22 mol) of 2.2 *M* *n*-butyllithium in hexane. With stirring, a solution of 20 g (0.2 mol) of benzonitrile in 100 ml ether was added dropwise. Considerable heat was evolved and the reaction mixture became dark in color. After complete addition, the reaction mixture was refluxed for 3 h, then allowed to cool. Anhydrous methanol (50 ml) was added dropwise and stirring was continued for an extra half hour. The mixture was then filtered and concentrated *in vacuo*, giving a dark oil, which was distilled (90–95°C, 0.8 Torr) to give 18.6 g (61%) of the product: ir 1620 cm^{-1} (C=N); nmr τ 0.7 (br m, 1, =NH), 2.4 and 2.7 (each m, total 5, aromatics), 7.4 (t, 2, J = 7 Hz, >C(=NH) —CH_2), 8.5 (br m, 4, methylenes), 9.05 (m, 3, methyl).

2. Synthesis of Phenyl-n-butyldiaziridine from n-Butylphenylketimine

A solution of 19 g (0.12 mol) of ketimine in 125 ml of methanol was added dropwise with stirring to 50 ml of liquid NH_3 at −50°C in a three neck 250 ml flask. After stirring for ½ h at −50°C, hydroxylamine-*O*-sulphonic acid (HOS, 25 g, 0.22 mol) was added in small portions. After stirring for 1 h at −50°C, the reaction mixture was allowed to warm up overnight. The mixture was added to 400 ml ether, filtered, washed with water, and dried. After filtering and removal of solvent, 21 g amber oil remained: ir 3450 cm^{-1} (N—H).

3. Synthesis of Phenyl-n-butyldiaziridine from Valerophenone (n-Butylphenylketone)

A mixture of valerophenone (13 g, 0.08 mol), benzylamine (13 g, 0.12 mol), *p*-toluenesulphonic acid (1 g), and benzene (100 ml) was heated to reflux for 68 h. The water formed during the reaction was trapped in a Dean Stark apparatus via benzene azeotrope. After this period, the theoretical quantity of water was collected and the reaction mixture was allowed to cool. After filtering the mixture the benzene solution was washed with saturated $NaHCO_3$, water, and was dried. Removal of benzene left a yellow oil which was distilled at 170–180°C (2 Torr) to give 16.43 g (82%) of *N*-benzyl-*n*-butylphenylketimine; ir 1625 cm^{-1} (C=N). This product was dissolved in 125 ml methanol and added dropwise to 75 ml of liquid ammonia at −30°C. After stirring at −30°C for 3 h, 18.65 g (0.165 mol) of HOS were added in small portions, and



SCHEME 3

the procedure continued in the same manner as in part 2 above. Yield was 18.4 g of amber oil.

4. Synthesis of Phenyl-n-butyldiazirine (1) from Phenyl-n-butyldiaziridine

The crude diaziridine (11.45 g) prepared by either method above was dissolved in 150 ml methanol and added to a suspension of freshly prepared silver oxide in 50 ml methanol. After stirring for 2 h, during which time a heavy silver mirror coated the interior walls of the flask, the solution was filtered, added to 600 ml ether, washed with several portions of water, and dried. Removal of ether left 11.5 g of yellow oil which was chromatographed on 100 g silica gel (100–200 mesh) with CH_2Cl_2 – petroleum ether (1:6). This resulted in 4.0 g (this represents an overall yield of 35% with respect to either *n*-butylphenylketimine or *N*-benzyl-*n*-butylphenylketimine) of diazirine as a nearly colorless liquid: ir 1580 cm^{-1} (N=N); nmr τ 2.8 (m, 3, *meta* and *para* aromatics), 3.13 (m, 2, *ortho*), 8.07 (br t, J = 7 Hz, 2, ), 8.7 (m, 4, methylenes), 9.1 (br t, 3, methyl); uv_{max} (petroleum ether) 372 (ε 235), 382 sh (ε 214); ms (70 eV) *m/e* 146 (parent − N_2). The synthetic procedures for phenyl-*n*-butyldiazirine are summarized in Scheme 3.

5. Product Analysis

a. Decompositions of 1 in DMSO

The reaction mixtures from two kinetic experiments were combined and diluted with 200 ml water. This was extracted with 2 × 25 ml ether and the combined ether extracts were washed with 50 ml water, dried and concentrated *in vacuo*, giving 340 mg of yellow oil. The vpc analysis on a 12 ft 20% Carbowax showed three components. Column chromatography (silica gel, 50% benzene–$CHCl_3$) resolved the mixture into two components. The minor fraction was identified as valerophenone (< 5%) while the major portion was a mixture of the other two components, which were identified as *cis* and *trans* (1:5) 1-phenyl-1-pentenes on the basis of identical retention times as authentic samples and nmr data: τ 2.8 (s, 5, aromatic), 3.8 (m, 2, olefinic) 7.9 (m, 2, allylic), 8.6 (m, 2, methylene), 9.1 (br, t, 3, methyl).

b. Decomposition of 1 in HOAc

The reaction mixture from one kinetic experiment was extracted as above to give 190 mg of oil. The vpc showed three components in a ratio of 1:5:19. Column chromatography on silica gel with CCl_4–$CHCl_3$ separated the mixture into two fractions. The first, 27 mg, was shown to be a mixture of *cis*- and *trans*-1-phenyl-1-pentenes. The second, 158 mg, was identified as 1-phenyl-1-pentyl-acetate on the basis of these spectral properties: ir 1745 cm^{-1} (ester C=O); nmr τ 2.77 (s, 5, aromatic), 4.35 (t, J = 6.5 Hz, 1, ), 8.04 (s, 3, acetate methyl), 8.2 (m, 2, methylenes), 8.7 (m, 4, methylenes), 9.13 (t, 3, J = 6 Hz, methyl); *m/e* parent 206; *Anal.* calcd. for $C_{13}H_{18}O_2$: C 75.69, H 8.80; found: C 75.33, H 8.76.

c. Isolation of 1-Phenyl-1-diazopentane (2)

Phenyl-*n*-butyldiazirine (0.5 g) in 20 ml DMSO was heated at 91°C for 2 h. At this time the now red mixture was added to 700 ml water at 10°C and the mixture was extracted with 2 × 50 ml petroleum ether. The combined petroleum ether fractions were washed with water, dried, and concentrated *in vacuo* to give 400 mg of dark-red oil. The ir of this material showed an intense band at 2040 cm^{-1} (diazo >C=N_2), plus indications of a little olefin and carboxyl material. The crude diazo mixture retained its color for several days at room temperature.

6. Photolysis of Phenyl-n-butyldiazirine (1) in Benzene; Isomerization to 1-Phenyl-1-diazopentane (2)

A solution of 400 mg diazirine in 100 ml benzene was degassed and was irradiated with light from a Hanovia 450 W type L lamp in a quartz immersion well, filtered through a 20 cm × 20 cm plate of Corning #5840 glass (transmit 330 < λ < 400 nm). The reaction was monitored by uv spectroscopy, which showed, after 1 h of irradiation, complete disappearance of the diazirine ab-

sorption and the appearance of a long band of low ε centered at about 520 nm (diazo isomer). Good isosbestic points were observed, indicating no other product was found. The solution was concentrated *in vacuo* giving 370 mg of a deep-red oil, the diazo compound.

7. Synthesis of Phenylmethyldiazirine (4)

Phenylmethyldiazirine, **4**, was synthesized from the *N*-benzylmethylphenylketimine in the manner of Schmitz and Ohme (14). The final yield of diazirine (colorless) was 23%, based on the starting ketimine. Spectral properties: ir 1600 cm^{-1} (N=N); nmr τ 2.8 (m, 3, *meta* and *para* aromatics), 3.2 (m, 2, *ortho*), 8.52 (s, 3, methyl) uv_{max} (methanol) 368 nm (ε 187).

8. Product Analysis

a. Decomposition of Phenylmethyldiazirine (4) in DMSO

The reaction mixtures from several DMSO kinetic experiments were combined and worked up as in part 5 above. The products were: styrene 10–15%, cyclopropyl products (carbene + styrene) 15%, acetophenone 45%, and acetophenone azine 10–15%.

b. Decomposition of 4 in Acetic Acid

The reaction mixtures from two kinetic experiments were combined and worked up as above. The product was identified as 1-phenyl-1-ethylacetate on the basis of the following spectral properties: ir 1745 cm^{-1} (ester C=O); nmr τ 2.76 (s, 5, aromatic), 4.22 (q, J = 6.5 Hz, 1,  8.03 (s, 3, acetate methyl), 8.50 (d, 3, J = 6.5 Hz, methyl); ms (70 eV) parent 164; *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.15, H 7.37; found: C 72.81, H 7.38.

9. Isolation of 1-Phenyldiazoethane (5)

Phenylmethyldiazirine **4** (0.5 g) in 20 ml DMSO was heated at 90°C for 2 h. The solution turned red. The red material has a strong ir absorption at 2040 cm^{-1} and was isolated as in part 5*c* and identified as 1-phenyl-diazoethane (**5**).

10. Kinetic Procedure

The methods described previously (*7b*, *c*) were employed for 10 ml solutions of diazirine (0.1 M) in either DMSO or HOAc.

Received February 7, 1977

RODERICK E. WASYLISHEN, BRIAN A. PETTITT, and WERNER DANCHURA. Can. J. Chem. **55**, 3602 (1977).

The viscosity and temperature dependence of ^1H, ^2H, and ^{13}C nmr relaxation rates of triphenylene were investigated. The observed η/T dependence of the reorientation correlation time, τ_c, is compared with that derived from the work of Hu and Zwanzig based on hydrodynamic rotation with 'stick' and 'slip' boundary conditions. In the hydrodynamic regime, $\tau_c = C\eta/T$. The observed slope, $C_{experimental}$, is 6.2 ± 2 ns K/cP and the calculated values are $C_{slip} = 4.1 \pm 0.6$ ns K/cP and $C_{stick} = 31.0 \pm 3.1$ ns K/cP. These data imply that the reorientation of triphenylene obeys a near-slip condition. That is, rotation in the plane of the molecule encounters little resistance, but rotation of the plane of the molecule is resisted by shear forces in the solvent displaced during rotation. Expressions are given for Boltzmann-averaged free rotation times and comparisons are made with the $\eta = 0$ intercept and the times for slightly hindered rotation.

RODERICK E. WASYLISHEN, BRIAN A. PETTITT et WERNER DANCHURA. Can. J. Chem. **55**, 3602 (1977).

On étudie par rmn ^1H, ^2H et ^{13}C l'effet de la viscosité et de la température sur les vitesses de relaxation du triphénylène. La dépendance observée η/T du temps corrélatif de réorientation τ_c est comparée avec celle obtenue des travaux de Hu et Zwanzig basée sur la rotation hydrodynamique dans des conditions limites "collantes" et "glissantes". Pour le régime hydrodynamique, $\tau_c = C\eta/T$. La pente observée $C_{expérimental}$ est 6.2 ± 2 ns K/cP et les valeurs calculées sont $C_{glissante} = 4.1 \pm 0.6$ ns K/cP et $C_{collante} = 31.02 \pm 3.1$ ns K/cP. Ces résultats impliquent que la réorientation du triphénylène suit une condition qui rapproche de la "glissante". Par exemple, on rencontre une petite résistance pour la rotation dans le plan de la molécule, mais la rotation du plan de la molécule est gênée par des forces de rupture développées au sein du solvant déplacé lors de la rotation. Des expressions sont présentées pour les temps de rotation libre moyens de Boltzmann et des comparaisons sont faites entre l'ordonnée $\eta = 0$ et les temps pour une rotation légèrement empêchée.

