FIG. 6. A plot of the H8 and H1′ proton T_1^{-1} data as a function of the ATP concentration. The experiments were carried out at 100.0 MHz in the Fourier transform mode (27°C) on samples prepared in D_2O at a pD of 8.4. The data represented by the open symbols are for solutions without EDTA, whereas the solid symbols represent the data obtained for solutions with EDTA.

TABLE 1. The nuclear Overhauser effect observed for proton H8 upon irradiation of proton H2 and the ribose protons[a]

[ATP] (M)	H1′	H2′	H3′	H2
0.44	~0	0.15±0.03	0.15±0.03	0
0.22	~0	0.15±0.03	0.19±0.03	0
0.11	~0	0.15±0.03	0.11±0.03	0
0.056	0.05±0.03	0.15±0.03	0.13±0.03	0

[a]The samples were degassed, and the temperature was 27°C. The solutions were at a pD of 8.4 and contained 2% EDTA. In addition, the adenine H2 proton was not affected when the ribose protons were irradiated.

solutions (with 2% EDTA) were remeasured (28). For two ITP solutions prepared in D_2O with [ITP] = 0.20 ± 0.03 M and a pD of 6.4 and 7.2, the average values of the proton T_1 data are: H8 = 1.3 ± 0.15 s, H2 = 3.0 ± 0.3 s, and H1′ = 1.6 ± 0.2 s. These relaxation times are significantly longer than those previously reported (28), suggesting that in the earlier study, even though some EDTA was added, the relaxation times were shortened by paramagnetic impurities.

Proton–proton nOe experiments were carried out as a function of the ATP concentration. The results are tabulated in Table 1. Large enhancements are observed for proton H8 upon irradiation of protons H2′ and H3′. Since the ribose proton resonances are not well resolved at 60.0 MHz, the measured values of the nOe must be treated with caution.

Data Treatment

In order to decide on the nature of the intermolecular complex present in solution, the data were first analyzed as a function of the ATP concentration using multiple regression. The equation that was used is

$$[3] \qquad f(c)\ [\text{observed}] = \sum_{i=0}^{k} \alpha_i c^i$$

where k is the order of the polynomial, α_i is the ith regression coefficient, and c is the concentration. This relationship is, in general, applicable for studies of self-aggregating systems (2, 4, 29, 30). In carrying out the regression analysis, each set of data was fitted to a power series and k was varied (k = 2, 3 . . . 6). Then, the significance of each of the regression coefficients thus obtained was tested using the F test (30, 31). The results indicate that for the chemical shift data for protons H8, H2, and H1′, and for the β and γ phosphorus, the coefficients α_0, α_1, and α_2 are significant in the regression analysis when a confidence limit of 99% is applied. For the α-phosphorus shifts, which are not very sensitive to the ATP concentration, only the α_0 and α_1 coefficients are significant. In analyzing the viscosity corrected relaxation rates for H2, the α_3 coefficient was found to be significant. Values of the α_0 coefficient are listed in Table 2. These are important in the following analysis, as this coefficient corresponds to the values of the chemical shifts and to the relaxation rates for the ATP monomer in the limit of infinite dilution.

The nature of the intermolecular association may now be considered. The intermolecular stacking interactions in solution are analyzed in terms of the following equilibria in solution (4, 5):

$$[4] \qquad \begin{aligned} m_1 + m_1 &\overset{K_2}{\rightleftharpoons} m_2 \\ m_1 + m_2 &\overset{K_3}{\rightleftharpoons} m_3 \\ m_1 + m_{n-1} &\overset{K_n}{\rightleftharpoons} m_n \end{aligned}$$

The terms m_i and K_i are the concentration and the association constant, respectively. These terms are related by the equations

$$[5] \qquad c = \sum_{i=1}^{n} i m_i$$

TABLE 2. Limiting values of the parameters for the ATP monomer (α_0 coefficient) obtained from the multiple regression analysis[a]

Measurement	α_0 coefficient
H8 chemical shift	7.32 ppm
H2 chemical shift	7.04 ppm
H1′ chemical shift	4.91 ppm
α-P chemical shift	−13.5 ppm
β-P chemical shift	−24.1 ppm
γ-P chemical shift	−8.3 ppm
H2 viscosity corrected relaxation rate $(\eta T_1)^{-1}$	0.047 s^{-1} cP^{-1}

[a]The limiting values of the chemical shift parameters for the ATP monomer (α_0) were obtained by a multiple regression analysis of the data using the polynomial $Y_{obs} = \alpha_0 + \alpha_1 x + \alpha_2 x^2$. The ATP concentration is represented by x. For the viscosity corrected relaxation rates, the polynomial $Y_{obs} = \alpha_0 + \alpha_1 x + \alpha_2 x^2 + \alpha_3 x^3$ was used.

TABLE 3. Results of the calculations for the monomer–dimer equilibrium model

Measurement	Association constant (M^{-1})	Value of p_2[a] for the dimer	Standard error[b] of the fit
H8 chemical shift	1.08±0.15	6.91±0.03 ppm	7.99×10^{-2}
H2 chemical shift	0.74±0.09	5.91±0.08 ppm	1.33×10^{-2}
H1′ chemical shift	0.88±0.17	4.62±0.03 ppm	6.48×10^{-3}
α-P chemical shift	0.32±0.23	−12.6±0.4 ppm	1.85×10^{-2}
β-P chemical shift	0.53±0.08	−20.6±0.3 ppm	2.69×10^{-2}
γ-P chemical shift	0.75±0.19	−6.4±0.3 ppm	3.16×10^{-2}
H2 viscosity corrected relaxation rate $(\eta T_1)^{-1}$	5.0 ±1.5	0.45±0.04 s^{-1} cP^{-1}	2.29×10^{-2}

[a]In the analysis, the characteristic values of p_1 used for the monomer are the corresponding values of α_0 ($\equiv p_1$) listed in Table 2.
[b]The standard error of the fit was calculated using the equation

$$[(Y_{obs} - Y_{predicted})^2/(\text{No. of data points} - \text{No. of parameters})]^{1/2}$$

TABLE 4. Results of the calculations for the monomer–dimer–trimer equilibrium model

Measurement	Association constant (M^{-1})	Value of p_2[a] and p_3	Standard[b] error of the fit
H8 chemical shift	1.29±0.15	6.99±0.02 ppm	7.52×10^{-2}
H2 chemical shift	0.92±0.09	6.16±0.05 ppm	1.25×10^{-2}
H1′ chemical shift	1.08±0.18	4.68±0.02 ppm	6.25×10^{-3}
α-P chemical shift	0.43±0.26	−12.9±0.3 ppm	1.83×10^{-2}
β-P chemical shift	0.66±0.09	−21.4±0.2 ppm	2.55×10^{-2}
γ-P chemical shift	0.90±0.19	−6.8±0.2 ppm	3.06×10^{-2}
H2 viscosity corrected relaxation rate $(\eta T_1)^{-1}$	5.1 ±1.3	0.40±0.03 s^{-1} cP^{-1}	2.17×10^{-2}

[a]For the analysis, p_2 was chosen equal to p_3. The characteristic values of p_1 used for the monomer are the corresponding values of α_0 ($\equiv p_1$) listed in Table 2.
[b]The standard error of the fit was calculated using the equation

$$[(Y_{obs} - Y_{predicted})^2/(\text{No. of data points} - \text{No. of parameters})]^{1/2}$$

and

$$[6] \qquad K_i = \frac{m_i}{m_i m_{i-1}} \quad (i \geq 2)$$

Under conditions of fast exchange, the observed chemical shift or relaxation rate is given by the equation

$$[7] \qquad f(c)[\text{observed}] = \sum_{i=1}^{n} x_i p_i$$

where p_i is the chemical shift or the relaxation rate of a given nucleus in the species with i ATP molecules in a stack, x_i is the corresponding mole fraction ($x_i \equiv i m_i/c$), and n is the degree of association.

The proton H8, H2, and H1′ chemical shift data, as well as the ^{31}P chemical shifts and the H2 viscosity corrected relaxation rates, were fitted to [5], [6], and [7] using a nonlinear least-squares program (32, 33). All the data for proton H2 (Fig. 5) were used in the analysis. When the analysis was carried out including only the solutions containing EDTA, very similar results were obtained. The results of the simple monomer–dimer equilibrium model are given in Table 3. The data were also analyzed in terms of a monomer–dimer–trimer equilibrium model present in solution. In this analysis, however, since K_2 and K_3, as well as p_2 and p_3, are perfectly correlated, a fit to the data could only be achieved with $K_2 = K_3$ and $p_2 = p_3$. The results of this analysis are given in Table 4. In these analyses, p_1 was set equal to the corresponding α_0 value from Table 2. Equilibria involving higher order species were also tested, up to $n = 10$, with $K_i = K_{i+1}$ and $p_i = p_{i+1}$.

Discussion

X-ray studies by Kennard *et al.* (34) show the presence of two molecules of ATP, four sodium ions, and six water molecules in the asymmetric unit. The triphosphate chain is in the folded conformation in both ATP molecules, and the base to sugar conformation is *anti*. In one molecule (A) of ATP, the triphosphate chain is folded so as to form part of a left-handed helix, while in the second molecule (B), it forms part of

a right-handed helix. The ribose ring is in the C3′ *endo* conformation in molecule A and C2′ *endo* conformation in molecule B. In addition, it was observed that for the base stacking, the base planes are stacked almost parallel to each other with A and B molecules alternating, with an average separation of 3.40 Å. The degree of overlap was considerable, and the base stacking is head-to-tail. Theoretical calculations (35–37) support the folded triphosphate chain. The molecular orbital calculations (36) indicate that the free ATP molecule has an intrinsic tendency to adopt a folded conformation due to a possible hydrogen bonding between the terminal OH and the adenine N7 nitrogen. In addition, recent phosphorus–proton nOe experiments (0.1 *M* ATP in D_2O, p*D* 7.5) indicate that the γ phosphorus interacts spatially with the ribose protons in the H3′ and H4′ region (38).

The H8, H2, and H1′ proton chemical shifts (Fig. 1) are independent of concentration up to an ATP concentration of about 0.02 *M*. As the ATP concentration increases, a sigmoid dependence of the chemical shifts is observed, and all resonances shift to high field, due to intermolecular association and ring-current shielding effects. The largest concentration effect is observed for proton H2, followed by proton H8. The smallest shift is for proton H1′. This same order of concentration effects was observed for adenosine 5′-monophosphate (12), a system in which the adenine bases stack in a head-to-tail manner (11, 12, 19). The ATP proton chemical shifts are consistent with a head-to-tail adenine base stacking, in agreement with the solid state observations.

Brown *et al.* (39) carried out water proton relaxation time measurements on ATP solutions in the presence of paramagnetic Mn(II) ions. Their results are independent of the ATP concentration when concentrations of about 0.02 *M* and lower are studied. Consequently, the proton chemical shift data and the results of Brown *et al.* (39) are self-consistent and indicate that the degree of self-association is very small or negligible for ATP solutions less than 20 m*M*. This result indicates that in the cell where the ATP concentration is less than 10 m*M* (40), the ATP molecules probably do not self-associate.

A comparison of the proton chemical shifts in the monomer (Table 2) and those calculated for the aggregate (Table 4) yields values of +0.33, +0.88, and +0.23 ppm for protons H8, H2, and H1′ respectively. These data further support, in a qualitative manner, the head-to-tail stacking model. With the aid of the theoretical calculations for the ring current shielding areas for the adenine base (41), the observed and calculated chemical shifts due to the base stacking are self-consistent. By placing one adenine base in a head-to-tail fashion over another base at a separation of 3.4 Å, and locating C2 of the top base on the +1 ppm contour line of the bottom base, protons H2 and H8 are then in the +0.8 and +0.3 ppm shielding regions, respectively.

In solution, the nOe experiments (Table 1) indicate that comparable enhancements are observed for the adenine H8 proton when the ribose H2′ or H3′ protons are irradiated, while an enhancement was not observed for the adenine H2 proton. In addition, the measured enhancements are independent of the ATP concentration. Since the nOe is sensitive to the distance between the observed proton and the proton under irradiation, comparable nOe effects, within experimental error, for H8 upon irradiating H2′ or H3′ indicate that proton H8 is located predominantly near protons H2′ and H3′ whereas proton H2 is far removed. These results indicate (42) that the ATP molecules are predominantly in the *anti* conformation over the concentration range studied, as is observed in the solid state. However, the nOe is also sensitive to a variety of effects (42–45), so the conclusions reached from the present nOe data must be treated with caution. To determine precisely the exact conformations of the ATP molecules and the exact stereospecificity of the intermolecular base–base orientation, proton relaxation rates must be obtained for 8-deutero ATP and compared with those for pure ATP, at 5°C (11, 17, 18, 19).

The behavior of $(T_1\eta)^{-1}$ for H2 (Fig. 5) is very similar to that observed for D8 in 8-deuteroadenosine 5′-monophosphate (16) as a function of the nucleotide concentration. Hence both sets of data measure the degree of intermolecular association (16), since H2 proton is relaxed primarily by the H8 proton of the neighboring base in the head-to-tail base stacking model (11, 12, 19). However, proton H8 is relaxed via intermolecular dipole–dipole interactions with a neighboring base H2 proton as well as by intramolecular dipole–dipole interactions with the ribose protons of the same molecule (19). This is only a qualitative conclusion. It has been

observed that 5′-AMP (19) at 5°C is almost exclusively in the *anti* conformation. However, at 30°C, a simple two-state model, in which the purine ring spends 92% of its time in the *anti* conformer and only 8% of the time in the *syn* conformer, fits the data, and so does a model which allows large amplitude rotations about the pure *anti* position (19).

A comparison of the standard errors in Tables 3 and 4 indicates that the monomer–dimer–trimer equilibrium model in solution fits the data better than the monomer–dimer model. The constants given in Table 4 were used to plot the solid curves to the data in Figs. 1, 2, and 5. However, when higher order complexes were introduced into the analysis, very little improvement in the fit to the data was obtained and the equilibrium constants increased slightly. For example, for the proton H8 data, when tetramers are included in the analysis, $K = 1.40 \pm 0.16$ and when pentamers are also included, $K = 1.45 \pm 0.17$. Consequently, the present results suggest the presence of higher oligomers and indicate that the ATP molecules in solution can undergo indefinite linear self-association. This conclusion is in agreement with the stacking model proposed on the basis of uv and cd studies (2, 3), a model with indefinite linear self-association where each step has the same equilibrium constant.

The average value of the association constant based on the proton and phosphorus chemical shift data (Table 4) is $0.9 \pm 0.3\ M^{-1}$. However, for the viscosity corrected H2 relaxation rates $(\eta T_1)^{-1}$, the association constant is $5.1 \pm 1.3\ M^{-1}$. The relaxation measurements give a slightly larger value for the association constant than is obtained from the chemical shift data. This may be due to the large macroscopic viscosity correction that has been applied to the relaxation rates (16, 46), whereas the microscopic viscosity is really necessary. Secondly, the chemical shift data may be more sensitive to initial dimerization or trimerization with higher order species exerting less influence, whereas the $1/T_1$ relaxation data should be continuously proportional to aggregate size, due to the dependence on the correlation time.

The crystal and molecular structure of diphenylsilanediol, a compound with recently demonstrated anticonvulsant activity, has been determined and its stereochemistry compared with other antiepileptics. Crystals of diphenylsilanediol are triclinic, space group $P\bar{1}$, with cell dimensions $a = 9.912$, $b = 15.048$, $c = 14.519$ Å, $\alpha = 120.83$, $\beta = 99.95$, $\gamma = 100.84°$, $Z = 6$ molecules per cell (3 molecules per asymmetric unit). The structure was determined by Patterson and Fourier methods and refined to a final discrepancy value $R = 0.034$. The phenyl ring planes in the molecule are rotated by 80° with respect to each other, and the hydroxyl oxygen atoms are 2.66 Å apart. The molecular parameters help to delineate limits of stereochemical variation in these molecules with retention of anticonvulsant activity.

J. KEITH FAWCETT, NORMAN CAMERMAN et ARTHUR CAMERMAN. Can. J. Chem. **55**, 3631 (1977).

On a déterminé la structure cristalline et moléculaire du diphénylsilanediol, composé ayant démontré une activité anticonvulsive et sa stéréochimie est comparée à d'autres composés antiépileptiques. Les cristaux du diphénylsilanediol sont tricliniques de groupe spatial $P\bar{1}$ avec des dimensions de maille suivantes: $a = 9.912$, $b = 15.048$, $c = 14.519$ Å, $\alpha = 120.83$, $\beta = 99.95$, $\gamma = 100.84°$, $Z = 6$ molécules par maille (3 molécules par unité asymétrique). La structure est déterminée par les méthodes de Patterson et Fourier et affinée à une différence finale de $R = 0.034$. Les plans des cycles phényles dans la molécule sont tournés de 80° l'un par rapport à l'autre et les atomes d'oxygène des groupes hydroxyles sont à une distance de 2.66 Å. Les paramètres moléculaires aident à délimiter la variation stéréochimique dans ces molécules ayant une activité retenue et anticonvulsive.

[Traduit par le journal]

Introduction

In previous papers in this series (1–5) we have described X-ray crystallographic determinations of the molecular structures of chemically different agents which all possess clinical or laboratory demonstrated activities against grand mal epilepsy. These researches resulted in the discovery and identification of certain stereochemical features common to the structures of the different drugs, features which may be the basis of their one mutual pharmacological activity, anticonvulsant efficacy. Thus diphenylhydantoin (DPH), diazepam, procyclidine, trihexyphenidyl, and ethylphenacemide all possess two hydrophobic regions of structure, and when the drug conformations are compared so that these regions are maximally superposed, each compound has two electron-donor groups situated in similar orientations and positions with respect to each other and to the hydrophobic groups.

Recently, reports have appeared ascribing anticonvulsant properties to the silicon-containing compound diphenylsilanediol (DPSD). DPSD has been shown to inhibit electroshock and chemically induced seizures in laboratory tests (6) and to be of use in controlling idiopathic epilepsy in animals (6).[3] There is evidence that the mechanism of action of DPSD is similar to that of diphenylhydantoin. We have undertaken the determination of the structure of DPSD in order to compare its three-dimensional molecular conformation and stereochemistry with those of the other anticonvulsants. The

[3]R. H. Rech. Personal communication.

quantitative description of the relative positions and orientation of the hydrophobic phenyl rings and the electron-donor hydroxyl moieties should prove valuable in further delineating the range of variation permitted for these features in drug structures with retention of anticonvulsant activity.

Experimental

Crystals of diphenylsilanediol, obtained by slow evaporation from ethanol–water solution, are colorless needles elongated along *a*. Unit cell parameters were determined by diffractometer measurement of 2θ values for 15 general reflections, and crystal data (Delaunay reduced cell) are:

$C_{12}H_{12}O_2Si$ fw = 216.31
Triclinic, $a = 9.912 \pm 0.002$, $b = 15.048 \pm 0.008$, $c = 14.519 \pm 0.008$ Å, $\alpha = 120.83° \pm 0.04°$, $\beta = 99.95° \pm 0.04°$, $\gamma = 100.84° \pm 0.04°$, $V = 1731$ Å^3, $Z = 6$, D_c 1.24 g cm^{-3}. Space group (confirmed by structure analysis) $P\bar{1}$. CuK_α radiation, $\lambda = 1.54178$ Å, $\mu(CuK_\alpha) = 15.8$ cm^{-1}.

The intensities of all independent reflections having $2\theta(CuK_\alpha) \leq 132°$ (corresponding to a minimum interplanar spacing $d = 0.84$ Å) were measured on an automated four-circle diffractometer with nickel-filtered CuK_α radiation using the 2θ–θ scan technique, with a scan range of 2° and stationary background counts at each end of the scan. The intensities were corrected for background and Lorentz and polarization factors applied; no absorption corrections were made. Three standard reflections monitored frequently showed no significant decrease in intensity during data collection. A total of 6048 unique reflections were measured of which 5506 (91%) had $I > 2\sigma(I)$ and were considered to be observed.

Structure Determination

The structure was determined using Patterson methods. Density calculations indicated that the triclinic unit cell probably contained either six molecules of diphenylsilanediol or fewer DPSD molecules plus some solvent. Two Patterson syntheses were calculated, one containing contributions from all observed reflections (5506) and the other including only those observed reflections having $\sin\theta/\lambda > 0.40$ Å^{-1} (3717). When peaks from the two maps were compared it was found that the three highest peaks *common to both maps* could represent cross-vectors between three silicon atoms in an asymmetric unit of a centrosymmetric unit cell. The corresponding three self-vectors were also present, but because of their size (half that of the cross-vectors) they did not stand out among the large number of other peaks. A weighted three-dimensional Fourier map, phased on the derived silicon positions, revealed one phenyl ring and parts of others. Two more weighted Fourier syntheses revealed the complete structure, which was found to have six molecules of diphenylsilanediol/unit cell with no solvent of crystallization. Three cycles of isotropic least squares, during which all 36 hydrogens were located on difference Fourier maps, resulted in the discrepancy index $R = 0.102$.

Five sets of least-squares cycles having three blocks/cycle (one molecule/block) completed the refinement. The heavy atoms were refined anisotropically; the hydrogen positions were refined and, after each set of cycles, the hydrogen isotropic *B*'s were made equal to the temperature factor of the atom to which they are attached. The 5506 observed reflections were used for the refinement. The function minimized was $\Sigma w(\Delta F)^2$; unit weights were employed and final residuals were $R = R_w = 0.034$. The maximum shift/error in the final cycle was 0.1 and the final $(\Sigma w(\Delta F)^2/(m-n))^{1/2} = 1.29$. Scattering factors used for silicon, oxygen, and carbon (7) and for hydrogen atoms (8) were as cited. Table 1 lists the fractional coordinates of the nonhydrogen atoms and Table 2 the hydrogen positional parameters.[4]

Results and Discussion

Molecular Structure

Figure 1 is a stereoscopic drawing of the three crystallographically independent DPSD molecules comprising the asymmetric unit of the crystal cell. The conformations of the three molecules are extremely similar, having only very small differences in torsional angles between comparable parts of the different molecules. The phenyl rings in each DPSD are in a nearly mutually perpendicular arrangement, the angles between normals to the two rings averaging 80° (±2°). The hydroxyl groups all participate maximally in an intricate hydrogen-bonding network which links molecules within each asymmetric triplet, as well as from triplet to triplet. There are two systems of H-bonds: (*1*) the even-numbered oxygens in a given triplet of DPSD molecules (O(2), O(4), O(6), the upper three in the stereoscopic drawing) form one end of a hydrogen-bonded chair of O atoms, the other being comprised of oxygens in a triplet related to these by a center of symmetry, i.e., resulting in a chair

O(2)...O(6)...O(4)...O(2′)...O(6′)...O(4′)
⋮.....⋮

with an average O...O distance of 2.74 Å; (*2*) the odd-numbered oxygen atoms (lower three in Fig. 1) in a DPSD triplet form a hydrogen-bonded chair of O atoms through alternating involvement with odd-numbered counterparts in molecules related by a different center of symmetry, i.e.,

O(1)...O(3′)...O(5)...O(1′)...O(3)...O(5′)
⋮.....⋮

average O...O distance is 2.70 Å.

Figure 2 shows the bond lengths and angles in DPSD, the values given being the averages over

[4]Tables of final observed and calculated structure factors and nonhydrogen atom thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

equivalent parameters in all three independent molecules.[5] (The figure in brackets under each value indicates the number of independent determinations contributing to that averaged value.) The coordination around the silicon is tetrahedral, the angles between groups reflecting the relative degree of steric and/or electronic repulsion between them. The Si—OH distance of 1.633 Å agrees closely with Si—OCH_3 and

[5]Tables of individual bond lengths and angles have been deposited. See footnote 4.

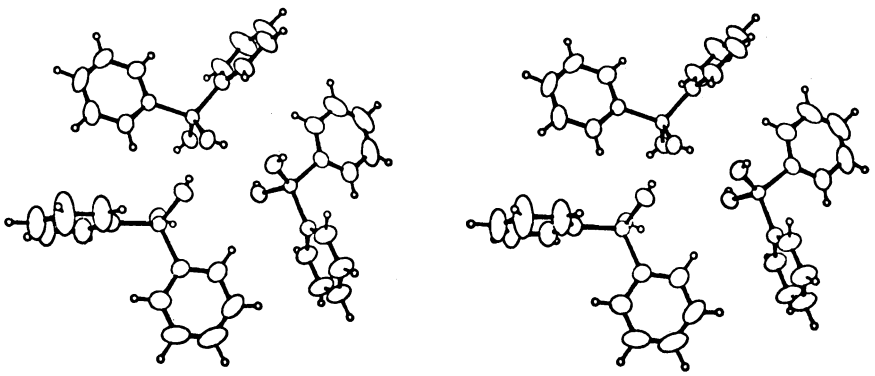

FIG. 1. Stereoscopic drawing of three molecules of DPSD comprising the asymmetric unit of the crystal cell.

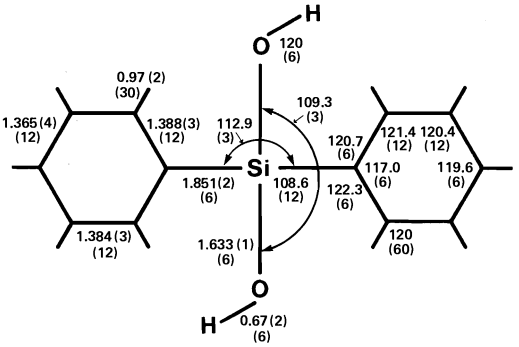

FIG. 2. Bond distances (Å) and valency angles (deg) averaged over equivalent parts of the independent DPSD molecules. Standard deviations of bond lengths are in parentheses. Standard deviations of angles are 0.1° for angles at Si and 0.2° for angles at C. The numbers in parentheses below the values are the number of independent measurements contributing to that averaged value.

Si—O(menthoxy) lengths of 1.636 and 1.630 Å in (+)-α-naphthylphenyl-1-menthoxymethoxysilane (9); the Si...C(phenyl) separation of 1.851 Å also compares closely to the value of 1.855 Å for a similar bond in that compound, and is a little shorter (though probably not significantly so) than an average of 1.866 Å for Si—C(phenyl) bonds in a number of phenylsilanes (10). The C—C bonds in the phenyl rings appear systematically shortened around the *para* carbon atoms; this is undoubtedly an artifact of the increased thermal vibrations at the distal ends of the rings. The significant decrease in C—C—C angle at the carbon bonded to silicon (117.0°) likely relieves intramolecular steric repulsions.

Comparisons With Other Anticonvulsants

In previous studies in this series we have shown that the molecular conformations of diphenylhydantoin, diazepam, procyclidine, trihexyphenidyl, and ethylphenacemide have stereochemical features in common. They all contain two bulky hydrophobic groups and two electron-donor functions, and when the drugs' three-dimensional structures are compared these entities occupy similar positions and orientations in space. These stereochemical similarities in chemically different anticonvulsants have led us to postulate that they may be the features responsible for antiepileptic activity (2).

The fact that DPSD has been reported to have anticonvulsant activity is further support for our postulation, as DPSD possesses *only* those stereochemical features common to the above drugs; i.e., it consists of a central silicon atom to which are bonded two phenyl rings (hydrophobic groups) and two hydroxyl groups (electron donors). Table 3 compares distances between these groups in DPSD with similar separations in diphenylhydantoin. The ring–ring separation is slightly larger in DPSD, but the main difference in dimensions in the two molecules involves the electronegative oxygen atoms.

TABLE 3. Distances (Å) between phenyl ring centroids and oxygen atoms in diphenylhydantoin (DPH) and diphenylsilanediol (DPSD)

	DPH	DPSD
Ring (1) – Ring (2)	4.84	5.43
Ring (1) – O(1)	5.68	4.09
Ring (1) – O(2)	3.97	
Ring (2) – O(1)	5.51	
Ring (2) – O(2)	4.23	
O(1) – O(2)	4.56	2.66

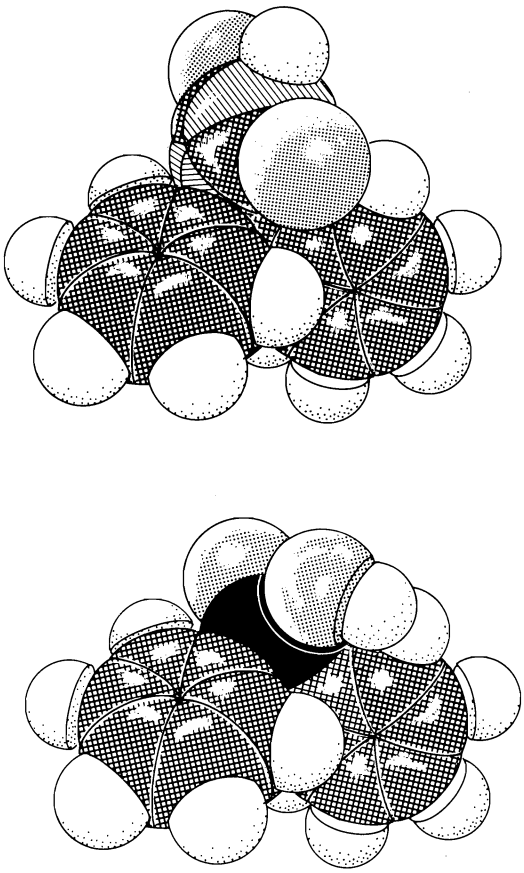

FIG. 3. Space filling models of diphenylhydantoin (top) and diphenylsilanediol.

Because both hydroxyls are on the same atom in DPSD, their separation is necessarily shorter than the distance between (ketonic) oxygens in DPH, 2.66 Å vs. 4.56 Å in DPH. This may indicate that either there is some flexibility in the receptor to accommodate electron donors of somewhat different separations, or that the groups on the receptor which interact with the electronegative atoms (—OH, $\diagdown$NH perhaps) $\diagup$ may do so by donating hydrogens in H-bond formation in the case of DPH and by accepting H-bonds from the hydroxyl oxygens of DPSD. There is slight evidence that either the latter possibility may be more likely, or that the oxygen...oxygen separation of 2.66 Å may be approaching a lower limit for retention of anticonvulsant action: the (ketonic) oxygen...oxygen separation of 2.45 Å in phenylbutansultam (1) is accompanied by only a weak anticonvulsant effect. (Figure 3 shows space filling models of DPH and DPSD and illustrates graphically the conformational similarities.) Because of the molecular symmetry of DPSD the ring...oxygen distances are all closely similar; the value of 4.09 Å in Table 3 represents the average of 12 independent measurements in the molecule (range = 4.01–4.19 Å).

Photolyse du *trans*-butène-2 vers 7.1 eV

ANDRZEJ WIĘCKOWSKI[1] ET GUY J. COLLIN

Département des Sciences pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 16 juin 1977

ANDRZEJ WIĘCKOWSKI et GUY J. COLLIN. Can. J. Chem. **55**, 3636 (1977).

Nous avons étudié la photolyse du *trans*-butène-2 (*t*B-2) dans un système statique en utilisant une lampe à azote: 7.10–7.11 eV (174.5–174.3 nm). Les principaux modes de fragmentation de la molécule *t*B-2 photoexcitée sont la rupture de la liaison terminale C—C avec libération de radicaux CH_3 et CH_3CHCH ($\Phi = 0.33$) et l'élimination d'hydrogène (atomique ou moléculaire) avec formation concurrente de butadiène-1,3 ($\Phi = 0.27$). Le radical CH_3CHCH s'isomérise en radical allylique, qui à son tour se fragmente en allène et atome d'hydrogène. Cette dernière réaction est sensible à la pression, de telle sorte que vers 13 300 N m^{-2} (100 Torr), certains intermédiaires sont stabilisés par collision. On n'a en outre pas pu mettre en évidence la stabilisation de la molécule *t*B-2 photoexcitée. En particulier, on n'observe pas ou très peu d'isomérisation du *t*B-2 en *cis*-butène-2 à basse pression: $P \leq 133$ N m^{-2}.

ANDRZEJ WIĘCKOWSKI and GUY J. COLLIN. Can. J. Chem. **55**, 3636 (1977).

The photolysis of *trans*-2-butene (*t*B-2) was studied at 7.10–7.11 eV (174.5–174.3 nm) in a static system using a nitrogen lamp. The main primary photochemical processes are the C—C split leading to the formation of CH_3 and CH_3CHCH radicals, the primary quantum yield, $\Phi = 0.33$ and the molecular or/and atomic hydrogen elimination, $\Phi = 0.27$ with concurrent formation of 1,3-butadiene. The excited CH_3CHCH radicals isomerize, followed by allene formation, or are stabilized by collisions. The stabilization of the photoexcited *t*B-2 molecules is an inefficient process in the pressure region studied (10–20 000 N m^{-2}). Only small isomerization of *t*B-2 was observed below 133 N m^{-2} ($\simeq$1 Torr).

Introduction

La photolyse des oléfines dans la région de l'ultraviolet sous vide est bien connue (pour une revue, voir ref. 1). Dans le cas particulier du *t*B-2 il faut noter le travail de Borrell et coll. (2). A 184.9 nm on remarque qu'il est facile de stabiliser non seulement les radicaux intermédiaires provenant de la fragmentation de la molécule photoexcitée, mais également la molécule photoexcitée (2). A plus courte longueur d'onde, à 147 nm, nous avons montré qu'il est pratiquement impossible de stabiliser par collision quelle qu'espèce excitée que ce soit (3). En outre l'isomérisation est relativement importante à 184.9 nm, alors qu'elle est pratiquement absente à 147 nm. Enfin on note à 147 nm le bris de la liaison C—C d'une façon plus marquée qu'à 184.9 nm (2, 3). Nous avons repris cette étude en photolysant le *t*B-2 entre ces deux longueurs d'onde. Notre but est d'obtenir plus d'informations sur la fragmentation de la molécule photoexcitée, sur la nature et la qualité de ces fragments et, bien sûr, d'essayer de réconcilier ces importantes divergences entre les deux travaux mentionnés plus haut.

Partie expérimentale

La préparation de la lampe à azote a déjà été décrite (4, 5) et est munie d'une fenêtre en quartz. Son spectre d'émission enregistré à l'aide d'un monochromateur McPherson, GCA-235, d'un demi-mètre, montre les deux raies situées à 174.3–174.5 nm dans le rapport 1:0.5 respectivement. Ces deux raies sont entourées d'un certain nombre de raies provenant probablement d'impuretés. On a estimé d'après l'enregistrement du spectre (fente 30 μm; vitesse de 5 nm/min) que la lampe débite 15% de son intensité entre 165 et 170 nm, 70% entre 170 et 175 nm (raies de l'azote) et 15% au-dessus de 175 nm.

L'actinométrie est réalisée par comparaison avec la photochimie de l'éthylène. Le rendement en acétylène est pratiquement indépendant de la longueur d'onde entre 163.4 et 193 nm et de la pression de l'éthylène tout au moins entre 133 et 2660 N m^{-2} (1 à 20 Torr) (6, 7). On a admis que $\Phi(C_2H_2) = 0.75$ dans ces photolyses.

Le *t*B-2 est un produit "Matheson" et contient du *cis*-butène-2 (0.48%), du butane normal (0.25%) et du butadiène-1,3 (0.063%) comme impuretés et est utilisé après dégasage sous haut vide 10^{-3} N m^{-2}, système à vide en pyrex équipé de robinets en verre-téflon. Les autres détails sont indiqués ailleurs (3, 8).

L'imprécision sur les valeurs expérimentales indiquées est en générale plus petite que 10%, sauf dans le cas où les valeurs calculées sont la différence de deux valeurs élé-

[1]Adresse permanente: Département de chimie, Université de Varsovie, Varsovie, Pologne.

mentaires (voir plus loin à l'usage de HI). L'analyse du butane normale, du *cis*-butène-2 et du butadiene-1,3 a été limitée à des pressions inférieures ou égales à 133 N m^{-2} (1 Torr) à cause du taux d'impuretés.

Résultats

Les résultats détaillés sont rapportés dans la tableau et les figures qui suivent. En bref, le rendement en acétylène est indépendant de la pression entre 13 et 20 000 N m^{-2} (0.1 et 150 Torr). Le rendement en méthane est aussi insensible à la pression. Il en est de même des rendements en méthyl-3-butène-1, isopentane, *cis*- et *trans*-pentène-2 entre 150 et 13 300 N m^{-2}. L'addition d'oxyde nitrique (5%) ne modifie pas les rendements en acétylène, éthylène, propylène, propyne, allène et butadiène-1,3. Par contre la formation de l'éthane, de l'isopentane et des pentène-2 disparaît. L'addition de 10% de HI augmente fortement les rendements du méthane et du propène, légèrement celui de l'éthylène (tableau 1). La pression a un effet important sur les rendements (elle les diminue) en éthylène, éthane, allène et propène (voir les figures qui suivent).

Discussion

Réactions radicalaires

L'effet de l'addition de 5% de NO, ou de 10% de HI montre sans ambiguités la présence de radicaux libres qui participent à la formation des produits observés. L'éthane et les C_5, sur la base de l'effet de NO, sont le résultat de réactions radicalaires. La présence de radicaux méthyles est confirmée par l'effet de HI, de même que la présence de radicaux C_3H_5. Ces radicaux formés en présence de HI, réagissent avec celui-ci (9) (réaction 1). L'augmentation de produit RH en présence de HI, permet d'estimer le rendement $\phi(R) = \phi(RH)_{HI} - \phi(RH)_{NO}$. En particulier $\Phi(CH_3) \simeq 0.70$.

TABLEAU 1. Photolyse du *t*B-2 vers 174 nm; rendements quantiques obtenus à 133 N m^{-2}

Produits	*t*B-2 pur	+5% NO	+10% HI

[a]En fait pic composite de butadiène-1,3, isobutène et butène-1.
[b]Rendement pratiquement indépendant de la pression entre 130 et 13 300 N m^{-2}.

[1] $$R + HI \rightarrow RH + I$$

Par contre, la formation de radicaux éthyles est très faible puisque le rendement en éthane en présence de HI est de l'ordre de 0.01. L'éthane est donc formé par combinaison de radicaux méthyles; l'isopentane l'est par combinaison de radicaux méthyles et butyles secondaires. Ces radicaux sont formés par addition d'atome d'hydrogène sur la double liaison. Le radical butyle formé est vibrationellement excité et se décompose s'il n'est pas stabilisé par collision (10)

[2] $$H + t\text{B-2} \rightarrow s\text{-}C_4H_9^*$$
$$\Delta H = -1.65 \text{ eV } (-38 \text{ kcal mol}^{-1})$$

[3] $$s\text{-}C_4H_9^* \rightarrow CH_3 + C_3H_6$$
$$\Delta H = 1.1 \text{ eV } (28 \text{ kcal mol}^{-1})$$

[4] $$s\text{-}C_4H_9^* + M \rightarrow s\text{-}C_4H_9 + M^*$$

Le rendement des radicaux méthyles décroît donc lorsque la pression augmente; celui des radicaux butyles secondaires au contraire augmente. Ces deux effets contraires expliquent partiellement l'insensibilité observée du rendement en isopentane avec la pression. Le rendement en propylène décroît rapidement avec la pression (fig. 1) conformément au mécanisme [2]–[4].

L'existence de radicaux butyles est définitivement prouvée par l'apparition de butane normal en présence de HI (tableau 1). Ce rendement constitue une limite inférieure du rendement en radicaux butyles dans la photolyse du *t*B-2 pur. En effet HI est un excellent intercepteur d'atome d'hydrogène. Des résultats de la littérature on peut estimer le rapport $k_2/k_5 \simeq 18$ (9, 11)

[5] $$H + HI \rightarrow H_2 + I$$

Ainsi dans le système pur, le rendement en radicaux butyles stables est égal à celui en butane normal observé en présence de 10% de HI multiplié par 2.8: $\Phi(C_4H_9) \simeq 0.42$. Le rendement de la réaction 2 est alors égal à la somme du rendement en radicaux butyles stables et de

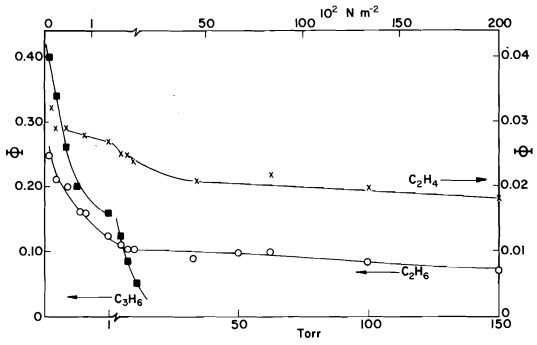

FIG. 1. Rendements quantiques du propène, de l'éthane et de l'éthylène obtenu dans la photolyse du *t*B-2 vers 7.1 eV en fonction de la pression.

celui de la réaction 3. Si le propène est entièrement formé dans le processus [3],[2] on obtient alors:

$$\Phi([2]) = \Phi([3] + \Phi(C_4H_9)) = 0.42 + 0.16 = 0.58$$

Pour obtenir le rendement en atomes d'hydrogène il faut à cette valeur ajouter participation de la réaction d'abstraction d'atome d'hydrogène:

[6] $$H + tB\text{-}2 \rightarrow H_2 + C_4H_7$$

En retenant pour le rapport k_6/k_2 une valeur proche de 0.08 (11, 13), le rendement de la réaction 6 peut être estimée: $\Phi([6]) \simeq 0.05$. Ce rendement est inférieur au rendement des produits insaturés en C_5 formés par combinaison des radicaux méthyles et C_4H_7, et explique donc partiellement leur formation. Au total le rendement $\Phi(H^{\cdot})$ est voisin de 0.63.

Enfin, une partie du pic composite de butadiène-1,3 (voir tableau 1) est sensible à la présence de NO. Bien que l'analyse complète de ce pic n'a pas été faite, il faut noter la présence de radicaux C_3H_5 dans ce système. Ceux-ci ont probablement la structure $CH_3\dot{C}HCH$ s'ils sont formés par fragmentation de la molécule *t*B-2 photoexcitée (2). Ils s'isomérisent probablement en radicaux allyliques comme cela est observé dans le cas du *cis*-butène-2 (8, 13).

[7] $$CH_3\dot{C}HCH^* \rightarrow \overline{CH_2CHCH_2}^*$$

La déduction du rendement $\Phi(C_3H_5)$ à partir de l'effet de HI n'est pas simple. Ce rendement est au moins égal au rendement en présence de HI, réaction 1, diminué de celui observé en présence de NO. Cependant, puisque HI intercepte facilement les atomes d'hydrogène (9), réaction 5, le rendement de la réaction 3, doit être diminué d'une valeur d'environ 0.10. Le rendement en radicaux C_3H_5 serait donc proche de 0.30 à 133 N m^{-2}. La réaction de combinaison des radicaux méthyles et $CH_3\dot{C}HCH$ d'une part et $\overline{CH_2\dot{C}HCH_2}$ d'autre part conduit respectivement au *cis*- ou au *trans*-butène-2 d'une part et au butène-1 d'autre part.

La nature du radical C_3H_5 peut-être davantage précisée sil l'on admet que les radicaux C_3H_5 sont partiellement excités lorsqu'ils sont formés (voir plus loin). Ceux qui ont la structure vinylique ne pouvant former l'allène, ceux ayant la structure allylique le formant.

[8] $$\overline{CH_2\dot{C}HCH_2}^* \rightarrow CH_2CCH_2 + H$$

[9] $$\overline{CH_2\dot{C}HCH_2}^* + M \rightarrow \overline{CH_2\dot{C}HCH_2} + M^*$$

Ce mécanisme de fragmentation–stabilisation par combinaison doit répondre à une équation de type Stern–Volmer. La fig. 2, montre que cela est le cas pourvu que la pression soit supérieure à 10 Torr. On peut même en déduire un rendement Φ' obtenu par extrapolation à pression nulle de l'ordre de 0.028. A basse pression la linéarité de l'équation Stern–Volmer est récupérée si l'on soustrait du rendement en allène, la valeur Φ' obtenue ci-haut, fig. 3. On peut en déduire une deuxième valeur Φ'' obtenue par extrapolation à pression nulle: $\Phi' = 0.037$. Cette façon de diviser l'échelle de pression en deux parties n'est pas nécessairement arbitraire. La linéarité observée dans les deux zones

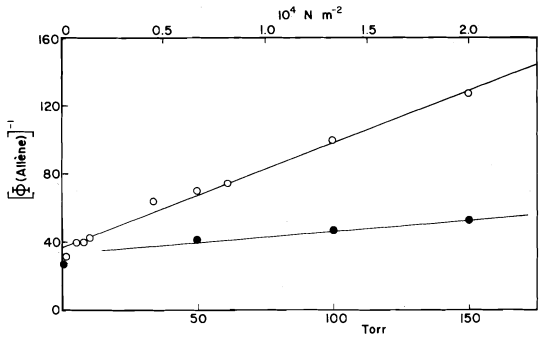

FIG. 2. Variation de $[\Phi(\text{allène})]^{-1}$ en fonction de la pression dans la photolyse du *t*B-2 pur entre 0 et 20 000 N m^{-2}, ○; et dans le système *t*B-2 (133 N m^{-2}) + hélium, ●.

[2]On n'a pas observé de formation de produit provenant de la réaction $CH_2 + tB\text{-}2 \rightarrow$ diméthylcyclopropane, même à haute pression (12). On peut donc en conclure que la fragmentation $tB\text{-}2^{**} \rightarrow C_3H_6 + CH_2$ est de peu d'importance dans ce système: $\Phi < 0.02$.

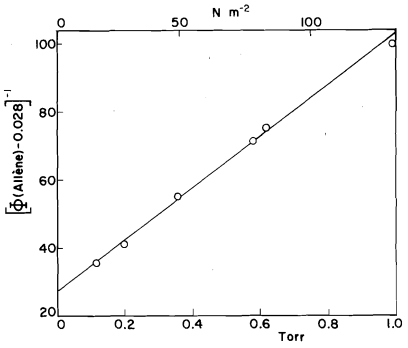

FIG. 3. Variation de $[\Phi(\text{allène}) - 0.028]^{-1}$ avec la pression dans la photolyse du *t*B-2 entre 0 et 133 N m^{-2}.

de pression peut indiquer l'existence de deux variétés de radicaux allyles, variétés différemment excitées. Ainsi la fragmentation de la molécule photoexcitée ne produirait pas des radicaux C_3H_5 avec une distribution d'énergie très large. Au contraire, cette distribution présenterait au moins deux "pics": ceux des radicaux ayant le plus d'énergie se décomposent même à haute pression; les autres ne se décomposant partiellement qu'à basse pression. Une observation supplémentaire qui sert à justifier le fait que le précurseur de l'allène qui est stabilisé n'est pas la molécule photoexcitée réside dans le fait que l'hélium et le *t*B-2 n'ont pas la même efficacité dans la stabilisation du précurseur (fig. 2) contrairement à ce qui est observé par Borrell et coll. à 184.9 nm (2).

Enfin, on observe la formation de radicaux éthyles et vinyles en faibles quantités et à travers le processus [1], on peut estimer le rendement $\Phi(C_2H_5) \simeq \Phi(C_2H_3) \simeq 0.01$.

Fragmentation de la molécule photoexcitée

A partir des données obtenues, il est tentant d'examiner la fragmentation de la molécule photoexcitée. Sur la base des produits obtenus en présence d'oxyde nitrique et de ceux en présence de HI, on peut reternir les processus suivants:

[10] $t\text{B-2} + h\nu \rightarrow t\text{B-2}^{**}$

[11] $t\text{B-2}^{**} \rightarrow C_4H_6 + 2H$ (ou H_2) $\quad \Phi \simeq 0.27$

[12] $t\text{B-2}^{**} \rightarrow C_2H_2 + 2CH_3 \quad \Phi = 0.07$

[13] $t\text{B-2}^{**} \rightarrow C_3H_4$(propyne) $+ CH_3 + H(CH_4)$ $\quad \Phi = 0.03$

[14] $t\text{B-2}^{**} \rightarrow C_3H_5^* + CH_3 \quad \Phi = 0.07$
$\hookrightarrow C_3H_4$(allène) $+ H$

[15] $t\text{B-2}^{**} \rightarrow C_3H_5 + CH_3 \quad \Phi = 0.26$

[16] $t\text{B-2}^{**} \rightarrow C_4H_7 + H$

Les rendements des réactions 11, 12, 13, 14 et 15 sont basées sur les rendements en butadiène-1,3, acétylène, propyne, allène (lorsque la pression est zéro), et en C_3H_5 (effet de HI) respectivement (la réaction 15 correspondant à la formation de radicaux C_3H_5 qui ne se décomposent pas à basse pression). Le rendement de la réaction 16 est difficilement appréciable. En admettant que les radicaux C_4H_7 réagissent avec les autres radicaux sur une base statistique, on obtient la relation,

$$\frac{k(CH_3 + C_4H_7)}{k(R + C_4H_7)} = \frac{\Phi(C_5H_{10})}{\Phi(RC_4H_7)} = \frac{\Phi(CH_3)}{\Phi(R)}$$

$\Phi(C_5H_{10})$ est égal à 0.025 (tableau 1), $\Phi(CH_3)$ à 1 Torr est voisin de 0.70 et $\Phi(R)$ est la somme des rendements de tous les radicaux: $\Phi(R) \simeq 1.8 \pm 10\%$. On obtient donc $\Phi(RC_4H_7) = 1.8 \times 0.095/0.70 \simeq 0.24 \pm 0.03$. De cette valeur qui est voisine du rendement $\Phi(C_4H_7)$, il faut soustraire le rendement de la réaction 6: $\Phi([16]) \simeq 0.19 \pm 0.05$.

Il faut ajouter que cette valeur est une valeur maximum, car si certains radicaux sont chauds, (H^*, CH_3^*) leur énergie interne favorise l'abstraction d'un atome d'hydrogène. Enfin le fait que les produits en C_5H_{10} aient des rendements insensibles avec l'augmentation de pression, montre que le radical C_4H_7 n'est pas le précurseur de l'allène ou de l'éthylène.

Ce dernier produit a un rendement qui suit la relation de Stern–Volmer: fig. 4. Ces résultats sont insuffisants pour proposer le mécanisme de formation ou tout au moins l'un de ces prédéces-

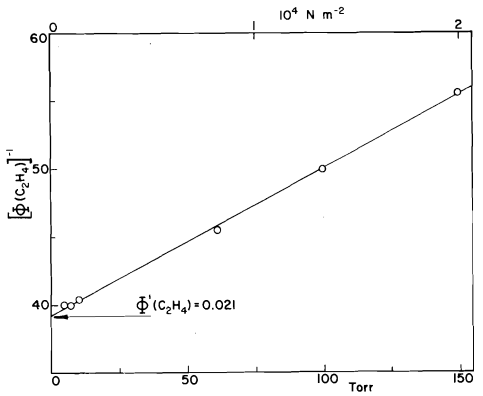

FIG. 4. Variation de $[\Phi(C_2H_4)]^{-1}$ avec la pression dans la photolyse du *t*B-2 entre 0 et 20 000 N m^{-2}.

seurs. A 184.9 nm, Borrell et coll. (2) montrent que la stabilisation de l'intermédiaire est insensible à la nature du stabilisant et en déduisent indirectement que l'espèce stabilisée est la molécule photoexcitée elle-même. Dans le cas du *cis*-butène-2 photolysé à 174 nm, nous avons récemment montré l'inverse (5). Ce qui tendrait à prouver qu'un fragment excité existe entre la molécule photoexcitée et la formation de l'éthylène. A 133 N m^{-2}, on trouve un rendement en radicaux éthyles et vinyles qui correspondraient assez bien à la faible stabilisation observée sur la fig. 4. On aurait donc:

[17] $$t\text{B-2}^{**} \rightarrow C_2H_3 + C_2H_5^*$$

[18] $$C_2H_5^* \rightarrow C_2H_4 + H$$

[19] $$C_2H_5^* + M \rightarrow C_2H_5 + M^*$$

La valeur obtenue par extrapolation à pression nulle donne un rendement maximum: $\Phi([17]) = 0.02$.

La somme des rendements de fragmentation: $\Phi([11] + \ldots [17])$ est égale à $0.91 \pm 10\%$. A l'imprécision expérimentale près, on a donc décomposition complète de la molécule photoexcitée, sans observer de stabilisation de celle-ci même à une pression en *t*B-2 de 20 000 N m^{-2} (150 Torr). Cette situation a été également observée avec le *cis*-butène-2 (5).

Ces résultats sont tout à fait différents de ceux observés par Borrell et James à 185 nm (15). La photochimie des butènes-2 y est expliquée en terme d'état Rydberg et d'état singulet π^*, π comme intermédiaires. L'état Rydberg se fragmente en une variété de produits à basse pression ou sont stabilisés par collision à haute pression avec retour dans l'état original: il n'y a pas d'isomérisation *cis–trans*. L'état singulet $V(\pi^*, \pi)$ conduit uniquement à l'isomérisation [15]. Ici, la longueur d'onde incidente correspond à peu près au maximum de l'absorption $V \leftarrow N$ (14) et en suivant l'argument présenté à Borrell et coll., on ne devrait observer que l'isomérisation contrairement à ce qui est observé. Il n'est pas interdit de penser à l'existence du mélange d'états Rydberg et d'états V, à moins que l'interprétation donnée par Borrell et coll. soit partiellement erronée [15].

Remerciements

Nous voulons exprimer notre gratitude au Ministère de l'Education du Québec (programme FCAC) et au Conseil national de recherches du Canada qui ont partiellement et conjointement financé cette étude.

Characterization of natural gas hydrates by nuclear magnetic resonance and dielectric relaxation[1]

D. W. DAVIDSON, S. K. GARG, S. R. GOUGH, R. E. HAWKINS, AND J. A. RIPMEESTER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received June 17, 1977

D. W. DAVIDSON, S. K. GARG, S. R. GOUGH, R. E. HAWKINS, and J. A. RIPMEESTER. Can. J. Chem. **55**, 3641 (1977).

Continuous-wave proton nmr spectra of the clathrate hydrates and/or deuteriohydrates of methane, ethane, propane, isobutane, and neopentane–D_2S have been recorded down to 2 K. Between 50 and 200 K each H_2O hydrate spectrum consists of a line 3 to 4 G wide from reorienting guest molecules and a broader band from rigid water molecules. Line shapes characteristic of non-rotating guests are obtained in D_2O hydrates at low temperatures, except for methane which gives a narrow line to 2 K. Neopentane, shown for the first time to be capable of enclathration, exhibits a Resing effect and other features related to its tetrahedral symmetry. Low-temperature dielectric absorption from reorienting guest-molecule dipoles has been measured in H_2S, propane, isobutane, and *n*-butane–H_2S hydrates. For steric reasons *n*-butane is encaged as a *gauche* rather than the *trans* isomer. Average barriers to reorientation estimated from nmr and dielectric data are 1.2 kcal/mol for ethane in type I hydrate and 0.6, 1.2, 1.4, and 0.8 kcal/mol for propane, isobutane, *n*-butane, and neopentane in type II.

D. W. DAVIDSON, S. K. GARG, S. R. GOUGH, R. E. HAWKINS et J. A. RIPMEESTER. Can. J. Chem. **55**, 3641 (1977).

On enregistre le spectre rmn du proton à onde continue des hydrates et des deutériohydrates de clathrate de méthane, éthane, propane, isobutane et néopentane jusqu'à une valeur inférieure de 2 K. Entre 50 et 200 K, chaque spectre hydrate H_2O consiste en une raie de largeur 3 à 4 G obtenue à partir de la réorientation des molécules encagées et d'une plus large bande obtenue à partir des molécules d'eau rigides. On obtient les courbes caractéristiques des molécules encagées qui ne tournent pas dans les hydrates D_2O à basse température, à l'exception du méthane qui donne une raie fine à 2 K. On montre pour la premiere fois que le néopentane a une aptitude à l'enclathration et manifeste un effet Resing et d'autres caractéristiques reliées à sa symétrie tétrahédrique. L'absorption diélectrique à basse température obtenue à partir de la réorientation des dipoles des molécules encagées est mesurée pour les hydrates de H_2S, le propane, l'isobutane et l'hydrate de *n*-butane–H_2S. Pour des raisons stériques, le *n*-butane est inséré sous forme d'isomère *gauche* plutôt que sous forme d'isomère *trans*. Les barrières moyennes d'énergie à la réorientation, évaluées à partir des données rmn et diélectriques, sont de 1.2 kcal/mol pour l'éthane sous la forme hydrate I et 0.6, 1.2, 1.4 et 0.8 kcal/mol pour le propane, l'isobutane, le *n*-butane et le néopentane sous la forme II.

[Traduit par le journal]

The discovery that natural gas occurs in the form of solid hydrate deposits in permafrost regions of the USSR (1, 2) and Canada (3) has revealed the need for more complete knowledge of the properties of natural gas hydrates. Practically all the numerous previous experimental studies of these hydrates (4, 5) have been concerned with thermodynamic properties and the determination of the temperature and pressure conditions of stability of hydrates in water–hydrocarbon systems.

Among the 91 molecular species now known (5, 6) to individually form gas hydrates are most of the common components of natural gas. Of the hydrocarbon components of natural gas, methane and ethane individually form hydrates of von Stackelberg's structure I, while propane and isobutane, which are too large for incorporation in the 12- and 14-hedral cages of structure I, form structure II hydrates in which they occupy the 16-hedral but not the 12-hedral cages.

Recent studies of a number of gas hydrates by nmr (5, 7) and dielectric (5, 8) techniques have shown the encaged or guest molecules in these clathrates generally to possess a remarkable degree of freedom of reorientation. We have now extended these studies to hydrates formed by

[1]NRCC No. 16178.

the components of natural gas. Wide-line proton magnetic resonance spectra have been recorded over wide temperature ranges for H_2O and/or D_2O hydrates of hydrocarbon molecules and hydrogen sulfide. In addition, low-temperature low-frequency dielectric absorption has been measured in the hydrates of H_2S and of slightly dipolar propane, isobutane, and *n*-butane molecules.

Although *n*-butane by itself is not known to form a gas hydrate, its presence is demonstrated in the 16-hedral cages of the double *n*-butane–H_2S hydrate, the hydrate being stabilized by the partial filling by H_2S of the 12-hedral cages of structure II. This result confirms the recent thermodynamic conclusions of Wu *et al.* (9) who found evidence of a double hydrate of *n*-butane and methane, with methane here serving as the 'Hilfsgas' (10). Likewise, our nmr measurements show neopentane (2,2-dimethylpropane) to form a double hydrate with H_2S, apparently the first evidence of the encagability of this relatively large molecule.

Experimental Methods

Preparation of Hydrates

Nominal purities of the gases employed were in excess of 99.5% except for ethane and neopentane which were 99.0+%.

Ethane hydrate (deuteriohydrate) was prepared over a period of about a month in a pressure vessel at 0°C (5°C) under 13 atm of ethane gas, the formation of hydrate being monitored by the fall in pressure. Propane and isobutane hydrates were prepared by condensing the liquid hydrocarbon onto cooled, powdered H_2O or D_2O ice and conditioning for a period of weeks at ~ -13°C. H_2S–*n*-butane double hydrate was formed from a cooled mixture of liquid butane and H_2O under H_2S gas at a pressure less than that required to form the single H_2S hydrate. This hydrate was nucleated in the melt by vigorous agitation with a Vortex mixer and grown at $\sim$2°C over several days until further uptake of H_2S became negligible. A similar procedure was used to prepare the neopentane–D_2S–D_2O hydrate, with a reaction temperature of 6°C. Three samples of CCl_4–H_2S hydrate of different H_2S content were prepared by shaking CCl_4–H_2O mixtures at 2°C in a large vessel containing H_2S gas. H_2S hydrate itself was grown at $\sim$22°C over a period of weeks in the dielectric cell itself (see below), which was placed in a pressure vessel and subjected to about 20 atm of H_2S. In most of the above cases, the samples were periodically cooled to low temperatures during the reaction period to crack the hydrate crust which tends to inhibit further hydrate formation.

The amount of unreacted hydrocarbon could be monitored by the intensity of the narrow liquid line in the nmr spectrum at temperatures above the hydrocarbon melting point. This showed none of the samples employed to contain more than a few percent of unreacted hydrate-former.

Nuclear Magnetic Resonance Measurements

Proton nmr spectra were recorded as the derivative of the absorption signal in a marginal oscillator circuit resonating at $\sim$21.4 MHz, with 84 Hz modulation and phase-sensitive detection using a PAR 124 lock-in amplifier. Samples in sealed glass tubes were set in a sample holder consisting of a coil wound on a threaded quartz tube which was mounted in an Andonian Associates liquid helium cryostat equipped with a tail-piece elongated to fit between the pole pieces of a Bruker electromagnet. Temperature control and measurement were as previously described (11).

Line widths were obtained as separations between the *extrema* of the recorded derivative curves. Second moments of absorption lines, corrected for small modulation broadening, were evaluated by a PDP8-E computer from spectra converted to digital form. No problems with signal saturation were encountered.

Dielectric Measurements

The brass dielectric cell used for the hydrocarbon hydrates was constructed with horizontal parallel plate electrodes, the lower electrode being provided with a concentric guard ring. The disc-shaped sample was held firmly between the electrodes by a bellows arrangement. Samples were finely ground in the cold vapour over liquid nitrogen and then pressed in a pre-cooled 1.9-cm diameter die under a pressure of about 1200 kg/cm^2. The sample disc was about 2 mm in thickness, thinner samples being found to be subject to cracking. The cell constant was calculated from the thickness of the sample measured at $\sim$77 K. As a result of uncertainty in cell constant and the effects of surface roughness and voids in the pressed samples, the measured low-temperature permittivities may be in error by as much as 5%.

H_2S hydrate was grown in a stainless-steel cylindrical dielectric cell similar in design and geometry to the brass cell used in previous low-temperature dielectric studies of ice (12).

Of the methods previously used (13) to measure the capacitance and conductance of gas hydrates, only the General Radio 1615A Bridge has resolution and sensitivity good enough to define the small dielectric loss associated with the reorientation of enclathrated propane, isobutane, and *n*-butane molecules. The conductance resolution of this bridge ($\Delta G = 10^{-12}\ \Omega^{-1}$) is associated with a limiting uncertainty $\Delta\varepsilon''$ in dielectric loss of $\pm\Delta G/(2\omega C_0)$, where ω is the angular frequency and C_0 the cell constant in farads. For our hydrocarbon hydrate samples C_0 was $\sim 10^{-12}$ F and measurements were undertaken only at frequencies of 1 kHz and greater, where $\Delta\varepsilon''$ was less than ± 0.0001.

Results

Dielectric Measurements

Dielectric absorption at sub-MHz frequencies has previously been observed at low temperatures in a number of hydrates of dipolar molecules (5, 13, 14). Since this absorption arises from reorientation of the dipole moment of the

guest molecule, it is expected to be absent in the hydrates of methane, nitrogen, carbon dioxide, and other components of natural gas which lack permanent dipole moments. This is true also of ethane in its centrosymmetric (staggered) form or in the presence of rapid rotation of the CH_3 groups with respect to one another. No low-temperature dielectric absorption was in fact found in ethane hydrate within the sensitivity of the measurements (~2% of the absorption shown by propane hydrate).

Figure 1 shows the temperature dependence of the real (ε′) and imaginary (ε″) parts of the complex permittivity of the structure II hydrates of propane (dipole moment 0.083 D) and isobutane (0.132 D), as measured at three frequencies. The maxima in the dielectric loss (ε″) curves associated with the reorientation of encaged propane molecules occur at temperatures less than half those of the corresponding absorption by isobutane and the two species are easily distinguished, even though the absorption associated with each is relatively broad. The corresponding dispersion of ε′ with temperature is likewise distinctive. (The difference in Fig. 1 between the absolute values of ε′ for the two hydrates is not experimentally significant.)

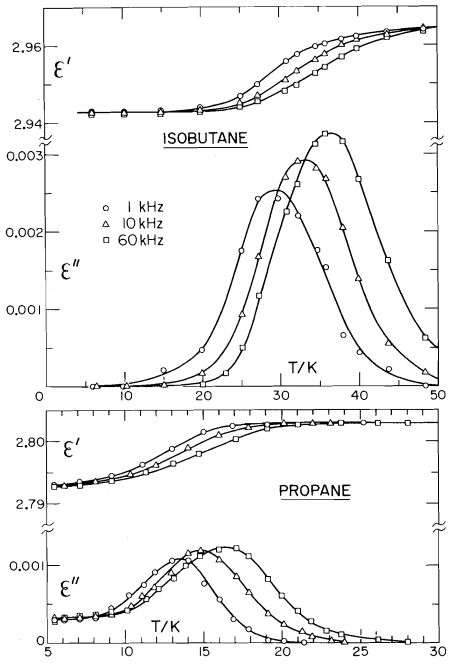

FIG. 1. Dispersion of permittivity (ε′) and dielectric loss (ε″) in propane and isobutane hydrates at low temperatures.

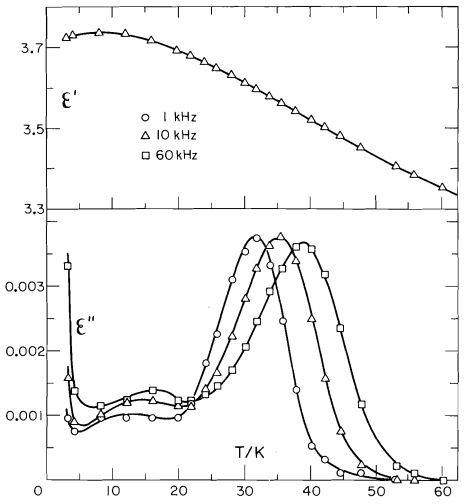

FIG. 2. Dielectric behavior of *n*-butane–H_2S hydrate at low temperatures.

Results for the double hydrate of *n*-butane and H_2S are shown in Fig. 2. The principal dielectric loss peaks from *n*-butane occur only 2 to 3 deg above those from isobutane at the same frequencies of measurement and these peaks would overlap in a hydrate containing both isomers. The secondary absorption region which occurs between 10 and 20 K for *n*-butane may serve to distinguish this guest from isobutane but propane also absorbs in this region. The relatively large value of ε′, its rise with decrease of temperature, and the sharp rise of ε″ below 4 K all arise from the presence of H_2S. Behavior of this kind has previously been observed for the structure II H_2S double hydrates of tetrahydrofuran and trimethylene oxide (13).

The structure I H_2S hydrate itself behaves as shown in Fig. 3. The maximum loss from reorienting H_2S molecules in both single and double hydrates occurs below 1.8 K even at 1 MHz. The extremely fast reorientation rate of enclathrated H_2S is unique among the polar guest molecules which have been studied.

Nuclear Magnetic Resonance Measurements

The formation of a H_2O clathrate by a hydrogen-containing species is generally to be recognized by a proton magnetic resonance spectrum which, at temperatures between roughly 50 and 200 K, consists of a narrow component 3 to 4 G wide arising from the protons of the 'rotating' guest species superimposed on a broad ice-like

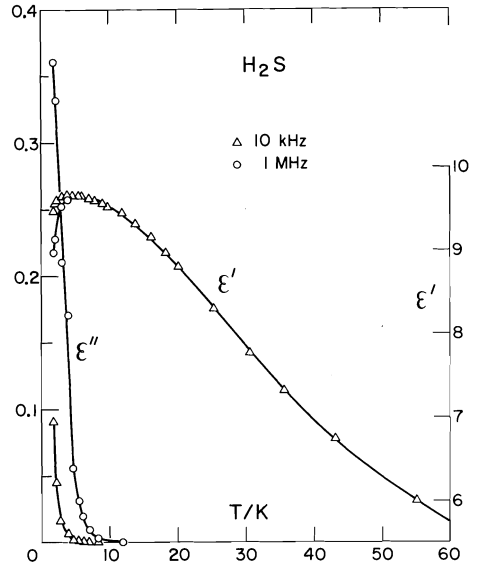

FIG. 3. Dielectric behavior of H_2S hydrate at low temperatures.

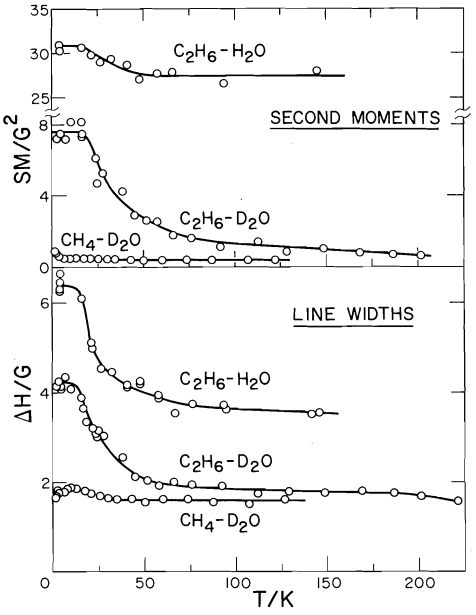

FIG. 4. The nmr line widths and second moments of structure I hydrocarbon hydrates.

resonance arising from 'rigid' water molecules (for examples, see refs. 15–17).

Most previous nmr studies of the motions of enclathrated molecules have been made in D_2O rather than H_2O lattices to eliminate the signal from the water protons (except for HDO impurity). This also greatly reduces the broadening effect of the magnetic nuclei of the host lattice on the spectrum of the guest molecule and more spectral detail is revealed at low temperatures (18).

In the present study of hydrocarbon hydrates more extensive measurements have been made in D_2O than in H_2O. Since deuteriation of the host lattice is likely to have a negligible effect on the motion of the guest molecules, it is normally possible to predict the hydrate spectrum from the deuteriohydrate spectrum of the same guest molecule.

Structure I Hydrates

The structure I hydrate of CH_4 in D_2O has previously been studied (19). At temperatures upward from 1.8 K there is a single structureless line whose width (Fig. 4) is 1.6 G and second moment 0.42 ± 0.02 G^2 between 30 K and 130 K. Although spectra of CH_4 in H_2O have not been obtained, it is anticipated from the D_2O results that these will resemble that shown for ethane hydrate at 146 K (Fig. 5), and remain unchanged over essentially the whole range of

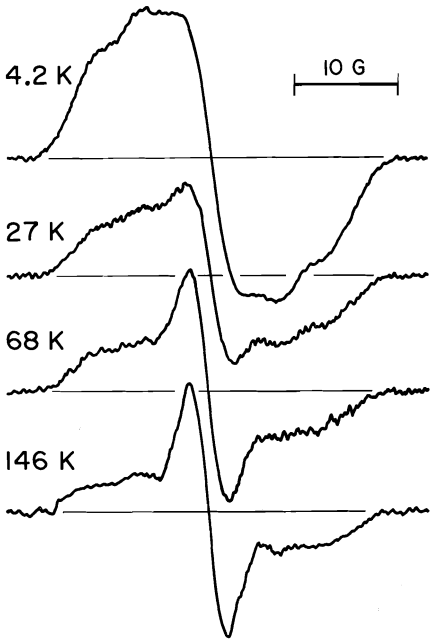

FIG. 5. Line shapes of ethane hydrate.

temperature between 1.8 and 200 K, the width of the narrow component being about 3.6 G.

Ethane has been studied in both D_2O and H_2O. Line shapes at a number of temperatures are shown in Figs. 5 and 6 and the temperature

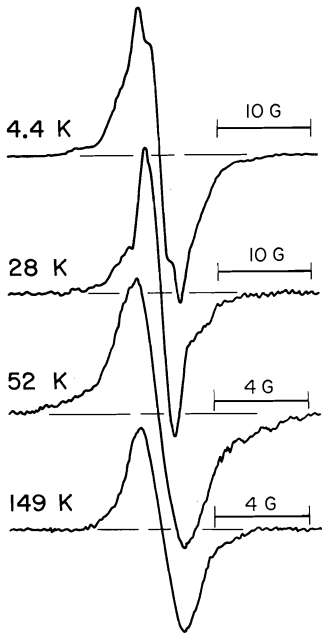

FIG. 6. Line shapes of ethane deuteriohydrate.

dependence of line width and second moment in Fig. 4. Below about 15 K the line shape of C_2H_6 in D_2O (and H_2O) is independent of temperature and shows the absence of overall reorientation of C_2H_6 molecules. The presence of tunnelling of the methyl groups, however, is clearly shown by a value of the low-temperature second moment ($7.6 \pm 0.5\ G^2$) of C_2H_6 deuteriohydrate which is much less than the value ($\sim 25\ G^2$ (20)) expected for rigid C_2H_6 molecules. With increase of temperature, narrowing occurs and the second moment falls to half its low-temperature value by about 36 K and thereafter with increasing slowness to $\sim 1.1\ G^2$ at 100 K and $\sim 0.75\ G^2$ at 200 K. The second moment of C_2H_6 in H_2O shows a corresponding fall which is less pronounced because this second moment is mostly determined by the protons of rigid H_2O molecules. There is overlap of the H_2O and C_2H_6 signals (Fig. 5) at very low temperatures where the widths of the narrow component plotted (Fig. 4) are only approximate.

Structure II Hydrates

Line shapes of the H_2O clathrates of propane and isobutane are illustrated in Fig. 7. Line widths and second moments of the deuteriohydrates are plotted in Fig. 8. The isotopically

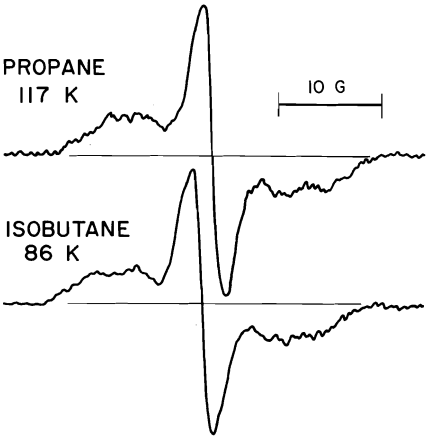

FIG. 7. Line shapes of propane and isobutane hydrates.

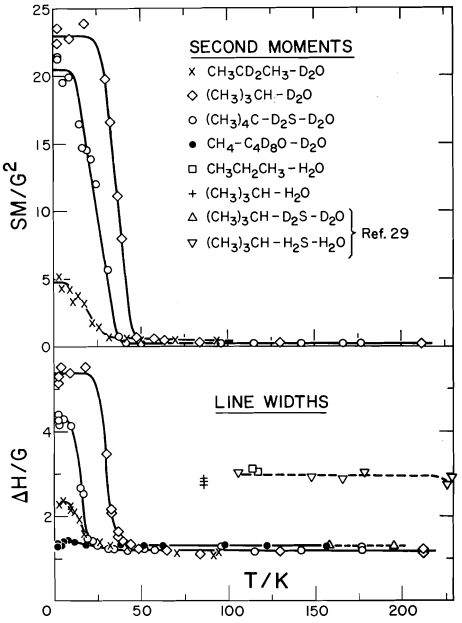

FIG. 8. Line widths and second moments of structure II hydrocarbon hydrates.

substituted $CH_3CD_2CH_3$ form was chosen for better definition of the low-temperature line shape of the CH_3 groups. The low temperature second moment of $5.0 \pm 0.5\ G^2$ (this would have been $\sim 8\ G^2$ for $CH_3CH_2CH_3$ in D_2O) falls to $2.5\ G^2$ at 18 K and to about $0.35\ G^2$ at 100 K. These values are not consistent with the very large second moments of $CH_3CH_2CH_3$ in D_2O previously reported above 77 K (21).

For $(CH_3)_3CH$ in D_2O the second moment is $22.4 \pm 1.5\ G^2$ below 25 K and falls to half

this value at ~37 K, to 0.30 G^2 at 90 K, and to 0.23 G^2 at 210 K. The line width of 1.20 ± 0.04 G between 60 and 210 K agrees with the width of 1.3 G reported by Chassonneau *et al.* (22) for the isobutane–D_2S–D_2O hydrate at two temperatures (see Fig. 8). (However, our second moments at comparable temperatures are only half the 0.55 ± 0.05 G^2 value obtained by these workers.) There is also agreement between their line width (3.0 G between 100 and 200 K) of the isobutane component in the isobutane–H_2S–H_2O system and our width (2.85 ± 0.10 G at 86 K) of isobutane in H_2O.

Line shapes of neopentane in the D_2S–D_2O double hydrate are illustrated in Fig. 9. The absorption begins to narrow at about 13 K, the second moment (Fig. 8) falling to half its low temperature value of 21.0 ± 1.5 G^2 at about 24 K and to about 0.30 G^2 at 50 K. Thereafter it shows little change with temperature, the second moment being 0.26 ± 0.03 G^2 between 60 and 180 K. The line width is 1.23 ± 0.04 G over this temperature range.

Any natural gas hydrate of structure II is likely to contain considerable quantities of methane, mainly in the 12-hedral cages. Previous measurements of the CH_4–tetrahydrofuran-d_8–D_2O type II hydrate (19) gave proton spectra rather similar to that of the structure I CH_4 deuteriohydrate itself, with second moments which hardly changed from 5 K upward. From these results one anticipates that the line width of the CH_4 absorption in a type II H_2O double hydrate should likewise remain independent of temperature above 5 K at a value of about 4.1 G. This width is estimated from the assumption that all CH_4 molecules occupy 12-hedra.

It does not seem possible to prepare for nmr study a sample of H_2S hydrate in D_2O because of the well-known rapid exchange of hydrogen atoms between water and hydrogen sulfide. Figure 10 shows a spectrum of a hydrate sample of approximate composition $0.9CCl_4 \cdot 0.40H_2S \cdot 17H_2O$. The narrow component, identified with H_2S from its variation with H_2S content, appears only as a central shoulder on the H_2O line which makes up 98% of the absorption intensity. It is inferred from the dielectric results that this line characteristic of rotating H_2S molecules should persist down to liquid helium temperatures.

We cannot agree with Chassonneau *et al.* (22) that the *very* narrow line (width <150 mG)

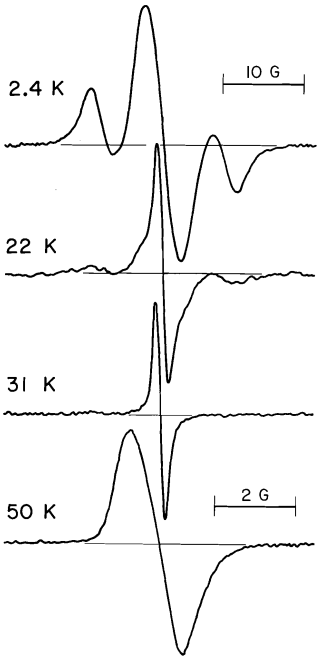

FIG. 9. Line shapes of neopentane in D_2O double hydrate with D_2S.

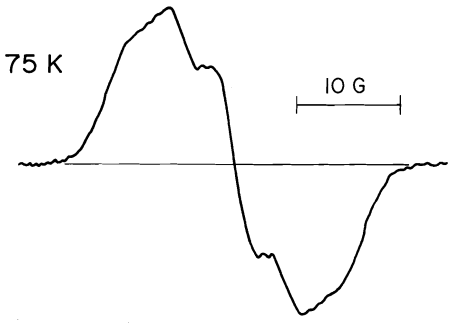

FIG. 10. Line shape of CCl_4–H_2S double hydrate at 75 K.

reported by them at all temperatures above 120 K in the H_2S double hydrates of CCl_4, tetrahydrofuran, isobutane, and thiophene is due to rapid reorientation *and diffusion* of encaged H_2S molecules. This line is much more likely to have arisen from the presence of liquid H_2S in their samples.

Discussion

Proton Nuclear Magnetic Resonance Line Shapes at Low Temperatures

None of the low-temperature proton spectra of the hydrocarbon deuteriohydrates show a line shape characteristic of either rigid CH_3

TABLE 1. Reorientational properties of guest molecules

Guest	Hydrate structure	Dielectric absorption: Temp. of max. ε'' at 100 kHz (K)	Dielectric absorption: E_A (kcal/mol)	Nuclear magnetic resonance line narrowing: $T_{1/2}$ (K)	Nuclear magnetic resonance line narrowing: V_0 (kcal/mol)
H_2S	I, II-double	<1.8			
CH_4	I, II-double			<1.8

groups or, at the other extreme, of CH_3 groups which are undergoing rotation in the fast tunnelling limit (23). More detailed analysis of methyl-group line shapes in hydrocarbon and other enclathrated molecules will be presented elsewhere.

Reorientation Rates of Encaged Molecules

For hydrogen sulfide the average reorientation rate is greater than 1 MHz even at 1.8 K and for methane is also too fast to be definable by the present techniques in the sense that the proton spectrum remains a narrow line to below 2 K. For the remaining guests the general reorientation rates and their dependence on temperature may be derived from analysis of the nmr and dielectric data. It is emphasized that both line-narrowing and dielectric absorption show the presence of wide distributions of reorientation rates in all the hydrates studied. These distributions are a general characteristic of clathrate hydrates and are ultimately attributable to the 'frozen-in' orientational disorder of the lattice water molecules, as discussed elsewhere (5, 13, 17).

Average reorientation rates and 'activation energies' for reorientation are given in Table 1. For dipolar guest molecules the temperature of maximum dielectric absorption at 100 kHz is given along with an effective Arrhenius activation energy E_A derived from the dependence of the temperature of maximum absorption on frequency (Fig. 11).

With increasing temperature an nmr line begins to narrow at the temperature where the molecular reorientation rate becomes approximately equal to the width (in frequency units) of the unnarrowed line. For the present hydrocarbon deuteriohydrates, this width, as the square root of the second moment, is about

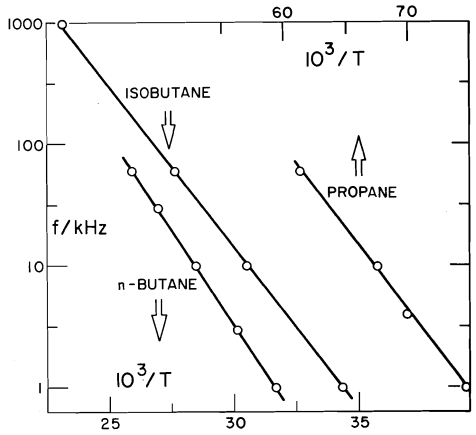

FIG. 11. Temperature dependence of the frequency of maximum ε'' in structure II hydrates.

10 kHz. For a single reorientation rate ν_c which varies with temperature according to $\nu_c = \nu_0 \exp(-V_0/RT)$, Waugh and Fedin (24) showed that, with 'normal' values of the rotational oscillation frequency ν_0 of about 10^{12} Hz, V_0 (kcal/mol) $\approx 37T_c$, where T_c is the temperature of the onset of narrowing. Where, as in the present cases, there is a wide distribution of reorientation rates, the temperature of initial narrowing not only loses its simple significance but is experimentally difficult to define. We have therefore chosen instead of T_c the temperature $T_{1/2}$ at which the second moment has fallen to one half its low temperature value. Under the assumption that the average reorientation rate is about 100 kHz at this temperature, the Waugh formula is modified to V_0 (kcal/mol) $\approx 32.4T_{1/2}$, the new factor being $37 - R \ln 10$. Values of V_0 estimated from this relationship are given in Table 1 where the $T_{1/2}$'s recorded are accurate to about ± 2 K.

There is good agreement between the activa-

tion energies E_A and V_0 derived from the two techniques for propane and isobutane hydrates.

Second Moments for Isotropically Rotating Guests

The second moments of proton absorption lines for isotropically rotating guest molecules in rigid D_2O lattices were calculated by the method given in the Appendix. The results are given in Table 3, where x is the atom fraction of H as impurity in the D_2O employed. The sensitivity of second moment to x is considerable, the effect of 1% HDO in the D_2O being to increase the second moment by one-third to three-quarters, depending on the hydrate.

Comparison of Table 3 with the experimental second moments of 0.40 ± 0.2 G^2 for CH_4 (30–130 K), 0.23 G^2 for $(CH_3)_3CH$ (210 K), and 0.26 ± 0.03 G^2 for $(CH_3)_4C$ (60–180 K) shows good agreement for somewhat less than 1 at.% H in the D_2O.

Effects of Cage Type and Guest-molecule Symmetry on Motional Averaging

For ethane in D_2O the second moment continues to fall with increasing temperature over the whole range of measurement (Fig. 4) and is well in excess of the value calculated for isotropic reorientation (Table 3) even at 200 K. This behavior probably results from the oblate shape of the 14-hedral cage which tends to favor orientations in which the long axis of the ethane molecule lies in and near the equatorial plane midway between opposite hexagonal rings of water molecules. The preference of ethane for equatorial configurations is likely to be somewhat greater than that already suggested (25), with some experimental support, for the smaller chlorine molecule in the same cage. With increase of temperature the motional averaging becomes somewhat more isotropic.

The 16-hedral cages occupied by the larger hydrocarbon molecules are much more spherical than the 14-hedra. The space average symmetry, or the symmetry averaged over the disordered orientations of the water molecules, is tetrahedral ($\bar{4}3m$). At temperatures below about 200 K the motion responsible for nmr line narrowing is reorientation within cages which are distorted from tetrahedral symmetry to an extent determined by the fixed (on an nmr time scale) positions of the hydrogen atoms of the cage water molecules. The variation of this distortion from cage to cage is mainly responsible for the distribution of reorientation rates of guest molecules in structure II hydrates. It may also lead to some residual lack of isotropy in the time averaged directions of the inter-proton magnetic fields of the guest molecules, even when the reorientation rates are very fast. The degree of this anisotropy varies with the geometry of the guest molecule, the greatest effect

on the proton second moment being observed for such relatively unsymmetrical molecules as tetrahydrofuran (17). The ^{19}F second moments of SF_6 and CF_4 encaged in H_2O and D_2O, on the other hand, show no residual anisotropy, even at temperatures down to ~ 20 K (19). Analysis shows that guest molecules of cubic symmetry (i.e., tetrahedral or octahedral molecules) in a cage *of any symmetry* should be characterized by a zero contribution to the second moment from interactions between magnetic nuclei within the guest molecule at all temperatures where the reorientation rates are sufficiently fast (say >1 MHz). It is only necessary that such a molecule undergo a thermally activated process which interchanges the σ equivalent orientations, where σ, the symmetry number, is 12 for tetrahedral and 24 for octahedral molecules. It is immaterial whether there is one or more distinguishable preferred orientations within the cage.

In agreement with these conclusions, the second moment of the tetrahedral neopentane molecule (Fig. 8) shows no change with temperature between 60 and 180 K and has a value indistinguishable from that for isotropic reorientation. Propane and isobutane on the other hand have, near 100 K, somewhat larger moments than the isotropic value.

The spectra of enclathrated neopentane recorded at seven temperatures between 14 and 35 K exhibit clearly the Resing 'apparent phase-change' effect (26) in the form of a superposition of the broad, structured 'rigid lattice' line and a narrow line of almost Gaussian shape, only the latter being observed above 50 K (cf. Fig. 9). This behavior is attributed to a broad distribution of correlation times τ_c such that at temperatures in the transition region $\omega_1\tau_c \gg 1$ (rigid molecules) or $\omega_1\tau_c \ll 1$ (rotating molecules) for most molecules and $\omega_1\tau_c \sim 1$ for relatively few, where ω_1 is approximately the square root of the rigid-lattice second moment ($\sim 2\pi \times 20$ kHz). For the reasons of symmetry already given, neopentane molecules which are rotating at all appear to do so isotropically. The temperature variation of the second moment may be analyzed in terms of a simple Gaussian distribution of activation energies E_c (or log-normal distribution of correlation times), as already described (19) for the Resing effect in SF_6 and CF_4 hydrates. For the mean correlation time $\tau_m = 10^{-12} \exp(E_m/RT)$ and the distribution $G(E_c) = \pi^{-\frac{1}{2}}A^{-1} \exp((E_c - E_m)/A)^2$, values of $E_m = 743$ and $A = 280$ cal/mol were found for the mean activation energy and width parameter, respectively.

Geometry of Encaged n-Butane

Of the two rotational isomers of *n*-butane which exist in the gaseous phase, the *trans* form is more stable than the *gauche* by about 760 cal/mol (27). The longest van der Waals dimension of the *trans* isomer is 7.9 Å if 2.0 Å is taken for the van der Waals radius of the CH_3 groups. This form is much too long for encagement in the structure II 16-hedron (5). Moreover, the *trans* isomer has zero dipole moment and cannot give rise to the dielectric absorption observed. The *gauche* form on the other hand is smaller (length 7.1 Å for the gas-phase dihedral angle of 62.3°) and has a finite dipole moment. The contribution of the interaction with the cage water molecules to the dependence of potential energy on dihedral angle will, in all probability, result in a smaller dihedral angle than in the gas, i.e., the geometry of encaged *n*-butane is likely to be intermediate between the *gauche* form of the gas and the *cis* form (length 6.7 Å).

The effect of the cage on the geometry of *n*-butane may have another consequence. The barrier to interchange of two *gauche* isomers via the *cis* form is considerably reduced by the interactions with the cage which favour the *cis* form and it is possible that the dielectric absorption observed (Fig. 2) between 10 and 20 K arises from this interchange, which would result in some dipole reorientation.

Appendix

Calculation of Second Moments of Isotropically Rotating Guests

These second moments include contributions from the absorption of protons present (mainly as HDO) as impurity in the D_2O as well as from the protons of the guest molecules:

$$[1]\quad \mathrm{SM(total)} = (1\text{-}z)\mathrm{SM(guest)} + z\mathrm{SM(HDO)}$$

where z is the fraction of the total number of protons which is present as impurity in the D_2O. The absorption by guest molecules is broadened by the magnetic fields of the protons of neighboring guests and by the deuterons (and protons) of the water lattice:

$$[2]\quad \mathrm{SM(guest)} = \mathrm{SM(interguest)} + \mathrm{SM(guest\text{–}host)}$$

where the second term depends on the atom fraction x of H in the D_2O according to

$$[3]\quad \mathrm{SM(guest\text{–}host)} = \mathrm{SM(guest\text{–}D_2O)} \times (1 + 34.8x)$$

Values of SM(interguest) and SM(guest–D_2O) were calculated (15) from the Van Vleck formula by taking the guest-molecule protons to be located at the cage centres and half deuterons to be distributed tetrahedrally around the oxygen atoms with OD bond lengths of 1.00 Å, one position lying on the radial extension of the position vector of each oxygen atom with respect to the cage centre (19).

The HDO impurity second moment is

$$[4]\quad \mathrm{SM(HDO)} = \mathrm{SM(HDO\text{–}host)} + \mathrm{SM(HDO\text{–}guest)}$$

where the first term is

$$[5]\qquad \mathrm{SM(HDO\text{–}D_2O)}\,(1 + 34.8x)$$

Since the second moments of both the structure I and structure II H_2O lattices are about 32 G^2 (5),

$$[6]\quad \mathrm{SM(HDO\text{–}D_2O)} = \frac{(4/15)I_D(I_D + 1)\gamma_D{}^2}{(3/5)I_H(I_H + 1)\gamma_H{}^2}32 = 0.89\ \mathrm{G}^2$$

where the I's are nuclear spin quantum numbers and the γ's gyromagnetic ratios. Values of SM(HDO–guest) were evaluated from the tetrahedral water molecule assumption, taking explicit account of the guest molecules in the four cages to whose walls each water molecule is common. The contribution of more distant guests was estimated as an additional 10%.

Complete occupancy of the large cages has been assumed for type II hydrates. For CH_4, 97.5% occupancy of cages of both sizes (corresponding to $CH_4 \cdot 5.9D_2O$) and for C_2H_6, 93.5% occupancy of the large cages ($C_2H_6 \cdot 8.2D_2O$), have been assumed.

The contributions for 100% D_2O are given in Table 2 and the total second moments for D_2O consisting of 100, 99.7, and 99.0 at.% D in Table 3.

The deprotonation and rearrangement of *N*-methyl methylphosphazenium quaternary salts: a novel synthetic route to cyclic azaphosphorins

RICHARD T. OAKLEY AND NORMAN L. PADDOCK[1]

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received February 2, 1977

RICHARD T. OAKLEY and NORMAN L. PADDOCK. Can. J. Chem. **55**, 3651 (1977).

The *N*-methyl methylphosphazenium salts $(NPMe_2)_{3,4}\cdot MeI$ and $N_3P_3Ph_4Me_2\cdot MeI$ can be deprotonated by a variety of bases to yield the novel azaphosphorins $Me_{2n-1}(NHMe)P_nN_{n-1}CH$ (n = 3, 4) and $Me(NHMe)Ph_4P_3N_2CH$, formed by a rearrangement in which the methylated nitrogen atom is displaced from the PN ring by the initially produced exocyclic methylene group. The ^1H nmr spectra of the azaphosphorins indicate a rapid proton exchange between the endocyclic carbon and the exocyclic nitrogen, which can be slowed by the addition of an auxiliary base. When KO-*t*-Bu reacts with the quaternary salts, nucleophilic attack competes with proton removal, and the linear oxides $(NHMe)(PMe_2N)_nPMe_2O$ (n = 2–4) have been isolated from these reactions. The azaphosphorins $Me_{2n-1}(NHMe)P_nN_{n-1}CH$ (n = 3, 4) are hydrolysed in aqueous ethanol to give the cyclic oxides $Me_{2n-1}(O)P_nN_{n-1}CH_2$, and react with methyl iodide by a proton transfer reaction to give the hydroiodides $Me_{2n-1}(NHMe)P_nN_{n-1}CH\cdot HI$. Their reaction with benzoyl chloride leads to the derivatives $Me_7(NHMe)P_4N_3CCOPh$ and $Me_7(NMeCOPh)P_3N_2CCOPh$, the initial substitution on carbon indicating that it is the primary basic centre. Model calculations of π-electron energies suggest that both the azaphosphorin rearrangement and the proton exchange reactions depend on the relative orbital electronegativity of the ring and exocyclic atoms, the less electronegative atom being more stable in the endocyclic position.

RICHARD T. OAKLEY et NORMAN L. PADDOCK. Can. J. Chem. **55**, 3651 (1977).

Les sels de *N*-méthyl méthylphosphazénium $(NPMe_2)_{3,4}\cdot MeI$ et $N_3P_3Ph_4Me_2\cdot MeI$ peuvent être déprotonés par une variété de bases conduisant à de nouvelles azaphosphorines $Me_{2n-1}(NHMe)P_nN_{n-1}CH$ (n = 3, 4) et $Me(NHMe)Ph_4P_3N_2CH$, formées par réarrangement, où l'atome d'azote méthylé est déplacé du cycle PN par le groupe méthylène exocyclique formé initialement. Le spectre rmn ^1H des azaphosphorines indique un échange rapide de protons entre le carbone endocyclique et l'azote exocyclique, qui peut être ralenti par l'addition d'une base auxiliaire. Lorsque le KO-*t*-Bu réagit avec les sels quaternaires, une attaque nucléophile concurrence l'abstraction du proton et il résulte de ces réactions des oxydes linéaires $(NHMe)(PMe_2N)_nPMe_2O$ (n = 2–4). Les azaphosphorines $Me_{2n-1}(NHMe)P_nN_{n-1}CH$ (n = 3, 4) sont hydrolysées dans l'éthanol aqueux pour conduire aux oxydes cycliques $Me_{2n-1}(O)P_nN_{n-1}CH_2$, et elles réagissent avec l'iodure de méthyle par une réaction de transfert de protons pour conduire aux hydroiodures $Me_{2n-1}(NHMe)P_nN_{n-1}CH\cdot HI$. Elles réagissent avec le chlorure de benzoyle pour conduire aux dérivés $Me_7(NHMe)P_4N_3CCOPh$ et $Me_7(NMeCOPh)P_3N_2CCOPh$; la substitution initiale sur le carbone indique que celui-ci est le premier centre basique. Des calculs modèles des énergies pour les électrons-π suggèrent que tant le réarrangement des azaphosphorines que les réactions d'échange de protons dépendent de l'électronégativité relative des orbitales du cycle et des atomes exocycliques, l'atome le moins électronégatif étant plus stable en position endocyclique.

[Traduit par le journal]

Introduction

The formation of carbanions from methylphosphazenes by their reaction with strong bases (1) parallels the acidic behaviour of simple alkylphosphine oxides (2) and exemplifies the many chemical similarities that exist between cyclic phosphazenes $(X_2PN)_n$ and simple phosphoryl compounds X_3PO. In a further study of the acidic properties of the methylphosphazenes, we have investigated the reaction of *N*-methyl methylphosphazenium salts $(NPMe_2)_n\cdot MeI$ with bases (3). As expected, these salts can be deprotonated by a variety of bases, as are such phosphonium salts as $Me_2P(NMe_2)_2{}^+X^-$ (4). However, the final products of such reactions indicate the occurrence of an unusual skeletal rearrangement, thereby illustrating that although many properties of phosphazenes correspond to those of mononuclear phosphorus compounds, certain chemical features are di-

[1]Author to whom correspondence should be addressed.

rectly related to their cyclic structure. The reaction leads to several new azaphosphorin derivatives.

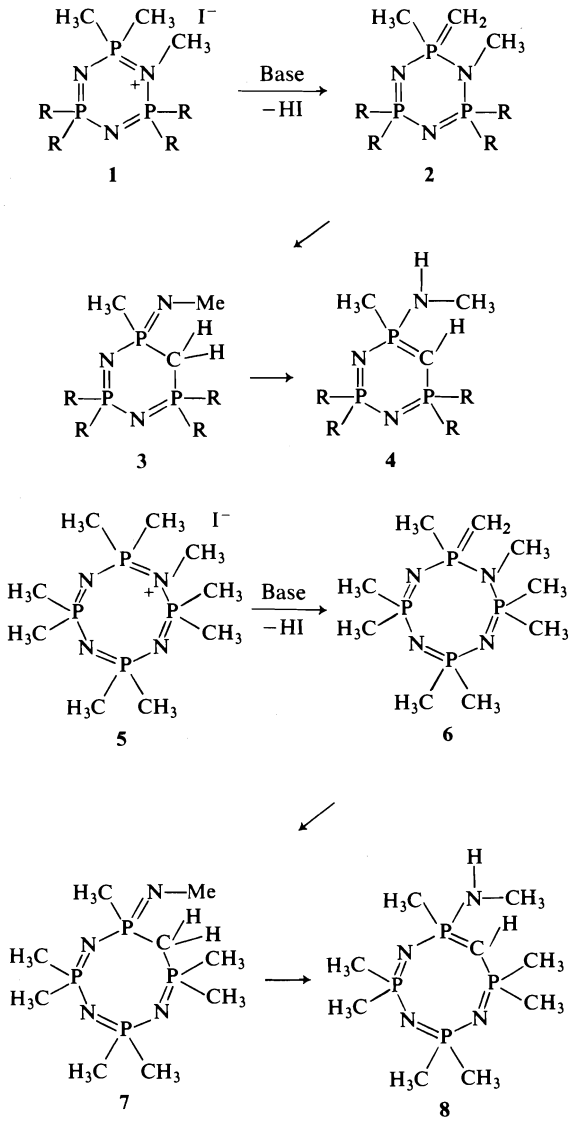
Results

Reactions of Quaternary Methylphosphazenium Salts with Bases

We have used chiefly the bases potassium *tert*-butoxide (KO-*t*-Bu) and sodium hexamethyldisilylamide. Both are appreciably soluble in hydrocarbons, which are the most convenient media for achieving a clean separation of the products, and both have been used successfully in the deprotonation of phosphonium salts (5–8). The reaction with the silylamide is the simpler. In boiling octane or toluene, $NaN(SiMe_3)_2$ reacts smoothly with the quaternary iodides $N_3P_3Me_6 \cdot MeI$ and *gem*-$N_3P_3Ph_4Me_2 \cdot MeI$, (**1**, R = Me, Ph) removing a proton from one of the P-methyl groups adjacent to the quaternized nitrogen atom. The final products are not the expected ylids **2**, but rather the novel azaphosphorins **4** (*a*, R = Me; *b*, R = Ph), formed from the ylids by a rearrangement in which the methylated nitrogen atom is displaced from the ring, the resulting exocyclic imine (**3**) then tautomerizing to give the aromatic amine form **4**. An exactly analogous reaction occurs with $N_4P_4Me_8 \cdot MeI$ (**5**), to give the azaphosphorin **8**.

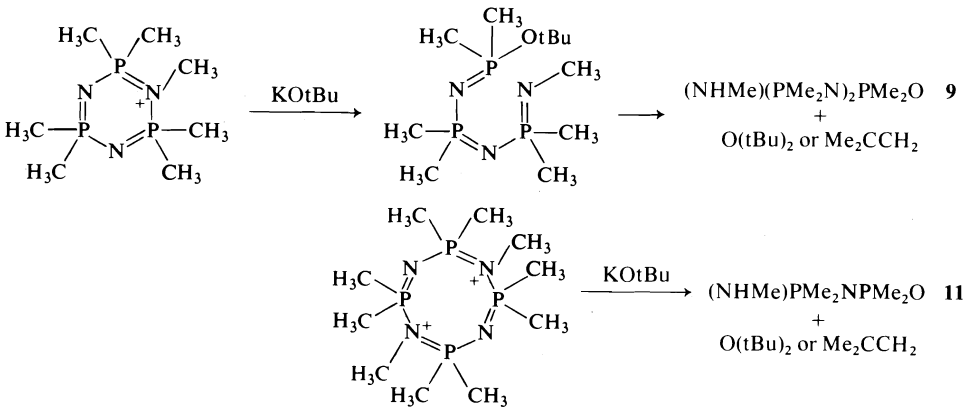
Potassium *tert*-butoxide reacts both as a base, removing a proton from an exocyclic group, (as in Scheme 1), to form an azaphosphorin, and as a nucleophile attacking a phosphorus atom adjacent to the quaternized nitrogen atom, to form a linear oxophosphazene. The products obtained from the reactions of the monoquaternary salts $(NPMe_2)_{3,4} \cdot MeI$ and the diquaternary salt $(NPMe_2)_4 \cdot 2MeSO_3F$ with KO-*t*-Bu collectively demonstrate both possibilities, and indicate that the relative importance of the two processes is strongly dependent on the size and charge of the cyclic phosphazenium cation.

In the reaction of $(NPMe_2)_3 \cdot MeI$ with KO-*t*-Bu, proton abstraction does not occur. Instead, the *tert*-butoxide ion effects a nucleophilic attack on phosphorus, and cleaves the PN skeleton (Scheme 2). The subsequent elimination of isobutene or (less probably) an ether (9, 10) then produces the novel linear oxophosphazene $(NHMe)(PMe_2N)_2PMe_2O$ (**9**) in high yield (92%). The reaction of the tetrameric salt $(NPMe_2)_4 \cdot MeI$ with KO-*t*-Bu shows a marked contrast to the one just described. Nucleophilic



SCHEME 1

attack of *tert*-butoxide ion still occurs, to give the open chain oxide $(NHMe)(PMe_2N)_3PMe_2O$ (**10**) but the yield of this product is low (~5%). The principal product (~80%) is the cyclic azaphosphorin **8**, formed presumably by a deprotonation reaction and a phosphazene–azaphosphorin rearrangement. The reaction of the diquaternary ion $[(NPMe_2)_4 \cdot 2Me]^{2+}$ with KO-*t*-Bu reflects the effect of an increase in charge on the tetrameric ring. Nucleophilic attack on phosphorus now predominates, the only product of the reaction, the linear oxophosphazene



SCHEME 2

(NHMe)(PMe_2N)PMe_2O (**11**), indicating that ring cleavage occurs twice.

Spectra and Structures

The structures of the azaphosphorins **4** and **8** have been established spectroscopically (see Table 1 for numerical details). The ^1H nmr spectrum of **4***b* in benzene (Fig. 1*a*) shows the expected features, the resonances of the MeP, the MeN, the NH, and the CH protons all being clearly distinguishable. The *N*-methyl signal is similar in position and appearance to the equivalent resonance in $N_3P_3(NHMe)_6$ (δ_H(NMe) = 2.57 ppm (11)), for which no ^1H–^1H coupling is observed. The chemical shift of the CH proton is close to that found in other phosphorins (12, 13), and as such is at lower field than in C-alkyl ylids $R_3P{=}CHR'$ (δ_H(CH) = −0.5 to −1.0 ppm (14)) in which the anionic nature of the ylidic carbon atom has a large shielding effect on the CH proton. It is at higher field than in those ylids which are stabilized by electron withdrawing substituents on carbon (e.g. δ_H(CH) in $Ph_3P{=}CHC(O)Me$ is 3.68 ppm (15)).

The lack of resolution of the CH resonance into the expected triplet is explicable in terms of a rapid proton exchange between nitrogen and carbon, a process which has already been observed for methylene diphosphine dioxides in the presence of aniline (16), and which, in the present case, corresponds to the tautomeric change between the imine and amine forms **3** and **4**. Similar effects have been observed elsewhere; the sulphur ylid **12** has been shown to exist in solution in two tautomeric forms (17), and the azaphosphorin $MeS(NPPh_2)_2CH$ (**13**), whose broad CH singlet at δ_H 1.6 ppm is not resolved into the expected triplet even at −30°C (13), may well undergo a similar exchange.

In the present system, proton transfer is believed to be promoted by traces of acid, as is found for simple ylids (13, 14, 18, 19) and, as in

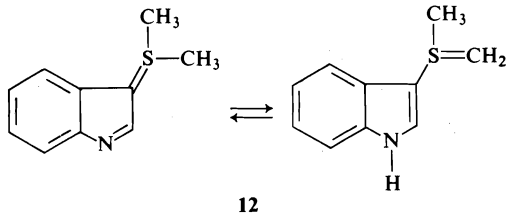
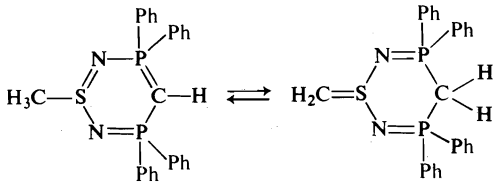
ylids (19), can be suppressed by the addition of an auxiliary base. For example, the ^{1}H nmr spectrum of **4***b* in pyridine (Fig. 1*b*) is better resolved than the same spectrum run in benzene (Fig. 1*a*), and shows clearly the ^{1}H–^{1}H coupling

[1]



12



13

in the NHMe group and also the ^{1}H–^{31}P coupling of the CH proton.[2]

The corresponding methyl derivative **4***a* is more basic, sufficiently so to decompose chloroform, and proton exchange from carbon to nitrogen is consequently more rapid. Its ^{1}H nmr spectrum in benzene (Fig. 1*c* and *d*) shows no NH or CH signals, even when pyridine is added. The other structural features, however, are observed; the resonances of the PMe group, the two inequivalent PMe_2 groups, and the NMe group are readily distinguished. The NH and CH resonances are also absent from the ^{1}H nmr spectrum of the corresponding eight-membered ring compound **8** but, for all the azaphosphorins listed in Table 1, the presence of the NHMe group is confirmed by the observation of a

[2]The dependence of the chemical shifts of the NH and CH resonances on the nature of the solvent, and on temperature, is noteworthy. Further work is required to relate this dependence to the imine–amine equilibrium.

ν(N—H) band in their infrared spectra. Its frequency (~3200 cm^{-1}) is similar to the value found for it in *N*-alkyl phosphoramidates (20). The high values of ν(N—C) indicate a single rather than a double exocyclic PN bond. In *N*-alkylphosphoramidates, for example, ν(N—C) is found in the region of 1020–1220 cm^{-1} (20), whilst in *N*-methyl phosphinimines (21, 22), its value is much lower (848 cm^{-1} in Ph_3PNMe (21)).

The ^{1}H and ^{31}P nmr spectra (Table 2) of the compounds $NHMe(PMe_2N)_nPMe_2O$ (n = 1, 2, 3) indicate an open chain structure, since all the phosphorus atoms, and PMe_2 protons, are inequivalent. Shielding of the phosphorus atoms is expected to decrease with increasing distance from oxygen, because of the polarization of charge towards the more electronegative end of the molecule, and, as in the analogous phenyl compounds (23), the δ_P values are so assigned. Hydrogen bonding is indicated for all the compounds listed in Table 2 by the low value of ν(P═O) (1170 cm^{-1} in Me_3PO (24)).

Reactions of Azaphosphorins

The chemical properties of the azaphosphorins reported here are primarily those of a strong base but, depending on the position of the equilibrium between the imine and amine tautomeric forms, the compounds can be regarded as being related either to phosphorus ylids R_3PCHR' or to imines R_3PNR'. In some respects their behaviour is similar to that of λ_5-phosphorins (25); they do not, for example, react with molecular oxygen (as do simple ylids (26, 27)), nor do they undergo the Wittig reaction, the P═C bond being insufficiently polar. In the reaction of **4***a* and **8** with aqueous ethanol, the exocyclic P—N bond is broken rather than the endocyclic P═C bond, to give the cyclic oxides **14**, **15**; the ready loss of the exocyclic methylamino group from these molecules is in contrast to the hydrolytic stability of aminophosphazenes. In related molecules, cleavage of the P═C bond can occur, as in the hydrolysis of the azaphosphorin $MeC(NPPh_2)_2CH$ (12). Both reaction paths are exemplified in the hydrolysis of the di-imine $PhN{=}PPh_2CH_2PPh_2P{=}NPh$. In basic solution, the expected diphosphine dioxide is produced, but acidic hydrolysis results in the cleavage of a central P—C bond, and the formation of the simple oxides $MePh_2PO$ and $(NHPh)Ph_2PO$ (28). The course of the reaction

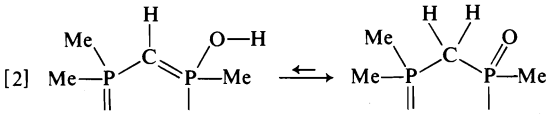
evidently depends sensitively on the conditions used.

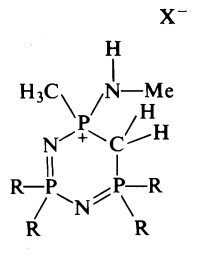
Like their parent azaphosphorins, the oxides **14**, **15** can be represented by either of two tautomeric forms **16***a*, *b*. However, the appearance of



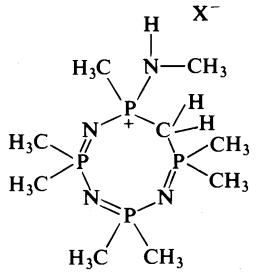
16*a* **16***b*

characteristic methylene signals in their ^{1}H nmr spectra (Table 3), and the absence of a ν(O—H) band from their infrared spectra, indicates that the equilibrium favours the oxide structure **16***b*. In the six-membered ring, the methylene protons are magnetically inequivalent, as expected, and give rise to an AB proton coupling pattern. In the eight-membered ring, the two protons are accidentally equivalent, and give rise to a simple triplet (Fig. 2).

Unlike other azaphosphorins (12), and simple ylids R_3PCHR' (14, 29–32), which react with methyl iodide to give C-methylated phosphonium salts, the azaphosphorins reported here react to give the corresponding C-hydroiodides, **17** and **18** (X = I). Presumably the initial



17



18

methylation is immediately followed by a proton transfer reaction with a second mole of azaphosphorin (eq. 3), as is found in the alkylation of

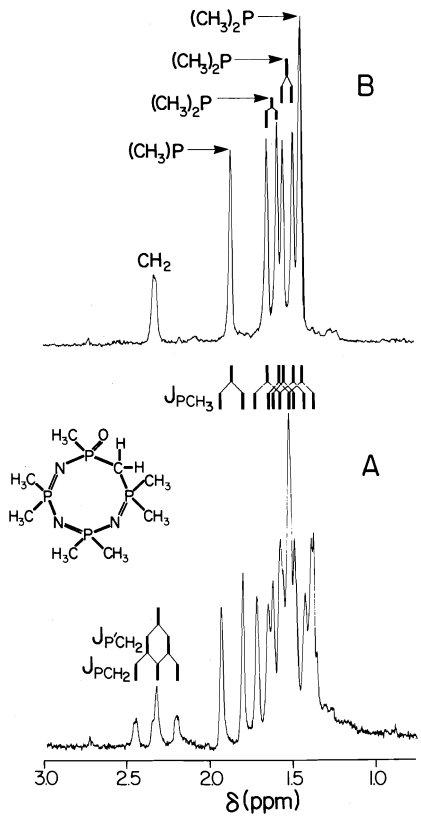


FIG. 2. ^{1}H nmr spectra of the phosphazene oxide **15** (100 MHz, $CDCl_3$); (*A*) direct, (*B*) ^{31}P decoupled.

phosphinimines (33). Protonation on carbon rather than on nitrogen is confirmed by the ^{1}H nmr spectra (Table 4) of the salts, which show a characteristic AB proton coupling pattern for the inequivalent methylene protons. The presence of a positive charge on the rings further facilitates the interpretation of their spectra; the charge distribution is less uniform than in the neutral compounds, and the various signals are better separated, as is illustrated in Fig. 3, which shows the ^{1}H nmr spectra of **17** (X = I).

The appearance and position of the resonance of the *N*-methyl protons is similar to that found in aminophosphonium salts (34), exhibiting both ^{31}P–^1H and ^1H–^1H coupling. However, the addition of one drop of D_2O to a solution of **17** (X = I) in $CDCl_3$ brings about the immediate collapse of ^1H–^1H couplings, and the loss of the NH resonance (Fig. 3*B*), indicating that proton exchange between the solvent and the exocyclic nitrogen is rapid. The methylene protons are expected to be less acidic, and their exchange with protic solvents is consequently slower, but the effect is nonetheless observable. When **17** (X = I) is dissolved in D_2O, the methylene resonance appears as a simple triplet which, upon allowing the solution to stand, becomes less intense and finally vanishes (after about 2 h).

In the reaction of the azaphosphorins with methyl iodide, the neutral product **20** cannot be isolated. It apparently undergoes a second methylation and proton transfer reaction, the overall yield of hydroiodide being such that 3 mol of azaphosphorin are converted into 2 mol of hydroiodide. In order to determine the position of primary substitution on the azaphosphorin ring (carbon or nitrogen), the reactions of **4***a* and **8** with benzoyl chloride have been examined. In the case of the eight-membered ring, the reaction yields the C-benzoyl derivative **22**. The reaction of the six-membered ring is more vigorous and, as with its reaction with methyl iodide, cannot be stopped at the first stage. Instead, the initially formed C-benzoyl derivative reacts with a second mole of benzoyl chloride, to give the *N*-benzoyl C-benzoyl compound **21**.

As in the case of their parent azaphosphorins, the ^1H nmr spectra of the benzoylated derivatives **21** and **22** (Table 5) reveal very little separation of the P-methyl resonances, thereby indicating

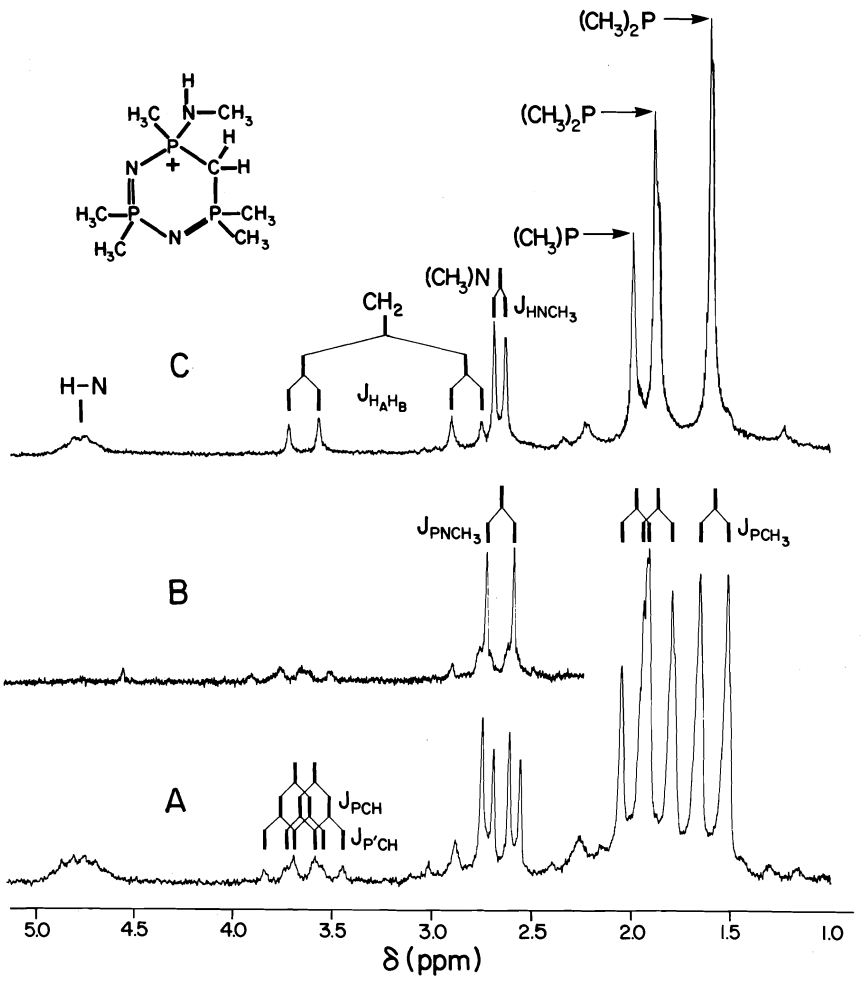

FIG. 3. ^1H nmr spectra (100 MHz) of the azaphosphorin hydroiodide **17** (X = I) in $CDCl_3$; (*A*) direct, (*B*) with one drop of D_2O added, (*C*) ^{31}P decoupled.

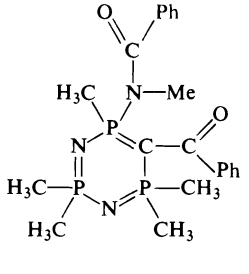
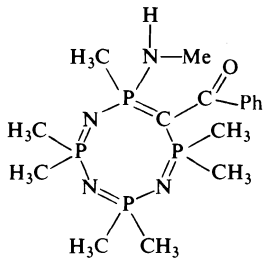
the uniformity of the charge distribution within the ring. For the tetrameric compound, ^1H–^1H coupling in the NHMe group is now observed (as it is in simple *N*-methyl amides); proton exchange is obviously suppressed by the low basicity of the nitrogen. The shielding of the *N*-methyl protons in **21** (δ_H(NMe) = 2.50 ppm) is greater than in *N*-methyl benzanilide (δ_H-(NMe) = 3.40 ppm, $CDCl_3$, reference internal TMS), suggesting that the diffusion of lone pair density from nitrogen to phosphorus is limited.



21



22

The infrared spectra of these compounds are too complex to allow a detailed interpretation, but their carbonyl stretching frequencies (Table 5) are well isolated and easily identified. For both the six- and the eight-membered ring, the low value of the carbonyl frequency is similar to that found in other acylated ylids (35–37), and reflects the extent to which resonance such as that depicted in eq. 4 weakens the C=O double bond. The lower frequency found in the six-

TABLE 5. ^{1}H nmr parameters[a] and carbonyl stretching frequencies[b] of azaphosphorin benzoyl derivatives **21**, **22**

Compound	δ(MeN)	δ(MeP)	δ(Me_2P)[c]	ν(C=O)

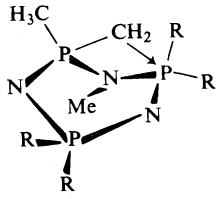
[4] 
membered ring suggests that electron release onto the C-benzoyl group is greater for that ring size. The amide carbonyl frequency of **17** (1642 cm^{-1}) is similar to that found in simple tertiary amides (e.g. ν(C=O) in $PhCONMe_2$ is 1640 cm^{-1} (38), and in $PhCONMePh$[3] is 1653 cm^{-1}). In these latter compounds, the presence of an *N*-phenyl group increases ν(C=O), the competitive electron withdrawing effect of the aromatic ring reducing the influence of the ionic form $Ph—N^+\equiv C—O^-$ (40). The relatively low value of the amide carbonyl frequency in **17** is consistent with the ^{1}H nmr evidence indicating that conjugative interactions between phosphorus and the exocyclic nitrogen are limited.

Discussion

N-Ethyl phosphazenium salts (41), like their pyridine analogues, react with bases to yield the neutral compound and ethylene. Such an elimination reaction is not possible for the *N*-methyl compounds, and their principal reactions with bases are deprotonation and nucleophilic attack. In the pyridine series, a 2-methyl group is deprotonated to give a methide, which is alkylated on carbon rather than on nitrogen, thereby conserving ring aromaticity (42). When an electron-withdrawing substituent is present in the 2- (or 4-) position, the susceptibility of the molecule to nucleophilic attack at these positions is increased, and, in basic solutions, such salts are hydrolysed to pyridones (42), the stability of which is enhanced by the strength of the carbonyl bond.

In the reactions reported here, deprotonation and nucleophilic attack both occur, but the balance between them is determined by the reagent and by the ring size. Open chain oxides are produced when KO-*t*-Bu is used, primarily because the elimination of isobutene or dibutyl ether allows the formation of a strong phosphoryl bond. The size of the ring has a marked effect on the relative yield of cyclic and linear products. The ^{31}P nmr shifts of $(NPMe_2)_{3,4}\cdot MeI$ (43) suggest that the partial positive charge on the phosphorus atoms adjacent to the *N*-methyl group is greater in the six-membered ring compound, nucleophilic attack and the formation of the linear oxide being thereby promoted, as found.

Deprotonation of the *N*-methyl methylphosphazenium salts occurs, as expected, at the 2-position, and the consequent rearrangement is probably aided by the electrophilic character of the phosphorus atoms adjacent to the alkylated nitrogen atom. Although the detailed mechanism is unknown, it seems likely to involve a four-centre interaction (as shown) similar to that of



the Wittig reaction.[4] A related mechanism has been suggested (44) for the base catalyzed rearrangement of $(Me_3PCSiMe_2)_2$, in which a

[3]Present work, CCl_4 solution; Nujol mull, 1650 cm^{-1}; cf. 1641 cm^{-1} (39).

[4]The possibility that the reaction is bimolecular, so reducing strain in the transition state, has been suggested by a referee, and cannot at present be excluded.

methylene group enters the ring. A rearrangement in the opposite sense, but also involving a 4-centre mechanism, occurs during the ammonolysis of bis(diphenylphosphino)methane in carbon tetrachloride to give $(MePPh_2NPPh_2NH_2)Cl$ (12), and may account for the apparent migration of a methyl group during the chloramination of bis(diphenylphosphino)methylamine, which yields the salt $[NHMePPh_2NPPh_2NH_2]Cl$ (45).

In the latter two examples, the driving force of the reaction is probably the formation of the resonance stabilized $(P{=}N{=}P)^+$ cation. The phosphazene–azaphosphorin system is more complicated, in that both a cyclic π-system and an exocyclic π-bond are involved, but we can nevertheless understand the rearrangements that take place by simple model calculations of the π-energy changes. The three related molecular forms are shown in Fig. 4. which shows how the π-electron energies of the three forms depends on the assumed Coulomb parameter of carbon. Isomer *a* is the exocyclic ylid **6** formed by the deprotonation of the quaternary cation, *b* is the product of its direct rearrangement to an *exo*-imide **7**, and *c* results from the further proton migration to give the azaphosphorin **8**. Form *c* is unique in restoring the cyclic delocalization of the initial quaternary compound **5**.

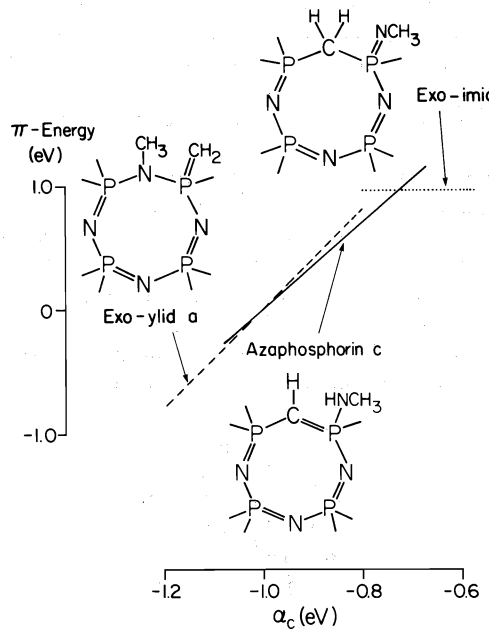


FIG. 4. π-Electron energies (eV, arbitrary zero) of the three isomers shown, as a function of the assumed Coulomb parameter of carbon. The values of α_P(2 eV) and α_N (−1 eV) used are not critical, but have been found useful for the description of other properties of $(NPMe_2)_n$. All resonance parameters were taken to be −1 eV, independent of overlap, in both out-of-plane and in-plane π-systems.

Although the energetic advantage of the delocalization may be important, the calculations show that it may be outweighed by a high localized π-energy in an exocyclic bond in *a* or *b*.

The general result is that the exocyclic position is favoured for the more electronegative atom. To take the extreme cases first, if $\alpha_C < -1$, (the value for nitrogen), *a* is the most stable form, and no rearrangement would be expected. On the other hand, if $\alpha_C < -0.7$ (approximately), rearrangement should take place, but should stop at the *exo*-imide stage *b*. In both cases the molecule is stabilized by a strong exocyclic π-bond. For intermediate values of α_C, the situation is more interesting. The azaphosphorin *c* is now slightly more stable than the *exo*-ylid *a*, because cyclic delocalization is now possible; if localized bonds are assumed, the azaphosphorin is never favoured over the *exo*-ylid. In terms of the simple model used, it is therefore possible to understand the azaphosphorin rearrangement as being driven by the increase of π-energy arising from the displacement of the more electronegative atom from the ring, and reinforced by the attainment of cyclic delocalization.[5]

Although the results of Fig. 4 are qualitative, the assumed parameters are realistic enough to show that the energy differences between the three forms are likely to be small, and it is not surprising that proton transfer between the endocyclic carbon and endocyclic nitrogen atoms of the azaphosphorins is fast enough to cause a collapse of the ^{31}P–^{1}H coupling of the CH signal. The results have another application. Since oxygen is more electronegative than nitrogen, the introduction of an exocyclic phosphoryl group in the cyclic oxophosphazenes **14**, **15** alters the equilibrium in favour of exocyclic π-bonding, lowering the energy of the *exo*-imide *b* without direct effect on the energies of *a* and *c*. It is consistent with this result that rapid proton

[5]In a reaction which is apparently similarly dependent on relative electronegativity, 2-arylaminopyrylium chlorides can be deprotonated to pyranimines, which then rearrange to pyridones in a reaction closely analogous to the azaphosphorin rearrangement described above. The corresponding reaction of the thiapyrylium iodides stops at the thiapyranimine stage (51).

migration is not observed in the cyclic oxophosphazenes described above. The general concepts are further supported by the structures of the phosphazenes $N_3P_3Ph_5(OH)$ and $N_4P_4Ph_6(OH)_2$ (non-geminal) for which hydroxy- rather than oxy-structures have been suggested (46, 47). From the present point of view, the potential tautomeric equilibrium is that between forms *b* and *c* of Fig. 4, N being substituted for CH in the ring, and O for NCH_3 in the exocyclic position. The increased electronegativity of the ring atom would tend, following the diagram, to stabilize the cyclically delocalized form *c*. The energy balance is sensitively dependent on the relative electronegativities of the relevant atoms. The same feature is found in pyridine chemistry; 2- and 4-hydroxy pyridines normally exist in the pyridone form, but when the oxygen is replaced by a less electronegative atom, as in 2-aminopyridine, the aromatic amino-form, rather than the exocyclic imide, is the more stable.

Experimental

Sodium metal, hexamethyldisilazane, methyl iodide, and benzoyl chloride were commercial products. Potassium *tert*-butoxide and methyl fluorosulphate were also obtained commercially. The former was purified by sublimation *in vacuo*, the latter by distillation under nitrogen. Hexane and octane were of reagent grade. Toluene, diethyl ether, and acetonitrile were dried by distillation from sodium, lithium aluminium hydride, and calcium hydride, respectively. All of the preparations were carried out under an atmosphere of nitrogen.

Quaternary Salts

The monoquaternary salts $(NPMe_2)_{3,4}\cdot MeI$ were prepared by the reaction of the neutral methylphosphazenes with methyl iodide (43). The preparation of the salt $(NPMe_2)_4\cdot 2MeCl$ by the reaction of Me_2PCl_3 and $MeNH_2\cdot HCl$ has already been reported (48); the diquaternary salt $(NPMe_2)_4\cdot 2MeSO_3F$ used here was prepared by treating $(NPMe_2)_4$ with two equivalents of $MeSO_3F$ in acetonitrile solution. The product was precipitated quantitatively from the solution by the addition of diethyl ether, and purified by recrystallization from acetonitrile: mp 231–233°C; ^1H nmr spectrum, 100 MHz (δ, $CDCl_3$, int. TMS), 2.84 (6H, triplet, J_{PH} = 11.5 Hz), 1.95 (24H, doublet, J_{PH} = 13.7 Hz); ir spectrum ν(P═N) 1275, 1330 cm^{-1}; ν(C—N), 1070 cm^{-1}. *Anal.* calcd. for $C_{10}H_{30}F_2N_4O_6S_2P_4$: C 22.7, H 5.7, N 10.6; found: C 22.9, H 5.9, N 10.6. *gem*-Dimethyltetraphenylcyclotriphosphazene $N_3P_3Ph_4Me_2$ was prepared by the reaction of $(NH_2PPh_2NPPh_2NH_2)Cl$ with Me_2PCl_3 (49) in chlorobenzene, the neutral compound being liberated from its hydrochloride by treatment with triethylamine; mp 142–144°C (lit. (50) 140–142°C). The methiodide was prepared from it by heating it in methyl iodide for 72 h. The precipitated salt was recrystallized from ethanol and dried at 60°C/0.01 Torr for 7 h to remove all the solvent: mp 226–227°C (dec.); ^{31}P nmr spectrum (δ, $CDCl_3$, ext. P_4O_6), 64.1 (1P, PMe_2), 81.0 (1P, PPh_2 adjacent to NMe), 93.5 (1P, remote PPh_2); ^1H nmr spectrum (δ, $CDCl_3$, int. TMS), 3.07 (3H, triplet, J_{PH} = 11.0 Hz), 2.22 (6H, doublet, J_{PH} = 14.0 Hz), 7.0–8.0 (20H, broad unresolved multiplet); ir spectrum; ν(P═N), 1220, 1260 cm^{-1}; ν(C—N), 1070 cm^{-1}. *Anal.* calcd. for $C_{27}H_{29}IN_3P_3$: C 52.7, H 4.75, I 20.6, N 6.8; found: C 52.9, H 5.0, I 20.4, N 6.8.

Reaction of $(NPMe_2)_4\cdot MeI$ with $NaN(SiMe_3)_2$

Sodium (0.20 g, 8.7 mmol) was added to a slurry of $(NPMe_2)_4\cdot MeI$ (3.54 g, 8.0 mmol) in 200 ml octane. About 0.5 ml of $HN(SiMe_3)_2$ was injected into the reaction mixture at the reflux temperature, and, to compensate for possible losses by evaporation, again at 24 h intervals to a total reaction time of 72 h. The mixture was cooled and filtered and the solvent distilled from the filtrate to leave a white solid, which was purified by sublimation at ~130°C/0.01 Torr and recrystallization from hot hexane to give colourless hygroscopic prisms of **8** (2.21 g, 7.0 mmol, 88%); mp 104–105°C. *Anal.* calcd. for $C_9N_{26}N_4P_4$: C 34.3, H 8.6, N 17.8; found C 34.4, H 8.5, N 17.6.

Reaction of $(NPMe_2)_3\cdot MeI$ with $NaN(SiMe_3)_2$

In a similar reaction, sodium (0.35 g, 15.3 mmol) and $(NPMe_2)_3\cdot MeI$ (5.11 g, 13.9 mmol) were allowed to react with $HN(SiMe_3)_2$ in octane (200 ml). After 96 h, the mixture was filtered while still hot and the solvent distilled from the filtrate. The white solid product was purified by sublimation at ~130°C/0.01 Torr and recrystallization from hot hexane to give colourless hygroscopic plates of **4***a*, (2.68 g, 11.2 mmol, 80%); mp 140–142°C. *Anal.* calcd. for $C_7H_{20}N_3P_3$: C 35.15, H 8.4, N 17.6; found: C 35.4, H 8.5, N 17.6.

Reaction of $Me_2Ph_4P_3N_3\cdot MeI$ with $NaN(SiMe_3)_2$

Sodium (0.06 g, 2.6 mmol), $Me_2Ph_4P_3N_3\cdot MeI$ (1.34 g, 2.2 mmol) dried as before to remove EtOH and $HN(SiMe_3)_2$ were allowed to react together in 60 ml boiling toluene for 24 h. The mixture was filtered and the solvent distilled off. The residual white solid was purified by recrystallization from benzene–octane to give colourless prisms of **4***b*, (0.95 g, 2.0 mmol, 93%); mp 147–149°C. *Anal.* calcd. for $C_{27}H_{28}N_3P_3$: C 66.1, H 5.3, N 8.9; found: C 65.9, H 5.55, N 8.65.

Reaction of $(NPMe_2)_4\cdot MeI$ with KO-t-Bu

Finely powdered $(NPMe_2)_4\cdot MeI$ (3.00 g, 6.8 mmol) was added to a slurry of KO-*t*-Bu (0.84 g, 7.4 mmol) in 100 ml hexane, and the mixture heated under reflux for 24 h. The solvent was distilled from the filtered solution to leave a white solid (1.82 g) which was sublimed at ~130°C/0.01 Torr on to a water cooled cold finger. The sublimate (**8**) was recrystallized from hot hexane (1.71 g, 5.4 mmol, 80%) and identified by comparison of its ir spectrum with that of an authentic sample, and by its mp, 104–105°C. The residual oil in the sublimation vessel solidified into a white solid, which was purified by recrystallization from hot hexane to give colourless hygroscopic cubes of **10** (0.11 g, 0.33 mmol, 5%); mp 72–74°C. *Anal.* calcd. for $C_9H_{28}N_4OP_4$: C 32.5, H 8.5, N 16.9; found C 32.6, H 8.6, N 16.9.

Reaction of $(NPMe_2)_3\cdot MeI$ with KO-t-Bu

Similarly, $(NPMe_2)_3\cdot MeI$ (1.38 g, 3.8 mmol) was

allowed to react with a slurry of KO-*t*-Bu (0.50 g, 4.5 mmol) in 50 ml boiling hexane. After 24 h, the mixture was filtered and the solvent removed from the filtrate to leave a colourless oil. Sublimation of this oil at ~130°C/0.01 Torr on to a cold finger at −78°C yielded **9** as a white hygroscopic solid (0.89 g, 3.4 mmol, 92%), which was recrystallized as colourless plates by cooling a concentrated solution of it in pentane to −23°C; mp 35–37°C. *Anal.* calcd. for $C_7H_{22}N_3OP_3$: C 32.7, H 8.6, N 16.3; found: C 32.6, H 8.5, N 16.0.

Reaction of $(NPMe_2)_4 \cdot 2MeSO_3F$ with KO-t-Bu

In a similar experiment, a slurry of KO-*t*-Bu (1.30 g, 11.6 mmol) and $(NPMe_2)_4 \cdot 2MeSO_3F$ (2.70 g, 5.1 mmol) was heated to reflux in 60 ml hexane. After 24 h, the solution was decanted from the pasty residue and the solvent distilled off to yield a white solid, which was recrystallized from hot hexane to give colourless feather-like crystals of **11** (0.93 g, 5.0 mmol, 50%); mp 73–75°C. *Anal.* calcd. for $C_5H_{16}N_2OP_2$: C 33.0, H 8.9, N 15.4; found: C 33.3, H 8.9, N 15.25.

Hydrolysis of Azaphosphorins 4a, 8

In separate experiments, samples of **4***a* and **8** (0.3–0.4 g) were dissolved in 25 ml of a 50/50 ethanol–water mixture. After 24 h, the solvent was removed at room temperature *in vacuo* to leave a white solid. Recrystallization from benzene of the solid from **4***a* gave colourless hygroscopic blocks of **14**, mp 184–186°C. *Anal.* calcd. for $C_6H_{17}N_2OP_3$: C 31.9, H 7.6, N 12.4; found: C 32.2, H 7.6, N 12.3. Recrystallization from hot hexane of the solid from **8** gave colourless feather-like crystals of **15**; mp 140–143°C. *Anal.* calcd. for $C_8H_{23}N_3OP_4$: C 31.9, H 7.7, N 13.95; found: C 32.1, H 7.9, N 14.0.

Reaction of Azaphosphorins 4a, b, 8, with Methyl Iodide

The addition of an excess of methyl iodide to a solution of **4***a* (1.04 g, 4.33 mmol) in ether resulted in the precipitation of the hydroiodide **17** (R = Me) (0.99 g, 2.7 mmol). Similarly, the azaphosphorins **4***b* (0.155 g, 0.32 mmol) and **8** (0.44 g, 1.4 mmol) yielded, respectively, the hydroiodides **17** (R = Ph) (0.14 g, 0.23 mmol) and **18** (0.43 g, 1.0 mmol). The neutral products of the transylidation reactions could not be isolated. The air-stable crystalline hydroiodides were recrystallized from acetonitrile–toluene: **17** (R = Me), mp 194–195°C. *Anal.* calcd. for $C_7H_{21}IN_3P_3$: C 22.9, H 5.8, I 34.6, N 11.45; found: C 23.0, H 5.9, I 34.2, N 11.3; **17** (R = Ph), mp 248–252°C. *Anal.* calcd. for $C_{27}H_{29}N_3P_3I$: C 52.7, H 4.75, N 6.8; found: C 52.7, H 4.75, N 6.9; **18**, mp 155–156°C. *Anal.* calcd. for $C_9H_{27}IN_4P_4$: C 24.45, H 6.15, I 28.7, N 12.7; found: C 24.5, H 6.3, I 28.55, N 12.6.

Reaction of Azaphosphorins 4a, 8, with Benzoyl Chloride

A solution of benzoyl chloride (0.21 g, 1.5 mmol) in 20 ml ether was added dropwise to a stirred solution of **4***a* (0.54 g, 2.25 mmol) in 100 ml ether. After 3 h the mixture was filtered, leaving the hydrochloride of **17** (R = Me) (0.45 g, 1.64 mmol): mp 194–197°C. *Anal.* calcd. for $C_7H_{21}ClN_3P_3$: C 30.5, H 7.7, Cl 12.9, N 15.2; found: C 30.2, H 7.8, Cl 12.6, N 15.0. Distillation of the solvent from the filtrate left the crude dibenzoyl derivative **21** (0.26 g, 0.59 mmol), which was recrystallized from hot benzene–octane as colourless blocks: (dec.) 181–184°C. *Anal.* calcd. for $C_{21}H_{28}N_3O_2P_3$: C 56.4, H 6.3, N 9.4; found: C 56.1, H 6.2, N 9.6.

In another experiment, a solution of benzoyl chloride (0.12 g, 0.9 mmol) in 10 ml ether was added dropwise to a stirred solution of the azaphosphorin **8** (0.56 g, 1.8 mmol) in 50 ml ether. A fine white precipitate was immediately formed. After 3 h the mixture was filtered, and the hygroscopic solid recrystallized from acetonitrile–benzene to give small colourless cubes of the hydrochloride of **18** (0.26 g, 0.7 mmol): mp 193–195°C. *Anal.* calcd. for $C_9H_{27}ClN_4P_4$: C 30.8, H 7.8, N 16.0; found: C 30.9, H 7.7, N 15.9. The solvent was distilled from the filtrate to leave a yellow oil which, on drying *in vacuo*, solidified to a yellow, air stable powder. Recrystallization of this solid from hot hexane yielded yellow mica-like plates of the benzoyl derivative **22**: mp 133–134°C. *Anal.* calcd. for $C_{16}H_{30}N_4OP_4$: C 46.0, H 7.2, N 13.4; found: C 45.7, H 7.3, N 13.1.

Received February 11, 1977

M. PERIĆ, S. D. PEYERIMHOFF, and R. J. BUENKER. Can. J. Chem. **55**, 3664 (1977).

Ab initio SCF and CI calculations for the potential surfaces of HCN in ground and various $^1(\pi,\pi^*)$ excited states are carried out using an AO basis of double-zeta quality augmented with various polarization functions. These results are then combined with transition moment data to allow for a Franck-Condon analysis of the vibrational structure of the lowest three electronic transitions in both HCN and DCN. The resulting intensity distribution is then compared with the corresponding experimental data reported by Herzberg and Innes. This work confirms the earlier conclusion of Schwenzer *et al.* that the upper state in the $\alpha \leftarrow \tilde{X}$ band system is the $^1\Sigma^- - ^1A''$ species, and not the $^1\Delta$ as originally believed. In addition a detailed mechanism for the observed predissociation of the α state is outlined, in which the gradual conversion of the π^* MO of bent HCN into a pure hydrogenic $1s$ AO plays a key role. Arguments are also presented in favor of assigning the $\beta \leftarrow \tilde{X}$ transition seen in DCN to a $^1\Delta$–$2^1A'$ upper state with the same D + CN dissociation limit as for the $^1\Sigma^- - ^1A''$ species.

M. PERIĆ, S. D. PEYERIMHOFF et R. J. BUENKER. Can. J. Chem. **55**, 3664 (1977).

Les calculs *ab initio* SCF et CI pour les surfaces de potentiel de HCN à l'état fondamental et à différents états excités $^1(\pi,\pi^*)$ sont effectués en se basant sur des AO de qualité double-zêta augmentées avec diverses fonctions de polarisation. Ces résultats sont ensuite combinés avec les données du moment de transition pour permettre une analyse Franck-Condon de la structure de vibration des trois transitions électroniques les plus basses dans HCN et DCN. La répartition de l'intensité résultante de ces calculs est comparée avec les données expérimentales correspondantes rapportées par Herzberg et Innes. Ce travail confirme la conclusion postulée auparavant par Schwenzer et ses collaborateurs à savoir que l'état supérieur dans la bande $\alpha \leftarrow \tilde{X}$ est l'espèce $^1\Sigma^- - ^1A''$ et non $^1\Delta$ comme on le croyait initialement. En plus, on schématise un mécanisme détaillé pour la prédissociation de l'état α dans laquelle une conversion graduelle de π^* MO pour le HCN courbé en $1s$ AO purement hydrogénique joue un rôle principal. Il est aussi proposé que la transition $\beta \leftarrow \tilde{X}$ observée dans DCN implique un état supérieur $^1\Delta$–$2^1A'$ avec la même limite de dissociation D + CN que pour l'espèce $^1\Sigma^- - ^1A''$.

[Traduit par le journal]

1. Introduction

The ultraviolet spectrum of HCN has been recorded in considerable detail experimentally (1–4) between 1120 and 2000 Å. Although the high-energy absorption in this region is quite strong (1, 2), that observed in the near-ultraviolet between 2000 and 1700Å (3, 4) is much weaker; under high resolution the latter feature appears to consist of two distinct band systems with fine structure, referred to as $\alpha \leftarrow \tilde{X}$ and $\beta \leftarrow \tilde{X}$ respectively (4). The first of these is observed in both the HCN and DCN isomers and shows diffuseness (predissociation) toward shorter wavelengths; the $\beta \leftarrow \tilde{X}$ system, on the other hand, has only been reported for DCN (4). Vibrational and rotational analyses of these bands have led to the conclusion that the molecule is bent ($\measuredangle$HCN = 125°) in the α upper state and (with somewhat less certainty) also in the β state ($\measuredangle$HCN = 114.5°). In the original work both of these states have been concluded to possess $^1A''$ symmetry ($\pi^3\pi^*$ configuration), correlating with $^1\Delta(\alpha)$ and $^1\Sigma^-(\beta)$ states of the linear HCN geometry respectively. The much stronger absorption lines of a third system ($C \leftarrow \tilde{X}$) around 1500 Å and below is believed to

correspond to a different upper state ($\measuredangle$HCN = 141°) of $^1A'$ symmetry which correlates with a $^1\Pi$ species in linear HCN. It should be noted that excitation from the $^1\Sigma^+$ ground state to the latter is allowed by the dipole selection rules, in contrast to the situation for the other states of $^1\Delta$ and $^1\Sigma^-$ symmetry.

Theoretical studies (5, 6) dealing with four HCN states of A' and three of A'' symmetry, on the other hand, predict that the second $^1A''$ state of this system should prefer a linear or nearly linear geometry. Furthermore this finding is in complete agreement with the qualitative predictions of molecular orbital theory (7, 8), but of course stands in strong contrast with the value of 114.5° derived by Herzberg and Innes (4) for the equilibrium internuclear angle of the β state. In addition the calculated excitation energies (5) to $2^1A''$ are seen to differ from the experimental ($\tilde{B}^1A''$) quantities by approximately 0.75 eV. More extensive theoretical treatments (6) have confirmed the originally calculated results and have also indicated that Rydberg characteristics are absent in all such $^1(\pi,\pi^*)$ states of this molecule.

In light of these discrepancies between the experimental inferences derived from the HCN spectrum and the above theoretical predictions it was decided to carry out a further theoretical study of the $^1(\pi,\pi^*)$ excited states of this system using the *ab initio* CI method. Such calculations (9) have recently been successful in reproducing and/or predicting details of the electronic spectra of a good number of molecular systems (water, hydrogen sulfide, ethane, diborane, formaldehyde, acetone, thioacetone, and butadiene, for example), quite generally leading to excitation energies which differ from their experimental values by no more than a few tenths of an eV. At the same time the vibrational structure of the HCN bands in question is also calculated using a priori methods, in a similar way as previously done for O_2 (10) and HSO (11), in order to allow for a more detailed theoretical comparison with the measured absorption spectrum than has heretofore been possible. The present paper reports the results of these investigations.

2. SCF Results for Excited States and Qualitative Aspects

The basis set employed in this study is essentially of double-zeta quality augmented by a few polarization functions, consisting of the lobe functions for N, C, and H derived by Whitten (12), i.e. 4*s* and 2*p* groups for each of the heavy atoms and two *s* groups for the hydrogen expansion with scaling factor $\eta^2 = 2.0$. In addition a one-component *p* function (exponent $\alpha = 0.735824$) is employed on H and one *s* Gaussian is located in each of the CN ($\alpha = 1.45$) and CH bonds ($\alpha = 1.54$) respectively. The influence of Rydberg functions on the lower-lying SCF states was tested (at $\measuredangle$HCN = 125°) and the conclusion reached earlier (6) was thereby supported, namely that such (π,π^*) states show no tendency to mix in Rydberg character; thus long-range Rydberg-like functions are omitted from the basis set in all further investigations. The total SCF energy obtained for the HCN ground state in this basis is −92.8467 hartree; this value is comparable with the −92.85738 hartree result obtained with a set of six contracted *s* and three contracted *p* functions on carbon and 3*s* groups on hydrogen (13), but is inferior to the same set including various *d*-type AO's (−92.90768 hartree (13)) or the double-zeta plus polarization value (−92.8897 hartree) of ref. 6. On the other hand, experience with a number of systems has shown that such additional polarization functions have a similar energy-lowering effect on both ground and excited states (14) (differences after CI have been observed to be generally less than 0.3 eV) and thus there is good reason to believe that the present basis should be capable of allowing for a sufficiently realistic description of the low-energy HCN spectrum.

For all calculations the HCN molecule is placed in the *xz* plane with the C—N bond lying on the *z* axis. Variations in the HCN internuclear angle and the corresponding CN and CH distances were then systematically undertaken relative to the experimental equilibrium ground state structure ($\measuredangle$HCN = 180°, CN = 2.1845 bohr, and CH = 2.0107 bohr).

The SCF calculations are carried out for all states accessible by the normal Roothaan procedure (15); the resulting angular potential curves are contained in Fig. 1. It is immediately seen that the SCF curves for the excited states do not correspond to states of pure symmetry in the linear nuclear arrangement; a very similar picture is also obtained for the corresponding states of isoelectronic HCO^+ (16). The lowest triplet states are thus expected to fall in the following energetic ordering: $^3\Sigma^+$ ($6a' \rightarrow 7a'$), $^3\Delta$ ($1a'' \rightarrow 2a''$, $1a'' \rightarrow 7a'$), and

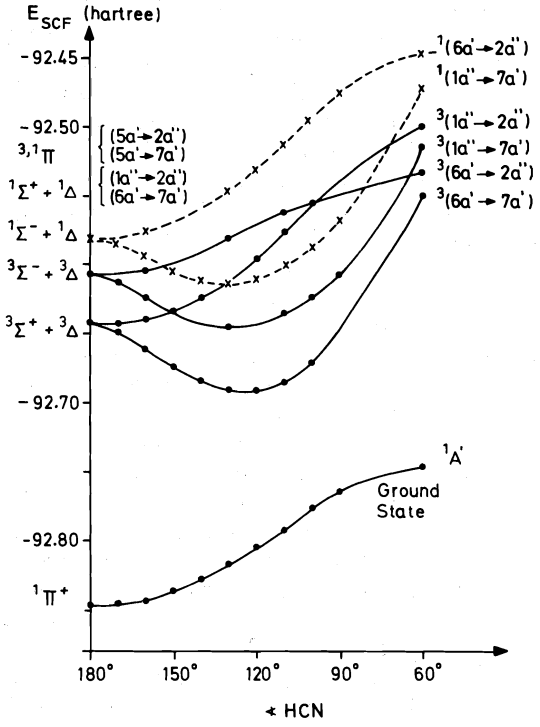

FIG. 1. SCF angular potential curves for various states of HCN. Note that at 180° the results obtained do not correspond to states of pure symmetry (CH = 2.0107 bohr, CN = 2.1845 bohr in all cases).

$^3\Sigma^-$ ($6a' \rightarrow 2a''$). Among the singlet states only ($1a'' \rightarrow 7a'$) and ($6a' \rightarrow 2a''$) are accessible in the SCF treatment, corresponding to a mixture of $^1\Sigma^- + {}^1\Delta$ species at 180°. The other pair, $6a' \rightarrow 7a'$ and $1a'' \rightarrow 2a''$, are in all likelihood *higher* in energy since the splitting between the corresponding singlet and triplet multiplets of such configurations (representing an excitation between orbitals lying *in the same plane*, i.e. with large exchange integral K) is considerably larger than for singlet–triplet states in which the two singly occupied MO's lie in different planes. The same situation is found in HCO^+ after CI is carried out (16), as well as in isoelectronic acetylene (17), for which the energy ordering of $\pi_u^3\,\pi_g$ states of $^3\Sigma_u^+ < {}^3\Delta_u < {}^3\Sigma_u^- \approx {}^1\Sigma_u^- < {}^1\Delta_u < {}^1\Sigma_u^+$ is well known (or alternatively upon inspection of the observed N_2 spectrum (18)).

It is also seen from Fig. 1 that occupation of the $7a'$ species (or the corresponding MO in acetylene), as found in many instances before (5, 7, 8, 16, 17), always results in a bent upper state, in complete agreement with qualitative MO theory. On the other hand, Fig. 1 also makes it clear that the shapes of the angular SCF potential curves may deviate considerably from the actual surfaces, particularly at large HCN angles, and thus that the SCF equilibrium data (especially force constants) for these $^1(\pi,\pi^*)$ states might thereby be in considerable error. From investigation of the charge density of the $7a'$ orbital it is also obvious that occupation of this MO promotes dissociation into H + CN, since (although it is a π^*-type MO at small C—H distances) it changes in bent geometries into a purely hydrogenic species at large internuclear separations. This behavior has been found in related molecules such as HCO^+ (16), HNO (19), HCO, HN_2 (18), HN_2^+ (20), and HNO^+ (21).

The variation of the SCF energy with CN and CH distances in various electronic states of this system is contained in Fig. 2 *a*, *b* (linear nuclear arrangement). A marked increase in the CN bond length is seen upon $\pi \rightarrow \pi^*$ excitation relative to the ground state, as one would expect; the corresponding potential curves for the various (π,π^*) states themselves are seen to bear a great similarity to one another, however. The results for CH stretching in the linear arrangement are not greatly different in ground and excited states, also as would be expected, but given the change in the $7a' - \pi^*$ component upon molecular bending discussed above, there is reason to believe that this uniform pattern may be broken in non-linear conformations.

To summarize then one expects the $^1\Sigma^-$–$^1A''$ state to be the lowest-lying singlet excited state of HCN, followed by the $^1\Delta$–($^1A''$,$^1A'$), i.e. the reverse ordering to what has been assumed in the original assignment of the observed band structure (4); vertical transitions to both states are dipole forbidden from the linear $^1\Sigma^+$ ground state. The remaining $^1(\pi,\pi^*)$ state ($^1\Sigma^+$) is not only less stable than $^1\Sigma^-$ and $^1\Delta$ but quite possibly even lies above $^1\Pi(\sigma \rightarrow \pi^*)$; transitions to both $^1\Sigma^+$ and $^1\Pi$ are dipole allowed. It thus seems clear that only the lowest three $^1(\pi,\pi^*)$ states, correlating with $^1\Sigma^-$ and $^1\Delta$ species, could be responsible for the relatively weak absorption observed in the 1700–2000 Å region of the HCN and DCN spectra and therefore the CI calculations to be discussed below will only consider electronic transitions to these upper states.

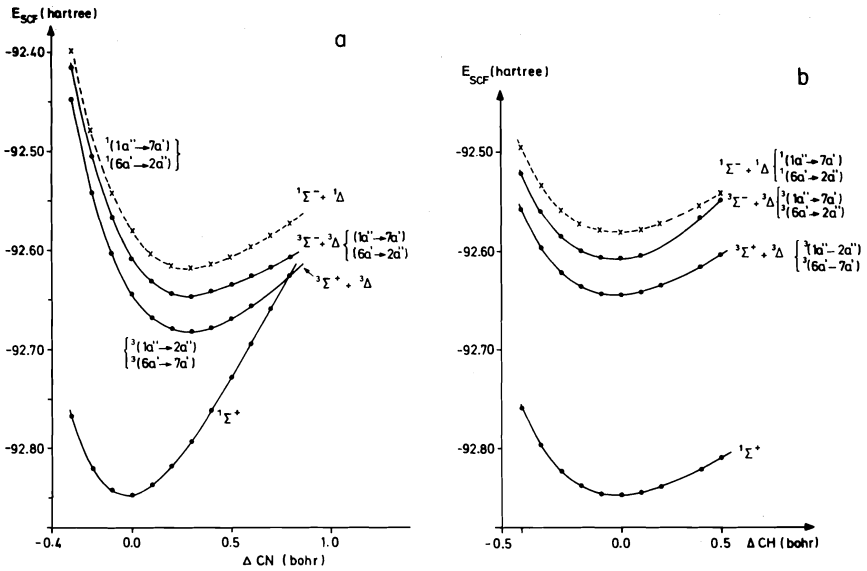

FIG. 2. SCF potential curves for CN stretch (*a*) and CH stretch (*b*) for various states of HCN. (Linear nuclear arrangement, CN = 2.1845 bohr, CH = 2.0107 bohr; the abscissa shows changes relative to the above values.)

3. CI Calculations and Potential Curves for the $^1\Sigma^+$–$\tilde{X}\,^1A'$, $^1\Sigma^-$–$^1A''$, and $^1\Delta$–$2^1A'$,$2^1A''$ (π,π^*) States

The CI calculations including configuration selection and energy extrapolation are carried out in the standard manner (9). In the present case four electrons are always kept in core, i.e. the inner shells of carbon and nitrogen are held doubly occupied, while the remaining electrons are allowed to variably occupy the other MO's in the basis. The natural orbitals of the lowest state of a given symmetry (i.e. $^1\Sigma^+$–$^1A'$ and $^1\Sigma^-$–$^1A''$) are employed for the construction of configurations; they are obtained in each instance by diagonalizing the first-order density matrix of a large-threshold CI (with a relatively small secular equation) for the lowest state. For the $^1A'$ space eight main configurations are used for constructing the configuration space and a 2-root selection procedure corresponding to $1^1A'$ and $2^1A'$ states is carried out. In order to represent the lowest two $^1A''$ states single- and double-excitation species with respect to *four* main configurations are generated, while configuration selection is based on the energy lowerings for both of these states. The same procedure (i.e. the same main configurations) is maintained for the construction of the entire potential curves. In this way 27 079 configurations are generated for the $^1A'$ space at each geometry and 15 007 for the $^1A''$ space; the orders of the secular equations actually solved in the energy extrapolation procedure fall between 1300 and 3000. Several examples for the expansion of the four states under consideration are contained in Table 1, always given at two different internuclear angles.

The angular potential curves thus obtained are given in Fig. 3. At $\measuredangle$HCN = 180° the two components of $^1\Delta$ are not entirely degenerate, primarily because in the $^1A'$ component two configurations with $|c_i| > 0.1$ are not included in the set of main configurations (see Table 1) and therefore this component lies too high compared to its $^1\Delta$–$^1A''$ counterpart by roughly 0.1 eV. At relatively small angles yet another configuration of $^1A'$ symmetry, correlating with $^1\Pi$ in linear geometry, makes a significant contribution to the $2^1A'$ (Table 1), and hence the repulsive part of this potential curve is probably calculated to be somewhat steeper than it would be in an exact treatment.

The first $^1A''$ state has a quite compact CI expansion in the NO basis employed, particularly for bent configurations. The $2^1A''$ state requires a larger number of reference species for

[a]The numbers in parentheses always indicate the main configuration; no number denotes the fact that the corresponding species has not been included in the set of main configurations. Note that the basis set consists of NO's derived for the lowest state of a given irreducible representation in C_s symmetry.

a proper description. Despite the fact that the $4a' \rightarrow 2a''$ configuration appears with sizeable coefficient at 120° (Table 1), it was not included in the generating set of configurations since a value of 120° for the internuclear angle is already quite far from the minimum for this electronic state.

The CN stretch potential curves obtained in the CI calculations do not differ greatly from their SCF counterparts but a general tendency toward larger equilibrium bond lengths in all states treated is noted (Table 2). The ground state CH stretch curve has not been calculated since very little change from the SCF results already discussed (Fig. 2*b*) is expected, at least in the neighborhood of the equilibrium structure, which is critical for representation of the absorption spectrum. The situation for the lowest excited state of HCN is more interesting, however, because of the dissociative behavior of this species. The calculated CI potential curve for the $^1A''$ state (Fig. 4) shows a maximum near 3.20 bohr, reflecting an avoided crossing between the bound $^1(\pi,\pi^*)$ curve of HCN and that for the $H(^2S) + CN(^2\Pi)$ dissociation products. As discussed in section 2 this circumstance arises because of the fact that the $7a'$ component of the π^* MO correlates with a pure hydrogenic $1s$ AO at infinite separation (for bent nuclear arrangements). The calculated barrier height for

dissociation along this channel is 1.0 eV relative to the $^1A''$ energy minimum.

A summary of the various calculated equilibrium structural parameters obtained via polynomial fits to all the data points for each of the states under investigation is given in Table 2. If the various vibrational modes are allowed to be coupled (22) the calculated equilibrium distances are found to be slightly larger than those obtained under the assumption of separability of modes, while the $^1A''$ internuclear angle is calculated to be reduced in this more elaborate procedure. The present calculated values are in close agreement with those of earlier theoretical treatments (5); the latter values generally fall between those of the present SCF and CI calculations respectively.

In general the various theoretical results are seen to be in reasonably good accord with their corresponding experimentally reported values for the lowest two states of HCN, with the possible exception of the CH distance in the $^1A''$

[a]Two values are obtained, corresponding to the Fourier and Hermite type ($R_0\theta$) expansion of the vibrational wavefunction.
[b]Values given in ref. 4 for the state of DCN; however, since the v_2 numbering is unclear, this result may not correspond to the zeroeth vibrational level.

upper state, for which uniformly smaller results are obtained in the calculations than the 2.154 value deduced by Herzberg and Innes (4) for this quantity. As remarked earlier (5, 6), however, the calculations are in clear disagreement with the earlier experimental assignment of the β state (with a small equilibrium ∠HCN value of 114.5°) as the $2^1A''$ state. On the other hand, an assignment for this experimental species as the $2^1A'$ state instead of $2^1A''$ does appear to fit in reasonably well with the observed structural data for the upper state in question.

4. Vibrational Structure of the $^1(\pi,\pi^*)$ Transitions

In order to obtain the vibrational levels associated with the various electronic states of HCN it is assumed (in contrast to the ground state treatment (22) given earlier) that the various modes, namely CH stretching, CN stretching, and ∠HCN (ϕ) bending can be treated independently of one another. The corresponding CI energy curves are taken as the potential in which the nuclear motion occurs; the CN and CH stretching species are represented via a polynomial fit in the corresponding internal coordinate, while for the bending motion a Fourier series in $\cos 2n\phi$ is employed or alternatively a polynomial in the variable $R_0\phi$ (where R_0 is the CH distance). Thus the anharmonicity of the potential is taken into account in this treatment, but the various vibrational modes are left uncoupled therein. The vibrational wavefunctions are similarly expanded in a series of Hermite polynomials or in $\cos 2n\phi$ and $\sin 2n\phi$ series (23) and the corresponding energy levels and expansion coefficients are obtained using the variational method by solving the appropriate secular equation. Normally up to 25 terms are employed in each expansion; more details on the general procedure employed may be found elsewhere (22–24). The vibrational frequencies thus obtained are given in Table 3 and are compared with the best experimental values available for these quantities. It is found that these calculated results agree with the corresponding observed

values to within an error of 50–200 cm^{-1}; similar error limits have been noted in other applications of this method, as for example for HSO (11) and N_2H_2 (25), for which coupling between the vibrational modes is neglected.

In order to calculate the intensity distribution for the transitions between various vibrational levels of the different electronic states, the electronic transition moment is assumed to be independent of the CN stretching and CH stretching coordinate. The latter quantity is assumed to depend strongly on the angle HCN, however, since $\boldsymbol{R}_{e'e''}$ between the ground and all three upper states vanishes at 180° ($^1\Sigma^- - \tilde{X}^1\Sigma^+$, $^1\Delta - \tilde{X}^1\Sigma^+$) while it has a non-zero value in the non-linear H—C—N arrangement. The calculated variation of $\boldsymbol{R}_{e'e''}$ for the upper states under consideration is found in Fig. 5. The total transition moment between different vibrational levels is then approximated by the expression[3]

$$\boldsymbol{R}_{e'v'e''v''} = \langle\psi_{v_1'}|\psi_{v_1''}\rangle\langle\psi_{v_3'}|\psi_{v_3''}\rangle \times \langle\psi_{v_2'}|R_{e'e''}(\phi)|\psi_{v_2''}\rangle$$

For the lowest-energy $^1A'' \leftarrow \tilde{X}^1A'$ ($^1\Sigma^+$) transition the Franck-Condon factors between $\tilde{X}^1A'$ ($v_3'' = 0$) and the v_3' (CN) vibrational levels of the upper state are plotted in Fig. 6*a* for both the HCN and DCN isotopes; because of the increased CN bond length in the $^1(\pi,\pi^*)$ upper state the largest overlap is not found for the corresponding O—O transition but rather between $v_1'' = 0$ and the second and third energy level of the excited electronic state. The situation is even more drastic for the corresponding quantities in the angular distribution (Fig. 6*b*); the highest intensity is predicted between the $v_2'' = 0$ level and the $v_2' = 6$ species of the $^1A''$ state. At the same time it is seen from Fig. 3 that the depth of the $^1A''$ angular potential well is such that the $v_2' = 7$ level lies above the energy maximum at 180°, while all other lower-energy v_2' levels are still found within the well. For DCN the situation is slightly changed since 7 (almost 8) vibrational levels are indicated to lie within the angular potential well, whereupon it is calculated that the most intense transition in DCN should occur for somewhat larger angular quantum number ($v_2' = 8$) than for the lighter isotope. No significant intensity shift between

[3]The last integral in this expression is evaluated by fitting $R_{e'e''}(\phi)$ in the same basis as is used for the expansion of ψ_{v_2}.

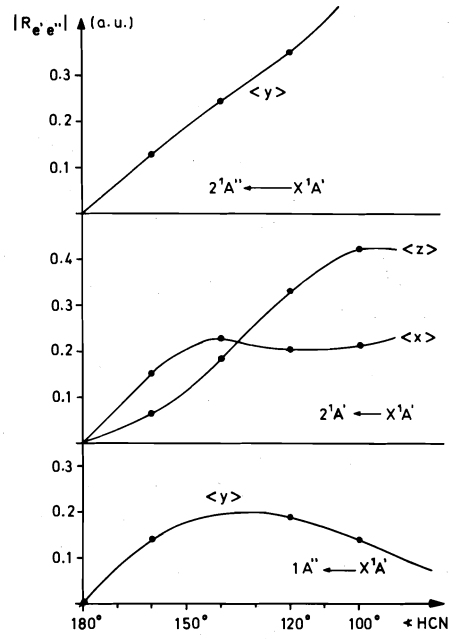

FIG. 5. Calculated electronic transition moments for various upper states of HCN as a function of internuclear angle. The direction of polarization is indicated in each instance.

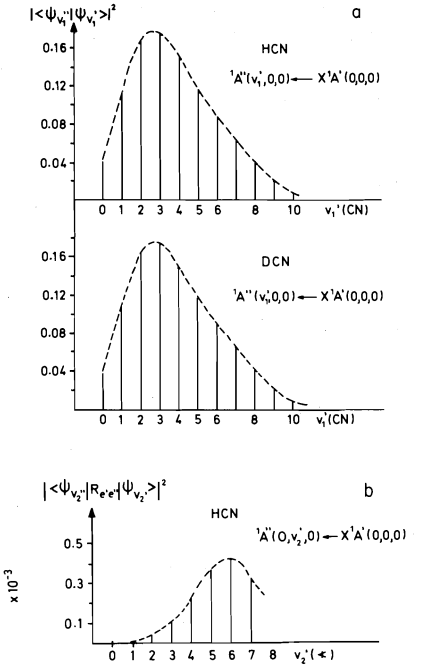

FIG. 6. Calculated Franck-Condon factors for various vibrational transitions in HCN and DCN; CN progressions are shown in part *a*, while a bending progression is given in part *b*.

HCN and DCN is expected for the CN vibrational pattern according to the present treatment, however (see also Table 3).

Finally, by far the largest Franck-Condon factor is calculated between the corresponding zeroeth CH vibrational levels of $\tilde{X}^1A'$ and α^1A''. It is also seen from Fig. 4 that excitation into higher-lying CH levels of the $^1A''$ state could lead effectively to dissociation into H + CN($^2\Pi$) via a tunnelling process.

The calculated results for the transition to the other bent $^1(\pi,\pi^*)$ upper state ($2^1A'$) are wholly analogous to those for $^1A''$, with the modification that the intensity maximum for ν_2 vibrations is shifted to somewhat smaller upper-state quantum numbers (4 or 5) compared to the latter case (since the depth of the angular well is found to be somewhat more shallow than for the $^1A''$ state). The $2^1A'$ species should also dissociate into H(^2S) + CN($^2\Pi$), and presumably with even greater facility since the absolute minimum in energy for this state lies above that of the $^1A''$ (see Fig. 3). Because the $2^1A''$ state is calculated to be linear, just as the ground state itself, the most intense vibrational transition in this case occurs for $v_2'' = 0$ to $v_2' = 1$, as required by the dipole forbiddenness of the corresponding electronic transition; also all higher-energy ν_2 vibrational transitions are calculated to be much weaker than the $1 \leftarrow 0$ species. The intensity distribution for the other two vibrational modes in this transition is found to be similar to that found for the $\alpha^1A'' \leftarrow \tilde{X}^1A'$ and $2^1A' \leftarrow \tilde{X}^1A'$ species. Finally it should be noted that, consistent with the results of Fig. 5, the overall intensity of the lowest-energy $^1A'' \leftarrow \tilde{X}^1A'$ transition is found to be markedly smaller than for either of the other two $^1(\pi,\pi^*)$ species calculated.

5. Comparison with Experiment

A. The $\alpha \leftarrow \tilde{X}(^1A'' \leftarrow \tilde{X}^1A')$ Transition

The calculated T_e and T_0 values for the various $^1(\pi,\pi^*)$ transitions of HCN treated in this study are compared with experiment and earlier theoretical findings in Table 4. The present CI treatment appears to overestimate the lowest T_0 value by some 0.25 eV, an error which is quite consistent with experience based on similar CI calculations for other small molecules. As noted above, however, this lowest $^1(\pi,\pi^*)$ species does not correlate with the $^1\Delta$ state in the linear nuclear arrangement but rather with $^1\Sigma^-$. The experimental data for this transition show a long bending progression, with an intensity maximum for $v_2' = 6$ (see Fig. 7*b*), which is rather faithfully represented in the calculated results of Fig. 6*b*. Similarly the shift of the maximum to $v_2' = 5$ in the corresponding hot bands [$\alpha(0,n,0)^0 \leftarrow \tilde{X}(0,1,0)$ and $\alpha(0,n,0)^2 \leftarrow \tilde{X}(0,1,0)$] for this transition is also mirrored in the calculated findings, which show $\langle\psi_{v_2'}|R^{\nu}_{e'e''}|\psi_{v_2''}\rangle$ values of 0.0652, 0.0654, and 0.0647 for the upper quantum numbers $v_2' = 4$, 5, and 6 respectively if the ground state $v_2'' = 1$ species replaces the $v_2'' = 0$ wavefunction. The results for DCN show quite similar behavior, except that the intensity maximum is shifted to higher v_2' quantum numbers because of the decreased magnitude in its vibrational frequency (Table 3).

The analogous findings for the ν_1 CN stretch progressions are not as easily understood, however, as can be seen by comparing calculated and experimental results in Figs. 6*a* and 7*a* respectively. The calculations show virtually no distinction between the intensity distributions in this vibrational species for the two isotopes HCN and DCN, a finding which seems reasonable in light of the small change in reduced mass which occurs for this mode upon deuteration. Yet the experimental spectrum shows a marked shift in both the overall shape and location of the maximum for the intensity distribution in such CN progressions in going from one isotope to the other. The calculated distribution for both systems is thus seen to agree reasonably well with the observed DCN spectral results, which show a maximum for $v_2' = 3$, but it is significantly less peaked than that reported for HCN. Whether a more nearly exact theoretical treatment of the vibrational structure of this transition can succeed in representing such a distinction between HCN and DCN remains to be seen, but at least at this point it is not immediately clear why the CN progressions of the two systems should appear so dissimilar.

In the higher-energy range of the $\alpha \leftarrow \tilde{X}$ transition the various absorption lines become increasingly diffuse, with this phenomenon setting in somewhat earlier in HCN than in DCN. In addition, in the latter isotope there is evidence of a second electronic transition, referred to as $\beta \leftarrow \tilde{X}$ by Herzberg and Innes (4) in this spectral region; the experimental intensity distribution for the strongest observed bending progression in this system is shown in Fig. 8.

TABLE 4. Relative energies (eV) calculated for the minima of the various states. (Ground state energy is −93.0700 hartree.)

	T_e	T_0 (HCN)	T_e (ref. 5)	T_0, Exptl. (ref. 4)
Ground state $^1\Sigma^+$	0.0	0.0	0.0	0.0
$^1A''$	6.76	6.73	6.48	6.48
$2^1A'$	7.55	7.52	6.78	[7.48][a]
$^1\Delta$–$2^1A''$	8.03	7.99	7.52	—
$CN(^2\Pi) + H(^2S)$	7.37(D_e)	7.12(D_0)	—	6.80(D_0)

[a]Deduced under the assumption that the $\beta(0,8,0) \leftarrow \tilde{X}(0,0,0)$ line of ref. 4 corresponds to the O—O transition (see text).

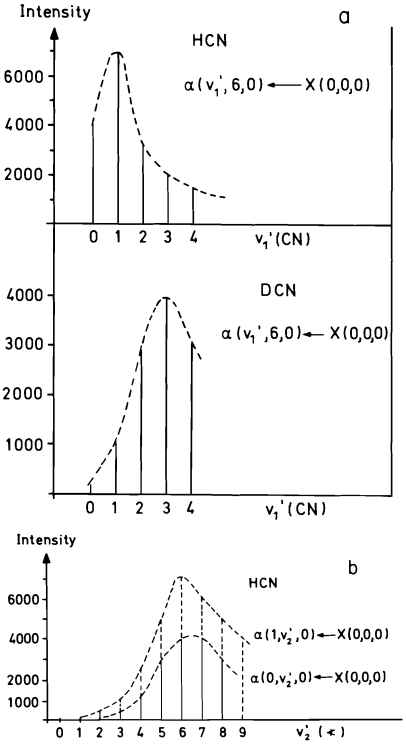

FIG. 7. Measured relative intensity values (taken from ref. 4) for various vibrational transitions in HCN and DCN. These results should be compared with the corresponding theoretical findings given in Fig. 6 *a*, *b* respectively.

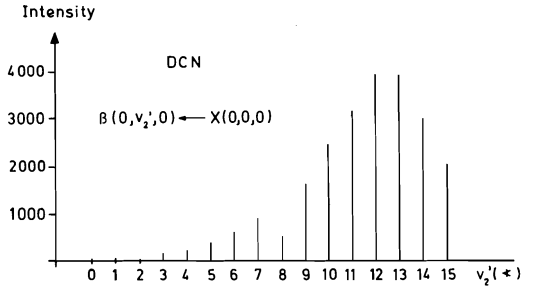

FIG. 8. Measured relative intensity values (taken from ref. 4) for a bending progression in the $\beta \leftarrow \tilde{X}$ transition.

Herzberg and Innes (4) have argued that the diffuseness in the $\alpha \leftarrow \tilde{X}$ bands is most likely caused by CH (or CD) predissociation, and this interpretation is certainly consistent with the calculated potential curve shown in Fig. 4. The D_0 value for dissociation of the upper state into $H(^2S) + CN(^2\Pi)$ is now believed to be 0.32 eV (4, 26), compared with the present calculated value of 0.40 eV (the energy of the dissociation products relative to that of the lowest ground state vibrational level is observed to be 6.80 eV, while the corresponding CI result is 7.12 eV; see Table 4). Because of the avoided crossing discussed in section 3, however, there is a barrier hindering this process which is approximately 1.0 eV in height. As indicated in Fig. 4 a potential well of this depth would allow for two stable CH vibrational levels in HCN and three such CD species in DCN. Tunnelling of H or D across the barrier obviously adds an additional instability factor to the overall physical situation, however, whereby Herzberg and Innes (4) have argued that distinctions in the masses of the hydrogenic isotopes and resultant differences in their ability to tunnel are at least partially responsible for the fact that diffuseness in the bands sets in at lower energies for the lighter HCN system.

B. The $\beta \leftarrow \tilde{X}$ *Transition*

Although the theoretical description of the $\alpha \leftarrow \tilde{X}$ transition fits in quite well with the corresponding experimental data (geometry, transition energy, intensity distribution, and predissociation features in HCN and DCN), the situation for the $\beta \leftarrow \tilde{X}$ band system at shorter wavelength is by no means clear. As indicated at the end of section 2, there seems to be general agreement that only the lowest three $^1(\pi,\pi^*)$ species of HCN fall in the energy range which corresponds to the $\alpha \leftarrow \tilde{X}$ and $\beta \leftarrow \tilde{X}$ absorption region. The observation that DCN is more

likely to possess a stable $v_3' = 1$ level in the $^1A''$ α state than HCN might lead to the conclusion that the $\beta \leftarrow \tilde{X}$ band system, which is only seen in the DCN spectrum, involves the same upper electronic state. On the other hand the calculated Franck-Condon factors of the previous section indicate that vibrational transitions to the $v_3' = 1$ level in the $\alpha \leftarrow \tilde{X}$ system should only be about 10% as intense as the corresponding $v_3' = 0$ species, whereas the observed $\beta \leftarrow \tilde{X}$ absorption lines are seen to be comparable in intensity to the *strongest* $\alpha \leftarrow \tilde{X}$ species found at longer wavelength. Thus when both energy and intensity results are considered, it does not appear that other than $v_3' = 0$ vibrational transitions are observed in the spectrum, and hence it seems best to conclude that the $v_3' = 1$ and higher species indicated to lie below the potential maximum in Fig. 4 for both isotopic species are in fact unstable relative to tunnelling across the corresponding barrier to dissociation; a similar conclusion has been reached earlier by Herzberg and Innes (4).

Consequently the list of choices for assignment to the β state can be narrowed down to the remaining two $^1(\pi,\pi^*)$ species, $2^1A'$ and $2^1A''$, but unfortunately there appear to be strong arguments against both of these possibilities as well. According to Herzberg and Innes (4) the β state is characterized by a strongly bent equilibrium geometry (~114.5°) and possesses $^1A''$ symmetry, the latter conclusion having been based on the appearance of the rotational fine structure in the $\beta \leftarrow \tilde{X}$ band. The present calculations find, on the other hand, that although one of these two states does show the desired (bent) geometrical characteristics, it is the $2^1A'$ species which does so and not the $2^1A''$, and thus there is clearly a conflict which needs to be resolved. Ordinarily a violation of selection rules is a more important consideration than the occurrence of such discrepancies in structural data but there is reason to believe the situation may not be so simple in the present case. First of all there is by now a large amount of evidence that *ab initio* calculations of the type employed in the present work are quite reliable for the prediction of such geometrical characteristics; both previous calculations as well as the conclusions based on qualitative MO theory agree with the present finding that the $2^1A''$ state is linear (or very nearly so (5)). Secondly there is some evidence that the operation of such rotational selection rules is unclear in the spectrum for a similar electronic transition in HO_2, namely in the 14 300 Å $^2A' \rightarrow {}^2A''$ band system.[4] In view of both these considerations it therefore seems worthwhile to look more closely into the possibility that the $2^1A'$ $^1(\pi,\pi^*)$ species is the upper state involved in the $\beta \leftarrow \tilde{X}$ absorption system observed by Herzberg and Innes (4).

Comparison of the observed intensity distribution in the bending progression of this transition (Fig. 8) with the calculated results of the previous section raises still further questions, however. The most intense lines in this progression are assigned by Herzberg and Innes (4) as $v_2' = 12$ and 13 respectively, for example, whereas the calculations suggest that the length of such bending progressions (in the $2^1A' \leftarrow \tilde{X}$ transition) from maximum to tail should actually be somewhat smaller than for the $\alpha \leftarrow \tilde{X}$ band (in which $v_{2'\,max} = 7$ or 8 for DCN; Fig. 3). On the other hand it seems possible that the observed group of vibrational transitions in question actually consists of two progressions, the weaker of which shows a maximum at $v_2' = 7$. Such an interpretation would then lead to an assignment for the origin of the stronger of the two progressions as the $\beta(0,8,0) \leftarrow \tilde{X}(0,0,0)$ member, thereby placing the absorption maximum for this system at $v_2' = 12$ (or 13) minus 8 = 4 (or 5), in much better agreement with the calculated results for the $2^1A' \leftarrow {}^1A'$ intensity distribution (see section 4).[5]

The fact that the $\beta \leftarrow \tilde{X}$ system can only be observed for the deuterated isotope of HCN also seems to be satisfactorily rationalized in terms of a $2^1A'$ assignment for the upper state. Both $2^1A'$ and $^1A''$ (α species) have the same dissociation limit, namely $H(^2S) + CN(^2\Pi)$, but the more stable $^1A''$ species appears to be some 0.8 eV

[4]In addition to $\Delta K = \pm 1$ the $\Delta K = 0$ line is observed to occur with relatively high intensity near the band centers (27).

[5]In support of this argument, it can be noted that there is also a plausible assignment for the lower-energy portion of the intensity distribution in Fig. 8, namely as a hitherto unassigned series of hot bands for the $\alpha \leftarrow \tilde{X}$ system. The cold bands for the $\alpha(2,v_2',0) \leftarrow \tilde{X}$ progression are relatively strong, with a maximum relative intensity of 3500 having been reported in the original paper (4). The latter species is assigned as $\alpha(2,7,0) \leftarrow \tilde{X}$ (0,0,0) and is found at 60 142 cm^{-1}, and hence one would expect the corresponding hot band species to occur some 500 cm^{-1} to the red thereof, with fairly substantial intensity; this description fits the previously assigned $\beta(0,7,0) \leftarrow \tilde{X}(0,0,0)$ member reasonably well, especially since the $\alpha(2,7,0) \leftarrow \tilde{X}(0,1,0)$ species remains unassigned in the original experimental interpretation.

more stable at their respective equilibrium geometries (Fig. 3). As a result it seems clear that the $2^1A'$ is marked by a relatively small potential barrier to dissociation (in the order of 2000 cm^{-1} according to the calculations), and hence, given the greater capacity of the proton to tunnel through this barrier (plus the fact that the zero-point energy of HCN is significantly greater than in DCN), it seems plausible that only the heavier isotope could be stable to predissociation in this electronic state.

The exact numbering of the individual members of the progression shown in Fig. 8 is very difficult to discern based on the relatively small range of wavelength over which the $\beta \leftarrow \tilde{X}$ band is actually observed. Consequently it appears impossible to locate the true T_0 value for the $\beta \leftarrow \tilde{X}$ transition. One of the most plausible alternatives from the standpoint of the present interpretation, however, is that the $\beta(0,8,0) \leftarrow \tilde{X}(0,0,0)$ line (at 60 350 cm^{-1}) in the original notation (see Fig. 8) corresponds to the O—O species and thus that T_0 is 7.48 eV for this DCN transition, which value in turn lies less than 0.1 eV below the corresponding calculated result of Table 4. If the latter vibrational species involves $v_1' = 1$ instead, the error between calculation and experiment would be greater by the amount of one additional ν_1' quantum, i.e. by roughly 0.15 eV (1300–1400 cm^{-1}). The earlier calculated T_0 result of Schwenzer *et al.* (5) is 0.7 eV below the present CI value (Table 4).

In summary it is found that the vibrational intensity distribution calculated for the $2^1A' \leftarrow {}^1A'$ transition appears to be in reasonably good agreement with the experimental observations for the $\beta \leftarrow \tilde{X}$ band, just as the results for the ${}^1A'' \leftarrow {}^1A'$ species are seen to satisfactorily reproduce the details of the measured spectrum for the $\alpha \leftarrow \tilde{X}$ system. Since such an assignment for the $\beta \leftarrow \tilde{X}$ species appears to be at odds with the rotational selection rules for such polyatomic systems there is still clearly a need to justify this interpretation in more detail, but in considering this point the difficulties with the alternative $2^1A'' \leftarrow {}^1A'$ assignment should not be overlooked. The presence of the rather long (and relatively intense) 500 cm^{-1} vibrational progression in the $\beta \leftarrow \tilde{X}$ transition of DCN needs to be explained in a manner which is consistent with the appearance of the associated rotational fine structure of this band system before it can be claimed that theory and experiment are fully reconciled in this instance, and the results of the present CI study indicate that none of the ${}^1A''$ states of this molecule possesses the type of potential surface required to account for such vibrational characteristics.

DAVID C. FROST, NICK P. C. WESTWOOD, NICK HENRY WERSTIUK, LUBOMIRA CABELKOVA-TAGUCHI, and JOHN WARKENTIN. Can. J. Chem. **55**, 3677 (1977).

The results of an ultraviolet photoelectron spectroscopic study of the thermolysis of 5,5-dimethyl-1-phenyl-Δ^3-1,3,4-triazoline-2-thione (**1**) are presented. That CS_2 is one of the major products establishes that carbon monosulfide (CS) is formed as a reaction intermediate in the thermolysis. Other products of thermolysis of **1** are molecular nitrogen and isopropylidenephenylamine (**2**). The photoelectron spectrum of the latter is also reported. Thermolysis of **1** in solution also leads to CS, which polymerizes extensively in the absence of trapping agents but is partly converted to CS_2 in the presence of S_8 and to COS in the presence of cyclohexanone.

DAVID C. FROST, NICK P. C. WESTWOOD, NICK HENRY WERSTIUK, LUBOMIRA CABELKOVA-TAGUCHI et JOHN WARKENTIN. Can. J. Chem. **55**, 3677 (1977).

On présente les résultats d'une étude ups sur la thermolyse du diméthyl-5,5 phényl-1 Δ^3-triazoline-1,3,4 thione-2 (**1**). Le CS_2 étant l'un des produits principaux implique que le monosulfure de carbone se forme comme intermédiaire dans la réaction de thermolyse. Les autres produits de la thermolyse de **1** sont l'azote moléculaire et l'isopropylidènephénylamine (**2**). Le spectre photoélectronique de ce dernier est aussi présenté. La thermolyse d'une solution de **1** conduit aussi au CS qui polymérise considérablement en absence d'agents piégeurs mais se convertit partiellement en CS_2 en présence de S_8 et en COS, en présence de cyclohexanone.

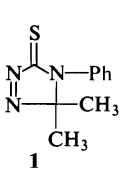
[Traduit par le journal]

Ultraviolet photoelectron spectroscopy (ups) is a technique for measuring the ionization potential for removal of electrons from molecular orbitals. The results, through the use of Koopman's theorem, give information about the nature of bonding in molecules. Although ups thus far has been used predominantly in a conventional way to study bonding in appreciably volatile and stable molecules of known structure (1–3), clearly the technique could be used to identify highly reactive intermediates, unstable molecules, and their reaction products in the gas phase. At present there are few studies of the latter, unconventional application of photoelectron spectroscopy documented in the literature (4–8).

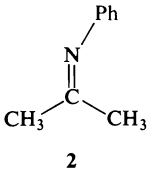
In this paper we describe an ups study of the products from vacuum thermolysis, at 225°C,

[1]Authors to whom enquiries should be addressed.

of 5,5-dimethyl-1-phenyl-Δ^3-1,3,4-triazoline-2-thione (**1**). Kinetics and products of thermolysis of **1** in chlorobenzene solution are also reported.



1



2

Experimental

Materials

Compound **1** was prepared from the 4-phenylthiosemicarbazone of acetone by oxidative cyclization on alumina (9). The sample used for this work was recrystallized from ethanol. It was homogeneous (tlc) and melted sharply at 170°C.

Ultraviolet Photoelectron Spectroscopy

The ups study was carried out with a versatile ups spectrometer of the design of Frost and co-workers (10). Thione (**1**) was sublimed ($P_{\text{initial}} = 10^{-6}$ Torr) into a pyrolysis tube (glass, $l = 10$ cm) maintained at 225 ± 10°C. The tube led through a U trap cooled to −100°C, directly into the photoionization chamber of the spectrometer. The spectrum[2] shown in Fig. 1*a* is that of the volatile thermolysis products that passed through the −100°C trap. That in Fig. 1*b* was obtained by warming the trap after pumping the volatiles out of the spectrometer.[2]

Kinetics

Thermolysis of **1** in chlorobenzene was followed by ^{1}Hmr. For a typical kinetics experiment, a solution of **1** (0.0268 *M*) in chlorobenzene containing toluene (0.0281 *M*) as internal standard for integration was degassed and sealed into an nmr tube. Five or more ^{1}Hmr spectra were recorded with a Varian HA-100 intrument before the tube was placed in an oil bath at 148 ± 0.1°C. The tube was removed at intervals, cooled quickly with liquid nitrogen, and warmed to room temperature before five or more spectra were recorded. Time outside the 148°C bath was not counted and the time scale was not corrected for warm-up and cooling periods which were short and partly cancelling.

As reaction progressed the intensity of the methyl singlet of **1** (1.2 δ) diminished and two new singlets of equal intensity appeared near 1.6 and 2.0 δ. A standard first-order plot of log (peak height at 1.2 δ, normalized with respect to that of the reference singlet) against time was a straight line with correlation coefficient in the range 0.9875 to 0.9983. The average first-order rate constant (seven runs) obtained from the slopes was $k_1 = 6.42 \times 10^{-5}$ s^{-1}.

Products

In spent solutions from kinetics runs the two product singlets, attributed to isopropylidenephenylamine (**2**), together accounted for more than 95% of the methyl groups of **1**. A gummy, brown solid qualitatively fitting the literature description of polymeric CS (11) was also obtained. Isopropylidenephenylamine (**2**) was prepared independently by the method of Kuhn and Jochims (12). The crude anil was vacuum redistilled twice: bp 80–81°C, ^{1}Hmr ($CDCl_3$) δ 2.05 (s, 3H), 1.70 (s, 3H), 3.0–7.4 (m, 5H). A sample of **2** isolated by gas chromatography (Varian Aerograph A90-P3, 5 ft × 1/4 in. column, 15% SE30 on 60–80 mesh Chromosorb P, 65°C) of the products from thermolysis of **1** had the identical ^{1}Hmr spectrum. Hydrolysis of either sample afforded acetone and aniline.

Trapping of CS with Sulphur

A sample of **1** (0.20 g) in chlorobenzene (35 ml) containing sulphur (1.5 g) was placed in a flask connected to a gas sampling bulb. The system was evacuated and purged with argon until the mass spectrum of a gas sample was free from air peaks. The system was then sealed off and heated at the reflux temperature for 6 h. The flask containing the solution was cooled to room temperature and then to Dry Ice temperature before a gas sample was taken for mass spectrometry. Major peaks at *m/e* 76 (CS_2), 40 (argon), and 28 (N_2) were recorded. A control experiment, run in the same way except for the absence of sulphur, gave a gas sample with large peaks at *m/e* 40 and 28 but a negligible signal at *m/e* 76.

Trapping of CS with Cyclohexanone

This experiment was analogous to the one described above. Compound **1** was decomposed in neat cyclohexanone and the gas phase was sampled for mass spectrometry. A signal at *m/e* 60, assigned to COS, was observed as well as masses 40 and 28. A control sample from decomposition of **1** in chlorobenzene under air instead of argon did not give a signal at *m/e* 60.

Results and Discussion

The spectrum[2] in Fig. 1*a* shows that CS_2 (IP 10.17, 12.80, 14.47, 16.16 eV) and N_2 (IP 15.57, 16.6–17.8 envelope, 18.73 eV) are the major volatile products from the gas phase thermolysis of **1** that pass through the −100°C trap. A small quantity of CS is indicated by the weak band at 11.28 ± 0.05 eV (13). Trace quantities of CO (IP 14.00 eV) are evident. The band at 8.62 eV and the broad bands centered at 10.44 and 12.30 eV cannot be assigned with confidence at this time. Their appearance and disappearance suggest that they arise from a single species and the band positions correspond to those of propanethione (14).

That CS_2 is one of the major products of the gas phase thermolysis of **1** is explained by invoking the intermediacy of CS. That CS is the source of CS_2 is supported by the work of Richardson and co-workers (15) who established that CS is converted to CS_2 at room temperature via a heterogeneous wall reaction.

When the volatiles were pumped off and the

[2]The thermolysis experiments and the resulting spectra were reproducible.

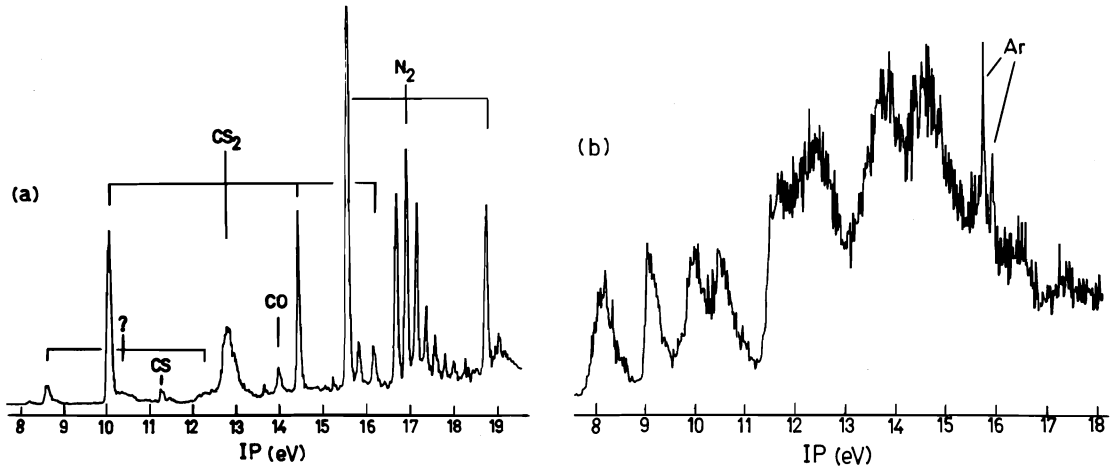


FIG. 1. *(a)* The He(I) photoelectron spectrum of the volatiles from the pyrolysis of **1**. *(b)* The He(I) photoelectron spectrum of **2**.

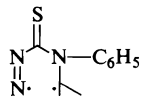
−100°C trap was warmed, an additional small amount of the unknown species[2] (IP 8.62, 10.44, and 12.30) was initially observed. At ambient temperature, the photoelectron spectrum[2] shown in Fig. 1*b* was obtained, which was assigned to isopropylidenephenylamine (**2**), the major product of the solution thermolysis of **1**. The first two IP's with maxima at 8.19 and 9.13 eV we assign, respectively, to the b_1 and a_2 type π MO's (local C_{2v} symmetry) which result from a separation of the degenerate π MO's (e_{1g}) upon substitution of benzene (16). As usual, the a_2 MO remains unperturbed since there is a node at the point of substitution and the b_1 MO is destabilized. The bands at 10.04 and 10.57 eV we assign to the C=N π MO and the nitrogen lone pair, respectively, on the basis of a comparison with other alkylidene alkyl and aryl amines (17, 18) and isoelectronic styrenes (19). This ordering could be reversed depending on the magnitude of the torsional angle about the phenyl–nitrogen single bond which determines the magnitude of the *n*–π separation (17).

The thermolysis chemistry of **1** in solution lends support to the conclusions drawn from the ups experiment. At 148°C, in chlorobenzene, decomposition of **1** is first order ($k_1 = 6.42 \times 10^{-5}$ s^{-1}) and isopropylidenephenylamine (**2**) accounts for more than 95% of the methyl and phenyl groups of **1**. Some attack by CS on **1** or on **2** probably accounts for the remaining 5%.

Several mechanisms for thermolysis of **1** have to be considered, including heterolytic and homolytic bond cleavages. The fact that an increase in solvent polarity decreases the rate constant ($k_{C_6H_5NO_2} = 0.53k_{C_6H_6}$ at 148°C) suggests that highly polar transition states and intermediates are not involved. Among homolytic pathways, stepwise decomposition via intermediate **3** is considered most likely because of growing evidence that some unsymmetric azo compounds thermolyze by the two-step mechanism (for examples and leading references see ref. 20). The



3

expected energy difference between C(sp^2)—N and C(sp^3)—N bonds should make **1** a strong candidate for stepwise decomposition. Further mechanistic conjecture is not warranted at this time.

Our brief ups study of the thermolysis of **1** illustrates the utility of the technique for studying the intermediates from gas phase organic reactions. The solution chemistry of **1** confirms that it is a thermal source of CS and suggests that it may be particularly useful for studies of the chemistry of that reactive intermediate in the liquid phase.

Substituent effects of phosphorus-containing groups on aromatic reactivity. Determination of substituent constants by ^{13}C nuclear magnetic resonance spectroscopy

TOMASZ A. MODRO

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 25, 1977

TOMASZ A. MODRO. Can. J. Chem. **55**, 3681 (1977).

^{13}C nmr spectra have been obtained for a series of benzene derivatives substituted with phosphorus-containing groups of the type PZ_2, $P(O)Z_2$, and $P(S)Z_2$. Inductive and resonance substituent constants were determined from the shielding of *meta* and *para* carbon atoms according to the dual-substituent parameter approach. Possible mechanisms of substituent effects of P^{III} and P^{V} derived functional groups are discussed and in some cases compared with effects of the analogous nitrogen derivatives.

TOMASZ A. MODRO. Can. J. Chem. **55**, 3681 (1977).

On a enregistré les spectres de résonance magnétique nucléaire ^{13}C d'une série de dérivés du benzène, substitués par des groupes d'atome central phosphore de types PZ_2, $P(O)Z_2$ et $P(S)Z_2$. Les constantes d'induction et de résonance des substituants sont déterminées à partir des effets de blindage des carbones *méta* et *para* selon l'approche paramètre substituant-double. Des mécanismes possibles pour l'effet des substituants du P^{III} et P^{V}, liés aux groupes fonctionnels, sont discutés et dans certains cas comparés aux effets de dérivés analogues de l'azote.

[Traduit par le journal]

The use of ^{13}C nmr spectroscopy in the elucidation of the electronic structure of organic molecules continues to increase (for a recent review see ref. 1). For aromatic systems, ring ^{13}C chemical shifts have been found to be a useful and sensitive probe in studies of the polar and resonance effects of substituents, particularly at the *para* and *meta* positions (2). Substituent-induced changes in ^{13}C chemical shifts have been correlated with various substituent constants, with a variable degree of success. It is now recognized that structural effects on the ^{13}C nmr chemical shift of the *para* and *meta* carbon atoms relative to benzene are best described by the dual-substituent parameter (dsp) approach (3). According to this approach, the relative change in shielding at a given position results from the contributions of inductive and resonance effects of the substituent, expressed in terms of σ_I and σ_R^0 constants:

$$[1] \qquad {}^{13}C\ \delta_X - {}^{13}C\ \delta_H = a\sigma_I + b\sigma_R^0$$

^{13}C nmr spectroscopy seems to be a particularly useful tool for investigations of substituent effects of phosphorus–containing groups. For both tervalent and tetravalent phosphorus derivatives $-PZ_2$ and $-P(Y)Z_2$, numerous structural variations are possible (in the nature of both Z and Y ligands) which modify the net electronic effect of the substituent. This effect is a function of various factors, such as the electronegativities of Z and Y, bond order at the P atom, donor properties of phosphorus non-bonding electrons (in case of PZ_2 substituents), and acceptor abilities of the vacant *d* orbitals on phosphorus. The evaluation of substituent effects by determination of the reactivities of a series of PZ_2 and $P(Y)Z_2$ substituted benzene derivatives can often be hindered by the high reactivity of the phosphorus-containing function itself (e.g. oxidation, hydrolysis, Arbuzov-type reactions, etc.).

^{13}C nmr spectra were employed by Retcofsky and Griffin (4) in determining the σ_p and σ_p^+ constants for some organophosphorus groups. The substituent constants derived could be used to compare the electron-withdrawing abilities of the related pairs of P^{III} and P^{V} functional groups, PZ_2 and $P(O)Z_2$. Although the $P(O)(OEt)_2$ substituent has been found to be more electronegative than $P(OEt)_2$ (σ_p values $+0.55$ and $+0.33$, respectively), according to Retcofsky and Griffin the substituent PPh_2 is *more* electron withdrawing than $P(O)Ph_2$ (σ_p values $+0.68$ and $+0.53$, respectively), and PCl_2 *more* electron withdrawing than $P(O)Cl_2$ (σ_p of $+0.61$ and $+0.43$). Such a conclusion (resulting most likely from erroneous ^{13}C chemical shift assignments)

[f]In $CHCl_3$.

is not only counter to chemical intuition, but also is not in accord with known facts about structure–reactivity relationships in organophosphorus chemistry. Substituent constants derived by Schindlbauer and Prikoszovich (5) from ^{19}F nmr chemical shifts for a series of *meta* and *para* substituted fluorobenzenes clearly show that $P(O)Z_2$ is always more electron withdrawing than the corresponding PZ_2 group. Recently, Klabuhn *et al.* (6) demonstrated that in various reactions (base-catalyzed ester hydrolysis, aromatic nucleophilic substitution, S_N2 and S_N1 reactions), the *p*-$P(O)R_2$ substituent (R = phenyl, cyclohexyl) is significantly more electron withdrawing than the corresponding *p*-PR_2 group; the reactivity ratio varied from 1.6 to 380.

Unfortunately, Retcofsky and Griffin's results have recently been uncritically cited by Nelson and Williams in their review article (ref. 1, p. 247) as an illustration of the application of ^{13}C nmr spectroscopy in estimating substituent constants which have not been determined chemically.

In continuation of our interest in the substituent effects of phosphorus-containing groups upon the properties of an adjacent aromatic system (ref. 7, and preceding papers of this series), we have used ^{13}C nmr chemical shifts to monitor changes in the electron distribution of the benzene ring in a series of Ph—PZ_2, Ph—$P(O)Z_2$ and Ph—$P(S)Z_2$ derivatives (including compounds investigated by Retcofsky and Griffin). The chemical shifts obtained were used to evaluate substituent inductive and resonance constants, according to the dual-substituent parameter approach.

Results and Discussion

^{13}C chemical shifts for the ring carbon atoms in 16 derivatives of benzene, substituted with PZ_2, $P(O)Z_2$, or $P(S)Z_2$ groups, have been measured in CCl_4 or cyclohexane solutions. No common solvent could be used for all compounds studied, because of either insolubility in cyclohexane (compounds **8**, **9**, **13**, **14** of Table 1) or reaction with carbon tetrachloride (compounds **1**, **7**, and to some extent compound **6**). However, the differences in the chemical shift values obtained for a given compound in these two solvents never exceeded 0.03 ppm, and did not affect the derived values of substituent constants. The identical values of ^{13}C chemical shifts for various monosubstituted benzenes measured in CCl_4 and cyclohexane have been reported previously (8). Chemical shifts (and ^{13}C–^{31}P coupling constants) for the substituted benzenes of interest are shown in Table 1.

The values obtained for $\Delta\delta$ do not confirm Retcofsky and Griffin's observations; in all cases

TABLE 2. Estimated σ_I and σ_R^0 constants for organophosphorus substituents

the carbon atom *para* to the $P(O)Z_2$ substituent is more deshielded than that *para* to the corresponding PZ_2 group.[1] In agreement with earlier results obtained for monosubstituted benzenes (10), the largest variation of shifts is found for the *ipso* carbon atom, and the smallest occur at the *meta* carbon. The variations at the *ipso* position, as well as at the *ortho* carbons, reflect not only polar, but also purely magnetic effects of the substituent and therefore cannot be used as reliable measures of substituent effects. The chemical shifts of the *meta* and *para* carbon atoms are believed to be essentially free of magnetic anisotropy effects of a substituent (11) and can be used without any correction in evaluating the appropriate substituent constants.

Inductive and resonance substituent constants of phosphorus-containing groups were calculated from the dsp fits for *meta* and *para* ^{13}C shifts, according to [2] and [3] (12). The

$$[2] \qquad \Delta\delta\,{}^{13}C_p = 3.98\sigma_I + 19.79\sigma_R^0$$

$$[3] \qquad \Delta\delta\,{}^{13}C_m = 1.54\sigma_I - 1.61\sigma_R^0$$

results are summarized in Table 2. Where possible, σ_I and σ_R^0 values are compared with those obtained by Schindlbauer and Prikoszovich (5) from the ^{19}F nmr chemical shifts for the *meta* and *para* substituted fluorobenzenes. Resonance parameters σ_R^0, calculated by Schindlbauer and Prikoszovich from the difference in shielding of the *para* and *meta* carbons, agree very well with our values obtained from [2] and [3]. The values of inductive substituent constants σ_I on the other hand are seriously different; in almost all cases the σ_I constants reported in ref. 5 are much more positive than our values obtained from the dsp approach. σ_I values were calculated by Schindlbauer and Prikoszovich according to the single substituent parameter approach ($\Delta\delta\ {}^{19}F_m = a\sigma_I + b$) and in our opinion these results tend to grossly overestimate the inductive electron-withdrawing properties of the organophosphorus groups studied. For example, their σ_I values for the PR_2 groups (R = Me, Ph) are almost identical with those for the corresponding NR_2 groups; a result not likely on the simple basis of the electronegativity difference of phosphorus and nitrogen. Similarly, it would be difficult to rationalize the stronger inductive effect of the $P(O)Me_2$ substituent ($\sigma_I = +0.35$ (5)) compared to that of the acetyl group ($\sigma_I = +0.28$ (13)).

The data presented in Table 2 permit one to arrange phosphorus-containing groups with respect to their electronic effects. As for the inductive effects, the electron-attracting properties decrease within each class of substituents in the following order of σ_I values.

For the PZ_2 type substituents:

[1]We believe that the values reported by Retcofsky and Griffin as *para* carbon shielding for the PPh_2, $P(O)Ph_2$, $P(O)Cl_2$, and $P(S)Cl_2$ groups probably represent the chemical shifts of the *ortho* carbon atoms.

$$PCl_2 > PF_2 > P(Ph)Cl > PPh_2 > PMe_2 > H > P(OEt)_2 > P(NEt_2)_2$$

For the $P(O)Z_2$ groups:

$$P(O)Cl_2 > P(O)Me_2 > P(O)Ph_2 > P(O)(OEt)_2 > H > P(O)(NEt_2)_2$$

For the $P(S)Z_2$ substituents:

$$P(S)Cl_2 > P(S)Me_2 > P(S)Ph_2 > H > P(S)(OEt)_2$$

The observed order of inductive withdrawal does not follow the order of decreasing electronegativity of atoms bonded to the phosphorus atom ($F > O > Cl \simeq N > C_{sp^2} > C_{sp^3}$). The effective charge density on the phosphorus results from the superimposition of the inductive withdrawal by groups Z (following the electronegativity scale) and the p_π–d_π electron back-donation from the groups Z to the vacant *d* orbitals of the phosphorus atom. Interestingly enough, the PF_2 group has a weaker inductive effect than the PCl_2 substituent, contrary to the significant difference in electronegativities of fluorine and chlorine.[2] This result remains, however, in agreement with the p_π–d_π electron feedback model; the 3*p* nonbonding orbitals of chlorine are less effective in resonance donation to the vacant *d* orbitals of phosphorus, relative to the 2*p* nonbonding electrons of fluorine (14*a*). In consequence, the less electronegative chlorine substituents increase the electron deficiency of phosphorus more than do the fluorine atoms. The high degree of the $2p_\pi$–d_π bonding between oxygen (or nitrogen) and the phosphorus atom is well documented for various organophosphorus systems (15). This effect results in a considerable net inductive electron donation (relative to hydrogen) of the ester and amide groups derived from the P^{III} atom (compounds **5** and **6**), as well as reducing the inductive electron withdrawal practically to zero for the phosphoryl and thiophosphoryl esters and amides (compounds **11**, **12**, and **16**).

Resonance effect parameters σ_R^0 are similar for all tetravalent phosphorus groups $P(O)Z_2$ and $P(S)Z_2$ (σ_R^0 range +0.10 to +0.18) and locate these substituents among strong, mesomerically electron-withdrawing groups such as nitro, cyano, or acetyl substituents. The resonance effects in this case are due to the p_π–d_π interactions between the P^V atom and the aromatic system; the σ_R^0 values indicate that this effect is of a similar order of magnitude to the p_π–p_π conjugation between the ring and the nitro or carbonyl functions. For the PZ_2 type groups, despite the presence of the nonbonding electrons on phosphorus, net conjugative *withdrawal* is observed for fluorine-, chlorine-, and alkoxy-substituted systems. In these cases, the high electronegativity of Z promotes the mesomeric electron withdrawal from the ring to the vacant *d* orbitals of phosphorus to an extent that is not counterbalanced by the p_π–p_π donation of the phosphorus lone pair.

According to the data in Table 2, the PR_2 substituents (R = Me, Ph) are weakly electron withdrawing by inductive effects and almost negligibly electron donating by resonance effects. This should result in total electronic effects for these substituents upon reactivity which are weak in magnitude and possibly variable in direction, depending on the relative response of the reaction center to inductive and resonance effects. In reactions studied by Klabuhn *et al.* (6), the PR_2 (R = cyclohexyl, phenyl) behaves in ester hydrolysis as a weakly electron-withdrawing (by a factor of ca. 2) and in S_N1 reaction as a weakly electron-donating (by a factor of ca. 3) substituent. Dissociation measurements for the *meta*- and *para*-PR_2 substituted benzoic acids (16) and phenols (17) demonstrate the weak electron-accepting properties of phosphorus-containing substituents, and therefore suggest greater importance of inductive effects upon the acidity of phenolic and carboxyl groups. On the other hand, the relative reactivity of P^{III} derivatives in Arbuzov-type reactions seems to follow the order of resonance electron release of the phosphorus moiety. These reactions involve nucleophilic attack of the phosphorus nonbonding electrons at saturated carbon atoms, and the relative reactivity of the system Z_3P decreases in the order Z = alkyl > aryl > alkoxyl (14*b*, 18), following the order of decreasing values of σ_R^0 constants.

There is little structural parallel between organic compounds of phosphorus and nitrogen; nevertheless the substituent effects of the few phosphorus-containing groups investigated can be directly compared with those of the nitrogen analogues. Such comparisons can involve tertiary phosphines and their oxides; substituent con-

[2]The difluoromethyl group is, as expected, more electron withdrawing than the dichloromethyl group, as can be demonstrated by the values of their Taft's substituent constants σ^* (+2.05 and +1.94, respectively) (13, Chapt. 3.6).

stants for the corresponding nitrogen derivatives are included at the bottom of Table 2. Comparison of σ values of MZ_2 groups (M = P, N; Z = Me, Ph) clearly demonstrates fundamental differences in electronic properties of phosphorus and nitrogen. While the inductive electron withdrawal, due to the higher electronegativity, is significantly greater for amino groups, the NZ_2 substituents show (relative to the negligible effects of the PZ_2 groups) powerful electron-donating resonance effects (−0.52 vs. −0.02 and −0.33 vs. 0.00, respectively). This reflects the dramatic difference in the conjugative abilities of the nitrogen 2*p* and phosphorus 3*p* nonbonding electrons with respect to an aromatic π system. In *N*,*N*-dimethylaniline-*N*-oxide (**19**), the substituent effect (if the hyperconjugative electron-release is ignored) operates solely via the inductive mechanism; consequently similar deshielding of the *meta* and *para* positions is observed.[3] The inductive effect of the $N(O)Me_2$ group is again much greater than that of the $P(O)Me_2$, because of the electronegativity difference, and also because oxygen lone pair back-donation is not possible for the nitrogen-containing substituent.

Experimental

Substrates **2**, **3**, **4**, **9**, **10**, **14**, **15**, and **18** were commercial products and were recrystallized or distilled where necessary. Substrates **1**, **5**, **6**, **7**, **8**, **11**, **12**, **13**, **16**, and **19** were synthesized according to standard procedures.

^{13}C chemical shifts were determined on a Varian CFT-20 spectrometer operating in pulsed Fourier transform mode at a probe temperature of 35–40°C. A capillary containing 80% D_2O – 20% dioxan was used as a lock in each case. The ^{13}C chemical shifts were measured relative to the internal solvent resonance and are reported relative to the chemical shift of benzene measured in the same solvent. Solutions of 0.5 *M* were used, solubility permitting. In a few cases chemical shifts were measured for various substrate concentration (0.5–0.1 *M*); no change in chemical shift values was observed. Chemical shift values are reproducible to better than ±0.02 ppm.

^{13}C chemical shift assignments were based upon relative intensities, off-resonance decoupling experiments, and values of ^{13}C–^{31}P coupling constants in related systems. The assignment of the C_{ipso} and C_{para} carbon atom resonances is simplified by the absence of a nuclear Overhauser effect for the quaternary C_{ipso} carbon atom, and therefore by its much lower intensity relative to the C_{para} signal. The assignment of the C_{meta} and C_{ortno} (and also of C_{ipso} and C_{para}) resonances was based upon the magnitude of the $J(^{13}C^{31}P)$ coupling. For all four ring carbon atoms the following ranges of the $J(^{13}C^{31}P)$ coupling constants were found (in Hz): P^V derivatives: C_{ipso} (82–187), C_{ortho} (8.6–14.4), C_{meta} (10.8–17.8), C_{para} (1.8–4.0): P^{III} derivatives: C_{ipso} (12.6–51.8), C_{ortho} (8.8–31.2), C_{meta} (2.8–8.0), C_{para} (~0). Some of the observed $J(^{13}C^{31}P)$ coupling constants could be compared with the available literature data; excellent agreement was found for both P^V (20) and P^{III} (21) derivatives.

[3]The NH_3^+ and NMe_3^+ groups give the identical deshielding of *meta* and *para* carbon atoms in the corresponding benzene derivatives (19).

A comparison of substituent effects on vicinal proton–proton and carbon–proton coupling constants

T. P. FORREST AND S. SUKUMAR

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 28, 1977

T. P. FORREST and S. SUKUMAR. Can. J. Chem. **55**, 3686 (1977).

Vicinal carbon–proton coupling constants have been determined for a series of *tert*-butyl derivatives and compared to the vicinal proton–proton coupling constants in the analogous series of isopropyl derivatives. In both series coupling constants were found to decrease with electronegativity of substituent, with $^3J_{C,H}$ decreasing more rapidly than $^3J_{H,H}$. The relationship between the two types of coupling was found to be $J_{C,H} = 1.2J_{H,H} - 3.5$. The regular change in the ratio of $J_{C,H}$ to $J_{H,H}$ indicates that substituent effects can be useful in predicting carbon–proton coupling constants from proton–proton models.

T. P. FORREST et S. SUKUMAR. Can. J. Chem. **55**, 3686 (1977).

Les constantes de couplage vicinales carbone–proton sont mesurées pour une série de dérivés *tert*-butylés et comparées aux constantes de couplage vicinales proton–proton obtenues pour une série analogue de dérivés isopropylés. Dans les deux séries, les constantes de couplage semblent diminuer avec l'électronégativité du substituant avec $^3J_{C,H}$ diminuant plus rapidement que $^3J_{H,H}$. La relation entre les deux types de couplage est établie comme étant $J_{C,H} = 1.2J_{H,H} - 3.5$. Le changement régulier dans le rapport de $J_{C,H}$ à $J_{H,H}$ indique que l'effet des substituants peut être utile dans la prédiction des valeurs des constantes de couplage carbone–proton à partir des modèles proton–proton.

[Traduit par le journal]

Proton–proton coupling constants are used much more frequently than carbon–proton coupling constants in structural and stereochemical analysis because of the well developed correlations between the coupling constants and molecular structure in the former case, and the greater ease with which the proton–proton couplings may in general be obtained. However, for many compounds the carbon–proton couplings are easily measured, yet the lack of an extensive background of structural correlations limits their usefulness. Because the major contributing mechanism, the Fermi contact mechanism, is the same for both couplings, attempts have been made to develop correlations between $J_{C,H}$ and $J_{H,H}$ in order that predictions of carbon–proton coupling sizes in particular structures might be made from proton–proton models. In the case of vicinal couplings, parallel behavior of $^3J_{C,H}$ and $^3J_{H,H}$ with respect to dihedral angle is suggested by several investigations which indicate that vicinal carbon–proton couplings have an angular dependence similar to the Karplus relationship found for proton–proton systems (1–3). The conclusions regarding the electronic effect of substituents on $^3J_{C,H}$ seem somewhat more equivocal. Attempts to correlate substituent electronegativity with $^3J_{C,H}$ have led to the conclusion that definite correlations were not easily made but electronegativity effects did not appear to be very important (4, 5). Other results indicate that the electronic effect is quite large (6–8).

A recent report (9) describes the correlation of proton–proton couplings with carbon–proton couplings in analogous compounds in which the proton is replaced by a carboxylic acid group. For the series of 20 pairs of coupling constants, which include ^2J, ^3J, ^4J, and ^5J values, through aliphatic, aromatic, and olefinic systems, a plot of $J_{C,H}$ values against the corresponding $J_{H,H}$ values gave a 'straight line' (correlation coefficient 0.95). Although the average value of the ratio of $J_{C,H}$ to $J_{H,H}$ was 0.76, the ratio of individual pairs of compounds varied between 0.45 and 1.64. It would appear that the use of a simple ratio for predicting $J_{C,H}$ values from $J_{H,H}$ values would not yield reliable results, and that the different stereoelectronic effects of groups on $J_{C,H}$ and $J_{H,H}$ must be taken into account. In this investigation we have attempted to compare the effect of substituent electronegativity on $^3J_{C,H}$ and $^3J_{H,H}$ while as much as possible maintaining other factors constant. For this purpose $^3J_{C,H}$ values have been determined for a series of *tert*-butyl derivatives and compared to $^3J_{H,H}$ values

of the isopropyl analogues. This yields a comparison of a methyl group vs. a proton in identical situations. In each case the observed coupling would be the average of three coupling constants, two *gauche*, ${}^{g}J^{H,X}$ and ${}^{g}J^{H,C}$, and one *anti*, ${}^{a}J$ (Fig. 1).

In order that no factor might be introduced due to conformer population differences, the substituents were restricted to groups with axial symmetry, i.e. the halogens, hydrogen, and the methyl group. The results (Table 1) indicate that the ${}^{3}J_{C,H}$ values follow the trend of the ${}^{3}J_{H,H}$ values, decreasing with increasing electronegativity of the substituent.

Figure 2 shows plots of $J_{C,H}$, $J_{H,H}$, and their ratios against electronegativity, all showing monotonic decreases with increasing electronegativity. A plot of $J_{C,H}$ against $J_{H,H}$ (Fig. 3) gives a straight line (correlation coefficient 0.991) fitting eq. 1.

$$[1] \qquad {}^{3}J_{C,H} = 1.2\,{}^{3}J_{H,H} - 3.5$$

The results indicate a parallel behavior of the carbon–proton and proton–proton couplings toward substituent electronegativity, with the carbon–proton coupling appearing to be slightly more sensitive to the electronegativity effect (Fig. 3, slope = $dJ_{C,H}/dJ_{H,H} = 1.2$). This parallel behavior of the two types of couplings should not be projected to situations in which the substituent is in different positions or orientations relative to the coupled atoms. The electronegativity effect

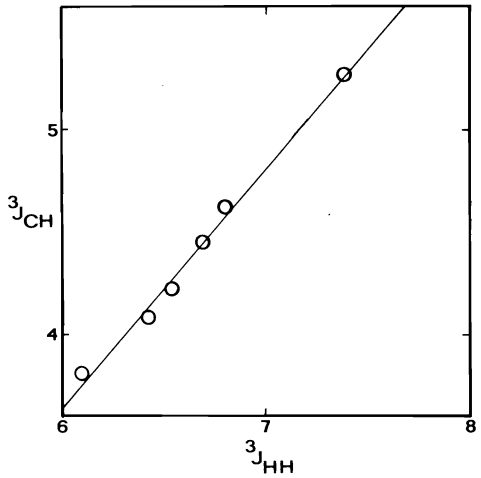

FIG. 3. Plot of vicinal proton–proton coupling constants from isopropyl derivatives against vicinal carbon–proton coupling constants in the *tert*-butyl analogues.

has been shown in the proton–proton case to be greatest when the substituent is *anti* to the proton (11). This effect has not been tested in this investigation since the electronegative substituent has always been *anti* to the proton in the compounds used. Furthermore, it has been reported (4, 8) that when the electronegative substituent is directly attached to the coupled carbon the size of the coupling constant increases with increasing electronegativity, although there seems to be some inconsistency in this trend.

Experimental

The coupling constants were obtained from ^{1}H spectra and natural abundance ^{13}C spectra, determined on a

Varian CFT 20 spectrometer using 65% v/v solutions in deuterochloroform at ambient temperature.

Application de la spectrométrie infrarouge, Raman et résonance magnétique nucléaire à l'étude des complexes en solution aqueuse. Al^{3+}–$H_2C_2O_4$

M. Jaber,[1] F. Bertin et G. Thomas-David

Laboratoire de Chimie Analytique II, Université de Lyon I, 43 boulevard du 11 Novembre 1918 69621 Villeurbanne, France

Reçu le 11 janvier 1977

M. Jaber, F. Bertin et G. Thomas-David. Can. J. Chem. **55**, 3689 (1977).

L'étude par spectrométrie Raman du système Al^{3+}–$H_2C_2O_4$ en solution aqueuse en fonction du degré d'acidité de solutions et du rapport t = [métal]/[coordinat] montre très nettement la formation successive de complexes $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$. La formation de l'espèce $Al(C_2O_4)^+$ qui avait été rejetée par certains auteurs est confirmée ici et l'on peut identifier facilement ses fréquences caractéristiques ainsi que celles de l'espèce $Al(C_2O_4)_2^-$. La rmn de deux noyaux ^{27}Al et ^{13}C confirme ces résultats et permet d'identifier chaque complexe par un signal bien caractéristique. De plus cette étude nous a permis de rejeter l'hypothèse d'une formation de complexes hydroxydés du moins en quantité importante.

Nous avons pu également utiliser les hauteurs de bandes de diffusion Raman aux huit fréquences sélectionnées caractéristiques des espèces $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$ pour déterminer leur distribution en fonction de l'acidité de la solution.

M. Jaber, F. Bertin, and G. Thomas-David. Can. J. Chem. **55**, 3689 (1977).

A study by Raman spectrometry of the system Al^{3+}–$H_2C_2O_4$ in aqueous solution as a function of the acidity of the solution and of the ratio t = [metal]/[ligand] shows very clearly the successive formation of the complexes $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$, and $Al(C_2O_4)_3^{3-}$. The formation of the species $Al(C_2O_4)^+$, which had been rejected by some authors, is confirmed and it was easily possible to identify its characteristic frequencies as well as those of the species $Al(C_2O_4)_2^-$. The ^{27}Al and ^{13}C nmr spectra confirm these results and allow the identification of each complex by means of a clearly characteristic signal. Moreover, the results of this study permit the rejection of the hypothesis of the formation of hydroxylated complexes, at least in important quantities.