[Traduit par le journal]

Introduction

Recent calculations by Hu and Zwanzig (1) relating rotational friction coefficients of spheroids under two sets of boundary conditions have proved useful in the study of molecular rotations in liquids by nuclear magnetic relaxation methods (2). When combined with Woessner's theory (3), their results bring calculated rotational correlation times, τ_c, into line with those measured by nmr. The important equations can be summarized as

$$\tau_c = C\eta/T \quad [1]$$

where η is the shear viscosity and T the temperature of the liquid, and the two models predict very different slopes.

In this paper, the method is outlined for a restricted class of molecules and results are presented from a detailed study of triphenylene (Fig. 1) by proton, deuterium, and carbon-13 relaxation. An appendix presents a brief discussion of rotation in the inertial limit.

Theory

A spin–lattice relaxation time, T_1, is calculated by manipulating the equations of motion for the decay of nuclear magnetization into the form (4)

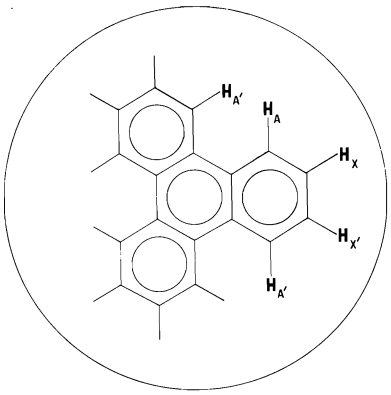

FIG. 1. Triphenylene within a circle of radius 6 Å.

$$[2] \quad \frac{d}{dt}\langle M_z\rangle = -\frac{1}{T_1}(\langle M_z\rangle - \langle M_z\rangle_0)$$

where $\langle M_z\rangle_0$ is the equilibrium value of $\langle M_z\rangle$. For quadrupolar and dipolar intramolecular relaxation in liquids, the time dependence of the spin–lattice interaction is a result of molecular rotation. Consequently, T_1 can be related to molecular parameters that characterize the dynamics of rotation; in particular, the rotational time τ_c. In the limit where rotational motion is much faster than the Larmor frequencies of the nuclei considered, the important relations for the molecules considered here are as follows.

(*a*) Carbon-13:

$$[3] \quad \frac{1}{T_1} = \frac{\gamma_H{}^2\gamma_C{}^2\hbar^2\,\tau_c}{r_{CH}{}^6}$$

(*b*) Protons:

$$[4] \quad \left(\frac{1}{T_1}\right)_i = \frac{3}{2}\gamma_H{}^4\hbar^2\tau_c\sum_j r_{ij}{}^{-6}$$

for proton i, where j is summed over other protons near enough to cause relaxation.

(*c*) Deuterium:

$$[5] \quad \frac{1}{T_1} = \frac{3\pi^2}{2}\left(\frac{e^2qQ}{h}\right)^2\tau_c$$

ignoring the asymmetry parameter for C—D bonds. Here $h = 2\pi\hbar \equiv$ Planck's constant; $\gamma_{H\text{ or }C} \equiv$ magnetogyric ratio of ^1H or ^{13}C; $r \equiv$ internuclear distance; and $e^2qQ/h \equiv$ quadrupolar coupling constant.

In the hydrodynamical model of molecular rotation (1, 3, 5–7), τ_c can be related to the components of the rotational friction tensor, $\bar{\bar{\zeta}}$, of the solid body representing the molecule in a continuous fluid. It is assumed that the molecule undergoes small, random jumps characterised by a rotational diffusion tensor, $\bar{\bar{R}}$. The elements of the diagonalized $\bar{\bar{R}}$ are defined such that the molecule diffuses through angles (rms)

$$[6] \quad \langle\Delta\theta_i{}^2\rangle^{1/2} = (2R_i\Delta t)^{1/2} \quad i = 1, 2, 3$$

in time Δt small on a macroscopic scale but large enough for several jumps to occur (8). Perrin (7*a*) has shown that, for small jumps at equilibrium,

$$[7] \quad R_i = kT/\zeta_i$$

For brevity, the equations of this model are restricted to those of spheroidal molecules ($R_1 = R_2 \neq R_3$) with all relevant internuclear vectors perpendicular to the symmetry axis (the 3 axis). Under the boundary condition that the fluid at the surface of the spheroid has the same velocity as the surface, the ζ's are (3)

$$[8] \quad \zeta_1 = \zeta_2 = \frac{32\pi\eta\,(c^4 - a^4)}{3\{(2c^2 - a^2)S - 2c\}}$$

$$\zeta_3 = \frac{32\pi\eta a^2(c^2 - a^2)}{3(2c - a^2S)}$$

where $a = b$ are the 1 and 2 semi-axes and c is the 3 semi-axis of the spheroid.

$$S = 2(a^2 - c^2)^{-1/2}\tan^{-1}\frac{(a^2 - c^2)^{1/2}}{c}$$

$$[9] \quad \text{for } a > c \text{ (oblate spheroid)}$$

$$S = 2(c^2 - a^2)^{-1/2}\ln\left(\frac{c + (c^2 - a^2)^{1/2}}{c}\right)$$

$$\text{for } a < c \text{ (prolate spheroid)}$$

Woessner's (3) calculation of τ_c then becomes

$$[10] \quad \tau_c = \frac{1}{24R_1} + \frac{3}{8(R_1 + 2R_3)} = \frac{\zeta_1}{24kT} + \frac{3\zeta_1}{8kT(1 + (2\zeta_1/\zeta_3))}$$

Inspection of [7], [8], and [10] shows that τ_c is proportional to η/T and the slope can be calculated from the size of the molecule.

Hu and Zwanzig (1) calculated the ζ_i's for spheroids under boundary conditions where the body slips through the fluid and resistive forces are due only to the displacement of fluid as the body rotates. Thus, $\zeta_3 = 0$ since

no fluid is displaced by rotation about the symmetry axis, and the viscosity dependence of T_1 is due to displacement of fluid by rotation of the symmetry axis. That is, as $\zeta_3 \rightarrow$ very small, $R_3 \rightarrow$ very large and τ_c of [10] is dominated by the first term

$$[11] \qquad \tau_c' = \zeta_1'/24kT$$

where the prime indicates that the calculation is done under 'slip' boundary conditions. Hu and Zwanzig tabulate their results in terms of the ratio

$$[12] \qquad \zeta_1'/\zeta_1 \equiv f(\rho)$$

where

$$\rho \equiv c/a \text{ for oblate spheroids}$$

$$\equiv a/c \text{ for prolate spheroids}$$

Hence,

$$[13] \qquad \tau_c' = f(\rho)\zeta_1/24kT$$

and $\tau_c' < \tau_c$ since $f(\rho) \leq 1$ and the contribution of the second term of [10] has been lost.

In precise terms, it is important to distinguish between hydrodynamical (continuum) and molecular (discrete) ideas, but the qualitative correspondence used here implies that the 'slip' condition is appropriate in the absence of attractive solute–solvent interactions, whereas the 'stick' condition requires these interactions to be strong. On this basis, the two types of boundary conditions would appear to represent lower and upper limits to τ_c. The 'stick' model is especially poor for large solvent molecules because the boundary is not even approximately hydrodynamical.

Experimental

Triphenylene was obtained from the Aldrich Chemical Company and from Dr. Herman Ziffer, N.I.H., Bethesda, Maryland. Triphenylene-d_{12} was obtained from Merck Sharp and Dohme. All solvents were available commercially. Non-deuterated solvents were all spectro-quality reagents.

Proton-decoupled ^{13}C nmr spectra were obtained on a Varian CFT-20 spectrometer (10 mm probe) using a sweep width of 500 Hz and a data acquisition time of 4.095 s. A co-axial tube containing D_2O provided the necessary deuterium lock for the CFT-20. Spin–lattice relaxation times were measured using the inversion–recovery pulse sequence ($d - 180° - t - 90°$), where d is a delay time ($d > 5T_1$) and t is a variable time. The 90° pulse was 18 μs. Nuclear magnetic resonance spectra were obtained for 11 different t values and T_1 was calculated from the slope of a plot of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ vs. t (9). All lines were broadened by approximately 3 Hz using a sensitivity enhancement factor. Approximately 1000 transients were required in order to obtain reasonable signal to noise. The nOe factors were measured using the gated proton decoupler on the CFT-20 ($d \simeq 10T_1$).

All triphenylene solutions used in the proton nmr studies were 0.02 M or less depending on the solubility of I. Solutions were degassed on a high vacuum gas line at least five times by the freeze–pump–thaw technique. All proton measurements were carried out on a Varian HR-200 MHz nmr spectrometer equipped with a Fourier transform accessory. No lock was required for this superconducting magnet therefore it was not necessary to add an internal reference to the solutions. The proton spectrum of triphenylene at 220 MHz is that of a typical AA′XX′ spin system. The H_A protons were typically 200 Hz or more downfield from H_X. Proton spin–lattice relaxation times were measured using non-selective pulses and the inversion recovery sequence. Spectra were obtained for at least 20 different values of t. Typically the 90° pulse was 40 μs while the 180° pulse was 80 μs. The data were accumulated, acquisition time 8 s, and the resulting free induction decay was weighted with an exponential weighting factor and Fourier transformed with a Varian 620L computer. The exponential weighting factor broadened all transitions by approximately 1.6 Hz at half height. Spin–lattice relaxation times were calculated from slopes of plots of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ vs. t. These plots were quite linear thus the recovery rates have been assumed describable in terms of a single exponential time constant (T_1) (see Figs. 2 and 3).

Deuteron relaxation rates of triphenylene-d_{12} were measured at 10 MHz on a Bruker B-KR322 variable frequency spectrometer. The inversion–recovery pulse sequence was used and T_1 was calculated from the slope of a plot of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ vs. t. The free induction decays were not Fourier transformed.

Results and Discussion

1. Geometric Considerations

a. τ_c from Carbon-13 Relaxation

For a 0.045 M solution of triphenylene in CCl_4 at 28.5 ± 2°C the value $T(^{13}C_{A,A'}) = T_1(^{13}C_{X,X'}) = 2.15 \pm 0.1$ s was observed. Equation 3, with a C—H bond length of 1.08 Å, gives $\tau_c = 20.5$ ps. For $C_{A,A'}$ and $C_{X,X'}$ the nOe's were 3.0 ± 0.1.

b. Proton–Proton Separations

To calculate τ_c for triphenylene from ^1H nmr spin–lattice relaxation rates and [4], it is necessary to know the various proton–proton separations. Only protons H_A and $H_{X'}$ are sufficiently proximate to H_X to be effective in its relaxation. Similarly, only $H_{A'}$ and H_X are effective in relaxing H_A. For a 0.02 M solution of triphenylene in CCl_4 at 28.5°C, $T_1(H_A) = 2.81$ s and $T_1(H_X) = 7.10$ s. Assuming $\tau_c = 20.5$ ps and $r_{AX} = r_{XX'}$, substitution into [4] gives $r_{AX} = r_{XX'} = 2.51$ Å and $r_{AA'} = 1.99$ Å.

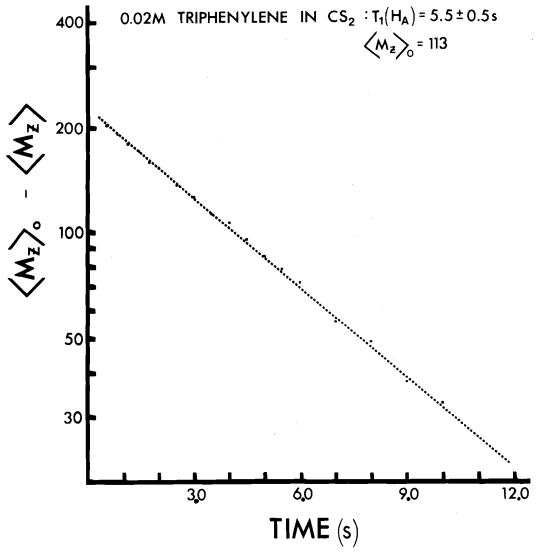

FIG. 2. Plot of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ vs. t for H_A.

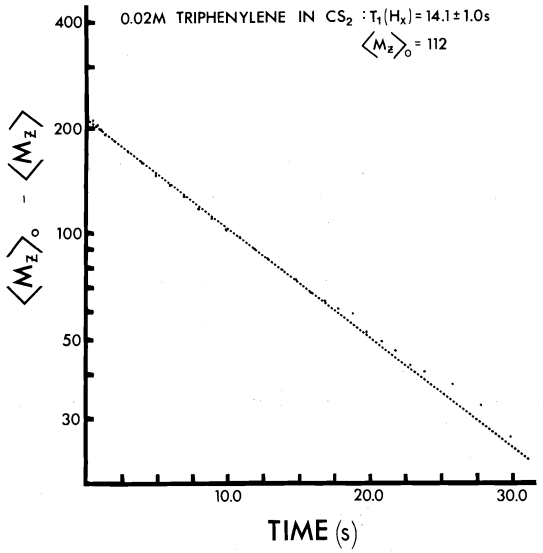

FIG. 3. Plot of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ vs. t for H_X.

These values of r_{HH} are used in all subsequent calculations of τ_c from proton T_1's of triphenylene.

From the carbon skeleton determined by X-ray crystallography (10) the values $r_{AX} = 2.46$ Å, $r_{XX'} = 2.48$ Å, and $r_{AA'} = 1.86$ Å were calculated assuming a planar molecule with all C—H bonds 1.08 Å and all CC_iC angles bisected by the C_i—H vectors. A neutron diffraction study (11) gave $r_{AA'} = 1.91$ Å.

Because we have ignored multi-spin effects (see footnote 1 in part 2*b*) the H—H separations obtained here may not be reliable.

c. Molecular Size

For the calculation of C_{slip} and C_{stick} from [11] and [10], an estimate of the size of triphenylene was necessary. The atomic volume increments given by Edward (12) give a molecular volume of 209.4 Å^3. X-ray data (10) indicate that the triphenylene ring planes are separated by 3.4 Å in the solid state (note: the accepted van der Waals radius for carbon is 1.65–1.7 Å). $V = 4/3\pi a^2 c = 209.4$ Å^3 and $c = 1.7$ Å gives $a = 5.42$ Å. This value for a was taken to be a lower limit. If the molecule is considered to extend one van der Waals radius (1.25–1.45 Å) beyond the periphery of the $H_{XX'}$ protons, then $a = 4.75 + 1.45 = 6.2$ Å can be regarded as an upper limit.

2. Comparison of Observed and Calculated η/T Dependence of τ_c

a. Proton Results

Proton spin–lattice relaxation times for 0.02 *M* solutions of triphenylene in a number of solvents at 20°C are given in Table 1. The observed ratio of $T_1(H_{X,X'})/T_1(H_{A,A'})$ is approximately constant, 2.61 ± 0.22 in all solutions. When a 0.1 *M* solution of triphenylene in CS_2 was saturated with oxygen, $T_1(H_A) = 1.94$ s and $T_1(H_X) = 2.23$ s. Intermolecular dipolar contributions to the proton T_1's were ignored on the basis of general agreement with the deuterium data, and measurements in benzene-d_6 (0.1 *M*) which were within the experimental error of the values in benzene-d_6 (0.02 *M*).

Proton T_1's were also measured for a 0.02 *M* solution of triphenylene in CCl_4 as a function of temperature. In Fig. 4, $\tau_c(H_X)$ is plotted vs. η/T (correlation coefficient = 0.994). A plot of approximately the same slope was obtained for $\tau_c(H_A)$ vs. η/T (correlation coefficient = 0.989). At temperatures greater than 60°C, the ratio $T_1(H_X)/T_1(H_A)$ appears to decrease slightly ($\simeq 2.34$ at 79°C).

b. Deuterium Results

Deuterium spin–lattice relaxation times and τ_c values for 0.1 *M* triphenylene-d_{12} in several solvents at 25°C are given in Table 2. A plot of τ_c vs. η gives a straight line with correlation coefficient = 0.996.

With the exception of the DMSO solutions, the τ_c values calculated for triphenylene and triphenylene-d_{12} are in good agreement. If inertial

TABLE 1. Proton spin–lattice relaxation times for 0.02 M solutions of triphenylene at 20°C

Solvent	Solvent viscosity η (cP)	$T_1(H_A)$ (s)	$T_1(H_X)$ (s)	$\tau_c(H_A)$ (ps)	$\tau_c(H_X)$ (ps)
Dimethylsulfoxide-d_6	2.203	0.91	2.45	64.0	59.7

effects were important, the τ_c's for the deuterated molecule would be longer, but the errors in the T_1's preclude serious consideration of the differences. The ^1H data is less reliable than the ^2H data for the following reasons. (*1*) Because protons have longer T_1's than deuterons, they are more likely to be affected by intermolecular relaxation with traces of paramagnetic species such as O_2. (*2*) Cross-relaxation and cross-correlation terms may become significant for spin $\frac{1}{2}$ nuclei under certain circumstances (13). Such effects result in non-exponential recovery of $\langle M_z \rangle$ after a 180° pulse, and a description in terms of a single time constant is then incorrect. Near-exponential recovery[1] of $\langle M_z \rangle$ and the agreement between the τ_c's derived from the proton and deuterium data suggest that errors due to these effects are relatively small.

Experimental and calculated values of C are summarized in Table 3. Agreement is especially good between the experimental values obtained by varying the temperature in CCl_4

[1]Non-exponential behavior became most evident at times greater than the T_1's derived from the initial recovery rates. One referee has correctly pointed out that the linear three-spin correlation power density $J_{A'AX}$ is greater in magnitude than the direct A–X interactions ($J_{A'AX} > J_{AX}$). By using more concentrated solutions and/or signal averaging for longer periods of time it would probably be possible to demonstrate that the ^1H recovery curves are actually logarithmically bilinear. If the errors due to multi-spin effects are indeed relatively large, then the derived r_{HH} values in part 1*b* are not real proton–proton separations.

(proton T_1's) and varying the viscosity for the deuterium T_1's. If the highly polar solvents dioxane and dimethyl sulfoxide are omitted from the proton data, C is substantially decreased. C_{exp} is best regarded as 6.2 ± 2 ns K/cP. If the plane of the triphenylene ring is assigned a radius $a = 5.8 \pm 0.2$ Å, then $C_{slip} = 4.1 \pm 0.6$ ns K/cP and $C_{stick} = 31.0 \pm 3.1$ ns K/cP. These data imply that the reorientation of triphenylene obeys a near-slip condition. That is, rotation in the plane of the molecule encounters little resistance but rotation of the plane of the molecule is resisted due to shear forces in the solvent displaced during rotation. That is also the case for benzene (2*a*), and preliminary work in this laboratory on pyrene and coronene indicates that it is also true for those molecules.

The intercepts of τ_c vs. η/T plots have been regarded (2*b*, 14) as quantitatively representing inertial rotation on the basis of heuristic use of the equipartition theorem. In the Appendix the free rotar time, τ_{FR}, is given as an ensemble average and compared with the results of Moniz, Steele, and Dixon (15) for small (but non-zero) friction coefficients. The results of triphenylene and a few other molecules are presented in Table 4. Free rotation is slightly faster than the slightly hindered rotation and considerably faster than the experimental intercept. It is not a satisfactory procedure to extrapolate linearly out of the hydrodynamic regime, through the kinetic regime, and into the inertial limit.

Appendix: Inertial Rotation of Spheroids

With angular velocity $\bar{\omega}$, a molecule rotates through angle θ in time

$$[A:1] \qquad \tau = \theta\omega^{-1}$$

The average value of this quantity in a Boltzmann distribution of energies is

$$[A:2] \quad \tau_{FR} = \frac{\theta(I_1I_2I_3)^{1/2}}{(2\pi kT)^{3/2}} \int d^3\omega\, \omega^{-1} \times \exp\left\{-\frac{(I_1{\omega_1}^2 + I_2{\omega_2}^2 + I_3{\omega_3}^2)}{2kT}\right\}$$

where I_i (i = 1,2,3) are the principal moments of inertia. This expression results in the following.

1. Spheres: $I_1 = I_2 = I_3 \equiv I$

$$[A:3] \qquad \tau_{FR} = \theta(2I/\pi kT)^{1/2}$$

2. Oblate spheroids: $I_1 = I_2 < I_3$

$$[A:4] \quad \tau_{FR} = 2\theta\left[\frac{I_1I_3}{2\pi kT(I_3 - I_1)}\right]^{1/2} \times \tan^{-1}\left[\frac{I_3 - I_1}{I_1}\right]^{1/2}$$

3. Prolate spheroids: $I_1 = I_2 > I_3$

$$[A:5] \quad \tau_{FR} = \theta\left[\frac{I_1I_3}{2\pi kT(I_1 - I_3)}\right]^{1/2} \times \ln\left[\frac{1 + \left(\frac{I_1 - I_3}{I_1}\right)^{1/2}}{1 - \left(\frac{I_1 - I_3}{I_1}\right)^{1/2}}\right]$$

If the molecule is crudely treated as a sphere with average moment of inertia I_{av} given by

$$[A:6] \qquad \frac{1}{I_{av}} = \frac{1}{3}\left(\frac{1}{I_1} + \frac{1}{I_2} + \frac{1}{I_3}\right)$$

the method of Moniz, Steele, and Dixon (MSD) (15) gives

$$[A:7] \qquad \tau_{MSD} = \tfrac{1}{2}(\pi I_{av}/3kT)^{1/2}$$

for rotation through $\theta = \sqrt{3}/3$ rad ([6] with $\Delta t = \tau_c$ and $\tau_c = 1/6R$).

Nuclear charge dispersion studies in the light-mass region formed in the fission of ^{238}U by protons of energy 35–85 MeV[1]

J.-L. GALINIER, M. DIKŠIĆ, AND L. YAFFE

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 25, 1977

J.-L. GALINIER, M. DIKŠIĆ, and L. YAFFE. Can. J. Chem. **55**, 3609 (1977).

Cross sections for the independent formation of ^{76}As and ^{78}As, for the partially cumulative formation of ^{77}As and ^{77}Ge, and the cumulative formation of ^{79}As, ^{78}Ge, and ^{75}Ge formed in the fission of ^{238}U by protons of energies 35–85 MeV have been determined. Charge dispersion curves have been obtained. Values of $(Z_A - Z_p)$ and full-widths at half-maximum of the curves show that the behaviour of these light-mass products is the same as their complementary fragment ($A \approx 152$). This is inconsistent with values found at $A = 96$.

J.-L. GALINIER, M. DIKŠIĆ et L. YAFFE. Can. J. Chem. **55**, 3609 (1977).

On mesure les sections efficaces pour la formation indépendante de ^{76}As et ^{78}As, la formation cumulative partielle de ^{77}As, ^{77}Ge, ainsi que pour la formation cumulative de ^{79}As, ^{78}Ge et ^{75}Ge issus de la fission de ^{238}U par des protons ayant des énergies comprises entre 35 et 85 MeV. Des courbes de distribution de charge sont ainsi obtenues. Les valeurs de $(Z_A - Z_p)$ et les largeurs à mi-hauteur de ces courbes indiquent que les produits ayant des masses légères se comportent de la même manière que leurs compléments lourds ($A \approx 152$). Ceci est en désaccord avec les valeurs trouvées à $A = 96$.