It also was possible to use the intensities of the Raman scattering bands at eight selected characteristic frequencies of the species $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$, and $Al(C_2O_4)_3^{3-}$ to determine their distribution as a function of the acidity of the solution.

[Journal translation]

Introduction

Dans un travail antérieur appliqué à l'acide oxalique (1), nous avons mis au point une méthode de détermination des concentrations des différentes espèces en équilibre: $H_2C_2O_4$, $HC_2O_4^-$ et $C_2O_4^{2-}$ en mesurant les hauteurs des bandes Raman caractéristiques de chaque espèce, et nous en avons déduit les constantes de formation de l'acide oxalique. Les résultats obtenus, en bon accord avec ceux de la méthode classique de pH, nous ont convaincu de l'utilité de la spectrométrie Raman pour suivre des équilibres se formant en milieu très acide, là où la potentiométrie ne peut pas donner des renseignements précis.

Nous avons étudié le système $H_2C_2O_4$–Al^{3+} pour lequel certains travaux mettent en évidence la présence de deux complexes seulement: $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$, et donnent des valeurs pour les constantes successives K_2 et K_3 (2) ou globales β_2 et β_3 (3, 4). Dutt et Sur (2) en particulier affirment que le complexe $Al(C_2O_4)^+$ ne se forme pas, la complexation conduisant directement à l'espèce $Al(C_2O_4)_2^-$. Seul Babko et Dubovenko (5) ont mis en évidence par spectrophotométrie d'absorption uv l'existence de trois espèces successives, mais les valeurs obtenues pour K_2 et K_3 diffèrent beaucoup de celles obtenues par Dutt. Enfin signalons que Zolotukhin (4) a remarqué la formation des complexes hydroxydés sans indiquer leur nature.

Devant ce nombre restreint de résultats et leur discordance, nous avons tenté de reprendre l'étude de ce système d'abord par la méthode de pH, mais celle-ci s'avère inadéquate car les complexes se forment en milieu trop acide; la courbe de formation de Bjerrum que nous avons obtenue pour ce système n'est pas exploitable

[1]Boursier du C.N.R.S. Libanais.

(1). Par contre l'évolution, en fonction du pH, des spectres Raman de solutions contenant le coordinat acide oxalique et les ions Al^{3+} permet de suivre les équilibres de formation de complexes et ce sont les résultats de cette étude que nous présentons ici. Jusqu'à présent seul le spectre de diffusion d'une solution aqueuse de $K_3Al(C_2O_4)_3$ a intéressé plusieurs auteurs (6–10, 14).

Parallèlement, nous avons examiné nos solutions par la résonance magnétique nucléaire de deux noyaux ^{27}Al et ^{13}C, afin de dénombrer et de caractériser les espèces en présence. Dans ce domaine, seule la rmn de ^{27}Al a été étudiée par Haraguchi et Fujiwara (11) et Toy et coll. (12); ces auteurs montrent l'existence d'une seule raie attribuée au composé $Al(C_2O_4)_3^{3-}$ mais de déplacement chimique nul par rapport à la raie de l'espèce $Al(H_2O)_6^{3+}$ (11).

Conditions expérimentales

Les solutions étudiées sont de concentration 0.50 M en acide oxalique avec des concentrations en Al^{3+} telles que le rapport (métal)/(coordinat): $t = \frac{1}{6}, \frac{1}{3}, \frac{1}{2}$ et 1. On fixe l'acidité des solutions qui sont absentes de sel de fond par addition de potasse 10 M ou d'acide chlorhydrique Prolabo R.P. L'acidité est exprimée soit par le pH, soit par la concentration équivalente en acide chlorhydrique mesurée par l'intermédiaire d'un potentiomètre Metrohm E 388, au moyen de la chaîne suivante: electrode en verre/solution titrée/NaCl saturé/Hg_2Cl_2–Hg, préalablement étalonnée.

Toutefois la précision sur la mesure du pH est faible compte tenu de la valeur élevée et variable de la force ionique, c'est pourquoi on donne les valeurs du pH à 0.1 unité près.

Le domaine d'étude est limité pour chaque rapport par le début de précipitation de l'hydroxyde d'aluminium: p$H \sim 3.0$ pour $t = 1$, p$H \sim 4$ pour $t = \frac{1}{2}$ et p$H \sim 6.4$ pour $t = \frac{1}{3}$. Dans l'ensemble une cinquantaine de spectres sont enregistrés afin de suivre de façon systématique l'évolution des spectres en fonction de l'acidité donc de la complexation.

Les solutions deutériées aux différentes acidités sont préparées à partir de l'oxalate de sodium et de chlorure d'aluminium, produits Merck, par addition de DCl ~ 7.8 N dont la teneur en D_2O est 99.5%.

Les spectres Raman sont enregistrés à la température ordinaire (20°C) dans un domaine de fréquences compris entre 1800 et 150 cm^{-1} avec un spectromètre Coderg modèle PHO équipé d'un laser à argon ionisé Spectra-physics. La longueur d'onde de la raie excitatrice est de 488 nm. L'échantillon à examiner est contenu dans une petite cuve en verre parallélépipédique de 0.3 ou 1 ml. Les spectres ir sont enregistrés dans un domaine de fréquences compris entre 2000 et 700 cm^{-1} avec un spectromètre Perkin-Elmer 457. L'épaisseur des cellules en Irtran II utilisées est de 27 μm.

Les spectres de rmn, sont enregistrés à la température ordinaire avec le spectromètre Varian XL 100 du centre de rmn (Fédération des Centres Lyonnais de Mesures et d'Analyses) à la fréquence de 25.2 MHz. Pour le ^{13}C, le champ est stabilisé grâce aux noyaux de deutérium de C_6D_6 utilisé également comme référence externe; l'enregistrement est effectué après une accumulation de 10^4 passages environ. Dans l'étude du noyau ^{27}Al, il est impossible d'utiliser la même technique de stabilisation; nous ne disposions pas, d'autre part, de lock externe. Néanmoins, le champ était suffisamment stable pour que les résultats obtenus soient très reproductibles. L'enregistrement est réalisé avec une accumulation de 10^2 passages; la référence est constituée par les ions $Al(H_2O)_6^{3+}$ contenus dans la solution, ou introduits en référence externe (solution de $AlCl_3$ à p$H \sim 0$) quand tous les ions Al^{3+} de la solution étudiée sont complexés.

Résultats de la spectrométrie Raman

L'évolution des spectres Raman en fonction de l'acidité des solutions pour différents rapports [métal]/[coordinat] est présentée dans les tableaux 1 et 2 où sont indiquées les bandes des spectres Raman les plus caractéristiques pour les trois rapports étudiés en donnant les fréquences et leur intensité relative par rapport à la bande de l'eau située à 1640 cm^{-1} (1).

L'observation globale des spectres Raman des solutions d'oxalatoaluminate, pour $t = \frac{1}{3}$, nous permet de distinguer trois domaines principaux (tableau 1).

Au degré d'acidité $[HCl_{eq}] = 4.8$ N le spectre comporte les bandes de l'acide oxalique situées à 456, 590, 848, 1335, 1460 et 1750 cm^{-1} et la bande de l'ion $Al(H_2O)_6^{3+}$ à 523 cm^{-1} (1). Pour $4.8\ N > [HCl_{eq}] > 1.7\ N$, ces bandes diminuent régulièrement en intensité et la formation des complexes se manifeste par l'apparition de bandes intenses situées aux fréquences: 373, 573, 915, 1423, 1698 et 1727 cm^{-1} qui augmentent d'intensité au fur et à mesure de la neutralisation.

Dans l'intervalle suivant jusqu'à p$H \sim 0.5$, les bandes du coordinat continuent à diminuer, celles des complexes situées à 373, 573, 1698 et 1727 cm^{-1} se déplacent progressivement pour atteindre les fréquences 370, 580, 1689 et 1732 cm^{-1} à p$H = 0.4$, tandis que les deux bandes 915 et 1423 cm^{-1} maintiennent leurs positions initiales. Les intensités relatives des bandes se modifient nettement.

Pour les solutions de $0.5 <$ p$H < 2.1$, nous remarquons la diminution d'intensité des bandes dues à $H_2C_2O_4$ et de la bande de $HC_2O_4^-$ apparue à 868 cm^{-1} et qui disparait complète-

ment à pH = 1.4. Les fréquences de vibration des complexes situées à 370, 580, 915, 1423 et 1689 cm^{-1} migrent respectivement vers 369, 583, 918, 1429 et 1686 cm^{-1} avec une modification considérable d'intensité. La bande à 1732 cm^{-1} tend à disparaître et il se forme dans ce domaine de fréquences une bande située à 1746 cm^{-1}; la présence simultanée de ces deux bandes se voit très nettement sur les spectres correspondants aux pH 0.8, 0.9, 1.2 et 1.5. En même temps cinq raies nouvelles situées à 273, 473, 811, 1408 et 1723 cm^{-1} sont observées.

Pour les valeurs du pH > 2.1, les positions et les intensités des bandes restent constantes. Deux raies de très faible intensité dues à l'ion $C_2O_4^{2-}$ en solution (1) apparaissent vers 1308 et 1486 cm^{-1} pour les pH > 5 (le pH varie brusquement par addition de soude de pH 2.3 à 5).

Pour $t = \frac{1}{2}$ (tableau 2), les spectres des solutions d'acidité 4.9 N > $[HCl_{eq}]$ > 1.9 N présentent les bandes déjà observées dans la première étape du rapport $t = \frac{1}{3}$. Les bandes des complexes augmentent d'intensité sans modification des fréquences. Dans l'intervalle $[HCl_{eq}] = 1.9\ N - pH < 0.6$ les bandes de $H_2C_2O_4$ diminuent pour disparaître complètement; celles des complexes qui augmentent d'intensité subissent la même modification importante signalée dans la deuxième étape du rapport $t = \frac{1}{3}$. Et pour des pH > 0.6, les bandes des complexes gardent des fréquences constantes, leurs intensités augmentent légèrement et il apparait une bande supplémentaire à 473 cm^{-1} attribuable aux complexes; enfin juste avant la précipitation de l'hydroxyde d'aluminium on aperçoit deux bandes très faibles situées à 273 et 811 cm^{-1} et deux épaules faibles aussi vers 1408 et 1746 cm^{-1}, intenses sur les spectres du rapport $t = \frac{1}{3}$ à pH > 0.5.

Pour $t = 1$ (tableau 2), les complexes commencent à se former dans un milieu très acide, à une concentration en $[HCl_{eq}] = 4.9\ N$. La neutralisation des solutions entraîne la même évolution observée pour $t = \frac{1}{3}$, dans le domaine 4.8 N > $[HCl_{eq}]$ > 1.7 N et pour $t = \frac{1}{2}$, 4.9 N > $[HCl_{eq}]$ > 1.9 N. Les bandes des complexes augmentent d'intensité sans changer de fréquence sur toute la gamme d'acidité à l'exception de celle à 573 cm^{-1} qui commence à se déplacer légèrement pour $[HCl_{eq}] \sim 1.8\ N$ pour atteindre 577 cm^{-1} à pH 0.2. A cette valeur de pH les bandes dues à $H_2C_2O_4$ et à $Al(H_2O)_6^{3+}$ ont disparu et il n'apparait aucune bande caractéristique de l'ion $HC_2O_4^-$.

Discussion

1. Mise en évidence des espèces $Al(C_2O_4)^+$, $Al(C_2O_4)_2^{2-}$ et $Al(C_2O_4)_3^{3-}$ par spectrométrie Raman

Pour le rapport $t = 1$ quelle que soit l'acidité de la solution, les fréquences observées pour les complexes ont une position constante à l'exception de la bande à 573 cm^{-1} qui se déplace légèrement. Ces mêmes fréquences étant observées pour les rapports $t = \frac{1}{2}$ et $t = \frac{1}{3}$ aux fortes acidités, on peut penser que dans ces domaines le complexe $Al(C_2O_4)^+$ est prépondérant, ses fréquences caractéristiques sont 373, 453, 573, 608, 859, 915, 1278, 1423, 1698 et 1727 cm^{-1}.

Pour le rapport $t = \frac{1}{3}$ à pH > 2.1, les bandes du coordinat ayant complètement disparu, le complexe en solution ne peut être que $Al(C_2O_4)_3^{3-}$ dont les fréquences de vibration caractéristiques sont 273, 369, 473, 583, 608, 811, 859, 918, 1278, 1408, 1429, 1686, 1723 et 1746 cm^{-1}. Notons que ces fréquences sont tout à fait comparables à celles observées pour le complexe $K_3Al(C_2O_4)_3 \cdot 3H_2O$ cristallisé (1). Par contre le déplacement très net de certaines bandes dans l'intervalle $[HCl_{eq}] < 1.7\ N - pH < 0.5$ pour le même rapport caractérise la présence d'une nouvelle espèce vraisemblablement $Al(C_2O_4)_2^-$. En effet une telle modification spectrale n'est pas attribuable à l'existence simultanée des deux espèces $Al(C_2O_4)^+$ et $Al(C_2O_4)_3^{3-}$ car on devrait constater simultanément une migration des deux bandes 915 et 1423 cm^{-1} vers 918 et 1429 cm^{-1}, d'autant plus que ces dernières possèdent des coefficients de diffusion beaucoup plus grands que les premières; de plus l'existence du composé $Al(C_2O_4)_3^{3-}$ doit se manifester par l'apparition des deux bandes fortes situées à 1408 et 1746 cm^{-1} ce qui n'est pas le cas. Les mêmes modifications se produisent pour le rapport $t = \frac{1}{2}$ dans l'intervalle d'acidité $[HCl_{eq}] < 1.9\ N - pH < 0.6$ confirmant une telle attribution. L'existence de deux espèces $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$ en solution pour $t = \frac{1}{3}$ se manifeste à pH = 0.9 par la juxtaposition très nette de deux bandes 1732 et 1746 cm^{-1}. Donc les fréquences de vibration dues à l'espèce $Al(C_2O_4)_2^-$ se situent à 370, 473, 580, 608, 859, 915, 1278, 1423, 1689 et 1732 cm^{-1}.

Il est à noter que dans le cas du rapport $t = 1$, pour les pH élevés, l'espèce $Al(C_2O_4)_2^-$ doit être présente en quantité non négligeable puisqu'on constate un déplacement de fréquence de la bande à 573 cm^{-1} vers 577 cm^{-1}. De même la présence du complexe $Al(C_2O_4)_3^{3-}$ en faible concentration, à des pH élevés dans un rapport $t = \frac{1}{2}$ explique l'apparition des bandes très faibles vers 273, 811, 1408 et 1746 cm^{-1}.

Sur la fig. 1, on donne les spectres des oxalatoaluminates enregistrés dans des conditions telles que chaque complexe est majoritaire. On observe nettement les modifications d'intensité relative des bandes reportée à la même intensité de la bande de l'eau, en passant d'une espèce à une autre. Les tableaux 1 et 2 montrent plus clairement la différence en fréquences.

Le spectre que nous attribuons au complexe $Al(C_2O_4)_3^{3-}$ en solution est très proche de celui obtenu récemment par Vaisserman et Gouteron avec toutefois quelques écarts dans les fréquences et une bande supplémentaire située à 811 cm^{-1} observée également par Murata.

On remarquera que la formation des complexes hydroxydés, si elle existe, ne peut avoir lieu en forte proportion car on devrait sans doute assister à une modification progressive du spectre pour les pH élevés surtout pour les rapports $t = 1$, et $t = \frac{1}{2}$, ce qui n'est pas le cas; de plus la concentration en ion oxalate calculée sur les deux bandes 1308 et 1486 cm^{-1} garde une valeur très faible.

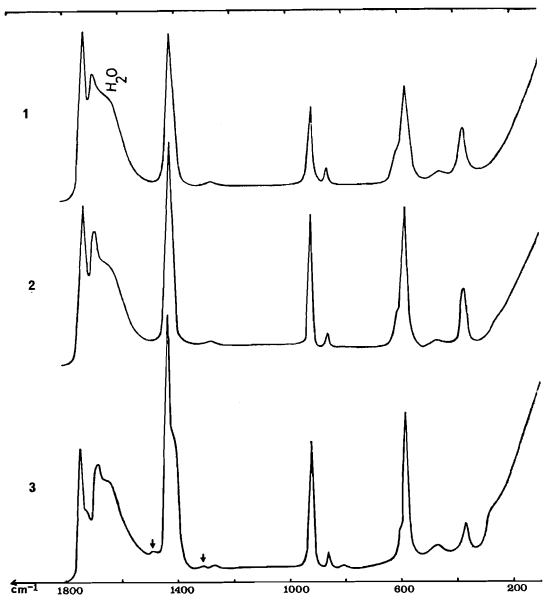

FIG. 1. Spectres Raman des oxalatoaluminates en solution aqueuse. (*1*) $t = 1$, p$H = 2.5$; (*2*) $t = \frac{1}{2}$, p$H = 1$; (*3*) $t = \frac{1}{3}$, p$H = 6.4$. (↓) Bandes de $C_2O_4^{2-}$ en solution.

2. Confirmation apportée par les spectres infrarouge

L'évolution des spectres ir des oxalatoaluminates à différentes acidités nous permet, pour un rapport $t = \frac{1}{3}$, de distinguer deux étapes différentes.

La première caractérise une espèce individuelle prépondérante à p$H > 2.1$ où les bandes du coordinat ont disparu. Puisque la précipitation de l'hydroxyde d'aluminium n'a lieu qu'à p$H \sim 6.4$ les ions Al^{3+} sont complexés et l'espèce ne peut être que $Al(C_2O_4)_3^{3-}$ caractérisée par les fréquences d'absorption ir 810, 825, 912, 1270, 1290, 1405, 1450?, 1690 et 1720 cm^{-1}, qui sont analogues à celles observées pour le complexe $K_3Al(C_2O_4)_3 \cdot 3H_2O$ à l'état cristallisé (7, 9, 14).

La seconde étape s'étend du $[HCl_{eq}] = 4.8\ N$ jusqu'à p$H \sim 0.5$; elle est caractérisée, outre les bandes du coordinat libre, par les fréquences 820, 912, 1280, 1415, 1440?, 1695 et 1725 cm^{-1}; ces fréquences sont observées aussi pour le rapport $t = 1$ sur toute la gamme d'acidité étudiée, elles correspondent donc au complexe $Al(C_2O_4)^+$, par analogie aux résultats de la spectrométrie Raman.

Les spectres ir ne subissent pratiquement pas des modifications résultant du passage de l'espèce $Al(C_2O_4)^+$ à $Al(C_2O_4)_2^-$. D'ailleurs pour le rapport $t = \frac{1}{2}$ à p$H \sim 3$ le spectre est analogue à celui du rapport $t = 1$, à ceci près qu'il présente deux bandes à 1720 et 810 cm^{-1} dues à la présence d'une quantité importante de complexe $Al(C_2O_4)_3^{3-}$ (1).

3. Confirmation obtenue par résonance magnétique nucléaire des noyaux ^{27}Al et ^{13}C

3.1. Résonance magnétique nucléaire du ^{27}Al

Les résultats obtenus sont schématisés sur la fig. 2. Pour les deux rapports $t = \frac{1}{3}$ et $t = \frac{1}{6}$ à pH 5, un seul signal symétrique est obtenu (*a*); il est caractéristique du composé $Al(C_2O_4)_3^{3-}$ et se situe à 405 Hz du signal de $Al(H_2O)_6^{3+}$ pris comme référence. Pour le rapport $t = 1$ et une acidité $[HCl_{eq}] \sim 1.5\ N$, le spectre comporte aussi un seul signal large, symétrique (*d*) situé à 160 Hz de la référence; quand on neutralise la solution par la potasse, ce signal s'éloigne de la

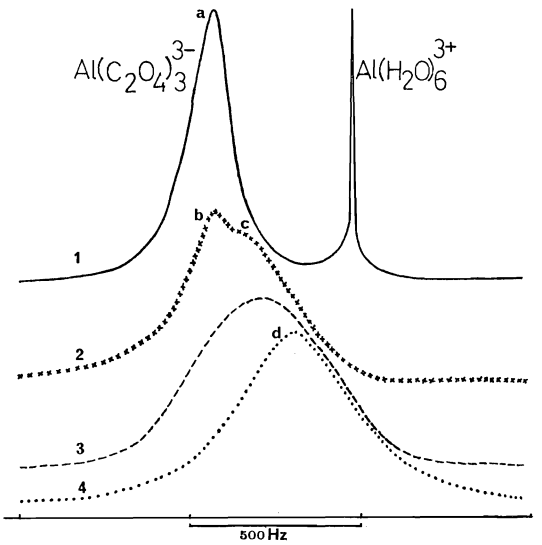

FIG. 2. Spectres rmn du noyau ^{27}Al des oxalatoaluminates à différentes acidités et pour différents rapports. (*1*) $t = \frac{1}{3}$, p$H = 5$; (*2*) $t = \frac{1}{2}$, p$H = 2$; (*3*) $t = \frac{1}{2}$, p$H =$ 0.1; (*4*) $t = 1$, p$H \sim 0$.

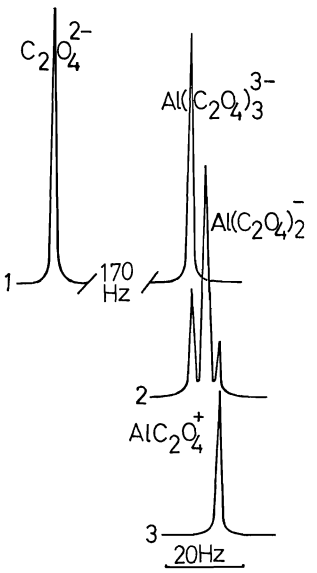

FIG. 3. Spectres rmn du noyau ^{13}C des oxalatoaluminates en solution. (*1*) $t = \frac{1}{6}$, p$H = 6$; (*2*) $t = \frac{1}{2}$, p$H = 3$; (*3*) $t = 1$, p$H \sim 0.1$.

référence tout en gardant sa symétrie sur toute la gamme d'acidité.

L'étude systématique du rapport $t = \frac{1}{2}$ en fonction du degré d'acidité conduit en milieu très acide aux mêmes résultats que ceux obtenus pour le rapport $t = 1$. L'augmentation du pH entraîne un déplacement régulier du signal sans changement de symétrie (exemple: courbe *3*) puis on observe dans l'intervalle $0.6 <$ p$H <$ 4 un dédoublement de la raie: une des deux raies se trouve à la fréquence caractéristique de $Al(C_2O_4)_3^{3-}$ (405 Hz) (*b*); la deuxième (*c*) qui se trouve à environ 330 Hz de la référence est due très probablement à l'espèce $Al(C_2O_4)_2^{-}$; il semble que la raie large observée aux fréquences intermédiaires résulte de l'échange des noyaux ^{27}Al entre les deux espèces $Al(C_2O_4)^{+}$ et $Al(C_2O_4)_2^{-}$ dont les concentrations relatives varient avec le pH.

3.2. Résonance magnétique nucléaire du ^{13}C

On donne sur la fig. 3 certains spectres caractéristiques. Pour le rapport $t = \frac{1}{6}$ à p$H \sim 5$, les spectres rmn comportent deux signaux de même intensité, l'un caractéristique de $C_2O_4^{2-}$, présent en excès, à 1170 Hz l'autre situé à 970 Hz est attribué à $Al(C_2O_4)_3^{3-}$. Pour le rapport $t = \frac{1}{3}$ on observe seulement le signal dû à $Al(C_2O_4)_3^{3-}$; ceci implique que tous les carbones de ce composé résonnent à la même fréquence.

Pour un rapport $t = 1$ à $[HCl_{eq}] = 1.5\ N$, on observe un seul pic situé à 965 Hz, qui ne peut être dû qu'à l'espèce $Al(C_2O_4)^{+}$. Pour un rapport $t = \frac{1}{2}$ à p$H \sim 3$, le spectre présente trois signaux voisins, les deux extrêmes se trouvent aux fréquences caractéristiques des espèces $Al(C_2O_4)^{+}$ et $Al(C_2O_4)_3^{3-}$, le troisième situé au milieu (967 Hz), le plus intense est certainement dû à $Al(C_2O_4)_2^{-}$ en solution. Cette attribution est confirmée par les variations d'intensité relative des trois raies en fonction du pH sur le même rapport. Plusieurs spectres d'un même échantillon enregistrés en faisant varier le temps d'acquisition et le temps d'attente entre deux passages montrent que les phénomènes de relaxation n'influencent pratiquement pas les intensités relatives des trois pics.

Les résultats de la rmn de deux noyaux ^{27}Al et ^{13}C recoupent ceux que nous avions observés par spectrométrie Raman; mais l'interférence des pics et la faible différence des déplacements chimiques, 2 et 3 Hz, ne permettent pas une mesure directe des concentrations en espèces.

4. Méthode de détermination des concentrations, par spectrométrie Raman, des différents complexes formés

4.1. Choix des bandes

Après avoir mis en évidence par Raman et rmn la présence de trois espèces en solution et identifié les bandes de diffusion propres à

chacune, nous tentons d'exploiter les hauteurs de ces bandes pour déterminer la concentration des oxalatoaluminates complexes; cette exploitation est d'autant plus difficile que ces espèces sont simultanément présentes en solution et que les bandes interfèrent entre elles.

Pour déterminer la concentration de deux espèces $H_2C_2O_4$ et $HC_2O_4^-$ on utilise la hauteur des bandes à 848 et 868 cm^{-1} caractéristiques de ces espèces et qui sont peu influencées par la bande très faible des complexes, située à 859 cm^{-1}; les deux bandes 1308 et 1486 cm^{-1} sont utilisées pour calculer $[C_2O_4^{2-}]$.

Pour calculer la concentration des trois complexes $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$ on peut utiliser les hauteurs des bandes aux fréquences 369, 373, 573, 583, 915, 918, 1423 et 1429 cm^{-1} qui n'interfèrent pas avec les fréquences de vibration propres au coordinat, en particulier les deux dernières bandes ne sont certainement pas influencées par le triplet 1380–1410–1444 cm^{-1}, dû à $HC_2O_4^-$: l'intensité de ce triplet doit en effet être très faible puisque la bande à 868 cm^{-1} caractéristique de cette même espèce et dont le coefficient de diffusion est trois fois supérieur à celui du triplet (1) n'est visible que pour un rapport $t = \frac{1}{3}$ et dans un domaine de pH étroit.

Pour tous les calculs, la bande de l'eau est utilisée comme étalon interne, dans les mêmes conditions que précédemment (1).

4.2. Principe de la méthode de calcul des concentrations

Les symboles utilisés ont la signification suivante: X, Y et Z sont respectivement les concentrations de $H_2C_2O_4$, $HC_2O_4^-$ et $C_2O_4^{2-}$; A_ν, B_ν et C_ν sont les coefficients de diffusion respectifs à la fréquence ν, déterminés dans un travail antérieur (1). P, Q et R sont les concentrations de $Al(C_2O_4)^+$, $Al(C_2O_4)_2^-$ et $Al(C_2O_4)_3^{3-}$, D_ν, E_ν et F_ν leurs coefficients de diffusion (paragraphe 4.3). h_ν représente à la fréquence ν l'intensité relative, par rapport à la bande de l'eau 1640 cm^{-1}, d'une bande qui peut être due à la contribution de plusieurs espèces. C_L et C_M sont respectivement les concentrations analytiques du ligand et du métal en solution.

Le principe de la méthode de calcul est le suivant: les bandes 848, 868, 1308 et 1486 cm^{-1} permettent de déterminer la concentration du coordinat libre selon les relations:

$$[1] \quad h_{848} = XA_{848} + YB_{848}$$

$$[2] \quad h_{868} = XA_{868} + YB_{868}$$

$$[3] \quad h_{1308} = ZC_{1308}; \quad h_{1486} = ZC_{1486}$$

Les relations de bilan pour le coordinat et le métal sont:

$$[4] \quad C_L = X + Y + Z + P + 2Q + 3R$$

$$[5] \quad C_M = [Al^{3+}] + P + Q + R$$

Etant donné l'interférence des bandes de diffusion dues aux trois complexes pour chacune des huit fréquences sélectionnées, on peut écrire huit relations du type:

$$[6] \quad h_\nu = PD_\nu + QE_\nu + RF_\nu$$

Ayant déterminé de proche en proche les coefficients de diffusion D_ν, E_ν, et F_ν un programme intitulé SPECTRAL, analogue au programme SPECTRAM (1) utilisé précédemment, permet de calculer par moindres carrés les concentrations optimales P, Q et R.

4.3. Calcul des coefficients de diffusion D_ν, E_ν et F_ν à différentes fréquences

On se place d'abord dans des conditions telles que $Al(C_2O_4)^+$ est le seul complexe présent en solution, ceci est réalisé pour les différents rapports t en milieu suffisamment acide. Les relations 1 et 2 donnent facilement le bilan du coordinat non engagé et par conséquent la valeur de P, d'après l'éq. 4. D_ν est ensuite calculé suivant la relation 6. Les résultats obtenus sont rassemblés dans le tableau 3.

On utilise ensuite les spectres obtenus dans un rapport stoechiométrique $t = \frac{1}{3}$ et dans un domaine de pH élevé, compris entre 2.5 et 6.4 où la formation du complexe $Al(C_2O_4)_3^{3-}$ est pratiquement totale, les bandes dues aux complexes gardent une intensité pratiquement constante; les bandes à 1308 et 1486 cm^{-1} du coordinat libre donnent une estimation de $Z \sim 0.01$ M soit 2% de C_L. Etant donné la grande stabilité du trioxalatoaluminate, on peut considérer P et $[Al^{3+}]$ comme pratiquement nulles et les éqs 4 et 5 entraînent:

$$R = C_M - Z; \quad Q = Z$$

Si de plus on néglige, en première approximation, l'influence du complexe $Al(C_2O_4)_2^-$ on peut calculer directement les différents co-

efficients F_v, par la relation 6 en mesurant les hauteurs relatives h_v sur les spectres.

L'utilisation de ces valeurs approchées de F_v permet d'estimer la valeur des E_v dont le calcul précis est difficile car il est impossible d'isoler un domaine d'acidité où l'espèce $Al(C_2O_4)_2^-$ est seule. Pour le rapport $t = \frac{1}{3}$ et dans un domaine de $0.1 < pH < 0.5$ nous pouvons considérer que $[Al^{3+}]$ et P sont nulles. En appliquant les relations 1 et 2 on détermine $(X + Y)$; les relations 4 et 5 donnent Q et R et par conséquent E_v d'après la relation 6 en utilisant les coefficients F_v approchés. Ces premières valeurs de E_v permettent de corriger les résultats obtenus pour F_v en tenant compte de la présence du complexe $Al(C_2O_4)_2^-$. Les résultats définitifs pour F_v sont présentés dans le tableau 4 et permettent de recalculer les valeurs de E_v.

A titre de vérification nous avons également déterminé E_v en nous plaçant dans un rapport $t = \frac{1}{2}$ et dans un domaine de $0 < pH < 0.5$ conditions dans lesquelles nous pouvons supposer que $[Al^{3+}]$ et R sont négligeables; seules P et Q sont prépondérantes; D_v étant donné.

Le tableau 5 résume toutes les valeurs obtenues pour E_v à différents pH et dans les deux rapports.

L'examen des tableaux montre que les coefficients D_v, E_v et F_v sont bien caractéristiques des différentes espèces aux huit fréquences

TABLEAU 6. Constantes de stabilité des oxalates complexes d'aluminium(III)

Auteurs	Log K_1	Log K_2	Log K_3	Log β_2	Log β_3	Methode
Lacroix (3)				13	16.3	Solubilité
Babko et Dubovenko (5)	7.26	4.85	1.31			Spectrométrie uv
Dutt et Sur (2)		5.45	3.69			Potentiométrie
Zolotukhin (4)				13	16.79	Fluorimétrie
Nos valeurs (1)	6.1±0.2	5.0±0.1	3.87±0.06	11.1	15.0	Potentiométrie
	7.3	6.0	3.87	13.3	17.2	Spectrométrie Raman

choisies. La déviation moyenne rend compte de l'imprécision sur la mesure des hauteurs de bandes des complexes et du coordinat libre (bandes 848 et 868 cm^{-1}).

4.4. Détermination des concentrations des complexes, répartition des différentes espèces en fonction du degré d'acidité de la solution et calcul des constantes de stabilité

Connaissant les coefficients de diffusion de trois espèces aux huit fréquences sélectionnées, nous avons, à l'aide du programme SPECTRAL, utilisant les concentrations du coordinat engagé et les hauteurs des bandes aux fréquences choisies, calculé la concentration optimale des espèces présentes en solution et déterminé l'écart quadratique sur chaque concentration. Les concentrations ainsi obtenues pour les rapports $t = \frac{1}{2}$ et $t = \frac{1}{3}$ sont présentées dans la fig. 4 en fonction du pH ou [HCl_{eq}].

Enfin ces valeurs de P, Q et R obtenues pour les rapports $t = 1$, $\frac{1}{2}$ et $\frac{1}{3}$ sont utilisées pour déterminer les valeurs optimales des constantes des équilibres de formation des complexes:

$$Al^{3+} + C_2O_4^{2-} \rightleftarrows Al(C_2O_4)^+ \qquad \beta_1$$

$$Al^{3+} + 2C_2O_4^{2-} \rightleftarrows Al(C_2O_4)_2^- \qquad \beta_2$$

$$Al^{3+} + 3C_2O_4^{2-} \rightleftarrows Al(C_2O_4)_3^{3-} \qquad \beta_3$$

L'affinement par moindres carrés est réalisé à l'aide d'un programme intitulé AFFIBETA, variante du programme AFFIPLNE mis au point ultérieurement (13). AFFIBETA est construit en remplaçant la fonction $\bar{n} = f(pH)$ du programme AFFIPLNE par les paramètres P, Q et R exprimés en fonction du pH et en utilisant les dérivées $\partial P/\partial\beta_1$, $\partial Q/\partial\beta_2$ et $\partial R/\partial\beta_3$ au lieu de $\partial\bar{n}_i/\partial K_j$.

L'affinement est effectué à partir de 17 points expérimentaux situés dans un domaine de p$H > 0.5$. Une variation de 0.2 unité sur la valeur numérique du pH n'a pas d'influence sensible sur la valeur des constantes:

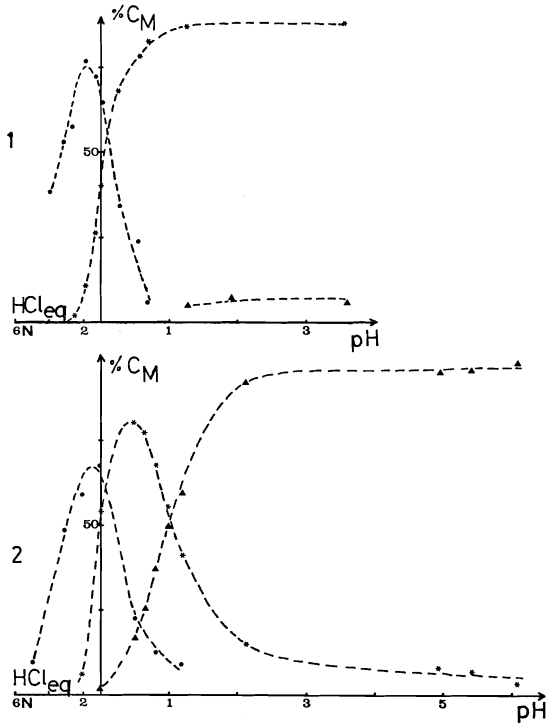

FIG. 4. Courbes de répartition de l'aluminium engagé dans chaque complexe par rapport à la concentration analytique C_M pour (*1*) $t = \frac{1}{2}$ et (*2*) $t = \frac{1}{3}$. (●) $AlC_2O_4^+$; (*) $Al(C_2O_4)_2^-$; (▲) $Al(C_2O_4)_3^{3-}$.

$$\beta_1 = 1.15 \times 10^7 \quad \beta_2 = 3.11 \times 10^{13} \quad \beta_3 = 3.37 \times 10^{17}$$

soit:

$$K_1 = 1.15 \times 10^7 \quad K_2 = 2.70 \times 10^6 \quad K_3 = 1.08 \times 10^4$$

Les constantes ont été utilisées pour tracer la courbe de répartition des complexes par le programme CALCON; on a constaté alors que pour les p$H < 0.5$ les points expérimentaux ne sont pas placés exactement sur cette courbe calculée; ceci est dû certainement au domaine étroite du

pH utilisé pour l'affinement. C'est pourquoi nous avons tenté de calculer une série de courbes de répartition en modifiant les valeurs des constantes successives K_1 et K_2, K_3 étant maintenue à la valeur précise obtenue par la méthode du pH ($K_3 = 7.53 \times 10^3$) de façon à obtenir la meilleure concordance possible entre les concentrations expérimentales et les courbes calculées. Les valeurs ainsi obtenues sont données dans le tableau 6 ainsi que celles déterminées par différents auteurs.

Additivity schemes permitting the estimation of partial molar heat capacities of organic compounds in aqueous solution

J. PETER GUTHRIE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 9, 1977

J. PETER GUTHRIE. Can. J. Chem. **55**, 3700 (1977).

The available $\bar{C}_{p_2}$ values for neutral organic compounds in aqueous solution can be fitted with useful precision by additivity schemes based on atomic, bond, or group contributions. For the set of 132 compounds these schemes require 11, 14, or 49 parameters and give weighted average deviations of 14, 9, or 6 J K^{-1} mol^{-1}. For acyclic molecules the atomic contributions scheme permits chemically useful estimates of $\bar{C}_{p_2}$ to be made for compounds of C, H, O, and N.

J. PETER GUTHRIE. Can. J. Chem. **55**, 3700 (1977).

Les données disponibles pour les valeurs de $\bar{C}_{p_2}$ de composés organiques neutres en solution aqueuse peuvent être ajustées avec une bonne précision grâce à des schémas d'additivité basés sur des contributions atomiques, de liaison et de groupe. Pour une série de 132 composés, ces schémas demandent 11, 14 ou 49 paramètres et conduisent à des écarts de moyenne pondérée de 14, 9 ou 6 J K^{-1} mol^{-1}. Pour des molécules acycliques, le schéma des contributions atomiques permet d'établir une bonne évaluation chimique des valeurs $\bar{C}_{p_2}$ qui peut être appliquée aux composés contenant les atomes C, H, O et N.

Introduction

In the course of another investigation a need was found for free energies of transfer from gas to solution for some small, water miscible organic compounds. Although free energies of transfer are readily determined for sparingly soluble compounds, the determination becomes more difficult for very soluble materials. Experimental activity coefficient data (equivalent to free energies of transfer) are frequently available at the boiling point, so that it would be advantageous to be able to correct these data to room temperature. Since the temperature difference is considerable, and the change in heat capacity from gas to aqueous solution is large (1), one may not assume that the enthalpy of transfer is temperature independent. Provided that heats of solution and vaporization were available, the remaining requirement if free energies at 25°C were to be calculated from data at higher temperatures was that a value for the change in heat capacity from gas to aqueous solution be available.

In the past decade there has been a marked increase in the quantity and quality of heat capacity determinations for aqueous solutes (2–10). Nevertheless, the number of compounds for which data are available is small compared to the number which might be studied. Benson *et al.* (11) have shown that heat capacities of gaseous molecules can be estimated quite successfully by various additivity schemes, and has reported tables of parameters for atom, bond, and group contributions (11, 12); this procedure has recently been extended to liquid hydrocarbons (13). It seemed worthwhile to investigate whether, and to what extent, such estimation procedures could be applied to partial molar heat capacities for solutes in water.

Several authors (4–6, 8–10) have considered the question of additivity of group contributions and Wadso and co-workers (10) in particular have analyzed their data in this way. All schemes published to date are, however, very limited in their range of applicability.

We wish to report here that partial molar heat capacities in aqueous solution, $\bar{C}_{p_2}$, can be estimated quite well using the atom, bond, or group contributions schemes (with increasing precision as one goes from atom contributions to group contributions), and in particular that estimates of useful reliability can be obtained using atom contributions. In the course of this investigation several additional $\bar{C}_{p_2}$ values were evaluated by analysis of published data.

Calculational Methods

Heat Capacities From Activity Data

Literature data (5, 14) in the form of ln (p/c) were fitted (16) to the equation

[1]Alfred P. Sloan Fellow, 1975–1977.

$$\ln\left(\frac{p}{c}\right) = -\frac{\Delta G_\theta{}^0}{R\theta} + \frac{\Delta H_\theta{}^0}{R}\left(\frac{1}{\theta} - \frac{1}{T}\right) + \frac{\Delta C_{p\theta}{}^0}{R}\left(\frac{\theta}{T} - 1 + \ln\frac{T}{\theta}\right)$$

(where θ is the reference temperature, here 298 K) by means of a nonlinear least squares (17) program. $C_p{}^0$(g) was estimated by Benson's group contributions method (12*a*) where experimental values were not available. Although this treatment permitted the evaluation of $\bar{C}_{p_2}$ values for several ketones, the values are of low precision. There is a clear need for more measurements on different carbonyl compounds.

Heat Capacities of Benzoic Acids

Partial molal heat capacities of sodium benzoate, sodium *m*-hydroxybenzoate, and sodium *p*-hydroxybenzoate have been reported (4). The corresponding $\bar{C}_{p_2}$ values for the carboxylic acids may be calculated using values of ΔC_p for ionization (18), and the $\bar{C}_{p_2}$ values for Na^+ and H^+ (19). Because of the indirect way these were calculated, and the necessity for using ΔC_p of ionization values derived as second derivatives from equilibrium data, the $\bar{C}_{p_2}$ values for benzoic acid were assigned an estimated precision of ± 25 J K^{-1} mol^{-1}.

Determination of Parameter Values

The $\bar{C}_{p_2}$ data were fitted to the equation

$$\bar{C}_{p_2 j} = \sum_i A_i X_{ij}$$

where A_i is the parameter for the *i*th structural feature and X_{ij} is the number of times the *i*th structural feature appears in compound *j*, by means of a least squares program. Initially the full set of data was employed, and then the set was restricted so that only parameters defined by three or more compounds were included. For the bond and group contributions, the set was further restricted by eliminating compounds for which calculated and observed values differed markedly. Compounds which were not included in the least squares fitting are indicated in Table 1.

The remaining parameters were evaluated for each scheme by taking the parameters determined by least squares as given and fitting the remaining compounds, one parameter at a time. As far as possible values for parameters determined this way were calculated from the set of compounds for which the new parameter was the only one needed besides the set already determined. Since the parameter values which were not determined by least squares are based upon small numbers of compounds they can only be regarded as provisional.

Results and Discussion

Atomic Contributions

The $\bar{C}_{p_2}$ data employed comprise a set of 132 compounds (see Table 1).[2] For the atomic contributions approach, different parameters were employed for H bonded to C, to O, or to N, and atoms were classed as to hybridization state. The rationale for this approach is that $\bar{C}_{p_2}$ contains a large contribution reflecting the interaction of water with the solute, or the effect of solute upon the organization of water molecules (10, 20). Thus it seemed important to choose parameters in a way which reflected the ability of groups to hydrogen bond to water; this leads to a larger set of parameters than Benson employed for gaseous molecules. This scheme seems justified because the different parameters for a given atom were assigned different value by the least square program. Thus H_C is 75 ± 3 while H_O is 60 ± 3 and H_N is 64 ± 3. Similarly C_4 is -68 ± 7 while C_3 is -14 ± 3 (all in J K^{-1} mol^{-1}).

Strictly speaking benzene ring carbons should be treated separately since, as will be seen below, cyclization normally leads to a significant change in $\bar{C}_{p_2}{}^0$. Initially, following Benson (11), C_B was used as a distinct parameter, incorporating one sixth of the cyclization effect. However C_B and C_3 (the parameter for an ethylenic or other sp_2 hybridized carbon) were indistinguishable and so in the final least squares calculation all sp_2 carbons were treated alike. For saturated cyclic molecules the fit was markedly poorer than for the acyclic compounds, so that the cyclic compounds were omitted from the least squares calculations. The fit was somewhat improved by the addition of parameters for five- or six-membered rings, but these parameters were ill defined and the fit remained poor. No obvious way to improve the fit with a small increase in the number of parameters presented itself.

For acyclic compounds or benzene derivatives the fit is really quite good, with a weighted average deviation (calculated as $(\Sigma(\bar{C}_{p_2}\text{(obs.)} - \bar{C}_{p_2}\text{(calc.)})^2/(\sigma\bar{c}_{p_2}\text{(obs.)})^2/(\text{degrees of freedom}))^{1/2}$)

[2]A few additional compounds containing new structural features (such as triple bonds (2) or seven-membered rings (21)) were not included in order to avoid introducing still more parameters.

[a]Reference 10 collects data from many sources; for compounds included in ref. 10 individual references are made only where one of several reported values was chosen as best and used for regression analysis.
[b]J deg^{-1} mol^{-1}.
[c]Uncertainty in the experimental value.
[d]Difference, observed − calculated.
[e]Average of two reported values; σ is |value-average|.
[f]Determined by least squares analysis of solubility data from the references cited.
[g]No indication of experimental error was given in the original reference.
[h]Calculated from $\bar{C}_{p_2}$ for the sodium salt (4), $\bar{C}_{p_2}$ for Na^+ and H^+ (19), and $\Delta\bar{C}_p$ for ionization of the acid (18).
[i]Not included in the regression analysis.
[j]This compound contains a unique group.

equal to 10.7 J K^{-1} mol^{-1} or 2.6 cal K^{-1} mol^{-1}. In terms of the precision commonly attainable experimentally this is really quite good, and in terms of the original motivation for this investigation, namely to allow extrapolation of data at 100°C to 25°C, it is more than adequate. Error analysis shows that the contribution of uncertainties in ΔC_p to uncertainties in ΔG_θ is

$$\theta\left|\frac{\theta}{T}-1+\ln\frac{T}{\theta}\right|\sigma_{\Delta C_p}$$

For $\theta = 298$, $T = 373$ K; this amounts to $7.0 \times \sigma_{\Delta C_p}$ (in kcal mol^{-1}), so that for errors in ΔC_p to contribute less than 0.1 kcal to the error in ΔG, $\sigma_{\Delta C_p}$ must be less than 4 cal K^{-1} mol^{-1}, a condition which is easily satisfied by the atomic contributions estimates.

In Table 1 may be found calculated values of $\bar{C}_{p_2}$ for all compounds used in this study as well as the differences between observed and calculated values; the parameters are given in Table 2.

Bond Contributions

For this approach the parameters were chosen in the manner employed by Benson and Buss (11) with C═O treated as a bivalent atom, C═C treated as a tetravalent atom (so that C_d—X includes a contribution for the carbon–carbon double bond) and a benzene ring treated as a hexavalent atom (so that C_B—X includes a contribution for the ring). The least squares analysis included 102 compounds and 12 parameters, with a weighted average deviation of 8 J K^{-1} mol^{-1}. The compounds containing ethylenic bonds were omitted from this cal-

TABLE 2. Atomic contributions to $\bar{C}_{p_2}$

Atom[a]	Parameter value (J K^{-1} mol^{-1})	Atom[a]	Parameter value (J K^{-1} mol^{-1})
H_C	75(3)	N_2	−80(4)
H_O	60(3)	O_2	−42(4)
H_N	64(3)	O_1	−12(4)
C_4	−68(7)	Five-membered ring	70(47)
C_3	−14(3)	Six-membered ring	31(41)
N_3	−119(8)		

[a]H_C is hydrogen bonded to carbon; H_O is hydrogen bonded to oxygen, H_N is hydrogen bonded to nitrogen; C_4 is tetracoordinate (sp^3) carbon, etc.; N_3 is tricoordinate (sp^3) nitrogen, etc.; O_2 is dicoordinate (sp^3) oxygen, etc.

TABLE 3. Bond contributions to $\bar{C}_{p_2}$

Bond[a]	Parameter value (J K^{-1} mol^{-1})	Bond[a]	Parameter value (J K^{-1} mol^{-1})
C—H	60(1)	CO—C	−60(2)
C—C	−35(2)	CO—C_B	20(16)[b]
C_B—H	60(6)	CO—O	14(2)
C_B—C	−37(32)	N—H	26(1)
C_d—H	61[b]	C—N	−64(2)
C_d—C	11(40)[b]	CO—N	−11(2)
O—H	36(4)	C_B—N	−45[b]
C—O	−44(4)	Five-membered ring	44(25)[b]
C_B—O	−24(14)[b]	Six-membered ring	17(35)[b]
CO—H	43(3)		

[a]C_B represents a benzene ring carbon: the ring is treated as a hexavalent atom; C represents an ethylenic carbon; the double bond is treated as a tetravalent atom; CO is treated as a divalent atom.
[b]Not fitted in the regression analysis.

culation because the parameters involved (C_d—H and C_d—C) were not well determined by the data, as were compounds containing C_B—O or C_B—N bonds, and all saturated cyclic compounds. The remaining parameters were calculated separately, taking the parameters determined by least squares as given. The ring compounds were not satisfactorily treated at the bond level of approximation, although corrections for five- or six-membered rings improved the fit; the parameters are given in Table 3.

Group Contributions

This approach requires a much larger set of parameters, and consequently a much larger data base if they are to be evaluated. When the condition was imposed that each parameter be determined by at least three compounds, only 12 parameters could be evaluated by least squares, from a set of 48 compounds. For this set the weighted standard deviation of calculated from observed values was 6 J K^{-1} mol^{-1}. The remaining parameters were evaluated (to give preliminary values) by taking the well determined set of 12 as given, and calculating the value required to fit a compound with one more parameter. This allowed a further 9 parameters to be determined. Then the process was repeated taking the 21 parameters as given to determine the final set of 28 parameters. When ring contributions were calculated as before there remained serious discrepancies between observed and calculated values. This situation could be considerably improved by introducing a 'ring parameter', and a 'heteroatom-in-ring parameter' for each of five- and six-membered rings. By using these four parameters, the cyclic compounds could be fitted about as well as the acyclic compounds. Clearly $\bar{C}_{p_2}$ for a cyclic molecule is much more sensitive to subtle steric efforts and solvation interactions than is $\bar{C}_{p_2}$ for an acyclic molecule, since the latter is satisfactorily fitted even by atomic contributions, whereas the former requires that the degree of substitution of each atom be taken into account, *and* that the presence of a heteroatom in a ring, rather than in a side chain, be explicitly allowed for. At the earlier levels of approximation the various contributions to $\bar{C}_{p_2}$ for cyclic compounds were not taken account of in a way which permitted any improvement when the presence or absence of heteroatoms in the rings was included as a parameter.

Several groups are specified by only one compound; such groups have been included in Table 4 only when $\bar{C}_{p_2}$ for the compound is reasonably precise, i.e. probably known to within less than 20 J K^{-1} mol^{-1}.

For the full set of 132 compounds for which $\bar{C}_{p_2}$ values were available, the atomic contributions scheme required 11 parameters to give a weighted average deviation of 14 J K^{-1} mol^{-1}; the bond contributions scheme required 19 parameters to give a weighted average deviation of 9 J K^{-1} mol^{-1}; and the group contributions scheme required 49 parameters to give a weighted average deviation of 6 J K^{-1} mol^{-1}. Although the group contributions scheme is superior, it requires a dramatically larger set of parameters, and is only markedly superior for ring compounds.

TABLE 4. Group contributions to $\bar{C}_{p_2}$

Group[a]	Parameter value (J K^{-1} mol^{-1})	Group[a]	Parameter value (J K^{-1} mol^{-1})
$CH_3(X)$	162(2)[b]	CO(O)(C)	−99[c]
$CH_2(C)_2$	84(1)[b]	$CH_2(C)(CO)$	90(8)
$CH(C)_3$	7(4)	$CH(C)_2(CO)$	14(7)
$C(C)_4$	−78(5)[b]	$C(C)_3(CO)$	−103(30)
CdH_2	122[c]	$CO(C)_2$	−83[c]
CdH(C)	6[c]	$C_B(CO)$ + $CO(O)(C_B)$	−41(16)
$CH_2(C)(C_d)$	150(25)	$NH_2(C)$	−5(4)[b]
C_BH	60(6)[b]	$NH(C)_2$	−32(5)[b]
$C_B(C)$	−33(3)[b]	$N(C)_3$	−129(35)
$CH_2(C)(C_B)$	87(24)[b]	$CH_2(C)(N)$	94(4)[b]
OH(C)	−4(5)[b]	$CH(C)_2(N)$	23[c]
$CH_2(C)(O)$	101(4)[b]	$C(C)_3(N)$	−50(29)
$CH(C)_2(O)$	65(28)	$NH_2(C_B)$ + $C_B(N)$	7[c]
$C(C)_3(O)$	−10(8)	$NH_2(CO)$	96[c]
O(C)	−76(6)[b]	NH(C)(CO)	18[c]
$CH_2(O)_2$	174[c]	$N(C)_2(CO)$	−68(9)
$CH_2(O)(C_d)$	233[c]	CO(C)(N)	−90(6)
$OH(C_B)$	−4(5)[d]	$CO(N)_2$	−95(9)
$CH_2(O)(C_B)$	134[c]	Five-membered ring	91[c]
$C_B(O)$	15(3)	Six-membered ring	32(17)
$O(C)(C_B)$	−46[c]	Heteroation in five-membered ring	−70(27)
HCO(Y)	−16[c]	Heteroation in six-membered ring	−34(10)
OH(CO)	112[c]		

[a]This list does not include several groups for which only one $C_{p_2}^0$ value of low precision is available. Following Benson (12) and Hine (25), $CH_3(X)$ has been assigned the same value for all X; C, C_d, C_B, O, N, CO; similarly HCO(Y) has been assigned the same value for all Y; C, O, N. The number in parentheses is the estimated standard deviation of the parameter, where this could be estimated.
[b]Determined by least squares analysis.
[c]Based on only one compound for which this was the new contribution.
[d]$OH(C_B)$ was assigned the same value as OH(C).

Conclusions

It appears clear from the results reported above that for acyclic compounds $\bar{C}_{p_2}$ can be estimated with a precision which is not only good enough to be useful, but competitive with all but the best experimental determinations. As reliable data for more classes of compounds become available it will be possible progressively to replace the atomic by the bond and finally the group contributions schemes. At present it will most often be necessary to employ the atomic contributions scheme to estimate an unknown $\bar{C}_{p_2}$ value because the higher order schemes lack parameter values.

Pyridine nitrosazones and their cobalt(III) chelates

AHMAD SAMI SHAWALI[1] AND IKHLASS M. ABBASS
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

Received May 3, 1977

AHMAD SAMI SHAWALI and IKHLASS M. ABBASS. Can. J. Chem. **55**, 3707 (1977).

Nitrosation of pyridine aldehyde *p*-tolylhydrazones **2** with amyl nitrite gives rise to *p*-toluneazopyridine aldoximes **4** which form stable tris chelates with cobalt(III). Spectral data (ir, uv, and ^{1}Hmr) indicate that the ligands exist mainly in the assigned azooxime structure **4**, and that their chelates have five-membered ring structure **7**. Also, the ^{1}Hmr spectra imply *mer*-configuration **9** for the chelates examined. No evidence for the tautomeric nitrosohydrazone structure **3** for the ligands and the *fac*-configuration **8** for Co(III) chelates could be obtained. Using the HMO method, the azooxime form **4** for the ligand was shown to be more stable than the nitrosohydrazone structure **3**. Also, good agreement was obtained between observed transition energies and those calculated by the HMO method. The acid dissociation constants of the ligands in 50 vol% ethanol–water at 25°C and ionic strength of 0.1 were determined spectrophotometrically.

AHMAD SAMI SHAWALI et IKHLASS M. ABBASS. Can. J. Chem. **55**, 3707 (1977).

La nitrosation de *p*-tolylhydrazones aldéhydiques de pyridine **2** par le nitrite d'amyle conduit à des aldoximes *p*-toluèneazopyridine **4** lesquels forment des chélates stables avec le cobalt(III). Les données spectrales (ir, uv et rmn) indiquent que les ligands existent principalement sous la forme azooxime **4** et leurs chélates possèdent une structure comportant un cycle à cinq membres **7**. De plus, les spectres rmn suggèrent une configuration *mer* **9** pour les chélates étudiés. On ne peut obtenir de preuves évidentes pour une structure tautomère nitrosohydrazone **3** pour les ligands et d'une configuration *fac* **8** pour les chélates Co(III). En utilisant la méthode HMO, on peut démontrer que la forme azooxime **4** pour le ligand est plus stable que la structure nitrosohydrazone **3**. Un bon accord est aussi obtenu entre les énergies de transition observées et celles calculées par la méthode HMO. Les constantes de dissociation acide des ligands dans une solution à 50% par volume éthanol–eau à 25°C à une force ionique de 0.1 sont déterminées spectrophotométriquement.

[Traduit par le journal]

Various nitrosazones of type **1** (X = H, alkyl, or aryl and Ar = substituted phenyl) have been described (1–4). However, nitrosazones in which X (in **1**) is a heterocyclic group have so far not been reported. In this paper we describe the synthesis of three heterocyclic nitrosazones, namely **4***a* to **4***c*, and report on their spectroscopic and acid dissociation properties. We have also probed the synthesis, structure, and stereochemistry of cobalt(III) chelates with these

X—C(:NOH)N:NAr
1

heterocylic nitrosazones, and the results are described in this report. The present investigation was undertaken to see the effect of the presence of a heteronitrogen atom in the X group on the tautomeric structure of **1**, and to establish the relative stability of the possible tautomeric forms of **1** within the framework of the Huckel molecular orbital method (HMO). Also, it was our intention to examine the effect of such a heteroatom on the structure and the stereochemical pattern of the Co(III) chelates with **1**.

[1]Author to whom all correspondence should be addressed.

Results and Discussion

Treatment of pyridinealdehyde *p*-tolylhydrazones **2***a* to **2***c* with amyl nitrite in methanol in the presence of sodium methoxide gives the corresponding nitrosation products. The spectral characteristics of the latter products indicate that they exist exclusively in the azooxime structure **4**. No evidence for the tautomeric nitrosohydrazone structure **3** could be obtained. The latter form is probably first formed in the nitrosation of **2**, and immediately tautomerises to **4**.

In ethanol each compound exhibits two characteristic bands: a weak n–π^* maximum ($\log \varepsilon < 4$) near 430 nm, and a strong π–π^* band ($\log \varepsilon > 4$) at 323 nm (Table 1). Such an electronic absorption pattern is similar to that reported (5) for *trans* azo compounds, and

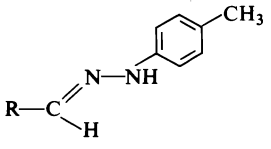
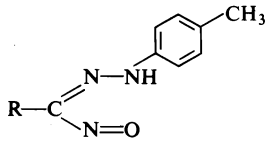
[d]Weak.

accordingly is in support of the assigned azo-oxime structure **4**.

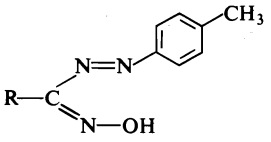
Infrared spectra of the compounds **4***a* to **4***c* in the solid state and in solution (CCl_4) show an intense band near 1040 ± 10 cm^{-1} assignable to the N—O stretch. Simple monoximes usually exhibit their N—O stretch in the region 930–960 cm^{-1}. The higher frequency position of the NO band in **4** might be due to the possible contribution of the resonance structure **5**, as was suggested for quinone monoximes ($\bar{\nu}_{NO}$ = 975–1007 cm^{-1}) (6). Furthermore, the spectra of **4** in the solid state (KBr) and in solution (CCl_4) show a broad band in the 2800–3150 cm^{-1}, due to the hydrogen bonded OH group. The parent hydrazones **2***a* to **2***c* exhibit a weak NH band near 3200 cm^{-1}. The solution phase of **4** shows an additional sharp band near 3500 cm^{-1} whose intensity is concentration dependent. Most probably the latter band arises from a free OH group.



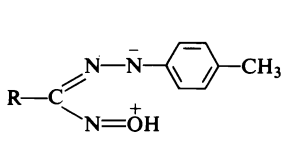
2



3



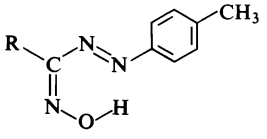
4



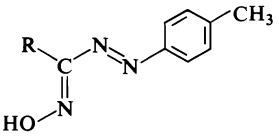
5

a R = 2-Pyridyl
b R = 3-Pyridyl
c R = 4-Pyridyl
d R = Phenyl

The ^{1}Hmr spectra of **4***a* to **4***c* also support their assigned structure. Thus, in $CDCl_3$ all compounds exhibit a one proton broad signal at δ 12.6–13.6 ppm (disappeared on shaking the solution with D_2O) assignable to =NOH. The Ar—CH_3 protons in **4** show two distinct but overlapping signals (Table 1). This observation suggests that each of the compounds exists in solution as a mixture of the *EE* and *ZE* isomers. Unsymmetrical ketoximes exhibit solution equilibria of isomers which can be identified by their ^{1}Hmr spectra (7). The arylazooximes (R = H, alkyl, or aryl) show a parallel behaviour (3, 4).



EE



ZE

To establish the relative stability of the azooxime and nitrosohydrazone tautomers of the compounds prepared within the framework of the Huckel molecular orbital (HMO) method (8), use has been made of the concept of bonding energy, defined by the equation:

$$BE = W - W'$$

where W is the total π-electrons localized on atomic orbitals. That is

$$W' = \sum_{i=1}^{n} s_i a_i$$

where n is the number of atomic centres, s_i is the number of electrons contributed by atom i to the π system, and a_i is the Coulomb integral for

atom *i*. For a given tautomeric pair, the tautomer with the greater bonding energy is expected to have the greater stability.

In the application of the HMO method, the standard convention was adopted for heteroatoms (X) in which h_X and k_{CX} were related, respectively, to the Coulomb integral (a_X) and the resonance integral (β_{CX}) by the relationships:

$$a_X = a_0 + h_X\beta_0$$

$$\beta_{CX} = k_{CX}\beta_0$$

The values used in this work are based on those given by Streitwieser (8); the values for the azo group have been successfully used by Block (9). In Table 2 are summarized the values of the heteroatom parameters used.

Bonding energies were calculated for the tautomers of compounds studied (**3***a* to **3***d*) and the values of ΔBE_{AO-NH} are given in Table 3. As shown for all the compounds, the ΔBE value is positive indicating greater stability for the azooxime form. The results are in agreement with the spectral evidence presented above. The energies for the first electronic transitions were also calculated and the results are given in Table 3 together with the observed transition energies. The good agreement between the two sets of values substantiates further the azooxime structure assigned.

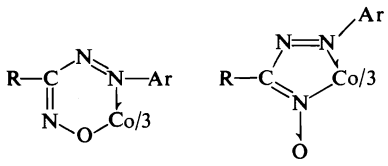
The acid dissociation constants of the nitrosazones **3***a* to **3***c* together with that of *p*-tolueneazobenzaldoxime (**3***d*) were determined spectrophotometrically in 50 vol% ethanol–water solution at 25.0 ± 0.1°C and ionic strength μ of 0.10. At p*H* < 7, each compound exhibits an intense π–π* band near 325 nm. In alkaline medium the ambident anion, RC(NO$^-$)N:NAr ↔ RC(NO):NN̄Ar shows an intense π–π* band at 350 ± 5 nm. Spectra recorded at different p*H* values showed an isosbestic point near 330 nm. The absorbance values of freshly prepared solution measured at λ_{max} of the anion plotted against p*H* showed a dependence in the shape of a dissociation curve of a monobasic acid. From the p*H*-absorbance data, the pK_a values for **3***a* to **3***d* were calculated. At least two independent runs were conducted for each compound. The pK_a values were reproducible to ±0.02 p*K* unit in different titrations, and the average values thus obtained are listed in Table 3. The data show that the heterocyclic nitrosazones **3***a* to **3***c* are more acidic than *p*-toluneazobenzaldoxime **3***d*. The low values of pK_a for **3***a* to **3***c* are due to the electron withdrawing character of the heterocyclic substituent (10).

TABLE 2. The HMO heteroatom parameters used in the study of azooxime–nitrosohydrazone tautomerism

Azooxime		Nitrosohydrazone	
h_N	0.50	h_{NH}	1.50
h_O	2.00	h_N	0.50
k_{C-N}	0.90	h_O	0.50
k_{NN}	1.00	k_{NN}	0.70
k_{N-OH}	0.90	k_{C-NH}	0.70
$k_{C=N}$	1.10	$k_{C=N}$	1.10
		k_{C-NO}	0.80
		$k_{N=O}$	0.70

Arylazooximes **4***a* to **4***c*, like **4***d*, combine quite readily with cobalt(II) acetate in aqueous ethanolic solution and the tris arylazooximato cobalt(III) separates out as dark-red crystals from such solutions. Analysis of the complexes synthesized substantiates the assigned composition. It is known (11) that cobalt(II) undergoes very fast oxidation by aerial oxygen in presence of nitrosazones.

Hunter *et al.* (4) described the cobalt(III) complexes of arylazobenzaldoximes and assigned them the six-membered ring formulation **6** on the basis of analogy with tris-(2-arylazophenolato)-Co(III). On the other hand Kalia *et al.* (11), on the basis of infrared spectra, assigned the five-membered ring structure **7** for such complexes. The infrared spectra of the complexes of this study seem to be compatible with the five-membered ring structure **7**. Thus, in their ir



6 **7**

spectra each compound exhibits its N—O band at a frequency which is about 200 cm^{-1} higher than that of the corresponding ligand. This large increase in ν_{NO} indicates that in the chelate the ligand does not exist in the oxime form. *N*-Oxides and nitrones exhibit their N—O bands at much higher frequency ranges than that of oxomes (12). It is assumed that the arylazooximes, by analogy with some oximes (11, 13), probably react momentarily in the nitrone form.

On the basis of the five-membered ring

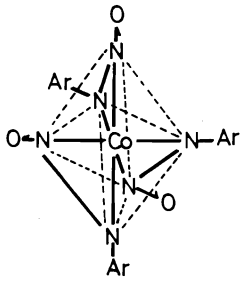
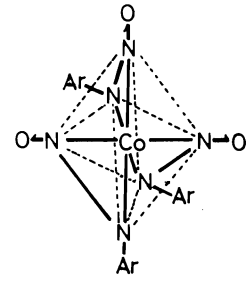
structure **7**, the Co(III) chelates can have the *fac*- and/or the *mer*-configurations, **8** and **9** respectively. To identify the exact configuration of such chelates, their ^{1}Hmr spectra in $CDCl_3$ were examined. The spectral data are summarized in Table 1. As shown, each chelate exhibits



8



9

three signals of equal intensity for the *p*-methyl protons. This observation indicates that the complexes have the *mer*-configuration, **9**. This is because the *mer*-isomer **9** has no symmetry element and this makes the three chelate rings magnetically unequivalent, and accordingly the *p*-tolyl groups would have different chemical shifts. On the other hand, the *fac*-form, **8**, has a threefold axis of symmetry and this renders all three chelate rings magnetically equivalent. This difference has been used to determine the configuration of several tris-chelates of Co(III) (14). That the complexes prepared take up the *mer*-formulation **9** rather than the *fac*-structure **8** seems to be due to the lower degree of steric crowding in **9** than in **8**. Thus, in the *fac*-isomer three *p*-tolyl groups project from corners of one of the faces of the octahedron, whereas in the *mer*-form a maximum of two *p*-tolyl groups project on each face. This difference renders the *mer*-isomer to be sterically more favourable than the *fac*-form.

Experimental

Melting points are uncorrected and were measured on a Gallenkamp electrothermal instrument model 1A6301. The ^{1}Hmr spectra were recorded on a Varian T60-A spectrometer. Electronic and vibration spectra were measured on Unicam SP8000 and SP1000 spectrophotometers respectively. Elemental analyses were performed by Alfred Bernhardt Mikroanalytisches Laboratorium, West Germany.

Hydrazones (2a to 2c)

The *p*-tolylhydrazones **2***a* to **3***c* were prepared by adding the appropriate aldehyde (0.01 mol) to *p*-tolylhydrazine hydrochloride (0.01 mol) in methanol (70 ml). In each case, the mixture was refluxed for 3 h, and working it up gave the corresponding hydrazone in 80–90% yield, which was crystallized from methanol. *Anal.* calcd. (found) for **2***a*: mp 177°C; $C_{13}H_{13}N_3$; C 73.90 (73.88), H 6.20 (6.20), N 19.89 (19.90); for **2***b*: mp 160°C; $C_{13}H_{13}N_3$; C 73.90 (73.79), H 6.20 (6.18), N 19.89 (18.87); for **2***c*: mp 182°C; $C_{13}H_{13}N_3$; C 73.90 (73.95), H 6.20 (6.19), N 19.89 (19.89).

Synthesis of Nitrosazones (4a to 4d)

These were prepared by allowing the appropriate hydrazone to react with excess *n*-amyl nitrite following the procedure as previously described by Bamberger (3). All compounds were crystallized from methanol. *Anal.* calcd. (found) for **4***a*: mp 139–140°C; $C_{13}H_{12}N_4O$; C 64.98 (64.54), H 5.03 (4.95), N 23.32 (23.28); for **4***b*: mp 164–165°C, $C_{13}H_{12}N_4O$; C 64.98 (65.02), H 5.03 (5.10), N 23.32 (23.30); for **4***c*: mp 180°C, $C_{13}H_{12}N_4O$; C 64.98 (64.82), H 5.03 (4.94), N 23.32 (23.31); for **4***d*: mp 110–111°C (lit. (2) 111°C).

Cobalt(III) Chelates: General Method

Nitrosazone (0.007 mol) was dissolved in ethanol (20 ml) and to it was added cobalt(II) acetate·$4H_2O$ (0.002 mol) dissolved in water (6 ml) at room temperature. The reaction mixture, which turned immediately deep pink in colour, was stirred for 2 h, left overnight at room temperature, diluted with water, and extracted with chloroform. The extract was dried ($MgSO_4$) and filtered. The solvent in the filtrate was removed and the residue

left was crystallized from benzene – petroleum ether. *Anal.* calcd. (found) for **7***a*: mp 194–195°C; $C_{39}H_{33}N_{12}O_3Co$; C 60.31 (60.15), H 4.28 (4.30), N 21.64 (21.49), Co 7.58 (7.32); for **7***b*: mp 218–219°C; $C_{39}H_{33}N_{12}O_3Co$; C 60.31 (60.04), H 4.28 (4.36), N 21.64 (21.63), Co 7.58 (7.67); for **7***c*: mp 205–207°C; $C_{39}H_{33}N_{12}O_3Co$; C 60.31 (60.50), H 4.28 (4.47), N 21.64 (21.51), Co 7.58 (7.36); for **7***d*: mp 145–146°C (lit. (4) 145°C).

*Acid Dissociation Constants of the Ligands **4**a to **4**d*

These were determined spectrophotometrically in 50 vol% ethanol–water at ionic strength of 0.10 and 25 ± 0.1°C as previously described (1). p*H* measurements were made using a Radiometer p*H* meter model 63, and the observed p*H* values (*B*) were corrected to hydrogen ion concentration using the relation: $-\log [H^+] = B + \log U_H$ where $\log U_H$ is the correction factor for the medium used (1). The pK_a values are given in Table 3.

Spectra of the 1:1 and 3:1 solid complexes of coronene–TCNQ

KIM DOAN TRUONG AND ANDRÉ D. BANDRAUK

Département de chimie, et Groupe de recherche sur les semiconducteurs et les diélectriques, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received May 31, 1977

KIM DOAN TRUONG and ANDRÉ D. BANDRAUK. Can. J. Chem. **55**, 3712 (1977).

Two new solid TCNQ complexes have been isolated, coronene–TCNQ 1:1 and 3:1. The infrared and electronic absorption spectra are presented for the two different stoichiometries. From these spectra we infer that the complexes are covalent in the ground state with a charge transfer band appearing at 730 nm. The out of plane vibrations of the individual molecules are noticeably perturbed upon complexation.

KIM DOAN TRUONG et ANDRÉ D. BANDRAUK. Can. J. Chem. **55**, 3712 (1977).

Deux nouveaux complexes de TCNQ ont été isolés à l'état solide, coronène–TCNQ 1:1 et 3:1. Les spectres d'absorption infrarouge et électronique sont présentés pour les deux stoichiométries. Nous avons établi que ces complexes sont covalents à l'état fondamental avec une bande de transfert de charge située à 730 nm. Les vibrations de déformation des molécules sont perceptiblement perturbées par la complexation.

Introduction

Much attention is presently being focused upon charge transfer complexes as these offer alternative possibilities for semiconductor materials (1). In particular, complexes with TCNQ as an acceptor have given rise to interesting systems, ranging from insulators to one-dimensional conductors. These latter complexes fall in the category of π-molecular charge transfer crystals and have unusual electrical properties (1, 2).

We have recently discovered a new stoichiometric form of perylene–TCNQ, i.e., its 3:1 modification (3). Together with the 1:1 form, they present interesting examples of solid state solutions of organic molecules. Of note was the fact that the vibrational structure of the absorption band of pure solid perylene (4) remained intact in the 3:1 complex but was completely broadened in the 1:1 complex. Furthermore, the charge transfer band of both complexes showed no room temperature structure. To our knowledge there is only one confirmed observation of vibrational structure in the organic solid state charge transfer band (5).[1] As it is generally believed that the mechanism of charge carrier formation in these crystals is associated with the charge transfer interaction between donor and acceptor molecules (1), the study of crystal spectra of these complexes is interesting in connection with the nature of their charge transfer excitons (6). These are thought to be responsible for the photoconductor properties of charge transfer systems (1).

In this work we present the synthesis and spectroscopic characterization of a system similar to the perylene–TCNQ system. We have obtained crystals of coronene–TCNQ in 1:1 and 3:1 stoichiometric ratios. In Fig. 1 we illustrate the structure of the individual molecules. Of note is the fact that perylene and coronene have very similar dimensions. In addition, TCNQ fits right into the middle of perylene. It is not surprising therefore that the crystal structure of perylene–TCNQ (1:1) shows an alternation of donor–acceptor in linear stacks (7). Furthermore, perylene in its β form (8) and coronene (9) have similar crystal structures. Both crystals are

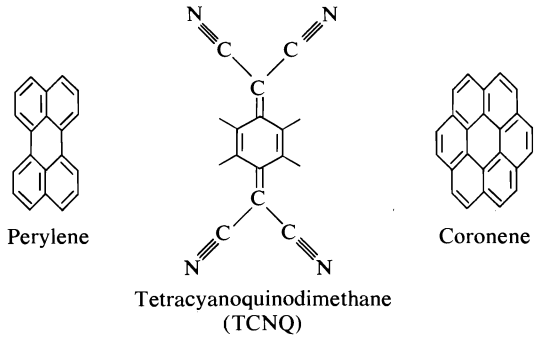

FIG. 1. Structures of perylene, tetracyanoquinodimethane (TCNQ), and coronene.

[1]Recently, Haarer (5) has observed a zero phonon transition for a charge transfer crystal. We thank the referee for this observation.

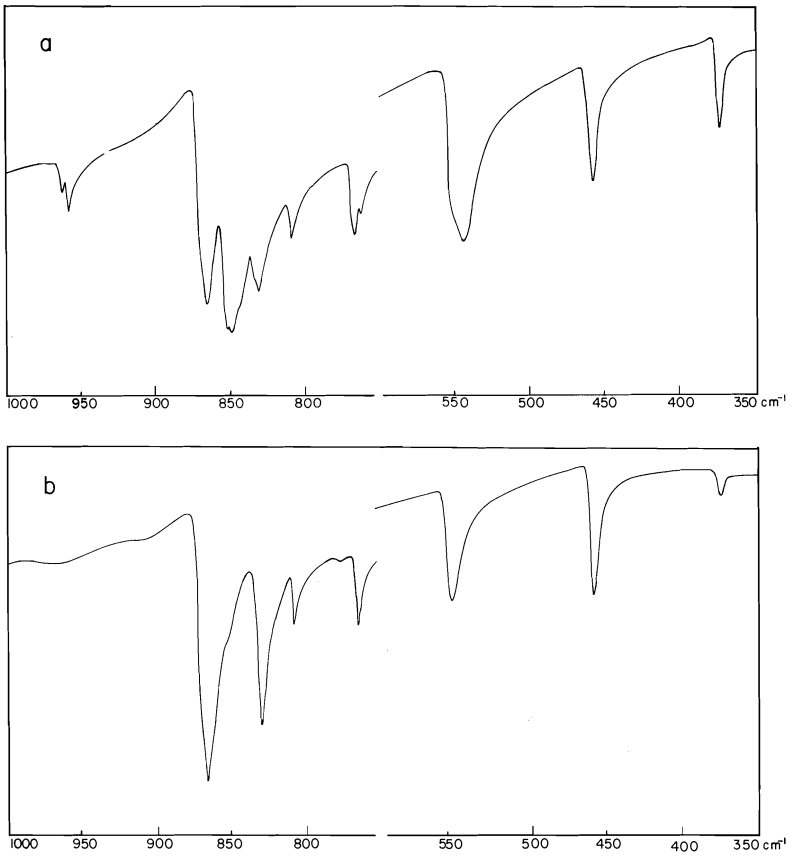

FIG. 2. Infrared spectra of: (*a*) 3:1 complex; (*b*) 1:1 complex.

monoclinic with nearly perpendicular linear stacks of molecules. Considering the similar structure both for the isolated molecules and their crystals, it is not surprising these form analogous complexes with TCNQ. We should add that we were unable to synthesize 3:1 crystals of pyrene with TCNQ. Although pyrene has physical similarities to perylene and coronene, its crystal structure (10), although monoclinic, shows four molecules per unit cell as opposed to two molecules for perylene and coronene. Thus a slight geometrical disparity seems to be important in controlling the stoichiometries of these charge transfer systems.

Experimental

Commercial coronene was recrystallized from benzene whereas pure TCNQ was obtained from acetonitrile solution. The purified coronene (0.001 mol) was dissolved in hot benzene. Purified TCNQ (0.003 mol) was also dissolved in hot benzene in a different flask. The two solutions were then mixed hot. An exothermic reaction was observed immediately and the solution became green. The solution was cooled overnight at room temperature. Green needles were found to precipitate. The same crystals were found when prepared by the diffusion method as described in ref. 11. Elemental analysis gives the following result (theoretical values in parentheses) for the 3:1 complex: C 91.28 (91.30), H 3.92 (3.62), N 4.87 (5.08).

The 1:1 complex was prepared as above but using equimolar ratios. Deep blue-black crystals were found after crystallization. Elemental analysis gives the following: C 85.72 (85.71), H 3.16 (3.17), N 10.9 (11.12).

Electronic absorption spectra were taken in KBr with a Varian Techtron 635 spectrometer. Infrared spectra were recorded on a Perkin-Elmer 621 model with a range of 200–4000 cm^{-1}. Spectra were taken in both Nujol mulls and KBr. Little difference was observed between the two media.

Infrared Spectra

In Fig. 2 we present the infrared spectra of the two different stoichiometric complexes. Table 1 also gives a résumé of the more important frequencies including measurements on pure TCNQ and coronene. The interpretation of these results will be based on the infrared and

TABLE 1. Infrared frequencies (cm^{-1})[a]

Raman study of TCNQ by Takenaka (12) where detailed calculations and assignments of TCNQ vibrational modes have been made. The vibrational spectra of coronene are less complete and here we rely on the partial assignments of Babkov *et al.* (13, 14).

A perusal of Table 1 for the high frequency modes reveals that these modes are little perturbed when compared to the isolated molecular frequencies. Thus the characteristic C=C vibration of TCNQ at 1540 cm^{-1} is essentially undisplaced with respect to pure TCNQ in the 1:1 and 3:1 complexes. Similarly the very strong absorption of coronene at 1314 cm^{-1} also remains unchanged in the complexes. The one slight difference between the complexes is the accentuation of an absorption at 1190 cm^{-1} in the 3:1 complex. This line occurs in pure TCNQ (1200 cm^{-1}) albeit weak (12) but is also accentuated in the 3:1 perylene TCNQ complex (3). Thus in the region of 800–1600 cm^{-1}, one can infer that one has superpositions of unperturbed TCNQ and coronene molecules.

The low frequency region of Fig. 2, 1000–700 cm^{-1}, shows more clearly the effect of the formation of the complexes. In particular the band in the region 900–800 cm^{-1} is quite different for the two stoichiometries. Thus the TCNQ and coronene C—H out of plane bending vibrations with corresponding frequencies at 856 and 848 cm^{-1} (12, 14) are visibly perturbed in the 3:1 complex. Thus the shoulder at 850 cm^{-1} in the 1:1 complex separates off in the 3:1 complex from the vibrations at 865 and 831 cm^{-1} and seems to be split into two components. We attribute the 865 cm^{-1} vibration to TCNQ, whereas the 831 cm^{-1} vibration would seem to belong to complexed coronene. The doublet at 854 cm^{-1} probably comes from a Davydov splitting occurring between two equivalent uncomplexed coronenes. This interpretation is supported by the fact that in the 1:1 complex the 865 and 831 cm^{-1} vibrations appear isolated. Of note is the fact that the same sort of behaviour occurs in the C—H region of the perylene–TCNQ complexes (3). As indicated in the Introduction, this is not surprising in view of the physical similarities between the two donors. We add, finally, that whereas the 962 cm^{-1} band of TCNQ is absent in the 1:1 complex, it reappears in the 3:1 complex.

Electronic Spectra

The infrared spectra in the previous section indicate that the complex is weak and therefore that one has hardly any charge transfer in the ground state. The charge transfer in fact occurs in the first excited state as shown in Fig. 3. A maximum occurs for both stoichiometries at 730 nm. This transition also appears in the solution spectrum of coronene with TCNQ observed at 740 nm by Beukers and Szent-Gyorgyi

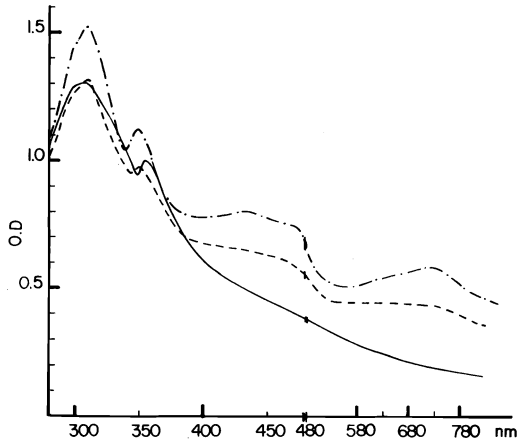

FIG. 3. Electronic spectra: (—) coronene; (---) 3:1 complex; (-·-) 1:1 complex.

(15). This corresponds to the charge transfer band. The maximum at 400 nm corresponds to TCNQ (16) whereas the maxima at 300 and 350 nm correspond to the characteristic β and *p* bands of coronene (17). In this region, the spectra of the individual moieties are well separated. Of interest is the fact that the *p* band of coronene remains virtually unchanged in pure coronene in the 1:1 and 3:1 complexes, as seen clearly in Fig. 3. This is in contrast to the perylene–TCNQ complexes, (3), where the vibrational structure of the perylene absorption persisted in the 3:1 complex but was completely broadened in the 1:1 complex. This aspect of the coronene spectra reinforces the suggestion that the *p* band is indeed a new electronic transition (17).

Returning once more to the charge transfer band at 730 nm, it must be noted that no vibrational structure is observed in the case of both 1:1 and 3:1 complexes. In the analogous perylene–TCNQ system this unstructured band appears at 930 nm. The difference in energy between the charge transfer bands of these two systems amounts to 0.36 eV. This corresponds precisely to the difference in ionization potentials of the last occupied molecular orbitals of the isolated perylene and coronene molecules as reported by Boschi *et al.* (18). Inasmuch as these orbitals are of a_u symmetry for perylene and of e_{2u} symmetry for coronene, one would expect some Jahn–Teller distortion in the charge transfer band of the coronene complexes. It would therefore be of interest to examine these bands at low temperature in order to resolve the vibrational structure and thus elucidate further the true nature of these charge transfer states.

Discussion

Our spectroscopic studies of the new 1:1 and 3:1 coronene–TCNQ complexes in the solid state show that both stoichiometric forms are weak complexes with a charge transfer band occurring at 730 nm. The infrared spectra of these complexes confirm the weak interaction in the ground state. In addition, it is observed that the C—H bending vibrations are perturbed in both stoichiometries. This phenomenon was also observed in the perylene–TCNQ analogous system (3). The crystal structure of the 3:1 modification of this system is now being investigated by Hanson[2] and this should help ascertain the cause of the splitting of these vibrations for that stoichiometry.

The coronene, perylene, and TCNQ systems deserve further study in view of the many similarities alluded to in the Introduction. In particular, there are phase transitions which occur in pure coronene (17, 19) and also in perylene (8). It will be interesting to see what is the effect of an acceptor such as TCNQ on these phase transitions. We are presently studying these by resonance Raman scattering experiments and plan to report these results shortly (20). Another outstanding problem in these systems is the vibronic couplings in the charge transfer bands. As mentioned in the previous section, the coronene cation should exhibit a Jahn–Teller distortion in the charge transfer state. This aspect and other problems will be examined at low temperatures to establish the true nature of charge transfer states in the solid state.

Acknowledgments

We thank the Defence Research Board for a grant to GRSD which financed this research. We further thank Dr. L. Caron, director of GRSD, for encouraging studies of the organic solid state.

Potential affinity and photoaffinity reagents for the membrane protein of human erythrocytes involved in glucose transport. Synthesis of 6-amino-6-deoxy derivatives of D-glucose[1]

MOHABIR RAMJEESINGH AND ARTHUR KAHLENBERG[2]

Laboratory of Membrane Biochemistry, Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, P.Q., Canada H3T 1E2

Received January 26, 1977

MOHABIR RAMJEESINGH and ARTHUR KAHLENBERG. Can. J. Chem. **55**, 3717 (1977).

From 1,2-*O*-isopropylidene-α-D-glucofuranose **1**, the 6-amino-6-deoxy-1,2:3,5-di-*O*-isopropylidene-α-D-glucofuranose **6** was prepared in a four-step sequence in an overall 50% yield. The conversion of **6** to the 6-bromoacetamido-6-deoxy **10**, 6-deoxy-6-isothiocyanato **11**, and 6-(*p*-azido-*o*-nitroanilino)-6-deoxy **12** derivatives of D-glucose is described.

MOHABIR RAMJEESINGH et ARTHUR KAHLENBERG. Can. J. Chem. **55**, 3717 (1977).

On prépare l'amino-6 déoxy-6 di-*O*-isopropylidène-1,2:3,5 α-D-glucofurannose (**6**) à partir du *O*-isopropylidène-1,2 α-D-glucofurannose (**1**) dans une synthèse comportant quatre étapes et de rendement global de 50%. On décrit la transformation de **6** en dérivés bromoacétamido-6 déoxy-6 (**10**), déoxy-6 isothiocyanato-6 (**11**) et (*p*-azido *o*-nitro-anilino)-6 déoxy-6 du D-glucose.

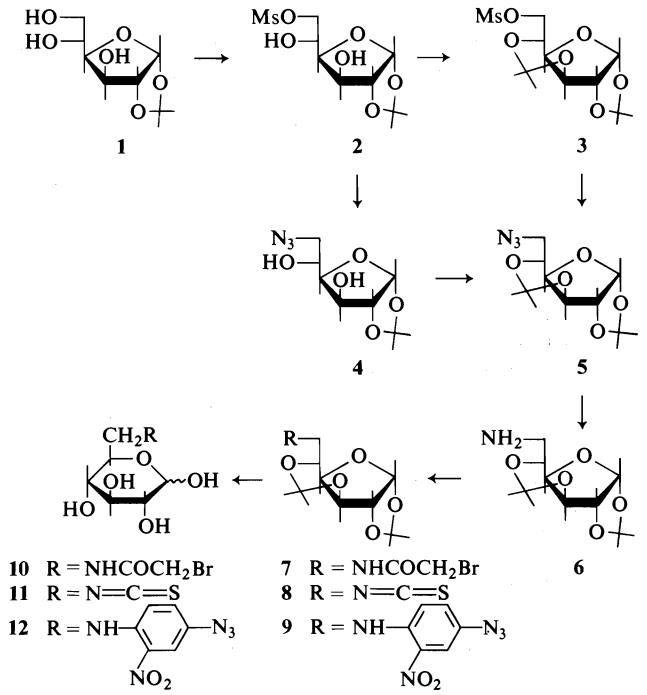
[Traduit par le journal]

The stereospecific transport of D-glucose across the human erythrocyte membrane represents a typical example of facilitated diffusion, mediated, apparently, by a membrane protein possessing one or more sugar binding sites (1, 2). However, the results of recent attempts to identify this D-glucose transport protein have been neither definitive nor in agreement (2–8). The application of the methods of affinity or photoaffinity labelling, currently in widespread use for the attachment of covalent labels at the active-site of protein molecules (9, 10), would aid in establishing the identity of the D-glucose transport protein and would allow subsequent investigation of its properties. In this paper we wish to report the synthesis of three potential substrate-directed alkylating agents of the D-glucose transport protein, namely 6-bromoacetamido-6-deoxy-D-glucose **10**, 6-deoxy-6-isothiocyanato-D-glucose **11**, and 6-(*p*-azido-*o*-nitroanilino)-6-deoxy-D-glucose **12**. Based on previous studies of the structural requirements and bulk tolerance for substituents on the D-glucose molecule for binding to the D-glucose transport protein (11, 12), these glucose derivatives should prove to be successful alkylating substrates for this transport protein. The bromoacetamido moiety of **10** is a well-known alkylating group for proteins by virtue of the facile displacement of the bromine atom by amino groups (13). The isothiocyano moiety of **11** is known to react readily with amino and sulfhydryl groups of proteins yielding thioureas and dithiocarbamic esters, respectively (14). Upon photolysis, the *p*-azido-*o*-nitroanilino moiety of **12** is converted into a nitrene derivative capable of insertion into neighbouring C—H bonds (15). Moreover the absorption maximum (452 nm) of **12** enables photolysis to be effected without damage to the protein.

Selective mesylation of 1,2-*O*-isopropylidene-α-D-glucofuranose **1** gave the methylsulfonate **2** (16). Treatment of **2** with acetone–dimethoxypropane in the presence of *p*-toluenesulfonic acid gave, after 2 days of refluxing, the diacetone derivative **3**. Displacement of the mesyloxy group of **3** with sodium azide in refluxing acetone–water yielded the azide **5** in good yield. Alternatively, displacement of the mesyloxy group of **2** with sodium azide gave **4** (17) which was then converted to **5** using acetone–dimethoxy-propane and a catalytic amount of *p*-toluenesulfonic acid. Reduction of **5** by either catalytic hydrogenation with 10% palladium on charcoal or excess sodium borohydride in refluxing isopropanol gave the syrupy amine **6** in good yield. The amine **6** had been obtained pre-

[1]Supported by a grant (MT-3120) from the Medical Research Council of Canada.

[2]To whom inquiries should be addressed.



viously and characterized as its crystalline *p*-toluenesulfonate salt by Grosheintz and Fischer (20) and by Ohle and v. Vargha (21).

Reaction of the amine **6** with bromoacetic anhydride in dimethylformamide gave the crystalline bromoacetamido-D-glucofuranose derivative **7**. Treatment of **7** with 50% aqueous trifluoroacetic acid gave the 6-bromoacetamido-6-deoxy-D-glucose **10**, mp 115–119°C.

Treatment of the amine **6** with dicyclohexylcarbodiimide and carbon disulfide in tetrahydrofuran (18) at −10°C yielded the crystalline isothiocyanate **8**. Mild cleavage of the diacetonide with 50% aqueous trifluoroacetic acid at 10°C gave the oily 6-deoxy-6-isothiocyanato-D-glucose **11**.

Upon treatment of the amine **6** with 4-azido-1-fluoro-2-nitrobenzene (19) in ethanol at 60°C for 24 h, 6-(*p*-azido-*o*-nitroanilino)-6-deoxy-1,2:3,5-di-*O*-isopropylidene-α-D-glucofuranose **9** was obtained as bright red crystals, mp 95°C. Cleavage of the diacetonide with 50% aqueous trifluoroacetic acid at room temperature gave the corresponding glucose derivative **12**, mp 180°C (dec.).

Experimental

Melting points were determined on a Mel-Temp block and are uncorrected. Mass spectra were obtained on a AE1-MS-902 mass spectrometer at 70 eV using a direct-insertion probe. Nuclear magnetic resonance spectra were recorded on a Varian Associates T-60 spectrometer using tetramethylsilane as an internal standard. Infrared spectra were obtained on a Unicam SP-200G Grating Spectrophotometer. Ultraviolet spectra were determined with a Beckman spectrophotometer Acta V. Microanalyses were carried out by C. Daessle, Montreal. Analytical thin layer chromatography was performed on silica gel coated plastic plates (Eastman Kodak) and on a preparative scale on silica gel (Merck $UV_{254,366}$) coated glass plates. Ascending paper chromatography was performed on Whatman No. 1 paper.

1,2-O-Isopropylidene-6-O-methylsulfonyl-α-D-glucofuranose **2**

The procedure of Freudenberg and v. Oertzen (16) was used with modifications in the work-up procedure. After the reaction was completed, the solvent was evaporated off and the residue dissolved in a small volume of chloroform was passed through a silica-gel column (act. III), using ethyl acetate as an eluent. The first several fractions collected gave the product as a clear viscous oil which crystallized on standing, mp 99°C (lit. (16) mp 99°C), yield 90%; ir (film) 1185, 1360 (—SO_2), 1385 (*gem*-dimethyl), 3500 cm^{-1} (OH); ^{1}Hmr($CDCl_3$) δ 1.30 (s, 3H, C—Me), 1.50 (s, 3H, C—Me), 3.06 (s, 3H, S—Me), 4.10 (2H, exchangeable, 2 OH), 4.15 (m, 2H), 4.48 (m, 3H), 4.52 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1).

1,2:3,5-Di-O-isopropylidene-6-O-methylsulfonyl-α-D-glucofuranose **3**

The mesylate **2** (6 g, 16.8 mmol) was heated under reflux in a mixture of acetone (50 ml) and dimethoxypropane (75 ml) containing *p*-toluenesulfonic acid (10 mg) with a Dean-Stark trap filled with molecular sieves. After 48 h, the mixture was evaporated to dryness and

purified on a silica-gel column (act. III) with ethyl ether – benzene (3:7) as eluent. The first fractions gave the oily diacetonide (4.8 g, R_f = 0.65, ether–benzene 3:7), yield 85%; ir (film) 1185, 1350, 3185 cm^{-1} (*gem*-dimethyl); ^{1}Hmr ($CDCl_3$) δ 1.30 (s, 3H, C—Me), 1.32 (s, 6H, C—Me_2), 1.44 (s, 3H, C—Me), 3.10 (s, 3H, S—Me), 4.06 (m, 2H), 4.48 (m, 3H), 4.60 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1).

6-Azido-6-deoxy-1,2:3,5-di-O-isopropylidene-α-D-glucofuranose ***5***

The diacetonide **3** (5 g, 14.8 mmol) was dissolved in acetone–water (80 ml, 5:3) and sodium azide (5 g) was added. The mixture was heated under reflux for 72 h. The solution was then evaporated down to dryness. Water (50 ml) and chloroform (25 ml) were added and the mixture transferred to a separatory funnel. The organic layer was collected and the aqueous layer was further extracted with chloroform (2 × 25 ml). Drying of the chloroform extract with sodium sulfate and evaporation gave the oily azido derivative **5**. The oil was chromatographed on a silica-gel column (act. III) with methylene chloride – hexane (3:2) as eluent. The first several fractions gave the oily azido derivative (3.4 g), yield 80%; ir (film) 1385 (*gem*-dimethyl), 2100 cm^{-1} (azide; ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.35 (s, 6H, C—Me_2), 1.52 (s, 3H, C—Me), 3.52 (m, 2H, H-6, 6′), 4.02 (m, 2H), 4.32 (1H), 4.50 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1).

Alternatively **5** can be prepared from **4** by refluxing the latter in a mixture of acetone (30 ml) and dimethoxypropane (45 ml) containing *p*-toluenesulfonic acid (10 mg) with a Dean Stark trap filled with molecular sieves. The work-up is the same as above giving **5** in good yield.

6-Azido-6-deoxy-1,2-O-isopropylidene-α-D-glucofuranose ***4***

The procedure of Cramer (17) was used for the preparation of **4**; ir (KBr disc) 1385 (*gem*-dimethyl), 2110 (azide), 3600 cm^{-1} (OH); ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.52 (s, 3H, C—Me), 3.52 (d, J = 2.5 Hz, H-6, 6′), 3.55 (b, 2H, OH), 4.04 (m, 2H), 4.32 (1H), 4.50 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1).

6-Amino-6-deoxy-1,2:3,5-di-O-isopropylidene-α-D-glucofuranose ***6***

The azide **5** (1 g, 3.5 mmol) was dissolved in absolute ethanol (50 ml) and hydrogenated at 2 atm pressure over 100 mg of 10% palladium on charcoal. After 16 h, the catalyst was filtered off, and the solvent was removed under reduced pressure to give a quantitative yield of the syrupy amine **6**.

Alternatively, to the azide **5** (1 g, 3.5 mmol) in isopropanol (50 ml) was added sodium borohydride (2.5 g) and the mixture refluxed for 14 h. The isopropanol was evaporated under reduced pressure, water (40 ml) added, and the aqueous solution extracted with methylene chloride (3 × 30 ml). Drying of the methylene chloride extract with sodium sulfate, and evaporation gave the amine (0.75 g), yield 82%; ir (film) 1385 (*gem*-dimethyl), 3350, 3410 cm^{-1} (NH); ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.35 (s, 6H, C—Me_2), 1.52 (s, 3H, C—Me), 2.90 (2H, exchangeable, NH_2), 3.52 (2H, H-6, 6′), 4.02 (m, 2H), 4.32 (1H, H-3), 4.50 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1).

The procedure of Grosheintz and Fischer (20) was used to prepare the crystalline *p*-toluenesulfonate derivative of the amine **6**; mp 172°C with heating at 10°C per minute (lit. (20) 171.5–172.5°C); $[\alpha]_D^{25}$ +30° (*c* 3.884, water). Ohle and v. Vargha (21) reported a rotation of +30.5° (*c* = 5.4, water).

6-Bromoacetamido-6-deoxy-1,2:3,5-di-O-isopropylidene-α-D-glucofuranose ***7***

The amine **6** (450 mg) was dissolved in dimethylformamide (5 ml). To this was added bromoacetic anhydride (460 mg) dissolved in dimethylformamide (2 ml). The reaction mixture was stirred overnight. The solvent was then evaporated off and the residue chromatographed on a silica-gel column (act. III). Elution with ethyl ether – petroleum ether (1:1) gave **7** (R_f = 0.5, ether – petroleum ether 1:1) which was recrystallized twice from ethyl ether, mp 152–154°C, $[\alpha]_D^{25}$ +12° (*c* 1.5, methanol), yield 95%; ir KBr (disc) 1385 (*gem*-dimethyl), 1550 (N—H), 1670 (amide), 3400 cm^{-1} (N—H); ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.35 (s, 6H, C—Me_2), 1.52 (s, 3H, C—Me), 2.92 (apparent d, J = 5 Hz, H-6, 6′), 3.58 (m, 2H), 3.82 (s, 2H, CH_2Br), 4.22 (m, 1H), 4.52 (d, J = 3.5 Hz, H-2), 5.90 (d, J = 3.5 Hz, H-1), 6.95 (1H, exchangeable, N—H). *Anal.* calcd. for $C_{14}H_{22}NO_6Br$: C 44.21, H 4.79, N 3.68, Br 21.05; found: C 44.32, H 5.71, N 3.79, Br 21.48.

6-Bromoacetamido-6-deoxy-D-glucose ***10***

Bromoacetamido-glucofuranose **7** (500 mg, 1.3 mmol) was added to 50% aqueous trifluoroacetic acid (10 ml) and the reaction mixture was stirred for 1 h. The solvent was then evaporated off under vacuum, leaving a solid residue which was dissolved in hot ethanol (15 ml). Addition of ethyl acetate (5 ml) and cooling gave the crystalline bromoacetamido-glucose **10**, mp 115–119°C, $[\alpha]_D^{25}$ +38° (after 2 h; *c* 4.425, water), yield 90%; ir (KBr disc) 1545 (N—H), 1655 (amide), 1640 (weak, aldehyde), 3450 cm^{-1} (broad, O—H); ^{1}Hmr (D_2O) δ 3.4–3.6 (3H), 3.90 (s, 2H, CH_2Br), 4.0 (m, 2H), 4.7 (1H, H-2), 5.18 (d, J = 2.5 Hz, C-1); mass spectrum (70 eV) *m/e* 265, 263 ($M^+ - 2H_2O$), 247, 245 ($M^+ - 3H_2O$), 166 ($M^+ - 3H_2O$ – Br), 139, 137. *Anal.* calcd. for $C_8H_{14}NO_6Br$: C 32.0, H 4.67, N 4.67, Br 26.67; found: C 31.75, H 4.62, N 4.57, Br 27.31.

6-Deoxy-1,2:3,5-di-O-isopropylidene-6-isothiocyanato-α-D-glucofuranose ***8***

The amine **6** (1.25 g, 4.8 mmol) dissolved in ethyl ether (10 ml) was added to an ethyl ether (25 ml) solution of dicyclohexylcarbodiimide (0.9 g, 0.9 mol. equiv.) and carbon disulfide (10 ml) stirred at −10°C. The reaction mixture was kept at −10°C for 1 h and then allowed to reach room temperature during 3 h. The solution was set aside at room temperature overnight after which the dicyclohexylthiourea was filtered off. The solution was evaporated to a small volume which was chromatographed on silica-gel plates eluting with ethyl ether – hexane (1:1). The band (R_f = 0.85, ethyl ether – hexane 1:1) was extracted with chloroform and evaporated to give an oil which crystallized on standing, mp 68°C, $[\alpha]_D^{25}$ +45° (*c* 2.1, acetone), yield 69%; ir (film) 1385 (*gem*-dimethyl), 2100 cm^{-1} (N=C=S); ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.38 (s, 6H, C—Me_2), 1.52 (s, 3H, C—Me), 3.24 (d of d, J_{AB} = 8 Hz, J = 2.5 Hz, H-6), 3.60 (d of d, J_{AB} = 8 Hz, J = 3 Hz, H-6′), 4.15 (m + s, 3H), 4.25 (d, J = 3.5 Hz, H-2), 5.92 (d, J = 3.5 Hz, H-1); uv λ_{max} (EtOH) 247 nm (ε = 1500). *Anal.* calcd. for $C_{13}H_{19}NO_5S$:

C 51.82, H 6.31, N 4.65, S 10.63; found: C 51.27, H 6.45, N 4.72, S 10.68.

6-Deoxy-6-isothiocyanato-D-glucose ***11***

The isothiocyanate **8** (600 mg, 2 mmol) was dissolved in 50% aqueous trifluoroacetic acid (15 ml) and stirred at 10°C for 1 h. The solvent was then evaporated off under vacuum leaving the 6-deoxy-6-isothiocyanato-D-glucose **11** as an oil. Paper chromatography had shown the product to be homogeneous with $R_f = 0.5$ (1-butanol–EtOH–H_2O, 6:4:3) and with $R_f = 0.75$ (EtOH–Py–H_2O, 6:4:3); ir (film) 2100 cm^{-1} (N=C=S); ^{1}Hmr (D_2O) δ 3.4–4.5 (5H), 4.7 (1H), 5.18 (d, $J = 2.5$ Hz, C-1). *Anal.* calcd. for $C_7H_{11}NO_5S$: C 38.05, H 4.98, N 6.33, S 14.48; found: C 37.92, H 5.02, N 6.31, S 14.30.

6-(p-Azido-o-nitroanilino)-6-deoxy-1,2:3,5-di-O-isopropylidene-α-D-glucofuranose ***9***

The amine **6** (250 mg, 1 mmol) and 4-azido-1-fluoro-2-nitrobenzene (550 mg, 3 mmol) were heated together at 60°C in ethanol for 48 h. Evaporation of ethanol gave a red residue which was chromatographed on silica-gel plates with benzene – methylene chloride (4:1) as eluent. The coloured band at $R_f = 0.55$ was extracted with chloroform. The oil so obtained was dissolved in hexane and refrigerated at 4°C to give the crystalline product, mp 98–100°C, $[\alpha]_D^{25}$ −142° (*c* 0.82, acetone), yield 65%; ir (KBr disc) 1385 (*gem*-dimethyl), 1520 (NO_2), 2100 (N_3), 3360 cm^{-1} (amine); ^{1}Hmr ($CDCl_3$) δ 1.32 (s, 3H, C—Me), 1.35 (s, 6H, C—Me_2), 1.54 (s, 3H, C—Me), 3.23 (m, 2H, H-6, 6′), 4.25 (m + s, 3H), 4.51 (d, $J = 3.5$ Hz, H-2), 5.90 (d, $J = 3.5$ Hz, H-1), 6.92 (1H, exchangeable, N—H), 7.7 and 8.82 (3H, aromatic protons). uv λ_{max} (EtOH) 252, 455 nm (ε = 28 200 and 4600). *Anal.* calcd. for $C_{18}H_{23}N_5O_7$: C 51.31, H 5.46, N 26.60; found: C 50.92, H 5.56, N 26.46.

6-(p-Azido-o-nitroanilino)-6-deoxy-D-glucose ***12***

The azido derivative **9** (150 mg) was stirred in 50% aqueous trifluoroacetic acid (10 ml) for 1 h in the dark. The reaction mixture was then evaporated to dryness. The residue after washing with methylene chloride (2 × 15 ml) was filtered giving 95 mg of the product, mp 192°C (dec.), yield 78%; ir (KBr disc) 1520 (NO_2), 1680 (C=O), 2110 (N_3), 3450 cm^{-1} (b, O—H); uv λ_{max} (EtOH) 252, 455 nm (ε = 28 000, 4600). *Anal.* calcd. for $C_{12}H_{15}N_5O_7$: C 42.23, H 4.40, N 20.53; found: C 41.24, H 4.45, N 19.86.

Received April 18, 1977

BO-LONG POH. Can. J. Chem. **55**, 3721 (1977).

A modified MacInnes equation is presented and its relationships with Taft and Brønsted equations discussed.

BO-LONG POH. Can. J. Chem. **55**, 3721 (1977).

On présente une équation modifiée de MacInnes; ses relations avec les équations de Taft et Brønsted sont discutées.

[Traduit par le journal]

Introduction

About 50 years ago MacInnes (1) found that the ionization constants of several homologous series of ω-substituted carboxylic acids could be expressed by

$$[1] \qquad pK_a = pK_\infty + S/n$$

where n is the number of methylene carbon atoms between the carboxylic acid group and the substituent and pK_∞ and S are empirical constants. Later, Greenstein (2) showed that the MacInnes equation could be modified to

$$[2] \qquad pK_a = pK_\infty + S'/l^2$$

where l is the distance between the carboxylic acid group and the substituent and S' is an empirical constant. In this paper we put forward a slightly modified MacInnes equation that encompasses [1] and [2] and discuss some interesting deductions from it.

Results and Discussion

The modified MacInnes equation has the form

$$[3] \qquad pK_a = pK_\infty + Sl_1^2/l^2$$

where l_1 refers to the distance between the carboxylic acid group and the substituent in the first member of the homologous series, namely XCH_2COOH. Equation 3 is similar to [2] with $S' = Sl_1^2$ and is also similar to [1] because the values of l_1^2/l^2 turn out to be close to the corresponding values of $1/n$ (see Table 1) when the fully extended conformation is used to calculate l in the usual manner (3). We suggest that those acids which give linear pK_a against $1/n$ plots are fully extended in conformation. Table 2 lists the acids that follow the MacInnes equation closely together with the calculated values of pK_∞, S, and the correlation coefficients. The results indicate that the dipolar and charged substituted acids listed in Table 2 are fully extended in

TABLE 1. Comparison of $1/n$ and l_1^2/l^2 for some $X(CH_2)_nCOOH$ and $X(CH_2)_n\overset{+}{N}H_3$

water. Similar conclusions have been reached for charged substituted acids but the conclusions for the dipolar substituted acids are not in agreement with earlier ones which are, however, not clear cut (4, 5). The deviation of malonic acid (2) from such a plot can be explained in terms of the folded structure of its monoanion due to the presence of intramolecular H-bonding (6–8). A folded conformation gives a smaller value of l and thus a smaller pK_a value. This is indeed the case for malonic acid. Equation 3 was applied to three series of carboxylic acids with known structures, namely 4-substituted bicyclo[2.2.1]heptane-1-carboxylic acids, 4-substituted bicyclo-[2.2.2.]octane-1-carboxylic acids, and *trans*-4-substituted cyclohexane-1-carboxylic acids, to test its applicability in predicting their pK_a values in water. The values of pK_∞ and S used were taken from Table 2 and the values of l were calculated from the known geometries of the molecules. The results given in Table 3 show that the observed and calculated values are in good agreement.

From the close agreement in the pK_∞ values for different substituents and their closeness to the pK_∞ value for the unsubstituted series we may approximate [3] to

$$[4] \qquad pK_a - pK_0 = Sl_1^2/l^2$$

where K_0 is the ionization constant for the unsubstituted acid. Equation 4 is analogous to the Taft equation

$$[5] \qquad pK_a - pK_0 = -\sigma^*\rho^*$$

with S and l_1^2/l^2 analogous to $-\sigma^*$ and ρ^*, respectively. For the ionization of substituted acetic acids, XCH_2COOH, in water at 25°C with $\rho^* = 1.72$ and $l_1^2/l^2 = 1$, and using $\sigma_I = 0.45\sigma^*$ (9, 10), we expect $\sigma_I = -0.26S$ from [4] and [5]. A plot of σ_I against S (Fig. 1) is linear and yields a slope of -0.23 which is close to the predicted value of -0.26. Comparing [4] and [5] we expect the ratio of the S values for the aliphatic carboxylic acids and amine conjugate acids to be

equal to the ratio of their ρ* values. A plot of the two sets of S values yields a slope of 2.30 (solid line, Fig. 2) which is close to the ρ* ratio of 1.85 (11) for the two series $XCH_2\overset{+}{N}H_3$ and XCH_2COOH, and 1.87 (11) for the two series $ArCH_2\overset{+}{N}H_3$ and $ArCH_2COOH$. The reason that the charged substituents fall on a separate and almost parallel line (slope 2.48) is not clear (9, 10).

Since the Taft equation is applicable to rate constants, eq. 4 can similarly be modified by replacing the equilibrium constant K_a by the rate constant k_x. For a general acid-catalyzed reaction

$$[6] \qquad HA + B \rightleftharpoons \overset{\delta+}{B}\text{---}H\text{---}\overset{\delta-}{A} \rightleftharpoons \overset{+}{B}H + A^-$$

where HA is an acid and B a base, the charge developed on A in the transition state is only a fraction (α, the Brønsted coefficient) of that of the conjugate base A. Therefore, the equation correlating the rate constants is

TABLE 4. Anomalous and corrected Brønsted exponent (α)

[a]The values of l that were used to calculate these numbers are given in the Appendix.

[7] $$-\log k_x = \alpha S l_1^2/l^2 - \log k_0$$

The combination of [4] and [7] yields

[8] $$\log k_x = m\alpha \log K_a + (\log k_0 - m\alpha \log K_0)$$

where $m = (l_e/l_r)^2$ and l_r and l_e denote the distances between the substituent and the center where the charge is located for the general acid-catalyzed reaction and the ionization equilibrium, respectively. When the charge is located on the same atom in both the transition state of the general acid-catalyzed reaction and in the conjugate base in the ionization equilibrium of the corresponding acid m is unity and [8] is reduced to the Brønsted (12) equation. The reactions that give anomalous α values (outside the range of zero to one) are those that do not have the charge located on the same atom in both the transition state of the general acid-catalyzed reaction and in the conjugate base in the ionization equilibrium of the corresponding acid. In such cases the reported α values should really be $m\alpha$ values. Table 4 gives a list of reactions which have anomalous α values (13). In the nitroalkane series the negative charge of fully formed nitronate ions is very probably largely delocalized onto the nitro group (13) whereas the partially developed negative charge in the transition state of the nitronate ions producing process is probably located on the α-carbon atom. By substituting the estimated l values the reported values were corrected and found to be normal (Table 4).

We are currently attempting to relate the modified MacInnes equation to the Kirkwood–Westheimer (3) equation. We hope to be able to explain why in the case of charged substituted acids their pK_a values are inversely proportional to the square of l in the modified MacInnes equation but are inversely proportional to l in the Kirkwood–Westheimer treatment.

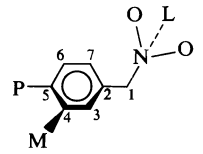
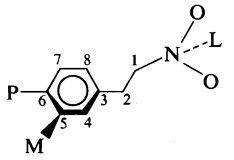
Appendix

The values of l used in Table 4 were calculated from the following data using chlorine as the substituent.



Arylnitromethanes

$l_r(para) = PC_1 = 5.18$ Å; $l_r(meta) = MC_1 = 5.12$ Å; $l_e(para) = PL = 6.46$ Å; $l_e(meta) = ML = 6.76$ Å; $m(para) = 1.56$; $m(meta) = 1.75$. Ring is at 90° to the NC_1C_2 plane; $C_4M = C_5P = 0.89$ Å; C—C(ring) = 1.38 Å; $C_1—C_2 = 1.53$ Å; $C_1—N = 1.44$ Å; angle $C_2—C_1—N = 120°$ for nitronate ion; negative charge is located at L, 0.62 Å beyond the N atom on the extension of the $C_1—N$ bond for the nitronate ion.



1-Arylnitroethanes

$l_r(para) = PC_1 = 5.86$ Å; $l_r(meta) = MC_1 = 5.78$ Å; $l_e(para) = PL = 7.90$ Å; $l_e(meta) = ML = 7.77$ Å; $m(para) = 1.82$; $m(meta) = 1.80$. Ring is at 90° to the NC_1C_2 plane; angle $C_1—C_2—C_3 = 109°$; others identical to those for arylnitromethanes.

Pyridine-catalyzed halogenation of aromatic compounds. III. Chlorination and the relative stabilities of trichloride and tribromide in chloroform

GERALD E. DUNN AND JAMES A. PINCOCK

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 7, 1977

GERALD E. DUNN and JAMES A. PINCOCK. Can. J. Chem. **55**, 3726 (1977).

The mechanism of catalysis of aromatic chlorination by pyridine was investigated by measuring the rates of chlorination of toluene in acetic acid with and without added pyridine, pyridinium nitrate, or lithium chloride. All three increase the rate of chlorination slightly and to about the same extent. The effect on the second-order rate constant for chlorination of *p*-chloranisole in chloroform was determined for pyridine, pyridinium chloride, *N*-ethylpiperidinium chloride, tetra-*n*-butylammonium chloride, and tetra-*n*-butylammonium perchlorate. Again, all additives increase the rate constant, with the increase being least for pyridine. It is concluded that, for chlorination in dilute solution, pyridine has no specific catalytic effect, but probably increases the rate by increasing the polarity of the medium. Tetra-*n*-butylammonium chloride was observed to have a decreasing accelerating effect on chlorination in chloroform as its concentration is increased. This was thought to be the result of complexation of chlorine as trichloride. The formation constant for tetra-*n*-butylammonium trichloride in chloroform was found by the Benesi–Hildebrand spectrophotometric method to be $17 \pm 3\ M^{-1}$. This, together with the previously determined value of $9 \times 10^4\ M^{-1}$ for the corresponding tribromide, shows that the order of stability of trihalides in nonaqueous solvents is $Br_3^- \gg Cl_3^-$, contrary to an earlier report.

GERALD E. DUNN et JAMES A. PINCOCK. Can. J. Chem. **55**, 3726 (1977).

On étudie le mécanisme catalytique de la pyridine dans la chloration de noyaux aromatiques, en mesurant les vitesses de chloration du toluène dans l'acide acétique avec ou sans addition de pyridine, nitrate de pyridinium ou chlorure de lithium. Ces derniers augmentent légèrement la vitesse de chloration et environ dans la même mesure. L'influence sur la constante de vitesse d'ordre 2 pour la chloration du *p*-chloroanisole dans le chloroforme est déterminée pour la pyridine, le chlorure de pyridinium, le chlorure de *N*-éthylpipéridinium, le chlorure et le perchlorate de tétra-*n*-butylammonium. Encore une fois, tous ces catalyseurs augmentent la constante de vitesse. Cette augmentation est moins marquée dans le cas de la pyridine. On en déduit que pour la chloration en solution diluée, la pyridine n'a pas un effet catalytique spécifique mais accroit probablement la vitesse en augmentant la polarité du milieu. On remarque que le chlorure de tétra-*n*-butylammonium a un effet d'augmentation de la vitesse de chloration dans le chloroforme qui diminue à mesure que sa concentration augmente. On pense que ceci soit le résultat d'une complexation du chlore sous forme de trichlorure. La constante de formation du trichlorure de tétra-*n*-butylammonium dans le chloroforme déterminée par la méthode spectrophotométrique de Benesi–Hildebrand est de $17 \pm 3\ M^{-1}$. Cette valeur avec celle déterminée antérieurement de $9 \times 10^4\ M^{-1}$ pour le tribromure correspondant montre que l'ordre de stabilité des trihalogénures dans des solvants nonaqueux est $Br_3^- \gg Cl_3^-$ et en opposition avec un rapport antérieur.

Introduction

In 1908 Cross and Cohen (1) reported the use of pyridine as a catalyst for aromatic halogenation, and its use for this purpose is still occasionally recommended (2, 3). Part I of this series examined the effect of pyridine upon the bromination of mesitylene in dilute solutions in chloroform or acetic acid and reported that, while pyridine and its salts increase the rate of bromination, the effect is no larger than those of several other electrolytes, so that under these conditions it appears to be no more than a simple salt effect (4). The present report concerns chlorination, which Cross and Cohen also found to be catalyzed by pyridine.

Results

Preliminary Experiments

Cross and Cohen (1) passed chlorine gas into benzene containing a few drops of pyridine at 50°C and isolated a 42% yield of chlorobenzene together with a little dichlorobenzene. When we attempted to repeat this procedure the only product isolated was α-benzenehexachloride, either in daylight or in the dark. On the other hand, when benzene was saturated with chlorine

at room temperature, then thermostated at 60°C in the dark and analyzed by gas chromatography, chlorobenzene was found. In the absence of pyridine the yield after 19 h was about 4% based on chlorine, whereas in the presence of 1–2% of pyridine the yield was about 85% after 6 h. Thus it is evident that pyridine does catalyze the chlorination of benzene even though we were unable to repeat Cohen's preparation.

Rate Studies

Many of the earlier kinetic studies of aromatic chlorination were done on methylbenzenes in acetic acid solution (5–8), so we began with toluene in acetic acid. The earlier workers reported the reaction to give exclusively nuclear substitution and to be first order with respect to each of aromatic hydrocarbon and chlorine (5–8). We followed the disappearance of chlorine iodimetrically and obtained good second-order plots over at least two half-lives. Table 1 shows the reproducibility of the rate constant at different initial concentrations of chlorine and toluene, and compares the results with literature values. It also shows that both pyridine and pyridinium nitrate increase the rate constant for chlorination, but the effect is small and not significantly larger than that of lithium chloride.

In an attempt to approach Cohen's nonpolar, aprotic reaction conditions more closely, attention was turned to other solvents. Chloroform was chosen because in the bromination studies it was found to be the least polar solvent which dissolves pyridinium salts and does not react with halogen (4). *p*-Chloroanisole was chosen as substrate because in chloroform solution it gives convenient rates and a single product, 2,4-dichloroanisole. The disappearance of chlorine was followed spectrophotometrically with the aromatic substrate in large excess, so that pseudo-first-order kinetics were expected. However, first-order plots were found to have a distinct accelerating curvature, as shown in Fig. 1, line A. On the other hand, when the concentrations of chlorine and substrate were varied, the initial rates measured over the first 10% of reaction show the reaction to be first-order with respect to each of chlorine and aromatic substrate. Table 2 shows the constancy and reproducibility of the second-order constant calculated from initial pseudo-first-order rate constants and *p*-chloroanisole concentrations. It also shows that pyridine increases the initial second-order rate constant by a factor of 4–5, but not in proportion to the concentration of pyridine.[1]

From the facts that pseudo-first-order plots of chlorination in chloroform are curved, although initial rates suggest that the reaction is first order with respect to chlorine, it was suspected that the curvature in the rate plots is due to acceleration by the HCl produced in the reaction. This was confirmed when the chlorination was carried out in the presence of an initial concentration of HCl in excess of that produced during the reaction. Figure 1, line B, shows that under these conditions a good first-order plot can be obtained, and Table 3 shows that the second-

[1]A referee makes the very reasonable suggestion that the apparent pyridine catalysis is due in large part to the pyridinium chloride formed from the HCl produced in the reaction, and that this explains why the catalysis is independent of the initial amount of pyridine.

order rate constant is proportional to the concentration of HCl. This could be interpreted as meaning that the reaction is third order (first order with respect to each of *p*-chloroanisole, chlorine, and hydrogen chloride), which suggests that the runs without added HCl should obey a rate law of the form:

$$[1] \quad -d[Cl_2]/dt = k_2[Ar][Cl_2] + k_3[Ar][Cl_2][HCl]$$

Integration of [1] with the assumption that absorbance A is proportional to $[Cl_2]$ yields [2].

$$[2] \quad -\log A = \frac{[Ar]}{2.3}(k_2 + k_3\,[HCl])t - \log A_0$$

Figure 1, line C, shows a plot of log $A/(k_2 + k_3$ [HCl]) vs. t in which k_2 is taken to be the rate constant for the initial reaction with no added HCl (Table 2), k_3 is the third-order rate constant in the presence of added HCl (Table 3), and [HCl] is calculated from the decrease in chlorine concentration. The fit is reasonably good, confirming that the downward curve in the ordinary rate plot is caused by the HCl produced as the chlorination proceeds.

That HCl exerts its effect as a specific reactant, however, is made doubtful by the observation that similar effects are produced by various other electrolytes. Table 3 shows that the second-order rate constants for chlorination of *p*-chloroanisole in chloroform are proportional to the concentration of each of hydrogen chloride, pyridinium chloride, *N*-ethylpiperidinium chloride (NEPCl), and tetra-*n*-butylammonium perchlorate ($TBAClO_4$). The first three of these contain chloride and an acidic cation, either of which could conceivably participate in the chlorination reaction, but the fourth contains neither, so it seems highly unlikely that any of these reagents are direct participants in the mechanism. It is more likely that their effect is on the polarity of the medium. That the effect should be linear in concentration of electrolyte is somewhat surprising, but perhaps the range of concentration of electrolytes available in chloroform is not large enough to reveal a deviation from linearity.

Tetra-*n*-butylammonium chloride (TBACl) behaves differently from the other electrolytes in two respects. Figure 1, line D, shows that the pseudo-first-order rate constant of a run using this salt decreases as the run progresses, so that the rate constants given in Table 3 are initial rates only. Furthermore, these initial rate constants are not directly proportional to the concentration of TBACl, as is the case with the other electrolytes, but increase much less rapidly than the salt concentration. This behavior is reminiscent of bromination in chloroform solution, where most electrolytes have an accelerating

effect but bromides retard bromination, with the retardation being greater for tetra-*n*-butylammonium bromide than for pyridinium or *N*-ethylpiperidinium bromides (4). The retardation was found to be caused by complexation of bromine as tribromide ion, with the formation constant of tribromide increasing with the size and symmetry of the accompanying cation. If the formation constants for trichloride ion show a similar dependence on cation, it is possible that the formation of trichloride could produce a retarding effect at high concentrations of TBACl but not with the other chlorides of Table 3. We therefore examined the formation constant for tetra-*n*-butylammonium trichloride.

Formation Constant

That TBACl does indeed form a complex with chlorine is indicated by the following observations. In the spectral region 250–400 nm chlorine in chloroform solution shows a single broad absorption maximum at 330 nm ($\varepsilon = 100$), whereas a mixture of chlorine with a 30-fold excess of TBACl shows a single sharper absorption maximum at 257 nm ($\varepsilon = 6.6 \times 10^2$ based on chlorine concentration). That the new absorption arises from interaction of chlorine with chloride rather than tetra-*n*-butylammonium ion is shown by the fact that a 30-fold excess of $TBAClO_4$ produces no change in the chlorine absorption in this region.

To determine the formation constant for $TBACl_3$ in chloroform the Benesi–Hildebrand spectrophotometric method (9) was used with slight modification. The form of the equation and the conditions used are the same as those described earlier for pyridinium tribromide (4). The absorbance data at 305 nm are given in Table 4 and plotted in Fig. 2. From a least-squares treatment of the data it was calculated that *K* (the formation constant) = $17 \pm 3\ M^{-1}$

TABLE 4. Absorbance at 305 nm of $TBACl_3$ solutions in chloroform at 25.0°C

and ε_c (the absorptivity of the complex) $= 1.9 \times 10^2\ M^{-1}\ cm^{-1}$.

Discussion

Rate Studies

Table 1 shows that pyridine, pyridinium nitrate, and lithium chloride at similar concentrations in acetic acid solvent all produce similar small increases in the rate of chlorination of toluene. Consequently, there seems no need to ascribe any specific catalytic role to pyridine other than the salt effect it (as pyridinium acetate) shares with the other electrolytes listed.

In chloroform the effects are larger. It is difficult to compare the effect of pyridine (Table 2) with those of other electrolytes (Table 3) because their concentration dependences vary, but interpolation or extrapolation of the data in Tables 2 and 3 give the following approximate factors for the increase in second-order rate constant produced by an $8.0 \times 10^{-2}\ M$ concentration of each additive: pyridine 4.8, hydrogen chloride 11, pyridinium chloride 64, NEPCl 21, and $TBAClO_4$ 90. It appears that the more ionic the additive, the larger is its effect. As in acetic acid solution, the results are consistent with a medium effect (larger in chloroform than in acetic acid because of the smaller polarity of chloroform). Certainly there is no evidence of any special catalytic effect by pyridine.

In general, then, the results for chlorination agree with those for bromination: although pyridine has an accelerating effect on the rates of aromatic halogenation by both bromine and chlorine in dilute solutions in either acetic acid or chloroform, the effect is of the same order of magnitude as that produced by soluble salts. Since the effect increases in less polar solvents, it is possible that it could be great enough to account for Cohen's results using the aromatic substrate (benzene) as solvent. Also, for each halogen, addition of the corresponding halide (particularly with tetra-*n*-butylammonium cation) causes a decrease in rate of halogenation by complexation of some of the halogen as trihalide.

Tetra-n-butylammonium Trichloride

There has been considerable disagreement in the literature about the relative stabilities of the trihalides in nonaqueous solvents. In 1964 Nelson and Iwamoto (10) reported the formation constants of the three trihalides in acetonitrile to be $10^{6.6}$, 10^7, and 10^{10} for I_3^-, Br_3^-, and Cl_3^-, respectively, thus indicating that the order of stabilities is the reverse of that in water. Subsequent investigators have disagreed with these results, finding trichloride to be much less stable than tribromide or triiodide in nitromethane, acetonitrile (11), and sulfolane (12). The values of the stability constants vary somewhat from one investigator to another. Using polarographic methods, Manchon (11) did not detect any trichloride in nitromethane or acetonitrile, whereas Benoit *et al.* (12) found a formation constant of $10^{3.1}$ for trichloride in sulfolane. Giordano *et al.* (13), using a vapor pressure method, found formation constants of trichloride in acetonitrile to vary from 107 at ionic strength 0.0095 to 7 at ionic strength 0.365. In view of our observation that stability constants of tribromide and trichloride in chloroform depend to some extent upon the accompanying cation, it may be that the different values obtained for trichloride formation by different workers are due in part to the different cations used: tetraethyl (11), tetra-*n*-butyl (10), and lithium (13).

However that may be, our results are in qualitative agreement with those which find trichlorides to be less stable than tribromides in nonaqueous solvents, just as in water. The formation constant for $TBABr_3$ is so large ($9 \times 10^4\ M^{-1}$) that addition of TBABr nearly stops bromination of mesitylene (4), whereas TBACl has only a small retarding effect on the chlorination of *p*-chloroanisole.

Experimental

Materials

Pyridine (Karl Fischer reagent), chlorobenzene, and 2,4-dichloroanisole were commercial products (Eastman) used without further purification. Chlorine and hydrogen

chloride (Matheson) were passed from the suppliers' cylinders through two concentrated sulfuric acid bubblers. Benzene and toluene were purified by the method of Fieser (14). Chloroform, acetic acid, TBACl, $TBAClO_4$, NEPCl, and pyridinium chloride were prepared as previously described (4). *p*-Chloroanisole (Eastman) was purified by distillation through a 90-plate column, collecting the fraction boiling at 89.0°C, 21 Torr.

Rate Measurements

The rate of disappearance of chlorine in acetic acid solutions was followed iodimetrically. Solutions of known concentrations of chlorine and toluene (or toluene plus salt) were mixed in a thermostat at 25.0 ± 0.1°C and aliquots were withdrawn for titration over periods up to three half-lives. Solutions containing only chlorine showed no concentration change over this period.

In chloroform solution the disappearance of chlorine was followed spectrophotometrically at a wavelength between 330 and 400 nm chosen to give initial absorbances in the range 0.5–1.0 and to keep the absorbance of salts below 0.05. Solutions containing only chlorine showed no change in absorbance over 24 h. Slow reactions were run in a thermostat with aliquots withdrawn at intervals for absorbance measurements. Faster reactions were carried out in the cuvette of a Beckman DK-1 spectrophotometer thermostated at 25.0 ± 0.1°C by circulating water from a constant temperature bath. Initial concentrations of chlorine and hydrogen chloride were obtained by titration of the stock solutions before mixing.

The product of chlorination of *p*-chloroanisole was determined by allowing a run to proceed for 10 half-lives or more, then injecting samples into a gas chromatograph (30% Apiezon-L on Chromosorb-W) at 180°C. Only two peaks were found: *p*-chloroanisole and 2,4-dichloroanisole, identified by comparison with authentic samples. Yields of 2,4-dichloroanisole ranged from 84 to 99%.

Formation Constants

Under conditions of high TBACl concentration and low chlorine concentration it was found that the absorbance of mixtures of the two in chloroform decreased with time. Stock solutions of known concentrations of TBACl and chlorine were mixed in the thermostated cuvette (25.0 ± 0.1°C) of the Beckman DK-1 spectrophotometer and absorbance readings were recorded over a 20 min period. Extrapolation to zero time gave initial absorbances with a spread of ±3% over several repetitions. Including the error in transferring small amounts of chloroform solutions, we estimate the overall error at ±5%. This gives rise to the error bars in Fig. 2.

Concerning the nonexistence of the intramolecular hydrogen bond in 2-nitrothiophenol

TED SCHAEFER AND WILLIAM J. E. PARR[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 13, 1977

TED SCHAEFER and WILLIAM J. E. PARR. Can. J. Chem. **55**, 3732 (1977).

The long-range spin–spin coupling constants between the sulfhydryl proton and the ring protons in 2-nitrothiophenol in $CDCl_3$ and C_6D_6 solutions suggest the presence of two conformers in which the S—H bond prefers the benzene plane. The conformer in which the S—H bond lies *trans* to the nitro group is favoured over the *cis* conformer by a free energy difference of 0.5 ± 0.2 kcal/mol at 305 K. Apparently any intramolecular hydrogen bond is very weak compared to that in 2-nitrophenol.

TED SCHAEFER et WILLIAM J. E. PARR. Can. J. Chem. **55**, 3732 (1977).

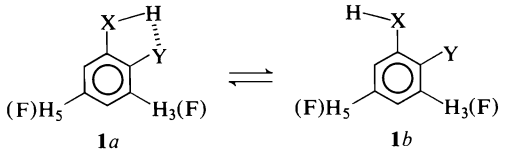
Les constantes de couplage spin–spin à longue distance entre le proton sulfhydryle et les protons du cycle aromatique du nitro-2 thiophénol dans des solutions $CDCl_3$ et C_6D_6 suggèrent la présence de deux conformères dans lesquels le lien S—H s'oriente dans le plan du cycle. Le conformère dans lequel la liaison S—H se situe *trans* au groupe nitro est favorisé par rapport au conformère *cis* par une différence d'énergie libre de 0.5 ± 0.2 kcal/mol à 305 K. Il apparait qu'une liaison hydrogène intramoléculaire quelconque est vraiment faible comparée à celle observée dans le nitro-2 phénol.

[Traduit par le journal]

Introduction

The energy of the intramolecular hydrogen bond in *o*-nitrophenol has never been directly determined (1). Indirect methods based on the chemical shift of the hydroxyl proton (2, 3) and on the torsional frequency of the hydroxyl group (4, 5) yield the energy as 6.7 ± 0.2 kcal/mol. These methods apparently work for weaker hydrogen bonds as well, agreeing with the measured enthalpy of formation of −1.4 kcal/mol for the intramolecular hydrogen bond in *o*-fluorophenol (5). Furthermore, the predictions based on chemical shifts and torsional frequencies are in accord with the deduction, from the contact shifts of hydroxyl protons induced by the di-*tert*-butyl nitroxide radical (5), that the intramolecular hydrogen bond in *o*-nitrophenol is somewhat weaker than in salicylaldehyde.

Another method for the determination of the relative energies of conformers such as **1***a* and **1***b* depends on the well-known stereospecificity



1*a* **1***b*

X = O, S

of the nuclear spin–spin coupling constants over five bonds, $^5J^{H,H(F)}$, between the proton on the sidechain, XH, and the protons or ^{19}F nuclei in the positions *meta* to XH. For example, in **1***a*, $^5J_m^{H,H_3} \equiv {}^5J_c \sim 0$ Hz and $^5J_m^{H,H_5} \equiv {}^5J_t \sim 0.6$ Hz in a variety of phenol derivatives (6, 7).

Now, if Y = NO_2 and if the energy of the hydrogen bond is as large as 6 to 7 kcal/mol, then **1***b* is negligibly populated at ambient temperatures; so that $^5J_c \sim 0$ Hz, in agreement with the observed spectra for 3-fluoro-6-nitrophenol and other nitrophenol derivatives (7). For *o*-dihalophenol derivatives, on the other hand, ^5J_c and ^5J_t have comparable magnitudes and ΔG^0 is a few hundred calories per mole at room temperature (6).

The enhanced intensity of the infrared band, corresponding to the S—H stretching frequency, of *o*-nitrothiophenol relative to thiophenol has been attributed to an intramolecular hydrogen bond; although, in contrast to the phenols, the shift in frequency is remarkably small (8). The dipole moment in benzene solution of *o*-nitrothiophenol has been interpreted as arising from 76 + 4% abundance of the hydrogen bonded form, **1***a*, the apparent increased population of the nonbonded conformer being attributed to intermolecular S—H...π bonding (8).

The small shift in the S—H stretching frequency does suggest a small proportion of the

intramolecularly bonded form. Therefore a measurement of ^5J_c and/or ^5J_t is indicated for *o*-nitrothiophenol. Recent work (9) has demonstrated that intermolecular proton exchange can be retarded, leading to multiplet structure in the proton magnetic resonance spectra of the sulfhydryl proton in thiophenol and some of its derivatives.

Experimental

The 2-nitrothiophenol was prepared and purified by the method of Foster and Reid (10). A 5 mol % solution in $CDCl_3$, containing a small amount of tetramethylsilane (TMS), was carefully degassed by the freeze-pump-thaw technique. The proton magnetic resonance spectrum was calibrated in the frequency sweep mode at sweep rates of 0.02 and 0.01 Hz/s on an HA 100 spectrometer. The probe temperature was 305 K. Decoupling experiments ascertained the presence of all splittings in the ring proton spectrum caused by spin–spin coupling to the sulfhydryl proton.

Another sample, consisting of a 5 mol% solution in 1:4 v/v $CDCl_3/C_6D_6$ was also calibrated by reading sweep and manual oscillator frequencies at approximately 5 Hz intervals.

Results and Discussion

Spectral Analysis

The spectrum of 2-nitrothiophenol in $CDCl_3$ solution was analyzed as a five spin system by means of the computer program LAME (11, 12). It turned out that the protons at positions 5 and 6 were very tightly coupled. The relative chemical shift is 0.8 Hz and the coupling constant is 8 Hz. The sulfhydryl proton, SH, couples to these two protons and also to that at position 3, H_3, leading to extensive overlap of peaks in its own spectral region. In consequence, the spectral parameters became imprecise, the couplings to SH being known to an estimated accuracy of 0.04 Hz.

However, the solution containing about 80% v/v of C_6D_6 yielded spectra with larger internal chemical shifts and could be analyzed satisfactorily. The results are given in Table 1. Note, however, that the couplings to SH from the ring protons are equal in the two solutions, to within experimental error.

The calculated and observed SH resonance peaks are displayed in Fig. 1 for both solutions.

The Conformational Populations

$^6J_p^{H,SH}$ and the Coplanarity of the SH and Benzene Moieties

$^6J_p^{H,OH}$ in phenol is less than 0.03 Hz, and $^6J_p^{H,SH}$ is -0.33 ± 0.02 Hz in thiophenol (13, 14). The nonzero value in the latter compound reflects the much smaller barrier to internal rotation in the thiophenol; ^6J being proportional to $\langle \sin^2\theta \rangle$, where θ is the angle by which the S—H bond twists away from the aromatic plane (14). The barrier in phenol is about 3.5 kcal/mol (15) but drops to about 1 kcal/mol in thiophenol (14). However, in *p*-nitrothiophenol the internal barrier to rotation about the C—S bond rises to about 2.5 kcal/mol (16), attributable to increased double-bond character induced by conjugation with the nitro group.

As the barrier increases, $\langle \sin^2\theta \rangle$ approaches zero. The observation that $^6J_p^{H,SH}$ in 2-nitrothiophenol is -0.03 ± 0.02 Hz (Table 1) suggests a barrier to internal rotation of greater than 3 kcal/mol (14) for the SH group. Of course, the barrier is no longer twofold in this compound, but it is reasonable to conclude that

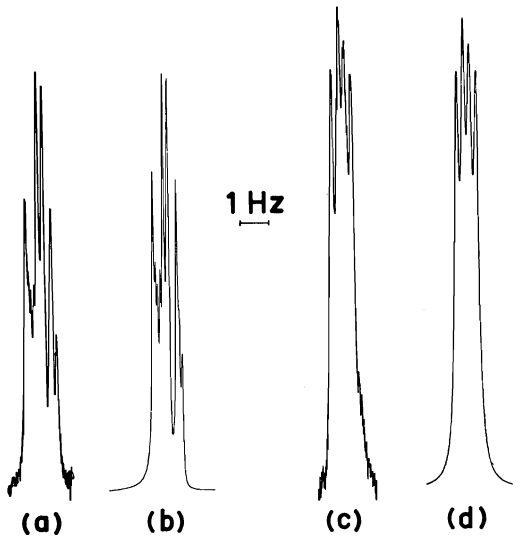

FIG. 1. In *a* and *b* the observed and calculated spectra of the sulfhydryl proton of 2-nitrothiophenol as a 5 mol% solution in 1:4 v/v $CDCl_3$–C_6D_6 solution are given; similarly in *c* and *d* for a 5 mol% solution in $CDCl_3$. The spectral parameters in Table 1 are used to calculate the spectra. The different appearance in the two solutions arises not from large differences in the couplings to the sulfhydryl proton, but from the different internal chemical shifts of the ring protons.

nonplanar conformations are inappreciably populated and that 2-nitrothiophenol can be discussed in terms of conformations **1***a* and **1***b*. This is not to say that the nitro group necessarily lies in the plane of the benzene ring.

The Populations of 1a and 1b

If nonplanar forms of 2-nitrothiophenol can be ignored, the σ–π mechanism does not contribute to $^5J_m^{H,SH}$ (16). If this coupling displays the stereospecificity of $^5J_m^{H,OH}$, then $^5J_c^{H,SH}$ is 0.0 Hz, i.e., $^5J^{H_3,SH}$ is zero in **1***a* and $^5J^{H_5,SH}$ vanishes in **1***b*. With these assumptions it follows that the free energy difference between **1***a* and **1***b* is 0.4 kcal/mol at 305 K, i.e., the *trans* form, **1***b* is approximately twice as abundant as the form **1***a*. Within experimental error, this conclusion applies to both solvents, $CDCl_3$ and C_6D_6.

On the other hand, if ^5J_c is as large as 0.1 Hz, then $^5J_t = 0.6$ Hz, and two equations can be written for the populations of **1***a* and **1***b*. The *trans* form is then 2.9 times as abundant as the *cis* form, corresponding to a free energy difference of 0.65 kcal/mol.

A third possibility, in which ^5J_t in **1***b* is somewhat smaller than ^5J_t in **1***a*, the most likely situation[2] if the electronegative nitro group polarizes the bonds in the coupling path in **1***b*, involves an even larger preponderance of the *trans* form, **1***b*.

Small Intermolecular Hydrogen Bonding

Strong intermolecular hydrogen bonding of the sulfhydryl group would favor form **1***b*. However, the equilibrium constant for the association of benzenethiol itself in CCl_4 is only 0.011 ℓ/mol (18), while infrared data on a variety of thiophenol derivatives suggest that noticeable intermolecular association occurs only at concentrations exceeding 1 *M* in CCl_4 (19).

The concentration of 2-nitrothiophenol in $CDCl_3$ is only ca. 0.6 *M*. The chemical shift of the sulfhydryl proton, ν_{SH}, of a 2 mol% solution of 4-nitrothiophenol in $CDCl_3$ is 3.73 ppm[3] and is 4.04 ppm for the 2-nitro isomer (Table 1). The relatively small shift to low field of 0.3 ppm can arise simply from the proximity of the nitro group in conformer **1***a* and is not an indication of intermolecular hydrogen bonding. Rather, when compared to the very large downfield shift of the hydroxyl proton caused by an *ortho* nitro substituent (3), the observed ν_{SH} in 2-nitrothiophenol is consistent with the conclusions based on $^5J_m^{H,SH}$ above.

In the presence of C_6D_6, ν_{SH} moves to high field, but no more so than the shifts of nearby ring protons (Table 1).

Conclusions

Contrary to the interpretation of infrared and dipole moment data, the present work implies that the S—H bond in 2-nitrothiophenol prefers to lie *trans* to the nitro substituent in $CDCl_3$ and C_6D_6 solutions. The *trans* form is favored over the *cis* form by a free energy difference of 0.5 ± 0.2 kcal/mol at 305 K. Any tendency to intramolecular hydrogen bond formation is clearly rather weak. Furthermore, the S—H bond apparently prefers the benzene plane in both forms and, as indicated by van der Waals radii, the nitro group may well twist out of the benzene plane so as to relieve steric strain.

The reaction of 2-aminopyridine 1-oxides with thiophosgene. 2*H*-[1,2,4]Oxadiazolo[2,3-*a*]pyridin-2-thiones

DANIELLE ROUSSEAU[1] AND ALFRED TAURINS[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received April 14, 1977

DANIELLE ROUSSEAU and ALFRED TAURINS. Can. J. Chem. **55**, 3736 (1977).

2-Aminopyridine 1-oxides react with thiophosgene in ethanol solution in the presence of sodium bicarbonate to produce 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thiones. The products are stable at room temperature, however, they explode on being heated at the temperature range 121 to 137°C.

DANIELLE ROUSSEAU et ALFRED TAURINS. Can. J. Chem. **55**, 3736 (1977).

Les oxydes d'amino-2 pyridine réagissent avec le thiophosgène en solution éthanolique en présence de bicarbonate de sodium pour conduire à des [2H]-oxadiazolo-[1,2,4] pyridine-[2,3-*a*] thiones-2. Les produits sont stables à la température de la pièce cependant, ils explosent par chauffage dans un écart de température se situant entre 121 et 137°C.

[Traduit par le journal]

2*H*-[1,2,4]Oxadiazolo[2,3-*a*]pyridin-2-one (**1**) has been prepared by heating ethyl *N*-2-pyridylcarbamate 1-oxide (**2**) at 150°C (1), and by treatment of 2-aminopyridine 1-oxide with phosgene (2, 3). Since compound **1** exhibited in its ir spectrum a carbonyl band at 1773 cm^{-1}, in the range for γ-lactones (~1770 cm^{-1}), it was concluded that it has a normal C=O group within a five-membered ring. It showed considerable stability towards heat (3), and underwent pyrolysis at 600°C (4).

An isomeric compound, 1,3,4-oxadiazolo[3,2-*a*]pyridin-2(3*H*)-one (**3**) was prepared by treating 1-amino-2(2*H*)-pyridone (**4**) with phosgene (3). Its ir spectrum showed bands at 1745 and 1785 cm^{-1}, a region assigned to *meso*-ionic carbonyl stretching.

On treatment with ethanol or ammonia, compound **1** yielded pyridine 1-oxide derivatives: *N*-2-pyridylcarbamate 1-oxide (**2**) and *N*-2-pyridylurea 1-oxide (**5**), respectively, whereas compound **3** with the same reagents gave 2-pyridone derivatives: ethyl *N*-[2(2*H*)-pyridon-1-yl]carbamate (**6**) and *N*-[2(2*H*)pyridon-1-yl]urea (**7**), respectively.

In this paper, the formation and properties of sulfur analogs of compounds **1** and **3** are described. When an ether solution of thiophosgene was mixed with an ethanolic solution of 2-aminopyridine 1-oxide in the presence of sodium bicarbonate, a cream colored solid was immediately deposited. On being heated to 132°C in a melting point tube, this product unexpectedly exploded. Its ir spectrum did not show any bands characteristic of the isothiocyanate group. The elemental analysis, nmr and mass spectra of the new compound agreed with the structure of 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thione (**8**). The compound reacted slowly at room temperature with methanol or ethanol by losing sulfur and deoxygenation of the N—O bond to give methyl or ethyl *N*-2-pyridylcarbamates. However, there was no reaction between ammonia and compound **8**. It has a low solubility in other organic solvents, except dimethylsulfoxide, from which it could be successfully recrystallized.

A number of methyl substituted 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thiones (**9**–**13**) were prepared from 2-amino-*x*-methylpyridine 1-oxides and thiophosgene, and all of them possessed the

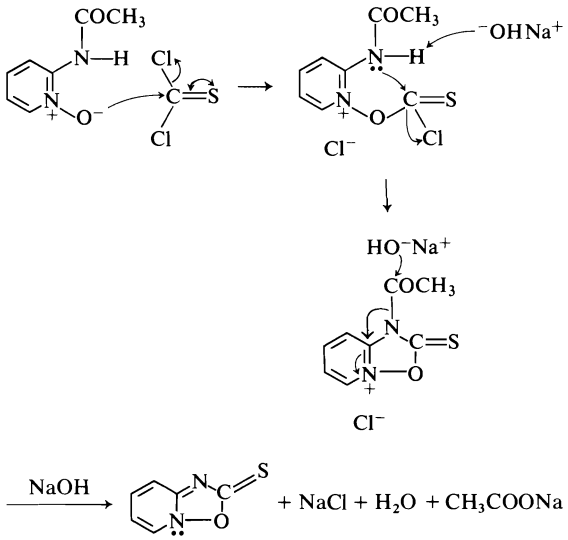
ability to explode on heating. The nature of the products formed during the explosion is being studied. In addition, it is necessary to mention that all 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thiones are stable at room temperature and do not decompose on standing in closed containers.

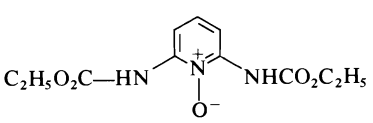
It was found that 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thiones are formed not only in the reaction of thiophosgene with 2-aminopyridine 1-oxides, but also with 2-acetamidopyridine and ethyl *N*-2-pyridylcarbamate 1-oxides. On the basis of this evidence the mechanism for this reaction must differ from that suggested for the analogous reaction of phosgene with 2-aminopyridine 1-oxide (3). In the latter mechanism, the first step involves the interaction of the amino group with phosgene to form an isocyanate group, followed by the attack of the N-oxide group on the isocyanate group and the ring closure. The mechanism of the thiophosgene reaction (Scheme 1) indicates that the oxygen



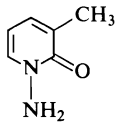
SCHEME 1. Reaction of 2-acetamidopyridine 1-oxide with thiophosgene.

atom of the N-oxide group initiates the reaction by attacking the carbon of the thiophosgene molecule to form a C—O bond. Since the reaction occurs in slightly basic solution, the hydroxyl ions are involved in establishing the N—C bond and eliminating the proton or acetyl group, respectively.

That this mechanism (Scheme 1) requires a free access by thiophosgene to the N-oxide group to initiate the reaction, is obvious from the fact that *N,N'*-diethoxycarbonylaminopyridine 1-oxide (**14**) does not react with thiophosgene, presumably because of the steric hindrance by the two bulky ethoxycarbonyl groups near the N-oxide oxygen.



14



15

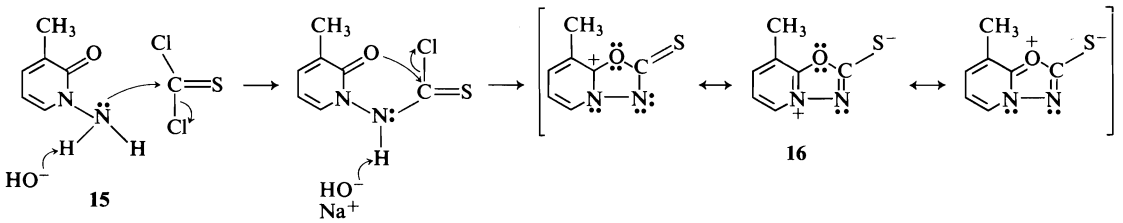
The previously proposed (3) formation of 2-isocyanatopyridine 1-oxide with phosgene is doubtful for the following reason. Since it is known that Hofmann degradation of acid amides involves the formation of intermediate isocyanates (6) one should expect a fast interaction between $-\overset{+}{N}-O^-$ and $-N=C=O$ groups, and formation of 2*H*-[1,2,4]oxadiazolo-[2,3-*a*]pyridin-2-one in the degradation of 2-pyridinecarboxamide 1-oxide. However, the only product observed in this reaction was 2-aminopyridine 1-oxide (7). In addition, compound **1** is stable toward prolonged alkaline hydrolysis.

Thiophosgene reacted also with 1-amino-3-methyl-2(2*H*)-pyridone (**15**), in a reaction analogous to that of phosgene (3) to give 8-methyl-[1,3,4]oxadiazolo[3,2-*a*]pyridin-2-thione (**16**) melting at 249–250°C without exploding (Scheme 2). Its mass spectrum revealed the presence of a molecular ion of *m/e* 166. The composition of compound **16** was confirmed by the high resolution mass spectrum. *Exact Mass* calcd. for $C_7H_6N_2OS$: 166.0201; found: 166.0200.

Experimental

2H-[1,2,4]Oxadiazolo[2,3-a]pyridin-2-thione, 8

(*a*) To 2-aminopyridine 1-oxide (0.5 g, 5 mmol) dissolved in 10 ml of water in presence of sodium bicarbonate (0.85 g, 10 mmol) was added gradually a solution of thiophosgene (0.6 g, 5 mmol) in 15 ml of ethyl ether. A white solid was immediately formed. The mixture was stirred for 2 h at 20°C, then filtered to give 0.660 g (87.5%) of 2*H*-[1,2,4]oxadiazolo[2,3-*a*]pyridin-2-thione



SCHEME 2. Reaction of 1-amino-3-methyl-2(2*H*)-pyridone (**15**) with thiophosgene.

(**8**), exploding at 132–133°C in the melting point tube. After recrystallization from DMSO it exploded at 134°C; nmr (DMSO-d_6): δ 9.59 (s, H-5), 7.75 (s, H-6), 8.47 (s, H-7), 8.08 (s, H-8); uv (C_2H_5OH): λ_{max} 289, 331.5 nm (log ε 4.27, 3.72); ir (KBr): 1619 (vs), 1577 (m), 1485 (s), 1449 (vs), 1400 (vs), 1382 (vs), 1290 (vs), 1146 (s), 1123 (m), 903 (m), 851 (m), 763 (vs), 623 (m), 434 (m) cm^{-1}. *Anal.* calcd. for $C_6H_4N_2OS$: C, 47.4, H, 2.6, N 18.4; found: C 47.1, H 2.9, N 18.2.

(*b*) A mixture of 2-acetamidopyridine 1-oxide (1.037 g, 6.8 mmol) and sodium bicarbonate (1.28 g, 15.2 mmol) in aqueous ethanol (25 ml) was treated with thiophosgene (0.88 g, 7.7 mmol) in 15 ml of ether. The mixture was stirred for 1 h and filtered to give 0.61 g (58.5%) of **8**, exploding at 134°C (recrystallized from dimethylsulfoxide), and showing the spectral characteristics mentioned under (*a*).

Compound **8** and ethanol produced ethyl *N*-2-pyridylcarbamate which was identified by its melting point, infrared spectrum (band at 1722 cm^{-1}), and mass spectrum (*m/e* 166). Treatment of **8** with refluxing methanol for 2.5 h gave colorless needles of methyl *N*-2-pyridylcarbamate, mp 128°C, lit. (5) 128–129°C.

5-Methyl-2H-[1,2,4]oxadiazolo[2,3-a]pyridin-2-thione, ***9***

(*a*) 2-Amino-6-methylpyridine 1-oxide hydrochloride (1.50 g, 9.3 mmol), thiophosgene (1.15 g, 10 mmol) and sodium bicarbonate afforded 1.286 g (81%) of **9**. Recrystallization from dimethylsulfoxide–benzene mixture produced cream-colored crystals, exploding at 134°C; uv (ethanol): λ_{max} 287, 333.5 nm (log ε 4.20, 3.61); ir (KBr): 1623 (m), 1569 (m), 1502 (m), 1413 (s), 1370 (s), 1322 (vs), 1255 (m), 1159 (m), 1086 (m), 1020 (m), 799 (s), 622 (vw), 427 (w) cm^{-1}. *Anal.* calcd. for $C_7H_6N_2OS$: C 50.5, H 3.6, N 16.9, S 19.3; found: C 50.2, H 3.7, N 16.8, S 18.9.

(*b*) By reacting 2-acetamido-6-methylpyridine 1-oxide (9.12 g, 54.9 mmol), thiophosgene (6.6 g, 57.4 mmol) and sodium bicarbonate in ethanol, 7.77 g (85.2%) of **9** was obtained, exploding at 134°C (dimethylsulfoxide–benzene).

6-Methyl-2H-[1,2,4]oxadiazolo[2,3-a]pyridin-2-thione, ***10***

(*a*) Treatment of 2-amino-5-methylpyridine 1-oxide hydrochloride (1.01 g, 6.2 mmol) with thiophosgene (0.81 g, 7 mmol) and sodium bicarbonate in ethanol gave 0.585 g (56.4%) of **10** as beige needles, exploding at 121°C (dimethylsulfoxide); uv (ethanol): λ_{max} 288, 330 nm (log ε 4.20, 3.65); nmr (DMSO-d_6): δ 9.50 (s, H-5), 8.33 (d, H-7), 8.00 (d, H-8). 2.77 (s, CH_3-6); ir (KBr): 1622 (m), 1503 (s), 1418 (vs), 1387 (vs), 1322 (vs), 1266 (s), 1024 (m), 819 (s), 733 (w), 559 (w) cm^{-1}. *Anal.* calcd. for $C_7H_6N_2OS$: C 50.5, H 3.6, N 16.9; found: C 50.7, H 3.9, N 16.6.

(*b*) Similarly, 2-acetamido-5-methylpyridine 1-oxide (7.04 g, 42.4 mmol), thiophosgene (5.1 g, 44.3 mmol), and sodium bicarbonate in ethanol gave 5.1 g (72.3%) of **10**, exploding at 121.5°C.

Compound **10** and refluxing ethanol gave ethyl (5-methyl-2-pyridyl)carbamate, mp 143°C; lit. (5) 144–145°C.

7-Methyl-2H-[1,2,4]oxadiazolo[2,3-a]pyridin-2-thione, ***11***

(*a*) By treatment of 2-amino-4-methylpyridine 1-oxide hydrochloride (1.06 g, 6.6 mmol) with thiophosgene (0.76 g, 6.6 mmol) and sodium bicarbonate in ethanol, 0.84 g (76.3%) of **11** was obtained. Colorless needles (dimethylsulfoxide–benzene) were obtained, exploding at 131.5°C; uv (ethanol): λ_{max} 289, 326 nm (log ε 4.28, 3.83); nmr (DMSO-d_6): δ 9.47 (d, H-5), 7.60 (d, H-6), 7.91 (s, H-8), 2.88 (s, CH_3-7). *Anal.* calcd. for $C_7H_6N_2OS$: C 50.5, H 3.6, N 16.9; found: C 49.9, H 3.7, N 16.7.

(*b*) Similarly, reaction of 2-acetamido-4-methylpyridine 1-oxide (8.09 g, 48.7 mmol) with thiophosgene (5.94 g, 51.6 mmol) afforded 70% of **11**, exploding at 132°C.

(*c*) The treatment of ethyl *N*-(4-methyl-2-pyridyl)carbamate 1-oxide (0.63 g, 3.2 mmol) with thiophosgene (0.36 g, 3.2 mmol) and sodium bicarbonate gave 0.48 g (90%) of **11**, exploding at 132°C.

8-Methyl-2H-[1,2,4]oxadiazolo[2,3-a]pyridin-2-thione, ***12***

In similar fashion, a mixture of 2-acetamido-3-methylpyridine 1-oxide (3.57 g, 21.5 mmol) gave upon treatment with thiophosgene (2.63 g, 22 8 mmol) and sodium bicarbonate in ethanol 2.69 g (75.4%) of **12** as a cream-colored precipitate. Colorless needles (dimethylsulfoxide–benzene) were obtained, exploding at 134°C; uv (ethanol): λ_{max} 287.5, 336 nm (log ε 4.16, 3.63); nmr (DMSO-d_6): δ 9.44 (d, H-5), 8.28 (d, H-7), 7.46 (t, H-6), 2.87 (s, CH_3-8); ir (KBr): 1607 (s), 1497 (s), 1440 (m), 1428 (m), 1388 (vs), 1310 (s), 1278 (s), 1064 (m), 1002 (m), 809 (s), 780 (s), 741 (m), 626 (w) cm^{-1}. *Anal.* calcd. for $C_7H_6N_2OS$: C 50.5, H 3.6, N 16.9, S 19.2; found: C 50.4, H 3.8, N 16.6, S 19.2.

5,7-Dimethyl-2H-[1,2,4]oxadiazolo[2,3-a]pyridin-2-thione, ***13***

2-Amino-4,6-dimethylpyridine 1-oxide hydrochloride (2.44 g, 14 mmol), thiophosgene (1.73 g, 15 mmol), and sodium bicarbonate in ethanol gave 1.87 g (74.4%) of **13**. Cream-colored crystals (dimethylsulfoxide–benzene were obtained), exploding at 137°C; nmr (DMSO-d_6): δ 7.71 (s, H-8), 7.10 (s, H-6), 2.74 (s, CH_3-5), 2.61 (s, CH_3-7); ir (KBr): 1628 (s), 1569 (s), 1418 (vs), 1381 (s), 1335 (s), 1271 (s), 1027 (m), 848 (s), 798 (m), 728 (w), 534 (w) cm^{-1}; ms no molecular ion of *m/e* 180 was present; the strongest peak at *m/e* 148 ($M^{\ddagger}$ − S) was

assigned to 4,6-dimethyl-2-pyridyl isocyanate. *Anal.* calcd. for $C_8H_8N_2OS$: C 53.3, H 4.4, N 15.5, S 17.8; found: C 53.0, H 4.4, N 15.8, S 17.8.

8-Methyl-[1,3,4]oxadiazolo[3,2-a]pyridin-2-thione, ***16***

1-Amino-3-methyl-2-pyridone (0.2 g) (**15**) (3) was dissolved in aqueous ethanol (10 ml) in the presence of sodium bicarbonate (0.5 g) and treated with a solution of thiophosgene (0.5 g) in ether (10 ml). The precipitate was filtered off and extracted with boiling ethanol. The evaporation of the ethanolic extract left 0.245 g of the product **16**, mp 249–250°C (short colorless needles after crystallization from dimethylsulfoxide) (Scheme 2).

Low resolution mass spectrum: *m/e* 166 is the $M^{\cdot+}$, in agreement with the composition of compound **16**. A fragment ion of *m/e* 109 may be assigned to 3-methyl-2-pyridone whose presence may be rationalized as being created by the expulsion of SCN from the molecular ion. High resolution mass spectrum: *Exact Mass* calcd. for $C_7H_6N_2OS$: 166.0201; found: 166.0200. The nmr spectrum (DMSO-d_6): δ 9.16 (d, H-5), 7.94 (t, H-6), 8.42 (d, H-7), 2.87 (s, CH_3-8).

Department of Chemistry, American University of Beirut, Beirut, Lebanon and Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received April 5, 1977

KHAMIS A. ABBAS and ROBERT D. COOK. Can. J. Chem. **55**, 3740 (1977).

The rates of the acid-catalyzed hydrolysis of methyl dimethyl-, diethyl-, diisopropyl-, and di-*tert*-butylphosphinate in D_2SO_4–D_2O and of *p*-methoxybenzyl, *p*-chlorobenzyl, *p*-nitrobenzyl, and benzyl diethylphosphinate in H_2SO_4 – 70% w/w DMSO–H_2O have been studied. The bell-shaped p*H*-rate profiles, the Bunnett–Olsen ϕ (0.91 to 1.28), Bunnett w (2.28 to 3.52) and w^* (−0.94 to +0.17), and Yates-McClelland r (0.61 to 2.6) values, and the entropies of activation (−18 to −24 eu) all support an A2 mechanism for the methyl esters. The suggested mechanism for the benzyl esters is a unimolecular hydrolysis ($A_{al}1$). This conclusion is supported by the p*H*-rate profiles, the ϕ_r values (−0.12 to −0.29) and the entropies of activation (−4 to −7 eu). The pK_a's of the esters are also reported and they range between −2.4 to −3.3.

KHAMIS A. ABBAS et ROBERT D. COOK. Can. J. Chem. **55**, 3740 (1977).

On étudie les vitesses d'hydrolyse catalysées par un acide du diméthyl-, diéthyl-, diisopropyl- et di-*tert*-butylphosphinate de méthyle dans une solution D_2SO_4–D_2O ainsi que pour les diéthylphosphinates de *p*-méthoxybenzyle, *p*-chlorobenzyle, *p*-nitrobenzyle et benzyle dans une solution H_2SO_4 – 70% w/w DMSO–H_2O. Les courbes obtenues en forme de cloche du p*H*-vitesse d'hydrolyse, les valeurs ϕ (0.91 à 1.28) de Bunnett–Olsen, de w (2.28 à 3.52) et w^* (−0.94 à +0.17) de Bunnett et les valeurs de r (0.61 à 2.6) de Yates-McClelland ainsi que les entropies d'activation (−18 à −24 ue) sont favorables à un mécanisme de type A2 pour les esters méthyliques. On propose un mécanisme d'hydrolyse unimoléculaire ($A_{al}1$) pour les esters benzyliques. Cette conclusion est appuyée par l'allure des courbes (p*H*-vitesse d'hydrolyse), les valeurs ϕ_r (−0.12 à −0.29) ainsi que les entropies d'activation (−4 à −7 ue). On présente aussi les valeurs des pK_a des esters qui se situent entre −2.4 et −3.3.

Introduction

Because of their biological importance, the hydrolysis reactions of phosphates (1), and to a lesser extent, phosphonates (2), have been extensively studied. Although phosphinates do not occur in nature, their hydrolysis reactions have also been the subject of several reports. Most of these studies have been carried out in alkaline medium (3). It has been shown that, in general, phosphinates hydrolyze via a mechanism involving attack of hydroxide on phosphorus and subsequent cleavage of the P—O bond. A few esters, *p*-nitrophenyl diphenylphosphinate (**1**) (4), some methyl methylarylphosphinates (**2***a–c*) (5), some l-arylethyl diphenylphosphinates (**3***a–d*) (6) and some alkyl phenylethylphosphinates (**4***a–e*) (7) have been studied in acid medium. There are four general possibilities for the hydrolysis of phosphinates in acid medium. These possibilities are: (*i*) water not involved in the rate-determining step and P—O bond cleavage ($A_{ac}l$); (*ii*) water not involved and C—O bond cleavage ($A_{al}1$); (*iii*) water involved and P—O bond cleavage ($A_{ac}2$); (*iv*) water involved and C—O bond cleavage ($A_{al}2$). An A2 mechanism with P—O bond cleavage as shown by O-18 studies has been proposed for the hydrolysis of **1** (4). A similar mechanism was suggested for compounds **2***a–c*; however, no evidence was presented to support P—O bond cleavage (5). Subsequently, McClelland has shown by O-18 experiments that compounds **2***a–c* undergo acid-catalyzed hydrolysis with approximately 90% P—O bond cleavage (8). A unimolecular ($A_{al}1$) pathway has been proposed for compounds **3***a–c* (6). Compounds **4***a* and **4***b* hydrolyze by an A2 mechanism with 49% and 65% C—O bond cleavage respectively (7). In this paper we report our results on the hydrolysis of methyl dimethyl- (**5***a*), diethyl- (**5***b*), diisopropyl- (**5***c*), and di-*tert*-butylphosphinate (**5***d*)

Results

Rate Data

The observed first-order rate constants for the hydrolysis of compounds **5***a–d* and **6***b–c* at different acid strengths[3] (C_{D^+} or C_{H^+}) are given in Tables 1 and 2 respectively. In subsequent correlations the Hammett acidity functions D_0 and H_0 are also used. The D_0 values are corrected for temperature (9, 10); however, the H_0 values are for 25°C (11). Rate–pH profiles are given in Figs. 1–3.

Basicity Data

The basicity measurements as determined by the nmr method (12) for compounds **5***a–d*, **6***b–d* and for ethyl diethyl- and isopropyl diethylphosphinate are given in Table 3. A typical plot of the nmr chemical shift versus the appropriate acidity function for methyl dimethylphosphinate (**5***a*) is given in Fig. 4. The value of M in Table 3 is the slope of the plot of $\log_{10}$

[3]C_{D^+} and C_{H^+} are the deuterium and hydrogen ion concentrations and were determined from calibration curves which were prepared by titrating weighted samples.

3).[5] The results of the application of these equations to the rate data obtained for compounds **5***a–d* are given in Table 5. All the

$$[2]\quad \log_{10} k_{obs} - \log_{10} d_0/(d_0 + K_{SD^+}) = w \log_{10} a_{D_2O} + C$$

[5]In [2] and [3] and the following equations the a_{D_2O} values (activity of deuterium oxide) are for 20°C (14) and $-\log_{10} d_0 = D_0$.

$$[3]\quad \log_{10} k_{obs} - \log_{10} C_{D^+}/(d_0 + K_{SD^+}) = w^* \log_{10} a_{D_2O} + C'$$

w plots are curved as is predicted when data obtained over a wide range of acid strength are used (13). The w^* plots give better correlations. However, if the rate data obtained in a medium range of acidities is used then that section of the w plot is relatively linear (see correlation coefficients). Figure 5 gives the w and w^* plots for compound **5***a*.

Bunnett and Olsen ϕ Approach (15)

Bunnett and Olsen suggested that the linear free energy relationship (lfer) represented by [4] would be useful in determining the mechanism of acid-catalyzed reactions when a wide range of acidities is used (15). The ϕ values obtained are composites of ϕ_e, which relates to the equilibrium protonation step, and ϕ_r, which relates to the reaction step. The values for ϕ_e and ϕ_r can be obtained from [5] and [6] respectively. Equation 6 represents the proper form of the Bunnett–Olsen lfer for a moderately basic substrate. The values obtained for ϕ, ϕ_e, and ϕ_r are given in Table 5. A typical ϕ plot is given

$$[4]\quad \log_{10} k_{obs} + D_0 = \phi(D_0 + \log_{10} C_{D^+}) + C''$$

Yates–McClelland Equation (16)

In order to eliminate the problems created by

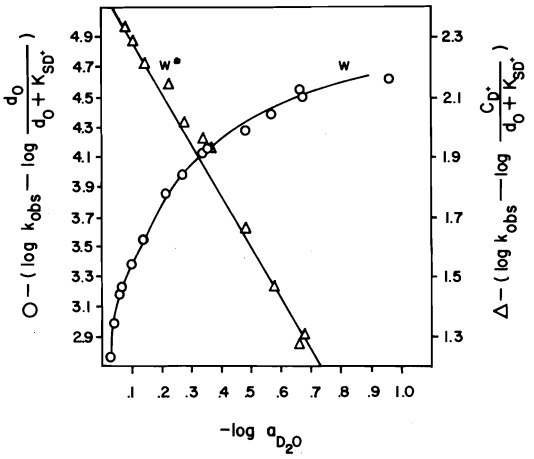

FIG. 5. Bunnett w and w^* plots of the rate data obtained for methyl dimethylphosphinate hydrolysis.

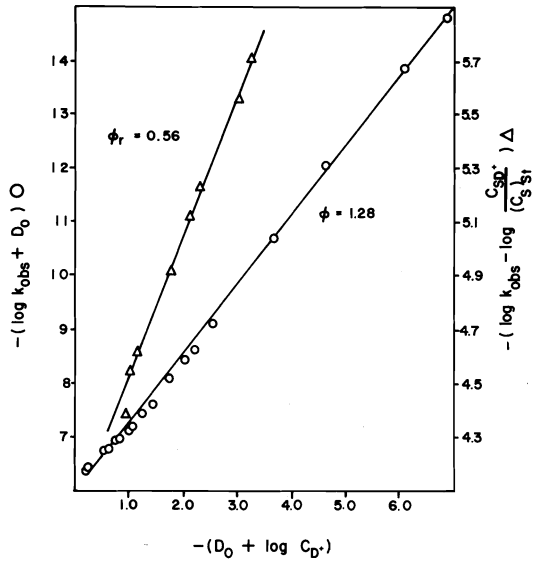

FIG. 6. Bunnett–Olsen ϕ and ϕ_r plots of the rate data obtained for methyl di-*tert*-butylphosphinate hydrolysis.

the non-cancellation of the activity coefficient ratios when analyzing the rate data of the acid-catalyzed hydrolysis of a non-Hammett substrate, Yates and McClelland suggested that the appropriate acidity function for that substrate be used (16). In order to avoid defining new acidity functions for every new type of substrate it was suggested that the Hammett acidity function be modified as in [7] (the M value comes

$$[7] \qquad H_{\text{phosphinates}} = MH_0$$

from [1]). The form of the Yates–McClelland equation used is given in [8]. The values obtained for r, which represents the number of water molecules involved in the rate-determining step, are given in Table 5. A typical r plot is given in Fig. 7.

$$[8] \quad \log_{10} k_{\text{obs}} - \log_{10} d_0^M/(d_0^M + K_{SD^+}^M) = r \log_{10} a_{D_2O} + C^\dagger$$

Discussion

Methyl Esters: General Comments

The pH-rate profiles for compounds 5*a–d* are given in Fig. 1 and an expanded profile for compounds **5***b–d* is given in Fig. 2. The rates of hydrolysis of these compounds show both acid catalysis and at higher acidities acid inhibition of reaction. The bell-shaped curves that are obtained are typical of acid-catalyzed reactions where water is involved in the rate-determining step (17). The acid-catalyzed portion of the curve represents an increase in reactivity due to increasing amounts of protonated ester while the acid-inhibited part is due to a decrease in the activity of water in more concentrated acid solution. The four esters are approximately 40% protonated at their maximum rate. Further proof for an A2 mechanism can be found in the application of the Bunnett w and w^* equations (13) as well as the Bunnett–Olsen ϕ (15) and Yates–McClelland r-value (16) approaches to the study of acid-catalyzed reactions (see next section).

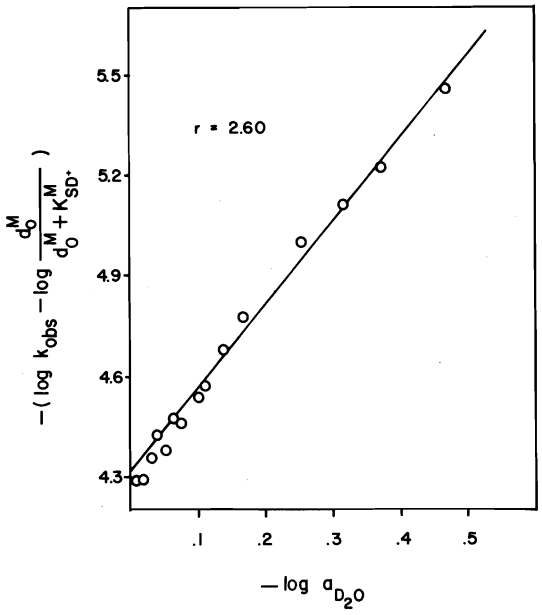

FIG. 7. Yates–McClelland r plot of the rate data obtained for methyl di-*tert*-butylphosphinate hydrolysis.

It is also important to note that the p*H*-rate profiles show no upward curvature at high acid concentrations unlike several acetate esters (16). These acetates, for example methyl acetate, have bell-shaped p*H*-rate profiles which at concentrations above 85% sulfuric acid show slight increases of rate. These upward tails have been explained as a change of mechanism from $A_{ac}2$ to $A_{ac}1$, that is, rate-determining formation of an acylium ion (16). The analogous species for phosphinates would be a phosphinylium ion ($R_2P(O)^+$). There is evidence from studies on the hydrolysis of phosphinyl chlorides that such species are not very stable (18) and therefore in the acid-catalyzed hydrolysis of phosphinates an $A_{ac}1$ pathway is most likely of high energy. An $A_{al}1$ mechanism in the case of the methyl esters is equally unlikely because of the instability of the methyl carbonium ion.

Treatment of the Kinetic Data

The hydrolysis of esters **5***a–d* has been studied over nearly the entire range of sulfuric acid concentration. Because of this factor, the *w* plots, as predicted, are curved, that is, the value of *w* is dependent on the concentration range of acid. If a medium concentration range is used (25–50% D_2SO_4), the values of *w* range from 2.28–3.52 increasing from **5***a* to **5***d*. These values are indicative of an A2 mechanism with water acting as a nucleophile or as a proton transfer agent in the rate-determining step. The *w** plots give straighter lines over a wider acid concentration range than those for *w* and again the results support an A2 mechanism. This mechanism is also suggested by the results obtained from the Bunnett–Olsen lfe relationship (ϕ values). The ϕ_e and ϕ_r values were also determined. Because the substrates are moderately weak bases the proper form of the Bunnett–Olsen relationship is that which is represented by [6] (ϕ_r). The ϕ_r values support a rate-determining step in which water participates as a nucleophile. The appropriate form of the Yates–McClelland equation (eq. 8) gives *r* values which range from 0.6 to 2.6. The value of *r* represents the number of water molecules needed in the rate-determining step. Clearly, for these methyl esters, at least one molecule of water is necessary.

Underlying all these results is the interesting relationship between solvation as represented by the value of *M* and the range of values for the different parameters *w*, *w**, and *r*. Further work is needed in this area although some progress has been achieved by the group of McClelland, Yates and co-workers (19).

Activation Parameters

The entropies of activation of compounds **5***a–d* are in the range of −17 to −24 eu. These values are typical of A2 reactions (20). The entropy of activation was also calculated for compound **5***a* from the rate data in 90.5% D_2SO_4 and the value obtained is the same as that in 50.5% acid. This result also supports the conclusion drawn from the p*H*-rate profiles that the mechanism does not change at very high acidities.

Relative Rate and Point of Cleavage

The relative rate values for a number of different ester systems under varying conditions of p*H*, solvent, and temperature are given in Table 6. The rates of acid-catalyzed hydrolysis of phosphinates are much less sensitive to the size of the substituents on phosphorus than are the corresponding rates in alkaline medium. This result is similar to that obtained for carboxylic esters. The mechanism for carboxylic ester hydrolysis in acid or base involves attack at carbonyl carbon to form a tetrahedral intermediate. It has also been shown that in the alkaline hydrolysis of phosphinates attack takes place on phosphorus with resultant cleavage of the P—O bond (3). However, in acid, water attacks both phosphorus and carbon leading to cleavage of both the P—O and C—O bonds (7, 8). The place of attack appears to be very sensitive to conditions, to the nature of the nucleophile, and to the size of the substituents on phosphorus. For example, compound **2***a* hydrolyzes in 1.0 *M* $HClO_4$ with 90% P—O bond cleavage (8) and compound **4***a* hydrolyzes in 3 *M* $HClO_4$ with 51% P—O bond cleavage (7).

It is likely that the energy barriers to attack at phosphorus and to attack at carbon are very similar and that these esters hydrolyze via both pathways with C—O cleavage becoming more favourable as the size of the alkyl groups on phosphorus increase.

At very high acid concentration hydrolysis does take place, although very slowly. The activity of water at these acid concentrations is extremely low and therefore, it is possible that HSO_4^- is the nucleophile affecting reaction (21). Above 85% H_2SO_4 the concentration of HSO_4^-

TABLE 6. Relative rates of ester hydrolysis

Reaction	R				Ref.

is more than 100 times greater than that of H_2O and this would more than offset their nucleophilicity difference (22).

In McCoy's study of the acid-catalyzed alcoholysis of phosphinates **4***a* and **4***b* with methanol and isobutyl alcohol, ethers were isolated as products (greater than 95% attack of alcohol on carbon) (7). In our hydrolysis experiments dimethyl ether is formed in the reactions run in acid strengths above 25% D_2SO_4. Although under these experimental conditions the product of our reaction, methanol, dehydrates, one cannot rule out the possibility that some of the ether is formed in an alcoholysis reaction similar to that observed by McCoy.

In conclusion it can be stated that the evidence clearly suggests an A2 mechanism for the hydrolysis of compounds **5***a–d*.

Benzyl Esters

Noyce and Virgilio (6) have studied the solvolysis of l-arylethyl diphenylphosphinates (**3***a–d*) in 80% ethanol–water at 75°C. The evidence clearly supports their suggested $A_{al}1$ mechanism. The title compounds, **6***a–d*, are less sterically hindered than **3***a–d* toward attack of water (associative mechanism) and they would give rise to a slightly less stable carbonium ion (dissociative mechanism), therefore the possibility of either an A2 or A1 mechanism exists for the hydrolysis of these compounds.

The methoxy ester (**6***a*) hydrolyzes too quickly for the determination of either the pK_{SH^+} or accurate rate constants. The nitro ester (**6***d*), on the other hand, only shows appreciable hydrolysis in solutions containing more than 60% H_2SO_4. The pH-rate profiles for compounds **6***b* and **6***c* are given in Fig. 3. These compounds show a continuous increase in rate with increasing acid concentration. Such profiles are indicative of hydrolysis reactions where water is not involved in the rate-determining step, i.e. dissociative mechanisms.

The ϕ values obtained for compounds **6***b* and **6***c* are positive (0.45 and 0.53 respectively) but the ϕ_r values are negative (−0.12 and −0.29 respectively). The positive values for ϕ would indicate the involvement of water; however, very little is known about the effect of organic solvents on the value of ϕ (15) and, in any case, the values do not take into consideration the amount of protonated substrate as do the ϕ_r values. Negative values of ϕ_r are consistent with an A1 mechanism.

The strongest evidence for a dissociative mechanism comes from the values of the entropy of activation. The $\Delta S^{\neq}$ values for compounds **6***b* and **6***c* at 77°C are −7 and −4 eu respectively. These values fall between the ranges of entropies of activation expected for an A1 and A2 reaction (20); however, there are several examples of A1 reactions which have small negative entropies (20). Tommila and Murto (23) have also found that the $\Delta S^{\neq}$ for the hydrolysis of ethyl acetate in HCl–DMSO–H_2O is smaller than the $\Delta S^{\neq}$ in HCl–H_2O (22). This result indicates that the $\Delta S^{\neq}$ values for com-

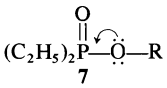
pounds **6***b* and **6***c* might even be slightly positive if the reaction were carried out in H_2SO_4–H_2O only.

The substrate which is least likely to undergo dissociation to a carbonium ion is the *p*-nitro ester (**6***d*). This compound undergoes hydrolysis at a reasonable rate only at an acid concentration where the activity of water is very low and beyond the point where the compound is completely protonated. Therefore it is reasonable to assume that this compound also hydrolyzes by a dissociative $A_{al}1$ mechanism. An $A_{ac}1$ mechanism cannot be completely ruled out but it is less likely given the apparent instability of the phosphinylium ion (18).

A Hammett ρ value was calculated for the reaction using relative rate data taken from the reaction half-lives at 40% H_2SO_4 and 50°C.[6] The value obtained using σ^+ was −3.5. This result also supports a unimolecular reaction involving carbonium ion formation. The ρ value obtained by Noyce and Virgilio for compounds **3***a–d* is −5.1 (6). Therefore, an $A_{al}1$ mechanism is suggested for compounds **6***a–d*.

Basicity of Phosphinates

Because of the similarity between the protonation behaviour of phosphine oxides and phosphinates, protonation undoubtedly takes place, in the latter compounds, on the oxygen of the P=O group. There appears to be no correlation between the pK_a of the phosphinates and the nature of the carbon groups attached to phosphorus. However, the methyl-, ethyl-, and isopropyl diethylphosphinates have pK_a values which decrease appreciably with the decreasing size of the alkyl group in the alcohol part of the ester (−3.56, −3.21, and −2.41 respectively). A possible explanation for this trend is to postulate that interaction of the type shown in structure **7** is important. As the R group becomes more electron donating the interaction as depicted in structure **7** will become more important and the ester would be expected to be more basic. Supporting evidence for this point comes from the large polar substituent effect of the R group in the alkaline hydrolysis of the identical esters (ρ* = 8) (3).



7

[6]Approximate calculated rate constants were used for compounds **6***a* and **6***d*.

The values of *M* given in Table 3 indicate how different phosphinates are from anilines (Hammett bases). The lower the *M* value the more that substrate is solvated. All the phosphinates have approximately the same *M* value (0.5) except for methyl di-*tert*-butylphosphinate and isopropyl diethylphosphinate. For these compounds there appears to be some steric inhibition of solvation. Phosphinates should be more highly solvated than anilines because of the presence of two oxygens each with two pairs of non-bonding electrons. Oxygen is also a harder base than nitrogen and therefore should interact better with the proton (12).

The results for benzyl diethylphosphinate are difficult to explain. The *M* value is 0.78, considerably higher than all of the other esters studied. One possible explanation would be that the compound is undergoing reaction even in the short time needed for the nmr measurement. Of all the compounds for which the pK_a was determined this ester is the most reactive.

Experimental

General

Elemental analyses were performed by E. Pascher, Bonn, Germany. Melting points were taken in capillary tubes and are uncorrected. All nuclear magnetic spectra were taken on a Varian model A60D spectrometer and infrared spectra were taken on a Perkin-Elmer model 257 spectrophotometer.

Synthesis of Esters

The synthesis and the physical and spectral data for compounds **5***a–c* as well as for ethyl diethyl- and isopropyl diethylphosphinate have been previously reported (3 and references therein). Benzyl diethylphosphinate has been synthesized by a method different from that reported here but the compound was not characterized (24). For all compounds nmr and infrared spectra were consistent with structural assignments. The elemental analyses and boiling points for the previously unreported esters are given in Table 7.

Methyl di-tert-Butylphosphinate

The ester was prepared by addition of diazomethane to a methanol solution of di-*tert*-butylphosphinic acid. The methanol was removed and the ester distilled. The acid was prepared by refluxing the acid chloride with aqueous 1 *N* sodium hydroxide for 48 h (25); mp 205–207°C (lit. 201°C (25), 208–210°C (26)). The di-*tert*-butylphosphinyl chloride was synthesized from *tert*-butyldichlorophosphine by a procedure similar to that of Crofts and Parker (25). The phosphinyl chloride (101–105°C/5 Torr) was recrystallized from petroleum ether; mp 80–81.5°C (lit. 82.5°C (25), 80.1–80.9°C (27)). The *tert*-butyldichlorophosphine was prepared by a method similar to that of Voskuil and Arens (27).

a stirrer, a condenser, a dropping funnel, and a thermometer were placed diethylphosphinyl chloride (0.1 mol) and 100 ml of dry ether. The flask was cooled to 5°C and a solution of the appropriate alcohol (0.15 mol) and freshly distilled triethylamine (0.15 mol) in 100 ml of ether was added with stirring over a period of 3 h. A second portion of alcohol (0.5 mol) was then added over a period of 1 h and the reaction was stirred for a further 4 h at 5°C. The mixture was allowed to come to room temperature and stand overnight. The triethylammonium chloride was filtered and the filtrate was washed first with 1% HCl and then with 5% sodium bicarbonate. The ether layer was finally washed with water, dried over sodium sulfate, and concentrated at room temperature on a rotatory evaporator. The separation of the alcohols from the esters was achieved by column chromatography using silica gel. The alcohols were eluted with a 4:1 benzene–chloroform solution and the esters with a 5:1 chloroform–methanol solution. The chromatogram was followed by thin-layer chromatography on silica gel with chloroform as solvent. When benzyl diethylphosphinate was distilled at 110–112°C/0.05 Torr, nmr showed that the ester had partially decomposed into acid and alcohol. Henning *et al.* (24) have prepared the benzyl ester by a transalkylation reaction of ethyl diethylphosphinate and benzyl chloride using a catalytic amount of triphenylphosphine. The ir and nmr spectra were not reported; however, the authors mentioned that the compound decomposed at 180°C. The crude yield for the preparation of the benzyl esters by the method reported in this paper is 85–90%.

Kinetic Measurements

The hydrolyses of compounds **5***a–d* were run in dideuterosulfuric acid – deuterium oxide solution and the hydrolyses of compounds **6***a–d* were run in solutions of sulfuric acid and 70% w/w dimethylsulfoxide–water. The molarities of the acids were determined from calibration curves. The calibration curves were prepared by titrating weighted samples of the acid solutions. The dimethylsulfoxide was purified by distillation.

The rates were followed by nmr spectroscopy. Aliquots of the reaction mixtures were capped in nmr tubes which were immersed in a bath at appropriate temperatures. The nmr spectra were recorded at different time intervals. Two runs were carried out in sealed nmr tubes. Identical results were obtained from the kinetic experiments with sealed and capped tubes. In the nmr the decrease in the intensity of the CH_3 of the OCH_3 or the CH_2 of the p-$XC_6H_4OCH_2$ of the esters and the increase in the intensity of the same groups in the respective alcohols were followed. Each aliquot was integrated 10–16 times and the results were averaged. The chemical shift difference between these resonances is between 20 and 24 Hz. At the higher concentrations of acid another peak appears; this peak was shown to be due to ether formation. Samples of methanol and *p*-methoxybenzyl alcohol were placed in acid under reaction conditions and after a period of time another peak appeared at a chemical shift difference equal to the shift difference observed during hydrolysis. This conclusion is also supported by nmr studies on mixtures of methanol and dimethyl ether (Matheson) in acid solution.

The spectra of ethyl diethyl- and isopropyl diethylphosphinate are too complex to be integrated properly and therefore the kinetics of hydrolysis of these compounds were not studied.

By plotting $\log_{10}$ (unhydrolyzed ester/original ester) versus time, straight lines were obtained. The slopes of the plots were obtained by a least squares computer analysis. The rate constant, k_{obs}, is then equal to 2,303 (slope)/3600 s^{-1}.

Measurement of pK_a's

The pK_a's of the esters were measured using the procedure of Haake *et al.* (12). The pK_a's of compounds **5***a–d* were measured in D_2SO_4–D_2O solution (concentration of the ester was approximately 0.1 *M*) and those for **6***a–d* were measured in H_2SO_4 – 70% w/w DMSO–H_2O solution. Trimethylammonium chloride was used as an internal standard.

Open-chain nitrogen compounds. Part III.[1] The formation of triazenes in the reaction of diazonium salts with α-aminoacetonitrile and related α-substituted alkylamines

THERESA A. DANIELS, SHIRAZ SIDI, AND KEITH VAUGHAN[2]

Department of Chemistry, Saint Mary's University, Halifax, N.S., Canada B3H 3C3

Received April 4, 1977

THERESA A. DANIELS, SHIRAZ SIDI, and KEITH VAUGHAN. Can. J. Chem. **55**, 3751 (1977).

Several triazenes of type $Ar{\cdot}N{=}N{\cdot}NH{\cdot}CH_2Y$, where Y is electron withdrawing, have been prepared by reaction of the diazonium salts $X{\cdot}C_6H_4N_2^+$ (X = H, *p*-NO_2, *p*-CO_2Me, *p*-COPh, and *o*-COPh) with the α-substituted alkylamines NH_2CH_2Y (Y = CN, CO_2Et, COPh, and $CH(OCH_3)_2$) in aqueous solution, without prior isolation of the diazonium salt. In all cases, the diazonium ion attacks at the NH_2 moiety exclusively and the methylene group in NH_2CH_2Y shows no tendency to compete for the diazonium ion.

THERESA A. DANIELS, SHIRAZ SIDI et KEITH VAUGHAN. Can. J. Chem. **55**, 3751 (1977).

Plusieurs triazènes de types $Ar{\cdot}N{=}N{\cdot}NH{\cdot}CH_2Y$, où Y est un groupe attracteur d'électrons, sont préparés, en solution aqueuse, par réaction de sels diazonium $X{\cdot}C_6H_4N_2^+$ (X = H, *p*-NO_2, *p*-CO_2Me, *p*-COPh et *o*-COPh) avec des alkylamines α-substituées NH_2CH_2Y (Y = CN, CO_2Et, COPh et $CH(OCH_3)_2$) sans isolation préalable des sels diazonium. Dans tous les cas, l'ion diazonium attaque exclusivement le site NH_2 et le groupe méthylène dans NH_2CH_2Y montre aucune tendance à entrer en compétition vis-à-vis de l'ion diazonium.

Introduction

The reaction of diazonium salts with proteins has been extensively used as a structural probe, typically in the elucidation of the topography of the active sites of enzymes (2). The azo-proteins formed in this way arise largely from diazo-coupling with the activated aromatic rings of tyrosine and histidine residues and the ε-amino group of lysines (3). The reaction of diazonium salts at the α-amino group of free amino acids leads to deamination of the amino acid (4, 5), via the unstable triazenes, $ArN{=}N{\cdot}NH{\cdot}CHR{\cdot}CO_2H$, but the rate of this *N*-diazo coupling is independent of the pK_a of the acid (6). By contrast, *N*-diazo coupling with glycine ethyl ester affords stable triazenes (5, 7, 8), which usefully decompose under acid catalysis to give ethyl diazoacetate, $N_2CH{\cdot}CO_2Et$ (7).

In part II (1) of this series, the preparation and characterisation of a number of monomethyltriazenes, $X{\cdot}C_6H_4{\cdot}N{=}N{\cdot}NH{\cdot}Me$, were described; the formation of triazenes by the reaction of aqueous diazonium salts with methylamine was favoured by the presence of an electron-withdrawing substituent (X) in the aryl group. It was of interest to us to extend the previous work by looking at the reaction of diazonium ions with amines of type NH_2CH_2Y (where Y is electron withdrawing), to examine the triazenes arising therefrom (eq. 1) and to assess the possibility of competitive coupling at the activated CH_2 group (eq. 2).

[1] $$ArN_2^+ + NH_2CH_2Y \longrightarrow ArN{=}N{\cdot}NH{\cdot}CH_2Y$$

[2] $$ArN_2^+ + CH_2\begin{matrix}NH_2\\Y\end{matrix} \longrightarrow Ar{\cdot}NH{-}N{=}C\begin{matrix}NH_2\\Y\end{matrix}$$

Discussion

Previous reports of the formation of triazenes of type **1** (7, 9) employed diazonium fluoroborates as starting materials, with an organic solvent or an aqueous–organic mixture as the medium. Since methylamine couples readily in aqueous solution with diazonium salts substituted with electron-withdrawing groups (1), it seemed worthwhile to attempt reaction of the same diazonium salts with α-substituted alkylamines in purely aqueous solution. Indeed, direct coupling of the diazonium salts, $X{\cdot}C_6H_4N_2^+$ (X = H, *p*-NO_2, *p*-CO_2Me, *p*-COPh, and *o*-COPh) with aminoacetonitrile, NH_2CH_2CN, in aqueous solution, in the presence of sodium acetate, proved to be most successful

[1]For part II see ref. 1.

g X = CO_2Me, Y = COPh
h X = NO_2, Y = COPh
i X = NO_2, Y = $-CH(OCH_3)_2$

and afforded the triazenes (**1***a–d* and **2***a*) in moderate to excellent yields. Similarly, reaction of the diazonium salts, *p*-X·$C_6H_4N_2^+$ (X = NO_2 and CO_2Me) with glycine ethyl ester gave high yields of the *N*-arylazoglycine ethyl esters (**1***e* and *f*). However, attempts to couple the diazonium salts from aniline and *p*-aminoacetophenone with glycine ethyl ester under identical conditions were unsuccessful.

The structures of the cyanomethyltriazenes (**1***a–d* and **2***a*) are corroborated by elemental analysis and spectroscopic data. The ir spectra all display NH absorption in the range 3200–3250 cm^{-1}; **1***c* displays ester-carbonyl absorption at 1695 cm^{-1} and **1***b* exhibits the nitro-group bands at 1530 and 1350 cm^{-1}. However, absorption due to the C≡N group is either absent, or extremely weak at 2260–2300 cm^{-1}, as in the ir spectra of **1***b* and **1***d*. Although the absence of strong cyano bands suggests that these triazenes may exist in a cyclic iminotriazoline form, the open-chain nature of the cyanomethyltriazenes is clearly demonstrated by the nmr spectral data. The *N*-methylene proton resonance appears consistently as a singlet in the range δ 4.53–4.68 ppm; NH proton resonance is observed in the spectrum of the ester (**1***c*) at δ 9.3 ppm. Preliminary studies of the chemistry of the cyanomethyltriazenes suggests that cyclization may be initiated by heating in ethanol and affords 5-arylaminotriazoles (**3**); the scope and synthetic use of this reaction are under further investigation. The spectral characteristics of the *N*-arylazoglycine ethyl esters (**1***e* and *f*) are also consistent with open-chain structures. Significant broadening of the *N*-methylene and aromatic proton resonance is seen in the nmr spectrum of **1***e*, suggesting that this triazene, like the monomethyl analogue (**1**, X = NO_2, Y = H), is in a state of rapid tautomeric equilibrium at room temperature (10).

Whereas the reaction of *p*-nitrobenzene diazonium tetrafluoroborate with α-aminoacetaldehyde dimethyl acetal (which, unlike the free aldehyde, is readily available) in acetonitrile at −10°C gave only dark red oils, aqueous coupling of diazotized *p*-nitroaniline with the dimethyl acetal gave a low yield of the solid triazene (**1***i*). Treatment of the *p*-nitrobenzene diazonium salt with ω-aminoacetophenone in aqueous solution afforded the keto-triazene (**1***h*), which, on the basis of spectroscopic evidence, exists exclusively as the cyclic 5-hydroxytriazoline (**4**), as proposed previously (9, 11). Carbonyl absorption is absent from the ir spectrum of **4**, whereas a broad band at 3200 cm^{-1} probably arises from the hydroxyl group. On the other hand the *p*-methoxycarbonylphenyltriazene (**1***g*), obtained in low yield in an analogous manner, appears to exist in the open-chain form, since the ir spectrum displays a keto-carbonyl band at 1660 cm^{-1}, in addition to NH and ester-carbonyl bands at 3350 and 1720 cm^{-1} respectively.

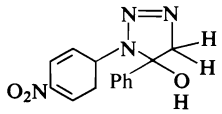
3



4

o-Acetylphenyltriazenes, e.g. **2***b* and **2***c*, are potential precursors of 4-methylenebenzotriazines, since other *o*-acetylphenyltriazenes cyclize over alumina (12). However, the keto-triazene (**2***b*) was unstable and decomposed in contact with alumina to give a mixture of *o*-aminoacetophenone and diazoacetophenone, $N_2CH·COPh$. The formation of the diazoketone was indicated by ir absorption at 2100 cm^{-1} and by methine proton resonance at δ 5.9 ppm in the nmr spectrum; analogous fragmentation of the *p*-nitrophenyltriazene (**1***h*) has been reported (9). Diazotization of *o*-aminoacetophenone, followed by treatment with glycine ethyl ester, is strangely anomalous and affords an unstable, bright red solid, which does not appear to be the expected triazene (**2***c*).

Considerable interest in the pharmacology of triazenes has been aroused by the potential of dialkyltriazenes ($ArN{=}NNR_2$) to act as anti-tumour agents (13). Recent studies have demonstrated the importance of monomethyltriazenes in the metabolism of these anti-tumour agents (14), and therefore it is important to establish the biological effects of the monoalkyltriazenes described here. Dialkyltriazenes display selective action against a broad spectrum of tumours, including plasma cell tumours and the R1 and TLX5 lymphomas (13). However, the nitrophenyltriazenes (**1***b* and **1***e*) were found to be inactive towards TLX5 lymphoma cells in in vivo tests, and the cyanomethyltriazenes (**1***b* and **1***c*) were inactive towards the P388 tumour in vivo. The inactivity of these triazenes suggests that they cannot metabolize to produce monomethyltriazenes, which is not an unexpected result.

In conclusion, it is evident that diazonium salts may be coupled with certain α-substituted alkylamines in aqueous media to afford monoalkyltriazenes directly from the reaction mixture. Isolation of the diazonium fluoroborate, prior to coupling, is certainly not always necessary, and may in some cases be less desirable than aqueous coupling. In all cases studied here, the diazonium ion attacks at the NH_2 moiety and shows no tendency to attack at the activated CH_2 (in NH_2CH_2Y), which would give rise to hydrazone formation (eq. 2). Although such hydrazone formation is well known (15) in the case of bifunctional methylene compounds, the methylene group in NH_2CH_2Y does not compete successfully for the diazonium ion and triazene formation is exclusive.

Experimental

Melting points were obtained on a hot stage apparatus and are uncorrected. Infrared spectra were recorded with Nujol mulls on Perkin-Elmer Infracord and 467 grating spectrophotometers, and nmr spectra were obtained in deuteriochloroform, with tetramethylsilane as internal standard, on a Varian EM 360 60 MHz spectrometer. Microanalyses were conducted by Chemalytics Inc., Tempe, Arizona.

Reaction of Diazonium Salts with Glycine Ethyl Ester or Aminoacetonitrile or α-Aminoacetophenone

General Procedure

The aromatic amine (0.013 mol) was dissolved in 2 *M* hydrochloric acid (30 ml), diluted with water (40 ml), and diazotized at 0°C with sodium nitrite (0.013 mol) in a minimum volume of water. A solution of *either* glycine ethyl ester hydrochloride *or* aminoacetonitrile hydrochloride *or* α-aminoacetophenone hydrochloride (0.013 mol) in water was added slowly to the diazonium salt solution. The mixture was stirred for 1 h at 0°C, whereupon the solution was normally clear. The clear solution was treated with a large excess of sodium acetate (25–30 g). and the triazene precipitated slowly from the reaction mixture. Precipitation was normally evident after 15 min, and was usually complete within 24 h after warming slowly to room temperature. (Note: addition of the diazonium salt solution *to* a solution of the amine hydrochloride, containing sodium acetate, did not decrease the time required for full precipitation of the triazene, but did increase the yield in one case.) This procedure afforded the following triazenes, which usually recrystallized from hexane or benzene or a mixture of the two solvents.

1-Phenyl-3-(α-cyanomethyl-)triazene (*1a*)—Yield 22%; mp 92–95°C; ν_{max} 3200, 1600 cm^{-1}; δ ($CDCl_3$) 4.53 (s, 2H, CH_2), 7.27 (s, 5H, aromatic), and 7.5 (br s, 1H, NH). *Anal.* calcd. for $C_8H_8N_4$: C 60.0, H 5.03, N 34.98; found: C 59.99, H 4.99, N 34.56.

1-(p-Nitrophenyl-)3-(α-cyanomethyl-)triazene (*1b*)—Yield 94%; mp 95–96°C (dec.); ν_{max} 3250, 2300(w), 1610, 1530, and 1350 cm^{-1}; δ ($CDCl_3$) 4.67 (s, 2H, CH_2), 7.33 (d, 2H, aromatic), and 8.23 (d, 2H, aromatic). *Anal.* calcd. for $C_8H_7N_5O_2$: C 46.80, H 3.41, N 34.15; found: C 46.65, H 3.40, N 34.29.

1-(p-Methoxycarbonylphenyl-)3-(α-cyanomethyl-)triazene (*1c*)—Yield 94%; mp 132.5–135.5°C; ν_{max} 3250, 1695, and 1610 cm^{-1}; δ ($CDCl_3$) 3.88 (s, 3H, O—Me), 4.59 (s, 2H, CH_2), 7.21 (d, 2H, aromatic), 7.99 (d, 2H, aromatic), and approx. 9.3 (v br s, 1H, NH). *Anal.* calcd. for $C_{10}H_{10}N_4O_2$: C 55.04, H 4.60, N 25.70; found: C 55.22, H 4.72, N 25.75.

1-(p-Acetylphenyl-)3-(α-cyanomethyl-)triazene (*1d*)—Yield 36%; mp 86–88°C; ν_{max} 3220, 2260(w), 1656, and 1620 cm^{-1}; *Anal.* calcd. for $C_{10}H_{10}N_4O$: C 59.40, H 4.98; found: C 59.72, H 4.66.

1-(o-Acetylphenyl-)3-(α-cyanomethyl-)triazene (*2a*)—Yield 78%; mp 80–82°C; ν_{max} 3180 (broad) and 1640 cm^{-1}; δ ($CDCl_3$) 2.66 (s, 3H, acetyl Me), 4.68 (s, 2H, CH_2), 6.8–8.0 (m, 5H, aromatic and NH). *Anal.* calcd. for $C_{10}H_{10}N_4O$: C 59.40, H 4.98, N 27.71; found: C 59.41, H 4.82, N 27.67.

N-(p-Nitrophenylazo-)glycine Ethyl Ester (*1e*)—Yield 80%; mp 98–99°C (lit. (9) 96–98°C); ν_{max} 3300, 1710, 1600(w), 1510, and 1340 cm^{-1}; δ ($CDCl_3$) 1.30 (t, 3H, CH_3), 4.30 (q, 2H, CH_2—O), 4.50 (br s, 2H, CH_2—N), 7.4 (br d, 2H, aromatic), 8.13 (d, 2H, aromatic), and 9.3 (br s, 1H, NH). *Anal.* calcd. for $C_{10}H_{12}N_4O_4$: C 47.62, H 4.80, N 22.21; found: C 47.47, H 4.73, N 22.18.

N-(p-Methoxycarbonylphenylazo-)glycine Ethyl Ester (*1f*)—Yield 84%; mp 70–71°C; ν_{max} 3320, 1720, 1708, and 1597 cm^{-1}; δ ($CDCl_3$) 1.23 (t, 3H, CH_3), 3.87 (s, 3H, O—CH_3), 4.2 (q, 2H, O—CH_2), 4.4 (br s, 2H, N—CH_2), 7.3 (d, 2H, aromatic), 8.0 (d, 2H, aromatic), and 9.5 (br s, 1H, NH). *Anal.* calcd. for $C_{12}H_{15}N_3O_4$: C 54.30, H 5.66, N 15.85; found: C 53.95, H 5.63, N 15.42.

1-(p-Methoxycarbonylphenyl-)3-phenacyltriazene (*1g*)—Yield 6%; mp 145–148°C; ν_{max} 3250, 1710, and 1660 cm^{-1}. *Anal.* calcd for $C_{16}H_{15}N_3O_3$: C 64.65, H 5.05; found: C 64.29, H 5.06.

1-p-Nitrophenyl-5-hydroxy-5-phenyl-Δ^2*-1,2,3-triazoline*

(*4*)—Yield 76%; mp 118–120°C, ν_{max} 3200 (br), 1595, 1520, and 1340 cm^{-1}.

This product was identical with material obtained by treatment of a mixture of *p*-nitrobenzene diazonium tetrafluoroborate and ω-aminoacetophenone hydrochloride, in suspension in ethanol, with aqueous sodium carbonate at 0°C, according to the method of McGarrity (9).

1-(p-Nitrophenyl-)3-(β,β-dimethoxyethyl-)triazene (*1i*)—*p*-Nitroaniline (1.78 g) was diazotized as described above and treated with α-aminoacetaldehyde dimethyl acetal (1.36 g). The mixture was stirred for 1 h, filtered to remove cloudiness, and the clear filtrate treated with a solution of sodium acetate (25 g). After stirring for a further 0.75 h, the yellow precipitate was separated to afford the triazene (0.55 g, 17%), mp 62–63°C; ν_{max} 3150, 1595, 1540, and 1330 cm^{-1}; δ ($CDCl_3$) 2.13 (s, 6H, O—Me), 2.60 (d, 2H, N—CH_2), 3.40 (t, 1H, CH), 6.0 (br d, 2H, aromatic), 6.8 (d, 2H, aromatic), and 8.2 (br s 1H, NH). *Anal.* calcd. for $C_{10}H_{14}N_4O_4$: C 47.20, H 5.50, N 22.00; found: C 46.40, H 5.10, N 21.50.

Reductive desulfurization using tributyltin hydride[1]

JOHN M. MCINTOSH AND CALVIN K. SCHRAM

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 6, 1977

JOHN M. MCINTOSH and CALVIN K. SCHRAM. Can. J. Chem. **55**, 3755 (1977).

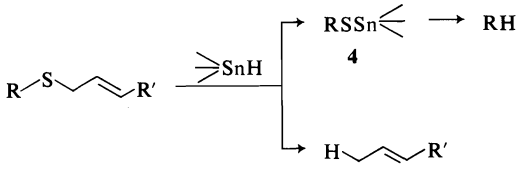
Reaction of tributyltin hydride with a variety of organic sulfides gives results which depend on the structure of the starting material. Acyclic sulfides undergo desulfurization leading to hydrocarbons in varying yields. However, 2,5-dihydrothiophenes give dienes and 3,6-dihydro-2*H*-thiopyrans are inert.

JOHN M. MCINTOSH et CALVIN K. SCHRAM. Can. J. Chem. **55**, 3755 (1977).

La réaction de l'hydrure de tributylétain avec une variété de sulfures organiques donne des résultats qui dépendent de la structure du produit de départ. Les sulfures acycliques subissent une désulfuration conduisant à des hydrocarbures avec un rendement variable. Cependant, les dihydro-2,5 thiophènes conduisent aux diènes tandis que les dihydro-3,6 2*H*-thiopyrannes sont inertes.

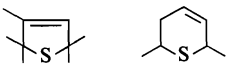
[Traduit par le journal]

For the past several years, we have been engaged in a study of the preparation and use of 2,5-dihydrothiophenes (**1**) (1) and 3,6-dihydro-2*H*-thiopyrans (**2**) (2) and as part of these investigations we considered a reductive desulfurization (Scheme 1). Considering the ease of



SCHEME 1

formation of **1** and **2**, a ready desulfurization which proceeded without isomerization would afford an operationally simple stereo- and regiospecific preparation of *cis*-olefins, which would have application in the area of pheromone synthesis.



1 **2**

Of the many reagents that have been used to effect desulfurizations of sulfides, Raney Nickel has been most commonly employed (3), but this reagent suffers from the concomitant reduction of other sites of unsaturation (4). More recently lithium in ethylamine (5) alone or in combination with Raney Nickel (6) has given excellent results in some cases. However, we felt that another method for effecting this transformation which would tolerate a wider range of functionality would be beneficial.

The well-known ability of divalent sulfur atoms to enter into radical reactions suggested that a reducing agent that functions by a radical mechanism might effect the desired reaction. One of the most common reagents of this type is the trialkyltin hydride (**3**) (7). We now report the results of a brief survey of the use of this reagent for reductive desulfurization.

Prior to our work, scattered reports on the use of **3** on divalent sulfur-containing products had appeared (8) which suggested that desulfurization would occur. However, two interfering reactions, viz. hydrostannylation and double-bond reduction, can occur when using olefinic substrates **1** or **2** and for that reason we began our investigations with saturated and aromatic substrates. When these were completed several olefinic substrates and two thioketals were examined.

Results and Discussion

The results of the reactions are summarized in Table 1. All reactions were carried out using tri-*n*-butyltin hydride (**3***a*) as the reducing agent and products were identified by comparison with authentic samples.

As can be seen, the results fall into three distinct categories. Most simple acyclic carbon–sulfur bonds are cleaved to some extent. As expected, allylic and benzylic bonds appear to cleave more easily than aliphatic ones. It must be noted that our work-up procedure (see Experi-

[1]Presented in part at the Annual Conference, Chemical Institute of Canada, Montreal, P.Q., June 1977.

[d]Starting material quantitatively recovered after all hydride consumed.

mental section) would not detect non-volatile hydrostannylated products, and therefore in cases where an olefinic product is formed, which may react further with **3***a* (runs 4–7 and 11), the yields indicated represent minimum values for the actual cleavage process.

Inspection of Table 1 further suggests that cleavage of a carbon–sulfur bond in a sulfide may be more difficult than that in which one of the sulfur bonds is joined to tin as in the presumed intermediate **4** (Scheme 1). Thus, the yield of alkanes in runs 2 and 5 (40–50%) is much larger than that in run 3.

We are unable to account satisfactorily for the complete inertness of thiopyrans **2** (runs 8 and 9). These were recovered quantitatively from the reaction mixtures. In view of the results of runs 4 and 5, it seems unlikely that both reductive desulfurization and hydrostannylation would be completely suppressed by an electronic interaction between the sulfur atom and the π-bond electrons. On the other hand, the presence of some degree of steric interference in the form of methyl group(s) at the α-position also seems insufficient to cause the observed results.

Reduction of dihydrothiophenes **1** (runs 6 and 7) resulted in a completely different reaction. The diene products obtained are identical with those obtained from the cheletropic sulfur dioxide elimination from the corresponding sulfone (1*a*). At this time, we are unable to say whether this reaction is concerted. In run 7, the sole product obtained is the E-isomer but while this is formally the result of a disrotatory ring opening, it is also the most stable product and its formation may simply reflect the preferred thermodynamic orientation. The low yield of product also makes any mechanistic conclusions tenuous at best.

Conclusion

It is clear from these rather limited results that we have not achieved our original goals of a viable olefin synthesis. At present we are considering other ways this might be achieved and will report any developments at a later date.

Experimental

Nuclear magnetic resonance spectra were run on a JEOL C60 HL spectrometer in $CDCl_3$ solution with

Me_4Si as internal standard: infrared spectra were run on a Beckman IR 12 in chloroform solution. Gas–liquid chromatographic analyses were run on an F & M Model 720 instrument using a 10 ft × 0.375 in. column packed with 20% SE-30 on Chromosorb W.

Materials

Starting materials for all runs except 2, 5, and 11 were purchased or prepared as outlined in the literature. Hydride **3***a* was routinely prepared by reduction of bis(tri-*n*-butyltin)oxide with polymethylhydrosiloxane (11).

Reduction Procedure

A mixture of 0.01 mol of the sulfide, 0.022 mol of **3***a*, and a catalytic amount of azobisisobutyronitrile (VAZO) was placed in a round-bottom flask fitted with a magnetic stirrer, and a condenser with a nitrogen inlet. The system was purged with dry nitrogen and heated at 80°C (oil bath temperature) for 8 h. In cases where more than 2.2 mol equivalents of **3***a* were used (in runs 10 and 11, 4.4 equiv. of **3***a* were used) the remainder of the hydride was added at intervals during the reflux period. Additional initiator was added occasionally to these reactions. The cooled solution was diluted with 20 ml of diglyme and distilled at atmospheric pressure to a head temperature of 162°C. The distillate was added to 10 ml of water, the organic phase separated, washed with an additional 10 ml of water and dried. Gas–liquid chromatographic analysis gave the ratio of products formed, which when multiplied by the weight of organic product gave the percentage yields. These were confirmed by nmr analysis. Products were identified by comparison of their retention times and nmr spectra with authentic samples. In the case of runs 6 and 7, the infrared and mass spectra were also identical to authentic samples (1*b*).

Heptyl Benzyl Sulfide

n-Heptyl mercaptan (6.6 g, 0.05 mol) was titrated to the phenolphthalein endpoint with a 1.0 *N* solution of sodium ethoxide. Benzyl chloride (6.3 g, 0.05 mol) was added dropwise with stirring at room temperature and then the mixture was stirred overnight. After filtration and evaporization of the filtrate, the remaining yellow oil was taken up in methylene chloride, dried and evaporated. Distillation afforded 9.6 g (86%) of a colourless oil, bp 174–180°C (17 Torr); nmr 7.25–7.30 (s, 5), 3.60–3.55 (s, 2), 2.45–2.18 (t, 2, J = 6 Hz), 1.65–1.05 (m, 12), 0.95–0.65 (t, 3, J = 4 Hz); ir($CHCl_3$) 3080, 3020, 2960, 2920, 2860, 2840, 1450, 700 cm^{-1}; n_D^{20} = 1.5204. *Anal.* calcd for $C_{14}H_{22}S$: C 75.61, H 9.97; found: C 75.77, H 9.88.

3-Cyclohexen-1-yl Heptyl Sulfide

3-Cyclohexen-1-yl heptyl sulfide was prepared by the same general procedure using 0.05 mol of 3-bromocyclohexene (12) and *n*-heptyl mercaptan. Distillation gave 8.0 g (76%) of a colourless oil, bp 92–96°C (0.04 Torr); nmr 5.90–5.80 (m, 2), 3.62–3.30 (m, 1), 2.84–2.52 (t, 2, J = 8 Hz), 2.30–1.75 (m, 6), 1.65–1.15 (m, 12), 1.05–0.85 (t, 3, J = 4 Hz); ir($CHCl_3$) 3020, 2970, 2950, 2850, 1465, 1455, 1440 cm^{-1}; n_D^{20} = 1.4951. *Anal.* calcd for $C_{13}H_{24}S$: C 73.51, H 11.39; found: C 73.35, H 11.55.

2-(3-Buten-1-yl)-2-methyl-1,3-dithiolane

A mixture of 10 g (0.1 mol) of allylacetone, 15 g (0.16 mol) of ethane dithiol, and 1 g of *p*-toluenesulfonic acid in 150 ml benzene was refluxed for 8 h under a Dean-Stark water separator. The cooled solution was washed with an equal volume of 1 *N* potassium hydroxide, once with water, and then was dried. Evaporation of the solvent and chromatographing the residue on basic alumina (pentane) gave 80% of a colourless liquid, bp 114–116 (14 Torr); nmr 6.05–5.5 (m, 1), 5.15–4.75 (m, 2), 3.30 (s, 4), 2.45–1.85 (m, 4); ir 3100, 2960, 2940, 2870, 2860, 1652, 1460, 925 cm^{-1}. *Anal.* calcd. for $C_8H_{14}S_2$: C 55.12, H 8.09; found: C 55.33, H 8.19.

Mise en évidence d'un nouvel acide tungstique en solution. Filiations avec d'autres polytungstates

JEAN LEMERLE ET JEAN LEFEBVRE

Laboratoire de Chimie III, Université Pierre et Marie Curie, 4, place Jussieu, 75230 Paris, Cedex 06, France

Reçu le 10 février 1977

JEAN LEMERLE et JEAN LEFEBVRE. Can. J. Chem. **55**, 3758 (1977).

Un nouvel acide tungstique est préparé en solution aqueuse par échange d'ions. A la température ambiante les solutions se gélifient en quelques heures, puis 3 à 4 jours plus tard précipitent l'oxyde jaune WO_3. En solution aqueuse, cet acide est constitué de tétramères des motifs élémentaires $W_6O_{19}^{2-}$, s'associant par la suite pour donner le gel. Isolé à l'état solide cet acide est amorphe aux rayons X. En milieu hydroorganique, l'acide tungstique est stabilisé en solution, mais existe alors en équilibre avec les ions tungstique Y et hexatungstique mis en évidence par Fuchs. La condensation de l'acide Y et d'une des formes réduites est discutée. Les formes acides des ions hexatungstique (Fuchs) et tungstique Y ont été préparées à l'état pur en solution et à l'état solide.

JEAN LEMERLE and JEAN LEFEBVRE. Can. J. Chem. **55**, 3758 (1977).

A new tungstic acid has been prepared in aqueous solutions by ion exchange. At room temperature gelation occurs in solutions in a few hours, and 3 or 4 days after, the yellow oxide WO_3 precipitates. In aqueous solutions, this acid is formed by tetramers of $W_6O_{19}^{2-}$ units, which give a gel after association. X-ray analyses of tungstic acid in the solid state demonstrate the absence of crystallinity. In hydroorganic medium, tungstic acid is stabilized in solution, but exists in equilibrium with the Y tungstic and hexatungstic (Fuchs) anions. The condensation of the Y acid and one of its reduced forms is discussed. The pure acid forms of hexatungstic (Fuchs) and Y ions are obtained in solutions and in the solid state.

Introduction

L'acidification de l'ion tungstate par un acide fort conduit à de nombreux polytungstates dont la nature et les propriétés dépendent du degré d'acidification (1). La préparation en solution d'acides tungsto VI antimoniques V pyrochlores (2) nous a amenés à préparer des solutions tungstiques où le seul cation présent est le proton (l'acide antimonique est floculé ou gélifié par de nombreux cations). Cette préparation d'acide tungstique conduit à un nouveau type de polymère que nous appellerons acide tungstique α et que nous précisons dans ce travail.[1]

Caractéristiques de l'acide tungstique α

Les solutions aqueuses d'acide tungstique α à la concentration voisine de 0.1 mol/ℓ en tungstène ne sont stables à la température ambiante ($t \simeq 20°C$) qu'une dizaine d'heures. Après ce temps elles deviennent opalescentes, se gélifient au bout d'une vingtaine d'heures, puis après 3 à 4 jours précipitent totalement l'oxyde $WO_3 \cdot H_2O$ jaune (caractérisé par son diffractogramme X). Cette évolution peut être ralentie, voire stoppée par l'addition de solvants organiques (DMSO) dès la préparation (50% de DMSO suffisent pour maintenir la solution indéfiniment limpide).

Les solutions aqueuses sont caractérisées par des spectres d'absorption dans l'uv présentant un épaulement vers 275 nm (fig. 1). Diluées à basse température elles suivent la loi de Beer. Par contre si les solutions sont préparées diluées, un épaulement apparaît vers 325 nm et se transforme en maximum pour les fortes dilutions ($[W] < 4.6 \times 10^{-3}$ mol/ℓ) (fig. 1). Ce maximum est caractéristique du décatungstate (3), qui dans ces conditions de concentration doit se former en quantité non négligeable. L'étude de l'acide tungstique α est donc conduite sur des solutions de concentration supérieure à 6×10^{-2} mol/ℓ en tungstène.

Pendant la période où les solutions aqueuses d'acide α sont limpides, celles-si sont constituées pour l'essentiel d'espèces contenant 24 atomes de tungstène. Il faut néanmoins noter la présence de particules très condensées, d'abord en quantité négligeable, dont la proportion croît au cours de l'évolution et devenant prépondérantes quand l'acide se gélifie.

[1]Lorsque l'acidification d'un anion conduit immédiatement à un acide bien défini mais instable, on désigne généralement par la lettre α cette forme initiale instable, souvent soluble dans l'eau, et par la lettre β la forme stable. Exemples: acides stanniques et acides antimoniques α et β.