[Traduit par le journal]

Introduction

Charge distribution in the fission of heavy nuclei has been the object of numerous studies. In the 20–85 MeV range, the McGill group has produced a substantial body of experimental data, particularly for the proton fission of ^{238}U (1–7). Charge dispersion curves have been found to be adequately represented by a Gaussian distribution. The study of the dependence of charge distribution parameters on the excitation energy imparted to the target nucleus shows that, for a given mass chain, Z_p, the most probable charge, moves towards stability with increasing incident energy, whereas the width of the distributions increases correlatively. Both effects are found to be more pronounced in the heavy partner (1, 4) than in the light one (3) when one considers the type of asymmetric mass split which is most probable ($Z = 55$ and $Z = 38$ regions respectively). Symmetric mass divisions yield intermediate results so far as the rate of displacement of Z_p is concerned (6). Recent results obtained show that in the case of very asymmetric fission, changes in Z_p are less sensitive to increases in incident energy and that only narrow charge distribution curves are compatible with the experimental data (7). This was explained as due to energy transfers involving deposition of energies far below what one can expect from compound nucleus formation, or the fission of a nucleus having undergone substantial neutron evaporation. The rather broad curves obtained in the $Z = 55$ region were assumed to be the result of competition between neutron evaporation and fission at each successive step in the de-excitation of the initial cascade nucleus (8).

Very little information has been available concerning nuclear charge distribution in fission of ^{238}U for mass number regions below $A = 90$–93 (3). The present work was undertaken to supplement data obtained in the medium-energy range, particularly to study the behaviour of fission products complementary to the rare-earths nuclides previously investigated (7). We have, therefore, chosen to look at isotopes of germanium and arsenic produced in ^{238}U fission, covering a mass range $A = 75$–79.

Experimental

(A) Irradiations

The target assembly consisted of three uranium foils (134 mg/cm^2) carefully aligned, the center foil constituting the master target and the other two serving to compensate for recoil losses of fission products, and two copper foils (44 mg/cm^2) of the same size placed upstream of the uranium stack with respect to the proton beam.

[1]With financial assistance from the National Research Council of Canada.

The outer copper foil was used to monitor the beam by means of the reaction $^{65}Cu(p,pn)^{64}Cu$. The whole stack was wrapped in thin aluminum foil, fixed on to the end of the cyclotron probe, and irradiated in the internal beam of the McGill synchrocyclotron for 10 min. The beam energy degradation at the level of the master target was of the order of the uncertainty in the beam energy (± 2 MeV) and hence could be neglected. The bombarding energies ranged from 35 to 85 MeV in steps of 5 MeV.

(B) Chemical Separations

(i) Arsenic and Germanium

Following irradiation, the leading edge of the target assembly was sheared off and the middle uranium foil was selected for chemical treatment. Arsenic and germanium were separated by adaptation of standard radiochemical procedures (9–11). The uranium target was dissolved in 0.1 ml 10 *N* HCl in the presence of 0.1 ml of 30% H_2O_2, to which is added 20 mg of sodium arsenate carrier, 1 ml each of ^{74}As and ^{69}Ge tracer solutions (prepared beforehand by (p,n) reaction on ^{74}Ge and ^{69}Ga respectively), and 6 ml of H_2O. The solution was transferred to a separatory funnel containing 7 ml 7.2 *N* HI and 20 ml of benzene. The funnel was immediately shaken for 30 s and the time of phase separation recorded as the time for the isolation of arsenic from the germanium parent. The aqueous phase containing the fission products, among which is germanium, was drained and set aside for subsequent germanium separation. The arsenic was back-extracted twice with 8 ml H_2O and the combined aqueous fractions washed with 10 ml benzene for 10 s. Then 1.0 ml (10 mg) of sodium tellurate hold-back carrier and 7.0 ml 10 *N* HCl were added to the solution which was heated nearly to boiling and reduced with SO_2. After elementary tellurium was filtered, the supernatant solution was boiled to eliminate excess SO_2. The solution was cooled, 1 ml of antimony hold-back carrier and 20 ml 6 *N* HCl were added, and arsenic reduced to the elementary state by adding 100 mg KI and 1 g of sodium hypophosphite. Coagulation was completed on a water bath and the arsenic transferred to a fiber-glass disk, washed with ethanol and isopropyl ether, dried at 110°C, and mounted for activity measurements. The time elapsed between the end of bombardment and the end of the separation was typically 20 min, thus making the measurement of 9.0 min ^{79}As feasible.

To the aqueous phase containing germanium and the other fission products, 10 ml of 10 *N* HCl and 10 ml of saturated H_3BO_3 solution were added. GeS_2 was precipitated with 5 ml of saturated Na_2S solution and centrifuged. The supernate was discarded and the GeS_2 precipitate washed and transferred with 15 ml 4.5 *N* HCl to a distillation unit. $GeCl_4$ was distilled at 120°C and recovered in 10 ml 4.5 *M* HCl, saturated with H_2S, and placed in an ice bath. After 20 min, the GeS_2 precipitate thus obtained was filtered on a fiber-glass disk, washed with ethanol and isopropyl ether, dried at 110°C, and mounted for activity measurements.

(ii) Copper

The chemistry of copper separation followed the standard procedure of Kraus and Moore (12). The copper monitor foil was weighed, dissolved in 3 *N* HCl to which 2 drops of 30% H_2O_2 had been added, the solution was evaporated to dryness, and the residue transferred with a minimum amount of 4.5 *N* HCl to a 20.0 × 0.7 cm anion-exchange column loaded with Dowex-1X8 resin (100–200 mesh size) pretreated with 4.5 *N* HCl. After Zn, Co, and Fe were removed with 4.5 *N* HCl, Cu was eluted with 1.5 *N* HCl, the middle fraction of the eluate being retained. Cu^{2+} was reduced to Cu^+ by heating in the presence of $NaHSO_3$, CuSCN was precipitated by addition of 1 ml of 10% NH_4SCN solution, and a solid sample for activity measurements was prepared as described previously.

(C) Activity Measurements and Treatment of Data

Relevant properties of the nuclides measured in this work are shown in Table 1. The γ-radiations were measured with a calibrated 30 cm^3 Ge(Li) detector operated in conjunction with a 4096-channel pulse-height analyzer equipped with magnetic tape readout. In the case of ^{64}Cu, the solid samples were sandwiched between two aluminum absorbers sufficiently thick to ensure complete annihilation of the positrons within them. Portions of the γ-ray spectra containing the peaks of interest were analyzed with the spectrum-stripping program GAMANAL (20) to locate peaks and to calculate net-peak areas after subtraction of the Compton background. The counting rate of each nuclide was usually followed for several half-lives and then extrapolated to the time of end of bombardment, or separation time from parent (whichever was applicable), with the aid of the CLSQ least-squares analysis program (21). These extrapolated counting rates were converted to disintegration rates by making the usual corrections for chemical yields, branching ratios, and detector efficiencies, and used to calculate formation cross sections following standard procedures. The monitor cross sections used to that effect are shown in Table 2.

Results

The independent formation cross sections for ^{76}As and the cumulative cross sections ^{78}Ge, ^{77g}Ge, and ^{78}Ge were computed directly at each incident energy. The independent cross sections of ^{78}As were calculated using the cumulative ^{78}Ge cross sections simultaneously measured in order to correct for the parent contribution during irradiation and between the end of bombardment and the time of As–Ge separation. The same method was applied to the calculation of the partially-cumulative cross section of ^{77}As using the cumulative cross section of ^{77g}Ge (this cross section includes a 24% isomeric transition contribution from the cumulative cross section of ^{77m}Ge (19)). In the case of ^{79}As, the branching ratio for the highly-converted 95.5 keV γ-ray was corrected by a total internal conversion coefficient of 9.57 (18). All cross sections determined in this work appear in Table 3. The error quoted with each value is associated with monitor cross sections (5.4%), detector efficiencies (1%), chemical yield (4%), and target superficial density (2%). In the case of ^{78}As independent cross sections, an additional 5% error was added, due to uncertainties in the cross-section values of the precursor ^{78}Ge. No error was associated with uncertainties in decay schemes and half-lives. An additional uncertainty due to counting statistics was added for each individual determination, as given by the CLSQ program. In most measurements, it rarely exceeds 2%. However, in the case of ^{76}As, due to the extremely low formation cross sections at low bombarding energies, this type of error could amount to 15%. The total error was assessed for each measurement by taking the square root of the sums of the squares of individual errors outlined above. The error varies between ±13% and ±28%. Excitation functions for the nuclides studied are shown in Figs. 1 and 2.

[a]Calculated from arsenic isotopic distribution.
[b]From Coryell (25).

The independent cross sections were converted into independent fractional chain yields for the purpose of constructing charge dispersion curves. The cumulative cross sections were used as a first estimate of the total chain yields for $A = 75$, 77, 78, 79, while for $A = 76$ the total chain yield value was estimated by interpolation. A first set of charge dispersion curves was thus generated with the help of the ORGLS program (23) using the usual constraint prescribed by Friedlander *et al.* (24). This in turn allowed for the adjustment of total chain yields to more realistic values. Two iterations were sufficient to arrive at the final results shown in Table 4. A representative sample of a charge dispersion curve is shown in Fig. 3.

The average precision on the most probable neutron-to-proton ratios (N/Z_p) and the full-widths at half-maximum (fwhm) in N/Z units is 2% and 3% respectively, as given by the ORGLS program. The most probable mass (A_p) was calculated, at each incident energy, for arsenic isotopic distribution and the corresponding Z_A values were deduced from Coryell (25). The precision on the resulting values of ($Z_A - Z_p$) and fwhm in Z units is, on the average, 3.5% and 8%, respectively, with the exception of the ($Z_A - Z_p$) value at 35 MeV which appears to be too low by ~15%, this being probably attributable to poor precision on ^{76}As and ^{78}As independent cross sections at that particular energy. The variation of ($Z_A - Z_p$) and fwhm as a

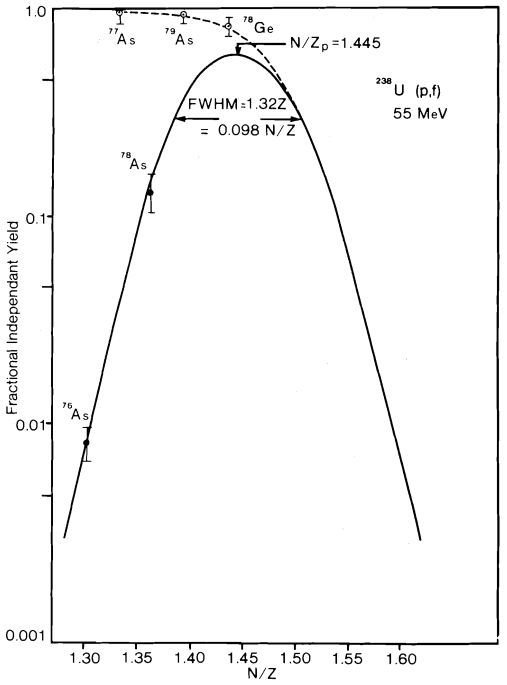

FIG. 3. Charge dispersion curve at 55 MeV.

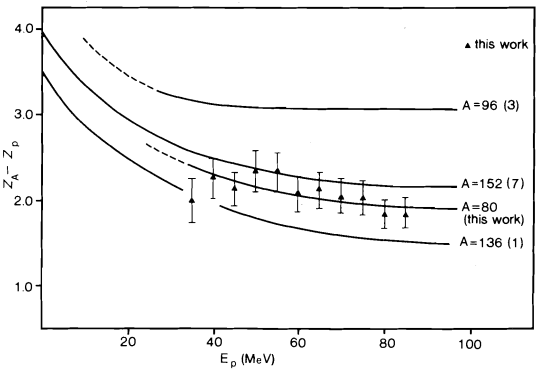

FIG. 4. Displacement of the most probable charge from stability as a function of incident energy.

function of bombarding energy is shown in Figs. 4 and 5 respectively, along with data of several other workers (1, 3, 5–7).