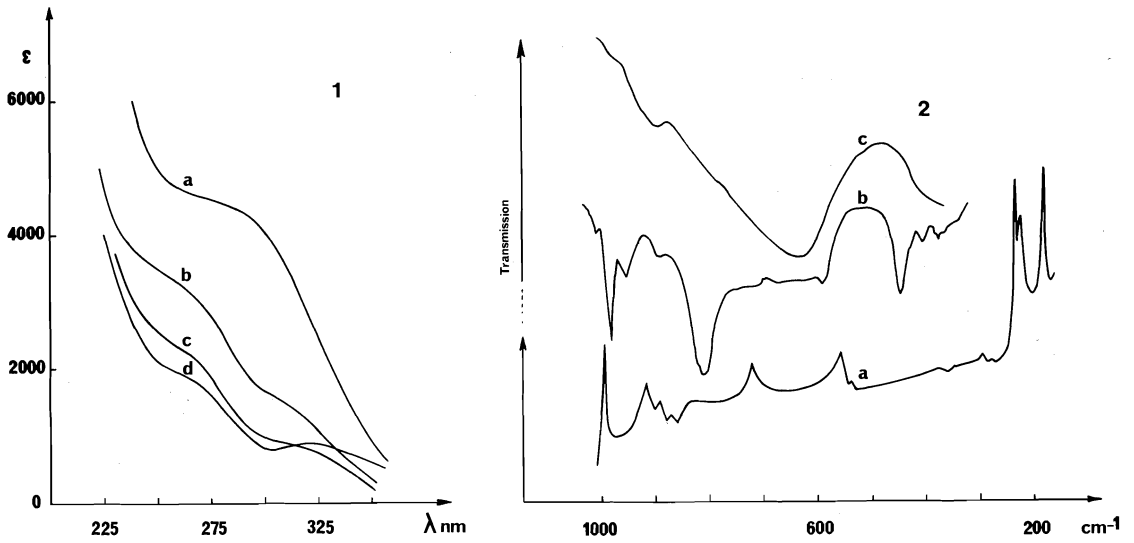

FIG. 1. Spectre uv des solutions aqueuses d'acide tungstique α dès la préparation. (*a*) [W] = 10^{-1} mol/ℓ; (*b*) [W] = 4.4×10^{-2} mol/ℓ; (*c*) [W] = 2×10^{-2} mol/ℓ; (*d*) [W] = 4.6×10^{-3} mol/ℓ.

FIG. 2. (*a*) Spectre raman de l'acide hexatungstique; (*b*) spectre ir de l'acide hexatungstique; (*c*) spectre ir de l'acide tungstique α.

D'autre part en solution hydroorganique (eau–DMSO 50%), la condensation apparente de l'acide tungstique α n'est plus que de 6. Néanmoins la baisse de condensation apparente en solution hydroorganique ne se produit pas immédiatement après l'addition de DMSO. On peut penser que l'édifice de base est constitué par un ion contenant six atomes de tungstène, pouvant s'associer dans l'eau, pour donner aux concentrations voisines de 0.1 mol/ℓ un ensemble soluble de quatre motifs élémentaires. L'association dans l'eau ne doit cependant pas procéder uniquement par liaisons hydrogène, car elles seraient rompues immédiatement par l'addition de DMSO. Au cours du vieillissement des solutions aqueuses l'association se poursuit pour donner le gel, et doit s'accompagner d'une déshydratation pour conduire à l'oxyde $WO_3 \cdot H_2O$ jaune.

L'addition d'un grand excès d'ions Li^+, Na^+ ou K^+ à une solution d'acide tungstique α provoque la précipitation de son sel.[2] On sépare alors par centrifugation un solide gommeux amorphe aux rayons X. La composition des solides est résumée au tableau 1. Ces précipités sont en tous points comparables à l'acide tungstique α solide obtenu par congélation rapide de la solution dès la préparation, et insolubilisé par l'éthanol au cours de la fusion à 0°C du glaçon dans ce solvant. Ils ont même spectre ir (fig. 2) et sont tous amorphes aux rayons X.

TABLEAU 1. La composition des solides

Cation (M^+)	[H^+] combiné/[W]	[M^+]/[W]
Li^+	1.59–1.61	0.26–0.28
Na^+	1.62–1.66	0.33–0.34
K^+	1.63–1.66	0.30–0.34

D'autre part les titrages protométriques rapides des solutions fraîchement préparées présentent deux points équivalents, l'un vers p*H* 5, l'autre vers p*H* 9. Le premier (p*H* ≃ 5) correspond à 0.37 [H^+]/[W]. Le spectre uv de la solution obtenue à ce p*H* n'est pas modifié par rapport à celui de l'acide initial. Il y a donc bon accord entre le nombre de protons titrables immédiatement et celui des cations contenus dans le sel de l'acide. Le polyion est donc porteur d'une charge négative pour trois atomes de tungstène. La formation du motif élémentaire peut se résumer ainsi:

$$6WO_4^{2-} + 10H^+ \rightleftharpoons W_6O_{19}^{2-} + 5H_2O$$

L'acide tungstique α n'est pas réductible à l'électrode à goutte de mercure. D'autre part le nombre de protons titrés, soit à p*H* 5, soit à

[2]L'addition d'ions Cs^+ ou $N(CH_3)_4^+$ provoque la précipitation d'un autre polytungstate (décatungstate) qui sera étudiée plus loin.

p*H* 9 varie avec le temps d'évolution de la solution (tableau 2).

La dégradation de l'acide tungstique α en WO_4^{2-} peut avoir comme intermédiaire l'ion paratungstique A, $HW_6O_{21}^{5-}$, comme c'est souvent le cas pour les polytungstates. Ceci peut être obtenu en ajoutant 0.8 $[OH^-]/[W]$ à l'acide, soit après 24 h de contact avec la base si l'acide α est utilisé en solution, soit dès la dissolution (quelques minutes) de l'acide α à l'état solide (obtenu par congélation) dans la base. La présence du paratungstate A seul dans ces conditions est mise en évidence par électrophorèse, centrifugation analytique et spectre ir du sel d'argent.

L'acide tungstique α est donc un isomère de l'ion hexatungstique isolé par Jahr, Fuchs et coll. (4–6) mais dont la forme solide est amorphe aux rayons X. Il est donc de composition très différente de celle annoncée par Richardson (7). Le problème pouvait se poser de savoir s'il était très différent d'un autre polytungstate formé rapidement dans ce domaine d'acidité: le ψ métatungstate. Le spectre ir du solide et la condensation de l'acide α en solution prouvent que ces deux tungstates sont bien différents.

Transformations de l'acide tungstique α en acide décatungstique

Le principe de cette transformation consiste à faire agir les ions $N(CH_3)_4^+$ ou Cs^+ en milieu aqueux sur une solution d'acide tungstique α. On obtient alors rapidement, avec un rendement de 90%, du décatungstate (tungstate Y) (3), caractérisé par le spectre ir du solide, le spectre uv et le polarogramme de la solution diluée.

A partir d'une solution hydroorganique (eau–DMSO 50%) de décatungstate de tétraméthylammonium ($[W] \simeq 10^{-2}$ mol/ℓ) on peut obtenir par échange $(N(CH_3)_4^+/H^+)$ dans une résine Dowex 50 WX2, une solution d'acide décatungstique. Après évaporation de celle-ci sous pression réduite à chaud, on isole l'acide décatungstique à l'état solide sous forme d'une poudre jaune bleuissant très rapidement à la lumière.

TABLEAU 2. Variation avec le temps d'évolution des solutions

Age de l'acide tungstique évolué à 20°C (h)	$[H^+]$ titré/[W]		
		p*H* 9	
	p*H* 5	Immédiatement	A t_∞ à p*H* constant
0	0.37	1	2
2	0.35	1	1.90
19	0.25	1.34	1.70
20	0.25	1.42	1.69
72	0.20	1.66	1.73

Le tungstate Y mis en évidence par Glemser et coll. (3) a été l'objet de controverses quant à sa masse molaire. Boyer et coll. (8, 9) ont montré que les propriétés électrochimiques de ce tungstate étaient en accord avec une dodécacondensation. Plus récemment Fuchs et coll. (10) ont déterminé la structure du sel de tributylammonium montrant qu'il s'agit d'un décatungstate. Les solutions aqueuses de tungstate Y ne sont stables qu'à basse température ($t \simeq 0$°C). Par contre l'addition de 20 à 30% de DMSO stabilise les solutions plusieurs jours à la température ambiante. Quelle que soit la préparation (tungstate Y de tétraméthylammonium ou forme acide obtenue à partir de l'acide α, tungstate Y de sodium (11) ou de potassium (12)), la condensation du polytungstate (déterminée par centrifugation analytique) est toujours la même dans le domaine de concentration étudié ($2 \times 10^{-3} \leq [W] \leq 8 \times 10^{-2}$ mol/ℓ). Elle est comprise entre 8 et 9 et le soluté est moléculairement homogène. Par contre le dérivé correspondant au premier stade de réduction de ce polytungstate est dodécacondensé. La masse molaire du tungstate Y en solution est donc plus en faveur de celle déterminée par Fuchs (décatungstate), mais la réduction doit s'accompagner d'une modification de structure du polyanion.

Transformation de l'acide tungstique α en acide hexatungstique

L'acide tungstique Y est alors préparé en dissolvant préalablement le tungstate de sodium (WO_4^{2-}) dans un mélange eau–DMSO 50% puis en réalisant l'échange Na^+/H^+ dans une résine Dowex 50 WX2 (réfrigérée à 2°C). Par évaporation sous pression réduite, à chaud, d'une solution récente d'acide tungstique α en milieu eau–DMSO 50% on recueille un solide jaune cristallisé ayant même spectre ir que l'hexatungstate de Fuchs et coll. (6). La solution dans le méthanol a un spectre uv présentant un maximum à 275 nm caractéristique de ce polytungstate. La condensation, déterminée par ultracentrifugation analytique en solution méthanolique est égale à 6. Par dissolution dans l'eau cet acide se transforme en acide décatungstique. En

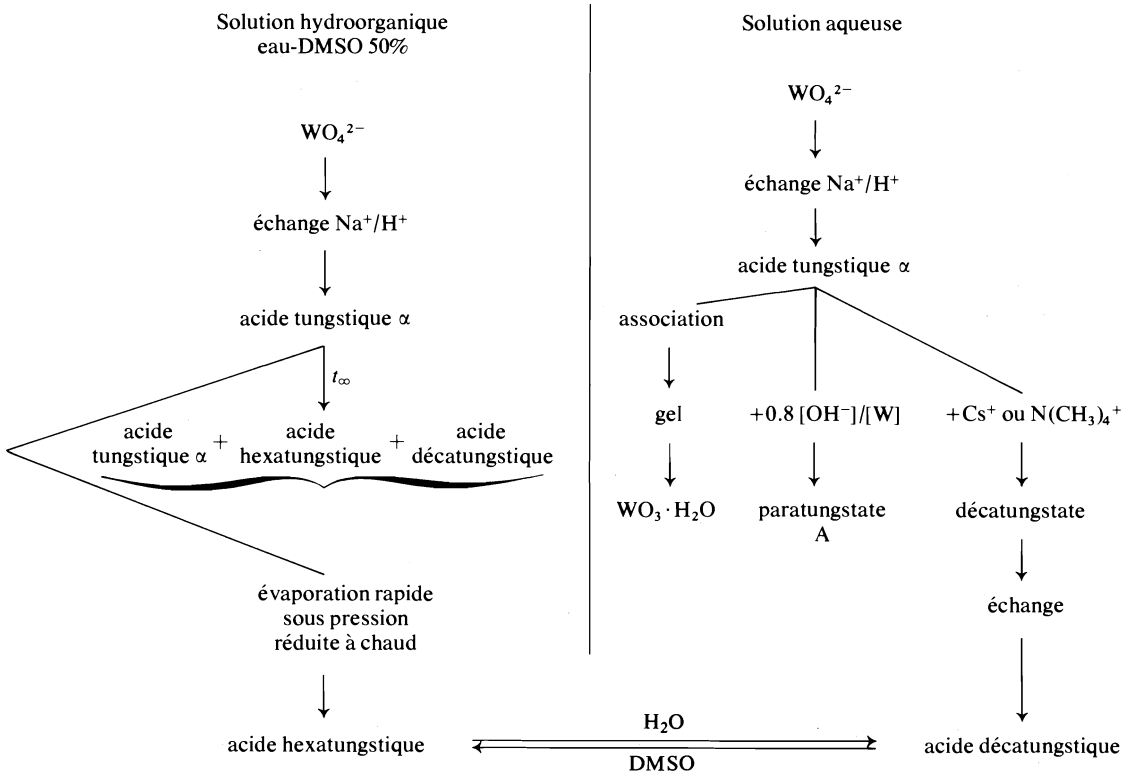

SCHÉMA 1

effet en suivant l'évolution des spectres uv après dissolution dans l'eau à basse température, on constate l'apparition de deux points isosbestiques à 268 nm et 303 nm. Le spectre final présente le maximum caractéristique du tungstate Y à 325 nm.

Par contre une solution hydroorganique (eau–DMSO 50%) d'acide tungstique α, âgée de plusieurs mois a un spectre uv présentant un épaulement à 325 nm indice de la présence de décatungstate. Cette solution peut être précipitée par différents cations. L'argent précipite l'acide α tandis que l'ion $N(CH_3)_4^+$ précipite l'hexatungstate (caractérisés par leur spectre ir). Dans les deux cas le spectre uv du filtrat présente un maximum très marqué à 325 nm. L'ion $P(C_6H_5)_4^+$ précipite un mélange de décatungstate et d'hexatungstate. Par contre le filtrat ne présente plus de maximum à 325 nm. On peut donc envisager la présence en solution de trois espèces tungstiques. La transformation en milieu eau–DMSO 50% aboutit aux équilibres:

[1] acide tungstique α ⇌ acide hexatungstique ⇌ acide décatungstique

On peut considérer qu'à l'équilibre on obtient 75% du tungstène sous forme de décatungstate. Par contre la proportion d'hexatungstate et de tungstate α est difficile à préciser.

Si certaines transformations de l'acide tungstique α en solution hydroorganique peuvent s'expliquer à partir du déplacement de l'équilibre, d'autres en contradiction, peuvent être expliquées par des considérations cinétiques.

L'évaporation à chaud d'une solution fraîchement préparée d'acide α enrichit le solvant en DMSO, donc favorise la formation de l'hexatungstate plutôt que celle du décatungstate (11). Par contre lorsqu'on évapore une solution d'acide décatungstique obtenu par échange en milieu eau–DMSO, le solvant s'enrichissant en DMSO, on devrait obtenir uniquement l'hexatungstate. Le fait que l'on obtienne de l'acide décatungstique pur peut s'expliquer par une vitesse d'évaporation du solvant organique beaucoup plus rapide que la transformation décatungstate → hexatungstate. Ceci a été confirmé en chauffant à reflux une solution de décatungstate dans le DMSO. On observe alors la transformation, mais dans un temps infiniment

plus long que celui mis pour l'évaporation conduisant à l'acide décatungstique solide.

On peut donc résumer les différentes filiations entre les ions polytungstiques par le schéma 1.

Partie expérimentale

Préparations des solutions

L'acide tungstique α est préparé par échange d'ions dans une résine Dowex 50 WX2, 100–200 mesh sous forme H^+ à partir d'une solution de tungstate de sodium. La colonne dans laquelle a lieu l'échange et le récipient recueillant l'acide sont thermostatés par une circulation d'alcool à 2°C.

Dosage des éléments

Les cations alcalins sont dosés par spectrophotométrie d'absorption atomique (appareil Jobin Yvon type Delta). Le tungstène est dosé par colorimétrie à 400 nm du complexe W réduit – KSCN (13). Le nombre de protons combinés est déterminé en mesurant la quantité de base nécessaire à la dégradation totale du polyion en WO_4^{2-} à p*H* 9 (combititreur Métrohm 3D).

Les différents composés obtenus sont caractérisés par: (*a*) leur spectre uv visible (spectrophotomètre Beckman Acta V); (*b*) leur spectre ir (échantillonnage en micropastilles de KBr, spectrophotomètre Perkin-Elmer modèle 457); (*c*) leur spectre Raman (spectromètre Coderg type PHO); (*d*) leur diffractogramme X (générateur Philips PW 1008 équipé d'une chambre Debye-Scherrer de 114 mm de diamètre (rayonnement utilisé: raie K_α du cuivre; filtre de nickel)); (*e*) leur mobilité électrophorétique (appareil LKB Multiphor); (*f*) leur masse molaire (ultracentrifugation analytique).

L'ultracentrifugation analytique est réalisée à l'aide d'une centrifugeuse Beckman modèle E équipée des optiques schlieren et à absorption, avec monochromateur et scanner. La masse molaire de l'acide tungstique α est déterminée à basse température ($t = 10$°C), selon la technique de transition vers l'équilibre de sédimentation (14) à 36 000 et 48 000 tours min^{-1} et à la concentration en tungstène égale à 7×10^{-2} mol/ℓ, en présence de divers solvants: solutions aqueuses $HClO_4$, LiCl, ou solutions hydroorganiques (eau–DMSO 50%) de HCl et NaCl. Tous les électrolytes sont à la concentration 0.1 mol/ℓ et sont ajoutés au moment de la mesure. Dans ces conditions aucune précipitation n'a lieu.

La condensation de l'acide décatungstique est déterminée à l'équilibre de sédimentation (vitesse de rotation 10 000, 15 000, 20 000, 22 000 tours min^{-1}) dans une cellule à six canaux. Un témoin de métatungstate à la même concentration que l'échantillon étudié est introduit dans l'un des compartiments de la cellule. Pour ce tungstate la dodécacondensation a toujours été vérifiée. Toutes ces déterminations sont faites en milieu eau–DMSO 30%.

Les volumes spécifiques partiels sont déterminés par picnométrie (15).

The synthesis, thermochromism, and cycloadditive properties of an *o*-methylenethioquinone system

P. DE MAYO AND H. Y. NG

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 3K7

Received May 27, 1977

P. DE MAYO and H. Y. NG. Can. J. Chem. **55**, 3763 (1977).

The irradiation of 4,5-benzo-1,2-dithiole-3-thione (**1**) in the presence of cyclopentene and of tetramethylethylene gives 1:1 adducts. In solution these adducts are in equilibrium with eight-membered-ring dimers. The thermodynamic parameters for this equilibrium have been determined. The available evidence suggests a head-to-head configuration. These same monomeric adducts give Diels–Alder addition products with normal dienophiles, but also react similarly with simple thiones (adamantanethione, norbornanethione, cyclohexanethione) to give thioorthoesters. The structures of the latter substances have been demonstrated both spectroscopically and, chemically, by hydrolysis to a thiosalicylic acid derivative. The thioorthoesters have been shown to undergo stereoisomerization on acid catalysis. Of the two mechanisms considered for this process (reversal to thiones and ion-pair formation) the former has been excluded.

P. DE MAYO et H. Y. NG. Can. J. Chem. **55**, 3763 (1977).

L'irradiation du benzo-4,5 dithiol-1,2 thione-3 (**1**) en présence de cyclopentène et de tétraméthyléthylène conduit à des adduits 1:1. En solution, ces adduits sont en équilibre avec des dimères cycliques à huit chaînons. On détermine les paramètres thermodynamiques pour ces équilibres. L'indice connue est en faveur d'une configuration tête à tête. Ces mêmes adduits monomères donnent des produits d'addition Diels–Alder avec des diénophyles normaux, mais ils réagissent d'une manière analogue avec des thiones simples (adamantanethione, norbornanethione, cyclohexanethione) pour conduire à des thioorthoesters. On détermine la structure de ces derniers spectroscopiquement et chimiquement en les hydrolysant en dérivés d'acide thiosalicylique. Les thioorthoesters démontrent une tendance à la stéréoisomérisation lors d'une catalyse acide. Deux mécanismes sont envisagés pour ce processus; l'inversion en thiones et la formation d'une paire d'ions; seul le dernier est retenu.

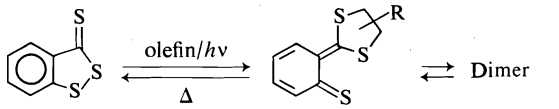
[Traduit par le journal]

Substances containing the *o*-quinonoid moiety are of considerable general interest because of the wide variety of chemical transformations of which they are capable (1, 2). Frequently they, or their derivatives, are so reactive that their ephemeral existence has only been detected by chemical trapping (see, for example, refs. 3–6) or by the nature of further transformation products (e.g. refs. 7–10). Our object, deriving from a general interest in the fundamental photochemistry of thiones, was to prepare an *o*-methylene thioquinone derivative, a species at that time unknown.

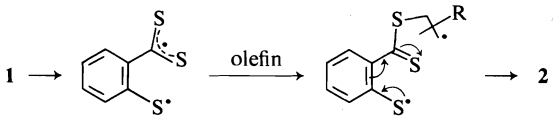
The photochemistry of 1,2-dithiole-3-thiones had previously been investigated (11–13) and the results obtained by Okazaki, Inamoto, and their collaborators and by ourselves suggested a route to such *o*-methylene thioquinones. This was successful; the present paper describes the preparation of two examples of such a system and an account of their unusual properties.[1]

[1]After our preliminary communication of part of this work (14) Okazaki and Inamoto described related and independent work which was, in part, complementary (15).

Irradiation of 4,5-benzo-1,2-dithiole-3-thione (**1**) in the presence of cyclopentene or of tetramethylethylene gave the desired quinonoid system (**2**) directly.



1 **2***a* R = $(CH_2)_3$ **3***a* R = $(CH_2)_3$
b R = $(CH_3)_4$ *b* R = $(CH_3)_4$



A **B**

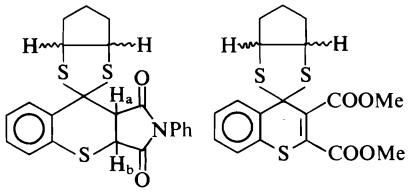
The formation of **2** may be envisaged as occurring, formally, via A and B (11–13).

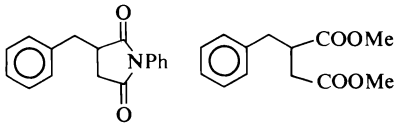
The adduct **2***a*, obtained with cyclopentene, when refluxed in carbon tetrachloride for 12 h regenerated **1** in high yield. This adduct was obtained as a colourless solid which was, at the time, surprising, and certainly incompatible with the monomeric formulation **2***a*: this, having a conjugated thione function, should be deep blue.

The solid adduct **2***b* obtained with tetramethylethylene, was, indeed, blue, but pale. Both substances, however, gave blue solutions whose intensities were temperature dependent, to the extent that in the case of **2***a* a solution in benzene became colourless near 5°C. The quite striking Prussian Blue colour was regenerated on warming to blood temperature and, in the absence of oxygen, the cycle would be repeated, apparently indefinitely (the substance evidently had potential use for magicians and others). In both cases, then, the supposed monomers **2** were in an equilibrium which was temperature dependent with some other species, **3**, which was colourless: the nature of this equilibrium will be discussed later.

The Monomer Structures, 2

The ready reversibility of the formation of **2***a* (together with its mode of formation) (11–13) strongly suggested that no deep seated rearrangement involving carbon–carbon bonds was involved. Presuming, therefore, that the blue entity, **2***a*, was the desired species, whatever its further and reversible transformation, a Diels–Alder addition was attempted with *N*-phenylmaleimide and with acetylenedicarboxylic acid, dimethyl ester. The adducts **4** and **5** were obtained.

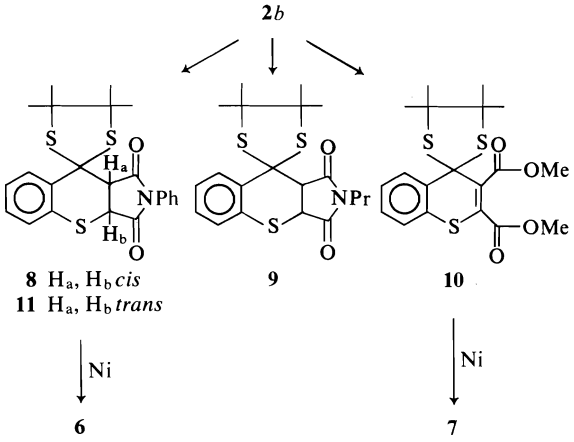




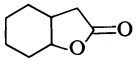
The ^{1}Hmr of **4** was consistent with that of a 1:1 adduct, and this was confirmed by the mass spectrum. Aside from the nine aromatic protons a singlet at 4.93 ppm for two protons was also present. In view of the different environments of H_a and H_b this was puzzling, but the coincidental identity of the chemical shifts was revealed by the resolution into two doublets (J = 9 Hz) on the addition Eu(fod)$_3$. Although two stereoisomers are possible the crystalline adduct appeared to be a single isomer (80°C). The structure assigned to **4** was further confirmed by total desulfurization with Raney nickel to benzyl-*N*-phenylsuccinimide, **6**.

The acetylene adduct, on the other hand, was not obtained crystalline. The mass spectrum of the amorphous solid nonetheless indicated a 1:1 adduct, and the infrared spectrum (ν_{max} 1721 cm^{-1}) the presence of the conjugated ester functions. Desulfurization gave, as expected, **7**.

In a similar manner **2***b* was allowed to react with *N*-*n*-propylmaleimide, *N*-phenylmaleimide, and acetylene dicarboxylic acid, dimethyl ester. The structures of the adducts (**8**–**10**) were confirmed in a similar way.



Attempted desulfurization of **8** with a vintage, 4 year old, sample of Raney nickel yielded **11**. This substance resembled **8** closely in its mass spectrum and infrared spectrum. It was, therefore, presumed to be the *trans* adduct, isomerisation having been induced by the basic catalyst. The coupling constant for the methine protons is 9 Hz in **8** and 19 Hz in **11**. There figures are in good accord with those for the corresponding protons in **12** (16).

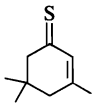


12

The ^{1}Hmr spectra of **8**, **9**, and **11** all showed four singlets for the nonequivalent methyl groups. With the ester **10** two six-proton singlets were observed, as expected for a rapid boat–boat interconversion of the central ring. Determination of the spectrum in carbon disulphide between +30°C and −110°C indicated a coalescence temperature near −70°C. Below this

temperature four peaks were seen to be partly resolved. These did not sharpen at −110°C, probably because of the high viscosity. The activation energy for the inversion, on the assumption that the above interpretation is correct, is 10.0 ± 1.0 kcal/mol (17, 18). The large uncertainty is partly due to the imprecision in the coalescence temperatures and the values of the chemical shifts.

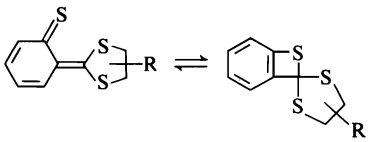
The total of the above evidence suggests that the adducts are adequately represented by the *o*-methylene quinonoid structures, and this is consistent with the visible and ultraviolet absorption spectra. Both **2***a* and **2***b* showed intense absorption at 585 nm. Most conjugated thiones show absorption in this region (19–22), indicative of transitions of $\pi^* \leftarrow n$ type, but there is no doubt that the present absorption has a different origin: the molar extinction coefficients observed are far too high for what is a symmetry forbidden transition. It is, therefore, almost certainly a $\pi^* \leftarrow \pi$ transition, the $\pi^* \leftarrow n$ absorption submerged and unresolved. There cannot be much ct (charge-transfer) contribution to this transition in view of the very slight solvent dependence of the absorption (Table 1). This is to be contrasted with the large shift observed for Michler's thione (22) where there is a large ct contribution. In fact, the extended π system, together with the effect of sulphur substitution (23–25) could be sufficient to account for the position of the $\pi^* \leftarrow \pi$ band. Thus the parent *o*-xylylene absorbs at 373 nm (26) and the corresponding thione would be expected at longer wavelength (compare 3-methylenecholest-4-ene (239 nm, ref. 24) with **13** (296 nm, ref. 19)).



13

Single sulphur substitution in enones results in displacements of ~85 nm (24).

The fact that the presently noted properties of the monomeric species **2***a* and **2***b* are adequately described by those representations does not exclude the possibility of the existence of an additional equilibrium with the cyclized valence tautomers of type **14**. Such equilibria have been



14

proposed for ketene imines and ketene thiones (27–29), but in the present case we have no evidence for its existence.

TABLE 1. Solvent effect on λ_{max} of **2***a*

Methylene chloride	585
Benzene	585

The Structure of the Dimers

The reversible equilibria observed with **2** were not, in themselves, indicative of dimerization. The first hypothesis, in fact, was that it represented something of the type **14**. That it represented a reversible dimerization was shown in two ways.

The first was by the establishment of the concentration dependence of the average molecular weight. The molecular weight, determined cryoscopically in benzene for **2***a* was 496 ± 10: that calculated for a dimer was 502. However, the molecular weights determined osmometrically in chloroform yielded the results shown in Fig. 1. Here, a concentration dependence is clearly indicated though, regrettably, values at very low concentrations could not be determined.

The second was by the use of optical method for measuring monomer concentration. With this technique (see Appendix) equilibrium constants (K_c) could be determined at various concentrations at constant temperature. Only for the system

$$A_2 \rightleftharpoons 2A$$

was the equilibrium 'constant', in fact, constant. The values are indicated in Table 2 for **2***a* and **2***b*; in addition, values for other conceivable equilibria for **2***a* are included to indicate the changes in K_c.

Given that the equilibrating species was a dimer, a number of possibilities existed for the actual structures. Diels–Alder addition, though known with such systems (see following section) and in general with *o*-quinonoid systems (for instance, refs. 26, 30–32), could be eliminated on spectroscopic grounds. The dimers were transparent above 300 nm: any $(2_\pi + 2_\pi)$ or $(2_\pi + 4_\pi)$ addition must leave a conjugated absorbing

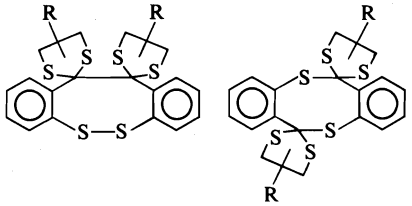
system, **15** detectable above 300 nm (33), or contain a spectroscopically recognizable thione group. In addition, the latter type of addition was excluded by the ^1H and ^{13}C nmr spectra

15

which clearly indicated symmetry and the lack of unsaturation aside from the aromatic rings. The ^{13}C spectrum of **2***b*, for instance, contained by 13 signals. The most probable structures were thus eight-membered rings **16***a,b* or **17***a,b*. An eight-membered ring has been reported for dithietenes. This is also an equilibrium, but requires higher temperatures (34). On desulphurization with Raney nickel at 40–60°C a small yield of bibenzyl (4%) was obtained. At face value this suggested **16***a* for the dimer structure, but the possibility of a *trans*-annular coupling (28) cannot be completely excluded, nor the formation of bibenzyl from monomeric precursors.



16*a* R = $(CH_2)_3$ **17***a* R = $(CH_2)_3$
b R = $(CH_3)_4$ *b* R = $(CH_3)_4$

Another argument may be adduced to support the same structure. It seems most probable that **3***a* and **3***b* should have the same regiospecificity. If that be accepted, then were the *trans* arrangement **17***a,b*, that obtaining the equilibrium for the two pairs might be expected to be very similar. In fact (section following) there is a free energy difference of 3.3 kcal/mol which should be steric in origin. Such an effect is hard to rationalize without involving **16***a,b*.

The Equilibrium

The position of the equilibrium was dependent on the polarity of the medium, the monomer

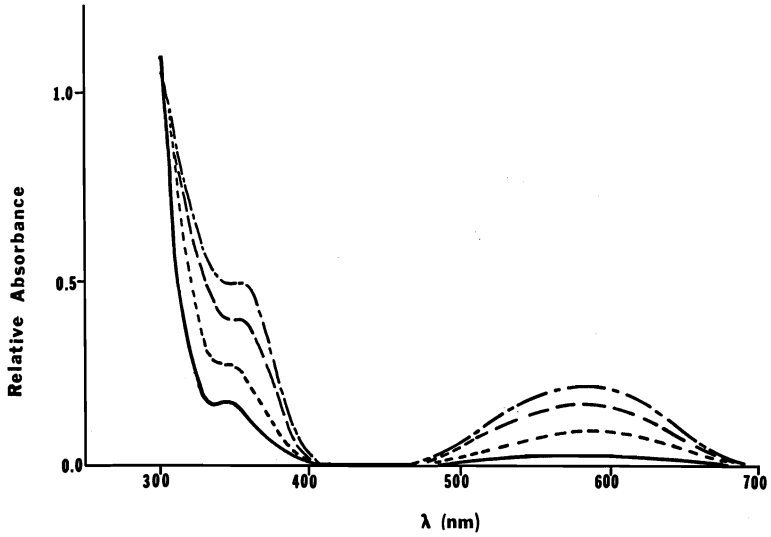


FIG. 2. Solvent effect on the absorption of **2***a*: (—) CH_2Cl_2–hexane 1:4; (---) 2:3; (——) 3:2; (····) pure CH_2Cl_2.

being favoured with increasing polarity (Fig. 2). In a particular solvent the position of the equilibrium was also temperature dependent. For a methylene chloride solution the change over the range $-16°C$ to $+33°C$ is shown in Fig. 3. Similar displacements could also be achieved by brief irradiation at both 254 nm and at 585 nm (Fig. 4). On removal of the light the original equilibrium was slowly restored.

Equilibrium constants (K_c) were measured at 585 nm (see Appendix) in benzene and chloroform over a range of $\sim 40°$. The values of K_c were obtained and plots of ln K_c against reciprocal temperatures are shown in Fig. 5. The values of ΔH^0 and ΔS^0 were computed (least squares) and are shown in Table 3. The value of ΔH^0 for **2***a* is about 2 kcal/mol larger than that of **2***b* in both solvents. We interpret this, as stated, in terms of steric crowding in **16**, but we recognize that the argument is not conclusive. It is interesting that in the recent extension to the naphthalene series (35) the isolation of the monomers has been reported without there being evidence for equilibria with dimers.

Cycloaddition Reactions

In the characterization of the monomers normal dienophiles were used. At a stage when Diels–Alder structures for the dimers were still thought possible the addition of **2***a* and **2***b* to alicyclic thiones was also attempted as a model reaction. Adducts were obtained and the chemistry thereof is here reported.[2]

The thiones selected were adamantanethione, norbornanethione, cyclohexanethione, and thiocamphor. From the first three substances and **2***a* pure adducts were obtained at room temperature. In the case of norbornanethione only one isomer could be obtained crystalline. With thiocamphor 3 days were necessary before the colour of the thione was discharged, and on attempted isolation **2***a* was regenerated. Similar experiments were performed with **2***b*, but only in the case of cyclohexanethione could an adduct be isolated.

The structure of the **2***a*–adamantanethione adduct followed from the evidence to be described. Similarity of analytical and spectral data allowed that of the other adducts to be allocated by analogy.

Two adducts were obtained from **2***a* and adamantanethione. These were 1:1 adducts and the four possibilities **18***a,b*, **19***a,b* were to be considered. Since the mass spectral fragmentation patterns for the two isomers were identical the choice lay between **18** and **19**: it seemed unlikely that structural isomers could behave so similarly. This view was supported by the isomerization to be described. Only one isomer was formed from

[2]For the addition of thiones to dienes, see refs. 36–38. For the use of α,β-unsaturated thiones as dienes, see refs. 35, 39–44.

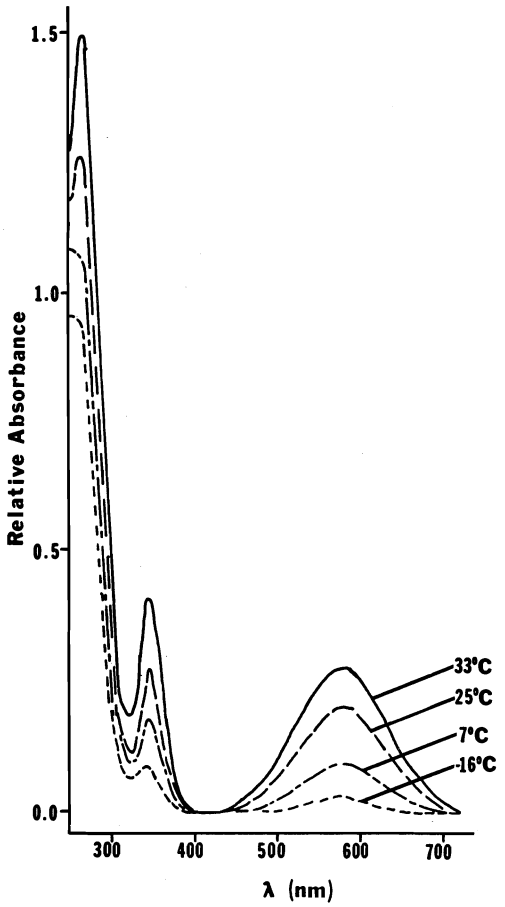

FIG. 3. Temperature effect on absorption of **2***a* in methylene chloride.

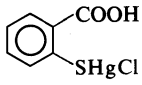
2*b* and cyclohexanethione, in agreement with this view.

The chemical distinction between **18** and **19** is that **19** is a thioorthoester whereas **18** is a disulphide. Under conditions of reduction with lithium aluminium hydride when a disulphide would be expected to be cleaved there was no reaction (45). This, though negative evidence, appeared to favour **19**, as did the reversibility of the Diels–Alder formation. Accordingly, the hydrolysis of the thioorthoester was undertaken. Stirring a mixture of **19** with mercuric oxide in the presence of boron trifluoride at 0°C gave adamantanone in 50% yield. In addition, the mercaptide chloride, **20**, of *o*-mercaptobenzoic acid was obtained in similar yield.



20

The possibility that the thiosalicylic acid was formed in some way from **2***a* itself was eliminated by showing that the adduct was thermally stable under the conditions used. Only isomerization occurred (see below).

The Adduct Isomerization

It was observed that a pure isomer of **19** showed a single methine proton signal at $\delta = 4.4$ ppm ($CDCl_3$). After 12 h the signal for the other isomer ($\delta = 4.0$ ppm) was also visible, and the presence of the second isomer was confirmed by isolation. The equilibrium could be approached from both sides, and the final ratio was ~1:1. The same isomerization could be achieved in benzene at 80°C but was slow and needed over 3 days.

The adduct of **2***a* with norbornanethione behaves similarly: in methylene chloride-d_2 – acetonitrile-d_3 (2:1) at 40°C 20% conversion of the δ 4.4 isomer to the other was achieved in 4 days. In carbon tetrachloride no change was observed in 4 days.

Since more polar solvents appeared to favour the isomerization and since chloroform frequently contains acid, it seemed likely that the process was heterolytic. This was confirmed when a solution of the **2***a* – cyclohexanethione adduct (mixture, major isomer $\delta = 4.4$, ratio 4:1) in carbon tetrachloride, which had been stable for at least 58 h, when acidified with dry hydrogen chloride equilibrated (final ratio: 2:1) in 1 h.

Two general possibilities existed for the inversion: a reversion of the adducts to starting materials, followed by recombination; or a cleavage of a single bond (C—S) of the thio-

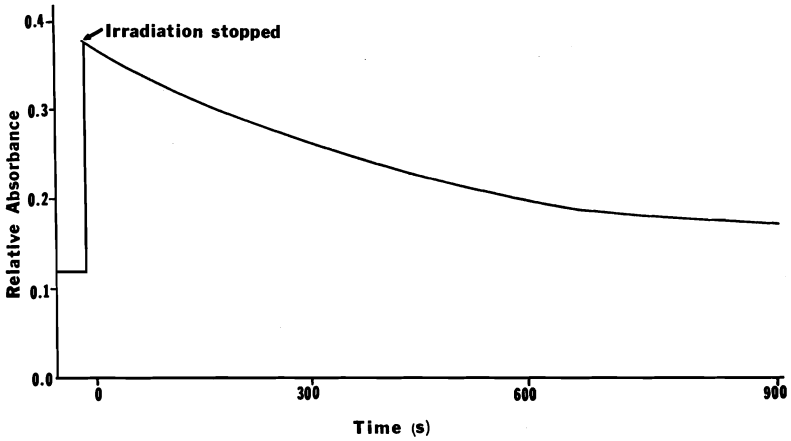


FIG. 4. Effect of light on the **2***a*–**3***a* equilibrium.

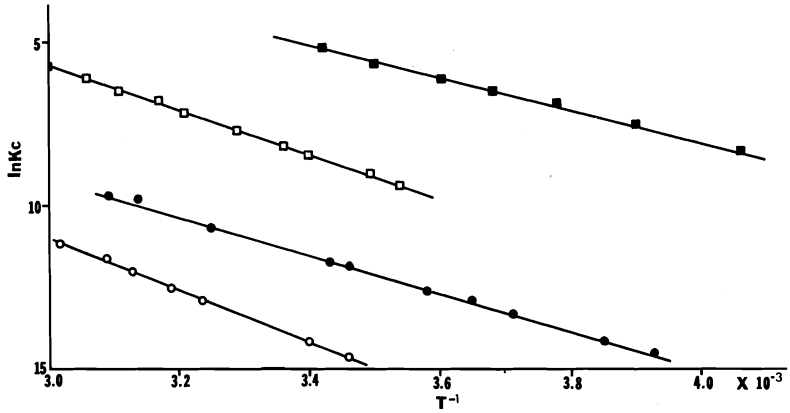

FIG. 5. Plot of ln K_c of (○) **2***a* in benzene, (●) **2***a* in $CHCl_3$, (□) **2***b* in benzene, (■) **2***b* in $CHCl_3$ as a function of the reciprocal absolute temperature.

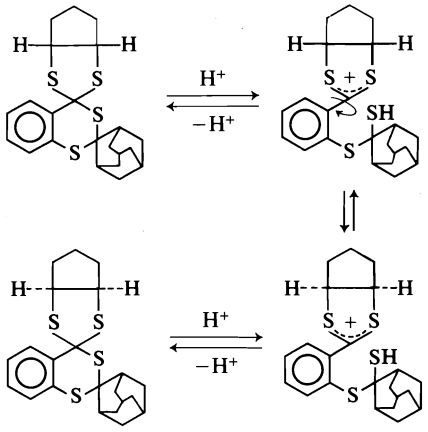
TABLE 3. Thermodynamic parameters

	2*a*		**2***b*	
	Dimer ⇌ Monomer		Dimer ⇌ Monomer	
Solvent	C_6H_6	$CHCl_3$	C_6H_6	$CHCl_3$
ΔH^0 (kcal/mol)	15.8±1.0	11.5±0.4	14.1±0.3	9.4±0.2
ΔS^0 (eu)	25.6±2.0	16.1±1.2	31.1±0.8	21.8±0.8

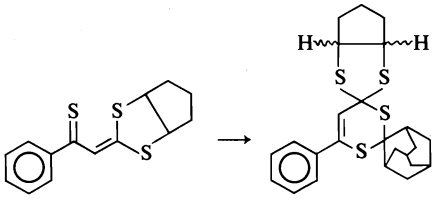
orthoester, followed by rotation and recombination (Scheme 1). If the first be not occurring in a solvent cage from which there is no escape, then the mechanisms are distinguishable. To reveal the distinction the isomerization of the norbornanethione – **2***a* adduct was carried out in benzene at 80°C in the presence of norbornanethione-α,α-d_2. The recovered, but partly isomerized, adduct contained no deuterium, as shown by mass spectrometry. Further, permitting the isomerization to occur in the presence of the powerful dienophile, *N*-phenylmaleimide both in benzene and chloroform, gave none of the adduct **4**. The route via the dithiolenium ion is thus preferred.

The allocation of the stereochemistry of the isomers may be reasonably made on the following grounds. The relevant protons are either *syn*



SCHEME 1

or *anti* to the aromatic ring. The higher field protons would, from the inspection of models, be expected to be those *syn* to the aromatic ring. To confirm this the adducts from **21** (13) and adamantanethione were prepared. Both were observed in solution but only one isomer could be isolated. However, both isomers, as shown by integration, had the relevant proton signals at 4.5 ppm.



21

Experimental

Melting points were determined on a Reichert hot stage apparatus. Cyclopentene and tetramethylethylene were refluxed over zinc dust and distilled. Benzene was purified by irradiation with chloranil for 7 days and fractionally distilled. Boron trifluoride etherate was purified according to Fieser (47). 4,5-Benzo-1,2-dithiole-3-thione was prepared according to the method of Lozac'h (48).

2-Benzyl-N-phenylsuccinimide

This was prepared according to Arcona (49) from 2-benzylsuccinic acid (0.4 g) and aniline (0.18 g) at 180°C, mp 128–130°C; ν_{max}: 1778, 1714 cm^{-1}. *Exact Mass* calcd. for $C_{17}H_{15}O_2N$: 265.1102; found (ms): 265.1090.

*Irradiation of **1** with Cyclopentene*

It was established optically that no reaction occurred between these substances in ethereal solution in the dark in several hours. Exposure to room light led to reaction.

A mixture of **1** (99 mg), cyclopentene (1 ml), and ether (30 ml) was irradiated with a 450 W medium pressure lamp until the solution turned deep blue (ca. 2 h). After evaporation of the solvent the residue was chromatographed (silica gel, 9 g; light petroleum (60–80°C) – benzene, 2:3) to give **2***a* as a white solid, recrystallized from methylene chloride – methanol, mp 158–160°C (dec.), 112 mg (80%); δ: 3.95 (m, ca. 1.5H, S—$(CH_2)_2$—S), 4.40 (m, ca. 0.5H, S—$(CH_2)_2$—S); λ_{max} (benzene, 5.24 × 10^{-3} *M*) 585 (24.8), 351 (139); (acetonitrile, 6.61 × 10^{-4} *M*) 580 (348), 346 (620); (methylene chloride, 5.02 × 10^{-3} *M*) 585 (97), 347 (136), 260 (3590).

When a solution of **2***a* (20 mg) in carbon tetrachloride (5 ml) was refluxed for 12 h the product showed one spot on tlc and crystallization (hexane) gave **1** in quantitative yield.

*Desulphurization of **2a***

The compound (1.08 g) and Raney nickel (10 g) was heated in benzene at 40°C for 20 h. Starting material remained, and the temperature was raised to 60°C for 4 h. From the mixture, by tlc, was isolated bibenzyl (4%) and benzyl alcohol (13.5%) both identified by comparison with authentic specimens.

*Reaction of **2a** with N-Phenylmaleimide*

The thione (39 mg) and imide (29 mg) in benzene (10 ml) were stirred at room temperature in the dark. The tlc yielded the adduct **4** (53 mg, 80%) crystallized from ethyl acetate, mp 93–95°C; ν_{max}($CHCl_3$): 1770, 1710 cm^{-1}; δ: 1.5–2.4 (m, 6H), 4.1–4.4 (m, 2H), 4.93 (s, 2H), 6.80–8.13 (m, 9H). When Eu(fod)$_3$ (53 mg) was added the peak at 4.93 became a pair of doublets (J = 9 Hz); λ_{max}(MeOH): 283 (sh) nm (ε = 300). *Anal.* calcd. for $C_{22}H_{19}NO_2S_3$: C 62.11, H 4.50, N 3.29; found: C 62.11, H 4.56, N 3.30.

Desulfurization of the adduct (300 mg) with Raney nickel (3 g) in benzene by refluxing for 24 h gave (ethanol–water, 1:1) the benzyl-*N*-succinimide **6** (142 mg, 77%), mp and mixture mp 128–130°C, further identified by ir, ^{1}Hmr, and mass spectrum.

The adduct with acetylene dicarboxylic acid, dimethyl ester prepared in the same way could not be obtained in crystalline form though apparently it was homogeneous on tlc. The ^{1}Hmr spectrum was consonant with the assigned structure; λ_{max}(CH_2Cl_2): 318 (3900), 253 nm (8400). Desulfurization gave dimethyl benzylsuccinate identified by ir and mass spectrum.

*Irradiation of **1** with Tetramethylethylene*

The irradiation was performed as with cyclopentene. From 90 mg **1** was obtained (methylene chloride – methanol) **2***b* as pale blue crystals (135 mg, 90%), mp 136–138°C (dec.); δ (220 MHz, CD_2Cl_2 at −50°C): 1.2 (s, 3H), 1.33 (s, 3H), 1.59 (s, 3H), 1.80 (s, 3H); λ_{max}(C_6H_6) (2.59 × 10^{-4} *M*) 585 nm (2270); ^{13}Cmr (CD_2Cl_2): 148.6 (s), 139.4 (d), 134.19 (s), 129.52 (d), 128.67 (d), 128.07 (s) (aromatic), 77.60 (s), 66.23 (s), 66.12 (s), 28.32 (q), 26.93 (q), 23.48 (q), 23.31 (q). *Exact Mass* calcd. for $C_{13}H_{16}S_3$: 268.0409; found (ms): 268.0405. *Anal.* calcd. for $C_{13}H_{16}S_3$: C 58.20, H 6.01, S 35.79; found: C 58.33, H 6.19, S 34.88.

The molecular weight determined at 5.8 mg/ml at 38°C by osmometry was 496. This is equivalent to the presence of 7.4% monomer. Determined by absorption at 585 nm a value of 9.7% was obtained.

*Reaction of **2b** with N-Phenylmaleimide*

A solution of **2***b* (500 mg) and the imide (400 mg) in benzene for 24 h yielded the adduct **8**, mp 242–245°C

(700 mg, 85%), from ethyl acetate; $\lambda_{max}(CHCl_2)$: 1775, 1710 cm^{-1}; ^{1}Hmr δ: 1.36 (s, 3H), 1.46 (s, 3H), 1.58 (s, 3H), 1.70 (s, 3H), 4.405 (s, 1H), 4.415 (s, 1H). After the addition of Eu(fod)$_3$ (28 mg) the signals at 4.41 were replaced doublets at 4.83 and 5.9 (J = 9 Hz). *Anal.* calcd. for $C_{23}H_{23}NO_2S_3$: C 62.58, H 5.25, N 3.17, S 21.75; found: C 63.28, H 5.55, N 3.20, S 21.55.

Desulfurization of **8** with Raney nickel (12 g) of **2***b* (500 mg) gave 2-benzyl-*N*-phenylsuccinimide (230 mg), mp and mixture mp 128–130°C. Attempted desulfurization of **8** with vintage (4 year old: stored in alcohol) Raney nickel in absolute alcohol (22 h, reflux) gave material which was separated by tlc. Aside from the adduct **8** recovered there was obtained the isomer **11**, mp 225–227°C (119 mg); ^{1}Hmr ($CHCl_3$) δ: 1.46, 1.55, 1.60, 166 (all s, all 3H), 3.34 (d, J = 19 Hz), 4.11 (d, J = 19 Hz); uv $\lambda_{max}(CH_2Cl_2)$: 298 nm (2500). *Anal.* calcd. for $C_{23}H_{23}NO_2S_3$: C 62.58, H 5.25, N 3.17, S 21.75; found: C 62.62, H 5.13, N 3.27, S 21.72.

Reaction of 2b with N-n-Propylmaleimide

The thione (100 mg) and the imide (50 mg) in benzene (30 ml) gave, in 30 min at room temperature, the adduct **9**, 128 mg (79%), mp 213–214°C; ν_{max}: 1724 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.4 (t, J = 4 Hz), 0.9–1.3 (m, 2H), 1.26, 1.46, 1.53, 1.70 (s, 3H each), 3.20 (t, 2H J = 4 Hz), 4.20 (s, 2H). *Anal.* calcd. for $C_{20}H_{25}NO_2S_3$: C 58.96, H 6.18, N 3.44, S 23.56; found: C 58.96, H 6.09, N 3.41, S 23.79.

Reaction of 2b with Acetylene Dicarboxylic Acid, Dimethyl Ester

The thione (100 mg) and ester (0.5 ml) in benzene (10 ml), after 12 h at room temperature gave, after tlc, the adduct **10** (67%, 95 mg) from methanol, mp 94–97°C; $\lambda_{max}(CHCl_3)$: 1721; ^{1}Hmr ($CDCl_3$): 1.4 (s, 6H), 1.54 (s, 6H), 3.94 (s, 3H), 3.96 (s, 3H). The spectrum was scanned (CS_2) from +30 to −110°. The separation of the resolved peaks at low temperature was 160 ± 15 Hz. *Anal.* calcd. for $C_{19}H_{22}O_4S_3$: C 55.61, H 5.40, S 23.39; found: C 56.10, H 5.70, S 22.88.

The ester was desulfurized to give dimethyl 2-benzylsuccinate by Raney nickel (15%).

Determination of Molar Extraction Coefficients

A Gilford spectrophotometer 240 was used with a double set of thermospacers with matched 1.0 and 10.0 cm cells at 24.5 ± 0.2°C. For variable temperature measurements a Kryothermat Haake model KT-62 constant temperature circulator with a cell in a Cary 14 was used. The temperature was measured with an iron–constantan thermocouple. One hour minimum was allowed for equilibration.

Thionorbornanone

This was prepared by the method described by Greidanus (50) for adamantanethione. The final product was distilled at 55–60°C/0.02 Torr. *Exact Mass* calcd. for $C_7H_{10}S$: 126.0503; found (ms): 126.0509.

Thionorbornane-d_2

Sodium metal (0.5 g) was added to a solution of methanol-*d* (10 g) and was stirred until all the metal had dissolved. Norcamphor (1 g) was added and the mixture refluxed 24 h. Deuterated water was added and the mixture extracted with ether. The residue, after removal of the solvent, was reacted with phosphorus pentasulfide to give the thione. The ratio $d_0:d_1:d_2$ was 1.1:1.0:1.9.

Diels–Alder Addition with Thiones

The following procedure is typical. A solution of a **2***a* (420 mg, 1.67 mmol) and adamantanethione (320 mg; 2.0 mmol) in benzene (20 ml) was kept in the dark at room temperature for 24 h. After removal of solvent the residue was separated by preparative tlc (light petroleum (60–80°C) – methylene chloride, 1:1). The adduct thus obtained, if containing two stereoisomers, was further separated by tlc using cyclohexane (4 cycles).

In the present instance one isomer (higher R_f) was obtained as a white solid (280 mg; 51%), mp 188–189°C (from ethyl acetate); λ_{max}: 298 (sh, 1500). *Anal.* calcd. for $C_{22}H_{26}S_4$: C 63.15, H 6.26, S 30.59; found: C 63.10, H 6.18, S 30.33.

The slower-moving material (109 mg, 22%) had mp 145–146°C (from ethyl acetate). *Anal.* calcd. for $C_{22}H_{26}S_4$: C 63.15, H 6.26, S 30.59; found: C 63.64, H 6.41, S 30.19.

With thionorbornanone the faster-moving compound was obtained in 63.5% yield (132 mg) from 120 mg of **2***a*. It had mp 143–145°C (from ethyl acetate); $\lambda_{max}(CH_2Cl_2)$: 300 (sh, 1200). *Anal.* calcd. for $C_{19}H_{22}S_4$: C 60.31, H 5.86; found: C 60.41, H 6.10. The slower-moving component could not be induced to crystallize.

With cyclohexanethione (51) **2***a* (92 mg) gave 79 mg (64%) of faster-moving material, mp 106–108°C; $\lambda_{max}(CH_2Cl_2)$: 296 (sh, 2750); ms (*m/e*): 366 (M^+, 9%) 252 (20), 184 (100), 120 (35), 114 (25), 67 (35). *Anal.* calcd. for $C_{18}H_{22}S_4$: C 59.01, H 6.05, S 35.94; found: C 59.45, H 5.74, S 35.08. The slower-moving isomer (31 mg, 25%) had mp 143–145°C; $\lambda_{max}(CH_2Cl_2)$: 270 (sh, 4000); ms (*m/e*): 366 (M^+, 10%) 252 (25), 184 (100), 120 (35), 114 (23), 67 (35). *Anal.* calcd. for $C_{18}H_{22}S_4$: C 59.01, H 6.05, S 35.94; found: C 59.21, H 6.01, S 35.02.

With cyclohexanethione and **2***b* a single adduct was obtained in 88% yield (250 mg), mp 142–144°C (from ethyl acetate); $\lambda_{max}(CH_2Cl_2)$: 270 (sh, 2000). *Anal.* calcd for $C_{19}H_{26}S_4$: C 59.67, H 6.85, S 33.47; found: C 60.20, H 7.01, S 33.08.

With adamantanethione and thionorbornanone the colour of **2***b* was discharged in 3 days. On evaporation of the solvent at 35°C reversion to the starting material occurred. With thiocamphor there was no reaction.

The Reaction of 21 and Adamantanethione

This was carried out as in the previous examples. Two isomers were obtained in about 25% total yield based on 28 mg thione. The ratio of isomers, based on singlets at 6.27 and 6.29 in the ^{1}Hmr spectrum, was 3:1. One isomer was separated by tlc and had mp 136–138°C (from ethyl acetate); δ: 4.5 (m, 2H), 6.29 (s, 1H); ms (*m/e*): 278 (M^+, 6%) 210 (80), 166 (100), 145 (60), 91 (45), 77 (20), 67 (25). *Anal.* calcd. for $C_{24}H_{28}S_4$: C 64.85, H 6.35; found: C 64.99, H 6.35.

Hydrolysis of 19 with Mercuric Oxide

A cooled solution of **19** (20 mg) in tetrahydrofuran (5 ml) was added to a stirred mixture of red mercuric oxide (2 mol equiv.) and boron trifluoride etherate (2 mol equiv.) in aqueous tetrahydrofuran (15%, 15 ml). After 30 min, diethyl ether was added and the precipitate filtered off.

The filtrate was washed (saturated $NaHCO_3$, saturated aqueous NaCl). The residue, after evaporation of the solvent gave adamantanethione, mp 258–259°C (3 mg, 50%), characterized as the 2,4-dinitrophenylhydrazone,

mp 219–220°C (52). The original precipitate from the hydrolysis was stirred with concentrated hydrochloric acid for 3 h at room temperature. The white solid (10 mg) was collected and washed with water. This compound was soluble in K_2CO_3 solution and had the same R_f as thiosalicylic acid mercaptide chloride on an Eastman 6060 sheet using isopropanol–triethylamine–water (2:1:1), mp 270°C (sub.); ν_{max}(KBr): 3400 (b), 1680 (vs), 1470, 1422, 1300, 1270, 745 cm^{-1}.

Isomerization of ***19***

A solution of each pure isomer (12 mg in 0.3 ml $CDCl_3$) was examined in an nmr tube over 48 h at the end of which both isomers were present in ~1:1 ratio. The reaction was also performed in a sealed nmr tube in benzene at 80°C.

Exchange Experiments

A solution of the **2***a*–norbornanethione adduct (12 mg) and deuterated norbornanethione (10 mg) in benzene (2 ml) was sealed under N_2 in a glass tube and kept at 80°C for 4 days. Under these conditions the thione itself is stable except for isomerization. The reaction mixture which contained only the starting materials was separated. The M, $M+1$, $M+2$ ratios were 100:24:17. The undeuterated material was 100:24:21. The minimum exchange detectable was estimated to be ~4%. Similar experiments using *N*-phenylmaleimide instead of the thionorbornanone at room temperature or in benzene solution at 80°C gave no trace of the adduct **4**.

Appendix

Optical Measurements

The absorption spectrum of the dimer of **2***a* could be obtained at low temperature in ether (no absorption at 585 nm). The spectrum of the pure monomer could not be obtained, but peaks at 346 and 585 and a shoulder at 260 nm were found in a wide variety of solvents and are attributed to the monomer. The molar extinctions for the monomers were obtained, at 585 nm, by the method of Keussler and Lüttke (46) used for nitroso compound association.

The dimer dissociation constant is

$$[1] \qquad K_c = C_m^2/C_d$$

where C_m and C_d are the molar concentrations. C, the total molar concentration is $C_m + 2C_d$. If α is the monomeric fraction

$$[2] \qquad K_c = 2C\alpha^2/(1-\alpha)$$

The effective molar absorbancy, ε, is given by

$$[3] \qquad \varepsilon = \alpha\varepsilon_m + \frac{(1-\alpha)\varepsilon_d}{2}$$

where ε_m and ε_d are the absorption extinctions for monomer and dimer. But since at 585 nm, the monitoring wavelength, $\varepsilon_d = 0$, then $\alpha = \varepsilon/\varepsilon_m$ where eq. 2 becomes

$$[4] \qquad K_c = \frac{2C(\varepsilon/\varepsilon_m)^2}{1-(\varepsilon/\varepsilon_m)}$$

or

$$[5] \qquad (\varepsilon_m - \varepsilon)K_c = 2C\varepsilon^2/\varepsilon_m$$

or

$$[6] \qquad \varepsilon = K\varepsilon^2 C + \varepsilon_m$$

where

$$K = -2/(\varepsilon_m K_c)$$

Hence ε_m at 585 nm could be obtained by plotting ε vs. $\varepsilon^2 C$ and extrapolating to zero concentration. The molar extinction coefficients were determined in benzene and chloroform at 24–25°C. The results are given in Table 4. The low degree of dissociation of **2***a* in benzene precluded the obtention of a reliable value. It was assumed that the same ratio held in this solvent as did for **2***a*/**2***b* in chloroform, giving $\varepsilon = 5250$.

Migration of hydroxyl in secondary systems during solvolysis in acid solution[1]

ROBERT C. CATHCART, JOHN W. BOVENKAMP, ROBERT Y. MOIR, ROBERT A. B. BANNARD, and ALFRED A. CASSELMAN. Can. J. Chem. **55**, 3774 (1977).

A system of compounds has been prepared which is well adapted for displaying the role of *trans* vicinal, secondary hydroxyl in solvolysis. On methanolysis in acid solution, compounds **5**, **7***a*, and **8***a* all gave the same products, **9***a* and **10***a*, and in practically the same proportions, suggesting that at least one intermediate was common to all three reactions. These intermediates were such that **7***a* and **8***a* were not interconverted during the solvolysis, a fact in support of **6** as a common intermediate. Several alternative explanations were shown to be untenable, largely by taking advantage of the remarkable differences between hydroxyl and methoxyl. The work provides the most decisive evidence available for the covalent participation of hydroxyl as a neighbor group in the solvolysis of secondary systems, and contributes also to the study of the reverse reaction, the acid-catalyzed scission of epoxides.

ROBERT C. CATHCART, JOHN W. BOVENKAMP, ROBERT Y. MOIR, ROBERT A. B. BANNARD, et ALFRED A. CASSELMAN. Can. J. Chem. **55**, 3774 (1977).

On prépare un système de composés lequel est bien adapté pour mettre en évidence le rôle du groupe hydroxyle *trans* vicinal dans des réactions de solvolyse. La méthanolyse en solution acide des composés **5**, **7***a* et **8***a* conduit aux mêmes produits **9***a* et **10***a* et essentiellement aux mêmes proportions suggérant qu'au moins un intermédiaire est commun aux trois réactions. Ces intermédiaires sont de telle sorte que **7***a* et **8***a* ne sont pas convertis l'un dans l'autre pendant la solvolyse, ce qui est en accord avec l'hypothèse que **6** soit un intermédiaire commun. Plusieurs interprétations ne peuvent être soutenues, essentiellement parce qu'elles ne tiennent pas compte des grandes différences entre un groupe hydroxyle et méthoxyle. Ce travail apporte l'évidence très nette de la participation covalente du groupe hydroxyle comme groupe voisin dans la solvolyse de systèmes secondaires et contribut aussi à l'étude de la réaction inverse, la scission catalysée par un acide des époxydes.

[Traduit par le journal]

The role of neighboring hydroxyl in the solvolysis of secondary systems is still not clear. As shown later, there seems little prospect of demonstrating its participation by isolating or trapping a bridged intermediate under the acid conditions needed to prevent confusion with another reaction.[3] Less direct and less compelling evidence has often been offered. The observed steric course for solvolysis has been said to be evidence for covalent participation by hydroxyl (1), but it is obviously not sufficient, since the similar methoxyl group has the same configura-

[1]Most of the work is taken from the Ph.D. Theses (Queen's University) by (*a*) J. W. Bovenkamp, November, 1973, and (*b*) R. C. Cathcart, September, 1975.

[2]Revision received June 22, 1977.

[3]Oxides have been demonstrated as intermediates (or by-products) in the solvolysis of tertiary systems (3*c*, 3*d*, 5), but as the authors point out, the nonacidic conditions were such that at least some participation by the conjugate anion of hydroxyl was to be suspected. Aside from this difficulty there would be little doubt that hydroxyl is capable of migration in tertiary systems, since in them even methoxyl has been observed to migrate (3*a*, 3*b*). A secondary oxide, *cis*-cyclooctene oxide, has been isolated (8*c*) in the solvolysis of the corresponding *trans*-bromohydrin with acetic acid and sodium acetate. One may infer from the contexts (8) that the authors suspected oxyanion intervention in this system also. Although epoxides have been demonstrated as 'intermediate by-products' in the acid-catalyzed pinacolic rearrangement of tetraphenylethylene glycols (13*a*), solvolysis of the similar 1,1,2-triphenyl-2-bromoethanol does not proceed through the epoxide (13*b*). Epoxides have been established as intermediates in one route for ketone–ketone rearrangements (14), and recently Ganem (15) has described the attack of *trans*-hydroxyl groups upon neighboring chloronium ions, in certain addition reactions of olefins.

tion-holding effect (2), and is, at least in secondary systems (3) at the vicinal position (4), known to show little or no covalent participation (5–7).[4] Rate enhancement by *trans, vicinal* hydroxyl is of course stronger evidence for participation (1, 8–11) but the fact that the net effect of hydroxyl is nearly always inhibitory (1) may be sufficient to indicate the difficulty of dissecting the effect due to covalent participation from the inductive effects, from steric effects, and from effects due to 'internal solvation' or 'ion-dipole stabilization' (1, 5, 8, 10–12). Ingenious but even less direct methods for detecting participation have been suggested (1, 8–11).

Much the most convincing practically available evidence would be the demonstration of hydroxyl wandering during the solvolysis of secondary systems. The only example[3] known to us is that reported by Dicko and Bodot (11) who showed that hydrolysis of **1** gave **2**, and pointed out that the most probable explanation is that the reaction proceeds through the intermediate **3**. Two reservations are possible. The reaction may not be typical, since **3** cannot be formed from the locked structure **1** through the usual chair-like conformations (16). Secondly, it is possible that the route may have lain partly through **4**, which is much more reactive than **1**, and hence difficult to detect. The suggested possible conversion of **1** to **4**, by way of a doubly-bridged transition state, or by anion migration within an intermediate ion-pair, is analogous to mechanisms most familiar in the equilibration of locked diaxial and diequatorial dibromides, or in the self-racemization of 2-norbornyl brosylate (17), but frequently proposed for other neighbor groups, including hydroxyl (13, 14, 18–21).

A more decisive approach is obtained by focusing attention upon the oxide **5** and its protonated form **6**. If a protonated epoxide is an intermediate in solvolysis with neighboring *trans* hydroxyl, then **6** is the common intermediate in the solvolyses of **5**, **7***a*, and **8***a*. In previous work we had shown (22) that the acid-catalyzed methanolysis of **5** gave two products, **9***a* and **10***a*, the former predominating greatly. If a protonated epoxide is an intermediate, *then methanolysis of the oxide* **5** *and of each of the tosylates* **7***a and* **8***a should give both* **9***a and* **10***a*. In this paper it is shown that not only does the indicated migration

[4]The strongest evidence for this lies in the success of Haworth's method for determining the structures of carbohydrates (7).

ix	Tosylate **8***a*	587 h	4.0(0.19)
—	Epoxide **5**	(few min.)	4.0(0.10)

[a]As their acetates.
[b]For referral to Experimental and to Table 2.
[c]As 100 (area due to **10***b*)/(total area due to **9***b* and **10***b*).
[d]Figures in parentheses are standard deviations of the mean for 5 or 6 successive injections of the sample into the chromatograph.
[e]Calibration of the method (isolation, acetylation, and injection) was done in the previous work (see footnote 1*a*) using the same detector, integrator, column packing, and nearly the same ratio **9***b*/**10***b*, but with somewhat different conditions of temperature and loading. Applying this calibration to the present results gives, for a peak area ratio of 4.0:96.0, a molar ratio of 6.5:93.5, and for a peak area ratio of 3.4:96.6, a molar ratio of 5.6:94.4. As a check, extrapolation of the value obtained in previous work (see footnote 1*a*) for the solvolysis of **5** in aqueous methanolic perchloric acid at 2.4°C gives the molar ratio 7.6:92.4 at 64°C under the condition $\Delta^2 S^{\ddagger} = 0$ (unpublished data). These corrections, unnecessary for the discussion of Scheme 1, are useful for Scheme 2 and for later papers.

of hydroxyl occur in the solvolyses of both **7***a* and **8***a*, but in addition, **7***a* and **8***a* each give the products **9***a* and **10***a* in approximately the same ratio as that observed for the oxide **5** (Table 1). When considered together with the kinetic evidence obtained by others (1, 8–11), these results seem to us to be direct evidence for the covalent participation of hydroxyl. This view has also been strengthened by an experimental investigation of the likely alternatives.

Methanolysis, catalyzed by perchloric acid at 64°C, was complete in a few minutes when the oxide **5** was the substrate, but was only about three-fourths complete after 200 h when the tosylate **7***a* was used, and was less than half complete in 500 h when **8***a* was used. Clearly, if Scheme 1 represents the mechanism there is no

Tosylate $\rightleftharpoons$ Protonated epoxide (**6**) $\rightarrow$ Products

(**9***a* and **10***a*)

SCHEME 1

prospect of verification by direct isolation of the epoxide. Mousseron, Bodot, and co-workers (10, 11) have used the reversibility of the first step in Scheme 1 (that is, the *external return* of the nucleophile) in gaining indirect evidence for the presence of intermediates analogous to **6**. Under the conditions of our solvolyses, this reversibility was suppressed, along with the consequent rearrangement pathway (22, 23):

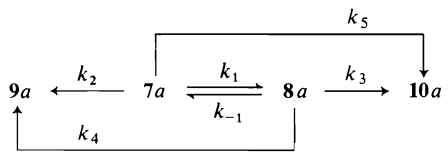
$$\mathbf{7}a \xleftarrow{\text{TsOH}} \text{Protonated epoxide } \mathbf{6} \xrightarrow{\text{TsOH}} \mathbf{8}a$$

Indeed, no such rearrangement of either tosylate was observed during the solvolyses. By attempting to fit reaction profiles to the sheaf of possibilities crudely represented by **11** (as transition state or intermediate, with varying degrees of concertedness, and with **12** and **13** as possible co-intermediates), one can therefore rule out the possibility of any important contribution from all those pathways,[5,6] alternative to Scheme 1, which involve the internal migration of tosylate:

Product $\leftarrow$ Tosylate **7***a* $\rightleftharpoons$ Tosylate **8***a* $\rightarrow$ Product

Another set of pathways alternative to Scheme 1 involve the anions[3] of the tosylates (e.g. **14**). Previous workers have felt that these routes could not have been important in their rate studies, on the basis of the curious method used to follow the kinetics of the reactions.[7] In spite

[5]If routes involving internal **7***a* $\rightleftharpoons$ **8***a* are a main contributor to the solvolyses, then the energy barrier between **7***a* and **8***a* must at the same time be very low, in order to allow each of them to give the same product ratio, and very high, in order to prevent appreciable equilibration between **7***a* and **8***a*; this is impossible of course. Competition between these routes and Scheme 1 gives rise to the following system, which as a limit problem can be solved exactly:



In the solvolyses, no rearranged tosylate was seen, though it would have been detected with certainty if it had amounted to as little as 3% of the reactant. Consequently the maximum possible intervention of **7***a* $\rightleftharpoons$ **8***a*, consistent with this, in the solvolysis of **7***a* can easily be shown to have entirely negligible results. However, calculations also show that the maximum intervention of **7***a* $\rightleftharpoons$ **8***a* in the solvolysis of **8***a* might cause its observed half-life to be as much as 20% lower than that appropriate to Scheme 1 alone; there might also be a very small effect upon the product ratio obtained from **8***a* (see footnote 14). There is of course no positive evidence for any of these effects.

[6]Corresponding internal migrations in other systems (13, 14, 17–21) have been supposed to occur easily. By far the simplest explanation for the failure of the migration in the present system lies in the preferred production of the protonated epoxide **6** either directly from **7***a* or **8***a*, or by a very rapid internal attack of hydroxyl upon its neighboring centre in **12** or **13**.

[7]The reactions were allowed to begin at neutrality and proceed to high acidity at the end, being followed by titration of aliquots. 'Straight line' plots have been reported both for derivatives of ethane (24) and of cycloalkanes (1, 8).

TABLE 2. Methanolysis of the tosylates **7***a* and **8***a*

Run No.[a]	Procedure[b]	Tosylate	Acid[c] added (ml)	Time of heating (h)	Crude[d] yield (mg)	P/R[e] ratio	Yield[d] of crude acetate (mg)

[c]Of 0.100 *M* methanolic perchloric acid. Total volume in procedure *a* was about 30 ml, and in *b* 15.00 ml at room temperature.
[d]From 0.20 g tosylate in procedure *a*, 0.10 g in *b*.
[e]The molar ratio **9***a*/tosylate, estimated by nmr, the less accurate values in parentheses, the ratio **9***a*/**8***a* being much more accurately estimated than **9***a*/**7***a*. From these ratios the apparent solvolysis rate constants *k* may be calculated (i.e. $k_3 = k_4 = 0$, Scheme 2) and compared with the titration value (see Experimental). The effect of nonzero values of k_3 and k_4 is to move the values of *k* for **7***a* and **8***a* closer together and closer to the ratio observed for the alkali-catalyzed reactions of the corresponding chlorohydrins. See Footnote 1*a*.
[f]Interrupted at 95 h, this run gave a P/R value of 0.89.

[j]Interrupted at 95 h, this run showed (nmr) little reaction.

of certain difficulties in the argument,[8] we believe their conclusions to be correct. To guard against the possible intervention of the anions of the tosylates, all but one of our solvolyses were conducted at high acidities, and in addition it was shown that large changes in the acidity had little effect upon the rates of solvolysis of **7***a* and **8***a* (see Table 2). Finally, a tedious but obvious analysis showed that at least in the present system, the small or zero effect on the rates, caused by changes in the acidity, could not be due to approximately offsetting catalysis by both acid and base.

Direct intervention of free anions such as **14** was therefore negligible. Nevertheless the great driving force available in routes involving the alkoxide anions such as **14** (5) would appear to be partially realized through general base catalysis by the solvent, that is, by hydrogen bonding through the hydrogen of the hydroxyl group. No other explanation seems possible for two facts brought to light by the careful work of Roberts and co-workers (1, 8). The ability of hydroxyl to

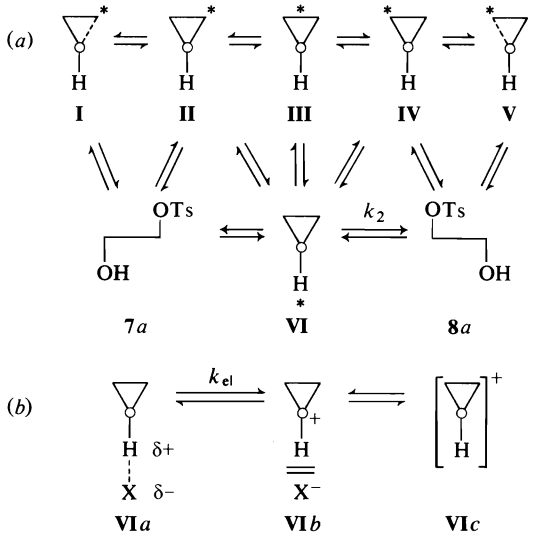

FIG. 1. Condensed illustration of ion-pair (and other) routes in acid-catalyzed epoxide scissions and in solvolyses with neighboring *trans*-hydroxyl. (*a*) The asterisks are meant to show the approximate position of the counterion, when appropriate. All possible routes are not shown, and in particular the separate positions, in the sequences, of the three subspecies are not shown. (*b*) Illustration of the three subspecies for one of the above ions; each of **I**–**V** is also supposed to possess forms *a*, *b*, and *c*, that is, tight, solvent-separated, and 'free', respectively. In particular, the process k_{el} connecting **VI***a* and **VI***b* has been supposed (31) to be rate-determining in certain epoxide scissions.

[8]Curvature has been reported in other plots, and attributed either to salt effects (10*c*), or to the reversibility of Scheme 1 (10). However, the much larger curvature due to base catalysis could not have been missed, and when rate constants are available both for the neutral and the base-catalyzed reaction (24, 25), it is clear that the latter is negligible at low p*H*.

participate was found to be very sensitive to the solvent used; paradoxically, the more nucleophilic the solvent, the more effective was the (nucleophilic) participation by hydroxyl. Alternative explanations[9] (based on the then current view that unaided solvolysis was nearly limiting in mechanism (26)) showed difficulty in coping with the second fact: while hydroxyl's effect on the rate was very sensitive to the solvent used, that of the very similar methoxyl was uniformly inhibiting in all solvents. These results are obviously in agreement with methoxyl's inability to respond to general base catalysis.[10]

The remaining alternatives to Scheme 1 are presented in condensed form in Fig. 1, which also serves to unite the chemistry of our previous (22, 23, 27, 28) and following (e.g. 29) papers on the mechanisms of epoxide scission and formation. Discussion of the ion-pair mechanisms (26, 30) is made easier by the recent application of these concepts to oxide scissions by Wylde and his co-workers (31, 32[11]). Figure 1 is essentially their scheme, considerably modified to allow for the two secondary centres and for the necessary stereochemical prescriptions.

Each of the species **I** to **VI** in Fig. 1(*a*) appears in the three forms of tight ion-pairs, solvent separated pairs, and 'free' (i.e., solvated) ions, as indicated for **VI** in Fig. 1(*b*). For example, **12** is a conventionalized drawing of **I***a*, **13** of **V***a*, and the free ions **II***c*, **III***c*, **IV***c*, and **VI***c* are identical to each other. The asterisks in Fig. 1(*a*) are meant to show the approximate positions of the counter ions; in all but **VI** they are *trans* to hydroxyl and (according to current theory) block their attached, but perhaps not their vicinal, positions from direct attack by outside reagents. Since the vicinal hydroxyl is a very effective block on the other side, the chemistry of oxide-related ion-pairs may actually be much simpler than those of more conventional ions, in spite of the following additional complexities. The number of ions is almost doubled because of the two possible counter-ions, and nearly doubled again on account of the stereochemistry about oxygen (33). According to the general theory, any of the 54 ionic species of Fig. 1 may lie either in a linear sequence of reactions, in a side-branch, or in loops; any of the species may be a true intermediate, a transition state, or simply an approximation to an ordinary point on the reaction profile, and which of these it is may vary with the environment. For example, the scission of **VI***c* to form **8***a* might proceed either through a route in which **IV***a* is a true intermediate, or by the process labelled k_2 in Fig. 1(*a*), in which **IV***a* might represent fairly well a transition state with some charge separation, that is, the 'borderline S_N2' favored in the past by most authors (32, 34). Only experiment can distinguish among the possibilities. Obviously, even when the experiments are brilliantly designed and executed, as by Shiner and co-workers (35), the rate constants (23 in the model (35) on which Wylde (31) based his mechanisms) will be hopelessly underdetermined, and the results will have to be interpreted with a long series of assumptions, a general procedure obviously subject to astronomically large errors (35, 36).

Fortunately, large simplifications are possible. In the first place, there is no need to consider other ionic species, such as those with 'free' hydroxyl groups (more open than **I** and **V**). This is shown by the strong configuration-holding effect of hydroxyl (1, 8, 11, 37, and present work). Confirmation is afforded (*a*) by the relative rates of solvolysis reported here for **7***a* and **8***a*, the inhibition of the rate caused by neighboring methoxyl being much less than that observed

[9]Some holders of the view that hydroxyl does not participate have been driven to the clearly wrong conclusion that the solvent acts by altering the inductive effect of hydroxyl (cf. methoxyl). Better versions of this view can be constructed, and operational distinctions between these versions and Scheme 1 can again be had in the contrast between methoxyl and hydroxyl as neighbors. Whereas methoxyl binds tightly enough to the reaction centre to enforce retention of configuration, during solvolysis (1, 2), it seems to have no rate-enhancing effect (5, 6) and, in secondary systems, it does not wander (7). Hydroxyl, besides possessing the same steric control and a modest rate-enhancing effect, clearly wanders with ease, passing through a symmetrical structure, which whether a true intermediate or not, clearly has hydroxyl covalently bonded to both reactive centres.

[10]Titration experiments, showing how easily **7***a* was converted to **5**, via **14**, by base, made it imperative to show that the base used in the isolation of the products had no appreciable effect on the results. This was done in two ways. The more reactive tosylate (**7***a*) was recovered unchanged when subjected to the process of isolation. The results obtained were unaffected either by the use of a weaker base or by subjecting the isolated product of an interrupted solvolysis to further reaction. Further formation of **9***a* and **10***a* during isolation was in any case impossible, since the half-life of **5** under more severe conditions of base catalysis is known to be about 30 h (27).

[11]Reference expressing a cautionary or contradictory opinion.

by Roberts *et al.* (8) in the absence of hydroxyl; (*b*) by the rate-enhancing effects observed for neighboring hydroxyl by Roberts (1); and (*c*) by the agreement of product distributions from **7***a* and **8***a* with that formerly seen for the epoxide **5** (28). Unlike the situation in the phenonium ion series (26*b*), the solvent in this system is unable to compete with the neighbor group for initial possession of the reactive centre. Finally, the fact that if ions with 'free' hydroxyl did exist, their only fate was collapse to more bonded systems, was shown by the failure of a careful search for reaction products typical of the 'free-hydroxyl' structures (i.e. from attack by solvent or by neighboring methoxyl). This search was conducted through proton magnetic resonance spectroscopy of both crude and acetylated reaction products, and by the more sensitive method of gas–liquid chromatography, the latter supported[1a] by the previous study of the retention times of a large number of related compounds (38).

A second simplification results from the clear requirement (Table 1) that there must be at least one common intermediate in the solvolyses of **7***a* and **8***a*. Intervention of any of the 34 ions **II**, **III**, **IV**, or **VI** as intermediate would be the equivalent of Scheme 1, and the only remaining alternative to Scheme 1 is that **I** and **V** exist as pairs of intermediates, with the more symmetrical systems **II**, **III**, **IV**, and **VI** existing at most as mere transition states. This alternative can only be held with the further postulate that **I** and **V** must be in rapid equilibrium with each other, in order to explain the fact that **7***a* and **8***a* give essentially the same product mixture. At first sight, therefore, the alternatives of Scheme 1 or of the rapidly interchanging pairs **I** and **V** would seem to involve the same difficulty as that in the controversy over nonclassical ions (26, 30).[12] However, in all probability, the corresponding ion (**6**) is both stable and easily reached. The results of Table 1 show that solvolysis of the epoxide **5** must involve intermediates which, except possibly for the counter-ion, are the same[13] as those involved in the solvolysis of the tosylates. The non-classical ion of hydroxyl-assisted solvolysis (e.g. **6**) is therefore merely the conjugate acid of a well-known and stable compound (e.g. **5**); furthermore there is some physical evidence (33, 42) for the existence of stable cyclic oxonium ions. There are excellent reasons (22, 28, 32) for the almost universal acceptance (34) of the cyclic protonated epoxide as an intermediate in epoxide scissions. Even those (43; see also 31) who look upon analogues of **I** and **V** as reactive intermediates postulate analogues of **6** as the structures for the protonated epoxides present in considerable amounts in their solutions.

While Scheme 1 is thus undoubtedly the main mechanism of solvolysis of the tosylates, intermediates such as **I** and **V** might still occur as small notches in the reaction profile. Partition at such intermediates might make them detectable. Indeed the results of Table 1 suggest that an intermediate resembling **I** may be a reality, since relatively more **9***a* is formed from **7***a* than from **5** or from **8***a*. According to the very careful standardization of the analytical method (29) in the previous work,[1a] the difference in product ratios (Table 1) is significant. Two constant errors, nearly always ignored in previous work, fortunately proved to be small in the present system. The first error, due to a possible side reaction, was estimated as mentioned previously,[5,14] while the second error (due to differential survival of the products under sol-

$$\text{Tosylate} \begin{cases} \xrightarrow{k_1} \mathbf{9}a \xrightarrow{k_3} \text{Further products} & k = k_1 + k_2 \\ \xrightarrow{k_2} \mathbf{10}a \xrightarrow{k_4} \text{Further products} & \Delta k = k_3 - k_4 \end{cases}$$

SCHEME 2

[12]Serious difficulties arise in the alternative hypothesis. Two of these will be clear to the reader from the initial considerations given already (see footnotes 6 and 9). A third stems from the hypothesis, not necessarily true (21, but see 39) though deeply embedded in recent interpretations of ion-pair theory (35*a*, 40; however, see 35*b*), that substrate (e.g. **7***a*) and intermediate (e.g. **I***a*) are in rapid pre-equilibrium. With the further requirement (in the alternative mechanism) that **I** and **V** are also approximately in equilibrium, **7***a* and **8***a* should interconvert, but they do not. Obviously, the easiest and most convincing escape from this dilemma lies in postulating the existence of a third intermediate, **6**.

[13]The agreement in product ratios between epoxide and tosylates (Table 1) cannot be a coincidence. Whether **9***a* and **10***a* are formed from a rapidly equilibrating pair such as **I** and **V**, or by direct attacks upon a protonated epoxide (e.g. **6**), the product ratios will be governed by Curtin–Hammett theory (28, 41). Diagrams will quickly show that both conformational and polar effects would result in much less **10***a* being formed from **I** and **V** than directly from **6**, and that it is impossible to escape the conclusion that oxide and tosylate must solvolyze in the same way.

volysis conditions) was determined by calculations based on the approximate mechanism shown in Scheme 2.[14] It was easily shown that the methods used previously for the purpose lacked the necessary accuracy. Neither correction had any important effect upon the results of Table 1.[14] Theory would also lead one to expect that structure **I** would be more important than structure **V** (Fig. 1). The polar effect of neighboring methoxyl is unfavorable to **V**, and the conformational effects favorable to **I**, each in comparison with routes involving pure S_N2. Nevertheless, in view of the difficulty of the experiments, it seems safer to say that while there may be some evidence for partition at an intermediate resembling **I**, at least three-fourths of **7***a* must solvolyze by Scheme 1. The proportions for **5** and for **8***a* must be even larger. These estimates are satisfactory for certain further applications of Curtin–Hammett theory.

The work was made possible by a new synthesis devised for **8***a* and **10***a*. Formerly **10***a* had been obtained (22) in very low yields after a difficult separation, from the direct methanolysis of **5**. In the new route, treatment of the stereoisomeric epoxide **15** with benzyl alcohol gave as the only product compound **16***a*, which was easily converted either to its tosylate **16***b* or its methyl ether **16***c*. Catalytic hydrogenation of **16***b* gave **8***a*, the benzyl group being removed in preference to the somewhat sensitive tosyl group (23). Hydrolysis of **16***c* with concentrated hydrochloric acid gave a good overall yield of **10***a*.

Experimental

Infrared spectra were recorded on a Perkin-Elmer model 180 grating spectrometer. Proton magnetic resonance spectra (nmr) were determined on a calibrated Brüker HFX 60 spectrometer or on a Varian T 60 spectrometer; some were repeated at the Canadian 220 MHz Centre. The apparent chemical shifts are reported in parts per million downfield from an internal TMS standard for solutions in chloroform-*d* and the apparent coupling patterns and constants (Hz) are taken directly from the spectra. Elemental analyses were performed by Alfred Bernhardt Microanalytisches Laboratorium, Bonn, liquid samples being homogeneous to glc. Analyses by glc were carried out with a Jarrell Ash Model 700 analytical gas chromatograph fitted with a strontium-90 detector and a recorder fitted with a mechanical integrator. The column, aluminum tubing of 6.35 mm outside diameter and length 366 cm, was packed for half its length with 4% diethylene glycol sebacate, and for the other half with 4% silicone fluid QF 1, both on Chromosorb G (70–80 mesh, acid washed, and treated with DMCS (Chromatographic Specialties, Brockville, Ontario). Melting points marked (p) are corrected (44); others were determined on a Koffler hotstage. *Trans*- and *cis*-3-methoxycyclohexene oxides (**5** and **15**) (22, 23) were shown by glc to be at least 99.5% pure.

*(±)-(1RS,2RS,3RS)-1-O-Benzyl-3-O-methyl-1,2,3-cyclohexanetriol (**16***a*)

Sodium (0.55 g) was dissolved in benzyl alcohol (6 ml) and the mixture was added to a solution of *cis*-3-methoxycyclohexene oxide (**15**) (5.15 g) in benzyl alcohol (40 ml, previously fractionated), heated on a steam bath for 70 h, and then neutralized with acetic acid. Most of the benzyl alcohol was then distilled away (0.04 Torr) through a micro-fractionating column. The organic product was separated from the residue by solution in ether, the ether was removed, and the oil distilled in a Späth apparatus. The fraction distilling at 58–115°C (bath temperature) and 0.004 Torr, yield 7.81 g, slowly crystallized on standing. One washing with light petroleum (bp 30–60°C) and one recrystallization from this solvent yielded 5.72 g of crystals (61%); mp 51.6–52.5°C (p). Five more recrystallizations gave the analytical sample; mp 53.4–53.6°C (p). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 71.15, 71.21, H 8.82, 8.85.

The *p-nitrobenzoate*, after one recrystallization from ethanol, had mp 81.8–82.2°C (p); nmr (T-60): 8.22 (aromatic, 4H), 7.24 (aromatic, 5H, narrow), 5.34 (geminal to nitrobenzoxyl, 1H, dd, *J*, 2.7 and 6.6), 4.60 (benzyl methylene, 2H, sharp), 3.80 (2H, overlapped), 3.34 (methyl). *Anal.* calcd. for $C_{21}H_{23}O_6N$: C 65.44, H 6.02, N 3.63; found: C 65.28, 65.34, H 6.01, 5.97, N 3.64, 3.72.

*(±)-(1RS,2RS,3RS)-1-O-Benzyl-2,3-di-O-methyl-1,2,3-cyclohexanetriol (**16***c*)

The general method is that of Diner *et al.* (45). The benzyl methyl ether (**16***a*) (2.86 g, made as just above) was dissolved in dry 1,2-dimethoxyethane (7.06 ml) together with methyl iodide (2.00 g). While the mixture was magnetically stirred, sodium hydride (0.376 g) was added in 5 equal portions during 30 min. Another portion (0.3 ml) of methyl iodide was added, the stirring was continued for 2.5 h, and the volume was then reduced to one-third by distillation. Dry ether (10 ml) was added to the residue, and the insoluble salts were washed with more ether. Evaporation of the dried ether filtrates gave a light yellow oil which after redistillation in the Späth apparatus was colorless, b.p. 96–97°C, bath temperature at 0.005 Torr; yield 2.56 g (85%). Comparison by nmr with starting material showed the disappearance of hydroxyl, and the appearance of a second methoxyl at 3.46 ppm. *Anal.*

[14]From the product-survival experiments, Δk was found to be 0.00023 h^{-1}. Calculations based on Scheme 2 showed that correction for product losses required only very small changes in the relative peak areas of Table 1 (to 3.2 from **7***a*, and to 3.8 from **8***a*). These experiments also showed that **9***a* and **10***a* were not equilibrated during the solvolysis. Further correction to remove the effects of intervention of routes involving internal **7***a* $\rightleftharpoons$ **8***a* (see footnote 5) was shown to require the value from **8***a* to move from that from **7***a* by an amount proportional to their difference. For example, the difference given in Table 1 implies that the corrected value for **8***a* should be moved upward by an amount not greater than 0.1, i.e. at the most from 3.8 to 3.9.

calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.94, 71.87, H 8.85, 8.86.

*(±)-(1RS,2SR,3RS)-1,2-Di-O-methyl-1,2,3-cyclohexanetriol (**10a**) (22), and Derivatives*

The benzyl dimethyl ether (**16c**) (2.91 g, made as just above) was stirred 1.5 h with concentrated hydrochloric acid (34 ml) at 95°C. The mixture was neutralized with sodium bicarbonate and then repeatedly extracted with ether (10 × 30 ml). Careful fractionation of the oil recovered from the dried ethereal solution yielded 0.953 g (51%) of a colorless oily product (b.p. 72–106°C, bath temperature at 14 Torr in the Späth apparatus). Analysis by glc showed the absence of starting material and the presence of an unknown impurity (0.2–0.4%); nmr (T-60): 3.81 (overlapped, 2H, b), 3.38 (methyl), 3.46 (methyl), 2.97 (geminal to 2-methoxyl, 1H, dd, *J*, 2.8, 9.1), 2.92 (hydroxyl, 1H, exchanged with D_2O). *Anal.* calcd. for $C_8H_{16}O_3$: C 59.96, H 10.07; found: C 59.82, 59.88, H 9.91, 9.96.

Unlike its isomers, the *p-nitrobenzoate* of **10***a* formed with difficulty. The alcohol (0.160 g) and *p*-nitrobenzoyl chloride (0.1865 g) were heated on the steam bath for 3 h with dry pyridine (0.8 ml). Water (0.25 ml) and a little potassium carbonate were added, and the complete solution subjected to Späth distillation. A solid subliming at 90°C bath temperature (20 Torr) was discarded, and a colorless oil, 0.053 g, was collected, b.p. 175°C at 0.6 Torr; nmr (T-60): 8.29 (aromatic, 4H, narrow), 5.44 (geminal to *p*-nitrobenzoxyl, 1H, m), 3.74 (overlapped, 2H), 3.53 (methyl), 3.46 (methyl). Two recrystallizations of the oil from aqueous ethanol gave crystals, 18 mg, mp 70.0–70.8°C (p) (lit. (22) 71.2–71.8°C).

The *acetate* (**10***b*) was obtained as a pure oil (glc), bp 77.5–78°C, bath temperature at 15 Torr, after two careful fractionations in the Späth apparatus; nmr (220 MHz): 5.13 (geminal to acetoxyl, 1H, dt, *J* 4.05 and 7.35), 3.33 (geminal to 2-methoxyl, 1H, dd, *J* 2.90 and 7.25), 3.62 (geminal to 1-methoxyl, 1H, m), 3.37 and 3.45 (methoxyls), 2.05 (acetate methyl). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.39, H, 8.97; found: C 59.24, 59.40, H 8.85, 8.85.

*(±)-(1RS,2RS,3RS)-1-O-Benzyl-3-O-methyl-2-O-p-toluenesulfonyl-1,2,3-cyclohexanetriol (**16b**)*

Crude crystalline benzyl methyl ether **16***a* (6.35 g, made as above from the *cis*-oxide) was warmed 1 h on the steam bath with dry pyridine (15 ml) and *p*-toluenesulfonyl chloride (6.3 g). When this mixture was poured into water, an oil separated which crystallized when stirred. After being recovered, washed with water, extracted with light petroleum (bp 60–110°C) and then recrystallized from this solvent, the product was obtained in a yield of 5.8 g (36%). Its mp (88–92°C) was raised to 91–92°C by two further recrystallizations; nmr (Brüker): 7.50 (aromatic, 4H, A_2B_2), 7.25 (aromatic, 5H, narrow), 4.56 (geminal to tosyloxyl, 1H, dd, *J* 2.6 and 7.2), 4.46 (benzyl methylene, 2H, narrow), 3.75 (2H, hump), 3.20 (methoxyl), 2.38 (aromatic methyl). *Anal.* calcd. for $C_{21}H_{26}O_5S$: C 64.59, H 6.71; found: C 64.68, H 6.84.

*(±)-(1RS,2SR,3RS)-1-O-Methyl-2-O-p-toluenesulfonyl-1,2,3-cyclohexanetriol (**8a**) (the '2-Tosylate')*

The benzyl ether (**16***b*) (2.90 g, mp 91–92°C, prepared as above) was shaken with absolute ethanol (200 ml) and palladized charcoal (0.13 g, 10%) for 28 h under a hydrogen pressure of 70 psi. The crude product (2.49 g) gave 2.11 g (95%) of feathery needles, mp 88.5–89°C, after two recrystallizations from ethanol – light petroleum (1:1); nmr (Brüker): 7.43 (aromatic, 4H, A_2B_2), 4.37 (geminal to tosyloxyl, 1H, dd, *J* 8.8 and 2.8), 3.98 (geminal to methoxyl, 1H, m), 3.65 (geminal to hydroxyl, 1H, hump), 3.20 (methoxyl), 2.43 (aromatic methyl). *Anal.* calcd. for $C_{14}H_{20}O_5S$: C 55.98, H 6.71; found: C 56.04, H 6.75.

The *acetate* (**8***b*) was obtained in 92% yield as colorless, feathery needles, mp 86.5–88°C. One recrystallization from light petroleum gave the analytical sample, whose mp (88.5–89.5°C) was similar to that of its isomer (**7***b*) (23). The nmr (Brüker) was distinctive: 7.57 (aromatic, 4H, A_2B_2), 5.1 (geminal to acetoxyl, 1H, broad m), 4.56 (geminal to tosyloxyl, 1H, dd, *J* 9.0 and 2.8), 3.92 (geminal to methoxyl, 1H, b m), 3.29 (methoxyl), 2.45 (aromatic methyl), 1.82 (acetate methyl). *Anal.* calcd. for $C_{16}H_{22}O_6S$: C 56.12, H 6.48; found: C 56.08, H 6.57.

*1,3-Di-O-methyl-r-1,t-2,c-3-cyclohexanetriol (**9a**) and its Acetate (**9b**)*

The alcohol (**9***a*) (22, 23, 27), available in the pure state (glc) from previous work, was recognizable in the nmr chiefly by its very sharp single methoxyl peak, appearing in spectra of the pure compound at 3.39 (T-60) or 3.40 (cal. A-60), but in spectra of synthetic mixtures with its isomer (**10***a*) overlapping the downfield methoxyl of the latter. Also characteristic were single small peaks on either side of the methoxyl peak, representing the outlying members of the triplet due to hydrogen geminal to hydroxyl. Its *acetate* (**9***b*), mp 68.5–68.9°C (p) (lit. (23) 65.5–66.5°C), pure to glc, had a much more distinctive spectrum (220 MHz): 4.85 (geminal to acetoxyl, 1H, t, *J* 9.35), 3.33 (methoxyls, 6H), 3.14 (geminal to methoxyl, 2H, m), 2.10 (acetate methyl). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.39, H 8.97; found: C 59.28, 59.40, H 8.67, 8.80.

*(±)-(1RS,2SR,3SR)-1-O-Methyl-3-O-p-toluenesulfonyl-1,2,3-cyclohexanetriol (**7a**) (the '1-Tosylate')*

This compound, made from the *trans*-oxide (**5**) as previously described (23), was obtained after two recrystallizations as colorless, poorly formed crystals, mp 129–130.5°C (lit. (23) 127.5–129°C); nmr (Brüker): 7.61 (aromatic, 4H, A_2B_2), 4.37 (geminal to tosyloxyl, 1H, unresolved m), 3.48 (geminal to hydroxyl, 1H, t, *J* 9.0), 3.40 (methoxyl), 3.0 (geminal to methoxyl, 1H, hump), 2.85 (hydroxyl, 1H, sharp), 2.44 (aromatic methyl). The *acetate* (**7***b*) of this tosylate, made as previously described (23), showed in particular a characteristic triplet at 5.10 ($J = 9$).

Solvolysis Experiments

Each solvolysis was carried out in a flask equipped with reflux condenser and drying tube, and heated under reflux, with stirring, in an oil bath. In particular, the five experiments reported in Table 1 were performed together under exactly the same conditions, using reagents from the same sources.

*Methanolysis of the trans-Oxide (**5**)*

The oxide (0.128 g) was dissolved in dry methanol (10.0 ml) and heated to reflux. In another flask, 0.1 *M* methanolic perchloric acid (made by dilution of 72% perchloric acid with dry methanol, thus introducing a trace of water) (5.00 ml) and methanol (15.0 ml) were heated to reflux, the hot oxide solution rapidly added, and the combined solutions heated an additional 5 min

under reflux. Most of the solvent was removed by rotary evaporation at room temperature, and then ethyl ether (15.0 ml) and an excess of sodium carbonate were added. The mixture was filtered, the solid washed with ether, and the combined ether extracts were evaporated to yield a pale yellow oil (0.243 g), the analysis of which is described later.

Methanolysis of the Tosylates (7a and 8a)

Procedure (a)—The tosylate (0.20 g) was dissolved in reagent methanol (25.0 ml) and 0.1 *M* methanolic perchloric acid (5.00 ml) was added. The mixture was heated for the prescribed time (Table 2), and the crude solvolysis product isolated as described for the product from the oxide, but usually with further purification (i.e. separation from small amounts of polymers) by extraction into light petroleum. Results are given in Table 2.

Procedure (b)—The tosylate (0.10 g) was treated with 0.1 *M* methanolic perchloric acid (amounts in Table 2), the volume made up to 15.0 ml with dry methanol, and the mixture was heated for the times shown in Table 2. After being cooled, the mixture was treated with sodium acetate in amounts equivalent to the *added* acid (0.050–0.25 mmol), the volume was reduced to about 1 ml by rotary evaporation under reduced pressure, the residue was treated with sodium carbonate (0.05 or 0.25 mmol), the rest of the solvent removed, and the residue extracted with light petroleum. Evaporation of the extract gave the pale yellow solvolysis product in yields given in Table 2.

Nuclear Magnetic Resonance Spectra of the Crude Solvolysis Products

The spectra from the reaction products of **7***a* were, except in the proportions of the contributors, all remarkably alike, and could be regarded as due to mixtures of the 1,3-dimethyl ether (**9***a*) and the unreacted '1-tosylate' (**7***a*), the latter distinguished by its aryl, aryl methyl, and methoxyl peaks, the last 0.05 ppm upfield from that of **9***a*. A total absence of signals near 3.78 showed that even moderate amounts of other likely compounds (rearranged reactant or product or diols from hydrolysis) could not be present, as their signals from H geminal to hydroxyl were absent. A more sensitive test for the absence of the rearranged tosylate (**8***a*) lay in the absence of its methoxyl signal in a clear region of the spectrum, so that as little as 2–3% would have been seen. The signal envelope from the methylene ring protons had the shape characteristic of 1,2,3-tri-equatorially substituted cyclohexanes. Not all impurities would have been as apparent as the rearranged tosylate; for example no certain sign of the 1,2-dimethyl ether (**10***a*), known to be present to the extent of about 5% (see glc results), could be detected. In synthetic mixtures of **10***a* with **9***a*, one of the methoxyl signals of **10***a* was resolved from that of its neighbor, but at much less than one-third the apparent area at equal concentrations. P/R ratios (see Table 2) were usually calculated by comparing the area of the aryl methyl signal with that from the 'methoxyl' region, the error being larger than that for **8***a*.

The spectra of the solvolyses products from **8***a* (runs *viii–x*, Table 2) were extremely similar to each other, and to that of a synthetic mixture containing '1-tosylate' (**7***a*) (3 mg), '2-tosylate' (**8***a*) (30 mg), and the 1,3-dimethyl ether (**9***a*) (6.5 mg). In the spectrum of the synthetic mixture *no trace of signal due to the 1-tosylate could be discerned*, showing the need for the separation described below. However, because the methoxyl peak of the '2-tosylate' (**8***a*) was well separated from those of the ethers **7***a* and **9***a*, it *was* possible to say that the lack of a second methoxyl peak from the ethers ruled out the presence of any considerable amounts of the direct product of solvolysis (**10***a*). This peak separation also allowed much more accurate determinations of the P/R ratios than for **7***a*.

Separation of Reactant and Product; Demonstration of Rearrangement in the Latter and Its Lack in the Former

The crude product from the methanolysis of the '2-tosylate' (**8***a*) from run *x* (Table 2) was dissolved in ethyl acetate (3 ml), and extracted twice with water (10 ml portions). The material from the organic layer was much enriched in the '2-tosylate', as shown by nmr, and two more similar extractions left in the organic layer a material whose nmr spectrum (compared to that of authentic **8***a*) showed it to be almost pure '2 tosylate', containing a trace of **9***a*. Comparison with a spectrum of **7***a*, and with a spectrum of a mixture of '2-tosylate' (30 mg) and '1-tosylate' (**7***a*) (3 mg), showed that as little as 2–3% of **7***a* would have been detectable in the spectrum of the extract, but none was seen.

The aqueous extracts were evaporated to small volume, taken up in ethyl acetate, dried over magnesium sulphate, and again evaporated to leave a residue (13 mg) whose nmr spectrum consisted mainly of a very large methoxyl signal shown to belong to **9***a* by comparison with the very small residual peaks of **8***a* that remained. This residue was heated at 110°C for 14 h with acetic anhydride (0.5 ml), the excess anhydride was destroyed with ethanol, and the solvents were removed. The residue (11 mg) showed in nmr the pattern decisive for **9***b* (23): absence of aromatic peaks; 4.85 (t, $J = 9.5$), 3.34 (methoxyl singlet), 2.04 (half the area of the methoxyl peak; acetate methyl, singlet). Fairly large shoulders on the methyl and methoxy peaks, as well as a small signal near the triplet, pointed to the presence of impurities. Distillation of the sample in the Späth apparatus (at 60°C *in vacuo*) gave a distillate (5 mg) which partly solidified. Its nmr spectrum showed that the feature near the triplet had been removed and the shoulders (due to unacetylated material **9***a*) much reduced, in comparison with the peaks due to **9***b*.

Solvolysis with No Added Acid; Rate by Titration

The '1-tosylate' (**7***a*) (0.201 g) was heated under reflux 95 h with dry methanol (30.0 ml). After being cooled, the solution was made up to 50.00 ml with methanol, and 10 ml aliquots were titrated with standard aqueous sodium hydroxide (0.01000 *N*, Fisher Scientific Certified). Equal amounts of bromthymol blue and phenol red were used as the mixed indicator (46), giving a sharp color change. The alkali consumptions (6.66 and 6.62 ml) in duplicates suggested the reaction had proceeded to 49.7% completion. (The titration procedure was checked by using *p*-toluenesulphonic acid as substrate.) However, the nmr spectrum of the product differed from those of runs *i–vi* (Table 2) in having a large water peak and in showing the presence of an impurity, likely *p*-toluenesulphonic acid, which made the regular procedure for determining P/R inapplicable. It was altered as follows. Quite satisfactory linear plots were obtained, from the other runs, for two different peak height ratios versus P/R; use of these gave

a P/R ratio for the present experiment of 0.7. The titrations had to be done with care; end-point colors faded quickly, and if pursued, the unknowns (or a test sample of pure reactant **7***a*) consumed, within a few minutes at room temperature, an amount of alkali equal to 100% reaction of **7***a* (showing its rapid conversion to **5**). This was the *only* result if bromthymol blue was used as the sole indicator, the color change then being insufficiently sharp.

Stability of the Reactant during Isolation

The '1-tosylate' (**7***a*) (76 mg) was dissolved in methanolic perchloric acid (2.5 ml of 0.1 *M* made up to 15.0 ml with methanol). The mixture was then worked up immediately according to procedure *a*, care being taken to make the conditions slightly more rigorous than those of the solvolysis. The product (76.5 mg), nearly all crystalline, showed in its nmr spectrum only peaks due to the reactant, except for extremely small peaks due to solvent impurities well downfield from the peak due to H geminal to tosyloxy in **7***a*.

Relative Stability of the Reaction Products towards the Conditions of Solvolysis

The nmr spectra were recorded for separate solutions of **9***a* (76.0 mg) and **10***a* (76.65 mg), each in $CDCl_3$ (1 ml). The two solutions were then mixed and made up to a total volume of 10 ml in chloroform; the resulting solution was accurately divided in two, and the solvent removed from each portion. One half was kept for reference; the other half of the mixture was treated with methanol (31.25 ml) and 0.100 *M* methanolic perchloric acid (6.25 ml of a solution made by adding 250 ml of methanol and 3.49 g of 72% aqueous perchloric acid). After the solution had been heated under reflux for 210 h, it was treated with an excess of solid sodium bicarbonate and then filtered. Solvent was removed on the rotary evaporator near room temperature, the residue was stirred with ether (50 ml) and magnesium sulfate, and the solid and solvent successively removed once more to yield a clear oil (67 mg, or 88%). (In a preliminary trial, using procedure *a*, the yield was 102%.) Infrared spectra of product and reference samples showed a band centered near 1713 cm^{-1} in both. In a preliminary trial, this band was considerably more intense for the product, but in the main experiment, using a different instrument, the reference sample gave the more intense band. In none of the spectra was there any band near 2700 cm^{-1} (aldehyde C—H stretch, to be expected from rearrangement products). The nmr spectra for $CDCl_3$ solutions of product and reference samples (taken with forward and backward scans, and with or without prior treatment of the solutions with D_2O) were alike, except for minor variations in the hydroxyl peak and in the degree of deuteration. Especially notable was the survival of the prominent quartet, upfield from the methoxyl signals, due to **10***a*, and of the outer parts of the triplet due to **9***a*, straddling the methoxyl signals. (In the preliminary, 200 h trial these bands were especially well resolved, and similar in product and reference). Methoxyl peak height ratios (5 trials each) were found to be 2.51 ± 0.03 for the product, and 2.53 ± 0.03 for the reference standard, in forward scans observed after treatment of the samples with D_2O. (It is noteworthy that this degree of accuracy is insufficient.) Each sample was then acetylated by the procedure described below, the reaction period being 4 h, and the excess acetic anhydride being removed with ethanol. The crude acetates so obtained (83 mg from the heated product, 92 mg from the reference standard) were then subjected to glc analysis, using the '4% DEGS' column and the instrument and conditions previously described (38), the analyses being performed in succession on the same day. The reference standard (5 trials) showed peak areas for **9***b*/**10***b* of 1.000:0.795 ± 0.002 and the reaction product (6 trials), 1.000:0.835 ± 0.002, respectively, the errors quoted being standard deviations of the means. The peaks due to **9***b* and **10***b* were identified by their retention times, 8.13 and 4.89 min, respectively, and also by successive additions of authentic **9***b* and **10***b*. The standard sample showed two small peaks, one at 9.95 min, 4% of the total integrated area, the other, smaller and broad, at approx 10.7 min, due to impurities in the original **9***a*; these persisted unchanged in position and relative area in the heated material, and likely represent diacetates, as suggested below. The glc of the heated sample showed two new peaks, one very small and broad, the other, 2% of the total integrated area (4 peaks) at 5.92 min. Successive injection of **9***a* and **10***a* showed that it was *not* due to unacetylated materials, so that the peaks identified as such in the solvolysis products (see below) probably also include a small proportion of this unknown by-product. The nmr spectra showed the expected three methoxyl and two acetate peaks, similar in product and reference standard.

Analyses by Gas–Liquid Chromatography of the Solvolysis Products

Lack of Interference by Tosylates

Trial acetylations of **7***a* and **8***a* under the conditions described below for the solvolysis products showed (nmr) no detectable products due to acetolysis; **7***a* was, however, incompletely acetylated. Heated at 180–200°C, compound **8***b* rapidly gave a blue-black tar. When the decomposition was followed at a lower temperature, no rearrangement products could be detected (nmr). A similar decomposition of **8***b* occurred at the injection port of the gas–liquid chromatograph, giving rise to small peaks reported below.

Acetylations of Samples prior to Analysis

The crude sample from solvolysis was heated overnight in an oil bath at 94°C with acetic anhydride (3 ml), the anhydride then being destroyed by the addition, and removal under reduced pressure, of successive portions (5 ml) of water, or in later runs, ethanol. Yield (from the solvolysis product of the oxide) 0.181 g or 90% based on the oxide **5**. Samples from the tosylates were treated in the same way, dark products being purified by re-extraction into light petroleum. Yields are given in Table 2. In one experiment (run *vi*, Table 2) the acetylated product from the solvolysis of **7***a* showed (nmr) the presence of **9***b* (the main product), **9***a*, and **7***a*; lines of **7***b*, if present, would have been hidden. Rearranged product **10***b* was possibly represented by one small peak on the side of a much larger acetate–methyl peak. An acetylated product from the solvolysis of the '2-tosylate' **8***a* (run *xi*, Table 2), gave a very well resolved spectrum (nmr) which showed, aside from aqueous acetic acid, the presence only of **8***b*, **9***a*, and **9***b*, the major product, thus confirming the lack of major side reactions already deduced from the spectra of unacetylated materials.

Gas–Liquid Chromatography

All analyses were performed under exactly the same conditions, an argon gas pressure of 40 psi and an oven temperature of 190°C being maintained. All five solvolysis samples were analyzed successively on the same day, and special care was taken to ensure that samples of the same size were taken for each injection, so that the highest peak on each chromatogram reached at least 80% of the maximum recorder reading. (Otherwise the nonlinearity of the detector had noticeable effects on the results for minor products.) Smaller peaks were read at 10× amplification. At least five injections were made for each sample. The principal results are given in Table 1, minor peaks being reported below. (In all cases, the peak due to **9***b* had at least 7 times the area of any other.)

The product from the trans-oxide (**5**) gave a peak due to the unacetylated alcohols (**9***a* and **10***a*), 8% of the total area, and two minor peaks, at 1.7 and 2.0 min, each less than 0.5% of the largest peak. The *product from the* '*1-tosylate*' **7***a* gave a peak due to **9***a* and **10***a*, 10% and 11% of the total area, and three small peaks, all less than 0.5% of the largest peak, at 1.6 min and at 6.0 and 8.4 min (diacetates). Preliminary trials were useful in showing that little or no bias was introduced by incomplete acetylation at the levels experienced. Successive acetylations of a sample gave products showing peak areas due to **9***a* of 15.0, 13.6, and 8% of the total, and area ratios 100 × (**10***b*)/(**9***b* + **10***b*) of 2.9, 3.0, and 3.3%, respectively. Much of this small bias appeared to be due to a slight tailing of the unacetylated material. The *product from the* '*2-tosylate*' **8***a* gave peaks due to unacetylated material, 3.2% of the total area in run *viii*, 7.4% in run *ix*. Two other peaks occurred at times characteristic of the decomposition of the '2-tosylate' or its acetate (**8***b*), that at 2.1 min amounting to 5.3% of the total in run *viii*, 7.4% in run *ix*, and that at 5.9 min, 3.5% in run *viii*, 11.3% in run *ix*. Two very small peaks, at 1.4 and 1.7 min, amounted to less than 0.5% of the largest peak in both runs.

Standard retention times were determined with purified samples under the conditions of the analyses: the acetate **9***b* of the 1,3-dimethyl ether, 4.7 min; its isomer **10***b*, 3.2 min; both unacetylated ethers (**9***a* and **10***a*), 2.6 min; from injection of the '2-tosylate' (**8***a*), 1.7 and 1.4 min (small peak); of its acetate (**8***b*), 2.1, 1.7 (small peak), and 5.9 min (trace). These times served not only for recognition of the peaks described in the analysis, but also by calibrating the times observed with those of the previous work[1a] (38) to eliminate from consideration the far wider range of possibilities previously studied.

Acknowledgements

The aid of the National Research Council of Canada, in financial support of the work, and in the grant of Scholarships to one of us (J.W.B.) is acknowledged. A special scholarship (to R.C.C.) from Queen's University is also acknowledged. We wish to thank Dr. A. Grey and the Canadian 220 MHz NMR Centre for obtaining the 220 MHz spectra mentioned.

Catalytic reduction of several *N*[2-diazo-3-oxo-4-(aryloxy)alkanoyl]glycine esters gives *N*-[2-hydrazono-3-oxo-4-(aryloxy)alkanoyl]glycine esters. A pyrazine is obtained by catalytic reduction in ethanolic hydrogen chloride of *N*-[2-diazo-3-oxo-4-(phenoxy)butanoyl]glycine ethyl ester. A two-step procedure involving reductive acetylation or trifluoroacetylation of the diazo function, and subsequent borohydride reduction of the keto group yields the corresponding acylamino alcohol derivatives.

JAMES H. LOOKER, JAMES W. CARPENTER et NORTON P. PEET. Can. J. Chem. **55**, 3786 (1977).

La réduction catalytique de plusieurs esters *N*-[diazo-2 oxo-3(aryloxy) alkanoyl-4] glycine conduit aux esters *N*-[hydrazono-2 oxo-3(aryloxy) alkanoyl-4] glycine. Une pyrazine est obtenue par réduction catalytique dans une solution éthanolique de chlorure d'hydrogène de l'ester éthylique *N*-[diazo-2 oxo-3(phénoxy) butanoyl-4] glycine. Une technique comportant deux étapes et impliquant une acétylation ou trifluoroacétylation par réduction de la fonction diazo et une réduction subséquente par le borohydrure du groupe carbonyle conduit aux amino-alcools acylés.

[Traduit par le journal]

Introduction

4-Phenoxyl derivatives of *N*-(2-diazo-3-oxobutanoyl)glycine esters are readily available from the interaction of *N*-(diazoacetyl)glycine ethyl ester (DGEE) with the appropriate acid chloride (1). Reduction under suitable conditions would lead to novel [γ-(aryloxy)threonyl]glycine derivatives. Previous studies of aroyldiazoacetic esters have shown that catalytic reduction over palladium–charcoal (2*a*) or platinum-on-carbon (2*b*, 2*c*) yields arylserines. Chemical reduction of aroyldiazoacetic esters gave nitrogen-free products. Because catalytic reduction procedures do not lead to threonylglycine derivatives (sequel), chemical reduction procedures were reexamined. Of particular interest were the observations of Albertson and co-workers (3*a*), who devised a procedure for the reductive acetylation of α-oximinoacetoacetic ester, of Regitz (3*b*), who effected the reductive acetylation of phenylbenzoylketazine, and of Pfister and co-workers (3*c*), whose synthesis of threonine utilized a reductive acetylation step.

In the present paper, we report both catalytic and chemical reduction studies of *N*-(2-diazo-3-oxoalkanoyl)glycine ester derivatives.

Results and Discussion

Catalytic reduction of aroyldiazoacetic esters is a useful route to arylserines (2). Its extension to previously described (1) 4-phenoxy derivatives of *N*-(2-diazo-3-oxobutanoyl)glycine esters has been investigated. Reduction at atmospheric pressure of esters **1**–**4** in aqueous acetic acid with 1.2 to 1.4 mol of hydrogen over 10% palladium-on-charcoal results in *N*-[2-hydrazono-3-oxo-4 (or 5)-(aryloxy)alkanoyl]glycine esters **5**, **7**, **8**, and **9** (eq. 1). In reduction of **1**, use of platinum-on-carbon, and a hydrogen pressure of 3 atm also gives **5**. Insolubility of product hydrazones accounts in part for their ready isolation. The resistant nature of the aliphatic carbonyl group in **1**–**4**, and **5**, **7**, **8**, and **9** towards reduction over palladium catalysts is not surprising (4). In our hands, platinum-on-carbon also is an ineffective catalyst for reduction of the carbonyl group in keto peptides. Data for catalytic reduction of **1** and **3** are given in Table 1.

In ethanolic hydrogen chloride, hydrogenation of **1** over palladium-on-charcoal leads to pyrazine **6**. Presumably **6** results from an intermediate 2-amino-3-oxo-alkanoylglycine ester (**10**) which undergoes dimeric condensation to a dihydropyrazine, which is oxidized to **6** (eq. 2). No reduction of **3** occurred over palladium-on-charcoal in ethanol in absence of added acid.

TABLE 1. Catalytic hydrogenation of *N*-[2-diazo-3-oxo-4-(aryloxy)butanoyl] glycine ethyl esters (**1**) (**3**)

Substrate	Solvent	Catalyst	Product (% yield)
1	70% HOAc	10% Pd/C[a]	Hydrazone (50.5)
1	Gl. HOAc	5% Pt/C[a]	Hydrazone (42.3)
1	EtOH–HCl	10% Pd/C[a]	Pyrazine (22.3)
1	Gl. HOAc	10% Pd/C[b]	Hydrazone (66)
1	80% HOAc	5% Pt/C[b]	Hydrazone (47.5)
3	EtOAc	5% Rh/C[b]	Hydrazone (28.5)[c]

[a]Atmospheric pressure, room temperature.
[b]Pressure 40 psig, room temperature.
[c]An 18% yield of an oil tentatively identified as *N*-[3-oxo-4-(*o*-methoxyphenoxy)butanoyl]glycine ethyl ester, from loss of nitrogen, also was isolated.

In previous studies (**5**, **6**) reduction of hydrazones to β-amino alcohols has been effected. An attempt to hydrogenate **5** in glacial acetic acid over palladium-on-charcoal at approximately 3 atm pressure gave no hydrogen uptake; 83% of **5** was recovered.

Catalytic reduction of α-diazo ketones of this study proceeds with addition of hydrogen to yield the hydrazone, or hydrogenolysis of a reduced diazo function of undetermined nature to give the amino ketone. The latter dimerizes even in strongly acidic medium.

An alternative to catalytic reduction involves a modification of reductive acetylation procedures cited (3). Diazo keto derivatives **3** and **11** from interaction of the appropriate acid chloride with DGEE can be purified without column chromatography. Reductive acetylation of **3** and **11** (eq. 3) yields [2-acetamido-3-oxo-4-(*o*-methoxyphenoxy)butanoyl]glycine ethyl ester (**12**) and the *p*-methoxy isomer (**13**) in 77% and 32% yields, respectively. Inasmuch as the trifluoroacetyl blocking group is useful in peptide synthesis, because of its ready removal in dilute base (7–9), treatment of **3** and **11** with zinc, trifluoroacetic acid, and trifluoroacetic anhydride has been carried out, and gives the trifluoroacetyl analogs **14** and **15** (eq. 4). Either the acetyl or the trifluoroacetyl blocking group is effective in preventing pyrazine formation.

In order to obtain the threonine or allothreonine amino alcohol unit, the *N*-acylamino ketones **12**, **14**, and **15** were reacted with sodium borohydride in methanol, in a procedure pre-

viously shown to effect reduction of a keto group without significant attack at an ester carbonyl function (10). The borohydride reduction product of **12** possessed a wide melting range, and could not be purified by crystallization. However, the [γ-(aryloxy)threonyl]glycine derivatives **16** and **17** were obtained (eq. 5) from **14** and **15** upon borohydride reduction in 71 and 40% yields, respectively. One stereoisomer, of unassigned configuration (*erythro* or *threo*), was isolated in each instance. Stereoselectivity for the reduction procedure was not in evidence, however.

Simultaneous removal of the *N*-trifluoroacetyl group and saponification of the carboethoxy function of **16** were attempted with alcoholic sodium hydroxide by the procedure of Schallenberg and Calvin (9). The infrared spectrum of the hygroscopic product did not possess ester and trifluoroacetamido carbonyl bands, but did have a band at 1660 cm^{-1}, tentatively attributed to the peptide amide carbonyl group. The product formed both hydrochloride and hydrobromide salts, also extremely hygroscopic.

Chemical reduction of **3** with zinc – acetic acid gives a low yield of 2,5-dimethyl-3,6-bis-carboethoxymethylcarbamoylpyrazine (**18**) (eq. 6). Formation of a pyrazine in acetic acid is not surprising. However, cleavage of the phenoxymethyl group during chemical reduction is noteworthy.

Experimental

All melting points are uncorrected, and were determined by the capillary tube method on a Mel-Temp apparatus. Elemental analyses were performed by A. Bernhardt, Mülheim, Germany, or by Micro-Tech Laboratories, Skokie, Illinois. Nuclear magnetic resonance spectra were recorded on a Varian A60 spectrometer with tetramethylsilane as internal standard. Infrared spectra were obtained with a Perkin-Elmer model 237 spectrophotometer. Mass spectra were recorded on a Hitachi RMU-6D spectrometer.

N-[2-Hydrazono-3-oxo-4-(phenoxy)butanoyl]glycine Ethyl Ester **5**

One gram of *N*-[2-diazo-3-oxo-4-(phenoxy)butanoyl]-glycine ethyl ester (**1**), prepared as previously described (1), was dissolved in 24.5 ml glacial acetic acid. Water (10.5 ml) and 50 mg of 10% palladium-on-charcoal were added, and hydrogenation carried out immediately. Hydrogen uptake was 101 ml over 47 min. A colorless precipitate appeared after 15 min and 23 ml of hydrogen uptake. The reduction mixture was filtered over Celite on a sintered glass funnel. The mixture of catalyst and insoluble organic material then was washed with methylene chloride until no organic solid remained in admixture with the catalyst. The filtrate was concentrated and cooled to give 0.51 g, (50.5%) of colorless crystalline **5**, mp 173.6–174.0°C; ir (CH_2Cl_2) 3460 (NH), 3310 (NH), 3150 (NH), 1750 (ester CO), 1678 (amide CO), 1642 (keto CO) cm^{-1}. *Anal.* calcd. for $C_{14}H_{17}N_3O_5$: C 54.72, H 5.58, N 13.68; found: C 54.79, H 5.62, N 13.54.

Hydrogenation of 0.54 g of **1** in 35 ml, of glacial acetic acid with 30 mg of 5% platinum-on-carbon resulted in uptake of 233 ml of hydrogen over 5.5 h. Catalyst removal by filtration, followed by solution of the total filtrate in methylene chloride, extraction of acetic acid with water (extract discarded), drying, and solvent removal gave a white residue. Crystallization of the latter from methylene chloride gave 0.23 g (42.3%) of **5**, mp 169–170°C.

N-[2-Hydrazono-3-oxo-4-(p-fluorophenoxy)butanoyl]glycine Ethyl Ester, 7

One gram of *N*-[2-diazo-3-oxo-4-(*p*-fluorophenoxy)butanoyl]glycine ethyl ester (**2**) in 35 ml of 70% acetic acid, with 50 mg of 10% palladium-on-charcoal, was hydrogenated with 111 ml of hydrogen over 53 min (room temperature, 1 atm). Product isolation was as described for **5**. Hydrazone **7** was removed from catalyst with methylene chloride and methanol. The extract was dried, concentrated, and cooled to yield 1.08 g of **7**, mp 183–184°C. Recrystallization from 60 ml of hot methanol gave colorless needles, yield 0.98 g (97%), mp 183–184.5°C; ir (KBr) 3395 (NH), 3360 (NH), 3160 (NH), 1740 (ester CO), 1680 (amide CO), 1650 (keto CO) cm^{-1}. *Anal.* calcd. for $C_{14}H_{16}N_3O_5F$: C 51.69, H 4.96, N 12.92, F 5.84; found: C 51.96, H 5.06, N 12.87, F 5.98.

N-[2-Hydrazono-3-oxo-4-(o-methoxyphenoxy)butanoyl]glycine Ethyl Ester, 8

One gram of *N*-[2-diazo-3-oxo-4-(*o*-methoxyphenoxy)-butanoyl]glycine ethyl ester (**3**) in 80 ml of 62% acetic acid, with 50 mg of 10% palladium-on-charcoal was hydrogenated with 102 ml of hydrogen (room temperature, 1 atm). The mixture was filtered and water added to the filtrate. The substance resulting was collected and dried *in vacuo*; yield 0.64 g (63.6%), mp 117–120°C. Recrystallization from ether – methylene chloride gave colorless needles of **8** (540 mg), mp 119.8–120°C; ir (CH_2Cl_2) 3465 (NH), 3320 (NH), 3155 (NH), 1747 (ester CO), 1677 (amide CO), 1645 (keto CO) cm^{-1}. *Anal.* calcd. for $C_{15}H_{19}N_3O_6$: C 53.40, H 5.68, N 12.46; found: C 53.30, H 5.73, N 12.30.

N-[2-Hydrazono-3-oxo-5-(o-methoxyphenoxy)pentanoyl]glycine Ethyl Ester, 9

N-[2-Diazo-3-oxo-5-(*o*-methoxyphenoxy)pentanoyl]-glycine ethyl ester (**4**) (160 mg) in 10 ml of 70% acetic acid with 10 mg of 10% palladium-on-charcoal was reacted with 14 ml of hydrogen over 18 min (room temperature, 1 atm). The mixture was filtered, and the mixture of catalyst and product washed with methylene chloride and methanol as for **7**. Filtrate was heated to effect complete solution, then cooled to yield 40 mg of **9** (24.8%), mp 143–144°C; ir (KBr) 3408 (NH), 3264 (NH), 3148 (NH), 1740 (ester CO), 1650 (amide CO), 1617 (keto CO?), 1600 (phenyl) cm^{-1}. *Anal.* calcd. for $C_{16}H_{21}N_3O_6$: C 54.69, H 6.02, N 11.96; found: C 54.52, H 5.95, N 12.00.

2,5-Bis-phenoxymethyl-3,6-bis-(carboethoxymethyl)carbamoylpyrazine, 6

N-[2-Diazo-3-oxo-4-(phenoxy)butanoyl]glycine ethyl

ester (650 mg) in 50 ml of absolute ethanol was added to 2.5 ml of 17% anhydrous hydrogen chloride in absolute ethanol. Hydrogenation over 200 mg of 10% palladium-on-charcoal (room temperature, 1 atm) gave 119 ml of hydrogen uptake (3 h). The reaction mixture was filtered, solvents removed by flash evaporation of the filtrate, and the colorless residue heated with 50 ml of ethyl acetate. A trace of insoluble material was removed by filtration and discarded. Filtrate concentration gave a light yellow oil (660 mg), which in methylene chloride solution was chromatographed on 65 g of silicic acid – Celite 545 (5:1 w/w). The column was eluted successively with 90 ml benzene, 235 ml of benzene – methylene chloride (1:1 v/v), 345 ml of benzene – methylene chloride (9:1 v/v), and methylene chloride – ethyl acetate (9:1 v/v). Removal of solvent from the latter eluate gave 131 mg of solid residue, recrystallized from ethyl ether – methylene chloride to give **6**, mp 133–136°C; ir (CH_2Cl_2) 3400 (NH), 1755 (ester CO), 1690 (amide CO), 1605 (phenyl) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.28 (t, 6H, CH_3 groups), 4.02–4.28 (m, 8H, carboethoxymethyl and ester CH_2 groups), 5.83 (s, 4H, phenoxymethyl CH_2 groups), 6.83–7.30 (m, 10H, aromatic), 7.93–8.23 (s, 2H, NH). *Anal.* calcd. for $C_{28}H_{30}N_4O_8$: C 61.08, H 5.49, N 10.18; found: C 60.79, H 5.59, N 10.18.

N-[2-Diazo-3-oxo-4-(p-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***11***

To 38.36 g of *N*-diazoacetylglycine ethyl ester (1, 11) in 500 ml of methylene chloride was added a solution of 22.49 g of *p*-methoxyphenoxyacetyl chloride in 100 ml of methylene chloride over 35 min. The reaction mixture was stirred for 43 h, washed with 100 ml water, dried, and solvent volume reduced to 100 ml. Addition of 200 ml ethyl ether and cooling yielded colorless **11** which was collected and air-dried; yield 17.78 g (47.3%), mp 86–88°C; ir (CH_2Cl_2) 3310 (NH), 2140 (CN_2), 1745 (ester CO), 1675 (amide CO), 1625 (keto CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.30 (t, J = 7.2 Hz, 3, ester CH_3), 3.82 (s, 3, OCH_3), 4.18 (d, J = 5.5 Hz, 2, glycine CH_2), 4.27 (q, J = 7.2 Hz, 2, ester CH_2), 4.91 (s, 2, ether CH_2), 6.93 (s, 4H, aromatic), 8.78 (b m, 1, NH). *Anal.* calcd. for $C_{15}H_{17}N_3O_6$: C 53.73, H 5.11, N 12.53; found: C 53.58, H 4.94, N 12.68.

N-[2-Acetamido-3-oxo-4-(o-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***12***

N-[2-Diazo-3-oxo-4-(*o*-methoxyphenoxy)butanoyl]glycine ethyl ester (**3**) (5.00 g), prepared as previously described (1), was dissolved in acetic acid (52.5 ml) and acetic anhydride (17.5 ml) added. Zinc dust (3.75 g) was added over 30 min; when the temperature rose to 35°C, the reaction mixture was maintained at 30–35°C. The reaction mixture was stirred for an additional 10 min, and then 52.5 ml of water added over 60 min. The reaction mixture was stirred 18 h, filtered, and extracted with methylene chloride (50 ml, ×5). The extract was washed with 100 ml of water, dried, and solvent removed. Trituration of residual oil with petroleum ether (bp 30–60°C) yielded colorless **12**, mp 131–133°C, yield 4.21 g (77.2%); ir (CH_2Cl_2) 3390 (NH), 3340 (NH), 1740 (ester CO), 1650–1685 (b, amide and keto CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.21 (t, J = 7.2 Hz, 3, ester CH_3), 2.08 (s, 3, acetyl CH_3), 3.88 (s, 3, OCH_3), 4.01 (d, J = 5.5 Hz, 2, glycine CH_2), 4.15 (q, J = 7.2 Hz, 2, ester CH_2), 4.82 (s, 1, ether CH_2), 4.86 (s, 1, ether CH_2), 5.79 (d, J = 6.5 Hz, 1, amide CH), 6.95 (s, 4, aromatic), 7.17 (b d, J = ~5.5 Hz, 1, acetamido NH), 8.08 (b t, J = ~6.5 Hz, 1, peptide NH). *Anal.* calcd. for $C_{17}H_{22}N_2O_7$: C 55.73, H 6.05, N 7.65; found: C 55.67, H 5.98, N 7.75.

N-[2-Acetamido-3-oxo-4-(p-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***13***

The title compound was prepared in 31.9% yield from 1.87 g of **11** as described for **12**. The product **13** melted at 137.5–139°C; ir (CH_2Cl_2) 3410 (b, NH), 1745 (ester CO), 1685 (b, amide and keto CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.23 (t, J = 7.2 Hz, 3, ester CH_3), 2.15 (s, 3, $COCH_3$), 3.73 (s, 3, OCH_3), 3.96 (d, J = 5.5 Hz, 2, glycine CH_2), 4.14 (q, J = 7.2 Hz, 2, ester CH_2), 4.79 (s, 2, ether CH_2), 5.56 (d, J = 6.5 Hz, 1, amide CH), 6.82 (s, 4, aromatic), 7.09 (b d, J = ~6.5 Hz, 1, acetamido NH), 7.46 (t, J = 5.5 Hz, 1, peptide NH). *Anal.* calcd. for $C_{17}H_{22}N_2O_7$: C 55.73, H 6.05, N 7.65; found: C 56.01, H 6.09, N 7.66.

N-[2-Trifluoroacetamido-3-oxo-4-(o-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***14***

N-[2-Diazo-3-oxo-4-(*o*-methoxyphenoxy)butanoyl]glycine ethyl ester (**3**) (3.79 g) was added to a mixture of trifluoroacetic acid (18 ml) and trifluoroacetic anhydride (6 ml) which had been precooled to 0°C. Zinc dust (3.0 g) was added over 35 min, when the temperature rose to 26°C. Methylene chloride (200 ml) was added, then 20 ml water over 10 min. The reaction mixture was filtered, and the aqueous phase washed with methylene chloride (30 ml, ×4). The extracts were washed with 75 ml water, dried, and solvent removed. The residual solid was recrystallized twice from methylene chloride – petroleum ether (bp 30–60°C) to give 1.81 g (38.3%) of colorless **14**, mp 133.5–134.5°C; ir (CH_2Cl_2) 3350 (NH), 1740 (ester CO), and 1685–1650 (b, amide and keto CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.93 (t, J = 7.2 Hz, 3, ester CH_3), 3.93 (s, 3, OCH_3), 4.07 (d, J = 5.5 Hz 2, glycine CH_2), 4.17 (q, J = 7.2 Hz, 2, ester CH_2), 4.83 (s, 2, ether CH_2), 5.93 (d, J = 6.5 Hz, 1, amide CH), 7.02 (m, 4, aromatic), 7.86 (b d, J = ~6.5 Hz, 1, trifluoroacetamido NH), 8.30 (b, t, J = ~5.5, 1, peptide NH). *Anal.* calcd. for $C_{17}H_{19}F_3N_2O_7$: C 48.58, H 4.56, F 13.56, N 6.66; found: C 48.52, H 4.70, F 13.78, N 6.60.

N-[2-Trifluoroacetamido-3-oxo-4-(p-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***15***

The title compound was prepared in 53.4% yield from 3.45 g of **11** as described for **14**, and melted at 136–137°C; ir (CH_2Cl_2) 3370 (b, NH), 1745 (ester CO), 1720 (trifluoroacetamido CO), 1690 (b, peptide and keto CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.27 (t, J = 7.2 Hz, 3, ester CH_3), 3.78 (s, 3, OCH_3), 4.04 (d, J = 5.5 Hz, 3, glycine CH_2), 4.20 (q, J = 7.2 Hz, 2, ester CH_2), 4.78 (s, 1, ether CH_2), 4.81 (s, 1, ether CH_2), 5.68 (d, J = 6.5 Hz, 1, amide CH), 6.98 (s, 4, aromatic), 7.42 (b t, J = ~5.5, 1, peptide NH), 7.86 (b d, J = ~6.5 Hz, 1, trifluoroacetamido NH). *Anal.* calcd. for $C_{17}H_{19}F_3N_2O_7$: C 48.58, H 4.56, F 13.56, N 6.66; found: C 48.72, H 4.75, F 13.88, N 6.67.

N-[2-Trifluoroacetamido-3-hydroxy-4-(o-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***16***

N-[Trifluoroacetamido-3-oxo-4-(*o*-methoxyphenoxy)-butanoyl]glycine ethyl ester (**14**) (1.81 g) was dissolved in dry methanol (250 ml) and the solution cooled to 10°C. Sodium borohydride (0.091 g) was added, and the re-

sulting mixture stirred in an ice bath for 3.75 h. Water (250 ml) was added and the aqueous solution extracted with methylene chloride (50 ml, ×6). The extracts were dried, solvent removed, and viscous residual oil triturated with petroleum ether (bp 30–60°C) to give a white solid. Recrystallization of the latter from methylene chloride – petroleum ether (bp 30–60°C) gave **16**, mp 121–123°C, in 1.30 g yield (71.5%); ir (CH_2Cl_2) 3575 (free OH), 3385 (b, NH and H-bonded OH), 1730 (ester CO), 1685 (b, amide CO groups) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.22 (t, J = 7.2 Hz, 3, ester CH_3), 3.83 (s, 3, OCH_3), ca. 4.15 (m, 8, ester, glycine and ether CH_2 groups, CHOH), 4.87 (m, 1, amide CH), 6.89 (s, 4, aromatic), 7.70 (b t, J = ~5.5 Hz, 1, peptide NH), 8.08 (b d, J = ~8.0 Hz, trifluoroacetamido NH). *Anal.* calcd. for $C_{17}H_{21}F_3N_2O_7$: C 48.34, H 5.01, F 13.49, N 6.63; found: C 48.20, H 5.19, F 13.13, N 6.52.

N-[Trifluoroacetamido-3-hydroxy-4-(p-methoxyphenoxy)butanoyl]glycine Ethyl Ester, ***17***

The title compound was prepared in 40.0% yield from 1.05 g of **15**, as described for **16**, and melted at 126–128°C; ir (CH_2Cl_2) 3575 (free OH), 3385 (b, NH groups and H-bonded OH), 1735 (ester CO), 1685 (b, amide CO groups) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.22 (t, J = 7.2 Hz, 3, ester CH_3), 3.75 (s, 3, OCH_3), ca. 4.15 (m, 8, ester, glycine and ether CH_2 groups, CHOH), 4.86 (m, 1, amide CH), 6.81 (s, 4, aromatic), 7.47 (b t, J = ~5.5, 1, peptide NH), 8.04 (b d, J = ~8.0, 1, trifluoroacetamide NH). *Anal.* calcd. for $C_{17}H_{21}F_3N_2O_7$: C 48.34, H 5.01, F 13.49, N 6.63; found: C 48.35, H 4.92, F 13.21, N 6.62.

2,5-Dimethyl-3,6-bis-carboethoxymethylcarbamoylpyrazine, ***18***

N-[2-Diazo-3-oxo-4-(*o*-methoxyphenoxy)butanoyl]glycine ethyl ester (**3**) (1.60 g) was dissolved in 20 ml of acetic acid. Zinc dust (2.5 g) was added over 30 min with external cooling (temperature at 30–35°C). The mixture was stirred for an additional 20 min, then 20 ml of water added over 30 min. The mixture was stirred for 1.5 h, filtered, and the filtrate extracted with methylene chloride (40 ml ×3). The extracts were washed with 25 ml of 5% sodium bicarbonate, dried, and solvent removed. Trituration of residual oil with a small amount of ether gave a yellow solid, which was recrystallized from methylene chloride – petroleum ether (bp 30–60°C) to give **18** in 41 mg yield, mp 169–170.5°C; ir (CH_2Cl_2) 3410 (NH), 1740 (ester CO), 1675 (amide CO) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.33 (t, J = 7.2 Hz, 6, ester CH_3 groups), 2.97 (s, 6, pyrazine 2,5-methyl groups), 4.24 (d, J = 5.5 Hz, 4, carboethoxymethyl groups), 4.29 (q, J = 7.2 Hz, 4, ester CH_2 groups), 8.55 (b t, J = ~5.5 Hz, 2, NH); ms *m/e* calcd. for $C_{16}H_{22}N_4O_6$: 366; found: 366. *Anal.* calcd. for $C_{16}H_{22}N_4O_6$: C 52.45, H 6.05, N 15.29; found: C 52.33, H 6.24, N 15.18.

1,2-Dioxenes **2**, **7**, and **14** are obtained from the reactions of potassium superoxide with 1,2-bishalomethylarenes. Rearrangement products are also formed in competition with the cyclization reaction. The relative yields of dioxenes depend on the relative concentration of superoxide to substrate as well as reaction conditions. Mechanisms for the formation of the rearrangement products are proposed.

L. H. DAO, A. C. HOPKINSON, E. LEE-RUFF et J. RIGAUDY. Can. J. Chem. **55**, 3791 (1977).

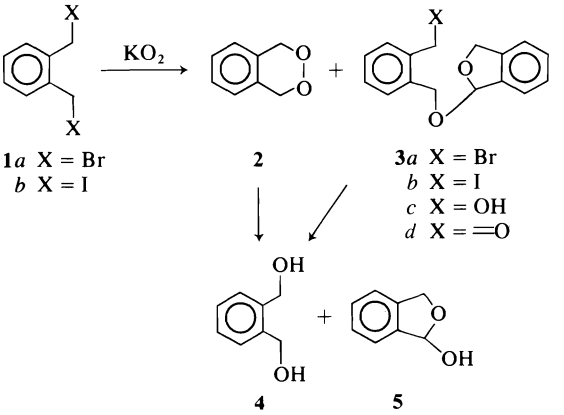
Les dioxènes-1,2 (**2**, **7** et **14**) sont obtenus par réaction du superoxyde de potassium avec les bis-halogénométhyl-1,2 arènes. Des produits de réarrangement sont aussi formés par une réaction compétitive avec celle de cyclisation. Les rendements relatifs en dioxène dépendent de la concentration relative du superoxyde aussi bien que des conditions de réaction. On propose des mécanismes pour la formation des produits de réarrangement.

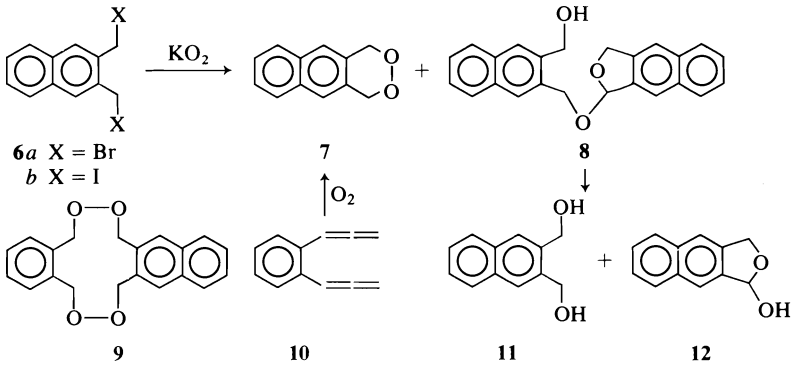
[Traduit par le journal]

During the past decade there has been good evidence for the production of superoxide ion (O_2^-) in the reduction of O_2 by several enzymes including some present in mitochondria and in the endoplasmic reticulum (1–3). This ion radical has been implicated to intervene in lipid peroxidation processes involving production of allylic hydroperoxides during the early stages of the reaction (2). It is not known whether O_2^- is directly involved or whether it acts as a precursor to other reactive species (e.g. singlet oxygen) in such processes. Non-enzymatic formation of alkyl and acyl peroxides and hydroperoxides using free superoxide with alkyl and acyl halides, and sulphonate esters have been reported (4–6). It was further shown that superoxide is a moderately active nucleophile in displacement reactions of alkyl and electrophilic aryl halides (6–9). With the idea of extending these reactions to include alkyl dihalides and the preparation of cyclic peroxides, we embarked on an investigation of the reactivity of a series of bishalomethylarenes with O_2^-. In this paper we wish to report the synthesis of the hitherto unknown *o*-xylylene peroxide (**2**) (a potential precursor to the theoretically interesting *o*-xylylene) and derivatives of **2** along with competitive rearrangements in the reactions of O_2^- with 1,2-bishalomethylarenes **1***a*, *b*.

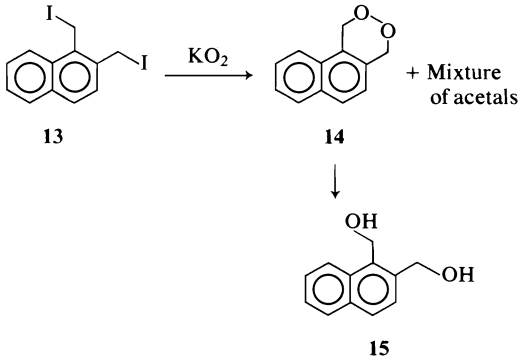
Results

The reactions of 1,2-bishalomethylbenzenes **1***a* and *b* with potassium superoxide (KO_2) complexed with dicyclohexyl crown-6 resulted in the formation of two products **2** and **3** with relative yields depending on relative concentration of KO_2 and substrate, nature of solvent, and reaction times. The yield of *o*-xylylene peroxide **2** was a maximum when the reaction was carried out in dimethylformamide (DMF) and stopped after 2–3 h using about a 2:1 equiv. ratio of KO_2 to substrate. Attempted isolation of **2** from solution led *inevitably to violent explosions*. The identity of **2** was inferred





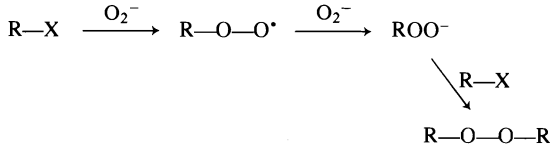
from the following observations: Purified **2** (in solution) gave a positive test for peroxide with I^-. Reduction of **2** with lithium aluminum hydride (LAH) gave the diol **4** (16) which was prepared independently by complete reduction of *o*-phthalaldehyde with LAH as well as hydrolysis of either **1***a* or *b* with hydroxide ion. The nmr spectrum of **2** exhibited two signals (δ 7.15(m), 5.12(s)) of equal intensities. Indirect evidence that **2** was not dimeric was gathered from the following experiment. Reaction of an equimolar mixture of dihalides **1** and **6** resulted in an equimolar mixture of peroxides **2** and **7**, in addition to acetals **3** and **8**. After separation of the more stable **7** from the mixture there was no evidence for the presence of the mixed peroxide **9** as seen by thin-layer chromatography and nmr spectrum of the mixture. The identity of acetals **3***a–c* was established by its acidic hydrolysis to a mixture of phthalanol **5** and diol **4** as well as by analysis of its spectral data (^1H, ^{13}C nmr, ir, and mass spectra). Acetals **3***c* and **3***d* appeared to be secondary products from subsequent oxidation of **3***a* and *b*. Reaction of dihalides **6***a* and *b* with crown ether complexed KO_2 resulted in similar products **7** (10–30%) and **8** (40–90%). The physical and spectral properties of **7** were identical to those reported for the product obtained from oxygenation of 1,2-bisallenylbenzene (**10**). The structure of acetal **8** was established by its hydrolysis to a mixture of **11** and **12** which were independently synthesized. The ^1H nmr spectra of derivatives **3**, **5**, **8**, and **12** all exhibited long range coupling between the methyne proton and one of the benzylic protons across the acetal bridge (J = 2 Hz). This phenomenon has been observed in other substituted naphthalans (10).



Extension of these reactions to dihalide **13** resulted in lower yields of the cyclic peroxide **14** (10–15%) along with an inseparable mixture of acetals inferred from the analysis of the spectral data and comparison with spectral data of acetals **3** and **8**. The structure of **14** was shown by analysis of its spectral data and reduction to the diol **15** as well as its positive test with I^- for peroxide.

Discussion

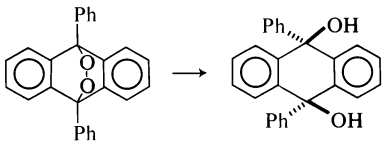
Formation of cyclic peroxides **2**, **7**, and **14** is presumed to follow a similar mechanism as in the case of acyclic peroxides, namely double nucleophilic substitution of O_2^- with the intervention of a peroxyl radical (4) (Scheme 1). Yields of peroxides were highly dependent on reaction times and relative concentration of O_2^-. It was found that peroxides **2** and **7**, when subjected to reaction conditions identical to those of their synthesis, underwent decomposition to a complex mixture over an extended period of time. On the other hand 9,10-diphenylanthracene-9,10-peroxide (**16**) was reduced by superoxide to diol **17**. Similar observations were made by San-Filippo and co-workers (12) in the reduction of diacyl peroxides to carboxylic acids in the presence of superoxide. These transformations may involve initial formation of an alkoxy



SCHEME 1

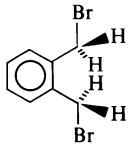
SCHEME 2

radical according to Scheme 2. Such radicals may undergo hydrogen abstraction or be further reduced by O_2^- yielding another equivalent of alkoxide. Precedent for such a mechanism was demonstrated by Peters and Foote (13) in the reduction of *tert*-butyl hydroperoxide to the *tert*-butoxyl radical.



16 **17**

Two mechanisms (Scheme 3) can be envisaged leading to cyclic acetals **3** and **8**: (*A*) *o*-xylylene peroxides **2** and **7** may be involved as intermediates to these acetals via hemiacetal anion **18** or (*B*) competitive formation of a dihaloperoxide **19** undergoing base-catalyzed disproportionation to **20** and **21** which upon recoupling generates the observed acetal **3**. Base-catalyzed rearrangements of cyclic peroxides possessing an α-hydrogen have been reported to generate hydroxycarbonyl products (14). However, it does not appear that mechanism *A* plays an important role in these transformations. The sodium salt of **18** was generated independently from phthalanol **12** and shown not to undergo nucleophilic substitution with **1** under identical conditions. Furthermore nucleophilic substitutions by alkoxide on **1** was found to be quite inefficient. The most stable conformation of **1** is likely to be such that both halogens occupy the *exo* positions as shown here.

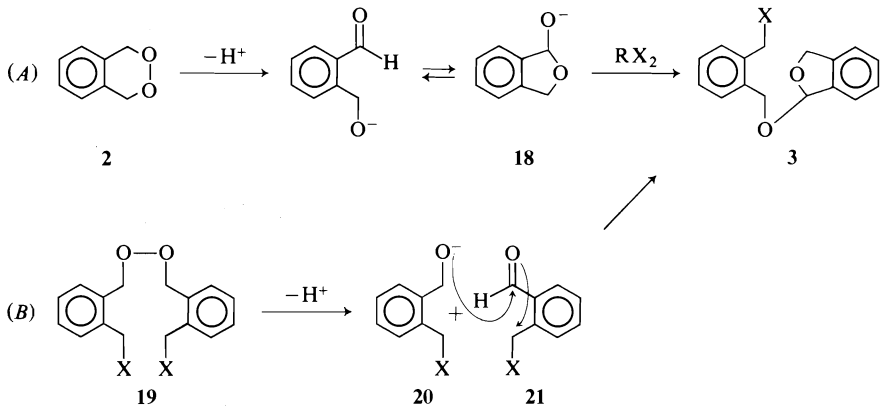


1

Thus bimolecular nucleophilic substitutions would require the nucleophile to approach the substrate from the more hindered *endo* side. On the other hand such steric constraints would not be as important for the linear and smaller O_2^- ion.

From our results it would appear that alicyclic peroxides can be obtained in moderate to good yields using superoxide. The advantage in using superoxide to hydroperoxy anion or peroxide is that O_2^- being a weaker base (22) will minimize competitive base-catalyzed reactions such as dehydrohalogenations and rearrangements of base sensitive peroxides.

We are extending these reactions to include 1,3- and 1,2-alkyl dihalides to explore the potential use of O_2^- in the synthesis of more strained peroxides such as dioxetanes. We are also exploring the nature of peroxides **2**, **7**, and **14** as potential sources of *o*-quinodimethanes. Derivatives of **2** have been obtained previously by oxygenation of the photoenols of *o*-toluylaldehyde and ketones (15).



2 **18** **3** **19** **20** **21**

SCHEME 3

Experimental

α,α-Xylylene dibromide was obtained from Aldrich Chemicals. 2,3- and 1,2-bisbromomethylnaphthalenes were obtained from bromination of 2,3- and 1,2-dimethyl naphthalenes according to the method of Wittig (20). The bisiodomethylarenes were prepared by reaction of the dibromides with sodium iodide in acetone and recrystallization of the resultant precipitate from chloroform. All of the diiodides gave correct analyses.

1,4-Dihydro-2,3-benzodioxin, 2

o-Xylene dibromide (2.64 g, 10 mmol) was added to a vigorously stirred mixture of powdered potassium superoxide (1.42 g, 20 mmol) in dry DMF (70 ml) at 25°C. The resulting mixture was allowed to stir for 2 h, then cautiously poured onto 100 ml ice-water, and extracted with three 50-ml portions of ether. The ethereal solution was washed with three 30-ml portions of ice-water and evaporated to dryness to give 1.05 g of a crude liquid which was purified by tlc (benzene as eluant); yield 0.60 g (44%); ir (neat) 2900, 1505, 1460, 1430, 1363, 1040, 1018, 977, 865 cm^{-1}; nmr (CCl_4) δ 5.12 (4H, s), 7.00–7.30 (4H, m); ms *m/e* 254 (M^+).[1] Positive iodine test. It was the only time we isolated **2** pure enough. Other attempts resulted in explosion or vigorous decomposition.

Reduction of 1,4-Dihydro-2,3-benzodioxin, 2

A solution of **2** in ether was added slowly to a stirred mixture of $LiAlH_4$ in ether at −50°C. The resulting mixture was stirred at −50°C for 30 min and 2 h at 25°C. A solution of 10% aqueous sodium hydroxide was added slowly until a clear solution had formed. The precipitate was filtered and washed with ether. The combined washings and filtrate were washed with water, dried over H_2SO_4, and concentrated to give an oily paste. Recrystallization of the product from benzene gave pure 1,2-bishydroxymethylbenzene, mp 65–66°C, which had ir and nmr spectra identical to those of authentic material prepared by reduction of phthalide with $LiAlH_4$ or hydrolysis of *o*-xylene dibromide **1***a* (16).

Phthalanyl Ethers 3

o-Bromomethylbenzenemethyl 1-Phthalanyl Ether, 3a

Potassium superoxide (250 mg, 3.52 mmol) in dry benzene (5 ml) or dry THF was carefully crushed with a glass rod. Dicyclohexyl-18-crown-6 (200 mg) and *o*-xylene dibromide (250 mg, 0.95 mmol) were added slowly. The resulting mixture was protected from moisture with a $CaCl_2$ drying tube and was stirred vigorously. Instant evolution of gas was observed and the reaction was followed by tlc. After 2 h at room temperature, the solid was filtered and washed with dry benzene. The filtrate was stripped to a pale yellow residue. The residue was applied to tlc and eluted with 1:1 v/v benzene–hexene. Starting material (153 mg) was isolated besides **3***c* and 61 mg (40%) of **3***a*; nmr ($CDCl_3$) δ 4.55 (s, 2H), 4.75 (s, 2H), 5.05–5.15 (2H, m, ABX), 6.30 (d, 1H), 7.10–7.40 (m, 8H); ir (neat) 3075, 1460, 1363, 1255, 1220, 1065, 1000, 905 cm^{-1}.

When the reaction was left for a longer period **3***a* was completely transformed to **3***c*.

o-Iodomethylbenzenemethyl 1-Phthalanyl Ether, 3b

The *o*-xylene diiodide **16** was converted to **3***b* and **3***c* as described above. **3***b* was purified by preparative tlc (benzene as eluant); nmr ($CDCl_3$) δ 4.62 (2H, s), 4.80 (2H, s), 5.15–5.30 (2H, ABX, m), 6.44 (1H, d), 9.25–7.55 (8H, m); ^{13}C nmr (ref. TMS) 140, 138, 137, 135 ppm (q. C's), 130–121 ppm (8 peaks, aromatic), 106 ppm (methine C), 73 ppm (methylene C), 66 ppm (methylene C), 4 ppm (methylene C).

o-Hydroxymethylbenzenemethyl 1-Phthalanyl Ether 3c

1*a* or **1***b* (10 mmol) was added to a stirred mixture of powdered potassium superoxide (1.42 g, 20 mmol) in dry DMF (70 ml) at 25°C.[2] After 15 h, the mixture was poured into 100 ml ice-water and worked up as for **2**. After purification by tlc, a pale yellow oil was obtained (0.768 g, 60%); nmr ($CDCl_3$) δ 4.85 (2H, s) 5.12 (2H, s), 5.10–5.20 (2H, ABX), 6.35 (1H, d), 7.20–7.50 (8H, m); ir (neat) 3500, 1616, 1460, 1365, 1257, 1075, 1000 cm^{-1}; ms (30 eV) 256 (M^+), 238 ($M - H_2O^+$), 135 (100%).

Hydrolysis of 3a, b, c

3*a*, *b*, *c* (2 mmol) were dissolved in 10 ml EtOH 95%. Concentrated H_2SO_4 (1 ml) was added and the mixture was refluxed for 1 h. The cooled solution was neutralized carefully with aqueous NaOH (20%), saturated with NaCl, and extracted with ether. The ethereal solution was dried over $MgSO_4$ and concentrated to an oil (the nmr spectra showed an equimolar mixture of **4** and **5**), which gave after separation by preparative tlc **4** and **5** (17).

5 was independently prepared by reduction of phthalide in toluene at −78°C under N_2 with diisopropyl aluminium hydride; nmr (CCl_4) δ 5.00–5.15 (2H, ABX) 6.15 (1H, d, J = 2 Hz), 7.15–7.40 (4H, m); ir (neat) 3480, 1465, 1365, 1100, 1075, 1000 cm^{-1}.

o-Formylbenzenemethyl 1-Phthalanyl Ether, 3d

1*a* (6.5 g, 24.6 mmol) was added to a stirred suspension of powdered potassium superoxide (3.0 g, 42.2 mmol) in dry DMSO (150 ml) at 25°C. After 2 h, the mixture was poured in ice-water and worked up in the usual way to give 2.0 g of yellow oil which was purified by preparative tlc ($CHCl_3$–benzene 80:20) to give 1.60 g of pure **3***d*; nmr (CCl_4) δ 5.00–5.25 (2H, m), 5.12 (2H, s), 6.28 (1H, d), 7.10–8.00 (8H, m), 10.10 (1H, s); ir (neat) 3490, 1770, 1700, 1600, 1480, 1367, 1287, 1220, 1050, 1000 cm^{-1}; ms (70 eV) 254 (M^+), 253 ($M - 1^+$).

3*d* (0.50 g, 1.96 mmol) was dissolved in 10 ml of 95% EtOH. H_2SO_4 (2 ml) was added and the mixture was refluxed for 1 h, cooled, neutralized with 20% NaOH, saturated with NaCl and extracted with ether. The ethereal solution was dried and concentrated to give exclusively pure **5**.

1,4-Dihydro-2,3-naphtho[2,3]dioxin, 7

To a suspension of potassium superoxide (220 mg, 3.1 mmol) in dry THF (10 ml) was added dicyclohexyl-16-crown-18 (150 mg) and diiodide **6***b* (614 mg, 1.5 mmol). The mixture was stirred for 3 h, filtered, and filtrate concentrated to a residue (300 mg) which gave by tlc 100 mg of **6***b*, 20 mg (7%) of **7**, mp 170–172°C (lit. (11) 166–167°C), which had nmr and uv spectra identical to those of

[1]The ms exhibited an identical fragmentation pattern as **3***d*. It was shown (see following) that **2** was thermally labile.

[2]If benzene or THF were used as solvent in presence of crown ether, the mixture was concentrated and directly purified by tlc to give **3***c*.

authentic material (11). A polar compound **8** was also isolated.

The dibromide **6***a* was converted to **7** and **8** in benzene and crown ether as described above.

*2-Hydroxymethylnaphthalene-3-methyl 2,3-Naphthalanyl Ether, **8***

The dibromide **6***a* (1.68 g, 5 mmol) was added to a stirred suspension of potassium superoxide (1.42 g, 20 mmol) in dry DMF (100 ml). After 20 h, the mixture was worked up with ether to give after purification by tlc pure **8** (200 mg, 25%), mp 135–136°C; nmr ($CDCl_3$) δ 4.88 (2H, s), 5.20 (2H, s), 5.00–5.25 (2H, m), 6.45 (1H, d), 7.40–7.90 (12H, m); ir (KBr) 3400, 1668, 1600, 1500 cm^{-1}, ms (70 eV) 356 (M^+).

*Hydrolysis of **8***

To dimer **8** (190 mg, 0.53 mmol) in 5 ml of 95% EtOH was added 1 ml H_2SO_4. The mixture was refluxed for 1 h, neutralized with NaOH 20%, saturated with NaCl, and extracted with ether. The ethereal solution was concentrated and the residue separated by tlc to give **11** (75 mg, 75%), mp 158–160°C (lit. (16) 159–160°C), and **12** (55 mg, 56%).

12 was oxidized by CrO_3 to naphthalide, mp 206°C (lit. (18) 206°C).

*1,4-Dihydro-2,3-Naphtho[1,2]dioxin, **14***

The diiodide **13** (600 mg) was added to a suspension of powdered KO_2 in 20 ml of dry tetrahydrofuran. The solution was stirred at room temperature for 48 h. The excess KO_2 was filtered off and the filtrate evaporated. The residue was chromatographed on five plates (benzene) to give 20 mg of peroxide **14**, mp 54–56°C; nmr ($CDCl_3$) δ: 8–7.1 (6H, m), 5.64 (2H, s), 5.33 (2H, s); *m/e* 186; positive iodine test.

*Reduction of **14***

To a solution of peroxide **14** (15 mg) in 5 ml THF was added 20 mg of $LiAlH_4$. The solution was stirred at room temperature for 10 min. Water (0.5 ml) was slowly added. The solution was filtered and the filtrate washed neutral with water, dried with anhydrous $MgSO_4$, and evaporated to yield a solid material (15 mg); mp ($CHCl_3$) 123–124°C (lit (21) 126°C).

*meso-9,10-Dihydroxy-9,10-diphenyl Anthracene, **17***

Peroxide **16** (1.0 g, 2.76 mmol) was added to a stirring mixture of potassium superoxide (2.4 g, 34 mmol) in dry DMF (100 ml) under N_2. After 5 days, the mixture was poured into ice-water and worked up with ether. The ethereal solution, after concentration, gave 1 g of crude product which recrystallized in chloroform–benzene to give 0.80 g of pure **17**, mp 255–256°C (lit. (19) 256°C).

*Reaction of **2** and **7** with KO_2*

Peroxide **2** (or **7**) was added to a stirring mixture of potassium superoxide in dry DMF. The reaction was followed by tlc. After complete reaction of **2** (or **7**), the mixture was poured in ice-water and extracted by ether. The work-up of the ethereal solution gave a complex mixture of products as seen by the nmr spectrum of the product.

*Dynamic Studies of **1** and **6** with KO_2 in Crown Ether – THF by Nuclear Magnetic Resonance*

Dibromide **1***a* (26.4 mg, 0.1 mmol) was added to a suspension of potassium superoxide (14.2 mg, 0.2 mmol) and dicyclohexyl-crown ether 6 (20 mg) in 0.5 ml dry THF in a nmr tube. The reaction was followed by ^1H nmr. After 10 min, there was a formation of ~10% of **2**. The percentage of **2** did not increase with the time (the same after 10 h). With the time (about 30 min after mixing) **3** slowly formed to reach the maximum (~30%) after 10 h. The proportions of **1***a*, **2**, and **3** did not change with the time. More KO_2 was added (14.2 mg, 0.2 mmol) and in 5 min, all starting material **1** was consumed, raising the yield of **3**, but in the same time all of **2** was destroyed to an unidentified product (dec.).

The same observation was made with **6** in a similar reaction.

*Reaction of **7** with KO_2 in the Presence of Silica Gel*

Peroxide **7** in chloroform was added to a mixture of KO_2, crown ether, and silica gel in chloroform. The mixture was stirred for 30 min and passed through a short column of silica gel – chloroform. The chloroform solution was concentrated to give naphthalide, mp 206–207°C (recrystallization benzene) (lit. (18) 206°C); nmr ($CDCl_3$) δ 5.50 (2H, s), 7.50–8.50 (6H, m); ir (KBr) 1770, 1640, 1610, 1470, 1330, 1230 cm^{-1}; ms (70 eV) 184 (M^+).

*Thermal Stability of **2** and **7***

Peroxide **7** (40 mg) in CCl_4 in a nmr tube was heated in a CCl_4 bath. The reaction was followed by nmr. **7** was unchanged after 4 days.

Peroxide **2** in CCl_4 in a nmr tube was heated in a CCl_4 bath. After 15 h, 70% of **2** was consumed (by following the decrease of the integration of the CH_2 signal of **2** and formation of new signals in the aromatic area). After 5 days, all of the CH_2 signal had vanished. Only the aromatic signal was observed.

*Attempts to Prepare **3a** and **3b***

NaH (50%) in oil (350 mg, 7 mmol) was added to a solution of phthalanol **5** (0.610 g, 4.5 mmol) in dry THF (20 ml) under nitrogen. The mixture was stirred and refluxed overnight. Dibromide **1***a* (1.18 g, 4.5 mmol) in 5 ml THF was slowly added and the mixture refluxed for 10 h. The mixture was then worked up to give, after separation by tlc, starting materials.

Different attempts were made in benzene, ether, and chloroform but without success.

Preparation of *N,N,N′,N′*-tetramethylphosphorodiamidate intermediates for reductive deoxygenation of alcohols using *N,N*-dimethylphosphoramidic dichloride

HSING-JANG LIU, SING PING LEE, AND WING HONG CHAN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 17, 1977

HSING-JANG LIU, SING PING LEE, and WING HONG CHAN. Can. J. Chem. **55**, 3797 (1977).

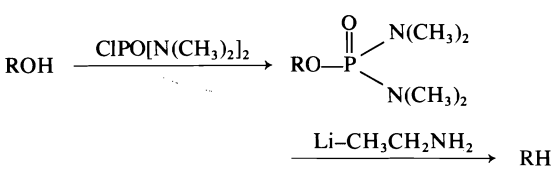
Treatment of alcohols with *n*-butyllithium and *N,N*-dimethylphosphoramidic dichloride followed by addition of dimethylamine gave rise to *N,N,N′,N′*-tetramethylphosphorodiamidates, intermediates involved in a process for reductive deoxygenation of alcohols. This procedure should prove especially useful for alcohols in which the hydroxyl group is sterically hindered.

HSING-JANG LIU, SING PING LEE et WING HONG CHAN. Can. J. Chem. **55**, 3797 (1977).

Le traitement d'alcools avec le *n*-butyllithium et du *N,N*-diméthyl amidodichlorophosphate suivi d'une addition de diméthylamine conduit aux *N,N,N′,N′*-tétraméthyl phosphorodiamidates qui sont des intermédiaires impliqués dans un processus de déoxygénation des alcools. Cette procédure peut s'affirmer spécialement dans le cas des alcools ayant un groupement hydroxyle stériquement encombré.

[Traduit par le journal]

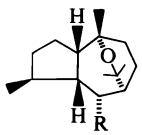
Recently, Ireland and his co-workers (1) reported an elegant method for replacing a hydroxyl group with a hydrogen, a process which is often required in organic synthesis. They showed that alcohols could be readily converted to the corresponding *N,N,N′,N′*-tetramethylphosphorodiamidates (TMPDA) by reacting the alkoxide anion with *N,N,N′,N′*-tetramethyldiamidophosphorochloridate and that subsequent treatment of the TMPDA derivatives with lithium–ethylamine resulted in reductive cleavage of the carbon–oxygen bond to give the deoxygenation products in high yields (Scheme 1). During the course of our synthetic studies on 5-epikessane (**1**), it became necessary to remove the hydroxyl group of alcohol **2**[1] and therefore the preparation of its TMPDA derivative was attempted. Apparently due to the steric congestion of the hydroxyl group, **2** was found to be completely unreactive towards *N,N,N′,N′*-tetramethyldiamidophosphorochloridate; under both the reported reaction conditions and modified conditions, the starting material was recovered intact. As a consequence of these findings an alternative method for preparing the TMPDA derivative of **2** was required. We wish to report a procedure for the formation of TMPDA from alcohols, which *should prove especially useful* for



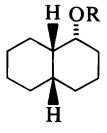
SCHEME 1

those alcohols in which the hydroxyl group is *highly hindered.*

The present procedure involves the use of the more reactive *N,N*-dimethylphosphoramidic dichloride (DMPADC) (2) as the phosphorylating reagent. In contrast to its observed lack of reactivity towards *N,N,N′,N′*-tetramethyldiamidophosphorochloridate, the anion of **2** generated by *n*-butyllithium reacted smoothly with DMPADC in 1,2-dimethoxyethane and *N,N,N′,N′*-tetramethylethylenediamine. At room temperature, the phosphorylation was found to be complete within 16 h. The resulting monochloride **3**, which was shown by thin-layer chromatography to be the sole product, was conveni-



1 R = H
2 R = OH
3 R = $OPO(Cl)N(CH_3)_2$
4 R = $OPO[N(CH_3)_2]_2$



5 R = H
6 R = $PO[N(CH_3)_2]_2$
7 R = $PO(Cl)N(CH_3)_2$

[1]Preparation of **2** will be reported elsewhere in connection with the total synthesis of **1**.

TABLE 1. Preparation of TMPDA from alcohols $ROH \xrightarrow[(3)\ (CH_3)_2NH]{(1)\ n\text{-BuLi};\ (2)\ PO(Cl)_2N(CH_3)_2} ROPO[N(CH_3)_2]_2$

[a]A small amount of dehydration products was also obtained.
[b]The product was obtained as a solid. Recrystallization from petroleum ether gave a constant mp of 136–137°C.
[c]The spectrum was taken in chloroform.

ently converted to the TMPDA **4** by addition of dimethylamine prior to the work-up of the reaction. The material thus obtained was virtually free of impurities and a rapid column chromatography afforded a 95% yield of **4**[2]. The synthetic applicability of this procedure is further illustrated with decalol **5**. While **5** was found also unreactive with *N,N,N′,N′*-tetramethyldiamidophosphorochloridate, its reaction with DMPADC resulted in total consumption of the starting material in 3 h and its TMPDA derivative **6**[2] was isolated in 81% yield after brief treatment of the phosphorylation product **7** with dimethylamine. The procedure is apparently a general one. Additional examples are to be found in Table 1 which also summarizes the physical data of the TMPDA prepared by this method.

On the basis of the mode of reactions, monochlorides such as **3** and **7** could be logically assumed to be involved as the first-stage products (i.e. products formed before the addition of dimethylamine) in the described transformation $ROH \rightarrow ROPO[N(CH_3)_2]_2$. Experimentally, it was verified as follows. Treatment of **5** with DMPADC without the subsequent addition of dimethylamine (*vide supra*) gave rise, as expected, to **7**[3,4], the structure of which was clearly indicated by its nmr [(CCl_4) δ 2.65 (d, 6H, J = 10 Hz, $-N(CH_3)_2$) and 4.48 (m, 1H, —CHO—)] and mass spectra [M^+ 279.1153 and 281.1128 (Anal. calcd. for $C_{12}H_{23}ClNO_2P$: 279.1155 and 281.1126)].

Experimental

General and Material

Elemental analyses were performed by the microanalytical laboratory of this department. Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared (ir) spectra were recorded on a Perkin-Elmer model 457 or 257 grating infrared spectrophotometer. Nuclear magnetic resonance spectra were recorded on Varian A-60, 90 MHz Perkin-Elmer 32 and HR-100 spectrometers using tetramethylsilane as internal standard. The following abbreviations are used: s = singlet, d = doublet, t = triplet, and m = multiplet. Mass (ms) spectra were recorded on an AEI MS-50 mass spectrometer.

With the exception of **2**[1] and **5**[5], commercially available alcohols were used without purification. DMPADC was prepared according to a reported procedure (2).

Preparation of TMPDA Derivatives of Alcohols

Other than reaction time (see Table 1), the conditions used for the transformation of the six alcohols studied to their TMPDA derivatives were identical to those illustrated below with 1-hexadecanol. Physical data and yields of all the products are compiled in Table 1.

To a solution of 1-hexadecanol (485 mg, 2 mmol) in 1,2-dimethoxyethane–*N,N,N′,N′*-tetramethylethylenediamine (4:1; 8 ml) was added a 2.38 *M* solution of *n*-butyllithium in hexane (1.3 ml; 3 mmol) under a nitrogen atmosphere. After stirring at room temperature for 15 min, DMPADC (1.619 g, 10 mmol) was introduced. Stirring was continued for 5 h at which time complete disappearance of the starting material was observed (thin-layer chromatography). An excess of dimethylamine (ca. 5 ml) was added at 0°C and after 30 min the reaction mixture was poured into water and extracted with ether. The extracts were washed three times with saturated aqueous sodium chloride solution, combined, dried with magnesium sulfate, and filtered. Concentration of the solution gave an oil which was subjected to silica gel column chromatography. Elution with ether afforded 590 mg of the corresponding TMPDA.

Acknowledgments

We are grateful to the National Research Council of Canada and the University of Alberta for financial support.

3. Z. Skrowaczewska and P. Mastalerz. Rocz. Chem. **27**, 443 (1953); Chem. Abstr. **49**, 3876 (1955).

[2]Upon treatment with lithium–ethylamine, both TMPDA **4** and **6** underwent smoothly the reductive cleavage of the C—O bond. Under the reported conditions (1), **6** afforded *cis*-decalin in 70% yield and a 75% yield of 5-epikessane (**1**) was obtained from **4**.

[3]This compound was found to be rather unstable. Satisfactory yield (55%) of the pure material was obtained by rapid column chromatography of the crude product on silica gel with ether–benzene (1:9) elution.

[4]Several *N,N*-dimethylphosphoramidic chlorides have previously been prepared by the reaction of DMPADC with sodium alkoxide – phenoxide (see ref. 3 for example). We are grateful to one of the referees for drawing our attention to this aspect.

[5]We wish to thank Professor W. A. Ayer for a generous gift of this alcohol.

Amino group acidity in aminopyridines and aminopyrimidines[1]

MADELEINE G. HARRIS AND ROSS STEWART

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received March 28, 1977

MADELEINE G. HARRIS and ROSS STEWART. Can. J. Chem. **55**, 3800 (1977).

The acidities of the amino group in 18 heterocyclic compounds, nine pyridines, eight pyrimidines, and one triazine, have been measured. The pK_{HA} values (standard state water) were calculated using the Bunnett–Olsen and Marziano–Cimino–Passerini extrapolative techniques from ultraviolet spectral changes accompanying ionization of the amino group in aqueous DMSO containing base. These compounds, together with seven anilines previously studied, constitute a well-behaved Hammett system (σ dependency) with a ρ value of 5.20, provided compounds containing nitro groups *ortho* or *para* to the amino group are excluded. The acid-strengthening effect of aza groups is additive and appears to be primarily due to induction rather than resonance, in contrast to the behaviour of the nitro group.

MADELEINE G. HARRIS et ROSS STEWART. Can. J. Chem. **55**, 3800 (1977).

On mesure les acidités du groupe aminé de 18 composés hétérocycliques: neuf pyridines, huit pyrimidines et une triazine. Les valeurs de pK_{HA} (l'état fondamental, l'eau) sont calculées en utilisant les techniques d'extrapolation Bunnett–Olsen et Marziano–Cimino–Passerini à partir des variations du spectre ultraviolet accompagnant l'ionisation du groupe aminé dans une solution aqueuse de DMSO contenant une base. Ces composés, réunis avec sept anilines étudiées antérieurement, constituent un système se comportant selon Hammett (dépendant de σ) avec une valeur de ρ de 5.20; on ne peut admettre des composés contenant des groupes nitro en *ortho* ou *para* du groupe aminé. L'effet qui renforce l'acidité des groupes aza est additif et semble être causé principalement par de l'induction plutôt que par de la résonance en opposition avec le comportement du groupe nitro.

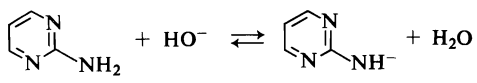
[Traduit par le journal]

Introduction

During the past 15 years polar aprotic solvents such as dimethyl sulfoxide (DMSO), sulfolane, and hexamethylphosphoramide have been widely used to increase the basicity of hydroxide ion towards carbon and nitrogen acids (1). We have previously developed acidity functions for such systems and determined acidity constants of a number of anilines and diphenylamines (2). We now turn our attention to the amino group acidity in amino-substituted nitrogen-containing heterocyclic systems. There are two reasons for so doing. First, useful information can be obtained regarding the effect of aza substitution on reactivity. Secondly the amino-substituted heterocycles adenine, guanine, and cytosine are of great biological interest, since the amino groups of these nucleotide bases participate in hydrogen-bonding in the double-stranded DNA helix. Indeed, the rate of hydrogen exchange in DNA has been linked to the acidity of the amino hydrogens in such compounds (3).

The present paper is concerned with a determination of the pK_{HA} values of the amino group in 18 aza-substituted anilines (nine aminopyridines, eight aminopyrimidines, and one aminotriazine) together with an analysis of the effect of the aza group on acidity. The following paper (36) deals with the acidities of the nucleotide bases, which, because of the smaller spectral changes that accompany ionization, present special difficulties in the determination of pK.

Although pK_{HA} is defined in terms of simple proton dissociation (1, 2) the reaction that takes place in the systems described herein can be illustrated as follows.



Competition from what is presumed to be hydroxide addition occurred in a few instances.

Experimental

Preparation of Compounds

Compounds **1–5**, **8**, **11–14**, **17**, and **19** (Table 1) were obtained commercially and purified by recrystallization or sublimation. Where discrepancies (usually minor) were noted with literature properties elemental and spectral analyses were performed.

[1]Taken in part from the Ph.D. Thesis of Madeleine G. Harris, University of British Columbia, Vancouver, B.C. 1976.

TABLE 1. Spectral data for neutral and anionic forms of **1–19**

Compound[d]	Neutral molecule[a] λ_{max} (nm)	Neutral molecule[a] log ε	Anion[b] λ_{max} (nm)	Anion[b] log ε
1 2-Aminopyridine	298.5	3.58	378	3.39
2 2-Amino-5-chloropyridine	314	3.54	395	3.31
3 2-Amino-3,5-dichloropyridine	321	3.72	397	3.54
4 2-Amino-3-nitropyridine	398	3.86	523	3.96
5 2-Amino-5-nitropyridine	362	4.22	445	4.46
6 2-Amino-3-chloro-5-nitropyridine	359	4.20	439	4.46
7 2-Amino-3,5-dinitropyridine	375(sh)	3.94	489	4.02
8 4-Aminopyridine	275(sh)	3.25	291	4.18
9 4-Amino-3-nitropyridine	368	3.69	468	3.84
10 4-Amino-3,5-dinitropyridine	383	3.85	[c]	
11 2-Aminopyrimidine	298	3.52	373	3.30
12 2-Amino-4-chloropyrimidine	300	3.57	360	3.63
13 2-Amino-4,6-dichloropyrimidine	301	3.60	351	3.38
14 2-Amino-5-nitropyrimidine	333	4.16	412	4.38
15 4-Aminopyrimidine	274	3.49	324	3.27

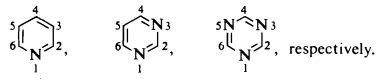
17 4-Amino-2,6-dichloropyrimidine	278	3.55	320	3.27
18 4-Amino-2-chloro-5-nitropyrimidine	348	3.78	430	3.76
19 2-Amino-*s*-triazine	266	3.29	316	3.06

[a]In DMSO.
[b]In 96–99.5% DMSO containing hydroxide or *tert*-butoxide ion.
[c]Initial red colour fades within seconds to yellow, owing probably to Meisenheimer adduct formation (35). Acidification restores spectrum of neutral **10**.
[d]The numbering of the pyridine, pyrimidine, and triazine rings is as follows:



respectively.

*2-Amino-3-chloro-5-nitropyridine (**6**)*

2-Amino-5-nitropyridine (1.39 g) in ethanol (100 ml) was treated with chlorine gas for a few minutes at 0°C until the solution turned bright orange. Evaporation of the solvent gave an orange oil. Addition of 20 ml water effected the precipitation of a rust-coloured solid, which was collected, washed with water, and dried. Two-fold recrystallization from ethanol (charcoal), then from ethanol alone, gave light yellow needles, mp 207–209.5°C (lit. (4) 211–213°C; (5) 205–206°C). *Anal.* calcd. for $C_5H_4N_3O_2Cl$: C 34.60, H 2.32, N 24.22; found: C 34.54, H 2.42, N 23.93.

*2-Amino-3,5-dinitropyridine (**7**)*

2-Amino-3-nitropyridine was converted to 2-nitramino-3-nitropyridine by the method of Talik and Talik (6). It isomerized to the dinitro compound upon standing in concentrated sulfuric acid for 24 h. Recrystallization from ethanol gave orange–yellow needles, mp 189.5–190.5°C (lit. (7) 190–191°C).

*4-Amino-3-nitropyridine(**9**)*

A modification of the procedure of Koenigs *et al.* (8) was used. A suspension of 4-aminopyridine (5 g) and 20 ml of concentrated sulfuric acid was kept at 0–10°C while fuming nitric acid (3.5 g) was added over a period of 30 min. The mixture was brought to room temperature, stirred for 60 min, and then poured onto ice. After overnight storage the mixture was filtered and the filtrate treated with concentrated aqueous ammonia. The resulting precipitate was crystallized from water to give yellow needles of 4-nitraminopyridine, mp 235°C (violent dec.). This compound (2 g) was added carefully to concentrated sulfuric acid (10 ml) to form a dark red solution, which was maintained at 90°C for 1 h. The solution was cooled to room temperature, left overnight, then poured onto crushed ice, and made just neutral with concentrated aqueous ammonia. Upon standing at 0°C, a granular dark brown solid precipitated. Recrystallization once from 80% ethanol, then twice from water (charcoal) gave a chartreuse-coloured powder, mp 203–204.5°C (lit (9) 200°C (dec.); (10) 200–202°C; (11) 204°C). *Anal.* calcd. for $C_5H_5N_3O_2$: C 43.16, H 3.63, N 30.21; found: C 43.14, H 3.81, N 30.24. (An elemental analysis was conducted because of discrepancies between observations made during the synthesis and those reported in the literature (8).)

*4-Amino-3,5-dinitropyridine (**10**)*

Prepared by the method of Koenigs *et al.* (9), but using an excess of sulfuric and nitric acids: light yellow needles, mp 169–171°C (lit. (9) 170–171°C; (12) 168–169°C).

*4-Aminopyrimidine (**15**)*

Kindly supplied by D. J. Brown; mp 149.5–151.5°C.

*4-Amino-2-chloropyrimidine (**16**)*

This compound was prepared from 2,4-dichloropyrimidine and ammonia by the method of Ballweg (13). Sublimation and recrystallization from water gave colourless needles, mp ~200°C, with decomposition to a red tar (lit. (14) 206–207°C; (15) 219–220°C; (16) 209–210°C). A satisfactory nmr spectrum was obtained.

*4-Amino-2-chloro-5-nitropyrimidine (**18**)*

Purified 2,4-dichloro-5-nitropyrimidine was treated

with 1.5 *M* aqueous ammonia at 0°C. The resulting solid was recrystallized from water to give white crystals, mp 217.5–218°C after coloration at 206°C (lit. colours, 205°C, mp (17) 217°C; (18) 220–221°C).

Preparation of Solutions

Solutions containing up to 90 mol% DMSO were prepared as previously described (2). Those in the range 90–100% were prepared by adding anhydrous DMSO (purified over calcium hydride, distilled, and then subjected to zone-freezing) to reagent bottles in a nitrogen-filled dry box; the bottles were sealed with a rubber serum cap, removed from the dry box, and various volumes of water added by syringe through the serum cap. The bottles were stored in a desiccator when not in use. Karl Fischer analysis of the anhydrous DMSO indicated a water content of less than 0.005% by weight.

Tetramethylammonium hydroxide was added either as a 10% by weight aqueous solution, or as the solid pentahydrate in the dry box. Anhydrous solutions containing base tended to turn yellow within 1–2 days if care was not taken to exclude light and traces of air. Potassium *tert*-butoxide solutions were also prepared in the dry box using the pure solid. Titration with acid was used in all cases to determine the concentration of base present. A DMSO solution of the amino compound to be studied was injected by syringe to a serum-capped uv cell containing the DMSO solution and the spectrum recorded.

Treatment of Data

Substantial changes in their uv spectra accompany the conversion of most of the aminopyridines and aminopyrimidines to their anions (Table 1). As the mole fraction of DMSO is increased the wavelength maxima of both the un-ionized and ionized forms of all the indicators studied shift to the red. The λ_{max} of the neutral form usually shifts 1–2 nm and λ_{max} of the anion 3–5 nm over the region of 10–90% ionization, although shifts in the latter are as much as 10 nm in some cases. Furthermore the ε_{max} of the un-ionized and ionized forms generally increase with increasing DMSO content.

Medium effects on the spectrum of HA and A^- were corrected for using a combination of the methods of Hammett *et al.* (19) and Katritzky and co-workers (20). Measurements of ε were made at λ_{A^-} max observed for each DMSO–water solution examined. Occasionally, in solutions where the indicator was partially ionized, the spectrum of HA overlapped that of A^- to the extent that λ_{A^-} max could not be determined with certainty. It was observed experimentally, however, that λ_{A^-} max varied linearly with the acidity function H_- (determined using aromatic amines (2*a*)) for nearly all the indicators studied. Assuming that the rate of lateral shift of λ_{A^-} is the same within and without the region of ionization, values of λ_{A^-} max where $\varepsilon_{HA} = 0$ were plotted against H_- and the least squares straight line extrapolated to give λ_{A^-} max in the desired solution.

Values of ε thus obtained were plotted against H_- yielding good sigmoidal titration curves in every case. The inflection point was estimated by eye and was taken to correspond to 50% ionization. To ensure that the values of ε_{A^-} on the arm of the titration curve corresponded to values greater than 99% ionization, only values of ε_{A^-} in solutions of H_- at least three units greater than H_- at half-ionization were used. (Plots of log *I* vs. mol% DMSO for the aminopyridines and pyrimidines rose less steeply than similar plots for the anilines and diphenylamines used to define the H_- function.) Extrapolation of the linear arm of the titration curve (ε_{A^-} vs. H_-) gave the value of ε_{A^-} in each solution where the indicator was partially ionized.

When using DMSO–water solutions ε_{HA} may be directly determined in each solution by injecting a volume of water equal to the volume of base into the cell, or by omitting the injection of extra water altogether with an appropriate correction in ε_{HA} due to the changed concentration. In practice, however, values of ε_{HA} were smoothed out by plotting against H_-. The ionization ratio *I* was then calculated for each solution using the equation $I = [A^-]/[HA] = \varepsilon - \varepsilon_{HA}/\varepsilon_{A^-} - \varepsilon$, where ε is the measured extinction coefficient at λ_{A^-}, and ε_{HA} and ε_{A^-} are the corrected extinction coefficients at this wavelength of the neutral and anionic species, respectively.

Acidity function studies often make use of ionization ratio data and we have deposited such data for the compounds described herein with the Depository of Unpublished Data,[2] together with sundry observations of the spectral changes that accompany ionization.

Results

The compounds studied in this work did not obey H_-, the acidity function derived using anilines and diphenylamines (2*a*). Although plots of log *I* of the indicators against H_- were invariably linear, the slopes were usually less than unity. The pK_{HA} of a given indicator may be arrived at without the construction of an appropriate acidity function by using two extrapolative procedures: the Bunnett–Olsen method (21) (the B.O. method) and the Marziano–Cimino–Passerini method (22) (the M.C.P. method). Both of these methods, originally derived for acid systems, have been adapted to basic DMSO–water systems by Cox *et al.* (23).

It was observed that, for most of the compounds studied in this work, log *I* varies linearly with mol% DMSO. (This data is also deposited with the Depository of Unpublished Data.[2]) Non-linear plots were observed only for indicators ionizing at high mol% DMSO. These observations suggest that log *I* values of the indicators are linear functions of one another as the DMSO content is varied.

The equations used to calculate pK_{HA} by the B.O. method is [1], and that used in the M.C.P. method is [2].

$$[1]\quad H_- - \log I = \phi(H_- - pK_w - \log [HO^-] + \log a_{H_2O}) + pK_{HA}$$

[2]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 2. Acidity constants[a] determined by the B.O. and M.C.P. methods

Compound	B.O. method		M.C.P. method			
	ϕ	pK_{HA}	Correlation coefficient	m^*	pK_{HA}	pK_{HA} (average)

[a] $K_{HA} = [H^+][ArNH^-]/[ArNH_2]$ in standard state, water.

H_- is a suitable acidity function, that determined for aromatic amines in the present case, and K_w and a_{H_2O} are the dissociation constant and activity (23, 24), respectively, of water.

$$[2] \quad pK_w + \log [HO^-] - \log a_{H_2O} - \log I = m^* \log (f_{A^-*}/f_{HA*} f_{HO^-}) + pK_{HA}$$

Here f_{A^-*} and f_{HA*} are the activity coefficients of a reference acid, in this case 2,4,4′-trinitrodiphenylamine. Using [1] the quantity $H_- - \log I$ is plotted against $(H_- - pK_w - \log [HO^-] + \log a_{H_2O})$ to give pK_{HA} as the intercept and ϕ as the slope. In analogous fashion [2] gives pK_{HA} as intercept and m^* as slope. The value of pK_w at 25°C has been taken as 13.996 (23). Table 2 contains the values of the acidity constants of the aminopyridines and aminopyrimidines determined by the B.O. method and the ϕ values obtained.

Table 2 also contains the pK_{HA} values obtained by the M.C.P. procedure, the values of log $(f_{A^-*}/f_{HA*} f_{HO^-})$ being taken from the values determined by Cox and Stewart (23*a*). The correlation coefficients are remarkably high for most of the compounds studied. (Correlation coefficients have little significance in the B.O. treatment when ϕ is small and they have accordingly not been given in Table 2.) It can be seen that the B.O. and M.C.P. methods give values in good agreement for all compounds except **11**.

Could these acidity constants have been determined using the standard acidity function approach? If the pyridines and pyrimidines were perfectly behaved indicators with respect to the aniline scale H_-, one would simply read off the H_- value at half-ionization to obtain pK_{HA}. In fact, the pyridines and pyrimidines give highly linear plots of log I against H_-, but the slopes vary between 0.8 and 1.1, most of them being less than unity. Not surprisingly, in several instances H_- at half-ionization is more than one pK unit different from the average values recorded in Table 2.

There are sufficient data available from the present work to enable an acidity function to be determined that would better reflect the ionization behaviour of pyridines and pyrimidines than does H_-, and such a function is described (reluctantly) in the accompanying paper (36).

Discussion

Cox and Stewart (23*a*) have proposed that a given set of indicators form an adequate acidity function set if their m^* values lie within a range of $m_{av}^* \pm 0.100$. Applying this criterion, the aminopyridines form such a set, $m_{av}^* = 0.962$

$\pm$ 0.084, if 2-amino-5-nitropyridine, **5**, and 2-amino-3,5-dinitropyridine, **7**, are omitted. The 2- and 4-aminopyrimidines, with the exception of 4-amino-2-chloro-5-nitropyrimidine, **18**, form another set, $m_{av}^* = 0.788 \pm 0.097$.

The value of m_{av}^* for the mono-aza compounds, the pyridines, is only slightly less than unity, but that for the di-aza compounds, the pyrimidines, is markedly less. More significant, perhaps, is the fact that the tri-aza compound, **19**, has a m^* value of only 0.492 (Table 2). Clearly, insertion of nitrogen atoms in the aromatic ring causes deviations from normal behaviour, using H_- and aromatic amines as the standard for comparison, and it is worthwhile speculating upon the reasons for this effect.

It can be readily shown that a less-than-unit value of m^* results from activity coefficient behaviour in the mixed solvent of the following type,

$$f_{A^-}/f_{HA^*} < f_{P^-}/f_{HP}$$

where HP and P represent the aza compounds and HA* and A* represent the reference compound and, hence, the entire aniline and diphenylamine series. Such behaviour can be associated with the extent of delocalization of charge in the anion of the compounds undergoing dissociation. Those with small degrees of charge delocalization, alcohols and to a lesser extent, phenols, will have small values of m^* (again using anilines as the reference), which corresponds to a flat acidity function vs. solvent composition curve. (This analysis ignores the contribution of changes in the activity coefficient of the neutral compounds with changing medium, a common but not always reliable practice (25).)

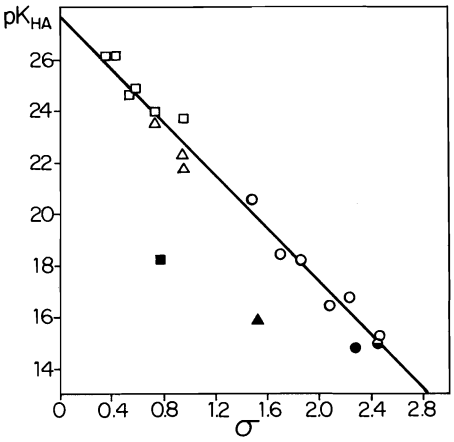

FIG. 1. Hammett plot for the acidity of pyridines (triangles), pyrimidines (circles), anilines (squares), and triazine (half-filled circle). The filled symbols represent compounds in which a nitro group is *para* to the anionic centre. In order of decreasing acidity the compounds are **14**, **19**, **17**, **5**, **16**, **13**, **12**, 4-nitroaniline, **15**, **11**, **2**, **8**, **1**, 3,4,5-trichloroaniline, 3,5-dichloroaniline, 3,4-dichloroaniline, 3-cyanoaniline, 3-trifluoromethylaniline, and 3-chloroaniline; the pK_{HA} values of the named compounds come from ref. 23*a*. The substituent constants come from refs. 27 and 31 The rho value is 5.20 (correlation coefficient 0.992), neglecting the *para* nitro compounds.

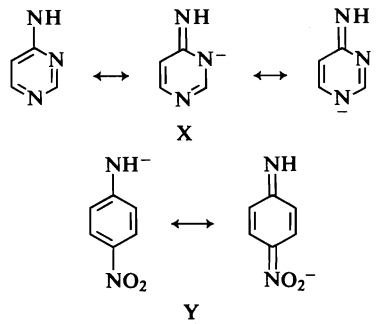
Consider the two compounds 4-nitroaniline, p*K* 18.2 (23*a*), and 4-aminopyrimidine, p*K* 18.4, both of which are measurably ionized in 70 mol% DMSO containing 0.01 *M* hydroxide ion. The lower value of m^* for the latter compound (0.724, compared to 0.958 (23*a*)) suggests that there is less formal delocalization of charge in the pyrimidine anion X than in the nitrophenyl anion Y, despite the presence of two loci for such charge dispersal in the former case.



X

Y

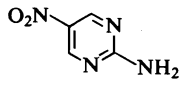
Previous work indicated that a *para* nitro substituent was extraordinarily proficient at dispersing negative charge in nitrogen and carbon anions, as revealed by the requirement for a greatly exalted value of σ^- for this group (26). On the other hand, as shown below, the aza substituent does not even require the use of the σ^- constant to correlate acidities, and this suggests that the aza substituent operates mainly by induction, in agreement with the activity coefficient argument delineated above.

Substituent constants for the aza group have been determined by Deady and co-workers (27) using the basic hydrolysis rates of methyl pyridine carboxylates in 85% methanol at 25°C, and a ρ value of 2.26, established for the basic hydrolysis of methyl benzoates using the same reaction conditions. The values for the aza substituent were $\sigma_{2N} = 0.75$, $\sigma_{3N} = 0.65$, and

$\sigma_{4N} = 0.96$, in good agreement with the σ_N values obtained previously using data for the basic hydrolysis of ethyl benzoates (28). (The steric effect of an aza substituent is negligible and for this reason the 2-aza group is better behaved than are ordinary *ortho* substituents.)

The additivity of aza substituent constants has been demonstrated by Deady *et al.* (29) using the basic hydrolysis rates of six methyl diazine carboxylates in 85% methanol at 10°C. Excellent correlations were obtained, even when the aza groups were adjacent to each other. Such additivity is consistent with the results of Chan and Miller (30) on the rate of nucleophilic substitution of chlorodiazines with *p*-nitrophenoxide ion.

The acidities of *meta* and *para* substituted anilines and their aza derivatives (including the 2-aza substituent) have been correlated with the substituents' Hammett σ values (31) in Fig. 1. An excellent correlation is obtained (correlation coefficient 0.992), provided *para* nitro substituted compounds are neglected. This substituent, of course, is able to conjugate directly with the negatively charged site, and we have previously observed that a greatly exalted value (considerably larger than σ^-) would be required to represent its acid-strengthening effect in aromatic amines. The enormous anion-stabilizing property of the nitro group that so affects the 4-nitroaniline equilibrium is very greatly reduced in the aza compounds. Indeed, in 2-amino-5-nitropyrimidine, **14**, the deviation in the Hammett plot is so modest that were σ^- to be used for the nitro group *para* to the amino group the conjugative effect would be overcompensated for.



14

It is interesting to note that the aza group, to which the nitro group is sometimes compared (32, 33), shows no such tendency. That is, the effect of an additional aza group is essentially unaffected by the number of aza groups already present in the molecule. Substituting a single nitro group at the 4-position of aniline has a much greater acid-strengthening effect than does the substitution of an aza group at this position ($pK_{HA} = 18.2$ for 4-nitroaniline (23*a*) and 22.3 for 4-azaaniline, **8**). Indeed, two aza groups are required to roughly equal the effect of one nitro group; the pK_{HA} of 2,4-diazaaniline, **15**, is 18.4. However, addition of a third aza group produces a slightly *greater* increase in acidity than does the addition of a second nitro group, 3.5 p*K* units compared to ~3 for the nitro compounds (2*b*). This effect is reminiscent of the differing effects of nitro and cyano groups on the acidities of alkanes (26*a*, 34).

Included in Fig. 1 are all substituted anilines for which data is available, except 4-cyanoaniline. The cyano group is in direct conjugation with the anionic site and it has been omitted, although its degree of deviation is not particularly great.

The plot in Fig. 1, covering some 11 p*K* units, extrapolates to a value of 27.8, in reasonable agreement with the value of 27.3 previously estimated for the pK_{HA} of aniline (2*a*).[3] The slope of the line, 5.20, is somewhat larger than the ρ value for diphenylamines, 4.07 (2*a*). This result is not unexpected, since in the latter case two rings are involved in charge dispersal.

The fact that an excellent linear correlation between p*K* and σ is obtained over a range of some 11 p*K* units using compounds with multiple substituents shows not only that substituent effects in these systems are additive, but also that the aza group transmits effects through the ring to essentially the same extent as does trigonal carbon. That is, benzene and heterocyclic nuclei are similar in their ability to transmit electronic effects.

[3]The pK_{HA} values used in the correlation in Fig. 1 are the average values listed in Table 2, together with the aniline values from ref. 23*a*. If the B.O. values are used a slightly higher correlation coefficient is obtained (0.993 compared to 0.992 for the average values), whereas the M.C.P. values give a slightly poorer correlation coefficient, 0.989. It is not possible to state at this point if the rather small difference in correlation coefficient obtained by the two methods is significant.

Amino group acidity in nucleotide bases[1]

ROSS STEWART AND MADELEINE G. HARRIS
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received March 28, 1977

ROSS STEWART and MADELEINE G. HARRIS. Can. J. Chem. **55**, 3807 (1977).

The acidities (standard state, water) of the amino groups in 17 *N*-alkylated derivatives of adenine, guanine, cytosine, and isocytosine have been determined in aqueous DMSO containing base. Adenine methylated at the 9-position is a weaker acid than its 7-methylated isomer by 2.0 pK units and this difference is explained in terms of the known stabilities of the parent tautomers. A similar situation exists with 1- and 3-methylcytosine ($\Delta pK = 3.3$). The position of alkylation of the isocytosine and guanine systems has a small or negligible effect on acidity, again consistent with known tautomeric effects. A modified ribosyl group attached to the 1-position of cytosine has an acid-strengthening effect of 1.9 units, relative to methyl. Of the amino groups involved in nucleotide base-pairing, that in the methyl derivative of guanine has the highest acidity, $pK_{HA} = 14.6$; those in the cytosine and adenine derivatives have identical acidities, 16.7. An acidity function for purines and pyrimidines is reported for aqueous DMSO containing 0.011 *M* tetramethylammonium hydroxide (H_-^P).

ROSS STEWART et MADELEINE G. HARRIS. Can. J. Chem. **55**, 3807 (1977).

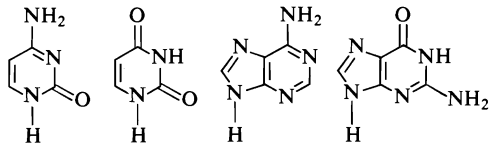
On détermine les acidités (l'état fondamental, l'eau) du groupe aminé de 17 dérivés *N*-alkylés de l'adénine, guanine, cytosine et isocytosine dans une solution aqueuse de DMSO contenant une base. L'adénine méthylée en position 9 est un acide plus faible que son isomère méthylé en position 7 par 2.0 unités de pK. Cette différence est expliquée en termes de stabilités connues pour les tautomères parents. Une situation analogue existe dans le cas de la méthyl-1 et méthyl-3 cytosine ($\Delta pK = 3.3$). La position du groupe alkyle dans l'isocytosine et la guanine, a peu ou très peu d'effet sur l'acidité et compatible avec les effets tautomères connus. Un groupe ribosyle modifié, fixé à la position 1 de la cytosine a un effet qui renforce l'acidité de 1.9 unités par rapport au méthyle. De tous les groupes aminés impliqués dans l'appariement d'une nucléotide avec une base, c'est le dérivé méthylé de la guanine qui possède la plus grande acidité $pK_{HA} = 14.6$; pour les dérivés de la cytosine et adénine, ceux-ci ont des acidités identiques de 16.7. On décrit une fonction d'acidité pour les purines et pyrimidines dans une solution aqueuse de DMSO contenant 0.011 *M* d'hydroxyde de tétraméthylammonium (H_-^P).
[Traduit par le journal]

Introduction

In the accompanying paper we examined the acidity of the amino group in some substituted aza-benzenes: pyridines, pyrimidines, and *s*-triazine (1). Herein we extend the work to another important group of heterocyclic compounds, the nucleotide bases. The amino groups in such compounds are involved in the base-pairing interaction that is responsible for the replicating ability of nucleic acids and, indeed, the acidity of the amino hydrogens is believed to determine to a considerable extent the strength of the base-pairing interaction (2).

Of the four main nucleotide bases, cytosine **1**, uracil **2**, adenine **3**, and guanine **4**, only uracil does not possess an amino group, and hence it is not included in this study.

The other three compounds all have one or more acidic centres in addition to the amino group and to avoid interfering with the measurement of the latter's acidity the other centres have been alkylated. This has the further advantage of increasing the resemblance to the naturally occurring nucleosides, in which a ribose unit replaces the acidic hydrogen at such locations.



1 **2** **3** **4**

The 18 compounds studied in this work include two derivatives of cytosine, three of isocytosine **5**, eight of adenine, two of guanine, one of isoguanine **6**, and a cytidine **7**.

Most of the compounds display only modest spectral changes upon deprotonation, generally much less than for pyridines and pyrimidines,

5 6

7, R = trityl

and special techniques were needed to determine their degrees of dissociation.[2] As before, aqueous dimethyl sulfoxide (DMSO) solutions containing added hydroxide ion were used to produce the basic media required to effect the deprotonation of the amino groups.

Experimental

Preparation of Compounds

Compounds **8**, **10**, **17**, **21**, and **22** (Table 1) were obtained from commercial sources and were purified by recrystallization. Elemental analyses were performed as checks on identity and purity.

*1-Methyl-5-bromocytosine (**9**)*

Prepared by bromination of 1-methylcytosine following the method of Doub and Krolls for the methyl analog (3). The compound was purified by chromatography on alumina to give yellow crystals, mp 210–211.5°C. *Anal.* calcd. for $C_5H_6N_3OBr \cdot \frac{1}{2}H_2O$: C 28.18, H 3.28, N 19.73, Br 37.50; found: C 28.25, H 3.30, N 19.51, Br 37.33. A complex of this compound has been previously reported (4).

*1-Methylisocytosine (**11**)*

Prepared by methylation of isocytosine with methyl iodide, essentially as described by Brown and Jacobsen (5); mp 280°C (dec.) (lit. (5) 283–285°C; (6) 275–280°C).

*3-Methylisocytosine (**12**)*

Kindly supplied by D. J. Brown; mp 257–260°C (lit. (5) 257–260°C).

*9-Methyladenine (**13**)*

Prepared from adenine and tetramethylammonium hydroxide (7). Sublimation and recrystallization gave white crystals, mp 305–306°C (lit. (7) 301–302°C).

*2-Chloro-9-methyladenine (**14**)*

2,6-Dichloropurine was methylated in DMSO with methyl iodide in the presence of potassium carbonate to give a mixture of the 7- and 9-methyl isomers (8). Separation of the isomers was best effected by chromatography over neutral alumina with ethyl acetate as eluant. The recrystallized 2,6-dichloro-9-methylpurine thus obtained was aminated (9) to give 2-chloro-9-methyladenine. Recrystallization from water gave white crystals which were dried *in vacuo* at 100°C before analysis. The compound turns yellow near 270°C but does not melt below 300°C; nmr δ 3.70 (s, 3H), 7.68 (m, 2H), 7.97 (s, 1H). *Anal.* calcd. for $C_6H_6N_5Cl$: C 39.23, H 3.27, N 38.15; found: C 39.26, H 3.14, N 38.45.

*2-Chloro-8-methoxy-9-methyladenine (**15**)*

2,8-Dichloro-9-methyladenine (0.05 g) was dissolved in 30 ml of warm methanol and a solution of 0.5 g of sodium hydroxide in 25 ml methanol added. The solution was refluxed for 5 h, then cooled to room temperature, and allowed to stand overnight. Recrystallization of the granular precipitate from 95% ethanol gave white crystals which were dried at 100°C *in vacuo* for 24 h before analysis, mp 270–270.5°C (dec.); nmr δ 3.43 (s), 4.12 (s), 7.28 (m). *Anal.* calcd. for $C_7H_8N_5OCl$: C 39.36, H 3.77, N 32.78; found: C 39.57, H 3.90, N 32.96.

*2,8-Dichloro-9-methyladenine (**16**)*

Uric acid was converted to 2,6,8-trichloropurine (10) and then methylated with methyl iodide (11). Treatment with ethanolic ammonia gave the product (12). White crystals, mp 266–268°C (lit. (12) 260–261°C).

*2-Chloro-7-methyladenine (**18**)*

Theobromine was converted to 2,6-dichloro-7-methylpurine (13) which was selectively aminated to the desired product as follows. A saturated solution of ammonia in methanol was heated in a sealed tube with 0.9 g of the dichloro compound at 90–100°C for 19 h. After work-up with base and then acid, followed by recrystallization, white needles were obtained; mp 284.5°C (gas evolution) (lit. (14, 15) 284°C (gas evolution)). Satisfactory elemental analyses and nmr spectra were obtained.

*2-Chloro-7-methyl-8-methoxyadenine (**19**)*

Prepared using Fischer's method (16) from **20**. White crystals which, upon heating, turn yellow at 227°C and melt at 248.5°C with gas evolution, nmr δ 3.67 (s, 3H), 4.12 (s, 3H), 7.03 (m, 2H). *Anal.* calcd. for $C_7H_8N_5OCl$: C 39.36, H 3.77, N 32.78; found: C 39.43, H 3.83, N 32.58.

*2,8-Dichloro-7-methyladenine (**20**)*

Prepared from theobromine according to the method of Fischer (14, 17). White needles which, upon heating, turn yellow near 270°C but do not melt below 300°C (17). Satisfactory elemental analyses and nmr spectra were obtained.

*3,7-Dimethylisoguanine (**23**)*

Prepared from theobromine, essentially by the method of Nikolaeva and Golovchinskaya (18). White needles, mp 350°C (dec.) (lit. (18) 360°C).

*2,3-Dihydro-1H-5-oxoimidazo(1,2-c)pyrimidine (**24**) Hydrochloride*

Prepared from uracil by the method of Ueda and Fox (19). Does not melt upon heating; a satisfactory elemental analysis was obtained.

2′,3′-O-Benzylidene-5′-O-tritylcytidine (7)

Kindly supplied by R. C. Lord and used without further purification.

Measurements and Treatment of Data

Spectral measurements were made in DMSO containing tetramethylammonium hydroxide as previously described (1, 20). Most of the nucleotide bases show spectra comprising two or more transitions for both the un-ionized and ionized forms. For example, the spectrum of **20** in the neutral form can be reconstructed with a Dupont 310 Curve Resolver using a minimum of five Gaussian transitions; the ionized form required three such functions. With the exception of **10**, **12**, **21**, and **22** the un-ionized and ionized spectra, though markedly

[2]The method of characteristic vector analysis, very recently described (40) might also be used to advantage in such cases.

TABLE 1. Spectral data for neutral and anionic forms

Compound	Neutral molecule[a]		Anion[b]	
	λ_{max} (nm)	log ε	λ_{max} (nm)	log ε
7 2′,3′-O-Benzylidene-5′-O-tritylcytidine	—	—[c]	275(sh)	3.89

[e]In 63 mol% aqueous DMSO.

different in shape from each other, overlap to a large extent and, because of medium effects on spectra, the ionization ratio *I* cannot be evaluated accurately using the approach taken with the pyridines and pyrimidines (1). In such cases no one method of correcting for medium effects appears to be entirely satisfactory and we have found it useful to exploit the spectral peculiarities of the individual indicator to calculate *I*. In one case, **23**, the spectral change with the medium is about the same as the change caused by ionization, too small for any meaningful estimate of *I* to be made.

Even though the shift in λ_{max} that accompanies ionization is quite small for most of the compounds under consideration the areas under the spectral curves of the neutral molecule and anion are sufficiently different in many cases to allow good estimates of *I* to be made.

The values of *I* so obtained were compared to those obtained using several other approaches, including that of Katritzky and co-workers (21) which makes use of measurements at a single wavelength, and the details are given elsewhere (22). With one exception, **8**, the values obtained by the area method and that of Katritzky and co-workers are quite close. Since the change in area that accompanies ionization of **8** is quite small the method of Katritzky and co-workers was used to calculate *I*, and similarly with **13**, **24**, **11**, and **7**, although in the latter cases the two methods give similar results. For **10**, **12**, **21**, and **22**, the method used previously was employed (1).

The equation used to calculate the ionization ratio *I* by the area method is [1], which is analogous to the equation using extinction coefficients used previously (1).

$$[1] \qquad I = [A^-]/[HA] = Z - P/Q - Z$$

Z is the area under the total spectral curve for the mixture of A^- and HA in any given solvent mixture; *P* is the area under the curve for a solution of HA in the same solvent mixture in the absence of base; and *Q* is the area for A^- determined by extrapolation from data obtained in the presence of base and higher concentrations of DMSO, the extrapolation being made by plotting area against H_- (20) and reading off the area for the H_- corresponding to the solvent mixture.

A difficulty with the area method (23, 24) arises from the fact that usually not all of the spectral transitions under consideration lie above 260 nm, the effective cut-off wavelength when DMSO is used. There are two alternative methods which were felt to be appropriate for choosing the wavelength ranges. The first is to use as much of the unobscured spectrum as possible by measuring the area from 260 nm to longer wavelengths. The second is to employ the area from the isosbestic point, defined by the two curves closest to 50% ionization (25), to longer wavelengths. These two methods were investigated for two representative compounds **18** and **20** and we have concluded that *I* does not depend significantly on the choice of wavelength cut-off, provided *Q* and *P* differ significantly (preferably by a factor of 1.5), a condition that was met by many of the compounds studied. For reasons of simplicity of operation we have used the 260 nm cut-off method. Areas were measured using a planimeter. Since the ionization data were to be converted to p*K* by an extrapolative procedure it was necessary to avoid as much as possible errors at the extrema. Accordingly, only log *I* values between +0.80 and −0.80 were, in general, used.

All compounds reacted instantaneously and reversibly with base and we have assumed, as before (20), that proton loss rather than hydroxide addition takes place.

The ionization ratio data for the compounds described

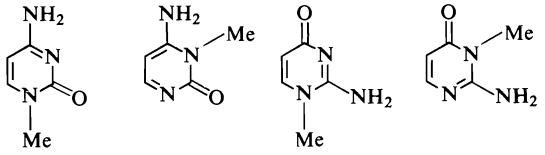
herein have been deposited with the Depository of Unpublished Data.[3]

Results and Discussion

The pK_{HA} values were calculated from ionization data by the extrapolative procedures of Bunnett and Olsen (B.O.) and Marziano, Cimino, and Passerini (M.C.P.), as described previously (1, 26–28). These values are given in Table 2, together with rounded-off averages that will be used in subsequent discussion.

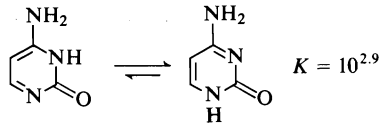
The Cytosine and Isocytosine Systems

Compounds **8**, **10**, **11**, and **12** are all much stronger acids than the aminopyrimidines (1), reflecting the considerable acid-strengthening effect of the carbonyl group.



8 (pK = 16.7) **10** (pK = 13.4) **11** (pK = 14.3) **12** (pK = 14.3)

There is an interesting difference between the cytosine system, **8** and **10**, and the isocytosine system, **11** and **12**, the latter two compounds having identical acidities whereas the former pair differ by 3.3 pK units. Acid-strengthening or acid-weakening effects in organic acids are usually rationalized in terms of electronic effects in the acid anion. One looks in vain, however, at the anionic structures of the four compounds for such a rationale. They are all isomeric species with apparently very similar charge distributions. On the other hand the neutral compounds **8** and **10** must differ markedly in stability; indeed, by an amount equivalent to about 3 pK units, provided that the same difference in stability exists as for the de-methylated compounds (29, 30, 31).



Katritzky and Waring (30) used a related argument based on *basicity* differences to determine this quantity. The greater acidity (and basicity) of **10** than of **8** is thus due to lower stability of the neutral molecule.[4]

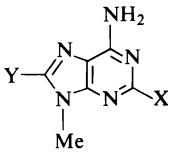
[3] Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

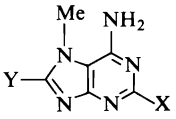
[4] It is unfortunate that **8** is the one compound studied in this work that gives I values that depend significantly on the method used. The area method gives a pK of 15.5, which were it correct would mean that the ΔpK between **8** and **10** is 2.1 instead of 3.3. We believe that the larger value is the more reliable, partly because the ionization data determined using a single wavelength (see Experimental) leads to a well-behaved Hammett indicator plot (Fig. 2).

Are the identical acidities of the isocytosines **11** and **12** also consistent with the known tautomeric constants of the corresponding de-methylated species? Yes, for it has been shown that isocytosine is a mixture of the two tautomers, both in aqueous solution and in the solid state, where, indeed, a 1:1 ratio exists (29, 32, 33).

The Adenine and Guanine Systems

9-Methyladenine **13** is 2.0 pK units weaker than the 7-methyl isomer **17** and similar differences, 1.5–2.0 units, exist for the three pairs of derivatives **14–16** and **18–20**.

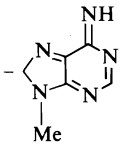




13, X = Y = H
14, X = Cl, Y = H
15, X = Cl, Y = MeO
16, X = Y = Cl

17, X = Y = H
18, X = Cl, Y = H
19, X = Cl, Y = MeO
20, X = Y = Cl

Like the cytosine and isocytosine systems discussed earlier the anionic charge distribution is much the same in the 9- and 7-methyl series except that here the anions of the weaker acids, those belonging to the 9-methyl series, have an additional contributing structure **13***a* that is not present in the anions of the 7-methyl series.

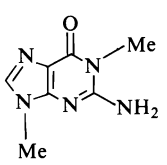


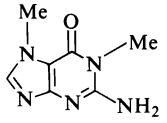
13*a*

Structure **13***a* has the negative charge on carbon and would not be expected to have a great effect on the ion's stability. Nonetheless, whatever influence it exerts would produce an effect in the opposite direction to that observed.

The difference in acidity of the two series can again be traced to the stabilities of the neutral molecules. Eastman's estimate for the tautomeric constant favouring the 9- over the 7-system in adenine is 16 (34, 29) corresponding to a difference of 1.2 pK units in the correct direction in the acid strengths of the alkylated derivatives, assuming there is no difference in the stabilities of the anions.

The guanines **21** and **22** differ in acidity by only 0.4 pK units and although precise data for the tautomeric constant of the parent compound is not available it has been suggested that guanine, itself, as we might now expect, exists in solution as a mixture of the 9- and 7-tautomeric forms, corresponding to the de-methylated forms of **21** and **22** (ref. 29, p. 523).





21 (pK = 14.6) **22** (pK = 15.0)

Substitution of chlorine at the 2-position in the two adenine systems produces an expected increase in acid strength, compare **13** and **14**, and **17** and **18**, although the effect is smaller than in the pyrimidine series (1). Further chlorine substitution at the 8-position, as in **16** and **20**, produces an additional, but smaller, increase in acidity. The smaller effect of the second group appears to be a consequence of the resonance effect exerted by +R groups in this position. This follows from a consideration of the 2-chloro-8-methoxy compounds **15** and **19**. The effect of a 2-chloro group (largely inductive and acid-strengthening) is cancelled by the effect of an 8-methoxy group (largely resonance and acid-weakening).

Effect of an Imidazole Ring

Fusing a methylated imidazole ring to 4-aminopyrimidine produces the adenines **13** and **17**. These are, respectively, 1.7 and 3.7 units stronger than the pyrimidine, an effect that can be attributed largely to the inductive effect of the sp^2 nitrogen atom in the five-membered ring. On the other hand, fusing a methylated imidazole ring to 3-methylisocytosine produces the guanines, **21** and **22**, which are 0.3 and 0.7 units *weaker* acids than the isocytosine. Presumably, the conjugation of the sp^3 nitrogen atom of the imidazole ring with the carbonyl group in the six-membered ring greatly reduces the latter group's acid-strengthening effect with the result that the imidazole's net effect becomes one of electron donation.

Ribonucleoside Acidity

The compounds studied in this work possess a methyl group at the position occupied by the ribose moiety in ribonucleosides and it is of interest to determine the effect of such substitution on amino group acidity. Fox and Van Praag

used a 5-nitro substituent to increase the acid strength of 1-methylcytosine and cytidine so that their acidities could be directly compared in aqueous solution (35, 36). They found the pK to be 10.55 for the 1-methyl compound and 9.12 for the cytidine, a 1.4 pK unit acid-strengthening effect of ribosyl over methyl. It was suggested that hydrogen bonding occurs between the unionized 2′-OH group and the carbonyl group of the pyrimidine ring since spectral changes in the pyrimidine spectrum accompanied hydroxyl ionization (37). No such shifts were observed in 2′-deoxyribosyl derivatives where the 2′-OH group is replaced by a proton.

Since we are able to measure the acidities of very weak acids we should be able to compare the effects of ribosyl and methyl groups in the absence of such acid-strengthening groups as nitro. Unfortunately, ionization of the hydroxyl groups in the ribosyl unit (37) occurs at lower basicities than those required to ionize the amino group and we have had to block the hydroxyl functions for this reason. The cytidine **7**, which has the interfering hydroxyls blocked with a benzylidine and a trityl group, has a pK_{HA} of 14.8 (half-ionized in 51.0 mol% DMSO), considerably lower than the value of 16.7 found for 1-methylcytosine **8** (half-ionized in 65.0 mol% DMSO).

This increase in acidity of 1.9 pK units is comparable to the 1.4 pK unit increase found by Fox *et al.* (35, 37) for the nitro-substituted compound. It is significant that **7** does not possess a 2′-hydroxyl group and, hence, the increased acidity cannot be attributed to the presence of such a group. We believe the ribosyl group's acid-strengthening effect is a result of the cumulative inductive effect of the oxygen atoms in the ribosyl group, particularly that in the ring.

It is difficult to give a very precise estimate of the acidity of the amino group in adenosine but it will certainly be greater than that of 9-methyladenine, whose pK is 16.7. Since the ribosyl and amino groups are further away from one another than in cytidine the inductive effect will be less and one might expect a value near 16 for the amino group in adenosine.