Discussion

The excitation functions of the independently formed nuclides ^{76}As and ^{78}As (Fig. 1) show a monotonic increase in the 35–85 MeV bombarding energy range, thus exhibiting, at least in this limited region, the classical behaviour of species close to the stability line found in medium-

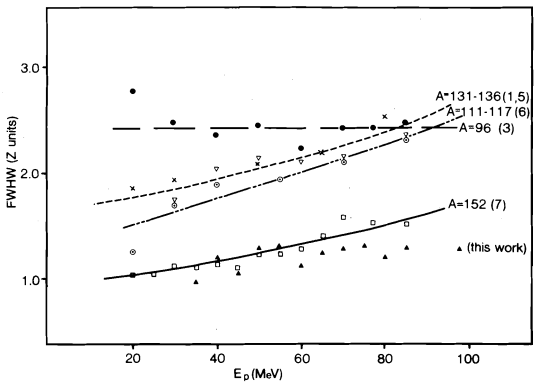

FIG. 5. Full-width at half-maximum of charge dispersion curves as a function of incident energy.

energy fission. The yield of ^{76}As (N/Z = 1.3030) increases by about 1.5 orders of magnitude, compared to a factor of ~4 for the more neutron-rich ^{78}As (N/Z = 1.3636). The scarcity of data at higher energy unfortunately does not allow for a precise determination of the incident energy at which these excitation functions would reach a maximum. However, the values of 0.8 mb at 170 MeV and 0.21 mb at 340 MeV reported respectively by Hagebø *et al.* (26) and Folger *et al.* (27) for the production of ^{76}As suggest that the excitation function of this particular nuclide goes through a broad maximum, or levels off, at an incident energy considerably lower (by about 1 order of magnitude) than the prediction from the systematics of Friedlander *et al.* (24) for nuclides in the vicinity of the cesium region. If this is the case, the light products appear to behave differently from their heavy partners. (For instance the excitation function for the production of independently formed ^{150}Pm is in accord with systematics by reaching its maximum at 100 MeV (7).) On the other hand, if we compare our data to those of Khan *et al.* (3) in the yttrium mass region, we observe a qualitative agreement (^{92}Y (N/Z = 1.3590) and ^{93}Y (N/Z = 1.3846) reach their maxima much below the predicted incident energy). However, one must await higher-energy data before drawing further conclusions.

The excitation functions for the cumulatively formed species ^{78}Ge, ^{77g}Ge, ^{78}Ge, and ^{79}As (Figs. 1 and 2) exhibit broad maxima shifting toward lower incident energies with increasing value of N/Z of the nuclide. The excitation function of ^{79}As (N/Z = 1.3939) is almost flat

within experimental uncertainties, while that of ^{75}Ge ($N/Z = 1.3438$) indicates a variation of cross sections of about a factor of 5 in the 35–85 MeV bombarding energy range. This trend agrees well with that found in the complementary mass region (7) and, again, as in the case of the heavier rare-earths, differs from that reported for heavy cumulatively formed products resulting from the most probable-fission mode (cesium region and its vicinity) where cross sections decrease sharply over the whole bombarding energy range (1, 2, 4, 5). This difference indicates that the displacement of the most probable charge along light isobaric chains plays a less prominent role in the decrease of cumulative cross sections with increasing bombarding energy.

The values of $(Z_A - Z_p)$ deduced in this work appear to be quite similar in magnitude to those found in the complementary mass region ($A = 152$) as shown in Fig. 4. A linear least-squares fit performed on the variation of Z_p (arbitrarily calculated for mass $A = 80$) against the variation of the average excitation energy E^* of the fissioning nucleus obtained by Dikšić *et al.* (5) using the Vegas Stepno code (28) followed by Monte Carlo evaporation (29, 30) gives a value of $\delta Z_p/\delta E^* = 0.0197\ \text{MeV}^{-1}$. This result is in excellent agreement with the value of 0.0208 MeV^{-1} found in the complementary mass region in the 20–85 MeV bombarding energy range (7), and the value of 0.0200 MeV^{-1} reported by Nethaway (31) in the excitation energy range 6.8–21.2 MeV for mass chain $A = 82$. However, our data differ considerably in magnitude from those reported at mass chain $A = 96$ (3), as seen in Fig. 4. This is a direct consequence of the very low values of N/Z_p found in the present work. Such a trend of sharply decreasing N/Z_p with mass below $A \sim 90$ has already been pointed out at higher energies by Hagebø *et al.* (26) and Pappas and Hagebø (32) at 170 MeV and Hogan and Sugarman (33) at 440 MeV. Wahl *et al.* (34) have also shown that, at thermal energies, ^{235}U fission gives rise to light products whose N/Z_p values are much below those of their complementaries (by about $\sim 0.05\ N/Z$ unit), even though these values do not seem to vary much below mass $A = 100$. Figure 6 shows the results of the McGill group (1–7) at 50 and 85 MeV, along with the curve constructed by Pappas and Hagebø (32) at 170 MeV. Both sets of data are in good agreement as far as trends are concerned. The reason as to why the light fission products exhibit such a sharp drop in N/Z_p values has been attributed, at 170 MeV, to fast fission events taking place at the highest excitation energy available (26). In our case, such an argument would contradict the conclusions drawn in the complementary mass region (7) where highly asymmetric mass divisions have been shown to be caused by low-deposition energy cascades, as demonstrated by the relatively small number of post-fission neutrons deduced from the variation of Z_p, using the method of McHugh and Michel (35). Our results on N/Z_p indicate also that the conclusion of Hagebø *et al.* (26) that the UCD hypothesis cannot be applied in its simple form to the fission reactions leading to light fragments at 170 MeV, may be extended to the lower excitation energy range involved in this work. This is also supported by the work of Lee *et al.* (36) on the isotopic distributions of rubidium and cesium formed in the fission of ^{238}U at 80 and 100 MeV. In order to explain the low N/Z_p value found for rubidium, these authors show that the ratio of the number of post-fission neutrons emitted by the heavy fragment to that emitted by its light partner should equal 0.78 if the UCD prescription is to describe the processes of charge division in an adequate fashion. This value is not consistent with the experimental findings of Cheifetz *et al.* (37) who report an experimentally measured ratio of 2.2 for the mass split, 1.5 in the 155 MeV proton-induced fission of ^{238}U, and Bishop *et al.* (38) who report ratios from 1.12 to 1.34 for similar mass divisions in the 11.5–22 MeV proton energy range. If we look at the

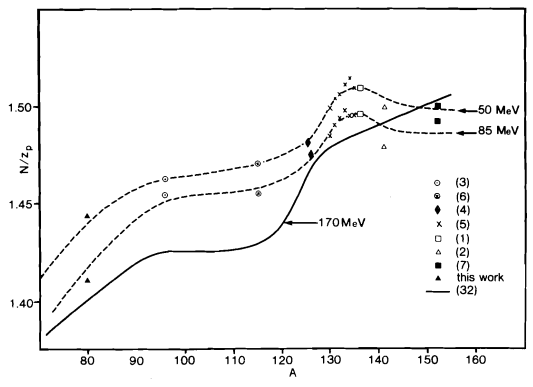

FIG. 6. Variation of the most probable neutron-to-proton ratio with the mass of the fission chains for three incident energies.

variation of the full-width at half-maximum as a function of bombarding energy (Fig. 5), we see that fission products of mass $A = 80$ behave virtually in the same fashion as their complementary partners, fwhm varying respectively from 0.99 to 1.31 Z units and 1.06 to 1.53 Z units (7). Again, we notice a large difference in magnitudes between the results of Khan *et al.* (3) at mass $A = 96$ and ours, as shown in Fig. 5. One qualitative explanation for both narrow widths and low N/Z_p could be that early members in the isobaric decay chains are likely to be delayed-neutron emitters. The occurrence of such a type of decay has indeed been observed in the vicinity of the mass region investigated, as reported by Kratz *et al.* (39), for nuclides such as ^{84}As, ^{85}As, and ^{86}As which are only 3 units of Z removed from the stability line. The extent to which delayed-neutron emission might alter the original charge dispersion features is, however, very difficult to assess as far as widths are concerned, while it probably contributes to substantial shift towards lower values in N/Z_p. It is then surprising to see that both N/Z_p and fwhm exhibit essentially the same variation in both the As–Ge and the rare-earths complementary mass regions. If this agreement is not to be fortuitous, it seems reasonable to assume that delayed-neutron emission superimposes itself to the de-excitation process of the primary fission fragments without masking the influence of increasing bombarding energy.

The reaction of iodine with lithium tri-*tert*-butoxyaluminohydride.[1] A reaction with variable stoichiometry unsuitable for analytical standardization

DONALD C. WIGFIELD AND FREDERICK W. GOWLAND
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 21, 1977

DONALD C. WIGFIELD and FREDERICK W. GOWLAND. Can. J. Chem. **55**, 3616 (1977).

Solutions of lithium tri-*tert*-butoxyaluminohydride (LTBA) have been standardized by reduction of cyclohexanone, followed by gas–liquid chromatography (glc) and/or spectral analysis of the extent of reaction. These results are compared with the standard titrimetric analysis of LTBA by iodine, to determine whether the standardizing equation is

[5] $$LiAl(OBu^t)_3H + I_2 \rightarrow HI + LiI + Al(OBu^t)_3$$

or

[3] $$LiAl(OBu^t)_3H + \tfrac{1}{2}I_2 \rightarrow \tfrac{1}{2}H_2 + LiI + Al(OBu^t)_3$$

It is clear that in fact both of these reactions occur, with [5] predominating at low hydride to iodine ratios, and [3] becoming increasingly significant when the hydride and iodine concentrations become comparable. The usual titrimetric method of standardizing LTBA is therefore essentially unusable.

DONALD C. WIGFIELD et FREDERICK W. GOWLAND. Can. J. Chem. **55**, 3616 (1977).

On étalonne des solutions de tri-*tert*-butoxyaluminohydrure de lithium (TBAL) par réduction de la cyclohexanone suivie par CPG ou par analyse spectrale du degré de réaction ou les deux à la fois. Ces résultats sont comparés à l'analyse titrimétrique étalonnée de (TBAL) par l'iode, afin de déterminer si l'équation de normalisation est:

[5] $$LiAl(OBu^t)_3H + I_2 \rightarrow HI + LiI + Al(OBu^t)_3$$

ou

[3] $$LiAl(OBu^t)_3H + \tfrac{1}{2}I_2 \rightarrow \tfrac{1}{2}H_2 + LiI + Al(OBu^t)_3$$

Il est clair qu'en fait les deux réactions se produisent, [5] étant prédominante à faibles rapports hydrure à iodure; [3] a un accroissement devenant important lorsque les concentrations en hydrure et en iodure deviennent comparables. La méthode titrimétrique habituelle pour étalonner (TBAL) est par conséquent inutilisable.

[Traduit par le journal]

Kinetics play a vital role in unravelling the mechanistic details of reductions of carbonyl compounds by complex metal hydrides (see, for example, ref. 3 and references cited therein). Since these reductions are generally first-order both in organic substrate and in hydride, an accurate knowledge of the concentration of the complex metal hydride in the reduction solution is required. Recently we have needed to measure the concentration of solutions of lithium tri-*tert*-butoxyaluminohydride (LTBA) for kinetic and other (4) studies; in doing so we have found that the currently used titrimetric method can give rise to anomalous results. We wish to report the unsuitability of this titrimetric method for LTBA analysis.

The Problem

Complex metal hydrides, such as lithium aluminum hydride (LAH), are generally analysed titrimetrically by reaction with iodine. The procedure involves two titrations: (*a*) titration of the iodine solution with thiosulfate (ref. 5, p. 453 *et seq.*); and (*b*) the addition of a deficient amount of lithium aluminum hydride to the same volume of iodine solution as in (*a*), followed by titration of the remaining iodine with thiosulfate. The difference between the two titrations clearly has equivalence to the quantity of hydride oxidized. Felkin (6) has shown that the following equation holds:

[1] $$LiAlH_4 + 2I_2 \rightarrow 2H_2 + LiI + AlI_3$$

[1]Often called lithium aluminum tri-*tert*-butoxyhydride. Related nomenclative problems occur for substituted borohydrides (1). Chemical Abstracts is currently (Vol. 83) referring to this compound as "aluminate (1-), hydrotris (2-methyl-2-propanolato) lithium". We have retained the name given to it by its discoverers (2).

This equation, in combination with the reaction of iodine with thiosulfate (ref. 5, p. 453 *et seq.*)

[2] $$2S_2O_3^{2-} + I_2 \rightarrow S_4O_6^{2-} + 2I^-$$

establishes the 1:4 equivalence between lithium aluminum hydride and sodium thiosulfate.

Direct extrapolation of the I_2–LAH reaction to LTBA gives the following equation

[3] $$LiAl(OBu^t)_3H + \tfrac{1}{2}I_2 \rightarrow \tfrac{1}{2}H_2 + LiI + Al(OBu^t)_3$$

This equation, in combination with [2], clearly implies a 1:1 equivalence between LTBA and thiosulfate. If the original titre of x ml of thiosulfate to reduce the iodine solution is diminished to z ml by the prior addition of y ml of LTBA solution, then the molarity of LTBA is given by:

[4] $$M_{LTBA} = M_{Na_2S_2O_3}\left(\frac{x - z}{y}\right)$$

This equation is equivalent to that suggested by Ayres *et al.* (7).

In the course of using [3] and resulting expressions, however, certain peculiarities led us to consider its basis more carefully. In the absence of further experimental data the alternative reaction (eq. 5), seemed equally plausible.

[5] $$LiAl(OBu^t)_3H + I_2 \rightarrow LiI + HI + Al(OBu^t)_3$$

This equation, in combination with [2], gives a 1:2 equivalence between LTBA and thiosulfate, and, retaining the same designation of the volumes x, y, and z, leads to [6].

[6] $$M_{LTBA} = M_{Na_2S_2O_3}\left(\frac{x - z}{2y}\right)$$

Equations 4 and 6 clearly differ by a factor of two, and an independent method of quantitative analysis is required to establish which of the two is correct. For this purpose we have chosen the reaction of LTBA with cyclohexanone, and evaluation of the extent of reduction. This reaction has the twofold advantage that, firstly, it is the reaction in which we are interested, and, secondly, that cyclohexanone is known to react with LTBA with a 1:1 stoichiometry (8).

Results and Discussion

In order to utilize the reduction of cyclohexanone as a measure of [LTBA], accurate assay of the extent of reduction is required. This was achieved with two independent methods.

The first of these methods involved glc determination of the relative amounts of cyclohexanol and unreacted cyclohexanone after reaction with a deficient amount of LTBA. With this method the molarity of a LTBA solution is given by

[7] $$[LTBA] = [Ketone]\left(\frac{q}{p}\right)\left(\frac{\%\ \text{reduction}}{100}\right)$$

where p and q are the volumes (ml) of the LTBA and ketone solutions, respectively. For the glc system used in this work a significant detector response differential between cyclohexanol and cyclohexanone was measured; the actual percent reduction was thus obtained by multiplying the apparent percent reduction by a factor of 0.92.

The second method involved the analysis of unreacted ketone by the absorbance of the n–π^* band at 288 nm. We have, in fact, utilized this method for following the kinetics of this reaction; this analytical application was somewhat simpler, involving only the initial absorbance and the absorbance after reaction was complete (~2 min). The molarity of a LTBA solution in this determination is given by

[8] $$[LTBA] = \left(\frac{A_0 - A_f}{a}\right)\left(\frac{q + p}{p}\right)$$

where A_f is the final absorbance value, A_0 is the initial absorbance value, already corrected for the change in volume that will occur on adding the LTBA solution, a is the molar absorptivity, and p and q are the volumes as indicated above. It was found that glc and spectral analyses were in close agreement.

Armed with reliable analyses of LTBA solutions, comparisons were made with the apparent analysis given by the iodine titration method using both [4] and [6]. From the results, summarized in Table 1, a number of points are evident.

1. At low hydride to iodine ratios, [5] apparently occurs and use of [6] gives reasonably good[2] agreement with the glc or spectral analysis. In fact these ratios were those actually used for our related kinetic work, and led us initially to believe that [5] was the chemistry involved.

2. At hydride concentrations comparable to the iodine concentration, [3] appears to occur and the use of [4] gives the correct analysis of the hydride concentration.

3. At most [hydride]:[iodine] ratios (i.e., those

[2]There is still a substantial error, however, due to the small quantity of iodine consumed and the crucial volume thus being a small difference between two large titres.

[a][LTBA], mol/ℓ.
[b]Iodine concentration 0.076 *M*.

lying between those covered in the above two cases), the true hydride concentration lies between the values obtained using [4] and [6]. Presumably, therefore, this corresponds to LTBA and iodine reacting by both [3] and [5].

4. The consequence of point *3* is that the iodine titration method for LTBA is an unreliable and almost useless analytical method. The stoichiometry is variable and unpredictable unless the concentration of LTBA is already known with sufficient accuracy to ensure that conditions for predominance of either [3] or [5] will be in effect.

These conclusions, although unexpected, are not unreasonable. Even if [3] were to occur, the first step of such a process would presumably be [5]. The second step would be

[9] $LiAl(OBu^t)_3H + HI \rightarrow H_2 + LiI + Al(OBu^t)_3$

From the data, therefore, it would appear that [9] is viable and the question of whether [3] or [5] is appropriate is essentially a question of competition between [5] and [9]. Clearly at low [hydride] to [iodine] ratios there will always be a predominance of I_2 over HI; [9] is effectively eliminated by this concentration effect, and the data will correspond to [5] and [6]. At higher hydride to iodine concentrations, more HI will be produced, [9] will compete more effectively with [5] to the point where [3] and [4] accommodate the data. We have attempted to illustrate this change of stoichiometry from the 1:1 of [5] to the 2:1 of [3] in the plot of Fig. 1.

The difference in chemistry between LTBA and LAH is worth considering. Clearly the reduction of HI by LAH competes more effectively with reduction of I_2 than it does in the LTBA case. One important difference between LAH and LTBA are the four hydrides of LAH compared to only one hydride of LTBA, and it is worth noting that after the reaction of LAH with I_2, the HI and the modified aluminum species (still containing three hydrides and still a reducing agent) are necessarily produced in the same vicinity. It is possible, therefore, that the efficient reduction of HI to H_2 by LAH is, at least in part, due to this local concentration or solvent cage effect. Such an effect, of course, would not be applicable in LTBA reductions.

Conclusions

The stoichiometry of the standardizing reaction between iodine and LTBA is variable, ranging from 1:1 to 1:2. This titrimetric method for determination of [LTBA] is therefore of no use unless the value of [LTBA] is already known with some accuracy beforehand. Data in the literature which may derive from this standard-

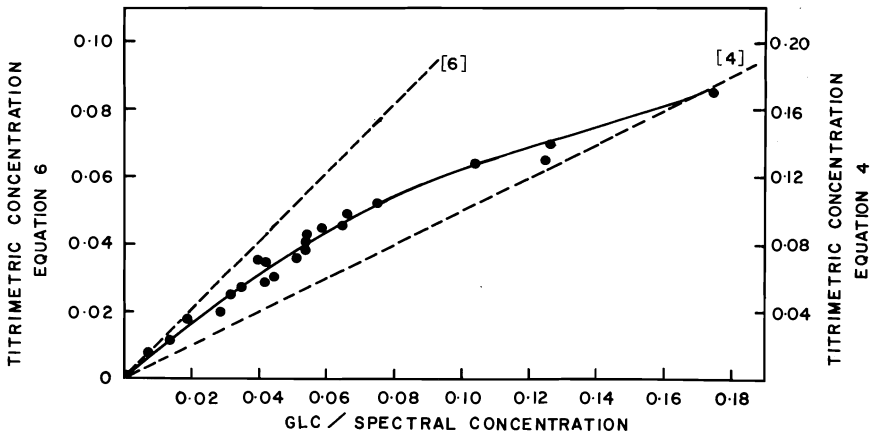

FIG. 1. Comparison of [LTBA] from glc/spectral determinations with apparent values from titrimetric analysis. The dashed lines correspond to [4] and [6], respectively.

izing reaction must therefore be regarded as suspect.

Experimental

Materials

Tetrahydrofuran (Fisher Certified) was distilled from lithium aluminum hydride (Ventron; Alfa Products) at atmospheric pressure, protecting the distillate from moisture. Benzene (Fisher) was distilled under nitrogen and stored over molecular sieves (Fisher; 4 Å). Iodine (Fisher), sodium thiosulphate (Baker), glacial acetic acid (Fisher), soluble starch (Fisher), cyclohexanone (Fisher), cyclohexanol (Fisher), diethyl ether (Mallinkrodt), and lithium tri-*tert*-butoxyaluminohydride (Ventron; Alfa Products) were used without further purification. Gas–liquid chromatography was performed on a Hewlett-Packard F and M 402 gas chromatograph equipped with a QF-1(5%) column. Carrier gas flow was 4 ml/min, oven 86°C, injector port 200°C, manifold 200°C. Peak areas were determined electronically with an Infotronics CRS-208 electronic integrator. The retention times for cyclohexanone and cyclohexanol were 2.9 and 5.8 min (9), respectively. Spectral analyses were performed on a Beckman 25 spectrophotometer at 288 nm.

Titrimetric Analysis

A typical determination follows; stock solutions of standardized sodium thiosulphate (ref. 5, p. 455 *et seq.*) (0.06382 *M*) and of iodine in benzene (6) (0.07605 *M*) were prepared. LTBA (0.05245 g) was dissolved in 10.0 ml of tetrahydrofuran; an aliquot (5.0 ml) of this solution was pipetted into a iodine flask containing 5.0 ml of the stock iodine solution. The flask was stoppered and swirled periodically (ca. 5 min). Glacial acetic acid (15 ml) was added and the solution was titrated against the standard thiosulphate solution to the starch indicator end point. A blank following the above outlined procedure was run omitting the hydride solution. The data were analyzed using [4] and [6], respectively.

Spectral Method

To 2.0 ml of hydride solution in a cuvette, which had been fitted with a cover, 1.0 ml of ketone solution of known concentration was injected. Simultaneously with injection the chart recorder was activated and the decay trace, characteristic of the second order reaction, was obtained. The limiting absorbance (A_f) was observed after 1–2 min. The initial absorbance (A_0) was obtained by dividing the absorbance of the ketone solution by three to allow for dilution.

Gas–Liquid Chromatography Method

To 5.0 ml of a stock cyclohexanone solution (0.05416 *M* in THF), 5.0 ml of the hydride solution was added and the vessel stoppered. After 2 days[3] at room temperature the solution was treated with 1 *M* HCl (1 ml), extracted with ether (2 ml), and analyzed by glc. In the glc system used (flame ionization detector), the detector response to cyclohexanol and cyclohexanone were found to be significantly (8%) different. Thus a correction to the cyclohexanol:cyclohexanone ratio needed to be applied in order to obtain the true amount of cyclohexanone remaining in the sample. Use of [7] then yielded the concentration of available hydride.

[3]The time is not critical, in the usual uv analysis procedure the absorbance had decreased to a finite value within 1–2 min under the conditions of our kinetic experiment.

Nuclear magnetic resonance studies on the self-association of adenosine 5′-triphosphate in aqueous solutions[1]

YIU-FAI LAM[2] AND GEORGE KOTOWYCZ

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 22, 1977

YIU-FAI LAM and GEORGE KOTOWYCZ. Can. J. Chem. **55**, 3620 (1977).