The pertinence of amino group acidity to the matter of base-pairing in nucleotide chains was alluded to in the Introduction. It is curious that the amino groups in 9-methyladenine **13** and 1-methylcytosine **8** have identical acidities, pK = 16.7 (although following the argument in the previous paragraph the ribosyl effect will be greater in cytidine than in adenosine). The amino group in adenine, of course, base-pairs with thymine and that in cytosine with guanine (Fig. 1). Each pair has, in addition, a link that does not involve an amino group, and the cytosine–guanine pair has a third link through guanine's 2-amino group. It is noteworthy that the latter appears to be the most acidic of the three amino groups under consideration (pK_{HA} of **21** is 14.6). Provided amino group acidity in the methylated bases is indeed related to hydrogen-bonding ability in the nucleotides, guanine can be assumed to have a more effective hydrogen-bonding amino unit than either adenine or cytosine.

An Acidity Function for Purines and Pyrimidines

The compounds studied in this work and most of the pyrimidines and pyridines studied previously are not well-behaved Hammett indicators with respect to the H_- scale previously developed using aromatic amines (20). In most cases the increase in ionization with increasing

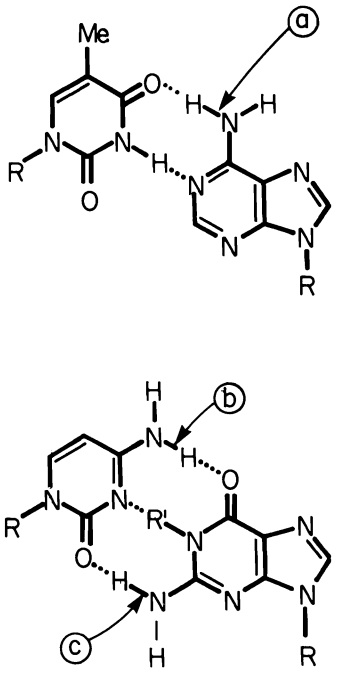


FIG. 1. The base-pairing arrangements in nucleotides, R = nucleotide attachment, R′ = H. Upper pair: thymine–adenine; lower pair: cytosine–guanine. The bonds whose acidities have been measured in the unpaired molecules with R = R′ = methyl are identified: pK_{HA} values are *a*, 16.7; *b*, 16.7; *c*, 14.6.

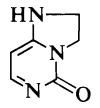
DMSO content is smaller than would be expected and the probable origins of this effect were described previously (1). We have made use of the B.O. and M.C.P. extrapolative techniques since, when sufficient ionization data is available, reliable pK values can be determined regardless of the adherence or lack thereof to an acidity function. The alternative approach to pK determination in mixed solvents is to attempt to construct an acidity function using the compounds in question (38). We have sufficient data to construct such a scale to which, it turns out, most of the pyrimidines and purines adhere satisfactorily. We are reluctant to inflict upon the body scientific yet another acidity function but we feel obliged to do so since it may be of use in examining acidities of compounds of related structure for which sufficient, accurate, ionization data have not or cannot be obtained to enable the extrapolative techniques to be used. In such cases estimating the DMSO concentration in which the compound is half ionized allows one to calculate a pK, on the assumption that the compound follows the acidity function constructed using compounds of similar structure. Such an operation is preferable to using the B.O. or M.C.P. techniques when only a few imprecisely determined values of the ionization ratio are available.

The scale has been anchored in the standard state water using **24**, whose pK_{HA} has been reported to be 12.6 (19). Our potentiometric measurements in water at 25°C give a value near this, 12.43, and we have used the latter value in our calculations.



24

A plot of log I for **24** against mol% DMSO is parallel to those for the slightly weaker acids 3-methylcytosine **10** and 2,8-dichloro-7-methyladenine **20**. An attempt was made to use **20** to anchor the scale by using a high enough concentration of hydroxide ion to enable the ionization ratio to be determined in water. This could be done using 0.1 M tetramethylammonium hydroxide. Plots of log I vs. mol% DMSO in 0.1 and 0.011 M base are parallel, but, unfortunately, the value of Δ log I is 1.12, appreciably larger than the value expected from the difference in base concentration (39).

TABLE 3. Acidity function for pyrimidines and purines in the system DMSO – H_2O – 0.011 M tetramethylammonium hydroxide

Mol% DMSO	H_-[a,b]
0.3	12.0
1.0	12.1
3.0	12.3
5.0	12.5
10.0	12.9
15.0	13.3
20.0	13.8
25.0	14.2
30.0	14.6
40.0	15.5
50.0	16.3
60.0	17.0
70.0	17.7
80.0	18.5
85.0[c]	19.0
87.6	19.3

[a]Interpolated and rounded-off values (22).
[b]Determined using indicators of Fig. 2.
[c]H_- value is 21.2 (20).

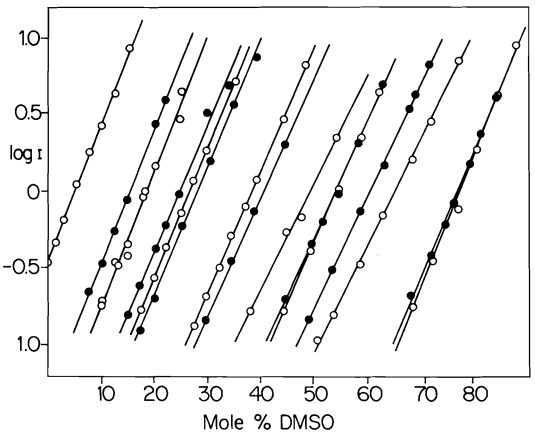


FIG. 2. Ionization ratio as a function of solvent composition. From left to right the compounds are **24, 10, 20, 18, 11, 12,** 4-amino-2,6-dichloropyrimidine (1), **16, 14,** 4-amino-2-chloropyrimidine (1), 2-amino-4,6-dichloropyrimidine (1), **15, 8,** 2-amino-4-chloropyrimidine (1), and 4-aminopyrimidine (1).

Table 3 gives values for aqueous DMSO of the scale, designated H_-^P where P signifies pyrimidine or purine. Figure 2 shows the excellent parallelism in the ionization plots of the indicators used to determine the scale. In the case of other purines or pyrimidines not used in constructing the scale, deviations between H_-^P at half-ionization and the pK determined by the B.O. and M.C.P. methods amounted in two cases, **13** and **17**, to as much as one pK unit.

Failure of the scaling laws in the thermal explosion of methyl isocyanide

JOHN L. COLLISTER AND HUW O. PRITCHARD
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received October 19, 1976[1]

JOHN L. COLLISTER and HUW O. PRITCHARD. Can. J. Chem. **55**, 3815 (1977).

Thermal explosions of methyl isocyanide have been studied in spherical reaction vessels with volumes in the range 300–5000 ml. The normal inverse dependence of the explosion limit on the square of the radius appears to hold over limited ranges, e.g. from 300–1000 ml and from 2000–3000 ml, but the explosion limits at 1000 ml and 2000 ml are characterized by markedly different values of the critical parameter δ_c. Temperature measurements were made at and near the vessel walls, but they do not reveal any abnormalities which could be used to explain these results.

An appendix reports measurements of the thermal conductivities of methyl cyanide and methyl isocyanide from 200–350°C

JOHN L. COLLISTER et HUW O. PRITCHARD. Can. J. Chem. **55**, 3815 (1977).

L'explosion thermique de l'isocyanure de méthyle a fait l'objet d'une étude dans différents vases réactionnels sphériques de volumes compris entre 300–5000 ml. L'expression de la dépendance normale inverse de la limite d'explosion sur le rayon au carré semble être valable au delà des écarts délimités, e.g. à partir de 300 à 1000 ml puis de 2000 à 3000 ml, mais les limites d'explosion à 1000 ml et 2000 ml sont caractérisées par nettement différentes valeurs du paramètre critique δ_c. Les mesures de la température sont faites à et près de la paroie du récipient, mais celles-ci ne révèlent pas d'anomalies qui pourraient être utilisées pour expliquer les résultats.

Un appendice rapporte les mesures de conductivité thermique du cyanure et isocyanure de méthyle à partir de 200 jusqu'à 350°C.

[Traduit par le journal]

It was suggested some time ago that the thermal isomerization of methyl isocyanide might be a good reaction with which to test the theory of explosions (1); principally, the kinetics of the isomerization are well understood, and since it is not a chain reaction, the usual problems of variable inhibition by impurities are absent. We have recently made an extensive study of the rate of this isomerization over wide ranges of both temperature and pressure (2) and we now report an attempt to use this reaction to make a test of thermal explosion theory over a wide range of one parameter, the radius of the vessel.

The experimental technique is simple and well known (1–4): methyl isocyanide is admitted to a spherical vessel held in a constant temperature air bath by momentarily opening an electrically operated valve; the temperature at the centre of the vessel is monitored using a fine thermocouple, and the pressure using a pressure transducer attached to the neck. If the pressure of isocyanide admitted is below the critical explosion pressure, a temperature rise of less than 40°C is recorded at the centre of the vessel,

[1]Revision received July 27, 1977.

whereas above this critical pressure, the temperature at the centre rises very markedly, and at the same time a peak appears in the pressure trace (1): the critical pressure is located by trial and error for each bath temperature and for each reaction vessel.

Experimental

The original aim of this experiment was to establish the precision of the scaling law by performing very accurate experiments in 500, 1000, and 2000 ml vessels. The reaction vessels were enclosed in an air thermostat, stirred by a large high-speed fan, and controlled by electronic proportionating devices fed with a primary signal from a Hewlett-Packard 2802A platinum resistance thermometer; the fine control heaters had a thermal time constant of less than 1 s, and the platinum resistance element was calibrated at the melting point of lead. For these three vessels (and also for the 300 ml vessel), both the spatial homogeneity and the resettability were of the order of ± 0.1°C. However, in later work, a 5000 ml vessel was used, which was rather too large to be properly accommodated in the furnace: in this case, the resettability was still ± 0.1°C, but the spatial homogeneity was no better than ± 0.5°C.

The electrically operated valve (Leybold–Hereaus NW10) was the same as has been used in previous work (1) and was held open for the required length of time by a 50 V dc square-wave pulse. The forepressure of methyl isocyanide was adjusted before each experiment to within 0.01 Torr using a Texas Instruments quartz spiral gauge: by this technique, and profiting from the fact that the methyl isocyanide isomerization is insensitive to both impurity and surface effects, it was an easy matter to locate the critical explosion pressure with high precision. However, it very quickly became apparent that the scaling law (eq. 1 below) failed disastrously between the 1000 and 2000 ml vessels and, thereafter, we were content to bracket the explosion limit with a critical and a subcritical experiment differing by less than 1% in pressure. Thus, the values of P_c listed in Table 1 may be regarded as being accurate to $\pm 1\%$ or ± 0.03 Torr, whichever is the greater.

In previous work, it had been thought that convective effects, signalled by a discontinuity in the temperature rise at the centre of the vessel (1), were important for Rayleigh numbers in excess of 400. We chose, therefore, to limit our experiments to cases having low Rayleigh numbers[2] and (with two inadvertent exceptions) the Rayleigh numbers for all experiments listed in Table 1 are less than 400, accounting for the absence of data for most sizes of vessel below either 320 or 300°C. We also imposed a high-temperature limit on these experiments of 360°C because we did not feel that it was possible to extrapolate the reaction rate data accurately in the fall-off region (2) beyond this point.

[2]A Rayleigh number of 400 does not, of course, correspond to the complete absence of convection. Ra = 400 corresponds to a Nusselt number ($Nu = 0.3(Ra)^{1/4}$) of about 1.3, and hence about 25% of the heat transport is by convection at this limit.

Results and Discussion

The results are reduced to non-dimensional form in Table 1, using rate constants derived from our own measurements (2) and thermal conductivities given in the Appendix. The explosion limits are characterized by the critical value of δ, δ_c, where δ is dimensionless and is given by (5)

$$[1] \qquad \delta = \frac{E}{RT_0^2}\frac{Q}{\lambda}r^2\frac{k_{uni}P}{RT_0}$$

E is the activation energy, T_0 is the vessel temperature, r is the vessel radius, λ is the thermal conductivity, Q is the (exothermic) heat of reaction, P is the pressure, and k_{uni} is the (fallen-off) rate constant for that pressure; for a spherical vessel, in the absence of diffusion effects, δ_c should have a value of between about 4 and 4.5 for this reaction ($B \simeq 60$ and $\varepsilon \simeq 0.01$ in the notation of ref. 5), and if anything, because both B and ε are temperature dependent, there should be a slight increase in δ_c as T_0 increases (cf. Table II of ref. 5).

First, we notice that for a fixed radius, the values of δ_c are approximately constant, but the magnitudes of the variations are disappointingly large. If the lack of constancy in δ_c for a given r were due to errors in the thermal conductivity, then each row of δ_c in Table 1 should show the same trends, which is not the case. Since the temperature in each experiment was stable and reproducible to within ± 0.1°C and each critical pressure was accurate to within $\pm 1\%$, we can only conclude that the fairly large scatter of δ_c within one row is inherent in the nature of the experiment. Since the reaction is in its fall-off region, and is almost second order at the lowest values of P_c, the value of δ_c contains (in effect) a power P_c^y where y approaches 2; this causes a relatively small magnification ratio but, with the precision in the temperature and pressure measurements attained in this work, should present no difficulties.

Second, we notice that in general the values of δ_c appear to be much greater than the predicted value of between 4 and 4.5 whereas, previously, values near 5 had been found (1): the agreement found previously was fortuitous, since it was based on an assumed value for Q of 15 kcal mol^{-1}; using the recently determined value of $Q = 23.7$ kcal mol^{-1} (6), together with our new thermal-conductivity data, the previous results

TABLE 1. Thermal explosion limits for methyl isocyanide as a function of vessel radius and temperature*

T (°C)		260	280	300	320	340	360

would now correspond to values of $\delta_c = 10.1$, 9.0, and 8.1 at 299, 323, and 351°C respectively. We note that there is a discrepancy between our values for δ_c in the 1000 ml vessel of 11.0 $\pm$ 0.4 and the previous ones, obtained in a 1200 ml vessel (1), which could be accounted for by an error in one or other of the temperature or pressure calibrations. We have checked very extensively both our temperature and pressure measurements, and found them to be accurate; unfortunately, it is not possible to reconstruct the original apparatus (1) to check for calibration errors there, so we cannot reconfirm their correctness; however, we note that the data in Table 1 show large changes to occur in the value of δ_c between the 1000 and 2000 ml vessels, so that the existence of this discrepancy does not necessarily imply any error.

Examining Table 1 in closer detail, we notice that the data from the 500 and 1000 ml flasks conform well to the scaling law, but the observed value of δ_c is almost a factor of 3 too large; the data from the 300 ml flask also conform, more-or-less, to the scaling law. Similarly the data from the pair of 2000 and 3000 ml flasks also scale reasonably well, and the corresponding value of δ_c is only some 20–50% larger than the theoretical value. Thus, it would appear that some kind of transition in the scaling behaviour occurs between 1000 and 2000 ml, and the earlier data (1) from a 1200 ml flask (as recalculated above) would actually fit in with the observed trend. We hoped to understand this trend better by performing experiments in another size of vessel ($V = 1500$ ml), but this vessel yielded a totally inconsistent set of δ_c values, usually the highest of any observed at each temperature in these experiments.[3] Finally, we decided to examine the explosion limits in a 5000 ml flask, the largest

[3]Although 1.5 ℓ spherical flasks are no longer commercially available, we were able to locate a 1.5 ℓ flat-bottomed flask, which we had blown into a sphere by hand; the radius of this flask varies by $\pm$1.5 mm, which is considerably more variation than is exhibited by the other (machine made) flasks; normally, this departure from roundness would be of only minor importance, but in view of the unexplained nature of the behaviour we have found, we note it here. We did not equip this particular flask with a thermocouple.

our furnace could accommodate, and found yet another unexpected result, a value of δ_c less than the theoretical value, which means that in this flask, the explosion takes place more readily than can be explained by the thermal theory. It is relatively easy to conceive of mechanisms which will dampen the explosion but there are few effects which could cause the explosion to become easier than expected.

We have carried out the following diagnostic tests in order to try to elucidate the cause or causes of these failures in the scaling law.

(*i*) As before (2) we tested for radical chain effects, which were shown to be absent previously at smaller volumes (2), by adding 1% of propylene to the reactant gas; again, δ_c was only slightly affected and it seems that this is not the problem.

(*ii*) Tests were made for spurious admission heating effects (7): different neck diameters were used, the time the electrically operated value was held open (normally 0.2 s) was varied from 0.05 to 0.4 s, and for the largest vessel (where such effects are normally the most prevalent) the geometry of the flow was altered; none of these tests revealed any spurious heating effects as the gas entered the vessels.

(*iii*) The temperature-rise profiles at the centre of the various vessels were always[4] normal in the sense that they approached 40°C (1) as the critical pressure was approached, and once above the critical pressure the induction times became progressively shorter the greater the excess pressure.

(*iv*) The observation, noted above, that in the 5000 ml flask the explosion is initiated more readily than thermal theory would predict is disturbing and so we decided to examine the assumption of infinitely rapid heat dissipation at the walls. Consequently, we constructed two flasks, 500 ml and 5000 ml, with a second thermocouple placed about 0.5 mm away from the wall, and compared the behaviour in the two vessels. In the subcritical range, we could detect no temperature rise near the wall in either vessel. However, in explosions whose initial pressures were within 2% of P_c, there was a significant difference in behaviour: in the 500 ml flask, temperature rises near the wall were still only of the order of 0.3–0.5°C whereas in the 5000 ml flask, they were 5–7°C. If the walls can be assumed to remain at the furnace temperature throughout, this observation shows no more than that once an explosion has occurred, the convective cooling is much more rapid in the smaller flask where the pressure is higher.[5]

Since it is important to know whether there is any change in temperature at the walls, we vacuum-coated the inside of two flasks (3000 and 5000 ml) with platinum. Electrical contact was established at two points about 10 cm apart such that the resistance of the platinum film was about 15 Ω, and using this as one arm of a conventional resistance bridge, we could detect a change of between 0.1 and 0.2°C in the mean wall temperature. In the 3000 ml vessel, there was no detectable change in resistance either below or above the explosion limit. In the 5000 ml vessel, we could not detect any temperature rise in subcritical experiments; however, when an explosion occurred, there appeared to be a consistent temperature rise of about 0.25°C at the wall, but this is so little in excess of our noise level during the explosion that it may not be significant.[6] Thus, the validity of this assumption of constant wall temperature appears to be confirmed.

In summary, we have been unable to find any experimental reason for the surprising variation of the critical parameter δ_c for this explosion from vessel to vessel at constant temperature, or for the same vessel at different temperatures; these variations far exceed our experimental precision. There is one theoretical possibility we have not yet examined, however: we have used in the calculation of our δ values the normal equilibrium thermal conductivity of methyl isocyanide and methyl cyanide. But newly formed methyl cyanide molecules are rather far from being equilibrium molecules, for although their translational temperature will be the same as that of the reactant molecules from which they were formed, they have in excess of 62 kcal mol^{-1} of internal energy: the validity of using equilibrium thermal conductivities (for molecules having about 3 kcal mol^{-1} of internal energy) under these conditions needs to be considered.

[4]Except in the 1500 ml flask, where they were not measured.

[5]We are indebted to Dr. B. J. Tyler and a referee for pointing this out.

[6]In these experiments, an opaque platinum film was deposited fairly evenly over the spherical part of the vessel: since the explosion limit remained unchanged, we can also rule out any hypotheses involving radiation losses.

Appendix

The thermal conductivities of methyl cyanide and methyl isocyanide were measured using the hot-wire column technique described by Chen, Jody, and Saxena (8, 9). The column used was a Pyrex tube 1 m long ($2L$), 6.061 mm in internal diameter ($2b$) and with a platinum wire of 0.204 mm in diameter ($2a$) stretched along the axis: the outer wall was water-cooled and maintained at 12°C, and the experiment consisted of determining the electric power dissipation (Q_H) required to maintain the platinum wire at a series of known temperatures (T_H); thence the thermal conductivity at the wire temperature is (8)

$$\lambda = \frac{\ln (b/a)}{4\pi L} \frac{dQ_H}{dT_H}$$

The method is very simple to use, especially so in the region of temperatures of interest in explosion studies, and of acceptable accuracy (say, within 10%) with a minimum of sophistication in instrumentation: the apparatus was tested out on He, Ar, N_2, and CO_2 and gave results within about 5% of the best accepted values; further details are available in thesis form (10) and in the original publications (8, 9). Table A1 summarizes the results of these measurements which are probably accurate to within ±10%: our values are about 30% lower at 300°C than those estimated previously (1), and somewhat less temperature dependent; slow decomposition of methyl isocyanide at 400°C and above to give noncondensable gases causes the thermal conductivity to rise abruptly, so results are quoted only up to 350°C.

TABLE A1. Thermal conductivity of methyl isocyanide

T (°C)	200	250	300	350
λ (mW cm^{-1} deg^{-1})	0.17	0.22	0.26	0.30

Using this technique, the measured thermal conductivity values for methyl cyanide are indistinguishable from those for methyl isocyanide, as given in Table A1.

Partial tosylation of 1,5-anhydro-D-glucitol[1]

YÔTARO KONDO, KAZUYOSHI YABUUCHI, AND SHIGEHIRO HIRANO
Department of Agricultural Chemistry, Tottori University, Tottori 680, Japan

Received May 10, 1977

YÔTARO KONDO, KAZUYOSHI YABUUCHI, and SHIGEHIRO HIRANO. Can. J. Chem. **55**, 3820 (1977).

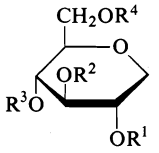
Dimolar tosylation of 1,5-anhydro-D-glucitol (**1**) in pyridine yielded the 2,6-di-*O*-tosylate (**6**) (35%) as the major product, along with the tetra-*O*-tosylate (**2**) (1%), the 3,4,6-tri-*O*- (**3**) (1%), 2,4,6-tri-*O*- (**4**) (8%), and 2,3,6-tri-*O*-tosylate (**5**) (6%), and the 3,6-di-*O*- (**7**) (4%) and 4,6-di-*O*-tosylate (**8**) (6%). The order of the relative reactivity of the hydroxyl groups in **1** towards tosyl chloride was predicted as 6-OH > 2-OH > 4-OH > 3-OH.

YÔTARO KONDO, KAZUYOSHI YABUUCHI et SHIGEHIRO HIRANO. Can. J. Chem. **55**, 3820 (1977).

La tosylation dimolaire de l'anhydro-1,5 D-glucitol (**1**) dans la pyridine conduit à un mélange contenant principalement le di-*O*-tosylate-2,6 (**6**) 35%, puis du tétra-*O*-tosylate (**2**) 1%, du tri-*O*-tosylate-3,4,6 (**3**) 1%, -2,4,6 (**4**) 8% et -2,3,6 (**5**) 6%, du di-*O*-tosylate-3,6 (**7**) 4% et -4,6 (**8**) 6%. L'ordre relatif de réactivité des groupements hydroxyles dans **1** vis-à-vis le chlorure de tosyle a été établi comme étant 6-OH > 2-OH > 4-OH > 3-OH.

[Traduit par le journal]

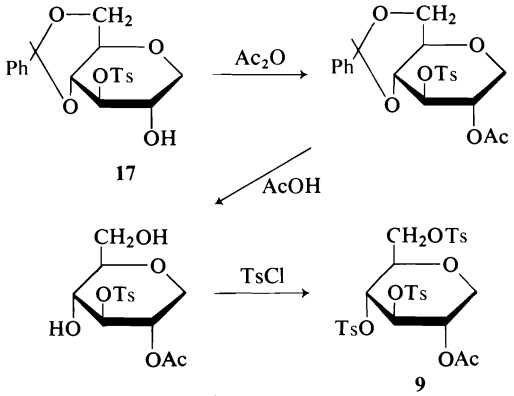
Systematic studies of selective sulfonylation of monosaccharides have been reported and the orientation of aglycon was found to greatly affect the reactivity of the ring hydroxyl groups (1–9). Selective sulfonylation of monosaccharides having no aglycon has received little attention. This communication describes dimolar tosylation of 1,5-anhydro-D-glucitol (**1**).



1 $R^1 = R^2 = R^3 = R^4 = H$
2 $R^1 = R^2 = R^3 = R^4 = Ts$
3 $R^1 = H, R^2 = R^3 = R^4 = Ts$
4 $R^1 = R^3 = R^4 = Ts, R^2 = H$
8 $R^1 = R^2 = H, R^3 = R^4 = Ts$
10 $R^1 = R^3 = R^4 = Ts, R^2 = Ac$
14 $R^1 = R^2 = Ac, R^3 = R^4 = Ts$

Treatment of **1** (10) with 2 mol equiv. of tosyl chloride in pyridine gave a mixture which was fractionated by column chromatography on silica gel to afford the tetra-*O*-tosylate **2** (1%), the 3,4,6-tri-*O*-tosylate (**3**) (1%), a mixture of the 2,4,6-tri-*O*- (**4**) (8%) and 2,3,6-tri-*O*-tosylate (**5**) (6%), and the 2,6-di-*O*- (**6**) (35%), 2,4-di-*O*- (**7**) (4%) and 2,3-di-*O*-tosylate (**8**) (6%). Tri-*O*-tosylates **4** and **5** could not be separated by column chromatography.

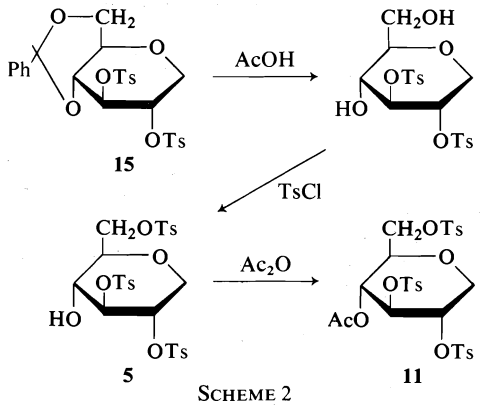
In order to determine the position of tosyl groups in the tri-*O*-tosylate **3** and a mixture of **4** and **5**, and in the di-*O*-tosylates **6**, **7**, and **8**, the respective compound was converted into the corresponding mono-*O*-acetyl-tri-*O*-tosyl derivatives **9** and a mixture of **10** and **11**, and di-*O*-acetyl-di-*O*-tosyl derivatives **12**, **13**, and **14**. Compound **9** was identical with 2-*O*-acetyl-1,5-anhydro-3,4,6-tri-*O*-tosyl-D-glucitol which was obtained by the sequential acetylation, debenzylidenation, and pertosylation of 1,5-anhy-



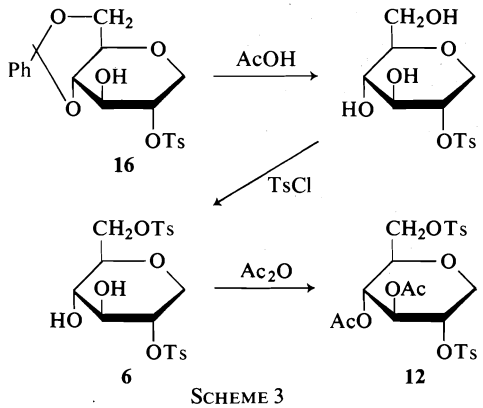
SCHEME 1

[1]Presented at the Annual Meeting of the Agricultural Chemical Society of Japan, April 1, 1977, Yokohama, Japan.

dro-4,6-*O*-benzylidene-3-*O*-tosyl-D-glucitol (**17**) (Scheme 1). Crystallization of the mixture of **10** and **11** gave 4-*O*-acetyl-1,5-anhydro-2,3,6-tri-*O*-tosyl-D-glucitol (**11**) which had physical constants in good agreement with those of the authentic sample prepared by successive debenzylidenation followed by preferential tosylation at the 6-OH group and acetylation of 1,5-anhydro-4,6-*O*-benzylidene-2,3-di-*O*-tosyl-D-glucitol (**15**) (11) (Scheme 2). The ^{1}Hmr spectrum of **11** showed the methyl proton of the acetoxyl group at τ 8.22. In the ^{1}Hmr spectrum of the



SCHEME 2

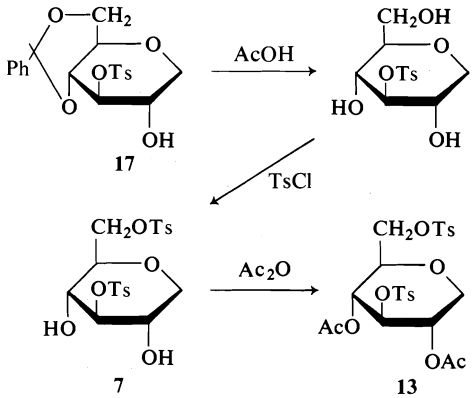


SCHEME 3

mixture of **10** and **11**, the signals of the methyl proton of the acetoxyl group appeared at τ 8.22 and 8.30 with relative proton intensities of 4:3. Therefore, the resonance at τ 8.30 was assigned to the acetyl-methyl proton signal of 3-*O*-acetyl-1,5-anhydro-2,4,6-tri-*O*-tosyl-D-glucitol (**10**). This indicates the ratio of **10** to **11** in the mixture to be 4:3.

The structures of **12** and **13** were determined as 3,4-di-*O*-acetyl-1,5-anhydro-2,6-di-*O*-tosyl-D-glucitol and 2,4-di-*O*-acetyl-1,5-anhydro-3,6-di-*O*-tosyl-D-glucitol by comparison of their physical properties with those of the authentic samples prepared from 1,5-anhydro-4,6-*O*-benzylidene-2-*O*-tosyl-D-glucitol (**16**) (12) and 1,5-anhydro-4,6-*O*-benzylidene-3-*O*-tosyl-D-glucitol (**17**), respectively, by sequential acetylation, debenzylidenation, 6-*O*-tosylation, and acetylation (Schemes 3 and 4). Accordingly, the remaining compound **14** must be the structure of 2,3-di-*O*-acetyl-1,5-anhydro-4,6-di-*O*-tosyl-D-glucitol.

In the dimolar tosylation of **1**, the preponderance of the 2,4,6-tri-*O*-tosylate **4** over **3** and **5** and that of the 2,6-di-*O*-tosylate **6** over **7** and **8** shows that the order of the relative reactivity of the hydroxyl groups in **1** is 6-OH > 2-OH > 4-OH > 3-OH.



SCHEME 4

In the sulfonylation of methyl α-D-glucopyranoside (5, 8) and methyl α-D-xylopyranoside (6), the relative reactivity order of the secondary hydroxyl groups was reported as 2-OH > 4-OH > 3-OH. The finding that the 2-OH groups are the most reactive of the ring hydroxyl groups is in agreement with the results of selective benzoylation (3, 9) of these compounds. Intramolecular hydrogen bonding between the 2-OH group and the glucosidic oxygen atom at C-1 has been invoked to rationalize the enhanced reactivity of the 2-OH group (3). In the sulfonylation of methyl β-D-glucopyranoside (5) and methyl 6-deoxy-β-D-glucopyranoside (7), the 4-OH groups are the most reactive of the secondary hydroxyl groups. The relative reactivity to sulfonylation of methyl β-D-xylopy-

ranoside (6) was in the order 4-OH > 3-OH > 2-OH. It is of interest to note that the 4-OH groups are the most reactive to sulfonylation of methyl β-D-glucopyranoside and methyl 6-deoxy-β-D-glucopyranoside since the 4-OH group in the latter is the least reactive to benzoylation (4). The lowest reactivity of the 4-OH group towards benzoyl chloride was interpreted (3, 4) as steric hindrance with the 5-benzoyloxymethyl (or 5-methyl) group. On the other hand, the greater reactivity to sulfonylation of the 4-OH group compared with the 3-OH group in methyl α- and β-D-glucopyranosides, methyl 6-deoxy-β-D-glucopyranoside, and **1** may be explained by the inductive effect (7) of the 5-tosyloxymethyl (or 5-methyl) group (sulfonylation at the primary hydroxyl group being assumed to occur first) or a hydrophobic interaction between the 5-tosyloxymethyl (or 5-methyl) group and the methylphenyl group of the incoming sulfonyl reagent. However, it is shown (7) that the tosyloxy group in the sugar ring has no substantial accelerating effect on the neighboring hydroxyl groups; the rate of tosylation is decelerated. It is noteworthy that the 4-OH group in methyl β-D-xylopyranoside and the 2-OH group in **1** are the most reactive of the secondary hydroxyl groups. The 2-OH group in **1** cannot take part in hydrogen bonding. This indicates that deoxygenation has an activating effect on a neighboring hydroxyl group.

From the results reported for sulfonylation of methyl α- and β-D-glucopyranosides and methyl 6-deoxy-β-D-glucopyranoside, it is clear that intramolecular hydrogen bonding is rather more important than the electronic effects to account for the difference in the reactivity of the secondary hydroxyl groups. The order of the reactivity of methyl α- and β-D-xylopyranosides to sulfonylation suggest that an accelerating effect of hydrogen bonding on the rate of sulfonylation is stronger than the stereochemical effect caused by the introduction of the deoxy group into C-5. The result in the present study on the sulfonylation of **1** indicates that this stereochemical factor is more important than the electronic effects.

Accordingly, the above argument suggests that the order of the factors governing the relative reactivity of the secondary hydroxyl groups to sulfonylation is intramolecular hydrogen bonding > stereochemical factors (whether or not hydroxyl groups are adjacent to deoxy groups, $—CH_2—$) > electronic effects. From this order it may be possible to predict the order of the relative reactivity of the secondary hydroxyl groups in methyl glycopyranosides with *gluco-* and *xylo*-configurations.

Experimental

Melting points were determined on a Yanagimoto micro hot-stage apparatus and are uncorrected. Optical rotations were measured with a Yanagimoto OR-50 polarimeter and ^{1}Hmr spectra were recorded on a Hitachi R-24 60 MHz instrument using chloroform-*d* with tetramethylsilane as an internal standard.

*Dimolar Tosylation of 1,5-Anhydro-D-glucitol (**1**)*

Tosyl chloride (2.555 g, 2.2 mol equiv.) was added portionwise to a solution of 1,5-anhydro-D-glucitol (10) (**1**, 1 g) in anhydrous pyridine (20 ml) at 0°C. The solution was kept at 0°C for 24 h and stirred at 5°C for 48 h, and then extracted with chloroform. The extract was washed with dilute sulfuric acid, saturated sodium bicarbonate, and water, and dried over Na_2SO_4. The residual syrup after evaporation of the solvent was subjected to a silica gel column (70–230 mesh, Merck). Elution with benzene–acetone (9:1 (v/v)) gave 1,5-anhydro-2,3,4,6-tetra-*O*-tosyl-D-glucitol (**2**, 34 mg, 0.7%), which was crystallized from chloroform, mp 212–213°C, $[\alpha]_D^{16}$ − 1.8° (*c* 4.4 in pyridine). *Anal.* calcd. for $C_{34}H_{36}O_{13}S_4$: C 52.29, H 4.66, S 16.42; found: C 52.11, H 4.38, S 16.13.

Benzene–acetone (4:1 (v/v)) eluted a mixture (541 mg, 14.1%) of 1,5-anhydro-2,4,6-tri-*O*-tosyl-D-glucitol (**4**) and 1,5-anhydro-2,3,6-tri-*O*-tosyl-D-glucitol (**5**), and 1,5-anhydro-3,4,6-tri-*O*-tosyl-D-glucitol (**3**, 32 mg, 0.8%). Benzene–acetone (2:1 (v/v)) eluted 1,5-anhydro-3,6-di-*O*-tosyl-D-glucitol (**7**, 124 mg, 3.6%). Benzene–acetone (1:1 (v/v)) eluted 1,5-anhydro-2,6-di-*O*-tosyl-D-glucitol (**6**, 1.168 g, 34.5%) and 1,5-anhydro-4,6-di-*O*-tosyl-D-glucitol (**8**, 197 mg, 5.8%). The above syrupy tosylates could not be crystallized.

*1,5-Anhydro-4,6-O-benzylidene-D-glucitol 2-O-Tosylate (**16**) and 3-O-Tosylate (**17**)*

1,5-Anhydro-4,6-*O*-benzylidene-D-glucitol (11) (965 mg) was partially tosylated with tosyl chloride (869 mg, 1.2 mol equiv.) in pyridine (8 ml) according to the method of Newth (12). Usual work-up afforded the crystalline residue which was chromatographed on silicic acid (100 mesh, Mallinkrodt) and eluted with benzene – ethyl acetate (9:1 (v/v)) to give 1,5-anhydro-4,6-*O*-benzylidene-2,3-di-*O*-tosyl-D-glucitol (**15**, 202 mg, 9.4%), mp 193–195°C, $[\alpha]_D^{22}$ − 40.8° (*c* 1.0 in chloroform) (lit. (11) mp 185–189°C, $[\alpha]_D^{20}$ − 48.5° (*c* 1.5 in chloroform)); ^{1}Hmr data τ 4.78 (s. 1H, ϕCH), 5.16 (t, 1H, $J_{2,3} = J_{3,4} =$ 8.5 Hz, H-3), 7.58, 7.78 (2s, 6H, $CH_3\phi$). Elution with benzene – ethyl acetate (4:1 (v/v)) gave 1,5-anhydro-4,6-*O*-benzylidene-2-*O*-tosyl-D-glucitol (**16**, 637 mg, 41.0%), mp 177–178°C, $[\alpha]_D^{24}$ − 15.8° (*c* 1.4 in chloroform) (lit. (12) mp 174–175°C); ^{1}Hmr data τ 4.52 (s, 1H, ϕCH), 7.23 (b s, 1H, OH exchanges in D_2O), 7.53 (s, 3H, $CH_3\phi$). Elution with benzene – ethyl acetate (2:1 (v/v)) gave 1,5-anhydro-4,6-*O*-benzylidene-3-*O*-tosyl-D-glucitol (**17**,

106 mg, 6.8%), mp 145–146°C, $[\alpha]_D^{22}$ − 42.3° (*c* 0.7 in chloroform); ^{1}Hmr data τ 4.45 (s, 1H, ϕCH), 6.53 (b s, 1H, OH exchanges in D_2O), 7.61 (s, 3H, $CH_3\phi$). *Anal.* calcd. for $C_{20}H_{22}O_7S$: C 59.10, H 5.46; found: C 58.71, H 5.48. Finally the starting material (247 mg, 25.6%) was eluted with ethyl acetate.

*2-O-Acetyl-1,5-anhydro-3,4,6-tri-O-tosyl-D-glucitol (**9**)*

Procedure A

Acetic anhydride (1 ml) was added to a solution of compound **3** (31 mg) in pyridine (1 ml) and the mixture was stirred overnight at room temperature. The reaction mixture was extracted with chloroform and the extract was washed with water. The residual syrup after evaporation of the solvent was crystallized from ethanol to give the title compound (33 mg, 96.7%), mp 181–182°C, $[\alpha]_D^{20}$ + 27.0° (*c* 0.2 in chloroform); ^{1}Hmr data τ 7.59 (s, 9H, $CH_3\phi$), 8.18 (s, 3H, CH_3CO). *Anal.* calcd. for $C_{29}H_{32}O_{12}S_3$: C 52.08, H 4.83, S 14.38; found: C 52.38, H 4.74, S 14.42.

Procedure B

1,5-Anhydro-4,6-*O*-benzylidene-3-*O*-tosyl-D-glucitol (**17**, 115 mg) was acetylated with acetic anhydride (1 ml) in pyridine (2 ml) in the usual way. The reaction mixture was extracted with chloroform, and the extract was washed with water, dried over Na_2SO_4, and concentrated. The residual syrup was dissolved in acetic acid – water (4:1 (v/v), 5 ml), and the solution was heated at 80°C for 1 h, and repeatedly evaporated after addition of water to afford a syrup. The debenzylidenated product was treated with tosyl chloride (650 mg) in pyridine (2 ml) at 40°C for 4 days. The reaction mixture was worked-up in the usual way and the resulting residue was recrystallized from ethanol to yield compound **3** (113 mg, 59.2%) which was identical with the substance prepared by procedure A.

*4-O-Acetyl-1,5-anhydro-2,3,6-tri-O-tosyl-D-glucitol (**11**)*

Procedure A

Acetylation of a mixture of **4** and **5** (540 mg) with acetic anhydride (3 ml) in pyridine (3 ml) in the usual way, followed by normal work-up, gave a syrup (522 mg, 90.6%) which on crystallization from ethanol yielded the title compound (200 mg, 34.7%), mp 132–134°C, $[\alpha]_D^{20}$ + 3.1° (*c* 1.0 in chloroform); ir data ν_{max} (KBr) 3450 cm^{-1} (hydrate); ^{1}Hmr data τ 7.55 (s, 9H, $CH_3\phi$), 8.22 (s, 3H, CH_3CO). *Anal.* calcd. for $C_{29}H_{32}O_{12}S_3 \cdot H_2O$: C 50.71, H 5.00, S 14.00; found: C 50.58, H 4.93, S 13.88.

Procedure B

A solution of 1,5-anhydro-4,6-*O*-benzylidene-2,3-di-*O*-tosyl-D-glucitol (**15**, 100 mg) in acetic acid – water (4:1 (v/v), 3 ml) was heated at 80°C for 1 h. The residual syrup after evaporation was treated with tosyl chloride (33 mg, 1 mol equiv.) in pyridine (2 ml) at 0°C. The mixture was stirred at the same temperature for 1 h, at room temperature for 1 h, and then at 40°C for 1.5 h. Acetic anhydride (1 ml) was added to the solution which was stirred overnight. The reaction mixture was extracted and purified as described above to give a syrup. Crystallization from ethanol yielded compound **11** (95 mg, 79.0%) which was identical with the substance prepared by procedure A.

*3,4-Di-O-acetyl-1,5-anhydro-2,6-di-O-tosyl-D-glucitol (**12**)*

Procedure A

Compound **6** (900 mg) was treated with acetic anhydride (5 ml) in pyridine (6 ml) overnight. Usual work-up followed by crystallization from ethanol gave the title compound (942 mg, 89.0%), mp 149–150°C, $[\alpha]_D^{20}$ +68.3° (*c* 1.4 in chloroform); ^{1}Hmr data τ 7.57 (s, 6H, $CH_3\phi$), 8.08, 8.27 (2s, 6H, CH_3CO). *Anal.* calcd. for $C_{24}H_{28}O_{11}S_2$: C 51.78, H 5.08, S 11.52; found: C 51.91, H 4.93, S 11.30.

Procedure B

1,5-Anhydro-4,6-*O*-benzylidene-2-*O*-tosyl-D-glucitol (**16**, 343 mg) was debenzylidenated with acetic acid – water (4:1 (v/v), 15 ml) in the usual way. The resulting syrup was tosylated with tosyl chloride (155 mg, 1 mol equiv.), and the reaction mixture was extracted with chloroform and the extract was washed with water, and dried over Na_2SO_4. Evaporation and acetylation with acetic anhydride (2 ml) in pyridine (3 ml) afforded compound **12** (305 mg, 59.8%) which was identical with the substance prepared by procedure A.

*2,4-Di-O-acetyl-1,5-anhydro-3,6-di-O-tosyl-D-glucitol (**13**)*

Procedure A

Acetylation of compound **7** (95 mg) with acetic anhydride (2 ml) in pyridine (2 ml) gave the title compound (109 mg, 97.3%), mp 167–168°C, $[\alpha]_D^{20}$ + 38.8° (*c* 1.1. in chloroform); ^{1}Hmr data τ 7.58 (s, 6H, $CH_3\phi$), 8.06, 8.15 (2s, 6H, CH_3CO). *Anal.* calcd. for $C_{24}H_{28}O_{11}S_2$: C 51.78, H 5.08, S 11.52; found: C 51.89, H 5.04, S 11.61.

Procedure B

1,5-Anhydro-4,6-*O*-benzylidene-3-*O*-tosyl-D-glucitol (**17**, 93 mg) was debenzylidenated with acetic acid – water (4:1 (v/v), 4 ml) and treated with tosyl chloride (44 mg, 1 mol equiv.) in pyridine (2 ml) at 0°C. The solution was stirred at 0°C for 1 h and at room temperature for 4 h, extracted with chloroform, and the extract was concentrated. The residual syrup was treated with acetic anhydride (1 ml) in pyridine (2 ml) to give compound **13** (90 mg, 65.0%) which was identical with the substance prepared by procedure A.

*2,3-Di-O-acetyl-1,5-anhydro-4,6-di-O-tosyl-D-glucitol (**14**)*

Compound **8** (196 mg) was treated with acetic anhydride (2 ml) in pyridine (2 ml) overnight. The reaction mixture was worked-up in the usual way to yield the title compound (219 mg, 94.8%) as a syrup which could not be crystallized, $[\alpha]_D^{20}$ + 20.2° (*c* 1.0 in chloroform); ir data ν_{max}(film) 3500 cm^{-1} (hydrate); ^{1}Hmr data τ 7.60 (s, 6H, $CH_3\phi$), 8.08, 8.12 (2s, 6H, CH_3CO). *Anal.* calcd. for $C_{24}H_{28}O_{11}S_2 \cdot 2H_2O$: C 48.63, H 5.45, S 10.82; found: C 48.52, H 5.21, S 10.45.

Polyol–Water interactions. Apparent molal heat capacities and volumes of aqueous polyol solutions

GIUSEPPA DIPAOLA[1] AND BERNARD BELLEAU[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H2A 2K6

Received April 28, 1977

GIUSEPPA DIPAOLA and BERNARD BELLEAU. Can. J. Chem. **55**, 3825 (1977).

Volumetric specific heats (25°C) and densities (24°C) were measured with a flow microcalorimeter and flow densimeter for 12 polyols in water (0.05 to 2 *m*), and for NaCl and *n*-Bu_4NBr in 1 *m* aqueous alditol solutions. The infinite dilution properties (ϕ_c^0 and ϕ_v^0) of the polyols show specificities in polyol–water interactions which are discussed in terms of the compatibility of the polyol stereochemistry and the existing water environment. The derived heat capacities and volumes of transfer of hydrophobic and hydrophilic probes to aqueous solutions of homologous polyols suggest that structural interactions are reduced in these systems as compared to pure water.

GIUSEPPA DIPAOLA et BERNARD BELLEAU. Can. J. Chem. **55**, 3825 (1977).

On mesure les chaleurs spécifiques volumétriques (25°C) et densités (24°C) à l'aide d'un microcalorimètre et densimètre dynamiques de 12 polyols dans l'eau (0.05 à 2 *m*), et du NaCl et *n*-Bu_4Br dans des solutions aqueuses d'alditol 1 *M*. Les propriétés de dilution infinie (ϕ_c^0 et ϕ_v^0) des polyols démontrent des spécificités pour les interactions polyol–eau qui sont interprétées en termes de compatibilité stéréochimique du polyol et de l'environnement aqueux existant. Les capacités calorifiques et volumiques dérivées du transfert de sondes hydrophobiques et hydrophiliques aux solutions aqueuses des polyols homologues suggèrent que les interactions structurales sont réduites dans ces systèmes en comparaison avec l'eau pure.

[Traduit par le journal]

Introduction

In a previous publication (1) we reported results of a study of apparent molal volumes and heat capacities of various 'structural' probes in aqueous glycerol solutions. We now wish to describe the results of similar studies for the case of alditols and related polyols in aqueous solution (2) in order to determine whether there exists a correlation between polyol–water interactions and the stabilizing effects of polyols on biological systems (1).

Thermodynamical studies giving information on the infinite dilution properties of hydrophilic solutes have been limited mainly to some measurements of heats of solution (3–5). Recently, standard apparent molal heat capacities were obtained for a number of low molecular weight alcohols and polyols (6). A number of volumetric studies of solutions of monosaccharides have also been reported (4, 6, 7).

[1]Holder of a Centennial Predoctoral Scholarship of the National Research Council of Canada; present address: Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A1.

Experimental

Heat capacities were measured with a flow microcalorimeter capable of detecting differences between the volumetric specific heat of a solution and that of a reference solvent to $\pm 3 \times 10^{-5}$ J K^{-1} cm^{-3}. Densities were determined with a flow digital densimeter sensitive to $\pm 3 \times 10^{-6}$ g cm^{-3}. Details of the experimental procedure have been published previously (1). Apparent molal quantities (ϕ_c, ϕ_v) were calculated in the usual way (1).

Reagent grade polyhydric alcohols were used without further purification: glycerol (Fisher Certified Spectranalyzed); ethylene glycol and 1,2-propanediol (Matheson, Coleman and Bell, Chromatoquality); 1,3-propanediol (Eastman Kodak Reagents); D-arabitol, D-xylitol, ribitol (Nutritional Biochemicals); D-mannitol, D-sorbitol, *myo*-inositol, sucrose (Fisher Certified Reagents); and *meso*-erythritol (Aldrich).

Results

Binary Systems

Relative densities (24°C) and volumetric heat capacities were measured for several alditols and other related polyhydroxy compounds in water in the concentration range of 0.05 to 2 *m*.[3]

[3]Complete sets of tabular data for d_0/d, σ/σ_0, ϕ_v, and ϕ_c are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

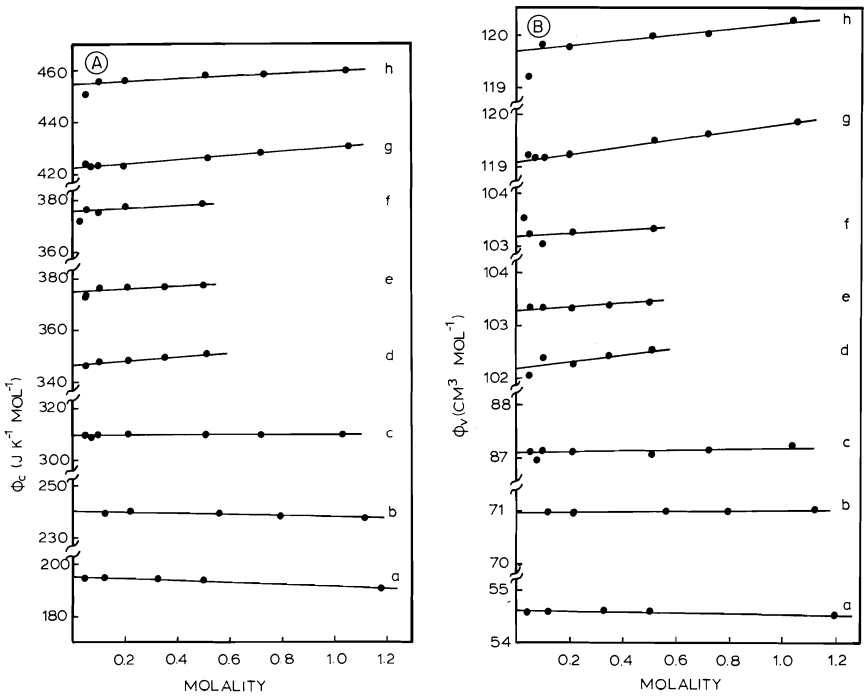

FIG. 1. Concentration dependence of the apparent molal quantities of the alditols [CH_2OH-$(CHOH)_nCH_2OH$] in water: (*a*) ethylene glycol; (*b*) glycerol; (*c*) *meso*-erythritol; (*d*) D-xylitol; (*e*) D-arabitol; (*f*) ribitol; (*g*) D-sorbitol; (*h*) D-mannitol. (*A*) ϕ_c at 25°C. (*B*) ϕ_v at 24°C. This temperature was selected because of the experimental set-up. The error introduced by taking the density ratios at 24 rather than 25°C is vanishingly small.

The derived ϕ_c and ϕ_v values for the alditols exhibit a linear concentration dependence (Fig. 1). These results were fitted by linear regression analysis to equations of the form

$$[1] \qquad \phi_x = \phi_x^0 + B_x m$$

where m represents the molal concentration of the polyol, and ϕ_x represents the appropriate apparent molal quantity. The resulting excess coefficients (B_c, B_v) are collected in Table 1, which also includes the limiting apparent molal quantities (ϕ_c^0, ϕ_v^0) for the 12 polyols studied. The estimated uncertainties on ϕ_v^0 and ϕ_c^0 are ± 0.1 cm^3 mol^{-1} and $\pm(1\text{–}2)$ J K^{-1} mol^{-1}. For most of the excess coefficients, only the magnitude is significant, owing to the limited number of data points (5–9 points were obtained in duplicate in the concentration range quoted for each polyol). A comparison of ϕ_c^0 and ϕ_v^0 data with earlier results (from the literature) shows excellent agreement for those few cases where such measurements have been previously undertaken (Table 1).

The present results reveal several interesting features.

(*1*) The replacement of a hydrogen atom (C—H) by an —OH group (for example, compare 1,3-propanediol and glycerol results) sharply reduces the apparent molal heat capacity, but only slightly affects the volume. This is in agreement with the results of Jolicoeur and Lacroix (6) and Franks *et al.* (4, 8).

(*2*) The limiting thermodynamic properties show significant differences between stereoisomeric molecules. For example, the ϕ_c^0 and ϕ_v^0 values for sorbitol are 32 J K^{-1} mol^{-1} and 0.55 cm^3 mol^{-1} lower than the corresponding values for mannitol. Similar trends in the volumetric properties of this stereoisomeric pair have also been observed by Franks *et al.* at 5°C (4).

Such specificity implies non-additivity of group contributions to the overall measured property. One must therefore exercise caution

TABLE 1. Apparent molal volumes and heat capacities of various polyols in water at 24°C and 25°C respectively

Polyol	ϕ_v^0 (cm^3 mol^{-1})	B_v	ϕ_c^0 (J K^{-1} mol^{-1})	B_c	Concentration range (m)
Ethylene glycol[a]	54.60	−0.06	195.0	−3.4	0.03–3.05
1,2-Propanediol	75.77	−0.01	312.9	−4.7	0.06–5.14
1,3-Propanediol	71.91	−0.27	268.6	−8.3	0.03–1.08
Glycerol	70.95	0.05	240.2	−1.8	0.12–4.49
meso-Erythritol	87.10	0.13	310.0	−0.03	0.04–1.04
D-Xylitol	102.14	0.76	346.4	8.8	0.05–0.51
D-Arabitol	103.31	0.21	374.6	5.6	0.05–0.50
L-Arabitol[b]	103.33	(0.58)	372.8	(11.5)	0.09–0.52
Ribitol	103.11	0.45	375.6	6.8	0.04–0.51
D-Mannitol	119.71	0.52	455.4	4.7	0.09–1.05
D-Sorbitol	119.16	0.60	423.1	6.9	0.05–2.10
Sucrose[a]	211.82	0.92	649.4	13.1	0.05–1.02

[a]Literature values of ϕ_c^0 data for aqueous polyols at 25°C: ethylene glycol 191.9 J K^{-1} mol^{-1} (6); $B_c = -5.5$. Literature values of ϕ_v^0 data at 25°C: for ethylene glycol 54.63 cm^3 mol^{-1} (6); $B_v = -0.08$. Sucrose 211.124 ml mol^{-1} (7); $B_v = 1.997$, sucrose 211.49 ml mol^{-1} (see reference cited in ref. 7).
[b]Data shown in parentheses are considered unreliable due to the limited number of points investigated (3 points).

when using group contributions for predicting solution behavior.

(*3*) There is no apparent difference in the limiting solution behavior of D- and L-configurations of the alditols, e.g. identical results (within experimental uncertainty for D- and L-arabitol.

(*4*) Both the B_c and B_v coefficients exhibit the same trends, i.e. negative signs which reach zero in the case of glycerol or *meso*-erythritol and become increasingly positive for the higher molecular weight polyols.[4] Monohydric alcohols and diols have negative B_v coefficients which decrease as the size of the hydrocarbon group increases (6). The corresponding B_c coefficient for α,ω-alcohols becomes positive with increasing chain length (6). It therefore appears difficult to draw any definite conclusions about the nature of polyol–polyol interactions from the excess coefficients.

Ternary Systems

Apparent molal volumes and heat capacities of transfer of 0.1 m NaCl and 0.1 m n-Bu_4NBr to 1 m aqueous alditol solutions are summarized in Table 2. The heat capacities of transfer are negative for the hydrophobic 'structure-maker' n-Bu_4NBr, and positive for NaCl. The volumes of transfer are positive, except in the case of the transfer of n-Bu_4NBr to glycerol and erythritol solutions. The electrostrictive structure-breaker, NaCl, appears to be more effective (as judged by the absolute magnitude of the transfer functions) than n-Bu_4NBr in differentiating the structural effects of stereoisomeric molecules.[5]

Discussion

Binary Systems

The polyhydroxy compounds studied behave ideally, i.e. the apparent molal quantities in water exhibit only a marginal concentration dependence (0.05–2 m), indicating the absence of any marked solute–solute interactions (no long-range interactions) in these systems.

It is interesting to examine a plot of the standard apparent molal quantities vs. the number of carbon atoms of the alditols (general formula $CH_2OH(CHOH)_nCH_2OH$, where $n = 0$ to 4) (Fig. 1). The experimental points for glycerol, *meso*-erythritol, arabitol, ribitol, and mannitol fall on a straight line (linear correlation coefficient 0.99). However, xylitol and sorbitol show marked negative deviations from such a line;

[4]It is interesting to note that ΔH_s also changes sign at the same crossover point, i.e. lower homologs show exothermic behavior; the higher molecular weight polyols show endothermic behavior (3–5).

[5]Although the dielectric constant of glycerol–water mixtures is similar to that of water, the difference in dipole moments could be significant in ion–solvent interactions with the smaller ions. This could be a possible reason for the better discrimination of NaCl as compared to n-Bu_4NBr towards various polyols (C. Jolicoeur, personal communication).

TABLE 2. Apparent molal volumes (24°C) and heat capacities (25°C) of transfer of 0.1 *m* NaCl and *n*-Bu_4NBr from water to 1 *m* aqueous alditol solutions[a]

Solvent	NaCl		*n*-Bu_4NBr	
	$\Delta\phi_{c\ tr}$ ($J\ K^{-1}\ mol^{-1}$)	$\Delta\phi_{v\ tr}$ ($cm^3\ mol^{-1}$)	$\Delta\phi_{c\ tr}$ ($J\ K^{-1}\ mol^{-1}$)	$\Delta\phi_{v\ tr}$ ($cm^3\ mol^{-1}$)
Glycerol	10	0.5	−50	−0.55
meso-Erythritol	8	0.31	−53	−0.74
D-Arabitol	20	1.10	−47	−0.02
Ribitol	18	1.34	−44	−0.15
D-Xylitol	27	1.65	−45	0.72
D-Mannitol	13	−0.01	−53	0.04
D-Sorbitol	41	3.34	−50	0.65

[a]The estimated uncertainties on $\Delta\phi_{c\ tr}$ and $\Delta\phi_{v\ tr}$ are $\pm 2\ J\ K^{-1}\ mol^{-1}$ and $\pm 0.15\ cm^3\ mol^{-1}$. Salt concentrations are expressed on the aquamolality concentration scale. Transfer functions are defined as $\Delta\phi_{x\ tr} = \phi_{x(soln)} - \phi_{x(H_2O)}$, where ϕ_x represents the appropriate molal quantity at a specific concentration.

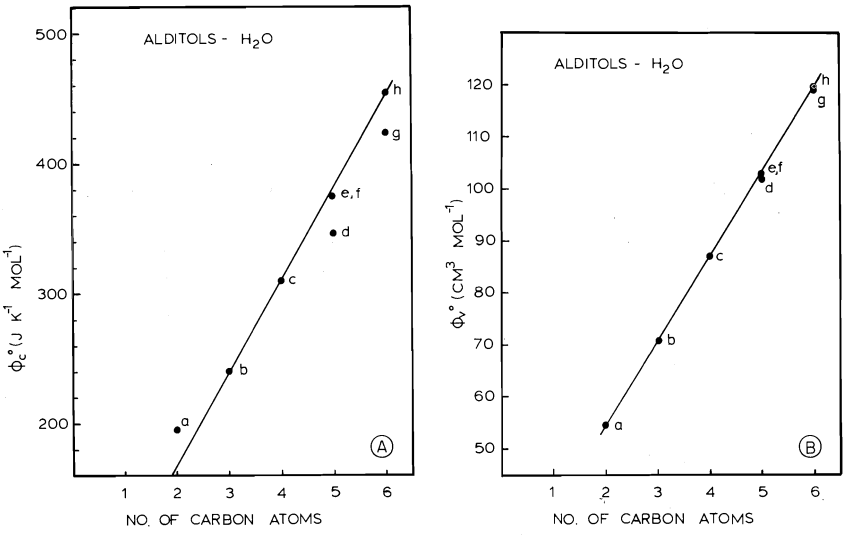

FIG. 2. Standard apparent molal quantities of the alditols in water: (*a*) ethylene glycol; (*b*) glycerol; (*c*) *meso*-erythritol; (*d*) D-xylitol; (*e*) D-arabitol; (*f*) ribitol; (*g*) D-sorbitol; (*h*) D-mannitol. (*A*) ϕ_c^0 at 25°C. (*B*) ϕ_v^0 at 24°C. This temperature was selected because of the experimental set-up. The error introduced by taking the density ratios at 24 rather than 25°C is vanishingly small.

conversely ethylene glycol shows a marked positive deviation from the line.

The present results can be explained in terms of the adaptability of the particular alditol molecule to its water environment. A consideration of alditol (solution) stereochemistry may be the key to a possible explanation. Nuclear magnetic resonance studies have shown that the most stable conformation of an acyclic polyhydric alcohol in solution is a planar, zig-zag arrangement of the carbon chain (9, 10), in which the O. . .O separation corresponding to C_n—O, $C_{(n+2)}$—O bonds is 2.50 Å (9, 11). If any 1–3 (OH—OH) unfavorable non-bonded interactions exist in the planar zig-zag form, then the molecule assumes a bent or 'sickle' conformation which is generated from the zig-zag form through a 120° rotation about an internal C—C bond (12–15). The polyols that fall on the line (Fig. 2) exist in the planar zig-zag conformation,[6]

[6]Ribitol seems to be an exception. Although it exists in the bent conformation (12–15), it appears to fall on the line. However, a careful examination of the data reveals that the numerical values for ribitol are considerably lower than those for arabitol, even if this difference is sometimes within the limit of experimental uncertainty.

whereas the others would assume the bent conformation. An excellent correlation thus exists between differences in the solution conformation of the alditols, and their limiting thermodynamic properties (ϕ_c^0, ϕ_v^0).

The lower standard apparent molal heat capacities of sorbitol and xylitol, as compared to the values for mannitol and sorbitol, suggest that sorbitol and xylitol are relatively more disruptive of the solvent structure than the corresponding stereoisomers.[7] Wilson (16) has reached the same conclusion from studies of heats of transfer of NaCl to the aqueous hexitols.

The steric discrimination effects, and the structure-altering characteristics shown by the polyols in water may be understood in terms of an observation made by Warner (17). If a hypothetical alcohol molecule could adopt a conformation in which the projected O—O distances were approximately 4.8 Å apart (corresponding to the second nearest neighbor oxygen distance in water), then the solvent would experience a minimum disturbance. However, if the polyol has negligible hydrophobic character, and if the orientation of the hydroxyl groups on the carbon chains is unable to assume a conformation completely compatible with the solvent, then the polyol would act as a 'structure-breaker'. The amount of structure-breaking would be determined by the compatibility of the polyol conformation with the solvent structure.

Studies supporting the present proposals include spectroscopic (7, 18) and thermodynamic measurements (7, 19) on the mutarotation equilibria of sugars, and volumetric studies (7, 20) on solutions of monosaccharides.

The present results are in accord with a specific hydration model (18) in which the structural emphasis is placed not only on the potential solute hydration sites, but also on their relative conformations.

Ternary Systems

Since the dielectric properties of dilute polyol–water solutions (4) do not differ greatly from those of water (21), transfer functions can be used to obtain information on structural hydration interactions. The heat capacities of transfer of NaCl and *n*-Bu_4NBr (Table 2) suggest that there is a decrease in structural order in solutions of the higher molecular weight polyols. The apparent molal volumes of transfer are consistent with the explanation centered on structural compatibility between glycerol and water (1), and the increasing incompatibility of the higher homologs (because of their greater rotational flexibility) and water. The anomaly in the sign of $\Delta\phi_{v\ tr}$ observed for transfers of hydrophobic probes to aqueous glycerol (1) disappears as the structural compatibility decreases. This is illustrated by the positive volumes of transfer of *n*-Bu_4NBr to aqueous solutions of the pentitols and hexitols (Table 2).

The results show that structural hydration effects for a homologous series of polyols in water are not too different from what was previously observed with aqueous glycerol systems (1). This work therefore further substantiates the hypothesis that an effect other than a simple alteration of water structure would be implicated in the stabilizing effect of polyols on biological macromolecules (i.e. proteins).

[7]The interpretation is based on structural hydration-interaction arguments.

Received June 6, 1977

IAN A. OXTON, T. STANLEY CAMERON, OSVALD KNOP, and ARCHIBALD W. MCCULLOCH. Can. J. Chem. **55**, 3831 (1977).

The ir spectrum of the isotopically isolated NH_3D^+ ion was used to deduce the possible site symmetries of the NH_4^+ ion in ammonium benzoate, NH_4PhCOO, and ammonium hydrogen bisbenzoate, $NH_4H(PhCOO)_2$. The NH_4^+ ion in both crystals is strongly hydrogen-bonded, one of the two isotopically isolated ND frequencies in ammonium benzoate being the lowest such frequency reported to date. The site symmetry C_2 of NH_4^+ in $NH_4H(PhCOO)_2$ has been confirmed by determining the crystal structure of this compound. The O···H···O bond in the dibenzoate ion, $(PhCOO\cdots H\cdots OOCPh)^-$, is short, 2.46(1) Å, and probably symmetric.

IAN A. OXTON, T. STANLEY CAMERON, OSVALD KNOP et ARCHIBALD W. MCCULLOCH. Can. J. Chem. **55**, 3831 (1977).

On a utilisé le spectre ir du NH_3D^+ isolé isotopiquement pour déduire les symétries de site possibles de l'ion NH_4^+ dans le benzoate d'ammonium, NH_4PhCOO, et dans le bisbenzoate d'ammonium et d'hydrogène, $NH_4H(PhCOO)_2$. L'ion NH_4^+ dans les deux cristaux est fortement lié par des ponts hydrogènes, et une des deux fréquences ND isotopiquement isolée dans le benzoate d'ammonium est la plus basse fréquence de ce type rapportée à date. La symétrie de site C_2 du NH_4^+ dans le $NH_4H(PhCOO)_2$ est confirmée par une détermination de la structure cristalline de ce composé. Le lien O···H···O dans l'ion dibenzoate $(PhCOO\cdots H\cdots OOCPh)^-$ est court, 2.46(1) Å, et probablement symétrique.

[Traduit par le journal]

The original aim of this investigation was to deduce the symmetry of the ammonium ion(s) in ammonium benzoate (AB), a compound of unknown crystal structure, using the dilute NH_3D^+ ion as an ir spectroscopic probe (1). This method has given correct results when applied to some structurally well-characterized ammonium salts (2), and we now wished to show that a prediction of the site symmetry of an ammonium ion can be made in a complete absence of structural information.

For compounds that are recoverable without change from aqueous solution, recrystallization from water containing 1–2% D_2O is the standard method of preparing suitable material. However, it was found that the crystals obtained from a hot aqueous solution of AB on cooling were not AB but ammonium hydrogen bisbenzoate (AHB), $NH_4H(PhCOO)_2$, or a mixture of AHB and hydrated AB. A closer investigation showed that under various conditions the products of recrystallization from aqueous media, including aqueous ammonia, might be AHB, AB, $AB\cdot H_2O$, or mixtures of these. The monohydrate has not been described previously, but hydrates of the alkali salts, $PhCOOLi\cdot H_2O$, $PhCOONa\cdot H_2O$, and $PhCOOK\cdot 3H_2O$, as well as $PhCOONH_4\cdot 1.5$-MeOH have been reported (3).

Very little information is available in the literature on the properties of AHB (cf. ref. 3), but salts of the type $K^+(XHX)^-$ (X = carboxylate ion) have been the subject of a number of studies (4–8; data compiled by J. C. Speakman in Table 5-4 of ref. 9), with much of the discussion centering on the nature of the X···H···X hydrogen bond. We therefore took advantage of the availability of AHB to make a prediction of the NH_4^+ site symmetry in this compound as well as in AB, and to verify the prediction from a determination of the crystal structure of AHB, with a view to providing, in addition, what information might be obtainable from the X-ray study about the O···H···O bond.

Experimental

The ammonium benzoate used in this work was from two sources: Mallinckrodt and Eastman. One supply was 25 years old and appeared to consist entirely of AHB.

[1]NRCC No. 16209.

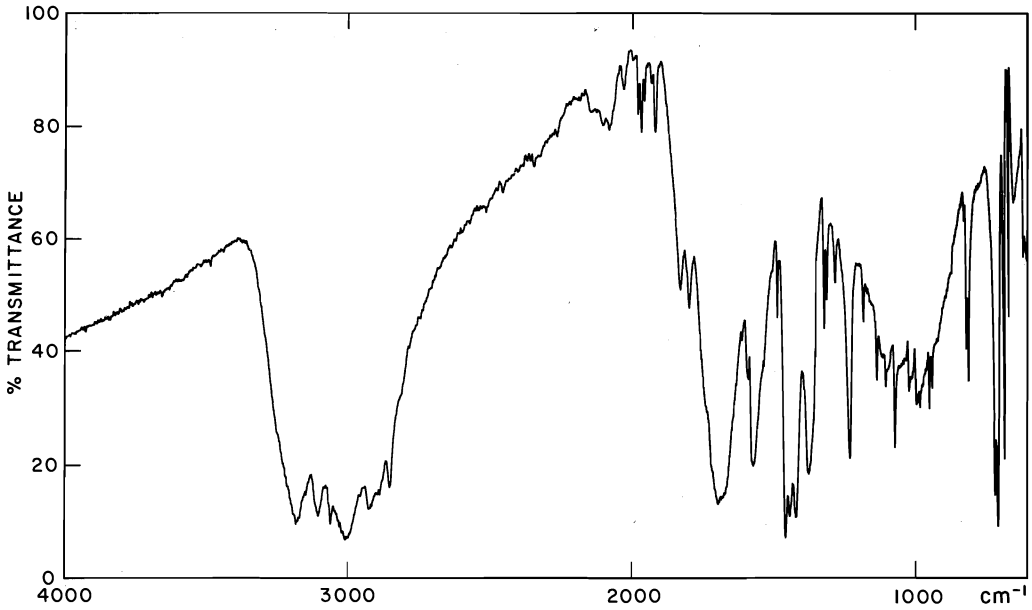

FIG. 1. Infrared spectrum of ammonium hydrogen bisbenzoate (AHB) at 77 K.

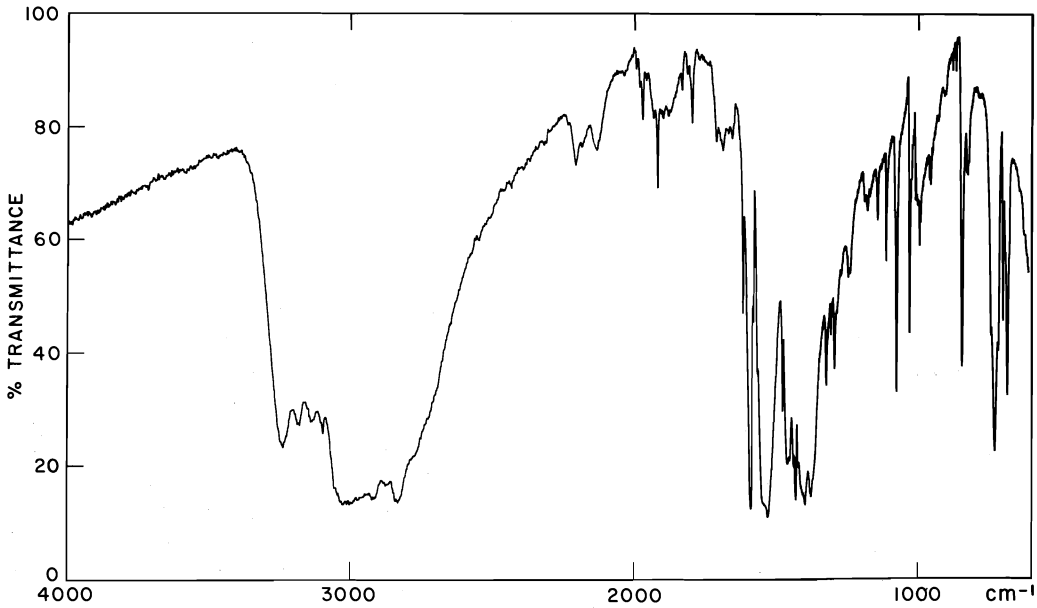

FIG. 2. Infrared spectrum of ammonium benzoate (AB) at 77 K.

The solubility of AB appeared to increase appreciably on heating, but it is not clear whether this is due to an intrinsic increase in the solubility of AB or to partial or complete conversion to AHB. Recrystallization of the fresh supply of commercial AB from hot aqueous solution usually resulted in a mixture of AHB and AB, the latter frequently hydrated; the proportion of AHB increased with the period of heating. Recrystallization of material from either source from concentrated ammonia solution produced AB alone (see below). Samples of the salts containing 1% D were prepared in a similar manner with the addition of an appropriate quantity of D_2O to the solvent.

Infrared spectra of Nujol and Fluorolube mulls were recorded with a Perkin-Elmer model 180 spectrophotometer fitted with a variable-temperature cryostat. No visible changes in the spectra accompanied cooling of the sample from room temperature to liquid-nitrogen temperature (Figs. 1 and 2) other than band sharpening and small frequency shifts. Vibrational frequencies are accurate to ± 1.0 cm^{-1}.

The ^{1}H nmr spectra were recorded at a concentration of 65 mg per 0.5 g of anhydrous dimethylsulfoxide-d_6, using a Varian A-60A spectrometer and Me_4Si as internal standard.

The crystal data of AHB are as follows:

$C_{14}H_{15}O_4N$ fw = 261.28
Monoclinic, $B2/b$, a = 29.301(8), b = 11.439(3), c = 3.901(1) Å, γ = 94.93(1)°, V = 1302 Å^3, ρ_o = 1.298 (flotation), Z = 4, ρ_c = 1.332 (18 ± 2°C); CuKα_1, λ = 1.54051 Å (carbon monochromator), μ = 7.73. $F(000)$ = 552 e.

Because of the high vapour pressure of AHB the single crystal that was used for the intensity measurements was sealed inside two concentric Lindemann-glass capillary tubes.[2] A Picker FACS 1 four-circle diffractometer was used to determine the unit-cell dimensions, from 12 general reflections with 2θ in the range of 50–60°, and to measure (ω–2θ scan) the intensities of 296 independent reflections (26% of those observable) with $I > 3\sigma$ and 2θ values between 4 and 120°. The minimum base width was 3.5°. Three standard reflections were measured every 60 reflections. The intensities of these three reflections decreased steadily throughout the data collection but could be adjusted to a standard scale from a least-squares fit (σ = 0.032) to a first-order decay; from the counting statistics the esd of these standard reflections was 2.2%. The data were reduced to $|F_o|$ by the routine procedure. No absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from ref. 10. Fifty reflections with $|E| > 1.0$ were used to solve the structure by an application of the tangent formula that examined $128 = 2^7$ sets of starting phases and successively eliminated all but the most likely. This program is part of an X-ray system written by Sheldrick (11). From the E map with the lowest Karle R factor (12) the positions of all non-hydrogen atoms could be found.

The structure was refined by full-matrix least squares, $\Sigma(\Delta|F|)^2$ = min., with isotropic temperature factors on all the atoms.[3] When the conventional R factor was 0.13 the H atoms of the ammonium ion and phenyl groups were located from a difference Fourier synthesis. The H atom of the carboxyl group could not be found. The final R factor with the H atoms included was 0.08; there were no significant features on the difference Fourier map calculated at this stage. The least-squares weights were calculated from $w = 1/(\sigma^2|F_o| - 0.001|F_o|^2)$. The positional parameters are given in Table 1, and interatomic distances and inter-bond angles in Table 2.

Results and Discussion

Characterization and Relative Stabilities of AB and AHB

The crystals obtained on cooling a hot aqueous solution of commercial AB were usually plate-like. Their ir spectrum is shown in Fig. 1. That this compound was AHB is apparent from its ^{1}H nmr spectrum which showed a six-proton multiplet (*meta* and *para*) at δ 7.43, a four-proton multiplet (*ortho*) at δ 7.98, and a broad singlet at δ 8.52 (exchangeable protons) integrating for five hydrogens.

However, the crystals freshly prepared from a strongly basic aqueous ammonia solution were laths which tended to be hygroscopic. After only brief drying they were dissolved in DMSO-d_6, with some difficulty; their ^{1}H nmr spectrum in this solution showed a three-proton multiplet at δ 7.35, a two-proton multiplet at δ 7.95, and a broad singlet at δ 6.12 (6.2 H). On this evidence the briefly-dried crystals were $AB{\cdot}H_2O$. Upon further drying anhydrous AB was obtained, but prolonged drying resulted in gradual loss of ammonia. This was reflected by increasing solubility in DMSO, a gradual downfield shift of the averaged signal for the exchangeable hydrogens and an obvious change in the relative integral for the latter. The end product of the decomposition was AHB.[4]

The ^{1}H nmr spectrum of anhydrous AB showed a multiplet for the *meta* and *para* ring hydrogens centred at δ 7.33. The broad singlet (δ 8.09) for the hydrogens of the ammonium ion was superposed on the multiplet (δ 7.92) for the remaining aromatic hydrogens. The spectrum integrated correctly for the normal salt AB. The ir spectrum of AB is shown in Fig. 2.

[2]The vapour pressure (presumably of NH_3) was sufficient to burst a single capillary tube after the crystal inside it had been irradiated for about 2 days.

[3]A list of the structure factors (Table 3) is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]Berzelius reported as early as 1805 that on evaporation of an aqueous solution of AB ammonia is liberated, with the formation of an acid salt (3).

*NOTE: ′ $1-x, -y, 1-z$; ″ $1-x, -y, -z$; ‴ $1-x, \frac{1}{2}-y, z$.

The ir spectrum of AHB (Fig. 1) is very similar to those of $KH(PhCOO)_2$ (13) and $KH(PhCH_2COO)_2$ (5) with the NH_4^+ absorptions added. The main differences between the spectra of AB and AHB are summarized in Table 4. No band which could be satisfactorily assigned to the OH stretching mode was observed. This also seems to be the case in several other compounds of this type (5, 13), although in AHB such a band could be obscured by the NH stretching bands of NH_4^+.

Although AB appears to decompose into AHB fairly readily, AHB may not itself be very stable in view of the observation[2] that it dissociates in the X-ray beam, presumably into benzoic acid and ammonia.

Isotopically Isolated NH_3D^+ Ions in AHB and AB

The ND stretching region of the isotopically isolated NH_3D^+ ion in AHB, at liquid-nitrogen temperature, is shown in Fig. 3. Two sharp bands are observed which are separated in frequency by about 100 cm^{-1} (Table 5). Of the two components of $\nu_1(NH_3D^+)$ that at the lower frequency is somewhat more intense. This is not surprising in view of the difference in hydrogen-bond strength implied by the frequency difference (cf. below). Assuming that only one set of equivalent NH_4^+ ions is present in the crystal the observed spectrum is consistent with an NH_4^+ ion of an effective (1) symmetry C_{2v} or C_2 and hence with the existence of two pairs of nonequivalent N—H bonds.

The corresponding region in the spectrum of AB (1% D) is complicated by the presence of an underlying absorption (see Fig. 2) but it seems more than likely that the absorption arising from the NH_3D^+ ion again consists of two sharp bands (Fig. 4, Table 5); overtone and combination modes may frequently appear with greater intensity than $\nu_1(NH_3D^+)$ when the NH_3D^+ ion is present at a 1% concentration level. The characteristically pronounced sharpening of this mode upon cooling (14) is often extremely useful in assisting assignment where interference from other absorptions occurs.

Upon the above assumption, and using the

	$\nu_1(NH_3D^+)$	$\Delta\nu_{1/2}$
AB	2271.9	8.0
	2195.7	*
AHB	2340.1	6.0
	2246.0	7.0

*Half-width uncertain because of underlying combination band.

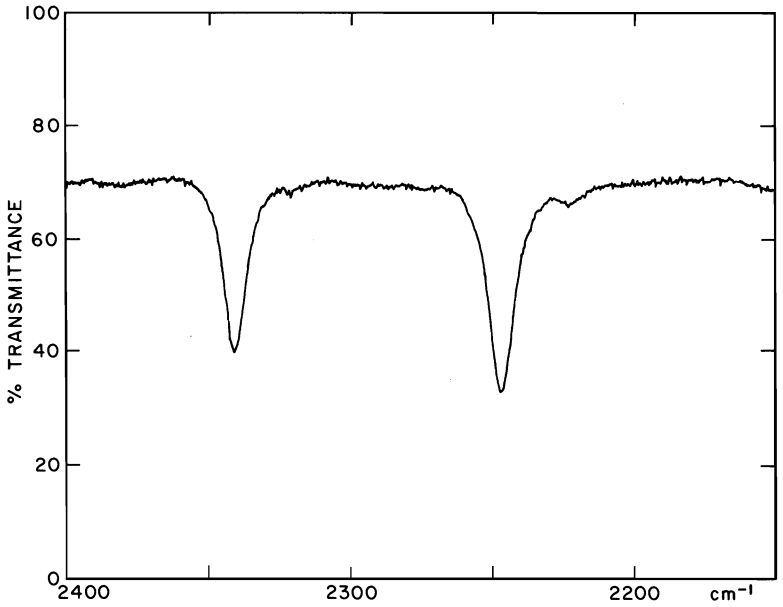

FIG. 3. The ND stretching region of the ir spectrum of the isotopically isolated NH_3D^+ ion in AHB at 77 K.

nomenclature of ref. 1, the possible site symmetries S of the ammonium ion in AHB and AB may be deduced as

$E'(NH_3D^+)$	$E(NH_4^+)$	$S(NH_4^+)$
$C_s(2)$, $C_s(2)$	C_{2v}	C_{4v}, D_{2h}, C_{2v}
	or	
$C_1(2)$, $C_1(2)$	C_2	C_4, C_{2h}, C_2

The spectra in both salts are indicative of strongly hydrogen-bonded ammonium ions. This is especially true of the lower-lying of the two absorptions in each compound. In fact, the isotopically isolated ND stretching frequency of 2195.7 cm^{-1} observed in AB is the lowest such frequency reported to date.

Crystal Structure of AHB

AHB is practically isostructural with $KH(PhCOO)_2$ (6) except that the ammonium ions in the AHB structure form with the dibenzoate ions $(PhCOO\cdots H\cdots OOCPh)^-$ hydrogen-bonded helices which lie in the zone of the b axis (Figs. 5 and 6). One hydrogen bond is between the centrosymmetrically related carboxyl oxygens O(2) and O(2′) of the dibenzoate ion and another between O(2) and N(1). The N(1) atom is located on a twofold axis and therefore able to propagate the helix through a hydrogen bond to a diad-related benzoate unit (Fig. 6). Adjacent helices are linked through hydrogen bonds between O(1) and N(1) to form a layer parallel to the (100) plane. The hydrogen-bonded distances O(2)···O(2′), N(1)···O(1), and N(1)···O(2) are 2.46(1), 2.78(1), and 2.93(1) Å, respectively.

Of the two non-equivalent H atoms of the ammonium ion, H(10) is clearly defined in the difference Fourier synthesis and forms an angle H(10)—N(1)—H(10′) of 148(10)° with its twofold-related atom. This large deviation from the tetrahedral angle could be the result of strong hydrogen bonding. H(11) is poorly defined, with H(11)—N(1)—H(11′) of 129(10)°. Both hydrogens are located about 1.0 Å from N(1).

There was no trace at, or near, the centre of symmetry in the difference Fourier synthesis, of the H atom that forms the bond between the benzoate units in the dibenzoate ion. Attempts to place and refine a hydrogen atom in all the reasonable positions produced a very large isotropic temperature factor. The O···O contact is short (15), comparable with the corresponding O···O separations in acid salts of other organic acids (9), and represents a strong hydrogen bond. The two C—O bond lengths in the carboxyl group are not significantly different: C(10)—O(1), 1.26(1) Å, and C(10)—O(2), 1.27(1) Å. They are similar to those found in $KH(PhCOO)_2$, 1.22(4) and 1.24(4) Å (6), and in the benzoate ion itself, in a thallous benzoate thiourea complex (16), where the ion has C_{2v} symmetry and a C—O bond length of 1.25(2) Å. It thus seems

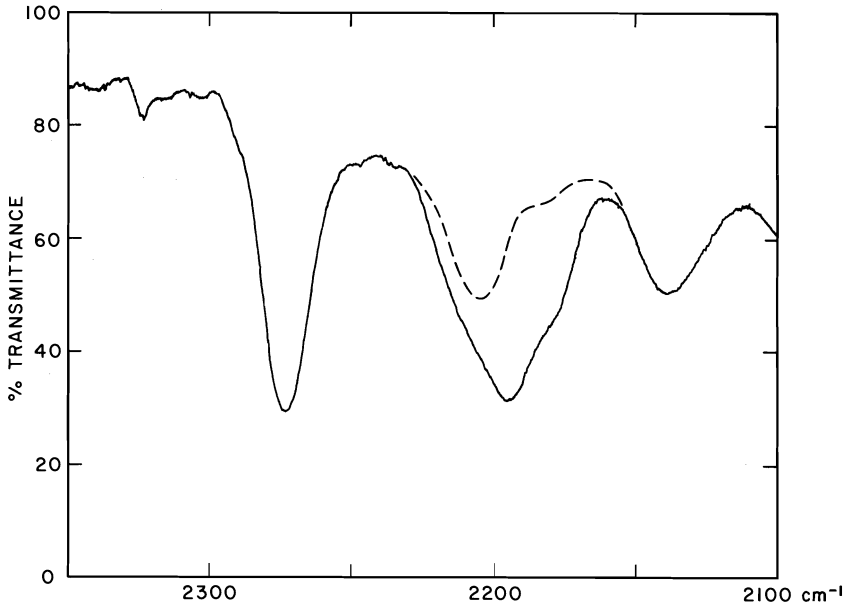

FIG. 4. The ND stretching region of the ir spectrum of the isotopically isolated NH_3D^+ ion in AB at 77 K. The dashed line corresponds to the estimated contour of the underlying absorption (see text).

unlikely that the proton in AHB is closely associated with either carboxyl oxygen in the O···H···O bond. The dimensions of the rest of the anion are unexceptional and there are no other unusually short inter-ion contacts.

Additional Observations

We have not investigated the structural features of AB in any detail beyond the effective symmetry of the NH_4^+ ion. Some statements are nevertheless possible when the information available in the literature is examined. The only crystallographic data are derived from optical-goniometer and optical measurements (3, 17, 18).[5] According to these the crystal symmetry of AB is *mmm*, with an axial ratio of 0.9873:1:2.1504 and a measured density (3) of 1.260, 1.262, or 1.213 g/cm^3, and there is perfect cleavage along (001). Assuming this point-group symmetry and the composition AB to be correct, the site symmetry of the NH_4^+ ion will be one of the following: D_{2h}, C_{2v}, C_{2h}, or C_2 (see above). Steinmetz (18) pointed out the similarity of the axial ratios of AB and benzoic acid[6] when the largest term in the ratio for AB is doubled; this would suggest that $Z(AB) = 4$. On this additional, reasonable assumption a symmetry $S = D_{2h}$ at the NH_4^+ site could only occur in space group no. 69; $S = C_{2v}$ only in nos. 63, 65, 67, 71, or 74; $S = C_{2h}$ only in nos. 63–67, 72, or 74; and $S = C_2$ only in nos. 48–58 or 60.

The unit cell of AHB shows dimensional and space-group similarity not only to $KH(PhCOO)_2$ (6) but also to $KH(PhCH_2COO)_2$ (4, 7).

Adducts of Na benzoate with two and three molecules of benzoic acid, NaB·2HB and NaB·3HB, have been reported (3). It would be of interest to establish whether ammonium analogues of these compounds exist.

Conclusions and Summary

Under different conditions of crystallization and drying, three salts (ammonium benzoate AB, ammonium benzoate monohydrate $AB·H_2O$, and ammonium hydrogen bisbenzoate AHB) have been obtained from solutions of commercial ammonium benzoate. Both AB and $AB·H_2O$ are readily converted to AHB.

Infrared spectra of the isotopically dilute NH_3D^+ ion in AB and AHB were used to predict that the effective symmetries E of the NH_4^+ ion in these crystals are C_{2v} (corresponding to site symmetries $S = C_{4v}$, D_{2h}, or C_{2v}) or C_2 (corresponding to $S = C_4$, C_{2h}, or C_2). This prediction was confirmed, for AHB, by a determination of the crystal structure of this com-

[5]Some of these are due to de Marignac and date as far back as 1857 (3).

[6]The axial ratio quoted in ref. 18 for benzoic acid is in fact the ratio of the unit-cell dimensions.

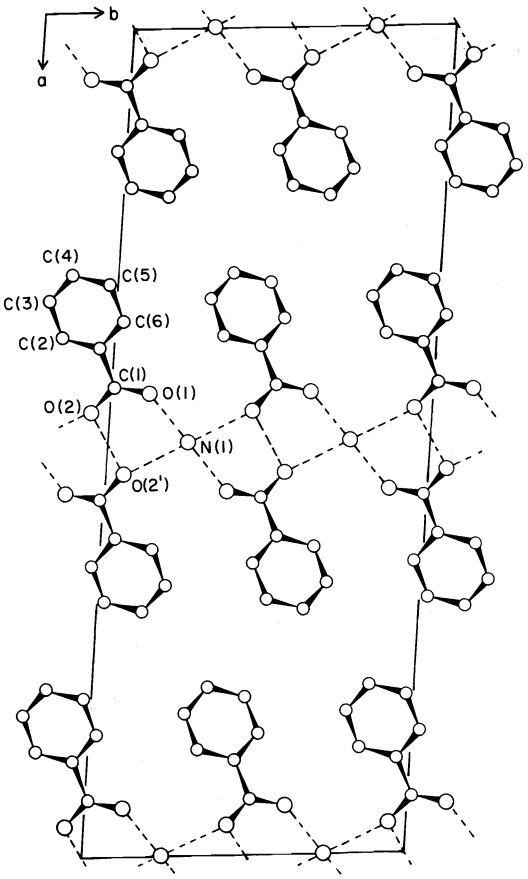

FIG. 5. The unit cell of AHB projected perpendicular to the *c*-axis.

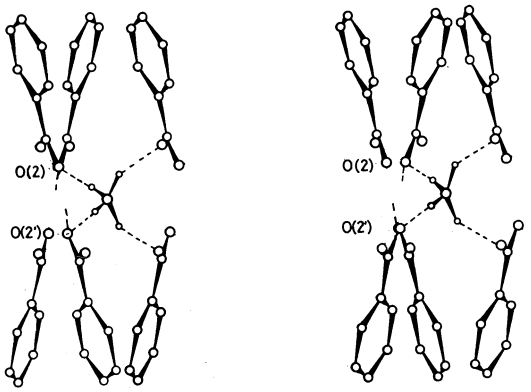

FIG. 6. Environment of the ammonium ion in AHB viewed along the *b*-axis.

pound. It is found that the single set of equivalent NH_4^+ ions occupies sites of C_2 symmetry. The NH_4^+ and $(PhCOO\cdots H\cdots OOCPh)^-$ ions form hydrogen-bonded layers whilst short O···H···O bonds link together the benzoate units in the centrosymmetric dibenzoate ions. AHB is essentially isostructural with its potassium analogue.

The N—H···O bonds in AB and AHB are strong. The isotopically isolated ND stretching frequency of NH_3D^+ in AB, 2195.7 cm^{-1}, is the lowest such frequency reported to date.

Placing a H atom at, or close to, the centre of the dibenzoate ion resulted in very large isotropic temperature factors for this atom when the structure of AHB was refined on this hypothesis. This finding is similar to that obtained by Bacon and Curry (7) in their neutron-diffraction study of the crystal structure of $KH(PhCH_2COO)_2$. While the O···H···O bond in AHB is *formally* symmetric, no definite conclusion can be made, in static terms, about the location of this hydrogen atom from the present evidence.

Mass and infrared spectra of some S_4N_4 complexes of group VIII metals[1]

IAN S. BUTLER AND TSUTOMU SAWAI

Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received April 4, 1977

IAN S. BUTLER and TSUTOMU SAWAI. Can. J. Chem. **55**, 3838 (1977).

The mass and ir spectra of the complexes formed between S_4N_4 and MCl_2 (M = Ni, Co, Pd) in methanol solution have been investigated. The mass spectral data indicate that the stoichiometry of the complexes is $M(S_2N_2H)_2$ and the principal fragmentation is the stepwise loss of SN units, as is the case for S_4N_4 itself. The ir spectra of the complexes show the presence of N—H groups and suggest *cis*-planar configurations for the S_2N_2H chelating ligands.

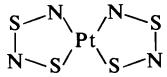
IAN S. BUTLER et TSUTOMU SAWAI. Can. J. Chem. **55**, 3838 (1977).

On étudie les spectres de masse et infrarouge de complexes formés dans une solution méthanolique entre S_4N_4 et MCl_2 (M = Ni, Co, Pd). Les données obtenues à partir du spectre de masse indiquent que la stoichiométrie des complexes est $M(S_2N_2H)_2$ et que la principale fragmentation est la perte successive des unités SN comme pour le cas de S_4N_4. Le spectre infrarouge des complexes montre la présence de groupes N—H et suggère une configuration planaire *cis* pour les ligands de chélation S_2N_2H.

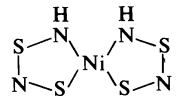
[Traduit par le journal]

Introduction

In 1953, the isolation of the first transition metal thionitrosyl complex, $Ni(NS)_4$, from the reaction of $Ni(CO)_4$ with S_4N_4 in benzene was reported (1). Following this, it was quickly established that monomeric $M(NS)_4$ complexes could be synthesized by three main routes: heating anhydrous MCl_2 (M = Ni, Co, Pd) with S_4N_4 in alcohols (2); reaction of metal carbonyls (e.g., $Co_2(CO)_8$ (3) and $Fe(CO)_5$ (4)) with S_4N_4; shaking finely divided metal powders (Ni, Co, Pd) with S_2N_2 in tetrahydrofuran (5). The analogous platinum derivative, $Pt(NS)_4$, was prepared by the reaction of H_2PtCl_6 with S_4N_4 in dimethylformamide–H_2O (6). Surprisingly, an X-ray analysis of $Pt(NS)_4$ revealed the presence of two S_2N_2 bidentate chelating ligands instead of the four coordinated NS groups expected and these chelating ligands were arranged in a *cis*-planar configuration (7):



Concurrent with this X-ray study, Piper was investigating the ir and nmr spectra of the complex obtained from the reaction of anhydrous $NiCl_2$ with S_4N_4 in methanol (8, 9) and he was able to show the presence of two N—H groups. Subsequent research on derivatives of $Ni(S_2N_2H)_2$ established that $Ni(S_2N_2Me)_2$ has a *trans*-planar configuration (10), while a *cis*-planar structure is preferred for $Ni(S_2N_2H)$-$[S_2N_2(CONHPh)]$ (11). In both cases, the substituent groups, H, Me, and CONHPh, are attached to the nitrogen atoms which are bonded directly to the central nickel atom. The *trans* stereochemistry for $Ni(S_2N_2Me)_2$ was rationalized on the basis of steric considerations and it was concluded that the *cis*-planar structure shown below was the most likely for $Ni(S_2N_2H)_2$, assuming that no rearrangement took place during the reactions. Furthermore, the analogous complexes of other group VIII metals were presumed to have the same structure. However, this has never been established definitively.



In this paper, we report the mass and ir spectra of the complexes formed by the reactions of MCl_2 (M = Ni, Co, Pd) with S_4N_4 in methanol. Our objectives were to verify the presence of N—H groups and, if possible, to determine the structures of the complexes. The products obtained from the reaction of H_2PtCl_6 with S_4N_4 in dimethylformamide–H_2O were also investigated.

Experimental

Tetrasulphur tetranitride (S_4N_4) was prepared according to the literature method (12). Other materials were obtained from the sources indicated: anhydrous $NiCl_2$

[1]Taken in part from the Ph.D. thesis of T.S., McGill University, Montreal, P.Q. 1973. Presented in part at the 173rd National Meeting of the American Chemical Society, New Orleans, LA, March, 1977.

and $CoCl_2$ (Alfa Inorganics, Inc.); anhydrous $PdCl_2$ and $H_2PtCl_6 \cdot 6H_2O$ (Research Organic/Inorganic Chemical Corp.); acid-washed alumina (Fisher Scientific Co.). The nickel, cobalt, and palladium complexes were prepared as described previously (2, 9). Complete details of these syntheses are contained in ref. 13. The synthesis of $Pt(S_2N_2H)_2$ according to the method of Fluck *et al.* (6) was attempted 10 times but no product analysing as $Pt(S_2N_2H)_2$ could be obtained. In every case, a white precipitate was formed which was identified by ir and elemental analysis as $(NH_4)_2SO_4$. *Anal.* calcd for $H_8N_2O_4S$: H 6.1, N 21.2, S 24.3; found: H 6.2, N 20.8, S 24.0.

Infrared spectra were recorded on a Perkin-Elmer model 521 grating spectrophotometer as KBr disks. The spectra were calibrated against the bands of polystyrene (accuracy ca. $\pm 2\ cm^{-1}$). Mass spectra were measured on an AEI MS-902 spectrometer under the following conditions: 70 eV electron energy, 145–180°C inlet temperature, 8 kV acceleration voltage, and resolution of 1000. The samples were introduced into the ion source using a direct insertion probe. The most important fragments observed, their relative intensities, and the proposed assignments for S_4N_4 and the nickel, cobalt, and palladium complexes are given in Figs. 1–4, respectively. The assignments for the complexes are based on the principal metal isotopes present: ^{58}Ni, ^{59}Co, and ^{106}Pd. A least-squares computer program was written to decompose the observed peak intensities into the intensities associated with the various fragment ions concerned, e.g., FH_2^+, FH^+, and F^+ where F = a metal-containing fragment.

Results and Discussion

The proposed fragmentation scheme for the mass spectrum of S_4N_4 is shown in Fig. 1. The principal fragmentation is the loss of SN units to give species such as $S_3N_3^+$; the transient SN molecule has been identified by microwave spectroscopy (14). One of the main peaks corresponds to $S_2N_2^+$; the S_2N_2 molecule is known to exist as a highly reactive species (5). Other reasonably abundant ions are $S_3N_2^+$, S_3N^+, S_2N^+, S_2^+, N_4^+, and the doubly charged species $S_3N_2^{2+}$. There is a major peak at *m/e* 76 which cannot be attributed to any of the $S_xN_y^+$ species; this peak is assigned tentatively to SN_2O^+ formed by combination with residual oxygen present in the mass spectrometer.

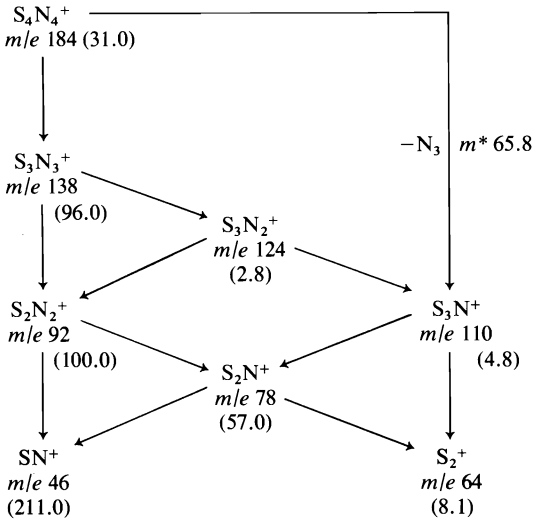


FIG. 1. Proposed mass spectral fragmentation scheme for S_4N_4.

There are several common features in the mass spectra of the nickel, cobalt, and palladium complexes. First, all three complexes exhibit parent molecular ions in which there are two hydrogen atoms present, thus confirming the previously assumed $M(S_2N_2H)_2$ stoichiometry of the species. Second, the successive loss of SN groups is the predominant fragmentation process. In particular, the loss of the first SN group from each of the parent molecular ions is verified by the appearance of the expected metastable ion. This behaviour is reminiscent of S_4N_4 itself. The final feature in common is the loss of hydrogen atoms from the various fragment ions throughout the spectra. Table 1 gives the ratios of the abundances of the fragment ions FH_2^+, FH^+, and F^+ (e.g., $MS_4N_4H_2^+$, $MS_4N_4H^+$, and $MS_4N_4^+$, respectively) calculated from the observed peak intensities assuming that they are sums of the intensities of the different fragments present. In the case of the nickel complex, the parent molecular ion, $NiS_4N_4H_2^+$ (*m/e* 244), is the dominant species, while the palladium complex apparently readily loses its two hydrogen atoms and $PdS_4N_4^+$ (*m/e* 290) is the most abun-

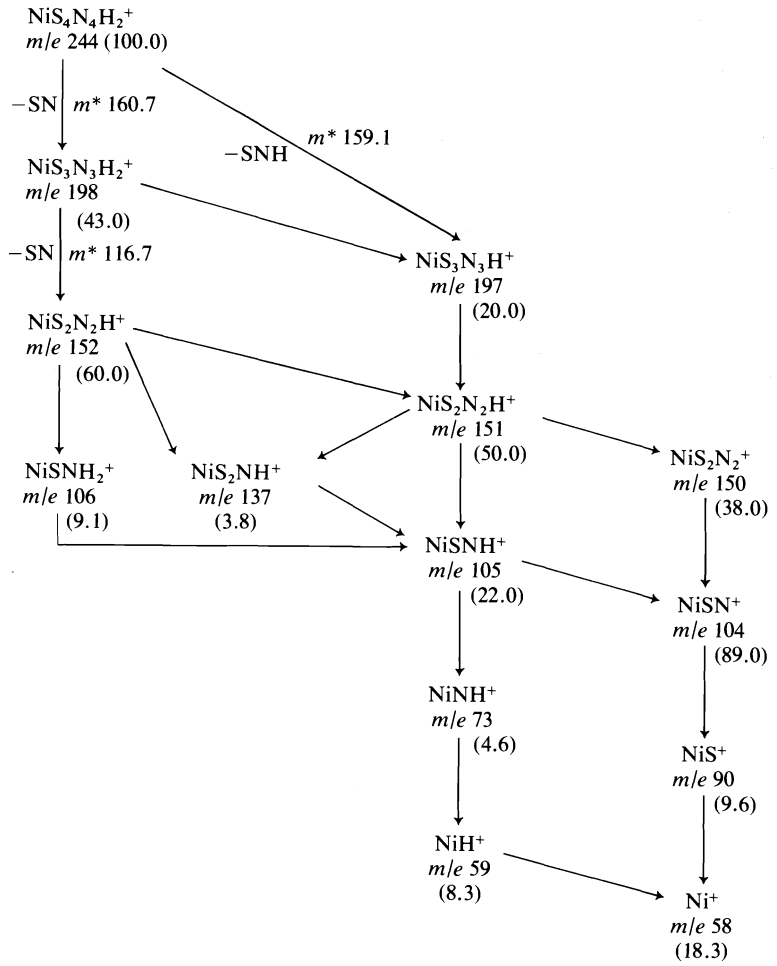

FIG. 2. Proposed mass spectral fragmentation scheme for $Ni(S_2N_2H)_2$.

dant of the $PdS_4N_4H_n^+$ ($n = 2, 1, 0$) ions. The cobalt complex lies in between these two extremes. These mass spectral observations are in accord with the nickel complex being generally considered to be the most stable of the three.

In the case of $NiS_4N_4H_2^+$, there is also a metastable peak corresponding to the release of an SNH group. Thus, bond rupture within the chelate ring seems to take place rather indiscriminantly. In contrast to the cobalt derivative, there is no evidence for the loss of S_2N_2 from any of the fragment ions nor is the dehydrogenated species, $NiS_4N_4H^+$, formed. The appearance of the expected metastable peak confirms the loss of SN from $NiS_3N_3H_2^+$ (*m/e* 198) to give $NiS_2N_2H_2^+$ (*m/e* 152).

The chief observation of Piper in his study of the ir spectrum of the nickel complex was the appearance of N—H stretching modes at 3235 and 3095 cm^{-1} (8, 9). He was apparently unable to deduce any more structural information but he favoured a *trans*-planar arrangement of the S_2N_2H chelating ligands with the location of the N—H groups being unknown. However, as mentioned in the Introduction, the structures of the substituted nickel complexes, $Ni(S_2N_2Me)_2$ (10) and $Ni(S_2N_2H)[S_2N_2(CONHPh)]$ (11), have since been determined by X-ray diffraction and these complexes adopt *trans*- and *cis*-planar structures, respectively. In both cases, the S_2N_2 chelate rings, the nickel atom, and the carbon atoms attached to the nitrogen atoms of the rings share the same plane. On the basis of these results and Piper's ir data, it is generally accepted that the parent $Ni(S_2N_2H)_2$ complex has two N—H groups bonded to the central nickel atom

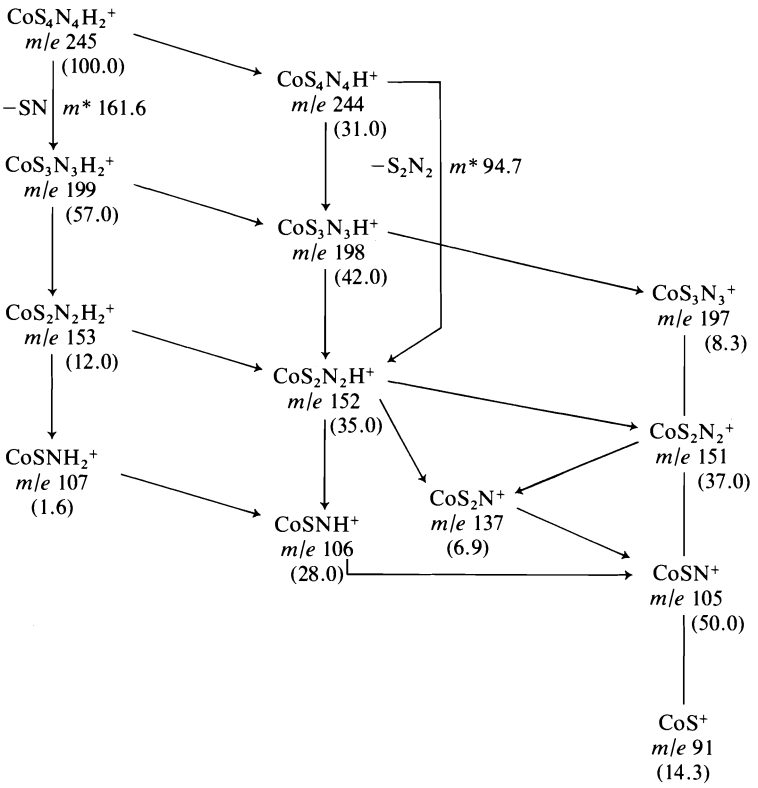

FIG. 3. Proposed mass spectral fragmentation scheme for $Co(S_2N_2H)_2$.

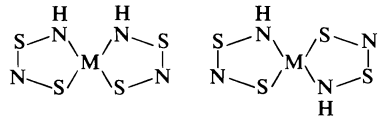
with the hydrogen atoms lying in the same plane as the chelate rings. Although the structure of $Pt(S_2N_2H)_2$ has been determined as *cis*-planar (7), it has yet to be established whether or not the other $M(S_2N_2H)_2$ (M = Ni, Co, Pd) complexes have the same structure.

The two possible geometrical isomers for the $M(S_2N_2H)_2$ complexes are shown below. From symmetry considerations, there are 23 ir-active vibrations ($10a_1 + 9b_1 + 4b_2$) for the *cis*-C_{2v} structure and 15 ($5a_u + 10b_u$) for the *trans*-C_{2h}



cis-C_{2v} *trans*-C_{2h}

structure. Moreover, two ir-active N—H stretching vibrations ($a_1 + b_1$) are expected for the *cis* isomer, while only one mode (b_u) should be observed for the *trans* isomer. The ir spectra of the nickel, cobalt, and palladium complexes are very similar and the data are compared in Table 2. There are two distinct N—H stretching bands observed for each complex observed at ~3265 and ~3145 cm^{-1}. Since the energy difference between these absorptions (~120 cm^{-1}) is too large to be attributable to site or factor group splitting, the *cis* structure is favoured. Furthermore, the close similarity of the ir spectra suggests that all three complexes adopt the same structure. On the basis of the number of bands in the spectra, the *cis* structure is again favoured because there are about 15 bands which may reasonably be considered as fundamentals, even ignoring the region below 300 cm^{-1} where some low energy modes are expected to absorb.

For comparative purposes, the ir data for S_4N_4 and $TiCl_4 \cdot S_4N_4$ (15) are also given in Table 2. The spectrum observed for S_4N_4 is in good agreement with that reported by Lippincott and Tobin (16). There is little coincidence between the spectra of the group VIII complexes and that of S_4N_4, while the spectrum of $TiCl_4 \cdot S_4N_4$ is quite similar to that of S_4N_4. This is consistent with the fact that the original S_4N_4 is not held intact in the complexes being considered in the present work.

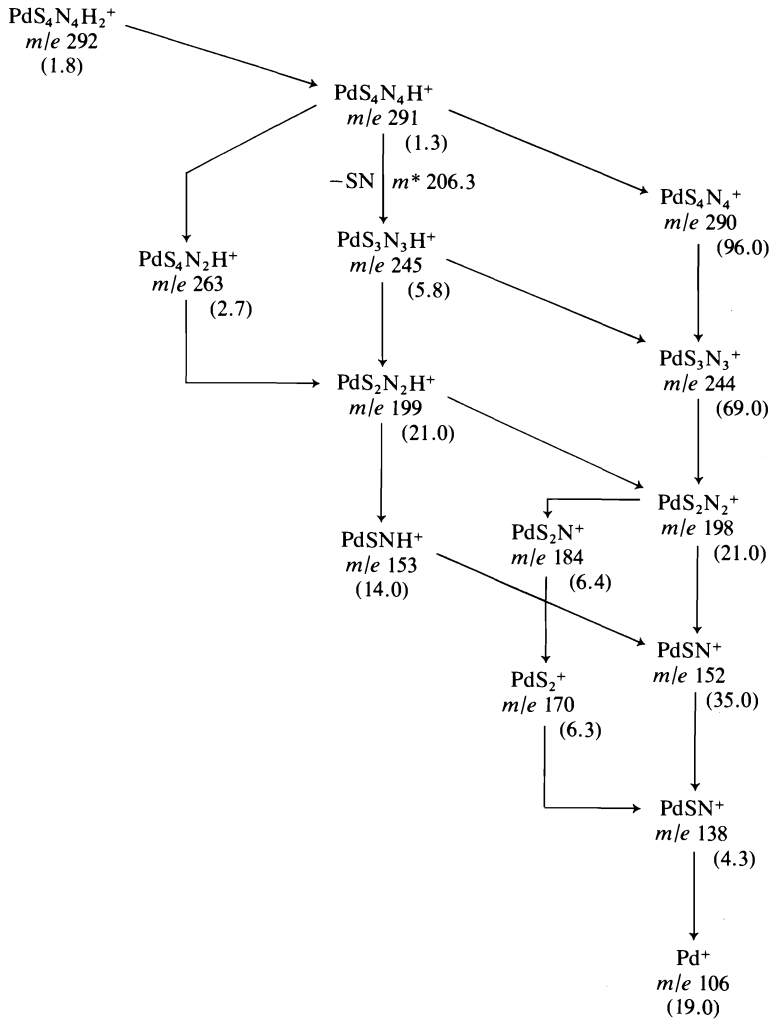


FIG. 4. Proposed mass spectral fragmentation scheme for $Pd(S_2N_2H)_2$.

Since only small amounts of the complexes were obtained from the syntheses, no far-ir spectra were recorded. Attempts were made to measure the Raman spectra using Kr^+ (647.1 nm) laser excitation, but these failed owing to the poor scattering properties of the dark-red–violet complexes. In view of this, it is pointless to give detailed vibrational assignments for the ir spectra, but some general assignments can be made and these have been included in Table 2.

The N—H bending modes in $S_4N_4H_4$ occur at $\sim 1300\ cm^{-1}$ (16), i.e., considerably lower in energy than those for saturated secondary amines (1580–1490 cm^{-1}) (17). In the present study, the very weak, broad bands observed in the 1400–1200 cm^{-1} range are assigned tentatively to the N—H bending modes. Banister *et al.* have examined the relationship between ν(S—N) and the S—N bond length (18). For example, the S—N bond length in S_4N_4 is 1.616 Å, and Banister *et al.*'s prediction for ν(S—N) is $\sim 940\ cm^{-1}$; the observed value for ν(S—N) is 925 cm^{-1}. From the X-ray study (7) on $Pt(S_2N_2H)_2$, the average S—N bond length is ~ 1.59 Å and accordingly the ir bands for the group VIII complexes appearing at $\sim 1030\ cm^{-1}$ have been assigned to ν(S—N) vibrations.

As part of our study on the structures of the group VIII metal S_4N_4 complexes, we attempted to prepare $Pt(S_2N_2H)_2$ according to the literature method but all our efforts proved in vain. Copious amounts of $(NH_4)_2SO_4$ and, in some cases, small quantities of a dark-violet compound could be isolated. Unfortunately, we

[a]Data from ref. 15

could not obtain a reproducible elemental analysis for this dark-violet compound. The formation of $(NH_4)_2SO_4$ is presumably the result of the acid-catalysed (H_2PtCl_6) reaction of S_4N_4 with water. The mass spectrum of the dark-violet product is complex but $Pt(S_3N)_2$ and a trace of $Pt(S_2N_2H)(S_3N)$ appear to be present. The ir spectrum (KBr disk) shows the presence of one N—H stretching absorption at ~3120 cm^{-1}. Complexes of the compositions, $M(S_3N)_2$ and $M(S_2N_2H)(S_3N)$, have been reported previously for nickel (9), and cobalt and palladium (19), but not for platinum.

In conclusion, the stoichiometry of the $M(S_2N_2H)_2$ (M = Ni, Co, Pd) complexes has been verified and it appears that all three complexes adopt a *cis*-planar geometry. These complexes are certainly not thionitrosyls and it is worth mentioning here that the first authentic thionitrosyls, $Mo(NS)(S_2CNR_2)$ (R = Me, Et, etc.), have only recently been reported (20). Finally, in view of the considerable current interest in polymeric sulphur nitride, $(SN)_x$, because of its metallic behaviour (21), we anticipate that there will be renewed interest in the chemistry of the $M(S_2N_2H)_2$ species and their derivatives as these complexes may well prove to be convenient precursors to $(SN)_x$ and related polymers.

Fluorine exchange between four-, five-, and six-coordinate silicon compounds[1]

RONALD KIRK MARAT AND ALEXANDER F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 2, 1977

RONALD KIRK MARAT and ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3845 (1977).

Intermolecular fluorine exchange in the systems SiF_4–SiF_5^-, $MeSiF_3$–$MeSiF_4^-$, $PhSiF_3$–$PhSiF_4^-$, SiF_5^-–SiF_6^{2-}, SiF_4–SiF_6^{2-}, and $MeSiF_3$–SiF_6^{2-} has been studied by fluorine and proton nmr spectroscopy. Exchange is postulated to involve fluorine-bridged intermediates; alternative pathways of exchange, such as fluoride dissociation or impurity (HF and H_2O) catalyzed exchange, have been eliminated. Addition of NH_3 to SiF_5^-–SiF_6^{2-} slows down exchange whereas addition of Et_2NH to $MeSiF_3$ promotes exchange.

RONALD KIRK MARAT et ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3845 (1977).

On étudie par rmn du proton et du fluor l'échange intermoléculaire du fluor dans les systèmes SiF_4–SiF_5^-, $MeSiF_3$–$MeSiF_4^-$, $PhSiF_3$–$PhSiF_4^-$, SiF_5^-–SiF_6^{2-}, SiF_4–SiF_6^{2-} et $MeSiF_3$–SiF_6^{2-}. On fait l'hypothèse que l'éxchange implique des intermédiaires à fluor ponté; on élimine la possibilité d'un autre mode d'échange comme la dissociation du fluor ou de l'échange catalysée par une impureté (HF et H_2O). L'addition de NH_3 au système SiF_5^-–SiF_6^{2-} a pour effet de ralentir l'échange; par contre l'addition de Et_2NH à $MeSiF_3$ la favorise.

[Traduit par le journal]

Introduction

On the basis of our study of catalyzed intermolecular fluorine exchange in the $MeSiF_4^-$ anion (1), we concluded that HF is a very effective fluorine transfer reagent and that any reagents such as H_2O or MeOH, which react with $MeSiF_4^-$ to liberate HF, can promote fluorine exchange, whereas reagents such as Pr_4NF or $(Me_3Si)_2NH$, which remove HF from solution, can inhibit fluorine exchange. Since the presence of HF and H_2O impurities could be monitored and their concentration reduced, it became feasible to study intermolecular fluorine exchange between four-, five-, and six-coordinate silicon fluorides without interference from impurity catalyzed processes.

Five- and six-coordinate silicon fluorides are known, e.g. SiF_5^-, $RSiF_4^-$, SiF_4:base, SiF_6^{2-}, $SiF_4(C_2O_4)^{2-}$, $SiF_2(C_2O_4)_2^{2-}$, $RSiF_5^{2-}$, SiF_4:2base, SiF_5:base$^-$ (2–9); however, less is known about the mechanism of exchange in silicon fluorides than about exchange processes in the analogous tin (10), phosphorus (11), antimony (12), or boron (13) fluorides.

Previously, we suggested that six-coordinate intermediates and four-center reactions may be important in reaction mechanisms of silicon and phosphorus compounds (1, 14). In this paper, we we wish to describe the effect that changes in the coordination number of silicon have on the intermolecular fluorine transfer process in systems such as SiF_4–SiF_5^-, $MeSiF_3$–$MeSiF_4^-$, $PhSiF_3$–$PhSiF_4^-$, SiF_5^-–SiF_6^{2-}, SiF_4–SiF_6^{2-}, $MeSiF_3$–SiF_6^{2-}, NH_3–SiF_5^-–SiF_6^{2-}, and $NHEt_2$–$MeSiF_3$.

[1]Presented at the 2nd Joint CIC–ACS Conference, Montreal, Canada, May 29 – June 2, 1977.

Experimental

General

Dichloromethane (Fisher), CH_3SiF_3 (PCR), $SiCl_4$ (M.C.B.), ammonia (Matheson), 49% hydrofluoric acid (Fisher), and 10% aqueous $(n\text{-}C_3H_7)_4NOH$ (Eastman) were used without further purification. SiF_4 was prepared from $SiCl_4$ and SbF_3 in a stainless steel cylinder. $C_6H_5SiF_3$ was prepared from $C_6H_5SiCl_3$ and SbF_3 in tetramethylene sulfone solvent (15). $(n\text{-}C_3H_7)_4NF$ (16), $(n\text{-}C_3H_7)_4N^+SiF_5^-$ (2), $(n\text{-}C_3H_7)_4N^+CH_3SiF_4^-$ (1, 3), and $(n\text{-}C_3H_7)_4N^+C_6H_5SiF_4^-$ (3) were prepared by literature methods and characterized by their mp, ir, and nmr spectra. $[(n\text{-}C_3H_7)_4N]_2SiF_6$ was prepared by neutralization of 10% aqueous $(n\text{-}C_3H_7)_4NOH$ with 3% aqueous HF followed by addition of an equimolar quantity of $(n\text{-}C_3H_7)_4N^+SiF_5^-$; water was evaporated with the addition of methanol and the product recrystallized from 1:1 chloroform – ethyl acetate in 77% yield. The white needle-like crystals, mp 75–77°C, had an ir spectrum characteristic of the SiF_6^{2-} anion (17).

Nuclear Magnetic Resonance Spectra

The nmr spectra were recorded on Varian A-56/60A and HA-100-D spectrometers at 56.4 and 100 MHz for fluorine and proton, respectively; proton decoupled ^{13}C nmr spectra were recorded on a Bruker WH90 spectrometer at 22.63 MHz. Temperatures were calibrated by the method of Van Geet (18) and are considered accurate to ±1°C. Calculated spectra for the SiF_5^-–SiF_6^{2-} system were produced with the program DNMR-3

[a]The bifluoride ion is observed as an impurity peak in the tetrapropylammonium fluoride sample.
[b]The chemical shift and line width of HF vary with solvent and temperature.

(19) using the Fortran H compiler on an IBM 370-158 computer. Calculated spectra for the CH_3SiF_3–$CH_3SiF_4^-$ system were produced as described previously (1). The pseudo-first-order rate constants for exchange were obtained by visual comparison of the calculated and experimental spectra and are considered accurate to ±10%.

The nmr samples were prepared by weighing solid reagents, recrystallized and dried under vacuum, directly into dry nmr tubes. Dichloromethane (0.5 ml) was added and nmr tubes degassed and sealed under vacuum. Small quantities (10 μl)) of C_6F_6 were added to produce a convenient internal chemical shift and line width standard. Table 1 lists the chemical shifts and coupling constants of compounds used in this study. Chemical shifts were converted to the $CFCl_3$ scale by adding the chemical shift of a dilute $C_6F_6/CFCl_3$ mixture in CH_2Cl_2 (162.87 ppm). All chemical shifts in Table 1 are reported to high field of $CFCl_3$; they agree well with literature values obtained under different conditions (1, 3, 8, 20).

Results and Discussion

It was essential to verify that impurities such as HF, H_2O, F^-, FHF^-, etc. were not the cause of the rapid intermolecular fluorine exchange processes observed in this study. This was accomplished in several ways: firstly, by observing ^{29}Si–F or F–Si–CH_3 coupling in all starting materials; secondly, by noting the effect on the nmr spectra of reagents, e.g. $(Me_3Si)_2NH$, which are known to react with trace amounts of HF; thirdly, by diluting the sample (an increase in the rate of exchange might be caused by impurities in the solvent whereas a decrease would be consistent with a bimolecular exchange mechanism).

Exchange between Four- and Five-coordinate Silicon Fluorides

The fluorine nmr spectra of $MeSiF_4^-$ (Fig. 1*A*) and $MeSiF_3$ (Fig. 1*B*) show well-resolved quartets with retention of F–Si–CH_3 coupling, thereby confirming that impurity catalyzed intermolecular exchange is not occurring in the

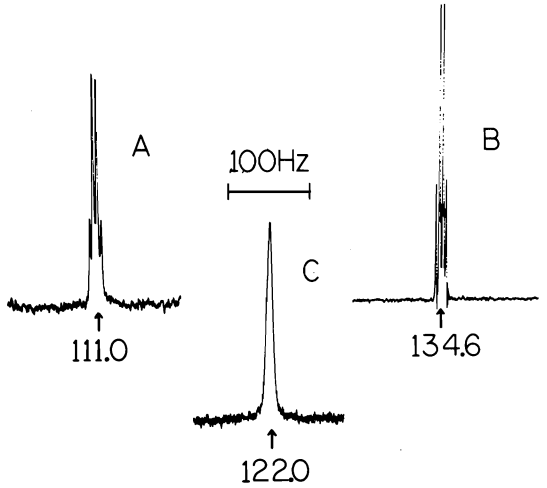

FIG. 1. Fluorine nmr spectra of 0.66 *M* $(n\text{-}C_3H_7)_4N^+CH_3SiF_4$ (1*A*) and 0.66 *M* CH_3SiF_3 (1*B*) in CH_2Cl_2 solution. Figure 1*C* shows mixture of samples 1*A* and 1*B* at +41°C.

starting materials. On mixing $Pr_4N^+MeSiF_4^-$ (0.66 *M*) and $MeSiF_3$ (0.66 *M*), the quartets are replaced by a single peak of half-height width ~20 Hz at +122.0 ppm (Fig. 1*C*). The proton nmr spectrum shows a single sharp peak at −0.2 ppm, assigned to the methyl group of rapidly exchanging $MeSiF_4^-$ and $MeSiF_3$.

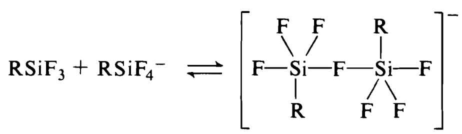
The temperature dependent proton nmr spectrum, from −50 to +33°C, of a sample containing $Pr_4N^+MeSiF_4^-$ (0.49 *M*) and $MeSiF_3$ (1.8×10^{-3} *M*) was analyzed by the method described previously (1) and gave an activation energy $E_a = 5.4 \pm 1.1$ kcal/mol. Attempts to determine the order in $MeSiF_3$ were unsuccessful, mainly because of the difficulty of measuring and condensing small quantities of $MeSiF_3$ into nmr tubes (the addition of as little as 2.5×10^{-7}

mol of $MeSiF_3$ to 2.45×10^{-4} mol of Pr_4N^+-$MeSiF_4^-$ in 0.5 ml dichloromethane produced coalescence).

In a similar experiment, the fluorine nmr spectrum of a mixture of SiF_4 (0.66 *M*) and $Pr_4N^+SiF_5^-$ (0.64 *M*) was recorded at −51°C. A single peak of half-height width ~10 Hz was observed at +152.3 ppm and only minor changes occurred in the spectrum from −51° to +40°C; for example, at −11°C the single fluorine peak shifted to +149.5 ppm (towards SiF_5^-), the half-height width increased to ~20 Hz and the intensity decreased slightly, suggesting that the concentration of SiF_4 in solution decreased slightly at higher temperature, thus slowing down the rate of fluorine exchange.

The $PhSiF_3$–$PhSiF_4^-$ system also showed rapid intermolecular fluorine exchange, as verified by ^{19}F and ^{13}C nmr.

Rapid intermolecular fluorine exchange between four- and five-coordinate silicon fluorides in the systems SiF_4–SiF_5^-, $MeSiF_3$–$MeSiF_4^-$, and $PhSiF_3$–$PhSiF_4^-$ is readily explained in terms of coordination changes Si 4 ⇌ 5, F 1 ⇌ 2, and intermediate (i) **1**.



i-**1**

R = F, Me, Ph

Five- and Six-coordinate Silicon Fluorides

The reagents $Pr_4N^+SiF_5^-$ and $(Pr_4N)_2SiF_6$ gave single sharp peaks in the fluorine nmr spectra (Table 1) with retention of ^{29}Si–F coupling. On mixing $Pr_4N^+SiF_5^-$ (0.5 *M*) and $(Pr_4N)_2SiF_6$ (0.5 *M*), the ^{29}Si–F coupling was lost and two broad peaks were observed at +41°C, with half-height width of 210 Hz for SiF_5^- and 150 Hz for SiF_6^{2-}. Coalescence of the peaks occurred at about +80°C. The Arrhenius plot over the temperature range −40 to +80°C was reasonably linear and gave an activation energy $E_a = 5.1 \pm 0.2$ kcal/mol (Fig. 2).

Intermolecular fluorine exchange can be explained in terms of coordination changes Si 5 ⇌ 6, F 1 ⇌ 2, and intermediate **2**. Dilution of the SiF_5^-–SiF_6^{2-} sample produced a decrease in the exchange rate, consistent with the postulated bimolecular mechanism; however, the

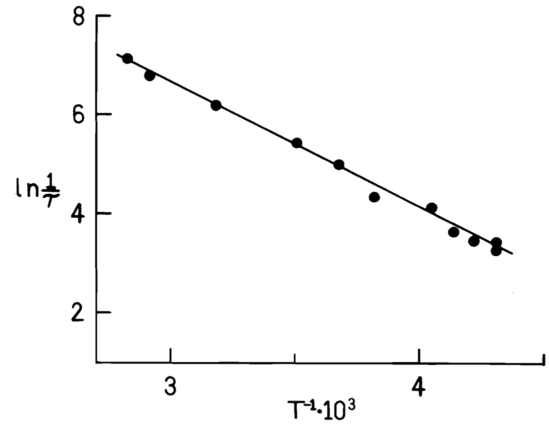


FIG. 2. Plot of ln $1/\tau$ vs. $1/T$. Sample contained $(n\text{-}C_3H_7)_4N^+SiF_5^-$ (0.5 *M*) and $[(n\text{-}C_3H_7)_4N]_2SiF_6$ (0.5 *M*) in CH_2Cl_2 (0.4 ml).

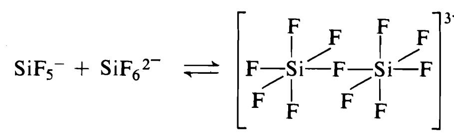
fact that both free ions are in equilibrium with ion-pairs or aggregates precludes a more definitive kinetic analysis. The addition of a small amount of $(Me_3Si)_2NH$ (3 µl) had no noticeable effect upon the exchange rate.



i-**2**

A comparison of the SiF_5^-–SiF_6^{2-} and $RSiF_3$–$RSiF_4^-$ systems shows that coalescence in the SiF_5^-–SiF_6^{2-} system occurs at higher temperature and higher concentration of reagents. This difference probably resides in the unfavourable dissociation of $Pr_4N^+SiF_5^-$ and $(Pr_4N)_2SiF_6$; hence, the concentration of free SiF_5^- and SiF_6^{2-} ions in solution is probably quite low as compared to the concentration of $RSiF_3$.

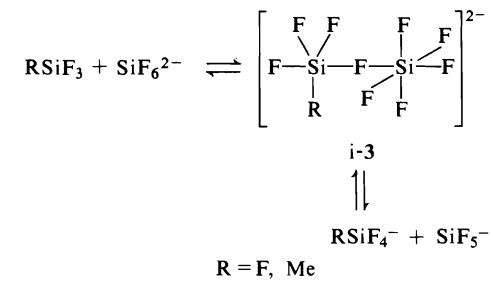
Four- and Six-coordinate Silicon Fluorides

A mixture of SiF_4 (0.49 *M*) and $(Pr_4N)_2SiF_6$ (0.49 *M*) showed a broadened peak at +136.6 ppm, close to the chemical shift of pure Pr_4N^+-SiF_5^- (Table 1). The reaction was repeated on a larger scale using 1.2 mmol SiF_4 and 0.14 mmol $(Pr_4N)_2SiF_6$. Evaporation of the solution and recrystallization gave pure $Pr_4N^+SiF_5^-$ as confirmed by comparison of its melting point, infrared, and nmr spectrum with that of an authentic sample.

Similarly, a mixture of $MeSiF_3$ (1.0 *M*) and $(Pr_4N)_2SiF_6$ (0.49 *M*) showed two broad peaks

in the region expected for $MeSiF_4^-$ and SiF_5^-. Evaporation and infrared and nmr examination of the white residue showed it to be a mixture of $MeSiF_4^-$ and SiF_5^-.

These reactions may be summarized by coordination changes Si $4 \rightleftharpoons 5 \rightleftharpoons 6$, F $1 \rightleftharpoons 2$, and intermediate **3**. They demonstrate that the



formation of five-coordinate silicon fluorides is thermodynamically and kinetically favoured in the SiF_4–SiF_6^{2-} and $MeSiF_3$–SiF_6^{2-} systems; therefore, simply mixing four- and six-coordinate silicon fluorides represents a convenient way of preparing five-coordinate silicon fluorides.[2] $(Pr_4N)_2PhSiF_5$ was also prepared (9) for this study; however, attempts to recrystallize the compound and remove impurities such as HF and FHF^- were not successful, therefore, we could not distinguish between impurity catalyzed or bimolecular fluorine exchange.

Base and Intermolecular Fluorine Exchange

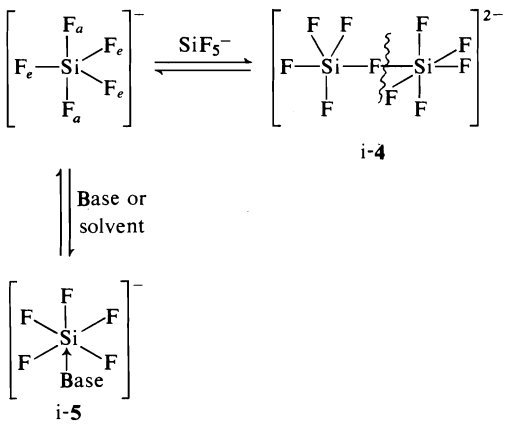
The results discussed above demonstrate that intermolecular fluorine exchange is rapid, on the nmr time scale, if the coordination number of silicon in the exchanging species is different. Conversely, fluorine transfer is extremely slow between silicon fluorides of the same coordination number, i.e. exchange is not observed in the systems SiF_4–SiF_4, $RSiF_3$–$RSiF_3$, SiF_5^-–SiF_5^-, $RSiF_4^-$–$RSiF_4^-$, and SiF_6^{2-}–SiF_6^{2-}.

The relationship between coordination number and intermolecular fluorine exchange may also be investigated by using a Lewis base, rather than a fluorine ligand, to vary the coordination number of silicon. In such an experiment it was found that addition of a large excess of NH_3 (10 *M*) to a sample containing $Pr_4N^+SiF_5^-$ (0.5 *M*) and $(Pr_4N)_2SiF_6$ (0.5 *M*) inhibited fluorine exchange, presumably because SiF_5^- is converted to $SiF_5(NH_3)^-$ (7, 8) and intermolecular fluorine exchange between six-coordinate $SiF_5(base)^-$ and SiF_6^{2-} is slow on the nmr time scale.

Base may also promote exchange, as illustrated by the addition of $NHEt_2$ (0.2 *M*) to a non-exchanging sample of $MeSiF_3$ (1.6 *M*) which produced single peaks in the ^{19}F and ^1H nmr spectra at +41°C with loss of F–Si–CH_3 coupling. In this case, the addition of base presumably facilitates fluorine transfer between the four-, five-, and six-coordinate silicon species $MeSiF_3$, $MeSiF_3$(base), and $MeSiF_3(base)_2$.

Intramolecular Axial–Equatorial Exchange

Intramolecular axial–equatorial exchange in SiF_5^-, $MeSiF_4^-$, and $PhSiF_4^-$ was found to be rapid on the nmr time scale under all experimental conditions. Although this study provides no direct evidence related to the mechanism of axial–equatorial exchange, the postulate that exchange occurs via intermediates **4** or **5** is consistent with our previous suggestion that the lowest energy pathway of axial–equatorial exchange in trigonal bipyramidal molecules involves Lewis acid–base interactions and rapid equilibration of five- and six-coordinate geometries (8). Since SiF_5^- samples do not exhibit



intermolecular fluorine exchange (in the absence of impurities (8)) it must be concluded that cleavage at six-coordinate Si in i-**4** is faster than at five-coordinate Si, hence, fluorine transfer will not occur despite the formation of i-**4**. Any Lewis base or solvent may also induce rapid coordination changes Si $5 \rightleftharpoons 6$ via i-**5** and lead to axial–equatorial exchange.

[2]It is of historical interest that Berzelius prepared SiF_6^{2-} salts from SiF_4 and metal fluorides in 1828 (*cited in* ref. 21). Perhaps the facile addition of ionic fluoride to SiF_5^-, combined with the volatility of SiF_4, prevented earlier detection of SiF_5^-.

Limiting equivalent conductances for selected substituted ammonium ions in water

SHEILA TERESA LOBO AND ROSS ELMORE ROBERTSON
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4
Received March 7, 1977

SHEILA TERESA LOBO and ROSS ELMORE ROBERTSON. Can. J. Chem. **55**, 3850 (1977).

The temperature dependence of the limiting equivalent conductances of the ions 2-methoxyethylammonium, bis-2-methoxyethylammonium, 3-methoxypropylammonium, piperidinium, quinuclidinium, cyclohexylammonium, and diethylammonium have been determined over the range 5–45°C. The probable effect of these ions on the adjacent water structure has been explored in terms of an approach used by Kay and co-workers and the behaviour in water has been compared with that of other alkylammonium ions.

SHEILA TERESA LOBO et ROSS ELMORE ROBERTSON. Can. J. Chem. **55**, 3850 (1977).

On étudie l'influence de la température sur les conductances équivalentes limites des ions méthoxy-2 éthylammonium, bis-méthoxy-2 éthylammonium, méthoxy-3 propylammonium, pipéridinium, quinuclidinium, cyclohexylammonium et diéthylammonium dans l'écart de température de 5 à 45°C. L'effet probable de ces ions sur la structure de l'eau adjacente est étudié en profondeur en fonction d'une approche utilisée par Kay et ses collaborateurs et le comportement dans l'eau de ces ions est comparé avec celui d'autres ions alkylammonium.
[Traduit par le journal]

Introduction

In our pK_b studies of various substituted amines in water, such as simple alkylamines (1, 2), cyclic amines (3), and aminoethers (4, 5)[1] by the Shedlovsky–Kay method (6), limiting equivalent conductances, Λ_0, of the corresponding amine hydrochlorides (BH^+Cl^-) were determined as a function of temperature between 5 and 45°C.

These experimental $\Lambda_0(BH^+Cl^-)$ can easily be dissected into their contributory ionic $\lambda_0(BH^+)$ and $\lambda_0(Cl^-)$ values. The $\lambda_0(BH^+)$ values, thus obtained, in combination with the viscosity of water, η, permit the calculation of the Walden product, $\lambda_0\eta$. Káy and co-workers (7–9) have used $\lambda_0\eta$ and its temperature dependence in classifying the effect of tetraalkylammonium ions, alkali metal, and halide ions on the surrounding water in terms of structure-making or -breaking. The various substituted ammonium ions studied by us lend themselves to such an analysis.

These ions are amphiphilic, consisting of a polar ionic part, i.e., $—NH_3^+$, NH_2^+, NH^+ and a nonpolar hydrocarbon part. The interaction of these two parts with the adjacent water structure is necessarily different. The ionic part of the solute will be hydrated electrostrictively, whereas the alkyl hydrocarbon part will be subjected to hydrophobic hydration to the extent permitted by the adjacent charge. The balance between these two types of hydration will determine whether a particular ion appears to be a water structure-breaker or -maker.

Most of the $\lambda_0(BH^+)$ values obtained here have not been reported before and the temperature dependence of these values as far as we know have never been examined. It is proposed in the present work to correlate λ_0, $\lambda_0\eta$, and $d(\lambda_0\eta)/dT$ of the ions studied with those available in the literature and determine their net effect on the neighbouring water structure. We examine as well the effect of variation in the structure of the ammonium ion, i.e. RNH_3^+, $R_2NH_2^+$, R_3NH^+, and R_4N^+, where R = Me, Et, *n*-Pr, on the above-mentioned physical quantities.

Experimental

The conductance method for determining Λ_0 of the amine hydrochlorides required the utmost care with respect to the purity of the salts and water, temperature control during measurements, and accuracy of conductance–concentration data. The experimental set-up and technique have been described previously (1) and were designed to achieve these standards.

The hydrochlorides were prepared from commercially available amines, which were purified prior to the preparation of the salt. Quinuclidine was available as quinuclidine hydrochloride (Eastman White Label) which was converted to the free base by the method of Brown and Eldred (10). The purity of the amines was checked by gc

[1]Tables reporting K_b as a function of temperature report $\Lambda_0(BH^+Cl^-)$ instead of $\Lambda_0(BH^+OH^-)$; this comment applies to refs. 3 and 4 as well.

and mass spectral analysis. The hydrochlorides of the amines were prepared by passing dry hydrogen chloride gas (Matheson of Canada Ltd.) through an ethereal solution of the purified amine. The salt was washed with ether and dried under vacuum over silica gel. The aminoether hydrochlorides presented added problems in that they were deliquescent. In these cases, after removal of most of the ether and water, the last trace impurities were removed by short path distillation under high vacuum. The bis-2-methoxylamine hydrochloride was recrystallized from a toluene–ethanol mixture, under anhydrous conditions.

Potassium chloride used for cell-constant determinations was of analytical grade, recrystallized from conductivity water twice, and fused in a platinum boat (11). $\Lambda_0(BH^+Cl^-)$ was determined as a function of temperature between 5 and 45°C at 10° intervals.

Results

The conductance–concentration data[2] were fitted by a linear least-squares fit to the Onsager equation, modified by Robertson and co-workers (1) to correct for any errors peculiar to our system of measurement, i.e. zeroing the titrimeter capable of delivering fixed concentration of salt solutions to the cell, possible adsorption on the walls of the cell at lower concentrations, and a check on the water correction. The equation used was

$$[1]\quad \frac{1000C_k\left[\frac{1}{R_i}-\frac{1}{R_0}\right]}{c_i - c_0} = \Lambda_0 - \frac{A[c_i^{3/2} - c_0^{3/2}]}{c_i - c_0}$$

where R_i and R_0 are resistances of the solution measured at concentrations c_i (c_i being between 10 and 15 values) and c_0, respectively, the concentration of the chloride being determined gravimetrically. A is the limiting slope, C_k is the cell constant, and Λ_0 is the intercept of the Λ vs. concentration plot. The concentration of the stock solution was approximately 0.05 M so that the concentration range used in determining Λ_0 was between 0.00015 M and 0.003 M. Since Λ_0 of the amine hydroxides (BH^+OH^-) was of interest in obtaining the basic dissociation constants, K_b, of amines, the Λ_0 values of the hydrochlorides (BH^+Cl^-) were converted into those of the corresponding hydroxides by using the Kohlrausch equation

$$[2]\quad \Lambda_0(BH^+OH^-) = \Lambda_0(BH^+Cl^-) + \lambda_0(OH^-) - \lambda_0(Cl^-)$$

$\lambda_0(Cl^-)$ used in [2] was from Harned and Owen (12), who fitted λ_0 vs. temperature data to the cubic equation

$$[3]\quad \lambda_0{}^t = \lambda_0{}^{25} + A(t - 25) + B(t - 25)^2 + C(t - 25)^3$$

Similarly $\lambda_0{}^t(OH^-)$ vs. temperature values from Robinson and Stokes (13, p. 465) were fitted to a cubic equation as above, to obtain the required constants (1) of [3] needed for interpolation.

The $\Lambda_0(BH^+OH^-)$ values vs. temperature data were fitted to a cubic equation by linear least squares. Although the standard deviation ($\sigma\Lambda$, cf. last column of Table 1) of the equivalent conductance vs. concentration plot is better than 0.03% for individual Λ_0 determinations, the reproducibility (precision) of the Λ_0 values at any given temperature may show somewhat larger errors (cf. column 4 of Table 1). Λ_0 vs. temperature data for bis-2-methoxyethylamine hydroxide are reported in Table 1 as a typical illustration of the type of results obtained. The table contains the observed $\Lambda_0(BH^+OH^-)$ values as a function of temperature, the difference between observed and calculated values, the latter obtained from the cubic equation used to fit the data, and the standard deviation of $\sigma\Lambda$ for individual Λ_0 determinations from plots of equivalent conductance vs. concentration. Table 2 contains values of the parameters A, B, C, and D of the cubic equation

$$[4]\quad \Lambda_0 = A + Bt + Ct^2 + Dt^3$$

used to fit $\Lambda_0(BH^+OH^-)$ vs. temperature data for all the amine hydroxides studied here. These parameters are useful for interpolating any desired Λ_0 value in the range 5–45°C.

Since the hydrochlorides examined here are salts of a weak base and strong acid, the possibility that hydrolysis might have a significant effect on the value of $\Lambda_0(BH^+Cl^-)$ was considered, particularly with respect to salts of the weaker amines, 2-methoxyethylamine and bis-2-methoxyethylamine (pK_a = 9.390 and 8.609, respectively). In the absence of the correction for hydrolysis, the experimental Λ_0 values will be higher, because ammonium ions are replaced by hydrogen ions of higher mobility.

The hydrolysis correction has been determined

[2]The original conductance data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

by taking into consideration the equilibrium

[5] $$BH^+ + H_2O \rightleftharpoons B + H_3O^+$$

and the procedure followed is essentially that of Campbell and Bock (14). The corrected conductance (Λ_{corr}) can be calculated by

[6] $$\Lambda_{obsd} = (1 - x)\Lambda_{corr} + x\Lambda_{0\ HCl}$$

where $\Lambda_{0\ HCl}$ values were obtained from Robinson and Stokes (13, p. 465), and x is the degree of hydrolysis. It was found that for 2-methoxyethylammonium hydroxide, the maximum difference in the observed and corrected Λ_0 values was 0.1% and for bis-2-methoxyethylammonium hydroxide 0.3%. It was therefore not necessary to correct for Λ_0 values of the hydroxides of 3-methoxypropylamine, cyclohexylamine, piperidine, quinuclidine, or diethylamine, all of which are salts of stronger bases than methoxyethylamine and bis-2-methoxyethylamine. The effect of hydrolysis on Λ_0 is illustrated for bis-2-methoxyethylammonium hydroxide in Table 3.

Discussion

The problems associated with estimating and interpreting solute–solvent interactions are varied and to a considerable degree dependent on the experimental method. It is well known that water, as a solvent, presents special problems in such studies because of its peculiar structure. The latter may be described in terms of a mixture model or a continuous model but each will treat bulk water as possessing, to a greater or lesser degree, three-dimensional hydrogen bonded structures. These structures are modified by the solute, as indicated by measurement of various physical properties of the solute–water system. In the case of ionic solutes the evaluation of the value of the physical property for the ion of

interest and, specifically, its effect on water structure may not be simple nor satisfactory, due to the inability of separating out the contribution of the counter-ion.

Conductance measurements offer the advantage in that accurate estimates of single ion limiting equivalent conductances, λ_0, can be obtained without introducing arbitrary assumptions. However, λ_0 alone does not give as satisfactory a parameter for determining the effect of an ion on water structure as the Walden product, $\lambda_0\eta$, and its temperature dependence. These have been used by Kay and co-workers (7–9) to classify ions as structure-breakers or -makers.

In order to obtain λ_0 values for the ions studied here, λ_0 values of the substituted ammonium ions are obtained from $\Lambda_0(BH^+OH^-)$ (cf. Table 2) and $\lambda_0(OH^-)$ values (13, p. 465) and η values have been taken from ref. 15. λ_0 and $\lambda_0\eta$ for all the substituted ammonium ions studied here are listed in Tables 4 and 5, repectively. For the sake of comparison, values for ethylammonium (1), trimethylammonium (2), and triethylammonium[3] ions are also included.

Figure 1 illustrates the temperature dependence of $\lambda_0\eta$ of the ions listed in Tables 4 and 5. As rationalized by Kay and Evans (8), structure-breakers usually have high Walden products. These values tend to decrease with increasing temperature, because there is less water structure to break at higher temperatures.

Such ions as $n\text{-}Pr_4N^+$ and $n\text{-}Bu_4N^+$, which show a positive temperature coefficient of $\lambda_0\eta$, are judged to be structure-makers since the hydrophobic cage-like structures formed by such ions melt with increasing temperature, producing smaller faster moving entities. From Fig. 1,[4] if we ignore the 5°C points, we conclude

[3]D. Northcott and R. E. Robertson. Unpublished data.

[4]The 5°C points for most of the compounds investigated here appear to be anomalous; however, we found no justifiable reason to ignore these data (cf. last column of Table 1).

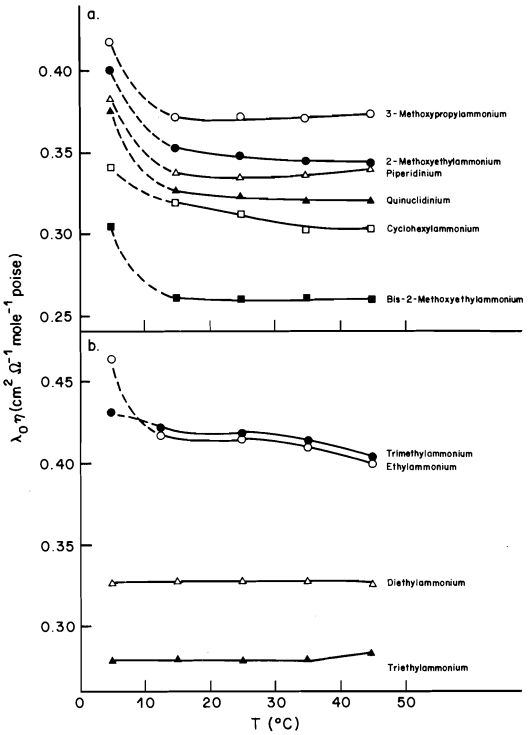

FIG. 1. Temperature dependence of Walden products for selected ammonium ions: (*a*) cyclic and methoxy substituted ammonium ions; (*b*) simple aliphatic ammonium ions.

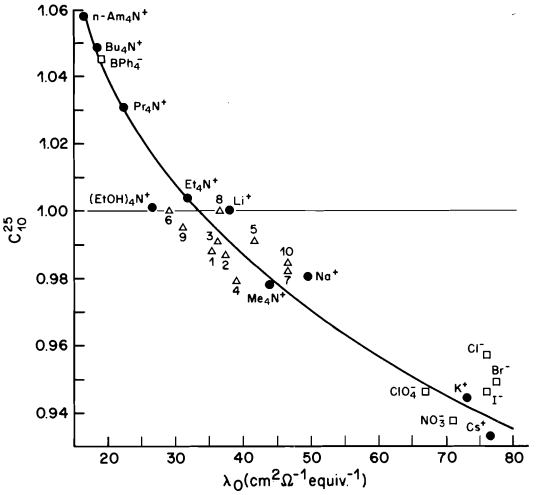

FIG. 2. Plot of C_{10}^{25} vs. λ_0^{25}: *1*, cyclohexylammonium; *2*, piperidinium; *3*, quinuclidinium; *4*, 2-methoxyethylammonium; *5*, 3-methoxypropylammonium; *6*, bis-2-methoxyethylammonium; *7*, ethylammonium; *8*, diethylammonium; *9*, triethylammonium; *10*, trimethylammonium.

that 2-methoxyethylammonium, cyclohexylammonium, quinuclidinium, ethylammonium, and trimethylammonium ions are structure-breakers. By the same criterion the piperidinium ion is seen to be a weak structure-maker. Bis-2-methoxyethylammonium, 3-methoxypropylammonium, triethylammonium, and diethylammonium ions appear to have no net effect on water structure. That the latter four ions should have no net effect on water structure is unexpected. Intramolecular hydrogen bonding in the case of 3-methoxypropylammonium ion may affect its structure-breaking ability. However, the secondary ammonium ions also appear to show anomalous behaviour. Rather than rely solely on the temperature dependence of $\lambda_0\eta$ of these ions, we have used a plot of C_{10}^{25} vs. λ_0^{25} for distinguishing between structure-breakers and -makers, as suggested by Kay (9). We have superimposed our values on Kay's original plot (9), Fig. 2. The results of this plot are interesting.

In Fig. 2, structure-making ions have high C_{10}^{25} values and lie in the upper left-hand corner of the plot, whereas structure-breakers lie in the lower right-hand corner of the plot. Ions that have both these features balanced have a C_{10}^{25} value of unity and lie on the centre of the plot. Thus the alkylammonium ions and the cyclic ammonium ions studied here lie slightly below the centre of the plot and indicate an overall structure-breaking effect, although it is not very strong. The bis-2-methoxyethylammonium ions and diethylammonium ions have no net effect on water structure, the reason, as mentioned earlier, not being obvious. Thus, although a smooth correlation is possible for the tetraalkylammonium ions, small variations are noted for the partially substituted ammonium ions.

In order to determine if these deviations are related to the size of the ion, we recall the Stokes relation (13, p. 125), which for univalent ions is

$$[7]\quad \lambda_0\eta = \frac{15.4}{6\pi r_s} = \frac{15.4}{6\pi}\left(\frac{4\pi N}{3}\right)^{1/3}\left(\frac{1}{\bar{V}^0}\right)^{1/3}$$

where r_s is the radius in aqueous solution, N is Avogadro's number, and $\bar{V}^0$ is the partial molar volume. If [7] is obeyed, the plot of $\lambda_0\eta$ vs. $(1/\bar{V}^0)^{1/3}$ should give a straight line. In Fig. 3 the well-known fact that the hypothetical line is not in accord with the experimental facts for small ions is of less significance here than the systematic deviations evident in the case of alkylammonium ions. The larger the alkyl groups and the more insulated the charge, the closer the

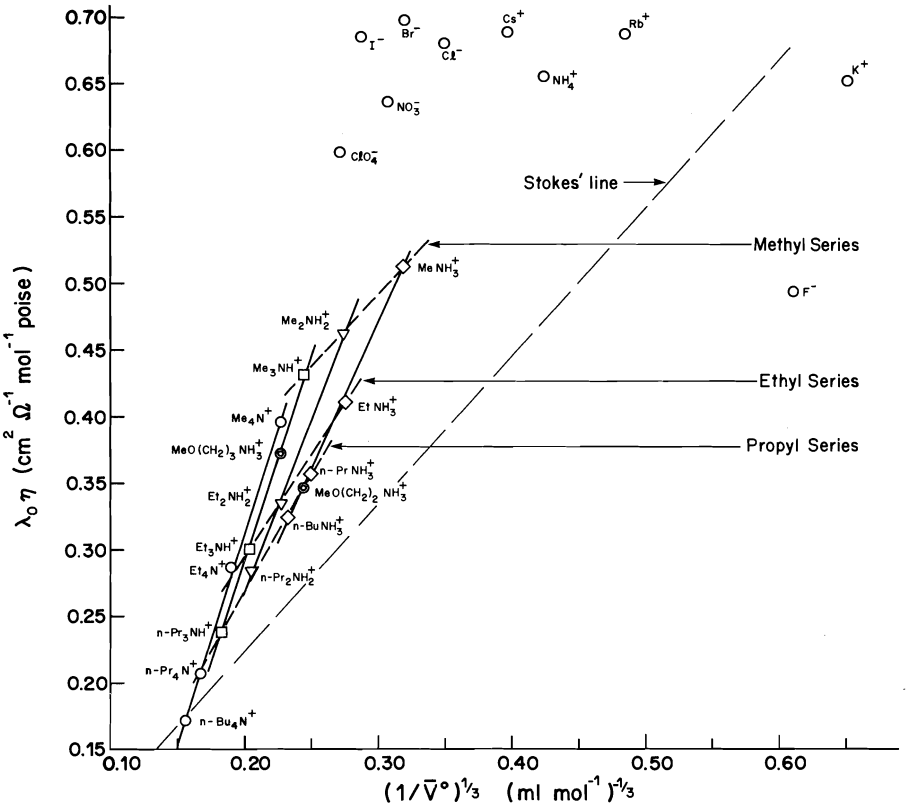

FIG. 3. Plot of $\lambda_0\eta$ vs. $(\bar{V}^0)^{-1/3}$ at 25°C. λ_0 and $\bar{V}^0$ data are taken from Kay (18) and Friedman and Krishnan (19) and this work, except for λ_0 of $MeNH_3^+$ (20), $EtNH_3^+$ (20), *n*-$PrNH_3^+$ (20), *n*-$BuNH_3^+$ (20), *n*-$Pr_2NH_2^+$ (16), Et_3NH^+ (16) and $\bar{V}^0$ of $MeO(CH_2)NH_3^+$ (17), $MeO(CH_2)_3NH_3^+$ (17).

adherence to the above relation (cf. Bu_4N^+). This trend has been explained by Kay (18). It appears that each category of ions, i.e. primary, secondary, tertiary, and quaternary ammonium ions, is well correlated by straight lines, although each series deviates from the Stokes line in the direction of higher mobility, with the quaternary ammonium ions deviating the most. The Me, Et, Pr, and Bu series are correlated among themselves, although in the case of the Me series, Me_4N^+ deviates from the line, but as we progress to the Bu series the deviation of the quaternary ammonium ion vanishes. Thus in any given series, be it type of ion or the type of substituent, size of the ion is related to the Walden product, and $\bar{V}^0$. No apparent correlation, dependent on size, is found for the ethyl substituted ammonium ions (the only series for which C_{10}[25] values are available, Fig. 2) and unfortunately no volumetric data are available for all the cyclic ammonium ions studied here. Neither are accurate conductance data available for all the members of the methyl, propyl, and butyl series to draw any firm conclusions about the scatter of points in the structure-breaking region in Fig. 2. As for the methoxyalkylammonium ions (cf. Fig. 3), $MeO(CH_2)_2NH_3^+$ falls on the line of the primary ammonium ions and its $\lambda_0\eta$ value appears to be related to size. However, $MeO(CH_2)_3NH_3^+$ deviates in the direction of larger $\lambda_0\eta$ although its size is close to that of *n*-$BuNH_3^+$. If this ion does break water structure in its immediate vicinity so as to have a higher mobility, one would naturally expect its apparent size in aqueous solution to be smaller. That the effective size of the ion in solution governs the magnitude of λ_0 and $\bar{V}^0$ is seen in Fig. 3. This was observed also by Desnoyers and co-workers (20) for ions of the type RNH_3^+.

Although on the basis of the above analysis, the ions studied here are classified as weak water structure-breakers, we must admit that the concept of structure-makers and -breakers is not entirely satisfactory, because it is not known

specifically what type of water structure is made or broken. However, we tend to agree with Kay and Evans (8) that analysis of λ_0 values based on the model of structure-breaking and -making properties of ions in aqueous solution is preferable to that based solely on the approach of electrostrictive hydration and arbitrary corrections to Stokes' law.

A radiochemical study of the kinetics of ion-exchange on zirconium antimonate

JOHN MATHEW AND SHIV NATH TANDON
Department of Chemistry, University of Roorkee, Roorkee – 247672, India

Received April 6, 1977

JOHN MATHEW and SHIV NATH TANDON. Can. J. Chem. **55**, 3857 (1977).

This paper reports the radiochemical study of the kinetics of ion-exchange of Rb^+ and Cs^+ with H^+ on zirconium antimonate. The slow step which determines the rate of exchange of these ions is diffusion through the particle. Values for the diffusion coefficients, energy of activation, and entropy of activation have been calculated. The data obtained have been compared with those reported for other organic and inorganic exchangers.

JOHN MATHEW et SHIV NATH TANDON. Can. J. Chem. **55**, 3857 (1977).

Cet article rapporte l'étude radiochimique de la cinétique de l'échange ionique de Rb^+ et Cs^+ avec H^+ sur de l'antimonate de zirconium. L'étape lente qui détermine la vitesse de l'échange de ces ions est la diffusion à travers la particule. On a calculé des valeurs pour les coefficients de diffusion, l'énergie d'activation et l'entropie d'activation. On a aussi comparé les valeurs obtenues avec celles rapportées pour d'autres échangeurs organiques et inorganiques.

[Traduit par le journal]

Introduction

The rate-controlling step in ion-exchange was first shown by Boyd *et al.* (1) to be diffusion either in the exchanger particles itself ('particle diffusion') or in an adherent stagnant liquid layer ('film diffusion'); in an intermediate range of conditions both mechanisms may affect the rate. Though many studies of the kinetics of ion-exchange on organic resins have been reported, rather less information exists on the kinetics of exchange on inorganic ion-exchangers. Nancollas and Paterson (2) have found particle diffusion to be the slow step which determines the rate of exchange on zirconium phosphate. Similar observations have also been made on some hydrous oxides (2–4) and tantalum arsenate (5). However, with less concentrated solutions, the rate-determining step for exchange on zirconium phosphate involves both film and particle diffusion (6).

Recently, we reported (7) the ion-exchange characteristics of zirconium antimonate and showed the utility of the material by demonstrating various separations of analytical and radiochemical interest. It was observed that Rb^+ and Cs^+ exchange stoichiometrically with this exchanger. In the present report, a radiochemical study of the kinetics of the exchange of Rb^+ and Cs^+ with H^+ on zirconium antimonate is described, and the thermodynamic parameters for the exchange are calculated. The data obtained for this material are compared with those for organic resins and other inorganic exchangers.

Experimental

Reagents and Apparatus

Zirconium oxychloride (Riedel, A. R.) and potassium pyroantimonate (E. Merck, G. R.) were used. All other chemicals were of analytical grade. ^{86}Rb ($t_{1/2}$ = 18.8 d) and ^{134}Cs ($t_{1/2}$ = 2.19 y) obtained from BARC, Bombay, were employed as tracers.

All radiometric determinations were done by scintillation counting, by means of a NaI/Tl well-type crystal employing a counter together with a single-channel analyser (ECIL, Hyderabad).

Kinetic Measurements

The synthesis of the exchanger is described elsewhere (7) and the sample No. 4A which has the highest exchange capacity was chosen for the study. The air-dried material was converted to the H^+ form by treatment with 1 *M* HCl. Finally, it was washed several times with deionised water and dried over saturated ammonium chloride solution (relative humidity 79%). The exchange capacities determined by a radiotracer technique (8) for Rb^+ and Cs^+ were 0.61 and 0.55 mequiv./g, respectively.

The radius of the particle of the sieved fractions was determined by measuring the diameter of 100 particles with a micrometer microscope. The mean radius of the particle measured was 6.42×10^{-3} cm for the smaller-sized fractions and 1.20×10^{-2} cm for the larger-sized fractions.

Rates of exchange were determined by the 'limited bath technique'. Twenty millilitres of the labelled metal chloride solutions (total ionic strength $\mu = 0.11$ *N*) were shaken in a thermostatic bath at the desired temperature. Then 0.2 g of the exchanger in the H^+ form was added. At preset time intervals, samples of the supernatent solution were removed for analysis to determine the extent of exchange. The experiments were conducted at 20, 30, 40, and 50°C (±0.5°C).

Analytical Procedures

Rubidium and cesium solutions were analysed radiometrically. The results are expressed in terms of the

TABLE 1. B values as a function of particle size and temperature

System	Particle size r (cm)	B values (s^{-1}) 20°C	30°C	40°C	50°C
Rb^+/H^+	1.20×10^{-2}	2.78×10^{-4}	3.33×10^{-4}	3.96×10^{-4}	4.76×10^{-4}
	6.42×10^{-3}	8.33×10^{-4}			
Cs^+/H^+	1.20×10^{-2}	1.67×10^{-4}	2.22×10^{-4}	2.78×10^{-4}	3.63×10^{-4}
	6.42×10^{-3}	5.55×10^{-4}			

exchange fraction F, with time according to the following expression

$$F = (S_0 - S_t)/(S_0 - S_\infty)$$

where F = fraction exchanged at time t, S_0 = counts s^{-1} ml^{-1} at $t = 0$, S_t = counts s^{-1} ml^{-1} at $t = t$, S_∞ = counts s^{-1} ml^{-1} at equilibrium.

The data obtained were analysed by the least-squares method (9). The estimated errors were within 5% for each measured value of the diffusion coefficient and other thermodynamic parameters.

Results and Discussion

The conditions of the present experiment were set to study the particle diffusion mechanism only. As the limited bath technique was employed, the equation developed by Boyd *et al.* (1) and improved by Reichenberg (10) can be used. If the rate-determining step is diffusion through the exchanger, then the following equation is valid.

$$[1] \qquad F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp(-n^2Bt)$$

where F is the fractional attainment of equilibrium, n is an integer, $B = \pi^2\bar{D}/r^2$, in which $\bar{D}$ is the effective diffusion coefficient of the exchanging ion inside the exchanger and r is the radius of the particle.

According to the above equation, F is a function of B and t only and is thus independent of the concentration of the external solution. Experimental results may be tested to determine whether they conform to the above equation by plotting values of Bt (calculated from the experimentally determined values of F) against corresponding values of t; Bt values are taken from Reichenberg's table (10).

The values of F as function of time for different concentrations of Rb^+ and Cs^+ on zirconium antimonate are shown in Fig. 1. The plots of Bt vs. t for the Cs^+/H^+ system are linear and pass through the origin with constant diffusion coefficients within experimental error only for

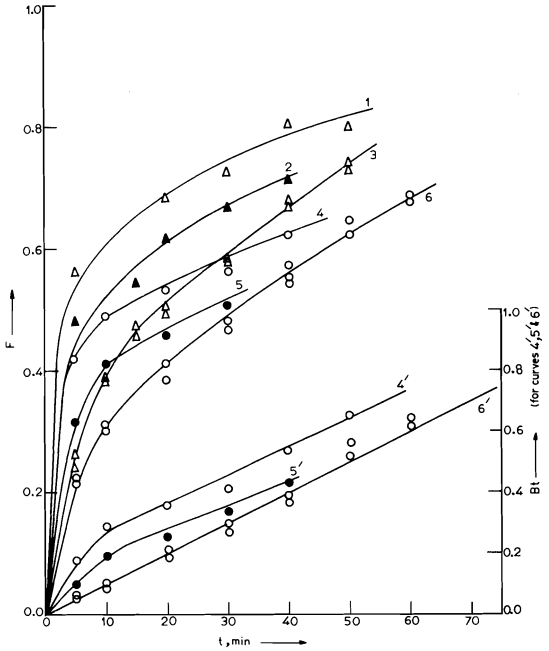

FIG. 1. Effect of the concentration of Rb^+ and Cs^+ on the rate of exchange on zirconium antimonate. (▲, △) Rb^+: *1*, 0.02 *M*; *2*, 0.05 *M*; *3*, 0.1 and 0.2 *M*. (●, ○) Cs^+: *4* and *4′*, 0.02 *M*; *5* and *5′*, 0.05 *M*; *6* and *6′*, 0.1 and 0.2 *M*.

concentrations above 0.1 *M*. Similar plots were obtained for the Rb^+/H^+ system. These results suggest that in the initial stages of the exchange, diffusion of Rb^+ and Cs^+ is not controlled by particle diffusion alone for 0.02 and 0.05 *M* solutions, while at concentrations $\geq$ 0.1 *M*, the slow step which determines the exchange is particle diffusion.

The results of the variation of particle size of the exchanger on the rate of exchange of Rb^+ and Cs^+ on zirconium antimonate are given in Table 1. For the Rb^+/H^+ system at 20°C, the ratio of the squares of the radii is 3.49 which agrees within experimental error with the inverse

ratio of the B values, 3.0, as required by [1]. Similarly, for the Cs^+/H^+ system at 20°C, the ratio of the squares of the radii is 3.49 and the inverse ratio of B values is 3.32. Thus the proportionality of B to r^{-2} is confirmed within experimental error and an effective diffusion coefficient can be calculated.

The rate of exchange increased with an increase in temperature from 20 to 50°C, suggesting that the mobility of these ions increases with increasing temperature. As a typical example, a plot of Bt vs. t obtained at different temperatures for the Rb^+/H^+ system is shown in Fig. 2; the values of B are tabulated in Table 1.

The resolution of the McKay plot (11), given in Fig. 3, in the case of the Rb^+/H^+ as well as the Cs^+/H^+ system indicates that the resulting graphs are curves similar to those of independently decaying activities. A complex exchange reaction likely occurs due to the presence of more than one type of functional site, or to the presence of $[Sb(OH)_6]^-$ bound in different ways. A similar exchange mechanism has already been observed in the isotopic exchange kinetics of phosphate ions between aqueous solution and solid zirconium phosphate (12).

When log D is plotted against $1/T$ (Fig. 4), straight lines are obtained, enabling the energy of activation (E_a) and the pre-exponential constant (D_0) to be estimated from an Arrhenius equation $D = D_0 \exp(-E_a/RT)$. The entropy of activation (ΔS^*) can then be calculated from D_0 by substituting in the equation proposed by Barrer *et al.* (13)

$$D_0 = 2.72(kTd^2/h) \exp(\Delta S^*/R)$$

where k = Boltzmann constant, T = 273 K, d = average distance between two successive positions in the process of diffusion, taken as equal to 5 Å, h = Planck's constant, R = gas constant.

The values of the diffusion coefficient obtained

TABLE 2. Diffusion coefficients and other thermodynamic parameters calculated for the exchange of Rb^+ and Cs^+ on zirconium antimonate

System	Particle size r (cm)	Diffusion coefficients D (cm^2/s)				D_0 (cm^2/s)	E_a (kcal/mol)	ΔS^* (cal deg^{-1} mol^{-1})
		20°C	30°C	40°C	50°C			
Rb^+/H^+	1.20×10^{-2}	4.06×10^{-9}	4.86×10^{-9}	5.78×10^{-9}	6.95×10^{-9}	7.71×10^{-7}	3.0	−21.50
	6.42×10^{-3}	3.64×10^{-9}						
Cs^+/H^+	1.20×10^{-2}	2.44×10^{-9}	3.24×10^{-9}	4.06×10^{-9}	5.30×10^{-9}	4.43×10^{-6}	4.4	−18.02
	6.42×10^{-3}	2.32×10^{-9}						

(Table 2) for Rb^+ and Cs^+ on zirconium antimonate are much less than those obtained for strongly cationic resins, but appreciably higher than those for zeolites. On Dowex 50-8.6X, $\bar{D}$ for rubidium and cesium ions are reported to be 13.8×10^{-7} and 13.7×10^{-7} cm^2/s respectively (14). For zeolites, however, the values of the effective diffusion coefficients are much smaller and are of the order of 10^{-12}–10^{-16} cm^2/s (15). The $\bar{D}$ value of Cs^+ at 20°C on zirconia, given by Hallaba *et al.* (4), is 2.2×10^{-9} cm^2/s and on zirconium phosphate (16) the reported value is 1.1×10^{-8} cm^2/s. Thus, a comparison of the values of the diffusion coefficient reported herein with that of inorganic resins and other exchangers indicates that zirconium antimonate shows rates of exchange approaching those of organic resins as well as some inorganic exchangers.

Energies of activation show an increase in magnitude with increase in ionic size. This is analogous to the behaviour of alkali metal ions migrating through analcite (17), where the diffusion coefficient decreases with increasing ionic size and energies of activation increase with increasing ionic size. It may therefore be said that rubidium and cesium ions suffer from a certain degree of dehydration while diffusing into the pores of zirconium antimonate and this may presumably explain why D for the Rb^+/H^+ system is higher than that for the Cs^+/H^+ system. The coefficient $\bar{D}_0$ also shows the trend of being higher in value with increasing covalent ionic size (18). A negative value for the entropy of activation suggests that upon exchange of these cations, no significant structural change occurs in zirconium antimonate.

Raman spectrum of solid CH_4 in phase II

A. Cabana and Nguyen Dinh Thé

Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 10, 1977

A. Cabana and Nguyen Dinh Thé. Can. J. Chem. **55**, 3862 (1977).

The Raman spectrum of crystalline CH_4 in phase II has been obtained. The ν_1, ν_2, and ν_3 bands have been observed as well as two weak bands in the lattice vibration region. The spectrum is found to be consistent with the structure originally proposed by James and Keenan. There is excellent agreement between a theoretical model proposed by Yamamoto and co-workers and the spectra presented here.

A. Cabana et Nguyen Dinh Thé. Can. J. Chem. **55**, 3862 (1977).

On a enregistré le spectre Raman du CH_4 cristallin dans la phase II. Les bandes ν_1, ν_2 et ν_3 ont été observées de même que deux bandes faibles dans la région des vibrations de réseau. On a pu conclure que le spectre peut être interprété sur la base de la structure proposée par James et Keenan. Il existe un accord excellent entre un modèle théorique proposé par Yamamoto et ses collaborateurs et les spectres présentés ici.

The infrared (1–3) and Raman (4) spectra of CH_4 in noble gas matrices were found to exhibit some fine structure which has been tentatively assigned to various rotation–vibration features. A suitable model for the hindered rotation of the molecule in the matrices was developed later (5, 6) and the assignment proposed by the experimentalists proved to be qualitatively correct.

The infrared spectra of neat CH_4 crystals have also been reported by several investigators (see ref. 7). Chapados and Cabana (7) compared the spectrum of the neat solid in phase II with the spectrum of the molecule in a krypton matrix and recognized that the spectrum is consistent with the theoretical model proposed by James and Keenan (8), a model which was confirmed later by Press (9) from a coherent neutron diffraction experiment of CD_4. The Raman spectra of the neat crystals have also been reported (10, 11). Only Anderson and Savoie (11) have obtained the spectrum of the solid in phase II. Considering that these investigators worked before the advent of powerful gas lasers their spectra were very satisfactory, and the phase I spectrum we have obtained is no different from theirs. However, the phase II spectrum lacked the resolution now available and is not good enough to reveal the weaker features that provide convincing evidence for rotation in that phase. We report here the Raman spectrum recorded with the higher resolution obtainable using the equipment and techniques described previously (12, 13), and discuss the spectrum in terms of the recent calculations of the ν_3 and ν_4 infrared and Raman bands reported by Yamamoto and co-workers (14). Their calculations have provided a quantitative basis for the assignment of the infrared data.

Of the four fundamental vibrations, ν_1, ν_2, and ν_3 have been observed, but ν_4 has not been found although the appropriate region was carefully scanned at wide slits and high gains. The spectrum of the neat crystal is shown in Figs. 1 (ν_3), 2 (ν_1), and 3 (ν_2) and the Raman shifts are collected in Tables 1 and 2. The weak band on the low frequency side of ν_1 has been assigned to the strong ν_1 band of C_2H_6 present at low concentration in our sample of CH_4.

Phase II CH_4 very likely belongs to space group O_h^6 (*Fm*3*c*). In this structure there are eight molecules per primitive cell of which six, occupying sites of D_{2d} (42*m*) symmetry, are ordered and two, occupying sites of *O* (432) symmetry, are free to rotate. Therefore, the molecules at sites of symmetry *O* should lead to rotational features in the spectrum whereas molecules at sites of symmetry D_{2d} could lead to site and factor group splittings as predicted from group theory (7). It is to be noted that the centrosymmetric structure imposes that all of the ir active components should be Raman inactive and vice-versa. The infrared spectrum (7) did not reveal any site or factor group splittings. It is likely that these splittings are too small to be resolvable; the same appears to be applicable to the Raman spectrum. Three lattice modes, of which one is of rotational origin, are expected for

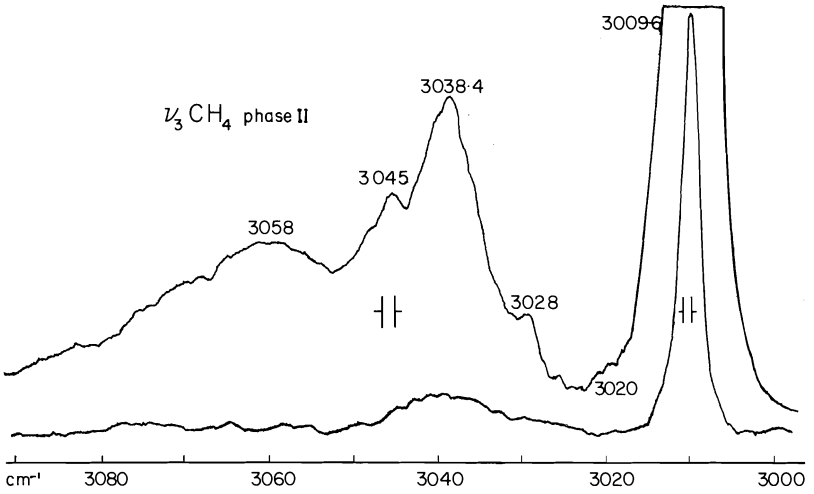

FIG. 1. The Raman spectrum of the ν_3 vibration region of CH_4 recorded at 9 K in phase II.

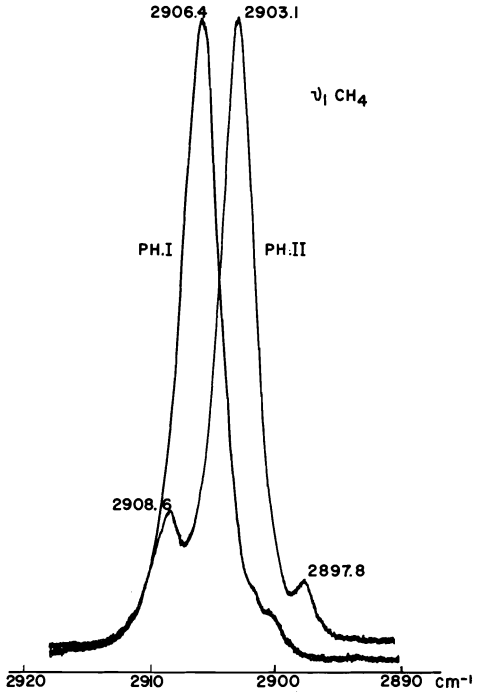

FIG. 2. The ν_1 Raman bands of CH_4 recorded at 9 K in phase II. The low frequency band at 2897.8 cm^{-1} arises from C_2H_6 present at low concentration in our sample. The phase I spectrum was obtained just above the transition temperature.

the D_{2d} molecules in the Raman as well as in the infrared spectrum (see Table 6, ref. 7) but only two of these have been observed in either the infrared (7) or the Raman spectrum (Table 2).

The ν_1 band of CD_4 at low concentration in crystalline CH_4 phase II has been recorded and is shown in Fig. 4. The vibrations of the guest CD_4 molecule should, under these conditions, be largely uncoupled from those of the host molecules such that factor group splitting

should be absent. Therefore, the component of lower intensity found at the higher frequency (2095.9 cm^{-1}) should arise from the rotating molecules. Since in the ν_1 band only $\Delta J = 0$ transitions are expected, this band should be mainly due to the $Q(1)$ and $Q(2)$ transitions. Several transitions due to the rotating molecules are identified in the ν_3 band of the neat crystal where agreement between theory and experiment is satisfactory (see Fig. 1 and Table 1). In the ν_1 band of the neat crystal it is very likely that the component of lower intensity found at the higher frequencies is also attributable to rotating

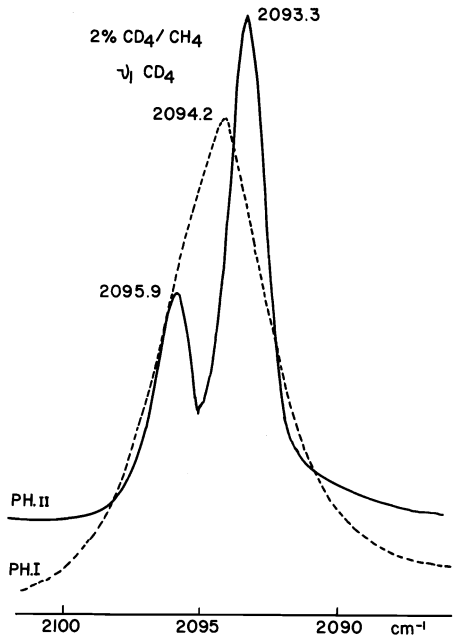

FIG. 4. The ν_1 Raman band of CD_4 at low concentration in CH_4 phase II at 9 K. The phase I spectrum was obtained just above the transition temperature.

molecules (see Fig. 2 and Table 2). Several features are also tentatively assigned to rotating molecules in the ν_2 band of the neat crystal (see Fig. 3 and Table 2). The two main components (1554.0 and 1526.7 cm^{-1}) are certainly too far apart to arise from site or factor group splitting. Although the assignment proposed here for some of the weaker lines is uncertain, the main features of these Raman spectra are found consistent with the structure generally accepted for the solid in phase II. The ν_3 Raman band, calculated by Yamamoto and co-workers (14), is certainly in good agreement with the experiment.

Acknowledgments

Financial support provided by the Ministère de l'Education de la Province de Québec and by the National Research Council of Canada is gratefully acknowledged. The authors wish to thank Professor Yamamoto for providing the results of the calculations prior to their publication.

Interactions solutés–solvants dans les mélanges eau – alcool *tert*-butylique. VIII. Volumes molaires apparents des benzoates halogéno-substitués[1]

NICOLE DOLLET, LEVON AVEDIKIAN ET JEAN JUILLARD

Laboratoire d'Etude des Interactions Solutés–Solvants, Université de Clermont II, Les Cézeaux, B.P. 45, 63170, Aubière, France

Reçu le 6 avril 1977

NICOLE DOLLET, LEVON AVEDIKIAN et JEAN JUILLARD. Can. J. Chem. **55**, 3866 (1977).

Les volumes molaires apparents du benzoate de potassium et de quelques benzoates *para*-substitués (−F, −Cl, −I, $-CH_3$) ont été déterminés dans les mélanges eau – alcool *tert*-butylique pour des teneurs en alcool comprises entre 0 et 40% en poids. Des variations importantes de volume sont observées en milieu riche en eau. L'effet de la taille des substituants sur ces variations et la situation des maxima de volume apparent sont discutés en relation avec la structure des mélanges solvants.

NICOLE DOLLET, LEVON AVEDIKIAN, and JEAN JUILLARD. Can. J. Chem. **55**, 3866 (1977).

Apparent molal volumes of potassium salts of *para*-substituted (−F, −Cl, −I, $-CH_3$) and unsubstituted benzoic acids in water – *tert*-butyl alcohol mixtures (0–40% by weight) are reported. Large volume changes are observed in media rich in water. Substituents size effects on both the location and the amplitude of the volume maxima are discussed in terms of the structure of the mixed solvents.

Les mélanges eau – alcool *tert*-butylique (TBA) sont parmi les plus étudiés des mélanges hydro-alcooliques. En effet, cet alcool apparait comme le type même des cosolvants promoteurs de la structure de l'eau. En particulier, l'addition de TBA à une solution aqueuse détermine souvent des variations spectaculaires des propriétés des solutés. De nombreux résultats concernant les propriétés thermodynamiques de solutés variés (halogénures alcalins, sels d'ammonium quaternaires, acides carboxyliques et leurs sels) ont été accumulés ces dernières années. Dans un mémoire récent (2) nous avons traité des enthalpies de transfert des benzoates *para* halogéno-substitués. L'étude de l'effet de substituant nous a permis de souligner l'existence d'un effet de taille et d'un effet spécifique dans la solvatation de ces composés, l'effet de taille déterminant l'existence de maxima endothermiques de l'enthalpie de transfert pour une composition bien définie ($x \approx 0.051$) des mélanges. Ce travail a été poursuivi et nous présentons aujourd'hui des résultats concernant les volumes molaires apparents des mêmes espèces dans ces mélanges. Une étude préliminaire (3) des *p*-bromobenzoate et benzoate de potassium nous a déjà permis de noter que l'effet de substituant est le plus notable pour une composition voisine de 0.055 en fraction molaire. Nous avons mesuré ici, dans des conditions expérimentales plus satisfaisantes, les masses volumiques de solutions de benzoate, *p*-fluoro, -chloro et -iodobenzoates de potassium dans des mélanges contenant de 0 à 40% de TBA. Nous avons aussi déterminé les volumes apparents et les enthalpies de transfert du *p*-méthylbenzoate, résultats utiles pour la discussion sur la nature des effets de substituants.

[1]Article précédent dans cette série, réf. 1.

Partie expérimentale

La préparation des sels et la purification des solvants: eau et TBA, sont effectuées selon les procédures déjà décrites (2, 4). Les masses volumiques des solutions sont mesurées à 25.00 ± 0.01°C à l'aide d'un densimètre à flux SODEV, modèle 0ID, conformément à la technique décrite par Picker *et al.* (5). Pratiquement, les masses volumiques des solutions de benzoates sont comparées à celle du mélange solvant correspondant, elle-même déterminée par rapport à celle de l'eau ($\rho = 0.997047$ g/cm³ à 25°C (6)). Compte tenu des conditions opératoires relatives à l'appareillage et à la nature des solutions, les masses volumiques sont connues à $\pm 1 \times 10^{-5}$ g cm^{-3} près.

La détermination des enthalpies de dissolution du *p*-méthylbenzoate de potassium dans les mélanges eau–TBA est faite selon la méthode utilisée précédemment (2).

Résultats

Les volumes molaires apparents ϕ_v se déduisent simplement des masses volumiques ρ et ρ_0, respectivement des solutions et du mélange solvant correspondant:

$$\phi_v = \frac{M}{\rho} - \frac{1000\,(\rho - \rho_0)}{\rho\rho_0 m}$$

[a]Pourcentage en poids de TBA.

où M est la masse molaire du soluté et m la molalité de la solution.

La variation avec la concentration est donnée par la relation de Redlich et Meyer (7):

$$\phi_v = \phi_v^0 + S_v\sqrt{c} + b_v c$$

où c est la molarité de la solution, b_v une constante empirique et S_v la pente limite de Debye–Hückel. Celle-ci ne dépend pas de la nature de l'électrolyte mais seulement de sa valence, de la température et des propriétés du milieu solvant (constante diélectrique D et son coefficient de pression $\partial D/\partial P$, compressibilité isotherme β_t).

La méthode expérimentale ne permettant pas d'atteindre le domaine des très faibles concentrations, une extrapolation à concentration nulle de ϕ_v en fonction de $\sqrt{c}$ ne saurait conduire à une valeur acceptable de ϕ_v^0, c'est-à-dire au volume molaire partiel à dilution infinie V^0. De plus, il n'existe pas de données sur la variation avec la pression de la constante diélectrique des mélanges étudiés, ce qui ne permet pas le calcul de S_v et donc l'extrapolation de $\phi_v - S_v\sqrt{c}$ en fonction de c. Ceci nous a conduit à ne considérer dans chaque solvant étudié, que les volumes molaires apparents des sels pour une molalité déterminée (0.08 m). Ces volumes apparents sont donnés dans le tableau 1. Notons à ce propos que, pour des solutions de NaCl dans les mêmes mélanges, ϕ_v et V^0 varient de façon analogue avec la composition du milieu solvant (8).

Sur le tableau 2 sont rapportées les enthalpies molaires de dissolution du *p*-méthylbenzoate pour une molalité de 10^{-2} environ dans tous les mélanges étudiés, ainsi que l'effet, sur les enthalpies de transfert, du substituant *p*-méthyl.

TABLEAU 2. Enthalpies molaires de dissolution ΔH_s et effet de substituant sur les enthalpies molaires normales de transfert $\delta_R\Delta H_t^{0a}$ du *p*-méthylbenzoate de potassium dans les mélanges eau–TBA à 298.15 K (ΔH_s et $\delta_R\Delta H_t^0$ en kJ mol^{-1})

X	ΔH_s	$\delta_R\Delta H_t^0$

[a]Calculées en utilisant les valeurs des enthalpies molaires normales de transfert du benzoate de potassium provenant de la réf. 2.

Discussion

Les volumes apparents de transfert sont portés sur la fig. 1. Toutes les courbes obtenues ont une allure analogue. On observe un minimum de volume molaire en milieu très riche en eau ($x \approx 0.02$), puis un accroissement brutal, enfin une décroissance après passage par un maximum. L'augmentation de la taille du substituant correspond à une augmentation rapide de l'amplitude du maximum et de façon moins sensible, à son déplacement vers les milieux plus riches en eau. On observe donc, mis à part l'existence du premier minimum, une allure des courbes comparable à celle des enthalpies de transfert.

L'analogie est encore plus frappante si l'on considère les effets de substituant sur ces gran-

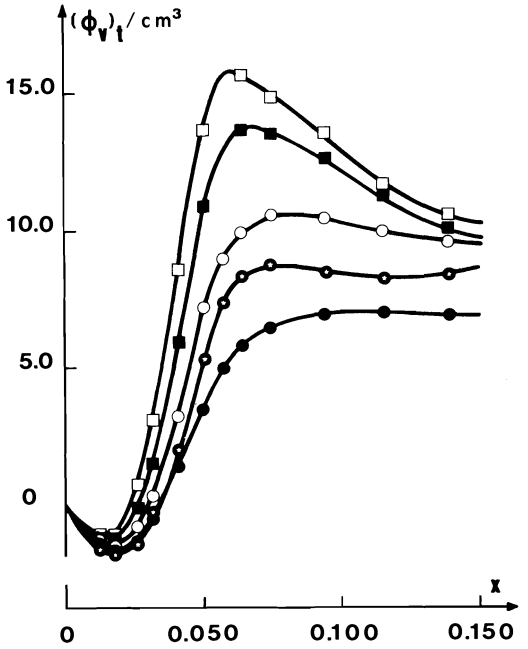

FIG. 1. Volumes apparents de transfert $(\phi_v)_t$ à 298.15 K des benzoates de potassium, de l'eau aux mélanges eau–TBA en fonction de la fraction molaire en TBA: ●, benzoate de K; ○, *p*-fluorobenzoate de K; ■, *p*-chlorobenzoate de K; □, *p*-iodobenzoate de K; ✪, *p*-méthylbenzoate de K.

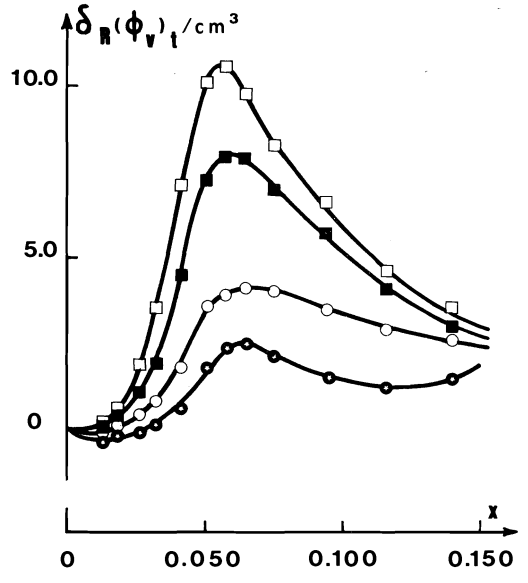

FIG. 2. Effets de substituants, à 298.15 K, sur les volumes apparents de transfert, des *p*-fluoro (○), *p*-chloro (■), *p*-iodo (□) et *p*-méthyl (✪) benzoates en fonction de la fraction molaire en TBA.

deurs de transfert:

$$\delta_R(\phi_v)_t = (\phi_v)_t(\text{benzoate substitué}) - (\phi_v)_t(\text{benzoate})$$

$\delta_R(\phi_v)_t$ traduit l'effet de la présence du substituant sur le volume de transfert de l'anion, celui du cation potassium étant éliminé dans la soustraction.

Les minima à $x \approx 0.02$ disparaissent sur ces courbes (fig. 2) et l'on obtient des maxima situés ici, à des compositions un peu plus riches en TBA que pour les enthalpies ($x \approx 0.06$).

On observe d'autre part, pour une composition quelconque des mélanges, une certaine corellation entre effets de substituant sur les enthalpies et les volumes de transfert des différents benzoates. Les effets observés ici semblent donc, comme dans le cas des enthalpies, directement liés à la taille du substituant. Toutefois, au seul vu des résultats concernant les benzoates halogéno-substitués, il n'est pas possible d'éliminer à priori l'hypothèse d'effets de substituant de type Hammett, ces effets variant pour ces substituants dans le même sens que la taille. Les résultats concernant le substituant *p*-méthyl dont le σ de Hammett est négatif, incitent à penser qu'il s'agit bien d'un effet de taille, encore qu'une correlation rigoureuse entre taille du substituant et amplitude du maximum impliquerait des effets plus voisins des substituants *p*-CH_3 et *p*-Cl.

Nous avons suggéré dans le travail précédent (2) l'existence de deux effets principaux dans la solvatation des solutés en mélange eau–TBA: un effet de solvatation spécifique et un effet de taille. Cet effet serait dominant dans les différences entre benzoate et benzoates substitués. Ces différences peuvent être estimées à partir des grandeurs thermodynamiques de formation de cavité pour les solutés correspondants. Des calculs utilisant la théorie des particules calibrées (scaled particle theory) sont exclus dans la mesure où il n'est pas possible de déterminer de façon simple les diamètres de sphère rigide de ces solutés. Par contre, la formule d'Eley (voir réf. 9) permet de calculer, à partir des volumes des benzoates, les enthalpies de formation de cavité: $\Delta H_c = T\gamma_v V^\theta$ où ΔH_c est l'enthalpie de formation d'une cavité de taille molaire à température et pression constantes, V^θ le volume molaire du soluté et γ_v le coefficient thermique de pression du milieu solvant:

$$\gamma_v = (\partial P/\partial T)_v = \alpha_P/\beta_T$$

Un exemple des résultats obtenus, comparés aux valeurs expérimentales, est donné sur la fig. 3 où nous avons porté, d'une part les différences calculées entre ΔH de transfert du benzoate et du *p*-iodobenzoate de potassium (en utilisant les valeurs de γ_v interpolées, aux concentrations considérées, à partir de celles données par Macdonald et Hyne (10)), et d'autre part, les différences expérimentales. La correspondance est acceptable jusqu'à $x = 0.05$ mais la formule de Eley ne permet pas de prévoir la décroissance brusque de la grandeur étudiée au-delà de cette fraction molaire en alcool *tert*-butylique.

En fait, la présence de maxima aigus, particulièrement sur les différences entre benzoates substitués et non-substitués pour des fractions molaires en alcool comprises entre 0.05 et 0.06, nous incite à interpréter l'effet de volume à l'aide du modèle des "cages fluctuantes" de Baumgartner et Atkinson (11). Ce modèle établit une analogie entre la structure des hydrates solides: clathrate de molécules organiques, et la structure des solutions aqueuses de ces molécules à température ordinaire, analogie déjà suggérée par divers auteurs (12). Compte tenu de la taille de l'alcool *tert*-butylique, il s'agit d'un clathrate de type II. Un clathrate de ce type stabilisé par une inclusion d'acide sulfhydrique (17 H_2O, 1 TBA, 2 H_2S) a d'ailleurs été signalé et étudié par Glew *et al.* (13). Baumgartner et Atkinson ont proposé (11) de considérer que les solutions aqueuses pourraient conserver partiellement, à l'état liquide, la structure de l'hydrate solide, celle-ci étant soumise toutefois à des fluctuations notables. Dans ces conditions la fraction molaire $1/18 \approx 0.055$ en TBA correspondrait au maximum de structuration des mélanges. Le minimum de compressibilité adiabatique est d'ailleurs observé sensiblement pour cette composition (11). Dans l'hypothèse d'une telle structure "quasi-clathrate" des solutions, les solutés d'une certaine taille ne pourraient entrer dans l'édifice qu'en le brisant ce qui correspondrait aux maxima endothermiques d'enthalpie. Ceux-ci seraient obtenus pour la composition 1–17 des mélanges et leur amplitude serait fonction de la taille des solutés.

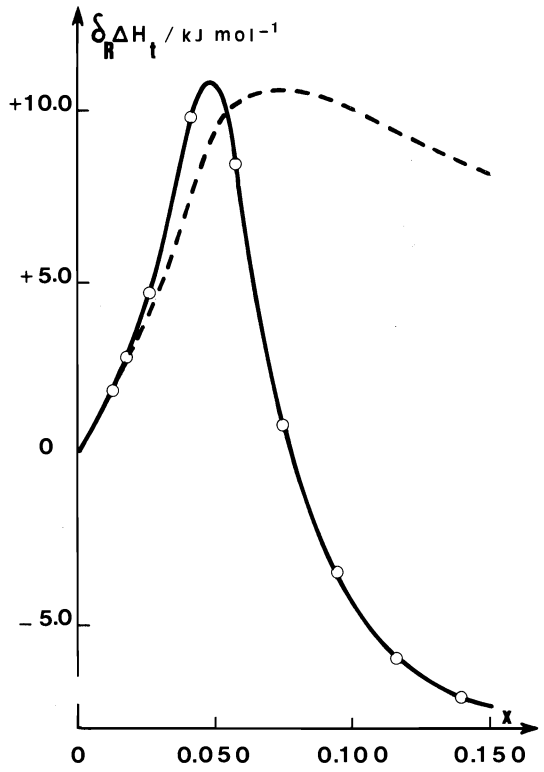

FIG. 3. Effet de substituant expérimental (—) et effet de substituant calculé (---) par la formule d'Eley sur les enthalpies de transfert du *p*-iodobenzoate à 298.15 K.

C'est bien ce que l'on observe avec des solutés volumineux tels que les sels de tétraphénylborate (14, 15) par exemple. L'effet de taille constaté précédemment sur les enthalpies de transfert des benzoates halosubstitués et confirmé ici par l'étude du méthylbenzoate s'explique bien dans ce cadre, l'introduction de substituants de plus en plus volumineux correspondant à un accroissement de l'amplitude des maxima d'enthalpie, maxima situés à une composition des mélanges voisine de $x \approx 0.055$.

On peut raisonnablement supposer que le bris de la structure détermine aussi un accroissement local de volume dans la solution, accroissement reflété par une augmentation du volume apparent des solutés. Cet accroissement serait le plus net pour le milieu le plus structuré et fonction de la taille du soluté introduit. L'addition de substituants de plus en plus volumineux correspond bien à un accroissement de volume molaire de plus en plus net, accroissement maximal pour une composition des mélanges de plus en plus proche de celle de la composition de "pseudo-clathrate" (fig. 2). Il convient de noter d'ailleurs, à propos de la situation exacte des maxima tant d'enthalpie que de volume de transfert, que celle-ci est difficile à préciser; les grandeurs mesurées: volumes

et enthalpies, le sont pour des concentrations finies; une correction de dilution convenable entrainerait sans doute de légers glissements. Il est clair toutefois que les maxima d'effet de substituant ici considérés sont observés pour des concentrations très voisines de la fraction molaire 1/17.

En conclusion donc, les résultats rapportés ici sont parfaitement compatibles avec le modèle "des cages fluctuantes" proposé par Baumgartner et Atkinson (11) pour rendre compte de la structure de certains mélanges hydro-organiques et en particulier des solvants mixtes eau – alcool *tert*-butylique.

The adsorption of nitrate ion at mercury has been studied from two systems at constant ionic strength, namely, x *M* $NaNO_3$ + $(0.2 - x)$ *M* NaF and x *M* KNO_3 + $(0.2 - x)$ *M* KF. The surface excess due to adsorbed nitrate ions was determined from differential capacity data using a modified version of the Hurwitz–Parsons analysis which takes into consideration variation in ionic activity coefficients with solution composition. The amount of adsorbed nitrate ion at a given electrode charge density and bulk nitrate ion concentration is shown to depend markedly on both ionic strength and the nature of the counter ion at the outer Helmholtz plane; when the charge in the diffuse layer is positive, an increase in ionic strength results in more anion adsorption and vice versa. A change in the cation from Na^+ to K^+ also results in increased anion adsorption. The effects observed are discussed in terms of the Stern–Grahame–Levine model for ionic adsorption which is based on an electrostatic description of the charged interface with consideration of discreteness-of-charge effects.

W. Ronald Fawcett et James B. Sellan. Can. J. Chem. **55**, 3871 (1977).

On étudie l'adsorption de l'ion nitrate par le mercure dans deux systèmes à force ionique constante à savoir x *M* $NaNO_3$ + $(0.2 - x)$ *M* NaF et x *M* KNO_3 + $(0.2 - x)$ *M* KF. L'excès de surface dû aux ions nitrate adsorbés est déterminé à partir des résultats sur la capacité différentielle en utilisant une version modifiée de l'analyse Hurwitz–Parsons qui tient compte de la variation des coefficients d'activité ionique avec la composition de la solution. La quantité d'ion nitrate adsorbé à une électrode de densité de charge donnée et à une concentration en ions nitrate donnée semble dépendre nettement de la force ionique et de la nature de l'ion opposé au plan Helmholtz de l'extérieur; lorsque la charge dans la couche diffuse est positive, un accroissement de force ionique produit une plus grande adsorption d'anion et vice versa. Un changement de nature de cation Na^+ à K^+ occasionne aussi un accroissement d'adsorption d'anion. Les effets observés sont interprétés en termes d'un modèle de Stern–Grahame–Levine pour l'adsorption ionique lequel est basé sur une description électrostatique de l'interface chargé tout en tenant compte des effets de caractère discret de charge.

Introduction

In a recent experimental study of the adsorption of iodide ion at mercury from solutions of constant ionic strength (1), it was shown that the amount of adsorbed iodide ion depends on the nature of the cation in the solution. More specifically, the adsorbed charge density increased for constant electrode charge density and bulk iodide concentration when the cation was changed from Na^+ to K^+. This result was rationalized on the basis of a model in which the thickness of the inner region of the double layer and the average potential profile as a function of distance from the electrode/solution interface depends on the nature of the counter ion forming the boundary of the inner region at the outer Helmholtz plane (oHp). Since the adsorption of iodide ion is strong, the field at the oHp is negative under normal experimental conditions and the counter ion is always a cation. On the other hand, the adsorption of nitrate ion at mercury is of intermediate strength (2, 3). Payne has shown (2, 3) that the parameters of the nitrate adsorption isotherm depend greatly on ionic strength. When nitrate adsorption is studied from solutions containing only an alkali metal nitrate salt, the magnitude of the adsorbed charge density, $|\sigma_a|$, at a positive electrode is greater than the electrode charge density, σ_m for bulk nitrate concentrations in the range 0.01 to 1 *M* (3). However, when the ionic strength is maintained at a high level by adding an indifferent electrolyte such as an alkali metal fluoride, the influence of the diffuse layer is reduced and $|\sigma_a|$ falls below σ_m at lower bulk nitrate concentrations (2). As a result, the field at the oHp for

a given positive electrode charge density changes from positive to negative and the nature of the counter ion at this plane from anion to cation. Thus, the variation of inner layer properties with the nature of the counter ion at the oHp may be investigated more extensively in this system.

The adsorption of nitrate ion and of some other polyatomic anions such as perchlorate (4) and hexafluorophosphate (5) can be characterized as anomalous with respect to the behaviour of most other anions (6). A particularly striking feature of their behaviour is the fact that the slopes of Christie plots, that is, plots of the potential drop across the inner layer against adsorbed charge density, decrease markedly with increase in electrode charge density becoming negative when σ_m is large and positive (2, 6). According to Grahame's electrostatic model of the inner layer (7), the slope of the Christie plot is equal to the reciprocal of the integral capacity of the region between the adsorption or inner Helmholtz plane (iHp) and the oHp. Thus, a negative slope cannot easily be rationalized on the basis of the electrostatic model. Furthermore, analysis of nitrate adsorption on the basis of an isotherm model which accounts for diffuse layer effects (8, 9) would lead to an adsorption isotherm at constant σ_m characterized by attractive interaction between adsorbed anions on the iHp. Damaskin (10, 11) has argued on the basis of data for anion adsorption from concentrated solutions that adsorbed nitrate and perchlorate anions are separated from the electrode by a layer of water molecules. If this interpretation is correct, then the iHp and oHp could be very close to one another; furthermore, Grahame's model of the inner layer could be inapplicable to these systems. On the other hand, the data for anion adsorption from solutions of constant ionic strength may be complicated by concomitant adsorption of fluoride ion at high positive electrode charge densities (5).

The present study was undertaken in an attempt to resolve the anomalous features of nitrate adsorption at mercury outlined above. The systems studied were $NaNO_3$ + NaF and KNO_3 + KF at constant ionic strength (0.2 *M*). The low ionic strength was chosen in order to minimize possible effects of fluoride ion adsorption and problems connected with defects in the Gouy–Chapman model used to estimate diffuse layer properties.

Experimental

Differential capacity against potential data for the mercury/aqueous solution interface were measured for 18 systems of composition x *M* $NaNO_3$ + (0.2 − x) *M* NaF and x *M* KNO_3 + (0.2 − x) *M* KF where x had the values 0, 0.01, 0.016, 0.025, 0.04, 0.063, 0.1, 0.14, and 0.20 *M*. The capacity data were obtained with an ac bridge at a frequency of 1000 Hz and at 50 mV increments in potential of the mercury electrode with respect to a saturated calomel reference electrode. The counter electrode was a platinum cyclinder whose area was much larger than that of the mercury drop. Procedures for operation of the bridge and determination of drop area at balance and of the potential of zero charge were those given by Hills and Payne (12). The experiments were carried out at 25.0 ± 0.1°C.

Variation in nitrate ion activity with solution composition was estimated from previously reported activity coefficients for the pure salts (13) as described previously (1). The analysis of the capacity against potential data was the same as described earlier (1).

Results

Capacity against potential curves for the $NaNO_3$–NaF system are shown in Fig. 1. As reported previously (2, 3), a pronounced capacity maximum is observed at potentials just positive of the potential of zero charge (pzc); as the bulk

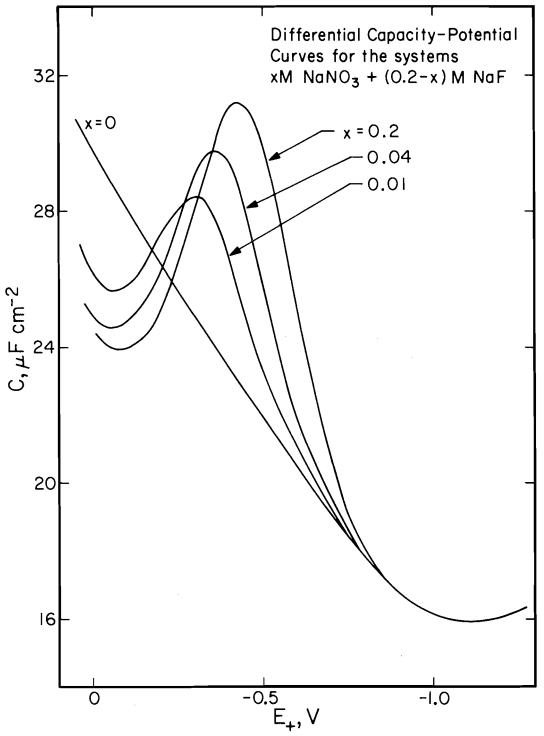

FIG. 1. Differential capacity against electrode potential curves for a mercury electrode in contact with aqueous solutions of x *M* $NaNO_3$ + (0.2 − x) *M* NaF at 25°C. The concentration of $NaNO_3$ is indicated for each curve.

concentration of nitrate ion increases, the position of the maximum shifts to more negative potentials with the pzc and its height increases. Capacity curves for the KNO_3–KF system are qualitatively similar. At potentials positive of the pzc there is negligible difference between capacities in the two systems at a given potential; at negative potentials, the capacity is somewhat higher in the K^+ system with a value of 16.25 μF cm^{-2} at the capacity minimum (−1.1 V), the corresponding value in the Na^+ system being 15.95 μF cm^{-2}.

The experimental potential scale was converted to one of thermodynamic significance corresponding to the potential of the polarizable electrode against a reference electrode reversible to the cation in the system, E_+ in the following way. Individual cationic activity coefficients in the mixed electrolyte were assumed to be given by

$$[1]\quad \ln \gamma_M = \frac{-A\mu^{1/2}}{1 + \beta \mathring{a}_M \mu^{1/2}} + \beta_{MNO_3} c_{NO_3} + \beta_{MF} c_F$$

where A and B are the Debye–Hückel constants, $\mathring{a}_M$, the ion size parameter for cation M^+ (Na^+ or K^+), μ, the ionic strength, β_{MX}, the interaction coefficient between cation M and anion X, and c_X, the concentration of anion X; anionic activity coefficients were assumed to be independent of solution composition (1). If β_{MNO_3} is significantly different from β_{MF}, one might expect γ_M to vary with solution composition at constant ionic strength. From the data reported by Robinson and Stokes (13), $\gamma_\pm(NaF) = 0.710$, $\gamma_\pm(NaNO_3) = 0.703$, $\gamma_\pm(KF) = 0.727$, and $\gamma_\pm(KNO_3) = 0.663$ at $\mu = 0.2\ M$. Since $\gamma_\pm(NaF) \simeq \gamma_\pm(NaNO_3)$, one may assume that $\beta_{NaF} \simeq \beta_{NaNO_3}$. The difference $(\beta_{KNO_3} - \beta_{KF})$ can be estimated from the following ratio

$$[2]\quad \ln \left(\frac{\gamma_\pm(KNO_3)}{\gamma_\pm(KF)} \frac{\gamma_\pm(NaF)}{\gamma_\pm(NaNO_3)} \right) = (\beta_{KNO_3} - \beta_{KF} + \beta_{NaF} - \beta_{NaNO_3})\mu$$

From the above data, $\beta = (\beta_{KNO_3} - \beta_{KF})\mu \simeq -0.082$. The corresponding shift in the thermodynamic potential scale E_+ with respect to that measured against a constant reference electrode E_r is given by (1)

$$[3]\quad dE_+ = dE_r - (\beta/f)dx$$

where $x = c_{NO_3}/(c_{NO_3} + c_F)$ and $f = F/RT$. According to this analysis, the potential scale shifts by 2 mV when the electrolyte is changed from 0.2 M KF to 0.2 M KNO_3. Although the above correction is small it is important that activity effects be carefully considered in the present context where the relatively minor effect of counter ion nature on ionic adsorption isotherms is being studied.

The capacity–potential data were twice integrated from negative potentials ($E_+ = -1.669$ V at $\sigma_m = -22$ μC cm^{-2} for the $NaNO_3$–NaF system, and $E_+ = -1.640$ V at $\sigma_m = -22$ μC cm^{-2} for the KNO_3–KF system) where anion adsorption could be assumed negligible. $\Delta\xi_+$, the value of Parsons' function ξ_+ at any charge density with respect to its value at $\sigma_m = -22$ μC cm^{-2} was calculated for integral increments in σ_m using well established techniques modified to take into account the variation in γ_{K^+} in the KNO_3–KF system as described previously (1). The adsorbed charge density due to NO_3^- ion, σ_a, was calculated according to the equation

$$[4]\quad \frac{f}{(1 + \beta x)} \left(\frac{\partial \Delta\xi_+}{\partial \ln x} \right)_{\sigma_m} = \sigma_a + \sigma_x^d \frac{\beta x}{(1 + \beta x)}$$

where σ_x^d is the surface excess of anions in the diffuse layer. The derivative $(\partial\Delta\xi_+/\partial \ln x)_{\sigma_m}$ was estimated using a least-squares fit of a cubic equation to $\Delta\xi_+$ against $\ln x$ data over the total experimental range (14). σ_x^d was estimated from the Gouy–Chapman theory according to which

$$[5]\quad \sigma_x^d = -\Theta\mu^{1/2} - \frac{(\sigma_m + \sigma_a)}{2} - \frac{[(\sigma_m + \sigma_a)^2 + 4\Theta^2\mu]^{1/2}}{2}$$

where $\Theta = (RT\varepsilon/2\pi)^{1/2}$, ε being the dielectric constant of the pure solvent. Initially, it was assumed that $\sigma_x^d \simeq -\Theta\mu^{1/2}$; the estimate was improved using an iterative technique, successive approximations for σ_a and σ_x^d being obtained by solving eqs. 4 and 5 for σ_a and σ_x^d respectively.

Adsorption isotherms for the $NaNO_3$–NaF and KNO_3–KF systems at constant charge density are shown in Fig. 2. When σ_m is positive, $|\sigma_a|$ falls below σ_m at low bulk nitrate concentrations but is greater than σ_m when the nitrate concentration is high. A similar result was obtained by Payne (2) for the case of adsorption from solutions of composition $x\ M$ NH_4NO_3 + $(1 - x)\ M$ NH_4F. The value of σ_a in the K^+ system is approximately the same as that in the Na^+ system when $|\sigma_a| < \sigma_m$ but significantly larger when $|\sigma_a| \geq \sigma_m$. Although one does not

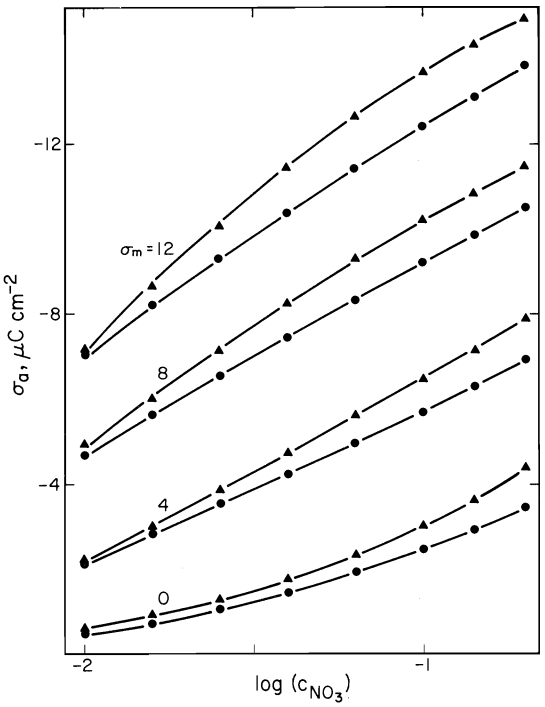

FIG. 2. Plots of adsorbed charge density due to NO_3^-, σ_a, against the logarithm of NO_3^- concentration in the bulk, log c_{NO_3}, for various constant charge densities on the electrode (indicated by the integers adjacent to each curve) for adsorption from the $NaNO_3$–NaF (●) and KNO_3–KF (▲) systems.

expect ionic adsorption isotherms to be congruent in either electrode potential or charge density on the basis of the electrostatic model for ionic adsorption (1, 8, 9), Payne (2, 3) was able to fit data for nitrate adsorption to a simple Frumkin isotherm congruent in electrode charge density. Examination of the present data on the basis of tests described by Parsons (15) showed that the interaction parameter in the adsorption isotherm varies significantly with electrode charge density. More specifically, plots of $1/C - 1/C_0$ against σ_a at constant charge density, where C is the differential capacity and C_0 that in the solution containing no nitrate, showed a maximum whose position and height depended on σ_m. Thus, there is no merit in fitting these data to a simple congruent isotherm, since any parameters derived would not be subject to direct interpretation.

The effects on ionic strength on nitrate adsorption at positive σ_m are illustrated in Fig. 3. At low nitrate ion concentration where $|\sigma_a| < \sigma_m$, the field at the oHp is positive. When the ionic strength is increased, the potential drop across the diffuse layer ϕ^d becomes less positive and the diffuse layer has a smaller enhancing effect on anion adsorption; thus, $|\sigma_a|$ decreases when the ionic strength increases. On the other hand, when bulk nitrate concentration is sufficiently high that $|\sigma_a| > \sigma_m$, ϕ^d is negative, and anions are repelled from the double layer. When the ionic strength is increased, $|\phi^d|$ decreases in magnitude and the amount of specifically adsorbed anion increases at constant electrode charge density and bulk anion concentration.

Plots of the potential drop across the inner layer, ϕ^{md}, against the adsorbed charge density σ_a at constant σ_m are shown for the $NaNO_3$–NaF system in Fig. 4. The plots are linear with positive slopes for lower values of σ_m. However, as σ_m becomes more positive, the slope decreases and eventually becomes negative. It should also be noted that the latter plots possess some curvature such that the slope increases with increase in σ_a. This observation would undoubtedly not have been made if the value of ϕ^{md} for $\sigma_a = 0$ had not been included. Indeed, these data are often missing in previously published Christie plots for systems studied at constant ionic strength so that their interpretation is subject to some doubt. The fact that the average slope of the Christie plots changes with $\sigma_m = 0$ is further support of the conclusion reached above, namely, that the adsorption of nitrate ion cannot be described by an isotherm congruent in either electrode potential or charge density. The average slope of the plots of ϕ^{md} against σ_a was determined by fitting the data to a straight line by least squares. The results for both the $NaNO_3$–NaF and KNO_3–KF systems are shown in Fig. 5. The behavior of both systems is qualitatively similar in that the average slope decreases with increase in σ_m. However, the average slope for the K^+ system is consistently smaller as was observed previously for the corresponding iodide systems (1).

The present data were tested to determine whether the variation in adsorbed charge density with bulk activity at constant electrode charge density could be described by a simple non-congruent adsorption isotherm. Since the nitrate ion concentration was limited to 0.2 M, the maximum adsorbed charge density, σ_{am}, could not be determined; it was assumed to be -25 μC cm^{-2}, the value obtained by Payne from analysis of nitrate adsorption data at bulk concentrations up to 1 M at both constant and varying ionic strength (2, 3). According to the Frumkin iso-

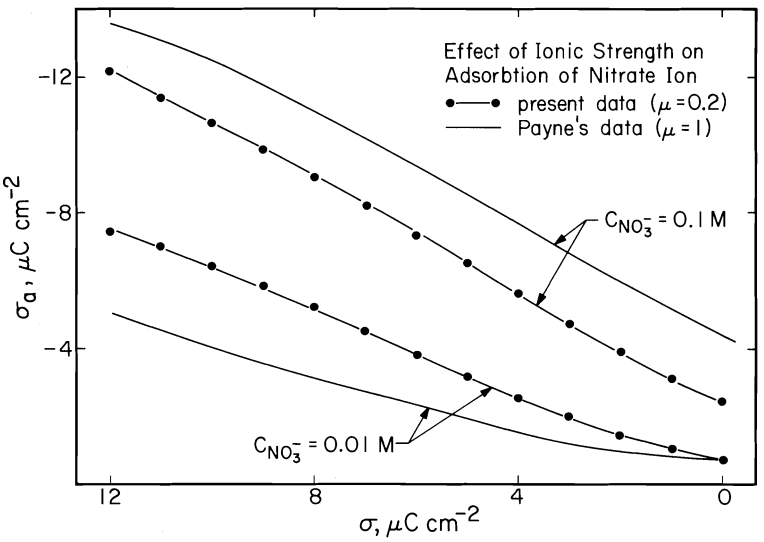

FIG. 3. Plots of adsorbed charge density due to NO_3^-, σ_a, against electrode charge density, σ_m, for bulk NO_3^- concentrations of 0.01 and 0.1 *M* at varying ionic strength μ; the data at $\mu = 0.2$ *M* are for the x *M* $NaNO_3$ + (0.2 − x) *M* NaF system and those at $\mu = 1$ *M* for the x *M* NH_4NO_3 + (1 − x) *M* NH_4F system (2).

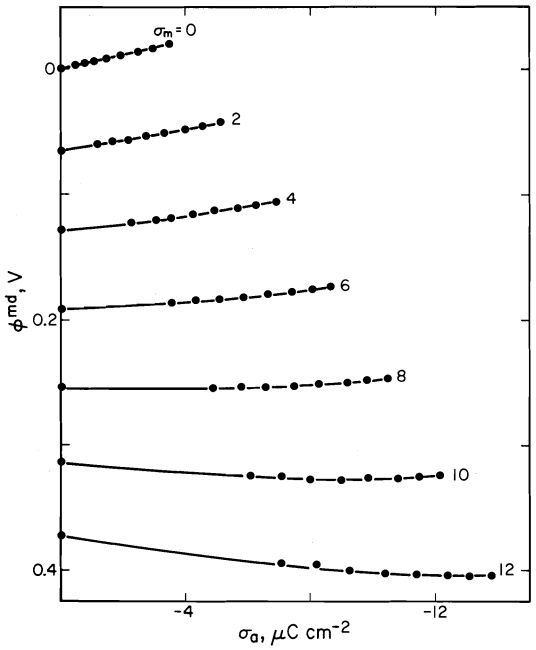

FIG. 4. Plots of the potential drop across the inner layer, ϕ^{md}, against the adsorbed charge density due to NO_3^-, σ_a, at constant electrode charge density σ_m (indicated by the integer adjacent to each plot) for adsorption from the system x *M* $NaNO_3$ + (0.2 − x) *M* NaF.

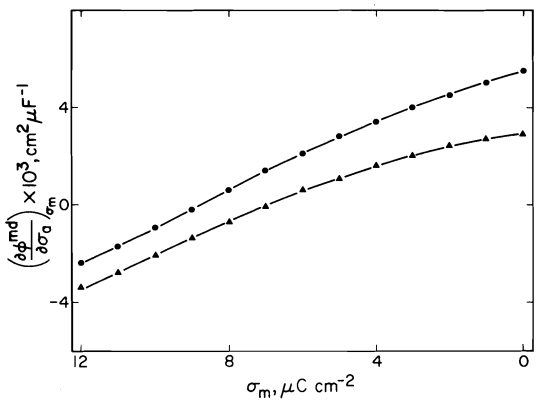

FIG. 5. Plots of the average slope of Christie plots, $(\partial\phi^{md}/\partial\sigma_a)_{\sigma_m}$, against electrode charge density, σ_m, for the $NaNO_3$–NaF (●) and KNO_3–KF (▲) systems.

therm, plots of ln $(-\sigma_a/c_{NO_3})$ − ln $(\sigma_a - \sigma_{am})$ against σ_a at constant electrode charge density σ_m should be linear with a slope independent of σ_m if the isotherm is congruent in σ_m. The corresponding plots for the $NaNO_3$–NaF system are shown in Fig. 6; it is apparent that, although the plots are approximately linear, their slope varies markedly with σ_m. Closer examination of the data at σ_m = 10 and 12 μC cm^{-2} shows that the corresponding plots are somewhat curved; however, the curvature could be due to errors in σ_a at the lowest and highest bulk concentrations where the numerical differentiation procedure used in the data analysis is least accurate (14). According to the electrostatic theory of ionic adsorption (1, 8, 9) which assumes Grahame's model of the inner layer, the Frumkin isotherm should contain a term in

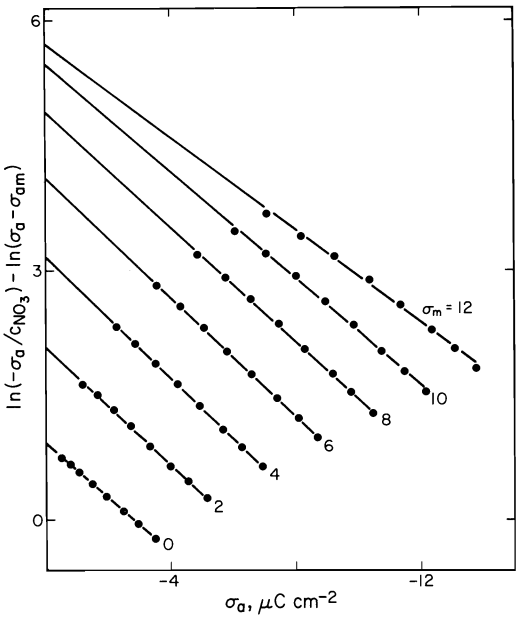

FIG. 6. Plots of adsorption data for the $NaNO_3$–NaF system at constant electrode charge density according to the Frumkin isotherm (eq. 13).