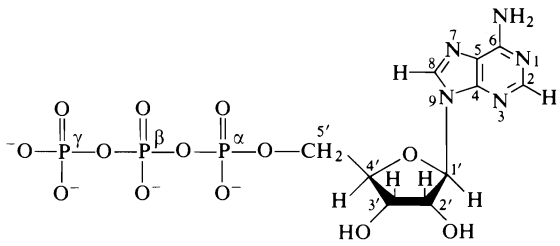
The self-association of adenosine 5′-triphosphate (ATP) in aqueous, basic solutions has been studied. The results indicate that the monomer–dimer–trimer equilibrium model for base association fits the data well, but so does a model which includes higher order species. This indicates that the ATP molecules in solution can undergo indefinite linear self-association. The average value of the association constant based on the ^1H and ^{31}P chemical shift measurements is 0.9 ± 0.3 M^{-1}. Longitudinal relaxation rates for the H8, H1′, and H2 protons of ATP were obtained as a function of the nucleotide concentration. The analysis of the viscosity-corrected proton H2 data yields an association constant of 5.1 ± 1.3 M^{-1}.

YIU-FAI LAM et GEORGE KOTOWYCZ. Can. J. Chem. **55**, 3620 (1977).

On a étudié l'auto-association du triphosphate-5′ d'adénosine (TPA) en solution aqueuse et basique. Les résultats indiquent que l'équilibre modèle monomère–dimère–trimère pour l'association basique se compare bien aux données, mais il en est de même pour un modèle qui inclut des espèces d'ordre supérieur. Ceci indique que les molécules TPA en solution donnent lieu à une auto-association linéaire indéfinie. La valeur moyenne de la constante d'association basée sur les mesures du déplacement chimique est de 0.9 ± 0.3 M^{-1}. Les vitesses de relaxation longitudinale pour le protons H8, H1′ et H2 du TPA sont obtenues comme étant fonction de la concentration du nucléotide. L'analyse des valeurs pour le proton H2 corrigées de la viscosité nous donne une constante d'association de 5.1 ± 1.3 M^{-1}.

[Traduit par le journal]

Adenosine 5′-triphosphate (ATP) self-associates in aqueous solutions (1–3) due to the base-stacking interactions which have been observed for many nucleotides (4–7). However, the exact nature of the complex or complexes formed in



ATP

solution, especially at neutral or slightly basic p*H*, is still not known. On the basis of circular dichroism and uv measurements (2), an association constant of 8.2 M^{-1} at 25°C was obtained at a p*H* of 8.7 in a 1 *M* Tris HCl buffer with 0.5 *M* $MgCl_2$. The proposed model (2) is one with indefinite linear self-association and each step has the same equilibrium constant. Heyn and Bretz (2) could not assign a unique geometry for the ATP molecules in the stack but feel that head-to-tail association of the adenine bases is most likely. Further circular dichroism measurements (3) were interpreted in terms of a monomer–dimer model. At a p*H* of 2.8 and 20°C, a dimerization constant of 88 M^{-1} was obtained. In the complex, the charged phosphate of one ATP molecule interacts electrostatically with the charged adenine ring of the second ATP molecule. In this model, the two adenine rings are stacked head-to-tail and the ATP molecule is in the *anti* conformation (3). At basic p*H*'s, the model of Heyn and Bretz (2) was applied (3) and an association constant of 51 M^{-1} was obtained (20°C, p*H* 8.7) with no $MgCl_2$ present. Stacking interactions have also been studied in the presence of 0.154 *M* NaCl (1) and a monomer–dimer–trimer association model at acidic p*H*'s describes the data best of all.

Nuclear magnetic resonance (nmr) experiments also offer valuable information concerning the self-association of ATP. Based on the ring proton chemical shift studies carried out at a

[1]This is paper No. 8 in the Nuclear magnetic resonance studies of nucleotide – metal ion interactions.

[2]Postdoctoral fellow, 1975–1976. Present address: Department of Life Sciences, University of Pittsburgh, Pittsburgh, PA 15260, U.S.A.

pH of about 7 (9), a dimerization constant of about 5 M^{-1} was obtained (8) when higher order associations were neglected. In addition, nmr techniques have been applied in the study of stacking interactions of a related system, adenosine 5′-monophosphate (10–19), or 5′-AMP. A head-to-head base association model has been proposed (10) as well as the head-to-tail (11, 12, 19). Deuterium substitution is now being applied extensively in these studies (11, 16–20). Ellis and co-workers (19) have studied the stereospecificity of stacking interactions by measuring the proton relaxation times of 5′-AMP and 8-deuteroadenosine 5′-monophosphate. Their results indicate that the base stacking of 5′-AMP is stereospecific at 5°C and, from their calculated internuclear distances, they propose a head-to-tail stacking model. They also observe that, at 30°C, even though the molecules may stack, the stereospecificity is gone. Egan (16) has also studied intermolecular association in 8-deuteroadenosine 5′-monophosphate by monitoring the deuterium magnetic resonance relaxation times over the concentration range 0.01–1.0 m (pH 7.0). He observed that a plot of $(\eta T_1)^{-1}$ vs. the solute concentration is concentration dependent (η = viscosity) and this was attributed to the effect of stacking. An analysis of the data in terms of a monomer–dimer equilibrium yields a value for the equilibrium constant of 2.1 ± 0.7 (30°C) and the analysis also indicates that the association may proceed past the dimer stage.

The object of the present study is to determine the nature of the ATP association complex at a pH of 8.4. With this in mind, the chemical shifts of the H8, H2, and H1′ protons, as well as the α, β, and γ phosphorus nuclei have been measured as a function of the ATP concentration. In addition, longitudinal relaxation times of the H2 proton, which are extremely sensitive to intermolecular effects, were measured as a function of the nucleotide concentration. A viscosity correction is applied to these longitudinal relaxation times. The data are analyzed in terms of several association models. The monomer–dimer–trimer equilibrium model fits the data well, but so does a model which includes tetramers, pentamers, and higher order species.

Experimental

Sample Purification and Preparation

ATP (disodium salt) was purchased from Sigma Chemical Co. It was purified by passing a 0.1 M ATP solution through a Dowex-50 cation exchange resin and then freeze-dried. For all ^{1}H and ^{31}P nmr experiments, samples were then freeze-dried three times from D_2O and then dissolved in D_2O. For the proton homonuclear nuclear Overhauser effect (nOe) experiments, samples were degassed four times using the freeze–pump–thaw technique and then were sealed in nmr tubes. The pD of all the solutions was 8.4. All nucleotide concentrations were determined by uv techniques. Two sets of samples were prepared for all of the nmr experiments with the exception of the ^{31}P shift studies and the proton–proton nOe experiments. The first series contained purified ATP, whereas the second series also contained 2% EDTA (as a mole fraction of the ATP concentration) to check for the effects arising from any trace metal ion impurities (21). The nmr experiments were repeated with both sets of samples. The ^{31}P chemical shifts were measured on solutions containing only purified ATP, whereas the proton–proton nOe experiments were carried out on solutions that contained 2% EDTA.

Inosine 5′-triphosphate (ITP) was purchased from Sigma Chemical Co. and was purified using Chelex 100. The purified ITP was freeze-dried several times from D_2O and then two solutions were prepared in D_2O for the proton spin–lattice relaxation time measurements. The 2% EDTA (as a mole fraction of the ITP concentration) was added to both solutions and the pD was 6.4 and 7.2. The ITP was slightly hydrolyzed ($\sim$10%) but this does not affect the present conclusions.

Viscosity Measurements

Viscosities of ATP solutions at 27°C were measured both in D_2O (pD 8.4) and in H_2O (triply distilled) (pH 8.0) following standard procedures using an Ostwald viscometer. For the measurements in D_2O, 2% EDTA (as a mole fraction of the ATP concentration) was added to the solutions.

Proton Magnetic Resonance Experiments

Proton chemical shifts, as well as spin–lattice relaxation times, were measured at 27°C in the Fourier transform mode (100.0 MHz) using the Varian HA-100-15 nmr spectrometer interfaced with the Digilab FTS/NMR-3 Fourier transform system including the pulse unit (FTS/NMR 400-2) and the Nova 1200 computer. The temperature was controlled using the Bruker B-ST 100/700 temperature controller. The deuterium resonance from the solvent D_2O was used for the lock signal. Depending on the signal to noise ratio, 30–200 free induction decay signals were collected for each spectrum. The sweep width for each spectrum and the number of data points were chosen for a resolution of 0.25 Hz per data point. The spin–lattice relaxation times were measured using the (π–τ–$\pi/2$) two-pulse sequence (22, 23). The $\pi/2$ pulse width was 45 μs. The ATP proton H8, H2, and H1′ chemical shifts were calibrated with respect to three internal references: *tert*-butyl alcohol, *p*-dioxane, and DSS. Since the behaviour of the proton chemical shifts as a function of the ATP concentration was the same with respect to both *tert*-butyl alcohol and *p*-dioxane, the results are expressed with respect to *tert*-butyl alcohol. The concentration of each internal reference was 2 mM. When the common internal reference compound DSS was used (sodium-2,2-dimethyl-2-silopentane-5-sulphonate), it was found that this reference signal shifted with the ATP concentration. DSS is

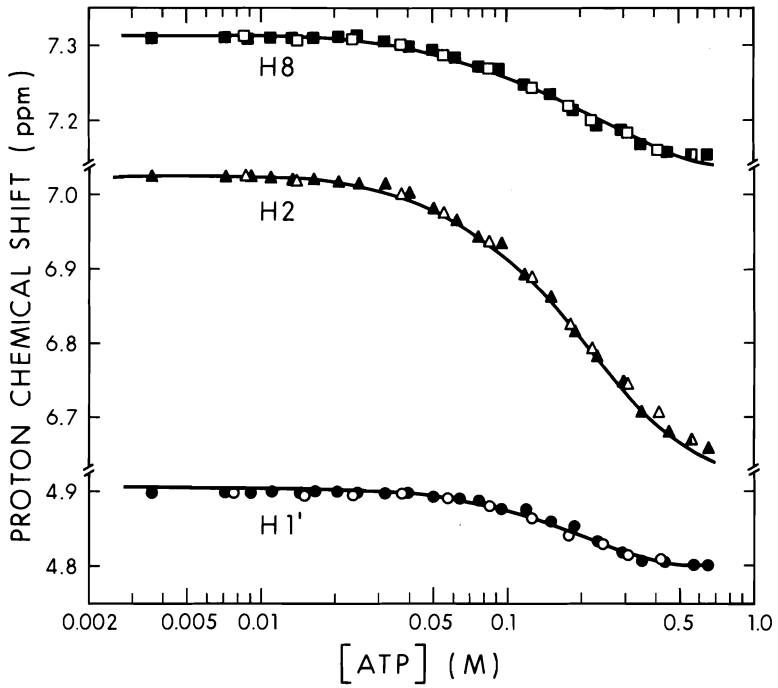


FIG. 1. Proton chemical shifts of protons H8, H2, and H1′ plotted as a function of the ATP concentration. All three protons experience a shift to high field with an increase in the ATP concentration. The data represented by the open symbols are for solutions without EDTA, whereas the solid symbols represent the data obtained for solutions with EDTA. The shifts are expressed in ppm to low field of internal *tert*-butyl alcohol. The experiments were carried out at 100.0 MHz at 27°C. Solutions were prepared in D_2O at a p*D* of 8.4. The solid curves represent the computer fit to the data based on the monomer–dimer–trimer equilibrium model.

therefore not a satisfactory reference compound for these studies (24).

^{31}P Nuclear Magnetic Resonance Experiments

Proton decoupled Fourier transform ^{31}P nmr spectra were obtained at 27°C using the Varian HA-100-15 nmr spectrometer (40.48 MHz) and the Digilab FTS/NMR-3 Fourier transform system, as was discussed in the preceding paragraph. One hundred free induction decay (fid) signals were collected for each spectrum and the resolution was 0.25 Hz per data point. The ^{31}P shifts for the α, β, and γ ATP resonances were calibrated with respect to an internal reference, Na_2HPO_4, and are expressed as ppm to high field of this reference.