ϕ^d, the potential drop across the diffuse layer. Plots of $\ln(-\sigma_a/c_{NO_3}) - \ln(\sigma_a - \sigma_{am}) - f\phi^d$ against σ_a were constructed for the same data, ϕ^d being calculated from the Gouy–Chapman model of the diffuse layer. The slope of these plots was much less than those shown in Fig. 6. For $\sigma_m = 0$, 2, and 4, the slope was approximately zero. At higher electrode charge densities, the plots had a negative slope at low σ_a which decreased to zero with increase in σ_a. It is important to note that since $\sigma_a + \sigma_m$ is close to zero, ϕ^d varies markedly with $\sigma_a + \sigma_m$. Since $f\phi^d$ is not negligible in comparison with $\ln(-\sigma_a/c_{NO_3}) - \ln(\sigma_a - \sigma_{am})$, small errors in σ_a will result in large errors in ϕ^d, and thus, large errors in the isotherm plots. On the other hand, if the negative slope observed at higher electrode charge densities is not due to experimental error, a naive interpretation of these plots is that ion–ion interactions on the iHp are attractive for these conditions. However, as is argued below, the results obtained can also be attributed to a significant change in inner layer properties with increase in adsorbed charge density. Because of the curvature, the isotherm plots according to the electrostatic model could not be used to determine the variation in standard free energy of adsorption with σ_m and, therefore, they are not presented. Qualitatively similar results were obtained for the KNO_3–KF system, the principal difference being that the slopes of the isotherm plots were lower at a given electrode charge density.

Discussion

Effects of Activity Coefficient Variation

As argued previously (1), the activity coefficients of anions in a mixed salt solution containing a single cation may be assumed to be constant to a first approximation. This follows from the fact that the nature of the counter ion atmosphere around a given anion does not change when solution composition is changed. On the basis of experimental mean ionic activity coefficients, and assuming that the effective radii of the ions in the present systems are approximately equal (16), one may assume that the activity of nitrate ion in a 0.2 *M* KNO_3 solution is less than that in a 0.2 *M* $NaNO_3$ solution. Thus, other factors ignored, one would expect less adsorption from the KNO_3–KF system at a given bulk nitrate ion concentration and electrode charge density. The fact that the opposite is observed must be attributed to other effects.

The parameter β, which accounts for the change in metal ion activity when F^- is substituted by NO_3^-, is negative in the KNO_3–KF system. In this case failure to account for the variation in γ_K with solution composition would result in $|\sigma_a|$ being underestimated by about 8% at the highest nitrate ion concentration. It is interesting to note that if the data analysis had been carried out without the correction described above, the derived charge densities for adsorbed nitrate ion would still be greater in the K^+ system than in the Na^+ system at higher bulk concentrations. In conclusion, the observed dependence of σ_a on the nature of the cation in the system cannot be attributed to bulk activity effects, or to the model used to account for variation in individual ionic activity coefficients with solution composition.

The Properties of the Inner Layer

According to Grahame's model, the potential drop across the inner layer is given by

$$[6] \qquad \phi^{md} = (\sigma_m/K_{md}) + (\sigma_a/K_{ad})$$

where K_{md} is the integral capacity of the inner layer and K_{ad}, the integral capacity of the region between the iHp and oHp. If K_{md} and K_{ad} are

constant for a fixed value of σ_m, then the slope of the Christie plot is equal to $1/K_{ad}$. It is apparent from Fig. 4, that this condition holds at lower values of σ_m where $\sigma_a + \sigma_m < 0$ over most of the experimental range. Then, the predominant counter ion at the oHp is the cation Na^+ and the thickness and dielectric properties of the inner layer may be assumed to be approximately independent of adsorbed charge density, σ_a. At higher values of σ_m, $\sigma_a + \sigma_m$ is positive for low values of σ_a and eventually becomes negative. Accordingly, the counter ion at the oHp changes from anion to cation, and variation in both the thickness and dielectric properties of the inner layer with σ_a is possible. In general, the slope of the Christie plot is given by

$$[7] \quad \left(\frac{\partial \phi^{md}}{\partial \sigma_a}\right)_{\sigma_m} = \frac{1}{K_{ad}} + \sigma_m \left(\frac{\partial(1/K_{md})}{\partial \sigma_a}\right)_{\sigma_m} + \sigma_a \left(\frac{\partial(1/K_{ad})}{\partial \sigma_a}\right)_{\sigma_m}$$

It seems reasonable to assume that the derivatives defining changes in K_{md} and K_{ad} with σ_a are approximately constant for a given value of σ_m. Since the slopes decrease with increasing σ_m for constant σ_a, one may assume that $(\partial(1/K_{md})/\partial\sigma_a)_{\sigma_m}$ is negative. Therefore, the inner layer capacity, K_{md}, decreases with increasing adsorption when the counter ion defining the boundary of the inner layer changes from anion to cation. Similarly, for fixed σ_m, the slope of plots at higher σ_m increases with increase in $|\sigma_a|$ indicating that $(\partial(1/K_{ad})/\partial\sigma_a)_{\sigma_m}$ is also negative; this change corresponds to a decrease in K_{ad} with increasing adsorption. Since a change in the nature of the counter ion will chiefly affect the properties of the outer region of the inner layer, K_{ad} is expected to vary much more than K_{md}.

Although variation in the nature of the counter ion at the oHp could affect the local dielectric constant of the solvent through its influence on solvent dipole orientation, it is probably valid to assume that the chief effect is a variation in thickness of the inner region with solvated size of the counter ion when the concentration of these ions on the oHp is low. Since the average slope of the Christie plots for the K^+ system are lower than those for Na^+ (Fig. 5), one may assume that K_{ad} is higher when K^+ is the counter ion. This corresponds to the inner layer being less thick when the more weakly solvated K^+ ion forms its boundary on the solution side. The fact that K_{ad} decreases when the counter ion at the oHp changes from anion to cation can be attributed to an increase in thickness of the inner layer when a weakly solvated anion is replaced by a more strongly solvated cation. Since the dependence of the slopes of the Christie plots on σ_a and σ_m is qualitatively similar for the K^+ system, one may assume that the thickness of the inner layer with K^+ ions at the oHp is greater than with anions. In the region where $\sigma_m + \sigma_a$ is positive, F^- is the predominant anion in the mixed electrolyte system. Thus, the anomalous behaviour of the Christie plots for the present systems can be rationalized if it is assumed that the thickness of the inner layer, x_d depends on the nature of the predominant counter ion at the oHp in the order $x_d(F^-) < x_d(K^+) < x_d(Na^+)$.

The form of the Christie plots observed in the present case is qualitatively similar to that observed by Payne for the system $x\ M\ NH_4NO_3 + (1 - x)\ M\ NH_4F$ (2), with the exception that no curvature was noted. This could be due to the fact that the value of ϕ^{md} in the limit $\sigma_a \to 0$ was not considered but it could also reflect smaller changes in K_{ad} with counter ion nature at higher ionic strength where diffuse layer screening is more effective. The behaviour of Christie plots for NO_3^- adsorption from KNO_3 solutions of varying ionic strength is entirely different (3). As pointed out by Payne (3), these plots appear to have a constant slope independent of σ_m. For the range of bulk concentrations involved, $\sigma_a + \sigma_m$ is negative so that the counter ion at the oHp is always the cation. Interpretation of these data is much more difficult since imaging conditions and the effective thickness of the inner layer probably change with ionic strength. It is undoubtedly true that the Christie plots would be curved in this case if data were available at very low nitrate ion concentrations.

Payne (2, 3) argued that one should consider the contribution to ϕ^{md} of solvent dipoles removed from the inner layer in the adsorption process. He also suggested that the decrease in average slope of the Christie plots with increase in σ_m could be attributed to the fact that water molecules compete more effectively for adsorption sites under these conditions. According to the above analysis, a change in the number and orientation of water dipoles with σ_a would effect the dielectric constant distribution in the inner

layer and lead to curved Christie plots. As pointed out by Levine (8), this effect is quantitatively accounted for by eq. 6 and does not require the addition of an explicit term to account for the potential drop across oriented solvent dipoles. However, it is much more difficult to rationalize the large difference in adsorption behaviour for single and mixed electrolyte solutions on the basis of more effective water adsorption at high σ_m; if this were important, one would also expect the slopes of the Christie plots in the single electrolyte system to decrease with increase in σ_m.

It is instructive to compare the present results with those obtained for the adsorption of chloride ion at Hg from solutions of constant ionic strength (17). Since Cl^- adsorption is moderate, the magnitude of σ_a falls below σ_m for the low bulk Cl^- concentrations. Thus for positive values of σ_m, the sign of the charge in the diffuse layer changes from negative to positive and the counter ion at the oHp, from anion to cation, when the bulk Cl^- concentration is increased at constant σ_m. However, in this case the Christie plots are not curved and have positive slopes over the range of values of σ_m studied. The lack of curvature can be interpreted as evidence that the distances of closest approach of a non-adsorbed Cl^- ion and the cation, in this case K^+, are approximately equal so that K_{ad} is independent of the nature of the counter ion at constant σ_m. The decrease in the slopes of these plots with increase in σ_m can be attributed to a change in dielectric properties of the inner region which results in an increase in K_{ad} and K_{ma}. This increase may well be associated with a break up of water clusters in the inner region with increase in σ_m (18). Another important difference between the present data and those for Cl^- adsorption (17) is that the integral capacity K_{ad} is significantly smaller in the Cl^- system. This suggests that the iHp is closer to the oHp in the NO_3^- system so that small changes in the distance of closest approach of the counter ion have a large effect on the integral capacity of the outer region of the inner layer. If the adsorption of NO_3^- does not result in displacement of water molecules next to the electrode, one would indeed expect the iHp to be further from the electrode than it is for halide ions which are assumed to interact directly with the Hg electrode. Thus, the present interpretation of inner layer properties in the presence of adsorbed NO_3^- is in agreement with that of Damaskin *et al.* (10), which was based on an analysis of thermodynamic data obtained at very high bulk NO_3^- concentrations.

Tilak and Devanathan (28) presented a detailed model for nitrate ion adsorption on the basis of a study of adsorption from NH_4NO_3 solutions in the concentration range 0.05 to 11.23 *M*. However, in their data analysis they failed to consider the fact that the experimentally derived relative surface excess is significantly different from the absolute surface excess for concentrated solutions (10, 11). Thus, the values of σ_a reported by these authors cannot be considered reliable. It is undoubtedly true that some of the apparent anomalies discussed in ref. 28 are due to the erroneous data analysis. Any assessment of their model for nitrate adsorption must await reanalysis of the data.

The Adsorption Isotherm

According to the electrostatic model for ionic adsorption (8, 9), the adsorption isotherm may be written

$$[8]\quad \ln(-\sigma_a) - \ln(\sigma_a - \sigma_{am}) = \Phi + \ln a_{NO_3} + f\phi^d + a\sigma_a + b\sigma_m$$

where a_{NO_3} is the bulk nitrate ion activity, a and b, parameters relating the change in free energy of adsorption to changes in σ_a and σ_m, respectively, and Φ, a parameter related to the standard free energy of adsorption. Φ, a, and b depend on the electrical state of the interface which is determined by the value of σ_m, but they are normally assumed to be independent of a_{NO_3} and thus, σ_a. When discreteness-of-charge effects are estimated on the basis of the cutoff-disc model, the following expressions for a and b are obtained (8):

$$[9]\quad a = \frac{f}{K_{ad}}\left(1 - g\frac{K_{md}}{K_{ma}}\right)$$

where K_{ma} is the integral capacity of the region between the metal and the iHp, and g, a dimensionless parameter which is often assumed to be close to unity (19), and

$$[10]\quad b = f/K_{ad}$$

According to the Gouy–Chapman–Stern model, the potential drop across the diffuse layer in the presence of specific adsorption is given by

$$[11]\quad \phi^d = \frac{2}{f}\sinh^{-1}\left(\frac{\sigma_m + \sigma_a}{2\Theta\mu^{1/2}}\right)$$

When $\sigma_m + \sigma_a < \Theta\mu^{1/2}$, $f\phi^d$ is given to a good approximation by

$$[12] \qquad f\phi^d = (\sigma_m + \sigma_a)/\Theta\mu^{1/2}$$

For the present systems $\Theta\mu^{1/2} = 2.62\ \mu C\ cm^{-2}$; examination of the data in Fig. 4 reveals that the sum $\sigma_m + \sigma_a$ is indeed small and that the limiting expression for $f\phi^d$ may be applied to the data over most of the experimental range. The adsorption isotherm may now be written

$$[13] \quad \ln(-\sigma_a) - \ln(\sigma_a - \sigma_{am}) = \Phi + \ln a_{NO_3} + \left[\frac{f}{K_{ad}}\left(1 - g\frac{K_{md}}{K_{ma}}\right) + \frac{1}{\Theta\mu^{1/2}}\right]\sigma_a + \left(\frac{f}{K_{ad}} + \frac{1}{\Theta\mu^{1/2}}\right)\sigma_m$$

Equation 12 is of the form of the Frumkin isotherm but gives explicit expressions for the interaction parameter and the variation in free energy of adsorption with σ_m.[1]

According to the data shown in Fig. 6, the Frumkin interaction parameter as determined from the slopes of the adsorption isotherm plots at constant σ_m varies from 0.36 $cm^2\ \mu C^{-1}$ at $\sigma_m = 0$ to 0.28 $cm^2\ \mu C^{-1}$ at $\sigma_m = 12\ \mu C\ cm^{-2}$. Since $1/\Theta\mu^{1/2} = 0.382\ cm^2\ \mu C^{-1}$, the term $f(1 - gK_{md}/K_{ma})/K_{ad}$ must be negative. Considering the fact that all parameters involved are positive by definition, it is concluded that $K_{ma} < gK_{md}$ for the present system over the range of values of σ_m considered. Furthermore, since the integral capacity of any portion of the inner layer must be greater than the total integral capacity of the inner layer, K_{md}, it is apparent that the dimensionless parameter g is greater than unity. Levine and Robinson (19, 21) have calculated g on the basis of models which assume both discontinuous (19) and continuous variations (21) of the dielectric constant ε with distance from the electrode. It is clear from these calculations that one expects g to depend significantly on the relative positions of the iHp and oHp. If the planar nitrate ion is adsorbed flat on the Hg surface without an intervening water molecule, then the iHp would be about 2 Å from the metal surface. Assuming the inner layer has a thickness of 5.5 Å when the counter ion is Na^+, this spatial arrangement of iHp and oHp would lead to values of g which are less than unity, independent of the model chosen for ε (19, 21). On the other hand, if adsorbed nitrate ions are separated from the electrode by an intervening layer of water molecules, the iHp would be approximately 5 Å from the electrode, and thus much closer to the oHp. Under these circumstances g is greater than unity and can reach values sufficiently large that the parameter a is negative (eq. 9) when ϕ^d is small (19, 21). Physically, these conditions are such that the individual charge centres on the iHp are very efficiently screened by their local ionic atmospheres in the diffuse layer.

Although analysis of the isotherm parameters at high values of σ_m would be complicated by variation in K_{ad} with σ_a, an approximate analysis can be carried out for the data obtained in the region $0 \leq \sigma_m \leq 4\ \mu C\ cm^{-2}$. From the Christie plot, $K_{md} = 30.3\ \mu F\ cm^{-2}$ and $K_{ad} = 222\ \mu F\ cm^{-2}$ at $\sigma_m = 2\ \mu C\ cm^{-2}$ in the Na^+ system. From the slope of the isotherm plot, $a = -0.02\ cm^2\ \mu C^{-1}$ and on the basis of eq. 9, $g = 1.3$. This parameter is constant in the given range of σ_m, and falls within the range of values of g estimated by Levine and Robinson (19, 21). Examination of the equivalent data for the K^+ system reveals that $K_{ad} = 417\ \mu F\ cm^{-2}$, $K_{md} = 30.8\ \mu F\ cm^{-2}$, and $a = -0.13\ cm^2\ \mu C^{-1}$ at $\sigma_m = 2\ \mu C\ cm^{-2}$. The corresponding value of g, 2.6, falls outside of the range considered in analysis of the discreteness-of-charge model but undoubtedly it indicates that the iHp is very close to the oHp. The fact that K_{ad} for the K^+ system is approximately twice that for the Na^+ system indicates that the distance between the iHp and oHp, x_{ad}, decreases by approximately a factor of two when the counter ion is changed from Na^+ to K^+.

On the basis of the above analysis, one can distinguish two factors which account for the increase in nitrate adsorption when the counter ion is changed from Na^+ to K^+. Firstly, the average potential drop across the region between the iHp and oHp, ϕ^{ad} which is given by

$$[14] \qquad \phi^{ad} = (\sigma_m + \sigma_a)/K_{ad}$$

becomes less negative as K_{ad} increases in magnitude ($\sigma_m + \sigma_a < 0$). Since ϕ^d is independent of counter ion nature to a first approximation, the average potential on the adsorption plane is less

[1]It should be noted that some variation in Φ with σ_m is expected due to a corresponding variation in the polarization and self-image energies of the adsorbed species (20).

negative and the concentration of nitrate ions increases. Secondly, as x_{ad} decreases, the screening of adsorbed ions by the diffuse layer becomes more effective so that the difference between the micro-potential at an adsorption site and the average potential on the iHp becomes more positive; accordingly, discreteness-of-charge effects also contribute to $|\sigma_a|$ being larger in the K^+ system. The effect is sufficiently large in the present system that the interaction parameter a in the Stern–Grahame–Levine isotherm (eq. 8) is positive, that is, attractive.

An alternative explanation of the increase in $|\sigma_a|$ in going from the Na^+ to the K^+ system is that alkali metal cations are weakly adsorbed, the extent of adsorption increasing with cation atomic number (22, 23). However, the field assisting possible cation adsorption is much weaker in the present case, than in systems where anion adsorption is strong, such as iodide (1). The fact that the differences in amounts adsorbed between the Na^+ and K^+ systems are quantitatively similar for NO_3^- and I^- adsorption suggests that cation adsorption is not the cause of the dependence of σ_a on the counter ion nature. As pointed out previously (24), the general features of Cs^+ adsorption estimated on the basis of double layer data for the system $x\,M$ CsCl + $(1 - x)\,M$ LiCl can be attributed to a dependence of the thickness of the inner layer on solvated cation size. More generally stated, the Gouy–Chapman theory does not account for differences in the sizes of ions present in the diffuse layer. For this reason the detailed arguments based on this model used by Damaskin (25) in support of alkali metal cation adsorption are subject to doubt. It is clear that further clarification of the possible role of cation adsorption must await the development of a model for the diffuse layer which properly accounts for finite ion size.

Finally, Hills and Reeves (5) have argued that the differences in adsorption behaviour observed for moderately adsorbed anions in solutions of varying and constant ionic strength can be attributed to coadsorption of F^- anion from the mixed electrolyte system at high positive values of σ_m. However, these authors did not consider the effect of ionic strength on ionic adsorption so that their conclusions are subject to some doubt. Schiffrin (26) showed that small but significant specific adsorption of F^- could be detected at Hg for $\sigma_m \geq 6\ \mu C\ cm^{-2}$ and $c_F \geq 0.1\ M$ at 15°C. When F^- ion specific adsorption is significant, the measured surface excess due to adsorbed anions is actually given by

$$[15] \qquad \sigma_a = \sigma_a(NO_3^-) - \frac{c_{NO_3}}{c_F}\,\sigma_a(F^-)$$

where $\sigma_a(NO_3^-)$ and $\sigma_a(F^-)$ are the adsorbed charge densities due to nitrate and fluoride ions, respectively. The effect of possible F^- ion adsorption would be greatest for $c_{NO_3^-} = c_{F^-} = 0.1\ M$; at lower F^- ion concentrations, $\sigma_a(F^-)$ goes to zero, and at higher concentrations, $c_{NO_3^-}/c_{F^-}$ is less than unity. Neglect of F^- ion adsorption leads to underestimation of the adsorbed charge density due to nitrate ions and would result in the Christie plots being less curved. It is extremely difficult to assess the role of F^- ion adsorption since errors in the analysis of the interfacial thermodynamic data for single fluoride salt solutions can be large (26) and the role of defects in the Gouy–Chapman theory used in data analysis very important (24). However, when one compares the present results with those for the PF_6^-–F^- system studied by Hills and Reeves (5), it is clear that F^- adsorption is much less important in the present case. If, as suggested by Baugh and Parsons (27), the adsorbed fluoride ion retains its primary hydration shell, it may be excluded from its adsorption plane when that plane is already occupied by the more strongly adsorbed NO_3^- ion.

Electrochemical oxidation of titanium, zirconium, or hafnium(IV) in the presence of a solution of chlorine or bromine (X) in acetonitrile (L) leads to direct synthesis of MX_4L_2 species in good yield. These compounds are easily transformed into other neutral adducts. On addition of tetraalkylammonium salts to the solution phase, the products are the salts $(R_4N)MCl_5$ or $(R_4N)_2MBr_6$, except that with titanium Et_4NTiBr_4 was also formed under some conditions. The advantages of this method are discussed, and a possible reaction mechanism proposed.

JACOB J. HABEEB, FAROUQ F. SAID et DENNIS G. TUCK. Can. J. Chem. **55**, 3882 (1977).

L'oxydation électrochimique du titane, du zirconium ou de l'hafnium(IV) en présence d'une solution de chlore ou de brome (X) dans l'acétonitrile (L) conduit à la synthèse direct d'espèces MX_4L_2 avec de bons rendements. On peut facilement transformer ces composés dans d'autres adduits neutres. Par addition de sels de tétraalkylammonium à la phase en solution, les produits sont les sels $(R_4N)MCl_5$ ou $(R_4N)_2MBr_6$, excepté avec le titane alors que le Et_4NTiBr_4 se forme aussi suivant quelques conditions. On discute des avantages de cette méthode et on propose un mécanisme possible pour la réaction.

[Traduit par le journal]

Introduction

The complexes of the elements titanium, zirconium, and hafnium, and in particular the neutral adducts of the tetrahalides, form one of the best explored topics in classical coordination chemistry. The parent tetrahalides are key compounds in the preparation of these derivatives, many of which have been obtained by direct reaction of the two components in non-aqueous solution (1). Various methods are available for the preparation of the tetrahalides themselves. Direct combination of the metal and halogen is not recommended for $TiCl_4$, which, like the bromide, is obtained by the high temperature (200–1250°C) treatment of TiO_2 by various chlorinated species. Direct bromination of the metal at 300–600°C yields $TiBr_4$. Similar methods have been used for tetrahalides of zirconium and hafnium (2).

We have now shown that the tetrachlorides and tetrabromides of these three chemically inert metals can be prepared at room temperature by electrochemical oxidation of the metal in a cell containing an organic solution phase. The products are either the adducts $MX_4 \cdot 2CH_3CN$, which can readily be converted to other adducts, or the anionic M(IV) halogeno complexes, depending on the composition of the solution. Only in the case of titanium were complexes of the M(III) state obtained, a pattern which parallels that established in the electrochemical preparation of β-diketonate complexes of these elements (3). This work completes a series of electrochemical preparations of anhydrous halides of the top row transition metals, work which has resulted in the production of VX_2 (X = Cl, Br, I) (4), $CrBr_3$ (5) and mono- or dihalides of Mn, Fe, Co, Ni, Cu, and Zn (6). Anionic bromo-complexes of these and other metals (7) have also been prepared in good yield at room temperature by direct electrochemical syntheses.

Experimental

Materials

The metals titanium (foil, 0.67 mm thick, m2N7), zirconium (foil, 0.25 mm thick, M3N), and hafnium (wire, 1 mm diameter, m3N7) were used as supplied (Alfa Inorganics). Solvents were dried over molecular sieve (acetonitrile, methanol) or sodium (benzene), and distilled under nitrogen before use.

Preparative Procedures

The electrochemical method was essentially that used in earlier work (5, 7). Samples of metal formed the anode of a cell containing an organic solvent phase with a platinum wire (0.5 mm diameter) as the counter electrode. The detailed experimental conditions are given in Table 1.

In certain specific cases noted below, we determined the current efficiency expressed as moles of metal dissolved per Faraday, in experiments of relatively short duration (1–2 h), during which time the current was held

constant. The chemical efficiency of the system, expressed as mole of complex obtained per mole of metal dissolved, was generally in the range 80–95%. In view of these high yields from room temperature experiments lasting 1–10 h, no attempt was made to study the effect of electrode size, current, temperature, etc., on the overall chemical efficiency.

The electrochemical preparation affords the bisacetonitrile adduct of the tetrachlorides and bromides, except in those cases where gram quantities of tetraethylammonium halide were present, when the appropriate anionic halogeno complexes were obtained. Thionyl chloride proved to be the most satisfactory solvent for the preparation of the anionic chlorocomplexes (see Table 1).

The bisacetonitrile adducts are soluble in acetonitrile, and the resultant solutions have been the starting point for the synthesis of other neutral adducts. The results of these experiments are in some respects at variance with the existing literature, and we return to this point below.

Analytical and Spectroscopic Methods

Halogen analysis was by the Volhard method. Titanium was determined by titration against ethylenediamine tetraacetic acid (EDTA, disodium salt). The sample was dissolved in nitric acid and oxidized with hydrogen peroxide; after addition of excess EDTA, and neutralization, the solution was titrated with standard bismuth(III) nitrate, using xylenol orange as indicator. A similar method was used for zirconium and hafnium, with solutions prepared by dissolving the sample in sulphuric acid plus sodium sulphate (8).

Infrared spectra were obtained on a Perkin-Elmer IR-12 instrument, and served to identify the presence of neutral ligands or substituted ammonium cations in the solids prepared.

Results and Discussion

Neutral Halides

The experimental conditions detailed in Table 1 allowed us to produce gram quantities of $MX_4 \cdot 2CH_3CN$ (M = Ti, Zr, Hf; X = Cl, Br) within a few hours. The presence of two *cis*-acetonitrile ligands was confirmed by doublet absorptions in the $\nu(C{\equiv}N)$ region of the infrared spectrum (Table 2). The frequencies are in good agreement with those previously reported (9) for these compounds, confirming the formulation based on the analytical results. Thus the first conclusion from our work is that these

TABLE 2. Infrared absorptions of $MX_4 \cdot 2CH_3CN$ adducts (M = Ti, Zr, Hf; X = Cl, Br)[a]

Compound	$\nu(C{\equiv}N)$
$TiCl_4 \cdot 2CH_3CN$	2286, 2310
$TiBr_4 \cdot 2CH_3CN$	2280, 2305
$ZrCl_4 \cdot 2CH_3CN$	2284, 2306
$ZrBr_4 \cdot 2CH_3CN$	2260, 2285
$HfCl_4 \cdot 2CH_3CN$	2275, 2303
$HfBr_4 \cdot 2CH_3CN$	2280, broad

[a]Frequencies in cm^{-1}; samples run as Nujol mulls between potassium bromide plates.

complexes are now readily available in high yield by a room temperature synthetic route which uses the metals as the accessible source of high purity element.

We have not been able to prepare any of the tetraiodo complexes of these elements (nor any anionic iodo-complexes), despite the fact that iodides of a number of other transition metals have been obtained by electrochemical synthesis (6). A range of experimental conditions was investigated, varying such factors as voltage, current, composition, metal surface pre-treatment, and the use of Br_2–I_2 mixtures, all without success, in that in no case were we able to isolate MI_4, or MI_4L_2 species. By monitoring the weight of the anode, we showed that appreciable quantities (0.5–0.05 g) of titanium (and zirconium) dissolved, and in some cases solids of indeterminate composition were obtained. For example, electrolysis of titanium (anode) with a solution of iodine in acetonitrile yielded a product containing 7.4% Ti, 32.5% I, and having no ν(C≡N) absorption in the infrared. In another case, zirconium was electrolytically dissolved (0.38 g) into a benzene–methanol solution of iodine and *n*-Pr_4NI; the final solid contained 36.7% Zr, 26.5% I. No explanation for these and similar results is forthcoming, and further work on this topic is planned.

Adducts of MX_4

The literature on the adducts of the tetrachlorides and tetrabromides of Group IVA is very extensive (1). Our experiments have revealed one aspect of the chemistry of these compounds not apparently reported, namely that bidentate ligands such as ethylenediamine and 2,2′-bipyridine may form both 1:1 and 1:2 adducts with $TiBr_4$. The existing literature on the preparation of the adducts of such ligands (10, 11) refers to experiments carried out in benzene solution, from which compounds such as $TiBr_4$·bipy precipitate. Our earliest preparations used electrochemically prepared solutions of MBr_4 in benzene–methanol (3:1); excess bromine was removed from the solution with a stream of nitrogen, and ethylenediamine (also in benzene–methanol) added dropwise until precipitation occurred. The resultant solids were shown to be the 1:1 adduct MBr_4·en (M = Ti, Zr, Hf: see Table 3). Later experiments used $TiBr_4 \cdot 2CH_3CN$ as the starting material, and acetonitrile as the reaction medium. Typical conditions would involve 50–100 mg of $TiBr_4 \cdot 2CH_3CN$ in 10 cm^3 acetonitrile; a solution of 50 mg of 2,2′-bipyridine in 15 cm^3 of the same solvent was added dropwise until yellow precipitation occurred. The product was collected and dried *in vacuo*. Under such conditions, we obtained the compounds $TiBr_4$·2en (12) and $TiBr_4$·2bipy, of which the latter does not appear to have been reported previously. Solvent dielectric constant may be the critical factor in these preparations; benzene may favour the neutral six-coordinate MX_4L, while in acetonitrile an ionic species $[MX_2L_2]X_2$ could be formed. Further investigation of this problem is planned.

Anionic Complexes

Although benzene–methanol proved to be a satisfactory reaction medium for the electrochemical preparation of a number of transition metal anionic bromo-complexes (7), we were not able to use it for the preparation of anionic complexes of Group IVA metals. For the chlorides, thionyl chloride proved very useful, and the electrochemical oxidation of titanium, zirconium, or hafnium in the presence of chlorine in this solvent (Table 1) containing tetra-*n*-propylammonium chloride leads to the formation of the salt *n*-$Pr_4N[MCl_5]$ in each case. With the two heavier metals, the compound precipitated from the solution as the electrolysis proceeded; for titanium, addition of diethylether to the final reaction solution resulted in precipitation of the salt. In cells containing benzene, bromine, and tetraethylammonium bromide, two different experimental conditions applied. For relatively low bromine concentrations (those marked [a] in Table 1), two phases are present; only the lower of these had any significant conductivity, and the cell was arranged so that both electrodes (and especially the Group IV metal of the anode) were immersed in this layer. As the electrolysis proceeded, precipitation of the $(Et_4N)_2MBr_6$ salts occurred, with the reaction visibly taking place in the lower phase.

The MCl_5^- and MBr_6^{2-} salts (or their analogues with other cations) have been reported previously, with one exception. The salt $Et_4N[TiCl_5]$ results from the reaction of Et_4NCl and $TiCl_4$ in dichloromethane (13) and a solvated salt $Et_4N[ZrCl_5]CH_3CN$ has been reported by Feltz (14). The hexabromo complexes of the Group IVA metals were prepared by Clark and co-workers (15), who also analysed the vibrational spectra. Thus only the salt

[a]en = ethylenediamine; bipy = 2,2′-bipyridyl.

n-$Pr_4N[HfCl_5]$ represents a new complex, and one which completes a group of lighter analogues. In view of the extensive literature on the structure and vibrational spectra of these anions, we have not carried out any further investigation of the compounds prepared.

If the bromine content is increased in the benzene–Br_2–Et_4NBr system, prepared by adding Et_4NBr to a solution of bromine in benzene, the two phases eventually coalesce; in the present case, this occurred when the benzene–bromine ratio was approximately 5:1 (v/v). Electrolytic oxidation of titanium in this solution, produced not titanium(IV), but the known titanium(III) salt (16) $Et_4N[TiBr_4]$. We discuss below a possible explanation of the anomaly that an increase in the concentration of the apparent oxidizing agent in solution (i.e. Br_2) results in a decrease in the oxidation state of titanium in the final product. Two relevant precedents for this synthesis can be noted immediately. Firstly, the electrochemical oxidation of titanium in the presence of β-diketonates and similar ligands results in the formation of titanium(III) TiL_3 complexes, which can be subsequently oxidized to $TiOL_2$. Zirconium and hafnium form only ML_4 species under such conditions (3). Secondly, the electrochemical oxidation of other top row transition metals to form anhydrous bromide under conditions similar to those used in the present work yields low oxidation state compounds, including vanadium(II) (4) and copper(I) (6). The formation of the $TiBr_4^-$ anion is therefore part of this pattern; we were not able to produce the M(III) states of either zirconium or hafnium, again in keeping with our results with diketonates.

We conclude that the electrochemical method of these various complexes represents a rapid and convenient synthesis which avoids the synthesis and isolation of the MX_4 intermediates.

Reaction Mechanism

In an earlier discussion of the electrochemical synthesis of other transition metal halides (6), it was pointed out that measurement of the current efficiency gives a good indication of the possible reaction mechanism. In the present work, we have carried out such experiments over short periods of time (1–2 h) at constant current (40–50 mA) for the M–Br_2 in benzene system. The measured current efficiencies were 1.1 mol Ti F^{-1}, 2.7 mol Zr F^{-1}, and 1.25 mol Hf F^{-1}, in terms of weight of metal dissolved. These values are somewhat lower than the range of 2–10 mol F^{-1} reported earlier (6), but higher than can be

accounted for by a primary process $M \rightarrow M^{4} + 4e^{-}$, for which the current efficiency should be 0.25 mol F^{-1}.

The proposed mechanism envisages the first step as being the formation of Cl_2^- or Br_2^-

[1] $$Br_2 + e^- \rightarrow Br_2^-$$

and the anode process is believed to be

[2] $$Br_2^- + M \rightarrow MBr + Br + e^-$$

with subsequent reactions

[3] $$MBr + Br \rightarrow MBr_2$$

[4] $$MBr + Br_2 \rightarrow MBr_3$$

[5] $$MBr_2 + Br_2 \rightarrow MBr_4$$

Other reactions are also possible; the main point of [3], [4], and [5] is to show that different oxidation states of a given metal may be produced in such systems. Reactions such as the sequence

[6] $$MBr + Br_2 \rightarrow MBr_2 + Br$$

[7] $$M + Br \rightarrow MBr$$

can be invoked to explain current efficiencies higher than 1 mol metal dissolved per Faraday.

In all but one case, the oxidation sequence obviously produces compounds in which the M(IV) oxidation state is stabilized. The exception is the oxidation of titanium in the presence of high concentrations of Br_2 and Br^- (and hence Br_3^-). This may point to the importance of [4] under such conditions. Certainly the stability of the M(III) state is significantly higher in titanium than in the heavier metals, and this, coupled with the observed precipitation of a salt that is insoluble and therefore kinetically resistant to oxidation, serves to rationalize the experimental result. Thus while the present results do nothing to bolster the previous arguments quantitatively, the information of an intermediate oxidation state does support a mechanism involving stepwise oxidation of the metal in these electrochemical experiments.

A new method for the macro- and microdetermination of tri- and tetrathionate

K. A. IDRISS, I. M. ISSA, AND M. R. MAHMOUD

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

Received December 22, 1976[1]

K. A. IDRISS, I. M. ISSA, and M. R. MAHMOUD. Can. J. Chem. **55**, 3887 (1977).

A rapid and precise method is described for the determination of tri- and tetrathionate. It is based on oxidation of $S_3O_6^{2-}$ or $S_4O_6^{2-}$ with $KMnO_4$ in sulphuric acid medium in the presence of fluoride, required for preventing the formation of insoluble oxides of manganese. The optimum conditions for both the visual and potentiometric end-point detection are 0.1–0.16 *M* H_2SO_4 and 0.24–0.38 *M* NaF. Trithionate is oxidized to sulphate as an end product, whereas the oxidation product of tetrathionate comprises dithionate and sulphate according to

$$3MnO_4^- + S_4O_6^{2-} + 6HF_2^- + 2H^+ \rightleftharpoons 3MnF_4^- + S_2O_6^{2-} + 2SO_4^{2-} + 4H_2O$$

Examination of the potentiometric titrations and the spectrophotometric scans of samples being titrated showed the presence of intermediate equilibria in solution. The species produced are identified and a theory is given for the net reactions. The method is thoroughly dependable for the determination of amounts of $S_3O_6^{2-}$ or $S_4O_6^{2-}$ corresponding to 0.1–10 mg of sulphur.

K. A. IDRISS, I. M. ISSA et M. R. MAHMOUD. Can. J. Chem. **55**, 3887 (1977).

On présente une méthode rapide et précise pour la détermination de tri- et tétrathionates. Cette technique est basée sur l'oxydation des espèces $S_3O_6^{2-}$ ou $S_4O_6^{2-}$ par le $KMnO_4$ en milieu acide sulfurique et en présence d'ions fluorure nécessaires pour prévenir la formation d'oxydes de manganèse insoluble. Les conditions optimums pour la limite de détection visuelle et potentiométrique sont: 0.1–0.16 *M* H_2SO_4 et 0.24–0.38 *M* NaF. Le trithionate est oxydé jusqu'au sulfate tandis que le produit d'oxydation du tétrathionate comprend le dithionate et le sulfate. Ce processus est représenté par l'équation suivante:

$$3MnO_4^- + S_4O_6^{2-} + 6HF_2^- + 2H^+ \rightleftharpoons 3MnF_4^- + S_2O_6^{2-} + 2SO_4^{2-} + 4H_2O$$

L'examen des titrations potentiométriques et des enregistrements spectrophotométriques des échantillons montrent la présence d'équilibres intermédiaires en solution. Les espèces produites sont identifiées et une théorie est proposée pour les réactions globales. La méthode est totalement précise et permet la détermination d'une quantité d'espèces $S_3O_6^{2-}$ ou $S_4O_6^{2-}$ pouvant correspondre à 0.1–10 mg de soufre.

[Traduit par le journal]

Introduction

The determination of macro-amounts of polythionates have been investigated by oxidation with vanadate (1), iodate, bromate (2), and periodate (3). The reaction of polythionates ($S_nO_6^{2-}$) where $n = 3$–5, with mercuric chloride was applied by Jay (4) for their analysis. The acidity produced from the reaction was measured. Nietzel and DeSesa (5) described a spectrophotometric method for determining as little as 5 mg/ℓ of $S_4O_6^{2-}$ based on the reduction of tetrathionate with cyanide to form thiocyanate, and the latter was determined colorimetrically with an excess of Fe(III) ions.

No method has yet been given involving the oxidation of tri- or tetrathionate with permanganate. The reaction in acid medium, however, is beset with difficulties due to its sluggishness and the precipitation of insoluble oxides of manganese. In the present method, this difficulty is overcome by carrying out the oxidation in a sulphuric acid medium in the presence of fluoride, since the latter is capable of capturing trivalent manganese as complex anions (6). The method is simpler than those given before and includes both the visual and potentiometric titration of thionate solution with MnO_4^- and vice versa. It is also planned to investigate the application of the method as an analytical procedure for the determination of micro-amounts of tri- and tetrathionate and to put forward a mechanism for the reactions involved.

Experimental

Solutions

Potassium permanganate solutions were prepared by a method similar to that of Stamm (7) and standardized with sodium oxalate (8). Sodium trithionate and tetrathionate solutions were prepared and standardized according to recommended procedures (3). Other solutions included ~2% *M* sodium fluoride, 2 *M* sulphuric acid, and 0.25 *M* copper sulphate.

[1]Revision received July 9, 1977.

Equipment

The emf of the titration cell was measured by a direct reading millivoltmeter of the Radiometer (28 Mb) type, using a Pt electrode with a saturated calomel electrode as reference half-cell. The uv and visible absorption spectra of solutions were recorded using a Unicam S.P. 8000 spectrophotometer within the wavelength range 200–600 nm using 1 cm matched silica cells.

Titration Procedure

A volume of tri- or tetrathionate solution containing 0.1–10 mg of sulphur was placed in a titration vessel and mixed with the required volume of 2 *M* H_2SO_4 to give an acidity of 0.2–0.32 *N* and also with 50 ml of 2% NaF solution. The mixture was diluted to 100 ml with twice-distilled water and then titrated with $KMnO_4$ solution. If a visual end-point was desired, an appropriate amount of 0.25 *M* $CuSO_4$ solution was added.

Results and Discussion

The reaction of both $S_3O_6^{2-}$ and $S_4O_6^{2-}$ with permanganate in the presence of fluoride proceeds less rapidly at the beginning of the titration, needing 2–3 min for attainment of equilibrium. However, as the volume of $KMnO_4$ consumed exceeds one-half that required for complete reaction, the oxidation process becomes rapid. It therefore appears that the oxidation of tri- or tetrathionate includes an intermediate equilibria. The stoichiometry of the reactions involved is proposed and the species produced in each case has been identified and confirmed by recording the spectrophotometric scans of the titrated solutions.

The results of the potentiometric titration are not affected by addition of Cu(II) which is essential for the detection of the end-point in the visual titration (9, 10) (to mask the pink colour of the MnF_4^- complex). The visual end-point method is suitable in the presence of copper sulphate solutions containing 0.07–1 g Cu.

Determination of Trithionate

Titration of Trithionate with Permanganate

From the results obtained the reaction appears to proceed quantitatively in accordance with the equation:

$$[1]\quad 2MnO_4^- + S_3O_6^{2-} + 4HF_2^- \rightleftharpoons 2MnF_4^- + 3SO_4^{2-} + 2H_2O$$

The potentiometric titration curves possess two inflections (Fig. 1), the first being due to the reduction of MnO_4^- to Mn(II) and the second to the formation of Mn(III). Trithionate is oxidized to dithionate in the first step, whereas in the second step an induced coupled reaction

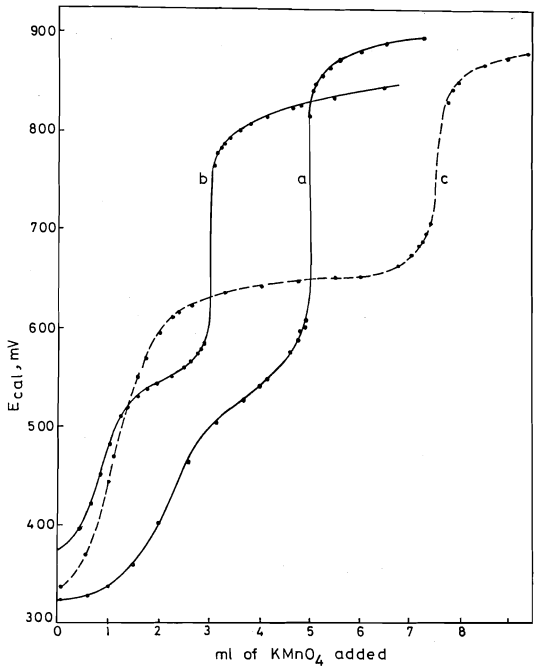

FIG. 1. Titration of $S_3O_6^{2-}$ with $KMnO_4$. (*a*) Titration of 2 ml 0.025 *M* $S_3O_6^{2-}$ with 0.02 *M* MnO_4^- in the presence of 0.12 *M* H_2SO_4 and 0.24 *M* NaF. (*b*) Titration of 1 ml 0.0020 *M* $S_3O_6^{2-}$ with 0.00124 *M* MnO_4 in the presence of 0.12 *M* H_2SO_4 and 0.24 *M* NaF. (*c*) Titration of 3 ml 0.025 *M* $S_3O_6^{2-}$ with 0.02 *M* MnO_4^- in the presence of 0.16 *M* H_2SO_4 and 0.24 *M* NaF.

of Mn(II) and $S_2O_6^{2-}$ with permanganate occurs.

As shown from data obtained in Table 1 and the spectrograms *a* and *b* in Fig. 2, the first inflection corresponds to reaction 2 and the second inflection to reaction 3.

$$[2]\quad 2MnO_4^- + 2S_3O_6^{2-} + 4H^+ \rightleftharpoons 2Mn^{2+} + 3S_2O_6^{2-} + 2H_2O$$

$$[3]\quad 2MnO_4^- + 2Mn^{2+} + 3S_2O_6^{2-} + 8HF_2^- \rightleftharpoons 4MnF_4^- + 6SO_4^{2-} + 2H_2O + 4H^+$$

The conversion of trithionate to SO_4^{2-} according to eq. 3 presumably takes place due to the presence of Mn(II) in solution. The stoichiometry of reaction 3 can be obtained from the following equations.

$$[3a]\quad MnO_4^- + 10HF_2^- + 4Mn^{2+} \rightleftharpoons 5MnF_4^- + 2H^+ + 4H_2O \text{ (ref. 11)}$$

$$[3b]\quad MnO_4^- + 2HF_2^- + 2S_2O_6^{2-} \rightleftharpoons MnF_4^- + 4SO_4^{2-} + 2H^+$$

NOTES: (*i*) Mn(VIII) → Mn(II); (*ii*) Mn(VII) → Mn(III); (*a*) Nos. 1–8, 5 ml 0.012 *M* $S_3O_6^{2-}$ titrated with 0.02 *M* $KMnO_4$, 9–11, 2 ml of 2×10^{-3} *M* $S_3O_6^{2-}$ titrated with 1.25×10^{-3} *M* $KMnO_4$; (*b*) 5 ml of 0.012 *M* $S_3O_6^{2-}$ titrated with 0.02 *M* $KMnO_4$; (*c*) Nos. 1–3, using 0.02 *M* $KMnO_4$ as titrant, 4–5, using 8.9×10^{-3} *M* $KMnO_4$ as titrant, 6–7, using 1.25×10^{-3} *M* $KMnO_4$ as titrant.

The overall reaction 1 can be obtained by combining [2] and [3]. Figure 2 reveals the absence of an absorption band for MnF_4^- (12) in the spectrum of the reaction mixture at the first inflection but it is present in the spectrum of the solution at the second step. It is apparent also that the absorption band due to Mn(II) and $S_2O_6^{2-}$ (10) disappears when the second end-point is attained.

Optimum Experimental Conditions

Reasonable accuracy in either the visual or potentiometric end-point detection is attained at acidities ranging from 0.1–0.18 *M* sulphuric acid in the presence of 0.24 *M* NaF. At low acidities (<0.04 *M*) the solution becomes slightly turbid owing to partial production of higher manganese oxides. At higher acidities the end-point occurs too early owing to the sluggishness of reaction 3.

The results obtained indicate that the fluoride concentration can be varied from 0.24–0.38 *M* at a constant concentration of sulphuric acid (0.12 *M*) without causing appreciable errors. The visual titration was found to be favourable for the determination of amounts of $S_3O_6^{2-}$ containing 0.3–8 g of sulphur, whereas the potentiometric procedure is applicable for amounts of $S_3O_6^{2-}$ containing 0.09–10 mg S. With higher trithionate concentrations the reaction becomes less rapid and the titration medium slightly turbid owing to hydrolysis of Mn(III) to

(*c*) Titration of 5 ml 0.02 *M* MnO_4^- with 0.012 *M* $S_3O_6^{2-}$ in the presence of 0.14 *M* H_2SO_4 and 0.24 *M* NaF. (*d*) Titration of 10 ml 0.00124 *M* MnO_4^- with 0.0021 *M* $S_3O_6^{2-}$ in the presence of 0.12 *M* H_2SO_4 and 0.24 *M* NaF.

Mn_2O_3 (11). The error is generally <0.7% when the optimum conditions are adopted. The curves obtained on titrating $KMnO_4$ solution with $S_3O_6^{2-}$ are shown in Fig. 3.

Determination of Tetrathionate

The reaction of tetrathionate with permanganate in acid solution containing fluoride proceeds relatively slowly at the start, needing ~3 min between each addition of titrant. As the end-point is approached the electrode equilibration becomes very rapid. The results obtained indicate that the reaction proceeds quantitatively in accordance with the equation:

[4] $3MnO_4^- + S_4O_6^{2-} + 6HF_2^- + 2H^+ \rightleftharpoons 3MnF_4^- + 2SO_4^{2-} + S_2O_6^{2-} + 4H_2O$

Titration of Tetrathionate with Permanganate

The titration curves obtained when tetrathionate solutions are titrated with MnO_4^- (cf. Fig. 4) are characterised by two inflections, the first of which corresponds to the equation

[5] $2MnO_4^- + S_4O_6^{2-} + 4HF_2^- + H^+ \rightleftharpoons 2MnF_4^- + 3HSO_3^- + SO_4^{2-} + H_2O$

The volume of MnO_4^- consumed at the first inflection, as well as the appearance of the absorption bands characterising HSO_3^- and MnF_4^- (10) in the spectrum of the reaction mixture at the first inflection, provides support for eq. 5.

Reaction 5, however, is experimentally verified by choosing the suitable p*H* range within which the solutions can be titrated successfully. The quantitative course of the reaction is achieved at p*H* 2.5–4.0. This range is suitable for the

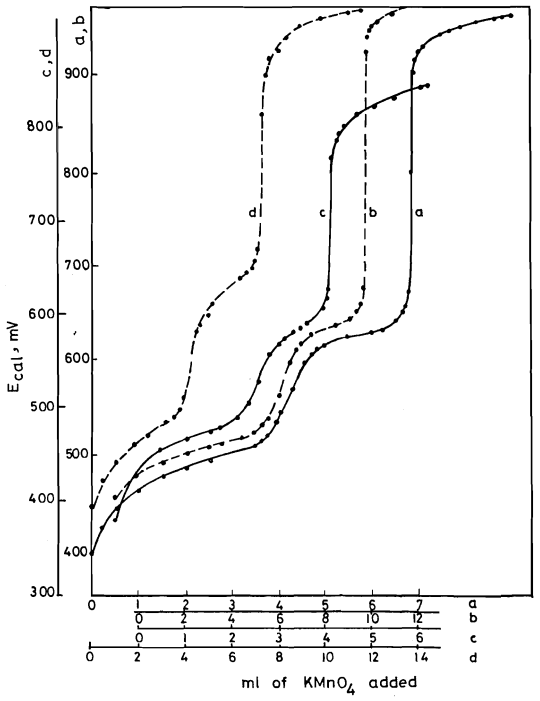

FIG. 4. Titration of $S_4O_6^{2-}$ with $KMnO_4$. (*a*) Titration of 5 ml 0.0091 *M* $S_4O_6^{2-}$ with 0.02 *M* $KMnO_4$ in the presence of 0.1 *M* H_2SO_4 and 0.24 *M* NaF. (*b*) Titration of 8 ml 0.0091 *M* $S_4O_6^{2-}$ with 0.02 *M* $KMnO_4$ in the presence of 0.1 *M* H_2SO_4 and 0.24 *M* NaF. (*c*) Titration of 2 ml 1.4×10^{-3} *M* $S_4O_6^{2-}$ with 1.8×10^{-3} *M* $KMnO_4$ in the presence of 0.1 *M* H_2SO_4 and 0.24 *M* NaF. (*d*) Titration of 5 ml 0.0091 *M* $S_4O_6^{2-}$ with 0.02 *M* $KMnO_4$ in the presence of 0.2 *M* H_2SO_4 and 0.24 *M* NaF.

quantitative reaction of HSO_3^- with MnO_4^- without decomposition of the sulphur compound to yield SO_2 (10). This intermediate oxidation product (HSO_3^-) is then further oxidized along the second step, according to the reaction

$$[6] \quad MnO_4^- + 3HSO_3^- + 2HF_2^- + H^+ \rightleftharpoons MnF_4^- + S_2O_6^{2-} + SO_4^{2-} + 3H_2O \text{ (ref. 10)}$$

The formation of dithionate is confirmed by the presence of an absorption band at 242 nm (10) in the spectrum of the reaction mixture at the second inflection (Fig. 2*d*), and by its analysis using the method of Murthy (13). Reaction 6 is also realized by determining the concentration of the MnF_4^- complex produced at the second end-point using the spectral data and comparing the results with theoretical values. It was found that the concentration of the MnF_4^- produced at the second inflection, as well as the volume of permanganate consumed at that step, each represent one-third of the total as given by the overall eq. 4. This verifies the validity of the suggested mechanism.

It is noteworthy that the end product in the oxidation of $S_4O_6^{2-}$ differs from that obtained in the case of $S_3O_6^{2-}$. Tetrathionate produces a mixture of $S_2O_6^{2-}$ and SO_4^{2-}. The production of $S_2O_6^{2-}$ can be attributed to the absence of Mn(II) necessary for the catalytic oxidation of dithionate according to eq. 3. If Mn(II) were added to a solution of $S_4O_6^{2-}$ prior to titration, SO_4^{2-} would be the only sulphur containing product. This can be shown by doing the following experiment.

A known excess of Mn(II) is added to a solution of tetrathionate (varying concentration), followed by the addition of the appropriate amount of 1 *M* sulphuric acid and 0.5 *M* NaF. The mixture is then titrated with $KMnO_4$.

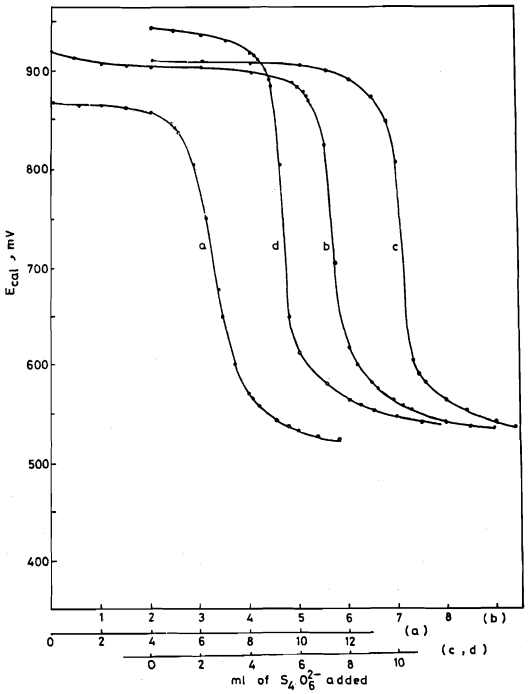

FIG. 5. Titration of $KMnO_4$ with $S_4O_6^{2-}$. (*a*) Titration of 8 ml 0.0058 *M* $KMnO_4$ with 0.0028 *M* $S_4O_6^{2-}$ in the presence of 0.08 *M* H_2SO_4 and 0.24 *M* NaF. NOTES: (*i*) At the first step; (*ii*) at the second step; (*a*) 5 ml of 0.0091 *M* $S_4O_6^{2-}$ titrated with 0.02*M* $KMnO_4$; (*b*) Nos. 1–3, using 0.02 *M* $KMnO_4$ as titrant, 4–5, using 1.8×10^{-3} *M* $KMnO_4$ as titrant.

By knowing the amount of permanganate consumed in reaction with Mn(II), the amount of $KMnO_4$ necessary for the oxidation of $S_4O_6^{2-}$ can be evaluated. The results obtained indicate that the oxidation of $S_4O_6^{2-}$ takes place in accordance with

$$[7]\quad 7MnO_4^- + 2S_4O_6^{2-} + 14HF_2^- + 2H^+ \rightleftharpoons 7MnF_4^- + 8SO_4^{2-} + 8H_2O$$

The last equation can be deduced, however, by combining eqs. 5, 6, and 3*b*. This leads to the opinion that the role played by Mn(II) to convert $S_2O_6^{2-}$ produced in reaction 6 can be represented stoichiometrically as given in eq. 3.

On the other hand, the catalytic effect of Mn(II) in the conversion of tetrathionate to sulphate as an end product is evidenced by performing titrations of mixtures of tri- and tetrathionate containing large amounts of $S_3O_6^{2-}$ (≥ 5 mg). The stoichiometry of the tetrathionate reaction does not remain the same as for the reaction carried out individually but proceeds according to eq. 7 and yields SO_4^{2-}. Thus the method can be applied under such conditions to determine the sum of $S_3O_6^{2-}$ and $S_4O_6^{2-}$ on the basis that the two reductants are oxidized to sulphate. However, this method cannot be used to determine either tri- or tetrathionate in a mixture of the two.

Optimum Experimental Conditions

Reasonable accuracy is obtained on titrating tetrathionate solutions with $KMnO_4$ at acidities ranging from 0.1–0.18 *M* sulphuric acid in the presence of 0.24 *M* sodium fluoride. At higher acidities, early end-points are obtained owing to the instability of tetrathionate under such conditions. At low acid concentrations (<0.08 *M* H_2SO_4), the reaction becomes rather slow or alternatively yields partially Mn(IV) as MnO_2. The fluoride concentration can be varied from 0.24–0.38 *M* when the acidity of the medium is kept constant at 0.12 *M* H_2SO_4. Table 2 indicates that when the optimum acidity and fluoride content are adopted, amounts of $S_4O_6^{2-}$ corresponding to 0.1–10 mg sulphur can be titrated either visually or potentiometrically with an error less than 1%. Figure 5 demonstrates the titration of permanganate with $S_4O_6^{2-}$.

A new route to ring-fused tetrahydrofurans: reaction of Δ^4-unsaturated alcohols with phenylselenenyl chloride

DERRICK L. J. CLIVE,[1] GIM CHITTATTU, AND C. K. WONG

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 4, 1977

DERRICK L. J. CLIVE, GIM CHITTATTU, and C. K. WONG. Can. J. Chem. **55**, 3894 (1977).

Δ^4-Olefinic alcohols react with phenylselenenyl chloride to produce tetrahydrofurans with a phenylseleno-group *trans* and β to the ether oxygen. The [4.3.0] and [3.3.0] oxabicyclic systems produced have *cis* ring fusion as in **5** and **7**.

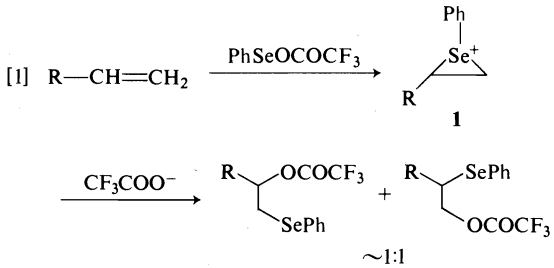
DERRICK L. J. CLIVE, GIM CHITTATTU et C. K. WONG. Can. J. Chem. **55**, 3894 (1977).

Les alcools Δ^4-oléfiniques réagissent avec le chlorure de phénylsélénényle produisant des tétrahydrofurannes ayant un groupe phénylséléné *trans* et en position β de l'hétéroatome. Les systèmes oxabicycliques [4.3.0] et [3.3.0] produits, ont une fusion de cycle *cis* comme pour **5** et **7**.

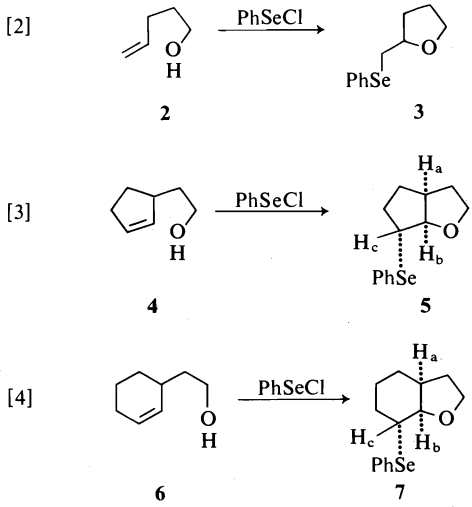
[Traduit par le journal]

The introduction of selenium into organic molecules as, for example, PhSe, is an important process since the resulting phenyl alkyl selenides have considerable utility in synthesis because they can be converted into olefins in high yield (e.g. ref. 1).

One route to selenides that is extremely rapid and gentle is the stereospecific addition across double bonds of species formally represented as PhSeZ, where Z can be CF_3COO (2), CH_3COO (3*a*), MeO (3*a*, 3*b*), EtO (3*b*), or Pr^iO (3*b*). This reaction is a clean *anti* addition (2, 3) but is characterized by poor regioselectivity (2, 3*b*, 4). The observations (2*a*, 3*b*) summarized by [1] are



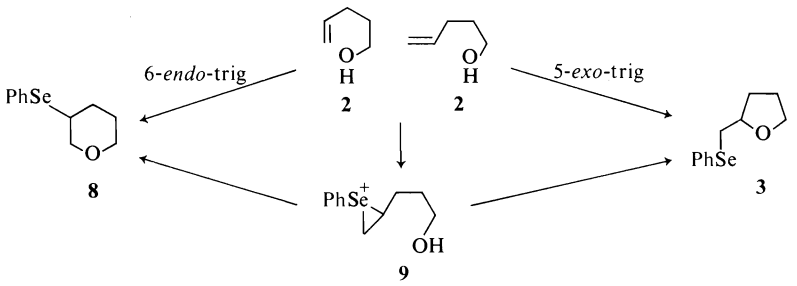
typical, so that any refinement of the process that makes it regiospecific would constitute a useful synthetic method. The product distribution of [1] results from attack at both electrophilic carbons (5) in the intermediate **1** but we have found that strict regiochemical control is possible by arranging for the intermediate (see **1**) to be captured in an intramolecular process. Of several ring systems that should be accessible in this way we have examined the preparation of tetrahydrofurans because of the widespread occurrence among natural products of structures with five-membered rings incorporating oxygen. Our route to these heterocycles (eqs. 2–4) involves



treating a Δ^4-olefinic alcohol with phenylselenenyl chloride (PhSeCl).

If the reaction is regarded as a trigonal cyclisation (see Scheme 1) then the empirically based rules for ring closure (6) suggest that both 5-*exo*- and 6-*endo*-trigonal pathways may be followed, leading, in the case of pent-4-enol **2** to the tetrahydrofuran **3** and the tetrahydropyran **8** (see Scheme 1). If the intermediate is of type **9** both modes of cyclisation are again allowed but production of a five-membered ring is expected

[1] Author to whom correspondence should be addressed.



SCHEME 1

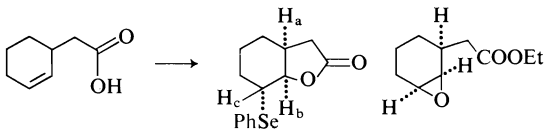
(7) to be preferred. It is known that ring closure of pent-4-enol with halogens leads to tetrahydrofurans (8) but that cyclisation with lead tetraacetate gives both five- and six-membered heterocycles (9).

In order to establish the preferred pathway with selenium reagents we treated pent-4-enol in ethyl acetate, with 1 equiv. of phenylselenenyl chloride and found that it is rapidly transformed into the tetrahydrofuran **3**, which can be isolated in 75% yield.[2] The proton magnetic resonance spectrum defines the structure of **3**, and, as expected, mass spectral analysis shows the production of fragments corresponding to $(PhSeCH_2)^+$, $(PhSe)^+$, and $(M—PhSeCH_2)^+$.

In order to have synthetic utility this cyclisation must be applicable to ring-fused ethers and should proceed in a clearly defined stereochemical fashion. Therefore, we examined the substrates **4** and **6**.

Compound **4** was converted cleanly into the bicyclic ether **5** which was isolated in 84% yield. Mass measurement on the molecular ion defined the elemental composition of **5**, and the stereochemistry shown at each of the asymmetric centres was evident from the proton magnetic resonance spectrum. The signal for H_b, which is centred at 4.36 ppm, is a doublet of doublets in which the smaller coupling is barely resolved. The larger coupling is 6.5 Hz. For *cis* ring fusion the dihedral angle between H_a and H_b is estimated from Dreiding models to be less than 20° and a value of ca. 7 Hz is therefore anticipated for J_{ab}. The small value of J_{bc} establishes that the PhSe-group is *trans* to the ether oxygen. For *trans* ring fusion neither relative orientation of the PhSe-group would make J_{bc} vanishingly small.

Compound **6** was cyclised in the same way and gave **7** in 77% yield. Mass measurement served to define the constitution of **7** and the stereochemistry of the ring fusion was established chemically by hydrogenolysis with Raney nickel (10) to the known (11) *cis*-perhydrobenzofuran. The proton magnetic resonance spectrum (270 MHz) of **7** shows a quartet (J = 5.1 Hz) due to H_c. This pattern is the result of three equal (or nearly equal) vicinal couplings as would be experienced by an equatorial hydrogen in a chair conformation of cyclohexane.[3] We have found a close analogy, using the same electrophile, for supporting the stereochemical assignment made to **7**. The olefinic acid **10** can be cyclised to the lactone **11** by treatment with phenylselenenyl chloride and the structure of the product **11**, in which H_c gives rise to a quartet with J = 4 Hz, was established by unambiguous synthesis from the known (13) epoxide **12** (14).



10 **11** **12**

13 **14**

In the preparation of the tetrahydrofurans **3**, **5**, and **7** the minimum reaction time was not established but small scale spectroscopic runs described below showed that cyclisation is very rapid. *A priori* it was possible that the first stage in these reactions is addition of phenylselenenyl chloride to the double bond to produce

[2]During preparation of this manuscript we received a report (19) of cyclisation of a *symmetrical* hydroxy olefin and of hydroxy olefins of the type shown in [3].

[3]1-Chloro-2-phenylselenocyclohexane exists at room temperature largely (60%) in the diaxial conformation (12).

a β-chloroselenide which is converted into the cyclic ether if the phenylseleno-group is *trans* to the hydroxyalkyl side chain. If the relationship is *cis* then chloroselenide formation would have to be a reversible process (15). When phenylselenenyl chloride was mixed (using CD_2Cl_2 solutions) at −80°C with 1 equiv. of **4** then low temperature (−60°C) ^1H nmr measurements, made within 5 min of mixing, showed no olefinic protons. The spectra obtained correspond to the cyclised product but the presence of at least some β-chloroselenide cannot be excluded. Evidently the ring closure is a very rapid process.

In order to establish whether formation of β-chloroselenides is easily reversible we heated compound **13** (16) in $CDCl_3$ at 60°C in the presence of an excess of cyclohexene. The cyclohexyl derivative **14** (12) was not formed and no change was seen during 16 h.

Although halogen-induced ring closures (*8a*) and cyclisations in tellurium chemistry (17) provide analogies for the reactions reported here, the examples in the selenium series allow advantage to be taken of the mildness with which selenides (18) can be subjected to further synthetic transformations.

Experimental

All reactions were conducted under nitrogen using oven-dried apparatus. Ethyl acetate was refluxed over phosphorus pentoxide (2 h) and then distilled from the mixture. Phenylselenenyl chloride was used as supplied by Aldrich. Pent-4-enol (**2**), 2-(2-cyclopenten-1-yl)ethanol (**4**), and 2-(2-cyclohexen-1-yl)ethanol (**6**) were prepared by the methods cited. Nuclear magnetic resonance spectra were run in $CDCl_3$ on a 100 MHz instrument, unless otherwise stated. Thin layer and preparative layer chromatography employed Merck Silica Gel PF-254 and the plates were activated at 110°C for 1 h before use. Merck Silica Gel 60 (particle size 0.063–0.200 mm) was used for column chromatography.

2-(Phenylselenomethyl)tetrahydrofuran ***3***

Phenylselenenyl chloride (382 mg, 1.99 mmol) in ethyl acetate (3 ml) was injected over 5 min into a cooled and magnetically stirred ethyl acetate solution (3 ml; internal temperature −77°C) of pent-4-enol (172 mg, 1.99 mmol). A further portion (0.5 ml) of ethyl acetate was used to wash residual reagent from the addition syringe into the reaction mixture. Within 5 min after the end of the addition the cold reaction mixture had become colourless and none of the alcohol could be detected by tlc (silica, ethyl acetate – 2,2,4-trimethylpentane (1:4 by volume)). The solvent was evaporated (water pump vacuum, room temperature) 15 min after the end of the addition and the resulting oil was chromatographed over silica gel (20 × 1.4 cm) with a mixture of ethyl acetate and 2,2,4-trimethylpentane (1:4 by volume). Appropriate fractions (tlc) were combined and evaporated. Bulb to bulb distillation (bath temperature 82°C; 0.01 Torr) gave compound **3** (362 mg, 75.1%) as a colourless oil that was chromatographically homogeneous (silica, ethyl acetate – 2,2,4-trimethylpentane (1:4 by volume); R_f 0.5); ir ν_{max} (neat) 1580, 1480, 1437, 735 cm^{-1}; ^1H nmr δ 1.45–2.14 (m, 4H), 2.8–3.2 (m, 2H), 2.55–4.2 (m, 3H), 7.1–7.3 (m, 3H), 7.35–7.65 (m, 2H); ms 242 $(M)^{+\cdot}$, 172 $(C_6H_5SeCH_2)^+$, 157 $(C_6H_5Se)^+$, 171 $(M - C_6H_5SeCH_2)^+$. *Anal.* calcd. for $C_{11}H_{14}OSe$: C 54.77, H 5.80, O 6.63; found: C 54.73, H 5.89, O 6.79. *Mol. Wt.* calcd. for $C_{11}H_{14}OSe$: 242.0204; found: 242.0210.

8-exo-Phenylseleno-2-oxabicyclo[3.3.0]octane ***5***

Phenylselenenyl chloride (382 mg, 1.99 mmol) in ethyl acetate (4 ml) was injected over 5 min into a cooled and magnetically stirred ethyl acetate solution (4 ml; internal temperature −78°C) of 2-(2-cyclopenten-1-yl)-ethanol (224 mg, 1.99 mmol). A further portion (0.5 ml of ethyl acetate was used to wash residual reagent from the addition syringe into the reaction mixture. After 1 h at −78°C the temperature was raised to 25°C during 30 min and kept at 25°C for 3 h. The reaction vessel was then immersed for 30 min in an oil bath preheated to 80°C by which time no alcohol remained (tlc control). The product was then isolated exactly as described above except that the solvent for chromatography was a 3:7 (by volume) mixture of ethyl acetate and 2,2,4-trimethylpentane. Compound **5** was obtained, after bulb to bulb distillation (bath temperature 104°C, 0.01 Torr), as a pale yellow oil (450 mg, 84.3%) that was chromatographically homogeneous (silica, ethyl acetate – 2,2,4-trimethylpentane (3:7 by volume); R_f 0.5); ir ν_{max} (neat) 1580, 1480, 1067, 1042, 1025 cm^{-1}; ^1H nmr δ 1.2–2.35 (m, 6H), 2.6–3.0 (m, 1H), 3.45–3.95 (m, 3H), 4.36 (d, J = 6.5 Hz; each signal broad, 1H), 7.0–7.38 (m, 3H), 7.38–7.65 (m, 2H); ms 268 $(M)^{+\cdot}$, 157 $(C_6H_5Se)^+$. *Anal.* calcd. for $C_{13}H_{16}OSe$: C 58.43, H 6.04, O 5.99; found: C 58.56, H 6.11, O 5.99. *Mol. Wt.* calcd. for $C_{13}H_{16}OSe$: 268.0366; found: 268.0357.

5-exo-Phenylseleno-7-oxabicyclo[4.3.0]nonane ***7***

Phenylselenenyl chloride (382 mg, 1.99 mmol) in ethyl acetate (5 ml) was injected over 45 min into a cooled and magnetically stirred ethyl acetate solution (5 ml, internal temperature −65°C) of 2-[2-cyclohexen-1-yl]ethanol (252 mg, 1.99 mmol). A further portion (1 ml) of ethyl acetate was used to wash residual reagent from the addition syringe into the reaction mixture. After the addition the cooling bath was removed and the mixture was stirred at room temperature for 18 h (with protection from light). The solvent was then evaporated (water pump vacuum at room temperature) and the residual oil, in dichloromethane (1.5 ml), was applied to two preparative layer silica plates (20 × 60 × 0.1 cm) which were developed once with benzene–ethylacetate (5:1 by volume). The product band (located under uv light) was extracted with ether. Removal of the solvent and bulb to bulb distillation (bath temperature 110°C, 0.005 Torr) gave compound **7** (431 mg, 77%) as a pale yellow oil that was chromatographically homogeneous (silica, benzene–ethylacetate (5:1 by volume); R_f 0.6); ir ν_{max} (neat) 1583, 1480, 1458, 1439, 1305, 1164, 1070, 1023, 1000, 967, 935, 737, 688 cm^{-1}; ^1H nmr (270 MHz) δ 1.25–1.80 and 1.86–2.07 (m, 8H), 2.36 (m, $W_{1/2}$ = 21 Hz, 1H), 3.50 (q, J = 5.1 Hz, 1H), 3.8–4.1 (m, 3H), 7.2 (m, 3H), 7.4 (m, 2H); ms 282

$(M)^{+\cdot}$, 157 $(C_6H_5Se^+)^+$, 125 $(M - C_6H_5Se)^+$. *Anal.* calcd. for $C_{14}H_{18}OSe$: C 59.79, H 6.41, O 5.69; found: C 59.64, H 6.49, O 5.91. *Mol. Wt.* calcd. for $C_{14}H_{18}OSe$: 282.0523; found: 282.0524.

Conversion of 5-exo-Phenylseleno-7-oxabicyclo[4.3.0]-nonane into 2-Oxabicyclo[4.3.0]nonane

Raney nickel (1 ml of settled W-2 catalyst, stored under ethanol) was rinsed under a nitrogen atmosphere with several portions of ether and was then covered with ether (5 ml). Compound **7** (281 mg, 1 mmol) in ether (1 ml) was injected and a further portion (0.5 ml) of ether was used as a rinse. The nitrogen atmosphere above the reaction mixture was replaced by hydrogen and the mixture was stirred at room temperature under hydrogen for 21 h. At this stage no starting material was left (tlc control). The catalyst was filtered off and washed with ether (4 × 10 ml). The combined organic extract was evaporated (water pump vacuum, room temperature) and the residual oil (96 mg) was applied in dichloromethane (1 ml) to a preparative layer silica plate (20 × 60 × 0.1 cm) which was developed once with chloroform–ethyl-acetate (9:1 by volume). The required band, located by spraying one edge of the plate with iodine vapour, was extracted with ether. Removal of the solvent under vacuum gave an oil (31.5 mg, 25%) identical with an authentic (11) specimen of *cis*-7-oxabicyclo[4.3.0]nonane.

Thiosemicarbazidedichloromercury(II) was synthesized in an ethanol–water solution by keeping the molar ratio of $HgCl_2$ and thiosemicarbazide (tsc) at 1:1. The crystal is monoclinic: a = 8.966(11), b = 6.817(9), c = 12.092(14) Å, β = 100.3(1)°, and space group $P2_1/c$ with four molecules per unit cell. The tsc is a bidentate ligand in this complex with Hg—S = 2.417(6) Å, Hg—N = 2.51(2) Å. The mercury atom is trigonal pyramidally four-coordinated, with two Hg—Cl distances of 2.366(6) and 2.770(5) Å. When the tsc is coordinated to the mercury(II) ions, the chemical shift of the ^1H atoms on the NH_2 and NH groups shift to a lower field.

CHUNG CHIEH et DIANNA H. COWELL. Can. J. Chem. **55**, 3898 (1977).

On a synthétisé la thiosemicarbazide de dichloromercure(II) dans une solution éthanol–eau en maintenant un rapport molaire de $HgCl_2$ et de thiosemicarbazide (tsc) à 1:1. Les cristaux sont monocliniques a = 8.966(11), b = 6.817(9), c = 12.092(14) Å, β = 100.3(1)° et groupe d'espace $P2_1/c$ avec quatre molécules par maille; tsc est un ligand bidentate dans ce complexe avec Hg—S = 2.417(6) Å, Hg—N = 2.51(2) Å. L'atome de mercure est tétracoordonné dans une pyramide trigonale avec deux distances Hg—Cl de 2.366(6) et 2.770(5) Å. Lorsque le tsc est coordonné aux ions de mercure(II), le déplacement chimique des atomes ^1H sur les groupes NH_2 et NH se déplace vers les bas champs.

[Traduit par le journal]

Introduction

During the synthesis of bisthiosemicarbazidedichloromercury(II) a thin needle-like crystalline product was formed at first (1). Those needles disappeared in the reaction in which the molar ratio of $HgCl_2$ to thiosemicarbazide (tsc) is 1 to 2. When the molar ratio was kept at 1:1, thiosemicarbizidedichloromercury(II) was synthesized and the crystals became prismatic as they grew. A similar complex was found with zinc(II) (2) instead of mercury(II) but the two compounds are not isostructural. The crystal structure and nmr spectra of $HgCl_2$(tsc) are described in this paper.

Experimental

Preparation of $HgCl_2$(tsc)

The chemicals used in this study are the same as those of ref. 1. To an ethanol–water solution containing 2 mM of tsc, 2 mM of $HgCl_2$ crystals were added. A new kind of needle-like crystal started to form and the crystals were visible in 10 min. The solution was covered and the reaction proceeded slowly at room temperature, 25 ± 3°C, overnight. The crystals were collected by filtration. There was a trace of black material due to decomposition and the sample appeared silvery.

The nmr spectra were measured on a WP-60 (Bruker) in DMSO-d_6 with TMS as standard.

Crystallographic Measurements

Photographic methods were used for space group determination. Cell constants were estimated from film data and then refined by the least-squares method from the 2θ values of 34 reflections measured on a G.E. XRD-6 diffractometer. Crystal data are:

$CCl_2H_5HgN_3S$ fw = 362.7

Monoclinic, a = 8.966(11), b = 6.817(9), c = 12.092(14), β = 100.3(1)°. V = 727.1 Å^3, D_o = 3.31 (by flotation), Z = 4, D_c = 3.313 g cm^{-3}, mp = 182°C. Systematic absences: $h0l$, $l = 2n + 1$, $0k0$, $k = 2n + 1$; space group $P2_1/c$, μ(MoKα) = 225.1 cm^{-1}.

The crystal used for intensity measurements had {0, 1, 1} and {1, 1, 1} faces developed. It was cut out of a prism perpendicular to a and a face (100) was included as boundaries for absorption correction which was done by a revised version of the program written by Coppens *et al.* (3). The dimensions of the crystal along a, b, and c are 0.14, 0.10, and 0.11 mm respectively. Among 1268 independent reflections with 2θ < 50° measured, 1031 reflections having $I > 3\sigma(I)$ were considered observed. The stability of the crystal and instrument were monitored by four standard reflections as described in ref. 1. Data reduction was also similar.

In the Patterson map, there was an intense (0.9 × origin) peak at (0, ½, ½). This led us to think that the mercury was located at a special position. However, the measured density corresponds to four molecules per unit cell; therefore, the intense peak was treated as one on a Harker line. The solution was then straightforward.

The atomic scattering factors from Cromer and Waber

(4) were used with anomalous dispersion coefficients for Hg from Cromer (5). At the final stage a weighting function $w = (\sigma(F^2))^{-1}$ was used and the R ($= \Sigma||F_o| - |F_c||/\Sigma|F_o|$) and R_w ($=(\Sigma w^2[|F_o| - |F_c|]^2/\Sigma wF_o^2)^{1/2}$) were 0.068 and 0.065. The difference Fourier at this stage showed only ripples around the mercury atom. The atomic coordinates are given in Table 1.[1] Refinement using data without absorption corrections gave R of 0.12 and some atoms had negative temperature factors.

Results and Discussion

The crystal consists of individual molecules. Bond lengths and angles are given in Fig. 1, which shows two molecules that are related to each other by a center of symmetry. The mercury is four coordinated with a trigonal pyramidal geometry. A least-squares plane calculated for Hg, S, N(3), and Cl(2) has a maximum deviation of 0.21 Å. The mercury atom is 0.30 Å above the plane containing S, N(3), and Cl(2). This coordination geometry is different from that of thiosemicarbazidedichlorozinc(II), in which the two crystallographically independent molecules are tetrahedrally coordinated.

However, the large angle found for ∠Cl(2)-HgS, 157.3°, indicated the preference of diagonal coordination in many mercury complexes (6). An alternative description is 'two plus two coordination'. There are two strong and nearly linear S—Hg—Cl bonds and two weak Cl—Hg—N bonds. The Hg—Cl bonds are not equivalent. The attraction between the two molecules is surprisingly weak with a Hg···S distance of 3.65 Å in contrast to the interaction found in other compounds (7).

The five-membered chelating ring is relatively flat; the maximum deviation from the least-squares plane is 0.14 Å. The ∠NNC and ∠NCS angles are greater than 120° for both the mercury and zinc complexes, but values for these angles in nickel complexes and the free tsc are close to 120° (8). The bond lengths for the tsc ligand are normal. The planarity, however, is not as good as that of free tsc or tsc in $HgCl_2(tsc)_2$ (1). The dihedral angle for NNCS is 5.5° for $HgCl_2(tsc)$.

The molecules are held together by very weak N—H···Cl hydrogen bonds. The significant short intermolecular distances are: Cl(1)···N(2) = 3.20(2), Cl(1)···N(1) = 3.22(2), Cl(2)···N(3) = 3.27(2), and Cl(2)···N(1) = 3.40(2) Å.

N—H	8.58	10.00	9.62

[a]A very broad peak due to NH_2 overlapped with the peak of the impurity in DMSO-d_6.

broadened peak due to H_2O present as impurity in DMSO. It is not clear whether the NNH_2 group is coordinated to the mercury in DMSO solution, since the solvent interacts rather strongly with the mercuric ion. The small net chemical shift for the NNH_2 proton in $HgCl_2$-(tsc) reflects this tendency.

Les sulfures de bithiényle-3,3′ et de bithiényle-2,2′ ont fait l'objet d'une étude par spectroscopie photoélectronique. L'analyse de ces données expérimentales a permis de proposer pour ces composés des conformations privilégiées de nature différente selon l'orientation des substituants.

P. MEUNIER and G. PFISTER-GUILLOUZO. Can. J. Chem. **55**, 3901 (1977).

3,3′-Bithienyl and 2,2′-bithienyl sulfides have been studied by photoelectron spectroscopy. Experimental data allow one to suggest different preferential conformations according the orientation of the substituents.

Introduction

Les oxyde et sulfure de biphényle, substitués ou non, ont fait l'objet d'études conformationnelles nombreuses. Divers travaux effectués par dipolemétrie (1–4), diffraction de rayons X (5–9), spectroscopie d'absorption dans l'ultraviolet (10, 11) et diffraction électronique (12) ont permis à leurs auteurs de conclure sans ambiguïté à la prédominance de formes non planes, l'existence privilégiée d'une forme asymétrique semblant, en revanche, beaucoup moins bien établie.

Récemment, dans le cas du sulfure de bipyridyle-2,2′ Chachaty et coll. (13), par une étude en rmn, concluent à l'existence de formes symétriques, twistées de 36° par rapport au plan CSC central.

Dans la série des sulfures de bithiényle, aucune étude n'a, à notre connaissance, été entreprise. Nous avons tenté d'aborder ce problème, comme dans le cas des bithiényles (14) et certains de leurs dérivés hétéropontés (15) à l'aide de la spectroscopie photoélectronique, en étudiant, parallèlement aux sulfures de bithiényle eux-mêmes, des dérivés dibromés susceptibles, a priori, de présenter des conformations hautement privilégiées.

Sulfure de bithiényle-3,3′ et dérivés

Spectres expérimentaux

Les spectres sont reproduits dans les figs 1–3,

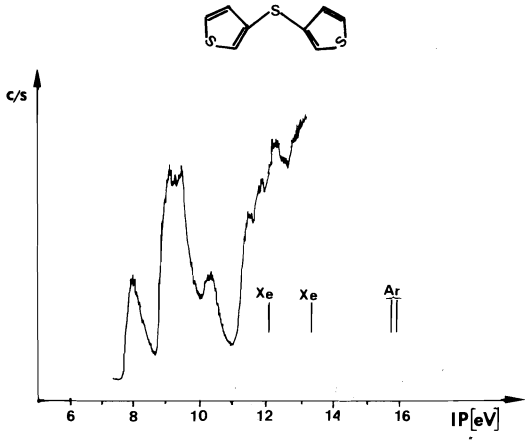

FIG. 1. Spectre photoélectronique du sulfure de bithiényle-3,3′.

et les valeurs des potentiels d'ionisation sont indiquées dans le tableau 1.

Le spectre photoélectronique du sulfure de bithiényle-3,3′ présente, entre 8 et 11 eV, trois bandes: (*a*) une première bande, peu intense, à 8.06 eV; (*b*) une deuxième bande, très intense, pour laquelle on observe distinctement deux potentiels à 9.16 et 9.50 eV; (*c*) une troisième bande, peu intense, à 10.40 eV.

Les spectres des deux dérivés dibromés étudiés sont assez semblables à celui du sulfure de bithiényle lui-même. La seule différence notable est l'écart sensiblement plus important observé entre les troisième et quatrième potentiels d'ionisation dans le cas du dérivé dibromé en 2,2′.

[1]A qui toute demande d'information devra être adressée.

*Pour tous les composés examinés l'interaction entre le système π des cycles thiophéniques et la paire du brome de même symétrie conduit à une stabilisation nette de cette dernière.

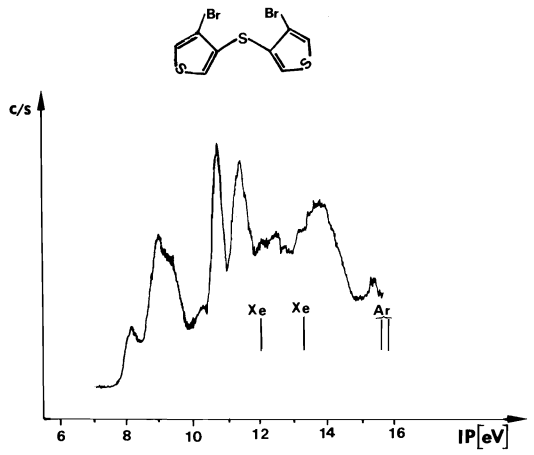

FIG. 2. Spectre photoélectronique du dibromo-4,4′ sulfure de bithiényle-3,3′.

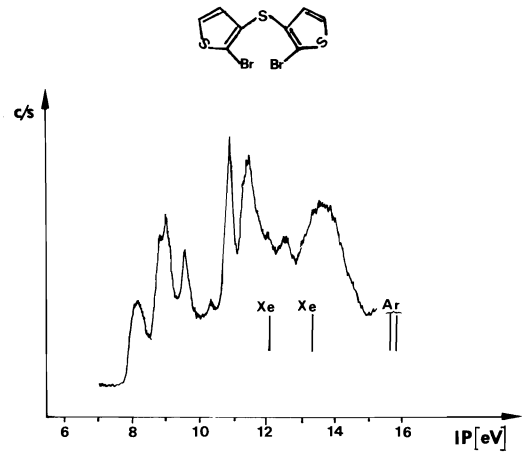

FIG. 3. Spectre photoélectronique du dibromo-2,2′ sulfure de bithiényle-3,3′.

Dans le cas des sulfures de bithiényles, les interactions entre le groupement sulfure et les noyaux thiophéniques seront très différenciées selon l'angle entre la paire π de l'atome de soufre et les deux cycles thiophéniques et selon la conformation de la molécule. En effet, pour une molécule plane ou présentant une certaine symétrie, l'influence du soufre ne se traduira que par une interaction destabilisante sur les orbitales totalement symétriques. Par contre, cette influence sera, pour une conformation dissymétrique, non négligeable pour tous les potentiels d'ionisation considérés.

On note dans les spectres des trois composés étudiés des bandes aux environs de 9 et 9.5 eV, valeurs très proches de celles observées pour le thiophène, le bromo-2 thiophène et le bromo-3 thiophène.

Ceci ne s'interprète que dans le cadre des hypothèses suivantes: (*a*) interaction négligeable entre les deux noyaux thiophéniques et quasi dégénérescence des combinaisons antisymétrique et symétrique des orbitales A_2 et $2B_1$ du thiophène; (*b*) interaction nulle entre les combinaisons antisymétriques des orbitales A_2 et $2B_1$ du thiophène et l'orbitale π du soufre du groupement sulfure.

On est donc conduit à penser que ce sulfure de bithiényle existerait plutôt sous une conformation pseudo-symétrique présentant une rotation des deux cycles en sens opposés, c'est-à-dire l'une ou l'autre des deux conformations suivantes.

L'ensemble du spectre s'interprète ainsi compte tenu des seules interactions entre la paire π de l'atome de soufre du groupement sulfure et les combinaisons symétriques des orbitales A_2 et $2B_1$ des noyaux thiophéniques (fig. 4).

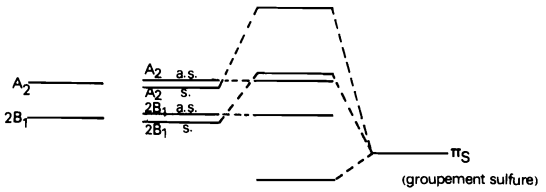

FIG. 4. Interactions orbitalaires mises en jeu: sulfure de bithiényle-3,3′.

Les considérations précédentes ne permettent pas de définir la conformation adoptée préférentiellement par les molécules de sulfure de bithiényle-3,3′; afin de chercher à préciser ce point, nous avons examiné les spectres des dérivés dibromés en 4,4′ et 2,2′.

Dans les deux cas on peut remarquer tout d'abord que, contrairement à ce qui a été signalé pour les dibromobithiényles (14) (qui pourtant présentent un angle de rotation important des deux cycles thiophéniques) on n'observe pas d'éclatement entre les paires libres des atomes de brome. Ce fait peut être attribué à un éloignement beaucoup plus grand entre ces deux atomes.

Dans le cas du dibromo-4,4′, un tel éloignement ne peut se concevoir que pour une conformation de type **1** assez "twistée." La stabilisation du premier potentiel (alors qu'on attend un effet destabilisant du brome) et la destabilisation du cinquième potentiel conduisent par rapport aux dérivé non substitué à conclure à une interaction légèrement plus faible entre le soufre central et les noyaux thiophéniques et donc à l'existence d'une conformation plus twistée.

Dans le cas du dibromo-2,2′, le maximum d'éloignement entre les deux atomes de brome ne peut être obtenu que pour une conformation de type **2**, assez fortement "twistée."

Nous avons cherché à confirmer les hypothèses précédemment formulées par une comparaison des données expérimentales avec les résultats tirés de calculs CNDO/S (tableaux 2 et 3) pour une conformation de type **1** et une conformation de type **2** (chaque noyau thiophénique faisant un angle de 30° avec le plan du groupe sulfure). Nous n'avons indiqué la contribution relative des orbitales atomiques que pour la conformation **1**, les résultats obtenus pour la conformation **2** étant très voisins. A noter que les deux structures choisies pour effectuer les calculs correspondent sensiblement à un contact de van der Waals entre les hydrogènes H_2 et $H_{2'}$ (conformation **1**) et H_4 et $H_{4'}$ (conformation **2**), ce type de conformation préférentielle ayant souvent été mis en évidence dans des problèmes du même type (13, 16, 17).

L'examen des tableaux 2 et 3 conduit aux remarques suivantes: (*a*) les spectres calculés

TABLEAU 3. Potentiels d'ionisation calculés pour le sulfure de bithiényle-3,3′ (conformation **2**)

Potentiels d'ionisation (verticaux) expérimentaux (eV)*	Valeurs théoriques (eV)	Nature	Symétrie

8.80	10.30	π	B
9.00	10.40	π	A
9.55	10.90	π	A
10.40	11.80	π	B

*Dérivé dibromé en positions 2 et 2′.

pour les deux conformations sont assez semblables, ce qui correspond bien aux spectres expérimentaux; (*b*) toutefois on constate sur les spectres calculés un écart entre les deux premiers potentiels d'ionisation plus faible (0.7 eV) pour une conformation de type **2** que pour celle de type **1** (1.1 eV).

Cette constatation s'accorde bien avec l'expérience, et ce compte tenu de la différence d'effet d'un atome de brome en α et en β.

L'étude des spectres photoélectroniques amène donc à proposer une structure de type **1** pour le sulfure de bithiényle lui-même et son dérivé dibromé en 4,4′, le dibromo-2,2′ présentant par contre une conformation privilégiée de type **2**.

Le fait que le sulfure de bithiényle-3,3′ présente des conformations différentes selon la substitution est d'ailleurs confirmé par l'allure nettement différenciée des spectres électroniques de ces mêmes dérivés.[2] En effet, pour le dérivé dibromé en 4,4′, les deux bandes de moyenne intensité à 271 et à 259 nm dans le *n*-heptane sont à rapprocher de celles observées à 278 et à 249 nm pour le dérivé non substitué. Au contraire, pour le dérivé dibromé en 2,2′ on observe une bande à 292 nm et un massif très intense aux environs de 240 nm.

Sulfure de bithiényle-2,2′ et dérivés

Spectres expérimentaux

Les spectres sont reproduits dans les figs 5–7 et les valeurs des potentiels d'ionisation sont rassemblées dans le tableau 4.

On constate que ces spectres sont assez semblables pour tous les composés considérés et comprennent: (*a*) une première bande, peu intense, aux environs de 8.5 eV; (*b*) une deuxième bande, très intense, entre 9 et 9.5 eV qui apparaît plus ou moins résolue selon le composé considéré; celle-ci résulte sans doute du recouvrement de plusieurs ionisations; (*c*) enfin, une dernière bande peu intense aux environs de 10.2 eV; celle-ci apparaissant sous forme d'un épaulement dans le cas du sulfure de bithiényle lui-même.

Discussion des résultats

Comme dans le cas du sulfure de bithiényle-3,3′: (*a*) on retrouve dans le spectre deux bandes aux environs de 9 et 9.5 eV; (*b*) on n'observe pas d'éclatement des paires libres des atomes de brome, ce qui nous incite à proposer une

*Confer tableau 1.

conformation pseudo-symétrique correspondant à une rotation en sens inverse des deux cycles thiophéniques.

De plus, étant donné la position même du premier potentiel d'ionisation, il semblerait que les interactions schématisées dans la fig. 8, entre la paire libre du soufre du groupement sulfure et les deux combinaisons symétriques des orbitales A_2 et $2B_1$ soient faibles. Ceci correspondrait ainsi, pour l'une ou l'autre des deux conformations envisageables **3** ou **4**, à un angle de rotation relativement important.

Nous avons enregistré également le spectre d'un dérivé plus encombré stériquement: celui du diiodo-3,3′ sulfure de bithiényle-2,2′. Bien que, dans ce cas, il y ait superposition partielle des ionisations dues aux atomes d'iode avec celles des cycles thiophéniques, les valeurs observées pour les cinq premiers potentiels d'ionisation sont très voisines de celles signalées pour son analogue bromé. Ceci semble indiquer que la conformation préférentielle d'un dérivé disubstitué en 3,3′ doit être celle pour laquelle les deux substituants sont le plus éloignés possible. Cette conformation, compatible avec l'encombrement relatif des atomes de soufre, doit être de type **3**.

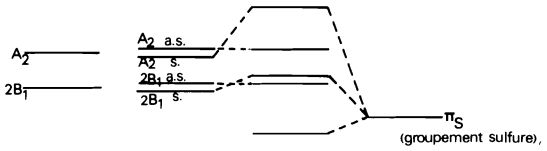

FIG. 8. Interactions orbitalaires mises en jeu: sulfure de bithiényle-2,2′.

Pour cette conformation remarquons que les atomes de soufre thiophéniques sont au contact de van der Waals pour un angle de chacun des deux cycles avec le plan CSC d'environ 50°.

Si l'on compare le dérivé dibromé en 4,4′ (pour lequel, on peut raisonnablement ne considérer que l'effet électronique) avec le dibromo-3,3′ (où intervient de plus l'effet stérique des substituants), on constate pour le composé le plus encombré, une destabilisation de 0.1 eV des premier et troisième potentiels d'ionisation et une stabilisation à peu près équivalente du potentiel d'ionisation associé à l'orbitale π du groupement sulfure. Cet effet peut être attribué à une interaction sensiblement plus grande entre les cycles et le soufre central.

Si l'on supposait que tous les composés examinés présentent une disposition spatiale du même type, la destabilisation observée lors de la substitution en 3,3′ ne pourrait s'expliquer que par un angle moins grand, entre les deux cycles, ce qui est tout à fait contradictoire avec l'effet stérique apporté par deux atomes de brome, *a fortiori* par deux atomes d'iode.

Il est vraisemblable au contraire que la substitution en position stériquement encombrée a un effet similaire à celui observé pour le sulfure de bithiényle-3,3′, c'est-à-dire modifie la conformation privilégiée de la molécule. On est donc tout naturellement amené à proposer pour le sulfure de bithiényle-2,2′ et son dérivé dibromé en 4,4′, une conformation du type **4**, avec un angle de torsion du même ordre que celui proposé pour la conformation de type **3**.

Nous avons rassemblé dans les tableaux 5 et 6 les résultats obtenus par la méthode CNDO/S pour les deux conformations **3** et **4** comme pour le sulfure de bithiényle-3,3′, nous n'avons indiqué les contributions des orbitales atomiques que pour l'une des deux conformations (chaque

*Dérivé dibromé en positions 3 et 3′.

noyau thiophénique faisant un angle de 50° avec le plan CSC central).

On constate tout d'abord une assez bonne concordance entre les valeurs théoriques et les valeurs expérimentales, concordance qui se traduit d'ailleurs par deux spectres théoriques assez voisins parallèlement à ce qui est observé expérimentalement.

De plus, on remarque dans le spectre théorique, pour la conformation **3**, une destabilisation du troisième potentiel d'ionisation et une stabilisation du cinquième potentiel d'ionisation. Ces constatations sont en excellent accord avec les caractéristiques spectrales signalées pour les deux dérivés dibromés.

Dans ce cas également l'hypothèse avancée de deux conformations différentes selon la substitution est confirmée par l'allure des spectres électroniques. Les dérivés substitués en positions 3 et 3′ présentent en effet un massif unique aux environs de 260 nm alors que les absorptions du produit non substitué et de son dérivé dibromé en 4,4′ correspondent à deux bandes à 270 et 240 nm.

Partie expérimentale

Synthèses

Les dibromo et diiodo thiophènes ont été obtenus selon les données de la littérature citées en référence: dibromo-2,4 thiophène: p $éb_{70}$: 120–125°C (litt. (19) p $éb_{9-10}$ 83–85°C); dibromo-3,4 thiophène: p $éb_{20}$: 115–120°C (litt. (20) p $éb_{12}$ 94–95°C); diiodo-2,3 thiophène: p $éb_{15}$: 160–163°C (litt. (21) p $éb_{11}$ 135–140°C). Le bromo-3 iodo-2 thiophène a été synthétisé par action du mélange iode – acide iodique sur le bromo-3 thiophène selon les modalités décrites pour la synthèse des bromoiodo thiéno(2,3-*b*) thiophènes (22). Au départ de 163 g (1 mol) de bromo-3 thiophène, on isole 260 g (rdt 90%) de dérivé bromoiodé: p $éb_{0.5}$ 87–90°C. *Anal.* calc. pour C_4H_2SBrI: C 16.63, H 0.70, S 11.10, Br 27.66, I 43.92; trouvé: C 16.9, H 0.8, S 11.3, Br 27.5, I 43.7. Caractéristiques rmn ($CDCl_3$): H_β: d/1, δ 6.92 ppm; H_α: d/1, δ 7.43 ppm; $J_{\alpha\beta}$ = 4.8 Hz.

Les sulfures de bithiényle ont été obtenus par action du sulfure de bis-phényl sulfonyle sur les thiényl-2 et thiényl-3 lithium selon les modalités opératoires proposées par De Jong et Janssen (23). Les sulfures ainsi obtenus ont été purifiés par chromatographie en phase gazeuse.

Sulfure de bithiényle-2,2′—Température de la colonne 235°C; temps de rétention 8.6 min; débit d'hélium 200 cm^3/min.

Sulfure de bithiényle-3,3′—Température de la colonne 255°C; temps de rétention 6.9 min; débit d'hélium 200 cm^3/min.

Les sulfures de bithiényles dihalogénés ont pour la plupart été synthétisés par action à −70°C d'une demi-mol de dichlorure de soufre ou de sulfure de bisphényl-sulfonyle sur l'organolithien obtenu par action de 1 mol de *n*-butyllithium sur 1 mol de dihalogéno thiophène convenable. Les caractéristiques des réactions sont rassemblées dans le tableau 7.

Quant au dibromo-2,2′ sulfure de bithiényle-3,3′, il a été obtenu par action du *N*-bromo succinimide sur le sulfure de bithiényle-3,3′ selon le mode opératoire suivant: 4 g (0.02 *M*) de sulfure de bithiényle-3,3′ sont

dissous dans 50 cm³ de chloroforme anhydre. A cette solution vigoureusement agitée sont ajoutés par petites fractions 7.1 g (0.04 *M*) de *N*-bromo succinimide. Le milieu réactionnel est maintenu 5 h à température ambiante puis traité par 30 cm³ d'eau. Le mélange est extrait au chloroforme et les phases organiques sont séchées, évaporées et le résidu obtenu est chromatographié sur gel de silice (éluant éther de pétrole). On isole 4.5 g (rdt 63%) d'une huile incolore. La purification est complétée par chromatographie en phase gazeuse: température de la colonne 235°C; temps de rétention 7.1 min; débit d'hélium 250 cm³/min. Les caractéristiques des sulfures dihalogénés synthétisés sont rassemblées dans le tableau 8.

Spectroscopie photoélectronique

L'étude spectroscopique a été réalisée sur un appareil Perkin-Elmer PS 18 muni d'une source à hélium I (21.21 eV ou 584 Å). Les spectres ont été calibrés à l'aide des pics associés aux doublets $^2P_{1/2}$ et $^2P_{3/2}$ de l'argon (15.755 et 15.933 eV), et du xénon (12.127 et 13.427 eV). Les potentiels d'ionisation sont estimés à ± 0.02 eV près.

Chromatographie en phase gazeuse

L'appareil utilisé était un chromatographe Aerograph Autoprep 700. La colonne présentait les caractéristiques suivantes: longueur 609.6 cm; diamètre 9.5 mm; phase stationnaire Chromosorb WAW, 45–60 mesh imprégné de SE30 à 15%.

Calculs

Ils ont été effectués à l'aide de la méthode CNDO/S étendue à la troisième période avec intervention des orbitales *d* (24). Les géométries utilisées ont été déduites des valeurs expérimentales indiquées pour le thiophène (25) et de celles couramment utilisées pour les dérivés sulfurés: longueur C—S = 1.76 Å (9), angle CSC = 100.0° (18).

Received December 22, 1976[1]

DENNIS G. MCMINN and BYRON KRATOCHVIL. Can. J. Chem. **55**, 3909 (1977).

Four mono-azo aryl dyes having the *o*-carboxy-*o'*-hydroxy functionality were investigated as reagents for the measurement of ionic Mg^{2+} in solutions containing complexing ligands. 2-(2'-Carboxyl-1'-benzeneazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid came closest to the ideal of having absorbance unaffected by p*H* over the p*H* range of interest and of differentiating between Ca^{2+} and Mg^{2+} complex formation. Ligand acid dissociation constants and formation constants for the metal–ligand complexes were measured.

DENNIS G. MCMINN et BYRON KRATOCHVIL. Can. J. Chem. **55**, 3909 (1977).

On a étudié quatre colorants mono-azo aryles ayant une fonction *o*-carboxy *o'*-hydroxy comme réactif pour la mesure de Mg^{2+} ionique dans des solutions contenant des ligands complexants. L'acide (carboxy-2' benzèneazo-1')-2 dihydroxy-1,8 naphthalène disulfonique-3,6 est celui qui se rapproche le plus de l'état idéal où l'absorption n'est pas affectée par le p*H* à des valeurs de p*H* intéressantes et où il est possible d'effectuer une différentiation entre la formation de complexes de Ca^{2+} et de Mg^{2+}. On a mesuré les constantes de dissociation acide des ligands et les constantes de formation des complexes métal–ligand.

[Traduit par le journal]

The measurement of free, or ionic, calcium and magnesium levels in biological systems is important because often the ionic concentration is of greater clinical significance than the total metal concentration. However, free metal ion levels (that is, aquated but not complexed to other species) are often difficult to determine in physiological fluids. The most widely used method of determining ionic calcium is the membrane ion selective electrode that, although of use in blood serum analysis, does not provide reliable results in urine. A corresponding ion selective electrode for magnesium is not yet available.

A second approach to the determination of ionic calcium or magnesium is by a spectrophotometric procedure involving formation of a weak but highly absorbing metal–ligand complex in a manner analogous to the measurement of p*H* by an indicator. The requirements of an indicator ligand for measurement of free metal ion concentration have been outlined by Scarpa (1). These include: (*a*) a small conditional formation constant for the metal ion of interest, but negligible tendency to complex other metals; (*b*) a large molar absorptivity for the metal–indicator complex at a wavelength free of interference from the uncomplexed ligand or other components of the sample; and (*c*) minimal side effects on the properties of the system under measurement. It is also advantageous if the spectrum and conditional formation constant of the metal–ligand complex undergo no appreciable change over a broad range of p*H*. In this way prior p*H* adjustment, which may shift equilibria and change ionic metal levels, can be avoided.

This approach has seen use in the determination of ionic concentrations of only two metals, calcium and magnesium. For calcium, murexide and tetramethylmurexide have been used as indicator ligands for measurements in urine and other biological systems (2). Tetramethylmurexide is the better of the two, but both have the disadvantage that the spectra of the free indicator and the calcium complex overlap extensively, and that the absorbance of the calcium complex fades relatively rapidly. Also, high concentrations of sodium interfere. For magnesium the most studied compounds have been of the *o,o'*-dihydroxyazoaryl class because the magnesium complexes of these ligands have high

[1]Revision received August 6, 1977.

molar absorptivities and are more stable than the corresponding calcium analogs. Eriochrome Blue SE and Calmagite (1, 3) have been investigated for this purpose; in each case calcium forms a complex of sufficient stability to interfere, and absorbance readings at two wavelengths are necessary to correct for the calcium present. Eriochrome Black T has also been studied (4); its properties and range of applicability are similar to the other two dyes.

Diehl and Ellingboe, in a study of the properties of a large number of azo dyes, demonstrated that complexation with calcium and magnesium occurs if one of the *ortho* positions in an azoaryl system is occupied by a hydroxyl group and the other by either a hydroxyl or carboxyl group (5). Further, they showed that conditional formation constants for calcium and magnesium are both smaller by a factor of about 100 when the second *ortho* position contains a carboxyl group. The hydroxyl–carboxyl combination is more attractive as a system for measuring ionic magnesium concentrations because a small formation constant minimizes disruption of equilibria already established in the system to be measured. Also, the larger acid dissociation constant of a carboxyl group increases the p*H* range over which the ligand possesses the same degree of protonation and the same spectral properties, which may permit measurement over a wider p*H* range without correction. In this work three compounds containing the *o*-carboxyl-*o'*-hydroxyl functionality were studied to obtain more information about the role of ligand structure in optimization of the measurement of ionic magnesium.

Experimental

Apparatus and Materials

Anthranilic acid (BDH) was purified by recrystallization from water using Norit-A (Fisher) and washing with cold water. Sodium 2-naphthol-6-sulfonate was purified by precipitation from water by bubbling in HCl gas, filtering, and washing with 30% aqueous HCl; brilliant white crystals were obtained (6). 2-Naphthol (British Drug House), chromotropic acid (practical grade, Eastman P-230 as disodium salt with two waters of hydration), and 3-methyl-1-phenyl-2-pyrazolin-5-one (Eastman 1397) were used as received.

Ammonia buffer, $\mu = 0.10$, was used for measurements at p*H* 10.1. A 0.0334 *M* solution of $MgCl_2$ was prepared and standardized by titration with standard 0.01 *M* EDTA. Stock solutions ($\sim 10^{-4}$ *M*) of sulfonated compounds were prepared in water; non-sulfonated compounds were dissolved in 98% ethanol. All solutions of the ligands were protected from light. Absorption spectra were obtained on a Unicam SP 1700 recording spectrophotometer. p*H* measurements were made on an Orion Model 801 digital p*H* meter. The meter and glass electrode were standardized with NBS standard buffers. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Microanalyses were performed in the Microanalytical Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alta. Thin layer chromatography (tlc) was performed on precoated Silica Gel 60 F-254 plates (Brinkmann) in a presaturated chamber (Gelman Model 51325) with 98% ethanol as eluting solvent.

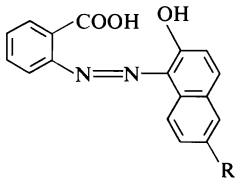
The acid dissociation constants for the hydroxylic and carboxylic protons were determined by potentiometric titration with NaOH or by spectrophotometry. Values of pK_1 for the non-sulfonated ligands could not be determined in water because of insolubility at low p*H*. Formation constants for the magnesium and calcium complexes of the four ligands at p*H* 10.1 and $\mu = 0.10$ were determined by pipetting 1.0 ml of stock solution[2] of dye and an aliquot of stock solution of metal ion into a volumetric flask, adding KCl as necessary to adjust ionic strength, then diluting the solution to volume with NH_3–NH_4Cl buffer. Absorption measurements were made immediately after mixing because solutions of the complexes decompose slowly with time, especially when exposed to light. Calculations of the conditional formation constants were performed by the method of Ramette (7), using a BASIC computer program supplied by the author and modified for use on a Digital Equipment Corporation PDP-11 computer. In all cases the 'initial' metal ion concentrations were adjusted to take account of complexation by the ammonia present in the buffer solution. No spectrophotometric evidence for formation of ML_2 or higher complexes was found.

Preparation of Dyes

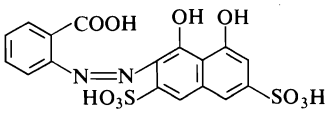
(*a*) 1-(2'-Carboxyl-1'-benzeneazo)-2-hydroxynaphthalene (**1**) was prepared according to the published method (5) and recrystallized from acetic acid: mp 275–277°C (lit. (8) 268°C; (9) 278°C; (5) 273.5–274.5°C). Thin-layer chromatography showed one spot ($R_f = 0.21$).

(*b*) 1-(2'-Carboxyl-1'-benzeneazo)-2-hydroxynaphthalene-6-sulfonic acid (**2**) (C.I. 15975) was prepared in an analogous manner from diazotized anthranilic acid and purified sodium 2-hydroxynaphthalene-6-sulfonate. It was isolated by bubbling in gaseous HCl, filtering the slurry as much as possible (sintered glass), then transferring to acetone. The suspension was warmed until the solid dissolved, then benzene added until precipitation began. The material was cooled, filtered, and washed with cold benzene. The hard brick-red solid was removed from the filter and dried under vacuum. Elemental analysis indicated the product was a mixture of the free acid and the sodium salt. Thin-layer chromatography showed one colored band which stretched from near the origin to

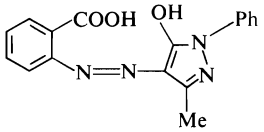
[2]In the approach used here the initial ligand concentration, and therefore the presence of non-complexing impurities in the dye, is not crucial since only differences in absorbances are necessary to measure the formation constant. Measurements of molar absorptivities of the ligand–metal complexes do, however, require knowledge of the analytical concentrations of both the ligand and the metal ion.



1, R = H
2, R = SO_3H



3



4

$R_f \sim 0.28$, and small spots of three colorless impurities at slightly higher R_f.

(*c*) 2-(2′-Carboxyl-1′-benzeneazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid (**3**) was prepared by slow addition of a cooled solution of diazotized anthranilic acid (7.25 mmol) to a solution of chromotropic acid (7.25 mmol) in 25 ml of 0.1 *M* NaOH. When the resulting solution was acidified with gaseous HCl a dark red solid precipitated. This material was filtered, washed with 30% aqueous HCl followed by a few drops of cold water, dried over calcium chloride, and ground to give a brick-red powder. The powder was taken up in methanol and added to the top of a 1.5 × 10 cm column containing 7.5 g of Amberlyst 15 strongly acidic cation exchange resin (Rohm and Haas, 120–325 mesh, de-fined). The resin had been converted previously into the hydrogen form by washing with HCl until free of sodium (flame test), with water until neutral, and finally with methanol until transparent in uv light. Elution of the dye mixture with additional methanol gave a dark eluate; a faint purple band remained on the column. The solid obtained on evaporation of the solvent from the eluate showed no sodium (flame test), no halogen (Beilstein test), and gave a ^1H nmr spectrum showing no aliphatic protons. Attempts to establish unambiguously the site of coupling on the chromotropic acid by ^{13}C and ^1H nmr were unsuccessful, but from reaction of other azo compounds with chromotropic acid the predicted position is *ortho* to one of the hydroxyl groups. Duplicate samples (82.7 mg and 77.2 mg) upon titration with NaOH gave equivalent weights of 184.6 and 186.7. From these results a formula $C_{17}H_{12}N_2O_{10}S_2 \cdot 5H_2O$ is proposed (equiv. wt. 186.2 based on three titrated protons). Thin-layer chromatography showed one spot ($R_f = 0.47$) plus a faint residue which remained at the origin. *Anal.* calcd. for $C_{17}H_{12}N_2O_{10}S_2 \cdot 5H_2O$: C 36.55, H 3.97, N 5.02, S 11.48; found (duplicate elemental analysis): C 36.36, 36.39, H 3.27, 3.09, N 4.51, 4.55, S 11.13, 10.08.

(*d*) 4-(2′-Carboxyl-1′-benzeneazo)-3-methyl-1-phenyl-2-pyrazolin-5-one (**4**) (C.I. 18690) was prepared by coupling diazotized anthranilic acid (7.25 mmol) to 3-methyl-1-phenyl-2-pyrazolin-5-one (7.25 mmol) dissolved in 25 ml of 0.3 *M* NaOH. Reaction was immediate at 5°C. The compound was isolated by filtration and recrystallized from ethanol–water giving fluffy orange crystals: mp 278–279°C. *Anal.* calcd. for $C_{17}H_{14}N_4O_3$: C 63.35, H 4.38, N 17.38; found (duplicate elemental analysis): C 62.10, 62.25, H 4.38, 4.36, N 17.04, 17.33.

Results

Figure 1 shows the absorption spectra for the four ligands studied, along with spectra of solutions of the ligand plus calcium or magnesium. In Fig. 2 are shown plots of spectral dependence on p*H* measured at selected wavelengths for each ligand. Table 1 summarizes the absorption data and Table 2 gives the experimentally determined acid dissociation constants and the conditional formation constants for the complexes of the four ligands with Mg^{2+} and Ca^{2+}. From these data equilibrium constants were calculated using the formula $K = K'\alpha_{ML}/\alpha_M\alpha_L$, where K is the equilibrium constant at $\mu = 0.10$; K' the conditional formation constant at $\mu = 0.10$, p*H* 10.1; α_{ML} the fraction of complex present in 1:1 ratio; α_M the fraction of uncomplexed metal present as aquated species; and α_L the fraction of uncomplexed dye present in the form available for complexing (10).

The value of α_L in each case was calculated from knowledge of K_a for the second acid dissociation constant of L and the p*H* at which K' was measured. α_{ML} was taken as 1.0, since no evidence for formation of other than 1:1 complexes was reported by Diehl and Ellingboe (5), nor was any detected in the present study. The other significant metal complex present, $M(NH_3)^{2+}$, was accounted for in determining the 'initial' metal concentration so α_M was also taken as 1.0. This could be done because the fraction of the total metal present that was converted to the metal ligand complex was less than 1% in all cases, and the ratio of the concentration of free M^{2+} to $M(NH_3)^{2+}$ was little affected by the addition of ligand. The results are tabulated in Table 2.

Discussion

Compounds **1–4** were synthesized and studied to provide information on the properties of azo dyes that might lead to improved reagents for the measurement of ionic magnesium levels over

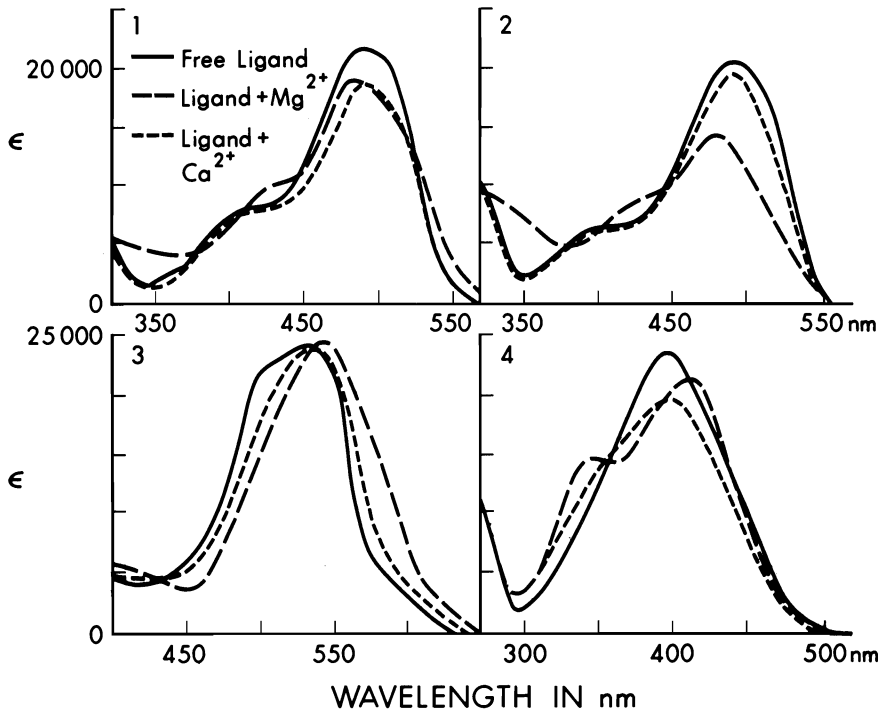


FIG. 1. Absorption spectra of ligand, ligand + Mg^{2+}, and ligand + Ca^{2+} ($[M^{2+}] \sim 10^{-3}$ *M*) at p*H* 10.1 and ionic strength 0.10. (*a*) 5×10^{-5} *M* **1**; (*b*) 2.7×10^{-5} *M* **2**; (*c*) 9.4×10^{-6} *M* **3**; (*d*) 1.8×10^{-5} *M* **4**.

a range of p*H*, particularly in the region of physiological p*H*. To achieve this goal the absorbance of the ligand must be independent of p*H* over the range of interest. All three of the *o*-carboxyl-*o'*-hydroxyl systems met this criterion over the range of p*H* 5 to 9. A second requirement is that the conditional formation constant for the magnesium–ligand complex not vary significantly over the p*H* range encountered in samples. Since K' depends on α_L, the p*K* of the hydroxyl group is the major factor determining the usable p*H* range. Thus compound **3**, which has the lowest p*K* for the hydroxyl group of the compounds studied, gives a spectral response to changes in Mg^{2+} concentration at lower p*H* values than do the other three compounds. Thirdly, the conditional formation constant between ligand and magnesium should be on the order of only a few hundred so that equilibria between ionic magnesium and other components of the sample are not greatly affected.

Diehl and Ellingboe (5) found the formation constants for complexes of the *o,o'*-substituted azoaryl ligands with magnesium to be greater than those for calcium. This was the case for all the compounds studied here except compound **1**. The uncertainty in measuring K' for the complex between Ca^{2+} and either **1** or **2** is large because spectra of the ligand and the metal–ligand complex are highly similar.

The ligands investigated so far for measurement of ionic magnesium in biological systems require careful p*H* adjustment during measurement because they undergo acid dissociation and corresponding spectral changes of the free ligand over the physiologically important p*H* range of 6.5 to 8. The free ligand properties are important because overlap of the spectra of uncomplexed ligand and complex make correction for free ligand absorbance necessary. With compounds **2** and **3**, overlap of the spectra of the free and complexed ligands still is present, but wavelengths can be chosen where absorbance of the free ligand is unaffected by p*H* over a relatively wide range. For these systems the factor limiting the usable p*H* range is that complexation with magnesium is too small at p*H* values below about 9 for **2** and 7 for **3** (three p*H* units below p*K*(OH)) for the systems to be useful analytically.

In an effort to reduce interference from calcium the pyrazole system **4** was investigated.

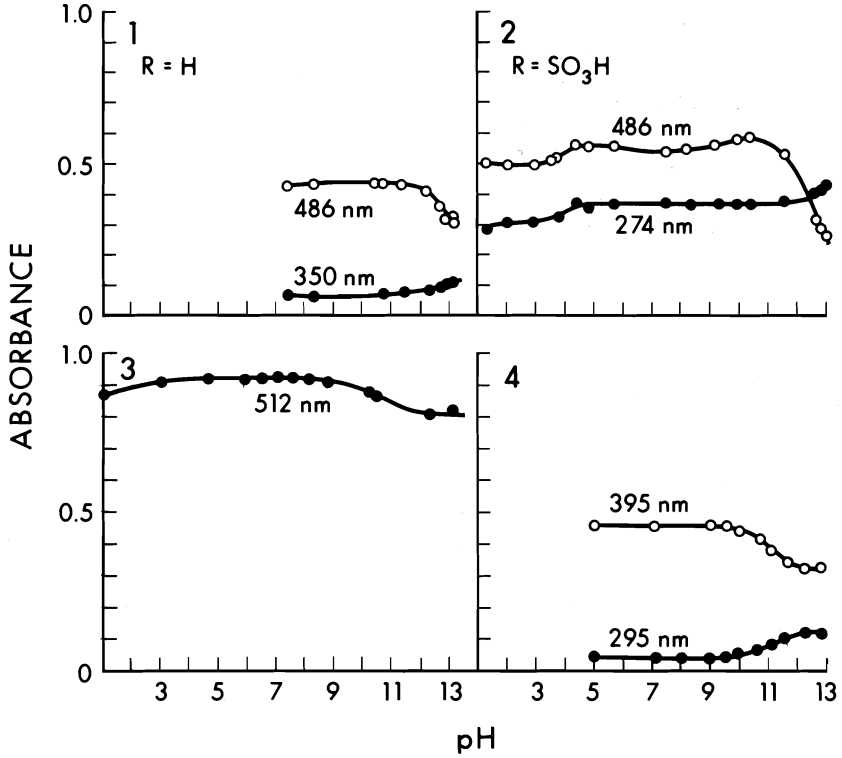

FIG. 2. Plots of absorbance of ligand vs. p*H* for ligands **1**–**4** at selected wavelengths.

TABLE 1. Spectral data for ligands and their magnesium and calcium complexes at p*H* 10.1

	λ_{max}			log ε^a

[a]Insoluble below p*H* 5.
[b]Reported: $pK_2 = 12.0$, log *K'* $(Mg^{2+}) = 2.10$ at $\mu = 0.10$, p*H* 10.1, no complex formation with Ca^{2+} (4).
[c]From spectrochemical data.
[d]From potentiometric titration.
[e]Measured at p*H* 10.2.

Snavely *et al.* reported an appreciable difference between Mg^{2+} and Ca^{2+} complex formation constants for the similar compound 4-(2′-hydroxyl-1′-benzeneazo)-3-methyl-1-phenyl-2-pyrazolin-5-one (log K' for Mg^{2+}, 10.94; for Ca^{2+}, 8.72 in 75% dioxane) (11). However, although the formation constant for magnesium with **4** is in the right range, that for calcium is too close to be useful in selective measurements. Also, the complexes are yellow, which would further hamper their use for the direct determination of ionic magnesium in some applications, as in urine.

Of the compounds synthesized, **3** appears the most useful for measurement of ionic magnesium. This compound is similar in structure to many analytically useful azo dyes, but has not been reported previously. The widely separate pK_a values of 3.5 and 10.2 make possible a wide variation in p*H* without accompanying spectral changes due to changes in concentration of HL^-, and the conditional formation constant with magnesium makes the system usable over a p*H* range of about 7 to 10. However, it shares with previously studied compounds the disadvantages that the free ligand absorbs significantly at the same wavelength as the magnesium complex, and the formation constant for calcium, while smaller than that of magnesium, is sufficiently large to cause some interference.

We conclude that the *o*-carboxyl-*o*′-hydroxyl azo function is not likely to provide a reagent capable of complexing magnesium and not calcium. The reagents previously proposed, Eriochrome Blue SE, Eriochrome Black T, and Calmagite, along with compound **4** discussed here, are similar in complexing properties; all require a correction for calcium. This correction is best done by recording the difference in absorbance readings at two wavelengths (1).

Un exemple d'isomérisation radicalaire en chaînes: la photoinduction de l'isomérisation *cis–trans* de la pentène-3 one-2

ARMEL RIOUAL, ANDRÉ DEFLANDRE ET JACQUES LEMAIRE

Laboratoire de Photochimie, U.E.R. Sciences Exactes et Naturelles, Université de Clermont II, Clermont-Ferrand, France

Reçu le 26 janvier 1977[1]

ARMEL RIOUAL, ANDRÉ DEFLANDRE et JACQUES LEMAIRE. Can. J. Chem. **55**, 3915 (1977).

Une étude des variations des rendements quantiques initiaux de l'isomérisation *cis–trans* photosensibilisée de la pentène-3 one-2 en fonction des concentrations initiales du donneur et de l'accepteur, de la longueur d'onde d'excitation, de la nature du donneur et du solvant permet de proposer des mécanismes de sensibilisation n'impliquant pas seulement des transferts d'énergie triplet–triplet. Les donneurs carbonylés (acétophénone, benzophénone, acétone) sont susceptibles d'induire une isomérisation radicalaire en chaînes dans les solvants où le sensibilisateur est réduit; l'exemple de l'acétophénone est particulièrement significatif. Dans les solvants qui ne conduisent pas à la photoréduction du donneur (comme le benzène ou le CCl_4), le mécanisme classique du transfert d'énergie triplet–triplet permet d'expliquer les résultats obtenus. L'isomérisation sensibilisée par les donneurs aromatiques (benzène, mésitylène) s'interprète par un double mécanisme: à faible concentration d'accepteur, les transferts d'énergie (triplet–triplet) sont prépondérants, alors qu'à forte concentration, il se forme un exciplexe entre l'aromatique excité dans son niveau singulet et la cétone; cet exciplexe se désactive en se dissociant et en provoquant l'isomérisation de la cétone α,β insaturée.

ARMEL RIOUAL, ANDRÉ DEFLANDRE, and JACQUES LEMAIRE. Can J. Chem. **55**, 3915 (1977).

Mechanisms of the photosensitized *cis–trans* photoisomerization of 3-penten-2-one which do not imply only classical triplet–triplet energy transfer are proposed; they are based upon measurements of the variations of initial quantum yields of isomerization with the initial donor and acceptor concentrations, the wavelength of excitation, and the nature of the donor and of the solvent. Carbonyl donors (acetophenone, benzophenone, acetone) induce a radical isomerization by a chain process in reducing solvents; the example of acetophenone is specially interesting. In solvents in which the donor is not photoreduced (as benzene or CCl_4) classical triplet–triplet energy transfers occur. Sensitization with aromatic donors (benzene, mesitylene) proceeds through triplet–triplet energy transfer at low concentrations of the acceptor. At higher concentrations of acceptor, an exciplex is formed between the ketone and the aromatic in its singlet excited state; this exciplex is deactivated by dissociation and by causing the isomerization of the α,β-unsaturated ketone.

De très nombreuses mesures du rendement quantique de transition inter-systèmes sont basées sur des isomérisations *cis–trans* photosensibilisées, tant en phase gazeuse (1) qu'en solution (cf. par exemple réfs 2–7). Les auteurs admettent alors que l'interaction entre la molécule à étudier et l'accepteur isomérisable peut se réduire à un transfert d'énergie triplet–triplet dans un domaine convenable de concentration de cet accepteur. Mais s'il est facile d'exclure la participation de l'état excité singulet d'un donneur fluorescent, il est parfois plus difficile d'assurer que le niveau triplet du donneur ne participe qu'à un transfert d'énergie.

Dans le cadre d'une étude des aspects quantitatifs du comportement photochimique des cétones α,β insaturées (8, 9), nous avons été amenés à examiner les processus d'isomérisation *cis–trans* sensibilisée de la pentène-3 one-2. Comme nous allons le rapporter plus loin, les résultats expérimentaux obtenus nous amènent à proposer d'autres mécanismes d'isomérisation que ceux impliquant de simples transferts d'énergie triplet–triplet.

[1]Revision reçue le 27 juillet 1977.

Techniques expérimentales

Préparation et purification des pentènes-3 ones-2 trans et cis

Les formes *trans* et *cis* de la pentène-3 one-2 sont extraites d'un produit technique Aldrich. La forme *trans* est séparée par une bidistillation sur une colonne à bande tournante Nester-Faust, suivie d'une chromatographie préparative en phase vapeur sur un appareil Hupe et Busch APG 402 (équipé d'une colonne à 5% de Carbowax 20M). La pentène-3 one-2 ainsi obtenue contient 4% de méthyl-4 pentène-3 one-2. Nous avons vérifié que la présence de ce dernier composé, que nous avons précédemment étudié (8), ne perturbait pas le comportement photochimique de la pentène-3 one-2 *trans*. La pentène-3

one-2 *cis* est ensuite préparée par irradiation de la forme *trans*. Après une nouvelle séparation par chromatographie préparative, l'isomère *cis* obtenu contient 6% de forme *trans* et environ 10% de pentène-4 one-2 et il doit être conservé à l'obscurité, à 0°C. La pentène-4 one-2 ne peut être excitée dans le mélange, ni par absorption directe, ni par transfert d'énergie, et nous avons vérifié qu'elle ne modifiait pas les processus photochimiques des pentènes-3 ones-2.

Techniques d'irradiation

Deux dispositifs d'irradiation monochromatique ont été utilisés: une lampe à vapeur de mercure type "basse pression" à résonance (Philips TUV 15 W) et une lampe à vapeur de mercure type "très haute pression" (Osram HBO 200 W) associée à un monochromateur Bausch et Lomb haute intensité. Les réacteurs sont en quartz Suprasil et l'oxygène dissous peut être éliminé par les cycles classiques congélation, pompage sous vide dynamique, liquéfaction. L'intensité lumineuse disponible est mesurée par des actinométries basées soit sur la photolyse de l'acide oxalique sensibilisée par les ions uranyles (10) soit sur la photoréduction de ferrioxalate (11) soit encore sur l'isomérisation *cis–trans* de l'azobenzène (12, 13).

Techniques analytiques

Les solutions diluées de pentène-3 one-2 *cis* ou *trans* ont été dosées soit par spectrophotométrie uv (Jobin et Yvon Monospac) soit par chromatographie en phase vapeur à l'aide d'un appareil Varian série 1400 équipé d'une colonne à 10% de Carbowax 20M de 10 pieds de longueur. Quelques dosages ont été également réalisés par spectroscopie infrarouge à l'aide d'un spectrophotomètre Perkin-Elmer modèle 180. Les spectres de fluorescence ont été enregistrés sur un appareil Perkin-Elmer-Hitachi MPF 3.

Expériences préliminaires sous excitation directe et photosensibilisations

Nous avons déjà rapporté l'essentiel des résultats acquis en excitation directe (9). Les rendements quantiques initiaux $\Phi^0_{c\to t}$ et $\Phi^0_{t\to c}$ mesurés et les régimes photostationnaires observés s'interprètent en admettant que le niveau triplet d'un isomère se désactive avec une égale probabilité vers les deux formes *cis* et *trans* de la pentène-3 one-2. Les principales propriétés des sensibilisateurs employés sont rassemblées dans le tableau 1.

Isomérisation *trans–cis* de la pentène-3 one-2 photosensibilisée par des composés carbonylés

Etude expérimentale de la sensibilisation par l'acétophénone

Le tableau 2 rassemble les rendements quantiques initiaux d'isomérisation *cis–trans* sensibilisée par l'acétophénone, mesurés dans diverses conditions expérimentales. Nous avons successivement examiné l'influence des concentrations initiales du donneur et de l'accepteur, l'influence de la longueur d'onde d'excitation et celle du solvant en milieu soigneusement dégazé. La présence d'oxygène provoque une nette diminution du rendement $(\Phi^S_{c\to t})^0$ (0.11 au lieu de 1.5 en milieu dégazé dans les mêmes conditions de concentration et d'irradiation). Il convient de noter les valeurs supérieures à l'unité des rendements quantiques mesurés dans le *n*-heptane. On a rapporté dans la littérature, des rendements quantiques d'isomérisation *cis–trans* du 2,4-hexadiène sensibilisée par la benzophénone, supérieurs à 160 (20); des mesures ultérieures ont ramené ces rendements à des valeurs plus habituelles (21). Le seul exemple non controversé concernerait l'isomérisation *cis–trans* du piperylène sensibilisée par la benzophénone, qui aux fortes concentrations (1 à 10 M), présente des rendements augmentant de 1 à 1.7 (22). Dans les solvants comme le tétrachlorure de carbone ou le benzène, les rendements quantiques initiaux d'isomérisation *cis–trans* de la pentène-3 one-2 reprennent des valeurs plus classiques. Dans le tableau 3, nous indiquons les valeurs du rendement $(\Phi^S_{c\to t})^0$ en solvant binaire (*n*-heptane–benzène) de composition variable.

Si la solution dans le *n*-heptane contient initialement la forme *trans*, le rendement quantique $(\Phi^S_{t\to c})^0$ reste toujours faible (0.02 dans une solution 2×10^{-2} M en acétophénone et 4×10^{-3} M en pentène-3 one-2).

Nous avons représenté, à titre d'exemple, sur la fig. 1, les variations des concentrations des formes *trans* et *cis* de la pentène-3 one-2 dans une solution contenant initialement 10^{-3} M de forme *cis*, 10^{-2} M d'acétophénone et irradiée à 313 nm. Ces courbes appellent trois remarques: (*a*) le rapport de la concentration de la forme *trans* à celle de la forme *cis* atteint des valeurs maximales aussi élevées que 7; (*b*) les processus d'isomérisation *cis* → *trans* sont accompagnés d'un processus de disparition irréversible de la pentène-3 one-2; nous avons rapporté dans le tableau 2 les rendements quantiques initiaux de ce processus; (*c*) l'acétophénone est susceptible d'être photoréduite par le solvant, mais la disparition du sensibilisateur ne devient mesurable que lorsque la concentration de pentène-3 one-2 n'est plus que de 10^{-4} M.

Etude expérimentale de la sensibilisation par la benzophénone

L'influence des paramètres macroscopiques usuels (concentrations initiales du donneur et de l'accepteur, longueur d'onde d'excitation, nature du solvant) sur les rendements quantiques initiaux d'isomérisation *cis* → *trans* de la pentène-3 one-2 sous forme *cis* a été à nouveau

TABLEAU 1. Caractéristiques des sensibilisateurs employés

Sensibilisateur (Références)	Acétophénone (14)	Benzophénone (14)	Acétone (14,15)	Benzène (6,14,16,17)	Mésitylène (14,17,18,19)
Energie du niveau T_1 kcal/mole	74	70	79-80	84,3	80,3
Rendement quantique de transition inter-systèmes $S_1 \rightarrow T_1$	1	1	1	0,25 à 0,71	0,60 à 0,55
Durée de vie de S_1 (ns)	-	0,02 0,005		30	37
Durée de vie de T_1 (μs)	100 (eau) 0,23(cyclohexane) 0,11(isopropanol)	20 (eau) 0,3 (cyclohexane) 0,04(isopropanol)	0,4 (n-hexane)	0,5 à 6×10^{-3}	-
ε (λ_{exc}) dans le n-heptane $mole^{-1}.l.cm^{-1}$	33 (297nm) 39 (313 nm) 6 (365nm)	116 (297nm) 73 (365nm)	9,5 (297nm, eau)	-	-

examinée et le tableau 4 rapporte les résultats de nos mesures. Nous avons également étudié les variations des concentrations des différents composants du mélange sous irradiation. Là encore, le rapport de la concentration de la forme *trans* à celle de la forme *cis* atteint des valeurs maximales très supérieures à l'unité (6 à 8 sous excitation à 297 ou à 313 nm, 4.2 sous excitation à 365 nm); les processus de disparition irréversible se superposent aussi à l'isomérisation de la pentène-3 one-2. Enfin, comme le montre la fig. 2, la benzophénone disparait dès les premiers instants de l'irradiation dans le *n*-heptane sans présenter la même "période d'induction" que l'acétophénone.

La benzophénone n'est pas susceptible de sensibiliser l'isomérisation *trans* → *cis* de la pentène-3 one-2 dans le *n*-heptane. Par contre, ce même donneur à 2×10^{-2} *M*, sensibilise cette isomérisation dans le tétrachlorure de carbone (cf. tableau 5); parallèlement, la phosphorescence, à température ambiante de la benzophénone dans le tétrachlorure de carbone est éteinte par la cétone insaturée selon une même loi de Stern–Volmer que l'isomérisation sensibilisée.

Etude expérimentale de la sensibilisation par l'acétone

L'acétone est un sensibilisateur d'emploi difficile; substance peu absorbante, elle doit être employée à des fortes concentrations où elle s'autodésactive. Mais ce donneur permet de comparer le comportement de la pentène-3 one-2 en solution aqueuse et en solution dans le *n*-heptane. Le tableau 6 rassemble les rendements quantiques initiaux dans ces deux solvants.

Interprétation des résultats expérimentaux

L'excitation de l'acétophénone dans un solvant pouvant participer à un processus de photoréduction du donneur provoque l'isomérisation *cis–trans* de la pentène-3 one-2 avec un rendement quantique initial très supérieur à 0.5. Un tel résultat ne peut être interprété par un transfert d'énergie rapide entre sensibilisateur et la cétone α,β insaturée. En effet, un sensibilisateur qui peuple totalement son niveau triplet peut

TABLEAU 2. Rendements quantiques initiaux des processus d'isomérisation et de disparition irréversible de la pentène-3 one-2 *cis* sensibilisées par l'acétophénone

provoquer au maximum la population quantitative du niveau triplet de la pentène-3 one-2; étant donné qu'en excitation directe, une population de 80 à 90% du niveau triplet de la forme *trans* ou *cis* conduit à un rendement quantique d'isomérisation de 0.40 à 0.45 (9), la population quantitative du niveau triplet de la pentène-3 one-2 permettrait d'obtenir un rendement maximum égal à 0.5. Cette situation se rencontre d'ailleurs dans les solvants qui ne peuvent participer à un processus de photoréduction du sensibilisateur, comme par exemple le benzène ou le tétrachlorure de carbone; il intervient alors un transfert d'énergie relativement rapide se manifestant par des rendements quantiques d'isomérisation sensibilisée inférieurs à 0.5 (cf. tableaux 2 et 4).

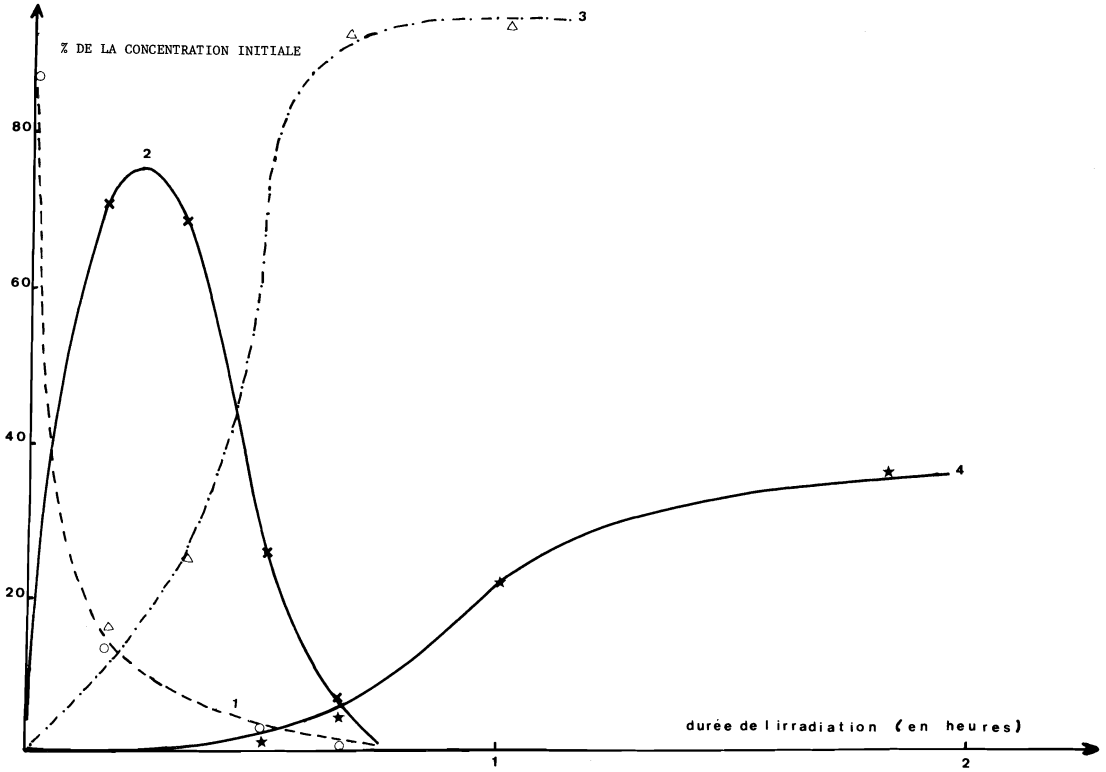

FIG. 1. Isomérisation de la pentène-3 one-2 *cis* (10^{-3} *M*) sensibilisée par l'acétophénone (10^{-2} *M*) (λ_{exc} = 313 nm; solvant: *n*-heptane dégazé): courbe 1: forme *cis*; courbe 2: forme *trans*; courbe 3: disparition de la pentène-3 one-2; courbe 4: disparition de l'acétophénone.

Il est à noter également que l'excitation de l'acétophénone ou de benzophénone dans un solvant réducteur ne conduit pas à l'isomérisation *trans–cis* de la pentène-3 one-2.

Par contre, dans un solvant non réducteur, un transfert d'énergie permet de sensibiliser tout aussi bien l'isomérisation *trans–cis* que l'isomérisation *cis–trans*. En particulier, l'étude effectuée dans le cas de la benzophénone le montre clairement (cf. tableau 5).

Il faut donc considérer que dans les solvants réducteurs, l'acétophénone est capable d'induire une isomérisation radicalaire de la forme *cis* et non de la forme *trans*. L'effet de solvant sur l'isomérisation sensibilisée de la forme *cis* montre que les radicaux responsables de l'isomérisation radicalaire ne sont pas issus d'une dissociation photochimique du sensibilisateur, mais plutôt d'un processus de photoréduction de ce sensibilisateur par le solvant SH.

$$(C_6H_5—CO—CH_3)_{T_1} + SH \rightarrow (C_6H_5—\underset{\displaystyle OH}{\overset{\displaystyle |}{\dot{C}}}—CH_3) + (S^{\cdot})$$

Une interprétation très analogue peut être proposée pour les résultats acquis en sensibilisation par la benzophénone, bien que l'isomérisation de la forme *cis* s'effectue avec un rendement $(\Phi^{S}_{c\rightarrow t})^{0} = 0.30$ suffisamment faible pour être interprétée en termes de transfert d'énergie. Deux remarques justifient le mécanisme d'induction radicalaire: (*i*) En solution dans le *n*-heptane le rendement quantique d'isomérisation sensibilisée par la benzophénone de la forme *trans* est nul et donc très inférieur à $(\Phi^{S}_{c\rightarrow t})^{0}$. Dans le benzène et le tétrachlorure de carbone où la sensibilisation implique un transfert d'énergie, les rendements quantiques $(\Phi^{S}_{c\rightarrow t})^{0}$ et $(\Phi^{S}_{t\rightarrow c})^{0}$ sont voisins. (*ii*) Le rapport [*trans*]/[*cis*] en régime photostationnaire est voisin de 1 dans le benzène ou le tétrachlorure de carbone, alors que dans le *n*-heptane ce rapport prend des valeurs maximales très supérieures à l'unité.

La benzophénone apparaît expérimentalement comme un inducteur moins efficace que l'acétophénone, alors que la population du niveau triplet de ces deux sensibilisateurs est

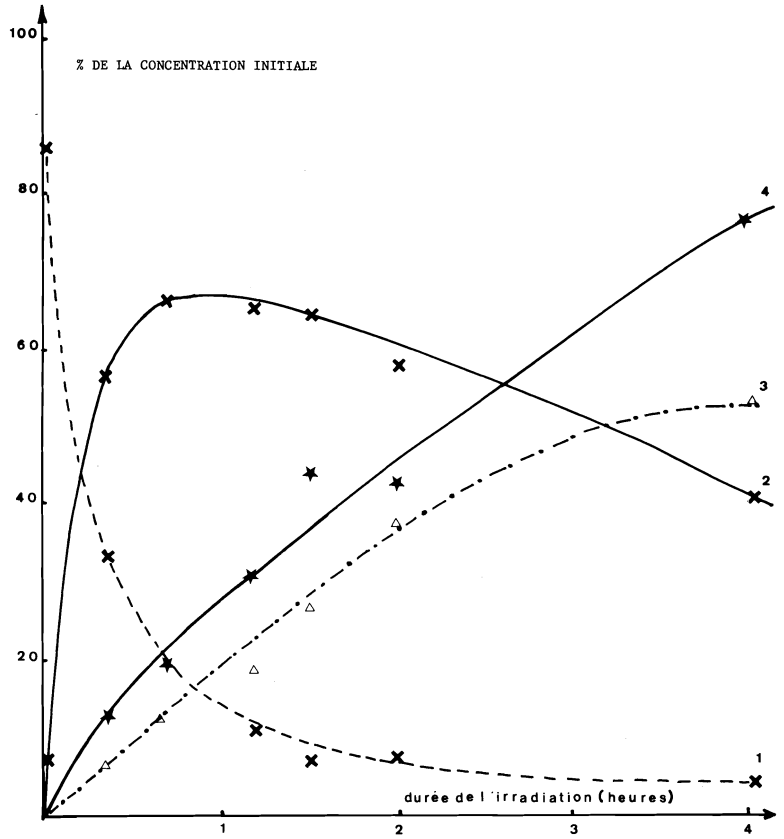

FIG. 2. Isomérisation de la pentène-3 one-2 *cis* (10^{-3} *M*) sensibilisée par la benzophénone (0.8×10^{-2} *M*) (λ_{exc} = 313 nm; solvant: *n*-heptane dégazé): courbe 1: forme *cis*; courbe 2: forme *trans*; courbe 3: disparition de la pentène-3 one-2; courbe 4: disparition de la benzophénone.

pratiquement totale et que leur photoréductibilité par le *n*-heptane reste voisine. La différence de comportement pourrait être attribuée à la nature des radicaux $C_6H_5—\dot{C}(OH)—C_6H_5$, plus encombrants que les radicaux issus de l'acétophénone.

L'induction radicalaire de l'isomérisation *cis–trans* de la pentène-3 one-2 par les deux cétones aromatiques employées peut s'interpréter par le mécanisme en chaînes suivant (schéma 1).

Amorçage photochimique

[1] $C_6H_5COR + n\text{-}C_7H_{16} \xrightarrow{\Phi_r I_a} C_6H_5\dot{C}(OH)R + n\text{-}C_7H_{15}$

$R = CH_3$ ou C_6H_5

Propagation

[2] $C_6H_5\dot{C}(OH)R$ +  $\xrightarrow{k_2}$ $C_6H_5C(OH)R$  ou $C_6H_5C(OH)R$  (radicaux r$^{\cdot}$)

[3] r$^{\cdot}$ $\xrightarrow{k_3}$ $(1-\alpha)$  + α  + $C_6H_5—\dot{C}(OH)—R$

Rupture

$C_6H_5—\dot{C}(OH)R + C_6H_5—\dot{C}(OH)R \xrightarrow{k_4}$
$C_6H_5—\dot{C}(OH)R + r^{\cdot} \xrightarrow{k_4'}$ produits
$r^{\cdot} + r^{\cdot} \xrightarrow{k_4''}$

	$(\Phi^{S}_{c\rightarrow t})^{0}$	0,32±0,03	0,26±0,03	0,12±0,01

Ce schéma appelle les remarques suivantes: (*a*) La catalyse par atomes libres ou radicaux de l'isomérisation *cis–trans* du dideuterioéthylène, du butène-2 et du stilbène a déjà été rapportée dans la littérature (23). (*b*) Les cétones aromatiques en se photoréduisant ne peuvent pas induire l'isomérisation de la forme *trans* de la pentène-3 one-2; ceci s'interprète en admettant que les radicaux $C_6H_5\dot{C}(OH)R$ ne peuvent réagir, pour des raisons stériques, avec l'isomère *trans*. On peut aussi supposer que la forme *trans*, plus stable que l'isomère *cis*, peut capturer les radicaux $C_6H_5\dot{C}(OH)R$ en donnant des radicaux (r′), non dissociatifs, disparaissant par recombinaison. (*c*) Si le processus de rupture prépondérant intervient par recombinaison des radicaux (r′), le schéma cinétique conduit aux relations suivantes:

$$[4] \qquad [r'] = (\Phi_r I_a/2k_4'')^{1/2}$$

$$[5] \qquad (\Phi^{S}_{c\rightarrow t})^{0} = \frac{k_3\Phi_r\alpha}{(2k_4'')^{1/2}}\frac{1}{I_a^{1/2}}$$

Si le processus de rupture prépondérant implique les radicaux $C_6H_5\dot{C}(OH)R$, de même

$$[6] \qquad [C_6H_5\dot{C}(OH)R] = (\Phi_r I_a/2k_4)^{1/2}$$

$$[7] \qquad (\Phi^{S}_{c\rightarrow t})^{0} = \frac{k_2\Phi_r\alpha}{(2k_4)^{1/2}}\frac{[\text{pentène-3 one-2}]}{I_a^{1/2}}$$

Seule la relation 5 est compatible avec nos résultats expérimentaux; en effet, les rendements quantiques d'isomérisation $(\Phi^{S}_{c\rightarrow t})^{0}$ sont indépendants de la concentration de pentène-3 one-2. Même à faible concentration, la cétone capte tous les radicaux $C_6H_5\dot{C}(OH)CH_3$ formés. La relation 5 nous permet en outre d'interpréter l'influence apparente de la longueur d'onde sur les rendements quantiques mesurés. Nous rapportons dans le tableau 7 les valeurs de la racine carrée des intensités lumineuses absorbées $I_a^{1/2}$ lors de nos mesures à différentes longueurs d'onde: on vérifie alors que les rendements quantiques sont inversement proportionnels à $I_a^{1/2}$.

Dans les solvants où le mécanisme de l'isomérisation sensibilisée implique un processus moléculaire de transfert d'énergie, les rendements quantiques apparaissent être très normalement indépendants de l'intensité lumineuse absorbée et donc aussi de la longueur d'onde d'excitation.

L'influence de l'oxygène se manifeste par une inhibition importante de l'isomérisation *cis* → *trans* induite radicalairement. L'oxygène peut réagir avec les radicaux présents dans le milieu pour donner naissance à des radicaux peroxydiques; ces radicaux oxygénés ne seraient donc plus susceptibles de s'additionner sur la double liaison de la pentène-3 one-2 et disparaitraient par duplication. L'oxygène est, en outre, susceptible de désactiver l'état triplet du sensibilisateur.

Au mécanisme radicalaire proposé doit, en fait, se superposer un mécanisme moléculaire mettant en jeu des transferts d'énergie entre le sensibilisateur et l'accepteur. De tels transferts provoquent une désactivation partielle du niveau

triplet du sensibilisateur, ce qui peut se manifester expérimentalement par l'inhibition de la photoréduction du sensibilisateur (comme dans le cas de l'acétophénone). Cependant, même dans la phase où la photoréduction du sensibilisateur par le *n*-heptane est inhibée par la pentène-3 one-2, nos résultats expérimentaux montrent que le mécanisme radicalaire en chaînes d'isomérisation reste prépondérant devant celui impliquant le transfert d'énergie. Le rendement $(\Phi^{S}_{c\rightarrow t})^{0}$ est toujours supérieur à $(\Phi^{S}_{t\rightarrow c})^{0}$; tout se passe comme si seule l'isomérisation *cis–trans* était possible. A des temps d'irradiation de plus en plus longs, le rapport [*trans*]/[*cis*] doit donc prendre des valeurs de plus en plus élevées et tendre vers l'infini. Mais à l'isomérisation se superpose une disparition de la penténone. La concentration de *trans* passe ainsi par un maximum pour ensuite décroître jusqu'à la disparition complète du réactif.

Enfin, dans le cas de l'acétone en solution aqueuse, l'existence du phénomène d'autodésactivation du sensibilisateur est facilement mise en évidence. A même concentration de pentène-3 one-2, un accroissement de la concentration d'acétone se manifeste par une diminution du rendement quantique d'isomérisation. Les radicaux formés au cours de ce processus d'autodésactivation ne peuvent donc pas initier une isomérisation radicalaire. L'isomérisation sensibilisée mise en évidence ne peut alors être qu'un processus moléculaire par transfert d'énergie.

En solution dans le *n*-heptane, le rendement quantique d'isomérisation $(\Phi^{S}_{c\rightarrow t})^{0}$ peut être supérieur à 0.5, et les rendements de disparition sont plus élevés qu'en solution aqueuse. Un transfert d'énergie entre l'acétone et la pentène-3 one-2 ne permet pas, à lui seul, de justifier ces valeurs; l'isomérisation est donc, au moins partiellement initiée par les radicaux issus de la photoréduction.

Une différence apparait cependant entre les valeurs du rendement quantique d'isomérisation sensibilisée d'une part par l'acétophénone, et d'autre part par l'acétone. En effet, alors que les rendements quantiques de l'isomérisation sensibilisée par l'acétophénone ne dépendent pas des concentrations du donneur et de l'accepteur dans le domaine étudié, les rendements de l'isomérisation sensibilisée par l'acétone dépendent de la concentration d'acétone. Cette difference de comportement peut signifier que l'autodésactivation de l'acétone est plus rapide que celle de l'acétophénone.

Parallèlement à l'isomérisation, une disparition importante est mesurée. Cette disparition peut être initiée par les radicaux issus de la photoréduction, mais également par les radicaux issus de l'autodésactivation; le rendement de disparition augmente avec la concentration d'acétone. Or l'acétone présente des coefficients d'extinction molaire plus faibles que l'acétophénone ou la benzophénone et doit alors être utilisée à concentration plus forte; l'autodésactivation, et par conséquent la disparition, sont favorisées au détriment de l'isomérisation.

Isomérisation *trans–cis* de la pentène-3 one-2 photosensibilisée par le benzène et le mésitylène

Par opposition aux "sensibilisateurs" carbonylés induisant des isomérisations radicalaires, en solution dans les alcanes, les sensibilisateurs aromatiques devraient impliquer uniquement des transferts d'énergie. Les résultats que nous rapportons ici montrent que les mécanismes d'interaction entre aromatiques excités et pentène-3 one-2 ne sont pas aussi simples.

Etude expérimentale de la sensibilisation par le benzène et le mésitylène

Nous avons d'une part mesuré les rendements quantiques initiaux d'isomérisation *trans* → *cis* et *cis* → *trans* de la pentène-3 one-2 sensibilisée par le benzène ou le mésitylène excité à 253.7 nm (cf. tableau 8) et d'autre part le degré d'extinction de fluorescence de ces donneurs par la cétone insaturée en solvant dégazé (cf. tableau 9).On peut observer l'apparition de régimes photostationnaires avec l'un ou l'autre des donneurs; ces régimes sont caractérisés par un rapport [*trans*]/[*cis*] voisin de l'unité.

Interprétation des résultats expérimentaux

A 10^{-2} *M* de pentène-3 one-2 *trans*, l'extinction de la fluorescence du benzène et du mésitylène atteint respectivement 77 et 83%. Si l'on se réfère à nouveau à l'excitation directe, on s'attend à mesurer un rendement quantique d'isomérisation sensibilisée par transfert d'énergie triplet–triplet respectivement égal à $0.23 \times 0.25 \times 0.50 = 0.03$ et à $0.17 \times 0.55 \times 0.50 = 0.05$ avec les deux donneurs envisagés (le rendement quantique de la transition $S_1 \rightarrow T_1$ du benzène en solution diluée est pris égal à 0.25 et celui du mésitylène à 0.55). Les rendements quantiques effectivement mesurés montrent que

$(\Phi^{S}_{c\to t})^{0}$					0,15	0,15	0,145

l'isomérisation ne résulte pas exclusivement d'un transfert triplet–triplet. En outre, il faut exclure un transfert singulet–singulet qui devrait, à la limite, provoquer la même isomérisation qu'en excitation directe. Pour interpréter nos résultats expérimentaux, nous devons alors proposer un mécanisme d'isomérisation sensibilisée impliquant une espèce instable justifiant de l'extinction de la fluorescence et conduisant à l'isomérisation de la pentène-3 one-2; cette espèce instable introduite pour les seules raisons cinétiques pourrait être un exciplexe conduisant à l'isomérisation de la pentène-3 one-2 lors de sa désactivation dissociative.

$$D(S_1) + A_{trans}(S_0) \rightarrow (A{-}D)^1 \text{ (D donneur aromatique)}$$

$$(A{-}D)^1 \rightarrow D(S_0) + (1 - \Phi^{e}_{tc})A_{trans}(S_0) + \Phi^{e}_{tc}A_{cis}(S_0)$$

Le calcul du rendement quantique d'isomérisation sensibilisée $(\Phi^{S}_{t\to c})^{0}$ peut être effectué à partir du mécanisme classique où interviendrait la formation d'un exciplexe et un transfert

TABLEAU 9. Extinction de la fluorescence du benzène ou du mésitylène par la pentène-3 one-2 *trans*

(Pentène-3 one-2 trans) mole.l^{-1}	0	10^{-3}	2.10^{-3}	6.10^{-3}	10^{-2}
Intensité de fluorescence du benzène (mesurée à 277,5 nm)	72,5	44	39	24,5	16,8
Intensité de fluorescence du mésitylène (mesurée à 290 nm)	98	74	47,5	26,5	16,7

TABLEAU 10. Importance des deux voies compétitives d'isomérisation de la pentène-3 one-2 *trans* sensibilisées par le benzène et le mésitylène

Sensibilisateur	Benzène					Mésitylène				
(Pentène-3 one-2 trans) mole.l^{-1}	10^{-2}	6.10^{-3}	5.10^{-3}	2.10^{-3}	10^{-3}	10^{-2}	6.10^{-3}	2.10^{-3}	10^{-3}	5.10^{-4}
$\frac{I_F}{I_F^0}$	0,23	0,34	/	0,54	0,61	0,17	0,27	0,485	0,755	/
$\Phi^e_{t\to c}(1-\frac{I_F}{I_F^0})$	0,135	0,115	/	0,080	0,070	0,175	0,155	0,110	0,051	0,026*
$(\Phi^S_{t\to c})^0_{exp}$	0,17		0,15		0,105	0,225	/	/	0,16	0,13
Pourcentage de l'isomérisation via l'exciplexe	80%		72%		67%	77%	≃ 67%*	≃ 57%*	32%	20%

d'énergie triplet–triplet; il conduit à l'expression suivante:

$$(\Phi^S_{t\to c})^0 = \Phi^e_{tc}\left(1 - \frac{I_F}{I_F^0}\right) + \Phi_{S_1\to T_1}\frac{k_T(A)}{k_d + k_T(A)}\Phi^t_{tc}\frac{I_F}{I_F^0}$$

où Φ^e_{tc} est la probabilité d'isomérisation issue de l'exciplexe, I_F^0 et I_F sont les intensités de fluorescence du donneur mesurées en l'absence et en présence de pentène-3 one-2, $\Phi_{S_1\to T_1}$ rendement de transition inter-systèmes du donneur, k_T est la constante de vitesse du transfert d'énergie triplet–triplet, k_d est la somme des constantes de tous les autres processus de désactivation du niveau triplet du donneur, Φ^t_{tc} est le rendement quantique de l'isomérisation consécutive à une population totale du niveau triplet de l'accepteur.

Une expression analogue peut être écrite pour

$(\Phi^{S}_{c\rightarrow t})^{0}$. A forte concentration de pentène-3 one-2, le terme $k_T(A)/(k_d + k_T(A))$ tend vers l'unité et il est alors possible de calculer $\Phi^{e}_{t\rightarrow c}$ (0.177 dans le cas du benzène, 0.21 dans le cas du mésitylène). On peut alors calculer la part de l'isomérisation issue du transfert d'énergie et celle impliquant l'exciplexe (cf. tableau 10).

Cette interprétation fait intervenir l'existence des deux mécanismes concurrents et complémentaires que sont la formation d'exciplexe et le transfert d'énergie triplet–triplet. Il permet d'interpréter les rendements quantiques d'isomérisation de la pentène-3 one-2 sensibilisée par le benzène et le mésitylène.

Catalytic asymmetric hydrogenation using ruthenium(II) complexes with chelating chiral sulfoxide ligands

BRIAN R. JAMES AND RODERICK S. MCMILLAN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received May 30, 1977

BRIAN R. JAMES and RODERICK S. MCMILLAN. Can. J. Chem. **55**, 3927 (1977).

A chelating sulfoxide ligand, (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane monohydrate, or 'dios', containing chiral carbons has been synthesized. A corresponding bis(benzyl sulfinyl) compound, 'bdios', and an acetal-cleaved derivative, 'ddios', are also reported. Ruthenium(II) neutral complexes have been made containing such ligands, which can bind via oxygen or sulfur; the complexes are active homogeneous catalysts for hydrogenation of prochiral olefinic acid substrates; optical purities of up to 25% were attained.

BRIAN R. JAMES et RODERICK S. MCMILLAN. Can. J. Chem. **55**, 3927 (1977).

On a synthétisé un ligand chélatant sulfoxyde, le monohydrate du (2*R*,3*R*) *O*-isopropylidène-2,3 dihydroxy-2,3 bis(méthylesulfinyl)-1,4 butane ou "dios", contenant des carbones chiraux. On rapporte aussi la préparation d'un composé correspondant bis(benzylsulfinyl), "bdios", et d'un dérivé dont l'acétal a été clivé, "ddios". On a préparé des complexes neutres du ruthénium(II) contenant de tels ligands qui se lient par l'intermédiaire d'un oxygène ou de soufre; les complexes sont des catalyseurs homogènes actifs pour l'hydrogénation de substrats acides oléfiniques prochiraux; on a obtenu des activités optiques allant jusqu'à 25%.

[Traduit par le journal]

Introduction

Our continuing interest in asymmetric homogeneous hydrogenation, especially using ruthenium(II) and rhodium(I) catalysts containing chiral phosphine and sulfoxide ligands (1–3), has led us to the development of three new chelating chiral sulfoxide ligands: (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(methyl sulfinyl)-butane monohydrate, the corresponding bis-(benzyl sulfinyl) derivative, and (2*R*,3*R*)-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane. We have named these ligands *dios*, *bdios*, and *ddios*, respectively, since they are patterned after the chelating phosphine derivative *diop*, developed by Kagan and Dang (4). Diop complexes of rhodium(I) and ruthenium(II) are known to be highly effective as catalysts for stereoselective hydrogenations (5–7).

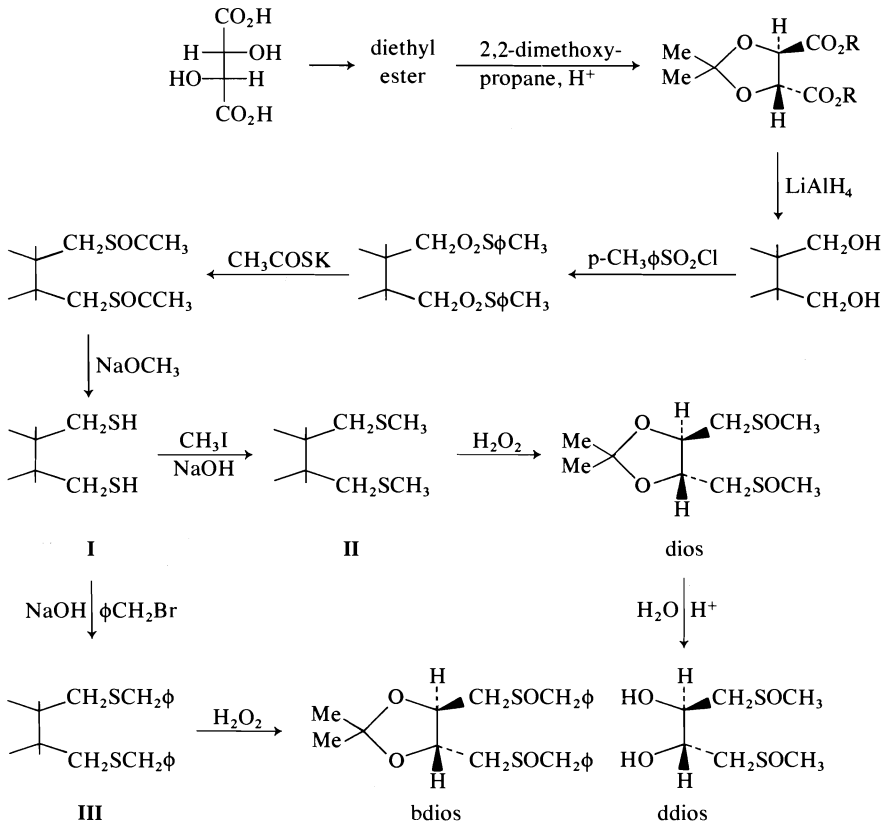
Three complexes of ruthenium(II), $(RuCl_2(ddios)_2 \cdot 2H_2O$, $RuCl_2(dios)(ddios)$, and $RuCl_2(ddios)(dmso)(CH_3OH)$, where dmso = dimethylsulfoxide), have been synthesized and characterized, and have been tested as catalysts for asymmetric hydrogenation of some prochiral olefinic substrates. Although the dios-type sulfoxide ligands are prepared as a mixture of the diastereomers, the corresponding catalysts do induce a moderate degree of asymmetry in the hydrogenated substrates.

Results and Discussion

Sulfoxide Ligands

The dios and bdios ligands were prepared from L-(+)-tartaric acid, although the non-naturally occurring acid may also be used. Scheme 1 summarizes the synthetic procedures. The route to the dithiol (**I**) follows literature procedures (8). Treatment with methyl iodide or benzyl bromide in aqueous NaOH then gives the methyl or benzyl sulfide derivative; this displacement of the halide by the anion formed from the mercaptan (9) went smoothly, and the use of a N_2 atmosphere prevented formation of a dithioketal (8). The sulfides were extracted from the aqueous mixtures in high yield. Efficient oxidation to the sulfoxides was carried out using a stoichiometric amount of H_2O_2 in acetone (10). The overall yield of dios and bdios from tartaric acid was 15 and 13%, respectively. The oxidation process at the sulfur should be non-stereospecific, although we were unable to determine the ratio of diastereomers by nmr using a lanthanide chiral shift reagent (2). Carbon atoms 2 and 3 will remain *R* while the configuration at the sulfurs will be (*S*,*S*), (*R*,*R*), (*S*,*R*), and (*R*,*S*), the last two giving identical products.

The dios and bdios products both contain an associated H_2O molecule. Dios is a white, hygroscopic solid, soluble in common solvents



SCHEME 1. Synthetic scheme for dios, ddios, and bdios.

except hexanes in which it is slightly soluble; bdios is a white, non-hygroscopic solid showing similar solubility characteristics although it is insoluble in hexanes and is only slightly soluble in benzene and diethyl ether.

The ddios ligand was originally detected during synthesis of the ruthenium complexes, and results from acid cleavage of the acetal; the acetone by-product is readily detected. Ddios will again be a mixture of diastereomers.

Dichlorobis(ddios)ruthenium(II) Dihydrate, ***1***

This complex was prepared by (*a*), the addition of dios to the 'blue solution' formed on refluxing $RuCl_3 \cdot 3H_2O$ in methanol under 1 atm H_2 (11, 12); and by (*b*), sulfoxide exchange with *cis*-$RuCl_2(dmso)_4$ (13) in methanol. Compound **1**, which gives the correct elemental analysis, is a yellow solid, insoluble in acetone, slightly soluble in alcohols, and more soluble in water and *NN*-dimethylacetamide (dma), in which it is non-ionic.

The ir shows ν(SO) of S-bonded sulfoxide at 1095 cm^{-1}, and a 970 cm^{-1} band is assigned to a methyl rocking mode (14); broad bands centred at 3370 and 1630 cm^{-1} are attributed to H_2O. A poorly resolved far ir region precludes assignment of ν(Ru—Cl).

The nmr spectra in dmso-d_6 and in D_2O show closely spaced narrow resonance peaks at δ 3.25–3.70 due to the methylene and methyl protons of S-bonded ddios (14), and broad absorbances from δ 3.70–4.30 due to methine and hydroxyl protons. No absorption due to O-bonded or free sulfoxide is present in the region δ 2.00–3.00 (14), and there are no peaks at δ 1.00–2.00 due to isopropylidene methyl protons of a coordinated dios (see Experimental). A narrow resonance at δ 3.25 in dmso-d_6 decreased in height on addition of molecular sieve, and is attributed to H_2O.

The spectral data show that the four sulfoxide moieties are all S-bonded, which contrasts with $RuCl_2(dmso)_4$ where one dmso is O-bonded, presumably due to steric reasons (13). The water molecules must be those of solvation, or be

H-bonded to the ligand alcohol groups. A *cis* geometry of chlorides is favoured on comparison with the *cis* yellow tetrakis(dmso) complex; the pale green solid observed during the synthesis of **1** (see Experimental) could be the *trans* isomer. There remains the uncertainty of the configuration at the sulfurs.

Dichloro(dios)(ddios)ruthenium(II), 2

The neutral yellow complex, synthesized from *cis*-$RuCl_2(dmso)_4$ by an exchange reaction with dios in $CHCl_3$, analyzes correctly and is soluble in polar and halogenated solvents, and is insoluble in ether and alkanes. Aqueous solutions are air-sensitive and become green, probably due to formation of ruthenium(III).

A strong ir band at 1100 cm^{-1} is assigned to ν(SO), S-bonded, and a medium band at 932 cm^{-1} could be ν(SO), O-bonded. Bands at 3500 and 1065 cm^{-1} are due, respectively, to ν(OH) and tentatively ν(CO) of the diol. A medium doublet at 1104 and 1113 cm^{-1} is assigned to the C—H bending mode of a geminal dimethyl group (15). The far ir region is not well resolved but a 335 cm^{-1} band could be ν(Ru—Cl).

The ^1H nmr of **2** in $CDCl_3$ shows a singlet at δ 1.42 due to the six isopropylidene methyl protons, and a singlet at δ 2.58 due to protons of a methyl group α to an uncoordinated sulfur; between δ 2.61–2.90 are multiplet resonances due to the protons of a methyl and a methylene group α to an uncoordinated or 'O-bonded' sulfur atom; between δ 3.07–3.80 and δ 3.90–4.70 are multiplets due to the remaining protons of S-bonded dios and ddios ligands. The integration ratios for the S-bonded, O-bonded, free sulfoxide methyl and methylene protons show that in $CDCl_3$ three of the four sulfoxides are S-bonded, the other O-bonded one is partly dissociated, and the amount of dios and ddios is equal. The nmr spectrum is essentially the same in D_2O; addition of DCl–D_2O rapidly removes the δ 1.42 singlet, and generates a singlet at δ 2.05 attributed to acetone. These data show the cleavage of the isopropylidene groups of coordinated dios to form ddios and acetone.

Apparently two dios ligands are not readily chelated, while cleavage to give one ddios likely increases the ligand flexibility and decreases the size, allowing coordination of one dios and one ddios. Even then, coordination through one sulfoxide oxygen atom appears necessary to decrease steric interactions. The dios ligand is considered more likely to coordinate through oxygen, and thus a probable structure involves a bidentate S-bonded ddios and a bidentate dios coordinated through one sulfur and one oxygen. The complex in $CDCl_3$ behaves like *cis*-$RuCl_2(dmso)_4$ in that the single O-bonded sulfoxide here also partly dissociates (16). In water, the O-bonded dmso of $RuCl_2(dmso)_4$ dissociates completely (17); a chelate effect presumably reduces the effective lability of the 'dangling O-atom' in complex **2**.

Dichloro(ddios)(dmso)(CH_3OH)ruthenium(II), 3

Exchange of dios with *cis*-$RuCl_2(dmso)_4$ in a 1:1 mole ratio in refluxing methanol resulted in the neutral complex **3**, which is soluble in water, and dma, and slightly soluble in alcohols. The ir shows bands at 3400 cm^{-1} ν(OH); 1123 and 1100 cm^{-1} ν(SO), S-bonded; a number of bands including a sharp one at 1018 cm^{-1} could be ν(CO) stretches of the alcohol groups. Bands at 325 and 305 cm^{-1} are tentatively assigned to ν(Ru—Cl), implying a *cis*-dichloride structure.

The ^1H nmr in D_2O shows sharp closely spaced resonances (perhaps singlets) at δ 3.52, 3.60, 3.63, and 3.75, and are due to the 12 methyl protons of S-bonded ddios and dmso, the three methyl protons of methanol, and the four methylene protons of ddios. A pair of broad peaks between δ 3.9–4.1 and 4.2–4.4 are due to methine protons (ddios) and alcohol protons (ddios, methanol). An integration ratio of the sharp to broad peaks is ~4:1, consistent with the assignments. Resonances due to O-bonded or free ddios or dmso (δ 2.0–3.0), or the isopropylidene methyl protons of dios (δ ~ 1.45) are not observed. The labile methanol is almost certainly displaced by the water (17).

Considering the nature of complexes **1** and **2**, the 1:1 exchange reaction was expected to produce $RuCl_2(ddios)(dmso)_2$ with one O-bonded sulfoxide (possibly of a dmso) to limit steric interactions, but clearly the methanol competes effectively for coordination. The ruthenium(II) cluster ($Ru_3(CO_2CH_3)_6(CH_3OH)_3$) features an ir band at 996 cm^{-1} (18); this and the 1018 cm^{-1} peak of **3** could be the ν(CO) of coordinated methanol.

Catalytic Asymmetric Hydrogenation

The results of some hydrogenations catalyzed by complexes **1**, **2**, and **3**, are summarized in Table 1.

TABLE 1. Asymmetric hydrogenation results using dios and ddios ruthenium(II) complexes in dma[a]

Catalyst[b]	$[Ru^{II}]$ (M)	Substrate	Molarity of substrate	H_2 (psi)	T (°C)	t (h)	% hydrogenation	Enantiometric excess[c] (%)
1	0.007	Diethyl itaconate	0.5	1800	60	288	100	3.8(*R*)[d]
1	0.015	Itaconic acid	1.8	45	42	144	0	—
2[e]	0.013	Itaconic acid	0.5	44	55	168	49	25.2(*R*)
2[f]	0.013	Itaconic acid	0.5	50	71	168	100	8.1(*R*)
2[e]	0.016	Atropic acid	0.6	46	52	144	17	4.1(*S*)
2[e]	0.016	2-Acetamidoacrylic acid	0.5	47	55	240	62	7.2(*S*)
3	0.016	Itaconic acid	0.6	48	63	240	29	5.4(*R*)

[a]5–10 ml solutions.
[b]**1**, $RuCl_2(ddios)_2{\cdot}2H_2O$; **2**, $RuCl_2(dios)(ddios)$; **3**, $RuCl_2(ddios)(dmso)(MeOH)$.
[c]Predominant enantiomer in parenthesis; ee's are based on the specific rotation of the chiral acid; (*S*)-*N*-acetylalanine, $([\alpha]_D^{26} = -66.5°$; C 2, $H_2O)$ ref. 19, (*R*)-α-methylsuccinic acid, $([\alpha]_D^{20} = +17.09°$; C 10, absolute EtOH) ref. 20, and (*S*)-2-phenylpropanoic acid, $([\alpha]_D^{25} = +76.1°$, C 8, $CHCl_3)$ ref. 20.
[d]0.006 *M* proton sponge added, some metal present at the end of the reaction; the succinate diester product was hydrolyzed to the diacid to determine ee.
[e]Initial yellow solutions became orange by the end of the reaction.
[f]Initial yellow solution became red by the end of the reaction.

In water or dma, 10^{-2} *M* solutions of $RuCl_2(ddios)_2{\cdot}2H_2O$ containing ~0.5 *M* olefinic substrate (e.g. acrylamide, itaconic acid) were unreactive toward 3 atm H_2 at 60°C. Similar solutions containing cationic derivatives of **1** (chloride being removed by filtering after treatment with $AgPF_6$) reacted extremely slowly with H_2. Addition of 'proton sponge' (the strong base 1,8-bisdimethylaminonaphthalene) enhanced these hydrogenation reactions somewhat, presumably by promoting formation of intermediate hydrides via a reaction such as [1] (21),

$$[1] \qquad Ru^{II}Cl + H_2 \rightleftharpoons Ru^{II}H + H^+ + Cl^-$$

Diethyl itaconate was completely hydrogenated using such a catalyst system at high H_2 pressure (Table 1) to give (*R*)-α-methylsuccinate in low but significant enantiomeric excess (ee); some metal precipitated during the hydrogenation and the extent of contribution from a heterogeneous process is uncertain.

The $RuCl_2$(dios)(ddios) catalyst without proton sponge effected homogeneous hydrogenation of itaconic, atropic, and 2-acetamidoacrylic acids under 3 atm H_2 with different degrees of stereoselectivity (Table 1); a maximum 25% ee was attained with itaconic acid. $RuCl_2$(ddios)(dmso)-(CH_3OH) was less effective.

All three catalyst systems give predominantly the *R* enantiomer of α-methylsuccinic acid, and data using **2** indicate decreasing asymmetric induction with increasing temperature; this might result from greater ligand dissociation, and hence less stereoselective catalytic species present with concomitant less restriction on motion of coordinated substrate. The higher rates observed (**2** > **1**) are probably due to the greater lability of the O-bonded sulfoxide present in **2**. The stereoselectivity sequence (**2** > **3**) parallels the number of bulky chiral chelated sulfoxides. The lower optical yields (using **2**) obtained for reduction of atropic and 2-acetamidoacrylic acids compared to itaconic acid likely result from differences in substrate bonding. This could include π-bonding, carboxylate coordination, and H-bonding (—COOH or $\rangle$NH with sulfoxide oxygen or —OH of ddios); for example, see ref. 5. The additional carboxyl acid group of itaconic acid almost certainly plays a role.

The high pressures necessary to effect catalysis, plus the effect of added base, suggest that activation of H_2 is a rate-determining step (eq. 1);

whether olefin is coordinated prior to or after this step cannot be ascertained without kinetic data.

Experimental

General

Dried, degassed reagent grade solvents were used throughout. Ru complexes were made under H_2, Ar, or N_2 atmospheres using schlenk-tube techniques. Spectra were run on a Perkin-Elmer 457 (ir, Nujol mulls between CsI), and a Varian T60 (^{1}H nmr using as references TMS in $CDCl_3$, acetone, and sodium 2,2-dimethyl-2-silapentane-5-sulfonate in D_2O). Optical rotations were recorded on a Perkin-Elmer 421 polarimeter at room temperature using a 10 cm path length microcell. Uncorrected melting points were measured on a Gallenkampt using evacuated capillary tubes. Microanalyses were done by P. Borda of this department.

Itaconic acid (Eastman) and 2-acetamidoacrylic acid (Fluka) were CP grade; atropic acid was prepared according to the literature (22). Ruthenium(III) trichloride trihydrate was obtained as $RuCl_3 \cdot 3H_2O$ (41.83% Ru) from Johnson Matthey Limited.

Sulfoxide Ligands

2,3-O-Isopropylidene-1,4-dithio-L-threitol, I

A preparation (8) from 104 g of L-(+)-tartaric acid ($[\alpha]_D^{25} = +12.8$, C 17, H_2O) gave 42 g (32%) of the colourless liquid **I**, bp 60°C (0.10 mm); $[\alpha]_D^{24} = -13.3°$, C 3.3, $CHCl_3$; δ_{TMS} (neat) 1.38 (singlet, 6H, CMe_2), 1.74 (triplet, $J = 8$ Hz, 2H, —SH), 2.58–2.95 (multiplet, 4H, —CH_2—), 3.76–4.05 (multiplet, 2H, —CH) (lit. (8) $[\alpha]_D^{23} = -13.0°$, C 3.2, $CHCl_3$; δ_{TMS} (neat) as observed).

(2R,3R)-(−)-2,3-Isopropylidene-2,3-dihydroxy-1,4-bis(methylthio)butane, II

To a 250 ml three-necked flask equipped with a gas-inlet tube, a reflux condenser, an addition funnel, and internal stirring, was added 12.7 g (0.32 mol) of NaOH in 75 ml of water. Compound **I** (30 g, 0.15 mol) was added slowly to the vigorously stirred, N_2-flushed solution (a white solid precipitated). Iodomethane (43.8 g, 0.31 mol) was then added as rapidly as the resulting exothermic reaction would allow, and the stirred reaction mixture was refluxed for 4 h. The sulfide layer was separated, washed with water, 10% sodium hydroxide, and finally water before drying with $CaCl_2$. The aqueous layer was extracted with petroleum ether (4 × 100 ml), washed with water, 10% sodium hydroxide, water, and the solvent then stripped off. The liquid residue was washed with 10% sodium hydroxide, water, and dried over calcium chloride. The two dried sulfide fractions were combined and vacuum-distilled to give 20.6 g (60%) of clear colourless liquid, bp 66°C (0.02 mm). $[\alpha]_D^{25} = -6.8°$, C 4.9, $CHCl_3$; δ_{TMS} (CCl_4) 1.37 (singlet, 6H, CMe_2), 2.17 (singlet, 6H, —CH_3), 2.58–2.80 (multiplet, 4H, —CH_2—), 3.77–4.05 (multiplet, 2H, —CH).

(2R,3R)-(−)-2,3-O-Isopropylidene-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane·H_2O; dios

Compound **II** (20.2 g, 0.09 mol) and 50 ml of acetone were placed in a 250 ml flask. Thirty percent hydrogen peroxide (9.6 ml, 0.18 mol) was added slowly to the cooled (5°C), stirred solution. After stirring overnight, the solvent was flash-evaporated with the final traces of water removed at the vacuum pump. The resulting clear oil solidified over a period of one week, to give 18.9 g (82%) of a hygroscopic white solid, mp 63–85°C; $[\alpha]_D^{23} = -85.8°$, C 5.2, $CHCl_3$; δ_{TMS} ($CDCl_3$) 1.43 (singlet, 6H, CMe_2), 2.66 (singlet, 6H, —CH_3), 2.90–3.35 (multiplet, 4H, —CH_2—), 4.05–4.02 (multiplet, 2H, —CH); δ_{TMS} (acetone-d_6) 3.0 (singlet, 2H, H_2O); ν(SO) 1042 cm^{-1}. *Anal.* calcd. for $C_9H_{20}O_5S_2$: C 39.68, H 7.40; found: C 39.24, H 7.05.

(2R,3R)-(−)-2,3-O-Isopropylidene-2,3-dihydroxy-1,4-bis(benzylthio)butane, III

Compound **I** (11.3 g, 0.06 mol) was added to 4.76 g (0.12 mol) NaOH in 30 ml H_2O in a N_2-purged 100 ml three-necked flask equipped with an addition funnel, reflux condenser, gas-inlet tube, and internal stirring. After dissolution was complete, 19.9 g (0.12 mol) of α-bromotoluene was added with vigorous stirring, and the reaction mixture heated to reflux for 3 h when the sulfide layer formed. Diethyl ether (400 ml) was added to the cooled reaction mixture to dissolve the sulfide. The ether layer was separated, and the aqueous layer further extracted with ether (3 × 75 ml). The ether fractions were combined, washed with water, 10% sodium hydroxide, and water, and dried over anhydrous $CaCl_2$. Removal of the ether gave a white solid, which could be recrystallized from CCl_4; 18.3 g (84%), mp 86–88°C. $[\alpha]_D^{25} = -56.7°$, C 2.7; $CHCl_3$; δ_{TMS} ($CDCl_3$) 1.38 (singlet, 6H, CMe_2), 2.50–2.70 (multiplet, 4H, —CH_2—), 3.65–3.95 (multiplet, 2H, —CH), 3.72 (singlet, 4H, $ArCH_2$—), 7.22 (singlet, 10H, Ar—H).

(2R,3R)-(−)-2,3-O-Isopropylidene-2,3-dihydroxy-1,4-bis(benzyl sulfinyl)butane·H_2O; bdios

Compound **III** (15.9 g 0.043 mol) and 50 ml acetone were placed in a 100 ml flask. Thirty percent H_2O_2 (9.0 ml, 0.086 mol) was added slowly to the cooled (5°C), stirred solution. The white solid which precipitated overnight was filtered, and the mother liquor flash-evaporated to give a colourless oil, which on addition of 50 ml diethyl ether gave more white precipitate. The ether precipitates were combined, washed with petroleum ether, and vacuum dried; 10.5 g (50%), mp 158–168°C (dec.); $[\alpha]_D^{25} = -15.0$, C 1.5, $CHCl_3$; ν(cm^{-1}) 1021 (SO), 1605 1591 (C=C); δ_{TMS} (acetone-d_6) 1.30–1.50 (multiplet 6H, CMe_2), 2.90–3.10 (multiplet, 6H, —CH_2—, H_2O), 4.0–4.5 (multiplet, 2H, —CH), 4.0–4.1 (multiplet, 4H, $ArCH_2$—), 7.32 (singlet, 10H, Ar—H). *Anal.* calcd. for $C_{21}H_{28}O_5S_2$: C 59.41, H 6.65; found: C 59.51, H 6.71.

Ruthenium Compounds

cis-$RuCl_2$(dmso)$_4$

A literature preparation was used (13, 16).

Dichlorobis[(2R,3R)-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane]ruthenium(II) Dihydrate; Dichlorobis(ddios)ruthenium(II) Dihydrate, I

To the blue solution, formed by refluxing 0.75 g $RuCl_3 \cdot 3H_2O$ in 50 ml CH_3OH under 1 atm H_2, was added 1.56 g dios. Refluxing under H_2 was continued for another 12 h, when a faint green solid precipitated (0.90 g, 46%) and this was filtered and washed with methanol. The filtrate was concentrated (10 ml) and a yellow precipitate filtered off (0.52 g, 27%). Combination of the solids and precipitation from a water solution with acetone yielded 1.33 g (68%) of pale yellow solid: δ_{DSS} (D_2O) 3.25–4.30 (multiplet, 26H, ddios); ir (see text). *Anal.* calcd. for $C_{12}H_{32}Cl_2O_{10}RuS_4$: C 22.6, H 5.07, Cl 11.14; found:

C 22.70, H 4.62, Cl 11.30. Compound **1** was also prepared from $RuCl_2(dmso)_4$ (0.50 g) and dios (0.63 g) by allowing them to react in refluxing methanol (40 ml) overnight, when a yellow precipitate formed. Concentration to 15 ml and cooling to 3°C, yielded, after washing with acetone and drying *in vacuo*, 0.45 g (69%) of product.

*Dichloro[(2R,3R)-(−)-2,3-O-isopropylidene-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane][(2R,3R)-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane]ruthenium(II); Dichloro(dios)(ddios)ruthenium(II), **2***

$RuCl_2(dmso)_4$ (0.94 g) and dios (0.80 g) in $CHCl_3$ (50 ml) were refluxed for 120 h; the solution changed from yellow to golden. Removal of the $CHCl_3$ left a residue which dissolved in acetone (15 ml). After filtering, addition of ether (50 ml) precipitated a light yellow solid, which was filtered off, washed with ether and vacuum-dried, 0.57 g (46%); δ_{TMS} ($CDCl_3$) 1.42 (singlet, 6H, CMe_2), 2.58 (singlet, 3H, S—CH_3, uncoordinated), 2.61–2.90 (multiplet, 5H, —CH_2SCH_3), 3.07–3.80 (multiplet, 17H, —CH_2SCH_3, —OH), 3.90–4.70 (multiplet, 4H, —CH); λ_{max} ($CHCl_3$) (log ε); 309 nm (2.67), 356 nm (2.74); ir (see text). *Anal.* calcd. for $C_{15}H_{32}Cl_2O_8RuS_4$: C 28.12, H 5.03, Cl 11.07; found: C 28.30, H 5.13, Cl 11.04.

*Dichloro[(2R,3R)-2,3-dihydroxy-1,4-bis(methyl sulfinyl)butane][dimethyl sulfoxide][methanol]ruthenium(II); Dichloro(ddios)(dmso)(MeOH)ruthenium(II), **3***

$RuCl_2(dmso)_4$ (1.0 g) and dios (0.57 g) were refluxed in 50 ml of methanol; after 42 h the reaction mixture was cooled and the yellow powder filtered off, washed with methanol and ether, and vacuum dried to yield 0.90 g (88%). Recrystallization from dma gave yellow microcrystals: δ_{DSS} (D_2O) 3.52, 3.60, 3.63, 3.75 (singlets, 19H, CH_3S—CH_2, CH_3S, CH_3O), 3.9–4.1, 4.2–4.4 (multiplets, 5H, OH, CH); ir (see text). *Anal.* calcd. for $C_9H_{24}Cl_2O_6RuS_3$: C 21.77, H 4.87, Cl 14.24; found: C 21.69, H 4.68, Cl 14.57.

Hydrogenation Procedures

The procedure for following H_2-uptake at 1 atm has been described previously (23). Hydrogenations at about 50 psi were performed in a Vortex apparatus; reactions at 1800 psi were carried out in a stainless steel Parr high pressure bomb (3000 psi). Solutions containing catalyst and substrate were prepared under Ar. The final reaction mixtures were filtered through celite, and the filtrate pumped to dryness. For the itaconic and atropic acid systems, the residue was dissolved in 10% aqueous NaOH; this was filtered, and the filtrate extracted with $CHCl_3$ to remove sulfoxide and catalyst and then made just acidic with aqueous HCl. The hydrogenated products and unreacted substrates were then extracted with ether, and the ether solution dried over anhydrous $MgSO_4$; reduction in volume yielded the acids. For the 2-acetamidoacrylic acid system, the dry residue was dissolved in water; filtering, extraction with $CHCl_3$, and removal of the water left a brown oil which on addition of ice-cold ether gave crystals of *N*-acetylalanine and unreacted substrate.

The composition of the product mixtures was determined by ^1H nmr, and the optical rotations measured in the appropriate solvent (see Table 1).

MASARU NISHIKAWA, KAZUO IMAI, and YUKO SOMA. Can. J. Chem. **55**, 3933 (1977).

The electron scavenging reaction with COS was studied in γ-irradiated supercritical butenes in the density range 0.24–0.48 g/cm^3 at 170 ± 1°C and in the liquid phase at room temperature. $G(CO)_{fi}$ estimated by means of the 'square root' model at each density studied agreed within experimental accuracy with $G(N_2)_{fi}$ obtained previously. In liquid butenes, $G(CO)_{fi}$, as well as $G(N_2)_{fi}$, agreed with G_{fi} obtained by electrical measurements. Rate constants estimated from the reactivity parameters for reactions with COS were less than 1/10 of those with N_2O at each density studied except at $d = 0.48$ g/cm^3 in *trans*-2-butene.

MASARU NISHIKAWA, KAZUO IMAI et YUKO SOMA. Can. J. Chem. **55**, 3933 (1977).

On a étudié les réactions de piégeages d'électrons avec COS dans des butènes à l'état supercritique irradiés par des radiations γ à des densités allant de 0.24–0.48 g/cm^3 à 170 ± 1°C et dans une phase liquide à température de la pièce. A l'intérieur des limites expérimentales les valeurs de $G(CO)_{fi}$ estimées par le modèle de la "racine carrée" à chacune des densités étudiées sont en bon accord avec les valeurs de $G(N_2)_{fi}$ obtenues antérieurement. Dans les butènes liquides $G(CO)_{fi}$ de même que $G(N_2)_{fi}$ sont en bon accord avec les G_{fi} obtenues par des mesures électriques. Les constantes de vitesses estimées à partir des paramètres de réactivité pour les réactions avec COS sont moins que 10 fois plus petites que celles de N_2O à chacune des densités étudiées excepté à $d = 0.48$ g/cm^3 dans le butène-2 *trans*.

Introduction

Electron scavenging reactions by N_2O have recently been studied in several supercritical hydrocarbons, and it has been established that they are quantitatively described by the 'square root' model (1). The treatment of the data by the model has allowed one to estimate the free ion yields (G_{fi}) and the kinetic parameters for the reaction of electrons with N_2O in supercritical hydrocarbons. The present work extends the observation to the system of COS in supercritical butenes. The objective of the study is to test the applicability of and the interpretation by the model in a system other than N_2O–hydrocarbon mixtures.

Experimental

Phillips Research Grade *cis*-2-butene (99.90%) and *trans*-2-butene (99.78%) were passed through a 1 m column of activated silica gel and were degassed. They were further purified by circulating overnight through traps filled with crushed potassium hydroxide and (bubbling through) Na–K alloy, respectively, by means of an electromagnetically operated pump. Matheson Research Grade carbonyl sulfide (96.0%) was used after passing through a trap filled with potassium hydroxide and bulb-to-bulb distillation.

Methods of sample preparation and irradiation in a ^{60}Co source were described previously (1). The irradiation was carried out at 170 ± 1°C; the critical temperatures are 160.0°C and 155.0°C for *cis*-2-butene and *trans*-2-butene, respectively. The dose rate was 4.66×10^{18} eV g^{-1} h^{-1} in Fricke solution and appropriate corrections were made for the electron density ratios. Total dose for most samples did not exceed 5×10^{18} eV/g, but it was ca. 1×10^{19} eV/g for the liquid.

The method of product analysis was essentially the same as described previously (1), except that a 50 cm column of Molecular Sieve 5A was used at 60°C and the whole contents of the irradiated cell was introduced into a gas chromatograph for the samples of lower density.

Results and Discussion

Carbonyl sulfide has been found to give carbon monoxide upon electron capture (2–4). Although the detailed mechanism is not yet known, some secondary reactions subsequent to electron capture by COS appear to be present in liquid benzene when the COS concentration is sufficiently high (3). Sato *et al.* (3) maintain that COS behaves in a quite similar manner to N_2O in the radiolysis of liquid benzene solutions.

The yields of CO from the γ-radiolysis of *cis*-2-butene–, and *trans*-2-butene–COS mixtures in the supercritical state over the density range 0.24–0.48 g/cm^3 and in the liquid phase can be adequately described by the square root model

$G(CO) = G(CO)_{fi} + G(CO)_{gi}(A[COS])^{1/2}$ in the lower concentration range (Figs. 1 and 2). $G(CO)_{fi}$ obtained as the intercepts in the square root plots agree within experimental accuracy with the values of $G(N_2)_{fi}$ previously observed with N_2O as the electron scavenger (1*c*) at each density studied in both isomeric butenes. The agreement, together with the fact that both $G(N_2)_{fi}$ and $G(CO)_{fi}$ obtained in the liquid butenes at room temperature agree quite well with G_{fi} determined by electrical measurements (5), supports our interpretation that secondary reactions are unimportant in the concentration range studied (<0.01 *M*) and there is a one-to-one ratio between the product and the electron captured both by N_2O and COS.

From the slope of the plot and assuming $G_{fi} + G_{gi} = 100/W = 4.2$ (5), one can calculate the reactivity parameter *A* (Table 1). At each density studied the value of *A* obtained in *trans*-2-butene is much larger than that in *cis*-2-butene. The trend has been observed previously with N_2O as the electron scavenger (1*c*). However, the magnitude of *A* for N_2O is always much larger in both hydrocarbons. The ratio of *A* for COS and N_2O ranges from 0.045, in *trans*-2-butene at $d = 0.36$ g/cm^3 to 0.08 in *trans*-2-butene at $d = 0.61$ g/cm^3 (liquid, 23°C), with an exception at $d = 0.48$ g/cm^3 where it is 0.16 (Table 1).

The parameter *A* is given by

$$A = k_s/\lambda$$

where k_s is the rate constant for charge scavenging, and λ a constant for a given solvent, representing the rate of geminate recombination (6). Since the ratio of *A*'s is taken at the same density, the values of λ should be the same. Hence, it is actually the ratio of the rate constants for charge scavenging by COS and N_2O. Thus, it is concluded that dissociative electron capture takes place with a much slower rate with COS in liquid and supercritical butenes.

Sato *et al.* argue that the rate constants for N_2O and for COS are equal in liquid benzene (3). The disparity is not unexpected since it is known that the reactivity of a solute for electrons is different in different media (8). Moreover, their argument is based on a competition study where complications such as charge transfer might be present. Recently determined values of electron affinities (4*b*, 7) suggest such a possibility. In addition, the concentration range of their study is much too high ($\gtrsim 0.4$ *M*) and a reaction mechanism including sequences of secondary reactions has to be constructed. In contrast, the present method offers a much simpler and less ambiguous way of determining relative k_s values for charge scavenging.

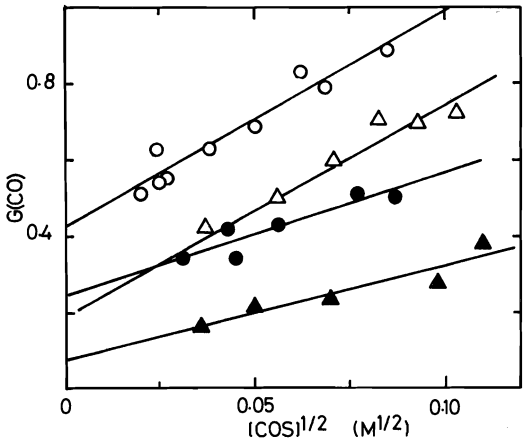

FIG. 1. Yields of CO from *trans*-2-butene–COS mixtures at 170°C as a function of the square root of the molar concentration of COS: ○, 0.24 g/cm^3; ●, 0.36 g/cm^3; △, 0.48 g/cm^3; ▲, 0.61 g/cm^3 (liquid, 23°C).

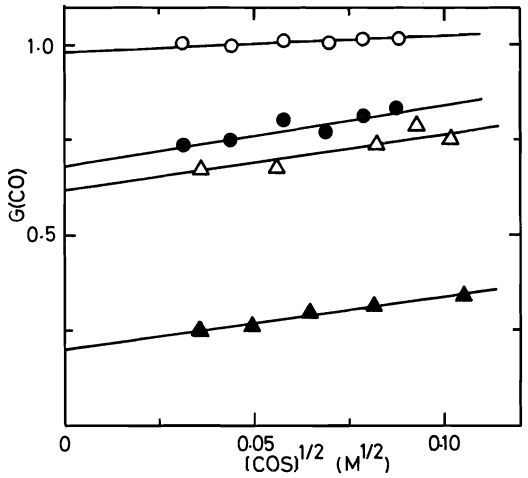

FIG. 2. Yields of CO from *cis*-2-butene–COS mixtures at 170°C as a function of the square root of the molar concentration of COS: ○, 0.24 g/cm^3; ●, 0.36 g/cm^3; △, 0.48 g/cm^3; ▲, 0.62 g/cm^3 (liquid, 23°C).

The variation in *A* ratios, i.e. k_s ratios, is difficult to understand until individual values of k_s and other information are obtained. However, perhaps it could be accounted for in terms of the relationship noted in liquid hydrocarbon between k_s and the energy of the electron in its conducting state V_0, or $V_0 - 0.8P_-$, P_- being

[b]The most probable range for ion–electron separation estimated from

$$G_{fi} = G_{tot}\int_0^\infty f(r)\exp(-r_c/r)\,dr$$

where $f(r)$ was taken to be a Gaussian with a power function tail (1*c*).
[c]Values for A_{N_2O} were taken from ref. 1*c*.
[d]The encounter efficiency for the reaction $COS + e^- \rightarrow CO$.

the polarization energy of the anion formed upon electron capture; the peak position in the k_s vs. V_0 or $V_0 - 0.8P_-$ curve may be different for N_2O and for COS (8, 9).

The encounter efficiency (f) of a reaction defined as the ratio of k_s to that in the diffusion-controlled case, $4\pi RD_e$, where R is the reaction radius and D_e the diffusion coefficiency of electrons, has been shown to be

$$f = 3Ar_c/4\pi R(6\times 10^{20})b^3$$

where r_c is the Onsager distance, $e^2/\varepsilon kT$, and b is the most probable distance of ion–electron separation, when the Nernst–Einstein relationship is assumed for geminate recombination of ion–electron pairs (1*c*). By taking $R = 5$ Å and by using b values estimated from $G(CO)_{fi}$ by the method previously described (1*c*), one can calculate f values for the electron reaction of COS. The salient features one notes in the f values summarized in Table 1 are: (*1*) the values in *trans*-2-butene are larger by an order of magnitude except at $d = 0.48$ g/cm³ than those in *cis*-2-butene, and (2) they are smaller approximately by an order of magnitude than the corresponding values observed for N_2O (1*c*). The trend (*1*) has been observed also for N_2O, though the nature of the behavior is not yet understood. Very small f values for COS may indicate that the reaction involves some processes which require large activation energies and/or negative entropies of activation.

Proton and fluorine magnetic resonance studies of some benzoyl fluoride derivatives. Sensitivity of the fluorine shifts to intramolecular van der Waals interactions and steric effects

TED SCHAEFER, KIRK MARAT, KALVIN CHUM, AND ALEXANDER F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 13, 1977

TED SCHAEFER, KIRK MARAT, KALVIN CHUM, and ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3936 (1977).

The syntheses and the analyses of the high resolution proton and fluorine magnetic resonance spectra of the 3-fluoro-4-methyl-, 2-fluoro-5-chloro-, 2-fluoro-6-chloro-, 2,6-difluoro-, and of the pentafluorobenzoyl fluorides are reported. The spin–spin coupling constants over five bonds between the sidechain fluorine-19 and the ring protons are sensitive to intrinsic substituent perturbations. Their use in the deduction of conformational preferences is much more problematical than is the use of the corresponding proton–proton couplings in benzaldehyde derivatives. The 2-fluoro-6-chloro compound is nonplanar, as indicated by a finite magnitude of the long-range proton–fluorine coupling over six bonds. The nonplanarity is also indicated by a comparison of the through-space fluorine–fluorine coupling to those in the other compounds. The chemical shift of the sidechain fluorine moves to low field by over 35 ppm as the size of the two *ortho* substituents increases. The individual shifts are discussed in terms of intramolecular van der Waals interactions and of out-of-plane twisting of the COF group.

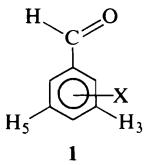
TED SCHAEFER, KIRK MARAT, KALVIN CHUM et ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3936 (1977).

On rapporte la synthèse et l'analyse des spectres de résonance magnétique nucléaire du proton et du fluor des fluorures du fluoro-3 méthyl-4, du fluoro-2 chloro-5, du fluoro-2 chloro-6, du difluoro-2,6 et du pentafluorobenzoyle. Les constantes de couplage spin–spin à travers cinq liaisons entre le fluor-19 de la chaîne latérale et les protons du cycle sont sensibles à des perturbations intrinsèques du substituant. Leur utilisation dans la déduction des conformations préférentielles est beaucoup plus problématique que l'usage des constantes correspondantes de couplage proton–proton dans les dérivés du benzaldéhyde. Le fluorure du fluoro-2 chloro-6 benzoyle n'est pas planaire tel qu'indiqué par une grandeur finie du couplage à longue distance à travers six liens entre le proton et le fluor. Il y a aussi une indication de non planarité par une comparaison du couplage fluor–fluor à travers l'espace avec celui observé dans d'autres composés. Les déplacements chimiques du fluor de la chaîne latérale se déplacent vers les bas champs par environ 35 ppm à mesure que l'encombrement des deux substituants *ortho* augmente. On discute des déplacements individuels en termes d'interactions de van der Waals intramoléculaires et de torsion hors plan du groupe COF.

[Traduit par le journal]

Introduction

The long-range coupling constants between the aldehydic proton and ring protons or fluorine nuclei in benzaldehyde (1) and its derivatives (2–7) indicate that $^5J_m^{H,CHO}$, the coupling involving protons in the *meta* position to the aldehyde group, is not very sensitive to intrinsic substituent effects but that it is highly stereospecific. In **1**,



1

$^5J_m^{H_3,CHO}$ apparently lies between 0.76 and 0.96 Hz depending on the nature and position of groups X, and there is no evidence that $^5J_m^{H_5,CHO}$ is other than zero (4). The observed $^5J_m^{H,CHO}$ values are never smaller than the 0.38 Hz in benzaldehyde.

In benzaldehyde itself, $^6J_p^{H,CHO}$ is perhaps −0.04 Hz (1), in agreement with a σ–π mechanism (8) which yields a nonzero $^6J_p^{H,CHO}$ for a nonplanar geometry. The barrier to internal rotation in benzaldehyde is at least 4.6 kcal/mol (9, 10), so that nonplanar conformations are not appreciably populated at ambient temperatures. However, when *ortho* substitution forces the aldehyde group out of the benzene plane, as in 2,6-dichloro- and 2,6-dinitrobenzaldehydes (11), $^6J_p^{H,CHO}$ becomes as large as 0.2 Hz in magnitude.

In benzoyl fluoride, $^4J_o^{H,CFO}$ is −0.60 Hz,

$^5J_m^{H,CFO}$ is 1.33 Hz, and $^6J_p^{H,CFO}$ is undetectably small (1). In *p*-chloro- and in *p*-methylbenzoyl fluoride (12), the first two couplings change by only about 0.05 Hz from their values in benzoyl fluoride, suggesting that $^4J^{H,CFO}$ and $^5J^{H,CFO}$ might be useful as indicators of conformational populations. In this paper we report a full analysis of the proton or fluorine magnetic resonance spectra of five derivatives of benzoyl fluoride, **1** to **5**. The long-range couplings to ^{19}F in the sidechain are discussed in terms of their stereospecificities and their substituent dependence. The ^{19}F chemical shift in COF is very sensitive to the presence of *ortho* substituents and is rationalized in terms of short-range interactions.

Experimental

Compounds

Fluorination of the commercial benzoic acid derivatives with SF_4 (13) yielded the corresponding benzoyl fluorides (13, 14). Product identity was confirmed by mass, ^1H, and ^{19}F spectra and by analysis (A. Bernhardt) for C, H, and F in **2**, **3**, and **4** which, respectively, had mp 30°C, bp 45°C/0.5 Torr, and bp 64°C/2 Torr; **5** had bp 35°C/5 Torr. **1** was a by-product of the synthesis of 3-fluoro-4-methyl benzotrifluoride and was separated from the mixture by gc on a 5 ft × ¼ in. 3% SE-30 column. The bp was not recorded. The yields ranged from 83% for **4** to 45% for **5**.

Spectral Work

Solutions of **1**, 5 mol% in C_6D_6; **2**, 20 mol% in $CDCl_3$; **3**, 20 mol% in CS_2; **4**, 25 vol.% in CF_3CCl_3; and **5**, 20 vol.% in CF_3CCl_3, were degassed and sealed into 5 mm sample tubes. Internal TMS or CF_3CCl_3 served as sources of lock signals.

Proton magnetic resonance spectra were calibrated at 5 Hz intervals in the frequency sweep mode on an HA100 spectrometer at 32°C. Fluorine magnetic resonance spectra were similarly calibrated on a DA60I spectrometer at 29°C. The manual oscillator in this spectrometer was replaced by an external HP 4204A audio-oscillator and either the high-field (for ring fluorines) or the low-field (for COF) sidebands of CF_3CCl_3 were used as lock signals. The resonance of internal $CFCl_3$ occurs at 82.2 ppm to low-field of CF_3CCl_3 (14).

Extensive double resonance experiments (15, 16) or standard spectral analysis procedures gave the signs of F,F and H,F coupling constants relative to known F,F or H,F couplings between nuclei on the benzene ring.

Results and Discussion

Spectral Analysis

These were performed in the usual manner by means of the computer program LAME (17, 18). Separate iterations were carried out for the proton spectra at 100 MHz and for the fluorine-19 spectra at 56.4 MHz. Table 1 presents the ensuing spectral parameters for 3-fluoro-4-methylbenzoyl fluoride. The standard deviations were ≤ 0.006 Hz, and a comparison between those parameters obtainable from both sets of spectra suggests an accuracy of 0.02 Hz in the coupling constants (except perhaps for $^4J_{12}$).

For reasons of space, somewhat briefer sets of spectral data for **2** to **5** are given in Tables 2 and 3. The previous data for **5** in CCl_4 gave no signs of the couplings to the sidechain fluorine nucleus (19) and gave $^4J_{35}$ as $<|0.6|$ Hz, whereas we find -0.54 Hz. Figure 1 shows the observed and calculated spectra for F_3 and F_5 (*meta* position).

Note that spectra were calibrated in the frequency sweep mode, so that, in the tables, a 'shift to low field' from the internal lock is taken as equivalent to a frequency higher than the lock frequency and vice versa.

Ring Proton and Fluorine Chemical Shifts and Coupling Constants within the Ring

These parameters have been repeatedly discussed (1, 4, 12, 19–21) for related compounds and nothing really new can be added here. This is not to say that the parameters are fully understood.

Proton Couplings to Fluorine in the COF Group Over Five and Four Bonds

From the $^5J_{15}$ and $^5J_{13}$ values for **1** to **4** in the Tables, it is clear that, in general, $^5J_m^{H,COF}$ displays an appreciable intrinsic substituent dependence, i.e. this coupling does not depend only on whether the C—H and C—F bonds lie *cis* ($^5J_{cis}$) or *trans* ($^5J_{trans}$) to one another. $^5J_m^{H,COF}$ varies between 0.76 and 1.55 Hz.

In benzaldehyde derivatives in which, for example, an *ortho* hydroxyl group holds the aldehyde group firmly in one conformation, $^5J_{cis}^{H,CHO}$ is zero (2, 4, 5). Unfortunately, this situation cannot be attained for benzoyl fluoride derivatives; reaction of phenols with SF_4 gave unidentifiable products. INDO MO FPT calculations appear to be of dubious validity for the purpose of finding whether $^5J_{cis}^{H,CFO}$ is zero (22). It is conceivable that $^5J_{cis} < 0$; a negative $^5J_{cis}^{F,OH}$ of −0.35 Hz exists in a *m*-fluorophenol derivative (23).

With these difficulties in mind, perusal of

§Coupling constants in Hz to an accuracy of 0.02 Hz for 2 and to 0.04 Hz for 5. The average difference between parameters derived from ^1H and ^{19}F spectra was 0.01 Hz for 2.

$^5J_m^{H,COF}$ and $^4J_o^{H,COF}$ in the tables suggests that a study of other accessible substitution patterns can hardly lead to regularities from which reliable estimates of conformer populations can be made.

These discouraging conclusions stand in sharp contrast to those reached for benzaldehyde derivatives (4, 6) or for fluorophenol derivatives (23). In the latter, $^5J_m^{F,OH}$ is a precise and accurate indicator of conformer populations.

Over Six Bonds, $^6J_p^{H,COF}$

As has been argued previously for phenol (24) and benzaldehyde (11), in which $^6J_p^{H,OH}$ and $^6J_p^{H,COH}$ are probably less than 0.04 Hz in magnitude, the unobservably small $^6J_p^{H,COF}$ in benzoyl fluoride is consistent with a barrier to internal rotation of greater than 4 kcal/mol. The argument depends on the assumption that ^6J is proportional to $\sin^2\theta$, where θ is the angle by which the COF group twists out of the benzene plane, i.e. that ^6J is transmitted via a σ–π mechanism (8, 25). If so, then in **1** $^7J_p^{CH_3COF}$ should be very nearly equal to $-^6J_p^{H,COF}$ in benzoyl fluoride (25). Indeed, these two couplings are less than 0.03 Hz in both compounds.

$^6J_p^{H,COF}$ is also <0.03 Hz in **2** and **4**, indicating planarity, or a very small twist, of the COF group, in the presence of one or two *ortho* fluorine substituents. On the other hand, in **3**, $^6J_p^{H,COF}$ is -0.29 ± 0.03 Hz, somewhat smaller in magnitude than the −0.37 Hz observed in 2,6-dimethylbenzoyl fluoride (22) for which an angle of twist of about 25° has been estimated. It is assumed here that $^6J_p^{H,COF}$ has an appreciable magnitude only when the COF group lies out of the aromatic plane. This assumption leads to no inconsistencies of interpretation, although it cannot be proved that intrinsic substituent effects will not give rise to a nonzero ^6J for a coplanar conformation. It may be noted that in 2,6-dinitro- and 2,6-dichlorobenzaldehydes the COH group very likely twists away from the aromatic plane (11).

The planarity of **1**, **2**, **4**, and **5**, and the nonplanarity of **3** and of 2,6-dimethylbenzoyl fluoride are in congruence with the large through-space $^4J_o^{F,CFO}$ values as well as with the peculiar chemical shifts of the COF fluorine nucleus to be discussed below.

Through-space F,F Couplings and the Chemical Shift of ^{19}F in COF

F,F Couplings

Through-space or proximate F,F couplings, arising from direct interactions between the orbitals centered on the fluorine atoms (26), are exceedingly sensitive to the internuclear distance, r_{FF}. For example, the empirical equation $J^{F,F}$ (Hz) $= 6800 \times \exp(-1.99\ r_{FF}(\text{Å}))$, apparently valid between 2.2 and 4.0 Å (27), roughly reproduces the observed $^4J^{F,F}$ values in 2-fluorobenzotrifluoride derivatives.

If, in the *trans* arrangement of the C—F bonds in **2**, $^4J^{F,F}$ is only about 1.5 Hz (28), a COF geometry based on microwave data on acetyl fluoride (29) and benzoyl fluoride (10) and on a regular benzene geometry entails $^4J^{F,F}$ as 69.6 Hz in the *cis* arrangement on the basis of the above equation. If the assumed rigid geometry is altered to change r_{FF} from 2.30 Å to 2.275 Å, exact agreement with the observed 37.5_3 Hz in **2** is achieved: (1.5 + 73.5)/2. Of course, this result does not prove the planar geometry of **2**, indicated by the near zero value of $^6J_p^{H,COF}$ above.

The increase of 1.3 Hz in $^4J^{FF}$ for **5** can be simply rationalized by a decrease of 0.01 Å in r_{FF} relative to **2**, arising perhaps from slightly greater crowding in the C_6F_5 compared to the $C_6F_2H_3$ moiety. Writing $^4J^{F,F} = 43.5_6$ Hz =

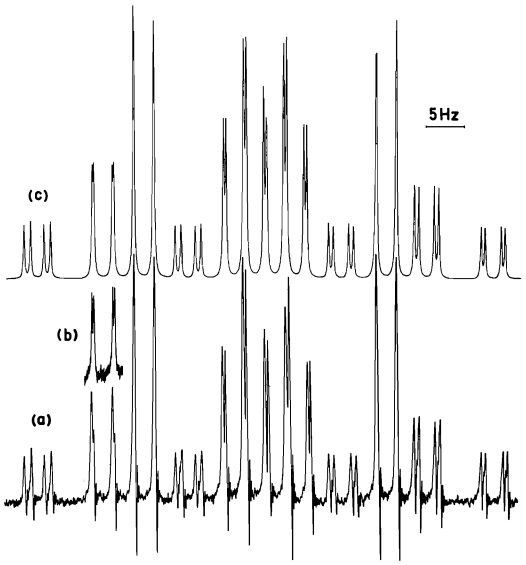

FIG. 1. The observed and calculated spectra at 56.443 MHz of the fluorine nuclei *meta* to COF in pentafluorobenzoyl fluoride, **5**, as a 20 vol.% solution in CF_3CCl_3 at 29°C. The observed spectrum was recorded at a sweep rate 0.1 Hz/s, clearly too large for a clean resolution of some of the small splittings. The inset shows a set of peaks recorded at a sweep rate of 0.02 Hz/s, used in calibration procedures.

$73.5p_{cis} + 1.5p_{trans}$, and $p_{cis} + p_{trans} = 1$, yields $p_{cis} = 0.5_8$ for **4**, i.e. **4***b* is probably somewhat more highly populated than **4***a*.

$^4J^{F,F}$ is 30.6 Hz in **3**, which is indicated as nonplanar by the finite magnitude of $^6J_p^{H,COF}$. An average increase of rather less than 0.1 Å in r_{FF} for the *cis* conformation accounts for the decrease in $^4J^{F,F}$, and is consistent with an average angle of twist of about 20° of the COF group.

The ^{19}F Shift in COF

The magnetic nuclei in the $^{13}C^1H^{17}O$ and $^{13}CO^{19}F$ groups are less shielded than are their counterparts in most other organic functional groupings (1, 20, 30, 31), perhaps as a consequence of low-lying excited electronic states in the C=O bond. Of interest here is the large shift to low-field caused by the *ortho* substituents in benzoyl fluoride derivatives. The shifts are, in Hz at 56.443 MHz relative to internal CF_3CCl_3: 5608 (H,H), 6397 (H,F), 7291 (F,F, **2**), 7297 (F,F, **5**), 7529 (F,Cl), and 7629 (CH_3,CH_3, (ref. 22)). Allowing for differential internal solvent shifts of up to 30 Hz (20, 32), the shielding range of near 2000 Hz, or about 35 ppm, is remarkable.

The change in shielding is clearly not a strong function of the mesomeric or inductive properties of the ring substituents. For example, **2** and **5** are characterized by almost identical $CO^{19}F$ shifts, whereas two *ortho* methyl groups cause the largest low-field shift (although the shifts were measured in different solvents, the shift difference between **1** and *p*-methylbenzoyl fluoride (12) is apparently only about 0.4 ppm (25 Hz)).

Large decreases in shielding in the presence of proximate atomic groupings have been interpreted (20, 33–36) either in terms of intramolecular van der Waals forces or in terms of steric effects. The distinction between these mechanisms rests on the 'distance', *r*, between the atomic groupings. The former are proportional to r^{-6} and are attractive forces, whereas steric effects come about when the electron clouds overlap and cause mutual distortion of the electron clouds or small changes in molecular geometry. The quantitative calculations of shielding changes from these two mechanisms are problematical (20, 36), although it appears certain that the van der Waals interactions cause deshielding and there is some evidence (35) that steric interactions do the same.

In Fig. 2, the observed $CO^{19}F$ shift is plotted versus the mean of the van der Waals radii of the two *ortho* substituents. Indications from $^6J_p^{H,COF}$ are that the molecule is planar for H,H,

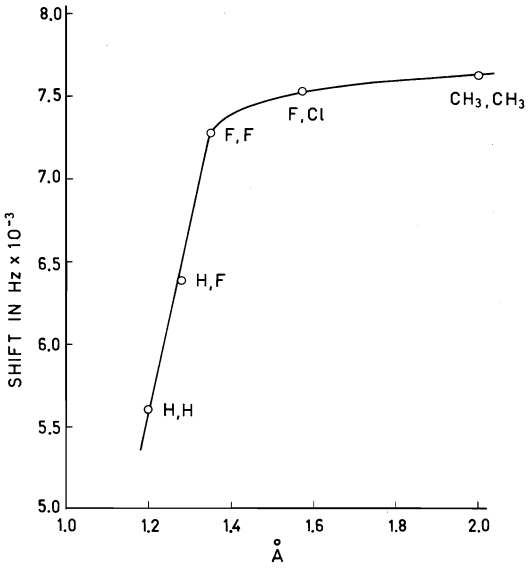

FIG. 2. The shift in Hz at 56.443 MHz to low-field of internal CF_3CCl_3 of the $CO^{19}F$ group is plotted versus the mean of the van der Waals radii in Å of the substituents *ortho* to COF.

H,F, and F,F substituents, suggesting that steric effects, as described above, are still relatively small or, in any event, not large enough to cause appreciable twisting about the partial double bond between the benzene ring and the COF group.

The use of microwave data for the geometry of the COF group suggests an overlap of at least 0.2 Å between the van der Waals radii of the fluorine atoms situated in the COF group and the ring C—F bonds, leading us to believe that the shift of ca. 30 ppm to low-field caused by two *ortho* F,F substituents may well contain a contribution from the steric effects.

The F,Cl and CH_3,CH_3 pairs induce a substantial out-of-plane twist of the COF moiety, as indicated by $^6J_p^{H,COF}$, the twist being largest for CH_3,CH_3. The curvature of the plot in Fig. 2 implies that further large down-field shifts by large substituents, like I,I, will be relatively small because overlap of electron clouds can be relieved by twisting of the COF group.

It may be noted that the ^{19}F shift in alkyl COF compounds lies to low-field of C_6H_5COF (37–39) and that therefore at least part of the observed low-field shifts caused by the F,Cl and CH_3,CH_3 pairs may arise from partial inhibition of conjugation with the benzene ring.

The resonance of $(CH_3)_3COF$ occurs at about 200 Hz to low field of that in C_6H_5COF. On the assumptions that this shift arises from conjugation and that it depends on the square of the cosine of the angle of twist in C_6H_5COF, an estimated angle of twist of 25° in 2,6-dimethylbenzoyl fluoride (22) would lead to a low-field shift of about 40 Hz in the latter compound. Apparently, the shift due to partial loss of conjugation is only a small fraction of the observed shift changes.

Réactions avec le diazométhane d'esters cinnamylidène maloniques ou cyanacétiques méthylés ou phénylés en γ des groupements fonctionnels et des malononitriles correspondants. Thermolyse des pyrazolines obtenues

J. MARTELLI ET R. CARRIÉ

Groupe de Recherches de Physicochimie Structurale, ERA No 389, Université de Rennes, B.P. 25 A, 35031 Rennes, Cedex, France

Reçu le 6 avril 1977

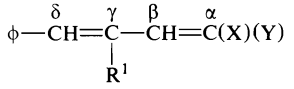
J. MARTELLI et R. CARRIÉ. Can. J. Chem. **55**, 3942 (1977).

La synthèse d'esters cinnamylidène maloniques ou cyanacétiques méthylés ou phénylés en γ des groupements fonctionnels est réalisée. Les configurations des divers isomères obtenus sont déterminées et les conformations discutées. Le diazométhane s'additionne exclusivement sur la double liaison α,β de ces dipolarophiles selon une orientation unique. La thermolyse des pyrazolines-1 obtenues est étudiée.

J. MARTELLI and R. CARRIÉ. Can. J. Chem. **55**, 3942 (1977).

The syntheses of cinnamylidene malonic or cyanacetic esters, bearing a methyl or a phenyl group in the position γ to the withdrawing groups, were achieved. The configurations of the various isomers were established and the conformations are discussed. Diazomethane adds exclusively to the α,β double bond of these dipolarophiles in only one orientation. The thermolysis of the resulting 1-pyrazoline was studied.

Dans le cadre de recherches expérimentales et théoriques sur l'addition des dipoles 1,3 à des dipolarophiles présentant plusieurs sites d'addition potentiels, l'étude de l'addition de diazocomposés à divers diènes conjugués *gem* diactivés a été entreprise (1). Afin de compléter



I

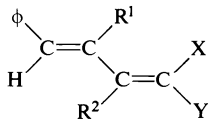
les résultats relatifs aux esters cinnamylidène maloniques, cyanacétiques et aux malononitriles correspondants (2) nous avons été conduit à préparer les composés I et à préciser leur comportement vis à vis du diazométhane dans le but de discuter l'influence d'un groupement en γ des substituants activants sur la réactivité des deux sites dipolarophiles et sur l'orientation de l'addition. Les composés I sont susceptibles d'exister sous différentes formes isomères géométriques qui sont quelquefois isolées et dans tous les cas caractérisées à l'aide des données spectroscopiques uv et de rmn. Le diazométhane est additionné à ces oléfines; les monocycloadduits obtenus sont étudiés ainsi que leurs produits de thermolyse.

Synthèse et étude structurale des diènes I (1 à 8)

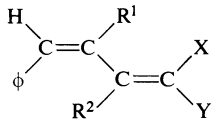
Ils sont préparés par condensation de l'aldéhyde cinnamique substitué et du composé à méthylène actif correspondant; quatre formes isomères géométriques peuvent exister (**1** à **4** avec $R^1 = CH_3$, $R^2 = H$, **5** à **8** avec $R^1 = \phi$, $R^2 = H$).

Les condensations conduisent (*1*) lorsque $R^1 = CH_3$, à l'isomère **1** avec **2** à l'état de traces et (*2*) lorsque $R^1 = \phi$, au mélange des isomères **5** et **6** qui peuvent être séparés dans certains cas.

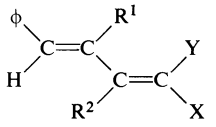
L'irradiation des composés **1**, **5** ou **6** en solution les isomérise au niveau soit de la double liaison γδ seulement lorsque le solvant est le méthanol soit à la fois des liaisons αβ et γδ si l'on opère dans le benzène pendant un temps suffisamment long. Ainsi, en solution benzénique, après 4 h d'irradiation à la température



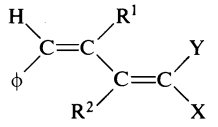
1, 5, 11, 15



2, 6, 12, 16



3, 7, 13, 17



4, 8, 14, 18

1 à **4** $R^1 = CH_3$, $R^2 = H$
5 à **8** $R^1 = \phi$, $R^2 = H$
11 à **14** $R^1 = CH_3$, $R^2 = CH_3$
15 à **18** $R^1 = \phi$, $R^2 = CH_3$

a X = CN, Y = CO_2CH_3
b X = CN, Y = $CO_2C_2H_5$
c X = Y = CN
d X = Y = CO_2CH_3

d'ébullition du solvant, on obtient, à partir de **1***a*, le mélange: **1***a* (41%); **2***a* (31%); **3***a* + **4***a* (28%) (détermination rmn).

Les divers composés sont isolés cristallisés ou caractérisés à l'aide de la rmn; leurs caractéristiques figurent au tableau 1.

Les composés **1** et **2** (**5** et **6**) sont des isomères de configuration au niveau de la double liaison γδ. En effet, l'isomérisation dans le méthanol des composés **1** donne **1** + **2** (**5** ou **6** donne **5** + **6**) et ceci est vérifié avec **1***c*, **1***d*, **6***c*, **6***d* pour lesquels il ne peut y avoir d'isomérisation au niveau de αβ. De plus les caractéristiques spectroscopiques uv des composés **1** (**5**) sont trop différentes de celles des composés **2** (**6**) pour qu'il puisse s'agir d'une isomérisation de configuration αβ.

Ces caractéristiques sont, dans le cas des composés **1**, tout à fait comparables à celles des esters cinnamylidène cyanacétiques, maloniques et des malononitriles correspondants non substitués en β et γ ou uniquement méthylés en β, que la configuration au niveau de αβ soit *E* ou *Z* (2); la double liaison γδ est donc de type *E* pour **1** et *Z* pour **2**.

Bien que la différence de valeur du couplage ^4J (du proton en δ et du substituant méthyle en γ) entre le composé **1** et le composé **2** correspondant ne soit pas suffisante pour prouver à elle seule la configuration de la double liaison γδ (3), les valeurs observées, ^4J = 1.3 à 1.5 Hz (cisoïd) > ^4J = 1.1 à 1.2 Hz (transoïd), sont en accord avec les structures proposées.

Lorsque l'étude rmn est effectuée en solution dans $CDCl_3$, les signaux dûs aux protons du substituant aromatique sont des singulets pour **1***a* à **1***d* et des multiplets plus ou moins larges pour **2***a* à **2***c*; or il est bien connu qu'un tel substituant s'il est coplanaire avec la double liaison (et en l'absence d'autres effets dûs éventuellement au reste de la molécule) donne un multiplet alors que le signal est singulet si la double liaison porte en *cis* du phényle un autre substituant stériquement important (4–7).

Enfin la proximité du phényle en *cis* de H_β dans les composés **2** explique le déblindage de ce proton par rapport à celui du composé **1** correspondant. Un déblindage semblable est observé par Pattenden et Weedon (8) pour les méthyl-2 phényl-5 pentadiènoates de méthyle correspondants.

Les données spectroscopiques uv et plus particulièrement les valeurs des coefficients d'extinction moléculaire des composés **5** et **6** pour les maxima d'absorption de plus grande longueur d'onde (respectivement $\varepsilon_M \simeq 14\,000$ et $\varepsilon_M' \simeq 30\,000$) rappellent celles des *cis* et *trans* stilbènes diversement substitués (9, 10). La configuration *Z* au niveau γδ (les deux φ sont en *cis* l'un de l'autre, composé **5**) entraîne la non coplanéïté des phényles et de la double liaison éthylénique d'où un abaissement important de ε_M. L'aspect des signaux rmn dûs aux phényles est également en accord avec les configurations γδ proposées.

Au niveau de la configuration de la double liaison αβ les attributions de structure sont en accord avec les données spectroscopiques de rmn: comme pour tous les méthylène cyanacétates étudiés jusqu'à présent (11, 2), l'ester en *cis* de H_β rend compte du déblindage plus élevé de **1***a* et **1***b*, **2***a* et **2***b* comparativement à **1***c* et **2***c*; de même pour les composés phénylés en γ **5** et **6** on constate un déblindage d'environ 0.40 à 0.50 ppm du proton H_β de l'ester nitrile par rapport à celui du dinitrile correspondant.

On note enfin la quasi identité des déplacements chimiques de H_β des composés phénylés **6***a* à **6***d* et des méthylés en γ de structure correspondante **2***a* à **2***d*.

Les composés **3***a* ou **4***a*, **7***a* et **8***a* obtenus photochimiquement sont des isomères de configuration au niveau de la double liaison αβ respectivement de **1***a* ou **2***a*, **5***a* et **6***a*, le proton H_β de ces derniers (H_β en *cis* du groupement ester en α) est déblindé par rapport au H_β des premiers. Pour ces composés de configuration *Z* au niveau de la double liaison αβ une interaction d'origine stérique au niveau de l'ester en α et du substituant en γ est susceptible d'expliquer leur obtention difficile dans l'éventualité d'une conformation S *trans*.

La conformation des diènes **1** à **8** est délicate à établir (absence de couplage $^3J_{\beta\gamma}$) cependant la similitude des caractéristiques spectroscopiques uv et de rmn des composés **1** avec celles des diènes du même type non substitués en γ (dont la structure est établie) (2, 8) suggère une conformation privilégiée S *trans*. Il est logique de penser que la conformation privilégiée des composés **2** reste voisine de S *trans*, au moins pour **2***a*, **2***b* et **2***c* (H_β nettement déblindé par le phényle en δ).

De même, une conformation S *trans* privilégiée, voisine de la planéïté, semble pouvoir être attribuée aux composés **6**: la comparaison des

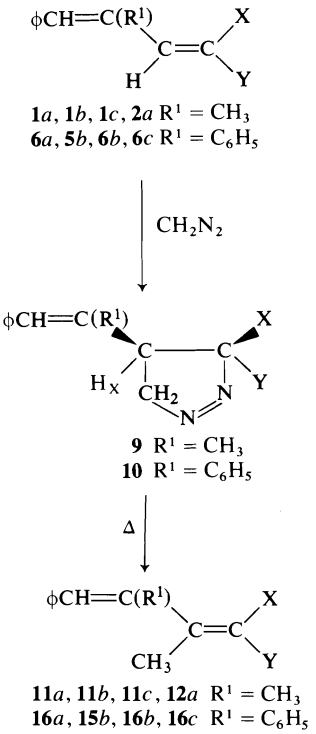
déplacements chimiques de H_β des composés **6** et **2** correspondants indique une analogie structurale.

Action du diazométhane

Le diazométhane s'additionne d'une manière stéréospécifique sur la double liaison αβ des composés I. De même que pour les composés non substitués en γ la vitesse de l'addition et la stabilité du monoadduit formé sont très différentes suivant la nature des substituants X et Y, nous envisagerons deux cas.

Composé I dinitriles et esters nitriles

Les composés I de configuration *E* en αβ conduisent quantitativement, par action d'une quantité stoechiométrique de dipôle, aux composés β-méthylés correspondants. Partant d'un mélange d'isomères géométriques au niveau de la double liaison γδ (en proportions connues), les deux isomères β-méthylés sont obtenus dans les mêmes proportions. La méthylation s'effectue (schéma 1) par l'intermédiaire d'une pyrazoline-1 instable qui est mise en évidence dans deux cas: **9***a* et **10***a* (X = CN, Y = CO_2CH_3), en opérant l'addition du diazométhane à −20°C sur **1***a* et **6***a* respectivement.



1*a*, **1***b*, **1***c*, **2***a* $R^1 = CH_3$
6*a*, **5***b*, **6***b*, **6***c* $R^1 = C_6H_5$

9 $R^1 = CH_3$
10 $R^1 = C_6H_5$

11*a*, **11***b*, **11***c*, **12***a* $R^1 = CH_3$
16*a*, **15***b*, **16***b*, **16***c* $R^1 = C_6H_5$

SCHÉMA 1

Le site et l'orientation de cette cycloaddition sont établis à l'aide de la rmn (système ABX). Les caractéristiques des pyrazolines **9***a* et **10***a* sont les suivantes (rmn $CDCl_3$): **9***a*: 6.46 (s élargi, φCH=), 1.67 (s élargi, $R^1 = CH_3$), 3.92 (s, CO_2CH_3); système ABX: $H_A = 5.19$, $H_B = 4.95$, $H_X = 3.50$; $J_{AB} = 18.2$, $J_{AX} = 3.2$, $J_{BX} = 7.8$. **10***a*: 6.44 (φCH=), 3.37 (s, CO_2CH_3); système ABX $H_A = 5.28$, $H_B = 4.97$; $J_{AB} = 17.8$, $J_{AX} = 7.7$, $J_{BX} = 7.8$.

Comme les diènes dont ils dérivent, les composés β-méthylés $R^1 = CH_3$ et $R^1 = \phi$ peuvent exister sous quatre formes isomères géométriques **11** à **18**.

L'isomérisation au niveau de la double liaison αβ seule, se produit lorsque le composé **11** ou **12** ($R^1 = CH_3$, X ≠ Y) est abandonné en solution éthérée. Un mélange photostationnaire de deux (X = Y = CN) ou quatre (X = CN, Y = CO_2R) isomères est obtenu lorsqu'on irradie une solution méthanolique ou benzénique des composés **11**, **12** ($R^1 = CH_3$), **15** ou **16** ($R^1 = \phi$). Les composés obtenus par perte d'azote à partir des monoadduits **9** ou **10** ont la même configuration que les diènes dont ils dérivent, cette caractéristique de la méthylation par le diazométhane est tout à fait conforme aux observations antérieures (12, 2).

Les attributions de structures sont effectuées sur les considérations spectroscopiques uv et de rmn développées pour les diènes précurseurs. Les résultats figurent au tableau 2.

L'aspect des signaux des protons aromatiques: singulet lorsque le phényle δ est en *cis* de $R^1 = \phi$ (**15** et **17**) ou $R^1 = CH_3$ (**11**); les couplages $^4J(H_\delta, CH_{3\gamma})$ lorsque $R^1 = CH_3$ (*J* cisoïd > *J* transoïd); l'examen des déplacements chimiques du méthyle β déblindé par le groupement ester en *cis* pour les composés **11**, **12**, **15** et **16** comparativement à **13**, **14**, **17** et **18**; la similitude des variations relatives (suivant les isomères considérés) de CH_3 en β et du H_β des diènes dont ils dérivent; enfin des comparaisons pouvant être effectuées avec les données spectroscopiques citées dans la littérature (3, 13, 14) permettent d'établir la structure des diènes β-méthylés.

A l'exclusion des composés **11** auxquels une structure S *trans EE* voisine de la planéïté peut encore être attribuée (Wiley et coll. ont montré que l'acide diméthyl-3,4 phényl-5 pentadiènoïque est S *trans EE* (13, 14)), les composés β-méthylés obtenus **12** à **18** ne semblent pas pouvoir être

plans à cause de fortes interactions stériques s'exerçant au niveau du substituant en γ et d'un substituant en α d'une part, du phényle en δ et du méthyle en β d'autre part.

Composés I diesters

Le diazométhane s'additionne exclusivement (même en présence d'un gros excès de dipôle) sur la double liaison αβ de ces diesters et selon le sens indiqué (schéma 2); il y a formation de pyrazoline-1 stable à la température ambiante. L'addition du dipôle est beaucoup plus lente que dans le cas des esters nitriles correspondants. **5***d* ne réagit pas avec le diazométhane (il faut remarquer que **7***a*, ester nitrile de structure analogue, additionne lentement le dipôle).

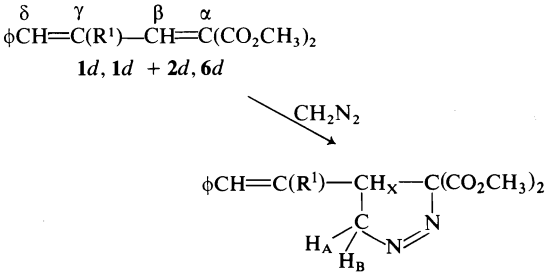

SCHÉMA 2

Les pyrazolines obtenues sont caractérisées à l'aide de la rmn. La valeur du déplacement chimique du méthyle ($R^1 = CH_3$), celle de la constante de couplage ^4J allylique sont des preuves de la conservation de la configuration de la double liaison au niveau de γδ. L'existence d'un système ABX donne l'orientation de l'addition.

Les caractéristiques de rmn ($CDCl_3$) des composés figurent au tableau 3.

Les pyrazolines-1 **19** et **21** sont décomposées thermiquement dans le xylène au reflux (schéma 3); elles conduisent respectivement aux oléfines **22** (65%) + **23** (35%) et **24** (65%) + **25** (26%) accompagnées d'un autre produit non identifié.

Les composés **22** à **25**, non isolés, sont caractérisés dans le mélange obtenu après thermolyse par leurs propriétés spectroscopiques (rmn) (tableaux 4 et 5).

Composés **22** et **24**: les trois protons éthyleniques (β, γ, ε) sont déblindés et le couplage avec $J_{\beta\gamma} = 15$ et 16 Hz, caractérise une stéréochimie *trans*. On observe un doublet correspondant au proton plus blindé porté par le carbone α substitué par deux esters dont les méthyles sont équivalents; on notera également la conservation, par rapport aux diènes de départ, de la forme des signaux dûs aux phényles et pour **22** le couplage du méthyle en δ avec H_ε.

Composés **23** et **25**: le dédoublement des signaux pour $CH_{3\gamma}$ et H_δ (**23**) est témoin d'un couplage ^4J entre ces protons; les deux esters ne sont pas équivalents, ce qui confirme l'existence d'une double liaison en αβ.

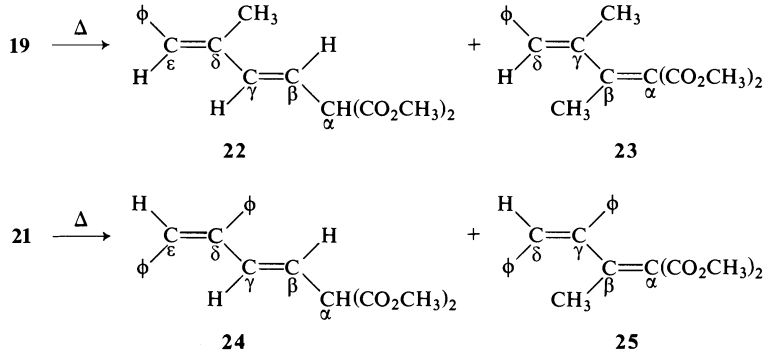

SCHÉMA 3

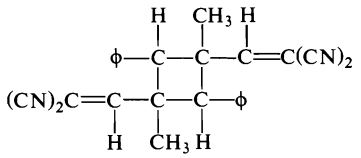
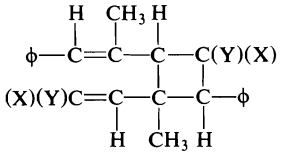
Dimérisation des diènes 1

Les composés **1***b*, **1***c* et **1***d* sont photosensibles à l'état solide. S'ils ne sont pas conservés à l'abri de la lumière, ils conduisent rapidement aux produits de dimérisation correspondants **26**, **27**, **28**, dont la structure est établie à l'aide



27



26 X = CN, Y = $CO_2C_2H_5$
28 X = Y = CO_2CH_3

de la rmn (la stéréochimie n'est pas précisée). **26** ($CDCl_3$): 0.80 et 1.34 (—CH_2—CH_3), 3.96 et 4.32 (—CH_2—CH_3), 1.46 (s, CH_3), 1.93 (s élargi, CH_3), 6.60 (s élargi, H), 8.47 (s, H), 4.20 (s élargi, H), 4.32 (s, H); ϕ aspect: deux multiplets étroits. **27** (DMSO-d_6): 8.30 (s, 2H), 1.48 (s, 6H), 4.39 (s, 2H); ϕ (aspects): deux multiplets étroits. **28** (C_6D_6): 4.27 (s, 1H), 4.95 (s, 1H), 6.61 (s élargi, 1H), 7.51 (s, 1H), 1.96 (d, 3H, J = 1.2), 1.73 (s, 3H), 3.06 (s, 6H, $2CO_2CH_3$ fortuitement équivalents), 3.26 (s, 3H, CO_2CH_3) et 3.29 (s, 3H, CO_2CH_3).

Conclusion

La synthèse d'esters cinnamylidène cyanacétiques ou maloniques γ substitués et des malononitriles correspondants est réalisée et leur stéréochimie discutée.

L'introduction d'une substitution en γ ne modifie pas le comportement de ces diènes vis à vis des diazocomposés: l'addition s'effectue exclusivement sur la double liaison $\alpha\beta$ et dans le sens attendu. Il convient cependant de noter la nette différence de réactivité entre certains isomères géométriques.

L'évolution thermique des pyrazolines-1 obtenues n'est pas non plus affectée par cette substitution en γ: lorsque l'un des groupements activants est un groupement nitrile la thermolyse, d'une manière quantitative et stéréospécifique, conduit à des diènes β-méthylés.

Les cycloadduits dérivés des diènes *gem*-diactivés par deux groupements esters se comportent différemment. Les oléfines résultant de la migration du groupe vinyle substitué sur le carbone 5 de la pyrazoline-1 sont principalement formées. Elles s'isomérisent par prototropie dans le milieu réactionnel.

Partie expérimentale

Les spectres de rmn sont réalisés avec un appareil JNM MH 100 (Jeolco) à 100 MHz. Les spectres uv sont obtenus à l'aide d'un appareil Unicam SP 700 à partir de solutions dans l'alcool à 95°. Les points de fusion sont pris au banc chauffant Kofler. Tous les composés pour lesquels le mot "analyse" est indiqué, suivi d'une formule moléculaire explicite, ont fourni des résultats analytiques correspondant à $\pm 0.4\%$ près, au plus, sur les éléments analysés (C, H, N) (Service de Microanalyse de l'Université de Rennes).

Le phényl-3 méthyl-2 propène-2 al est obtenu par crotonisation de l'aldéhyde benzoïque et de l'aldéhyde propionique en présence de méthylate de sodium selon la technique de Burton (15). L'aldéhyde phényl-2 cinnamique est également préparé par crotonisation suivant la méthode de Etienne et Weill-Reynal (16) décrite par Bargain (17).

Dienes 1 à 8

Les méthodes sont: *A*, condensation suivant Cope et coll. (18); *B*, condensation du type précédent modifiée

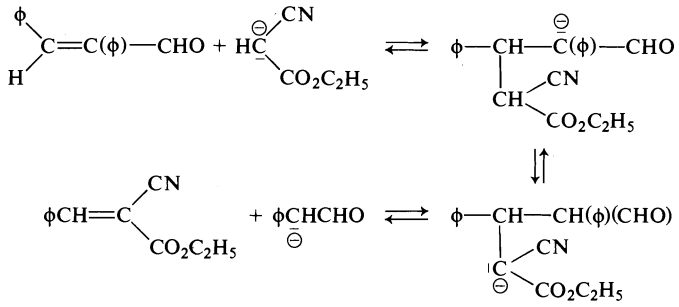


SCHÉMA 4

selon Mowry (19); *C*, condensation suivant Allen et Spangler (20).

1*a* (*A*, rdt 38%), pf 108°C (méthanol). Analyse $C_{14}H_{13}NO_2$.

1*b*, **2***b* (*A*, rdt 73%, mélange **1***b* (88%) + **2***b* (12%)) (intégration du signal rmn dû à H_β).

1*b*, pf 81°C (éthanol). Analyse $C_{15}H_{15}NO_2$.

1*c* (*B*, quantité de solvant doublée, rdt 55%), pf 129°C (éthanol). Analyse $C_{13}H_{10}N_2$.

1*d*, pf 50–52°C (éther). Analyse $C_{15}H_{16}O_4$.

5*a*, **6***a* (*A*, rdt 73%, mélange **5***a* (20%) + **6***a* (80%)).

6*a*, pf 151°C (éthanol). Analyse $C_{19}H_{15}NO_2$.

5*b*, **6***b*. La méthode *A* conduit avec un rendement global de 40% à un mélange des deux isomères dans des proportions relatives très variables suivant la manipulation. De l'huile obtenue à partir du produit brut de réaction après distillation du cyanacétate en excès, cristallisent les diènes par addition d'éthanol; du résidu distille, à 140°C sous 2 mm, un composé qui cristallise par refroidissement pf 50°C, c'est l'ester α-cyanocinnamique $\phi CH{=}C(CN)(CO_2C_2H_5)$, dont la formation résulte d'une addition de Michael de l'anion cyanacétate sur la double liaison de l'aldéhyde (schéma 4), il est identifié par comparaison avec un échantillon authentique (21).

5*b*, pf 148°C (éthanol). Analyse $C_{20}H_{17}NO_2$.

6*b*, pf 78°C (éthanol). Analyse $C_{20}H_{27}NO_2$.

5*c*, **6***c*. La méthode *B* conduit au mélange des deux isomères. Après distillation du solvant, on recueille 9 g de cristaux jaunes (pf 173°C) et 1 g d'une huile constituée du mélange des deux isomères.

6*c*, rdt 59%, pf 176°C (éthanol).

5*d*, **6***d*. La condensation (*C*) conduit à un mélange de deux isomères, ils cristallisent ensemble par addition de quelques cm^3 de méthanol à l'huile épaisse obtenue par distillation du solvant; rdt 64%. **6***d* cristallisé est obtenu à partir d'une solution benzénique concentrée du produit brut de la réaction en distillant partiellement le solvant.

5*d*, pf 81–83°C, est obtenu par cristallisation fractionnée d'un mélange enrichi en **5***d* par irradiation.

Isomérisation photochimique

Les composés **1** ou **6** sont isomérisés en solution (1 g dans 130 cm^3 de méthanol ou de benzène sec). La solution contenue dans un ballon de quartz surmonté d'un réfrigérant est irradiée au moyen d'une lampe Hanau (brûleur TQ 81) placée extérieurement; l'irradiation est effectuée à la température de reflux du solvant.

Action du diazométhane sur les oléfines

Le dipôle, préparé à partir de la nitrosométhylurée (22) (0.5 *M*) et le diène sont abandonnés en solution éthérée à 0°C; les composés β-méthylés ou les pyrazolines correspondants sont obtenus par simple distillation du solvant sous vide à basse température. Dans le cas des esters nitriles et dinitriles, la réaction est généralement totale après 24 h avec une quantité de dipôle égale ou légèrement supérieure à la stoechiométrie. On notera cependant une méthylation partielle dans un cas: **5***a* (18%) + **7***a* (82%) + CH_2N_2 (1.5 fois la quantité stoechiométrique) conduit après 24 h à une méthylation totale de **5***a* (**5***a* → **15***a*) et une méthylation partielle de **7***a* (**7***a* → **7***a* + **17***a*). L'addition du diazométhane aux diesters nécessite une plus grande proportion de dipôle (1.5 à 4 q.s.) et un temps de réaction plus long; dans ces conditions le dipôle est sans action sur **5***d*.

X = *CN*, *Y* = *CN ou* CO_2R (*R* = CH_3, C_2H_5)

Pyrazolines—Si la réaction d'addition du dipôle sur le diène est conduite à −20°C l'adduit obtenu est suffisamment stable à basse température, pour permettre une étude de ses caractéristiques de rmn.

Oléfines β méthylés—**11***c*, pf 71°C (éthanol). Analyse $C_{14}H_{12}N_2$. **12***c*, pf 108–109°C (éthanol). Analyse $C_{14}H_{12}N_2$. **15***a*, pf 110°C (éthanol). **16***a*, pf 126–127°C (éthanol). **15***b*, pf 125°C (éthanol). **16***b*, pf 134°C (éthanol). **16***c*, pf 109–111°C (éthanol). Analyse $C_{19}H_{14}N_2$.

X = *Y* = CO_2CH_3

Pyrazolines—Les pyrazolines-1 obtenues sont des huiles: **20** est étudiée à partir du mélange **19** + **20** dans lequel elle est minoritaire.

Photodimérisation des diènes 1

Les composés **1***b*, **1***c* et **1***d* abandonnés à la lumière du jour à l'état finement pulvérisé, conduisent en quelques jours aux dimères correspondants **26** à **28**.

26, analyse $C_{30}H_{30}N_2O_4$; pf 123°C (éthanol).

27, pf 264°C ($CHCl_3$, éther); très peu soluble.

28. La dimérisation est plus lente que pour les composés précédents (plusieurs semaines). Le produit résultant pf 95–100°C, trop soluble dans les solvants organiques usuels, n'a pu être recristallisé.

ROBERT J. CRAWFORD, STUART LUTENER, and HIROKAZU TOKUNAGA. Can. J. Chem. **55**, 3951 (1977).

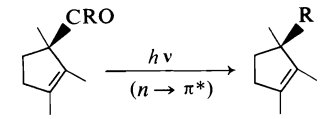
The thermal decarbonylation of 2,2-dimethyl-3-butenal is shown to be an intramolecular extrusion of carbon monoxide concerted with the transfer of hydrogen (deuterium) to the γ-position. The reaction displays a kinetic isotope effect of 2.8 (at 296.9°C) and follows first order kinetics (E_a = 44.2 ± 0.2 kcal mol^{-1}, log A = 13.4 ± 0.3).

ROBERT J. CRAWFORD, STUART LUTENER et HIROKAZU TOKUNAGA. Can. J. Chem. **55**, 3951 (1977).

On démontre que la décarbonylation thermique du diméthyl-2,2 butène-3 al est une extrusion intramoléculaire de monoxyde de carbone concertée avec un transfert d'hydrogène (deutérium) vers la position γ. La réaction présente un effet isotopique cinétique de 2.8 (à 296.9°C) et suit une cinétique du premier ordre (E_a = 44.2 ± 0.2 kcal mol^{-1}, log A = 13.4 ± 0.3).
[Traduit par le journal]

Introduction

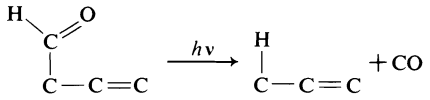
Recently we examined the thermolysis of 2-vinyloxirane (1) and concluded that one of the initial products was 3-butenal which, depending upon the surface of the vessel, was tautomerized to *E*- or *Z*-2-butenal or produced propylene and carbon monoxide. Traces of oxygen brought about a catalytic reaction and large amounts of CO and propylene were produced, but even after the most careful conditioning propylene and CO were present. We suggested that the decarbonylation of 3-butenal was both radical catalyzed and under oxygen free conditions proceeding via an intramolecular mechanism. To study this more thoroughly we have examined the thermolysis of the non-enolizable 2,2-dimethyl-3-butenal (**1**). There are few instances of decarbonylation of β,γ-unsaturated aldehydes. The most thoroughly studied is the work of Schaffner (2) where the singlet photosensitized decarbonylation of *R*-(+)-laurolenal (**2**) to *S*-(−)-1,2,3-trimethylcyclopentene (**3**) is observed.



2 **3**

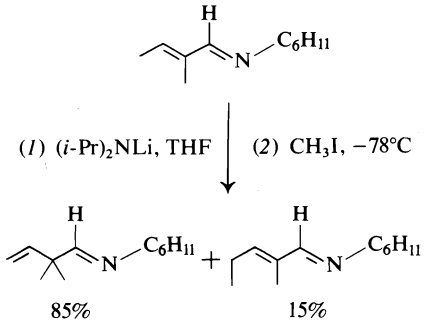
a R = H *a* R = H
b R = D *b* R = D

The stereochemistry in this, and other steroid cases (3), leads to the suggested skeletal mechanism wherein the hydrogen (or deuterium) is attached in the product to the same carbon to which the aldehyde carbon was attached in the reactant; this was accompanied by a small amount of allylic rearrangement.

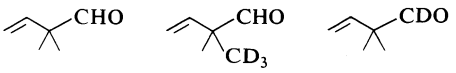


Synthesis of Deuterated 2,2-Dimethyl-3-butenals

We required for our mechanistic studies 2,2-dimethyl-3-butenal (**1**) and its deuterium labelled derivatives **1**-d_1, and **1**-d_3. The aldehyde **1** was conveniently prepared from the cyclohexylimine of tiglaldehyde using lithium diisopropylamide in tetrahydrofuran (THF) at −78°C and methylating the resulting anion with methyl iodide to

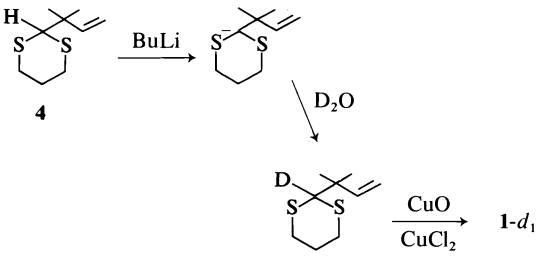


produce the imine of **1**. Methyl-d_3 iodide was used to produce **1**-d_3. The C(1) labelled aldehyde (**1**-d_1) was prepared using the method of Corey



1 **1**-d_3 **1**-d_1

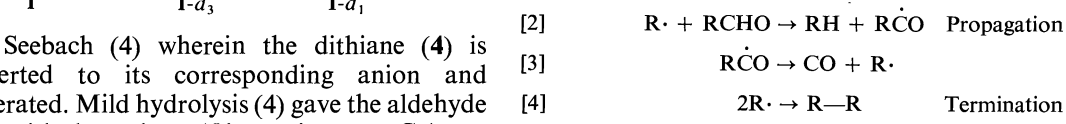
and Seebach (4) wherein the dithiane (**4**) is converted to its corresponding anion and deuterated. Mild hydrolysis (4) gave the aldehyde **1**-d_1 with less than 1% protium at C(1) as assessed by ^{1}H nmr.



4

Kinetics

The rate of decarbonylation of **1** was followed by measuring the pressure increase as a function of time. The reaction vessel consisted of a 1 ℓ well-conditioned Pyrex sphere as described in our earlier paper (1) except that a side-arm was attached and extended through the wall of the thermostated vessel. A National transducer LX 3702 A reading 0–10 V was interfaced with a Hewlett-Packard 5150 A thermal printer equipped with a time interval control, thus pressure readings were taken automatically at regular intervals. That the reaction followed first order kinetics was established by measuring the rate at different pressures and finding the rate constant to be unchanged on going from 50 to 200 Torr initial pressure of **1**. Having observed a 1 to 2 min warm-up period from the time of injection of our sample we decided to use the method of Guggenheim (5) to obtain more precise values of the rate constants. While it is possible that the warm-up period was in fact an induction period for a chain reaction, samples of pentanal required the same length of time to come to temperature equilibrium, and with a thermocouple well extended to the centre of the reaction vessel we were able to observe a comparable initial temperature differential upon admission of any gas. The values of the rate constants obtained over the temperature range 282 to 302°C are listed in Table 1. Aliphatic aldehydes such as acetaldehyde undergo high temperature pyrolysis and under certain conditions can give rise to first order kinetics for the chain process outlined in eqs. 1–4 (6). We



have examined the effect of two radical chain inhibitors, toluene and 1,4-cyclohexadiene, upon the reaction rate constant, and these data are presented in Table 2.

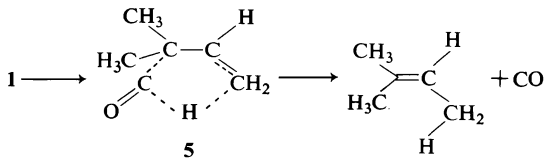
Product Studies

The thermolysis of **1**, **1**-d_1, and **1**-d_2 at 300°C leads to carbon monoxide and 2-methyl-2-butene with less than 0.5% of any other hydrocarbon present. The ^{1}H nmr spectra of **1**-$d_1$and **1**-d_3 indicate that the aldehydic hydrogen (deuterium) has been transferred to the C(4) position of the original butenal.

The reaction was shown to be intramolecular by attempted crossover experiments involving **1**-d_1 and **1**-d_3. The 2-methyl-2-butene produced was carefully examined by mass spectrometry for the presence of C_5H_{10}, C_5H_9D, $C_5H_7D_3$, and $C_5H_6D_4$. After correcting for the natural abundance of ^{13}C and deuterium incorporation level, we found no evidence for the crossover products C_5H_{10} and $C_5H_6D_4$. Our mass spectra were sufficiently reproducible that if either of these were present at the 0.5% level they would have been detected.

Discussion

The experimental data demonstrate that the thermal decarbonylation of **1** is an intramolecular, nonradical scavengeable process of a highly reproducible rate. These data are best interpreted in terms of a molecular mechanism involving the transfer of the aldehydic hydrogen to the γ-position as in **5**.



5

The reaction is very similar to that involving the decarboxylation of the corresponding car-

boxylic acid, 2,2-dimethyl-3-butenoic acid (log A = 11.13, E_a = 36.6 kcal mol^{-1}) (7). The magnitude of the kinetic isotope effect, k_H/k_D = 2.8 at 296.9°C corresponds to a value of 7.2 at 25°C (see Table 3), indicates that the hydrogen is extensively transferred in the transition state; this coupled with the low activation energy in comparison with that normally associated with the thermolysis of RCO—H bonds (E_a 44.2 kcal mol^{-1} vs. bond dissociation energy of greater than 82 kcal mol^{-1} (6)) suggests that the process is highly concerted.

Experimental

All boiling points are uncorrected. Purifications by preparative gc were carried out on a Nester Faust model 850 'Prepkromatic'. The columns used were 6 ft biwall tubing packed with 20% Carbowax 1500 on Chromosorb W 30–60 mesh. The carrier gas was helium at a flow rate of 500 ml min^{-1}. The nuclear magnetic resonance (nmr) spectra were obtained using a Varian A 60 or HA 100 spectrometer.

Thermolysis Kinetics

Quantitative rate experiments were conducted in a static Pyrex vacuum system constructed as described earlier (1). The rates were followed by means of a pressure transducer (National LX 3702 A) attached to the cell via a 3 mm Pyrex tube. The transducer was mounted on the outside of the oven wall thus the dead space was less than 1% of the total reactor volume. The transducer was calibrated against a mercury manometer and was found to be linear over the desired pressure range. The output signal from the transducer (0–10 V range) was recorded at regular intervals on a Hewlett-Packard 5150 A thermal printer equipped with a time interval control.

All samples for kinetic runs were prepared from materials dried over 4A molecular sieves, transferred to breakseals, and degassed by standard procedures. At least 20 points were taken for each rate measured.

1-d_1	1.17±0.01	2.85±0.04

2,2-Dimethyl-3-butenal (1)

The aldehyde **1** was prepared by alkylation of the cyclohexylimine of tiglaldehyde which was prepared by adding cyclohexylamine (10.9 g, 0.11 mol) to a solution of tiglaldehyde (8.4 g, 0.11 mol) in benzene (125 ml). The solution was stirred and the water removed by azeotropic distillation using a Dean Stark trap (2 h). The benzene was then removed on a rotary evaporator and the residual liquid was essentially identical (nmr, ir) with that of an aliquot purified by distillation, bp 60–65°C/2 Torr (8). The undistilled residual liquid was used directly for the alkylation step.

A solution of *n*-butyllithium (21.4 ml, 52.5 mmol) was reduced to half volume under reduced pressure and dry tetrahydrofuran (THF) (50 ml) was added. After the addition of bipyridyl (12 mg) the solution was cooled to −50°C and diisopropylamine (5.30 g, 52.5 mmol) in THF (25 ml) was slowly added and the red solution cooled to −78°C. The afore-mentioned tiglaldehyde imine (8.25 g, 50 mmol) was dissolved in THF (25 ml) and added dropwise. The solution was maintained at −78°C and methyl iodide in THF was added in a titration-like procedure. The colour of the solution abruptly changed to pale yellow upon the addition of 1 equiv.; this was then followed by an additional 20%. The resulting solution was diluted with approximately three volumes of ether and poured into ice water (100 ml), washed with saturated NaCl solution, and the solvent evaporated. Gas chromatography (Carbowax, 1500, 150°C) indicated the residual product to be a 5:1 mixture of imines and an nmr spectrum of the crude indicated that the imine of 2,2-dimethyl-3-butenal was the major product and the imine of 2-methyl-2-pentanal was the isomer.

The imine derivatives were then placed in a flask with a solution of oxalic acid (40 g) in water (100 ml) and the

TABLE 4. Attempted crossover experiments at 248°C

1:1	12	0.42	3.16	100	1.31	108	0.0

aldehydes steam distilled. Extraction of the distillate with ether, followed by drying and distillation, resulted in two fractions, exclusive of solvent, bp 93–94°C/700 Torr, 2,2-dimethyl-3-butenal (2.6 g, 60%) (9) and bp 130–131°C/700 Torr 2-methyl-2-pentanal (0.4 g, 10%) (10). Yields were improved to 80% upon scaling up by fourfold.

*2-Methyl-2-trideuteriomethyl-3-butenal (**1**-d_3)*

The method of synthesis was the same as that above for **1** only that trideuteriomethyl iodide was used. The ^{1}H nmr spectrum displayed a peak at δ 1.21 which was three times the size of the peak at δ 9.39.

*1-Deuterio-2,2-dimethyl-3-butenal (**1**-d_1)*

The propanedithiol derivative of **1** was prepared in a 250 ml round bottom flask equipped with a magnetic stirrer, $CaCl_2$ drying tube, and a gas inlet. A solution of 2,2-dimethyl-3-butenal (11.0 g, 0.11 mol) and 1,3-propanedithiol (12.0 ml, 0.12 mol) was stirred and cooled to 0°C. Hydrogen chloride gas was bubbled through the solution for 5 min, after which the temperature rose to +5°C and fell back to zero. After work-up in the conventional manner a vacuum distillation on the residual oil gave 15.0 g, 73%, of a pale yellow oil, bp 103°C/2.5 Torr; ^{1}H nmr ($CDCl_3$) δ_{TMS}: 1.23 (s, 6H), 2.0 (m, 2H), 2.9 (m, 4H), 4.04 (s, 1H), 4.9–6.2 (m, 3H).

The dithiane (15 g, 96 mmol) was dissolved in dry THF and cooled to −40°C after which 1.2 equiv. of *n*-butyllithium in hexane was added over ½ h, and stirred for 2 h under a nitrogen atmosphere. The reaction was quenched with D_2O and the dithiane isolated as above: 15 g recovered, ^{1}H nmr same as above except for the signal at δ 4.04 which was less than 1% of its original intensity.

A solution of the dithiane (4.72 g, 25 mmol) in 200 ml acetonitrile containing 2 ml H_2O was warmed to 70°C on cupric oxide (7.9 g, 100 mmol), $CuCl_2$–$2H_2O$ (8.5 g, 50 mmol) was added, and the solution maintained at 70°C for an additional 30 min (4). The solution was then cooled and filtered, the precipitate washed with acetonitrile, the solution plus wash diluted with H_2O (150 ml) extracted with pentane and dried, and the aldehyde purified by distillation (2.3 g, 95%). The aldehydic signal at δ 9.39 was less than 0.005 times its original intensity.

Attempted Crossover Experiments

Sample tubes containing **1**-d_1, **1**-d_3, and mixtures of these were carefully degassed and then heated at 298°C. Table 4 gives the experimental conditions and the intensities corrected for ^{13}C for each of the runs.

Acknowledgements

We wish to thank Professor S. Masamune for helpful discussions concerning the dithiane hydrolysis and Dr. A. Hogg for the mass spectrometric measurements.

Simultaneous diffusion and chemical activation control of the kinetics of the binding of carbon monoxide to ferroprotoporphyrin IX in glycerol–water mixtures of high viscosity[1]

BRIAN B. HASINOFF

Department of Chemistry and the Faculty of Medicine, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received June 7, 1977

BRIAN B. HASINOFF. Can. J. Chem. **55**, 3955 (1977).

The kinetics of the reaction of ferroprotoporphyrin IX with CO have been studied in mixed glycerol–water solvents of high viscosity in order that the simultaneous influence of chemical activation and diffusion control of the reaction might be observed. Analyses of curved Arrhenius plots indicated that in the low temperature high viscosity limits the reaction is largely diffusion controlled. The deviation of the second order diffusion rate constants, from that predicted by simple theory for reaction between uniformly reactive spheres of equal radii, is a factor of 0.3 to 0.9, depending upon the solvent composition. A couple of other models for diffusion controlled reaction, ascribing these deviations to changes of steric requirements, were also examined.

BRIAN B. HASINOFF. Can. J. Chem. **55**, 3955 (1977).

On a étudié la cinétique de la réaction de la ferroprotoporphyrine IX avec le CO dans des solvants mixtes de glycérol–eau de grande viscosité de façon à pouvoir observer simultanément l'influence de l'activation chimique et du contrôle de la diffusion sur la réaction. L'analyse des courbes d'Arrhenius indique qu'aux limites de basse température et de haute viscosité la réaction est grandement contrôlée par la diffusion. La déviation des constantes de vitesse de diffusion du deuxième ordre par rapport à celles qui sont prédites par la théorie simple de la réaction entre des sphères réactives uniformes qui ont un rayon égal est d'un facteur de 0.3 à 0.9 dépendant de la composition du solvant. Une couple d'autres modèles pour une réaction contrôlée par la diffusion et attribuant ces déviations à des changements dans les facteurs stériques ont aussi été examinés.

[Traduit par le journal]

In a previous study (1) the reaction of ferroprotoporphyrin IX (heme) with carbon monoxide was studied by laser flash photolysis as a function of temperature and pressure in 100% glycerol and 80% v/v ethylene glycol – water. A comparison of the activation enthalpies and activation volumes with the viscosity activation parameters indicated that in 100% glycerol the kinetics are almost totally controlled by diffusion. From a consideration of $\Delta V^{\ddagger}$ (1), obtained in 80% v/v ethylene glycol – water, a dissociative mechanism was indicated.

This study extends the range of viscosities studied by using mixtures of glycerol and water, such that both chemical activation and diffusion control contribute to the kinetics. It is of interest to measure the kinetics in this region as a test of the applicability of the theory of diffusion controlled reactions. Glycerol–water solvent mixtures exhibit a wide range of viscosities (2) with large temperature coefficients so that the

[1]This work has been supported in part by a National Research Council of Canada Grant, No. A9430.

diffusion controlled region can be easily distinguished from the chemical activation controlled region of normally lower activation energy.

The theory of the effects of diffusion controlled rates on chemical kinetics is historically due to von Smoluchowshi (3) and has been reviewed and critically examined by Noyes (4). Since the classical theory is only strictly applicable to spherical molecules of uniform surface reactivity, a number of refinements to the basic theory have been proposed. The theory has been extended to molecules with orientation constraints due to limited accessibility of their active sites (5–9). Even moderate steric requirements (5–7) can produce drastic reductions in the diffusion controlled rate constants. A recent related study (10) of the binding of CO and O_2 to myoglobin in glycerol–water indicated the importance of diffusion control on these reactions.

For the reaction of spherical, uniformly reactive molecules in a homogeneous fluid the diffusion controlled second order rate constant, k_D is (4)

$$[1] \qquad k_D = 4\pi RD$$

where R is the sum of the radii of the reacting molecules ($r_A + r_B$) and D is the sum of the translational diffusion coefficients. Use of the Stokes–Einstein expression

$$[2] \qquad D = kT/6\pi r\eta$$

for r_A and r_B and eq. 1, with conversion to units of M^{-1} s^{-1}, gives

$$[3] \qquad k_D = \frac{2000RT}{3\eta}\frac{(r_A + r_B)^2}{r_A r_B}$$

where R is the gas constant in J K^{-1} mol^{-1}, η the viscosity in Pa s (1 Pa s $\equiv$ 1 kg m^{-1} s^{-1} $\equiv$ 10 P). If $r_A = r_B$ then

$$[4] \qquad k_D = 8000RT/3\eta$$

Note that eq. 4 has no adjustable parameters and depends only on T and η of the solvent. Modifying eq. 4 to include a factor, α, that is a measure of the departure of the reaction from that predicted for reaction between spheres of equal radii and uniform reactivity, yields

$$[5] \qquad k_D = \alpha(8000\ RT/3\eta)$$

The factor α may include steric, probability, interaction, and radius factors. With $\alpha = 1$ in eq. 5 for 100% glycerol at 20°C (η = 1.41 Pa s) $k_D = 4.6 \times 10^6\ M^{-1}$ s^{-1}, which compares to water at the same temperature (η = 1 mPa s) $k_D = 6.4 \times 10^9\ M^{-1}$ s^{-1}.

The activation enthalpy of a diffusion controlled reaction is (1)

$$[6] \qquad \Delta H_D^{\ddagger} = -R\,\partial \ln (k_D/T)/\partial T^{-1} = B$$

and for the solvent

$$[7] \qquad B = R\,\partial \ln \eta/\partial T^{-1}$$

where B is the viscosity activation energy in the empirical relationship

$$[8] \qquad \eta = \eta_0 \exp (B/RT)$$

In the more general case where there is simultaneous chemical activation and diffusion contributing to the observed kinetics (4, 6)

$$[9] \qquad k^{-1} = k_0^{-1} + k_D^{-1}$$

where k is the observed second order rate constant and k_0 is the rate constant that would be observed if diffusion effects were absent. In eq. 9, k_D represents the maximum rate at which an association reaction can proceed.

Experimental

Reagents

Heme (as hemin chloride, Eastman) was dissolved in 1 M aqueous NaOH on the day of use. The spectrophotometrically determined (1) heme solution in N_2 saturated glycerol–water of known composition was added to a serum cap sealed fluorescence cell containing a few crystals of sodium dithionite to reduce the iron. The final [NaOH] was either 0.01 or 0.02 M. The CO stock solution was prepared by bubbling C.P. CO through water for 20 min at a known temperature and pressure, and its concentration determined using Henry's Law (11). This CO saturated solution was then transferred to the reaction cell with a gas tight syringe. Using published densities, the weights of additions, and known dilutions, the final concentrations of the glycerol–water solution, heme, and CO were determined.

Apparatus

The flash photolysis apparatus, the spectrophotometric detection system, and the analog-to-digital data acquisition system have been described (10). The reaction of heme and CO was followed at a wavelength of 430 nm (7 nm band pass). The first order rate constants, k_{obs}, were obtained by fitting 256 digitized voltage–time values to a three parameter nonlinear least squares equation of the form $A = A_0 \exp(-k_{obs}t) + A_\infty$, where A, A_0, and A_∞ are the absorbances at time $t = t$, $t = 0$, and $t = \infty$ respectively. Only the last 10% of the reaction was followed for about 6 half-lives. Three or more values of k_{obs} were averaged, giving a relative standard deviation of 2–5%. The temperature of the reaction cell was held constant to ±0.03°C.

Results

Dependence of the Kinetics of the Heme + CO Reaction on Solvent Composition and Temperature

The recombination of heme with CO after flash photolysis may be represented by

$$\text{heme—CO} \xrightarrow{h\nu} \text{heme} + \text{CO} \qquad \text{(dissociation)}$$

$$\text{heme} + \text{CO} \xrightarrow{k} \text{heme—CO} \qquad \text{(recombination)}$$

The reaction has been well studied (1, 13, 14) and the rate has been shown to be proportional to [CO]. Upon flash photolysis of heme—CO in the presence of 15- to 30-fold excess ligand, recombination was first order where heme varied from 2.9 to 7.3 μM and k_{obs} fell in the range 25 to 480 s^{-1}. The second order rate constant was calculated from $k = k_{obs}/[CO]$. The variation of log k with T^{-1} is plotted in Fig. 1. The reaction was studied over a temperature range of 10 to 60°C which gave a variation in viscosity of 0.01 to 1.7 Pa s. Data from ref. 14 are plotted in Fig. 2. The curvature in the plots is ascribed to diffusion control. The magnitude of the curvatures makes it unlikely that this effect is due to a change in heat capacity of activation of the reactants.

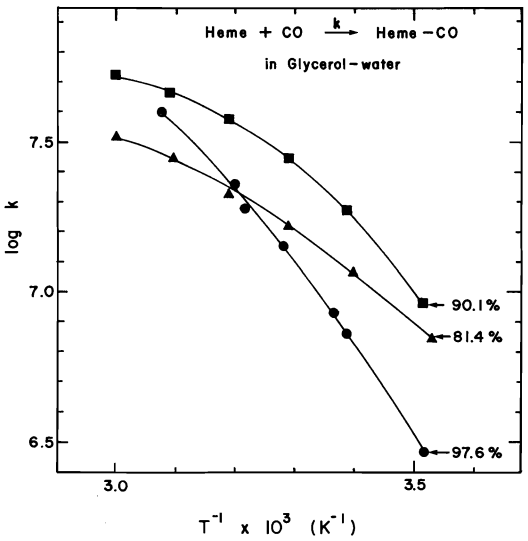

FIG. 1. Log k vs. T^{-1} in glycerol–water mixtures for the reaction of heme and CO. The curved solid lines are those calculated from the three parameter nonlinear least squares analysis of the rate and viscosity data in eq. 10. At the high temperature limit the reaction kinetics are controlled by chemical activation and by diffusion at the low temperature limit. At the highest and lowest viscosities studied the reaction is 92% and 18% diffusion controlled respectively.

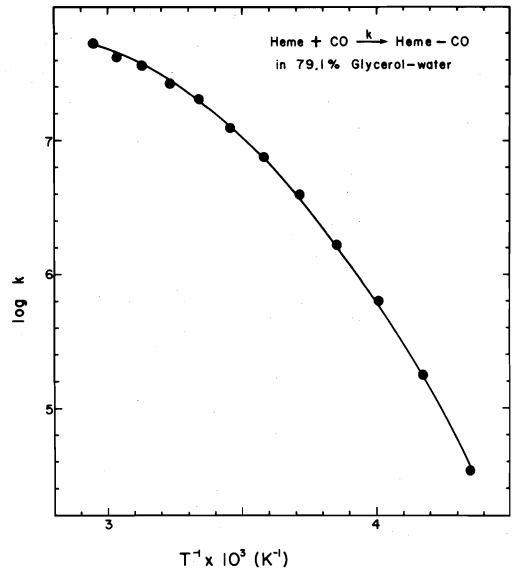

FIG. 2. Log k vs. T^{-1} for the reaction of heme and CO from the data of ref. 14 in 79.1 wt.% glycerol–water. Other comments as in Fig. 1.

The data were analyzed with eq. 5 in eq. 9 yielding

$$k^{-1} = k_0^{-1} + k_D^{-1}$$

$$[10] \quad k^{-1} = \left(\frac{kT}{h}\exp\frac{\Delta S^{\ddagger}}{R}\exp\frac{-\Delta H^{\ddagger}}{RT}\right)^{-1} + \left(\alpha\frac{8000RT}{3\eta}\right)^{-1}$$

where k_0 is assumed to have the usual temperature dependence.

Nonlinear least squares analysis (12) was used to obtain the three best fit parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and α. The results are listed in Table 1 and plotted as the continuous curves in Figs. 1 and 2. Equation 10 has two independent variables, T and η; the latter was obtained from an empirical equation (10) at the appropriate temperature and solvent composition.

Also listed in Table 1 are values of $\Delta H_D^{\ddagger}$ obtained from a four parameter ($\Delta H_D^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and α/η_0) nonlinear least squares analysis of eqs. 5, 6, and 8 substituted in eq. 9. This analysis provides a semiquantitative independent test of eq. 9. Since B, the viscosity activation energy parameter, varies considerably with temperature (Table 1), the kinetically determined

[a]Error values are standard deviations from nonlinear least squares analysis.
[b]Activation parameters for pure chemical control of reaction.
[c]From an analysis of eq. 10 and is the factor by which k_D departs from reaction between uniformly reactive spheres of equal radii; eq. 4.
[d]From a reanalysis of data in ref. 14.
[e]From ref. 1 in 80% v/v ethylene glycol – water containing 10 mM NaOH.
[f]When constrained to a positive value, a value of 0 was obtained with no significant difference in the standard deviation of the fit. The value of α was the same within its standard deviation.
[g]Indeterminate error.

$\Delta H_D^{\ddagger}$ would be expected to show only a rough correspondence. In general, it is seen that values of $\Delta H_D^{\ddagger}$ do approach the values of B at the low temperature limits where diffusion control is the greatest. Also since both the previously determined $\Delta H_D^{\ddagger}$ and $\Delta V_D^{\ddagger}$ in 100 wt.% glycerol (1) showed a close correpondence with both the temperature and pressure viscosity activation parameters, it is with some assurance that the results may be analyzed with the three parameter eq. 10.

The $\Delta H^{\ddagger}$ at the highest glycerol composition is not very well determined as the contribution from chemical activation ranges from only 8 to 45%. In general the values of $\Delta H^{\ddagger}$ are somewhat lower than for reaction in 80% v/v ethylene glycol – water (1) even though the $\Delta G^{\ddagger}$'s are similar.

Discussion

Interpretation of the Diffusion Controlled Reaction of Heme with CO

Clearly it is possible to write more complex reaction schemes to explain curved Arrhenius plots. In a temperature study (14) extending from 5 to 340 K, at a single glycerol–water composition, results were rationalized on the basis of a sequential mechanism with one bimolecular and three unimolecular steps. After making assumptions about the relative magnitudes of the observed rate constants, the data were interpreted in the high temperature limit, using three rate constants (six activation parameters). The effect of diffusion control on the kinetics was considered (14) and the conclusions reached agreed partly with results given in ref. 1. However, the situation was described as being different for the less viscous glycerol–water mixture as a correspondence with k_D was not achieved with the three-step mechanism. In the discussion given here the curved Arrhenius plots are ascribed to simultaneous chemical activation and diffusion control, with nonunity values of α being due to steric and other requirements. At the closest comparable solvent compositions of the two studies the rate constants agree absolutely within about 20% ($k = 3.3 \times 10^7\ M^{-1}\ s^{-1}$ in 81.4 wt.% glycerol at 60.1°C and $k = 4.2 \times 10^7\ M^{-1}\ s^{-1}$ in 79.1 wt.% glycerol at 56.8°C), which is fair considering the different solvent compositions and methods of preparation.

At the highest glycerol composition employed α is close to 1, indicating that the rate of the reaction is close to that predicted for reaction between uniformly reactive spheres of equal radii. Obviously heme and CO are not uniformly reactive spheres and their radii would be significantly different.[2]

With these considerations, taking a slightly more sophisticated model (17) and factoring α into components

$$[11]\quad \alpha = \tfrac{1}{4}\sigma_{CO}\sigma_{heme}\frac{(r_{heme} + r_{CO})(r_{heme} + r_{CO}^{S})}{r_{heme}r_{CO}^{S}}$$

where r_{CO}^{S} is the Stokes radius of CO, and σ_{CO} and σ_{heme} are steric factors on CO and heme which may be visualized as the fraction of the total surface area on each reactant over which reaction can occur. It is known that the radii of O_2 molecules in glycerol–water, calculated from eq. 2 and polarographically determined diffusion coefficients (18), are anomalously

[2]The radius of the heme molecule from X-ray data is estimated from the shortest in-plane dimension (15) on tetraphenylporphine to be ~4 Å. The radius of CO is estimated from gas viscosity data (16) to be 1.8 Å.

small (the Stokes radii vary from 0.15 Å in 80 wt.% glycerol to 0.086 Å in 92.5 wt.% glycerol). These radii are between 12 and 21 times smaller than might be reasonably expected. Conversely, the diffusion coefficients are abnormally large in these solvents. Similarly, for the diffusion of H_2O in glycerol–water (19) the Stokes radii have also been found to be anomalously small. Whatever the cause for the failure of the Stokes–Einstein expression, since eq. 3 is based on eq. 2, the contribution of the smaller Stokes radii should be considered in eq. 11. Assuming a value of σ_{CO} of $\frac{1}{2}$ (17), the values of σ_{heme}, calculated from the Stokes radii for O_2, physically reasonable radii for heme and CO[2], and experimentally determined values of α in eq. 11, are given in Table 2.

A reasonable independent approximation to σ_{heme} might be the ratio of the area of the binding site, considered to be equal to the cross-sectional area of a CO molecule, to the surface area of the heme considered as a sphere.[2] This ratio is $\sigma_{heme} = A_{CO}/A_{heme} = \pi r_{CO}^2/4\pi r_{heme}^2 = 0.05$. The experimental values range from 0.04 to 0.1 which is in good agreement, considering the model and its assumptions. These values of σ_{heme} are up to 26 times larger than corresponding values (10) found for the reaction of myoglobin and CO where, as might be expected, the steric requirements are more severe. The reasons for the decline in σ_{heme} or α with solvent composition cannot be explained with any certainty. Qualitative changes in the hydration shell from lowest to highest water compositions could conceivably change the steric requirements of the reactants. This change might come about through a change in the long range interaction potential (16) due to changes in the dielectric constant ($\Delta\varepsilon/\varepsilon \sim 25\%$ (2)) or charge distribution. Possibly the model is oversimplified in its assumptions.

In a more sophisticated theoretical treatment of diffusion controlled reactions (5–7), a model was employed that included the effects of both translational and rotational diffusion. This model made the following assumptions: (*1*) the center of the incoming ligand (a mobile orientatable sphere of radius r_{CO}) must lie on the surface of a small target hemisphere of radius r_T centered at a distance r_{CO} above the reactive site on the surface; (*2*) the reactive site vector must lie within the reaction cone of constraint (half cone angle θ); and (*3*) $\theta r_{CO} = r_T$ (θ in radians). From these considerations, an equation, said to be valid to better than 20%, was presented (5) that was not formally derived but rather inferred from the results of numerical integrations.

$$[12]\quad k_D = \frac{(1 - \cos\theta)\,\theta r_{CO}\,(r_{CO}^S + r_{heme})2000RT}{3r_{CO}^S\, r_{heme}\,\eta}$$

A feature of eq. 12 is its extreme sensitivity to θ, particularly at low θ. A measure of α as before may be obtained from eq. 12 by comparison with eq. 5.

$$[13]\quad \alpha = \frac{(1 - \cos\theta)\,\theta r_{CO}\,(r_{CO}^S + r_{heme})}{4r_{CO}^S\, r_{heme}}$$

From the experimental values of α and eq. 13, values of θ and r_T are given in Table 2. Both θ and r_T decrease at higher water compositions, which accords with the decrease in σ_{heme} in the previous model. The large values of θ indicate that the heme binding site does not have a high steric requirement. The values of θ obtained for the heme–CO reaction range approximately between 50% and a factor of six larger (depending on the solvent composition) than that found (10) for the reaction of myoglobin and CO. These differences undoubtedly reflect the increased accessibility of heme compared to myoglobin. One possible interpretation of the large θ's is that reaction with Fe^{2+} may even be from either side of the planar heme molecule. The size of the target radius is also quite reasonable, being about the same order as that of the CO molecule.[2] Probably this model should not be relied upon to give much better than order-of-magnitude estimates in k_D.

TABLE 2. Diffusion control and steric factors for the reaction of heme and CO in mixtures of glycerol–water

Wt.% glycerol	α	Radius factor[a]	σ_{heme}[b]	θ (°)[c]	r_T (Å)[d]
97.6	0.89	71	0.10	130	4.0
90.1	0.79	69	0.09	120	3.7
81.4	0.26	46	0.05	80	2.4
79.1	0.21	38	0.04	70	2.2

[a]Equal to $(r_{heme} + r_{CO})(r_{heme} + r_{CO}^S)/r_{heme}r_{CO}^S$ in eq. 11.
[b]Fraction of total surface area for reaction on heme. Compares to a calculated value of 0.05.
[c]Half cone angle of constraint for ligand entry.
[d]Target radius. Compares to $r_{CO} \simeq 1.8$ Å.[2]

KUMARDEV BOSE and KIRON K. KUNDU. Can. J. Chem. **55**, 3961 (1977).

Free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer at 25°C of the nonelectrolyte *p*-nitroaniline from water to various alcohol + water mixtures have been determined from solubility measurements at seven temperatures from 10–40°C. Increasing specific solute–solvent interactions have been proposed to interpret the nature of the ΔG_t^0-composition profiles and the enhanced structure of water in the water-rich mixed solvents has been correlated with maxima in the ΔS_t^0-composition profiles. The effectiveness of *p*-nitroaniline as a useful probe for studying solvent structure has been pointed out.

KUMARDEV BOSE et KIRON K. KUNDU. Can. J. Chem. **55**, 3961 (1977).

On a déterminé les énergies libres (ΔG_t^0) et les entropies (ΔS_t^0) de transfert à 25°C du nonélectrolyte *p*-nitroaniline de l'eau vers divers mélanges d'alcool + de l'eau; ces valeurs ont été déterminées à partir de mesures de solubilité à sept températures entre 10–40°C. On a proposé une augmentation spécifique des interactions soluté–solvant pour interpréter la nature des profils ΔG_t^0 des compositions et l'on a pu effectuer une corrélation entre l'augmentation d'orientation de l'eau dans des solvants mixtes riches en eau et les maxima dans les profils ΔS_t^0 composition. On a mis en évidence l'efficacité de la *p*-nitroaniline comme sonde utile pour étudier la structure de solvants.

[Traduit par le journal]

Introduction

From the study of a wide variety of processes in aqueous mixtures of simple monohydric alcohols (1–3), it is now a fairly well-established fact that small amounts of alcohols strengthen the three-dimensional structure of liquid water. In terms of Frank and Wen's "flickering clusters" (4), the average lifetime of such bulky ice-like clusters is extended; in other words, the equilibrium, bulky "icebergs" ↔ monomeric water, existing in pure water is shifted to the left in water-rich aquo-alcoholic mixtures.

The thermodynamic quantities, specifically the enthalpy and the entropy, of transfer of quite a number of inert nonelectrolytes have been used to glean structural information in aquo-organic mixtures (5–7). The determination of these transfer parameters is very simple, being obtainable from heat of solution and/or solubility data at different temperatures. These observations support the findings obtained by use of more direct techniques like nmr spectroscopy (8), ultrasonic absorption and relaxation (9), and X-ray diffraction (10), and may prove to be as valuable and as reliable probes to solvent-structure studies as any of the more sophisticated methods.

Recently, interpretation of entropies of transfer of hydrogen halides in terms of solvent structure has been attempted for a few solvent systems, notably ethylene glycol + water (11*a*,*b*), urea + water (11*c*), *tert*-butyl alcohol + water (12*a*), propan-2-ol + water (12*b*–*e*), and ethanol + water (12*c*–*e*). The ionic entropies of transfer obtained (11*b*) or guessed (11*c*) therefrom have proved useful but electrostatic contributions necessarily confuse the issue. In this regard, neutral nonelectrolytes should be better suited as structural probes. Furthermore, as pointed out by Arnett (5), the entropy, rather than the enthalpy, of transfer of these species should be considered to reflect structural features more accurately.

In this study the solute chosen by us is *p*-nitroaniline (*p*NA). Although it cannot accurately be called a nonelectrolyte, *p*NA, having a predominant resonance contribution from a zwitterionic structure (see Discussion), has an appropriately low solubility in alcohol + water solvents, yet a high enough optical molar extinction coefficient at 380 nm to be determined accurately by spectrophotometry. Saturated solubilities of *p*NA in water and in aqueous

[1]Author to whom correspondence should be addressed.
[2]Revision received July 13, 1977.

mixtures of methanol, ethanol, isopropanol, and *tert*-butyl alcohol were measured at seven equidistant temperatures ranging from 10 to 40°C and the free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer from water to the mixed solvents were obtained therefrom.

Experimental

The alcohols were purified by standard methods (13). The water used was distilled in an all-glass apparatus after prior de-ionization and distillation with alkaline permanganate. The *p*NA (Riedel) was recrystallized twice from 95% ethanol and dried *in vacuo*. The mixed solvents were prepared by mixing weighed quantities of alcohol and water. The aqueous mixtures of methanol and ethanol contained 10, 20, 30, 50, and 70% while those of isopropanol and *tert*-butyl alcohol contained 10, 20, 30, and 50% by weight of alcohol. The measurement of solubilities at each temperature in the various solvents was essentially similar to that described previously for ethylene glycol + water (14*a*) and methanol + propylene glycol mixtures (14*b*) at 25°C. In order to restrict the absorbance values within the range 0.100–0.800 the saturated solutions were diluted (200–5000 times) with water. Optical absorbances of the diluted solutions were measured by a Beckmann DU model G 2400 spectrophotometer at 380 nm. The molar extinction coefficient of *p*NA in water was taken to be 12 800 (15). Saturation at a given temperature was attained in all solvents within 7–10 days. The error in measuring solubility was about ±2%.

Results

Molar solubilities (S_s) of *p*NA in the aquo-alcoholic solvents as well as in pure water at different temperatures, expressed as $-\log S_s$ are available elsewhere.[3] The free energies of solution (ΔG_s^0) on the molar scale were calculated for each solvent using [1]

$$[1] \qquad \Delta G_s^0 = -RT \ln S_s$$

and fitted by the method of least squares to an equation of the form

$$[2] \qquad \Delta G_s^0 = a_s + b_s T + c_s T \ln T$$

where T is the absolute temperature. The values of the coefficients a_s, b_s, and c_s are listed in Table 1. The free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer at 25°C were calculated using [3] and [4]

$$[3] \quad \Delta G_t^0 = (a_s - a_w) + (b_s - b_w)T_0 + (c_s - c_w)T_0 \ln T_0$$

$$[4] \quad \Delta S_t^0 = -[(b_s - b_w) + (c_s - c_w) + (c_s - c_w) \ln T_0]$$

where $T_0 = 298.15$ K, and the subscript w indicates quantities for water. ΔG_t^0 and ΔS_t^0 values are given in Table 1; the maximum uncertainties in these quantities as calculated by Please's method (16) are ±0.06 kJ mol^{-1} and ±4.0 J K^{-1} mol^{-1} respectively.

Discussion

As seen from Fig. 1, ΔG_t^0 for *p*NA decreases as the proportion of alcohol in the solvent increases, while ΔS_t^0 passes through a maximum for all alcohols. Since the *p*NA molecule is a resonance hybrid and the most important contributor is the zwitterionic form

the observed behaviour will be dictated by the solvation of the hydrocarbon nucleus as well as of the charged ends relative to their solvation in pure water.

It has been observed by various workers (1, 5, 11, 17) that entropies of transfer of various electrolytes, polar nonelectrolytes, and neutral nonelectrolytes pass through maxima at certain critical compositions of alcohol + water mixtures. In our recent papers (12) we have attempted to explain the ΔS_t^0 values for hydrogen halides in these mixtures in terms of a four-step mechanism proposed earlier (11*a–c*). Lately, this approach has been rationalized by a semi-quantitative treatment of the transfer process (12*e*). The same approach may be used, with some modifications, to deal with the present problem concerning ΔS_t^0's of *p*NA. As will be shown, the same formulation of the process provides a satisfactory interpretation of ΔG_t^0 as well.

The hydrophobic effect (18, 19) of the aromatic nucleus in *p*NA is a characteristic feature of all such solutes possessing a bulky organic group and provides the key to the understanding of the problem. It has been suggested by Parker and co-workers (20) that water molecules around a hydrophobic solute form a hydrogen-bonded network among themselves and the formation of such a highly ordered surface or 'skin' contributes appreciably to the ΔS_t^0 of the solute.

The model we adopt for discussion of the solvated state of the *p*NA molecule is shown in Fig. 2. The general amphiphilic solute molecule

[3] Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

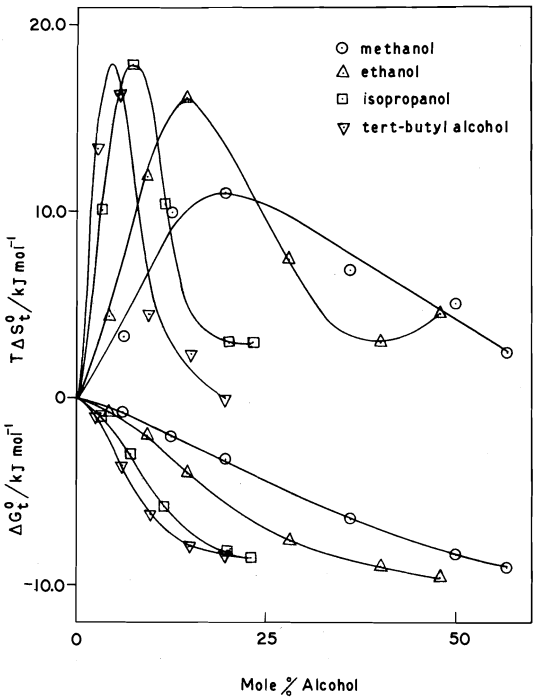

FIG. 1. Variation of ΔG_t^0 and $T\Delta S_t^0$ of *p*-nitroaniline at 25°C on the molar scale with alcohol mole percent.

M is represented by R (X_1,X_2...), where R is the hydrophobic moiety and X_1,X_2... are hydrophilic groups capable of undergoing hydrogen-bonded interactions with water or any other suitable solvent. In pure water as well as in a mixed aqueous solvent, M is enclosed by the hydrophobically created skin and X_1,X_2... enter into hydrogen-bonding with water or cosolvent molecules at the skin surface. If the cosolvent is an amphiphilic molecule R′Z (R′ = hydrophobic part, Z = hydrophilic part), in the mixed solvent R′Z molecules may enter the cavity and participate in two types of interactions: (*i*) dispersion interaction between R′ and R, (*ii*) hydrogen-bonded interaction between Z and the skin surface. Collectively, these interactions may be called 'buffer bonds', as the R′Z molecule acts as a buffer, so to speak, between the R group and the skin.

The transfer of the molecule M from water to the mixed solvent, i.e. from state (*a*) to state (*b*) (Fig. 2) may be considered to take place in four successive steps: (*1*) rupture of the H-bonds between X_1,X_2... and the skin surface, followed by the removal of M from the cavity; (*2*) collapse of the skin to form normal water structure; (*3*)

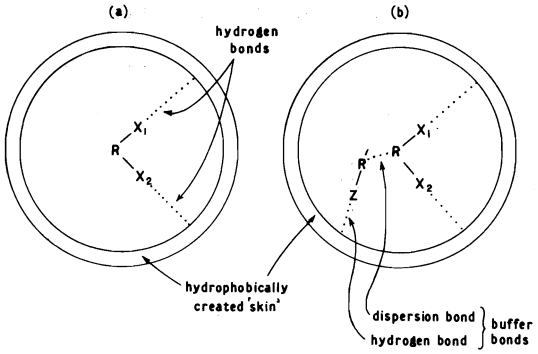

FIG. 2. An amphiphilic molecule in (*a*) water, (*b*) mixed aqueous solvent. In the transfer process, (*a*) is the initial state and (*b*) is the final state.

creation of a suitable cavity inside the mixed solvent; (*4*) introduction of M into the solvent cavity and formation of buffer bonds.

The change of any standard thermodynamic function X^0 (free energy, enthalpy, heat capacity, etc.) in the overall process will then be given by

$$[5] \qquad \Delta X_t^0 = \sum_{i=1}^{4} \Delta X_i$$

with

$$[6a] \qquad \Delta X_1 = -\Delta X_{HB}{}^w$$

$$[6b] \qquad \Delta X_2 = X_b{}^w - X_a{}^w$$

$$[6c] \qquad \Delta X_3 = X_a{}^s - X_b{}^s$$

$$[6d] \qquad \Delta X_4 = \Delta X_{HB}{}^s + \Delta X_{BB}$$

where the subscripts a and b respectively signify states of solvent molecules in the 'skin phase' and in the 'bulk phase', the superscripts w and s refer to pure water and mixed solvent respectively, and ΔX_{HB} and ΔX_{BB} are the thermodynamic functions of formation of the total number of hydrogen bonds and buffer bonds respectively.

Combining [6*a*]–[6*d*] with [5], we get

$$[7] \quad \Delta X_t^0 = (X_a{}^s - X_a{}^w) + (X_b{}^w - X_b{}^s) + (\Delta X_{HB}{}^s - \Delta X_{HB}{}^w) + \Delta X_{BB}$$

This equation is quite general and may be used to predict the behaviour of ΔX_t^0 for any amphiphilic solute in aquo-organic solvents. In the present case where M = *p*NA and the cosolvent is an alcohol R′OH, the analysis of ΔG_t^0 and ΔS_t^0 in terms of [7] is as follows.

Free Energies of Transfer

The skin phase is a more compact and more stable structure in pure water than in a mixed solvent, because steric inhibition (by R′) and fewer H-bonding sites in R′OH discourage strong solvent–solvent interactions when R′OH is present in that phase. With the increasing addition of R′OH, the skin phase becomes more and more loosely bound, which means that the term $(G_a{}^s - G_a{}^w)$ is increasingly positive. In the mixed solvent as compared to water, the strength of individual H-bonds in the bulk phase increases while their total number decreases (17). Consequently, the change in the total interaction energy in the bulk solvent with increasing proportions of alcohol should be small, i.e. the term $(G_b{}^w - G_b{}^s)$ is small, whatever its sign may be, at least when the alcohol content is not too high.

The term $(\Delta G_{HB}{}^s - \Delta G_{HB}{}^w)$ relates to the H-bonding interactions of the NH_2 and NO_2 groups with the skin surface. The positively charged NH_2 group is likely to be solvated preferentially by the more 'basic' alcohol molecules and the negatively charged NO_2 group by the more 'acidic' water molecules (21). Thus, out of the four H-bonds formed, two are progressively strengthened and two weakened with increasing proportions of R′OH. It follows that the value of $(\Delta G_{HB}{}^s - \Delta G_{HB}{}^w)$ should remain approximately zero with changing solvent composition.

With increasing alcohol content, dispersion interactions between R′ and the hydrocarbon nucleus of *p*NA grow increasingly strong causing ΔG_{BB} to assume increasingly large negative values.

The sharp fall of ΔG_t^0 in water-rich compositions arises from the predominance of ΔG_{BB} over the other terms in these regions. With further amounts of added alcohol, dispersion interactions reach saturation and the term $(G_a{}^s - G_a{}^w)$ becomes sufficiently large to cause a flattening out of the ΔG_t^0 curve, as observed. The observed order in $|\Delta G_t^0|$: *tert*-butyl alcohol > isopropanol > ethanol > methanol, is a consequence of the increasing strength of dispersion interactions with increasing size of R′.

Entropies of Transfer

For reasons cited above, the skin phase is a more ordered region in pure water than in a mixed solvent, hence $(S_a{}^s - S_a{}^w)$ is a positive quantity which increases in magnitude with increasing alcohol mole percent.

Small quantities of alcohol are known to extend and reinforce the hydrogen-bonded three-

dimensional structure of water (17). The 'supernormal' structure in water-rich compositions is rapidly broken up by further addition of alcohol, with the commencement of formation of alcohol–water H-bonded associates, the so-called two-dimensional structure (17). In the region where the supernormal structure is being built up, order is being created in the bulk solvent and $(S_b^w - S_b^s)$ is increasingly positive. In the region of structural collapse and destruction of bulk order, the positive value of this term decreases. This means that $(S_b^w - S_b^s)$ should pass through a maximum at the point of maximum structure promotion.

The third term at [7], $(\Delta S_{HB}^s - \Delta S_{HB}^w)$, is even less important than the corresponding free energy term, since the change in configuration and disposition of the H-bonds formed by the NH_2 and the NO_2 group is hardly significant to cause appreciable changes in entropy.

The formation of buffer bonds in the mixed solvent leads to an ordering effect of a kind which slightly increases with increasing alcohol content; ΔS_{BB} is thus increasingly negative, although the increase is slow.

In water-rich compositions of alcohol + water mixtures, the behaviour of ΔS_t^0 ought to be guided almost exclusively by the bulk structure term $(S_b^w - S_b^s)$ since the opposing smaller effects of the skin phase term $(S_a^s - S_a^w)$ and the buffer-bond term are likely to neutralize each other. At higher alcohol contents, where these terms are of comparable magnitude, the observed ΔS_t^0 contains a significant contribution from each. Since the bulk structure term first increases and then decreases, the appearance of a maximum near the region of maximum solvent structuredness is an expected feature of the ΔS_t^0 curves in alcohol + water mixtures.

The position, height, and sharpness of the maximum depends on the structure-forming propensity of the alcohol concerned. Indeed, as Fig. 1 shows, ΔS_t^0 for *tert*-butyl alcohol not only reaches the highest maximum and reaches it the earliest, but also falls away the most rapidly. This is because, of all the hydrocarbon groups (R′), the *tert*-butyl group is the largest and hence the most effective in promoting water structure. As R′ decreases in size, the maximum shifts towards higher alcohol mole percents, becoming shorter and broader at the same time, till at methanol, it is only a smooth hump. The maximum appears for *tert*-butyl alcohol at 0.04, for isopropanol at 0.07, for ethanol at 0.15, and for methanol at 0.20 mole fraction of alcohol. These positions agree more or less with those obtained from other studies (1) and seem to represent the solvent composition at which the highest degree of water structure prevails.

It may be questioned whether it is justified to ignore the effect of simple electrostatic solvation in our discussion, since *p*NA has a predominantly zwitterionic structure. In mixed solvents having dielectric constants less than that of water, the electrostatic contributions to ΔG_t^0 and ΔS_t^0 of a pair of ions, as estimated tentatively by the Born equation, may be shown (12) to have positive and negative values respectively. This would mean that after correcting for this effect, ΔG_t^0 values will become more negative and ΔS_t^0 values more positive, while their essential behaviour remains unaltered, and the present model still explains the observed trends satisfactorily.

The infrared carbonyl stretching frequencies of acyl-substituted *p*-tolyl, phenyl, and *p*-chlorophenyl benzoates, $XC_6H_4COOC_6H_4Y$, have been determined in carbon tetrachloride. Each of the substituted phenols generated an independent $\bar{\nu}$–σ plot which was correlated precisely with the Hammett equation (r = 0.999–0.998). The values of ρ_X so obtained show no tendency to vary with the structure of the parent phenol and are all within $\pm$0.202 of the mean value of 13.899. Similar correlations were obtained with the Hammett plots made by varying the aryl moieties of the esters while holding the acyl portions constant. For the four sets (**4**–**8**) studied, the mean value of ρ_Y is 8.964 $\pm$ 0.266. Using the slopes of $\bar{\nu}_{C=O}$ vs. σ correlations in the series studied, the transmissive factor for the ether bridge in carbon tetrachloride was calculated (π' = 0.64). An expression relating substituents in both acyl and aryl moieties to the monosubstituted compounds suggests that substituents on the two different groups act reasonably independently of each other; $\Delta\bar{\nu}_{XY} = 1.021\ (\pm 0.031)\ (\Delta\bar{\nu}_X + \Delta\bar{\nu}_Y) - 0.44\ (\pm 0.254)$. For all esters studied the equation $\bar{\nu}_{XY} = 127.215\ (\pm 1.444)\ ((\sigma_X/\rho_Y) + (\sigma_Y/\rho_X)) + 1734.9\ (\pm 0.078)$ was found to hold with r = 0.998.

AHMAD SAMI SHAWALI et NAMEK FARAHAT EWEISS. Can. J. Chem. **55**, 3967 (1977).

On a déterminé, dans le tétrachlorure de carbone, les fréquences d'élongation du carbonyle dans l'infrarouge de benzoates de *p*-tolyle, de phényle et de *p*-chlorophényle, substitués dans la portion acyle, $XC_6H_4COOC_6H_4Y$. Chacun des phénols substitués génère une courbe $\bar{\nu}/\sigma$ indépendante qui présente une corrélation précise avec l'équation de Hammett (r = 0.999–0.998). Les valeurs de ρ_X ainsi obtenues ne présentent aucune tendance de variation avec la structure du phénol de base et sont toutes à l'intérieur de $\pm$0.202 de la valeur moyenne de 13.899. On a pu obtenir des corrélations semblables avec les courbes de Hammett en faisant varier la portion arylée des esters et en maintenant les portions acylées constantes. Pour les quatre séries (**4**–**8**) étudiées, la valeur moyenne de ρ_Y est de 8.964 $\pm$ 0.266. Utilisant les pentes de $\bar{\nu}_{C=O}$ vs. σ dans les séries étudiées, le facteur de transmission du pont éthéré dans le tétrachlorure de carbone a pu être calculé (π' = 0.64). Une expression reliant les substituants à la fois des portions acylés et arylés avec les composés monosubstitués suggère que les substituants sur les deux groupes différents agissent d'une façon raisonablement indépendante l'un de l'autre $\Delta\bar{\nu}_{XY} = 1.021\ (\pm 0.031)\ (\Delta\bar{\nu}_X + \Delta\bar{\nu}_Y) - 0.44\ (\pm 0.254)$. Pour tous les éthers étudiés l'équation: $\bar{\nu}_{XY} = 127.215\ (\pm 1.444)\ ((\sigma_X/\rho_Y) + \sigma_Y/\rho_X)) + 1734.9\ (\pm 0.078)$ est suivie avec r = 0.998.

[Traduit par le journal]

Linear correlation of the infrared group frequencies in *meta*- and *para*-substituted benzene derivatives with the Hammett σ constant have been reported by several workers (1). The relation is usually expressed by a Hammett-type equation,

$$[1] \qquad \bar{\nu} = \rho\sigma + \bar{\nu}_0$$

A survey of literature indicates that the sensitivity, as measured by ρ, of the group frequency to substituents in structurally related compounds seems to exhibit little, if any, change with the structure of the parent compounds. For example, the values of ρ reported for ethyl benzoates (2) and acetophenones (3) in carbon tetrachloride are 14.81 and 15.9, respectively. To shed more light on this problem, the carbonyl stretching frequencies of phenyl benzoates (**1**–**8**), which were substituted in both the acyl and aryl moieties, were determined in carbon tetrachloride. Each aryl derivative was used to generate an independent Hammett plot by systematic substitutions on the acyl groups. The present infrared investigation was also undertaken to obtain quantitative information pertinent to the effectiveness of the transmission of electronic

effects through the ether bridge, and to examine the effects of multisubstitution.

Results and Discussion

The Effect of Substituents on the Acyl Moiety

The carbonyl stretching frequencies (cm^{-1}) obtained for the esters studied in carbon tetrachloride are listed in Table 1. As can be seen in the table, electron attracting groups shift the absorption band to higher frequency values (cm^{-1}), as compared with the unsubstituted compound, in the three series (**1–3**) studied. An opposite shift is observed in the compounds with substituents that supply electrons. The values of $\bar{\nu}_{C=O}$ (cm^{-1}) have been correlated with the σ constants as taken from Ritchie and Sager (4). A computer program was written to carry out the least-squares and statistical treatment of the data with the σ constants according to the method of Jaffe (5). The results of the computation for the three series of esters are given in Table 2. It is obvious that there is no apparent tendency of the ρ values to vary as the pK_a of the phenol changes. All of the ρ values are within one standard deviation from the mean value of 13.899. The ρ value of ~13.90 obtained for phenyl benzoates should be compared with the value of 14.81 obtained from a similar study on ethyl benzoates (2). The ratio of these ρ values, being close to unity, further substantiates the foregoing conclusion that the value of ρ appears to be independent of the nature of the alcohol portion of the ester molecule.

In order to get a further estimate of the relative importance of resonance (*R*) and field (*F*) effects, the treatment reported by Swain and Lupton (6) has been employed using the equation

$$[2] \qquad \bar{\nu} = \alpha F + \beta R + \bar{\nu}_0$$

where α and β represent the sensitivity of C=O stretching frequency to the field and resonance effects, respectively. The equation that fits the data for phenyl benzoates, **1**, is

$$\bar{\nu} = 7.76(\pm 0.344)F + 14.518(\pm 0.688)R + 1735.225; \quad r = 0.999$$

The value for the resonance contribution, % *R*, to the correlation is ca. 45 (7).[2] Comparison of this value with that reported for benzophenones (% *R* = 43) (3) indicates that sensitivity of the carbonyl stretching frequencies to resonance effects in these two series of compounds is approximately the same.

The Effect of Substituents on the Aryl Moiety

In 1960, Freedman (7) observed that the C=O stretching frequencies of aryl acetates failed to correlate with σ for the *para*-substituents. To explain this behaviour, he concluded that the frequency was dependent only on the inductive component of σ. In 1973, Cohen and Takahashi (8) determined the absorption frequencies of the C=O group in a series of 48 mono- and polysubstituted phenyl hydrocinnamates in CCl_4, and found the values to correlate well with σ^0 (or $\Sigma\sigma^0$) constants for the ring substituents. They concluded that the carbonyl frequency is thus dependent on the electronic effects (inductive and resonance) that the substituent group would exercise on the C-1 bearing the acyloxy group. More recently, do Amaral and do Amaral (9) observed that the values of the carbonyl group absorption frequencies for three series of phenyl esters of allylacetic, diphenylacetic, and allyldiphenylacetic acids in CCl_4 are satisfactorily correlated with σ as well as σ^0 constants.

In the present study, the application of Hammett's equation for the carbonyl group absorption frequencies of the four sets of aryl benzoates, **4** to **7**, using σ as well as σ'' and σ^0 constants was tried. Values of σ, σ'', and σ^0 were taken from the compilation of Ritchie and Sager (4). The results of the statistical analysis of the data by the least-squares method are given in Table 3. It can be seen that for a given set of esters the values of ρ, ρ'', and ρ^0 are in very close agreement, and that the values of the correlation coefficients do not permit a judgement as to

[2]Percent resonance contribution was calculated as indicated in ref. 6; ϕ and ψ were calculated internally, based upon the number of points used in the correlation.

Series	Best-fit linear equation	r	S_ρ[b]	S_i[b]	n
1	$\bar{\nu}=13.703\sigma+1734.98$	0.998	0.395	0.177	7
2	$\bar{\nu}=13.803\sigma+1733.23$	0.999	0.316	0.161	5
3	$\bar{\nu}=14.191\sigma+1736.90$	0.999	0.134	0.065	5

[a]Hammett's ρ value is dimensionless. In this work it has the dimension of cm^{-1} as is common in the literature in spectroscopic comparison.
[b]Standard deviations in the slope (S_ρ) and intercept (S_i).

which one of the σ value series our results fit best. This probably results from the fact that the values of σ, σ^n, and σ^0 for the substituents examined are so similar that a statistically valid distinction becomes impossible. The mean values of ρ, ρ^n, and ρ^0 for the four sets of esters are 8.966, 9.274, and 8.836 and the mean standard errors are ±0.266, ±0.674, and ±0.473, respectively.

These data also show that the ρ value appears to be insensitive to the nature of the acyl portion of the esters over the range studied. This result is in accord with the finding of Kirsch *et al.* (10) that the values of ρ obtained for the rates of alkaline hydrolysis of acyl-substituted *p*-nitrophenyl, *m*-nitrophenyl, *p*-chlorophenyl, phenyl, and *p*-tolyl benzoates show no tendency either to increase or decrease with the intrinsic reactivity of the parent phenol. All values are within ±0.040 of the mean of 2.021.

A comparison of the results reported in Tables 2 and 3 reveals that the stretching frequency of the ester carbonyl group is more sensitive to substituent effects in the acyl portion than in the phenolic moiety. This greater sensitivity is obvious in terms of the vibrating CO group being one bond closer to the acyl substituent than it is to the phenol. Taft and Lewis (11) have shown,

TABLE 3. Correlation between the carbonyl frequencies (cm^{-1}) of substituted phenyl benzoates in CCl_4 and the Hammett substituent constants

empirically, from a consideration of substituent effects upon the dissociation constants of acids, that the transmission of electronic effects through saturated atoms falls off according to the equation $\rho \simeq (2.8 + 0.5)^{1-i}$, where i = the number of saturated atoms between the benzene ring and the reaction centre.

The correlation of the data for series **4** with F and R constants gave the relation

$$\bar{\nu}_4 = 5.450(\pm 0.515)F + 8.230(\pm 1.510)R + 1734.83(\pm 0.302)$$

and a value of 34% for the resonance contribution to the correlation was obtained. This value suggests that the ether bridge can transmit resonance effects.

Using the ρ values obtained for acyl-substituted phenyl benzoates and aryl-substituted phenyl benzoates (cf. Tables 2 and 3) we calculated the transmissive factor of the electronic effects for the ether bridge, π_0', from the equation

$$[3] \qquad \pi_0' = \rho_Y/\rho_X$$

where ρ_X and ρ_Y are the slopes of the $\Delta\bar{\nu}$ vs. σ_X and $\Delta\bar{\nu}$ vs. σ_Y linear free-energy relationships, respectively. The average value of π_0' obtained from the different series studied was found to be 63.97 ($\pm$2.358)%. This value is, within statistical limits, close to the value of 62% calculated from the reaction constants of alkaline hydrolysis of substituted phenyl benzoates (12).

Substitution in Acyl and Aryl Moieties

In an attempt to gain further information as to the influence of a substituent on the acyl group or of a substituent on the phenolic ring, the disubstituted phenyl benzoates in Table 1 were examined. If an acyl substituent has the same effect on the carbonyl frequency, regardless of the substituent on the aryl group, then a plot of the sum of $\Delta\bar{\nu}$ values for the two monosubstituted compounds vs. the $\Delta\bar{\nu}$ value for the corresponding disubstituted compound should give a linear relationship. Least-squares analysis of the data provides eq. 4, with correlation coefficient, $r = 0.995$.

$$[4] \quad \Delta\bar{\nu}_{XY} = 1.021(\pm 0.031) \sum (\Delta\bar{\nu}_X + \Delta\bar{\nu}_Y) - 0.44(\pm 0.0254)$$

The good correlation obtained (Fig. 1) suggests that substituents on the phenolic ring influence the carbonyl stretching frequency in a manner which is reasonably independent of substituents on the benzoyl group and vice versa. This observation suggests, therefore, that the effect of substituents on the carbonyl stretch ing frequency of aryl aroate would be correlated by

$$[5] \qquad \Delta\bar{\nu}_{XY} = \rho_X\sigma_X + \rho_Y\sigma_Y$$

A similar equation was proposed by Jaffe (5) for compounds containing two substituted benzene rings that are not symmetrically placed with respect to the reaction site. To test the

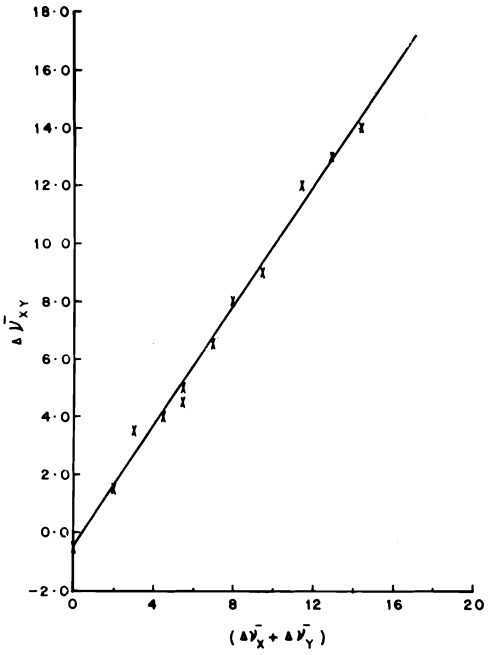

FIG. 1. Correlation of $\Delta\bar{\nu}_{XY}$ (cm^{-1}) for disubstituted phenyl benzoates with ($\Delta\bar{\nu}_X + \Delta\bar{\nu}_Y$) for the monsubstituted analogs.

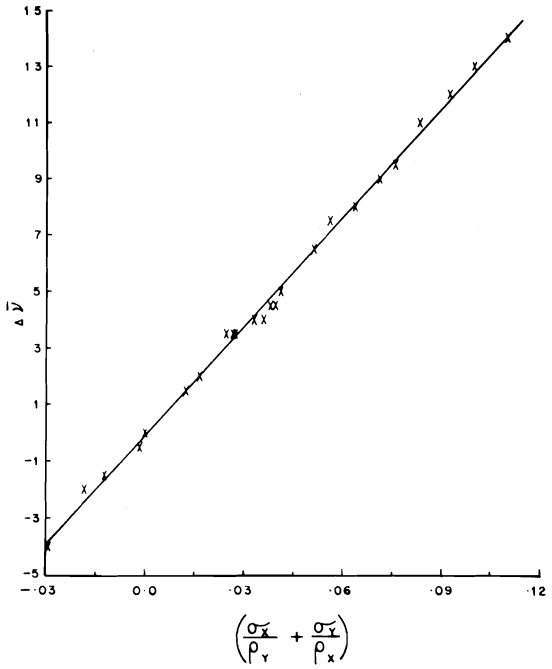

FIG. 2. Hammett plot of the carbonyl stretching frequency (cm^{-1}) versus the combined substituent effects for mono- and polysubstituted phenyl benzoates.

applicability of this equation, its linear form (eq. 6) was used.

$$[6] \qquad \Delta\bar{\nu}_{XY} = \rho_X\rho_Y\left(\frac{\sigma_X}{\rho_Y} + \frac{\sigma_Y}{\rho_X}\right)$$

In Fig. 2 are plotted the $\Delta\bar{\nu}$ values for the CO absorption (cm^{-1}) of the 25 compounds in the series studied as ordinate and the $(\sigma_X/\rho_Y) + (\sigma_Y/\rho_X)$ function as abscissa. It is seen that all mono- and disubstituted esters follow this Hammett relation closely. The equation of the straight line in Fig. 2,

$$\bar{\nu}_{XY} = 127.215(\pm 1.444)\left(\frac{\sigma_X}{\rho_Y} + \frac{\sigma_Y}{\rho_X}\right) - 1734.9(\pm 0.078)$$

(with correlation coefficient, r, of 0.998) can be used to predict the $\bar{\nu}_{C=O}$ stretching frequencies of other substituted phenyl benzoates.

Experimental

Materials

The substituted phenyl benzoates were generally prepared by the interaction of equivalent amounts of aroyl chloride and phenol in 10% sodium hydroxide solution or in pyridine while stirring as previously described (12). The products precipitated were collected by filtration, washed with 5% sodium carbonate solution, crystallized from ethanol until a constant melting point was obtained, and then dried over P_2O_5 in a vacuum desiccator. Table 1 lists the uncorrected melting points obtained with an electrothermal melting point apparatus (Gallenkamp 1A6301), and literature references for compounds prepared.

Infrared Frequencies

The ir stretching frequencies for all the esters were determined in spectral grade carbon tetrachloride using a Beckman IR-12 grating spectrometer operated in the expanded scale mode at a scan rate of 8 cm^{-1}/min, chart speed of 1 in./min, and period setting of 2. Calibration and paper alignment difficulties were minimized by recording the 1583.1 cm^{-1} polystyrene band on each spectrum. The carbonyl absorption band had a symmetric shape that simplified the determination of its position in the spectrum. The band frequencies were taken at the half-width of the half-height. All frequencies reported were obtained from averaging at least three different scans, all of which gave frequencies which were within 0.3 cm^{-1} of one another. The estimated relative error in frequencies is approximately 0.5 cm^{-1}.

Calculations

The least-squares treatment, the multiple regression analysis, and other statistical computations (5) were performed using a Hewlett-Packard calculator model 9830A.

Acknowledgments

We wish to thank Professor J. F. Ogilvie for

providing the computer program, and Mr. A. El-Moussa for assistance in recording the spectra.

Effect of an external electric field on the yield of trapped electrons in a γ-irradiated hydrocarbon glass

NORIYUKI KATO, TOYOAKI KIMURA, AND KENJI FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received May 9, 1977

NORIYUKI KATO, TOYOAKI KIMURA, and KENJI FUEKI. Can. J. Chem. **55**, 3973 (1977).

Trapped electron yields were measured by means of optical absorption spectroscopy for a hydrocarbon glass γ-irradiated at 77 K in the presence of an external electric field. It was observed that the yield of trapped electrons increased in the presence of an external electric field as compared with that in the absence of an external electric field. The experimental results were analyzed theoretically and interpreted as due to overall effects involving changes in geminate recombination times which were caused by an external electric field.

NORIYUKI KATO, TOYOAKI KIMURA et KENJI FUEKI. Can. J. Chem. **55**, 3973 (1977).

On a mesuré les rendements d'électrons piégés—en faisant appel à la spectroscopie d'absorption optique—dans un verre hydrocarboné irradié par des radiations γ à 77 K en présence d'un champ électrique externe. On a observé que le rendement des électrons piégés augmente en présence d'un champ électrique externe par comparaison avec l'absence d'un tel champ. On a analysé les résultats expérimentaux d'une façon théorique et on les a interprétés en fonction d'effects globaux impliquant des changements dans les temps de recombinaison géminale qui sont causés par un champ électrique externe.

[Traduit par le journal]

Introduction

The properties of trapped electrons in organic glasses at low temperatures have extensively been investigated in the last decade (1–3). It is now well established that trapped electrons can be produced with significant yields in γ-irradiated organic glasses. Trapped electron yields produced in γ-irradiated nonpolar hydrocarbon glasses at 77 K were reported by several investigators (4–10). The largest yield of trapped electrons (e_t^-) in γ-irradiated hydrocarbon glasses was obtained for 2-methylpentane (2MP) glass in which $G(e_t^-)$ was reported to be 1.1 at 77 K (10).

The effect of an external electric field on the yield of trapped electrons in a γ-irradiated 2MP glass at 77 K was first observed in the present work. By applying high voltages during γ-irradiation, the yield of trapped electrons produced in 2MP glass was increased almost linearly with increasing external electric field strength under our experimental conditions. In order to interpret the experimental results, we have calculated theoretically the yield of trapped electrons in the presence of an external electric field by applying the Nernst–Einstein relation to the motion of thermalized electrons in the Coulombic field and assuming a modified exponential distribution function for thermalized electrons.

Experimental

2-Methylpentane was used as a hydrocarbon matrix which forms a clear glass at 77 K and yields the most trapped electrons among hydrocarbon matrices reported hitherto. Tokyo Kagaku Seiki standard pure 2MP was dried over calcium hydride and purified with freshly activated molecular sieve (13X 1/16) pellets in vacuum. The sample preparation was carried out by distilling purified solvent into a quartz cell on a vacuum line. The cell was of a rectangular type (10 mm × 20 mm) with Suprasil windows and two stainless steel mesh electrodes separated by 1 mm from each other. A Fluke Model 410B power supply was used to apply a high voltage between the electrodes during γ-irradiation. The sample was γ-irradiated at 77 K at a dose rate of 4.5×10^5 rad h^{-1} to a dose of 1.5×10^5 rad. The range of external electric field strengths was 10–80 kV cm^{-1}. The relative yield of trapped electrons at 77 K was determined by optical absorption measurements with a Hitachi Model 323 recording spectrophotometer; the analyzing light was passed through the cell in the direction perpendicular to the electrode plane and the bleaching light from a slide projector was passed through the cell in the direction parallel to the electrode plane. The optical absorption measurements were made in such a way that the optical absorption of trapped electrons at 1700 nm was measured 5 min after the termination of γ-irradiation.

Results and Discussion

The experimental results are given in Figs. 1 and 2. Figure 1 shows optical absorption spectra of trapped electrons produced in 2MP glass γ-irradiated at 77 K in the absence (curve *1*) and

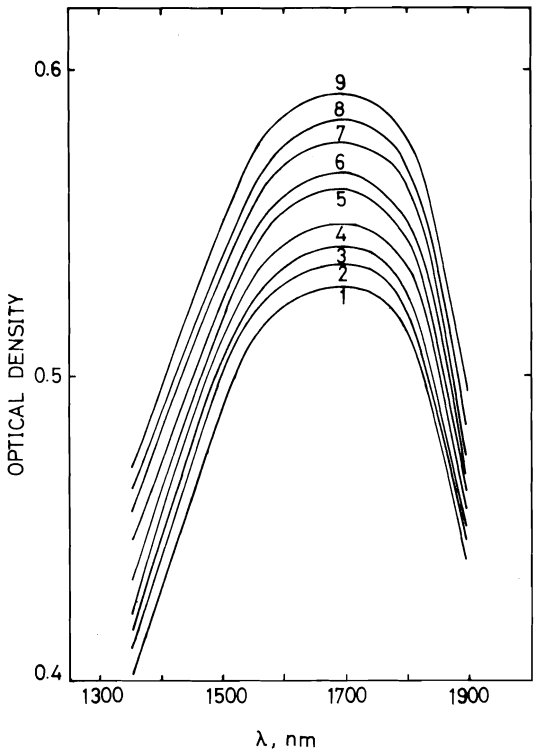

FIG. 1. Optical absorption spectra of trapped electrons in 2-methylpentane glass γ-irradiated at 77 K in the presence and absence of an external electric field: *1*, $E = 0$; *2–9*, $E = 10$, 20, 30, 40, 50, 60, 70, and 80 kV/cm, respectively.

presence (curves *2–9*) of an external electric field. It can be seen in Fig. 1 that the optical absorption increases in intensity with increasing applied voltage, but the shape and position of the absorption spectra remain essentially the same. Figure 2 shows the optical density ratio, OD^E/OD^0, plotted against the applied electric field, E. Here OD^E and OD^0 are, respectively, the optical densities at 1700 nm of the trapped electron absorption observed for the samples γ-irradiated in the presence and absence of an external electric field. The experiments were repeated several times at each applied field. As a result, it was found that the values of OD^E/OD^0 given in the present paper were somewhat smaller than those in the previous communication (11). The values of OD^E/OD^0 represented by vertical bars in Fig. 2 indicate the range of reproducibility in the experiments.

Our theoretical analysis of the experimental results is based on an estimation of changes in recombination times of thermalized electrons by

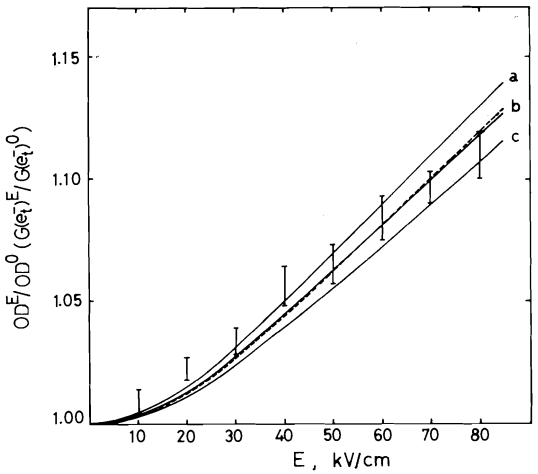

FIG. 2. Plots of observed OD^E/OD^0 at 1700 nm and calculated $G(e_t^-)^E/G(e_t^-)^0$ versus applied electric field strength: (—) $n = 1.0$: $b = 75$ (a), 72 (b), and 70 (c) Å; (---) $n = 0.1$: $b = 55$ Å.

the presence of an external electric field which would affect the efficiency of electron trapping in the matrix. Figure 3 shows the potential energy, $U(r)$, of an electron versus the separation distance, r, between a positive ion and an electron. The potential energy in the presence of an external electric field is given by eq. 1.

$$[1] \qquad U(r) = (-e^2/\varepsilon r) + eEr\cos\theta$$

Here e is the electronic charge, ε the dielectric constant of the matrix, E the applied field strength, and θ the angle between the direction joining the electron to the positive ion and that

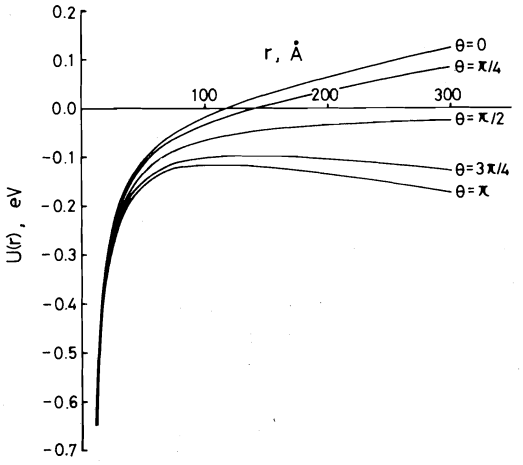

FIG. 3. Potential energy curves of an electron in the presence of an external electric field. $E = 50$ kV/cm; $\varepsilon = 2.2$.

of the external electric field. Figure 3 illustrates the potential energy curves for several values of θ at $E = 50$ kV cm^{-1}. The curve for $\theta = \pi/2$ is identical to that in the absence of an external electric field. The potential energy increases monotonously with increasing separation distance for $0 \leqq \theta \leqq \pi/2$, and it goes through a maximum for $\pi/2 \leqq \theta \leqq \pi$, where the distance, r_m, at which the potential energy is maximum, depends on θ. The recombination times, τ_1 and τ_2, of thermalized electrons with positive ions can be calculated separately in the two regions of potential energies corresponding to $0 \leqq \theta \leqq \pi/2$ and $\pi/2 \leqq \theta \leqq \pi$, respectively. The motion of thermalized electrons at 77 K can be described to a good approximation by the Nernst–Einstein relation, neglecting the random diffusion of electrons due to their thermal motion. The Nernst–Einstein relation is given by eq. 2.

$$[2] \qquad \frac{\partial r/\partial t}{-\partial U(r)/\partial r} = \frac{D}{kT}$$

where D, k, and T are the diffusion constant of an electron, Boltzmann's constant, and the absolute temperature, respectively. The diffusion constant is related to the electron mobility, μ, by $D = kT\mu/e$. The value of μ was taken as 0.1 cm^2 V^{-1} s^{-1}, which was the measured electron mobility in 3-methylpentane glass at 77 K (12). Equation 3 gives $-\partial U(r)/\partial r$ under an external electric field.

$$[3] \qquad -\partial U(r)/\partial r = (-e^2/\varepsilon r^2) - eE\cos\theta$$

Substituting eq. 3 into eq. 2, we get

$$[4] \qquad \partial r/\partial t = (D/kT)[(-e^2/\varepsilon r^2) - eE\cos\theta]$$

The recombination time, τ, of the thermalized electron with the positive ion can be written as eq. 5 by integrating eq. 4.

$$[5] \qquad \tau = -\frac{kT\varepsilon}{De^2}\int_r^0 \frac{dr}{(1/r^2) + (\varepsilon E\cos\theta/e)} = -\frac{kT\varepsilon}{De^2}(e/\varepsilon E\cos\theta)\int_r^0 \left[1 - \frac{(e/\varepsilon E\cos\theta)}{(e/\varepsilon E\cos\theta) + r^2}\right] dr$$

Performing the integration of eq. 5, we get eqs. 6 and 7 for the two regions of θ, respectively.

$$[6] \qquad \tau_1 = \left(\frac{1}{Dr_c}\right)\left(\frac{e}{\varepsilon E\cos\theta}\right)[r - \sqrt{e/\varepsilon E\cos\theta}\,\tan^{-1}(\sqrt{\varepsilon E\cos\theta/e}\,r)] \qquad \text{for } 0 \leqq \theta \leqq \pi/2$$

$$[7] \qquad \tau_2 = \left(\frac{1}{Dr_c}\right)\left(\frac{e}{\varepsilon E\cos\theta}\right)\left[r + \tfrac{1}{2}\sqrt{-e/\varepsilon E\cos\theta}\,\ln\frac{\sqrt{-e/\varepsilon E\cos\theta} - r}{\sqrt{-e/\varepsilon E\cos\theta} + r}\right]$$
$$\text{for } \pi/2 \leqq \theta \leqq \pi,\ r \leqq r_m$$

where $r_c = e^2/\varepsilon kT$ ($\varepsilon = 2.2$). It is assumed that all the thermalized electrons at $\pi/2 \leqq \theta \leqq \pi$ and initial separation distances $r > r_m$ have escaped from the positive ion, since in this case $\partial U(r)/\partial r < 0$. Thus, the theoretical yield of trapped electrons in the presence of an external electric field can be expressed as

$$[8] \qquad G(e_t^-)^E = G_t\left[\int_0^{\pi/2}\int_0^{\infty} f(r)\{1 - \exp(-k_T\tau_1)\}2\pi\sin\theta\, d\theta\, r^2\, dr + \int_{\pi/2}^{\pi}\int_0^{r_m} f(r)\{1 - \exp(-k_1\tau_2)\}2\pi\sin\theta\, d\theta\, r^2\, dr + \int_{\pi/2}^{\pi}\int_{r_m}^{\infty} f(r)2\pi\sin\theta\, d\theta\, r^2\, dr\right]$$

where $r_m = \sqrt{-e/\varepsilon E\cos\theta}$; k_T represents the electron trapping rate, which was determined by equating the theoretical value of $G(e_t^-)^0$ in eq. 8 to the experimental value of $G(e_t^-)^0 = 1.1$ in the absence of an external electric field; G_t is the total yield of thermalized electrons. The value of G_t in hydrocarbon glasses is not known at present. Since the glass and the liquid are both disordered systems and the density of glasses is only slightly higher than that of liquids, electron energy loss processes, leading to ionization, in glasses would be similar to those in liquids. Therefore, it seems reasonable to assess the value of G_t in hydrocarbon glasses on the basis of the value of G_t in hydrocarbon liquids. Although the value of G_t in hydrocarbon liquids is not exactly known, it is considered to lie in the range 4–5 from several investigations (13–18). Thus, we have assumed $G_t = 4.2$ in the present calculations. This value is also close to the gas

phase value. $f(r)$ is the initial spacial distribution function of thermalized electrons. In the present calculations we have used a modified exponential distribution function (eq. 9).

$$[9] \quad f(r) = \frac{n+1}{4\pi n b r^2} \times [1 - \exp(-nr/b)] \exp(-r/b)$$

where b and n are adjustable parameters, and $\int_0^\infty f(r) 4\pi r^2 \, dr = 1$. This function behaves like a simple exponential distribution function $f(r) = (1/4\pi b r^2) \exp(-r/b)$ for large values of r, and the value of $4\pi r^2 f(r)$ becomes zero at $r \fallingdotseq 0$. The property of this function appears to be more realistic than that of the simple exponential distribution function at $r = 0$. Equation 9 reduces to the simple exponential distribution function for $n \to \infty$. The mean range, $\bar{r}$, of thermalized electrons can be derived from eq. 9 as

$$[10] \quad \bar{r} = \left(\frac{n+2}{n+1}\right) b$$

A number of studies have been made on the spacial distribution function of thermalized electrons in liquid hydrocarbons (19–22). Gaussian functions and exponential functions are the most representative types of electron distribution functions used in such studies. A one-parameter Gaussian function gives too low values for G_t when its parameter is adjusted so that the theoretical curves best fit the experimental curves for the electric field dependence of free ion yields (22). On the other hand, a one-parameter simple exponential function gives too high values for G_t (22). A Gaussian-power function gives better theoretical results, but still somewhat too low values for G_t (22). Our two-parameter modified exponential function can well account for the electric field dependence of free ion yields in several liquid hydrocarbons with reasonable values of G_t.[1] Thus, we have applied the modified exponential distribution function to thermalized electrons in a hydrocarbon glass.

The first term of eq. 8 represents the yield of trapped electrons arising from the region $0 \leqq \theta \leqq \pi/2$, and the second and third terms give the trapped electron yield from the region $\pi/2 \leqq \theta \leqq \pi$. It can be shown that the calculated relative yield of trapped electrons reproduces well the observed relative yield of trapped electrons at each applied field strength by using the two common parameters, b and n, of the electron distribution function.

[1]T. Kimura and K. Fueki. Unpublished results.

TABLE 1. Electron trapping rate and the mean range of the thermalized electron distribution in 2-methylpentane at 77 K

n	b (Å)	$\bar{r}$ (Å)	k_T (s^{-1})
1.0	75	113	3.2×10^9
1.0	72	108	3.6×10^9
1.0	70	105	4.0×10^9
0.1	55	105	3.9×10^9

Comparison of the calculated trapped electron yield with the experimental one is made in Fig. 2. The curves show the calculated $G(e_t^-)^E/G(e_t^-)^0$ plotted against the applied electric field, where $G(e_t^-)^E$ and $G(e_t^-)^0$ are the trapped electron yields in the presence and absence of an external electric field, respectively. The solid curves a, b, and c show the theoretical curves for $n = 1.0$ and for $b = 75$, 72, and 70 Å, respectively. The dashed curve was obtained for $n = 0.1$ and $b = 55$ Å. It can be seen from Fig. 2 that the calculated $G(e_t^-)^E/G(e_t^-)^0$ increases almost linearly with increasing applied field strength except at low field strengths, and this is in accord with the experimental results. The solid curve b and the dashed curve best fit the experimental data. Table 1 shows the calculated values of the mean range, $\bar{r}$, of the initial electron distribution and the electron trapping rate, k_T, determined so as to be consistent with the observed yield of trapped electrons. The average time required for electron trapping in 2MP glass may be given by $1/k_T$ which is $\sim 3 \times 10^{-10}$ s. The mean range, $\bar{r}$, is 100–110 Å for both values of $n = 1.0$ and 0.1. In a paramagnetic relaxation study of trapped electrons, Lin and Kevan (5) concluded that the average distance of trapped electrons from other paramagnetic species in 3-methylpentane glass at 77 K was greater than 130 Å. It should be noted, however, that the mean range obtained in the present work is associated with the initial distribution of thermalized electrons, while the trapped electron distribution as studied by paramagnetic relaxation is associated with the distribution of stably trapped electrons. Therefore, it is reasonable that our value of the electron range is somewhat less than that ob-

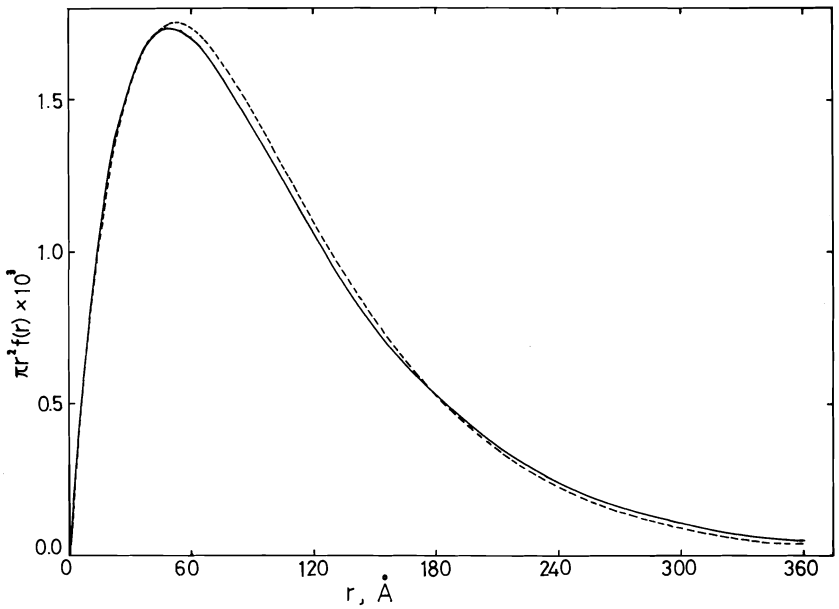

FIG. 4. Distribution functions of thermalized electrons: (—) $n = 1.0$, $b = 72$ Å, (---) $n = 0.1$, $b = 55$ Å.

tained by Lin and Kevan. It is interesting to note that the shape of the electron distribution function is almost the same, in spite of the large difference in the n values used. Figure 4 shows the electron distribution functions used to calculate the yield of trapped electrons which agree well with the experimental results, where the parameters $n = 1.0$ and $b = 72$ Å (solid curve) and $n = 0.1$ and $b = 55$ Å (dashed curve) are used. The close similarity of the electron distribution functions in Fig. 4 indicates that the electron distribution function obtained in the present calculation is appropriate for describing the spacial distribution of thermalized electrons within the framework of the modified exponential distribution function.

Received April 11, 1977

BERT FRASER-REID, NEVILLE LEWIS HOLDER, DAVID ROY HICKS, and DAVID LOUIS WALKER. Can. J. Chem. **55**, 3978 (1977).

The photochemically induced conjugate addition of simple alcohols to a variety of α-enones has been investigated. With hex-2-enopyranosid-4-uloses (**1**), the alkylations occur from the less-hindered side and are completely stereo- and regioselective. The resulting 1,4-ketoalcohols (**2**) are readily cyclized to α-cyclopropyl ketones which have been prepared by alternative, less desirable routes. Alkylative additions of hex-1-enopyran-3-uloses occur also although less readily and without stereospecificity, giving *C*-glycosides. 2-Cyclohexenone and carvone are also photoalkylated by methanol giving moderate yields of the 1,4-ketols. In the case of carvone, carvone camphor was not detected as a by-product. Steroidal α-enones and mesityl oxide both fail to be photoalkylated by methanol.

BERT FRASER-REID, NEVILLE LEWIS HOLDER, DAVID ROY HICKS et DAVID LOUIS WALKER. Can. J. Chem. **55**, 3978 (1977).

L'addition conjuguée photochimiquement induite d'alcools simples à une variété d'énones-α est étudiée. L'alkylation des hexéno-2 pyrannosiduloses-4 (**1**) a lieu sur le côté le moins encombré de la molécule et est complètement stéréo et régiosélective. Les cétoalcools-1,4 (**2**) résultants sont ensuite cyclisés en α-cyclopropyl cétones lesquelles ont été préparées par des routes moins désirables. L'addition par alkylation des hexéno-1 pyrannuloses-3 se produit aussi quoique moins facilement et sans stéréospécificité, conduisant à des *C*-glycosides. La cyclohexène one-2 et la carvone sont aussi photoalkylées par le méthanol conduisant avec un rendement moyen aux cétols-1,4. Dans le cas de la carvone, la carvone-camphre n'est pas détectée comme produit secondaire. Les énones-α dans la série des stéroïdes ainsi que l'oxyde de mésityle ne sont pas photoalkylés par le méthanol.

[Traduit par le journal]

The ready availability in recent years of carbohydrate α-enones (1) has prompted the use of these versatile compounds in a variety of syntheses (see for example ref. 2). Conjugate-addition–alkylation of these enones offers simple access to biologically important branched-chain sugars, and hence we undertook an examination of a number of such reactions (3). In an accompanying paper (4) we report our results on the stereochemical course of copper-induced addition of organometallic reagents to some carbohydrate enones. In this and the following paper (5) we describe the photoinduced addition of oxycarbinyl species to these enone receptors.

The photoinduced addition of alcohols to α-enones is not popular, although it dates back to 1957 when, in connection with a synthesis of terebic acid, Schenck *et al.* added isopropanol to maleic acid (6). The reaction has been of interest to photochemists (7) but prior to our own work (3) there was only one recorded investigation of its synthetic utility (8), and the results therefrom were not encouraging. In this and the accompanying paper (5), it will be shown that the photoalkylation reaction is a simple and highly promising method of carbon–carbon bond formation. Experiments to determine some mechanistic aspects of these reactions are currently underway and will be reported in the future.

Additions to Alkyl Hex-2-enopyranosid-4-uloses (1)

Photoalkylation was effected by irradiating the enones (**1**) derived from D-glucose in methanol[3] containing benzophenone at 350 nm. In the case of the keto alcohol **1***a*, a single 1,4-

[1]For preliminary accounts of this work see ref. 3.

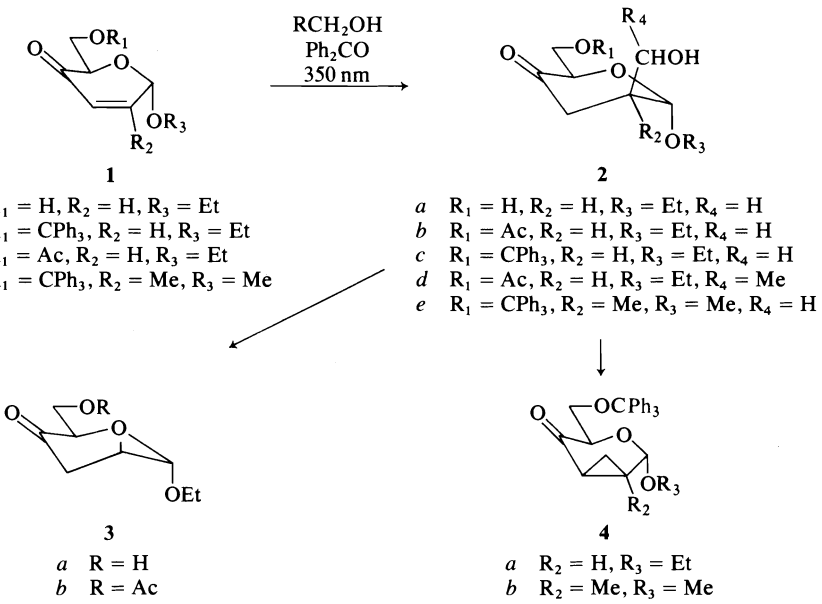
[3]For the addition of species other than methanol see the accompanying paper (5).



SCHEME 1

adduct, **2***a*, was isolated in 66% yield after chromatography. For characterization **2***a* was (*i*) acetylated and converted to the 2,4-dinitrophenylhydrazone, (*ii*) converted to a di-*p*-nitrobenzoate, and (*iii*) converted to a di-*O*-trityl derivative.

The tritylated (**1***b*) and acetylated (**1***c*) enones were similarly photoalkylated with methanol to give **2***c* (75% yield) and **2***b* (50% yield) respectively, and the adducts were readily correlated with those described in the preceding paragraph. In all cases there were variable amounts (5–16%) of carbohydrate-aromatic contaminants which were removed during the chromatographic separation.

Addition of ethanol to the enone acetate **1***c* gave a 50% yield of the adduct **2***d* which was characterized by formation of a crystalline derivative.

In order to correlate the stereochemistries of the products of photoalkylation with those obtained from cuprate additions (4), the primary alcohol in the adduct **2***b* was converted to a methyl group via tosylation, iodinolysis, and hydrogenolysis. The resulting acetate **3***b* was prepared alternatively by acetylation of the cuprate adduct **3***a* described in the accompanying paper (4).

Thus both modes of alkylation proceeded with the same stereoselectivity. However the ^{1}H nmr spectrum did not allow an unambiguous assignment of orientation. Thus in compound **2***a*, H-1 was located around 4.8 ppm with a coupling constant, $J_{12} \cong 4.0$ Hz. This value seemed to indicate *cis* hydrogens (i.e. axial H-2) as in α-D-*gluco* derivatives (9).[4] However, when the primary hydroxyl group in **2***c* was tosylated and the product treated with base, the *lyxo*-cyclopropyl ketone **4***a* was formed rapidly and in virtually quantitative yield. Compound **4***a* and the related *ribo* diastereomer (cf. **7**) have both been prepared in this laboratory (10).

The effect of substitution at the β-carbon upon the course of the photoalkylation was assessed by use of enone **1***d*. Addition of methanol gave a 61% yield of **2***e* which was cyclized to **4***b* in the previously described manner. In order to confirm the structure of **4***b* the diastereomer **7** was synthesized as shown in Scheme 2. In view of the stereochemistry of Simmons–Smith cyclopropanation of olefins such as **5** (11), *ribo* configuration of **7** is assured. Thus the presence of a β-substituent on the α-enone system does not affect the stereochemistry of the photoalkylation.

Additions to Hex-1-enopyran-3-uloses (8–11)

In view of the successful experiments detailed above, we decided to examine additions to the hex-1-enopyran-3-uloses since, if the reactions

[4]This conclusion was reached erroneously in our preliminary communication (3*a*).

SCHEME 2

proceeded with the same degree of regioselectivity, this would offer a simple entry into *C*-glycosyl compounds.[5] The latter are of current interest for the elaboration of biologically important nucleoside analogues (for reviews see ref. 13).

The enones **8–11** required in this study had been synthesized previously either by Collins *et al.* (14) and (or) ourselves (15).

Irradiation of enone **8** in methanol containing benzophenone for 6 h afforded two polar products (**12** + **13**) which were isolated as a mixture by chromatography. The formation of a trityl ether indicative of a primary alcohol suggested that the desired photoalkylation had occurred, but the yield of material was low (~45%) and there seemed to be little hope of resolving the two products.

The isopropylidene analogue **9** proved even less encouraging in that the mixture of alcohols was obtained in 25% yield.

The conformationally mobile systems **10** and **11** were next investigated.[6] Enone **10** yielded only ~40% of a substance which could have been an addition product of methanol. However, the results with **11** were more encouraging. Thus the product from irradiation of **11** in methanol for 12 h was chromatographed, and a crystalline material was obtained in 65% yield. The mass spectrum showed a molecular ion at *m/e* 460 as expected for the methanol adduct. However, the melting point range (157–165°C) suggested a mixture (**14***a* + **15***a*). This was supported by the presence, in the nmr spectrum, of two overlapping doublets ($\delta \sim 5.5$) assignable to H-6 of the proposed structures.

In an attempt to achieve fractionation, the mixture was detritylated and, in order to remove any confusion arising from acetyl migration, the product was converted to the triacetates (**14***b* + **15***b*), but these also were unresolved on thin layer chromatograms.

Attempts to obtain the triols by deacetylation of the triacetate mixture revealed that the compounds in this series (**14** and **15**) are labile to base. Reduction of the ketone gave base-stable products but the reduction was not stereoselective and therefore of little use. A mode of base-induced fragmentation which necessitates a carbonyl group at C-4 is expressed in **16**.

Finally resolution of **14***a* + **15***a* was achieved using the method of 'short-fat' column chromatography (16). Recovery from the column was only 80%, but components **14***a* and **15***a* were obtained as crystalline substances, mp 171–173°C and 175–177°C respectively, in the ratio 7:3.

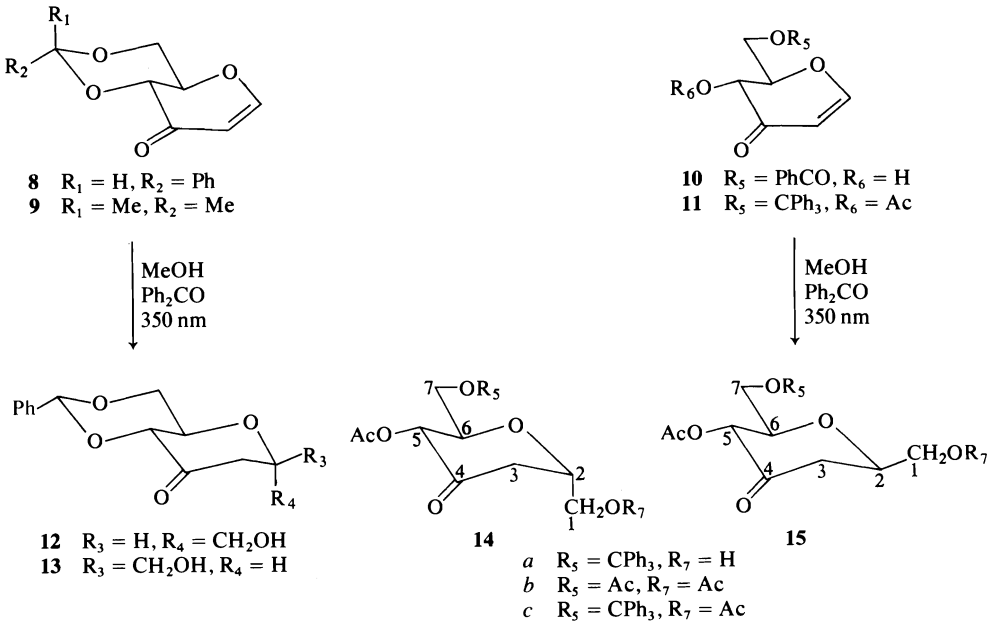
Structural assignments were made by studying the signals for H-2, H-3*a* and H-3*e* in the 220 MHz spectra of the derived acetates **14***c* and **15***c*, the coupling constants being determined by double irradiation. In each case, the *geminal* H-3 protons were identified as two double doublets with common coupling constants of 16.0 Hz in **14***c*, and 14.4 Hz in **15***c*. For the latter isomer H-3*a* should show an additional large coupling for $J_{2,3a}$, while H-3*e* should show a corresponding small coupling. Accordingly the signal with the additional coupling $J_{2,3a}$ of 12.0 Hz at 2.72 ppm was ascribed to H-3*a*, while that with the smaller coupling ($J_{2,3e}$) of 2.8 Hz at 2.58 ppm was ascribed to H-3*e*.

Similar reasoning when applied to the major photoproduct **14***c* gives H-3*a* at 2.94 ppm ($J_{2,3a}$ = 7.0 Hz), and H-3*e* at 2.53 ppm ($J_{2,3e}$ = 2.5 Hz), $J_{3a,3e}$ being 16.0 Hz.

Further evidence substantiating the above assignment was obtained from the ^{13}C nmr spectra of the triacetates **14***b* and **15***b*. Carbons 2, 3, and 5 are α, β, and δ, respectively, to the C-1 substituent and should be more shielded in the axial than in the equatorial adduct. Accord-

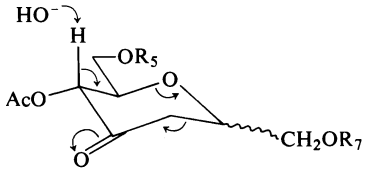
[5]For some other syntheses of *C*-glycosyl compounds see ref. 12.

[6]Possible effects of conformational mobility of these receptors in photoalkylation reactions are currently being examined and will be discussed in future publications.



SCHEME 3

ingly, the resonances for C-2, -3, and -5 are at 72.4, 41.6, and 73.0 ppm respectively in **14***b* and, at 75.2, 43.5, and 77.2 ppm in **15***b*.



16

Photoalkylation of Some Noncarbohydrate Enones

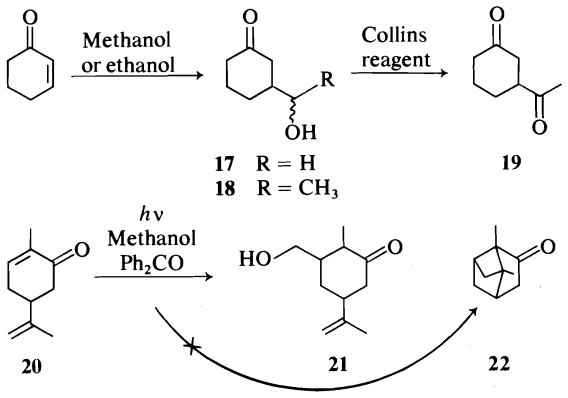
There have been only a few reported instances where the photoinduced alkylation described herein has been applied to carbocyclic enones. Following Schenck *et al.*'s addition of isopropanol to maleic acid (6), the same alcohol was added to cyclopentenone (7*a*), a steroidal enone (8), and addition of methanol (7*e*) or ethanol (8) has been observed only rarely. Following upon our initial report (3*a*), Bundy (17) and Wissner (18) added methanol and *n*-octanol, respectively, to substituted cyclopentenones in connection with synthetic studies in the prostaglandin area.

In view of the foregoing successful additions to the carbohydrate enones, a sampling of noncarbohydrate enones was investigated.

Although benzophenone sensitized irradiation of 2-cyclohexenone in methanol was still incomplete after 25 h, the reaction was stopped because a large number of products was evident on tlc. The major product was isolated by chromatography in 33% yield and shown to be the known 3-hydroxymethylcyclohexanone, **17** (19).

With ethanol, the addition was complete within 24 h and there seemed to be fewer by-products. The keto alcohol **18** was isolated as a mixture of epimers in 33% yield and oxidized to the diketone **19** for characterization (20).

Carvone **20** was regarded as an interesting test case because of the ease with which cycliza-



SCHEME 4

tion to carvone camphor, **22**, occurs in polar solvents (21). In fact the product mixture from the reaction of carvone with methanol showed no trace of carvone camphor prepared independently (21), judging from glc. Instead chromatographic fractionation afforded a 58% yield of keto alcohols judged to be a mixture of the diastereomers of **21** because of the overlapping doublets for the 2-methyl groups. Repeated careful fractionation afforded one of these diastereomers as a crystalline substance. Elemental analysis and spectroscopic data indicated the gross structure to be **21**, although the stereochemistry was not deduced.

Noteworthy failures in the alkylation with ethanol or methanol were the 1- and 4-cholestene-3-ones. The enones were consumed in both cases and a number of products were formed. However, these did not contain a hydroxyl group, judging from the infrared spectrum. Crotonaldehyde and mesityl oxide similarly failed to give any evidence of photoalkylation.

Experimental

Melting points were determined in capillary tubes in a Mel-Temp block and are uncorrected. Elemental analyses were performed by Micro-analyses Laboratory, Toronto, Ontario. The nmr spectra ($CDCl_3$, TMS) were determined on a Varian T-60, a Varian HA 100, or a Varian HR-220 spectrometer, the J values quoted being the spacing measured directly from the spectra. Infrared spectra were determined on a Beckman model IR-10 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent). Optical rotations were determined on a Carl Zeiss model LEP nür 370740 Lichtelektrishes Prazision polarimeter at 23°C.

Thin-layer chromatography was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The following solvent systems were used to develop the plates; ethyl acetate – petroleum ether (30–60°C) (1:4); ethyl acetate – petroleum ether (30–60°C) (1:1); ethyl acetate; or benzene. For column chromatography E. Merck silica gel (0.063–0.20 mm, 70–230 mesh A.S.T.M.) was used.

General Conditions for Photoalkylation Reactions

The apparatus used was a Rayonet Photochemical Reactor (model RPR-100). A solution of the enone (1.0 mmol) and benzophenone (0.16 mmol) in the alcohol-addend (80 ml) was placed in a Pyrex photolysis cell equipped with a cold finger through which cold water was circulated. Nitrogen gas was bubbled into the solution through a glass capillary for 1 h to remove oxygen, and then the lamps (350 nm) were switched on, the gas flow being maintained. The reaction was monitored by tlc and when it was completed, the solvent was removed, and the residue chromatographed on a silica gel column in order to isolate the product.

Ethyl 2,3-Dideoxy-2-C-hydroxymethyl-α-D-threo-hexopyranosid-4-ulose, **2a**

A solution of enone **1a** (1.54 g, 8.9 mmol) (1*b*) and benzophenone (0.255 g, 1.44 mmol) in methanol (720 ml) was irradiated as described in the general procedure above. After 5 h the reaction was finished and chromatography on silica afforded compound **2a** (1.1 g, 66%) as a syrup. There were small amounts of slow-running material showing features of aromatic and carbohydrate compounds which were discarded. $R_f = 0.4$ in ethyl acetate; ir 3367, 1720 cm^{-1}; nmr (60 MHz) δ: 5.05 (d, 1, H-1, $J_{12} = 4.0$ Hz), 2.1–2.7 (m, 3, H-2, H-3*a*, H-3*e*), 4.20 (m, 1, H-5, $J_{56} = J_{56'} = 4.0$), 3.42–3.90 (m, 2, H-6, H′-6).

For the di-*p*-nitrobenzoate of **2a**: mp 134.5–135°C; $[\alpha]_D^{23}$ +75.04° (*c* 5, $CHCl_3$). *Anal.* calcd. for $C_{23}H_{22}N_2O_{11}$: C 54.97, H 4.41, N 5.57; found: C 54.85, H 4.13, N 5.06.

For the ditritylate of **2a**: mp 180.5–181°C; $[\alpha]_D^{23}$ +79.2° (*c* 2.5, $CHCl_3$). *Anal.* calcd. for $C_{47}H_{44}O_5$: C 81.94, H 6.43; found: C 81.57, H 6.60.

Ethyl 6-O-Acetyl-2,3-dideoxy-2-C-hydroxymethyl-α-D-threo-hexopyranosid-4-ulose, **2b**

The acetylated enone **1c** (1.73 g, 8.94 mmol) (1*b*) and benzophenone (0.255 g, 1.4 mmol) in methanol (720 ml) was irradiated as described in the general procedure for 5 h. Chromatographic fractionation on silica using ethyl acetate – petroleum ether (30–60°C) (1:1) afforded the major product **2b** (1.1 g, 50%) as well as slower-running material showing aromatic and carbohydrate features.

$R_f = 0.46$ in ethyl acetate – petroleum ether (1:1); nmr (60 MHz) δ: 5.01 (d, 1, H-1, $J_{12} = 4.0$ Hz), 2.2–2.9 (m, 3, H-2, H-3*a*, H-3*e*), 4.1–4.3 (m, 3, H-5, H-6, H′-6), 3.5–3.9 (m, 4, OCH_2CH_3 and OCH_2OH), 1.1 (t, 3, OCH_2CH_3).

For characterization, **2b** was acetylated and converted to the 2,4-dinitrophenylhydrazone, mp 146–148°C. *Anal.* calcd. for $C_{19}H_{24}N_4O_{10}$: C 48.72, H 5.16, N 11.96; found: C 48.87, H 4.94, N 12.21.

Ethyl 2,3-Dideoxy-2,3-C-methylene-6-O-triphenylmethyl-α-D-lyxo-hex-2-enopyranosid-4-ulose, **5a**

(*a*) The tritylated enone **1b** (1*b*) (2.5 g) was irradiated with benzophenone (500 mg) in methanol (400 ml) for 8.5 h in the usual manner described above. Fractionation on a silica column using ethyl acetate – petroleum ether (30–60°C) (1:1) afforded 1.97 g (75% yield) of **2c**. (This compound was identified by tritylation to the above-described ditritylate of **2a**).

A portion of the photoproduct **2c** (900 mg) was treated with a twofold excess of *p*-toluenesulfonyl chloride (800 mg) in pyridine (20 ml) and methylene chloride (10 ml) at 0°C overnight. Customary work-up gave the expected tosylate ($R_f = 0.68$ in 50% ethyl acetate – petroleum ether (30–60°C) which showed signs of being unstable.

The tosylate (0.81 g, 1.35 mmol) was dissolved in dry THF (50 ml) and a solution of diazabicyclononene (0.20 g, 1.6 mmol) in THF (10 ml) was added. After 0.5 h the solution was poured into ice water (50 ml) and extracted three times with chloroform. The chloroform was washed successively with dilute hydrochloric acid, water, and saturated sodium bicarbonate and then dried. The solu-

tion yielded **4***a* (0.53 g, 92%) having identical nmr spectra to the previously described material (10).

(*b*) Alternatively the tosylate described in (*a*) (180 mg) was refluxed in butanone (1.5 ml) with sodium iodide (310 mg) for 1.5 h when tlc indicated completion. The derived iodide (R_f = 0.76 in 50% ethyl acetate – petroleum ether (30–60°C)) (0.17 g) was dissolved in dry pyridine (4 ml), and silver fluoride (0.17 g) was added with stirring. The solution turned black immediately and a silvery mirror was deposited within minutes. Thin-layer chromatography (petroleum ether (30–60°C) – ethyl acetate (4:1)) after 5 min showed the absence of the starting iodide (R_f = 0.52) and one product of lower R_f (0.35). The reaction mixture was poured into ice water (10 ml) and extracted with diethyl ether (2 × 15 ml). The combined ether layers were washed with 5% hydrochloric acid (until the aqueous layer remained acidic), a sodium bicarbonate solution, and then dried over sodium sulphate. Subsequent evaporation afforded **4***a* (0.061 g, 36%).

(*c*) Silver fluoride (0.10 g, 4.25 mmol) was added to a stirred acetonitrile (5 ml) solution of the iodide described in (*b*) (0.105 g). The reaction was monitored by tlc (petroleum ether (30–60°C) – ethyl acetate (4:1)) and after 20 h was complete. The solution was filtered and evaporated and the resulting residue taken up in diethyl ether (20 ml) and filtered again. Evaporation of the ether after decolourization gave **4***a* (0.060 g, 78%).

Ethyl 6-O-Acetyl-2,3-dideoxy-2-C-[(R,S)-hydroxy(methyl)methyl]-α-D-threo-hexopyranosid-4-ulose, **2***d*

A solution of the ketoacetate, **1***c* (1.5 g, 7.73 mmol) and benzophenone (0.200 g, 1.12 mmol) in ethanol (720 ml) was irradiated for 7 h when tlc indicated completion. The photoadduct **2***d* was isolated in the usual way (see general procedure above) and characterized by mesylation and then conversion to the 2,4-dinitrophenylhydrazone. For the latter derivative: mp 138–140°C; $[\alpha]_D^{23}$ +72.22° (*c* 5.2, $CHCl_3$). *Anal.* calcd. for $C_{19}H_{26}N_4SO_{11}$: C 44.09, H 4.86, N 10.82, S 6.19; found: C 44.07, H 5.10, N 10.72, S, 6.01.

The nmr spectrum of **2***d* shows two doublets ~5.0 ppm (J = 4 Hz for both), corresponding to the (*R*) and (*S*) configurations at the secondary alcohol.[7]

Methyl 2,3-Dideoxy-2-C-hydroxymethyl-2-C-methyl-6-O-triphenylmethyl-α-D-threo-hexopyranosid-4-ulose, **2***e*

A solution of enone **1***d* (0.246 g, 0.59 mmol) and benzophenone (0.020 g, 0.1 mmol) dissolved in methanol (50 ml) was irradiated in the manner described above. After 5.5 h tlc indicated that no starting material remained and that a new compound, R_f 0.24 in ethyl acetate – petroleum ether (30–60°C) (1:4), had been formed. After evaporation of the solvents the residue was chromatographed on a silica gel column using the same solvent mixture. Compound **2***e* (0.163 g, 61%) was recovered as a syrup; $[\alpha]_D^{23}$ +27.4° (*c* 2.08, $CHCl_3$); ir ν_{max}: 3430 (OH), 1720 (C=O) cm^{-1}; ms *m/e*: 369 (M^+ − Ph), 203 (M^+ − Tr); nmr (60 MHz) δ: 5.56 (s, 1, H-1), 2.0–2.35 (m, 2, H-3*a*, H-3*e*), 4.20 (m, 1, H-5), 3.5–3.8 (m, 2, H-6, H′-6), 0.98 (s, 3, CCH_3), 3.5–3.8 CH_2OH.

Methyl 2,3-Dideoxy-2-C-methyl-2,3-C-methylene-6-O-triphenylmethyl-α-D-lyxo-hexopyranosid-4-ulose, **4***b*

The tritylated photoproduct **2***e* (0.122 g, 0.25 mmol) was dissolved in dry pyridine (5 ml) and *p*-toluenesulphonyl chloride (0.190 g, 1.0 mmol) was added. The reaction mixture was placed in an oil bath (45°C) and stirred for 4 h. At this time, no starting material remained (tlc) and a new compound, R_f = 0.42 in ethyl acetate – petroleum ether (30–60°C) (1:4), had been formed. The cooled reaction mixture was poured into ice water (50 ml) and extracted with ether (50 ml). The ether layer was washed successively with a 5% hydrochloric acid solution (50 ml), a saturated sodium bicarbonate solution (50 ml), and water (50 ml) and then dried over sodium sulphate. The residue obtained upon evaporation of the solvent weighed 0.068 g (65%). Compound **4***b* was a syrup which gave the following data: ir ν_{max}: 1695 (ketone conjugated to cyclopropyl ring) cm^{-1}; ms *m/e*: 351 (M^+ − Ph), 185 (M^+ − Tr); nmr δ: 0.9–1.3 (m, 2, cyclopropyl methylene), 1.25 (s, 3, C—CH_3) 1.90 (m, 1, H-3), 3.41 (s, 3, OCH_3), 3.40–3.80 (m, 2, H-6, -6′), 4.0 (t, 1, $J_{5,6}$ = $J_{5,6'}$ = 6.0 Hz, H-5), 4.95 (s, 1, H-1), 7.2–7.8 (m, 15, phenyl).

Methyl 2,3-Dideoxy-2-C-methyl-2,3-C-methylene-6-O-triphenylmethyl-α-D-ribo-hexopyranosid-4-ulose **7**

The alcohol **5***a* (1*a*) (1.0 g, 2.4 mmol) was dissolved in dry pyridine (10 ml) and cooled to 0°C in an ice bath. Acetic anhydride (1 ml) was added and the reaction mixture stirred for 6 h at 0°C. At this time, tlc indicated the formation of a new compound, R_f = 0.60 in ethyl acetate – petroleum ether (30–60°C) (1:4), and no starting material. The reaction mixture was worked up in the usual manner and afforded the syrupy acetate **5***b* (0.950 g, 86%). Significant nmr features were: δ 1.75 (m, 3, C—CH_3), 1.90 (s, 3, $OCOCH_3$), 3.2–3.4 (m, 2, H-6, -6′), 3.58 (s, 3, —OCH_3), 3.90–4.2 (m, 1, H-5), 4.8 (s, 1, H-1), 5.2–5.4 (m, 1, H-4), 5.58 (m, 1, H-3), 7.2–7.8 (m, 15, phenyl). The material (**5***b*) was used directly as follows.

Zinc/copper couple (0.500 g), methylene iodide (0.72 ml), one crystal of iodine, and dry diethyl ether (5 ml) were placed in a dry 25 ml round bottom flask. The acetate **5***b* (0.900 g, 1.96 mmol) dissolved in dry diethyl ether (5 ml) was added. After 24 h at reflux the starting material had all been consumed and tlc indicated that a new product, R_f = 0.18 in ethyl acetate – petroleum ether (30–60°C) (1:10), had been formed. The reaction mixture was diluted with ether (20 ml), washed with a saturated ammonium chloride solution (2 × 20 ml), a saturated sodium bicarbonate solution (20 ml), water (20 ml), and dried over sodium sulphate. The residue obtained upon evaporation of the solvent was chromatographed on a silica gel column to afford **6***b* (0.256 g, 28.4%). Significant nmr features were: δ 1.21 (s, 3, C—CH_3), 1.05–1.55 (m, 3, cyclopropyl), 1.85 (s, 3, —$OCOCH_3$), 3.10–3.85 (m, 3, H-5, -6, -6′), 3.50 (s, 3, —OCH_3), 4.87 (s, 1, H-1), 5.08 (dd, 1, $J_{4,5}$ = 10.0 Hz, $J_{3,4}$ = 5.0 Hz, H-4), 7.18–7.80 (m, 15, phenyl).

The crude cyclopropyl acetate **6***b* (0.225 g, 0.49 mmol) was dissolved in methanol (10 ml) and sodium carbonate

[7]For other examples and further discussion, see the accompanying paper (5).

(0.126 g) was added. The reaction mixture was stirred at room temperature for 4 h. At this time, tlc indicated that deacetylation was complete and a new product, $R_f = 0.21$ in ethyl acetate – petroleum ether (30–60°C) (1:4), had been formed. The reaction mixture was filtered and the residue obtained upon evaporation of the solvent was extracted with ethyl acetate. The ethyl acetate solution was filtered and evaporated to afford **6***a* (0.187 g, 89%). Compound **6***a* exhibited the following nmr features: δ 0.92–1.35 (m, 3, cyclopropyl), 1.05 (s, 3, C—CH_3), 1.96 (bs, 1, OH), 3.1–3.5 (m, 3, H-5, -6, -6′), 3.40 (s, 3, —OCH_3), 3.82 (dd, 1, $J_{4,5} = 10.0$ Hz, $J_{3,4} = 6.0$ Hz, H-4), 4.65 (s, 1, H-1), 7.10–7.6 (m, 15, phenyl).

The cyclopropyl alcohol **6***a* (0.175 g, 0.4 mmol) was dissolved in methylene chloride (10 ml). To this vigorously stirred solution was added the chromium trioxide – dipyridine complex (1.05 g, 4.0 mmol). After 1 h at room temperature tlc indicated the reaction was complete and a new compound $R_f = 0.37$ in ethyl acetate – petroleum ether (30–60°C) (1:4) had been formed. The reaction mixture was diluted with ether (40 ml) and stirred for an additional 15 min. The solution was then filtered through a bed of Celite. The filtrate was washed with a 5% hydrochloric acid solution (30 ml), a saturated sodium bicarbonate solution (30 ml), and water (30 ml). The organic layer was then decolourized, dried over anhydrous sodium sulphate, and evaporated to give **7** (0.142 g, 83%). Compound **7** was a syrup which gave the following data: ir ν_{max}: 1690 (ketone conjugated to cyclopropyl ring) cm^{-1}; ms *m/e*: 351 ($M^+ - Ph$), 185 ($M^+ - Tr$); nmr δ: 1.0–1.4 (m, 2, cyclopropyl methylene), 1.35 (s, 3, C—CH_3), 1.95 (m, 1, H-3), 3.40 (s, 3, OCH_3), 3.4–4.0 (m, 2, H-6, -6′), 4.2 (m, 1, H-5), 5.35 (s, 1, H-1), 7.2–7.8 (m, 15, phenyl).

*5-O-Acetyl-2,6-anhydro-3-deoxy-7-O-triphenylmethyl-*D*-arabino-hept-4-ulose,* ***14c*** *and 5-O-Acetyl-2,6-anhydro-3-deoxy-7-O-triphenylmethyl-*D*-ribo-hept-4-ulose,* ***15c***

4-*O*-Acetyl-6-*O*-triphenylmethyl-D-*erythro*-pyran-3-ulose **11** (2.0 g, 4.67 mmol) (16), and benzophenone (0.32 g, 1.7 mmol) were dissolved in methanol (800 ml) and irradiated in the usual manner for 12 h at which time tlc (ethyl acetate – petroleum ether (30–60°C) (1:1)) showed completion. The solvent was removed under reduced pressure and the resultant residue chromatographed to yield **14***a* and **15***a* as a mixture (1.35 g, 65%).

A portion of this product (0.70 g) was eluted through a short column (20 cm × 2.5 cm) of tlc silica gel using petroleum ether (30–60°C) – ethyl acetate (3:2). Upon identification of resultant fractions (nmr) **14***a* (0.397 g) and **15***a* (0.158 g) were isolated in a total recovery of 80%. Compound **15***a* constituted 30% of the mixture (20% yield from photolysis), **14***a* constituting 70% (45% yield from photolysis). Both **14***a* and **15***a* were recrystallized from cold ethanol.

For compound **14***a*: mp 171–173°C; $[\alpha]_D^{23}$ +168.2° (*c* 1.46, chloroform); *Anal.* calcd. for $C_{28}H_{28}O_6$: C 73.03, H 6.13; found: C 72.83, H 6.29.

For compound **14***c*: nmr (220 MHz) δ: 2.53 (dd, 1, $J_{3a,3e} = 16.0$ Hz, $J_{2,3e} = 2.5$ Hz, H-3*e*), 2.94 (dd, 1, $J_{2,3a} = 7.0$ Hz, H-3*a*), 3.13 (dd, 1, $J_{7e,7a} = 9.8$ Hz, $J_{6,7e} = 3.9$ Hz, H-7*e*), 3.48 (dd, 1, $J_{6,7a} = 2.0$ Hz, H-7a), 4.08 (dd, 1, $J_{1e,1a} = 12.2$ Hz, $J_{1e,2} = 3.8$ Hz, H-1*e*), 4.18 (m, 1, H-6), 4.45 (dd, 1, $J_{1a,2} = 7.0$ Hz, H-1*a*), 4.75 (m, 1, H-2), 5.50 (d, 1, $J_{5,6} = 10.0$ Hz, H-5).

For compound **15***a*: mp 171–173°C; $[\alpha]_D^{23}$ +293.4° (*c* 1.85, chloroform). *Anal.* calcd. for $C_{28}H_{28}O_6$: C 73.03, H 6.13; found: C 73.18, H 6.28.

For compound **15***c*: nmr (220 MHz) δ: 2.58 (dd, 1, $J_{3a,3e} = 14.4$ Hz, $J_{2,3e} = 2.8$ Hz, H-3*e*), 2.72 (dd, 1, $J_{2,3a} = 12.0$ Hz, H-3*a*), 3.12 (dd, 1, $J_{7e,7a} = 10.3$ Hz, $J_{6,7e} = 3.8$ Hz, H-7*e*), 3.49 (dd, 1, $J_{6,7a} = 1.7$ Hz, H-7*a*), 3.75 (dq, 1, H-6), 3.95 (m, 1, H-2), 4.30 (d, 2, $J_{1,2} = 4.6$ Hz, H-1*a*, H-1*e*), 5.47 (d, 1, $J_{5,6} = 10.0$ Hz, H-5).

Photoadditions to 2-Cyclohexenone. Compounds ***17*** *and* ***18***

2-Cyclohexenone (1.1g), benzophenone (150 mg), and methanol (600 ml) were irradiated for 24 h in the usual manner. The crude oily product was chromatographed on a silica gel column using ethyl acetate – petroleum ether (30–60°C) (1:1). Unreacted starting material (410 mg) was recovered, as well as the adduct **17** ($R_f = 0.21$), 308 mg (33% corrected for unreacted starting material).

In agreement with the literature (19*b*), the nmr spectrum of compound **17** shows (CCl_4) δ_{TMS}: 3.72 (d, 2, CH_2OH), 1.4–2.5 (m, 10, ring protons and O*H*); ir: 3400, 1705 cm^{-1}.

Similar reaction of 2-cyclohexenone (1.5 g), benzophenone (200 mg), and ethanol (800 ml) for 24 h, and subsequent chromatographic fractionation with ethyl acetate – petroleum ether (30–60°C) (1:1) afforded **18** (880 mg, 33%), $R_f = 0.47$. The 220 MHz nmr spectrum ($CDCl_3$) showed δ_{TMS}: 3.5 (m, 1 C*H*-OH), 2.0–2.46 (m, 4, CH_2COCH_2); ir: 3400, 1705 cm^{-1}. Compound **18** was oxidized to 3-acetyl cyclohexanone (20).

*Photoaddition of Methanol to Carvone (****20****)*[8]

Carvone (**20**) (1.26 g) and benzophenone (255 mg) were dissolved in methanol (700 ml) and irradiated for 34 h in the usual manner. Under these conditions carvone camphor (**22**) prepared independently (21) was not formed, judging by glc; however, if benzophenone was excluded, **22** was formed (21). The crude photoproduct was chromatographed on a silica column using ethyl acetate – petroleum ether (30–60°C) (1:2) in order to remove aromatic substances. A fraction (700 mg, 58%) was obtained which was consistent with the gross structure, **21** judging from nmr evidence. Refractionation afforded a pure isomer of **21**, which was crystallized from ether–hexane, mp 104.5–105°C; nmr (60 MHz, $CDCl_3$) δ_{TMS}: 4.78 (bs, 2, CH_2=C), 3.6 (m, 2 CH_2OH), 1.68 (bs, 3, CH_3—C=), 1.0 (d, 3, CH_3CH); ir: 3500 cm^{-1} (OH), 3090 (=CH_2), 1645 (C=C). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.44, H 9.95.

Synthetic applications of the photochemically induced addition of oxycarbinyl species to α-enones. Part II.[1] The addition of ketals, aldehydes, and polyfunctional species[2,3]

BERT FRASER-REID, ROBERT CHARLES ANDERSON, DAVID ROY HICKS, AND DAVID LOUIS WALKER

Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received April 11, 1977

BERT FRASER-REID, ROBERT CHARLES ANDERSON, DAVID ROY HICKS, and DAVID LOUIS WALKER. Can. J. Chem. **55**, 3986 (1977).

Alcohols possessing an α-hydrogen, acetals, and aldehydes undergo photochemically induced conjugate addition to a variety of α-enones to give 1,4-ketols, 1,4-keto ketols and 1,4-diketones respectively. It appears that the aldehydes frequently succeed where acetals and alcohols fail, and acetals where alcohols fail. It is therefore possible to employ polyfunctional addenda and achieve addition at only one of the activated sites. The reactions are always regiospecific and are frequently completely stereoselective.

BERT FRASER-REID, ROBERT CHARLES ANDERSON, DAVID ROY HICKS et DAVID LOUIS WALKER. Can. J. Chem. **55**, 3986 (1977).

Les alcools possédant un hydrogène en α, les acétals et les aldéhydes subissent une addition conjuguée photochimiquement induite avec une variété d'énones-α pour conduire respectivement à des cétols-1,4, céto-cétols-1,4 et dicétones-1,4. Il apparait fréquemment que les aldéhydes réussissent où les acétals et alcools échouent, puis les acétals où les alcools échouent. Il est maintenant possible d'employer des produits polyfonctionnels fixés par addition et d'effectuer l'addition seulement à l'un des sites actifs. Les réactions sont toujours régiospécifiques et sont souvent complètement stéréosélectives.

[Traduit par le journal]

In the accompanying paper (1), we report several examples of the photochemically induced conjugate addition – alkylation of α-enones by simple alcohols. Other projects in our laboratory (2) required that the synthetic potential of these reactions be explored. In contemplating the utility of these products we were mindful of the recent work of Schlessinger and co-workers (3) who have shown that 1,4-dicarbonyl species can be extremely versatile synthons. Differentiation of the two hydroxyl groups could, at times, be advantageous as has been ably demonstrated by Stork and Jung (4). The appeal of the photoadducts is therefore apparent since, being at different oxidation levels, the 1,4-functionalities lend themselves to selective manipulation.

In view of the excellent promise of this simple, economical procedure in synthetic organic chemistry, we wondered whether more complex addenda could be attached in an equally undemanding experimental operation. In this paper we describe some results of these investigations.

In the previous studies (1), the reacting alcohol also served as the solvent, a requirement which obviously posed a severe limitation. However, it was found that cyclohexane or acetonitrile were excellent solvents, even though the ratio of addend to substrate still had to be very high (~40:1) for the reaction to proceed at a useful rate. For purposes of solubility, acetonitrile is our preferred solvent.

The readily prepared enone **1** (5) was our favorite substrate primarily because its photoalkylation reactions had been found to go with complete stereoselectivity (1), yielding the axial adduct at carbon-2.

Ethylene glycol, propane-1,3-diol, methyl hydracrylate, and methyl glycollate were chosen as polyfunctional alcohols for the studies summarized in Table 1 (entries 1–4). With ethylene glycol and the enone **1***a*, the ketodiol **3***a* was

[1]For Part I, see ref. 1.

[2]For preliminary accounts of this work, see refs. 9 and 12.

TABLE 1 (*Concluded*)

Entry	Substrate	Addend	Time (h)	Product	Percent yield (after chromatography)
10	 **1a**	PhCHO	2	 **25**	58
11	 **27**	CH_3CHO	12	 **28**	42
12		CH_3CHO	2	 **29**	31

obtained in 75–79% yield after chromatography. Similarly the photoadduct **4***a* was obtained in 49% yield.

The adduct with methyl hydracrylate (**5***a*) decomposed during silica column chromatography, and as a result the isolated yield was low (32%). If, however, the crude photoproduct was protected as the tetrahydropyranyl ether prior to chromatography, the adduct **5***b* could be isolated in 74% yield.

There was no evidence for photoaddition when methyl glycollate was used under the usual conditions (Table 1, entry 4).

The photoadducts **3***a*, **4***a*, and **5***a* showed hydroxyl and strong carbonyl absorptions in the infrared indicating that internal hemiacetal formation had not occurred. In support of this **3***a* and **4***a* were converted readily at room temperature to the ditritylates **3***b* and **4***b*. The photoproducts were, as expected, epimeric at the newly created secondary alcohol (C-7) and this was apparent from the presence of two doublets ~5 ppm for two anomeric protons, $J_{12} \cong 4.5 \pm 0.5$ Hz. The epimers were not resolved in any of these cases but oxidation of **3***b*, **4***b*, and **5***a* give the diketones **7**, **8**, and **9** respectively which now showed only one doublet ~5 ppm, $J_{12} \doteq 4.5$ Hz.

The photoproduct of enone **2** with ethylene glycol provided a contrast in that chromatography afforded two substances **6***a*$_1$ and **6***a*$_2$ in 38 and 33% yields respectively. These compounds were assigned hemiacetal structures because of the absence of ketonic absorption in the infrared and the fact that tritylation did not proceed at room temperature. However, at 50°C, reaction occurred slowly, requiring 36 h for complete formation of the corresponding ditritylates **6***b*$_1$ and **6***b*$_2$ as amorphous solids.

	Alk	R	X
3*a*	Et	H	OH
3*b*	Et	H	$OCPh_3$
4*a*	Et	H	CH_2OH
4*b*	Et	H	CH_2OCPh_3
5*a*	Et	H	CH_2CO_2Me
6*b*, **6***b*$_1$	Me	Me	$OCPh_3$

	Alk	R	X
7	Et	H	$OCPh_3$
8	Et	H	CH_2OCPh_3
9	Et	H	COOMe
10	Me	Me	$OCPh_3$

SCHEME 1

Each of the ditritylates **6***b*$_1$ and **6***b*$_2$ upon oxidation gave the same amorphous diketone **10** (Scheme 1).

In contemplating alternative methods for differentiating the 1,4-functionalities in the photo-

adducts we recalled the photosensitized addition of dioxolane to olefins, a reaction first demonstrated by Rosenthal and Elad (6). Its utility in the synthesis of branched-chain sugars has been explored by Jewel and Szarek (7) and Matsuura and co-workers (8). However, with these simple olefins, the additions are usually neither regio- nor stereoselective.

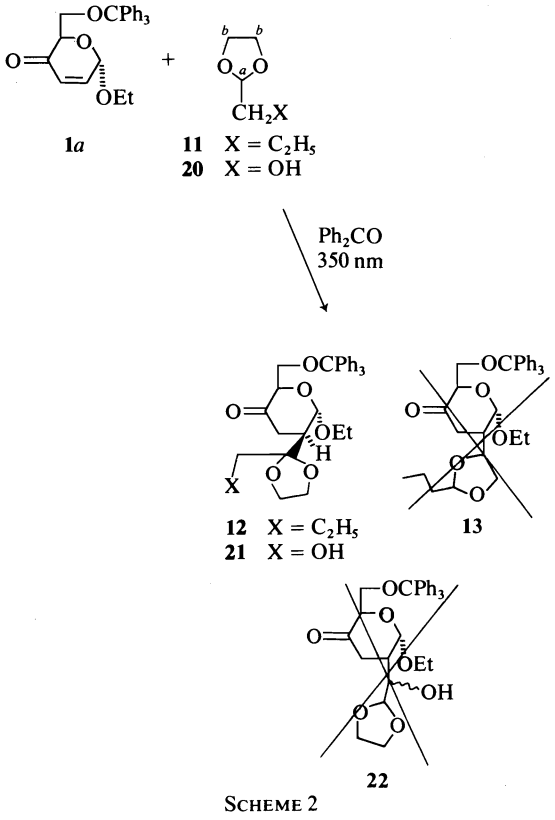
To our knowledge, there were no instances of alkylation of α-enones with acetals prior to our preliminary report (9). However, an example of *acid catalyzed intra*molecular addition (the outcome of which was a six-membered ring component of a linear tetracyclic molecule) had been reported by Barton and co-workers (10).

Attempts to alkylate **1***a* with dioxolane as solvent were abandoned because of the formation of a heavy oily residue from which the photoproduct could not be extricated. This problem was not encountered when 2-propyl-1,3-dioxolane (**11**) was used as a reagent (Table 1, entry 6). The ketone **12** was the sole product, its stereo- and regiochemistry being apparent from the appearance of the H-1 signal (5.12 ppm, $J_{12} = 4.0$ Hz).

However, the dioxolane could conceivably add to the receptor **1***a* either at the dioxycarbinyl site *a* giving **12**, or at the monoxycarbinyl site *b* giving an adduct such as **13** (Scheme 2). Had the latter been formed the nmr spectrum would have shown a signal of ~5 ppm for the acetal proton of the dioxolane residue. This was not observed.

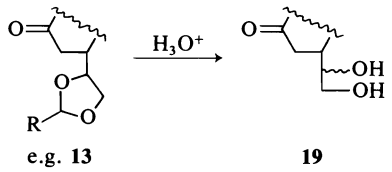
Chemical proof for this aspect was desirable but the carbohydrate adducts were not suitable because of their lability to acid hydrolysis. Consequently it was decided to examine the reactions of 2-cyclohexenone (routes *d*, *e*, *f*) summarized in Scheme 3. Addition of ethanol to 2-cyclohexenone (**14**) gave a 40% yield of the previously described keto alcohol **15** (1) which upon oxidation gave a substance whose nmr data were identical to those published by Corey and co-workers (11) for the diketone **18**.

Alternatively addition of the dioxolane **16** gave a 54% yield of a substance judged to be **17** on the basis of nmr and mass spectral data. Furthermore acid hydrolysis gave the same diketone, **18**, obtained in route *d*. In order to detect whether a product such as **13** had been formed, the total photoproduct from reaction of **14** and **16** was hydrolyzed, and the crude



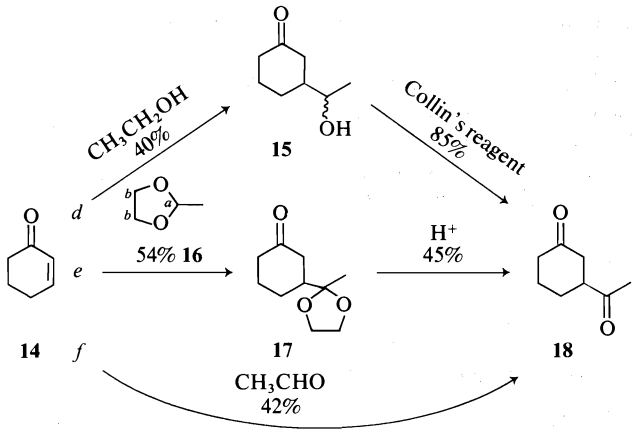
SCHEME 2

hydrolysate examined for the presence of a glycol (such as **19**) by periodate oxidation. A negative result indicated that addition at site *b* of the dioxolane ring had not occurred.



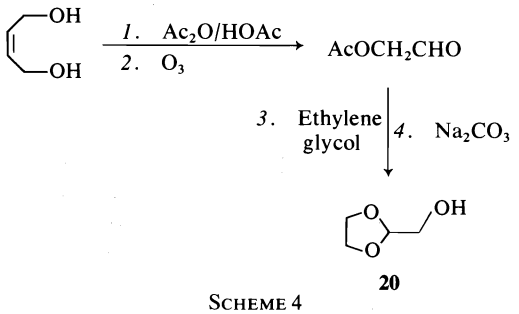
The interesting acetal **20**, prepared as indicated in Scheme 4, added equally selectively at the 2-position, giving the highly functionalized substance **21** (Table 1, entry 7), in 42% yield after chromatography. Again addition at the alternate carbinyl sites *a* or *c* (Scheme 2) to give structures such as **13** or **22** respectively were ruled out by the presence of only one acetal proton in the nmr spectrum.

Addition of **20** to enone **2** (Table 1, entry 8) proved understandably more difficult, considering the fact that a maximally substituted



SCHEME 3

carbon–carbon bond is being forged in **23**. After being allowed to go 10 times longer than with **1***a*, the reaction was still incomplete. However, it was stopped, since there was evidence of decomposition of the product. The isolated yield of **23** was 46%, based on unrecovered starting material.



SCHEME 4

The success with the acetals suggested that it might be possible to add aldehydes directly to the enones in cases where differentiation of the carbonyl groups was not desired (12). We were encouraged by the work of Stockmann involving free-radical addition of acetaldehyde to norbornene (13).

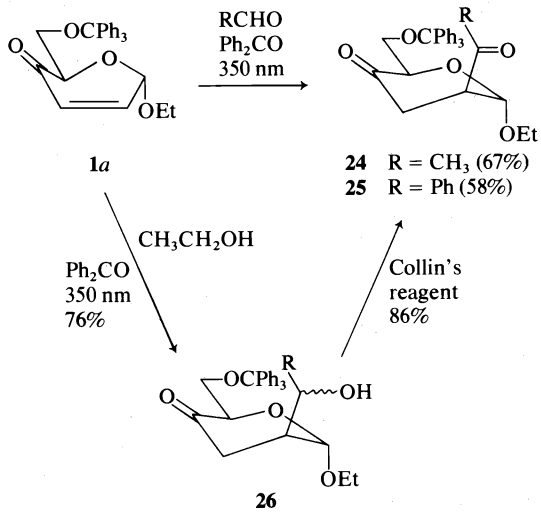
The enone **1***a* was irradiated under the usual conditions using acetaldehyde as the addend (Table 1, entry 9). The diketone **24** was obtained in 67% yield after chromatography. Similarly, benzaldehyde was added to **1***a* to give **25** in 58% yield (Table 1, entry 10).

The stereochemistry and identity of aldehyde addition were established as shown in Scheme 5 via the previously described keto alcohol **26** (1).

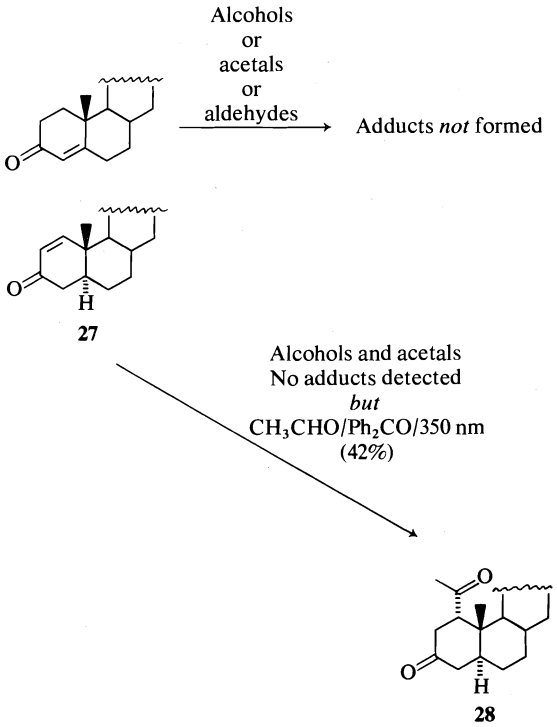
Some noncarbohydrate enones were also found to react moderately well with aldehydes. Thus 2-cyclohexenone and acetaldehyde afforded a 42% yield of diketone **18** completing the series shown in Scheme 3.

The results with 1-cholesten-3-one **27** and 4-cholesten-3-one are interesting (Scheme 6). The latter fails to give a photoadduct with alcohols, acetals, or aldehydes; with the former (**27**) we have had success *only* with acetaldehyde. Thus the diketone **28** was obtained in 42% yield after chromatography.

Assignment of configuration of the acetyl group in **28** is based on our interpretation of the 220 MHz nmr spectrum in which H-1 appears as a doublet of doublets with spacing of 1.8 and 6.0 Hz. These values suggest that H-1 is equatorially oriented and coupled to two *gauche* protons. Furthermore we have noted (1)



SCHEME 5



SCHEME 6

that these photoalkylations like cuprate additions are very sensitive to steric effects; hence the incoming addend should add *anti* to the C-19 methyl group.

The alkylation of mesityl oxide (Table 1, entry 12) is noteworthy since other additions (i.e. of alcohols and acetals) to acyclic systems have usually been unsuccessful. However, the addition of acetaldehyde was complete within 2 h, the yield after isolation of the known diketone (**29**) (13) being 31%.

The results in this and in the accompanying paper (1) indicate a wide disparity between the success of various α-enones as receptors in the photoalkylation reactions. An understanding of the factors responsible for these differences is obviously desirable and studies aimed at this objective are continuing in our laboratories.

Experimental

Materials and methods used have already been given in ref. 1.

General Conditions for Photoalkylation Reactions

Method A

A solution of the enone (1.0 mmol) and benzophenone (0.16 mmol) dissolved in the solvent-addend (80 ml) was placed in a Pyrex photolysis tube. The reaction mixture was cooled by means of a cold finger extending into the solution. Nitrogen gas was bubbled into the solution throughout the length of the irradiation by means of a glass capillary tube. The reaction was photolyzed at 350 nm in a Rayonet Photochemical reactor (model RPR-100) until tlc indicated the reaction was complete. At this time the solvent was removed and the residue chromatographed on a silica gel column in order to isolate the product.

Method B

A solution of the enone (1.0 mmol), benzophenone (0.16 mmol), and the addend (40 mmol) was dissolved in either hexane or acetonitrile (80 ml) and photolyzed as above. The reaction mixture was worked up as above except that in cases where the addend was a high boiling liquid it was removed by high vacuum distillation.

Ethyl 2,3-Dideoxy-2-C-(R,S)-hydroxy(hydroxymethyl)-methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, 3a

The enone **1***a* (1.0 g, 2.42 mmol) and benzophenone (0.12 g, 0.68 mmol) were dissolved in acetonitrile (40 ml) and ethylene glycol (400 ml) and the solution was photolyzed in the usual manner (method B). Thin-layer chromatography (diethyl ether – benzene (1:1)) after 4 h showed no starting material and one spot of lower R_f (0.16). The solvents were evaporated under reduced pressure and the resulting residue was chromatographed on a silica column to yield **3***a* (0.79 g, 69%) as a thick colourless oil. The nmr spectrum of the oil showed two doublets at 5.28 ppm (J_{12} = 4.1 Hz) and 5.08 ppm (J_{12} = 5.0 Hz) in 2:1 ratio; ir: 1730 cm^{-1} (saturated ketone).

Ethyl 2,3-Dideoxy-2-C-(oxo(triphenylmethoxymethyl)-methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, 7

The photoproduct from the preceding experiment, **3***a* (0.79 g, 1.66 mmol) was tritylated in pyridine (20 ml) with trityl chloride (1.38 g, 5.0 mmol) over 5 days. Normal work-up and subsequent column chromatography (petroleum ether (30–60°C) – ethyl acetate (4:1)) afforded the ditritylate **3***b* (0.81 g, 97%) as a thick oil. This oil was dissolved in methylene chloride (30 ml) and chromium trioxide – dipyridine (4.0 g, 1.55 mmol) was added with vigorous stirring. At 1 h the solution was diluted with diethyl ether (100 ml), stirred for an additional 5 min, and then filtered through Celite. The filtrate was washed with 5% hydrochloric acid and then a saturated solution of sodium bicarbonate, dried over anhydrous sodium sulphate, and decolourized with activated charcoal. Evaporation under reduced pressure gave **7** (0.68 g, 85%) which crystallized on standing. Recrystallization from diethyl ether gave fine white fibers; mp 180–181.5°C; $[\alpha]_D^{23}$ +90.8° (*c* 1.31, chloroform); ir ν_{max}: 1730 cm^{-1}; nmr (60 MHz) shows one doublet δ 5.27 (J_{12} = 5.0 Hz).[4] *Anal.* calcd. for $C_{48}H_{44}O_6$: C 80.42, H 6.18; found: C 80.35, H 6.22.

Ethyl 2,3-Dideoxy-2-C ((R,S)-hydroxy(β-hydroxyethyl)-methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, 4a

A solution of the enone **1***a* (0.82 g, 1.98 mmol) and benzophenone (0.16 g, 0.88 mmol) in acetonitrile (40 ml) and 1,3-propanediol (300 ml) was irradiated in the usual

[4]For characteristic nmr features of these systems see the analysis of the 220 MHz spectrum of **8**.

way (method B) for 5 h. Thin-layer chromatography (diethyl ether – benzene (1:1)) at this time showed only photoproduct (R_f 0.14). The solvents were evaporated under reduced pressure (0.01 Torr and bath temperature of 94°C to remove propanediol). Column chromatography of the resulting residue afforded **4***a* (0.470 g, 49%) as an oil; ir: 1730 cm^{-1} saturated ketone; nmr (60 MHz) shows two doublets δ 5.24 (J_{12} = 50) and 5.08 (J_{12} = 4.2) in 2:1 ratio.

Ethyl 2,3-Dideoxy-2-C-(oxo(β-triphenylmethoxyethyl)-methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, ***8***

The photoproduct from the preceding experiment, **4***a* (0.287 g, 0.58 mmol), was tritylated in pyridine (5 ml) with trityl chloride (0.65 g, 2.34 mmol) over 72 h. Normal work-up and column chromatography (petroleum ether (30–60°C) – ethyl acetate (4:1)) gave the ditritylate **4***b* (0.225 g, 53%). This ditritylate was oxidized in methylene chloride (20 ml) with chromium trioxide – dipryidine (1.1 g, 4.3 mmol) for 0.5 h. The solution was diluted with diethyl ether (80 ml) and filtered through Celite. The filtrate was processed in the usual manner to afford **8** (0.210 g, 93%). Recrystallization from diethyl ether gave needles, mp 140–141°C; $[\alpha]_D^{23}$ +99.8° (*c* 1.96, chloroform); nmr (HR-220) δ: 2.42 (dd, 1, $J_{2,3e}$ = 4.2 Hz, $J_{3e,3a}$ = 15.2 Hz, H-3*e*) 2.64–2.92 (m, 3, H-3*a*, 8, 8′), 3.05 (m, 1, $J_{2,3a}$ = 12.2 Hz, H-2), 3.38 (dd, 1, $J_{5,6e}$ = 6.1 Hz, $J_{6e,6a}$ = 10.0 Hz, H-6*e*), 3.49 (dd, 1, $J_{5,6a}$ = 2.9 Hz, H-6*a*), 3.30–3.50 (m, 2, H-9, 9′), 4.20 (dd, 1, H-5), 5.25 (d, 1, $J_{1,2}$ = 5.5 Hz, H-1). *Anal.* calcd. for $C_{49}H_{46}O_6$: C 80.52, H 6.34; found: C 80.49, H 6.42.

Ethyl 2,3-Dideoxy-2-C-((R,S)-hydroxy(carbomethoxy-methyl)methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, ***5a***, *and Its Tetrahydropyranyl Derivative* ***5b***

(*a*) A solution of the enone **1***a* (0.25 g, 0.60 mmol) and benzophenone (0.03 g, 0.17 mmol) in methyl 3-hydroxy propionate (90 ml) was irradiated for 5.5 h in the usual manner (method A). Thin-layer chromatography (petroleum ether (30–60°C) – ethyl acetate (13:7)) revealed the absence of enone (R_f 0.60) and the production of **5***a* (R_f 0.32). The methyl 3-hydroxy propionate was evaporated at 0.01 Torr with a bath temperature of 60°C. Column chromatography of the resulting residue gave **5***a* (0.112 g, 32%) as a yellow oil.

(*b*) A solution of enone **1***a* (1.50 g, 3.62 mmol) and benzophenone (0.18 g, 0.99 mmol) in methyl 3-hydroxy propionate (600 ml) was irradiated for 6 h in the usual manner (method A). The methyl 3-hydroxy propionate was evaporated off as described in (*a*) and the resultant residue was treated with 3,4-dihydropyran (3.0 g, 35 mmol) and toluenesulphonic acid (0.020 g, 0.10 mmol) in methylene chloride (40 ml) at −10°C for 0.75 h. The reaction mixture was poured into a sodium bicarbonate solution and the methylene chloride layer separated, washed with water, dried over sodium sulphate, and evaporated. Compound **5***b* (1.62 g, 74% from **1***a*) was isolated after column chromatography (petroleum ether (30–60°C) – ethyl acetate (4:1)) of the resulting oil. R_f 0.30 in petroleum ether (30–60°C) – ethyl acetate (4:1); ir: 1730 cm^{-1}. Treatment of **5***a* (prepared in (*a*)) with dihydropyran gave an identical derivative.

Ethyl 2,3-Dideoxy-2-C-(oxo(carbomethoxymethyl)-methyl)-6-O-triphenylmethyl-α-D-threo-hexo-pyranosid-4-ulose, ***9***

The photoproduct **5***a* (0.090 g, 0.17 mmol) was treated with chromium trioxide – dipyridine (0.80 g, 3.14 mmol) in methylene chloride (10 ml) for 0.5 h. The reaction mixture was then diluted with diethyl ether (30 ml) and filtered through Celite. The filtrate was washed with 5% hydrochloric acid and then a saturated sodium bicarbonate solution. Evaporation, after drying over sodium sulphate gave **9** (0.031 g, 34%) as an oil; nmr (HR-220) δ: 2.50 (dd, 1, $J_{2,3e}$ = 4.4 Hz, $J_{3e,3a}$ = 15.6 Hz, H-3*e*), 2.85 (dd, 1, $J_{2,3a}$ = 12.5 Hz, H-3*a*), 3.18 (m, 1, H-2), 3.39 (dd, 1, $J_{5,6e}$ = 6.1 Hz, $J_{6e,6a}$ = 9.6 Hz, H-6*e*), 3.49 (dd, $J_{5,6a}$ = 2.5 Hz, H-6*a*), 3.60 (s, 2, H-8, 8′), 3.73 (s, 3, OMe), 4.24 (dd, 1, H-5), 5.23 (d, 1, $J_{1,2}$ = 5.8 Hz, H-1).

Methyl 2,3-Dideoxy-2-C-(R,S)-hydroxy(hydroxymethyl)-methyl)-2-C-methyl-6-O-trityl-α-D-threo-hexo-pyranosid-4-uloses, ***6a***$_1$ *and* ***6a***$_2$*, and Their Ditrityl Derivatives,* ***6b***$_1$ *and* ***6b***$_2$

The enone **2** (1.242 g, 3.0 mmol) and benzophenone (0.087 g, 0.48 mmol) were dissolved in ethylene glycol (240 ml) and photolyzed in the usual manner (method A). After 7 h tlc indicated that the reaction was complete and that two new products had been formed. Evaporation of the solvent and chromatographic separation afforded **6***a*$_1$ (0.810 g, 38%) (R_f 0.16, in petroleum ether (30–60°C) – ethyl acetate (4:1)) which on tlc charred red on spraying with sulphuric acid, and **6***a*$_2$ (0.70 g, 33%) (R_f 0.20, same solvent mixture) which on tlc charred black on spraying with sulphuric acid.

The diol **6***a*$_1$ (or **6***a*$_2$) (0.500 g, 1.05 mmol) was dissolved in dry pyridine (10 ml) and trityl chloride (0.836 g, 3.0 mmol) was added. The reaction mixture was placed in an oil bath (50°C) and stirred for 36 h. At this time tlc indicated that the starting material had been consumed and a new compound had been formed. Conventional work-up and chromatography of the reaction product afforded **6***b*$_1$ (or **6***b*$_2$) (0.653 g, 91%).

Compound **6***b*$_1$ was an amorphous solid: R_f 0.57 in petroleum ether (30–60°C) – ethyl acetate (4:1); ir ν_{max}: 3600, 3440 (OH), 1735 (saturated ketone) cm^{-1}; ms *m/e*: 463 (M^+ − Tr); nmr (220 MHz) δ: 0.88 (s, 3, C—CH_3), 1.77 (d, 1, $J_{3e,3a}$ = 12.0 Hz, H-3*e*), 2.14 (d, 1, H-3*a*), 2.91, 3.27, 3.45, 3.82, 4.09 (set of multiplets (2 ABM systems), 6, H-5, -6, -6′ and H-7, -8, -8′), 3.09 (s, 3, OCH_3), 5.70 (s, 1, H-1), 7.2–7.8 (m, 30, phenyl).

Compound **6***b*$_2$ was a syrup: R_f 0.64 in petroleum ether (30–60°C) – ethyl acetate (4:1); ir ν_{max}: 3440 (OH), 1735 (saturated ketone) cm^{-1}; ms *m/e*: 463 (M^+ − Tr); nmr (220 MHz) δ: 0.83 (s, 3, C—CH_3), 1.75 (d, 1, $J_{3e,3a}$ = 11.5 Hz, H-3*e*), 2.0 (d, 1, H-3*e*), 3.05, 3.45, 3.77, 4.05 (set of multiplets (2 ABM systems), 6, H-5, -6, -6′, and H-7, -8, -8′), 3.25 (s, 3, OCH_3), 5.55 (s, 1, H-1), 7.2–7.8 (m, 30, phenyl).

Methyl 2,3-Dideoxy-2-C-(oxo(triphenylmethoxymethyl)-methyl)-2-C-methyl-6-O-trityl-α-D-threo-hexo-pyranosid-4-ulose, ***10***

(*a*) The ditritylated alcohol **6***b*$_1$ (0.350 g, 0.49 mmol) was dissolved in methylene chloride (10 ml) and the chromium trioxide – dipyridine complex (2.1 g, 8.1 mmol)

was added to the vigorously stirred solution. After 1 h at room temperature a tlc of the reaction mixture indicated that all of the starting material had been consumed and a new slower-running compound had been produced. The reaction mixture was diluted with ether (40 ml) and stirred an additional 15 min. The solution was then filtered through a bed of Celite and the filtrate was washed successively with a 5% hydrochloric acid solution (20 ml), a saturated sodium bicarbonate solution (20 ml), and water (20 ml). The organic layer was then decolourized, dried over sodium sulphate, and evaporated to afford **10** (0.312 g, 89%).

(*b*) The ditritylated alcohol **6**b_2 (0.320 g, 0.45 mmol) when subjected to the same reaction as above afforded **6**b_1 (0.272 g, 85%).

The compounds produced in parts (*a*) and (*b*) had the same R_f 0.52 in petroleum ether (30–60°C) – ethyl acetate (4:1) and gave identical ir and nmr spectra.

The diketone **10** was a noncrystalline foam which gave the following data: ir ν_{max}: 1730 (saturated ketone) cm^{-1}; ms *m/e*: 461 ($M^+ - Tr$); nmr (220 MHz) δ: 1.07 (s, 3, C—CH_3), 2.34 (d, 1, $J_{3e,3a}$ = 16.0 Hz, H-3*e*), 2.73 (d, 1, H-3*a*), 3.40 (m(ABX), 2, $J_{6,6'}$ = 11.0 Hz, $J_{5,6}$ = 7.0 Hz, $J_{5,6'}$ = 2.5 Hz, H-6, -6′), 3.45 (s, 3, OCH_3), 3.96 (s, 2, H-8, -8′), 4.03 (dd, 1, H-5), 5.05 (s, 1, H-1), 7.2–7.8 (m, 30, phenyl).

Ethyl 2,3-Dideoxy-2-C-(2-propyl-1,3-dioxolan-2-yl)-6-O-trityl-α-D-threo-hexopyranosid-4-ulose, ***12***

The enone **1***a* (0.248 g, 0.6 mmol), benzophenone (0.018 g, 0.1 mmol), and 2-propyl-1,3-dioxolane (2.80 g, 24 mmol) were dissolved in acetonitrile (70 ml) and photolyzed in the usual manner (method B). After 2 h tlc indicated that the reaction was complete and a new product (R_f 0.33, petroleum ether (30–60°C) – ethyl acetate (4:1)) had been formed. The residue obtained after evaporation of the solvents was chromatographed on a silica gel column using the same solvent system and afforded **12** (0.197 g, 62%). Compound **12** was a syrup which gave the following data: ir ν_{max}: 1730 (saturated ketone) cm^{-1}; ms *m/e*: 485 ($M^+ - OEt$), 287 ($M^+ - Tr$); nmr δ: 0.7–1.9 (m, 10, —CH_2CH_3, alkyl side chain), 2.2–2.75 (m, 3, H-2, -3*e*, -3*a*), 3.3–4.4 (m, 9, H-5, -6, -6′, —CH_2CH_3, ketal methylene), 5.12 (d, 1, $J_{1,2}$ = 4.0 Hz, H-1), 7.2–7.8 (m, 15, phenyl).

2-(3-Oxocyclohexyl)-2-methyl-1,3-dioxolane, ***17***

2-Cyclohexenone (5 g, 0.05 mol), benzophenone (600 mg, 3.3 mmol), and 2-methyl dioxolane (50 ml) in cyclohexane (800 ml) was irradiated in the usual manner (method B) for 57 h. The product was fractionated on a silica column using petroleum ether (30–60°C) – ethyl acetate (4:1) and the material of R_f 0.19 was collected (5.2 g, 54%). Compound **17** gave the following data: ir ν_{max}: 1730 (saturated ketone) cm^{-1}; ms *m/e*: 183 ($M^+ - 1$); nmr (60 MHz) δ: 1.2 (s, 3, CH_3), 1.4–2.5 (m, 9, ring protons), 3.87 (s, 4, ketal methylene).

2-Hydroxymethyl-1,3-dioxolane, ***20*** *(Scheme 5)*

Acetic anhydride (118 ml, 1.25 mol) and acetic acid (120 ml, 2.1 mol) were refluxed in a 500 ml flask while *cis*-2-butene-1,4-diol (44.0 g, 0.5 mol) was added dropwise. The reaction mixture was refluxed for 24 h. At this time the reflux condenser was replaced by a Vigreux column (30 cm) and the reaction mixture was fractionally distilled under aspirator vacuum. The product, 1,4-di-*O*-acetyl-*cis*-2-butene-1,4-diol, was collected by high vacuum distillation after the acetic anhydride and acetic acid had been removed: yield 66.0 g, bp 75–80°C (1.5 Torr).

The diacetate (10.0 g, 0.058 mol) was dissolved in ethyl acetate (100 ml) and cooled to 0°C in an ice bath. Ozone was bubbled through the solution until the starting olefin had been consumed (tlc). Pd/C (5%) (0.5 g) was added and the reaction mixture was hydrogenated at atmospheric pressure at 0°C. The crude product obtained upon filtration and evaporation was dissolved in benzene (20 ml). Ethylene glycol (1.86 g) and *p*-toluenesulphonic acid (0.018 g) were added and the reaction mixture was refluxed using a Dean–Stark trap to remove the water formed during the reaction. After 6 h the reaction mixture was poured into a separatory funnel and diluted with ether (20 ml). The organic layer was washed with a saturated sodium bicarbonate solution (20 ml) and water (20 ml), dried over sodium sulphate, and evaporated. The residue was fractionally distilled to give 2-acetoxymethyl-1,3-dioxolane: yield 5.1 g; bp 49–51°C, 0.4 Torr; R_f 0.44 (petroleum ether (30–60°C) – ethyl acetate (1:1)); nmr δ: 2.03 (s, 3, —$OCOCH_3$), 3.90 (m, 4, —CH_2CH_2—), 4.0 (d, 2, J = 4.0 Hz, —CH_2CH—), 5.03 (t, 1, J = 4.0 Hz, acetal proton).

The acetylated acetal (5.0 g, 0.034 mol) was dissolved in methanol (30 ml) and sodium carbonate (4.25 g, 0.051 mol) was added. The reaction mixture was stirred at room temperature for 4 h, filtered through a bed of Celite, and evaporated to dryness. The residue was extracted with chloroform and filtered. The filtrate was evaporated to dryness and the resulting oil was distilled under high vacuum to give **20**: yield 2.9 g; bp 44–48°C, 0.5 Torr; R_f 0.18 (petroleum ether (30–60°C) – ethyl acetate (1:1)); nmr δ: 2.9 (bs, 1, OH), 3.68 (d, 2, J = 3.0 Hz, —CH_2OAc), 4.0 (m, 4, —CH_2CH_2—), 5.05 (t, 1, J = 3.0 Hz, acetal proton).

Ethyl 2,3-Dideoxy-2-C-(2-hydroxymethyl-1,3-dioxolan-2-yl)-6-O-trityl-α-D-threo-hexopyranosid-4-ulose, ***21***

The tritylated enone **1***a* (0.620 g, 1.5 mmol) and the acetal **20** (6.0 g, 60 mmol) were dissolved in acetonitrile (140 ml) and photolyzed in the usual manner (method B). After 4 h the reaction was complete (tlc) and a new product had been formed, R_f 0.23 in petroleum ether (30–60°C) – ethyl acetate (2:1). The residue obtained after normal work-up was chromatographed on a silica gel column using the same solvent system as eluant to afford **21** (0.319 g, 42%). Compound **21** was a syrup which gave the following data: ir ν_{max}: 3460 (OH), 1735 (saturated ketone) cm^{-1}; ms *m/e*: 487 ($M^+ - CH_2OH$), 441 ($M^+ - Ph$); nmr δ: 1.26 (t, 3, J = 7.0 Hz, CH_2CH_3), 2.3–2.9 (m, 3, H-2, -3*e*, -3*a*), 3.3–4.4 (m, 10, H-5, -6, -6′, ketal methylene, —CH_2OH), 5.15 (d, 1, $J_{1,2}$ = 4.0 Hz, H-1), 7.2–7.8 (m, 15, phenyl).

Methyl 2,3-Dideoxy-2-C-(2-hydroxymethyl-1,3-dioxolan-2-yl)-2-C-methyl-6-O-trityl-α-D-threo-hexopyranosid-4-ulose, ***23***

The tritylated enone **2** (0.435 g, 1.05 mmol), the acetal **20** (4.2 g, 42 mmol), and benzophenone (0.032 g, 0.18 mmol) were dissolved in acetonitrile (100 ml) and photolyzed in the usual manner. The reaction was stopped after 48 h. At this time tlc indicated that a new product had been formed, R_f 0.21 in petroleum ether (30–60°C) –

ethyl acetate (4:1). Some starting material was still present, and some decomposition had occurred. After the usual work-up the residue was chromatographed on a silica gel column using the same solvent system, whereby unreacted starting material (0.152 g) was obtained. On this basis the yield of compound **23** (0.163 g) was 46%. Compound **23** was a syrup which gave the following data: ir ν_{max}: 3450 (OH), 1720 (saturated ketone) cm^{-1}; ms *m/e*: 487 ($M^+ - OCH_3$) or ($M^+ - CH_2OH$); nmr δ: 0.85 (s, 3, C—CH_3), 1.92 (m, 2H, H-3*e*, -3*a*), 3.22 (s, 3, OCH_3), 3.3–4.5 (m, 10, H-5, -6, -6′, ketal methylenes, —CH_2OH), 4.88 (s, 1, H-1), 7.2–7.8 (m, 15, phenyl).

Ethyl 2-C-Acetyl-2,3-dideoxy-6-O-trityl-α-D-threo-hexo-pyranosid-4-ulose, ***24***

(*a*) The enone **1***a* (0.465 g, 1.12 mmol), benzophenone (0.036 g, 0.2 mmol), and acetaldehyde (6.3 ml, 0.112 mol) were dissolved in acetonitrile (90 ml) and photolyzed in the usual manner (method B). The reaction was complete in 5 h (tlc) and a new compound had been formed (R_f 0.40 in petroleum ether (30–60°C) – ethyl acetate (4:1)). The residue obtained after evaporation of the solvents was chromatographed on a silica gel column in the same solvent system to afford compound **24** (0.344 g, 67%).

(*b*) The enone **1***a* (1.5 g, 3.72 mmol) and benzophenone (0.113 g, 0.62 mmol) were dissolved in ethanol and photolyzed in the usual manner (method A). After 7 h tlc indicated that the reaction was complete and a new product had been formed (R_f 0.20 in petroleum ether (30–60°C) – ethyl acetate (4:1)). The residue obtained after the usual work-up was chromatographed on a silica gel column and afforded **26** (1.29 g, 76%) as a mixture of epimers. The material (0.59 g, 1.3 mmol) was dissolved in methylene chloride (35 ml) and the chromium trioxide – dipyridine complex (1.8 g) was added to the vigorously stirred solution. After 1 h tlc indicated that the starting material had all been consumed and a new product had been formed. The reaction mixture was diluted with ether (100 ml) and stirred for an additional 15 min. The solution was then filtered through a bed of Celite, decolourized, and dried over sodium sulphate. Compound **24** (0.515 g, 86%) was recovered when the solvents were evaporated.

Compound **24** after crystallization from ethanol gave the following data: mp 107–108°C; $[\alpha]_D^{23}$ +150° (*c* 1.0, $CHCl_3$); ms *m/e*: 381 (M^+ – Ph), 215 (M^+ – Tr); nmr δ: 1.3 (t, 3, J = 8.0 Hz, CH_2CH_3), 2.21 (s, 3, —$COCH_3$), 2.47 (m, 1, H-3*e*), 2.79 (m, 1, H-3*a*), 3.03 (m, 1, H-2); 3.3–4.2 (m, 5, H-5, -6, -6′, —CH_2CH_3), 5.32 (d, 1, $J_{1,2}$ = 5.0 Hz, H-1); 7.20–7.70 (m, 15, phenyl). *Anal.* calcd. for $C_{29}H_{30}O_5$: C 75.96, H 6.59; found: C 75.98, H 6.53.

Ethyl 2-C-Benzoyl-2,3-dideoxy-6-O-trityl-α-D-threo-hexo-pyranosid-4-ulose, ***25***

The enone **1***a* (0.464 g, 1.12 mmol), benzophenone (0.036 g, 0.2 mmol), and benzaldehyde (10 ml) were dissolved in acetonitrile (80 ml) and photolyzed in the usual manner (method B). After 2 h tlc indicated that the starting material had all been consumed and a new product had been formed R_f 0.41 in petroleum ether (30–60°C – ethyl acetate (4:1)). The residue obtained upon evaporation of the solvents was dissolved in ether (50 ml) and washed successively with a saturated sodium bisulphite solution (3 × 50 ml) and water (50 ml). The solution was then dried over sodium sulphate and evaporated to dryness. The residue was separated on a silica gel column using the same solvent system and afforded **25** (0.338 g, 58%). Compound **25** was crystallized from ether–hexane and gave the following data: mp 127–128°C; $[\alpha]_D^{23}$ +178.7° (*c* 1.83, $CHCl_3$); nmr δ: 1.3 (t, 3, J = 7.0 Hz, —CH_2CH_3), 2.4–3.0 (m, 3, H-2, -3*a*, -3*e*), 3.2–4.4 (m, 5, H-5, -6, -6′, —CH_2CH_3); 5.4 (d, 1, $J_{1,2}$ = 5.0 Hz, H-1), 7.2–8.3 (m, 20, phenyl). *Anal.* calcd. for $C_{34}H_{32}O_5$: C 78.44, H 6.20; found: C 78.50, H 6.17.

3-Acetylcyclohexanone, ***18***

(*a*) 2-Cyclohexenone (0.432 g, 4.5 mmol), benzophenone (0.136 g, 0.75 mmol) and acetaldehyde (40 ml) were dissolved in acetonitrile (320 ml) and photolyzed in the usual manner (method B). After 10 h an nmr spectrum of the crude reaction mixture indicated that the reaction was complete. The residue was chromatographed on a silica gel column and afforded compound **18** (0.317 g, 42%); R_f 0.23 in petroleum ether (30–60°C) – ethyl acetate (4:1). The structure of **18** was confirmed by comparison of its nmr and ir spectra with published data for the compound prepared by another route (11).

(*b*) 3-(-1-Hydroxyethyl)cyclohexane (1) (0.564 g) was dissolved in methylene chloride (20 ml) and treated with 3.0 g of chromium trioxide – dipyridine complex. After 1 h, the reaction was worked up as described above for **10** and the material was purified by column chromatography: R_f 0.31 in benzene–ether (1:1); nmr (60 MHz) δ: 1.4–2.4 (m, 8, ring protons), 2.10 (s, 3, CH_3), 2.5–3.0 (m, 1, methine). These data were in excellent agreement with those described for compound **18** (11).

(*c*) The ketal **17** (500 mg) was dissolved in dioxane (5 ml) and 1 *N* sulfuric acid (5 ml) added. The solution was stirred at room temperature and after 1 h, tlc in benzene–ether (1:1) indicated that the hydrolysis was complete. Customary work-up and chromatography afforded 300 mg of **18**. (The ketal **17** on standing at room temperature decomposes to diketone **18**.)

1-Acetyl-3-cholestanone, ***28***

1-Cholesten-3-one **27** (0.431 g, 1.1 mmol), benzophenone (0.036 g, 0.2 mmol), and acetaldehyde (10 ml) were dissolved in acetonitrile (100 ml) and irradiated for 12 h in the usual manner (method B). The product was chromatographed on a silica column using diethyl ether – benzene (1:9) and the substance having R_f 0.22 was recovered (0.192 g, 42%) and recrystallized from methanol; mp 139–140°C; ms *m/e*: 428 (M^+), 413 ($M^+ - CH_3$), 385 (M^+ – Ac), 385 (M^+ – (Ac + CH_3)); 315 ($M^+ - C_8H_{17}$); nmr δ: 2.00–2.31 (m, 3, H-2 ax., H-4 eq., H-4 ax.), 2.21 (s, 3, $COCH_3$), 2.40 (q, 1, H-2 eq.), 3.26 (dd, 1, H-1). *Anal.* calcd. for $C_{29}H_{28}O_2$: C 81.25, H 11.29; found: C 81.28, H 11.12.

3,3-Dimethyl-2,5-hexanedione, ***29***

Mesityl oxide (0.440 g, 5.1 mmol), benzophenone (0.154 g, 0.85 mmol), and acetaldehyde (40 ml) were dissolved in acetonitrile (320 ml) and photolyzed in the usual manner (method B). After 2 h an nmr spectrum of the crude reaction mixture obtained upon evaporation of the solvents indicated that the starting material had all

been consumed. The residue was chromatographed on a silica gel column using petroleum ether (30–60°C) – ethyl acetate (4:1). One fraction (R_f 0.33) which was detected by exposing the tlc plate to iodine vapor, gave compound **29** (0.205 g, 31%) as a light yellow oil. The nmr spectrum of **29** exhibited the following: δ: 1.25 (s, 6, C—CH_3), 2.12 (s, 3, $COCH_3$), 2.18 (s, 3, $COCH_3$), 2.8 (s, 2, CH_2). Compound **29** was characterized as its bis-2,4-nitrophenylhydrazone, mp 216–217°C, (lit. (13) 217–218°C).

Synthetic routes to 2′,3′-cyclopropanated and 2′,3′-unsaturated nucleosides[1]

STEVE YIK-KAI TAM[2] AND BERT FRASER-REID

Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received April 11, 1977

STEVE YIK-KAI TAM and BERT FRASER-REID. Can. J. Chem. **55**, 3996 (1977).

Cyclopropyl glycopyranosides which solvolyze via a stabilized cyclopropyl carbinyl-oxocarbonium ion react under neutral conditions with nucleoside bases in nitromethane at 200°C to give good yields of the corresponding cyclopropanated nucleosides. Under similar conditions hex-2-enopyranosides (which solvolyze by allyl-oxocarbonium ions) do not react. However, under catalysis by mercuric bromide or acetic acid, the corresponding 2′,3′ unsaturated nucleosides are formed although accompanied by appreciable amounts of 1′,2′-unsaturated-3′-nucleosides. Formation of the latter may be avoided if the hex-2-enopyranosides are first converted to the hex-2-enopyranosyl acetates by treatment with boron trifluoride and acetic anhydride. The derived acetates react with the nucleoside bases without catalysis to give anomeric mixtures of nucleosides, there being no trace of the unwanted 3′-nucleosides.

STEVE YIK-KAI TAM et BERT FRASER-REID. Can. J. Chem. **55**, 3996 (1977).

Les cyclopropyl glycopyrannosides lesquels se solvolysent via un ion cyclopropyl-oxocarbonium stabilisé, réagissent dans des conditions de neutralité avec des bases nucléosides dans le nitrométhane à 200°C pour conduire avec de bons rendements au nucléoside cyclopropylé correspondant. Dans des conditions similaires, les hexéno-2 pyrannosides (lesquels se solvolysent par un ion allyl-oxocarbonium) ne réagissent pas. Par contre, ces réactions catalysées par le bromure mercurique ou l'acide acétique conduisent aux nucléosides 2′,3′-insaturés correspondants quoique accompagnés d'une quantité appréciable de nucléosides-3′ 1′,2′-insaturés. La formation de ce dernier peut-être évitée si on transforme en premier lieu les hexéno-2 pyrannosides en acétate d'hexéno-2 pyrannosyle par action du trifluorure de bore et de l'anhydride acétique. Ces acétates réagissent, sans catalyseur, avec les bases nucléosides pour conduire à des mélanges anomériques de nucléosides. On n'observe aucune trace des nucléosides-3′ non désirés.

[Traduit par le journal]

Introduction

In a previous paper from our laboratory, the synthesis and chemistry of some cyclopropyl glycopyranosides (e.g. **1** and **2**) were described (1). The fact that the glycosides, **1** and **2**, were readily hydrolyzed by boiling water to the carboxaldehyde **4** was attributed to the remarkable stability of the intermediate cyclopropylcarbinyl-oxocarbonium ion (**3**)[3] (2, 3), the existence of which was supported by the exclusive formation of **4** in the silver-ion assisted hydrolysis of the homoallyl iodide **5** (1, 5). Further study of the solvolysis of the cyclopropyl compounds revealed that in **3** the stabilization of the anomeric cation by the ring oxygen completely overwhelms that by the cyclopropyl ring (4). Thus the stabilized ion **3** may be regarded as an 'activated' intermediate for carbonium ion reactions occurring at the anomeric center. In this paper we report that this stable intermediate (Scheme 1) may be exploited for the preparation of 2′,3′-cyclopropanated nucleosides which proceed via an anomeric cation (for a review see ref. 6), and as an extension of this study we have developed a new approach to the synthesis of 2′,3′ unsaturated nucleosides by making use of stabilized allyl-oxocarbonium ions (**6**) (7).

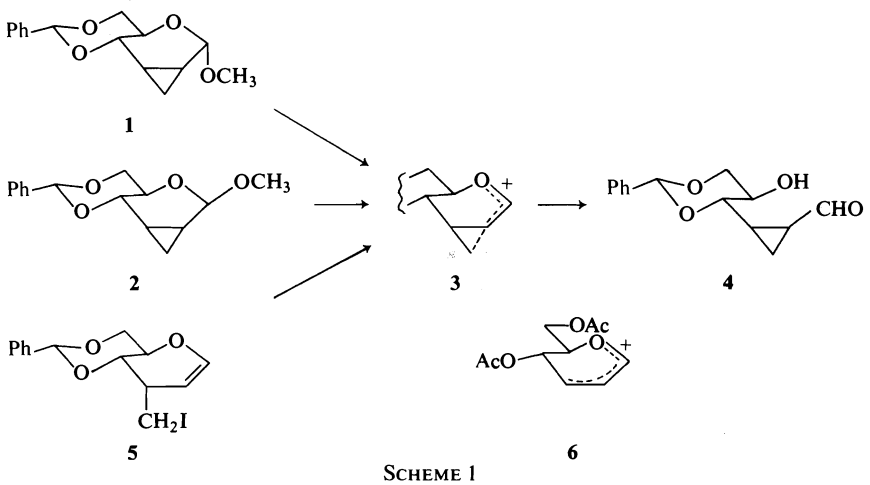
Results and Discussion

Condensation of **1** with 6-chloropurine was effected by heating the reactants in nitromethane without any added catalyst (Scheme 2). After 6 h of reaction, a 1:1 anomeric mixture of the 2′,3′-cyclopropanated nucleosides **7** was isolated in 71% yield. The anomers could be partially separated by silica gel column chromatography,

[1]Cyclopropylcarbinyl-oxocarbonium ions, Part VIII. For Part VII see ref. 4.

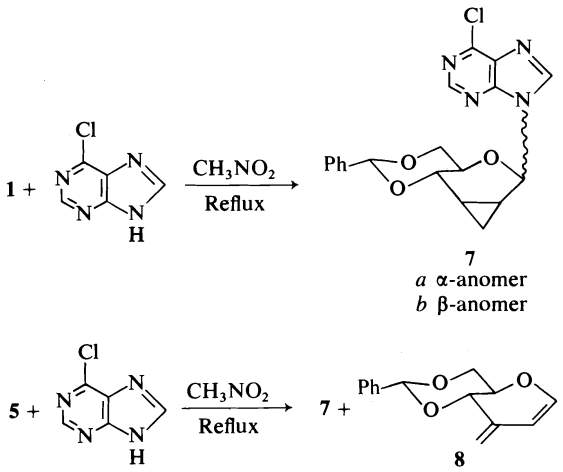
[2]Taken from the Ph.D. Thesis of S. Y-K. Tam. Present address: Sloan Kettering Institute for Cancer Research, 145 Boston Post Road, Rye, New York, NY 10580, U.S.A.

[3]An alternative name for **3** is cyclopropyl(oxo)methylium ion (4).



SCHEME 1

and anomeric configurational assignments were made by comparing their ^{1}H nmr spectra to those of their glycosidic counterparts **1** and **2** (1) (Table 1). Thus α-configuration was assigned to the anomer showing the larger $J_{1',2'}$ value.



SCHEME 2

The position of substitution on the purine residue was determined to be N-9 by the uv data in ethanol: 263 nm (ε = 10 383) and 257 nm (ε = 9161). These values are closer to those usually observed for N-9 substitution (8, 9) than to those (278–283 nm, ε = 7400) for N-7 substitution (10).

Reaction of the homoallyl iodide **5** with 6-chloropurine under the agency of silver nitrate and sodium carbonate afforded the same mixture of the anomers of **7** in 58% yield. In the latter reaction the previously described (3, 4) diene **8** resulting from elimination of hydrogen iodide was isolated in 20% yield.[4]

The reaction of the 2,3-unsaturated glycopyranoside **9** with 6-chloropurine in refluxing nitromethane was very slow in comparison to the cyclopropyl glycopyranoside **1**, and **9** remained largely unreacted even after 1 day. Addition of mercuric bromide or acetic acid to the reaction mixture resulted in formation of a significant amount of the unwanted 3′-nucleosides, **11**, identifiable by characteristic (see for example ref. 11) ^{1}H nmr signals, ~6.6 and ~5.0 ppm for the glycal protons H′-1 and H′-2.

We suspected that the formation of **11** might be due to the acidic catalyst employed and consequently decided to examine a substrate which would not require such catalysis. Thus the glycoside **9** was first converted to the glycosyl acetate **12** by treatment with acetic anhydride in the presence of a catalytic amount of boron trifluoride etherate (Scheme 3), and **12** was then reacted with 6-chloropurine in refluxing nitromethane. This alteration proved advantageous since a 1:1 anomeric mixture of **10** was obtained in 48% yield, and **11** was not detected in the reaction mixture. Interestingly, small amounts of glycal sugars, **13** and **14**, were also formed in the boron trifluoride – acetic anhydride reaction of **9**. However, these were recovered unreacted in the nucleoside-formation reaction.

[4]Attempts were made to obtain the free nucleosides from **7**. Since the usual methods of debenzylidenation, viz. hydrogenolysis and acid hydrolysis, were incompatible with the cyclopropane ring, the Hanessian–Hular reaction (22) was attempted, but this led to a complex mixture.

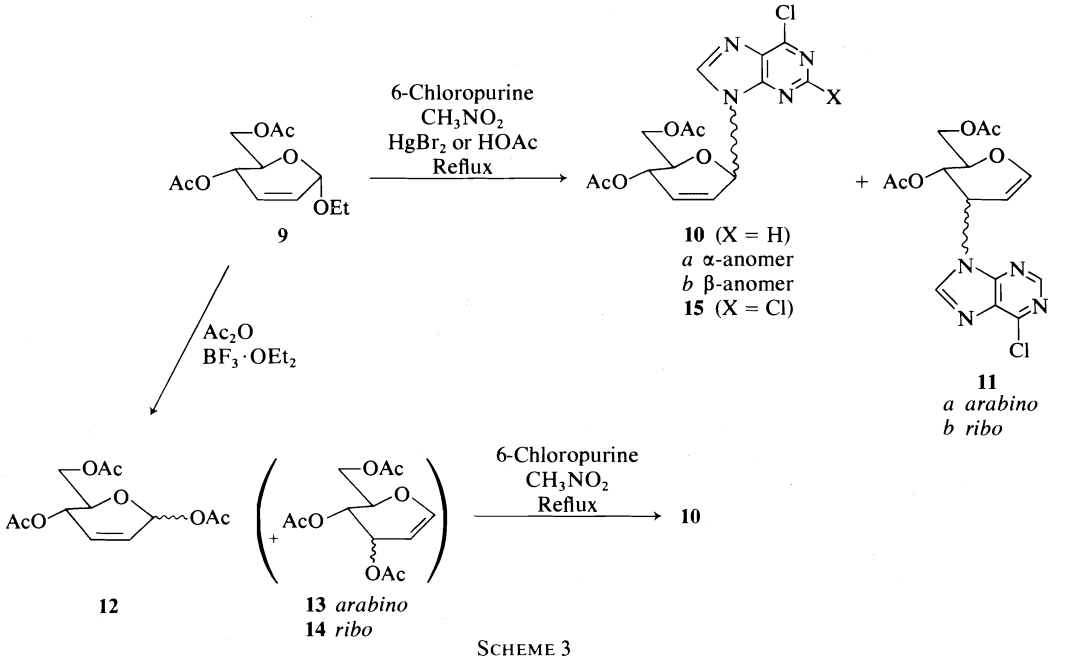


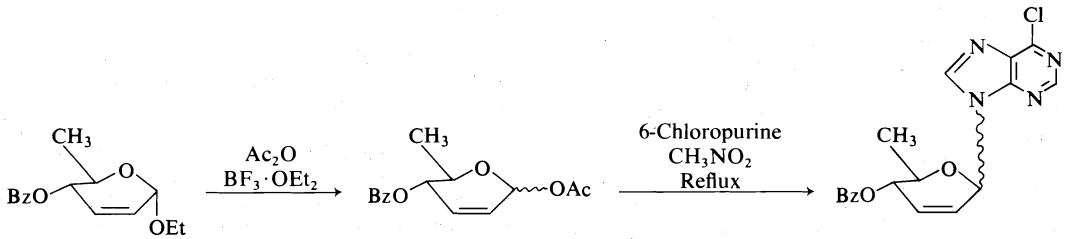
SCHEME 3

The anomers of **10** could be partially separated by silica gel column chromatography. The ^1H nmr parameters and optical rotation values (Table 2) of the pure anomers are in good agreement with the reported data for the authentic anomers, which were obtained by Garcia-Munoz and co-workers, from the reaction of triacetylglucal with 6-chloropurine (8). Accordingly, the β-anomer was identified as the isomer showing the larger homoallyl coupling ($J_{1',4'}$) and smaller $J_{1',2'}$ value. For purposes of comparison, the parameters of the 2,6-dichloropurine derivatives (**15**) which were prepared by Ferrier and Ponpipom (9) are also included in Table 2.

When the same sequence of reactions (Scheme 4) was applied to the 6-deoxy olefinic sugar **17** obtained from **16** (12), an overall yield of 33% of the 6′-deoxy-2′,3′-unsaturated nucleosides **18** was obtained. In this case, the β-anomer (**18***b*) could be fractionally crystallized from the anomeric mixture. Again, no trace of nucleosides of the glycal type (e.g. **11**) was detected.

Summary

Compound **7** is the first example of a 2′,3′-cyclopropanated nucleoside. Its formation from **1** without the need for acid catalysis demonstrates once again the exceptional stability of the cyclopropylcarbinyl-oxocarbonium ion[3] intermediate (**3**) which results upon cleavage of the glycoside bond (5). The formation of **7** from the homoallyl iodide **5** further confirms the intervention of **3** in these reactions. The comparatively slower



Bz = PhCO
SCHEME 4

reaction of the 2,3-unsaturated glycopyranoside **9** parallels the previously observed differences in the rate of hydrolysis of **1** and **9** (13). All these results indicate that **3** is a more highly stabilized carbonium ion than the allyl-oxocarbonium ion, **6**.

Conversion of the glycoside, **9**, to the glycosyl acetate, **12**, facilitated the formation of the ion **6** for obvious reasons. This approach to the synthesis of 2′,3′-unsaturated nucleosides from a 2,3-unsaturated hexopyranoside via the corresponding acetate, offers at least one advantage over the existing and most commonly used 'glycal approach' (8, 9, 14–16). The method provides exclusively the 2′,3′-unsaturated nucleosides, whereas the 'glycal approach' furnishes the 1′,2′-unsaturated 3′-nucleosides (17, 18) and/or 2′-deoxy nucleosides (8, 19–21) as side products, thereby increasing the difficulty in isolating the desired product. Further experiments to test the generality of the method are underway and will be reported in due course.

Experimental

General

Melting points were determined on a Fischer-Johns heating stage or a Mel-Temp apparatus, and are uncorrected. The nmr spectra were determined, unless otherwise stated, in deuteriochloroform containing 1% tetramethylsilane as internal standard with either a Varian T-60, a Varian HA 100, or a Varian HR 220 spectrometer. Coupling constants were obtained by measuring spacings of spectra judged to be first order.

Thin-layer chromatography (tlc) was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm and developed with petroleum ether (35–60°C) – ethyl acetate (1:1) unless otherwise stated. The chromatograms were first viewed under ultraviolet light, then exposed to iodine vapor, and finally sprayed with concentrated sulfuric acid. Heating in an oven is required for complete visualisation.

For column chromatography, E. Merck silica gel (0.05–0.20 mm, 70–325 mesh A.S.T.M.) was used.

6-Chloro-9-(4′,6′-O-benzylidene-2′,3′-dideoxy-2′,3′-C-methylene-(α and β)-D-allopyranosyl)purine, **7**

(*a*) 6-Chloropurine (2 g, 12.9 mmol) was dissolved in 95 ml freshly dried nitromethane and methyl 4,6-*O*-benzylidene-2,3-dideoxy-2,3-*C*-methylene-α-D-allopyranoside **1** (1) (2 g, 7.3 mmol) was added. After refluxing vigorously under anhydrous conditions for 6 h, the reaction mixture was allowed to cool. Evaporation of the solvent afforded a solid residue the nmr spectrum of which indicated the presence of unreacted starting material and a 50:50 mixture[5] of **7**α and **7**β. The product mixture was fractionated on a column of silica with 50% ethyl acetate in petroleum ether (30–60°C) as irrigating solvent. The chromatogram afforded 550 mg of starting material (**1**), 60 mg of pure **7**β, 1.45 g of a mixture of the two anomers (**7**β (R_f 0.29) and **7**α (R_f 0.22)) and about 0.9 g of 6-chloropurine. The total yield of nucleosides was thus calculated to be 71% based on the recovered starting material. A further amount (32 mg) of **7**β could be crystallized out from the mixture with ethyl acetate – petroleum ether as solvent.