Proton–Proton Nuclear Overhauser Effect Measurements

These experiments were carried out at 27°C in the Fourier transform mode using the Bruker WP-60 nmr spectrometer (60.0 MHz) and the Bruker temperature controller B-ST 100/700. The pulse angle was set at 20° less than the normal π/2 pulse angle, and the repetition rate was 8 s, which was sufficiently long for the nuclei to relax back to thermal equilibrium. The signal areas were integrated digitally. Throughout the experiments, the proton decoupler was on, except during the digitization of the fid signal. In the present experiments, protons H2′ and H3′ were separately irradiated. However, the chemical shift between these two protons was ~0.17 ppm with H2′ to lower field (12, 25). Consequently, irradiation of one of these protons may affect the other proton. The nOe is defined as $(A_2 - A_1)/A_1$ where A_2 is the area of the observed peak with irradiation while A_1 is the area of the same peak without irradiation.

Results

A plot of the H8, H2, and H1′ proton chemical shifts as a function of the ATP concentration is shown in Fig. 1. The results clearly indicate that, as the ATP concentration increases, the proton resonances shift to high field due to stacking and hence to ring-current shielding. Sigmoid curves are observed for the three proton chemical shifts and the largest high-field shift is observed for proton H2 (0.37 ppm). Excellent agreement is obtained when the results are compared with and without EDTA.

A plot of the ^{31}P chemical shifts for the α, β, and γ resonances is shown in Fig. 2. All three resonances shift to low field as the ATP concentration increases, an effect that is opposite to that observed for the proton chemical shifts.

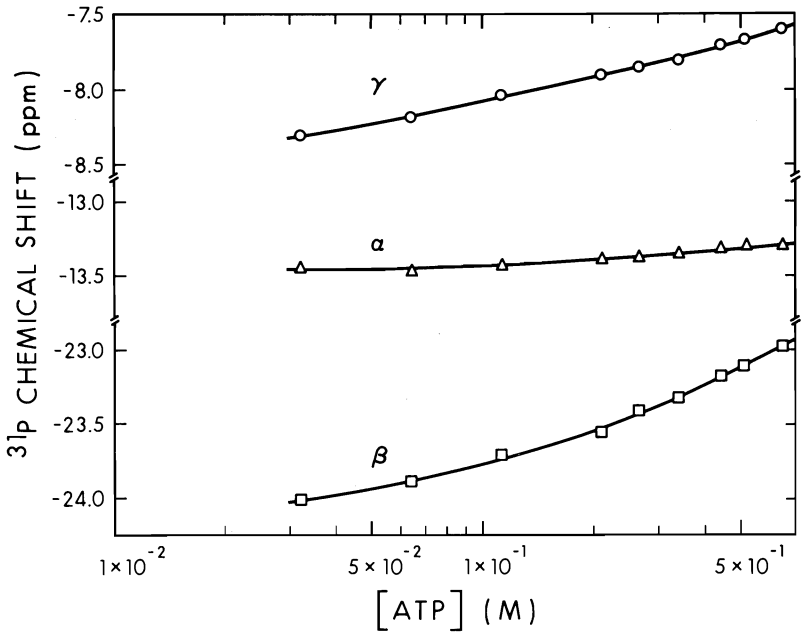

FIG. 2. ^{31}P chemical shifts of the α, β, and γ phosphorus nuclei plotted as a function of the ATP concentration. All three phosphorus nuclei experience a shift to low field with an increase in the ATP concentration. The shifts are expressed in ppm to high field of internal inorganic phosphate (~3 mM) so that shifts with the most positive value (in ppm) are to lowest field. The experiments were carried out at 40.48 MHz in the Fourier transform mode at 27°C. Solutions were prepared in D_2O at a pD of 8.4.

The greatest shift is observed for the β resonance (1 ppm) whereas the α phosphorus resonance is very slightly affected. No significant changes in the coupling constants between the phosphorus nuclei are observed. For 0.034 M ATP solutions, $J(\alpha,\beta) = 19 \pm 1$ Hz and $J(\beta,\gamma) = 19.5 \pm 1$ Hz. For 0.51 M ATP, $J(\alpha,\beta) = 18 \pm 1$ Hz and $J(\beta,\gamma) = 18.5 \pm 1$ Hz.

The results of the relaxation measurements on proton H2 are shown in Fig. 3, both in the absence and presence of 2% EDTA. Protons relax predominantly via the dipole–dipole relaxation mechanism which is given by the equation (26)

$$[1] \qquad \frac{1}{T_1}(^1\mathrm{H}) = \frac{3}{2}\gamma_H{}^4\hbar^2 \sum_i \langle r^{-6}\rangle_i \tau_{ci}$$

In [1], γ is the magnetogyric ratio of hydrogen, $\langle r^{-6}\rangle$ is the conformationally averaged value of the inverse sixth power of the distance and i represents the protons which affect the T_1 of the proton under consideration via the dipolar interaction. The average reorientational correlation time, τ_c, can be approximated by the Stokes or Einstein equation (27)

$$[2] \qquad \tau_c = \frac{4\pi\eta a^3}{3kT}$$

where η is the viscosity of the solution and k is the Boltzmann constant.

With this in mind, viscosities were measured on ATP solutions, at 27°C, both in H_2O and in D_2O. The results of these measurements are shown in Fig. 4. Applying the viscosity correction for the solvent D_2O, a plot of $[\eta T_1]^{-1}$ vs. the concentration of ATP for proton H2 is shown in Fig. 5. A significant change is observed up to a nucleotide concentration of about 0.20 M, and then the results are concentration independent. For protons H8 and H1′, T_1 measurements were also carried out, but the results are sensitive to the presence of EDTA (Fig. 6) and hence to the presence of trace metal ions in solution. In addition, since the relaxation of these protons is not due only to intermolecular dipole–dipole effects as is the case for proton H2, the data in Fig. 6 were not further analyzed in the study of intermolecular association equilibria.

In view of the results in Fig. 6, T_1 values for the H8, H2, and H1′ protons of purified ITP

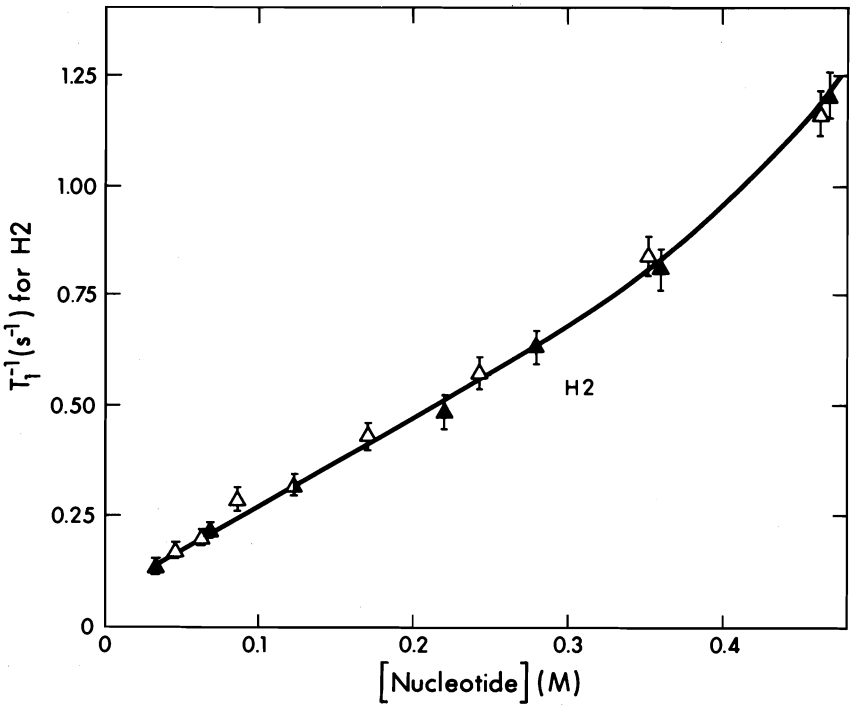

FIG. 3. The T_1^{-1} values for proton H2 of pure ATP are plotted as a function of the nucleotide concentration in solution. These T_1^{-1} measurements were carried out at 100.0 MHz in the Fourier transform mode (27°C) on samples prepared in D_2O at a pD of 8.4. The data represented by the open symbols are for solutions without EDTA, whereas the solid symbols represent the data obtained for solutions with EDTA.

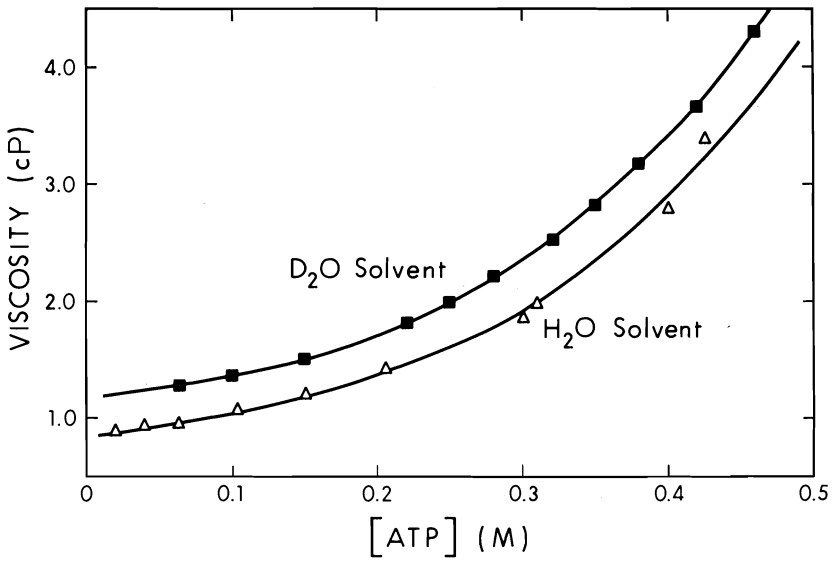

FIG. 4. A plot of the viscosities of ATP solutions measured in H_2O and D_2O as a function of the ATP concentration. The experiments were carried out at 27°C.

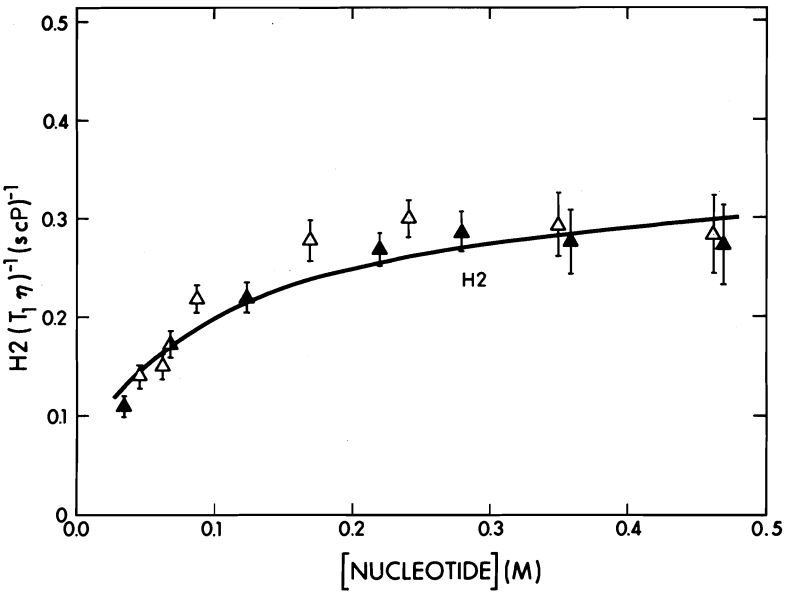

FIG. 5. A plot of the viscosity corrected relaxation rate $(T_1\eta)^{-1}$ for proton H2 of pure ATP plotted as a function of the nucleotide concentration in solution. As discussed in the caption to Fig. 3, the solid symbols represent the data obtained for solutions with EDTA, whereas the open symbols are for solutions without EDTA. The solid curves represent the best fit to the data based on the monomer–dimer–trimer equilibrium model.