(*b*) 6-Chloropurine (200 mg, 1.3 mmol) was dissolved in 20 ml of hot nitromethane and then treated with sodium carbonate (400 mg), silver nitrate (100 mg), and 4,6-*O*-benzylidene-1,2,3-trideoxy-3-*C*-iodomethyl-D-*ribo*-hex-1-enopyranose, **5** (200 mg, 0.56 mmol). After refluxing vigorously under anhydrous conditions for 6 h, the reaction mixture was allowed to cool. Evaporation of the solvent afforded a solid residue, the nmr spectrum of which showed the complete disappearance of the starting material and the presence of the known (3, 4) diene **8** and a 50:50 mixture[4] of **7**α and **7**β. Column chromatography afforded 22 mg of the diene **8** (20% yield) and 125.1 mg of a mixture of **7**α and **7**β (58% yield). A small amount of unreacted 6-chloropurine was also recovered.

For compound **7**β after recrystallization from methanol: mp 222.0–224.5°C; $[\alpha]_D^{23}$ +23.54° (*c* 1, $CHCl_3$); uv λ_{max} (EtOH): 263 nm (ε 10 383) and 257 nm (ε 9161). The nmr parameters are presented in Table 1. *Anal.* calcd. for $C_{19}H_{17}O_3N_4Cl$: C 59.31, H 4.45, N 14.56, Cl 9.21; found: C 59.30, H 4.62, N 14.25, Cl 9.73.

Compound **7**α has not been obtained completely free of **7**β. The nmr parameters shown in Table 1 were obtained on a slightly impure sample.

6-Chloro-9-(4′,6′-di-O-acetyl-2′,3′-dideoxy-(α and β)-D-erythro-hex-2′-enopyranosyl)purine, **10**

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside **9** (2 g, 7.7 mmol) was dissolved in a mixture of acetic anhydride (9 ml) and dry benzene (20 ml) and then boron trifluoride etherate (0.02 ml) was added. After stirring at room temperature for 8 h, the light brown solution mixture was poured into ice-cold sodium bicarbonate solution (50 ml) and stirred for 0.5 h. The mixture was then extracted with ether and washed with water. The dried (Na_2SO_4) solution on evaporation afforded a thick syrup from which methanol was evaporated a few times to remove acetic acid. The final syrupy product weighed 1.98 g and showed, on tlc, two overlapping spots of R_f 0.45 and 0.40. The latter was later shown to be the glycosyl acetate **12** and the former was a mixture of the unreacted starting material **9** and the glycal side products **13** and **14**. The nmr spectrum of the product showed that **12** constituted 77% of the mixture and since fractionation could not be effected the mixture was used directly for the following synthesis.

The syrupy mixture containing **12** (1.4 g) was dissolved in nitromethane (50 ml), and 6-chloropurine (1.0 g) was added. The mixture was then refluxed vigorously for 8 h. After removal of the solvent, the solid residue was fractionated on a silica column with 40% ether in benzene as eluant. The first zone afforded 325 mg of a mixture of **13**, **14**, and unreacted **12**. The second zone afforded a pure syrupy sample of the β-nucleoside **10**β (25 mg), and the third a (50:50) mixture of **10**α and **10**β (883 mg). The pure α-nucleoside **10**α (24 mg) was obtained from

[5]Nuclear magnetic resonance estimate based on relative intensity of the (H-1′)'s of (**7**α) and (**7**β) at τ 3.39 and 3.67 respectively.

the fourth zone. The total yield of the nucleosides was thus calculated to be 48% based on compound **9**, or 66% based on the glycosyl acetate **12**.

For **10**α: $[\alpha]_D^{23}$ +65.7° (*c* 1, $CHCl_3$); λ_{max} (EtOH): 263 nm.

For **10**β: $[\alpha]_D^{23}$ +80.5° (*c* 0.5, $CHCl_3$); λ_{max} (EtOH): 263 nm.

Nuclear magnetic resonance parameters are shown in Table 2. The physical constants of **10**α and **10**β are in good agreement with published data for the compounds prepared by another route (8).

*6-Chloro-9-(4′-O-benzoyl-2′,3′,6′-trideoxy-(*α *and* β*)-*D*-erythro-hex-2′-enopyranosyl)purine,* ***18***

Methyl 4-*O*-benzoyl-2,3,6-trideoxy-α-D-hex-2-enopyranoside **16** (12) (1 g) was dissolved in a mixture of acetic anhydride (4.5 ml) and dry benzene (10 ml), and boron trifluoride etherate (0.01 ml) was added. The mixture was stirred at room temperature for 5 h and then worked up as described above for **12**. The syrupy product weighed about 1 g and appeared to be homogeneous on tlc (R_f 0.69 in 50% ether in benzene), although the nmr spectrum showed that there were some glycal derivatives (cf. **13** *and* **14**) in addition to **17**.

The syrupy product mixture (1 g) was dissolved in 30 ml of nitromethane and 6-chloropurine (600 mg) was added. The mixture was then heated in a Wood's alloy bath at a temperature of 200°C for 7 h. After removal of the solvent, the solid residue was fractionated on a silica column with 50% ether in benzene as eluant to afford 154 mg of a mixture of **17** and glycal impurities. The nucleosides obtained from the column had a total weight of 489 mg. The nmr spectrum of the mixture closely resembled that of **10**α and **10**β (Table 2). The composition of the α and β anomers of **18** in the mixture was about 50:50 based on the relative intensity of the signals centered at τ 8.62 and 8.70 for the methyl doublets. The yield of the anomeric mixture of **18** was calculated to be 33% based on compound **16**.

Fractional crystallization of the mixture with hexane afforded 135 mg of pure **18**β: mp 186–188°C; $[\alpha]_D^{23}$ +162.3° (*c* 1, $CHCl_3$); λ_{max} (EtOH): 263 and 232 nm. *Anal.* calcd. for $C_{18}H_{15}O_3N_4Cl$: C 58.31, H 4.08, N 15.11, Cl 9.56; found: C 58.27, H 4.26, N 15.21, Cl 9.53.

The stereochemistry of conjugate addition of lithium dialkyl cuprate reagents to some carbohydrate α-enones

MARK BERNARD YUNKER,[1] DIETER ERNEST PLAUMANN, AND BERT FRASER-REID

Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received April 11, 1977

MARK BERNARD YUNKER, DIETER ERNEST PLAUMANN, and BERT FRASER-REID. Can. J. Chem. **55**, 4002 (1977).

Conjugate addition–alkylation reactions of lithium dialkyl cuprates to hex-2-enopyrano-4-ulosides (**1**), hex-3-enopyrano-2-ulosides (**2**), and hex-1-enopyrano-3-uloses (**3**) have been investigated. Extensive studies with **1** show that the homogeneous system using the soluble tri-*n*-butylphosphine copper(I) complex is less satisfactory than the heterogeneous medium in which copper(I) iodide is used. The use of Grignard reagents versus alkyl lithiums has also been investigated, the latter being found preferable. 1,2-Addition was observed in some cases, but conditions were developed to avoid formation of these side products.

With α-enones **1** and **2** alkylation is completely stereoselective, the newly introduced alkyl group being in axial orientation. With **3** a complex mixture is obtained from which equatorial and axial adducts can be isolated in approximately equal amounts.

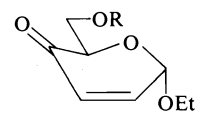
MARK BERNARD YUNKER, DIETER ERNEST PLAUMANN et BERT FRASER-REID. Can. J. Chem. **55**, 4002 (1977).

On étudie les réactions conjuguées d'addition–alkylation des dialkyl cuprates de lithium aux hexéno-2 pyrannoulosides-4 (**1**), hexéno-3 pyrannoulosides-2 (**2**) et hexéno-1 pyrannoulose-3 (**3**). Une étude développée sur **1** montre que le système homogène utilisant le complexe soluble tri-*n*-butylphosphine–cuivre(I) est moins satisfaisant que le milieu hétérogène dans lequel l'iodure de cuivre(I) est utilisé. On étudie aussi l'utilisation des réactifs de Grignard par rapport aux alkyllithiums, ces derniers ayant été trouvés préférables. Dans quelques cas, on observe une addition-1,2, mais les conditions sont développées de façon à avoir le moins de ces produits secondaires.

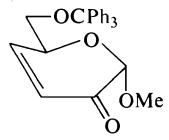
Avec les énones-α **1** et **2**, l'alkylation est entièrement stéréosélective et le groupement alkyle introduit a une orientation axiale. En utilisant **3**, un mélange complexe est obtenu dans lequel des adduits axiaux et équatoriaux peuvent être isolés dans des quantités approximativement égales.

[Traduit par le journal]

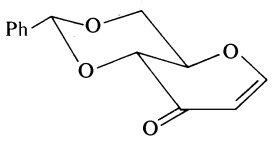
A programme of research in this laboratory involves the preparation of unsaturated derivatives of sugars and investigation of their usefulness for introducing new functionality into the pyranose ring (1). In pursuing this objective we have developed efficient syntheses of the α-enones **1** (2), **2** (3), **3** (4), and **4** (5), each of which opens the possibility for attaching new substituents at one, two, or three different sites of the molecule. Carbon–carbon branched sugars are of particular importance in view of their omnipresence among the major antibiotics. As a result we have investigated the stereochemical course of alkylation of enones **1**, **2**, and **3** and we report our findings herein. In accompanying papers (6, 7) we describe some photoalkylation reactions of these receptors.



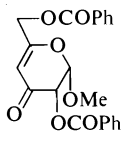
1



2



3



4

Lithium dialkyl copper(I) complexes are the preferred reagents for achieving conjugate-addition–alkylation of α-enones (8) and although the mechanism of the reaction has not been established firmly (9), it is apparent that the course of addition is strongly influenced by steric factors (10).

The reagent may be generated in either

[1]Taken in part from the Ph.D. Thesis of M. B. Yunker, University of Waterloo, 1975. Holder of NRCC Studentships 1972–1975. Present address: Chemistry Department, University of Victoria, Victoria, B.C., Canada.

TABLE 1. Copper(I) induced addition of alkyl residues to some carbohydrate α-enones

Entry	Substrate	Organoalkyl (4 equiv.)	Equivalents of nBu$_3$PCuI	1,4-Adduct (% yield)[a]	1,2-Adduct (% yield)[a]
1	**1***a*	MeMgI	2.00	**5***a* (50)	**6***a* (trace)
2	**1***a*	MeLi	0.02	**5***a* (29)	**6***a* (19 and 7)
3	**1***a*	MeLi	2.00	**5***a* (79)	**6***a* (trace)
4	**1***b*	MeMgI	2.00	**5***b* (88)	**6***b* (2 and 1)

9	**2**	$LiMe_2Cu$	—	**12** (83)	None

[a]After isolation by column chromatography.

homogeneous or heterogeneous systems (9) and we decided to examine both.[2]

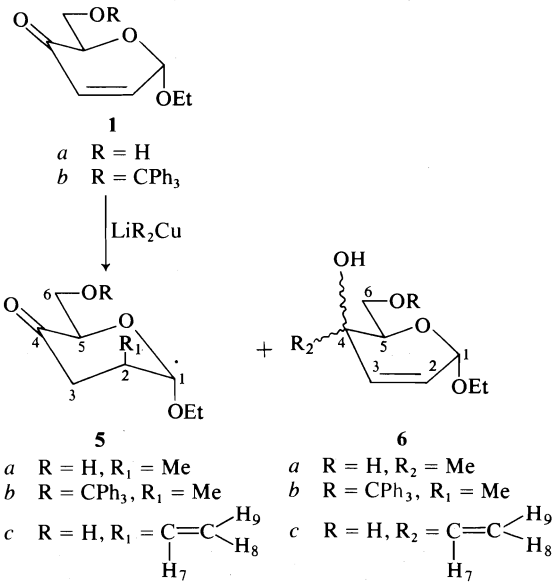
Additions to Alkyl Hex-2-enopyranosid-4-uloses (1)

Enone **1**, being the most accessible of the three, was used for our preliminary studies. The results in Table 1 show that with the homogeneous systems, the best yields of conjugate addition were achieved with alkyl lithiums rather than Grignards as the organometallic reagents. Also evident from the results is the fact that substantial amounts of the soluble copper complex must be used, and entries 1–3 versus 4–8 indicate the general superiority of the tritylated enone **1***b* for producing **2***b*.

With the heterogeneous system, the yield of adduct was somewhat less (Table 1, entry 8). However, this method is preferable since (*a*) preparation of the phosphine complex and (*b*) chromatography of the reaction product to remove the liberated phosphine are both avoided.

In either case the reaction gave a single 1,4-adduct (Scheme 1). The methyl **5***a* and vinyl **5***c* adducts were characterized as their 2,4-dinitrophenylhydrazones. Adduct **5***b* was detritylated and found to be identical to **5***a*.

The additions are therefore completely stereoselective and because of the sensitivity to steric effects (10), we had anticipated that addition would occur on the side opposite to the aglycon of **1**. However, the nmr spectra of **5** did not allow an unambiguous assignment of orientation. Thus in **5***a*, H-1 was located at 4.71 ppm with an observed spacing, J_{12} = 4.0 Hz. This value seemed consistent with *cis* hydrogens (i.e. axial H-2) as in α-D-*gluco* derivatives (11), implying that the addition had occurred from the *most* hindered side.

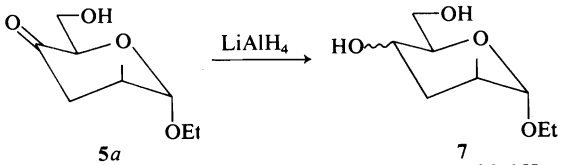


SCHEME 1

In order to gain clarification of this question, **5***a* was reduced with lithium aluminium hydride (Scheme 2). The product, **7**, was evidently a mixture of epimers judging from the elongated 'spot' on thin-layer chromatograms. Although the epimers could not be resolved, the 220 MHz nmr spectrum showed two anomeric protons at 4.47 and 4.57 ppm in the ratio 2:3 respectively, and with associated coupling constants J_{12} = 0.0 and 2.6 Hz. The value of these couplings is definitive evidence (12, 13) for a diequatorial relationship of H-1 and H-2.[3]

[2]Since this work was initially done (14) another soluble copper complex, Me_2S–CuBr, has been developed which is reported to be superior to Bu_3P–CuI (20).

[3]Additional, more rigorous proof for the stereochemistry at C-2 of **5***a* was obtained by correlation with the product from the photochemical addition of methanol to **1** (6, 14).

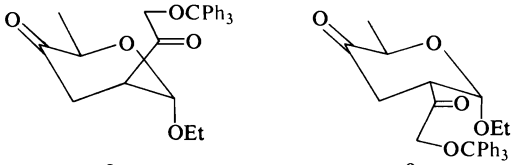


5*a*
J_{12} = 4.0 Hz

7
J_{12} = 0.0 and 2.6 Hz

SCHEME 2

It is evident that changing the hybridization at C-4 from sp^2 (in **5***a*) to sp^3 (in **7**) affects significantly the magnitude of J_{12}. Special caution in making assignments on systems such as these is therefore advisable, particularly since the value, $J_{12} \cong 4$, is usually diagnostic (11, 12) of axial–equatorial protons as in **9**. Thus with the epimers **8** and **9** prepared recently in connection with the



8
J_{12} = 5.2 Hz

9
J_{12} = 4.6 Hz

synthesis of pillarose (15), the J_{12} values are 5.2 Hz for the equatorial–equatorial hydrogens, and 4.6 for the equatorial–axial pair (16).

As indicated in Table 1, (entries 2 and 5) 1,2-addition products were also obtained, especially when smaller amounts of catalyst were employed. These products were recognized by their polar nature on thin-layer chromatograms and, after isolation, by their nmr spectra which showed olefinic signals and their infrared spectra which showed hydroxyl absorptions.

The epimeric tertiary alcohols **6** were usually isolated from chromatograms as syrupy, unstable mixtures. However, one epimer of **6***a* was obtained in sufficient quantity and purity (Table 1, entry 2) to be characterized as its *p*-nitrobenzoate.

There was only one vinyl adduct **6***c* obtained, and it was characterized by its nmr spectrum. The complex olefinic region consisted of superimposed AB(H-2,3) and ABM(H-7,8,9) patterns, and this analysis was verified by computer simulation (Fig. 1).

The orientation of the vinyl group in **6***c* is assigned as equatorial by comparison with the epimeric pair of allylic alcohols **10** and **11** prepared by Walker and Fraser-Reid in connection with the synthesis of pillarose (15). From the nmr data for **6***c*, **10**, and **11** shown in Table 3, it is

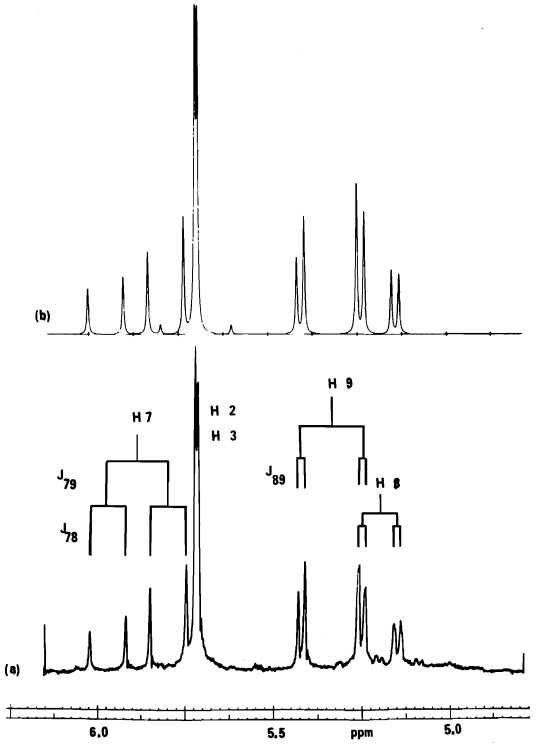


FIG. 1. (*a*) 220 MHz nmr spectrum of ethyl 2,3-dideoxy-4-*C*-vinyl-α-D-*threo*-hex-2-enopyranoside, **6***c*; (*b*) simulated spectrum (see also Table 3).

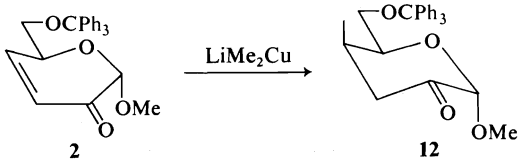
evident that those of **10** and **6***c* are closer than those of **11** and **6***c*.

It is seen from Table 1 (entries 6 and 8), that by judicious choice of reagent and substrate, the occurrence of 1,2-addition products may be obviated.

Additions to Hex-3-enopyranosid-2-uloses, 2

With the foregoing evidence from enone **1**, we turned our attention to enone **2**. Alkylation using the heterogeneous method (Scheme 3) gave



2 **12**

SCHEME 3

a single product, **12**, obtained in 83% yield, there being no evidence of a 1,2-adduct.

The structure of **12** was deduced from its 100 MHz ^{1}H nmr spectrum; data from this spectrum are shown in Table 2. Assignment of the stereochemistry at C-4 rests on information obtained, with the aid of decoupling experiments,

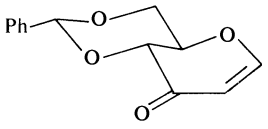
[d]See refs. 15 and 16.

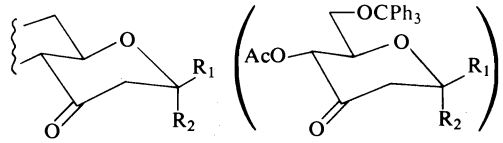
from the C-3 of methylene protons. Usually with a geminal pair of protons, the equatorial one occurs at lower field than the axial. This trend is increased in **12** by the anisotropy of the carbonyl group (17). Hence H-3 equatorial occurs at 2.98 ppm while H-3 axial is at 2.20 ppm. The signal for H-3 axial appears as a doublet of doublets $J = 15.0$ and 2.5 Hz, the former value being obviously the geminal coupling. The small value of 2.5 Hz is consistent only with an equatorial H-4 proton. The signal for H-3 equatorial is also a doublet of doublets with $J = 15.0$ and 6.0.

Additions to Hex-1-enopyran-3-uloses, 3

With the α-enone **3**, reaction with lithium dimethyl cuprate using either the homogeneous or heterogeneous system (Scheme 4) gave a complex



3



13

a $R_1 = H, R_2 = Me$
b $R_1 = Me, R_2 = H$

b $R_1 = CH_2OAc, R_2 = H$

SCHEME 4

mixture from which two conjugate addition products **13***a* and **13***b* were isolated by column chromatography in 18 and 20% yields respectively. There was no evidence for 1,2-addition in the other components of the complex mixture.

The stereochemistries of the epimeric pair **13***a* and **13***b* were assigned by comparison with the pair of *C*-glycosides **14***a* and **14***b* prepared by Walker and co-workers (6, 16). The data in Table 4 show that in the case of the equatorial congeners, **13***b* and **14***b*, H-2 resonates at 4.0 and 3.95 ppm respectively while with the axial pair, **13***a* and **14***a*, H-2 is at lower field, 4.6 and 4.76 ppm respectively. Similarly, in **13***b* and **14***b*, H-3 axial is ~2.5 and 2.72 ppm respectively, while in **13***a* and **14***a*, this proton is at 2.93 and 2.94 ppm respectively.

In summary, in the alkylation of enones **1** and **2**, the products of conjugate addition are exclusively axial. This is in agreement with the usually observed course of addition to 2-cyclohexenones (9, 10), as well as the observations of Gero and co-workers on the direction of kinetically controlled addition of nucleophiles to **1** (18). With enone **3**, however, this rule is apparently not obeyed.

Experimental

Melting points were determined in capillary tubes in a Mel-Temp block and are uncorrected. Elemental analyses were performed by Micro-analyses Laboratory, Toronto, Ontario. The nmr spectra ($CDCl_3$, TMS) were determined on a Varian T-60 a Varian HA 100, or a Varian HR-220 spectrometer, the *J* values quoted being the spacing measured directly from the spectra. Infrared spectra were

determined on a Beckman model IR-10 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent). Optical rotations were determined on a Carl Zeiss model LEP nür 370740 Lichtelektrishes Präzision polarimeter at 23°C.

Thin-layer chromatography was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The following solvent systems were used to develop the plates. Ethyl acetate – petroleum ether (30–60°C) (1:4); ethyl acetate – petroleum ether (30–60°C) (1:1); ethyl acetate; benzene. For column chromatography E. Merck silica gel (0.063–0.20 mm, 70–230 mesh A.S.T.M.) was used.

Ethyl 2,3-Dideoxy-2-C-methyl-α-D-threo-hexopyranosid-4-ulose (5a) and Its 6-O-Triphenylmethyl Derivative (5b)

The procedure in part (*b*) is generally preferred since chromatography is not needed for obtaining pure product.

(*a*) Methyl iodide (0.75 ml, 12 mmol) was added to a suspension of dry magnesium (0.296 g, 12 mmol) in anhydrous ether (20 ml) containing a crystal of iodine, an N_2 atmosphere and efficient stirring being maintained throughout. The mixture was then refluxed until the magnesium had all reacted, after which the solution was cooled to −78°C in a Dry Ice – acetone bath. The desired amount of tri-*n*-butylphosphine copper(I) iodide (19) (see Table 1) was added in ether (~15 ml) to give a bright yellow suspension.

Alternatively, the ethereal solution of tri-*n*-butylphosphine copper(I) iodide was added to methyl lithium at −78°C and diluted with ether to give a bright yellow solution.

In either case, after 15 min the enone **1***a* or **1***b* (3.0 mmol) (2) in ether (30 ml) was added dropwise. The mixture was stirred for 25 min and then poured into stirred saturated aqueous ammonium chloride (0.25 ℓ). The ether layer was separated, the aqueous layer extracted several times with ether, and the ether phases combined and dried. The residue resulting after evaporation was chromatographed on a silica column.

Results of various experiments using differing concentrations of the phosphine catalyst are shown in Table 1.

For compound **5***a* $R_f = 0.34$ in ethyl acetate – petroleum ether (30–60°C) (1:1); nmr data additional to those in Table 2; δ 3.56 and 3.85 (m, 2, $OCH_AH_BCH_3$, $J_{AB} = 9.5$ Hz), 1.25 (t, 3, OCH_2CH_3, $J = 7.0$), 1.11 (d, 3, CH—CH_3, $J = 6.0$).

For the 2,4-dinitrophenylhydrazone of **5***a* recrystallized from ethyl acetate, mp 188.5–189°C; $[\alpha]_D^{23} + 203°$ (*c* 0.51, $CHCl_3$). *Anal.* calcd. for $C_{15}H_{20}N_4O_7$: C 48.91, H 5.47, N 15.21; found: C 48.80, H 5.62, N 15.34.

Compound **5***b* was characterized by detritylation to **5***a*. For **5***b*, $R_f = 0.46$ in ethyl acetate – petroleum ether (30–60°C) (1:4); nmr data for **5***b* additional to those in Table 2: 3.3–4.1 (m, 2, OCH_2, CH_3), 1.24 (t, 3, OCH_2, CH_3, $J = 7.0$ Hz), 1.06 (d, 3, CH—CH_3, $J = 6.5$), 7–7.6 aromatic.

(*b*) Into a dry three-necked round bottom flask equipped with a nitrogen inlet and stirring bar were placed cuprous iodide (22.4 g, 0.118 mol) and anhydrous ether (500 ml). The suspension was cooled to −78°C and methyl lithium (0.238 mol) was added dropwise giving, eventually, a yellow solution. After 0.5 h the enone **1***b* (24.0 g, 0.0585 mol) (1*b*) dissolved in the minimum amount of ether was added dropwise and then stirring was continued for 1 h. The mixture was poured into saturated aqueous ammonium chloride and the product isolated by ether extraction in the usual way. The residue remaining after evaporation (21.0 g, 84%) was usually chromatographically pure **5***b* described above.

Ethyl 2,3-Dideoxy-4-C-methyl-α-D-hex-3-enopyranoside, 6a and its 6-O-Trityl Derivative 6b

If in the reaction described in (*a*), the reactant ratios in entries 3 and 7 (Table 1) were used, quantities of the epimeric tertiary alcohols **6***a* or **6***b* were obtained. These were readily recognized since they moved more slowly on tlc than the major products **5***a* or **5***b* respectively.

For the epimers **6***a*: $R_f = 0.13$ and 0.07 in ethyl acetate – petroleum ether (30–60°C) (1:1).

For component of $R_f = 0.13$: ir 3600 cm^{-1}, no car-

bonyl; nmr data additional to those in Table 2: δ 3.5–4.2 (m, 2, OCH_2—CH_3), 1.25 (t, 3, OCH_2—CH_3), 1.18 (s, 3, C—CH_3) exchangeable OH, J_{12} = 2 Hz, J_{23} = 10 Hz.

p-Nitrobenzoate derivative recrystallized from ether – petroleum ether (30–60°C), mp 83.5–84°C; $[\alpha]_D$ +29.0° (*c* 1.88, in $CHCl_3$). *Anal.* calcd. for $C_{10}H_{19}NO_7$: C 56.97, H 5.68, N 4.15; found: C 56.88, H 5.64, N 4.22.

For component of R_f = 0.07: ir 3600 cm^{-1}, no carbonyl; nmr data additional to those in Table 2: δ 3.3–4.1 (m, 2, OCH_2CH_3), 1.22 (t, 3, OCH_2CH_3), 1.25 (s, 3, C—CH_3) exchangeable OH.

For the epimers of **5***b*: R_f = 0.29 and 0.18 in ethyl acetate – petroleum ether (30–60°C) (1:4).

For compound of R_f = 0.29: ir 3600 cm^{-1}, no carbonyl; nmr data additional to those in Table 2: δ 3.1–4.2 (m, 2, OCH_2CH_3), 1.25 (t, 3, OCH_2CH_3), 1.26 (s, 3, CCH_3), aromatic and exchangeable OH, J_{12} = 3 Hz, J_{23} = 10 Hz.

For component of R_f = 0.18: ir 3600 cm^{-1}, no carbonyl; nmr data additional to those in Table 2: δ 3.2–4.2 (m, 2, OCH_2CH_3), 1.32 (t, 3, OCH_2CH_3), 1.28 (s, 3, CCH_3), aromatic and exchangeable OH.

Ethyl 2,3-Dideoxy-2-C-vinyl-α-D-threo-hexopyranosid-4-ulose, **5***c*

A few crystals of iodine were added to dry magnesium (0.483 g, 20 mmol) in dry tetrahydrofuran (25 ml) and vinyl bromide (1.4 ml, 20 mmol) was added, and the mixture was brought to reflux under a nitrogen atmosphere and with constant stirring. It was necessary to use a Dry Ice–isopropanol condenser during the reflux. After 1 h the magnesium had all reacted. The solution was cooled to −78°C, and tri-*n*-butylphosphine copper(I) iodide (see Table 1) dissolved in ether (~20 ml) was added. Enone **1***a* (0.86 g, 5 mmol) (1b) in ether (40 ml) was added dropwise and the stirring continued for 0.5 h. After the usual work-up procedure (see above) the residue was fractionated on a silica column using ethyl acetate – petroleum ether (30–60°C) (1:1).

For compound **5***c*: R_f = 0.52 in ethyl acetate – petroleum ether (30–60°C) (1:1); nmr data additional to those in Table 2: δ 3.60 and 3.85 (m, 2, $OCH_AH_BCH_3$, J_{AB} = 9.5 Hz), 1.25 (t, 3, OCH_2CH_3, *J* = 7.0 Hz). For —CH_7=CH_8H_9: δ 5.85 (m, 1, H-7, J_{27} = 6.5 Hz, J_{78} = 10 Hz, J_{79} = 17 Hz), 5.18 (d, 1, H-8, J_{89} = 1.25 Hz), 5.14 (d, 1, H-9).

2,4-Dinitrophenylhydrazone of **5***c* was recrystallized from ethyl acetate, mp 175–175.5°C; $[\alpha]_D^{23}$ +144° (*c* 1.13, $CHCl_3$). *Anal.* calcd. for $C_{16}H_{20}N_4O_7$: C 50.53, H 5.30, N 14.73; found: C 50.37, H 5.39, N 14.59.

Ethyl 2,3-Dideoxy-4-C-vinyl-α-D-threo-hex-2-enopyranoside, **6***c*

The chromatographic fractionation described immediately above (see also Table 1) afforded compound **6***c*, R_f 0.19 in ethyl acetate – petroleum ether (1:1); ir 3600 cm^{-1}, no carbonyl; nmr data additional to those in Table 3: δ 3.6–4.2 (m, 2, OCH_2CH_3), 1.25 (t, 3, OCH_2CH_3). For —CH_7=CH_8H_9: δ 5.88 (dd, 1, H-7, J_{78} = 10.25, J_{79} = 17.13), 5.21 (dd, 1, H-8, J_{89} = 1.80), 5.35 (dd, 1, H-9).

Methyl 3,4-Dideoxy-4-C-methyl-6-O-triphenylmethyl-α-D-threo-hexopyranosid-2-ulose, **12**

Into a dry three-necked flask equipped with a stirrer, nitrogen inlet, and dropping funnel was placed 9.0 g (0.047 mol) of cuprous iodide and dry ether (250 ml). The suspension was cooled to −78°C in a Dry Ice – acetone bath, and to it was added dropwise 79 ml of 1.3 *M* methyl lithium (0.102 mol). The solution became clear and a trace of yellow material remained in suspension. After 10 min, a solution of enone **2** (9.5 g, 0.023 mol) in the minimum amount of dry ether was added dropwise. Once the addition was completed, the solution was stirred for a further 45 min and was then poured into aqueous saturated bicarbonate solution (2 ℓ) and stirred for 1 h. The solution was then poured into a separatory funnel and the ether layer was recovered. The aqueous layer was washed with chloroform (2 × 150 ml) and the organic phases were combined and dried (Na_2SO_4). Evaporation under reduced pressure yielded 9.5 g of crude product which was eluted down a column of silica gel using 50% ethyl acetate – petroleum ether (30–60°C). Compound **12** (8.1 g, 83%) was a crystalline substance, mp 164–165°C; $[\alpha]_D^{23}$ +4.6° (*c* 3.10, chloroform); nmr data for **12** additional to those in Table 2: δ 3.56 (s, 3, OCH_3). 7.25–7.60 (m, 15, aromatic), $J_{12} \cong 0$, J_{3ax4} = 2.5, J_{3eq4} = 6.0, J_{3ax3eq} = 15.0, J_{56} = 6.0, $J_{56'}$ = 7.0, $J_{66'}$ = 12.0. *Anal.* calcd. for $C_{26}H_{28}O_4$: C 77.86, H 6.71; found: C 77.98, H 6.71.

2,6-Anhydro-5,7-benzylidene-1,3-dideoxy-D-arabino-hept-4-ulose, **13***a*, *and 2,6-Anhydro-5,7-benzylidene-1,3-dideoxy-D-ribo-hept-4-ulose*, **13***b*

Conjugate addition of methyl to the enone **3** (0.230 g, 1.0 mmol) (4) was carried out as described above for preparation of **5***a*. The two products **13***a* and **13***b* were isolated by silica column chromatography, 0.044 g (20%) and 0.043 g (18%) respectively, using ethyl acetate – petroleum ether (30–60°C) (1:1); R_f = 0.36 and 0.42 respectively.

For compound **13***a*: nmr (60 MHz) δ: 1.32 (d, 3, J_{12} = 8.0 Hz, H-1), 4.60 (ddq, 1, H-2), 2.93 (dd, 1, J_{3a3e} = 14 Hz, J_{23a} = 6, H-3*a*), 2.35 (dd, 1, J_{23e} = 1.5, H-3*e*), 3.5–4.5 (m, 4, H-5, H-6, H-7, H′-7), 5.5–6 (s, 1, H-8), 7.1–7.5 (m, 5, aromatic).

2,4-Dinitrophenylhydrazone: mp 243–243.5°C; $[\alpha]_D^{23}$ −58° (*c* 0.34, $CHCl_3$). *Anal.* calcd. for $C_{20}H_{20}N_4O_7$: C 56.07, H 4.71, N 13.08; found: C 56.04, H 4.62, N 13.09.

For compound **13***b*: nmr (60 MHz) δ: 1.32 (d, 3, J_{12} = 7.0 Hz, H-1), 4.0 (m, 1, H-2), 2.5 (m, 2, H-3*a*, H-3*e*), 3.5–4.7 (m, 4, H-5, H-6, H-7, H′-7), 5.56 (s, 1, H-8), 7.2–7.6 (m, 5, aromatic).

2,4-Dinitrophenylhydrazone: mp (sealed tube) 256–257°C. $[\alpha]_D^{23}$ −128° (*c* 0.20, $CHCl_3$). *Anal.* calcd. for $C_{20}H_{20}N_4O_7$: C 56.07, H 4.71; found: C 55.94, H 4.80.

Reçu le 5 avril 1977

GABRIEL LORD, LUC FOISY, LUCIE BARIL, DENIS GRAVEL et GILLES DUROCHER. Can. J. Chem. **55**, 4010 (1977).

L'étude des processus photophysiques ainsi que de la photolyse des dérivés diphénylés en position 4 du γ-pyranne (**1**) et du γ-thiopyranne (**2**) est discutée dans cet article. Les effets de solvants, de températures et de variations dans l'intensité de la source photolytique sont parmi les paramètres expérimentaux utilisés lors de cette étude. Il est démontré que la première transition électronique singulet–singulet chez les molécules (**1**) et (**2**) est de nature ππ*. Les chromophores divinyléther et divinylthioéther contribuent à la première transition électronique de ces molécules et également ils participent à la désactivation non-radiative de l'état premier singulet excité de ces molécules. Par ailleurs, l'énergie de l'état triplet ππ* inférieur semble surtout localisée dans les groupements phénylés.

Il est également démontré que la photolyse du diphényl-4,4 pyranne (**1**) s'effectue suivant un mécanisme monomoléculaire pour produire une photoaldéhyde qui à son tour est décomposée sous l'effet du rayonnement. Il est de plus montré que cette aldéhyde est un photoproduit secondaire dans la séquence photoréactionnelle du diphényl-4,4 pyranne.

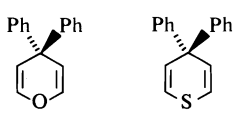
GABRIEL LORD, LUC FOISY, LUCIE BARIL, DENIS GRAVEL, and GILLES DUROCHER. Can. J. Chem. **55**, 4010 (1977).

The photophysical processes along with the photolysis of 4,4-diphenyl-γ-pyran (**1**) and 4,4-diphenyl-γ-thiopyran (**2**) are discussed in this paper. The solvent effect, the temperature effect, and the photolytic source intensity dependence of the yield of the secondary photoproduct are all among the experimental parameters investigated. It is shown that the first singlet–singlet electronic transition in molecules **1** and **2** is ππ* in nature. The divinyl ether and divinyl thioether chromophore play a role in this transition and also directly contribute to the radiationless deactivation of the first excited singlet states of these molecules. On the other hand the energy of the first triplet ππ* state seems to be more localized in the phenyl groups of the molecules **1** and **2**.

It is also shown that the photolysis of molecule **1** occurs by a monomolecular mechanism to produce a photoaldehyde which is also photolysed under prolonged irradiation. This aldehyde has also been shown to be a secondary photoproduct in the photoreaction sequence of 4,4-diphenyl-γ-pyran.

Introduction

Dans le cadre plus général de l'étude des propriétés photophysiques et photochimiques de systèmes divinyliques cycliques substitués par différents hétéro atomes en position 1 du cycle, nous rapportons dans ce travail le comportement photophysique de deux molécules types: le diphényl-4,4 γ-pyranne (**1**) et le diphényl-4,4 γ-thiopyranne (**2**).



1 **2**

[1]Etudiant au doctorat, boursier du Ministère de l'éducation du Québec.

Alors que peu de réactions photochimiques ont été étudiées aussi intensément que le réarrangement di-π-méthane surtout par le groupe de Zimmerman et ses collaborateurs (1–3), on ne relève que deux études dans la littérature sur les dérivés disubstitués en position 4 du pyranne et ce sont des substitutions de type aryl-benzyl (4, 5). Récemment, Gravel et coll. ont publié la synthèse de même qu'une étude photochimique du diphényl-4,4 γ-pyranne (6). A notre connaissance, aucune étude spectroscopique ni photophysique des dérivés disubstitués en position 4 du pyranne et du thiopyranne n'a été publiée jusqu'à ce jour. Ce travail s'insère dans le projet d'étude de la photochimie et de la spectroscopie des chromophores du type —C—C—O—C—C— et —C—C—S—

C—C—. Deux articles sur ces derniers ont déjà été publiés (7, 8).

Conditions expérimentales

Produits chimiques

Le diphényl pyranne (**1**) et le diphényl thiopyranne (**2**) ont été synthétisés puis purifiés par recristallisation et sublimation par Gravel et coll. (6). Le méthyl-3 pentane utilisé comme solvant était de marque "Pure grade" de la compagnie Phillips Petroleum. Il a été traité sur H_2SO_4, distillé, neutralisé puis redistillé sur sodium. L'éthanol 95% de marque commerciale a été distillé sur H_2SO_4 puis redistillé sur sodium. Ces deux solvants ainsi traités formaient de beaux verres à 77 K dans des tubes cylindriques de 3 mm de diamètre intérieur ou encore dans des cellules rectangulaires de 2 mm de parcours optique. De plus l'intensité de l'émission provenant des impuretés résiduelles étaient nettement inférieure par un facteur 10 environ à l'intensité des émissions provenant des molécules **1** et **2**.

Mesures spectrales

Les spectres d'absorption ont été enregistrés à la température ambiante ainsi qu'à 77 K sur un spectrophotomètre Cary 17 et également dans quelques cas (pour les cinétiques) sur un appareil Spectronic 505 de Bausch and Lomb. Les spectres de fluorescence et de phosphorescence ont été enregistrés à l'aide d'un spectrofluorophosphorimètre Aminco-Bowman à focalisation ellipsoïdale; la correction des spectres en unité de quanta s^{-1} a été décrite antérieurement de même que le module expérimental pour l'observation de la phosphorescence (9). Une lampe xénon a été utilisée à l'excitation avec un arrangement de fentes nous procurant une bande passante de 3 nm.

La méthode d'obtention des rendements quantiques de fluorescence à la température ambiante a déjà été décrite en utilisant le diphényl-9,10 anthracène (DPA) comme substance étalon (10). Alors que l'on continue dans la littérature de référer à deux valeurs bien distinctes pour le rendement quantique de la DPA en solution diluée ($< 5 \times 10^{-5}\ M$) dans le cyclohexane soit 0.83 (11) et 1.0 (12), nous avons utilisé la première valeur pour des raisons déjà énumérées précédemment (10). Les solutions ont d'abord été dégazées et le pourcentage de désactivation de la fluorescence par l'oxygène a été obtenu et utilisé à nouveau pour d'autres solutions, la reproductibilité s'est avérée très bonne. Le rendement quantique de fluorescence à 77 K des molécules **1** et **2** a été obtenu par comparaison des surfaces sous les bandes de fluorescence à la température ambiante et à 77 K. Nous avons alors tenu compte de la variation dans l'indice de réfraction des solvants entre les deux températures de même que de la variation dans la densité optique à la longueur d'onde d'irradiation (13).

Les rendements quantiques de phosphorescence à 77 K des composés **1** et **2** ont été obtenus à l'aide de deux substances étalons différentes avec le même résultat compte-tenu de la précision expérimentale de l'ordre de 15% dans les rendements de phosphorescence. La fluorescence de la DPA à 77 K avec un rendement quantique de 0.83, a été utilisée puisqu'il a été démontré que ce rendement quantique ne dépend pas de la température (13). La phosphorescence du naphtalène à 77 K avec un rendement quantique de 0.06 a également été utilisée (14). Pour chacune des substances étalons la densité optique à 77 K a été ajustée à celle du produit dont le rendement était inconnu à la longueur d'onde d'excitation.

Photolyse

Les irradiations à 2537 Å ont été effectuées avec deux montages différents: *1.* Une lampe au mercure basse pression (Hanovia "Flat Spiral" Z1500-203) a été utilisée dans toutes les mesures de cinétique d'apparition des photoproduits observés. Un dispositif a été conçu pour intercaler des filtres de densité neutre entre le faisceau lumineux produit par cette lampe et l'échantillon à photolyser. Ces filtres de densité neutre faits en grillage métallique possédaient les pourcentages de transmission suivants: 75, 64.6, 50.1 et 27.5%. *2.* D'autres séries d'expériences ont été effectuées dans un réacteur Rayonet.

Résultats et discussion

(1) Spectres d'absorption

Les spectres d'absorption des molécules **1** et **2** sont tracés sur les figs 1 et 2 et cela pour un solvant non polaire et un solvant polaire. Comme on peut le constater l'effet de solvant est minime sur l'énergie du premier système de bandes, un faible effet bathochrome est observé en passant d'un solvant non polaire à un solvant polaire comme l'éthanol. Le second système de bandes à énergie plus élevée est davantage influencé par le solvant, ce qui contribue à expliquer le recouvrement plus marqué des deux premiers systèmes de bandes électroniques de ces molécules dans un solvant comme l'éthanol. Par ailleurs les spectres d'émission sont tout à fait identiques lorsqu'enregistrés dans les solvants polaires et non polaires. Ceci est caractéristique d'une transition $\pi^* \leftarrow \pi$ faiblement permise comme celle observée chez le benzène ($^1B_{2u} \leftarrow {}^1A_g$).

Les coefficients d'extinction molaire confirment également cette dernière attribution. Par soustraction du deuxième système de bandes, nous avons été amenés à mesurer les coefficients d'extinctions molaires (ε) au maximum d'absorption de la première transition électronique de ces molécules: la molécule **1** montre un ε de 440 M^{-1} cm^{-1} à 38 460 cm^{-1} (2600 Å) dans le méthyl-3 pentane (3MP) pour lequel le recouvrement entre les deux systèmes est réduit à son minimum. Par ailleurs ils nous a fallu utiliser l'approximation de la bande de type gaussien à 41 kK pour en déduire un ε de 540 M^{-1} cm^{-1} à 34 250 cm^{-1} dans le 3MP pour la molécule **2**. Les énergies des transitions électroniques pures ($\bar{\nu}_{00}$) ont été évaluées en faisant la moyenne arithmétique

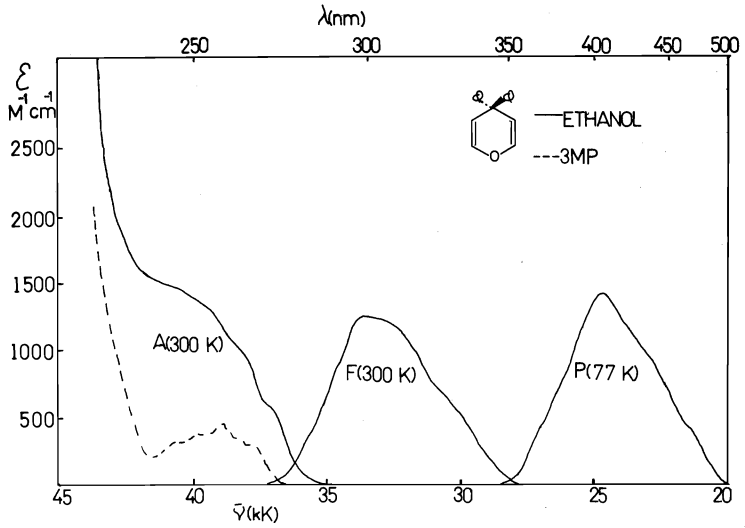


FIG. 1. Spectres d'absorption, de fluorescence et de phosphorescence du diphényl-4,4 pyranne (**1**) dans l'éthanol et dans le méthyl-3 pentane. Les spectres d'émission sont corrigés et tracés en unités relatives de quanta $cm^{-3}\ s^{-1}$ en ordonnée.

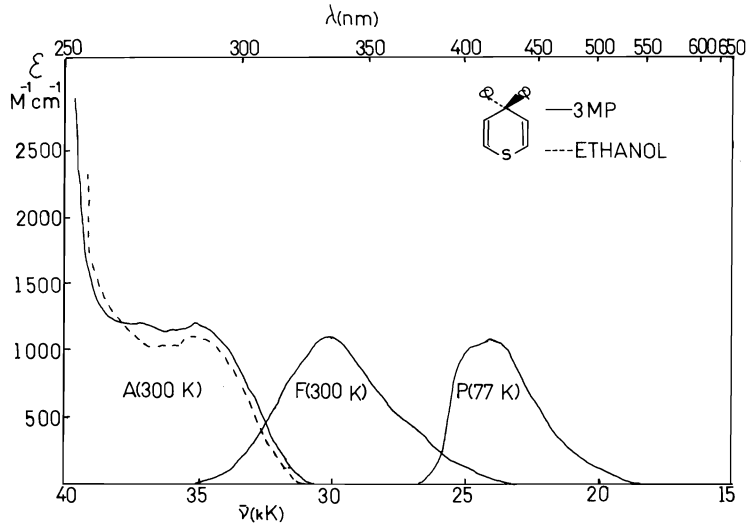

FIG. 2. Spectres d'absorption, de fluorescence et de phosphorescence du diphényl-4,4 thiopyranne (**2**) dans l'éthanol et le méthyl-3 pentane. Les spectres d'émission sont corrigés et tracés en unités relatives de quanta $cm^{-3}\ s^{-1}$ en ordonnée.

entre les maxima en absorption et en fluorescence puisque l'image miroir entre les deux spectres, telle que calculée par la méthode de Birks et Dyson (22), est bonne. En conséquence nous croyons que la configuration électronique des molécules **1** et **2** dans l'état électronique premier singulet excité (S_1) doit s'apparenter à celle dans l'état fondamental (S_0). Les énergies des transitions électroniques pures évaluées sont données dans le tableau 1.

Dans le même tableau nous retrouvons la valeur de la constante radiative théorique k_F telle que calculée à partir des spectres d'absorption des molécules **1** et **2** dans le 3MP. Par examen des spectres corrigés pour le recouvrement, ces valeurs de k_F ne seraient que peu modifiées dans un solvant comme l'éthanol. La méthode de calcul de k_F proposée par Birks et Dyson (11, 15) a été utilisée et ses limites ont été discutées dans un article antérieur (10). Etant donné le recouvrement assez important des deux premiers systèmes de bandes pour la

[c]En matrice vitreuse à 77 K, $\lambda_{exc} = 260$ nm.

molécule **2** surtout, la précision sur ces constantes est de $\pm 2 \times 10^6\ s^{-1}$, ce qui implique que les deux molécules **1** et **2** possèdent la même probabilité intrinsèque d'émettre des photons en fluorescence.

En conclusion, la première transition électronique dans les molécules **1** et **2** semble être de nature $\pi^* \leftarrow \pi$ et de type benzénoïde. L'effet de solvant, la valeur des coefficients d'extinction molaire ainsi que la comparaison des spectres d'absorption et de fluorescence jouent en faveur d'une telle interprétation. Cependant, alors que le benzène absorbe à 38 400 cm^{-1} (bande 0–0) dans un solvant non polaire, la première transition de la molécule **1** a subit un déplacement bathochrome de 2660 cm^{-1} et celle de la molécule **2** a subit un déplacement bathochrome de 6370 cm^{-1} par rapport au benzène. Nous croyons que ceci démontre une participation du chromophore divinyléther à la première transition électronique de ces molécules. Bien qu'il soit généralement admis que les électrons *d* du soufre ne jouent pratiquement pas de rôle dans l'énergie de la transition $\pi\pi^*$ de chromophores semblables —C=C—S—C=C— (7, 16), l'électronégativité du soufre étant identique à celle du carbone, il a été proposé que chez le thiophène la délocalisation des électrons p–π du soufre sur le noyau aromatique puisse expliquer le déplacement bathochrome de 6000 cm^{-1} de la première transition $\pi\pi^*$ du thiophène comparé à celle du furane qui est l'analogue oxygéné (17, 18). La participation du chromophore divinyléther semble donc être impliquée dans la première transition électronique des molécules **1** et **2**. Une preuve irréfutable serait obtenue si les spectres du diphényl tétrahydropyranne et tétrahydrothiopyranne étaient disponibles.

(2) Spectres d'émission et rendements quantiques

(A) Fluorescence

Les spectres de fluorescence et de phosphorescence des molécules **1** et **2** sont reproduits aux figs 1 et 2. Ces spectres sont totalement indépendants du solvant qu'il soit polaire ou non polaire et ceci aussi bien en ce qui concerne l'énergie des transitions que pour les rendements quantiques. Le spectre d'action corrigé de ces fluorescences se superposent en tout point aux spectres d'absorption. Les spectres de fluorescence forment une image en miroir avec le spectre d'absorption dans des conditions de résolution spectrale identiques. Ceci nous permet d'utiliser avec une bonne approximation la constante de désactivation radiative théorique k_F comme paramètre dans l'étude cinétique de l'état S_1 de ces molécules (10). Les rendements quantiques de fluorescence sont rapportés au tableau 1 pour une excitation à 260 nm dans l'éthanol. Ce sont des valeurs corrigées pour l'effet géométrique et l'effet de concentration et donc obtenues par extrapolation à une densité optique nulle. Etant donné la faible valeur des rendements, l'erreur relative sur la reproductibilité se situe à 25%. Les rendements ϕ_F sont donc identiques pour les deux molécules étudiées dans les conditions de précision expérimentale actuelle.

Compte-tenu de la définition du rendement quantique de fluorescence: $\phi_F = k_F(k_F + k_{nr})^{-1}$, la constante de désactivation non radiative (k_{nr}) de l'état premier singulet excité des molécules **1** et **2** est rapportée dans le tableau 1. Cette constante non radiative globale est en fait la somme de trois constantes du premier ordre correspondant aux processus de conversion interne $S_1 \rightsquigarrow S_0(k_c)$, d'intercombinaison $S_1 \rightsquigarrow T_1(k_i)$ et de réaction photochimique à l'état $S_1(k_{RS})$. A température ambiante dans un milieu fluide, la conversion interne peut en toute probabilité compétitionner aussi bien avec l'intercombinaison qu'avec la photochimie d'autant plus que les spectres d'absorption de même que les constantes radiatives k_F démontrent claire-

[a]Phosphorescence.

ment l'influence des groupements phényliques dans cette première transition électronique. Examinons l'effet du milieu sur la constante non radiative k_{nr}.

(A.1) Effet de la température et/ou de la rigidité du milieu sur les rendements de fluorescence—Alors que les intensités intégrées des spectres d'absorption des molécules **1** et **2** ne sont pas modifiées en passant d'un milieu fluide à température ambiante à un milieu vitreux à 77 K, le rendement quantique de fluorescence du dérivé oxygéné (**1**) est augmenté par un facteur 30 à 77 K pendant que le rendement ϕ_F du dérivé soufré (**2**) n'est pas affecté par la température ou la rigidité du milieu comme le démontre les résultats au tableau 1. Etant donné que la formation du photoproduit primaire est probablement l'étape cinétique lente dans le processus de décomposition de la molécule (**1**), et étant donné que nous avons vérifié que la vitesse d'apparition du photoproduit aldéhydique (voir sect. 3) sous l'effet de la photolyse à 2537 Å est à peu de chose près inchangée lorsque l'on travaille à la température ambiante ou en matrice vitreuse à 77 K, la variation obtenue dans le rendement quantique ϕ_F de la molécule **1** pourrait surtout être attribuée à l'un ou à l'autre des phénomènes de conversion interne ou d'intercombinaison, bien que l'on ne puisse exclure à coup sur une influence possible de la température sur k_{RS}. Comme il est peu vraisemblable que la probabilité d'intercombinaison diminue par un facteur 30 à 77 K étant donné que l'énergie de la première transition électronique S_0–S_1 dans ces molécules est très peu modifiée par l'abaissement de la température, nous attribuons la variation du rendement ϕ_F surtout à une diminution de la constante k_c dans la molécule **1** lorsque cette molécule est piégée dans une matrice vitreuse. Cette hypothèse possède cependant son corollaire sur la cinétique de la molécule **2**. Ou bien la conversion interne dans cette dernière molécule est constante en fonction de la température (car ϕ_F est constant en fonction de T) ou encore, l'intercombinaison dans la molécule **2** est beaucoup plus probable que dans la molécule **1** rendant $k_c \ll k_i$ aussi bien à 300 K qu'à 77 K. Pour que la deuxième hypothèse soit valable, il faudrait que k_i (**2**) $\geq 10\, k_i$ (**1**) de façon à pouvoir expliquer la compétition entre k_c (**1**) et k_i (**1**) à température ambiante.

(B) Phosphorescence

Les spectres de phosphorescence des molécules **1** et **2** sont représentés aux figs 1 et 2 respectivement. Même si ces spectres de phosphorescence sont pratiquement au même endroit (une différence de 500 cm^{-1} existe entre les deux), il a été vérifié que leurs spectres d'action corrigés correspondent bien aux spectres d'absorption des molécules **1** et **2** à 77 K. La transition (0, 0) en phosphorescence a été évaluée en prenant le nombre d'onde qui correspond au dixième de l'intensité maximale du spectre. Cette valeur ne peut qu'être approximative et elle est exprimée entre parenthèses dans le tableau 2 à côté du nombre d'onde correspondant au maximum Franck–Condon de la transition.

Les rendements quantiques de phosphorescence de même que les durées de vie sont également indiqués au tableau 2. Tout comme pour les rendements de fluorescence, une erreur de 25% sur la reproductibilité de ces rendements a été observée. L'erreur sur la durée de vie n'est cependant que de ± 0.1 s. Les rendements ϕ_p et les temps de vie τ_p des molécules **1** et **2** sont donc pratiquement identiques.

Les spectres de phosphorescence ainsi que la cinétique de l'état T_1 démontrent 1° que l'état triplet de plus basse énergie dans les molécules **1** et **2** est de nature $\pi\pi^*$ et que 2° la phosphorescence de ces molécules est de nature benzénoïde et doit prendre son origine dans l'un ou l'autre des noyaux aromatiques sans être influencée par les hétéroatomes de ces molécules.

Le rendement quantique de phosphorescence est défini comme suit:

$$[1] \qquad \phi_p = \frac{k_i}{k_F + k_{nr}} \frac{k_p}{k_p + k_{ip} + k_{RT}}$$

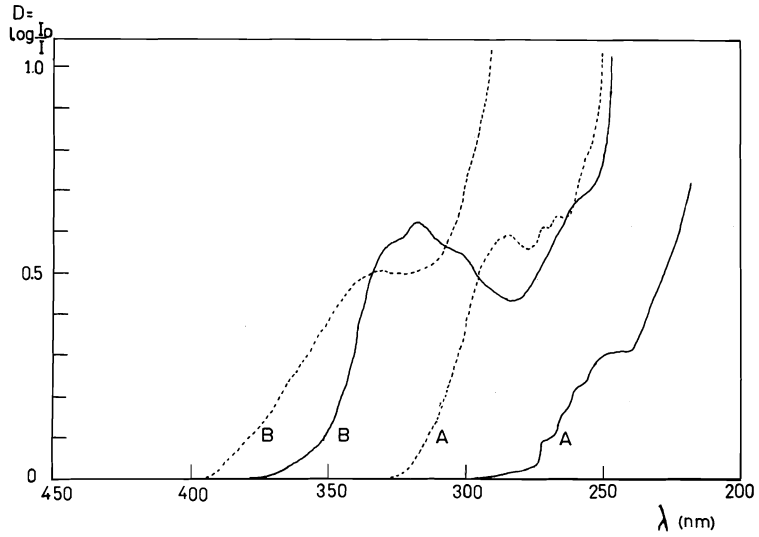

FIG. 3. Spectres d'absorption avant (A) et après (B) un temps de photolyse (2 min pour la molécule (**1**) et 7 min pour la molécule (**2**)) du diphényl-4,4 pyranne (trait continu) et du diphényl-4,4 thiopyranne (trait discontinu) dans le méthyl-3 pentane à température ambiante.

où k_p est la constante de désactivation radiative de l'état triplet, k_{ip} est la constante de désactivation non radiative pour l'intercombinaison $T_1 \rightsquigarrow S_0$ et k_{RT} est la constante de désactivation de l'état triplet par le processus photochimique réactionnel. Du fait que la durée de vie de phosphorescence $\tau_p = (k_p + k_{ip} + k_{RT})^{-1}$, des tableaux 1 et 2 et appliquant [1] aux deux molécules **1** et **2** à 77 K on tire que:

$$[2] \qquad \frac{k_i(\mathbf{2})/k_p(\mathbf{2})}{k_i(\mathbf{1})/k_p(\mathbf{1})} = 13$$

Etant données les valeurs identiques de ϕ_p et de τ_p pour les deux molécules, aucun effet d'atome lourd interne ne peut être mis en évidence (19) et il est alors très probable que $k_p(\mathbf{2}) \simeq k_p(\mathbf{1})$. Ainsi donc, le rapport des constantes pour l'intercombinaison serait de l'ordre $k_i(\mathbf{2}) \cong 10k_i(\mathbf{1})$. Ce résultat vient confirmer la deuxième hypothèse discutée à la sect. A.1 à l'effet que le processus d'intercombinaison $S_1 \rightsquigarrow T_1$ est beaucoup plus probable dans le dérivé soufré que dans le dérivé oxygéné.

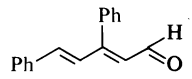
En conclusion des parties 1 et 2, les spectres d'absorption ainsi que les cinétiques de l'état S_1 des molécules **1** et **2** semblent démontrer la participation du chromophore divinyléther à la première transition électronique $S_0 \rightarrow S_1$ de type $\pi\pi^*$ de ces molécules. Par ailleurs la transition $T_1 \rightarrow S_0$ semble être indépendante du chromophore divinyléther dans les mêmes molécules. Les spectres de phosphorescence, les rendements de phosphorescence ainsi que les temps de vie semblent démontrer une localisation de l'énergie triplet au niveau des groupements phényliques.

(3) Photolyse et étude du photoproduit aldéhydique

Lorsque l'on irradie à l'aide de lampes "basse pression" (appareil Rayonet) à 2537 Å les molécules **1** et **2** dans le méthyl-3 pentane ou dans l'éthanol, un nouveau système d'absorption électronique apparaît centré à 3180 Å pour la molécule **1** et à 3330 Å approximativement pour la molécule **2** dans le 3MP comme l'indique la fig. 3.

(A) Nature de la transition à 3180 Å

Il a été démontré par Gravel et coll. (6) que l'un des photoproduits secondaires était l'aldéhyde suivant



3, diphényl-3,4 pentadiène-2,3 al
(+ isomères géométriques)

Ce produit a été isolé et caractérisé par rmn (6). Il montre un spectre d'absorption tout à fait identique à celui observé sur la fig. 3 avec un maximum à 3180 Å dans le 3MP et une structure fine vibrationnelle assez bien définie dans le même solvant. Cette transition électronique centrée à 3180 Å subit un effet bathochrome dans

un solvant polaire comme l'éthanol et le maximum de la bande se retrouve à 3340 Å soit un déplacement de 1510 cm^{-1}. La photolyse de la molécule **1** en matrice vitreuse de 3MP fait également apparaître avec à peu près la même vitesse la bande du produit aldéhydique qui est cependant déplacée vers le rouge (3300 Å) comparativement au spectre à température ambiante, le déplacement est de 1150 cm^{-1}.

Le fait que la réaction photochimique s'effectue avec approximativement la même facilité en milieu fluide et en milieu rigide démontre que l'apparition de l'aldéhyde doit s'effectuer par l'intermédiaire d'un mécanisme monomoléculaire. D'autre part, les effets de solvant sur la position de la bande d'absorption de l'aldéhyde démontre que cette transition est de nature $\pi\pi^*$. Dans le cas de la molécule **2**, la réaction photochimique semble procéder par le même mécanisme, la bande dont le maximum est mal défini vers 3400 Å serait la bande caractéristique de la première transition $\pi\pi^*$ de la thioaldéhyde correspondante. La bande s'étend jusque dans la région du visible et doit englober la transition $n \rightarrow \pi^*$ aux plus grandes longueurs d'onde (20).

*(B) Cinétique d'apparition et de disparition de l'aldéhyde (**3**)*

A l'aide d'une lampe au mercure "basse pression" (Hanovia flat spiral) focalisée sur une des faces d'une cellule rectangulaire de 1 cm de parcours optique, nous avons observé la variation de la densité optique à 3180 Å en fonction du temps de photolyse de la molécule **1** dans le 3MP. La figure 4 montre cette variation pour deux échelles différentes des temps de photolyse. Le graphique démontre clairement que l'aldéhyde une fois formé est détruite sous l'effet du rayonnement à 2537 Å. Il est évident sur la fig. 3 que l'aldéhyde absorbe fortement à 2537 Å, région correspondante à une transition $\pi\pi^*$ supérieure. La cinétique d'apparition de l'aldéhyde est du premier ordre aux temps de photolyse courts, dans l'intervalle de temps où la décomposition n'affecte pas encore la cinétique de montée. Entre 150 et 400 s de photolyse, l'aldéhyde disparaît en suivant également une loi cinétique du premier ordre pour atteindre un palier aux temps plus longs, ce qui semble démontrer que le produit formé de la photolyse de l'aldéhyde absorbe également à 2537 Å. Ceci confirme que l'apparition de l'aldéhyde est un phénomène monomoléculaire ainsi que sa disparition.

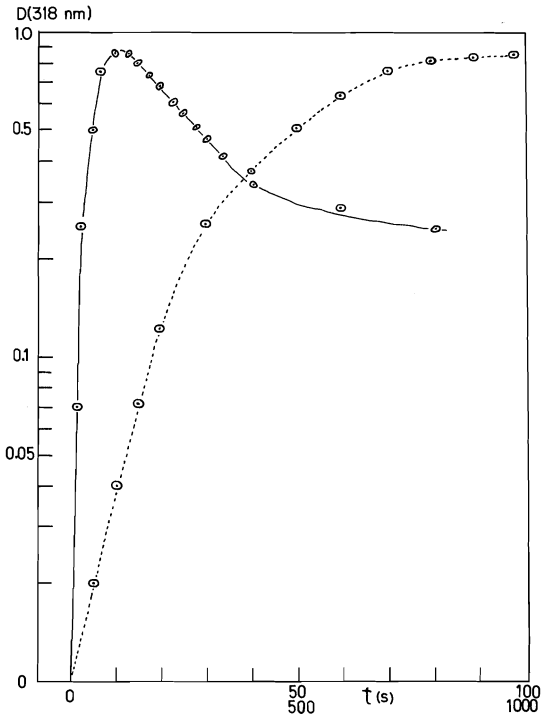


FIG. 4. Variation du logarithme de la densité optique du photoproduit aldéhydique (**3**) en fonction du temps de photolyse de la molécule (**1**) dans le méthyl-3 pentane ($C = 1.22 \times 10^{-4}$ *M*) avec la raie du mercure à 2537 Å. (---) correspond à l'échelle 0–100 s en abscisse; (—) correspond à l'échelle 0–1000 s en abscisse.

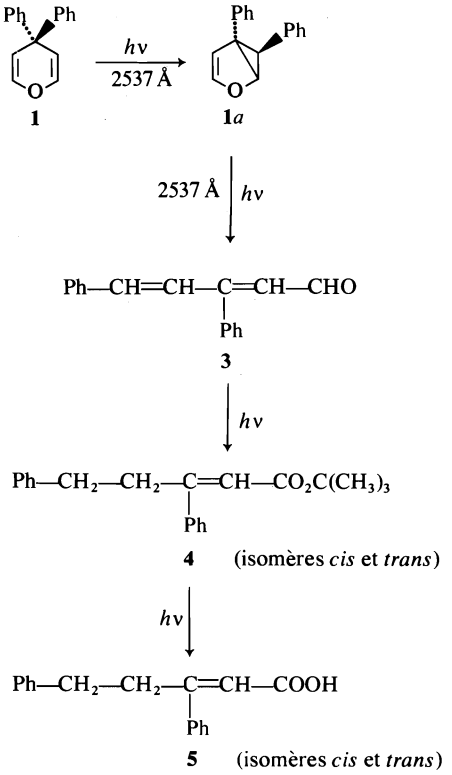
*(C) Effet de l'intensité de la lampe photolytique sur la vitesse d'apparition de l'aldéhyde (**3**)*

Des filtres de densité neutre décrits à la partie expérimentale ont été intercalés entre la source photolytique et la cellule optique. La densité optique de l'aldéhyde à 3180 Å a été mesurée pour un temps de photolyse fixe de 20 s, temps où l'apparition de l'aldéhyde obéit à une loi cinétique du premier ordre comme en fait foi la fig. 4. Une solution fraîche (1.22×10^{-4} *M*) du produit **1** a été photolysée pour chacun des quatre filtres utilisés. De la relation générale existant entre la vitesse d'une réaction photochimique et l'intensité de la lumière absorbée (I_a), on tire pour de faibles densités optiques que $D = aI_0^n$ où I_0 est l'intensité de la lumière excitatrice (21). Une valeur de $n = 1.9 \pm 0.1$ a été obtenue montrant bien que deux photons à 2537 Å sont nécessaires pour produire une molécule d'aldéhyde **3**. L'aldéhyde est donc un photoproduit secondaire provenant d'un photoproduit primaire suite à l'irradiation de la molécule **1**.

Gravel et coll. (6) ont récemment isolé et caractérisé les produits secondaires suite à une irradiation de la molécule **1** à 2537 Å en plus de mettre en évidence l'unique photoproduit primaire de la réaction. La séquence réactionnelle proposée est la suivante dans l'alcool *t*-butylique comme solvant:



Le diphényl-5,6 bicyclo [3.1.0] oxa-2 hexène-3 *trans endo* (**1***a*) est en fait l'unique photoproduit primaire formé à la suite du réarrangement di-π-méthane (6). Les autres produits isolés: **3**, **4** et **5** ainsi que les isomères géométriques résulteraient de l'irradiation du photoproduit primaire et de l'irradiation subséquente des sous-produits secondaires. Etant donné que les molécules **1***a*, **4** et **5** absorbent dans la région de 2800–2300 Å, la spectroscopie ultraviolette ne peut en aucun cas les caractériser. Cependant l'étude cinétique effectuée sur l'aldéhyde **3** et décrite plus haut confirme en tout point cette séquence réactionnelle. En effet l'apparition du photoproduit **3** doit obéir à une loi cinétique du premier ordre et de plus sa vitesse d'apparition doit être proportionnelle au carré de l'intensité de la lumière absorbée par la molécule **1** c'est-à-dire proportionnelle au carré de l'intensité de la source de photolyse aux faibles densités optiques du produit **1**. Par ailleurs, nous avons aussi montré que la molécule **3** se décompose également par un mécanisme cinétique de premier ordre au cours de l'irradiation continue à 2537 Å confirmant ainsi que les molécules **4** et **5** sont des photoproduits secondaires obtenus de la photodécomposition de l'aldéhyde **3**.

Remerciements

Cette étude a été subventionnée par le Conseil national de recherches du Canada et par le Ministère de l'éducation du Québec. L'un de nous (G.L.) a bénéficié de l'octroi d'une bourse du Ministère de l'éducation du Québec.

Salt effects on adsorbed nonelectrolytes

ROBERT AVEYARD AND SYED M. SALEEM
Department of Chemistry, The University, Hull, HU6 7RX, England

Received May 9, 1977

ROBERT AVEYARD and SYED M. SALEEM. Can. J. Chem. **55**, 4018 (1977).

An approach to the study of the influence of electrolytes on adsorbed nonelectrolytes at liquid surfaces is described. The adsorption of tetrabutylammonium bromide (Bu_4NBr) from aqueous solution to the interfaces with octane, decanol, and air has been determined. Results are presented for the effects of some inorganic salts (NaCl, NH_4Br, and Na_2CO_3), and of Bu_4NBr on monolayers of butanol at the air – aqueous solution interface, and of Bu_4NBr on dodecanol adsorbed at the octane – aqueous solution interface. The interfacial salt effects differ from the bulk effects in the cases studied. The inorganic salts, which salt-out butanol (and alkanols generally) in aqueous solution, have little or no effect on adsorbed butanol. On the other hand, Bu_4NBr which salts-in alkanols in bulk aqueous solution has a strong salting-out effect on dodecanol at the liquid–liquid interface; a similar but less marked effect is observed for butanol at the liquid–vapour surface. Salting-in of alkanols by Bu_4NBr in bulk has previously been ascribed to hydrophobic interactions between cations and alkyl groups of the alkanol, whereas the surface effect is assumed to result from interactions between alcoholic OH groups and cations.

ROBERT AVEYARD et SYED M. SALEEM. Can. J. Chem. **55**, 4018 (1977).

On décrit une manière d'approche à l'étude de l'influence des électrolytes sur les nonélectrolytes adsorbés à la surface des liquides. L'adsorption du bromure de tétrabutylammonium (Bu_4NBr) provenant d'une solution aqueuse aux interfaces avec l'octane, le décanol et l'air est déterminée. On présente les résultats de l'effet de quelques sels inorganiques (NaCl, NH_4Br et Na_2CO_3), et du Bu_4NBr sur les monocouches de butanol à l'interface air – eau de la solution ainsi que celui du Bu_4NBr sur le dodécanol adsorbé à l'interface octane – eau de la solution. Dans les cas étudiés, les effets interfaciales de sels diffèrent des effets de masse. Les sels inorganiques relarguant le butanol (généralement un alkanol) en solution aqueuse, ont peu ou très peu d'effet sur le butanol adsorbé. D'un autre côté, le Bu_4NBr qui absorbe les alkanols en solution concentrée dans l'eau a un grand effet relarguant sur le dodécanol à l'interface liquide–liquide; un effet similaire mais moins marqué est observé pour le butanol à la surface liquide–vapeur. L'absorption des alkanols par Bu_4NBr en solution concentré a été attribuée antérieurement aux interactions hydrophobiques entre les cations et les groupes alkyles de l'alcanol, tandis que l'effet de surface semble résulter des interactions entre les groupes hydroxyles (des alcools) et les cations.

[Traduit par le journal]

Introduction

A considerable body of literature exists stretching back over several decades, concerning the ways in which electrolytes, both organic and inorganic, influence the chemical potential of nonionic solutes in aqueous solution. Much of the current interest centres on effects of salts on proteins. Frequently the solutes studied have been polar and, to some extent, surface-active (1, 2). The question naturally arises as to what effect electrolyte has on the solute adsorbed at an interface, particularly if the electrolyte itself is surface-active. Only a very limited amount has been reported on interfacial salt effects (3, 4) even though they are intrinsically as interesting as bulk effects, and are likely to be of relevance in a variety of systems, including some of biological and of industrial importance. Of course, there have been many investigations into the effects of inorganic salts on adsorbed *ionic* surfactants in connection with electrical double layer theory (*5a*). In such studies the much smaller effects of the kind reported here are usually neglected.

We have previously studied the ways in which some simple inorganic electrolytes influence alkane–water interfacial tensions (6) and decanol–water interfacial tensions (3). In addition we have considered the effects of NaCl on very dilute adsorbed films of alkanols at the dodecane – aqueous solution interface (3). In the present work we propose an approach to the study of surface salt-effects, and extend previous investigations to take in adsorbed films at air–

solution interfaces, and to include a surface-active organic electrolyte, tetra-*n*-butylammonium bromide, Bu_4NBr.

We are unable at this stage to view our results in terms of theory, as we were in recent studies on bulk salt effects on alkanols (7, 8). Our main aim has been to obtain experimental results to ascertain the magnitude and nature of the effects. Nonetheless, interesting empirical observations emerge which may prove of value in the surface and colloid chemistry of systems involving interfaces which contain polar organic surfactants.

Experimental

Measurement of Surface and Interfacial Tensions

Surface and interfacial tensions were determined, as described in ref. 9, using the drop-volume technique in conjunction with the smoothed correction factors of Harkins and Brown (10). The apparatus was immersed in a water thermostat maintained at the required temperature to within ± 0.01 K. All necessary densities were determined to within $\pm 2 \times 10^{-4}$ g cm^{-3} using a 25 cm^3 density bottle. Surface tensions were reproducible to better than ± 0.10 mN m^{-1}, and interfacial tensions to better than ± 0.05 mN m^{-1}.

Distribution of Bu_4NBr between Water and Decanol

This salt is soluble in decanol, and in order to calculate equilibrium concentrations in the aqueous phase, as required for the determination of adsorption at the decanol–solution interface, we have determined distribution ratios, K, defined as (salt molality in water)/(salt molality in decanol). Weighed amounts of decanol, water, and Bu_4NBr were placed in stoppered conical flasks and immersed in a water thermostat at 25°C for at least 24 h, with frequent shaking of the flasks. Weighed amounts of aqueous phase were then withdrawn and analysed for Bu_4NBr, in terms of Br^- concentration using the Volhard method. The amount of salt in the decanol phase was estimated by mass balance. The values of K, given in Table 1, cannot be regarded as being very precise since in the presence of Bu_4NBr the mutual low solubilities of water and decanol may be enhanced, and this has not been allowed for. As far as this system is concerned, however, we have only sought to obtain rough adsorption values, as mentioned later

Materials

Two samples of *n*-octane, *puriss* grade from Newton-Maine (England), were passed over chromatographic alumina before use, and each had a purity (estimated, as were other quoted purities, by glc) of >99.5%. One sample had an interfacial tension against water at 20°C of 51.55 mN m^{-1}, and the other 51.71 mN m^{-1}. Dodecanol (*puriss* grade from Koch-Light, England) was redistilled using a spinning band fractionating column, and had a purity >99.9%. A Fluka *puriss* sample of butanol was found to have a purity $\simeq$99.8% and was used without further treatment.

The inorganic salts (NaCl, NH_4Br, and Na_2CO_3) were all 'Analar' grade from Hopkin and Williams, England, and were treated as described in ref. 6. Tetrabutylammonium bromide was obtained from Eastman, with a quoted purity (by titration) of at least 98%. It was further purified in the way described by Conway *et al.* (11).

All water used was twice distilled, the second time using an all-Pyrex glass still. The best test of purity in the present context is the surface tension. Our values of 72.67, 71.89, and 71.14 $\pm$ 0.10 mN m^{-1} at 20, 25, and 30°C, respectively, are in very good agreement with those (72.75, 71.97, and 71.18 $\pm$ 0.05 mN m^{-1} respectively) quoted in the International Critical Tables (12).

TABLE 1. Values of K for Bu_4NBr distributed between water and decan-1-ol at 25°C, for various aqueous phase molalities, m, of salt

K	$10m$	K	$10m$
2.78	0.600	0.86	1.717
2.72	0.702	0.76	2.188
1.70	1.002	0.72	3.234
1.68	1.051	0.73	3.251
0.84	1.594	0.68	5.162

Results

Adsorption of Tetrabutylammonium Bromide

Unlike the inorganic salts discussed later, Bu_4NBr is positively adsorbed at the interfaces of present interest, and it is the *adsorbed* salt which gives rise to the salt effects on adsorbed nonelectrolytes. We have therefore determined the extent of adsorption at the octane–solution (o–s), air–solution (a–s), and decanol–solution (d–s) interfaces, using interfacial tensions measured in the present work,[1] in conjunction with the Gibbs equation.

The Gibbs adsorption equation for an i-component system is

$$[1] \quad -d\gamma = \sum_i \Gamma_i \, d\mu_i = \Gamma_o \, d\mu_o + \Gamma_w \, d\mu_w + \Gamma_{A^+} \, d\mu_{A^+} + \Gamma_{Br^-} \, d\mu_{Br^-}$$

where γ is the interfacial tension and Γ_i the surface excess of i; subscripts o, w, and A^+ refer to the organic liquid (octane or decanol), water, and Bu_4N^+ respectively. Terms for H^+ and OH^- arising from dissociation of water are negligible, and are omitted from eq. 1.

[1]These interfacial tensions, and others referred to subsequently, are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont. Canada K1A 0S2.

In octane + water systems $d\mu_o \ll d\mu_{A^+}, d\mu_{Br^-}$ and so $\Gamma_o d\mu_o$ is negligible. For the decanol + water system, where higher concentrations of Bu_4NBr (which is soluble in decanol) are employed, the approximation of neglecting $\Gamma_o d\mu_o$ will be less valid, but in the present context this is probably not important. Choosing a Gibbs dividing surface such that $\Gamma_w = 0$, eq. 1 becomes (*5b*)

$$[2] \quad \Gamma^w_{A^+Br^-} = (0.5/RT)(d\pi/d \ln a_\pm) = (0.5a_\pm/RT)(d\pi/da_\pm)$$

where π is the surface pressure, defined as the lowering of interfacial tension caused by adsorption (so that $-d\gamma = d\pi$), and $a_\pm$ is the mean activity of the electrolyte. For strong adsorption as at the o–s and a–s interfaces, $\Gamma^s_{A^+Br^-}$, the *total* surface concentration of Bu_4NBr, does not differ much from the excess $\Gamma^w_{A^+Br^-}$.

The molal activity $a_\pm$ is equal to $mf_\pm$; m is the molality of electrolyte, and $f_\pm$ the mean molal activity coefficient. For dilute solutions of salt (such as those used for adsorption to the o–s and a–s interfaces) $f_\pm$ differs only slightly from the mean *molar* activity coefficient, $y_\pm$, and hence can be obtained to a very good approximation using an equation of Guntelberg (see ref. 13):

$$[3] \quad f_\pm \simeq y_\pm = \exp\left\{-\frac{4.2021 \times 10^6 c^{1/2}}{(\varepsilon T)^{3/2}(1 + c^{1/2})}\right\}$$

in which c is the salt molarity and ε the relative permittivity of the solution, taken here to be equal to that of water at the appropriate temperature (14). Values of $f_\pm$ from eq. 3 are very close to those obtained by interpolation of the experimental data of Lindenbaum and Boyd (15).

The π–$a_\pm$ data for the various temperatures between 17 and 30°C are, within experimental errors, superimposable both for the o–s and for the a–s interfaces, and can be expressed, for the o–s interface, by

$$[4] \quad \pi/(\text{mN m}^{-1}) = 4.11747 \times 10 + 9.93776 \ln a_\pm + 6.24598 \times 10^{-1} (\ln a_\pm)^2$$

for $m \leq 1 \times 10^{-2}$ mol kg^{-1}, and for the a–s interface by

$$[5] \quad \pi/(\text{mN m}^{-1}) = 6.33503 \times 10^{-2} + 4.55516 \times 10^2 a_\pm - 1.30563 \times 10^4 a_\pm^2$$

for $m \leq 0.9 \times 10^{-2}$ mol kg^{-1}. Combination of [4] or [5] with the appropriate form of [2] yields surface excesses.

In the case of the d–s interface at 25°C we have fitted interfacial tensions to

$$[6] \quad \gamma/(\text{m}M\ \text{m}^{-1}) = -0.66932 - 4.10705 \ln a_\pm - 0.45568 (\ln a_\pm)^2$$

for m (aqueous phase) ≤ 0.33 mol kg^{-1}. In this system both phases contain all three components, and higher concentrations of salt have been used. Values of $a_\pm$ for Bu_4NBr in the aqueous phase have been interpolated directly from the results of Lindenbaum and Boyd (15), and no account has been taken of the effect of decanol in the aqueous phase on $a_\pm$. For this, and other reasons mentioned earlier, surface excesses of Bu_4NBr at the d–s interface are less reliable than those obtained for the o–s and a–s interfaces.

Tamaki (16) has studied the adsorption of Bu_4NX (X = Cl, Br, I) at the a–s and hexane–solution interfaces. The results are not fully reported, however, and are only given in graphical form so that comparisons with our data have not been possible.

Adsorption of Dodecanol at the Octane – Aqueous Bu_4NBr Interface

Dodecan-1-ol, mole fraction x in dilute solution in octane, has been adsorbed to interfaces with aqueous Bu_4NBr of varying molality m at 20°C, and to the interface with 1.26×10^{-3} m Bu_4NBr at several temperatures between 17 and 30°C.

Standard free energies of adsorption, $\Delta_a\mu^\ominus$, for dodecanol have been obtained from the interfacial tensions by use of the expression (*5c*)

$$[7] \quad \mu^{\ominus,\sigma} - \mu^{\ominus,l} = \Delta_a \mu^\ominus = -RT \ln (\lim_{x \to 0} [\pi/x])$$

where $\mu^{\ominus,\sigma}$ and $\mu^{\ominus,l}$ are standard chemical potentials of alcohol in surface and bulk (alkane) respectively, and π is the surface pressure of adsorbed alkanol. The standard states are unit π for the surface and unit x for bulk, both assumed ideal. In the range of x studied, π is a rectilinear function of x (see Fig. 1*a*) and $\lim_{x \to 0} [\pi/x]$ is equal to the slope of this line. Values of $\Delta_a\mu^\ominus$ are given in Table 2, and their significance is discussed later.

A mean standard enthalpy, $\Delta_a h^\ominus$, and entropy, $\Delta_a s^\ominus$, of adsorption of dodecanol from octane to the interface with 1.26×10^{-3} m Bu_4NBr have been obtained, in the range 17 to 30°C, using

$$[8] \quad \Delta_a\mu^\ominus = \Delta_a h^\ominus - T\Delta s^\ominus$$

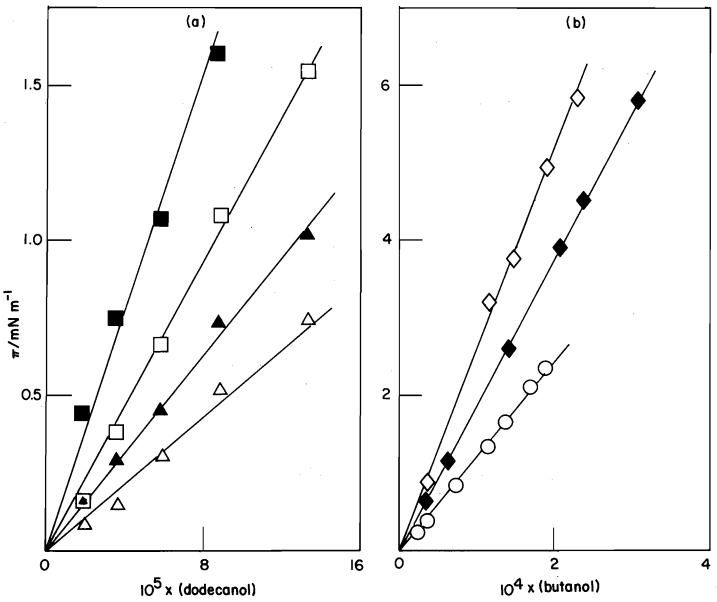

FIG. 1. Surface pressures, π, of alkanol monolayers as a function of mole fraction, x, of alkanol in bulk, at 20°C. 22.5	22.94	30.0	22.94

The $\Delta_a\mu^{\ominus} - T$ data, plotted in Fig. 2*a*, were treated by the method of least squares, yielding the values for $\Delta_a h^{\ominus}$ and $\Delta_a s^{\ominus}$ given in Table 3.

There is a contribution to the variation of $\Delta_a\mu^{\ominus}$ with T from the variation of $\Gamma^w_{A^+Br^-}$ with T, but by assuming $d\Delta_a\mu^{\ominus}/d\Gamma^w_{A^+Br^-}$ is independent of T in the range studied, we have allowed for the very small contribution from this source, and the $\Delta_a\mu^{\ominus}$ used are 'corrected' values.

Adsorption of Butanol from Aqueous Electrolyte to the Air–Solution Interface

Aqueous Solutions of Bu_4NBr

Surface tensions of various solutions containing Bu_4NBr and butanol have been determined, and standard free energies of adsorption of butanol, given in Table 4, have been calculated using eq. 1, where $\mu^{\ominus,1}$ is now a standard chemical potential of the alcohol in the aqueous phase. The mean standard enthalpy and standard

entropy of adsorption of butanol from 1.26×10^{-3} *m* Bu_4NBr to the a–s interface were calculated using eq. 8 (see Fig. 2*b*) and the values are given in Table 3.

Aqueous Solutions of Inorganic Salts

We have previously studied the bulk salt effects of various inorganic salts, including NH_4Br, NaCl, and Na_2CO_3, on butanol. These salts influence the chemical potential of butanol to widely different extents and for that reason we have chosen them for the present study.

Adsorption free energies for butanol, obtained from the appropriate surface tensions (see Fig. 1*b*), are given in Table 5. Three concentrations of NaCl have been studied and $\Delta_a\mu^{\ominus}$ for butanol is a linear function of salt molality. Only one concentration each has been used for Na_2CO_3 and NH_4Br, both concentrations being close to 1 *m*.

Discussion

Thermodynamic Parameters Associated with Surface Salt Effects

It is convenient to discuss the effects which salts have on adsorbed nonelectrolytes in terms of the parameters $\Delta X^{\ominus,\sigma}$ (where $X^{\ominus,\sigma}$ = standard chemical potential $\mu^{\ominus,\sigma}$, partial molar enthalpy $h^{\ominus,\sigma}$, or partial molar entropy $s^{\ominus,\sigma}$ of nonelectrolyte in an infinitely dilute film), defined as

$$[9]\quad \Delta X^{\ominus,\sigma} = X^{\ominus,\sigma}(\text{Salt present}) - X^{\ominus,\sigma}(\text{Salt absent})$$

These quantities are in turn related to the adsorption parameters $\Delta_a X^{\ominus}$ (see eq. 7) by

$$[10]\quad \Delta_a X^{\ominus}(\text{Salt present}) - \Delta_a X^{\ominus}(\text{Salt absent}) = \Delta(\Delta_a X^{\ominus}) = \Delta X^{\ominus,\sigma} - \Delta_{tr} X^{\ominus}$$

The quantity $\Delta_{tr} X^{\ominus}$ is defined by

$$[11]\quad \Delta_{tr} X^{\ominus} = X^{\ominus,1}(\text{Salt present}) - X^{\ominus,1}(\text{Salt absent})$$

it being understood that the bulk standard state is the same for adsorption and bulk transfer.

There are two special, but important cases. First, in the event that the nonelectrolyte is adsorbed from (*a*) an organic solvent in which the electrolyte is insoluble, or (*b*) an aqueous phase in which the bulk salt effect on the nonelectrolyte is negligible, eq. 10 becomes

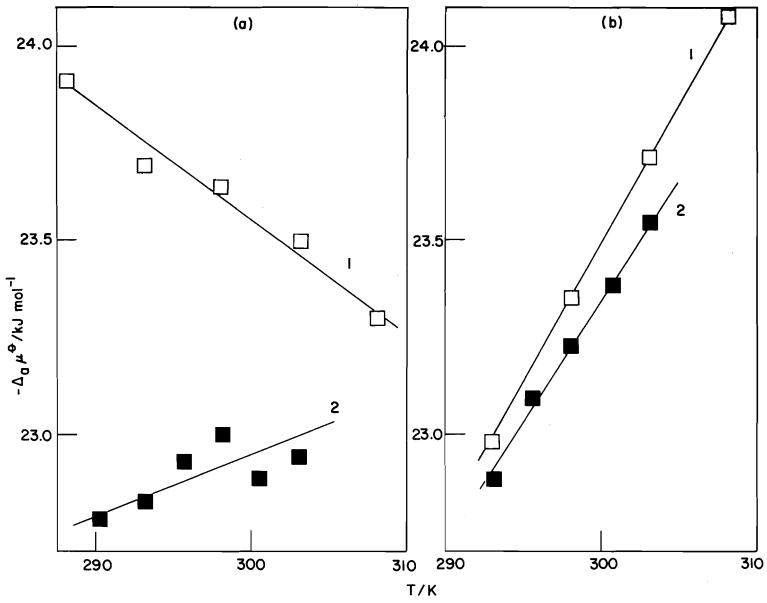

FIG. 2. Plots of free energies of adsorption, $\Delta_a\mu^{\ominus}$, against T for (*a*) dodecanol at (1) octane–water, (2) octane – Bu_4NBr solution interface, and (*b*) butanol at (1) air–water, (2) air – Bu_4NBr solution interface. The salt solution is 1.26×10^{-3} *m*, and at 20°C the surface excess is 3.2×10^{-7} mol m^{-2} at the o–s interface and 1.1×10^{-7} mol m^{-2} at the a–s interface.

TABLE 5. Standard free energies of adsorption, $\Delta_a\mu^{\ominus}$, of butanol from aqueous inorganic salts, molality *m*, to the air–solution interface at 20°C

	H_2O	NaCl	NaCl	NaCl	Na_2CO_3	NH_4Br
m/(mol kg^{-1})	—	0.518	0.907	1.578	1.002	1.008
$-\Delta_a\mu^{\ominus}$/(kJ mol^{-1})	23.05	23.62	23.98	24.77	25.91	23.61

[12] $$\Delta(\Delta_a X^{\ominus}) = \Delta X^{\ominus,\sigma}$$

Second, if the surface salt effect is negligible eq. 10 reduces to

[13] $$\Delta(\Delta_a X^{\ominus}) = -\Delta_{tr} X^{\ominus}$$

Positive values of $\Delta\mu^{\ominus,\sigma}$ correspond to salting-out, and negative values to salting-in.

Much of the data for bulk effects is reported in terms of so-called salting constants k (2). It may be useful to define a similar quantity for surface effects to facilitate comparisons in future work. By analogy with the treatment of bulk effects, we may define a salting constant, k^{σ}, for the surface in a system where $\Delta\mu^{\ominus,\sigma}$ is a linear function of *m*, such that

[14] $$\Delta\mu^{\ominus,\sigma}(m = 1) = 2.303RTk^{\sigma}$$

The constant k^{σ} is in turn related to an activity coefficient, f^{σ}, for adsorbed nonelectrolyte, by

[15] $$k^{\sigma} = \log f^{\sigma}(m = 1)$$

If $\Delta\mu^{\ominus,\sigma}$ and *m* are not linearly related then

[16] $$k^{\sigma} = [\mathrm{d} \log f^{\sigma}/\mathrm{d}m]_{m=0}$$

The activity coefficient is a distribution ratio for the nonelectrolyte between the surface of water and of salt solution, the activity coefficient on water being unity.

In the case of surface-active electrolytes one might choose to define k^{σ} and f^{σ} in terms of *surface* concentrations of electrolyte rather than bulk concentration.

Systems Containing Inorganic Salts

The inorganic salts studied are negatively adsorbed at both the o–s and a–s interfaces, and from the point of view of surface or interfacial tensions, the systems behave as if there were a salt-free layer of water at the interface of the

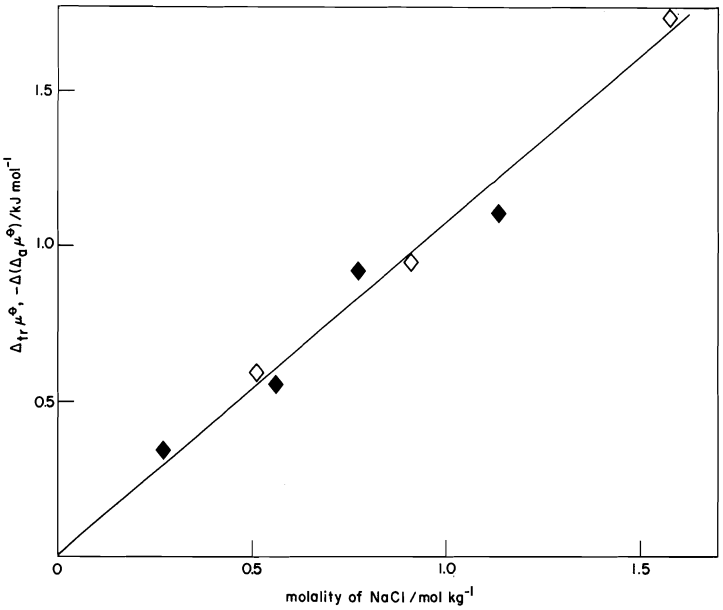

FIG. 3. Effects of NaCl on butanol at the a–s interface (◇), the o–s interface (◆), and in bulk aqueous solution (full line).

order of 0.3 to 0.6 nm thick (6). If ions in the vicinity of the surface are to interact with adsorbed alcohol molecules it must therefore be from below the salt-free layer. We have shown elsewhere (3) that NaCl up to bulk concentrations of about 2 mol kg^{-1} in water has a negligible effect on the free energy of adsorption of dodecanol from dodecane so that, since NaCl is insoluble in the alkane, $\Delta\mu^{\ominus,\sigma}$ is negligible (see eq. 12). On the other hand $\Delta_a\mu^{\ominus}$ for the adsorption of butanol from aqueous NaCl to the dodecane solution interface is significantly dependent on salt concentration. In this case it was found that $\Delta(\Delta_a\mu^{\ominus})$ is equal to $-\Delta_{tr}\mu^{\ominus}$, so that again NaCl has no effect on the chemical potential of adsorbed alkanol (eq. 13).

From the present results for butanol at the a–s interface we find that for NaCl up to concentrations of about 1.5 mol kg^{-1}, $-\Delta(\Delta_a\mu^{\ominus})$ is within experimental errors equal to $\Delta_{tr}\mu^{\ominus}$, so that here too $\Delta\mu^{\ominus,\sigma}$ is zero. This can be appreciated from Fig. 3 where we show $-\Delta(\Delta_a\mu^{\ominus})$ for butanol adsorbed from aqueous NaCl to the a–s interface, together with $\Delta_{tr}\mu^{\ominus}$ for transfer of butanol from water to aqueous NaCl; the latter results are taken from ref. 8. Also included are the results for the adsorption of butanol from aqueous NaCl to the dodecane–solution interface (3); all three sets of data are coincident.

We thus have the rather surprising result that NaCl up to quite high concentrations does not affect the properties of surface water, at the o–s or a–s interface, in any way which alters the chemical potential of adsorbed alkanol. We note that butanol is salted-out by NaCl in bulk aqueous solution (8), but that the OH group gives a salting-in contribution to the overall effect (17). The values of $\Delta_{tr}\mu^{\ominus}$ for 1 *m* NaCl are, for butanol 1.07 kJ mol^{-1} (at 20°C), and for OH -0.17 kJ mol^{-1} (at 25°C).

For NH_4Br and Na_2CO_3, $-\Delta(\Delta_a\mu^{\ominus})$ for butanol adsorption at the a–s interface (0.56 and 2.86 kJ mol^{-1} respectively from Table 5) differs slightly from $\Delta_{tr}\mu^{\ominus}$ (0.42 and 3.14 kJ mol^{-1} for the molalities shown in Table 5), indicating a slight salting-out of adsorbed butanol by NH_4-Br and a slight salting-in by Na_2CO_3.

Systems Containing Bu_4NBr

Adsorption of Bu_4NBr

As mentioned, Bu_4NBr is positively adsorbed from dilute aqueous solution at the interfaces of present interest. Results are presented in Fig. 4 as plots of ln ($\Gamma^{w}_{A^+Br^-}/a_{\pm}$) vs. π for 25°C; the plots are linear and limiting values of ln ($\Gamma^{w}_{A^+Br^-}/a_{\pm}$) at $\pi = 0$ have been obtained by extrapolation. The extent of adsorption at the interfaces increases in the order d–s < a–s < o–s, the ratios of ($\Gamma^{w}_{A^+Br^-}/a_{\pm}$) at infinite dilution being 1:11:48. The standard free energy of adsorption of Bu_4NBr is therefore more

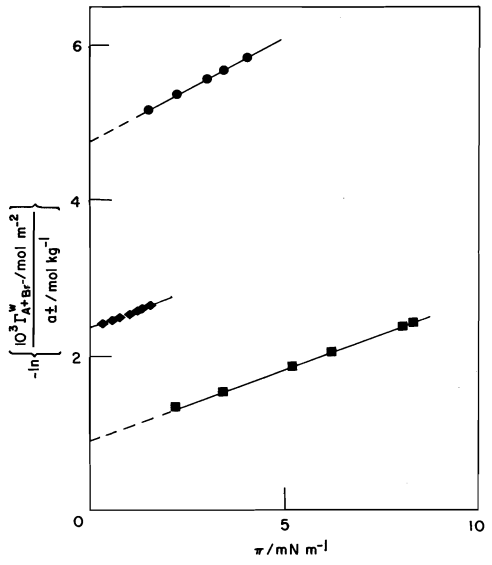

FIG. 4. Adsorption of Bu_4NBr at decanol–water (●), air–water (◆), and octane–water (■) interfaces at 25°C.

negative for the o–s interface than for the a–s interface by an amount $RT \ln (48/11) = 3.67$ kJ mol^{-1} at 25°C. For straight chain homologues the standard free energy of adsorption of the methylene group from water is more negative by about 0.5 kJ mol^{-1} for the o–s interface than for the a–s interface (*5d*). Assuming the same to be true for CH_2 groups in Bu_4N^+, and that the cation is immersed in water to the same extent at the o–s and a–s interfaces, we may say as a rough estimate that 3.67/0.5 ($\simeq$7) CH_2 groups per Bu_4N^+ ion leave the aqueous phase on adsorption. That is, the adsorbed cation is a little over half immersed in water, as might be expected intuitively.

In a relative sense adsorption of Bu_4NBr at the d–s interface is weak. We have reported elsewhere (3) that of the three types of interface studied here, alkali halides are *least desorbed* at the d–s interface. Thus it is probably not a simple charge effect that causes the relatively low adsorption of Bu_4NBr. The effect may originate in the nature of the different kinds of hydration layers around the alcoholic OH groups and the alkyl groups of the cation. This point is mentioned again later.

Effect of Bu_4NBr on Dilute Adsorbed Layers of Alkanols

We first remark that alkanols are salted-in (i.e., $\mu^{\ominus,1}$ made more negative) by Bu_4NBr in bulk aqueous solution, the effect being greater the greater the alkanol chain length (7). Here we consider the effect of *adsorbed* Bu_4NBr on (*i*) dodecanol at the o–s interface and (*ii*) butanol at the a–s interface.

The free energy for the adsorption of dodecanol from octane to the o–s interface is shown as a function of both molality and the surface excess of Bu_4NBr in Fig. 5*a*. The relationship involving the surface excess is rectilinear. Since the salt is insoluble in octane eq. 12 is applicable and we find that $d\mu^{\ominus,\sigma}/d\Gamma^w_{A^+Br^-} = 0.256$ kJ mol^{-1}/10^{-7} mol m^{-2}. Similar results for butanol at the a–s interface are shown in Fig. 5*b*, and again the plot of $\Delta_a\mu^{\ominus}$ vs. surface excess of salt is linear, but of smaller slope. For the concentrations of salt used ($m < 0.9 \times 10^{-2}$ mol kg^{-1}) it is known that $\Delta_{tr}\mu^{\ominus}$ for butanol is negligible (7) and so eq. 12 is again applicable and $d\mu^{\ominus,\sigma}/d\Gamma^w_{A^+Br^-} = 0.094$ kJ mol^{-1}/10^{-7} mol m^{-2}.

Earlier, we quoted standard heats and entropies of adsorption of butanol and dodecanol to interfaces involving 1.26×10^{-3} *m* aqueous Bu_4NBr (Fig. 2 *a*,*b*; Table 3). Also included in Figs. 2*a* and *b* are corresponding plots of $\Delta_a\mu^{\ominus}$ vs. *T* for adsorption to the interfaces with water, the data being taken from refs. 18 and 19. Various relevant free energy, enthalpy, and entropy changes are presented in Table 3, and referred to below.

Contrary to the situation for bulk solutions, adsorbed alkanols are salted-out by adsorbed Bu_4NBr. The bulk effects have been attributed to hydrophobic interactions between alkyl chains of alkanol and cation (7). At the surface, however, the OH groups of the alcohol are constrained in a way which they are not in bulk, to come into close proximity with the hydrophobic cations. The salting-out of dodecanol at the o–s interface is about 3 times greater than that of butanol at the a–s interface. For dodecanol it is likely that the major part of the salt effect results from interactions occurring on the water side of the interface since all the materials on the alkane side consists of hydrocarbon groups. Thus, we believe that interactions between alcoholic OH groups and adsorbed ions, probably Bu_4N^+ ions but possibly to some extent Br^- ions, are responsible for the salting-out. In this connection we recall that Bu_4NBr is absorbed much less strongly to the d–s interface than either the a–s or o–s interfaces.

The values of $\Delta h^{\ominus,\sigma}$ and $T\Delta s^{\ominus,\sigma}$ for dodecanol at the o–s interface (where $\Gamma^w_{A^+Br^-} = 3.2 \times 10^{-7}$ mol m^{-2}), given in Table 3, are both large

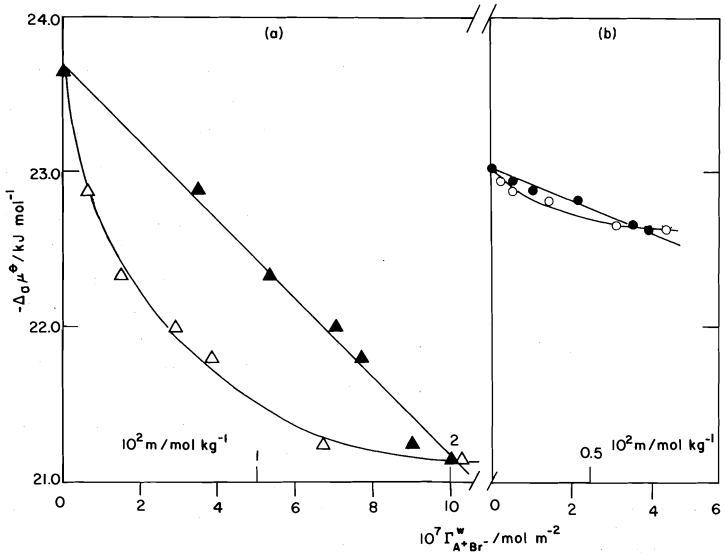

FIG. 5. Standard free energies of adsorption of alkanols to interfaces containing Bu_4NBr at 20°C. (*a*) Adsorption of dodecanol from octane to octane – Bu_4NBr solution interface as a function of surface excess of salt (▲), and molality of salt (△). (*b*) Adsorption of butanol from salt solution to air – Bu_4NBr solution interface as a function of surface excess of salt (●), and molality of salt (○).

and *positive*, almost compensating, giving the relatively small positive free energy change. It is not possible at present to account quantitatively for these results. If however, salting-out does result in the main from interactions between 'incompatible' hydration shells around OH and Bu_4N^+, it appears likely from the sign of $\Delta h^{\ominus,\sigma}$ and $\Delta s^{\ominus,\sigma}$ that a net disruption of water structure occurs in the salting-out process.

Similar interactions between OH and Bu_4N^+ presumably also exist in films of butanol at the a–s interface, and yet butanol is less strongly salted-out than dodecanol. It appears then that there is an additional salting-in component for butanol; this could result from interactions between the alkyl chains of the alcohol and those chains of the Bu_4N^+ which are not immersed in water. Values of $\Delta h^{\ominus,\sigma}$ and $T\Delta s^{\ominus,\sigma}$ for butanol (with $\Gamma^w_{A^+Br^-} = 1.1 \times 10^{-7}$ mol m^{-2}) are *negative* and almost compensating. The salting-in component clearly gives rise to a large negative contribution to both $\Delta h^{\ominus,\sigma}$ and $\Delta s^{\ominus,\sigma}$ which is to be expected for a quasi-condensation process for alkyl chains.

In conclusion, we have established an approach to the study of salt effects on adsorbed nonelectrolytes. Only a limited number of what might be called 'model' systems have been investigated, and there is much scope to consider more complex nonelectrolytes such as might be of direct technical or biological importance, together with a wider range of electrolytes. It is clear, however, from the present findings that, for a given nonelectrolyte and surface-active salt, surface salt effects can be quite different at different kinds of interfaces, and that the effects can operate in an opposite sense to those in bulk. For the salts which are desorbed, the surface salt effects are small or zero, even though the salt-free layer of water at the surface is only a few Å thick, and the bulk effects are sizeable. It is probable that in the case of alcohol films at the alkane–water interface however, the surface salt effect should really be compared with the effect on the OH group in bulk, rather than on the whole molecule, since the alkyl chain of the adsorbed alcohol is presumably 'dissolved' in alkane.

Metal complexation by α-mercapto-β-aryl acrylic acids

JOSEPH WAGNER,[1] PIERRE VITALI, JOSIANE SCHOUN, AND EUGENE GIROUX[2]

Centre de Recherche Merrell International, 16, rue d'Ankara, 67084 Strasbourg, Cedex, France

Received June 21, 1977

JOSEPH WAGNER, PIERRE VITALI, JOSIANE SCHOUN, and EUGENE GIROUX. Can. J. Chem. **55**, 4028 (1977).

Protonation constants of several α-mercapto-β-aryl acrylic acids and constants for formation of complexes between these ligands and bivalent metal cations were determined by computer-assisted analysis of p*H*-titration data. Ligand–metal ion mixtures in 50% (v/v) dioxane–water and in water, $I = 0.1$ *M* ($NaClO_4$) were titrated at 25°C with sodium hydroxide. Initial estimates of complex formation constants were refined with the SCOGS program. The ligands were shown to complex zinc(II) and nickel(II) metal ions avidly. These ligands potently inhibited the metal-dependent enzymes alkaline phosphatase, carboxypeptidase A, coeruloplasmin, and thermolysin. Partition of zinc(II) between aqueous and *n*-butanol or *n*-octanol phases was enhanced in favor of the organic phase by several of these complexants.

JOSEPH WAGNER, PIERRE VITALI, JOSIANE SCHOUN et EUGENE GIROUX. Can. J. Chem. **55**, 4028 (1977).

Les constantes de protonation et les constantes de formation de complexes de métaux bivalents avec une série d'acides α-mercapto-β-aryl acryliques ont été déterminées par analyse à l'ordinateur des courbes de titration p*H*-métriques. Les titrations ont été effectuées sur des mélanges de ligand et du cation métallique dans des solutions de 50% (v/v) dioxane–eau et dans l'eau, $I = 0.1$ *M* ($NaClO_4$) à 25°C avec de la soude. Les valeurs initiales des constantes ont été déterminées à partir des courbes de formation et ont été affinées par utilisation du programme SCOGS. Les constantes obtenues montrent que les ligands présentent une grande affinité spécialement pour le zinc(II) et le nickel(II). Ces ligands inhibent fortement les metalloenzymes, phosphatase alcaline, carboxypeptidase A, ceruloplasmine et thermolysine. Plusieurs de ces ligands augmentent l'extraction du zinc dans la phase organique dans des essais de partition du zinc(II) entre l'eau et le *n*-butanol ou le *n*-octanol.

Introduction

Some β-aryl derivatives of α-mercaptoacrylic acid influence the distribution and metabolism of zinc in the rat. Following administration of a single dose of α-mercapto-β-(2-furyl) acrylic acid or α-mercapto-β-phenyl acrylic acid, blood plasma zinc concentration increased many-fold within a few hours and remained elevated for as long as 5 days (1). Evidence for formation of a ternary complex of plasma albumin, zinc, and the furyl derivative was obtained (2). While the complexation of metal ions by many α- and β-mercapto acids and amino acids has been well studied (3), few data of a similar nature are available for the α-mercapto-β-aryl acrylic acids. Foye and Lo (4) reported stability constant data for complexes of the phenyl derivative with Al^{3+}, Cu^{2+}, and Fe^{3+}; they also found this compound to have antimicrobial activity. In this report we present data characterizing complexation by several α-mercapto-β-aryl acrylic acids of zinc and of other metal cations and data on the inhibition of four metal-dependent enzymes by these ligands and other metal-complexing agents.

Experimental

Syntheses

The α-mercapto-β-aryl acrylic acids depicted in Scheme 1 were prepared by alkaline hydrolysis of the corresponding rhodanine derivatives obtained from the condensation of the appropriate aldehyde with rhodanine, following the procedure of Campaigne and Cline (5). Melting points were determined on a Kofler hot stage apparatus and are uncorrected. The nmr spectra were recorded on a Varian T60 using tetramethylsilane (TMS) or 3-(trimethylsilyl)-1-propane sulfonic acid as internal standards. Chemical shifts are given in ppm (δ, TMS = 0) and coupling constants in Hz. The abbreviations s, d, m, and br refer to singlet, doublet, multiplet and broadened, respectively. Compounds **1**, **2**, **5**, **6**, **7**, and **10**, already described in the literature (6–9) presented analytical data in agreement with their structure.[3] Thiosalicylic acid **9** (Fluka) was recrystallized from methanol.

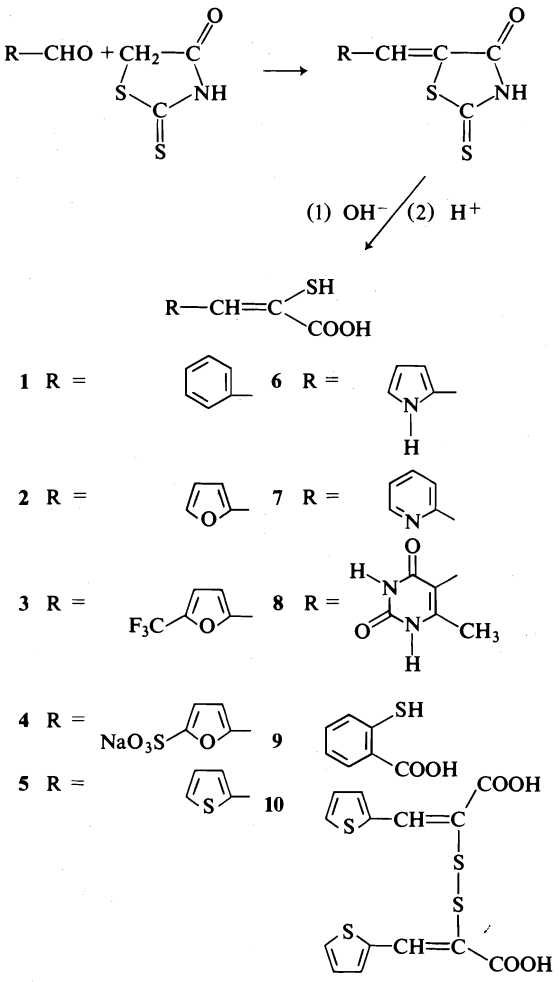

SCHEME 1

5-(5-Trifluoromethyl-2-furylmethylene) Rhodanine

5-Trifluoromethyl-2-furfural (3.4 g, 2.1 mmol) (10), rhodanine (2.92 g, 2.2 mmol), and dry sodium acetate (5.16 g) in 35 ml of glacial acetic acid were stirred together and heated to reflux. After 10 min, a precipitate occurred and heating was continued for 2 h. The reaction mixture was cooled, 30 ml of water was added, and the precipitate was filtered, washed with water, and dried. Chromatography over silica gel (eluent CH_2Cl_2), followed by recrystallization in dichloromethane–pentane yielded 3.7 g (63%) of yellow crystals, mp 174°C; nmr ($CDCl_3$): 6.80 (m, 2H, ring protons), 7.38 (s, 1H, exocyclic —CH=). *Anal.* calcd. for $C_9H_4F_3NO_2S_2$: C 38.71, H 1.44, N 5.01, S 22.96; found: C 38.70, H 1.56, N 5.10, S 22.91.

α-Mercapto-β-(5-trifluoromethyl-2-furyl) Acrylic Acid (3)

5-(5-Trifluoromethyl-2-furylmethylene) rhodanine (1.58 g, 5.66 mmol), 25 ml of 1 *N* sodium hydroxide solution, and 25 ml of water were stirred under nitrogen at room temperature for 10 h. After cooling and acidification at p*H* 1.5 with concentrated hydrochloric acid, a precipitate was recovered by filtration. The material was washed by stirring with 50 ml of water under nitrogen at room temperature, acidified with concentrated hydrochloric acid and filtered to yield 0.8 g (60%) of slightly brown crystals, mp 158°C; nmr (acetone-d_6): 7.1 (m, 2H, ring protons), 7.6 (s, 1H, exocyclic —CH=). *Anal.* calcd. for $C_8H_5F_3O_3S$: C 40.34, H 2.11, S 13.46; found: C 40.26, H 2.11, S 13.60.

5-(5-Sodiumsulfonate-2-furylmethylene) Rhodanine

5-Sodiumsulfonate-2-furanaldehyde was converted as above to the rhodanine derivative. Recrystallization in water gave yellow crystals (73% yield), mp 280°C (dec.); nmr (DMSO-d_6): 6.62 (d, J = 3, 1H, ring proton), 7.03 (d, J = 3, 1H, ring proton), 7.4 (s, 1H, exocyclic —CH=). *Anal.* calcd. for $C_8H_4NO_5S_3Na$: C 30.67, H 1.29, N 4.47; found: C 30.63, H 1.32, N 4.51.

α-Mercapto-β-(5-sodiumsulfonate-2-furyl) Acrylic Acid (4)

This compound was obtained from the corresponding rhodanine derivative (89% yield); mp >220°C (dec.); nmr (D_2O): 6.88 (s, 2H, ring protons), 7.45 (s, 1H, exocyclic —CH=). *Anal.* calcd. for $C_7H_5O_6S_2Na$: C 30.88, H 1.85; found: C 30.69, H 1.81.

5-(1,2,3,4-Tetrahydro-6-methyl-2,4-dioxo-5-pyrimidylmethylene) Rhodanine

This compound was obtained from 5-carbaldehyde-6-methyluracil (11) (83% yield); orange crystals, mp >260°C; nmr (DMSO-d_6): 2.33 (s, 3H, CH_3), 7.21 (s, 1H, exocyclic —CH=), 11.46 (s, 1H, NH), 12.33 (b s, 1H, NH). *Anal.* calcd. for $C_9H_7N_3O_3S_2$: C 40.13, H 2.62, N 15.60; found: C 40.20, H 2.74, N 15.64.

α-Mercapto-β(1,2,3,4-tetrahydro-6-methyl-2,4-dioxo-5-pyrimidyl) Acrylic Acid (8)

This compound was obtained from the preceding compound (68% yield); yellow crystals, mp 240°C (dec.); nmr (DMSO-d_6): 2 (s, 3H, CH_3), 7.2 (s, 1H, —CH=), 11.1 (b s, 3H, NH, COOH). *Anal.* calcd. for $C_8H_8N_2O_4S$: C 42.09, H 3.54, N 12.27; found: C 41.99, H 3.72, N 12.31.

Potentiometric Titrations

Water with greater than 10 MΩ cm^{-1} resistivity was prepared using a Millipore 'Milli-Q' system. Dioxane (Baker AR) was refluxed 48 h over sodium and distilled through a Vigreux column. Solutions (0.1 *M*) of sodium perchlorate, zinc(II) nitrate, nickel(II) chloride (all from E. Merck) or of the perchlorates of cobalt(II), iron(II), manganese(II), nickel(II), or zinc(II) (all from Pierce Chemical) in water or in 50% (v/v) dioxane–water were slightly acidified with perchloric acid (p*H* = 3) to suppress hydrolysis; concentrations were determined by Schwarzenbach's procedure (12). Sodium hydroxide solutions were standardized by titration with hydrochloric acid (Titrisol, E. Merck). Solutions (0.1 *M*) of ligands in 50% (v/v) dioxane–water were prepared by dissolving the ligands in 5 ml of dioxane (degassed by bubbling of nitrogen) and adjusting to 10 ml with degassed water. One half equivalent of $HClO_4$ was added in preparation of solutions of ligands **1**, **2**, **5**, and **9**. Ligand solutions were stored under nitrogen at 5°C. Fresh stock was prepared each day, as some ligands in solution, especially **6** and **7**, oxidized to disulfide (5–10%) after 6–10 h.

Mixtures (20 ml) of ligand and metal ion were titrated

with NaOH (0.3 *M* in water, or in 50% (v/v) dioxane–water). At each of two ligand concentrations (2 and 4 m*M*), metal ion concentrations were employed to yield ligand–metal stoichiometries of 8:1, 4:1, and 2:1. Ligand solutions also were titrated in the absence of metal ion. All titrations were carried out in a water-jacketed vessel thermostated at 25 ± 0.1°C. The titration cell was tightly covered and nitrogen saturated with solvent was bubbled through the solution.

A Mettler semi-automatic titration system consisting of modules DK 10, 12, 13, and 15 connected to a DV 11 burette and equipped with a Metrohm glass electrode EA 109 and an E 430 saturated calomel electrode was used. The electrodes and p*H* meter were calibrated to read p*H* with four aqueous buffer solutions (p*H* = 4.01 to 10.01). For measurements in 50% aqueous dioxane, the glass electrode was conditioned for several days in the mixed solvent (13). The sleeve-type calomel electrode was refilled with saturated KCl after five to six titrations. The p*H* values were measured to ±0.01 unit.

Protonation and Formation Constants

Formation constants β_{pqr} correspond to the general equation

$$[1]\quad pL^{2-} + qM^{2+} + rH^{+} \rightleftharpoons (L_pM_qH_r)^{(-2p+2q+r)+}$$

'Practical' protonation constants of the ligands are

$$[2]\qquad \beta_{101} = [HL^{-}]/(H^{+})\,[L^{2-}]$$

$$[3]\qquad \beta_{102} = [H_2L]/(H^{+})^2[L^{2-}]$$

Initial estimates for β_{101} and β_{102} were obtained from titration curves and formation curves ($\bar{n}_H = f(pH)$) and were refined using the computer program SCOGS (14) on a UNIVAC 1110 computer. For the calculation of H^+ and OH^- concentrations from H^+ activities as measured by the glass electrode, a correction factor of -0.06 ± 0.02 was determined by titrating at a constant ionic strength of 0.1 at 25°C a 0.01 *M* solution of HCl in 50% (v/v) dioxane–water with a solution of NaOH in 50% (v/v) dioxane–water. The pK_w was calculated to be 15.38 ± 0.02, in agreement with previous results (15, 16). For measurements in water, the mean activity coefficient $f_{\pm}$ was taken as 0.79 and the pK_w as 13.996 (17) at 25°C and $I = 0.1$ *M* ($NaClO_4$). Approximate values of formation constants β_{110} and β_{210} were obtained at $\bar{n} = f(pL)$, given by [4] and [5]. C_M and C_L are total ligand and

$$[4]\quad \bar{n}_L = \frac{C_L - [L^{2-}][1 + \beta_{101}(H^{+}) + \beta_{102}(H^{+})^2]}{C_M}$$

$$[5]\quad [L_2^{-}] = \frac{2C_L + [EX_{acid}] - [H^{+}] + [OH^{-}] - C_{base}}{\beta_{101}(H^{+}) + 2\beta_{102}(H^{+})^2}$$

metal concentrations, respectively, $[EX_{acid}]$ is the excess of perchloric acid added in preparation of stock solutions and C_{base} is the concentration of added base. Constants were refined over the entire range of experimental data by the use of the SCOGS program. If by adding other species, no further reduction in the standard deviation of titre could be achieved, the last set of values was retained. Experimental and calculated formation curves were compared on a Hewlett-Packard 9820 desk calculator fitted with a HP 9862 plotter.

Ligands and Zinc Partition Experiments

Two millilitres of a solution of zinc sulfate (33.5 μ*M*), prepared in 0.05 *M* 3-(*N*-morpholino)propanesulfonic acid, 0.15 *M* NaCl, p*H* 6.0, was shaken with complexant and *n*-octanol (8 ml) or *n*-butanol (2.5 ml). The complexant (4 mol/mol $ZnSO_4$) was freshly dissolved either in the organic solvent or in the zinc sulfate solution. After 5 min of contact the phases were separated by centrifugation. Zinc concentration in the aqueous phase was determined by atomic absorption spectroscopy. Zinc standards were prepared by dilution of Titrisol standard (E. Merck), using aqueous solvent contacted with organic solvent. Each partition mixture was analyzed in triplicate.

Inhibition of Enzymes by Complexants

E. Coli alkaline phosphatase (E.C.3.1.3.1., Sigma Chemical) was assayed spectrophotometrically (18), using the kit supplied by Boehringer-Mannheim. Enzyme was incubated with inhibitor (freshly dissolved in dimethylsulfoxide or in buffer) for 15 min at 30°C in p*H* 10.5 buffer before initiation of the enzymatic reaction by addition of substrate. In all assays dimethylsulfoxide was present at a final concentration of 5% (v/v). Bovine carboxypeptidase A (E.C.3.4.12.2, Sigma Chemical) was assayed by a p*H*-stat technique (19). Enzyme was incubated with inhibitor (freshly dissolved in polyethylene glycol 300 or in buffer) for 10 min at 30°C at p*H* 7.5 before initiation of the enzymatic reaction by addition of substrate, hippuryl-D,L-β-phenyllactic acid (Fox Chemical). The final concentration of polyethylene glycol 300 was 5% (v/v). The p*H* of the reaction mixture was maintained at 7.5 with a Mettler titration system. Human coeruloplasmin (E.C.1.16.3.1., Sigma Chemical) was assayed spectrophotometrically using *o*-dianisidine (Sigma Chemical) as substrate (20). The rate of reaction was determined after preincubation of enzyme with inhibitor (freshly dissolved in ethanol; final ethanol concentration 2.5% (v/v)) for 15 min at 30°C in p*H* 5.0 buffer. Assay mixtures contained 0.1 m*M* disodium EDTA (21) to suppress enhancement of activity due to traces of iron. The possibility of decolorization of the assay mixture by inhibitor was checked by the method of Curzon and Cumings (22). Thermolysin (E.C.3.4.24.4., Sigma Chemical) was assayed fluorimetrically using enzyme freed of low molecular weight contaminants by gel chromatography on Sephadex G-25 (Pharmacia Fine Chemicals). Enzyme solution was stored at −25°C and thawed prior to assay. An aliquot was diluted to 1.8 ml with a buffer of 10 m*M* 5,5-diethylbarbituric acid, 90 m*M* NaCl, p*H* 7.5. (23). To the enzyme solution was added inhibitor freshly dissolved in buffer or in ethanol (a total of 0.1 ml ethanol in all assay tubes). The mixture was heated for 10 min in a water bath at 40°C. The enzymatic reaction was initiated by addition of 0.1 ml of a 20 m*M* solution of carbobenzoxyglycyl-L-leucineamide (Protein Research Foundation, Osaka, Japan) in ethanol. The reaction mixture was maintained at 40°C and six aliquots of 0.2 ml were removed at 5 min intervals. Hydrolysis of the peptide bond was measured in these samples by the fluorescamine technique (24).

In all inhibition studies the effect of four or more con-

centrations of a given inhibitor was assessed. Remaining enzyme activity was plotted as a function of inhibitor concentration. From a smooth curve drawn through the data, the concentration of inhibitor necessary to reduce activity to 50% of the control value was obtained by interpolation.

Results

Protonation Constants

Computer-refined values of protonation constants of the thiol and carboxyl groups of the ligands are presented in Table 1. In the series of α-mercapto-β-aryl acrylic acids the nature of the aryl substituent did not influence strongly the ionization of the carboxyl group, but ionization of the thiol group was influenced by the electron donation ability (25) of the aryl group (compare **1**, **2**, and **5**). For the furan derivatives, ionization of the carboxyl and thiol groups varied in the same order as the inductive effect of the substituent (26) in position 5 of the furan ring (compare **2**, **3**, and **4**). The pK_a values found for ligands **1** and **9** are in agreement with those of other workers (4, 27, 28) if we take into account that our results are 'practical' pK_a values.

Metal Complex Formation Constants

Computer-refined values of formation constants of metal–ligand complexes are presented in Table 2. An emphasis was placed upon the study of zinc complexes because of the effect these ligands have upon zinc metabolism. In Fig. 1 are illustrated titration curves of two concentrations of α-mercapto-β-furyl acrylic acid **2** in the absence and in the presence of zinc(II) at ligand–metal ratios of 8:1, 4:1, and 2:1. Similar curves were prepared for the other ligands. The formation curves ($\bar{n}$ versus log $[L^{2-}]$) corresponding to the titration curves of Fig. 1 for $C_L = 4$ mM were all superimposable. This indicated that for the zinc(II)–ligand system only the mononuclear species ZnL and ZnL_2^{2-} were present. Approximate values of the stability constants log β_{110} (11.1) and log β_{210} (20.5) obtained at $\bar{n} = 1/2$ and $\bar{n} = 3/2$ were refined with the SCOGS program over the entire pH range (2.8–9.7) to an estimated standard deviation in titre of 4.1×10^{-3} (6 curves and 161 points). The value found for the estimated standard deviation of titre in calculation of the protonation constants was 3.8×10^{-3}. Qualitatively similar conclusions were reached for all ligands listed in Table 2: only mononuclear zinc(II) complexes appeared to be formed.

Only mononuclear complexes appeared to form between nickel(II) and the ligands. Titration curves obtained with α-mercapto-β-thienyl acrylic acid **5** and several bivalent metal ions at a ligand–metal ratio of 2:1 are illustrated in Fig. 2. In titrations with iron(II) and manganese(II), hydrolysis occurred at high pH values, especially at lower ligand–metal ratios. Attempts to titrate ligand–copper(II) mixtures failed; dark-colored solutions occurred upon adding copper(II) salt to carefully degassed ligand solutions, indicating, presumably, oxidation–reduction involving the thiol group (29). Cadmium(II) and lead(II) precipitated with ligands **1** to **8** in the mixed solvent when the pH was raised to 3–5. No formation constants were obtained. The values obtained for formation of calcium(II)–ligand **5** complexes indicated, as expected, that affinity of these ligands for alkaline earth cations was relatively low.

Using data in Tables 1 and 2, species distributions in metal–ligand systems were calculated as a function of pH. In Fig. 3 are illustrated concentrations across the pH range of zinc ion, ligand **2** species, and zinc–ligand complexes in 50% aqueous dioxane at two ligand–metal ratios. In Fig. 4 are illustrated species distributions of the zinc ion – ligand **4** system in two media, an aqueous and a mixed solvent. Under any of these conditions essentially all of the metal is complexed by these ligands at neutral pH.

TABLE 1. Protonation constants (β_{pqr}) of ligands at 25°C and $I = 0.1$ M ($NaClO_4$) in 50% (v/v) aqueous dioxane

Ligand	Log $\beta_{pqr} \pm \sigma$[a]

[d] Values determined in aqueous medium.
[e] Log $\beta_1 = 9.95$; log $\beta_2 = 18.52$ in 75% (v/v) dioxane–water at 30°C, $I = 0.02$ *M* (KCl) (28).
[f] Log $K_1 = 8.1$; log $K_2 = 5.25$ in 50% (v/v) dioxane–water at 25°C, $I = 0.1$ *M* ($NaClO_4$) (27).

Partition Studies of Zinc(II)–Ligand Complexes

Data on extraction of zinc(II) from an aqueous phase into immiscible alcohols are presented in Table 3. In the absence of complexant, little zinc (added as zinc sulfate) partitioned into the organic phase. Some water-soluble complexants such as EDTA did not induce transfer of zinc into either alcohol. Other complexants did solubilize zinc(II) in the alcohols. Alcohol-soluble species were presumably those in which complexation was involved, although complexant concentration was not determined in any phase. Ligands **1**, **2** and **5** appeared to extract zinc ion well, relative to most of the complexants tested.

Inhibition of Metalloenzymes

Also presented in Table 3 are data on inhibition by complexants of enzymatic activity of the zinc-dependent enzymes, alkaline phosphatase and carboxypeptidase A, and the copper-dependent enzyme, coeruloplasmin. The tabled values were obtained from plots of inhibition vs. concentration curves, but the precision with which such concentrations were determined was not evaluated by statistical techniques, since in several cases the curves appeared to indicate complex inhibition kinetics. However, the mercapto acrylic acids were judged to be potent inhibitors. Results of the study of inhibition of thermolysin, a zinc-dependent enzyme, are plotted in Fig. 5, in which the concentration of complexant necessary to inhibit half of the total enzymatic activity appears related to the value of the formation constant of the 1:1 complex of zinc ion and inhibitor.

Discussion

Compared to many α- and β-mercapto acids and amino acids described in the literature (3), α-mercapto-β-aryl acrylic acids complex bivalent metal cations with relatively high affinity. Results obtained for β_{210} complexes of α-mercapto-β-thienyl acrylic acid **5** with several metals showed that the affinity of complexation followed the Irving–Williams order, $Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} > Zn^{2+}$. With a given metal ion, but different α-mercapto-β-aryl acrylic acids, values of the complex formation constants varied with values of the protonation constants, as expected. Protonation constants of ligand **4** in aqueous solvent and in 50% (v/v) aqueous

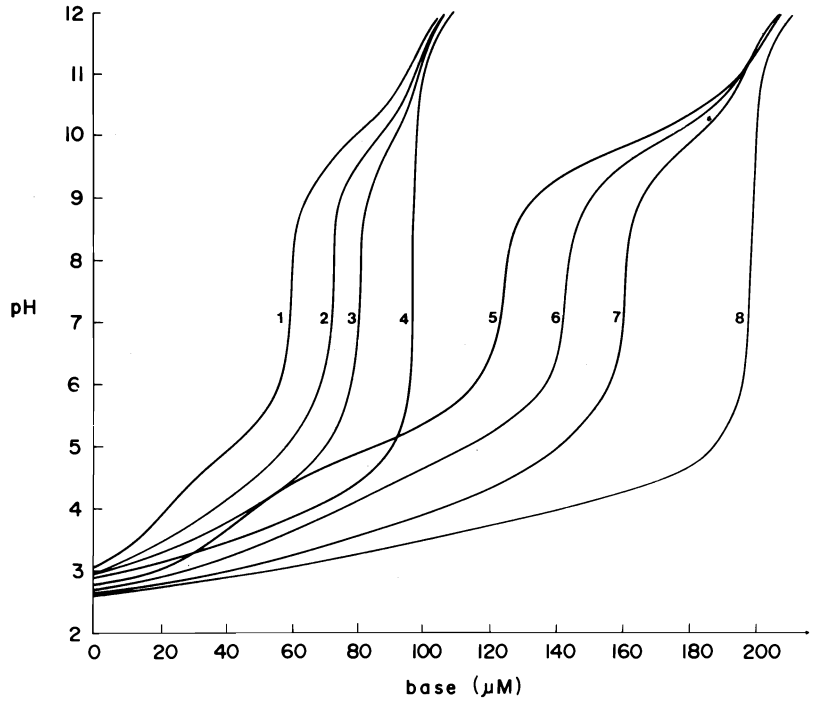

FIG. 1. Titration curves for α-mercapto-β-furyl acrylic acid – $Zn(NO_3)_2$ in 0.1 *M* $NaClO_4$ in 50% (v/v) dioxane water. FIG. 2. Titration curves for α-mercapto-β-thienyl acrylic acid alone (L) and in the presence of cations in 50% (v/v) dioxane–water. C_L = 4.0 m*M*; C_M = 2.0 m*M*.

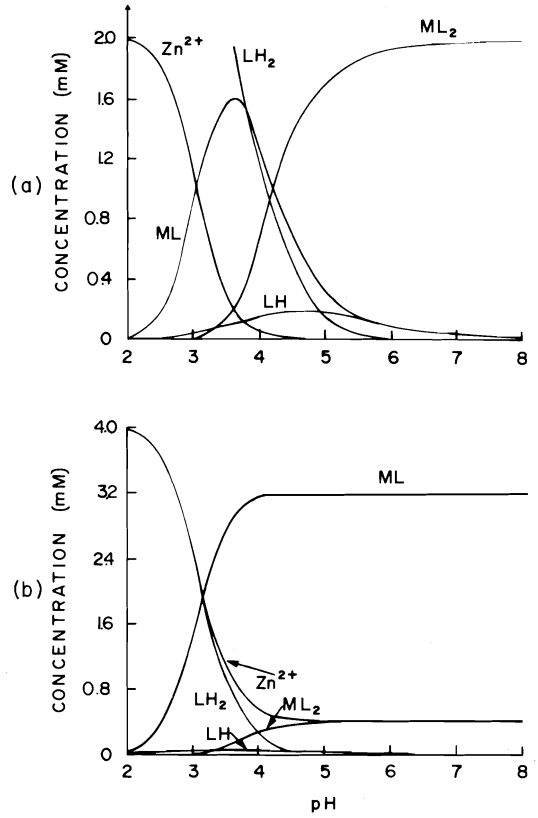

FIG. 3. Computed species distribution as a function of pH for solutions of α-mercapto-β-furyl acrylic acid (4.0 mM) with (*a*) Zn^{2+} (2.0 mM) and (*b*) Zn^{2+} (4.0 mM) in 50% (v/v) dioxane–water.

dioxane indicated increases in pK_a of 1.4 and 1.75 units in passing to the mixed solvent. One may compare pK_a values of ligand **4** in aqueous solution for dissociation of the carboxyl and thiol groups, 3.2 and 7.35, respectively, with those for a molecule such as α-mercapto acetic acid, 3.5 and 10.2, respectively (29). The more facile ionization is due in part to the double bond in the α position and the inductive effect of the aryl substituent. This characteristic underlies the potent complexation of metal ions by these compounds at physiological pH. Lipid solubility of zinc – mercapto acrylic acid complexes may be another important feature underlying their physiological effects. **1** and **2** were among the most effective ligands in enhancing the alcohol solubility of zinc, compared to many ligands previously studied in the aqueous buffer – butanol system (30).

Consistent with the generalizations drawn from the potentiometric study of complex formation, results of the study of inhibition of metalloenzymes were compatible with avid complexation of metals by mercapto acrylic acids. Alkaline phosphatase contains two zinc atoms per enzyme molecule (31) and coeruloplasmin contains at least six copper atoms (32). Carboxypeptidase contains a single zinc atom per molecule, but hydrolysis by the enzyme of the ester substrate does not follow simple Michaelis-Menten kinetics (33). Thermolysin contains a single zinc atom (34).

Relative differences in inhibitory potency may reflect characteristics of the interaction of enzyme with inhibitor, or they may reflect less profound properties such as the stability of the compound in the assay milieu. The four enzymes were assayed at acid pH (coeruloplasmin), at neutral pH (carboxypeptidase and thermolysin), and at alkaline pH (alkaline phosphatase). At micromolar concentrations of total zinc, ranking of the degree to which zinc would be complexed

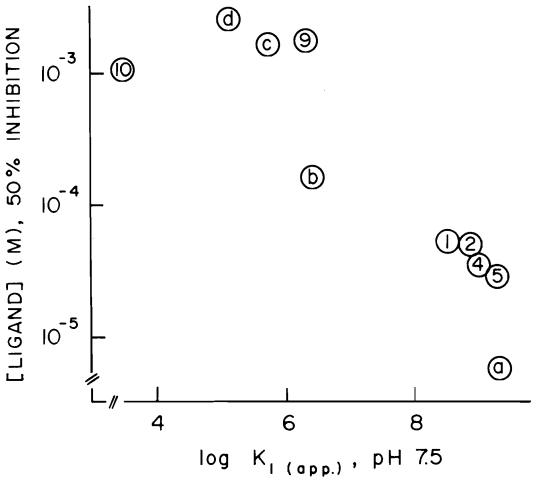

FIG. 5. Ligand concentration calculated for 50% inhibition of activity of thermolysin versus apparent formation constant at pH 7.5 for the ML complex. Formation constants of reference inhibitors were taken from the literature: a = 8-thioquinoline (35); b = 1,10-phenanthroline (36); c = 8-hydroxyquinoline (37); d = mercapto acetic acid (29).

at neutral pH by a considerable excess of ligand was calculated to be **5** > **4** > **2** > **3** > **6** > **8** > **1** > **7** > **9**. This order bears some relationship to that observed in the inhibition studies.

We have demonstrated that mercapto acrylic acids form complexes with a variety of metal cations. Yet in rats, these compounds affect zinc metabolism most markedly. While α-mercapto-β-furyl acrylic acid **2**, for example, raised zinc concentration in serum 10- to 15-fold, it had little or no effect on serum copper and iron concentration (1). Presumably the avidity of metal complex formation, the lipid solubility of the complexes, the stability of the complexant, and other features as well are involved in the effects of these compounds on trace metal metabolism.

Acknowledgements

The electro-deposition of silver on stationary and rotating glassy carbon discs

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, AND SANDOR SZABO[1]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received June 3, 1977

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, and SANDOR SZABO. Can. J. Chem. **55**, 4037 (1977).

The deposition of silver onto glassy carbon is described. The solution consisted of 10^{-2} *M* $AgClO_4$ in 1.0 *M* $HClO_4$. Experiments reveal the difficulties in trying to separate nucleation and growth phenomena from mass transport effects. A simple semi-quantitative model is proposed to explain the experimental data. It is also shown that the deposition reaction is not completely reversible under certain experimental conditions.

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER et SANDOR SZABO. Can. J. Chem. **55**, 4037 (1977).

On décrit le dépôt de l'argent sur du carbone vitreux. La solution est formée de $AgClO_4$ 0.01 *M* dans du $HClO_4$ 1.0 *M*. Des expériences montrent les difficultés qui existent lorsque l'on veut séparer les phénomènes de nucléation et de croissance des effets de transport de masse. On propose un modèle simple semi-quantitatif pour expliquer les données expérimentales. On montre aussi que la réaction de déposition n'est pas complètement réversible sous certaines conditions expérimentales.

[Traduit par le journal]

Introduction

The electrochemical formation of new phases on foreign substrates is of considerable importance in electrocatalysis. Modification of catalysts by metal deposition reactions is now commonplace. Studies of metal deposition on glassy carbon are of particular interest in work of this kind because the carbon remains inert during the deposition reaction. This is in sharp contrast to most metal surfaces, for which complex surface area changes accompany the reaction proper. Also, bulk metals have oxide layers, adsorbed molecules, crystal defects, intergrain boundaries, etc. which further complicate the interpretation of data. Avoidance of these complications can usually be realized on metal-amalgam substrates (1), or else on specially prepared single-crystal electrodes, as has been demonstrated for the deposition of Ag^+ on Ag (2). In the latter case, it is possible to observe the propagation of steps of monomolecular height across the electrode surface accompanied by two-dimensional nucleation.

Although glassy carbon is superior to metals in many respects, its structure is still little understood. It is believed, however, to consist of a network of ribbon stacks obtained by pyrolysis of a polymeric material; possibly a phenolic resin (3). Consequently, even a highly polished surface must exhibit local inhomogeneities related to the carbon structure. A second minor difficulty is that glassy carbon has a high resistivity, and this contributes to ohmic problems in the measurement of accurate current–voltage and current–time relationships. Nevertheless, glassy carbon is an excellent material for the study of metal deposition reactions.

In the present investigation the principal techniques employed were the linear potential sweep and the single and double potential step methods. These were chosen because they allowed straightforward measurement of the processes occurring, while at the same time ensuring some degree of separation between nucleation and growth phenomena and the influence of mass transport from the bulk of solution. Rotating disc electrodes were also employed for the same reasons.

Experimental

The glassy carbon used in the present work was purchased directly from the Tokai Electrode Manufacturing Co. Ltd. (Japan). Rotating disc electrodes were sealed in Araldite and machined into small cylinders. Before use, the surfaces were polished with ceric oxide to a mirror finish and washed many times with double-distilled water. It was observed that further polishing with tissue paper resulted in a hydrophobic surface; this procedure was therefore avoided.

[1]On leave from Central Research Institute for Chemistry of the Hungarian Academy of Sciences, H-1525/17, Budapest, Hungary.

The cell used in voltammetric measurements was divided by a glass frit, while the counter electrodes were made of platinized platinum sheets of large surface area. An adjustable-luggin reference probe was included in the cell design in order to minimize the solution component of the total ohmic resistance in the measuring circuit. All potentials are quoted with respect to the hydrogen electrode in the same solution.

Unless otherwise stated, the plating solution consisted of 10^{-2} *M* silver perchlorate in 1.0 *M* (Aristar) perchloric acid. The constant potential source was a PAR 170, and experimental data were recorded directly on the same instrument. Deoxygenation was achieved by flushing the solution with purified nitrogen.

Results

Figure 1 shows the results of applying linear scans of potential to a freshly prepared glassy carbon electrode, over the potential range +800 mV to +400 mV. For clarity, only the deposition reaction is shown, while the reverse reaction is omitted. It is immediately apparent that the second and subsequent scans (curve B) are displaced from the original data (curve A) by a factor of approximately 60 mV. Removal of the electrode, followed by polishing with ceric oxide, resulted in the regeneration of curve A upon repeating the experiment. This remarkable behaviour may be explained in terms of residual nuclei of electrodeposited silver on the electrode surface after the first potential scan. The presence of these nuclei obviates the need for nucleation on the carbon surface in the second and successive scans. This hypothesis could be tested in three ways. Firstly, examination of the electrode surface *in situ* with bright illumination clearly indicated the presence of a silvery white deposit remaining on the electrode surface at +800 mV. Secondly, removal of the electrode at this potential, followed by examination using scanning electron microscopy, indicated the presence of a large number of residual silver nuclei associated with minute scratches on the electrode surface (Fig. 2). Thirdly, the chemical identity of the nuclei could be confirmed by switching the electrode to open circuit. After a few minutes, the electrode assumed the equilibrium potential of bulk silver in the same solution. The conclusion, therefore, is that the Ag^+/Ag deposition reaction is not entirely reversible at the glassy carbon electrode in 1.0 *M* $HClO_4$ (cf. ref. 4).

A similar conclusion may be achieved by repeatedly cycling the electrode potential until a pseudo steady state is reached. The results of

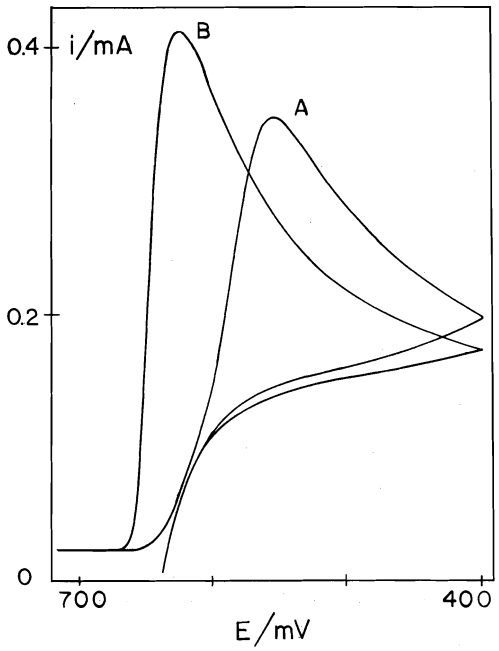

FIG. 1. 1 *M* $HClO_4$, 10^{-2} *M* $AgClO_4$, glassy C electrode. Linear potential scan from +800 mV to +400 mV. $v = 10$ mV s^{-1}, $\omega = 0$. (A) Clean surface, (B) second and successive cycles.

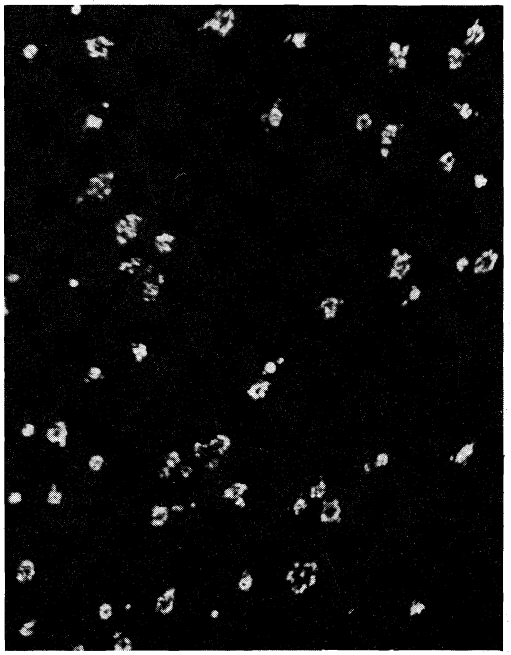

FIG. 2. Electrode surface viewed by scanning electron microscopy. Magnification 1000×, showing residual silver nuclei after 2 cycles between +800 mV and +400 mV at 50 mV s^{-1}.

this procedure are illustrated in Fig. 3. The voltammogram obtained is complex, and may not be analysed in a completely quantitative way. This is because the curves contain contributions from both the deposition reaction and from the relaxation of diffusion zones associated with mass transport from the bulk of solution. What is clear, however, is that a residual current is observed at +800 mV. The lack of complete reversibility therefore appears to be kinetic in origin, rather than being an intrinsically thermodynamic phenomenon.

The presence of the complicating features described above was of fundamental importance in designing further experiments. Because of surface roughness considerations, it was decided that the use of freshly prepared surfaces for every measurement might introduce small irregularities into the experimental data of a purely random nature. These irregularities would particularly influence the nucleation phenomena, and so this approach was rejected. Instead, it was decided to bring the electrode surface to a standard state prior to making any measurements. This could easily be carried out by linearly scanning the applied potential in the manner of Fig. 3, so that throughout the present work a large number of 'seed' nuclei were already present on the glassy carbon substrate. After this process, the electrode was also rotated before each measurement to ensure that the bulk concentration of Ag^+ extended to the electrode surface.

Investigation of Nucleation Processes

The transient response of the pretreated electrode following the application of a single potential step is illustrated in reduced variable form in Fig. 4. The transient exhibits a t^2 rise of current, which reaches a maximum and then decays as $t^{-1/2}$. The reaction is therefore proceeding via a nucleation and growth mechanism which at longer times is dominated by mass transport from the bulk of solution. In the limit the well-known equation for semi-infinite linear diffusion is obeyed

$$[1] \qquad i = nFA_sC_b(D_0/\pi t)^{1/2}$$

where i (mA) is the transient current, t (s) the transient time, D_0 ($cm^2\ s^{-1}$) the diffusion coefficient, C_b (mol cm^{-3}) concentration, and A_s surface area of electrode, respectively. Equation 1

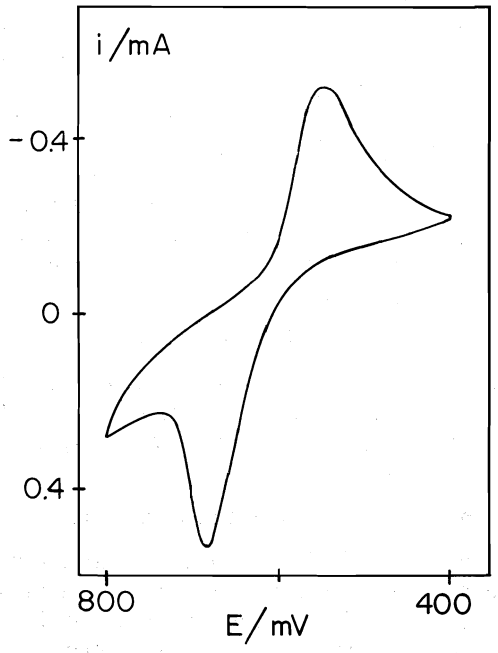

FIG. 3. 1 *M* $HClO_4$, 10^{-2} *M* $AgClO_4$, glassy C electrode. Continuous cycling linear potential scans from +800 mV to +400 mV. $\nu = 100$ mV s^{-1}, $\omega = 0$. Note residual current at +800 mV.

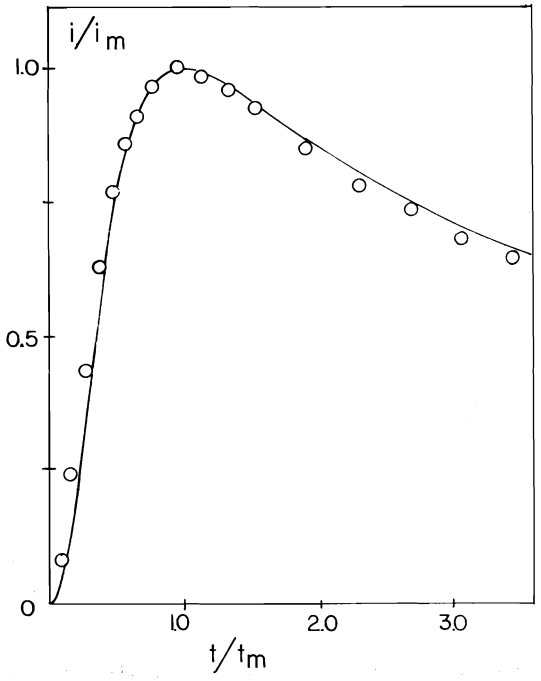

FIG. 4. Reduced variable test for complete experimental transient. Single potential step from +800 mV to +620 mV. Solid line is the theoretical shape according to eq. 9.

indicates that any diffusion zones surrounding the original nuclei have expanded and overlapped. The rising sections of the transients are tested in Fig. 5. The t^2 dependence is closely obeyed, in agreement with the data of Harrison (5, 8). Also, from the gradients of Fig. 5, it is possible to calculate the rate of growth of the deposit as a function of potential. This is shown in Fig. 6, where a very extreme dependence on potential is noted, about 5 mV per decade.

The use of the double potential step technique proved to be particularly interesting. A small pre-step (+450 mV for 40 ms) was first applied, followed by a second step on the time scale of seconds. In this case the current rises as t^1, while it decays as $t^{-1/2}$. Investigation of the rising transients as a function of potential is shown in Fig. 7. The linear dependence of current on time is observed at each potential, although extrapolation shows that the lines do not pass through the origin. This effect is quite usual with the double pulse technique, merely indicating that the current from the first step has not entirely decayed before the onset of growth at the lower overpotential. The gradients of the linear portions of the current–time curves (Fig. 7) are shown plotted versus potential in Fig. 8. As expected, an extreme dependence (~6.5 mV decade^{-1}) is noted in accord with the single step results (Fig. 6).

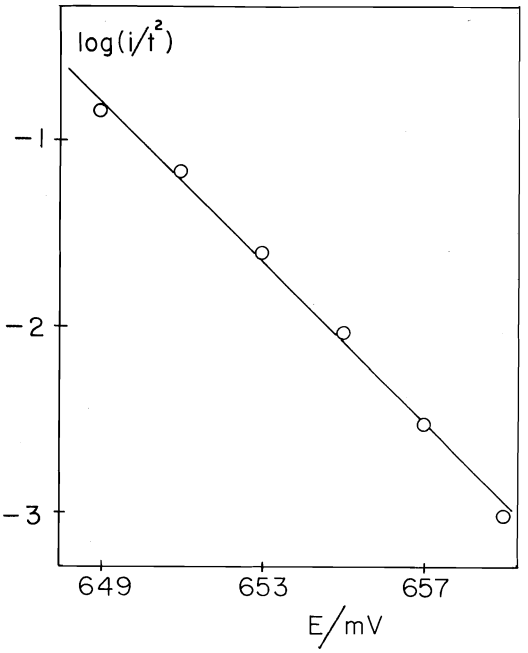

FIG. 6. Potential dependence of the function i/t^2 from single potential step experiments.

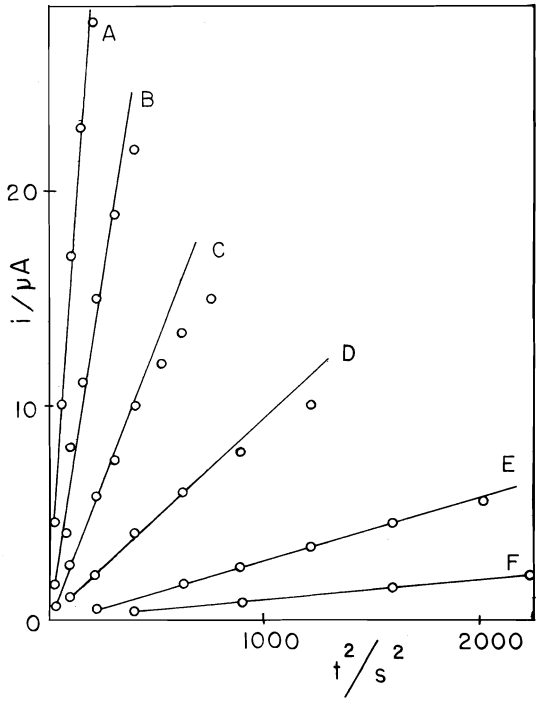

FIG. 5. 1 M $HClO_4$, 10^{-2} M $AgClO_4$, glassy C electrode. Single potential steps from +800 mV to (A) +649 mV, (B) +651 mV, (C) +653 mV, (D) +655 mV, (E) +657 mV, (F) +659 mV. Note t^2 dependence of current. Data recorded at short times, $\omega = 0$.

It is apparent from comparison of the single and double potential step results that the short-time behaviour of the current depends upon t^2 in the former case and upon t^1 in the latter instance. These two limiting cases may be understood on the assumption of a first-order nucleation law (1) of the form

$$[2] \qquad N = N_0[1 - \exp(-At)]$$

where N is number of nuclei and A (nuclei cm^{-2} s^{-1}) nucleation rate constant, respectively. At short times the exponential term may be expanded so that

$$[3] \qquad N \simeq N_0At \text{ (progressive nucleation)}$$

Alternatively, if N_0 is intrinsically large (or is enhanced by the double potential step technique) then $N \simeq N_0$. Consequently, the additional time dependence of the single step results may be explained on this basis.

However, a contradiction arises here because the pretreatment of the electrode indicates that

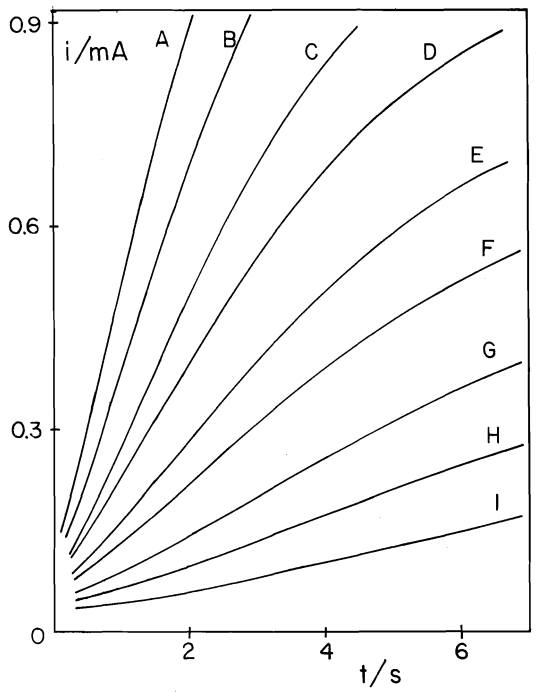

FIG. 7. Transients obtained by the double potential step method. Electrode potential switched from +800 mV to +400 mV (10 ms) then to (A) +662 mV, (B) +663 mV, (C) +664 mV, (D) +665 mV, (E) +666 mV, (F) +667 mV, (G) +668 mV, (H) +669 mV, (I) +670 mV. Note the linear dependence of i on t at short times.

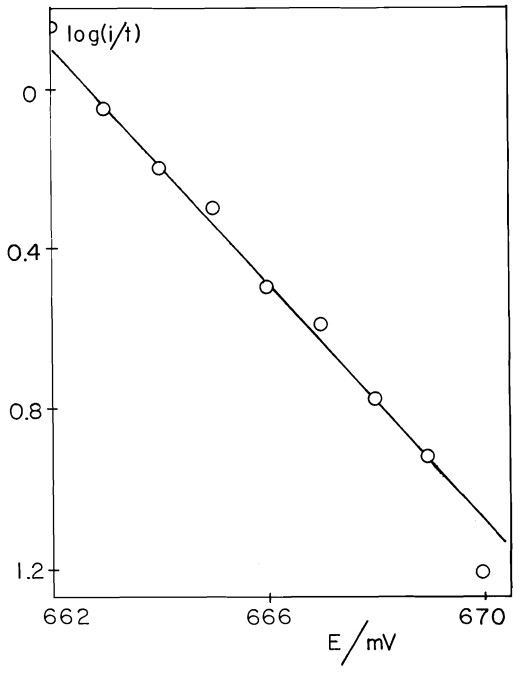

FIG. 8. Potential dependence of the function i/t from double step experiments.

N_0 should always be large, so that progressive nucleation will not be possible. The only realistic resolution of this dilemma is that the number of 'seed' nuclei on the carbon substrate must indeed be considered fixed by the pretreatment process, whereas progressive nucleation occurs at the same site during deposition at higher overpotentials.

This hypothesis is tested by scanning electron microscopy in Fig. 9. Although it is seen that nucleation is indeed occurring at the same sites, about four times as many 'seed' nuclei are present at +500 mV as compared to the electrode pretreatment (Fig. 2). This does not seriously invalidate the assumption of a constant number of seed nuclei, however, because (*a*) the overpotential used in obtaining Fig. 9 was much larger than that employed in the accumulation of the single-step data and (*b*) the nucleation rates observed at the sites of the 'seed' nuclei exhibit an extreme dependence on overpotential, and this is not detected by scanning electron microscopy.

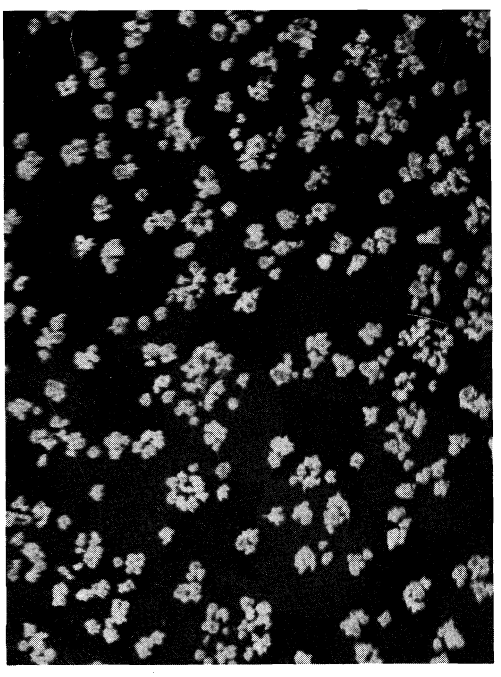

FIG. 9. Electrode surface viewed by scanning electron microscopy. Magnification 1000×, showing silver nuclei after potential step from +800 mV to +500 mV for 28 s.

The Influence of Mass Transport on the Nucleation Processes

The influence of mass transport on the nucleation processes is best observed by the use of rotating disc electrodes. Figure 10 shows a typical Levich plot for the deposition reaction, data being obtained from limiting currents observed during slow linear potential scans at various electrode rotation speeds. The experimental result is distinctive and highly reproducible. The unusual divergence from linearity at 0.2 $Hz^{-1/2}$ is noteworthy; it arises because of complex surface area changes during the growth of the electrodeposit. Thus

$$[4] \qquad i = 0.62nFA_sC_bD_0^{2/3}\nu^{-1/6}\omega^{1/2}$$

where A_s is the actual surface area of the electrode, ν kinematic viscosity, and ω (Hz) electrode rotation speed, respectively. Under these circumstances a well-developed Nernst diffusion layer must be present at the electrode surface, so that

$$[5] \qquad \delta = 1.62D^{1/3}\nu^{1/6}\omega^{-1/2}$$

where δ (cm) is diffusion layer thickness. It is of interest to conduct single and double potential step measurements under these circumstances. The results of single step experiments are shown in Fig. 11 for various rotation speeds. Once again a t^2 dependence is noted (cf. $\omega = 0$), but the absolute rate of reaction is related to the flux of Ag^+ to the electrode surface. That the flux occurs through a semi-infinite linear diffusion zone, rather than a hemispherical diffusion zone, is shown in Fig. 12. The current is obviously proportional to $1/\delta$.

The response of the rotating electrodes to the double potential step technique complicates the picture even further. Figure 13 shows a typical current–time plot obtained at $\omega = 25$ Hz. At short times $i \propto t^{1/2}$, rather than t^1 when $\omega = 0$ Hz. This implies that the flux of Ag^+ from the bulk of solution is having a profound effect upon the growth mechanism.

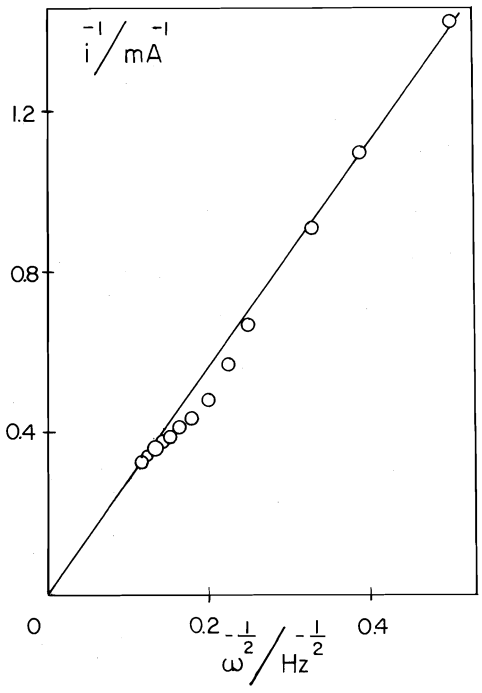

FIG. 10. 1 *M* $HClO_4$, 10^{-2} *M* $AgClO_4$, glassy C electrode. Limiting current versus $\omega^{1/2}$ for the deposition reaction. Linear potential scans from +800 mV to +400 mV, $\nu = 10$ mV s^{-1}, ω = various.

Discussion

When the Nernst diffusion zone hypothesis is applicable, a simple model for the growth of the electrodeposit may be proposed. Written for

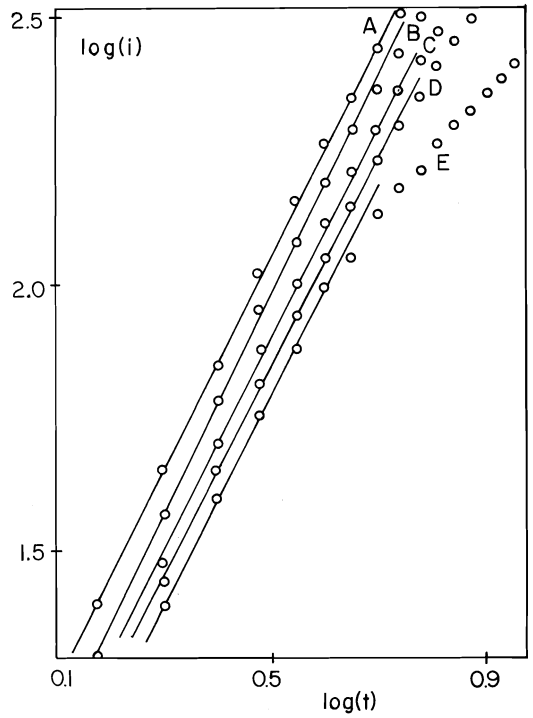

FIG. 11. Transient response to single potential step (+800 mV to +635 mV) with electrode rotation. (A) 60 Hz, (B) 50 Hz, (C) 40 Hz, (D) 30 Hz, (E) 10 Hz. The gradient $\simeq$ 2.0.

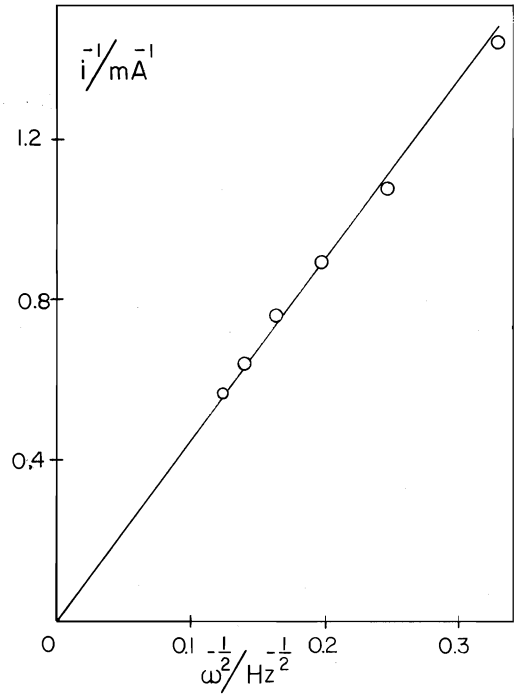

FIG. 12. Rotation speed dependence of growth transients measured at short times (t = 6.25 s). Double potential step, +800 mV to +400 mV (10 ms) then to +640 mV.

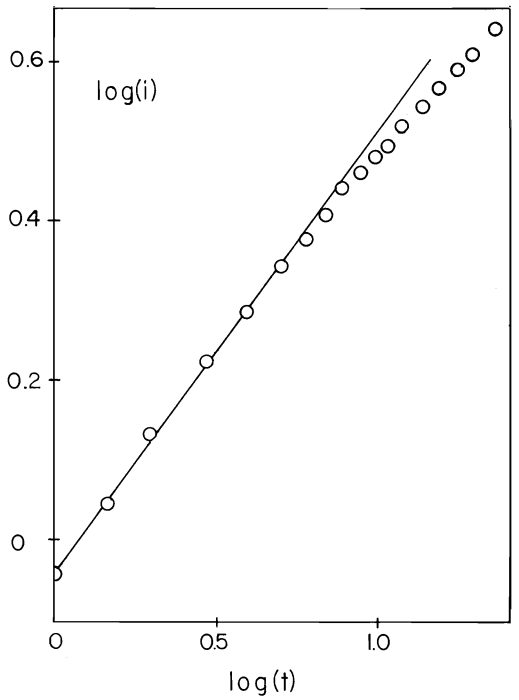

FIG. 13. Growth transient obtained from double potential step method with electrode rotation. Data recorded at short times. Potential switched from +800 mV to +400 mV (10 ms), then to +646 mV. ω = 25 Hz. Gradient $\simeq$ 0.50.

instantaneous nucleation

$$[6] \qquad \frac{i}{A_s} = \frac{N_0 A'}{A_s} nF \frac{D_0}{\delta}(C_b - C_s)$$

where A' is the 'effective' area of the Nernst diffusion layer per nucleus experiencing linear flux, and δ is the diffusion layer thickness. This equation therefore predicts $i_{growth} \propto \omega^{1/2}$ for a rotating disc electrode. Also, at long times, $N_0 A' \simeq A_s$ so that a $t^{-1/2}$ dependence of the current is predicted (eq. 1). At short times at a stationary laminar electrode, however, the problem is considerably more complex because it involves the overlap of individual hemispherical diffusion zones around each nucleus as well as the possible overlap of nuclei themselves. Various models for this type of growth have been proposed by Harrison and co-workers (6, 9, 10). In the present case, the observed results (Fig. 4) suggest

$$[7] \qquad \frac{1}{i/A_s} = \left(\frac{1}{i/A_s}\right)_{t\to 0} + \left(\frac{1}{i/A_s}\right)_{t\to \infty}$$

That is, the growth of the electrodeposit and the relaxation of the diffusion layer may be considered to be consecutive processes

$$[8] \qquad 1/i = (a/t^x) + (b/t^{-1/2})$$

where x represents the time dependence of the growth process at short times. In reduced variable form

$$[9] \qquad \frac{i}{i_m} = \frac{1 + 2x}{(t/t_m)^{-x} + 2x(t/t_m)^{1/2}}$$

where i_m (mA) is the current maximum in experimental transient and t_m time taken to achieve i_m respectively. This equation is shown in Fig. 14 as a function of x. Experimental data are in close agreement with this formulation (Fig. 4) although explanation of x in terms of models is still far from satisfactory (6).

An interesting conclusion follows from eq. 9. This is that accurate observation of growth transients at short times may only be achieved for currents below $\sim i_m/10$. This is because the influence of the falling section of the transient makes itself apparent above this value.

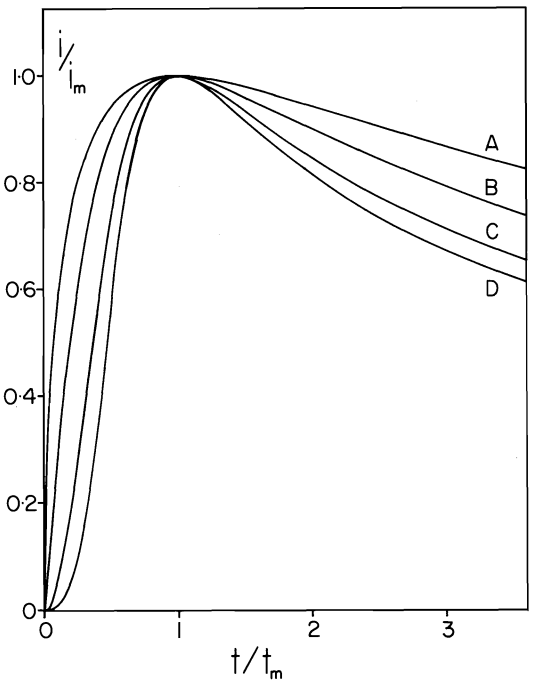

FIG. 14. Graphical representation of eq. 9. x = (A) 0.5, (B) 1.0, (C) 2.0, (D) 3.0.

Although a more complete model for the growth of Ag on glassy carbon cannot as yet be proposed, inspection of the experimental data shows that two types of nucleation are occurring. Firstly an approximately constant number of 'seed' nuclei are created by the pretreatment process. Secondly, new nuclei of silver are created on top of the seed nuclei progressively in time.

It should be noted that the three-dimensional silver deposits created on the electrode surface were rather amorphous in structure, and were crudely hemispherical in shape. Consideration of the crystallographic orientation of the deposits was therefore precluded. What was clear, though, was that the nuclei almost certainly grew into hemispherical diffusion zones emanating from the seed nuclei, and that at longer times these diffusion zones overlapped to create a condition of semi-infinite linear diffusion.

According to Frank (7) the growth of a three-dimensional deposit into a hemispherical diffusion zone should follow an equation of the form

$$[10] \qquad i = N_0 AnF(\rho/M)\pi S^3 D_0^{3/2} t^{1/2}$$

where S is a constant defined by Frank (6), M (g) gram-molecular weight, and ρ (g cm^{-3}) density of deposited material, respectively. However, in the present work the $t^{1/2}$ dependence is not observed (Fig. 7). The reason for this is somewhat obscure, although two possibilities present themselves. Either the mass transport has an unpredicted influence on the growth mechanism (e.g. the nucleation rate may be determined in part by the flux) or else the establishment of diffusion zones occurs so rapidly that overlap takes place on the time scale of the experimental data acquisition.

The interaction of pulsed CO_2-laser radiation with common monomers[1]

A. GANDINI

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 20, 1977

A. GANDINI. Can. J. Chem. **55**, 4045 (1977).

Several monomers were submitted to pulsed TEA-CO_2 laser radiation. In the condensed phase neither polymerization nor decomposition was observed. In the vapour phase, polymerization did not take place but extensive decomposition occurred, mainly through molecular elimination reactions. Possible reasons for the lack of polymerization are discussed.

A. GANDINI. Can. J. Chem. **55**, 4045 (1977).

On a soumi plusieurs monomères à la radiation d'un laser à CO_2 à impulsions. En phase condensée ces monomères n'ont polymérisé ni souffert aucune décomposition. En phase vapeur on n'a observé que des importantes réactions de fragmentation moléculaire. On propose des interprétations visant à expliquer l'absence de polymérisation.

The recent development of high-power infrared lasers has promoted a number of studies dealing with the interaction of this intense radiation with organic and inorganic substrates. The often selective character of the excitation, which can lead to isotope enrichment (1), and other unique features of this new type of photochemistry (2–5) have already been recognised and are attracting considerable interest.

Following a report by Chin (6) that ethylene can be partly converted into low molecular-weight paraffins by pulsed radiation from a TEA-CO_2 laser, we decided to investigate the susceptibility of various monomers to polymerization by this technique.

The monomers were purified by standard procedures and stored under conditions which guaranteed the absence of thermal or photo-induced polymerization.

Experimental

Condensed-phase Experiments

Monomers in the liquid and solid phase were introduced into a test-tube type cell (3.5 cm id) provided with a side arm and a NaCl window. After purging the cell contents with pure nitrogen, irradiation with the appropriate line of a Lumonics 103 TEA tunable CO_2 laser was started. The beam could be focused onto the monomer surface with a NaCl lens (7.5 cm focal length). Typically, a reaction would last 30 to 60 min, at a pulse rate of about 1 Hz. Power densities of 1 to 3 MW/cm^2 were measured for the unfocused beams. The search for polymers at the end of the experiments consisted of pouring a portion of the liquid monomer (or a solution of the solid monomer) into an excess of a precipitant for the polymer in question. Another portion of the monomer was vacuum distilled at room temperature to search for possible residual oligomers. Infrared and nmr spectra of the monomers before and after the experiments were also taken to look for nonpolymeric products arising from the interaction.

Acrylonitrile

The liquid was irradiated with the 10.247 μm line (focused and unfocused) both at room temperature and at −78°C.The monomer slowly turned yellow and its temperature was raised by about 15°C. However, no polymer was obtained nor was any appreciable quantity of other products detected.

Methyl Methacrylate

The liquid was irradiated at room temperature with the 10.653 μm line with focused and unfocused beams. Warming was observed (to about 40°C). No polymer or any other products were obtained. Experiments at −78°C and −196°C with the solid monomer were equally unsuccessful.

Vinyl Acetate

The liquid was irradiated at room temperature and at −78°C with the 10.532 μm line (focused and unfocused). No products were formed in detectable quantities.

Styrene

The 10.220 μm line was used to irradiate the liquid at room temperature and the solid at −78°C. The monomer was recovered unchanged in both experiments.

N-Vinylcarbazole

The solid crystalline monomer was irradiated at room temperature with the 10.532 μm line. During irradiation some monomer crystals melted. Some polymerization was observed, but the yields were very small (less than 1% in 30 min). The same results were obtained with annealed, glassy monomer.

Acenaphthylene

The solid monomer (crystalline and glassy) was irradiated at room temperature with the 9.271 μm line. As in the case of *N*-vinylcarbazole the monomer sublimed in part to the side walls of the vessel. Traces of a brown product precipitated from *n*-pentane, but the yield was so small that no analysis could be carried out.

Gas-phase Experiments

Experiments with vapours were conducted with a

[1]NRCC No. 16239.

cylindrical cell provided with NaCl windows (8 cm optical path, 3.5 cm diameter). Following evacuation, a known pressure of the monomer vapour was introduced and an infrared spectrum taken. The cell was then placed in front of the CO_2 laser (Lumonics 101 TEA-CO_2 laser) and its contents submitted to pulsed radiation at 10.57 μm with a frequency of 1.2 Hz. The beam was focused in the middle of the cell, using a germanium lens (10 cm focal length). Infrared spectra were taken periodically to follow the appearance of products. At the end of each run the volatile products were analyzed by mass spectrometry after a rough separation based on vapour pressure. The solid products (if any) were analyzed by infrared spectroscopy.

Acrylonitrile (70-80 Torr)

The first 20–25 pulses produced an intense plasma. Thereafter the breakdown was less frequent and towards the end of the experiments (500–700 pulses) it was very sporadic. After 50 pulses a faint brown deposit was noticed on the cell walls and windows. This increased as the reactions proceeded. After 50 pulses the ir spectrum showed appreciable amounts of acetylene and HCN. After 200 pulses at least 50% of the acrylonitrile had been consumed and the only products detected by ir were acetylene and HCN. After 700 pulses there was little monomer left in the cell. The concentration of acetylene and HCN had increased correspondingly. Mass spectra of the products confirmed the predominance of these two compounds among the products, but also revealed the presence of smaller amounts of acetylene dimers, benzene, and hydrogen. The brown polymeric material deposited during the irradiation was *not* polyacrylonitrile; its aspect and ir spectrum suggested that it could be polyacetylene of low molecular weight.

Methyl Methacrylate (30 Torr)

Breakdown in the vapour was very infrequent and absent during the first 50 pulses. The formation of several products could be followed by taking ir spectra. Already after 50 pulses the presence of acetylene, methane, CO_2, and CO could be assessed. As the reaction proceeded, the concentration of methyl methacrylate decreased and, correspondingly, the typical bands of these four major products increased. After 1600 pulses more than 90% of the monomer had been consumed and a slight brown deposit was visible on the walls. Mass spectra of the final mixture confirmed the importance of the four major products and also indicated the presence of hydrogen, diacetylene, benzene, and probably isobutylene. No polymethylmethacrylate was deposited in the cell.

Vinyl Acetate (70 Torr)

Breakdown with this vapour occurred at every pulse for the first 100 pulses, then became less frequent. Extensive decomposition was noticed. The formation of CO, acetylene, methane, and CO_2 was followed by taking ir spectra during the reaction. After 300 pulses more than 70% of the monomer had been consumed. Mass spectra confirmed the predominance of CO, acetylene, and methane among the products. CO_2 and other products were also present. No polyvinylacetate was formed.

Vinyl Choride (50–500 Torr)

Irradiation of this monomer did not produce any plasma. Extensive decomposition into acetylene and hydrochloric acid occurred and as conversion increased a slight brown deposit began to form on the cell walls and windows. No polyvinylchloride was formed in these reactions. The decomposition of vinyl chloride also occurred with unfocused pulsed radiation of 10.611 μm and 9.603 μm from a tunable Lumonics 103 TEA-CO_2 laser. Again, no polymerization of the substrate occurred.

Discussion

From the experiments in the condensed phase it is obvious that, despite the fact that the radiation was strongly absorbed by the monomers, the concentration of free radicals generated by the pulse must have been minimal in all the systems studied, i.e., insufficient to induce a significant amount of chain initiation. It can be argued that either the energy absorbed is rapidly dissipated into the medium as heat or the interaction produces chemical changes of a non-radical nature, i.e., molecular decomposition processes giving volatile products. No important reaction forming aggregation products can be involved, since such products would have remained in the substrate and been detected.

The experiments in the gas phase indicate that decomposition of monomer molecules indeed occurs and without any appreciable polymerization. These fragmentation reactions seem to take place essentially through molecular elimination processes, the initial characteristic step being

$$CH_2{=}CHX \rightarrow CH{\equiv}CH + HX$$

Acrylonitrile and vinyl chloride follow this simple mechanism and only at high conversions other products, arising from the pyrolysis of acetylene, become important. Vinyl acetate probably produces acetic acid which in turn decomposes into methane, CO, and CO_2. The decomposition of methyl methacrylate is more complex, but the products again suggest the predominance of molecular splits.

It can be concluded that in the conditions selected for this work the energy from a high-power CO_2 laser is not effective in promoting polymerization. This has been attributed to a failure to produce radicals in sufficient concentration. Another explanation which might be considered is that radicals are formed after each pulse but the transient temperature attained *in the reaction zone* is higher than the ceiling temperature for the system and thus chain growth is thermodynamically precluded. If during thermal equilibration the radicals decay by other pro-

cesses, then the net result would be the absence of aggregation products.

Ethylene oligomerization seems to take place under high pressure (6). However, the very low yields of paraffins obtained (<0.1%) indicate that chain processes are not favoured. Although in that study (6) no search for other products was made, it is known that CO_2 laser radiation induces the decomposition of ethylene, to give mainly acetylene and hydrogen (7). Thus, in the experiments described by Chin (6) most of the energy absorbed is channelled into pathways which do not involve chain-propagation reactions with the substrate. It seems therefore inappropriate to consider the behaviour of that system as typical of a polymerization process.

Ligand effects upon the reactions of Ni(II) with sodium tetrahydroborate: Ni(I) complexes of bipyridyl and 1,10-phenanthroline

DAVID G. HOLAH, ALAN N. HUGHES, AND BENJAMIN C. HUI

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received May 18, 1977

DAVID G. HOLAH, ALAN N. HUGHES, and BENJAMIN C. HUI. Can. J. Chem. **55**, 4048 (1977).

The reactions between $NaBH_4$ and Ni(II) have been studied in the presence of a variety of ligands in an effort to determine (*a*) the conditions under which reduction occurs, (*b*) the extent of the reduction (e.g. to Ni(I), Ni(0) complexes, or to Ni metal or boride), and (*c*) whether intermediate Ni complexes can be isolated.

With ligands having no π-bonding capabilities (NH_3, ethylenediamine, edta, citrate), reduction depends upon the Ni:ligand ratio and, in the presence of an excess of the ligand, reduction of Ni(II) is very slow. When vacant coordination sites exist on the metal through dissociation of, for example, $Ni(NH_3)_6^{2+}$, allowing for the interaction of the BH_4 group with the metal, then rapid reduction to the metal (or boride) takes place.

With the π-bonding N-donor ligands 1,10-phenanthroline (phen) and 2,2′-bipyridyl (bipy) reduction of the stable ML_3^{2+} complexes probably occurs via an outer-sphere electron transfer mechanism but, in these cases, new species of the type NiL_2X (L = phen, bipy; X = BH_4, PF_6, BPh_4), which formally contain Ni(I), have been isolated.

DAVID G. HOLAH, ALAN N. HUGHES et BENJAMIN C. HUI. Can. J. Chem. **55**, 4048 (1977).

On a étudié la réaction entre $NaBH_4$ et Ni(II) en présence d'une variété de ligands afin de déterminer (*a*) les conditions permettant la réduction, (*b*) le niveau de la réduction (par exemple jusqu'à des complexes de Ni(I), Ni(0) ou vers le Ni métallique ou le borure) et (*c*) si l'on peut isoler des complexes intermédiaires de Ni.

Lorsque les ligands n'ont pas de capacité de liaisons π (NH_3, éthylènediamine, edta, citrate), la réduction dépend du rapport Ni:ligand et, en présence d'un excès de ligand, la réduction de Ni(II) est très lente. Quand des sites de coordination vacants existent sur le métal par l'intermédiaire d'une dissociation, par exemple de $Ni(NH_3)_6^{2+}$, permettant une interaction du groupe BH_4 avec le métal, il y a alors une réduction rapide conduisant au métal (ou borure).

Avec des ligands donneurs par l'azote et pouvant créer des liens π comme la phénanthroline-1,10 (phen) et bipyridyl-2,2′ (bipy) la réduction des complexes stables ML_3^{2+} se produit probablement par l'intermédiaire d'un mécanisme de transfert électronique au niveau de la sphère extérieure mais dans ces cas on peut isoler de nouvelles espèces du type NiL_2X (L = phen, bipy; X = BH_4, PF_6, BPh_4) qui contiennent d'une façon formelle du Ni(I).

[Traduit par le journal]

Introduction

It is known that the presence of certain ligands prevents the rapid reduction by $NaBH_4$ of metal salts to the metal or to the insoluble borides (1). Without doubt, reactions between $NaBH_4$ and transition metal complexes containing phosphines are best documented and, in the case of nickel, these proceed by two different routes.

$$NiCl_2L_2 + BH_4^- \rightarrow NiHClL_2 \rightarrow NiH(BH_4)L_2$$

or

$$NiCl_2, L, BH_4^- \rightarrow NiClL_3 \rightarrow Ni(BH_4)L_3 \rightarrow NiL_2$$

depending on the nature of the phosphine (1–4).

The extent to which other ligands such as N-, O-, C-, or S-donors are able to prevent the reduction of metal salts by $NaBH_4$ has not been well studied. In the case of N-donors, Ni(II) in liquid ammonia (5) or in the presence of an excess of concentrated ammonia (6, 7) is not reduced by $NaBH_4$, the product being $Ni(NH_3)_6(BH_4)_2$. The reaction of $NaBH_4$ with $Nien_3Cl_2$ (en = ethylene diamine) in concentrated ammonia produces $Nien_3(BH_4)_2$ (6), while $Nien_2Cl_2$ is rapidly reduced to the metal or boride (8). Also, $NaBH_4$ does not reduce a variety of Ni(II) – cyclic nitrogen base complexes (9) even at 60°C.

Other ligands allow the incomplete reduction of metal ions. Thus Co(I) (10, 11) and Rh(I) (10) complexes of 1,10-phenanthroline (phen) and 2,2′-bipyridyl (bipy) have been obtained from $NaBH_4$ reductions (Ni(II) has not been studied) and the presence of dimethylglyoxime ($DMGH_2$) stabilizes a Co(I)–DMGH complex from Co(III)–$NaBH_4$ reactions (12, 13). Of industrial importance is the reaction of $NaBH_4$ with Ni(II)

and Co(II) in the presence of CN^- to produce $Ni_2(CN)_6^{4-}$ and $HCo(CN)_5^{3-}$, which catalyze the $NaBH_4$ reduction of dyes (14). Both the Ni and Co systems have been extensively studied in the homogeneous hydrogenations of a variety of unsaturated substances (15). Also, $NaBH_4$ solutions are used in electroless metal plating, where amines are usually present in solution (16).

In view of the considerable industrial interest in the use of $NaBH_4$, the object of this work is to study the effects that influence the course of Ni(II)–ligand–$NaBH_4$ reactions. These include the nature and electronic properties of the ligand, the stereochemistry of the starting metal complex, the molar ratios of the reactants, the time of the reaction, and the nature of the solvent.

Results and Discussion

I. Reactions With Nickel Complexes Containing N-donor Ligands

We have investigated the reactions between $NaBH_4$ and Ni(II) salts in the presence of a range of NH_3 and en concentrations in air and under nitrogen and find that the ability of these ligands to stabilize Ni(II) depends on the Ni:ligand ratio in solution. For example, aqueous solutions of $Ni(NH_3)_6Cl_2$ are rapidly reduced to the metal (or boride) while from aqueous or more concentrated ammonia solutions, the known (5–7) $Ni(NH_3)_6(BH_4)_2$ can be isolated. Only traces of metal (or boride) are formed when aqueous $Nien_3Cl_2$ is treated with $NaBH_4$ (reflecting the greater stability of $Nien_3^{2+}$ over $Ni(NH_3)_6^{2+}$) and reduction is suppressed completely in 50% en solutions. However, $Nien_2Cl_2$ is rapidly reduced (8).

The complexes $Ni(NH_3)_6(BH_4)_2$ and $Nien_3(BH_4)_2$ both slowly decompose in air, but no intermediate reduced-Ni complex could be isolated.

Reduced-Ni Complexes

In air, reactions between Ni(II) and $NaBH_4$ in the presence of phen and bipy lead initially to the complexes $NiL_3(BH_4)_2$ (L = phen, bipy) although decomposition generally occurs on drying and only $Nibipy_3(BH_4)_2 \cdot 3H_2O$ was isolated in reasonable purity ($\nu_{BH_4^-}$ at 2200 cm^{-1}). As decomposition occurs, the solids turn to the deep purple color typical of reduced-Ni complexes (see later) but all attempts to extract such species into organic solvents accelerated decomposition. In air, the decomposition products are slowly reoxidized to the tris(ligand)Ni(II) ions.

Under N_2, however, aqueous solutions of $Niphen_3Cl_2$ react with an excess of $NaBH_4$ to precipitate the air sensitive $Niphen_2BH_4 \cdot H_2O$ (Table 1). Solutions of this complex also result from similar reactions in alcohol. When $Niphen_2BH_4 \cdot H_2O$ is stirred in ethanol with $NaPF_6$ or $NaBPh_4$, the complexes α-$Niphen_2PF_6$ and $Niphen_2BPh_4$ precipitate. The former complex is converted into a second form, β-$Niphen_2PF_6$, when recrystallized from acetone while the latter is unchanged on recrystallization (Table 1). Reactions between $NaBH_4$ and $NiCl_2$–phen mixtures (1:2 and 1:1) in water produce $Niphen_2BH_4 \cdot H_2O$ and a blue solid (possibly $NiphenBH_4 \cdot H_2O$?), respectively.

The Ni:ligand ratio is also important in similar reactions involving bipy. Thus, reductions by $NaBH_4$ of aqueous Ni–bipy mixtures where the ratio is 1:6 result in no reduction, where the ratio is 1:3 a mixture of Ni(I) and Ni(II) is obtained, while a ratio of 1:2 produces $Nibipy_2BH_4 \cdot 2H_2O$. In ethanol, the reduction of $Nibipy_3Cl_2$ by $NaBH_4$ produces a dark blue solution. The only solid that could be isolated from this reaction (unlike the corresponding phen reaction) is an unstable pyrophoric solid, tentatively identified as $NibipyPF_6$, obtained after the addition of $NaPF_6$. This proved so difficult to handle that no further work on it was carried out. However, similar reductions in the presence of an excess of bipy produce solutions (of $Nibipy_2BH_4$) from which $Nibipy_2PF_6$ and $Nibipy_2BPh_4$ can be isolated (Table 1). The former complex can be recrystallized unchanged from acetone while the BPh_4^- complex is much less stable in organic solvents and, in acetonitrile for example, readily disproportionates to $Nibipy_3(BPh_4)_2$ and metal. The extreme air sensitivity of these complexes renders good analytical data difficult to obtain, but the close agreement of analyses and the magnetic and spectroscopic data leave little doubt that the structure assignments are correct.

Attempts to Prepare NiL_3^+ (L = Phen, Bipy)

It has not been possible to synthesize complexes containing the NiL_3^+ ion and indeed there appear to be no reports in the literature of six-coordinated Ni(I) complexes. Reactions between $Niphen_3Cl_2$ and $NaBH_4$ in the presence of an excess of ligand result in the formation of $Niphen_2BH_4 \cdot H_2O$. Decomposition of the initially formed pink precipitate (presumably $Niphen_3(BH_4)_2$) formed from $NiCl_2$–phen–$NaBH_4$ reactions in alcohol in the presence of an excess of

†Ni: found 16.5%, calculated 16.3%.

phen produces, after ~4 h, $Niphen_2BH_4 \cdot H_2O$, which on longer stirring (3–4 days) reacts to form a purple solution. Addition of $NaPF_6$ or $NaBPh_4$ to this produces α-$Niphen_2PF_6$ and $Niphen_2BPh_4$, respectively. In the absence of free phen, $Niphen_3(BH_4)_2$ decomposes in alcohol to a pyrophoric purple solid tentatively identified as $NiphenBH_4 \cdot H_2O$. Recrystallization of α-$Niphen_2PF_6$ from acetone in the presence of an excess of phen produces only the β complex, which does not react with either pyridine or PPh_3. Reactions between $Niphen_2BH_4 \cdot H_2O$ and $NaBPh_4$ in ethanol in the presence of an excess of phen result in the slow production of $Niphen_3(BPh_4)_2$, probably formed by the oxidation of the Ni(I) compound by water (17).

Attempts to synthesize $Niphen_3^+$ as the perchlorate salt from $Niphen_3(ClO_4)_2$ and $NaBH_4$ in a similar manner to that used in making $Cophen_3(ClO_4)$ (11) were also unsuccessful. No reaction was observed after 8 h at −5°C in 10% ethanol–water and at room temperature impure $Niphen_2BH_4$ is produced. Also, reactions between $Niphen_3X_2$ (X = BPh_4, PF_6) in THF and $NaBH_4$ lead only to the (slightly impure) $Niphen_2X$ complexes.

Similarly, no evidence for $Nibipy_3^+$ has been observed even from reactions involving a 10-fold excess of bipy. Indeed, the fact that $Nibipy_2^+$ can only be produced in the presence of an excess of ligand suggests that dissociation of $Nibipy_3^+$ and even of $Nibipy_2^+$ is more extensive than in the case of phen.

Physical Data

In the absence of single crystal X-ray data, it has proved difficult to assign structures to these Ni(I) complexes and to account satisfactorily for their electronic properties. Spectroscopic, magnetic, and electrical conductivity measurements are recorded in Tables 2 and 3 and some spectra are also illustrated in Figs. 1 and 2. Room temperature magnetic moments (Table 2) are, in general, consistent with one unpaired electron, although the moments of the $Nibipy_2X$ (X = PF_6 and BPh_4) are somewhat high. These values are reproducible and there is no evidence for the presence of small amounts of either paramagnetic Ni borides or, less likely, Ni(II) impurities.

Regarding electronic spectra, the complexes appear to fall into three clear structural types. There is obviously a close resemblance between the structures of $Niphen_2BH_4 \cdot H_2O$ and α-$Niphen_2PF_6$, as shown from their reflectance spectra (Fig. 1, Table 2). These spectra show no similarities with those of either tetrahedral (4, 18) or square planar (19) Ni(I) complexes and are probably therefore due either to five-coordinated metal, to which the spectra have some similarities (20), or to extensively distorted 6-coordinated structures. In either case, the weakly interacting, BH_4^- or PF_6^- groups dissociate in dilute solutions producing the 1:1 electrolytes $[Niphen_2]^+$-BH_4^- and β-$[Niphen_2]^+PF_6^-$. The infrared spectrum of the solid BH_4^- complex shows the B—H deformation and stretching frequencies at 1080 cm^{-1}, and 2150 sh, 2230, and 2300 cm^{-1} respectively, not inconsistent with very weakly coordinated BH_4 groups (4, 2). (It is interesting to note in passing that $Cobipy_2(ClO_4)$ is thought (10) to contain coordinated perchlorate.)

The second group of complexes having similar electronic spectra include β-$Niphen_2PF_6$, $Niphen_2BPh_4$, $Nibipy_2X$ ($X = BH_4^-$, PF_6^-, BPh_4^-), and dilute solutions of $Niphen_2BH_4 \cdot H_2O$, although measurement of the reflectance spectra of the bipy complexes is complicated by exceptionally high background absorption in the visible and near ir regions (see Table 2 and some representative spectra in Fig. 2). These spectra are all characterized by a band or shoulder in the ~20 000 cm^{-1} region ($\varepsilon \sim 1500$), which compares very favorably with the spectra of other

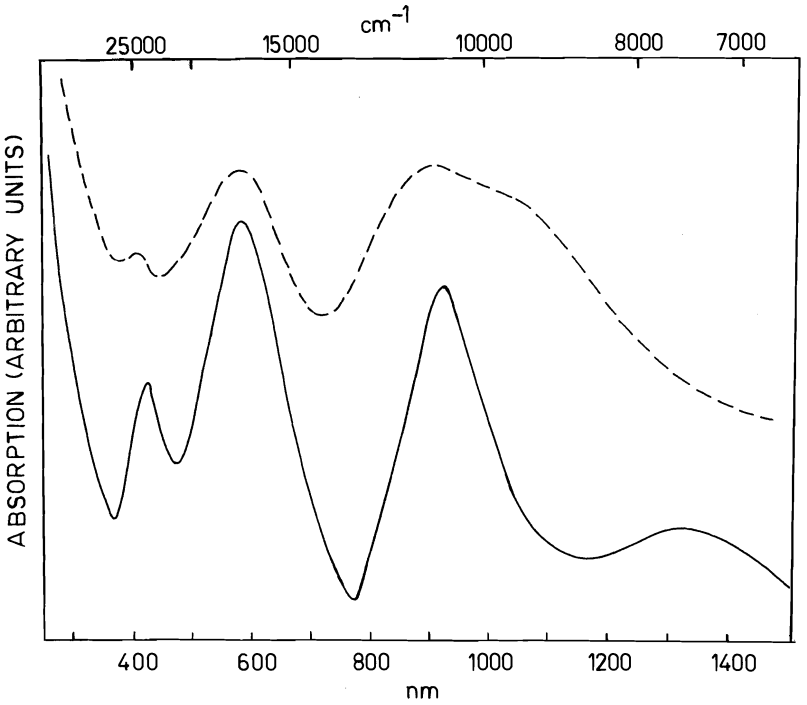

FIG. 1. Electronic spectra: — $Niphen_2BH_4 \cdot H_2O$ (reflectance); --- α-$Niphen_2PF_6$ (reflectance).

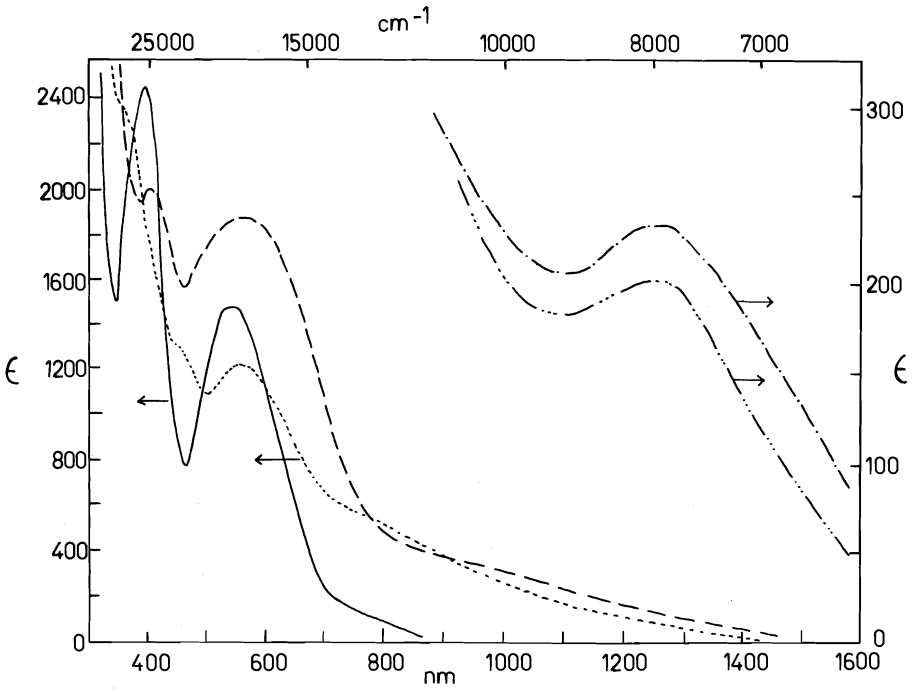

FIG. 2. Electronic spectra: — $Niphen_2BPh_4$, 1.78×10^{-3} *M* in acetone; – – – $Niphen_2BPh_4$, reflectance; --- $Niphen_2BH_4 \cdot H_2O$, 5.39×10^{-4} *M* in DMSO; ----- $Niphen_2BH_4 \cdot H_2O$, 8.88×10^{-3} *M* in DMSO saturated with $NaBH_4$; –·–·– $NiphenBH_4$, 4.91×10^{-3} *M* in DMSO.

square planar Ni(I) compounds (19) and with that of $Agbipy_2^{2+}$, which shows a band at $\sim 20\,000\ cm^{-1}$ ($\varepsilon \sim 1500$) (22). The absorption in the $25\,000\ cm^{-1}$ ($\varepsilon \sim 2500$) region in these complexes is probably due to an electron transfer band. A band similar to the weak low energy shoulder ($\sim 14\,000\ cm^{-1}$), which is particularly noticeable in the solution spectra of the $Niphen_2X$ ($X = PF_6^-$, BPh_4^-) complexes, has also been observed previously (20).

The reflectance spectrum of β-$Niphen_2PF_6$, after only one recrystallization, still shows the very weak remains of the $9800\ cm^{-1}$ band of the α compound, although this is totally absent in the solution spectrum. All the complexes in the group are 1:1 electrolytes in $\sim 10^{-3}$ *M* DMSO solutions (Table 3).

The remaining structural type is shown by $NiphenBH_4 \cdot H_2O$, which in DMSO solution shows (Table 2) a band at $7810\ cm^{-1}$ ($\varepsilon \sim 234$), although in more dilute DMSO solutions the compound dissociates to a 1:1 electrolyte. The above absorption spectrum is typical of a tetrahedral d^9 configuration (4, 18), and the ir spectrum of the solid is consistent with bidentate BH_4^- (21), having bands at 1970 (b), 2150, 2220, 2380, and $2480\ cm^{-1}$. It has already been mentioned that, in DMSO solution, $Niphen_2BH_4 \cdot H_2O$ changes to the square planar $[Niphen_2]^+$ species, but in the presence of an excess of $NaBH_4$, a further reaction occurs. This is probably the Ni(I) catalyzed decomposition of BH_4^- with the liberation of H_2 gas, and in the course of the reaction the solution develops a spectrum with a maximum at $7870\ cm^{-1}$ ($\varepsilon \sim 203$) very similar to that of $NiphenBH_4 \cdot H_2O$ (Table 2). The dissociation

$$Niphen_2BH_4 \rightleftharpoons NiphenBH_4 + phen$$

is probably involved. The analogous treatment of α-$Niphen_2PF_6$ with an excess of $NaPF_6$ in DMSO immediately produces $Niphen_3(PF_6)_2$.

Preliminary studies show that $Niphen_2BH_4 \cdot H_2O$ is an extremely active catalyst in the tetrahydroborate reductions of various functional groups. For example, $NaBH_4$, in the presence of a suspension of the above complex in methanol, reacts with acetonitrile and nitromethane (the latter reaction is extremely vigorous) to produce the corresponding amines, which were identified by mass spectrometry and by their odor. ($NaBH_4$ alone does not reduce either of these compounds.) The complex itself reacts with both compounds, although less extensively than with added $NaBH_4$.

Finally, attempts to use the above complex as a starting material to synthesize other Ni(I) complexes (of, for example, $DMGH_2$ and *N*,*N*-diethyldithiocarbamate (dtc)) resulted in oxidation to the corresponding Ni(II) derivatives.

Throughout this discussion the complexes have been presented in terms of Ni(I) species, with the unpaired electron localized on the metal. While we feel that this is the most reasonable arrangement, especially in view of results obtained from closely related Ni(II)–$NaBH_4$–phosphine reductions (23), the unpaired electron cannot be unambiguously located without epr results and even then some confusion exists in terms of the interpretation of the data (see, for example, ref. 24). The complexes could be formulated as Ni(II) species with one ligand present as a radical anion (it is difficult to explain why only one ligand would be reduced in reactions where such a large excess of $NaBH_4$ was used) or as Ni(III) species containing two one-electron reduced ligands. Such phenomena have been observed in electrochemically reduced Ni macrocyclic amine complexes (25, 26) where epr has proved useful (25) in establishing the location of the unpaired electrons.

II. Reactions with Ni Complexes Containing C, O, and S Donor Ligands

Reactions between $NaBH_4$ and Ni(II) in the presence of a variety of other ligands, such as edta, citrate (used in the preparation of high surface area heterogeneous catalysts of Co and Ni (27)), DMGH, dtc, and CN^- have been studied. In no case has any Ni(I) complex been isolated even from reactions where large cations, e.g. Ph_4P^+, had been added. Reduction of Ni(II) is prevented by edta and metal production is very slow in the presence of an excess of citrate. Reduction of $Ni(CN_4)^{2-}$ occurs, as has been observed previously (28), probably via the formation of an intermediate BH_4 complex, which would be facilitated by the lability and rapid exchange of CN groups in $Ni(CN)_4^{2-}$. On the other hand, the complexes $Nidtc_2$ and $Ni(DMGH)_2$ (non-labile ligands) are remarkably stable towards $NaBH_4$, even on heating, and metal production is very slow. These data are consistent with the results obtained from reactions between $NaBH_4$ and cationic Ni(II) complexes of cyclic tetramines and non-cyclic

tetradentate amines (9) and it seems that five-coordinated BH_4 complexes do not readily form under these conditions.

Conclusions

With the Ni(II) complexes of ligands with no π-bonding capabilities (edta, en, NH_3), the first step in the reduction appears to be the formation of a Ni–BH_4 link, which is facilitated by a vacant coordination site on the octahedral metal ion. This is related both to the stability constants for a given M–L system (edta > phen > bipy > en > NH_3 (29)) and to the lability and ease of dissociation of the ligands. When dissociation is prevented, reduction does not occur (or is dramatically slowed down), but with more dilute ligand concentrations, reduction to the metal or boride is rapid and complete.

Reductions by $NaBH_4$ of the very stable $Niphen_3^{2+}$ and $Nibipy_3^{2+}$ ions probably occur via an outer-sphere electron transfer mechanism, the π-bonding properties of the ligands enabling the Ni(I) species to be isolated.

With square planar Ni(II) complexes (DMGH, dtc) there appears to be a marked reluctance for BH_4 to interact in the axial positions. $Ni(CN)_4^{2-}$ is reduced, but in this case, the CN groups are extremely labile. It appears, however, that square planar cationic bidentate phosphine–Ni(II) species, unlike the cyclic amine complexes mentioned earlier, can interact with BH_4^- to produce Ni(I) complexes (23).

Experimental

Materials

All chemicals were reagent grade and were used without purification. Solvents were purified in the usual way, degassed, and stored over molecular sieves (4A).

$Ni(NH_3)_6Cl_2{\cdot}2H_2O$, $Nien_3Cl_2{\cdot}2H_2O$, $Nibipy_3Cl_2{\cdot}6H_2O$, $Niphen_3Cl_2{\cdot}7H_2O$, $Niphen_3(ClO_4)_2$, $Niphen_3(BPh_4)_2$, $Ni(DMGH)_2$, $Ni(dtc)_2$, $Na_2[Ni(edta)]$, and $K_2[Ni(CN_4)]$ are well known compounds and were prepared according to literature methods.

Physical Measurements

Physical measurements were carried out as previously described (4).

Syntheses

$NiL_3(BH_4)_2$ (L = Phen, Bipy)

The addition of aqueous solutions of $NaBH_4$ (10 *M* excess) to aqueous solutions of NiL_3Cl_2 caused the rapid precipitation of pink solids, which are probably $NiL_3(BH_4)_2$. Both solids decomposed and became dark purple when dried under a stream of dry N_2 or by pumping under reduced pressure. When dried over concentrated H_2SO_4, $Nibipy_3(BH_4)_2{\cdot}3H_2O$ was obtained but the phen complex again decomposed to a brown residue. This bipy complex turned to a pink paste and then to a purple solid under reduced pressure.

Aqueous suspensions of the above pink solids reacted further with $NaBH_4$ and produced green (bipy) or blue (phen) solutions with the liberation of H_2. Reactions left exposed to air continued to develop a surface pink layer, which disappeared on shaking, until all the BH_4^- was consumed when both solutions finally became pink. Heating speeded up this process and the Ni(II) starting materials were obtained from such solutions.

The following syntheses were carried out in a glove box under nitrogen.

$Niphen_2BH_4{\cdot}H_2O$

A solution of $NaBH_4$ (~0.5 g) in water (5 ml) was added to a stirred solution of $Niphen_3Cl_2{\cdot}7H_2O$ (1 g) dissolved in water (20 ml). The initially formed pink precipitate slowly turned first to green and then, after 2 h, to blue. The blue precipitate was filtered off, washed with water and, when almost dry, washed again with benzene and ether before being dried under high vacuum for ~5 h. The complex is insoluble in water, slightly soluble in ethanol, and soluble in DMSO. Solvents such as nitromethane and acetonitrile cause rapid decomposition (oxidation).

$Nibipy_2BH_4{\cdot}2H_2O$

A solution of $NaBH_4$ (0.65 g) in water (~10 ml) was added very slowly to a suspension of $Nibipy_2Cl_2$ (1.0 g) in water (~10 ml). A large volume of gas was evolved as the mixture became dark blue. The solution was stirred for ~15 min when the blue precipitate was filtered off, washed with water and, when almost dry, with ether, before high-vacuum drying.

$Niphen_2PF_6$

$Niphen_2BH_4{\cdot}H_2O$ was stirred with a 5 *M* excess of $NaPF_6$ in ethanol for 4 days to yield α-$Niphen_2PF_6$, which was filtered off, washed with ethanol, water–ethanol, ethanol, and finally ether, and then vacuum dried.

Alternatively, $NiCl_2{\cdot}6H_2O$ (0.67 g) and phen (3.16 g) were heated in ethanol (~40 ml). The mixture was cooled to room temperature and a suspension of $NaBH_4$ (0.53 g) in ethanol (~10 ml) was added dropwise. The mixture slowly turned green and after 2 days, became purple. After filtration, $NaPF_6$ (0.77 g) dissolved in ethanol (~10 ml) was added to the purple filtrate; the dark purple α-form precipitated immediately. Recrystallization from acetone–ethanol produced β-$Niphen_2PF_6$.

$Niphen_2BPh_4$, $Nibipy_2X$ (X = PF_6, BPh_4)

These complexes were prepared in a manner similar to that used for $Niphen_2PF_6$. A suspension of $NaBH_4$ in ethanol was added to a mixture of $NiCl_2{\cdot}6H_2O$ and the ligand (1:6). In the case of the bipy complexes, the anions were added after the mixture was stirred for ~24 h.

$NiphenBH_4{\cdot}H_2O$

$NiCl_2{\cdot}6H_2O$ (0.72 g) and phen (2.15 g) were heated together briefly in EtOH (~25 ml). After cooling the mixture, $NaBH_4$ (1.06 g) was added as an EtOH suspension. The mixture slowly turned purple on stirring overnight. A small amount of $NaBH_4$ (~0.2 g) was then added and the mixture was again stirred for ~30 min before the purple solid was separated, washed with EtOH, H_2O, EtOH, and ether.

$NibipyPF_6$

$Nibipy_3Cl_2{\cdot}6H_2O$ (0.71 g) was dissolved in EtOH

(~15 ml) and $NaBH_4$ (0.11 g) was added as an EtOH suspension. The solution became blue quickly. It was stirred for ~2 h before the solution was filtered. To the filtrate, $NaPF_6$ (0.71 g) in EtOH (~5 ml) was added, when a blue solid precipitated instantaneously. The product was filtered and washed with EtOH, H_2O, EtOH, and ether.

DANIEL COZAK et IAN S. BUTLER. Can. J. Chem. **55**, 4056 (1977).

L'effet écran dû à la circulation paramagnétique des électrons *d* non-liants du métal de transition a été calculé pour la rmn ^{13}C des complexes octaédriques hexacarbonylés $M(CO)_6$ du groupe VIB. On trouve que les seules contributions d'importance au déplacement chimique de ces complexes produit par le remplacement du métal sont à l'opposé du déplacement observé expérimentalement. Le déplacement chimique produit par le remplacement d'un ligand carbonyle est discuté en fonction de la structure électronique du métal et de la distance métal–carbonyle des complexes $M(CO)_5L$.

DANIEL COZAK and IAN S. BUTLER. Can. J. Chem. **55**, 4056 (1977).

The ^{13}C nmr shielding effect at the carbonyl ligands due to the paramagnetic current in the non-bonding *d* orbitals of the metal in the group VIB $M(CO)_6$ complexes has been evaluated. For these complexes, the only contribution of significant importance to the chemical shielding calculated for the carbonyl ligands is opposite to that observed experimentally. The carbonyl chemical shift produced by substitution of one of the carbonyl ligands is discussed in terms of electronic structure of the metal and the metal–carbonyl bond lengths in the $M(CO)_5L$ complexes.

Introduction

Depuis l'utilisation de la résonance magnétique nucléaire du carbone (rmn ^{13}C) pour caractériser les fragments organiques des complexes organométalliques, l'interaction électronique des métaux de transitions avec le ligand a été le plus souvent invoquée pour rendre compte des déplacements chimiques observés. Par exemple, Cooper *et al.* (1) dans leurs études spectroscopiques de la rmn ^{13}C des ligands oléfiniques et allyliques complexés au platine(II) et au paladium(II) ont attribué le déplacement chimique des carbones complexés au métal a l'effet écran produit par les électrons *d* des orbitales libres de celui-ci. C'est-à-dire à un blindage paramagnétique qui résulterait de la circulation des électrons non-liants sur le métal. Depuis, plusieurs autres chercheurs ont candidement fait allusions à cet effet pour rendre compte, du moins en partie, du déplacement chimique observé pour la rmn ^{13}C des groupes carbonyles des séries de complexes homologues tel que $M(CO)_6$ et $M(CO)_5L$ (M = Cr, Mo, W; L = ligand donneur de deux électrons) (2–4). Dans tous les cas, ces attributions ont été très contreversées et demeurent jusqu'à date incertaines (5–7).

Les complexes carbonylés des métaux de transition du groupe VIB $M(CO)_6$ et $M(CO)_5L$, en ce qui concerne leurs structures, sont comparables au cas hypothétique des hydrures octaédriques des métaux de transition ayant une configuration électronique d^6 et à partir duquel le déplacement chimique à champ fort de la rmn ^1H fut interprété de la théorie et avec brio par Buckingham et Stephens (8). Il est bien connu que le pouvoir acide des orbitales π^* des groupes carbonyles a pour effet d'augmenter le nombre d'oxydation du métal, modifiant ainsi en quelque sorte la configuration d^6 de celui-ci. Cependant, la rmn ^1H des complexes carbonylés étudiée à date ex. $(\eta^6\text{–}C_6H_6)CrH(CO)_2L$ (9), $(\eta^5\text{–}C_5H_5)WH(CO)_3$ (10) et $(\eta^5\text{–}C_5H_5)$-$MnH(CO)_2L$ (11) indique un déplacement chimique à champ fort du proton hydrure. Alors, il est raisonnable de croire que malgré

[1]Cette communication fut extraite de la thèse de doctorat présentée par D.C., Université McGill, Montréal (Qué.), Canada, 1977.

l'interaction d–π^* entre le métal et ses ligands, le courant paramagnétique des électrons d du métal pourrait aussi dominer le blindage des ligands liés au métal même dans les complexes carbonylés.

Nous avons effectué les calculs nécessaires pour évaluer cet effet pour la liaison M—C(O) dans les complexes de la forme $M(CO)_6$ de symétrie O_h et $M(CO)_5L$ de symétrie C_{4v} (M = Cr, W) en se basant sur la théorie exposée par Buckingham et Stephens (8, 12) et revue par Lipscomb (13). Nous présentons ici nos résultats ainsi que les conclusions qui en découlent pour le déplacement chimique de la rmn ^{13}C des ligands carbonylés dans les complexes en question.

Partie expérimentale

Les équations utilisées pour le blindage sont indentiques à celles données par Buckingham et Stephens (8) pour les nombres quantiques principaux $n = 3$ et $n = 5$ correspondant ici, respectivement, au cas du chrome et du tungstène. Les calculs ont été effectués sur un ordinateur IBM 360-75 et les graphiques de σ vs. k ont été tracés à l'aide d'un programme PLOTON pour des incréments de l'abscisse k égales à 0.2 unités à partir de $k = 0.4$. Dans nos calculs la valeur approximative de l'énergie moyenne des niveaux électroniques excités ΔE figurant dans l'équation du blindage a été choisie comme étant égale à la plus basse transition singulet d–d du métal pour $M(CO)_6$. La seule qui soit permise d'après les règles de sélection de symétrie O_h pour les opérateurs du moment angulaire du blindage est la transition $^1A_1(t_{2g}^6e_g^0) \rightarrow {}^1T_{2g}(t_{2g}^5e_g^1)$. Beach et Gray (14) dans leurs études spectroscopiques des complexes $Cr(CO)_6$ et $W(CO)_6$ ont attribué les bandes à 32 500 et 33 500 cm^{-1}, respectivement, à cette transition. La longueur du lien metal–carbonyle R utilisée comme valeur représentative est la longueur du lien M—C(O) rapportée pour l'état solide de $Cr(CO)_6$, 1.92 Å et de $W(CO)_6$, 2.06 Å (14, 15). La valeur de l'exposant k de la fonction d'onde atomique de Slater $r^{(n-1)} \exp(-kr)$ (16) calculée d'après les règles du même auteur est de 1.6 pour les orbitales $3d$ du chrome complexées (i.e. configuration d^6 à spin bas). De façon semblable, en prenant la valeur du rayon covalent du chrome ou la valeur estimée à partir de la longueur du lien Cr—C(O),[2] on trouve $k = 1.3$. Il faut cependant mentionner que les fonctions d'ondes atomiques de Slater représentent mieux la distribution électronique radiale lorsque k est supérieur à la valeur calculée par ses règles (18). Alors, dans la discussion qui suit k sera considéré comme étant supérieur à 1.6 pour les orbitales d du chrome et du tungstène.

Résultats

L'effet écran du courant paramagnétique métallique sur les ligands carbonyles a été

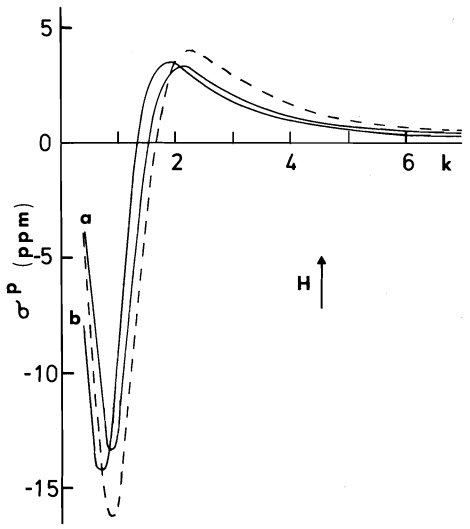

FIG. 1. Graphe de σ^p vs. k pour $\Delta E = 32\,000\ cm^{-1}$: (*a*) $W(CO)_6$, — $R = 2.06$ Å, --- $R = 1.92$ Å; (*b*) $Cr(CO)_6$, $R = 1.92$ Å.

évalué pour le cas plus général des complexes $M(CO)_6$ de symétrie O_h. Pour les complexes correspondants $M(CO)_5L$ de symétrie C_{4v}, l'expression mathématique du blindage demeure la même à l'exception des termes ΔE comme nous le verrons ici.

M(CO)₆

Les calculs effectués pour différentes valeurs de R indiquent que le blindage paramagnétique σ^p est très sensible aux variations de ce paramètre.[3] Comme le démontre les courbes de la fig. 1, une diminution de R égale à 0.14 Å entraine pour $W(CO)_6$ une augmentation de l'intercepte de la courbe avec l'abscisse k de 0.1 unité. Bien que les minima se trouvent à la même valeur de k, le fond du puits de la courbe se trouve déplacé de 3 ppm à champ faible et le maximum de la courbe ($R = 1.92$ Å) de 0.8 ppm à champ fort. Parallèlement, pour le complexe, on observe pour cette diminution de R une augmentation du blindage diamagnétique σ^d de 1.4 ppm ($k = 1.6$) (cf. fig. 2). L'ampleur de ses déplacements est liée au choix de la valeur de ΔE pour σ^p seulement. Par exemple, le minimum de la courbe σ^p de $W(CO)_6$ passe de -12.7 ppm à -13.9 ppm pour $\Delta E = 33\,000$ et $30\,000\ cm^{-1}$, respectivement. Les mêmes observations ont été notées pour $Cr(CO)_6$, mais les déplacements étaient plus petits.

[2]L'orbitale coordinante 5σ de CO peut être considérée comme étant un hybride *sp* du carbone (17).

[3]Dans cette ouvrage les termes σ^p et σ^d se rapportent qu'à l'effet écran étudié.

L'examen de la fig. 1 nous révele qu'un déplacement chimique significatif à champ faible des carbonyles de $W(CO)_6$ par rapport à ceux de $Cr(CO)_6$ est à prevoir pour les valeurs de k entre 1.6 et 2.0. Dans la fig. 2, malgré la du lien métal–carbonyle plus grande dans $W(CO)_6$, on constate que le blindage diamagnétique des carbonyles de ce dernier est plus important. Ainsi, par rapport à leur analogues du chrome les groupes carbonyles de $W(CO)_6$ se trouvent déblindés de ~ 4 ppm dû à σ^p et blindés de ~ 2 ppm dû à σ^d. Un déplacement chimique total $\sigma = \sigma^p + \sigma^d$ de l'ordre de 2 ppm à champ faible est à prévoir, pour une même valeur de k, entre le blindage des carbonyles de ces deux complexes. D'autre part, pour les valeurs de $k > 2$ un déplacement chimique total σ du même ordre de grandeur, à champ fort, est prévu à cause des contributions positives de σ^p et de σ^d (cf. figs 1 et 2).

$M(CO)_5L$

Pour les complexes monosubstitués $M(CO)_5L$ il est possible de prédire la direction et l'intensité de la contribution paramagnétique du métal σ^p sur les groupes carbonyles en considérant les valeurs calculées pour $M(CO)_6$. L'état électronique excité $^1T_{1g}(t_{2g}{}^5e_g{}^1)$ du métal pour la symétrie O_h se scinde en deux composantes pour la symétrie C_{4v} de $M(CO)_5L$, soit $^1E(b_2{}^2e_g{}^3a_1{}^1)$ et $^1A_2(b_2{}^1e_g{}^4b_1{}^1)$ comme indiqué dans la fig. 3. La transition électronique $^1A_1 \rightarrow {}^1E$ n'est compatible qu'avec la symétrie de l'opérateur du moment angulaire l_{xx} et l_{yy}, et la transition $^1A_1 \rightarrow {}^1A_2$ qu'avec celle de l_{zz}. Ainsi, les équations du

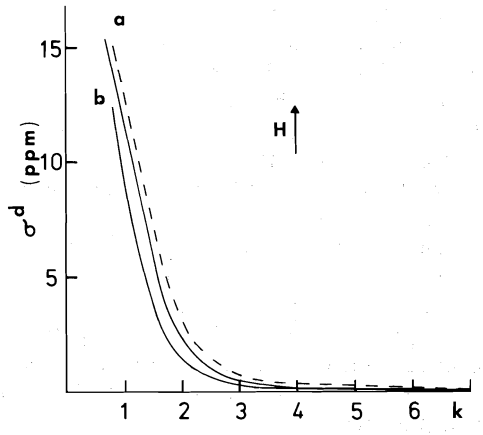

FIG. 2. Graphe de σ^d vs. k: (*a*) $W(CO)_6$, — R = 2.06 Å, --- R = 1.92 Å; (*b*) $Cr(CO)_6$, R = 1.92 Å.

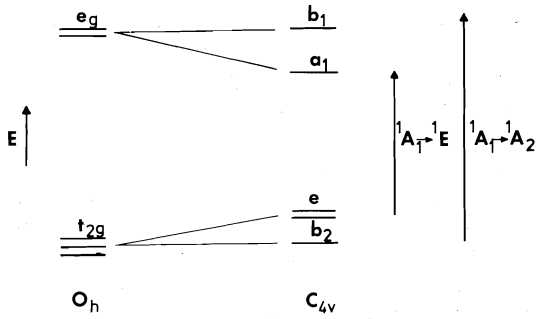

FIG. 3. Diagramme d'orbitales moléculaires pour les orbitales *d* dans un champ de symétrie O_h et C_{4v}.

blindage σ^p prennent la forme (8):

$$[1] \qquad \sigma_{xx}{}^p = \sigma_{yy}{}^p = \frac{A}{R^3\Delta E(E)}F(R)$$

$$[2] \qquad \sigma_{zz}{}^p = -\frac{4A}{R^3\Delta E(A_2)}G(R)$$

où A est une constante, $F(R)$ et $G(R)$ des fonctions de R, $\Delta E(E) = E(E) - E(^1A_1)$ et $\Delta E(A_2) = E(^1A_2) - E(^1A_1)$, respectivement. Pour les complexes octaédriques neutres $M(CO)_5L$, l'énergie $\Delta E(E)$ est de beaucoup inférieur à celle de la transition $\Delta E(A_2)$ (19). Donc, nous avons $|\sigma_{xx}{}^p + \sigma_{yy}{}^p|$ (pour $M(CO)_5L$) $> |\sigma_{xx}{}^p + \sigma_{yy}{}^p|$ (pour $M(CO)_6$) et $|\sigma_{zz}{}^p|$ (pour $M(CO)_5L$) $> |\sigma_{zz}{}^p|$ (pour $M(CO)_6$) pour $k >$ 1.6 étant donné que $\Delta E > \Delta E(A_2) > \Delta E(E)$. La figure 4 montre les courbes du blindage paramagnétique indépendant de l'énergie, soit $\sigma_{xx}{}^p\Delta E$ et $\sigma_{zz}{}^p\Delta E$ ainsi que $\sigma^p\Delta E = (\frac{2}{3}\sigma_{xx}{}^p + \frac{1}{3}\sigma_{zz}{}^p)\Delta E$ pour $W(CO)_6$. A l'aide de ces courbes et des eqs 1 et 2 un déplacement chimique à champ fort pour $\sigma_{xx}{}^p$ de $M(CO)_5L$ par rapport à $M(CO)_6$ est prévu étant donné son signe positif ($k > 1.6$) et un déplacement, moins important que celui de $\sigma_{xx}{}^p$, à champ faible pour $\sigma_{zz}{}^p$. Donc, une augmentation du blindage due à l'énergie est prévue pour les carbonyles des composés monosubstitués par rapport au composé hexacarbonylé correspondant.

Les variations de R, comme pour $M(CO)_6$, sont très importantes à la fois pour σ^d et σ^p. De façon générale les liaisons M—C(O) des dérivés monosubstitués $M(CO)_5L$ sont égales ou inférieures à celles du complexe parent et le lien du carbonyle-*trans* est le plus court, $R > R_{cis} > R_{trans}$ (15, 20). Donc, l'effet de R est sans équivoque d'accroître le blindage des carbonyles par le biais des blindages accrus de σ^p et

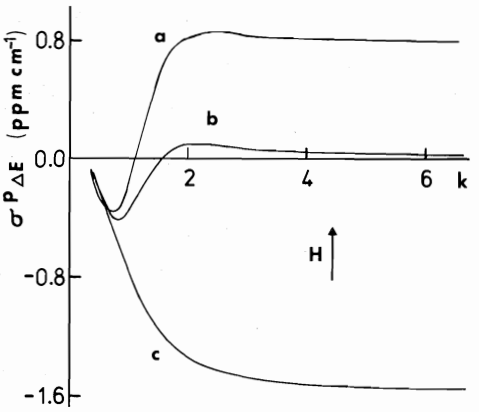

FIG. 4. Graphe du blindage paramagnétique indépendent de l'énergie pour $W(CO)_6$ (R = 2.06 Å) vs. k; (*a*) $\sigma_{xx}{}^p\Delta E$; (*b*) $\sigma^p\Delta E$; (*c*) $\sigma_{zz}{}^p\Delta E$.

σ^d pour $k > 2$. Etant donnée une différence très nette entre R_{cis} et R_{trans} le carbonyle-*trans* sera le plus affecté. Cependant, comme le démontre les courbes de la fig. 1, pour les valeurs de k inférieures au pointe d'intercepte des deux courbes de $W(CO)_6$ les carbonyles sont déblindés et l'ordre relatif des carbonyles-*cis* et -*trans* se trouve renversé.

Discussion

Le déplacement chimique de 20 ppm à champ fort observé (21) pour la rmn ^{13}C des carbonyles de $W(CO)_6$ par rapport à ceux de $Cr(CO)_6$ ne peut pas être expliqué que par l'effet considéré ici. Au maximum un déplacement de 2–5 ppm dans cette direction pourait être obtenu pour des valeurs appropriées de k, R et ΔE. Si nous considérons les valeurs de k comprisent entre 1.3 et 2.0, l'effet écran calculé prévoit un déblindage total de 2 ppm pour les ligands carbonyles. Bien que les valeurs de k inférieures à 2.0 peuvent être un choix discutable[4] pour les métaux de groupe VIB, il n'en demeure pas moins que la valeur de k = 1.3 calculée ici est une approximation du même ordre et tout aussi valable que les fonctions d'onde atomique de Slater qui ont servi au calcul du blindage chimique. Ce déplacement chimique ne demeure cependant pas sans explication. Selon Mann (6), il serait attribuable au nombre croissant de la charge nucléaire du métal du transition et aux orbitales d plus diffusent des métaux plus lourds, réduisant ainsi l'interaction liante d–π^* du métal avec les carbonyles. De même Mahnke *et al.* (22) ont calculé que le déplacement chimique de la rmn ^{13}C, observé lorsque la molécule diatomique CO est complexée à un atome métallique, était lier principalement à l'interaction d–π^* et par conséquent au terme ΔE du ligand. En plus vient s'ajouter le blindage diamagnétique du carbone qui est directement proportionnel au nombre atomique du métal (23). Notons que ces explications sont en accord avec le déplacement à champ fort observé lorsque CO est complexée à des métaux de transition du groupe IB (24).

Le déplacement chimique de la rmn ^{13}C à champ faible observé pour les complexes octaédriques monosubstitués $M(CO)_5L$ (21) des métaux du groupe VIB ainsi la position relatif des carbonyles-*cis* et -*trans* est l'opposé du déplacement prévu ici pour $k > 2.0$. Cependant, pour les valeurs de k entre 1.3 et 2.0 l'ordre relative *cis*/*trans* est consistant avec les résultats expérimentaux (i.e. le carbonyle-*trans* est à champ faible par rapport aux *cis*). Il est intéressant de noter que même si les complexes octaédriques neutres des métaux de transition des groupes VIIB et VIII ne sont pas encore connus. La résonance observée pour le carbonyle-*trans* des complexes $M(CO)_5X$ (M = Mn (25); M = Re (26)) et *cis*-$M(CO)_4X_2$ (M = Fe, Ru, Os (27)) où X = ligand donneur de 1 électron, se trouve à champ fort par rapport aux carbonyles-*cis*.

Le déplacement des carbonyles à champ fort prévu ici dans les complexes monosubstitués est dû principalement à la séquence des niveaux électroniques des orbitales d du métal tel qu'il est indiqué dans la fig. 3. Cette représentation des niveaux ènergitiques des orbitales d est celle généralement admise pour le fragment $M(CO)_5$ de symétrie C_{4v} (19, 28). Cotton *et al.* (29) pour expliquer l'énergie plutôt faible des transitions d–d observées des spectres uv des complexes $Cr(CO)_5$(amine), ont utilisé un diagramme où l'ordre des orbitales moléculaires a_1 et b_1 serait inverti par rapport à celui utilisé ici. Evans *et al.* (30) et dernièrement Fenske (31), ont démontré dans leurs études photoélectroniques des complexes $Mn(CO)_5X$ et $Re(CO)_5X$ que l'ordre des niveaux électroniques supérieurs remplis de symétrie e et b_2 varie selon le caractère acid/base du ligand X. Dans l'éventualité d'un tel renversement la valeur de $\Delta E(A_2)$ serait plus petite

[4]Voir la discussion traitant de ce sujet aux réfs 8 et 12.

que celle de $\Delta E(E)$ et un déblindage des carbonyles en résulterait par rapport au composé hexacarbonylé.

Isolation of intermediates in the rearrangement of 4-cyano-4,5-dihydroazepines to furo[2,3-*b*]pyridine derivatives

BRIAN GREGORY,[1] ERIC BULLOCK, AND TENG-SONG CHEN

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received June 24, 1977

BRIAN GREGORY, ERIC BULLOCK, and TENG-SONG CHEN. Can. J. Chem. **55**, 4061 (1977).

4-Cyano-4,5-dihydroazepines, when treated with an acidic ion-exchange resin in aqueous alcohol, undergo hydrolytic cleavage to a cyanooctanedionediester. The cyanooctanedionediester and its thermal cyclization product, a 4,7-dihydrofuro[2,3-*b*]pyridine, are shown to be intermediates in the rearrangement of cyanodihydroazepines to furo[2,3-*b*]pyridines by aqueous alcoholic silver nitrate. The mechanism of this rearrangement and the role of silver(I) are discussed. Ethyl 2-(2-cyanoethyl)acetoacetate cyclizes to a 1,2,3,4-tetrahydro-2-oxopyridine when refluxed with silver nitrate in aqueous ethanol.

BRIAN GREGORY, ERIC BULLOCK et TENG-SONG CHEN. Can. J. Chem. **55**, 4061 (1977).

Le traitement de cyano-4 dihydro-4,5 azépines par une résine échangeuse d'ions acide en milieu alcool aqueux provoque une hydrolyse conduisant à un cyanooctanedionediester. Cet ester et son produit de cyclisation thermique, une dihydro-4,7 furo[2,3-*b*] pyridine sont des intermédiaires dans le réarrangement des cyanodihydroazépines en furo[2,3-*b*] pyridine par le nitrate d'argent en solution alcoolique aqueuse. On discute du mécanisme de ce réarrangement et du rôle de l'argent(I). Le (cyano-2 éthyl)-2 acétoacétate d'éthyle se cyclise en tétrahydro-1,2,3,4 oxo-2 pyridine lorsqu'on le porte au reflux avec du nitrate d'argent dans l'éthanol aqueux.

[Traduit par le journal]

Earlier we have shown that the 4-cyano-4,5-dihydroazepine **3** gave a mixture of the furo[2,3-*b*]pyridine **8** and the pyrrolo[2,3-*b*]pyridine **9** when refluxed with silver nitrate in aqueous ethanol (1). It was suggested that the mechanism may involve acid-catalyzed hydrolytic ring-opening to give the acyclic vinylogous urethanes **11** and **13** and further hydrolysis to the octanedionediester **15**, followed by cyclization, dehydration, and oxidation to give **8** (1). The pyrrolopyridine **9** was thought to arise in a similar manner from **11** or **13**. In agreement with this hypothesis it was shown that aqueous nitrous acid gave only **8**, and that the characteristic ultraviolet absorption spectrum of **3** was rapidly lost in acidic media. Further indirect support was provided by Johnson and co-workers who showed that a dihydroazepine lacking the 4-cyano group was hydrolyzed to an octanedionediester (2) and that the reaction of an *N*-methyl-4-chloromethyldihydropyridine with potassium cyanide gave, after chromatography on silica gel, the furopyridine **4** and other products (3). We now report the isolation of intermediates and by-products which provide very strong evidence in support of the suggested mechanism, and suggest new potential synthetic applications of silver(I).

The lability of vinylogous urethanes to aqueous acid is well documented. Thus Robinson showed that ethyl 3-aminocrotonate is hydrolyzed in aqueous acid to ethyl acetoacetate and postulated that this involves protonation on the carbon atom situated β to the nitrogen (4). Similar protonation of Hantsch dihydropyridines (5) and esters of tetrahydronicotinic acid (6) has been suggested. Experimental support for β-protonation of vinylogous urethanes has been obtained using infrared (7), ultraviolet (6), and nuclear magnetic resonance spectroscopy (8). Protonation of **1** at C-3 or C-6 followed by attack of water on the resulting iminium salt would give the acyclic vinylogous urethanes **10** and **12**, which could either cyclize or be hydrolyzed further to the cyanooctanedionediester **14**. Early attempts to hydrolyze **1** to **14** using mineral acid gave very complex mixtures. Careful hydrolysis, using aqueous methanol in the presence of an acid-form ion exchange resin under an inert atmosphere, afforded a colorless oil, $C_{13}H_{17}NO_6$, which exhibited properties consistent with structure **14**. In particular, the posi-

tive ferric chloride test and the shift and intensification of its ultraviolet absorption band in basic media are consistent with the presence of a β-ketoester moiety. The infrared spectrum showed the presence of cyano, saturated ester, and saturated ketone groups and additional peaks at 3474 and 1657 cm^{-1} which were assigned to hydroxyl and chelated carbonyl of an enol form of **14**. The infrared spectrum showed many similarities with that reported for the closely related dimethyl 2,7-octanedione-3,6-dicarboxylate (2). The mass spectrum showed fragments typical of a β-ketoester (9) and was entirely consistent with the structure **14**. In addition to compound **14**, traces of the furopyridine **4** and the pyrrolopyridine **5** were also isolated, and were identical with the products formed when the cyanodihydroazepine **1** was refluxed with aqueous methanolic silver nitrate. The furopyridine **4** was also formed by exposure of solutions of the cyanooctanedionediester **14** to air in the presence of a trace of acid, or to aqueous methanolic silver nitrate. It is therefore clear that in acidic media the furopyridine **4** is formed via **14**. When aqueous methanolic silver nitrate was used, silver(I) cation functioned as a dehydrogenating agent in the penultimate step (see below). This resulted in the drop in p*H* which was observed during the course of the reaction. It is not clear whether the ring opening occurs entirely by acid catalysis or whether silver cation can itself catalyze hydrolysis.

Attempts have been made to decide whether the cyclization of dimethyl 4-cyano-2,7-octanedione-3,6-dicarboxylate **14** involves nucleophilic attack by the nitrile nitrogen on a ketone carbonyl or by enolic hydroxyl on the nitrile carbon, and how silver(I) is involved. Attack by the nitrile group on the 2- or 7-ketone groups would give, after loss of water, the nitrilium ions **16** or **17**. Although cyclization to give **16** would appear to be precluded by the failure to find pyrrole or pyrrolopyran derivatives in the reaction product, the involvement of **17**, which could cyclize to give a dihydrofuropyridine, is supported by the nature of the final product and by the isolation, from a related system **2**, of a 1,2,3,4-tetrahydro-2-oxopyridine (see below). Further, the cyclization of δ-ketonitriles in acid media to give 1,2,3,4-tetrahydro-2-oxopyridines is well known (10–12) and has been postulated to proceed via nitrilium ions (10). In particular, ethyl 2-(2-cyanoethyl)acetoacetate is known to give ethyl 6-methyl-1,2,3,4-tetrahydro-2-oxopyridine-5-carboxylate (13) in the presence of hydrochloric acid, and we have shown that this cyclization can also be accomplished using silver nitrate in refluxing ethanol.

Cyclization by attack of enolic hydroxyl at C-7, on the 4-cyano group to give the iminopyran **19**, or a tautomer, is not considered to be involved in view of the absence of pyrrolopyran[2] derivatives in the reaction product. However, similar attack by the enolic hydroxyl at C-2 would give, after tautomerism, the 2-aminofuran **20**.[3] The coordination of silver(I) with the nitrogen of the nitrile[4] should render the nitrile carbon more susceptible to nucleophilic attack,[5] e.g. by the enolic hydroxyl, thus facilitating the formation of **20**. However, compound **14**,

[2]In the Knoevenagel reaction of malononitrile with cyclic β-ketoesters, iminopyran derivatives have been considered to be intermediates in the formation of alkoxypyridinols (14).

[3]Temnikova and co-workers (15) have observed the formation of 2-aminofurans from γ-ketonitriles in basic media.

[4]The formation of complexes between silver(I) and nitriles, e.g. $2AgNO_3 \cdot C_2H_4(CN)_2$, is well known (16–19).

[5]During the hydration of the nitrile function of 2-cyano-1,10-phenanthroline, transition metal ions are believed to function as general acid catalysts (20). Homogeneous hydration of nitriles may be catalyzed by transition metal derivatives and is believed to involve attack of hydroxide ion on the carbon of a coordinated nitrile (21).

when heated alone at 160°C, slowly solidified to give a product $C_{13}H_{15}NO_5$ whose spectroscopic properties were in accord with the 4,7-dihydrofuropyridine structure **21** and which was easily oxidized by air, silver nitrate, or nitrous acid to the furopyridine **4**. Thus the cyclization of **14** can be accomplished in the absence of protons or silver(I). This is in contrast to ethyl 2-(2-cyanoethyl)acetoacetate which was recovered unchanged after prolonged heating at 160°C and from refluxing aqueous ethanol. In this latter case, silver(I) or proton catalysis would appear to be essential. This difference in behaviour may indicate that the formation of **21** from **14** proceeds by attack of the enolic hydroxyl group on the cyano carbon to give the 2-aminofuran **20** which then cyclizes to give **21**.

The action of silver nitrate in refluxing aqueous methanol on the 4-cyanodihydroazepine **2**[6] resulted in the formation of the expected furopyridine **6** and pyrrolopyridine **7** and, in addition, a third product, $C_{14}H_{19}NO_6$. The structure of this latter compound follows from its spectroscopic properties. Thus the presence of a methyl acetoacetate moiety was suggested by the presence of saturated ester and ketone carbonyl absorptions in the infrared spectrum, the presence of singlets at δ 2.28 (methyl of acetyl) and 3.78 (methyl ester) in the nmr spectrum, and the loss of methyl acetoacetate by McLafferty rearrangement in the mass spectrum (base peak at *m/e* 181). The ultraviolet spectrum (cf. ref. 22) was reminiscent of unsaturated γ- or δ-lactam ester chromophores. As a result of these observations structures **22** and **23** were considered. The latter structure was, however, eliminated by the absence of a band in the infrared spectrum at 1724–1730 cm^{-1} (cf. ref. 22) and, more significantly, by the nmr spectrum which showed a double doublet at δ 3.57. The structure was confirmed when **22** gave the furopyridine **6** when treated with concentrated sulfuric acid. The formation of the 2-oxo-1,2,3,4-tetrahydropyridine **22** from **2** may be the result of nucleophilic attack by water, rather than enolic hydroxyl, on some intermediate such as **18**, although silver(I) catalyzed hydration of the nitrile and cyclization (cf. refs. 11, 12) of the resulting amide cannot be excluded.

The foregoing results establish that the rearrangement of the cyanodihydroazepine **1** to the furopyridine **4** involves the intermediates **14** and **21**. Although the cyclization of **14** to **21** would appear to be initiated by nucleophilic attack of enolic hydroxyl on the cyano carbon, the present work does not eliminate completely the participation of nitrilium ion **17**. The possibility that coordination of a nitrile nitrogen with silver(I) renders the nitrile carbon more susceptible to nucleophilic attack under conditions near neutral p*H* has many synthetic implications, some of which are under investigation and will be reported in a subsequent communication.

Experimental

All details concerning spectral measurements, analyses, etc. are provided in an earlier publication (23). Ethyl 2-(2-cyanoethyl)acetoacetate was prepared by the method

[6]The preparation of this compound will be described in a forthcoming publication.

of Albertson (24) and has bp 123–125°C/1 Torr (lit. (24) 121°C/2 Torr).

The Reaction of Dimethyl 4-Cyano-4,5-dihydro-2,7-dimethylazepine-3,6-dicarboxylate ***1*** *with Silver Nitrate*

A solution of the cyano compound **1** (2.0 g) and silver nitrate (1.4 g) in methanol (30 ml) and water (2 ml) was heated under reflux for 2 days. The deposited silver was filtered off and the filtrate evaporated *in vacuo*. The residue was dissolved in chloroform and chromatographed on basic alumina using benzene and ethyl acetate as eluent. The first fraction yielded, after removal of solvent, dimethyl 2,6-dimethylfuro[2,3-*b*]pyridine-3,5-dicarboxylate **4** as white needles (1.32 g, 66%), mp 122–123°C (lit. (3) 122.5–124°C); ms *m/e*: 263(100, M^+), 232(96), 231(70), 203(46). The product had ir, uv, and nmr spectra which were identical with those of an authentic specimen prepared by the method of Childs and Johnson (3).

The second fraction yielded dimethyl 2,6-dimethylpyrrolo[2,3-*b*]pyridine-3,5-dicarboxylate **5** as fine white crystals (0.22 g, 11%), mp 250–251°C; ir ν_{max}: 3426 (NH str.), 1709 cm^{-1} (aryl ester); uv λ_{max}: 235.5 nm (ε 35 400), 255 nm (infl. ε 16 500), 298 nm (ε 8250); ^{1}Hmr (DMSO-d_6) δ: 2.67 and 2.75 (each s, methyls at C-2, -6), 3.84 and 3.88 (each s, methyl esters), 8.70 (s, H at C-4); ms *m/e*: 262 (99.5, M^+), 231(100), 230(43), 202(43), 171(49). *Anal.* calcd. for $C_{13}H_{14}N_2O_4$: C 59.54, H 5.38, N 10.68; found: C 59.49, H 5.38, N 10.51.

The Acid-catalyzed Hydrolysis of the 4-Cyano-4,5-dihydroazepine, ***1***

A mixture of the cyano compound **1** (2.0 g) and Dowex 50W-X8 (15 g) in methanol (60 ml) and water (10 ml) was stirred at 45°C for 4 h under a nitrogen atmosphere. After cooling, the resin was filtered off and the solvent removed under reduced pressure. The residue was transferred to a sublimation apparatus and distilled at 135–140°C (oil bath temperature) under 0.02–0.03 Torr to give dimethyl 4-cyano-2,7-octanedione-3,6-dicarboxylate **14** as a colorless viscous oil (1.74 g, 81%); ir ν_{max}: 3474 (enol OH), 2252 (C≡N str.), 1752 (saturated ester), 1729 (saturated ketone), 1657 (chelated carbonyl of enol form); uv (95% ethanol) λ_{max}: 218 nm (ε 1350), 260 nm (ε 1700); (0.01 *M* sodium hydroxide in 95% ethanol) λ_{max}: 275 nm (ε 27 000); ms *m/e*: 283 (1.5, M^+) 263(3), 241(3), 210(9), 168(7), 167(5), 155(22), 129(20), 117(15), 116(12), 112(5), 98(5), 97(20), 87(28), 85(5), 59(5), 55(16), 43(100). *Anal.* calcd. for $C_{13}H_{17}NO_6$: C 55.12, H 6.05, N 4.95; found: C 55.13, H 6.14, N 5.13.

Compound **14** was quantitatively converted to dimethyl 2,6-dimethylfuro[2,3-*b*]pyridine-3,5-dicarboxylate **4**, mp 122–123°C, when refluxed with silver nitrate in aqueous methanol.

Dimethyl 4,7-Dihydro-2,6-dimethylfuro[2,3-b]pyridine-3,5-dicarboxylate, ***21***

Dimethyl 4-cyano-2,7-octanedione-3,6-dicarboxylate **14** (1 g) was sealed under vacuum in a tube and heated at 160°C for 24 h. The oil gradually solidified to give a pale yellow product which was rapidly recrystallized twice from chloroform–ether – petroleum ether to give dimethyl 4,7-dihydro-2,6-dimethylfuro[2,3-*b*]pyridine-3,5-dicarboxylate **21** as pale yellow crystals (0.54 g, 58%); ir ν_{max}(KBr): 3297 (NH), 1720 (aryl ester), 1686 (unsaturated ester), 1654 cm^{-1} (C=C); uv λ_{max}: 223 nm (ε 9400), 347 nm (ε 8550); ^{1}Hmr (DMSO-d_6) δ: 2.20 (d, $J_{homoallyl}$ 0.5 Hz, CH_3 at C-6), 2.47 (s, CH_3 at C-2), 3.60 (q, $J_{homoallyl}$ 0.5 Hz, protons at C-4), 3.65, 3.78 (s, s, methyl esters), 9.48 (s, NH); ms *m/e*: 265 (50, M^+), 264(35), 250(100), 234(24), 232(33), 206(19), 204(35), 190(20). *Anal.* calcd. for $C_{13}H_{15}NO_5$: C 58.84, H 5.70, N 5.28; found: C 58.86, H 5.49, N 5.05.

Compound **21** was quantitatively oxidized to the furopyridine **4** by the action of silver nitrate in boiling aqueous methanol.

The Reaction of Dimethyl 4-Cyano-4,5-dihydro-2,5,7-trimethylazepine-3,6-dicarboxylate, ***2*** *with Silver Nitrate*

A solution of the cyano compound **2** (2.0 g) and silver nitrate (1.4 g) in methanol (30 ml) and water (2 ml) was heated under reflux for 2 days. The deposited silver was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in benzene and chromatographed on silica gel H using benzene – ethyl acetate as eluent. The first fraction yielded, after evaporation and recrystallization from aqueous dioxane, dimethyl 2,4,6-trimethylfuro[2,3-*b*]pyridine-3,5-dicarboxylate **6** as colorless prisms (0.39 g, 19.5%), mp 98–98.5°C; ir ν_{max}: 1727 (aryl ester); uv λ_{max}: 218 nm (ε 23 800) 251 nm (ε 9150), 260.5 nm (infl. ε 8000), 287 nm (ε 8500); ^{1}Hmr δ: 2.55, 2.64, and 2.71 (s, s, s, CH_3's at C-2, C-5, and C-6), 3.91 and 3.97 (s, s, methyl esters); ms *m/e*: 277(100, M^+), 246(84), 245(63), and 217(44). *Anal.* calcd. for $C_{14}H_{15}NO_5$: C 60.64, H 5.45, N 5.05; found: C 60.52, H 5.58, N 4.89.

The second fraction was recrystallized four times from benzene to give white prisms of methyl 3-(1-methoxycarbonyl-2-oxopropyl)-4,6-dimethyl-2-oxo-1,2,3,4-tetrahydropyridine-5-carboxylate **22** (0.37 g, 17%), mp 151–153°C; ir ν_{max}: 3395 (NH, free), 3218 (NH, bonded), 1753 (saturated ester), 1714 (ketone), 1701 (unsaturated ester), 1641 (lactam); uv λ_{max}: 214 nm (ε 3200), 279.5 (ε 11 500); ^{1}Hmr δ: 0.94 (d, *J* 7.0 Hz, CH_3 at C-4), 2.28 (s, acetyl), 2.45 (s, CH_3 at C-6), 3.09 (m, *J* 7.0 and 5.5 Hz, H at C-4) 3.57 (d d, *J* 11.4 and 5.5 Hz, H at C-3), 3.78 and 3.81 (s, s, methyl esters), 4.01 (d, *J* 11.4 Hz, H at C-1 of side chain), 8.63 (s, NH); ms *m/e*: 297 (14, M^+), 182(34), 181(100), 180(39), 142(56), 110(46), and 43(58). *Anal.* calcd. for $C_{14}H_{19}NO_6$: C 56.56, H 6.44, N 4.71; found: C 56.44, H 6.47, N 4.52.

The third fraction was recrystallized from ether – petroleum ether and yielded white prisms of dimethyl 2,4,6-trimethylpyrrolo[2,3-*b*]pyridine-3,5-dicarboxylate **7** (0.82 g, 41%), mp 157.5–159°C; ir ν_{max}: 3435 (NH, free), 3205 (NH, bonded), 1727 (aryl ester at C-3), 1709 (aryl ester at C-5); uv λ_{max}: 228 nm (ε 24 900), 250 nm (infl. ε 15 500), 294 nm (ε 11 000); ^{1}Hmr δ: 2.58, 2.65, and 2.68 (s, s, s, CH_3's at C-2, C-4, and C-6), 3.89 and 3.97 (s, s, methyl esters), 12.05 (s, NH); ms: *m/e*: 276 (100, M^+), 245(83), 244(35), 216(48), and 107(20). *Anal.* calcd. for $C_{14}H_{16}N_2O_4$: C 60.86, H 5.84, N 10.14; found: C 60.73, H 5.99, N 10.10.

The Reaction of Methyl 3-(1-Methoxycarbonyl-2-oxopropyl)-4,6-dimethyl-2-oxo-1,2,3,4-tetrahydropyridine-5-carboxylate, ***22****, with Sulfuric Acid*

Compound **22** (20 mg) in concentrated sulfuric acid (1 ml) was stirred at room temperature for 3 h and then

poured into ice water (30 ml). The acidic solution was neutralized with dilute sodium hydroxide and extracted with ether (3 × 20 ml). The ether extract was washed with water and dried over $MgSO_4$. After evaporation of the solvent, the residue was recrystallized from aqueous methanol to give prisms (6 mg, 32%), mp 95–96°C. This substance had uv and ms which were identical with those of authentic **6** and its mp was undepressed on admixture with **6**.

Reactions of Ethyl 2-(2-Cyanoethyl)acetoacetate

(*a*) Freshly distilled ethyl 2-(2-cyanoethyl)acetoacetate (0.454 g) was heated at 160°C in a sealed, evacuated tube for 12 h. Although the oil acquired a slight yellow color, it was found to be homogeneous by tlc and identical with starting material by ir, ms, and nmr and contained no ethyl 6-methyl-2-oxo-1,2,3,4-tetrahydropyridine-5-carboxylate.

(*b*) Freshly distilled ethyl 2-(2-cyanoethyl)acetoacetate (0.343 g) and silver nitrate (1.119 g) in ethanol (8 ml) and water (4 ml) were refluxed for 32 h. The solution was then filtered and concentrated to remove most of the ethanol. The aqueous mother liquors were extracted using chloroform (3 × 10 ml) and the chloroform extract washed with water (5 ml), dried with $MgSO_4$, filtered, and evaporated. The colorless slightly oily solid (330 mg) was recrystallized from ethanol to give ethyl 6-methyl-2-oxo-1,2,3,4-tetrahydropyridine-5-carboxylate (290 mg, 85%), mp 156–157°C (lit. (13) mp 154–156°C), which had ir, ms, and ^{1}Hmr spectra identical with those of an authentic sample.

When ethyl 2-(2-cyanoethyl)acetoacetate was refluxed in aqueous ethanol under the above conditions but lacking silver nitrate, no ethyl 6-methyl-2-oxo-1,2,3,4-tetrahydropyridine-5-carboxylate was detected using tlc or nmr after 37 h.

The synthesis of methyl 2-*O*-benzoyl-3,4-*O*-(*S*)- and methyl 2-*O*-benzoyl-3,4-*O*-(*R*)-benzylidene- β-L-ribopyranoside

DAVID M. CLODE

Department of Chemistry, University of Cape Coast, Cape Coast, Ghana

Received June 16, 1977

DAVID M. CLODE. Can. J. Chem. **55**, 4066 (1977).

Benzylidenation of methyl β-L-arabinopyranoside, by the method of Oldham and Honeyman, followed by benzoylation, gave methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-L-arabinopyranoside (**1**). Selective acid hydrolysis of a 1:1 mixture of the diastereomeric forms of methyl 2-*O*-benzoyl-3,4-*O*-benzylidene-β-L-arabinopyranoside gave the (*R*)-isomer (**3**). Debenzoylation of **1** and **3** gave methyl 3,4-*O*-(*S*)-and methyl 3,4-*O*-(*R*)-benzylidene-β-L-arabinopyranoside (**2** and **4**) respectively. Oxidation of **2**, followed by reduction and benzoylation, gave methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-L-ribopyranoside (**7**). A similar reaction sequence with **4** gave methyl 2-*O*-benzoyl-3,4-*O*-(*R*)-benzylidene-β-L-ribopyranoside (**8**).

DAVID M. CLODE. Can. J. Chem. **55**, 4066 (1977).

La benzylidénation du β-L-arabinopyrannoside de méthyle par le méthode de Oldham et Honeyman, suivie par une benzoylation, conduit au *O*-benzoyl-2 *O*-(*S*)-benzylidène-3,4 β-L-arabinopyrannoside de méthyle (**1**). Une hydrolyse acide sélective de mélange 1:1 des formes diastéréoisomères du *O*-benzoyl-2 *O*-benzylidène-3,4 β-L-arabinopyrannoside de méthyle fournit l'isomère (*R*) (**3**). Les débenzoylations de **1** et de **3** conduisent respectivement aux *O*-(*S*)-benzylidène-3,4 et au *O*-(*R*)-benzylidène-3,4 β-L-arabinopyrannoside de méthyle (**2** et **4**). L'oxydation de **2** suivit par une réduction et une benzoylation fournit le *O*-benzoyl-2 *O*-(*S*)-benzylidène-3,4 β-L-ribopyrannoside de méthyle (**7**). Une séquence similaire de réaction avec **4** fournit le *O*-benzoyl-2 *O*-(*R*)-benzylidène-3,4 β-L-ribopyrannoside de méthyle (**8**).

[Traduit par le journal]

Introduction

In order to study the condensation of methyl β-D-ribopyranoside with benzaldehyde (following paper) it was considered necessary to prepare an *O*-benzylidene-ribopyranoside of known structural configuration. A suitable starting material for such a derivative is methyl 3,4-*O*-benzylidene-β-D-arabinopyranoside which by inversion of the configuration at C-2 would give methyl 3,4-*O*-benzylidene-β-D-ribopyranoside.

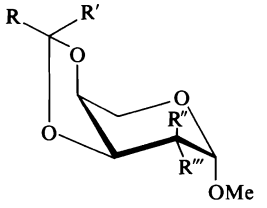
Using the Gerhardt (3) method of benzylidenation Oldham and Honeyman (1) isolated the two diastereomers of methyl 3,4-*O*-benzylidene-β-L-arabinopyranoside as their benzoates. They found that an old sample of methyl 3,4-*O*-benzylidene-β-L-arabinopyranoside, which had been freed from methyl β-L-arabinopyranoside, gave an acid stable (hot 0.05 *N* hydrochloric acid in aqueous acetone) benzoate, mp 126–127°C. This was probably a pure diastereomer. They also found that benzoylation of a freshly prepared sample of the acetal gave a mixture of benzoates having mp 100–102°C. The predominant isomer was acid labile (0.05 *N* hydrochloric acid) and fractionation of this mixture gave what was probably a second pure diastereomer, mp 120–122°C. No other physical measurements were made.

Baggett *et al.* (2) benzylidenated methyl β-L-arabinopyranoside, using Oldham and Honeyman's method (1), and the crude product showed benzyl proton signals at δ 5.70 and 5.44 with integrated areas in the ratio ca. 1:2.5. Benzoylation of this mixture gave a product, with benzyl proton signals at δ 5.82 and 5.47, from which was separated a benzoate, mp 119–120°C, with a single benzyl proton signal at δ 5.49. This benzoate was assigned the structure methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-L-arabinopyranoside(**1**).

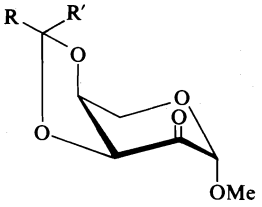
Results and Discussion

Benzylidenation of methyl β-L-arabinopyranoside, using Oldham and Honeyman's method (1), and benzoylation of the product, gave **1**. Debenzoylation of **1** gave methyl 3,4-*O*-(*S*)-benzylidene-β-L-arabinopyranoside (**2**). In subsequent reactions it was possible to crystallize out the (*S*)-isomer **2** directly from the initial product of the benzylidenation. Benzoylation of the mother liquors from this fractional crystallization gave a crystalline product **A** whose nmr spectrum showed two benzyl protons of equal

integrated area. This benzoate **A** was evidently an equimolar mixture of diastereomers. From the work of Oldham and Honeyman (1) it is apparent that the (*S*)-benzoate isomer **1** (mp 120–122°C) is acid labile, compared with the (*R*)-benzoate isomer **3** (mp 126–127°C). Thus **A** was treated with acid and the hydrolysis of the (*S*)-isomer was followed by nmr spectroscopy.



1 R = H, R′ = Ph, R″ = H, R‴ = OBz
2 R = H, R′ = Ph, R″ = H, R‴ = OH
3 R = Ph, R′ = H, R″ = H, R‴ = OBz
4 R = Ph, R′ = H, R″ = H, R‴ = OH
5 R = H, R′ = Ph, R″ = H, R‴ = OCH_2SCH_3
6 R = Ph, R′ = H, R″ = H, R‴ = OCH_2SCH_3
7 R = H, R′ = Ph, R″ = OBz, R‴ = H
8 R = Ph, R′ = H, R″ = OBz, R‴ = H



9 R = H, R′ = Ph
10 R = Ph, R′ = H

Initially the behaviour of the isomers, with acid, under essentially anhydrous (i.e., non-hydrolysing) conditions, was examined. The benzoate **A** was dissolved in chloroform-*d* containing *p*-toluenesulphonic acid (4%) and the signals in the benzyl region of the nmr spectrum were examined at intervals. After 24 h there was no change observed in the initial spectrum indicating that the 1:1 mixture of isomers was an essentially equilibrium mixture,[1] a result which agreed with the findings of Baggett *et al.* (2). This is in contrast to recent work by Buchanan and Edgar (4), on the acid-catalyzed ethylidenation of some methyl pentopyranosides, where they show that there is a strong preference for the isomer in which the methyl group has the *endo* configuration. A drop of water was then added and the high-field benzyl proton signal, corresponding to the (*S*)-isomer, slowly decreased in size. After 21 h and the addition of more acid this signal could no longer be detected. The reaction mixture was then processed in the normal way and methyl 2-*O*-benzoyl-3,4-*O*-(*R*)-benzylidene-β-L-arabinopyranoside (**3**) was isolated. In subsequent large scale reactions dioxan was used as the solvent and 5 *N* hydrochloric acid was added dropwise. Debenzoylation of **3** gave methyl 3,4-*O*-(*R*)-benzylidene-β-L-arabinopyranoside (**4**).[2]

Oxidation of **2** with methyl sulphoxide – acetic anhydride (5) gave methyl 3,4-*O*-(*S*)-benzylidene-β-L-*erythro*-pentopyranosidulose (**9**) directly in 32% yield. Fractionation of the mother liquors gave more of the ketone **9** (13%) plus methyl 3,4-*O*-(*S*)-benzylidene-2-*O*-(methylthio)methyl-β-L-arabinopyranoside (**5**), an expected by-product from these reactions (6). In a similar manner oxidation of **4** gave the ketone **10** in 60% yield and a syrupy product which was considered to be the (methylthio)methyl derivative **6**.

Reduction of **9** with sodium borohydride in aqueous ethanol, following the general method of Theander (7), gave a syrupy product **B** whose nmr spectrum showed two benzyl proton signals at δ 5.91 and 5.83 with integrated areas in the ratio 3:17. Part of this product was hydrolysed and examination of the hydrolysate by paper chromatography showed two components corresponding to reference standards of L-arabinose and D-ribose, and clearly different from D-lyxose and D-xylose. The ribose component appeared to be the major product. The riboside has been shown (8) to be the major product of the reduction of methyl 3,4-*O*-isopropylidene-β-L-*erythro*-pentopyranosidulose. A similar result was obtained from the reduction of **10** and the nmr spectrum of the syrupy product **C** showed two benzyl proton signals at δ 6.17 and 6.04 with integrated areas in the ratio 14:3.

Benzoylation of **B** and **C** gave crystalline benzoates, in good yield, which were clearly

[1]A similar treatment of methyl 3,4-*O*-(*S*)-benzylidene-β-L-arabinopyranoside (**2**) (benzyl proton signal δ 5.75) resulted in the rapid appearance of a second signal at δ 6.03 in the nmr spectrum. After 3 min the two signals had equal integrated areas, which did not alter during a further 18 h, indicating that an equilibrium mixture of two diastereomers had been formed. The addition of a drop of water to this mixture resulted in the rapid disappearance (10 min) of the signal at δ 5.75.

[2]Compound **4** could also be isolated, following the selective hydrolysis of a 1:1 mixture of **2** and **4** (dioxan and 5 *N* hydrochloric acid), but this procedure was less satisfactory.

TABLE 1. Nuclear magnetic resonance data for compounds **2, 4–10**

[b]In carbon tetrachloride.
[c]Abbreviations for nmr: s, singlet; d, doublet; t, triplet; and m, multiplet.

different from the arabinoside isomers **1** and **3**. These benzoates were thus methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-L-ribopyranoside (**7**) and methyl 2-*O*-benzoyl-3,4-*O*-(*R*)-benzylidene-β-L-ribopyranoside (**8**) respectively.

Experimental

All melting points are uncorrected. Evaporations were performed under diminished pressure with a bath temperature below 40°C. Light petroleum refers to the fraction boiling at 60–80°C. Thin-layer chromatography was performed with Silica Gel G (E. Merck, Darmstadt, Germany), activated at 110°C, and components were detected with iodine vapour or vanillin – sulphuric acid solution, as appropriate. Column chromatography was conducted with Silica Gel 7734 (70–325 mesh ASTM, E. Merck). Solvent systems A, B, C, D, and E, used in the above chromatography, refer to the following systems of carbon tetrachloride – ethyl acetate 9:1, 8:2, 7:3, 6:4, and 1:1 respectively. Paper chromatography was carried out by downward irrigation, using Whatman No. 1 paper, and sugars were detected with alkaline silver nitrate. The nmr spectra were measured at 60 MHz with a Perkin-Elmer R-10 instrument. Chemical shifts refer to an internal standard of tetramethylsilane (δ = 0.00) and are recorded, together with spin-coupling values (Hz), in Table 1. The ir spectra were measured with a Perkin-Elmer model 257 ir spectrometer.

Methyl 2-O-Benzoyl-3,4-O-(S)-benzylidene-β-L-arabinopyranoside (1) (1, 2)

A mixture of methyl β-L-arabinopyranoside (3.5 g, 21.34 mmol) and benzaldehyde (20 ml) was heated for 4 h at 135°C with removal of water as described by Oldham and Honeyman (1). Excess of benzaldehyde was then removed by distillation and the syrupy residue was poured into benzene. Unchanged starting material (0.53 g) was filtered off and the filtrate was shaken with 2% sodium hydroxide solution, washed with water, dried ($MgSO_4$), and evaporated. The syrupy product was benzoylated during 18 h with benzoyl chloride (5 ml) in anhydrous pyridine (10 ml) to give a syrup which crystallized from chloroform – light petroleum. Recrystallization from ethanol – light petroleum gave **1** (1.4 g, 20%), mp 123–124°C; $[\alpha]_D^{25}$ +224° (*c* 1.0, $CHCl_3$) (lit. (2) mp 119–120°C, $[\alpha]_D^{20}$ +224° in $CHCl_3$); ν_{max} 1712 cm^{-1} (C=O).

Methyl 3,4-O-(S)-Benzylidene-β-L-arabinopyranoside (2)

Sodium (catalytic quantity) was added to a solution of **1** (1 g, 2.81 mmol) in anhydrous methanol (50 ml) and the reaction mixture was kept overnight at room temperature. A few drops of water were added to the reaction mixture and carbon dioxide was bubbled through it for 15 min. The solution was then evaporated and the resulting syrup was dissolved in ethyl acetate. The solution was filtered and the filtrate evaporated to give a syrup which crystallized. Recrystallization from ethyl acetate – light petroleum gave **2** (0.49 g, 64%), mp 81°C; $[\alpha]_D^{25}$ +162° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.9, H 6.4; found: C 62.0, H 6.5.

In another experiment methyl β-L-arabinopyranoside (9 g) was benzylidenated as above and **2** (3 g, 19%) was isolated directly by fractional crystallization, with the aid of a seed crystal.

Methyl 2-O-Benzoyl-3,4-O-(R)-benzylidene-β-L-arabinopyranoside (3)

The mother liquors from the above fractional crystallization were evaporated and the resulting syrup was

benzoylated during 18 h with benzoyl chloride (3.5 ml) in anhydrous pyridine (5 ml) to give a solid product. Recrystallization from ethanol – light petroleum gave mixture **A** (6.4 g) whose nmr spectrum (CCl_4) showed two benzyl proton signals at δ 5.81 and 6.17 of equal integrated area.

Fused *p*-toluenesulphonic acid (5 mg) was added to a solution of **A** (120 mg, 0.34 mmol) in chloroform-*d* and the signals in the benzyl proton region of the nmr spectrum were examined at intervals. After 24 h there was no change in the initial spectrum, with signals at δ 5.80 and 6.12, and a drop of water was then added. After 4 h the signals had integrated areas in the ratio ca. 1:2, but in another 12 h there was no further change. More acid (5 mg) was added and after another 5 h only the signal at δ 6.12 was detected. The solution was then diluted with chloroform, washed with saturated aqueous sodium hydrogen carbonate and water, dried ($MgSO_4$), and evaporated. The resulting syrup crystallized and was recrystallized from ethanol to give **3** (20 mg, 17%), mp 125–127°C; $[\alpha]_D^{25}$ +168° (*c* 1.0, $CHCl_3$); (lit. (1) mp 126–127°C; $[\alpha]_D^{18}$ +174° in $CHCl_3$); ν_{max} 1725 cm^{-1} (C=O).

In subsequent large scale reactions **A** was dissolved in dioxan and 5 *N* hydrochloric acid was added dropwise. Aliquots were withdrawn at intervals and the benzyl proton region of the nmr spectrum examined. The reaction was complete when the initial signals at δ 5.54 and 5.90 were replaced by a single signal at δ 5.90, and was processed as above to give **3** in 35–40% yield.

*Methyl 3,4-O-(R)-Benzylidene-β-L-arabinopyranoside (**4**)*

Sodium (catalytic quantity) was added to a solution of **3** (0.91 g, 2.56 mmol) in anhydrous methanol (50 ml) and the reaction mixture was kept overnight at room temperature. The reaction was processed in the normal manner to give **4** (0.43 g, 66%), mp 72–74°C; $[\alpha]_D^{25}$ +173° (*c* 0.6, $CHCl_3$). *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.9, H 6.4; found: C 62.1, H 6.3.

*Methyl 3,4-O-(S)-Benzylidene-β-L-erythro-pentopyranosidulose (**9**)*

Acetic anhydride (40 ml) was added to a solution of **2** (2 g, 7.94 mmol) in methyl sulphoxide (60 ml) and the reaction mixture was stirred for 21 h at room temperature. The solution was then diluted with water, neutralized with aqueous potassium carbonate solution, and extracted with chloroform. The chloroform extract was washed with water, dried ($MgSO_4$), and evaporated. The resulting syrup crystallized on the addition of diisopropyl ether and recrystallization from the same solvent gave **9** (0.64 g, 32%), mp 106–107°C; $[\alpha]_D^{25}$ +136° (*c* 1.0, $CHCl_3$); ν_{max} 1757 cm^{-1} (C=O). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.4, H 5.6; found: C 62.4, H 5.8.

The tlc (solvent B) examination of the mother liquors showed two components, the slower moving corresponding to **9**. This material was placed on a column of silica gel (100 g) and eluted with solvent B, collecting 100 ml fractions. The fractions were examined by tlc and fractions 5 and 6, containing the faster moving component, were evaporated to give a syrup (0.36 g, 14.5%) which crystallized on standing. Recrystallization from ethanol gave methyl 3,4-*O*-(*S*)-benzylidene-2-*O*-(methylthio)methyl-β-L-arabinopyranoside (**5**), mp 45–47°C; $[\alpha]_D^{25}$ +67° (*c* 2.0, $CHCl_3$). *Anal.* calcd. for $C_{15}H_{20}O_5S$: C 57.7, H 6.4, S 10.3; found: C 57.8, H 6.2, S 10.5.

Fractions 9–14, containing the slower moving component, were evaporated to give more **9** (0.26 g, 13%).

*Methyl 3,4-O-(R)-Benzylidene-β-L-erythro-pentopyranosidulose (**10**)*

Compound **4** (0.4 g, 1.59 mmol) was oxidised as described above to give a syrup that showed two major components by tlc (solvent B). The syrup was placed on a column of Silica Gel (34 g) and eluted with solvent B, collecting 25 ml fractions. The fractions were examined by tlc and fractions 8–12, containing the slower moving component, were evaporated. The crystalline residue was recrystallized from ether – light petroleum to give **10** (0.24 g, 60%), mp 74–75°C; $[\alpha]_D^{25}$ +122° (*c* 1.0, $CHCl_3$); ν_{max} 1745 cm^{-1} (C=O). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.4, H 5.6; found: C 62.2, H 5.6.

Fractions 4 and 5, containing the faster moving component, were evaporated to give syrupy **6** (68 mg, 14%), $[\alpha]_D^{25}$ +45° (*c* 1.2, $CHCl_3$).

*Methyl 2-O-Benzoyl-3,4-O-(S)-benzylidene-β-L-ribopyranoside (**7**)*

Sodium borohydride (100 mg) was added to a solution of **9** (100 mg, 0.40 mmol) in 70% aqueous ethanol (40 ml) and the reaction mixture stirred for 4 h at room temperature. Water (15 ml) was then added and the solution was extracted with ethyl acetate (8 × 15 ml). The extract was dried ($MgSO_4$) and evaporated to give a syrup **B** (81 mg, 80%). The nmr spectrum (chloroform-*d*) showed two benzyl proton signals at δ 5.91 and 5.83 with integrated areas in the ratio 3:17; tlc (9:1 benzene–methanol) showed two components, the minor corresponding to **2**.

Treatment of **B** (80 mg) with 1 *N* sulphuric acid (15 ml) at 100°C and examination of the neutralized (barium carbonate) hydrolysate by paper chromatography (8:2:1 ethyl acetate – pyridine–water), with D-xylose, D-ribose, L-arabinose, and D-lyxose as standards, showed two components corresponding to ribose and arabinose, the former predominating.

Benzoylation of **B** (150 mg) with benzoyl chloride (0.15 ml) in anhydrous pyridine (0.3 ml) during 18 h gave a syrupy product that solidified after 2 days. Recrystallization from ethanol gave **7** (105 mg, 50%), mp 106–107°C; $[\alpha]_D^{25}$ +170° (*c* 0.6, $CHCl_3$); ν_{max} 1720 cm^{-1} (C=O). *Anal.* calcd. for $C_{20}H_{20}O_6$: C 67.4, H 5.7; found: C 67.7, H 5.4.

*Methyl 2-O-Benzoyl-3,4-O-(R)-benzylidene-β-L-ribo-pyranoside (**8**)*

Compound **10** (50 mg, 0.20 mmol) was reduced as described above to give a syrup **C** (34 mg, 65%). The nmr spectrum (chloroform-*d*) showed two benzyl proton signals at δ 6.17 and 6.04 with integrated areas in the ratio 14:3.

Hydrolysis of **C** as described above and examination of the neutralized hydrolysate by paper chromatography showed two components corresponding to ribose and arabinose, the former predominating.

Benzoylation of **C** (155 mg) with benzoyl chloride (0.15 ml) in anhydrous pyridine (0.3 ml) during 18 h gave a syrupy product that solidified after 2 weeks. Recrystal-

lization from ether–pentane gave **8** (90 mg, 41%), mp 83–85°C; $[\alpha]_D^{25}$ +57° (*c* 0.6, $CHCl_3$); ν_{max} 1724 cm^{-1} (C=O). *Anal.* calcd. for $C_{20}H_{20}O_6$: C 67.4, H 5.7; found: C 67.3, H 5.6.

The acid-catalyzed rearrangement of methyl 3,4-*O*-benzylidene-β-D-ribopyranoside

DAVID M. CLODE

Department of Chemistry, University of Cape Coast, Cape Coast, Ghana

Received June 16, 1977

DAVID M. CLODE. Can. J. Chem. **55**, 4071 (1977).

Methyl 3,4-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**2**) rapidly rearranged, under anhydrous acidic conditions, to give methyl 2,3-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**6**). Further rearrangement of **2** and **6** gave the (*S*)-isomers **4** and **8**, an equilibrium mixture of the four pyranoside acetals **2**, **4**, **6**, and **8** resulting. At higher acid concentrations, the rearrangement proceeded, with ring contraction, to give the diastereomeric forms of methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**) as the sole product. Treatment of methyl 3,4-*O*-(*S*)-benzylidene-β-D-ribopyranoside (**4**) with acid resulted in the immediate formation of the equilibrium mixture of pyranoside acetals. On increasing the acid concentration this mixture again underwent ring contraction to give the diastereomers **11** and **13** as the final product. The rearrangement of **2** and **4** was monitored by following the change in signals in the benzyl proton region of the nmr spectrum.

DAVID M. CLODE. Can. J. Chem. **55**, 4071 (1977).

Le *O*-(*R*)-benzylidène-3,4 β-D-ribopyrannoside de méthyle (**2**) se réarrange rapidement dans des conditions acide anhydre pour conduire au *O*-(*R*)-benzylidène-2,3 β-D-ribopyrannoside de méthyle (**6**). Des réarrangements subséquents de **2** et de **6** fournissent les isomères (*S*) **4** et **8**; il en résulte un mélange à l'équilibre des quatre acétals des pyrannosides **2**, **4**, **6** et **8**. A des concentrations plus élevées d'acide, le réarrangement se produit avec une contraction de cycle pour conduire aux formes diastéréoisomères des *O*-benzylidène-2,3 β-D-ribofurannoside de méthyle (**11** et **13**) comme seuls produits. Le traitement acide du *O*-(*S*)-benzylidène-3,4 β-D-ribopyrannoside de méthyle (**4**) par de l'acide conduit à la formation immédiate d'un mélange à l'équilibre d'acétals de pyrannoside. Par augmentation de la concentration d'acide, ce mélange subit à nouveau une contraction de cycle pour conduire aux diastéréoisomères **11** et **13** comme produits finals. On a suivi le réarrangement de **2** et **4** en surveillant le changement dans les signaux des protons benzyliques dans le spectre de résonance magnétique nucléaire.

[Traduit par le journal]

Introduction

Levene and Stiller (1) isolated methyl 2,3-*O*-isopropylidene-D-ribofuranoside following the condensation of acetone with methyl D-ribopyranoside. They also isolated a second product which they considered to be methyl 2,3-*O*-isopropylidene-D-ribopyranoside. Barker *et al.* (2) reexamined this reaction and showed that methylation of the mixed products, followed by hydrolysis, yielded 2-, 4-, and 5-*O*-methyl-D-ribose. This suggested that both methyl 2,3- and methyl 3,4-*O*-isopropylidene-D-ribopyranoside are products of the condensation. It was subsequently shown (3) that the supposed methyl 2,3-*O*-isopropylidene-4-*O*-*p*-toluenesulphonyl-D-ribopyranoside, obtained by Levene and Stiller (1), was in fact methyl 3,4-*O*-isopropylidene-2-*O*-*p*-toluenesulphonyl-D-ribopyranoside. It was concluded by Levene *et al.* (4) that, since methyl D-ribopyranoside is normally formed from the furanoside under acidic conditions, the ring contraction must have taken place after condensation with acetone. This reaction has recently been reinvestigated by Hughes and Maycock (5) who showed that the formation of methyl 2,3-*O*-isopropylidene-D-ribofuranoside probably arose from the presence of methyl D-ribofuranoside in the starting material and not from a ring contraction.

Barker *et al.* (2) also reported that the benzylidenation of methyl β-D-ribopyranoside gave a syrupy methyl 2,3-*O*-benzylidene-D-ribofuranoside of unspecified configuration. In this reaction, because pure methyl β-D-ribopyranoside was used, the formation of the furanoside acetal must have been the result of a ring contraction. The present work describes an examination of this ring contraction as part of a programme concerned with the formation and migration of cyclic acetals of carbohydrates.

Results and Discussion

It seems reasonable to assume that benzylidenation of methyl β-D-ribopyranoside gives an

initial product consisting of a mixture of the diastereomeric forms of methyl 2,3- and methyl 3,4-*O*-benzylidene-β-D-ribopyranoside. Rearrangement of these pyranoside acetals, to give the thermodynamically most stable product, a methyl 2,3-*O*-benzylidene-D-ribofuranoside, then occurs. The driving force for the reaction is the formation of the favourable *cis*-fused system of two five-membered rings (6). In order to test this proposition it was proposed to treat an *O*-benzylidene-ribopyranoside of known structural configuration, under anhydrous acidic conditions, in an attempt to promote a ring contraction.

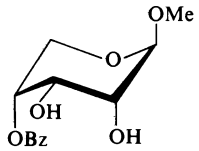
14



15

Methyl 2-*O*-benzoyl-3,4-*O*-(*R*)- and methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-D-ribopyranoside, (**1**) and (**3**) respectively, were prepared as described in the preceding paper for the L-enantiomer, starting with D-arabinose. Debenzoylation of **1** gave methyl 3,4-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**2**) as a homogeneous (tlc and nmr spectroscopy) syrup. The rearrangement of **2**, under anhydrous acidic conditions, was then followed by nmr spectroscopy. A solution of **2** in chloroform-*d* was treated with acidic chloroform (chloroform containing ca. 0.2% hydrogen chloride) and aliquots were removed at various intervals and the signals in the benzyl proton region of the nmr spectrum examined. After 10 min a new benzyl proton signal at δ 5.88 had appeared with a corresponding diminution of the initial signal at δ 5.80. There was no further change in the nmr spectrum and so after 30 min more acidified chloroform was added. A third benzyl proton signal at δ 6.32 then appeared and after 1 h the three signals at δ 5.80, 5.88, and 6.32 had integrated areas in the ratio 13:8:15, which did not alter during a further 24 h with the addition of more acid.

Since a significant amount of **2** still remained in the mixture, it appeared that this isomer had rearranged to give an equilibrium mixture of pyranoside acetals but that no ring contraction had occurred. This suggested that the acidic conditions may not have been drastic enough to effect a change in ring size and, therefore, anhydrous hydrogen chloride was bubbled directly into the reaction mixture. An immediate change in the benzyl proton signals was observed; the signals at δ 5.80 and 5.88 merged to form a broad hump and two new signals at δ 5.75 and 5.98 appeared. After 30 min only the new signals at δ 5.75 and 5.98 remained. These were of approximately equal size and the difference in chemical shift was consistent (7, 8) with their being the benzyl protons corresponding to the diastereomeric forms of methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**) (2, 9).

Acetal migration is a fairly well established phenomenon. One of the earliest examples was observed by Hibbert and co-workers (10) who found that the isomeric methylidene, benzylidene, and *p*-nitrobenzylidene cyclic acetals of glycerol were readily interconverted in the presence of hydrogen chloride. Acetal migration has more recently been studied (11, 12) by following the change in the signal pattern in the

benzyl proton region of the nmr spectrum. Other examples include the observation made by Williams (13) that methyl 2,3-*O*-isopropylidene-β-D-allofuranoside and methyl 2,3:5,6-di-*O*-isopropylidene-β-D-allofuranoside were two of the products obtained during the acid-catalyzed methanolysis of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose. This rearrangement has also been studied by Haga *et al.* (14) who showed that treatment of the above di-*O*-isopropylidene-allofuranose with acidic acetone resulted in the formation, in good yield, of the 2,3:5,6-di-*O*-isopropylidene derivative. Closely related to the above is the rearrangement of 5-*O*-benzoyl-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-ribofuranose to the 2,3-*O*-isopropylidene derivative in acidic methanol solution (15).

Migration of an *O*-isopropylidene group on a pyranose ring is also known; thus the 2,3-*O*-isopropylidene derivative is formed as an intermediate in the hydrolysis, in aqueous acetic acid, of 1,6-anhydro-3,4-*O*-isopropylidene-β-D-talopyranose (16). Inch (17) has shown that methyl 4,6-*O*-benzylidene-2-deoxy-2-halogeno-α-D-altropyranoside undergoes facile, acid-catalyzed, acetal migration to give methyl 3,4-*O*-(*S*)-benzylidene-2-deoxy-2-halogeno-α-D-altropyranoside. It was also shown that the (*S*)-isomer is the thermodynamically more-stable form of this compound since a sample of the (*R*)-isomer rearranged into this isomer under acidic conditions. Closely related to the rearrangement of **2** is the observation (18) that 1,2:4,5-di-*O*-isopropylidene-D-psicopyranose rearranges in acidic acetone to give 1,2:3,4-di-*O*-isopropylidene-D-psicofuranose. In this case it is reasonable to assume that we have migration of the 4,5-*O*-isopropylidene group to the 3,4-position prior to ring contraction.

Treatment of **2** with acid had resulted in the rapid formation of an isomer with a benzyl proton signal at δ 5.88. Previous work on the correlation of configuration of substituted derivatives of 2-phenyl-1,3-dioxan and 2-phenyl-1,3-dioxolan with the chemical shifts for the benzyl proton signals in the nmr spectra (7,8), and also a mechanistic interpretation of the formation and migration of benzylidene acetals, enabled this signal to be assigned to the benzyl proton of methyl 2,3-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**6**). The benzyl proton signal at δ 6.32, which had appeared more slowly, was tentatively assigned to the benzyl proton signal of **4**. It was, however, considered possible that the benzyl proton signal of methyl 2,3-*O*-(*S*)-benzylidene-β-D-ribopyranoside (**8**) might also have the same chemical shift.

To confirm these assigned structures the various acetals present in the early stages of the rearrangement were isolated and characterized. Thus the rearrangement was repeated and the reaction terminated after 4.5 h before the direct introduction of anhydrous hydrogen chloride. Fractionation of the product gave three homogeneous (tlc) syrups **A**, **B**, and **C**, in order of elution. Compounds **B** and **C** had identical nmr spectra to **4** and **2** respectively and the structure of these products was proved conclusively by converting them into their known crystalline benzoates **3** and **1**. Syrup **A** showed benzyl proton signals at δ 5.88 and 6.32 which were considered to belong to the benzyl protons of the diastereomers **6** and **8** respectively, the signal at δ 6.32 in the rearrangement thus representing the signal from the benzyl proton of both **4** and **8**. This assignment of structure for **A** was confirmed by the following sequence of reactions. Mixture **A** was converted into syrupy methyl 4-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribopyranoside (**5** and **7**) and hydrogenolysis of this benzoate gave homogeneous (tlc) syrupy methyl 4-*O*-benzoyl-β-D-ribopyranoside (**15**). Isopropylidenation of **15** gave methyl 4-*O*-benzoyl-2,3-*O*-isopropylidene-β-D-ribopyranoside (**9**), in fair overall yield, which had physical properties in agreement with those of a sample of the L-enantiomer prepared by a benzoate displacement reaction on methyl 2,3-*O*-isopropylidene-4-*O*-*p*-toluenesulphonyl-α-D-lyxopyranoside. Displacement at C-4 in D-lyxoside derivatives with various nucleophiles is known (19–21) and these give the corresponding 4-substituted L-riboside derivatives. It was noted, however, that attempted displacement at C-4 in D-rhamnose derivatives, with a variety of nucleophiles, resulted in ring contraction to give 5-substituted furanosides (22).

As pointed out earlier in the discussion, the first product of the rearrangement (benzyl proton signal δ 5.88) was assigned the structure **6**. This compound was isolated by termination of the reaction, when only the starting material (benzyl proton signal δ 5.80) and compound **6** (benzyl proton signal δ 5.88) were present, and fractionation of the mixture. Benzoylation of **6** gave a crystalline product whose nmr spectrum (Table 1) was consistent with its being methyl

[a]In chloroform-*d*.
[b]Abbreviations for nmr: s, singlet; d, doublet; and m, multiplet.

4-*O*-benzoyl-2,3-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**5**). Compound **5** had the same mobility (tlc) as the slower moving component of the mixture **5** and **7**, prepared by the benzoylation of **A**.

The final product of the rearrangement was expected to be the diastereomeric forms of methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**) and this was proved by the following reaction sequence. Benzoylation of the above product gave methyl 5-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribofuranoside (**10** and **12**) (23). Hydrogenolysis of this benzoate gave, in good yield, methyl 5-*O*-benzoyl-β-D-ribofuranoside (**14**), identical with an authentic sample, confirming the assigned structures. The formation of the furanoside isomers **11** and **13** from the acid-catalyzed rearrangement of **2** may be attributed to the thermodynamic stability of the system of two *cis*-fused, oxygen-containing, five-membered rings (6). The ring contraction proceeded with retention of configuration at the glycosidic centre since only the benzyl proton signals at δ 5.75 and 5.98, corresponding to methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**), were observed in the nmr spectrum. Retention of configuration at the glycosidic centre has been observed (24) during the acid-catalyzed conversion of methyl 3,6-anhydro-α-D-glucopyranoside into the α-furanoside. Methyl 3,6-anhydro-β-D-glucopyranoside underwent a similar conversion to give the β-furanoside derivative. Closely related is the recently reported (25) rearrangement of 3,6:3′,6′-dianhydro-α,α-trehalose into the difuranoid form. Other examples of the opening of the sugar ring accompanying acetal migration are known. Thus 1,2-*O*-isopropylidene-α-D-apio-L-furanose and its 5-thio analogue rearrange, in the presence of anhydrous methanolic hydrogen chloride, to give the respective methyl 2,3-*O*-isopropylidene-β-D-apio-D-furanoside derivative (26, 27). In the latter product the oxygen atom of the hemiacetal ring has been replaced by a sulphur atom. Extensive studies by Maeda *et al.* (28) on the acetalation mechanism of L-sorbose have confirmed that a pyranose to furanose ring conversion takes place following condensation with acetone. These workers have postulated that this change in ring size takes place via keto-form intermediates. Treatment of 1,2:4,5-di-*O*-isopropylidene-D-psicopyranose with acidic acetone resulted in migration of the 4,5-acetal and ring opening to

give 1,2:3,4-di-*O*-isopropylidene-D-psicofuranose (18). From the results obtained and from the above discussion it is clear that the change in ring size observed by Barker *et al.* (2) probably occurred after condensation of the methyl β-D-ribopyranoside with benzaldehyde. The pyranoside acetals, which would be formed initially, isomerize to give the final product, methyl 2,3-*O*-benzylidene-β-D-ribofuranoside.

The rearrangement of methyl 3,4-*O*-(*S*)-benzylidene-β-D-ribopyranoside (**4**) under anhydrous acidic conditions, was again conveniently followed by observing the change in the benzyl proton signals in the nmr spectrum. After 25 min two new benzyl proton signals at δ 5.80 and 5.88 had appeared with an accompanying decrease in the size of the initial signal at δ 6.32. These two new signals increased in size until after 3 h the three signals at δ 5.80, 5.88, and 6.32 had integrated areas in the ratio 7:4:9, which did not alter during a further 24 h. Anhydrous hydrogen chloride was then introduced directly into the reaction mixture. An identical change in the benzyl proton signals, to that noted at the corresponding point in the rearrangement of **2**, was observed and after 2 h only the two new signals at δ 5.75 and 5.98 remained. No change in this pattern was observed during another 24 h. The reaction mixture was then neutralized and the isolated product had identical nmr, ir, and chromatographic properties to methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**).

It is thus obvious than an essentially identical rearrangement, to that observed for the (*R*)-isomer **2**, had occurred and that the (*S*)-isomer **4** had rearranged ultimately to give a mixture of the diastereomers **11** and **13**. It is also clear, however, that in the early stages of this rearrangement there are some significant differences. In the above rearrangement we observed the simultaneous appearance of benzyl proton signals at δ 5.80 and 5.88 which may be assigned to **2** and **6** respectively. It is also probable that the benzyl proton signal for **8** appeared at the same time; however, it could not be observed since it had the same chemical shift as **4**. Thus from the start of the rearrangement we were observing the formation of an equilibrium mixture of pyranoside acetals. There did not appear to be any kinetic phase in this reaction. In contrast we did observe an initial kinetic phase in the rearrangement of the (*R*)-isomer **2**, where we have the selective formation of **6**, equilibration then taking place to give **4** and **8**. This initial kinetic control must reflect the low energy barrier for the conversion of the (*R*)-isomer **2** into the (*R*)-isomer **6**, compared with that for the conversion of **2** into the (*S*)-isomer **4** or **8**.

Experimental

The general methods are described in the preceding paper. Acidified chloroform refers to chloroform which has been shaken with water, dried ($MgSO_4$), and stood over anhydrous calcium chloride for 2 days. The chloroform solution was then filtered and anhydrous hydrogen chloride was bubbled through it for ca. 2 min. This procedure gave a chloroform solution containing ca. 0.2% of hydrogen chloride.

Methyl 3,4-O-(R)-Benzylidene-β-D-ribopyranoside (2)

Methyl 2-*O*-benzoyl-3,4-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**1**), mp 109–110°C; $[\alpha]_D^{25}$ −168° (*c* 0.6, $CHCl_3$), was prepared as for the L-enantiomer (see preceding paper) starting with D-arabinose.

Sodium (catalytic quantity) was added to a solution of **1** (0.8 g, 2.25 mmol) in anhydrous methanol (75 ml) and the reaction mixture was kept overnight at room temperature. The reaction was then processed in the normal manner to give a syrup contaminated with methyl benzoate. Column chromatography with Silica Gel and elution with solvent C gave pure syrupy methyl 3,4-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**2**) (567 mg, 99%), $[\alpha]_D^{25}$ −100° (*c* 1.6, $CHCl_3$).

Methyl 3,4-O-(S)-Benzylidene-β-D-ribopyranoside (4)

Methyl 2-*O*-benzoyl-3,4-*O*-(*S*)-benzylidene-β-D-ribopyranoside (**3**), mp 84–85°C, $[\alpha]_D^{25}$ −43° (*c* 0.6, $CHCl_3$), was prepared as for the L-enantiomer (see preceding paper) starting with D-arabinose.

Sodium (catalytic quantity) was added to a solution of **3** (0.3 g, 0.84 mmol) in anhydrous methanol (35 ml) and the reaction mixture was kept overnight at room temperature. The reaction was processed as above to give pure syrupy methyl 3,4-*O*-(*S*)-benzylidene-β-D-ribopyranoside (**4**) (167 mg, 79%), $[\alpha]_D^{25}$ −107° (*c* 1.1, $CHCl_3$).

Rearrangement of Methyl 3,4-O-(R)-Benzylidene-β-D-ribopyranoside (2)

(*a*) Acidified chloroform (0.1 ml) was added to a solution of **2** (0.5 g, 1.98 mmol) in chloroform-*d* (2.5 ml). Aliquots were removed at various intervals and the signals in the benzyl proton region of the nmr spectrum examined. After 10 min the initial benzyl proton signal (δ 5.80) had been replaced by two signals at δ 5.80 and 5.88, with integrated areas in the ratio 9:4, which did not alter during a further 20 min. More acidified chloroform (0.1 ml) was added and a third signal then appeared at δ 6.32. After 1 h the three signals at δ 5.80, 5.88, and 6.32 had integrated areas in the ratio 13:8:15, which did not alter during a further 24 h and with the addition of more acid (0.1 ml after 3 h and 8 h); tlc (solvent E) showed three components (R_F ca. 0.5), respectively, having the same mobilities as **2** and **4**, and a third component of higher mobility.

Anhydrous hydrogen chloride was then bubbled through the reaction mixture (ca 30 s) and after 30 min the three benzyl proton signals had been replaced by two

new signals at δ 5.75 and 5.98 with integrated areas in the ratio 5:6. This ratio did not change during a further 24 h. The reaction mixture was then poured into saturated aqueous sodium hydrogen carbonate and extracted with chloroform. The chloroform extract was washed with water, dried ($MgSO_4$), and evaporated to give syrupy methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**) (2, 9) (0.3 g, 60%); tlc (solvent D) showed two components (R_F ca. 0.5) which did not correspond to any of the three components observed previously. The nmr spectrum (9) *inter alia* two benzyl proton signals at δ 5.75 and 5.98 with integrated areas in the ratio 5:6.

Benzoylation of **11** and **13** (300 mg, 1.19 mmol) with benzoyl chloride (0.2 ml) in anhydrous pyridine (0.8 ml) during 18 h gave syrupy methyl 5-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribofuranoside (**10** and **12**) (23) (320 mg, 80%); ν_{max} 1724 cm^{-1} (C=O); tlc (solvent A) showed two components.

(*b*) In a second experiment acidified chloroform (0.1 ml) was added to a solution of **2** (0.87 g, 3.45 mmol) in chloroform-*d* (4.5 ml) and the reaction terminated after 3.5 h. The reaction was processed as before to give a syrup (0.78 g, 90%). The nmr spectrum showed benzyl proton signals at δ 5.80, 5.88, and 6.32 with integrated areas in the ratio 14:7:12 and tlc (solvent E) showed components, respectively, having the same mobilities as **2** and **4**, and a third component of higher mobility. Separation of this product by column chromatography on Silica Gel and elution with solvent C gave three homogeneous (tlc) syrups **A**, **B**, and **C**, in order of elution.

Compound **C** (208 mg, 0.83 mmol), whose nmr spectrum was identical with that of **2**, gave a crystalline benzoate (129 mg, 44%) that was indistinguishable from authentic **1**.

Compound **B** (100 mg, 0.40 mmol), whose nmr spectrum was identical with that of **4**, gave a crystalline benzoate (60 mg, 42%) which was identical with authentic **3**.

Syrup **A** (100 mg, 0.40 mmol) was benzoylated in the normal manner with benzoyl chloride (0.07 ml) in anhydrous pyridine (0.5 ml) during 18 h to give syrupy methyl 4-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribopyranoside (**5** and **7**) (128 mg, 88%) which showed two components by tlc (chloroform).

(*c*) In a third experiment acidified chloroform (0.1 ml) was added to a solution of **2** (0.63 g, 2.50 mmol) in chloroform-*d* (3 ml) and the reaction terminated after 30 min. The reaction was processed as before to give a syrup (0.47 g, 75%). The nmr spectrum showed benzyl proton signals at δ 5.80 and 5.88 with integrated areas in the ratio 17:7 and tlc (solvent E) showed two components, the slower moving corresponding to **2** and the faster to **A**. Fractionation of this mixture gave **2** (285 mg), which on benzoylation gave the crystalline benzoate **1** (287 mg, 71%) and methyl 2,3-*O*-(*R*)-benzylidene-β-D-ribopyranoside **6** (123 mg).

Benzoylation of **6** (123 mg, 0.49 mmol) with benzoyl chloride (0.09 ml) in anhydrous pyridine (1.0 ml) during 18 h gave a solid that was recrystallized from ethanol to give methyl 4-*O*-benzoyl-2,3-*O*-(*R*)-benzylidene-β-D-ribopyranoside (**5**) (108 mg, 62%), mp 78–79°C; $[\alpha]_D^{25}$ +7.5° (*c* 0.8, $CHCl_3$); ν_{max} 1724 cm^{-1} (C=O). *Anal.* calcd. for $C_{20}H_{20}O_6$: C 67.4, H 5.7; found: C 66.8, H 5.7.

Rearrangement of Methyl 3,4-O-(S)-Benzylidene-β-D-ribopyranoside (4)

Acidified chloroform (0.1 ml) was added to a solution of **4** (0.15 g, 0.60 mmol) in chloroform-*d* (0.8 ml) and the signals in the benzyl proton region of the nmr spectrum were examined at intervals. After 25 min two new signals at δ 5.80 and 5.88 had appeared and after 3 h the three signals at δ 5.80, 5.88, and 6.32 had integrated areas in the ratio 7:4:9 which did not alter during a further 24 h; tlc (solvent E) showed components, respectively, having the same mobilities as **2**, **4**, and **A**.

Anhydrous hydrogen chloride was then bubbled through the reaction mixture (ca. 30 s). After 2 h the three benzyl proton signals had been replaced by two new signals at δ 5.75 and 5.98 with integrated areas in the ratio 7:8 which did not change during a further 24 h. The reaction was worked up as in the preceding experiment to give a syrupy product (106 mg, 71%) that had identical nmr, ir, and chromatographic properties to methyl 2,3-*O*-benzylidene-β-D-ribofuranoside (**11** and **13**).

Methyl 5-O-Benzoyl-β-D-ribofuranoside (14)

Methyl 5-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribofuranoside (**10** and **12**) (320 mg, 0.90 mmol) was dissolved in ethanol (100 ml) and 5% palladium-on-charcoal (100 mg) was added. The reaction mixture was then shaken at room temperature, with hydrogen, at a pressure slightly greater than atmospheric, for 24 h, when the theoretical quantity of hydrogen (40 ml) had been absorbed. The catalyst was then filtered off and the filtrate evaporated to give a syrup which rapidly crystallized. Recrystallization from ether–pentane gave **14** (133 mg, 60%) indistinguishable from an authentic sample.

Methyl 4-O-Benzoyl-2,3-O-isopropylidene-β-L-ribopyranoside

(*a*) Methyl 2,3-*O*-isopropylidene-4-*O*-*p*-toluenesulphonyl-α-D-lyxopyranoside, mp 105–106°C, $[\alpha]_D^{25}$ −12° (*c* 1.85, EtOH) (lit. (29) mp 96–97°C, $[\alpha]_D^{22}$ −10.2° in EtOH), was prepared by the method of Kent and Ward (29).

(*b*) Sodium benzoate (4 g, 27.8 mmol) was added to a solution of methyl 2,3-*O*-isopropylidene-4-*O*-*p*-toluenesulphonyl-α-D-lyxopyranoside (1 g, 2.79 mmol) in dimethylformamide (200 ml) and the reaction mixture was stirred for 70 h at 130°C; tlc (solvent B) showed two components, the slower corresponding to the starting material. The reaction mixture was then poured into water (400 ml) and the aqueous solution was extracted with chloroform. The chloroform extract was washed with water, dried ($MgSO_4$), and evaporated. The syrupy product was placed on a column of Silica Gel (75 g) and eluted with solvent A, collecting 10 ml fractions. The fractions were examined by tlc and fractions 17–20, containing the faster moving component, were evaporated to give a crystalline residue (113 mg, 13%) which was recrystallized from ethanol–water to give methyl 4-*O*-benzoyl-2,3-*O*-isopropylidene-β-L-ribopyranoside, mp 53–55°C; $[\alpha]_D^{25}$ +56° (*c* 1.0, $CHCl_3$); ν_{max} 1716 cm^{-1} (C=O). *Anal.* calcd. for $C_{16}H_{20}O_6$: C 62.3, H 6.5; found: C 62.0, H 6.8. Fractions 23–32, containing the slower moving component, were evaporated to give the starting material (311 mg, 31%).

Methyl 4-O-Benzoyl-β-D-ribopyranoside (15)

Syrupy methyl 4-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribopyranoside (**5** and **7**) (170 mg, 0.48 mmol) was dissolved in ethanol (100 ml) and 5% palladium-on-charcoal (100 mg) was added. The reaction mixture was then shaken at room temperature with a slight overpressure of hydrogen. After 21 h the uptake of hydrogen (21 ml) was complete and the catalyst was removed by filtration; tlc (solvent E) showed a single component and the filtrate was evaporated to give a syrup (**15**) (111 mg, 78%).

Methyl 4-O-Benzoyl-2,3-O-isopropylidene-β-D-ribopyranoside (9)

Syrupy **15** (100 mg, 0.37 mmol) was dissolved in anhydrous acetone (10 ml) and concentrated sulphuric acid (0.5 ml) was added. The reaction mixture was shaken for 24 h at room temperature and then neutralized with anhydrous sodium carbonate. The mixture was filtered and the filtrate, which showed two components by tlc (solvent B), the minor corresponding to the starting material, was evaporated to give a syrup which crystallized. Recrystallization from ethanol–water gave **9** (58 mg, 53%), mp 53–55°C; $[\alpha]_D^{25}$ −58° (*c* 0.38, $CHCl_3$). The ir spectrum was identical with the methyl 4-*O*-benzoyl-2,3-*O*-isopropylidene-β-L-ribopyranoside prepared earlier.

Preparative synthesis of 1-deoxy-D-*erythro*-2-pentulose and some of its derivatives[1]

JEAN-CLAUDE FISCHER, DEREK HORTON, AND WOLFGANG WECKERLE
Department of Chemistry, The Ohio State University, Columbus, OH 43210, U.S.A.

Received April 5, 1977

JEAN-CLAUDE FISCHER, DEREK HORTON, and WOLFGANG WECKERLE. Can. J. Chem. **55**, 4078 (1977).

Methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**1**) was converted, by means of lithium hydroxide in a two-phase system, into 3,5-*O*-benzylidene-1-deoxy-*keto*-D-*erythro*-2-pentulose (**2**) in 55% yield. Compound **2** was further characterized as its (2,4-dinitrophenyl)hydrazone **3**, its 4-acetate **4**, and the 4-benzoate **5**. The configurational assignment for the corresponding pentitol derivatives (**6** and **8**) of **2** was achieved by ^{1}Hmr analysis of the cyclic carbonates **11** (from **6**) and **13** (from **8**) and confirmed by comparing the physical constants of the 1-deoxypentitols having the D-*ribo* (**12**) and D-*arabino* (**14**) configurations with literature data. Hydrolysis of **2** with mild acid afforded the title ketose (**9**) as a syrup that gave a crystalline (2,4-dinitrophenyl)hydrazone (**10**), and an acyclic triacetate (**15**) as an oil. A mechanism for the chain degradation of compound **1** to give **2** is proposed.

JEAN-CLAUDE FISCHER, DEREK HORTON et WOLFGANG WECKERLE. Can. J. Chem. **55**, 4078 (1977).

On a préparé le *O*-benzylidène-3,5 déoxy-1 *céto*-D-*érythro*-pentulose-2 (**2**) avec un rendement de 55% en faisant réagir l'hydroxyde de lithium dans un système à deux phases sur le *O*-benzylidène-4,6 déoxy-2 α-D-*érythro*-hexopyranosidulose-3 de méthyle (**1**). Le composé **2** a également été converti en ses dérivés caractéristiques; le dinitro-2,4 phénylhydrazone (**3**), l'acétate-4 (**4**) et le benzoate-4 (**5**). La configuration absolue des composés **6** et **8**, dérivés des pentitols de **2**, a été établie par analyse rmn des carbonates cycliques **11** (de **6**) et **13** (de **8**) puis confirmée par comparaison des constantes physiques de déoxy-1 pentitols de configuration D-*ribo* (**12**) et D-*arabino* (**14**) avec les données de la littérature. L'hydrolyse acide douce de **2** a donné une cétose sirupeuse **9** qui a été convertie en sa dinitro-2,4 phénylhydrazone cristalline (**10**) et en son triacétate acyclique se présentant sous forme huileuse (**15**). On propose un mécanisme pour la dégradation du composé **1** en **2**.

Introduction

In an earlier publication (1) it was reported that scaled-up experiments of the reaction of butyllithium with methyl 2,3:4,6-di-*O*-benzylidene-α-D-mannopyranoside initially led to a complex mixture containing a wide range of products accompanying the methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**1**) that was desired as an intermediate in a proposed synthesis of daunosamine (1) and related sugars (2). From the mixture, a crystalline product was isolated in relatively low yield and subsequently identified as the 3,5-benzylidene acetal **2** of the title ketose. As compound **2** is synthetically interesting in its own right, a more practical procedure for its synthesis was considered a desirable objective and is described in the present article. This compound (**2**) has been obtained before by Overend and his coworkers (3) from the ketone **1** via its trimethylhydrazone iodide, but attempts to effect the direct conversion resulted in decreased yields of **2** and gave other unidentified and apparently unstable products.

The parent sugar of **2**, 1-deoxy-D-*erythro*-2-pentulose (**9**), constitutes one of the two possible, to the best of our knowledge thus far unknown, 1-deoxy analogs derived from (D or L)-*erythro*-pentulose ('ribulose') and the *threo* epimer ('xylulose'), although **9** must have been the (unidentified) intermediate in a study (4) correlating the configuration of 2-*C*-methyl-D-ribonic acid ('α'-D-glucosaccharinic acid) with 1-deoxy-D-arabinitol. The tribenzoate of 1-deoxy-L-*threo*-pentulose has been prepared (5), but attempted saponification failed to give the free sugar.

The value of **2** as precursor in the synthesis of

[1]Portions of this work were presented at the 171st National Meeting of the American Chemical Society, New York, NY, March 1976, CARB-3, and the Joint Meeting of the American Chemical Society and the Chemical Institute of Canada, Montreal, Canada, May 1977, CARB-39.

compounds of potential interest is demonstrated by the convenient preparation of the uniquely protected epimeric 1-deoxypentitols having D-*ribo* (**6**) and D-*arabino* (**8**) configurations in high yields. A synthesis, utilizing **2** as key intermediate, of optically pure analogs of atrolactic aldehyde is the topic of another report (for a preliminary report see ref. 6). These aldehydes constitute precursors of dioxolane derivatives that may exhibit anticholinergic activity (7).

Results and Discussion

The unexpected formation of the *O*-benzylidenepentulose **2** in the aforementioned reaction of methyl 2,3:4,6-di-*O*-benzylidene-α-D-mannopyranoside with butyllithium was traced to decomposition of the ketone **1** as the initial product under the strongly alkaline conditions of the original (8) isolation procedure. Consequently, the ketone **1** was treated with base under a wide variety of conditions, as by altering the nature and proportion of alkaline reagent, changing the solvent(s), and examining the mode of addition of the reagent to the substrate (or *vice versa*). From an estimated yield of **2** as low as 5–10% in the crude, complex mixture obtained under the original conditions (8), the procedure could be effectively improved by using a two-phase system of water and ether and employing stoichiometric amounts of lithium hydroxide as the base. The product **2** could then be isolated pure in 55% yield simply by recrystallization without recourse to chromatographic purification; further improvement in net yield was realized by processing the mother liquor.

The structure of **2** was corroborated from its elemental composition as well as from its spectral (ir, strong OH and C=O absorption bands; ms, M^{+}, $M - \cdot OH$, $M - Ac\cdot$) behavior, and especially from the ^{1}Hmr data. The complex, poorly resolved spectrum in chloroform-*d* (compare ref. 3) was rendered essentially first order by using benzene-d_6 as the solvent. In particular, the spectrum displayed (Table 1) a noteworthy multiline pattern for H-4 that collapsed to a six-line signal after the hydroxyl proton had been exchanged by deuterium. The physical constants of **2** were in fair agreement with those reported by Overend and co-workers (3) for the same compound obtained by an independent route.

The reactions exhibited by **2** provided additional evidence for the proposed structure. The presence of the carbonyl group was confirmed by the formation of a (2,4-dinitrophenyl)hydrazone (**3**) and by the reduction to the epimeric pentitols (**6** and **8**), discussed in more detail in the next paragraph. Chemical evidence for a free hydroxyl group was obtained by formation of the acetate **4** (as a distillable oil) and the crystalline benzoate **5**, both of which gave (Table 1) well-resolved ^{1}Hmr spectra in chloroform-*d*, in contrast to **2**, as a result of the anticipated downfield shift of the H-4 signal.

Treatment of the *O*-benzylidenepentulose **2** with sodium borohydride led to a semicrystalline product that was shown by tlc analysis to consist of two components (**6** and **8**), which were readily separated, without recourse to chromatography, by exploiting the very low solubility of **8** in cold toluene to isolate crystalline **8**, essentially quantitatively, from syrupy **6**. Conventional acetylation of the latter gave the crystalline diacetate **7**.

Configurational assignment at the newly formed, secondary alcoholic centers in **6** and **8** was accomplished by analysis of the spin-coupling interactions exhibited by H-2 in the ^{1}Hmr spectra of the corresponding 2,4-carbonates **11** and **13**. Carbonates were chosen for the formation of the cyclic derivatives instead of more common protecting groups (such as benzylidene or isopropylidene acetals) to achieve adequately dispersed ^{1}Hmr spectra (Figs. 1 and 2). Inspection of these figures and Table 1 shows that the multiplet attributable to H-2 (readily identified by double irradiation at the position of the methyl resonance) appears at lowest field in both instances, and is well separated from the doubled doublet for H-3. In the spectrum of **11** (Fig. 1), the large $J_{2,3}$ value (9.2 Hz) clearly indicates the *trans*-diaxial disposition of the protons at C-2 and C-3, thereby unequivocally establishing the D-*ribo* stereochemistry for the parent pentitol.

The other product (**13**) must, therefore, be the D-*arabino* isomer. The $J_{2,3}$ value (6.2 Hz) determined from its spectrum (Fig. 2), although still within the usual range (9*a*; for extensive studies on pyranoid sugar systems see ref. 9*b*) for the interaction of axially–equatorially disposed, vicinal protons on a six-membered ring, is somewhat larger than anticipated. This may be explained by the well-known (10) tendency of the chair form of the 1,3-dioxane ring to be additionally puckered in the O—C—O region and at the same time flattened in the C—C—C

region. Such flattening leads to diminution of the H-2e–H-3a torsional angle and, in accordance with the Karplus equation, the $J_{2,3}$ value should consequently be larger.[2]

Further evidence for the configurational assignments made for **6** and **8** was provided by comparing the physical data of the parent pentitols with values for these compounds recorded in the literature. Mild acidic hydrolysis of **6** furnished crystalline 1-deoxy-D-ribitol (5-deoxy-L-ribitol, **12**), mp 69°C and $[\alpha]_D$ +15° in water. This product has been described (11) as having mp 74–75°C and $[\alpha]_D$ +9° in water. The physical characterization of the enantiomer of **12** in the literature is somewhat ambiguous; mp 77–80°C for a product containing solvent of recrystallization, 65–69°C for the solvent-free compound (12), and mp 80–85°C (13) have been reported.

Likewise, acidic hydrolysis of **8** led to the crystalline 1-deoxy-D-arabinitol (5-deoxy-D-lyxitol, **14**) whose physical constants (mp 130°C, $[\alpha]_D$ +1.4° in water) are in excellent agreement with data given in the literature for **14** (14) and (allowing for the sign of the specific rotation) for its enantiomer (14, 15).

The ratio between the products **6** and **8** in the borohydride reduction of **2** was determined by ^{1}Hmr spectroscopy to be 3:4 in favor of the crystalline D-*arabino* isomer **8**. When the benzoate **5** was treated with the same reducing agent, with subsequent debenzoylation, the overall high yielding (91%) sequence gave a slightly higher proportion of **8** (2:1 ratio of **8**:**6**). A noteworthy change in favor of **8** was observed, however, when catalytic hydrogenolysis of the *O*-benzylidenepentulose **2** was attempted under

[2]The same holds true for adjacent diaxial protons (as in **11**), but the respective spin-coupling interaction is not very sensitive to small decreases of this angle (compare ref. 10).

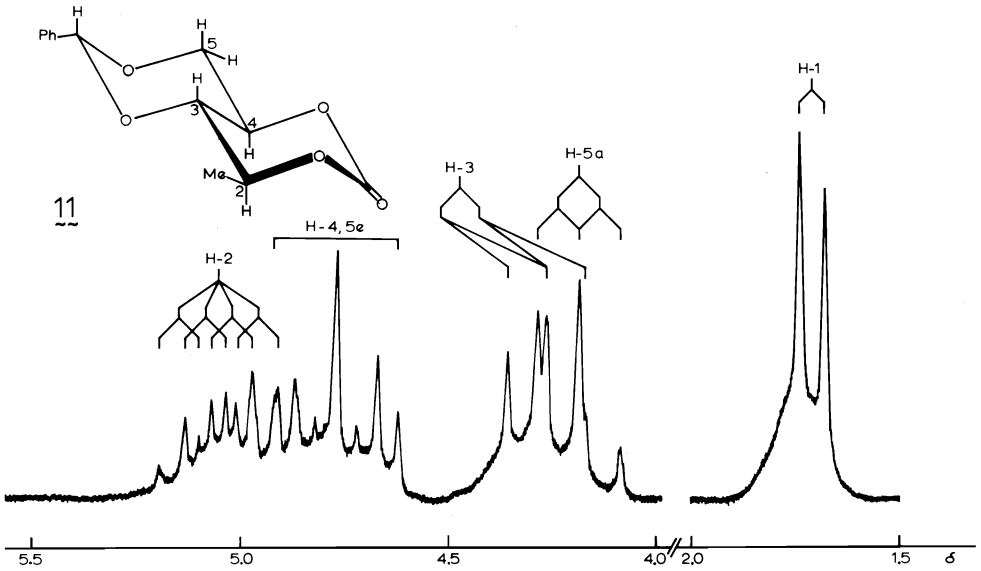

FIG. 1. Partial 100-MHz ^{1}Hmr spectrum of 3,5-*O*-benzylidene-2,4-*O*-carbonyl-1-deoxy-D-ribitol (**11**) in methyl sulfoxide-d_6.

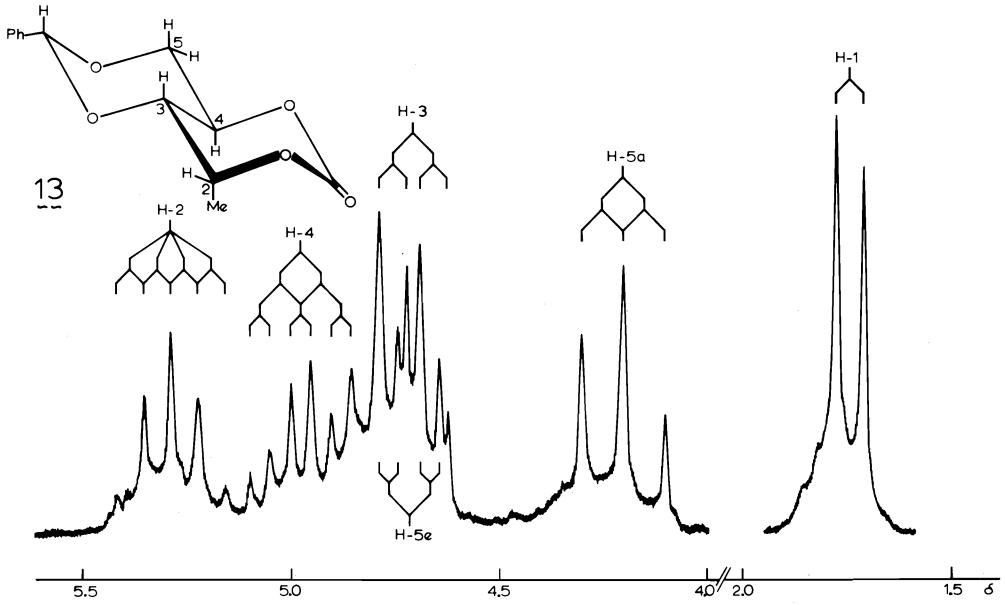

FIG. 2. Partial 100-MHz ^{1}Hmr spectrum of 3,5-*O*-benzylidene-2,4-*O*-carbonyl-1-deoxy-D-arabinitol (**13**) in methyl sulfoxide-d_6.

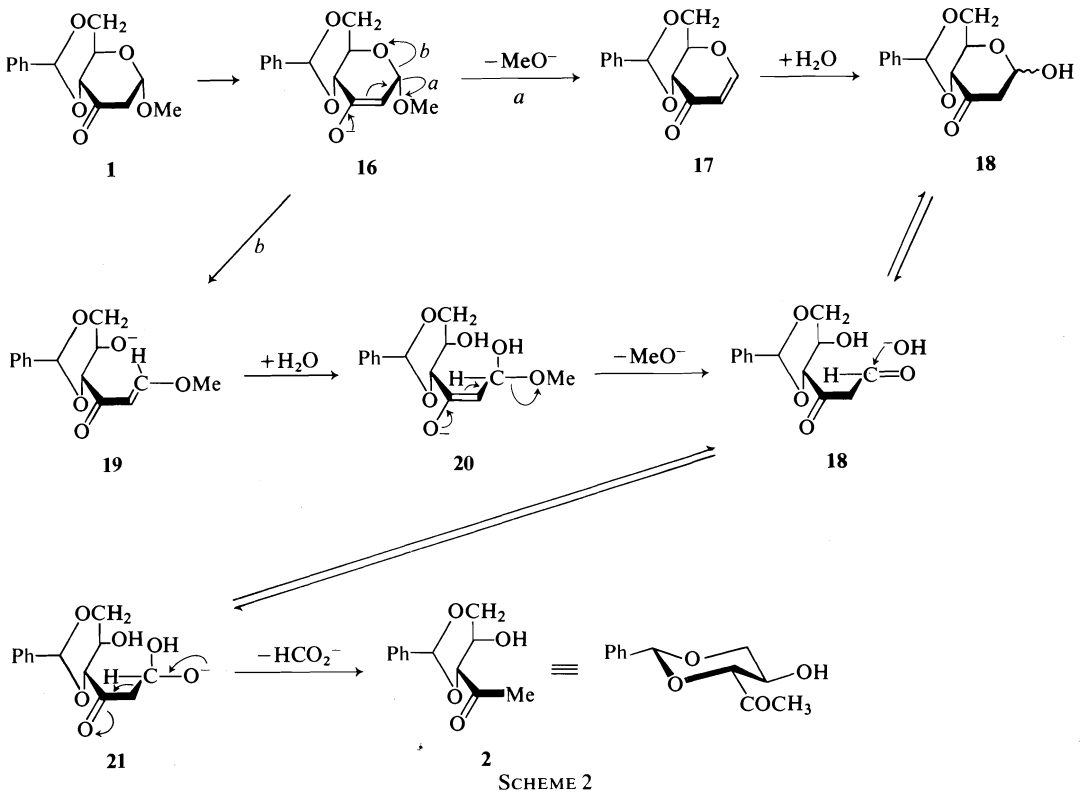
conditions under which the carbonyl function was anticipated to be stable. Originally envisaged for the conversion of **2** into the free ketose **9**, no reaction occurred at all during 24 h under atmospheric pressure, and under more-forcing conditions (1 kg cm^{-2} pressure of hydrogen) scarcely any debenzylidenation took place but, instead, the deoxypentitols **6** and **8** were formed in good net yield, the ratio being 1:5 in favor of **8**.

The conversion of **2** into 1-deoxy-D-*erythro*-2-pentulose (**9**) was achieved by mild acidic hydrolysis. The syrupy ketose **9** was isolated in good yield and was further characterized as its



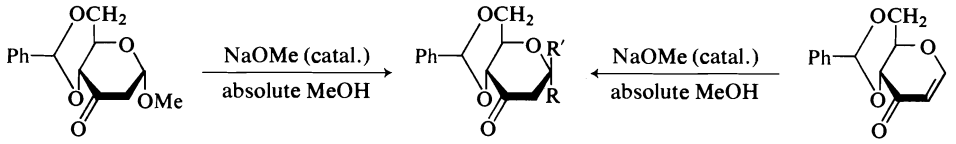
SCHEME 2

(2,4-dinitrophenyl)hydrazone **10**. Compound **9** may be assumed to exist mainly in the open-chain form, as a strong carbonyl-stretching absorption is evident at 1705 cm^{-1} in its ir spectrum. In solution, considerable proportions of the anomeric furanoses coexist with the open-chain form, as manifested by the ^{1}Hmr spectrum in methyl sulfoxide-d_6; the spectrum displayed three signals for the methyl group, having estimated intensities of 1:1:2.

Finally, the pentulose triacetate **15** was prepared, as it was needed as precursor for the dithioacetal of **9** that was required in ongoing studies (for reviews see ref. 16) in this laboratory. Compound **15** was prepared by acetylating **9** with acetic anhydride – zinc chloride and was obtained as a chromatographically homogeneous, colorless syrup that could be distilled *in vacuo*.

A plausible mechanism for the formation of **2** is illustrated in Scheme 2. Under basic conditions the corresponding enolate (**16**) of **1** may eliminate (route *a*) the glycosidic methoxyl group to give the enulose **17**. Hydration of this product and subsequent attack on **18** by hydroxide ion would lead, with elimination of formate, to the pentulose derivative **2**. The reaction does require a stoichiometric amount of base, together with an excess of water, to afford the product. The idea of elimination of the glycosidic group (route *a*) was supported by the fact that **1** anomerizes readily (Scheme 3) under alkaline conditions in anhydrous, methanolic solution, and gives an approximately equimolar ratio of the two anomers **1** and **22**; no degradation product **2** could be detected under these conditions. The β anomer **22** was isolated by column chromatography and was fully characterized.

In a further effort to support the foregoing mechanism, the enulose **17** (17) was prepared. When subjected to alkaline treatment in absolute methanol (Scheme 3), the anomeric glycosides **1** and **22** were indeed formed. However, when treated under the conditions used for the conversion of **1** into **2**, only minor proportions of the degradation product **2** could be detected, together with unchanged **17**, even after an extended period of reaction. This observation parallels a report by Garegg and Norberg (18) on the reaction of methyl 4-*O*-benzyl-2,6-dide-



1 **1** R′ = H; R = OMe; **22** R′ = OMe; R = H; **17**

SCHEME 3

oxy-α-L-*threo*-hexopyranosid-3-ulose with methyllithium, which afforded an enulose analogous to **17**. Obviously, once this product is formed, it is fairly stable, even under the strongly alkaline conditions of the isolation procedure.

Therefore, route *a*, although conceptually appealing, cannot constitute the major avenue for the chain degradation, and an alternative mechanistic course must be available. A proposal is presented in Scheme 2 (route *b*): the enolate **16** may rearrange with cleavage of the C-1–O-5 bond to form the enone **19**. β-Addition of a hydroxyl ion to this product, and subsequent expulsion of the methoxyl group would lead to the glycosulose **18**. This intermediate, common to both possible pathways, would be transformed by the route outlined before, to give **2**. Route *b* is, of course, in accord with the requirements mentioned before (presence of water and a stoichiometric amount of base), but is difficult to prove.

Experimental

General Methods

Evaporations were performed under diminished pressure at a bath temperature below 50°C. Melting points were determined with a Thomas-Hoover apparatus and are uncorrected. A Perkin-Elmer model 141 polarimeter and 1-dm tubes were used for measurement of specific rotations in chloroform, unless otherwise stated. Infrared spectra were recorded on a Perkin-Elmer model 457 grating ir spectrometer with solids dispersed in potassium bromide and syrups as film on sodium chloride discs. The ^{1}Hmr spectra were recorded at 100 MHz with a Varian HA-100 spectrometer; chemical shifts refer to an internal standard of tetramethylsilane (δ = 0.00), and are listed together with first order spin-coupling values (Hz) in Table 1. The assignments were confirmed in most instances by decoupling experiments. Thin layer chromatography was performed on precoated plates of Silica Gel 60 (E. Merck, Darmstadt); zones were detected by uv light and by spraying with sulfuric acid and subsequent heating. Solvent volumes are v/v; petroleum ether refers to the fraction boiling at 65–110°C. Column chromatography was performed with silica gel (Merck No. 7734; 63–200 μm). Microanalyses were performed by W. N. Rond. Mass spectra were recorded by C. R. Weisenberger with an AEI MS-9 double-focusing, high resolution spectrometer operating at an ionizing potential of 70 eV and an accelerating potential of 8 kV; the source temperature (direct-inlet system) was 120°C. Data and probable assignments for compounds **9**, **10**, **12**, **14**, and **15** are summarized in Table 2. The spectra of all benzylidene acetals displayed intense peaks of aromatic ions (*m/e* 107, 106, 105, 91, 79, and 77); the notations h_1 and h_2 in the assignments refer to the *h*-rupture process proposed by Chizhov *et al.* (20). X-ray powder diffraction data give interplanar spacings, Å, for CuKα radiation. The camera diameter was 114.59 mm. Relative intensities were estimated visually: m moderate, s strong, v very, w weak. The strongest lines are numbered (1, strongest); double numbers indicate approximately equal intensities.

*3,5-O-Benzylidene-1-deoxy-keto-*D*-erythro-2-pentulose (2)*

To a suspension of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (1) (**1**, 50 g, 189 mmol) in ether (2 ℓ) was added a solution of lithium hydroxide monohydrate (8 g, 191 mmol) in water (1200 ml) and the mixture was vigorously stirred at ~20°C for 16 h, after which time tlc (4:1 ether – petroleum ether) indicated that all **1** had reacted. The organic layer was separated and the aqueous, yellow phase was extracted with ether. The combined extracts were washed with ice–water and evaporated to give a white, crystalline residue (~28 g). Recrystallization from 10 parts of 1:4 ethyl acetate – petroleum ether afforded the title compound **2** as fine needles; yield 23.2 g (55%), mp 82.5°C, $[\alpha]_D^{23}$ +40.5° (*c* 1) (lit. (3) mp 76.5–78.5°C, $[\alpha]_D$ +38.7° in chloroform); ν_{max}(KBr) 3430 (OH), 1710 cm^{-1} (C=O); *m/e* (rel. intensity) 222 (0.6, M$^{+\cdot}$), 205 (0.7, *M* − •OH), 180 (12, *M* − ketene), 179 (100, M − Ac•), 149 (6, h_2), 107 (100, PhCHOH$^+$; m* at 64.0, calcd. for 179 → 107: 63.96), 106 (50, PhCO$^+$; m* at 75.4, calcd. for 149 → 106: 75.41), 91 (21, PhCH$_2^+$; m* at 46.3, calcd. for 179 → 91: 46.26), 71 (5; m* at 33.8, calcd. for 149 → 71: 33.83), 43 (74, Ac$^+$); X-ray powder diffraction data: 9.25 m (3), 6.06 vw, 5.84 s (1), 5.50 m, 4.47 m, 4.36 s (2), 3.85 m, 3.77 m, 3.66 m, 3.55 m, 3.41 w, 2.59 w and 2.44 vw. *Anal.* calcd. for $C_{12}H_{14}O_4$ (222.24): C 64.85, H 6.35; found: C 64.99, H 6.42.

*3,5-O-Benzylidene-1-deoxy-*D*-erythro-2-pentulose (2,4-Dinitrophenyl)hydrazone (3)*

To a solution of the pentulose derivative **2** (150 mg, 0.68 mmol) in methanol (5 ml) was added (2,4-dinitrophenyl)hydrazine (150 mg, 0.76 mmol) and the mixture was kept for 15 h at ~25°C. The solvent then was distilled off, and the residue triturated with ether. The extract was filtered and evaporated to afford a yellow solid that was shown by tlc (4:1 ether – petroleum ether) to be a mixture of two components. The slower moving, major product was obtained pure by preparative tlc and was recrystallized from ethanol – petroleum ether; yield 120 mg (44%), mp 180°C, $[\alpha]_D^{21}$ +13.1° (*c* 0.4); ν_{max}(KBr)

[a]Prominent metastable fragments observed in the spectra are indicated by an asterisk at the daughter ion of the process involved.
[b]Metastable ions were observed for the following transitions: 61 → 43 (calcd. 30.31/found 30.3); $M^{+\cdot}$ → 74 (60%; 40.87/40.9); 74 → 56 (22%; 42.38/42.4); 91 → 73 (58.56/58.5).
[c]Additional metastable ions were found for the following transitions: 74 (77%) → 56 (73%; 42.38/42.3); 75 → 57 (38%; 43.32/43.3).
[d]Additional metastable ions were recorded for the following transitions: 119 → 60 (11%, 30.25/30.3); 74 (70%) → 56 (67%; 42.38/42.4); 75 → 57 (48%; 43.32/43.3); 137 → 119 (103.36/103.3).
[e]Subsequent fragmentation of *m/e* 217 leads (19) to ions of the *CC series*: 157 (1%, CC_2), 115 (4%, CC_3), and 73 (3.5%, CC_4).

3500 (OH), 3330 (NH), 1625 (C=N), 1600 and 1505 (phenyl), 1525 and 1340 cm^{-1} (NO_2); *m/e* (rel. intensity) 402 (11, $M^{+\cdot}$), 265 (6), 253 (18, h_1), 220 (3, $M - \cdot NHC_6H_3(NO_2)_2$), 205 (9), 183 (9, $(NO_2)_2C_6H_3NH_2^{+\cdot}$), 179 (7, $M - \cdot C(Me)=NNHC_6H_3(NO_2)_2$), 163 (19), 150 (12), 149 (100, h_2), 117 (11), and 43 (34); X-ray powder diffraction data: 11.04 m (3), 9.02 w, 7.34 w, 6.91 m, 6.48 s (2), 5.50 m, 4.96 m, 4.58 w, 4.27 m, 3.87 w, 3.55 m (4), and 3.41 vs (1). *Anal.* calcd. for $C_{18}H_{18}N_4O_7$ (402.37): C 53.73, H 4.51, N 13.92; found: C 53.54, H 4.72, N 13.93.

4-O-Acetyl-3,5-O-benzylidene-1-deoxy-D-*erythro-2-pentulose (4)*

The pentulose derivative **2** (300 mg, 1.35 mmol) was treated with 1:2 acetic anhydride – pyridine (6 ml) for 18 h at ~25°C. Methanol (5 ml) was then added with cooling and, after 1 h, the mixture was evaporated. Pyridine and then toluene (two 10 ml portions each) were added to and evaporated from the residue to afford syrupy **4** in theoretical yield (360 mg). To secure an analytical sample, a portion was distilled under diminished pressure (5 mTorr, bath temperature ~150°C); $[\alpha]_D^{23}$ +26.6° (*c* 1); ν_{max}(film) 1750 (ester C=O) and 1730 cm^{-1} (C=O); *m/e* (rel. intensity) 264 (0.1, $M^{+\cdot}$), 221 (24, $M - Ac\cdot$), 204 (0.3, $M - HOAc$), 149 (2.4, h_2), 115 (100, 221 − PhCHO; m* at 59.9, calcd. 59.84), 43 (80, Ac^+; m* at 16.1, calcd. for 115 → 43: 16.08). *Anal.* calcd. for $C_{14}H_{16}O_5$ (264.28): C 63.63, H 6.10; found: C 63.74, H 6.21.

4-O-Benzoyl-3,5-O-benzylidene-1-deoxy-D-*erythro-2-pentulose (5)*

To a mixture of the pentulose derivative **2** (6.0 g, 27 mmol) in pyridine (30 ml) was added benzoyl chloride (5 ml, 43.3 mmol). After 18 h at ~25°C, the mixture was poured into ice–water (500 ml) saturated with potassium carbonate. The crystalline precipitate was collected, washed with water, dried, and recrystallized from ether (or ethyl acetate) – petroleum ether to give pure **5**; yield 7.98 g (91%); mp 95–96°C, $[\alpha]_D^{22}$ −23.1° (*c* 1); ν_{max}(KBr) 1730 (ester C=O), 1715 (C=O), 1600 and 1580 cm^{-1} (monosubstituted phenyl); *m/e* (rel. intensity) 326 (0.3, $M^{+\cdot}$), 283 (22, $M - Ac\cdot$), 221 (0.1, $M - PhCO\cdot$), 220

(0.1, M − PhCHO), 204 (0.7, M − $PhCO_2H$), 178 (17, 283 − PhCO•), 177 (100, 283 − PhCHO; m* at 110.7, calcd. 110.70), 149 (5, h_2), 122 (6, $PhCO_2H^{+\cdot}$), 105 (89, $PhCO^+$; m* at 90.3, 62.3, and 33.8, calcd. for 122 → 105: 90.37, for 177 → 105: 62.29, and for 326 → 105: 33.82), 43 (22, Ac^+); X-ray powder diffraction data: 11.78 s (3), 9.66 w, 8.07 vw, 7.62 vw, 7.10 m, 5.60 m, 5.26 m, 5.01 m, 4.79 m, 4.54 s (2), 4.34 vw, 4.18 w, 3.79 s (1), 3.61 w, 3.43 vw, 3.15 vw, and 3.04 m. *Anal.* calcd. for $C_{19}H_{18}O_5$ (326.35): C 69.93, H 5.56; found: C 70.14, H 5.70.

*3,5-O-Benzylidene-1-deoxy-*D*-ribitol (**6**) and its* D*-Arabino Analog **8***

*From **2** with Sodium Borohydride*

Sodium borohydride (1.7 g, 44.9 mmol) was added to a cooled (0°C) solution of the pentulose derivative **2** (4 g, 18 mmol) in aqueous methanol (95%, 60 ml) and the mixture was kept for 18 h at ~25°C. Methanol was then distilled off and the residue was dissolved in dichloromethane (150 ml) and washed with water. The aqueous phase was extracted again with dichloromethane, and the combined organic solutions were dried (magnesium sulfate) and evaporated. The resultant, semicrystalline residue (3.46 g, 86%) was shown by ^{1}Hmr spectroscopy to be a 3:4 mixture of **6** and **8**. Recrystallization from toluene (90 ml) afforded the pure D-*arabino* isomer **8** as light, fluffy crystals; yield 1.97 g (49%); mp 138–139°C, $[\alpha]_D^{21}$ −17.3° (*c* 1); R_F 0.17 (ether); *m/e* (rel. intensity) 224 (12, $M^{+\cdot}$), 180/179 (9/36, M − $CH_3CHO\bullet$/$CH_3CH(OH)\bullet$; m* at 144.6/143.0, calcd. 144.65/143.04), 162 (0.9, 180 − H_2O/179 − •OH), 119 (1.5, M − PhCO•), 108 (18, $PhCH_2OH^{+\cdot}$; m* at 64.8, calcd. for 180 → 108: 64.80), 107 (100, $PhCHOH^+$; m* at 64.0, calcd. for 179 → 107; 63.96), 91 (14, $PhCH_2^+$; m* at 46.3, calcd. for 179 → 91: 46.26), 73 (9, $\overset{1}{CH_3}—\overset{2}{CH(OH)}—\overset{3}{CO^+}$), 45 (16), 44 (9), 43 (25); X-ray powder diffraction data: 10.77 w, 9.06 w, 6.73 s (2), 6.28 s (1), 5.43 m, 4.55 m, 4.21 s, 4.04 m, 3.78 s (3), 3.59 s, and 3.28 s. *Anal.* calcd. for $C_{12}H_{16}O_4$ (224.26): C 64.27, H 7.19; found: C 64.05, H 7.04.

Evaporation of the mother liquor after separation of **8** gave the D-*ribo* isomer **6** as an essentially pure syrup that solidified to an opaque glass after keeping for several days *in vacuo* over paraffin; yield 1.49 g (37%). For analytical purposes, a sample was further purified by column chromatography on silica gel with ether as eluant: $[\alpha]_D^{21}$ −28.6° (*c* 1.8); R_F 0.26 (ether); *m/e* (rel. intensity) 224 (20, $M^{+\cdot}$), 181/180/179 (4.6/10.5/3.7, M − Ac•/$CH_3CHO\bullet$/$CH_3CH(OH)\bullet$; m* at 146.2/144.7/143.0, calcd. 146.25/144.65/143.04), 162 (1, 180 − H_2O/179 − •OH), 119 (1.3, M − PhCO•; m* at 63.3, calcd. 63.22), 108 (12.2, $PhCH_2OH^{+\cdot}$; m* at 64.8, calcd. for 180 → 108: 64.80), 107 (100, $PhCHOH^+$; m* at 64.0, calcd. for 179 → 107: 63.96), 91 (7.8, $PhCH_2^+$; m* at 46.3, calcd. for 179 → 91: 46.26), 73 (5, $\overset{1}{CH_3}—\overset{2}{CH(OH)}—\overset{3}{CO^+}$), 45 (8), 43 (9). *Anal.* calcd. for $C_{12}H_{16}O_4$ (224.26): C 64.27, H 7.19; found: C 64.26, H 6.99.

*From **2** by Catalytic Hydrogenation*

The pentulose derivative **2** (2 g, 90 mmol) in methanol (40 ml) was hydrogenated under pressure (1 kg cm^{-2}) in the presence of 5% palladium-on-charcoal (200 mg). After 20 h, tlc (ether or 2:3 benzene–acetone) revealed that scarcely any debenzylidenation had occurred, but that the epimeric deoxypentitols **6** and **8** had been formed instead. The catalyst was filtered off and the filtrate evaporated. The resulting residue was dissolved in chloroform and the solution processed as described in the preceding section to afford a 1:5 mixture (as estimated from ^{1}Hmr data) of compounds **6** and **8**, identical with the products isolated by the first procedure; yield 1.52 g (75%).

*From **5** with Sodium Borohydride*

A cooled (−15°C) solution of sodium borohydride (2 g, 52.8 mmol) in 9:1 methanol–water (40 ml) was added to a cooled solution of the benzoate **5** (7.9 g, 24.5 mmol) in a mixture of methanol (150 ml) and ethyl acetate (50 ml). The solution was kept for 3 h at −15°C, water (100 ml) was then added, and the organic solvent was distilled off. To the remaining turbid, aqueous phase was added a 4 *M* solution of potassium hydroxide in 2:3 water–methanol (50 ml). After 4 h at ~20°C, water (100 ml) and acetic acid (10 ml) were added and the product was extracted with chloroform. Processing as described in the previous sections gave a 1:2 mixture (as judged from ^{1}Hmr data) of the epimers **6** and **8**, yield 5 g (91%). Fractional crystallization afforded the pure, crystalline *arabino* derivative **8** (3.17 g, 58%) and the syrupy *ribo* analog **6** (1.7 g, 31%); both products were indistinguishable from those prepared by the previous procedures.

*2,4-Di-O-acetyl-3,5-O-benzylidene-1-deoxy-*D*-ribitol (**7**)*

The benzylidene acetal **6** (400 mg, 1.78 mmol) was treated with 1:2 acetic anhydride – pyridine (9 ml) for 18 h at ~25°C. After conventional processing, the crystalline product (480 mg, 88%) was recrystallized from hexane: mp 62–63°C, $[\alpha]_D^{21}$ −72.7° (*c* 1.1); ν_{max}(KBr) 1725 (C═O), 745 and 695 cm^{-1} (aryl); *m/e* (rel. intensity) 308 (3.7, $M^{+\cdot}$), 265 (0.3, M − Ac•), 248 (1.2, M − HOAc), 231 (0.4, M − Ph•), 221 [4.5, M − •$CH(CH_3)$-OAc], 205 (0.3, M − HOAc − Ac•), 203 (0.25, M − PhCO•), 186 (1.9, M − $PhCO_2H$), 149 (6.7, h_2), 142 (10, M − PhCHO − HOAc), 115 (55, $OCH—\overset{+}{(CH_3)C}═OAc$), 43 (100, Ac^+); X-ray powder diffraction data: 9.30 s, 7.79 s, 6.30 s (3), 5.11 w, 4.94 m, 4.41 m, 4.29 vs (1), 4.17 w, 3.98 vs (2), 3.57 m, and 3.45 w. *Anal.* calcd. for $C_{16}H_{20}O_6$ (308.33): C 62.33, H 6.54; found: C 62.18, H 6.45.

*1-Deoxy-*D*-erythro-pentulose (**9**)*

A solution of the pentulose derivative **2** (4 g, 18 mmol) in acetic acid (30 ml) and water (70 ml) was heated for 1 h on a water bath whereupon tlc (2:3 benzene–acetone) indicated that deacetalation was complete. The solution was concentrated and small portions of toluene and then 2-propanol were repeatedly distilled from the residue. A solution of the remaining, yellow syrup in water (50 ml) was extracted with ether, and then lyophilized, to give **9** as a chromatographically homogeneous, colorless syrup; yield 1.76 g (73%), $[\alpha]_D^{21}$ −37° (equil., *c* 1.3, water); ν_{max}(film) 3500–3200 (OH), 1705 cm^{-1} (C═O); for ms data see Table 2; ^{1}Hmr (methyl sulfoxide-d_6; hydroxyl protons exchanged by deuterium) δ 4.60–3.70 (4 H, complex m, H-3,4,5,5′), 2.59, 2.57, 2.55 (total integrated peak area 3 h, 3 s, estimated ratio 1:1:2, H-1). *Anal.* calcd. for $C_5H_{10}O_4$ (134.13): C 44.77, H 7.51; found: C 44.64, H 7.19.

After being kept for several days, the product turned yellow, and fast-moving, uv light-absorbing compounds could be detected by tlc.

1-Deoxy-D-erythro-pentulose (2,4-Dinitrophenyl)hydrazone (10)

A mixture of the pentulose **9** (1.1 g, 8.2 mmol) and (2,4-dinitrophenyl)hydrazine (2 g, 10.1 mmol) in aqueous ethanol (95%, 50 ml) was heated for 6 h on a water bath. Thin layer chromatography (2:3 benzene–acetone) of the residue obtained after evaporation of the solvent revealed the presence of two products (R_F 0.30 and 0.36) as well as unchanged reagent that was present in excess. Column chromatography on silica gel, with 1:1 benzene–acetone as eluant, furnished the slower-moving, major product **10**; yield 1.47 g (57%). After recrystallization from ethyl acetate it had mp 116–118°C, $[\alpha]_D^{21}$ −53.7° (*c* 0.3, acetone); ν_{max}(KBr) 3500–3300 (OH, NH), 1615 (C=N), 1595 and 1500 (phenyl), 1515 and 1340 cm^{-1} (NO_2); for ms data, see Table 2; X-ray powder diffraction data: 11.94 vw, 10.39 w, 7.08 m, 5.88 m, 5.01 w, 4.56 m, 4.27 s (2), 3.95 m, and 3.63 s (1). *Anal.* calcd. for $C_{11}H_{14}N_4O_7$ (314.26): C 42.04, H 4.49, N 17.83; found: C 42.03, H 4.62, N 17.60.

3,5-O-Benzylidene-2,4-O-carbonyl-1-deoxy-D-ribitol (11)

To a cooled (0°C) solution of the pentitol derivative **6** (450 mg, 2 mmol) in pyridine (20 ml) was added a solution of phosgene in benzene (12.5%, w/v, 10 ml, 12.6 mmol). After 1 h at ~25°C the excess of phosgene was decomposed by adding a saturated solution of sodium hydrogen carbonate (100 ml), and the mixture was extracted with dichloromethane. Evaporation of the dried (magnesium sulfate) extract and removal of residual pyridine by evaporating a little toluene from the residue gave crystalline **11**; yield 490 mg (98%). After recrystallization from ethanol, it had mp 181–183°C, $[\alpha]_D^{21}$ +5.3° (*c* 0.8); ν_{max}(KBr) 1750 (C=O), 750 and 700 cm^{-1} (aryl); *m/e* (rel. intensity) 250 (63, M$^{+\cdot}$), 251/249 (6/16, *M* ± 1), 206 (3.3, *M* − CO_2; m* at 169.8, calcd. 169.74), 191 (1.1, 206 − Me•), 173 (1.2, *M* − Ph•), 163 (1.4, 206 − Ac•), 149 (1.6, h_2), 145 (3.8, *M* − PhCO•), 144 (15, *M* − PhCHO), 134 (1.5, *M* − CO_2 − Ac• − CHO•; m* at 71.8, calcd. 71.82), 115 (1, 145 − CH_2O) 105 (100, PhCO$^+$; m* at 44.1, calcd. for 250 → 105: 44.10), 71 (11.5, 115 − CO_2), 57 (57, $\overset{3}{O}CH—\overset{2}{C}H—\overset{1}{C}H_3]^+$), 43 (16, Ac$^+$); X-ray powder diffraction data: 7.13 m, 6.10 s (2), 5.08 s (3, 3), 4.64 s (3, 3), 3.81 w, 3.60 s (1), 3.22 w, and 3.07 w. *Anal.* calcd. for $C_{13}H_{14}O_5$ (250.23): C 62.39, H 5.64; found: C 62.28, H 5.58.

1-Deoxy-D-ribitol (5-Deoxy-L-ribitol, 12)

A solution of the benzylidene acetal **6** (1.7 g, 7.6 mmol) in acetic acid (15 ml) and water (35 ml) was heated for 90 min on a water bath. The solvent then was evaporated off and 1-propanol (three 10 ml portions) was added to and distilled from the residue to remove last traces of benzaldehyde. The resulting white solid was recrystallized from acetonitrile (15 ml) to afford **12**; yield 880 mg (85%), mp 69°C, $[\alpha]_D^{21}$ +15° (*c* 0.9, water) and +11.8° (*c* 1, methanol); R_F 0.35 (3.17 methanol–ether); for ms data, see Table 2; X-ray powder diffraction data: 10.39 vs (2, 2), 8.00 vs (2, 2), 6.73 vw, 6.19 vw, 5.12 w, 4.95 s, 4.61 w, 4.35 w, 4.12 m, 3.93 vs (1), and 3.78 m. *Anal.* calcd. for $C_5H_{12}O_4$ (136.15): C 44.11, H 8.88; found: C 44.10, H 8.69.

For this compound, Foster and co-workers (11) reported mp 74–75°C, $[\alpha]_D$ +9° in water; the enantiomorph of **12** has been reported (12) to have mp 77–80°C (for a product containing solvent of recrystallization) and 65–69°C (solvent-free), $[\alpha]_D$ −10.6° in water, and (13) mp 80–85°C, $[\alpha]_D$ −11.2° in methanol.

3,5-O-Benzylidene-2,4-O-carbonyl-1-deoxy-D-arabinitol (13)

Treatment of the benzylidene acetal **8** (500 mg, 2.2 mmol) in pyridine (20 ml) with phosgene (12.5% w/v solution in benzene, 12 ml, 15.2 mmol) afforded, after processing as described for **11**, crude, crystalline **13**; yield 540 mg (97%). After recrystallization from ethanol, it had mp 158–159°C, $[\alpha]_D^{21}$ +99.7° (*c* 0.7); ν_{max}(KBr) 1750 (C=O), 748 and 700 cm^{-1} (aryl); *m/e* (rel. intensity) 250 (39, M$^{+\cdot}$), 251/249 (55/15, *M* ± 1), 206 (5, *M* − CO_2), 191 (1.4, 206 − Me•), 173 (1.1, *M* − Ph•), 163 (1, 206 − Ac•), 149 (2, h_2), 145 (5.7, *M* − PhCO•; m* at 84.1, calcd. 84.10), 144 (18, *M* − PhCHO), 134 (6, *M* − CO_2 − Ac• − CHO•; m* at 71.9, calcd. 71.82), 115 (2.7, 145 − CH_2O), 71 (7, 115 − CO_2) 57 (12, $\overset{3}{O}CH—\overset{2}{C}H—\overset{1}{C}H_3]^+$), 43 (20, Ac$^+$); X-ray powder diffraction data: 7.19 m, 6.10 m, 5.15 s (3), 4.68 s (2), 3.82 vw, 3.70 s (1), and 3.16 m. *Anal.* calcd. for $C_{13}H_{14}O_5$ (250.25): C 62.39, H 5.64; found: C 62.11, H 5.44.

1-Deoxy-D-arabinitol (5-Deoxy-D-lyxitol, 14)

The benzylidene acetal **8** (2.8 g, 12.5 mmol) was hydrolyzed in the way already described for the *ribo* analog **6**. Recrystallization from ethanol gave **14** as white crystals; yield 1.48 g (87%), mp 130°C, $[\alpha]_D^{21}$ +1.4° (*c* 1.2, water) and −0.6° (*c* 2.3, methanol); R_F 0.25 (3.17 methanol–ether); for ms data, see Table 2; X-ray powder diffraction data: 7.16 vs (1), 6.58 vw, 4.82 vs (2), 4.63 vs (3), 4.15 vw, 3.86 m, 3.55 m, 3.33 vw, 3.27 vw. 3.10 vw, 2.92 m, 2.74 m, and 2.49 m. *Anal.* calcd. for $C_5H_{12}O_4$ (136.15): C 44.11, H 8.88; found: C 44.41, H 8.71.

For this compound, Bollenback and Underkofler (14) found 131–132°C, $[\alpha]_D$ +2.46° in water, and, for the enantiomorph, mp 129–131°C, $[\alpha]_D$ −1.46° in water; for the latter the mp 131–133°C has also been reported (15).

3,4,5-Tri-O-acetyl-1-deoxy-keto-D-erythro-pentulose (15)

A mixture of the pentulose **9** (2.1 g, 15.7 mmol) and powdered, anhydrous zinc chloride (500 mg) in acetic anhydride (50 ml) was kept for 18 h at 0°C. After a further 15 h at ~20°C, the mixture was poured into ice-water (250 ml) saturated with sodium hydrogencarbonate. The product was extracted with dichloromethane (three 50 ml portions), the extract washed with aqueous sodium hydrogencarbonate, dried (magnesium sulfate), and evaporated. Pyridine and toluene (two 10 ml portions each) were successively added to and evaporated from the residue to give crude **15** as a pale yellow syrup; yield 3 g (74%). To secure an analytical sample, a portion was distilled under diminished pressure (0.05 Torr, bath temperature ~120°C); $[\alpha]_D^{21}$ −8° (*c* 2.3); ν_{max}(film) 1740 cm^{-1} (C=O); for ms data, see Table 2. *Anal.* calcd. for $C_{11}H_{16}O_7$ (260.25): C 50.77, H 6.20; found: C 51.09, H 6.15.

Treatment of Methyl 4,6-O-Benzylidene-2-deoxy-α-D-erythro-hexopyranosid-3-ulose (1) with Base under Anhydrous Conditions

To the glycoside **1** (400 mg, 1.5 mmol), dissolved in absolute tetrahydrofuran (10 ml), was added 30 m*M* sodium methoxide (5 ml) and the solution was kept at ~25°C for 24 h, whereupon tlc (4:1 ether – petroleum ether) revealed the presence of another product (R_F 0.38) accompanying **1** (R_F 0.27) in the mixture. The solution was poured with vigorous mechanical stirring into ice–water (100 ml) containing ammonium chloride (5 g). Extraction with dichloromethane (two 40 ml portions) and evaporation of the dried (magnesium sulfate) extract furnished a crystalline residue (340 mg, 85%) that was shown by ^{1}Hmr to be a 1:1 mixture of the anomeric methyl hexulosides **1** and **22**. Separation was effected by column chromatography on silica gel using the tlc solvent as eluant. The component having R_F 0.38 crystallized upon evaporation of the solvent and was recrystallized from ethanol to give pure *methyl 4,6-O-benzylidene-2-deoxy-β-D-erythro-hexopyranosid-3-ulose* (**22**); mp 194–195°C, $[\alpha]_D^{21}$ −51.3° (*c* 0.8); ν_{max}(KBr) 1725 (C=O), 750 and 690 cm^{-1} (aryl); *m/e* (rel. intensity) 264 (3, M$^+$), 233/232 (1.2/2.2, *M* − MeO•/MeOH), 204 (2, *M* − HCO_2Me), 190 (4.5, 232 − ketene; m* at 155.6, calcd. 155.60), 177 (19, *M* − OCH—CH_2—HC—OMe; m* at 118.7, calcd. 118.67), 161 (3, 204 − Ac•), 149 (100, h_2; m* at 84.1, calcd. 84.09), 145 (12), 129 (18, *M* − PhCO• − CH_2O), 115 (18, h_1), 97 (11), 87 (76, h_1 − CO), 59 (43, 87 − CO; m* at 40.0, calcd. 40.01), 58 (82), 43 (21, Ac$^+$); ^{1}Hmr (chloroform-*d*) δ 7.64–7.28 m (5 H; m, aryl), 5.56 (1 H, s, PhC*H*), 4.75 (1 H, dd, $J_{1,2a}$ 7.6 Hz, H-1), 4.45 (1 H, dd, $J_{5,6}$ 4.3 Hz, H-6), 4.32 (1 H, d, $J_{4,5}$ 9.4 Hz, H-4), 3.89 (1 H, t, $J_{6,6'}$ 10 Hz, H-6′), 3.68 (1 H, dt, $J_{5,6'}$ 10 Hz, H-5), 3.51 (3 H, s, OMe), 2.84 (1 H, dd, $J_{1,2e}$ 3.7 Hz, H-2e), 2.64 (1 H, dd, $J_{2e,2a}$ 15 Hz, H-2a); X-ray powder diffraction data: 11.86 w, 10.52 m, 8.54 s (3), 7.79 w, 6.13 s (2), 4.82 w, 4.38 m, 4.18 m, 3.97 s (1), 3.89 m, 3.73 m, 3.59 m, 3.25 m, and 3.07 w. *Anal.* calcd. for $C_{14}H_{16}O_5$ (264.28): C 63.63, H 6.10; found: C 63.56, H 6.06.

The second fraction (R_F 0.27) was indistinguishable (by mixture mp and spectroscopic data) from the starting material **1**.

1,5-Anhydro-4,6-O-benzylidene-2-deoxy-D-erythro-hex-1-eno-3-ulose (17)

1,5-Anhydro-4,6-*O*-benzylidene-2-deoxy-D-*ribo*-hex-1-enitol (4,6-*O*-benzylidene-D-allal, 780 mg, 3.3 mmol) (21) was oxidized with the chromium trioxide – dipyridine complex as described by Collins (17) to afford the title compound **17**; yield 520 mg (67%). After recrystallization from 2-propanol, **17** was obtained as white, cottonlike crystals: mp 128–129°C, $[\alpha]_D^{21}$ +170° (*c* 0.8) (lit. (17) mp 128–129°C, $[\alpha]_D$ +189° in chloroform); ν_{max}(KBr) 1685 and 1590 (C=C—C=O), 750 and 695 cm^{-1} (aryl); *m/e* (rel. intensity) 232 (5, M$^+$), 204 (4.5, *M* − CO), 190 (3.3, *M* − ketene), 162 (3.6, *M* − CO − ketene), 160 (1, 204 − CH_3CHO; m* at 125.5, calcd. 125.49), 145 (15, 162 − •OH; m* at 110.7, calcd. for 190 → 145: 110.66), 105 (100, PhCO$^+$; m* at 68.1, calcd. for 162 → 105: 68.06), 97 (20, O(CH=CH)$_2$C=OH$^+$), 71 (23, OCH—CH_2—CO$^+$); ^{1}Hmr (chloroform-*d*) δ 7.60–7.25 (5 H, m, aryl), 7.19 (1 H, d, $J_{1,2}$ 5.9 Hz, H-1), 5.52 (1 H, s, PhC*H*), 5.37 (1 H, d, H-2), 4.50–3.80 (4 H, m, H-4,5,-6,6′); X-ray powder diffraction data: 10.27 s, 5.82 s, 5.57 s, 5.14 m, 4.95 w, 4.68 w, 4.50 s, 4.20 vs (1), 2.83 s, 3.60 s (3), and 3.48 vs (2). *Anal.* calcd. for $C_{13}H_{12}O_4$ (232.24): C 67.23, H 5.21; found: C 67.18, H 5.42.

When the glycenulose **17** was treated with catalytic amounts of sodium methoxide in absolute methanol – tetrahydrofuran, approximately equal amounts of the anomers **1** and **22** were formed (detected by tlc).

For the attempted conversion into **2**, a mixture of the enulose **17** (200 mg, 0.86 mmol), dissolved in ether (20 ml), was shaken with 100 m*M* aqueous solution of lithium hydroxide (10 ml) for 48 h at ~20°C. Thin layer chromatography (4:1 ether – petroleum ether) of the ethereal phase then revealed that unchanged **17** (R_F 0.29) was mostly still present, together with small amounts of the pentulose derivative **2** (R_F 0.36; estimated yield 10%) and minor, unidentified side-products

CHI-KIT WAT, A. GAVIN MCINNES, DONALD G. SMITH, JEFFREY L. C. WRIGHT, and LEO C. VINING. Can. J. Chem. **55**, 4090 (1977).

Tenellin and bassianin are deduced from chemical and spectroscopic evidence to be the 3-[(*E*,*E*)-4,6-dimethylocta-2,4-dienoyl] and 3-[(*E*,*E*,*E*)-6,8-dimethyldeca-2,4,6-trienoyl] derivatives of 1,4-dihydroxy-5-(*p*-hydroxyphenyl)-2(1*H*)-pyridone. Spin–spin coupling information in the ^{1}H and ^{13}C nuclear magnetic resonance spectra after biosynthetic enrichment of tenellin with ^{13}C and ^{15}N isotopes was a valuable aid in elucidating the structure.

CHI-KIT WAT, A. GAVIN MCINNES, DONALD G. SMITH, JEFFREY L. C. WRIGHT et LEO C. VINING. Can. J. Chem. **55**, 4090 (1977).

A partir des indications chimiques et spectroscopiques, il apparait que la ténelline et la bassianine sont les dérivés [(*E*,*E*) diméthyl-4,6 octadiène-2,4 oyl]-3 et [(*E*,*E*,*E*) diméthyl-6,8 décatriène-2,4,6 oyl]-3 de la dihydroxy-1,4 (*p*-hydroxyphényl)-5 (1*H*)-pyridone-2. L'information sur le couplage spin–spin tirée des spectres de résonance magnétique nucléaire du ^{1}H et ^{13}C de la ténelline par un enrichissement biosynthétique préalable en isotopes ^{13}C et ^{15}N est d'un grand intérêt dans l'élucidation de la structure.

Introduction

Cultures of the insect pathogenic fungi *Beauveria bassiana* (Bals.) Vuill. and *B. tenella* (Delacroix) Siem. often develop a yellow color which is due to the formation of a mixture of related pigments (1, 2). Two of these substances, tenellin (**1**) and bassianin (**8**), have been isolated; their structures were reported in a preliminary communication (3) and we present here the evidence that establishes them as members of a new group of fungal biochromes. A related compound, ilicicolin H, has recently been isolated as an antifungal antibiotic from the imperfect fungus *Cylindrocladium ilicicola* (4).

Results and Discussion

Molecular formulae for tenellin, $C_{21}H_{23}NO_5$, and bassianin, $C_{23}H_{25}NO_5$, were determined by elemental analyses and high resolution mass spectroscopy. A terminal *sec*-butyl substituent in **1** was indicated by characteristic signals in the ^{1}Hmr spectrum (Table 1), and confirmed by double resonance experiments (vicinal coupling of H-13 to H-12 and H-14, and of H-12 to H-15). The chemical shift of the methine hydrogen H-12, and its vicinal coupling to an olefinic hydrogen H-11, required the *sec*-butyl group to be attached to a double bond. Double resonance studies also showed H-11 to be long-range coupled to the hydrogens (H-16) of a vinylic methyl group, and to one (H-9) of a pair of vinylic protons (H-8, H-9) which were *trans* vicinally coupled, and gave an AB sub-spectrum. Thus tenellin possesses an (*E*,?)-3,5-dimethyl-1,3-heptadienyl residue.

Since the ^{1}H and ^{13}C nmr spectra of **1** and its methylated derivative **2** were essentially indistinguishable, except for differences associated with replacement of a hydroxyl by a methoxyl substituent (Tables 1 and 2), the structural, stereochemical, and conformational features of **1** must be retained in **2**. Consequently a complete description of the stereochemistry of double bonds in the alkenyl substituent obtained by a nuclear Overhauser enhancement (nOe) study on **2** applies equally to **1**. The nOe measurements for **2** (irradiated proton(s) in parentheses) gave H-9 (H-11) 22%, H-8 (H-16) 20%, H-8 (H-11)

*Chemical shifts are given in ppm relative to tetramethylsilane (average value for complex multiplets). Coupling constants (J) and shift differences ($\Delta\nu_{AB}$) are given in Hz. Multiplicities are denoted by b = broad, d = doublet, m = multiplet, s = singlet, t = triplet. Spectra for compounds **1–4** were recorded in dimethylsulfoxide-d_6, and for **5–8** in tetrahydrofuran-d_8.

†These four protons formed an AA′BB′ system typical of a *para*-disubstituted benzene ring. $N = J_{AB} + J_{AB'}$, with $J_{AB'}$ probably < 0.5 Hz (5).

‡The hydroxy proton signals (R_2 in **5**, and R_1, R_2 in **6**) were too broad to detect.

TABLE 2. ^{13}C chemical shifts (δ_c TMS) and ^{13}C—^{1}H coupling constants (^nJ Hz) for tennelin (**1**), its mono-, di-, and trimethyl ethers (**2**, **3**, **4**), and bassianin (**8**)†

*Values may be interchanged. Multiplets were not resolved in the high resolution spectrum.

†Pulse Fourier transform spectra recorded at 30°C on 0.3–0.4 *M* solutions in dimethylsulfoxide-d_6 at 25.16 MHz, acquisition time 0.8 s, data accuracy ±0.6 Hz, spectra width 5120 Hz, flip angle 40°, internal ^2H pulse lock to solvent, proton noise decoupling $\gamma H_2/2\pi$, ca. 3800 Hz. Multiplicities (high resolution spectra) are denoted by b = broad, d = doublet, m = multiplet, q = quartet, s = singlet, t = triplet. Multiplet signals from carbons 12 through 16 in the high resolution spectra of **2**, **3**, **4**, and carbons 14 through 18 in **8** were not resolved sufficiently to estimate coupling constants to ±0.6 Hz. Separations were in the range of 126 ± 2 Hz. Values for carbons which are shown as approximations are probably within ±1 Hz. ^{13}C—H couplings in 2(1*H*)-pyridone involving H-6 were $^2J_{5,6}$ 3.3; $^3J_{2,6}$ 7.5; $^3J_{4,6}$ 8.6 Hz (11).

0%, and H-9 (H-16) 0%, establishing the presence of an (*E,E*)-3,5-dimethyl-1,3-heptadienyl unit.

Pulse Fourier transform ^{13}C nmr studies provided further structural information. The ^{13}C spectral data were obtained from proton noise decoupled (pnd) and high resolution (hr) spectra; assignment of resonances arising from carbons bonded to hydrogen were aided by off-resonance decoupling (ord) experiments which permitted the ^{1}H and ^{13}C spectra to be correlated (6). In some cases isotopic labelling with ^{13}C facilitated assignments. Thus splitting of resonances due to ^{13}C–^{13}C spin–spin coupling ($^{1}J_{CC}$) in the pnd ^{13}C spectrum of **1** enriched with [1,2-^{13}C]acetate (90% ^{13}C) showed that five pairs of carbons had been incorporated as intact two carbon units. Four of these pairs were C-7,C-8 ($^{1}J_{CC}$ 55.9 Hz); C-9,C-10 ($^{1}J_{CC}$ 53.6 Hz); C-11,C-12 ($^{1}J_{CC}$ 43.2 Hz); and C-13,C-14 ($^{1}J_{CC}$ 34.4 Hz). As resonances for the carbons bonded to hydrogen (C-8 and C-9, and C-11 through C-16) were readily assigned the results of the [1,2-^{13}C]acetate experiment enabled C-7 (δ_c 193.8) to be identified as a ketone carbonyl carbon, permitted the resonance for the quaternary olefinic carbon C-10 (δ_c 132.6) bonded to the vinylic methyl (C-16) group to be assigned, and, together with the ^{1}Hmr data, proved the carbon skeleton of the fragment C-7 through C-14 in structure **1**. The combined evidence establishes the presence of an *E,E*-4,6-dimethyl-octa-2,4-dienoyl unit in tenellin.

8 $R_1 = R_2 = R_3 = H$; R_4 = 
Chemical evidence also supported the above conclusion. Treatment of **1** under retro-aldol conditions gave a mixture of volatile aldehydes which were characterized as ethanal, propanal, 2-methylbutanal, and 2,4-dimethylhex-2-enal. The other fragment was isolated as the non-volatile crystalline compound **7**, which had a molecular formula $C_{13}H_{11}NO_5$, and gave a ^{1}Hmr spectrum which closely resembled that of **1** with signals for H-8 through H-16 replaced by an acetyl methyl (δ 2.70) resonance. Proton magnetic resonance evidence (Table 1) also showed that the double bonds of the acyl group in **1** could be selectively reduced by catalytic hydrogenation to give a tetrahydro derivative **6**, which lacked the strong ultraviolet absorption maximum exhibited by tenellin at 340 nm (2).

Apart from replacement of the A(H-8)B(H-9) system of **1** by an A(H-8)B(H-9)M(H-10)N(H-11) sub-spectrum, the ^{1}Hmr spectrum of bassianin (**8**) matched that of tenellin very closely (Table 1). The magnitudes of the three vicinal coupling constants, obtained by analysis of the ABMN system, indicated that adjacent olefinic hydrogens in **8** were *trans*-oriented (7). The ^{13}C nmr spectrum of **8** differed from that for **1** only by the presence of two additional resonances arising from the vinylic methine carbons C-10 and C-11 (Table 2). Consequently, related acyl groups must account for the structural difference between the metabolites, and by analogy bassianin must contain an (*E,E,E*)-6,8-dimethyl-deca-2,4,6-trienoyl unit. This is consistent with the bathochromic shift of maxima seen when the ultraviolet and visible absorption spectra of bassianin are compared with those of tenellin (2).

Another structural fragment was identified when oxidation of tenellin with alkaline hydrogen peroxide gave *p*-hydroxybenzoic acid. Three other more volatile acidic reaction products which gave molecular ions of *m/e* 168, 156, or 142 on mass spectral analysis were identified as C_{10}, C_9, and C_8 acids derived by cleavage of the acyl substituent. The *p*-hydroxyphenyl group accounted for the typical A(H-2′)A′(H-6′)B(H-3′)B′(H-5′) multiplets in the ^{1}Hmr spectra of **1** and **8**, and for four distinctive resonances in their corresponding ^{13}C nmr spectra. Two of these ^{13}C signals arose from the chemically equivalent pairs of carbons C-2′,C-6′ and C-3′,C-5′, which were characteristically one- and three-bond ^{13}C—H coupled and gave the

most intense ^{13}C signals. The signals for the hydrogens and carbons at the 3′- and 5′-positions occurred at higher field because they were shielded by the neighbouring phenolic hydroxy group. Typical deshielding by this group combined with three-bond ^{13}C—H coupling (**1**, $^3J_{CH}$ 8.8 Hz; **8**, $^3J_{CH}$ 9.1 Hz) to a pair of chemically equivalent aromatic hydrogens (H-2′, H-6′) permitted the triplet resonance occurring at δ_c 156.9 for both metabolites to be assigned to C-4′. Consistent with this assignment, the resonance at δ_c 158.8 for the corresponding carbon in derivative **3** (see below) was a multiplet (triplet of quartets) due to additional coupling with the hydrogens of the methoxyl substituent which had replaced the phenolic hydroxy group of **1**. Distinctive three-bond coupling (**1**, $^3J_{CH}$ 7.4 Hz; **8**, $^3J_{CH}$ 8.1 Hz) to another pair of chemically equivalent hydrogens (H-3′, H-5′) identified the resonance (δ_c 122.8) for C-1′ in both **1** and **8**, although the carbon was also coupled ($^3J_{CH}$ 3.5 Hz) to another hydrogen (H-6). Remaining unidentified resonances for quaternary carbons (C-2, C-3, C-4, and C-5 in Table 2) could not be confused with those for C-1′ and C-4′ since they had different multiplicities.

Three hydroxyl groups in **1** gave rise to resonances in the ^{1}Hmr spectrum (δ 9.48, δ 11.67, and δ 16.98) which had clear counterparts (δ 8.50, δ 10.80, and δ 17.08) in the corresponding spectrum of **8** (chemical shifts were temperature dependent, and signals disappeared when hydrogens exchanged with the deuterium of D_2O). The groups were progressively methylated with methyl iodide and silver oxide to yield derivatives with one (**2**), two (**3**) or three (**4**) methoxyl groups (Tables 1 and 2). Differences observed in the chemical shifts of corresponding hydroxyl groups in the two metabolites were largely due to the use of different solvents (**1**, DMSO-d_6; **8**, THF-d_6). The *p*-hydroxyphenyl hydroxyl group in **1** (δ 9.48), and **2** (δ 9.51), was easily identified because its replacement by a methoxyl substituent in **3** (δ 3.79, δ_c 55.1) was accompanied by the extra three-bond ^{13}C—H coupling to C-4′ referred to above.

The remaining structural fragment of tenellin and bassianin, accommodated by the partial formula $C_5H_3NO_3$, contained the unassigned sp^2 carbons C-2 through C-6 and the two unidentified hydroxyl groups (**1**, δ 11.67, δ 16.98; **8**, δ 10.8, δ 17.08). High resolution mass spectral studies together with precursor ion experiments showed that a major fragmentation pathway for both metabolites involved initial loss of an oxygen atom; in contrast the methyl ether derivatives **2**, **3**, and **4** lost CH_2O. These uncommon reactions suggested that the metabolites possessed a cyclic hydroxamic acid unit (8), and the combination of mass spectral and nmr results established that the hydroxamate hydroxyl group (δ 11.67) of **1** was methylated preferentially. Similarly, the monoacetate derivative (acetyl methyl δ 2.22, Table 1) was assigned structure **5** because the acetoxyl substituent was clearly not on C-4 (OH, δ 17.1), and a hydroxamic acid hydroxyl group, like those of the aspergillic acids (9), should be preferentially acetylated because of its acidic properties.

Carbons in and adjoining the hydroxamic acid group were identified with the aid of ^{15}N-labelling. Tenellin was 95% enriched with ^{15}N by supplying potassium nitrate-^{15}N as the sole nitrogen source for cultures of *B. bassiana*. Intense satellite resonances arising from ^{15}N—H($^nJ_{NH}$) and ^{15}N—^{13}C($^nJ_{NC}$) spin–spin coupling (10) in the ^{1}Hmr and pnd ^{13}C spectra of the labelled metabolite revealed that the nitrogen atom was directly bonded to C-6 (δ_c 140.0; $^1J_{NC}$ 15.0 Hz) and C-2 (δ_c 157.5; $^1J_{NC}$ 11.0 Hz), and geminal to C-3 (δ_c 105.9; $^2J_{NC}$ 9.2 Hz) and the only coupled hydrogen H-6 (δ 8.10; $^2J_{NH}$ 1.0 Hz). For all compounds in Table 2 spin–spin coupling between C-6 and H-6 ($^1J_{CH}$ 183–186 Hz) was similar to that in 2-pyridone ($^1J_{CH}$ 179.7 Hz).[3] Also C-2 and C-3 were identified as the fifth pair introduced as an intact unit ($^1J_{CC}$ 75.3 Hz) in the study with doubly labelled acetate (12) mentioned above. The high $^1J_{CC}$ value suggested that one of these carbons belonged to a carbonyl group (13). High ^{13}C-enrichments permitted coupling to be observed between adjacent ^{13}C—^{13}C units (C-3,C-7, $^1J_{CC}$ 65 ± 2; C-8,C-9, $^1J_{CC}$ 70 ± 2; C-10,C-11, $^1J_{CC}$ 70 ± 2; C-12,C-13, $^1J_{CC}$ 37 ± 2 Hz) in the [1,2-^{13}C]acetate study, and between C-2 and C-7 ($^2J_{CC}$ 4.6 ± 0.3 Hz) and C-3 and C-8 ($^2J_{CC}$ 7.7 ± 0.3 Hz) when **1** was labelled with [1-^{13}C]- and [2-^{13}C]acetates (12). Besides establishing the positions of C-2, C-3, and C-6 (hence H-6) relative to nitrogen, these results placed the acyl substituent on the shielded quaternary carbon C-3, and enabled the low-field C-2 resonance to be assigned to the hydroxamate carbonyl carbon.

[3]A. G. McInnes and J. A. Walter. Unpublished results.

Further nOe measurements on **2** showed that the *p*-hydroxyphenyl and methoxyl substituents were both in a vicinal relationship to H-6: H-6 (H-2′,-6′) 26%; H-2′,-6′ (H-6) 10%; H-3′,-5′ (H-6) 0%; H-6 (>$NOCH_3$) 8%. This implied that the carbon (C-5, δ_c 110.9) bearing the *p*-hydroxyphenyl substituent in **1** was shielded by a β-nitrogen, and that the remaining carbon (C-4, δ_c 173.0), which must carry the only unidentified hydroxyl group (δ 16.98), was attached to both C-3 and C-5. The conclusion, that tenellin possesses a 1-hydroxy-2(1*H*)-pyridone ring substituted as shown in structure **1**, was supported by the following observations.

Replacing the hydroxyl group common to **1** (δ 16.98), **2** (δ 17.40), and **3** (δ 17.48) with a methoxyl substituent (δ 3.41, δ_c 60.5) in **4** increased the multiplicity of the C-4 resonance due to additional ^{13}C—H coupling with the methoxyl hydrogens (Table 2), locating this hydroxyl group on C-4 of **1**. The deshielding of C-3 (≈9 ppm), and slight shielding of C-7 (≈1 ppm), accompanying this exchange of substituents was similar to the chemical shift trends exhibited by analogous carbons in juglone and its derivative (14). Moreover, a β-diketone system in enol form containing C-4, C-3, and C-7 in **1**, **2**, **3**, and **8** was consistent with the chemical shifts observed for these carbons, and the characteristic resonance for a strongly hydrogen-bonded hydroxyl group appearing at lowest field in the ^1Hmr spectrum. The chelate ring in structures **1**, **2**, **3**, and **8**, due to hydrogen bonding of the C-4 hydroxyl and C-7 carbonyl groups, restricts the conformational mobility of the acyl substituent and places H-8 in the deshielding region of the C-2 carbonyl group. This explains why H-8 (δ 8.03) was unexpectedly at lower field than H-9 (δ 7.54). The AB system for the corresponding hydrogens in **4**, on the other hand, was at appreciably higher field. Decoupling experiments indicated that H-11 in **4** was coupled to the hydrogen at H-9 (δ 7.17) giving rise to the low-field component of the AB system, as in the case of **1** ($J_{9,11} \leq 0.5$ Hz). In addition a 25% nOe of the high-field component (H-8; δ 6.36) was observed on irradiating the vinylic methyl hydrogens (H-16). The results indicated that methylation of the C-4 hydroxyl group caused a marked change in orientation of the acyl substituent, thereby removing H-8 from the deshielding effect of the C-2 carbonyl group. The chemical shifts of C-4 (δ_c 173–176) in **1**, **2**, and **3** were similar to those for the carbonyl carbons (≈δ_c 176) of 4-pyridones (15, 16), whereas the corresponding carbon in **4** (δ_c 162.6) and C-4 (δ_c 164.9) of 4-methoxypyridine (15) was considerably more shielded. This suggested considerable double bond character in the bond between C-4 and oxygen in **1**, **2**, and **3**, but not **4**, as a result of electron delocalization in the chelate ring of the β-diketone system (17). Published ^{13}C nmr data on 2-pyridones (15, 16) permitted the chemical shifts of the other carbons in the 1-hydroxy-2(1*H*)-pyridone ring to be rationalized when the probable effects of the acyl and aromatic substituents were taken into account. Furthermore, ^{13}C—H spin–spin couplings between H-6 and the carbons in the heterocyclic ring of the metabolite and its derivatives were similar to those observed for 2(1*H*)-pyridone (see footnote † to Table 2).

The mass spectral fragmentation patterns observed for tenellin and bassianin were consistent with the proposed structures. Most of the reaction sequences depicted in Fig. 1 to account for the more abundant fragment ions from tenellin were indicated by metastable ions or were established by precursor ion experiments. Alkyl fragments were lost in a stepwise and predictable manner but there was some branching of reaction pathways because tenellin, as well as the intermediate ions formed from it, were susceptible to the loss of a single oxygen atom from the hydroxamate grouping. The product ions then underwent further fragmentation in the alkyl moiety leading eventually to bond scission between C-7 and C-8, which gave rise to the relatively stable ion at *m/e* 230.

Biosynthetic labelling experiments have shown that C-4 and C-6 of **1** are enriched by [1-^{13}C]- and [2-^{13}C]phenylalanine, respectively (12). A structural unit consisting of C-4, C-5, C-6, and the aromatic substituent of **1** accounts for all of the amino acid carbons if it is assumed that the carboxyl carbon of phenylalanine migrates to the carbon adjacent to the aromatic ring at some stage in the biosynthetic process. The contiguous relationship of C-4 and C-5 and the nature of the intramolecular rearrangement have been confirmed in a more recent study (18) which demonstrated that only these two carbons were ^{13}C—^{13}C coupled ($^1J_{CC}$ 62 Hz) in the pnd ^{13}C spectrum of **1** enriched with [1,3-^{13}C]phenylalanine.

It follows that tenellin is 3-(4,6-dimethyl-*E*,*E*-

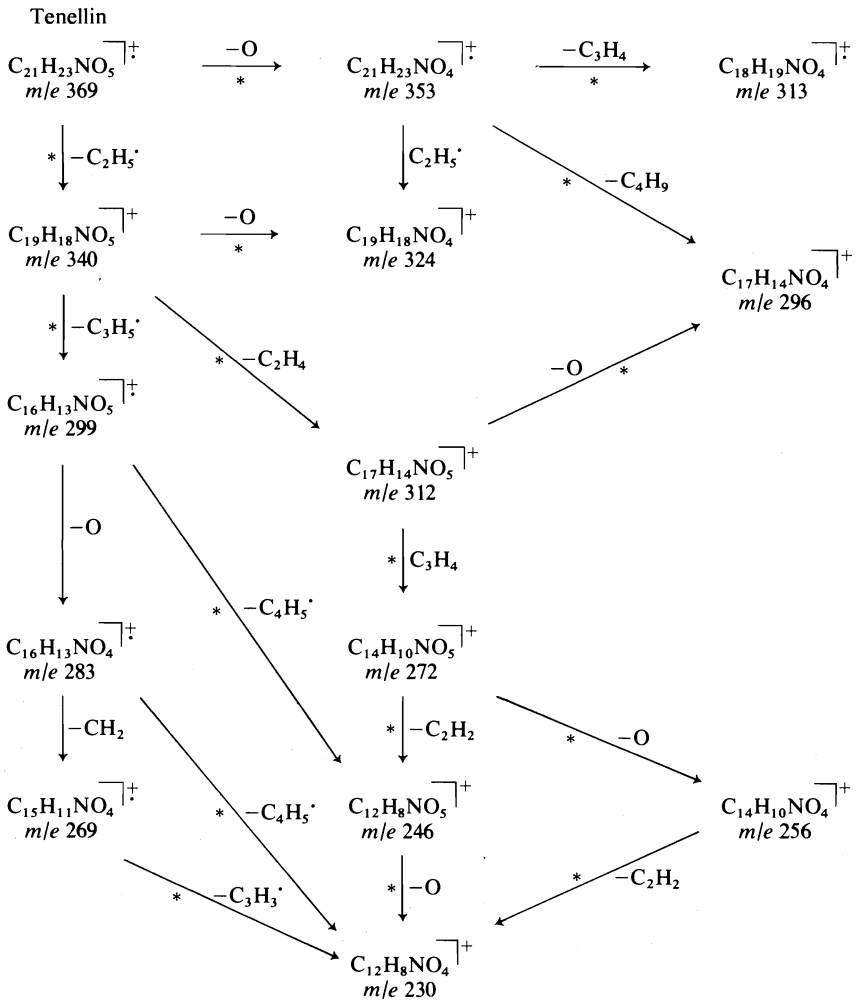

FIG. 1. Fragment ions in the mass spectrum of tenellin. Pathways marked with an asterisk were demonstrated by precursor ion experiments or deduced from the presence of metastable ions.

octa-2, 4-dienoyl)-1, 4-dihydroxy-5-(*p*-hydroxyphenyl)-2(1*H*)-pyridone, and bassianin is 3-(6,8-dimethyl-*E,E,E*-deca-2,4,6-trienoyl)-1,4-dihydroxy-5-(*p*-hydroxyphenyl)-2(1*H*)-pyridone.

Experimental

Melting points were measured with a Fisher-Johns hot plate and are uncorrected. Ultraviolet and infrared absorption spectra were recorded with Beckman model DK-2 and Perkin-Elmer model 237 spectrophotometers respectively. Mass spectra were obtained with a Dupont model 21-110B double-focusing spectrometer used in the electrical detection mode with 8 kV accelerating voltage and 70 eV electron energy. Accurate mass measurements were made by peak matching against a perfluorokerosene reference. In precursor ion measurements the ion accelerating voltage was varied while the voltage applied to the plates of the energy-focusing sector was kept constant (10).

A Varian Associates model HA 100 spectrometer was used to measure ^1H nmr spectra, and a Varian Associates model XL 100 was used to record the pulse Fourier transform ^{13}C nmr spectra. Operating conditions are given in the footnotes to Tables 1 and 2.

Biosynthetic Enrichment with Isotopes

Methods of culturing *B. bassiana* HLX 83 are described in detail elsewhere (2). The fungus was grown in a medium containing D mannitol (5%), potassium nitrate (0.5%), potassium dihydrogen phosphate (0.1%), magnesium sulfate heptahydrate (0.05%), sodium chloride (0.01%), calcium chloride (0.01%), and a trace mineral solution (1% v/v) containing zinc sulfate heptahydrate (880 mg), cupric sulfate pentahydrate (40 mg), manganous sulfate tetrahydrate (7.5 mg), boric acid (6 mg), and ammonium molybdate monohydrate (4 mg) per litre of water. To

obtain ^{15}N-enriched tenellin potassium (^{15}N) nitrate (95% enriched) replaced the usual nitrogen source at the same (0.5%) concentration. Sodium (^{13}C)acetate (90% enriched) was added to the cultures as a sterile aqueous solution, on the 3rd day after inoculation to give a concentration of 10 m*M* in the broth. In each experiment the volume of cultures grown was 500 ml.

Tenellin

Samples were isolated and purified as described previously (2). Measurements of the optical activity gave $[\alpha]_D^{24} - 44.0°$ (1%, acetone). The mass spectrum showed M^+ at *m/e* 369 (15% of base peak) and fragment ions at *m/e* 353 (2.5%), 340 (0.8%), 334 (1.2%), 324 (0.8%), 313 (19.6%), 312 (100%), 299 (0.7%), 296 (6.9%), 283 (0.7%), 272 (4.7%), 269 (0.4%), 246 (23.9%), and 230 (11.9%). Selected ions were accurately mass measured as *m/e* 369.1576 ($C_{21}H_{23}NO_5$ calcd.: 369.1576), 353.1626 ($C_{21}H_{23}NO_4$ calcd.: 353.1630), 312.0874 ($C_{17}H_{14}NO_5$ calcd.: 312.0872), 272.0561 ($C_{14}H_{10}NO_5$ calcd.: 272.0559). Metastable ions were present at *m/e* 312 (369 → 340), 264 (340 → 299) and 279 (353 → 313). Precursor ion measurements showed the following ion fragmentation pathways: *m/e* 369 → 353, 353 → 324, 353 → 296, 340 → 324, 340 → 312, 312 → 296, 312 → 272, 272 → 246, 299 → 246, 283 → 230, 269 → 230, 246 → 230.

Methylation

To a mixture of potassium carbonate (1.2 g) in acetone (20 ml), tenellin (185 mg) and methyl iodide (10 ml) were added. The reaction vessel was flushed with nitrogen and the contents were stirred in the dark for 2 h. Chloroform was added and the filtered solution evaporated. Examination of the greenish residue by thin-layer chromatography (tlc) on silica gel F_{254} (E. Merck, Darmstadt) in methanol–chloroform (1:20) showed unreacted tenellin (R_f 0.16) and three less polar components (R_f 0.30, 0.44, and 0.76) as quenching zones under ultraviolet light. The material was fractionated by tlc on preparative plates (500 × 20 × 2 mm) using methanol–chloroform (1:50) as solvent; zones were scraped off the plate and eluted with ethyl acetate or chloroform.

The product with R_f 0.30 yielded tenellin monomethyl ether as a greenish yellow solid (125 mg), mp (194°C; *m/e* at 383 (13.2%), 353 (12.3%), 326 (100%), 296 (73.6%), 260 (17.5%), and 230 (50%); accurate measurement of M^+ gave *m/e* 383.1731 ($C_{22}H_{25}NO_5$ calcd.: 383.1726). The upper zone with R_f 0.76 by tlc afforded tenellin dimethyl ether as a greenish yellow solid (40 mg), mp 96–98°C; *m/e* at 397 (23%), 381 (3%), 367 (9%), 340 (100%), 310 (43%), 274 (19%), 261 (28%), 244 (44%), 231 (18%), and 230 (25%). Accurate mass measurements gave *m/e* 397.1876 ($C_{23}H_{27}NO_5$ calcd.: 397.1889), 274.0713 ($C_{14}H_{12}NO_5$ calcd.: 274.0715), 244.0611 ($C_{13}H_{10}NO_4$ calcd.: 244.0610). From the middle zone (R_f 0.44 by tlc) a small amount of tenellin trimethyl ether was obtained as a gum (10 mg).

With methyl iodide and silver oxide as the methylating system higher yields of the trimethyl ether could be achieved by extending the reaction time. Thus when tenellin (100 mg) was shaken for 18–20 h with silver oxide (200 mg) and methyl iodide (30 ml) and the filtered and evaporated reaction mixture fractionated by preparative tlc the trimethyl ether was the main product (80 mg), *m/e* at 411 (5.9%), 397 (9.1%), 395 (7.36%), 340 (41.2%), 261 (100%), 231 (40.3%), 230 (48.3%), and 219 (82.4%); accurate measurement of M^+ gave 411.2052 ($C_{24}H_{29}NO_5$ calcd.: 411.2038).

Acetylation

Tenellin (100 mg) and acetic anhydride (1.5 ml) in pyridine (0.1 ml) were allowed to react at ambient temperature for 18 h. Chromatography of the product on a column of silicic acid – Celite with chloroform as eluant gave two fractions, one of which was recrystallized from chloroform–ether as orange-yellow needles (82 mg) mp 175–177°C, ν_{max} (carbon tetrachloride) at 1770, 1645 cm^{-1}; λ_{max} (ethanol) at 254 and 343 nm (log ε 4.31 and 4.35); *m/e* at 411 (8.8%), 354 (100%), 338 (21.6%), 312 (18.6%), 288 (12.7%), 272 (8.8%), 246 (13.2%), and 230 (10.8%); R_f (tlc, silica gel, and chloroform) 0.11.

The second fraction, R_f (tlc, silica gel, and chloroform) 0.24, was not purified but showed ν_{max} (potassium bromide) 1775, 1750, 1660, and 1645 cm^{-1}; M^+ at *m/e* 453.

Hydrogenation

Tenellin (80 mg) in methanol (35 ml) was reduced with hydrogen over 5% palladized charcoal. Hydrogen uptake (2.3 mol/mol) ceased after 1 min. The product was crystallized from aqueous methanol as cream needles, mp 145–147°C, λ_{max} (ethanol) at 254, 285 (inflection) and 358 nm (log ε, 4.37, 4.09, and 3.71); ν_{max} (potassium bromide) at 1650, 1620 cm^{-1}; M^+ at *m/e* 373.1873 ($C_{21}H_{27}NO_5$ calcd.: 373.1889), *m/e* at 373 (36.1%), 356 (11.5%), 274 (100%), 261 (61.5%), 246 (26.4%), and 230 (16.3%).

The same product was obtained when tenellin was hydrogenated under acidic conditions (a 1:1 mixture of methanol – acetic acid containing 1.2% (v/v) of concentrated hydrochloric acid) for 18 h; tlc of the crude reaction product showed no evidence of a deoxy derivative.

Retro-aldol Cleavage

Tenellin (55 mg) was heated under reflux in a slow stream of nitrogen with 2 *N* potassium hydroxide solution (10 ml) for 2 h. Volatile aldehydes from the reaction were trapped in a 0.3% solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid, and the precipitated hydrazones chromatographed on a column of silicic acid developed with benzene – petroleum ether (bp 60–80°C). Four orange-colored zones separated and the products, in order of elution, were characterized as: ethanal-2,4-dinitrophenylhydrazone (1 mg), mp 168°C, M^+ at *m/e* 224; propanal-2,4-dinitrophenylhydrazone (13 mg), mp 153°C, M^+ at *m/e* 238; 2-methylbutanal-2,4-dinitrophenylhydrazone (13 mg), mp 128.5–129°C, M^+ at *m/e* 266.1019 ($C_{11}H_{14}N_4O_4$ calcd.: 266.1015), δ (chloroform-*d*) at 1.00 (t, 3H), 1.20 (d, 3H), 1.56 (m), 2.48 (m), 7.45 (d), 8.13 (AB part of ABX, J_{AX} 2.5 Hz), 9.14 (X part of ABX), and 10.99 (bs) ppm; 2,4-dimethylhex-2-enal-2,4-dinitrophenylhydrazone (16 mg), mp 160–161°C, M^+ at *m/e* 306, δ (chloroform-*d*) at 0.88 (t, 3H), 1.03 (d, 3H), 1.42 (m), 1.97 (d, 3H), 2.60 (m), 5.75 (bd), 7.73 (s), 8.11 (AB part of ABX, J_{AX} 2.7 Hz), 9.11 (X part of ABX), and 11.08 (bs) ppm. The derivatives of ethanal, propanal, and 2,4-dimethylhex-2-enal were identified by melting point measurements after admixture with authentic specimens.

The reference sample of (+)2,4-dimethylhex-2-enal-2,4-dinitrophenylhydrazone derived from sclerotiorin (11) was a gift from Dr. W. B. Whalley, School of Pharmacy, University of London.

A nonvolatile product was removed from the acidified reaction mixture by extraction with ether. After sublimation *in vacuo* at 145–160°C and crystallization from methanol–ether it was obtained as cream-colored needles (8.5 mg), mp 230–231°C; λ_{max} (ethanol) at 254, and 360 nm (log ε 4.19 and 3.64); ν_{max} (potassium bromide) 1655, 1620 cm^{-1}; $M^{\ddagger}$ at *m/e* 261 (50% of base peak) and fragment ions at *m/e* 245 (100%) and 230 (72%). Accurate mass measurements gave *m/e* 261.0635 ($C_{13}H_{11}NO_5$ calcd.: 261.0637) and 245.0682 ($C_{13}H_{11}NO_4$ calcd.: 245.0688).

Oxidation with Alkaline Peroxide

Tenellin (100 mg) was heated with hydrogen peroxide (3 ml of a 3% solution) in 0.1 *N* sodium hydroxide (40 ml) on a steam bath for 6 h. Ether extraction of the acidified reaction mixture and sublimation in high vacuum gave two main fractions: at 30–90°C, a viscous liquid (6 mg) which was separated by gas–liquid chromatography using FFAP as liquid phase into three components; A (trace) $M^{\ddagger}$ at *m/e* 168; B, $M^{\ddagger}$ at *m/e* 156.1148 ($C_9H_{16}O_2$ calcd.: 156.1150); and C, $M^{\ddagger}$ at *m/e* 142.0992 ($C_8H_{14}O_2$ calcd.: 142.0994); the second fraction (12 mg) subliming at 100–125°C gave, after resublimation, *p*-hydroxybenzoic acid, mp 213–214°C, identified by comparison with an authentic specimen.

Acknowledgements

Décharge triboélectrique dans le système propane – vapeur d'eau

JAN A. HERMAN
Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Reçu le 29 décembre 1976[1]

JAN A. HERMAN. Can. J. Chem. **55**, 4099 (1977).

Le propane gazeux additionné de quantités variables de vapeur d'eau est soumis à la décharge triboélectrique dans un système verre borosilicaté-mercure. Le taux de décomposition du propane semble être indépendant de la présence de la vapeur d'eau jusqu'à $p(H_2O) \approx 2$ Torr. Au-delà de cette valeur de la pression du H_2O la décharge disparaît. La composition relative en produits de décomposition du propane varie en fonction de la concentration de la vapeur d'eau.

JAN A. HERMAN. Can. J. Chem. **55**, 4099 (1977).

Gaseous propane containing various amounts of water vapour was subjected to a triboelectric discharge in an apparatus of mercury in borosilicate glass. The extent of decomposition of propane appeared not to depend on the presence of water vapour below a partial pressure of about 2 Torr. Above this pressure of H_2O the discharge disappeared. The relative composition of the products of the propane decomposition varied with the concentration of water vapour.

Introduction

L'étude des effets chimiques résultant de la décharge triboélectrique nous a conduit à examiner de plus près l'influence de la vapeur d'eau sur une telle décharge. En effet, il n'est pas facile de contrôler la teneur, surtout en trace, de la vapeur d'eau, aussi bien dans l'échantillon que celle adsorbée sur les parois du récipient. Or, il est reconnu que d'une part certaines réactions ioniques sont très sensibles à la présence de la vapeur d'eau, et d'autre part parmi les facteurs intervenant sur la triboélectrisation la nature de la surface joue un rôle très important (1, 2). Ces deux aspects liés à la présence éventuelle de la vapeur d'eau justifient la présente étude.

L'influence sur l'électrisation par contact de la vapeur d'eau adsorbée sur les parois est mal définie en raison de facteurs structuraux des matériaux utilisés et de la présence d'autres contaminants (au sens de la triboélectrisation) qui peuvent, selon les prétraitements des surfaces, modifier ou masquer la participation éventuelle des couches adsorbées de l'eau (3, 4). Kunkel (5), par exemple, a montré qu'un changement d'humidité n'affecte pratiquement pas la formation des charges électriques par friction à 20°C de la poudre de quartz.

Dans le cas qui nous préoccupe la présence de l'eau dans le système peut se manifester de deux manières: (*1*) son influence sur l'accumulation de charges électrostatiques sur les surfaces dans l'électrisation de contact, et (*2*) sa présence en phase gazeuse modifiant le caractère de la décharge (tribo)électrique. Dans le premier cas son influence pourrait se faire sentir au niveau de l'intensité de la décharge à travers le gaz en raison de l'importance de la charge superficielle. Dans le deuxième cas la présence des molécules de vapeur d'eau dans le gaz peut jouer un rôle modérateur de l'énergie cinétique (moyenne) des électrons accélérés par le champ électrique. De plus la présence de la vapeur d'eau influencera les réactions ioniques, mais cet aspect ne sera pas abordé dans ce travail.

L'examen partiel de ces deux aspects de l'influence de la vapeur d'eau sur la décharge triboélectrique est essayé sur le système $C_3H_8 + H_2O$, où la pression du propane est maintenue constante, tandis que celle de la vapeur d'eau est variable.

Procédure expérimentale

Les cellules de réactions de forme cylindrique (volume: 232 ± 15 cm^3) sont en verre borosilicate (Pyrex). Elles sont équipées de pointes cassables.

L'électrisation de contact étant très sensible à la qualité de la surface nous avons adopté une procédure rigoureuse de nettoyage des réacteurs (6). La cellule propre est soudée à une rampe à vide (limite du vide $\sim 10^{-5}$ Torr) et chauffée pendant 12 h à environ 350°C dans un four amovible. Simultanément dans un dispositif approprié connecté au système à vide au-dessus du réacteur on chauffe à reflux à environ 250°C pendant

[1]Révision reçue le 2 août 1977.

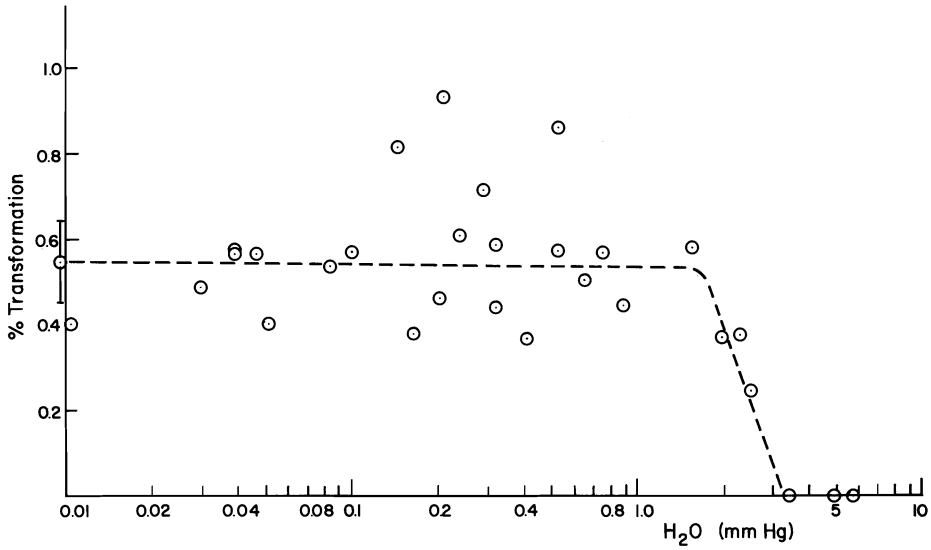

FIG. 1. Taux de décomposition du propane dans une décharge triboélectrique en présence de la vapeur d'eau. Le point à gauche de l'axe des ordonnées se rapporte au propane sec.

2 à 3 h sous haut vide ($\sim 10^{-5}$ Torr) 130 g de mercure. Une connection articulée permet de transvaser le mercure dans le réacteur sans détérioration du vide établi dans le système. Cette opération de transvasement du mercure dans le réacteur est exécutée après refroidissement à la température ambiante et juste avant l'admission d'une quantité contrôlée de vapeur d'eau et de propane. Ensuite le réacteur est scellé et mis en rotation autour de l'axe longitudinale du récipient pendant 60 min à une vitesse linéaire d'envion 21 cm s^{-1} (72 révolutions/min). Toutes les expériences sont faites à la température ambiante, soit 23 ± 2°C.

La provenance des réactifs et la procédure analytique sont déjà décrites (6). Précisons cependant que la présence du propane masque sur le chromatogramme le propyne et l'allène. L'hydrogène, les composés alkylmercuriques et les produits oxygénés (aldéhydes, alcools) n'ont pas été analysés systématiquement, cependant on n'a pas détecté de méthanol parmi les produits formés.

Résultats et discussion

La pression du propane est maintenue constante à 9.6 Torr pendant toutes les expériences, tandis que la pression partielle de la vapeur d'eau est variable. Les résultats de la décomposition du propane dans la tribodécharge sont présentés dans les figs 1 à 3. La fig. 1 montre le taux de décomposition du propane en fonction de la pression partielle du H_2O. Les figs 2 et 3 présentent les variations de la composition relative des produits provenant de la décomposition du C_3H_8 en fonction de la teneur en H_2O. Dans toutes ces figures l'échelle des pressions partielles du H_2O (axe des abscisses) est logarithmique. Les points se rapportant à la décomposition du *propane sec* (séché sur du sodium métallique) sont rapportés en dehors et à gauche de l'axe des ordonnées. On a indiqué par un segment vertical l'écart moyen des mesures, qui est de l'ordre de 20% pour les valeurs de la composition relative.

Le taux de décomposition du C_3H_8 (fig. 1) est calculé suivant l'expression $-\Delta(C_3H_8) = 0.33C_1 + 0.66\Sigma C_2 + (C_3H_6) + 1.33\Sigma C_4$. Pour nos conditions expérimentales ce taux de décomposition du *propane sec* est de 0.55 ± 0.10% pour tous les réacteurs utilisés. Pour des pressions partielle <2 Torr de la vapeur d'eau les résultats du taux de décomposition du C_3H_8 fluctuent dans une large zone et ne manifestent pas de tendance précise. Cela résulte des particularités propres de chacun des réacteurs utilisés. Certains réacteurs affichaient systématiquement des taux de décomposition du C_3H_8 plus élevés que d'autres. De plus, au fur et à mesure que les nettoyages des réacteurs se succèdent il apparaît un effet favorable à l'électrisation de contact résultant selon toute vraisemblance d'une modification irréversible de la surface du verre. On peut conclure prudemment que jusqu'à $p(H_2O) < 2$ Torr l'adsorption de la vapeur d'eau ne semble pas diminuer en moyenne la capacité triboélectrique du système. Mais au-delà de cette valeur de pression du H_2O la décharge diminue progressivement pour dis-

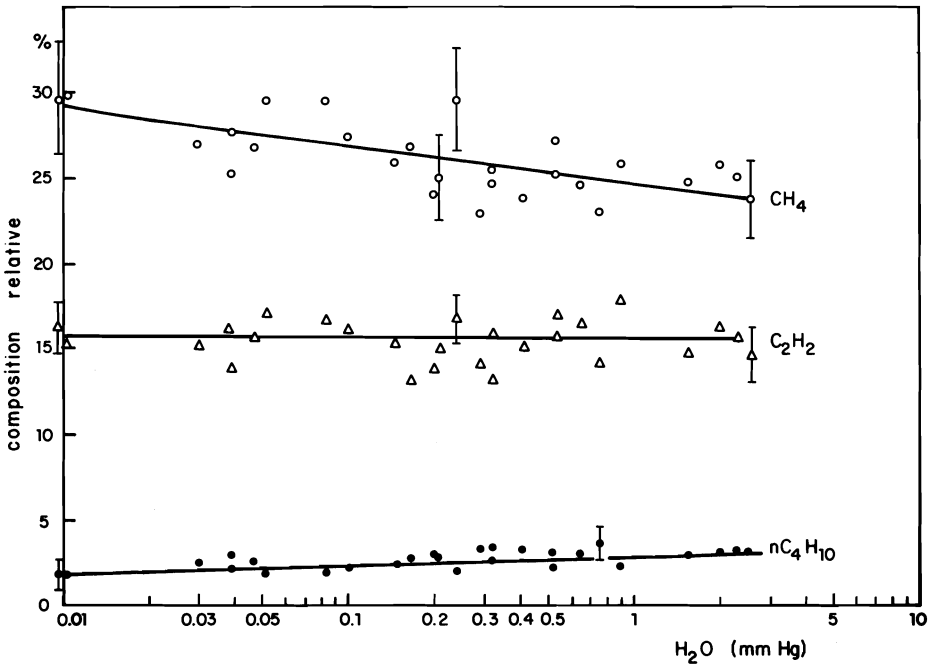

FIG. 2. Variation de la composition relative du méthane, de l'acétylène et du *n*-butane dans une décharge triboélectrique en présence de la vapeur d'eau. Les points à gauche de l'axe des ordonné se rapportent au propane sec.

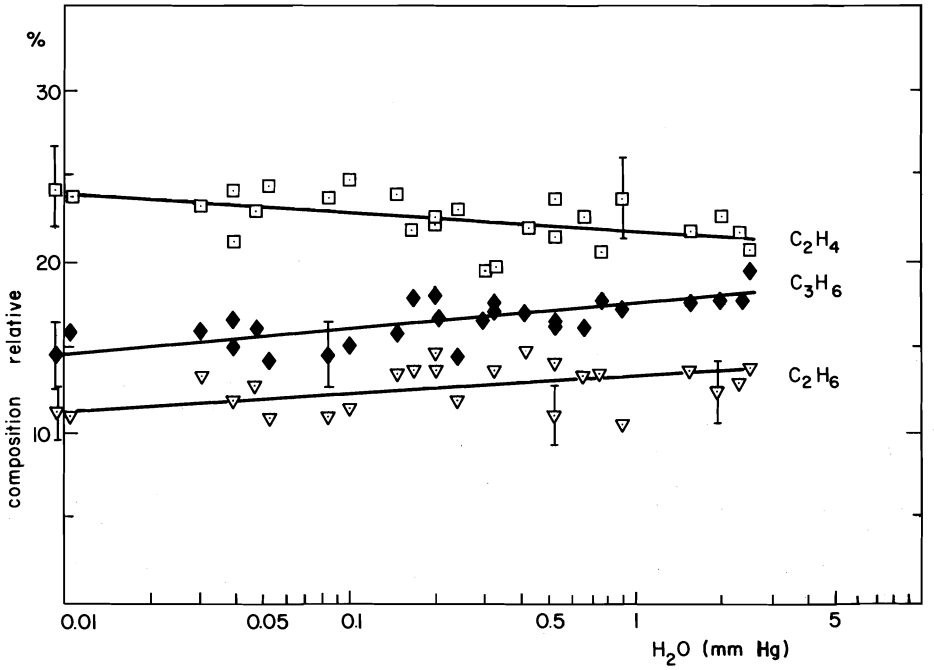

FIG. 3. Variation de la composition relative de l'éthylène, de l'éthane et du propène dans une décharge triboélectrique en présence de la vapeur d'eau. Les points à gauche de l'axe des ordonnées se rapportent au propane sec.

paraître complètement vers environ 3 Torr. Les causes de la diminution jusqu'à disparition complète de la décharge peuvent être multiples, p.ex. recombinaison des charges par migration superficielle sur les parois humides, blocage des sites préférentielles à la formation des charges, extinction "chimique" de la décharge électrique, etc.

Les compositions relatives des produits formés dans la tribodécharge du C_3H_8 en fonction de la pression partielle du H_2O (figs 2 et 3) montrent des écarts de l'ordre de 20% par rapport à la valeur moyenne, ce qui est normal pour ce genre d'expériences (6). Ici on peut déceler nettement des tendances: (*a*) les concentrations en CH_4 et C_2H_4 diminuent progressivement avec l'augmentation de la pression de la vapeur d'eau, (*b*) le pourcentage en C_2H_2 ne semble pas être influencé par la présence du H_2O, et (*c*) tous les autres produits analysés C_2H_6, C_3H_6, *n*-C_4H_{10} et iso-C_4H_{10} (ce dernier coïncide en grandeur à peu de chose près avec le *n*-butane) augmentent leur proportion avec la teneur de vapeur d'eau.

L'attachement d'électrons à la vapeur d'eau explique les diminutions progressives des concentrations des produits dont la formation exige l'existence de précurseurs hautement excités. En effet, il est reconnu que le principal mécanisme de perte d'électrons dans une décharge à travers le gaz est l'attachement d'électrons. L'attachement dissociatif d'électrons à la vapeur d'eau est bien établi et on connaît deux pics de résonance de l'ion H^- à 6 et 8 eV et deux pics de l'ion O^- à 9 et 11 eV (7). Malheureusement, on ne connaît pratiquement rien en ce qui concerne l'attachement d'électron au propane, ce qui rend toute comparaison avec H_2O impossible. Le "refroidissement" des électrons accélérés dans le champ par attachement à H_2O entraînera une augmentation de collisions inélastiques moins énergétiques entre les électrons et le propane, de sorte que les produits de décomposition tels le C_3H_6 et les radicaux méthyl et propyl seront favorisés au détriment de produits moléculaires du genre C_2H_4 ou CH_4, ou ceux formés par réactions avec le radical CH_2, dont la formation exige des précurseurs excités à des niveaux d'énergie plus élevés. La comparaison des spectres par impact électronique du H_2O et du C_3H_8 va dans le même sens. Celui de la vapeur d'eau montre une bande d'absorption située entre 6.8 et 8.7 eV et centrée sur $\sim$7.4 eV (transition $1b_1 \rightarrow 3s$) (8, 9), laquelle empiète à peine sur le début du spectre d'excitation électronique du propane commençant à 7.5 eV (10). Par contre les potentiels d'ionisation de la vapeur d'eau et du propane sont respectivement 12.6 et 11.1 eV (11), donc si l'ionisation comptait pour le principal mode de perte d'énergie c'est le propane qui en subirait la plus grande partie.

La formation de l'acétylène échappe apparemment à ce mécanisme. La concentration constante en C_2H_2 est, soit le résultat d'une réaction ion–molécule, soit d'une réaction hétérogène, par exemple la décomposition du propane adsorbé sur les sites d'où s'initie ou se termine la décharge.

En conclusion on peut dire que des faibles quantités de vapeur d'eau ne semblent pas influencer de manière appréciable les phénomènes chimiques accompagnant la décharge triboélectrique.

Remerciements

Nous remercions Mme M. Villard-Pittion pour l'aide apportée dans l'analyse des échantillons gazeux. Nos remerciements vont aussi au Conseil national de recherches du Canada et au Ministère de l'education du Québec (Octroi FCAC) pour l'aide financière.

Pyrrole chemistry. XVI. Acylation of the pyrrolyl ambident anion

NAM-CHIANG WANG AND HUGH J. ANDERSON

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received May 19, 1977

NAM-CHIANG WANG and HUGH J. ANDERSON. Can. J. Chem. **55**, 4103 (1977).

An investigation of the acylation of the pyrrolyl ambident anion has been carried out. The results have been rationalized in terms of the 'principle of hard and soft acids and bases.' The metal cation, solvent or complexing agent, halide of the pyrrole Grignard reagent, and temperature were varied. As well, the reactions of acylating agents of the carbonyl, cyanide, and carbimine type with the pyrrole Grignard reagent were studied to determine N/C acylation ratios under the same conditions. Several new products were isolated and identified.

NAM-CHIANG WANG et HUGH J. ANDERSON. Can. J. Chem. **55**, 4103 (1977).

On a effectué une étude de l'acylation de l'anion ambivalent pyrrolyle. On a rationalisé les résultats en termes du principe des acides et des bases durs et mous. On a fait varier le cation métallique, le solvant ou l'agent de complexation, l'halogénure du réactif de Grignard pyrrole et la température. On a de plus étudié les réactions des agents acylants de type carbonyle, cyanure et carbimine avec le réactif de Grignard pyrrole afin de déterminer les rapports d'acylation N/C dans les mêmes conditions. On a isolé et identifié plusieurs nouveaux produits.

[Traduit par le journal]

Introduction

The reactivity of the N-hydrogen of pyrrole and many of its C-substituted derivatives has made it possible to prepare numerous metal salts, including those of the Grignard type (1). Modern physical evidence has confirmed that it is the N-hydrogen which exchanges with methylmagnesium halide (2), that the proton magnetic resonance spectra of pyrrolylsodium and pyrrolylmagnesium chloride are similar, and that bonding to these metals is through the nitrogen (3). However, reaction products from these and other metal derivatives often include both N- and C-substitution products. The proportions of these products change with solvent, temperature, metal cation, reactant, and other factors (1*a*). Thus, these metal derivatives show ambident anion behaviour.

In his review of ambident anion reactivity, Shevelev (4) provides a thorough discussion of the reactions of metal derivatives of pyrrole with alkylating agents. Much less is known of their reactions at unsaturated carbon during acylations. We have been interested in the latter reactions because they serve to introduce functional groups at either carbon or nitrogen. The fact that pyrrolylmagnesium bromide reacts in ethyl ether with ethyl carbonate to give almost entirely N-acylation, but with ethyl dithiolcarbonate to give only C-acylation (5), suggested a need for further study and an attempt to provide a rationalization.

The 'principle of hard and soft acids and bases' (hsab) of Pearson (6) was used by Shevelev in his review (4) and appeared to us to provide a satisfactory method for attempting to rationalize the observed results. However, as Shevelev points out, there are complicating factors. The hardnesses of the various unsaturated carbons may be modified by coordination of the nucleophilic part of the acylating agent with the metal cation and the electrophilic part with the metal – ambident anion pair.

The nitrogen of the pyrrolyl anion is more electronegative, less polarizable, and a harder base, while the carbon (usually C-2, sometimes C-3) is less electronegative, more polarizable, and a softer base. Thus, the hard electrophilic carbon of an attacking carbonyl group would be expected to attack nitrogen, and does so when pyrrolylmagnesium bromide reacts in ethyl ether with ethyl carbonate. When the carbonyl carbon is softened, as in ethyl dithiolcarbonate, acylation is on carbon under the same conditions (5).

To rationalize pyrrole acylations, we have varied the metal, solvent, temperature, concentration, and acylating agent. In addition, complexing agents have also been employed in some experiments. Through these alterations various

*TMED = *N,N,N′,N′*-tetramethylethylenediamine.

N- and C-acylated mixtures have been obtained. The results have been used to establish trends in behaviour and to correlate these with the hsab principle. Some experiments in alkylation will be reported separately (7).

Discussion

1. The Metal Cation

Alkylation studies of pyrrole and indole metal salts and Grignard reagents (8–10) suggested that a decreasing coordinating ability of the metal (or other) cation leads to increasing dissociation of the ion pair and to an increasing N/C ratio. Shevelev has equated the trend with the decreasing hardness of $Mg^{2+} > Li^+ > Na^+ > K^+ > R_4N^+$, leading to lowered association with the hard centre (N) and decreased hindrance to attack at that position.

Previous acylation experiments (11, 12) have usually involved a single comparison of the Grignard reagent with another metal derivative in reaction with a single reagent and appear to follow the expected pattern. Treibs and Dietl (13) made somewhat wider comparisons in both alkylation and acylation reactions. Many of their observations fit the expected pattern, although their report of mainly C-acylation of pyrrolyllithium by ethyl chloroformate in ethyl ether was neither confirmed by Hodge and Rickards (11) nor by us.

Our observation (Table 1) was that in ethyl ether, pyrrolylmagnesium bromide and ethyl chloroformate gave more C- than N-acylation while the K^+, Na^+, and Li^+ salts all gave exclusively N-acylation under comparable conditions. Similarly, ethyl chlorothiolformate gave mainly C-acylation with the pyrrole Grignard and entirely N-acylation with the lithium salt.

2. The Solvent

The most important factor for ambident anion reactions is the capacity of the solvent to solvate cations (4). Increased solvation of the cation weakens the attraction between the metal cation and the harder center of the ambident ion permitting attack by the alkylating or acylating agent on the nitrogen. In solvents other than ethyl ether, the Schlenk equilibrium may also be involved (14).

We have carried out a series of acylations of pyrrolylmagnesium bromide in ethyl ether, with ethyl chloroformate, to which was added $1\frac{1}{2}$ mol

I	10	28	0	5	27	28:72	43

*The ratio of TMED to pyrrolylmagnesium halides was 2:1.
†Based on the ethyl chlorothiolformate used.

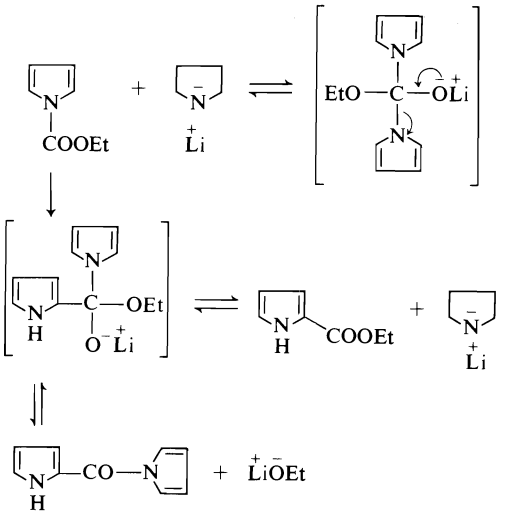
equiv. of dioxane or of 1,2-dimethoxyethane. As shown in Table 2, neither of these caused a significant change in the N/C acylation ratio of about 1:4. However, the addition of 1½ mol equiv. of tetramethylethylenediamine (TMED) produced almost exclusive N-acylation. When ethyl chlorothiolformate was the acylating agent in ethyl ether there was a small amount of N-acylation. The N/C ratio increased steadily as the proportion of TMED was increased (Table 3), becoming mostly N-acylation above about 2:1 TMED–Grignard reagent, and almost completely N-acylation at about 4:1. The results of acylation were consistent with those for alkylation under like conditions (7). The harder solvating agent probably displaced the coordinated ether molecules from the metal cation first, then caused a further separation of the ion pair and increased N-attack.

3. The Halide of the Grignard Reagent

In order to determine whether acylation is sensitive to alterations in halide ion, we added 2 mol equiv. of TMED to the ethereal pyrrole Grignard solution and then acylated with ethyl chlorothiolformate. As shown in Table 4 there was a marked decrease in the N/C ratio going from the chloride to bromide to iodide that almost exactly paralleled the results of Reinecke *et al.* (10) in methylations of the indole Grignard where HMPA (hexamethylphosphoric triamide) was their added reagent. Our rationalization is: the softer the halide, the softer the magnesium becomes, weakening its coordinating ability. Thus the ion pair is less separated by TMED or HMPA complexing and less N-attack occurs. An alternative explanation is that ethyl chlorothiolformate exchanges halide ion with Br^- and I^- to form increasingly soft acylating agents which increasingly attack carbon. There is no evidence that such exchange occurs, however.

4. Temperature

A few alkylations of the pyrrolyl anion are known where the temperature has been varied from the normal 0–35°C range (8, 15, 16). We found that while pyrrolyllithium was N-acylated by ethyl carbonate in dioxane at room tempera-



SCHEME 1

ture, there was a substantial amount of C-acylation at the boiling point. Closer examination of this reaction suggested that the kinetically formed 1-ester was slowly converted to the thermodynamically more favorable 2-ester under these conditions (see Scheme 1). These observations agree with the proposition that when a reversible reaction permits thermodynamic control of products, the electrophilic reagent forms a bond preferentially with the atom of an ambident anion that is most basic in relation to the proton, and here C is more basic than N (17). No such rearrangement took place when 1-butylpyrrole was refluxed with the pyrrole Grignard in ethyl ether (18).

5. Substituent Groups

The presence of substituent groups on the ambident pyrrolyl anion produced predictable results. It would be expected that electron withdrawing groups would stabilize the ambident anion and aid in dissociation of the N-metal bond while electron donor substituents would reduce this dissociation. While ethyl chloroformate with pyrrolylmagnesium bromide in ethyl ether gave both C- and N-acylation, it gave only C-acylation with 2-methylpyrrolylmagnesium bromide (19). Treibs (13) acylated the potassium salt of 2,4-dimethylpyrrole in xylene with ethyl chloroformate and obtained only the N-ester in moderate yield, while the corresponding lithium salt gave only the C-ester in unspecified yield. We found that the Grignard reagent from ethyl 2-pyrrolecarboxylate in ethyl ether was N-acylated by ethyl chloroformate in high yield under the usual conditions.

6. The Acylating Agent

The reaction of pyrrolylmagnesium bromide in ethyl ether with a variety of acylating agents was studied. We determined the N/C ratios for each under identical reaction conditions. Some of the initial products reacted further, so it was necessary to realize that a 1,2-(or 1,3-)disubstituted product could only arise from an initially C-acylated product which had undergone metal–hydrogen interchange with more pyrrolylmagnesium bromide. While N-acylated pyrroles do react with pyrrolylmagnesium bromide it is not by loss of a proton from the ring but by addition to the carbonyl leading to 1,2′-dipyrrolyl ketone (20).

Table 5 shows our results, supplemented by others in the literature, in a sequence to demonstrate that the N/C ratio depends on the hardness of the carbonyl carbon when all other parameters are constant. Thus, the hardest carbonyl compound examined was the carbonate ester where two hard ether oxygens are bonded to it. When one of these was replaced by softer atoms the N/C ratio fell. Our observation is that the order of decreasing hardness is O > C=O > Cl ~ CH_3 ~ SEt ~ H. When both ether oxygens were replaced by softer groups the amount of N-substitution was very small.

The much softer thiocarbonyl group of $(EtO)_2C{=}S$ gave only C-acylated pyrroles, while the much harder C=N— of dicyclohexylcarbodiimide gave only N-substitution. The behavior of the cyanides was closely similar to that of the carbonyl compounds.

There are two possible rationalizations for these N/C ratios. First, the carbonyl group of the acylating agent may have displaced a coordinated ether molecule from the metal cation, altering the degree of hardness of the metal, and the degree of separation of the ion pair. Second, there may be a difference in the reactivity of the carbonyl group itself toward the metal cation – ambident anion combination in a solvent whose bonding to metal remains constant. In any case, the hsab principle may be conveniently used to rationalize and to predict.

7. Products from Acylations

(*a*) When pyrrolylmagnesium bromide reacted

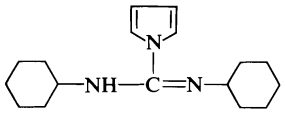
with ethyl acetate in ether, only 1- and 2-acetylpyrroles were obtained in modest yield under our conditions. However, in the presence of 1.5 mol equiv. of TMED a new compound, 1-acetoacetylpyrrole, was obtained as the major product. The compound could be obtained in good yield by adding ethylmagnesium bromide to a solution of 1-acetylpyrrole in the same ether–TMED solution, followed by ethyl acetate. So, the most acidic proton of 1-acetylpyrrole is on the acetyl group. A similar acylation of substituted pyrroles using an acyl halide and sodium hydride in THF gave 1-acylation followed by (*i*) in some examples O- and C-acylation of that group and (*ii*) in others exclusively O-acylation (25).

(*b*) The reaction with ethyl oxalate gave a mixture of ethyl 1-pyrrolylglyoxylate and the known ethyl 2-pyrrolylglyoxylate (21).

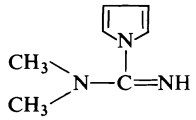
(*c*) The reaction with dicyclohexylcarbodiimide gave an excellent yield of *N,N'*-dicyclohexyl-1-pyrrolylcarbamidine (**1**). The lithium aluminum hydride reduction of this compound gave a good yield of *N,N'*-dicyclohexylformamidine (**2**) (26), confirming that the pyrrole N was the position attacked by the hard reagent, R—N=C=N—R.



1

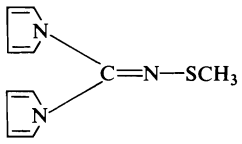
2

(*d*) The reaction with dimethylcyanamide gave exclusively *N,N*-dimethyl-1-pyrrolylcarbamidine (**3**) in low yield. The same product, also in low yield, was obtained from pyrrolyllithium and dimethylcyanamide.

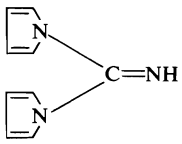


3

(*e*) The reaction with methyl thiocyanate, as reported before (5), gave only the 2-nitrile. However, using pyrrolyllithium a mixture of 1,1'-dipyrrolyl *N*-methylthioketimine (**4**) and



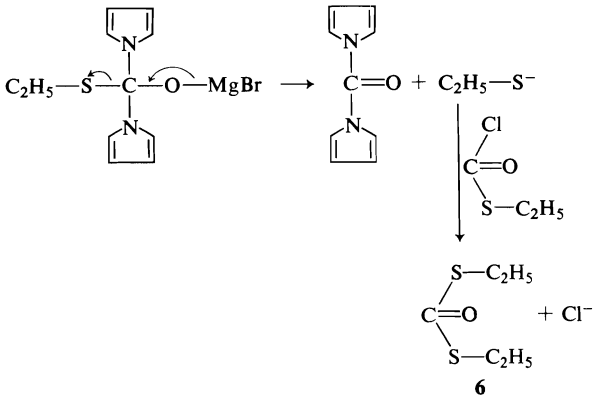
4



5

1,1'-dipyrrolyl ketimine (**5**) was isolated instead of the 1-nitrile.

(*f*) The reaction with ethyl chlorothiolformate gave the usual 1- and 2-thiolesters as well as traces of 1,2'-dipyrrolyl ketone and *S,S*-diethyl dithiocarbonate (**6**). The latter product probably arises from the reactions shown in Scheme 2.



6

SCHEME 2

(*g*) As reported in Section 4, the reaction of pyrrolyllithium with ethyl carbonate in boiling dioxane gave a lower N/C ratio than reaction at 35°C. Refluxing a mixture of pyrrolyllithium and the 1-ester in dioxane resulted in its conversion to the 2-ester and much 1,2'-dipyrrolyl ketone. On the other hand, subjecting the 2-ester to this treatment gave only the 1,2'-dipyrrolyl ketone and none of the 1-ester. It was also found that lithium ethoxide acted on 1,2'-dipyrrolyl ketone under these conditions to give only the 2-ester. These observations are consistent with Scheme 1.

Experimental

The instrumental and related data are described in ref. 5. Analysis of reaction mixtures was carried out as follows. Each product was dried, the volume reduced to 50 ml or 100 ml, and a 1 ml sample retained for analysis. The rest of the solution was used for isolation and identification of products. A standard solution of an authentic sample of each compound to be analyzed by gas chromatography was prepared and used to select the analytical conditions. Suitable attenuation enabled selection of peaks of appropriate size to be cut and

weighed. In this way calibration and the percentage composition of mixtures could be determined.

1. Pyrrolylmagnesium Bromide

A solution of ethylmagnesium bromide was prepared under nitrogen from ethyl bromide (11.99 g, 0.110 mol), magnesium (2.43 g, 0.100 mol) in absolute ethyl ether (60 ml). After 1 h reflux, pyrrole (6.70 g, 0.100 mol) was added slowly followed by a further 1 h reflux.

2. Pyrrolyllithium

Following the method of Hodge and Rickards (11), a solution of butyllithium (0.100 mol) in ethyl ether (40 ml) was stirred under nitrogen at 0°C while a solution of pyrrole (7.37 g, 0.110 mol) in absolute ether (40 ml) was added. The mixture was stirred at room temperature a further ½ h.

3. Pyrrolylsodium

In a procedure similar to that of Hobbs *et al.* (8), a solution of pyrrole (8.41 g, 0.125 mol) in absolute tetrahydrofuran (10 ml) was added slowly to a suspension of sodium hydride (2.40 g, 0.100 mol) in tetrahydrofuran (75 ml). After 4 h reflux, the solvent was removed under vacuum and the residue flushed with dry nitrogen. Absolute ether (100 ml) was added and the suspension refluxed ½ h.

4. Pyrrolylpotassium

In a procedure similar to that of Clemo and Ramage (27), a solution of pyrrole (8.41 g, 0.125 mol) in absolute ether (25 ml) and absolute ethanol (2 drops) was added to potassium (3.91 g, 0.100 mol) and absolute ether (75 ml) under nitrogen. The reaction mixture was refluxed until all potassium had reacted.

5. Acylation with Ethyl Chloroformate and Ethyl Chlorothiolformate

(*a*) The Grignard solution (0.100 mol) was cooled to −20°C and a solution of ethyl chloroformate (10.9 g, 0.100 mol) in absolute ether (90 ml) was added over 1½ h. The cold mixture was stirred ½ h and then hydrolyzed with 1 *M* aqueous ammonium chloride (200 ml). When all solid had dissolved, the layers were separated and the aqueous layer extracted twice with equal volumes of ether. The combined ether extracts were washed twice with water and dried ($MgSO_4$). The volume was reduced to 100 ml and 1 ml was used for gc analysis.

After removal of ether, the residue was vacuum distilled to give ethyl 1-pyrrolecarboxylate (2.74 g, 19%), bp 78–81°C/14 Torr, and ethyl 2-pyrrolecarboxylate (5.97 g, 44%), bp 86–87°C/1 Torr. These are known compounds (28), possessing spectral properties in accord with the methyl esters (11).

(*b*) The reaction between pyrrolyllithium (0.100 mol) and ethyl chloroformate (0.100 mol) was carried out in ether (80 ml) at room temperature over 17 h. Hydrolysis was with ether saturated with water, while cooling, to yield ethyl 1-pyrrolecarboxylate (39%) and 1,1′-dipyrrolyl ketone (11%), bp 78–81°C/1 Torr; uv (ethanol): 243 nm (ε 16 700); ir (KCl): 1725 cm^{-1}; nmr τ: 2.70 (2H, t, αH), 3.65 (2H, t, βH). *Anal.* calcd. for $C_9H_8N_2O$: C 67.49, H 5.03, N 17.49; found: C 67.62, H 4.96, N 17.44.

(*c*) Following procedure 5(*b*), reaction of pyrrolylsodium (0.100 mol) and ethyl chloroformate (0.100 mol) gave only ethyl 1-pyrrolecarboxylate (87%).

(*d*) Reaction between pyrrolylpotassium suspension (0.100 mol) and ethyl chloroformate (0.100 mol) was carried out at reflux for 1½ h. Work-up was as described in 5(*b*). Only ethyl 1-pyrrolecarboxylate (64%) was obtained.

(*e*) As described in 5(*a*) a solution of ethyl chlorothiolformate (12.46 g, 0.100 mol) was added to the cold ether solution of pyrrolylmagnesium bromide (0.100 mol). After stirring 3 h the mixture was worked up to give ethyl 1-pyrrolethiolcarboxylate (3%) and ethyl 2-pyrrolethiolcarboxylate (42%) (5).

Ethyl 1-pyrrolethiolcarboxylate was also prepared by the addition of ethyl iodide (25.0 g, 0.150 mol) to 1-pyrrolylthiocarboxanilide (12*b*) (23.0 g, 0.120 mol) in aqueous 6 *M* sodium hydroxide (100 ml) followed by stirring at 100°C for 1 h. After cooling and separation of layers the aqueous layer was extracted twice with ether and the combined organic layers washed with water. The ether was removed and the residue heated to 100°C for 1 h with 6 *M* aqueous sulfuric acid (100 ml). After cooling, the ether extract was washed with 10% aqueous sodium bicarbonate and dried ($MgSO_4$). After removal of ether the product was distilled to give ethyl 1-pyrrolethiolcarboxylate (6.25 g, 24%), bp 105–106°C/10 Torr; uv (ethanol): 248 nm (ε 12 300); ir (film): 1680 cm^{-1}; nmr τ: 2.72 (2H, t, αH), 3.73 (2H, t, βH), 6.92 (2H, q, S—CH_2) 8.63 (3H, t, —CH_3). *Anal.* calcd. for C_7H_9NOS: C 54.19, H 5.85, N 9.03, S 20.65; found: C 54.32, H 5.79, N 9.13, S 20.78.

(*f*) Following procedure 5(*b*) but using ethyl chlorothiolformate, the products were ethyl 1-pyrrolethiolcarboxylate (4.85 g, 31%), 1,1′-dipyrrolyl ketone (1.11 g, 14%), and a trace of ethyl 2-pyrrolethiolcarboxylate. In addition, diethyl dithiolcarbonate (1.48 g), bp 105–109°C/42 Torr, was obtained. The infrared spectrum was identical to that of an authentic sample prepared by the literature method (29).

6. Solvents and Coordinating Agents

(*a*) After 1,2-dimethoxyethane (13.0 g, 0.150 mol) had been added to the solution of pyrrolylmagnesium bromide (0.100 mol), reaction 5(*a*) was repeated (see Table 2).

(*b*) Procedure 6(*a*) was followed, after adding dioxane (13.2 g, 0.150 mol) (see Table 2).

(*c*) After N,N,N′,N′-tetramethylethylenediamine (11.6 g, 0.100 mol) had been added to the solution of pyrrolylmagnesium bromide (0.100 mol), the mixture was refluxed 3 h, cooled, and treated as in 5(*a*). Products obtained were ethyl 1-pyrrolecarboxylate (7.09 g, 51%), ethyl 2-pyrrolecarboxylate (0.71 g, 5%), and 1,2′-dipyrrolyl ketone (0.18 g, 2%), mp 60–61°C (petroleum) (lit. (5) mp 58–60°C), mixture mp undepressed.

(*d*) Procedure 6(*c*) was followed, using TMED (0.150 mol) (see Table 2).

(*e*) After adding various molar ratios of TMED to the solution of pyrrolylmagnesium bromide (0.100 mol), reaction 6(*c*) was repeated using ethyl chlorothiolformate (0.100 mol) (see Table 3).

7. Pyrrolylmagnesium Halide Changes

(*a*) Pyrrolylmagnesium chloride was prepared from butylmagnesium chloride. After addition of TMED (2 mol equiv.), the mixture was refluxed 3 h. The procedure 5(*a*) was then followed (see Table 4).

(*b*) Procedure 7(*a*) was followed, using pyrrolylmagnesium bromide (see Table 4).

(*c*) Pyrrolylmagnesium iodide was prepared from

ethylmagnesium iodide, then 7(*a*) was followed (see Table 4).

8. Temperature Changes

(*a*) Pyrrolyllithium was prepared as usual but in absolute dioxane. To this solution was added an equimolar quantity of ethyl carbonate in dioxane and the reaction mixture stirred at 36°C (oil bath) for 36 h. After removal of much dioxane under reduced pressure and addition of ether, the mixture was worked up in the usual manner. The products isolated were ethyl 1-pyrrolecarboxylate (41%) and ethyl 2-pyrrolecarboxylate (1%). The N/C ratio was 98:2.

(*b*) Procedure 8(*a*) was followed; the reaction mixture was kept at reflux for 13 h. The products isolated were ethyl 1-pyrrolecarboxylate (37%), ethyl 2-pyrrolecarboxylate (16%), and 1,2′-dipyrrolyl ketone (19%). The N/C ratio was now 65:35.

(*c*) Equimolar quantities of pyrrolyllithium and ethyl 1-pyrrolecarboxylate were refluxed in dioxane for 24 h. After the usual work-up the products were found to be ethyl 2-pyrrolecarboxylate (32%) and 1,2′-dipyrrolyl ketone (22%).

(*d*) A solution of ethyl 2-pyrrolecarboxylate in dioxane was refluxed with 2½ times its molar equivalent of pyrrolyllithium for 24 h. After work-up, 1,2′-dipyrrolyl ketone (62%) was isolated. No ethyl 1-pyrrolecarboxylate was detected.

(*e*) A mixture of lithium ethoxide (1.04 g, 0.020 mol) and 1,2′-dipyrrolyl ketone (1.60 g, 0.01 mol) was refluxed in dioxane (100 ml) for 24 h. After work-up, ethyl 2-pyrrolecarboxylate (0.47 g, 34%) was isolated. No ethyl 1-pyrrolecarboxylate was detected. About 20% of the ketone was recovered.

9. Acylation of the 2-Ester

A solution of ethyl 2-pyrrolecarboxylate (6.95 g, 0.050 mol) in ethyl ether (30 ml) was added slowly to ethylmagnesium bromide (0.05 mol) in ether (50 ml). Heat was evolved as well as large quantities of gas, and a white precipitate was observed. After 30 min reflux, the solution was cooled in a bath to about −20°C. To the cold solution, ethyl chloroformate (5.43 g, 0.050 mol) in ether (60 ml) was added over about 1½ h. Then the reaction was stirred at room temperature 17 h, hydrolyzed with saturated aqueous ammonium chloride, and worked up as usual. The product was ethyl 1,2-pyrroledicarboxylate (8.80 g, 83%), bp 86–87°C/1 Torr.

10. Reactions of Pyrrolylmagnesium Bromide

(*a*) Ethyl acetate (8.81 g, 0.100 mol) in absolute ether (90 ml) was added to a cold (−20°C) solution of pyrrolylmagnesium bromide (0.100 mol) in ethyl ether (60 ml) over 1½ h. The reaction mixture was stirred ½ h longer at −10°C. After the usual work-up, the product mixture was analyzed. Unreacted starting material was distilled, followed by 1-acetylpyrrole (0.69 g, 6%), bp 80–81°C/12 Torr, identical in physical properties to a sample prepared by the method of Reddy (30). The residue was cooled and recrystallized from cyclohexane to give 2-acetylpyrrole, mp 89–90°C (2.03 g, 19%), identical to authentic material (31).

(*b*) When this reaction was repeated with stirring at room temperature for 17 h there was no significant change in yield or ratio of products.

(*c*) When reaction 10(*a*) was repeated in the presence of a 1½:1 molar ratio of TMED – pyrrolylmagnesium bromide, and the product hydrolyzed with 6 *M* hydrochloric acid, the organic extract gave 1-acetylpyrrole (3%), 2-acetylpyrrole (1%), and 1-acetoacetylpyrrole (80%), bp 80–84°C/1 Torr; mp (cyclohexane) 49–51°C; uv (ethanol): 350 nm (ε 30 700); ir (KCl): 1710, 1685, 1625 cm^{-1}; nmr (CCl_4) τ: 0.24 (0.6H, s, —OH), 2.80 (2H, t, αH), 3.80 (2H, t, βH), 4.45 (0.6H, s, C=CH), 6.24 (0.8H, s, $—CH_2—$), 7.75 (1.2H, s, $—CH_3$), 7.95 (1.8H, s, $—CH_3$). *Anal.* calcd. for $C_9H_8NO_2$: C 63.57, H 6.00, N 9.27; found: C 63.67, H 5.98, N 9.25. A pink color was obtained with aqueous $FeCl_3$.

(*d*) To a solution of ethylmagnesium bromide (0.050 mol) and TMED (0.075 mol) in ethyl ether (40 ml) was added a solution of 1-acetylpyrrole (0.050 mol) in ethyl ether (20 ml) at such a rate as to keep at reflux. Following 1 h at reflux, the solution was cooled to room temperature and ethyl acetate (4.84 g, 0.055 mol) in absolute ether (40 ml) was added over a period of 1 h. After 17 h stirring at room temperature it was worked up as in 10(*c*) and, after removal of solvent, 1-acetoacetylpyrrole (60%) was isolated by vacuum distillation.

(*e*) Reaction 10(*a*) was repeated using acetyl chloride (7.85 g, 0.100 mol). After removal of the 1-acetylpyrrole (0.10 g, 1%) and 2-acetylpyrrole (4.08 g, 35%) by vacuum distillation, the residue was taken up in 1:1 ether – carbon tetrachloride. This solution was warmed to evaporate some of the ether causing 3-acetylpyrrole to crystallize, mp 113–114°C (0.43 g, 4%), identical in physical properties to an authentic specimen (32).

(*f*) Following the procedure of 10(*a*), reaction with ethyl carbonate gave ethyl 1-pyrrolecarboxylate (13.76 g, 70%) and ethyl 2-pyrrolecarboxylate (0.20 g, 2%).

(*g*) A solution of 1,1′-dipyrrolyl ketone (1.60 g, 0.010 mol) in ethyl ether (20 ml) was added slowly to pyrrolylmagnesium bromide (0.025 mol) in ethyl ether (40 ml). After ½ h reflux, the product was worked up as usual to give 1,2′-dipyrrolyl ketone (1.13 g, 70%). No 1,1′-dipyrrolyl ketone was recovered.

(*h*) Following procedure 10(*a*) reaction with ethyl oxalate (14.61 g, 0.100 mol) gave ethyl 1-pyrrolylglyoxylate ((3.10 g, 19%), bp 70–71°C/1 Torr; ir (KCl): 1760, 1725 cm^{-1}; nmr ($CDCl_3$) τ: 2.60 (2H, t, αH), 3.62 (2H, t, βH), 5.55 (2H, q, $—CH_2—$), 8.59 (3H, t, $—CH_3$). *Anal.* calcd. for $C_8H_9NO_3$: C 57.48, H 5.43, N 8.38; found: C 57.57, H 5.53, N 8.45) and ethyl 2-pyrrolylglyoxylate ((3.69 g, 22%), bp 105–109°C/1 Torr, mp 39–40°C (lit. (21) mp 44.5°C); ir (film): 1730, 1645 cm^{-1}; nmr ($CDCl_3$) τ: 2.77 (1H, m, H_5), 2.92 (1H, m, H_2), 3.80 (1H, m, H_4), 5.71 (2H, q, $—CH_2—$), 8.72 (3H, t, $—CH_3$)).

(*i*) The procedure of 10(*a*) was followed using N,N′-dicyclohexylcarbodiimide (20.63 g, 0.100 mol). After stirring at room temperature for 17 h, the reaction mixture was worked up in the usual manner. Vacuum distillation gave N,N′-dicyclohexyl-1-pyrrolylcarbamidine (25.5 g, 93%) at 140–141°C/1 Torr; mp 42–44°C; uv (ethanol): 223 nm (ε 13 400); ir (KCl): 1640 cm^{-1}; nmr ($CDCl_3$) τ: 3.25 (2H, t, αH), 3.86 (2H, s, βH), 6.00 (1H, b s, NH), 6.78 (2H, s, N—CH), 8.5 (20H, m, 10-CH_2—). *Anal.* calcd. for $C_{17}H_{27}N_3$: C 74.68, H 9.95, N 15.37; found: C 74.48, H 10.11, N 15.25.

(*j*) The procedure of 10(*a*) was repeated with dimethylcyanamide (7.00 g, 0.100 mol). Following 17 h of stirring

at room temperature, the customary work-up gave unreacted pyrrole, dimethylcyanamide, and N,N′-dimethyl-1-pyrrolylcarbamidine (1.03 g, 8%), bp 109–110°C/15 Torr; uv (ethanol): 224 nm (ε 13 000); ir (film): 1635 cm^{-1}; nmr ($CDCl_3$) τ: 3.15 (2H, t, αH), 3.83 (2H, t, βH), 3.90 (1H, b s, NH), 7.20 (6H, s, NCH_3). *Anal.* calcd. for $C_7H_{11}N_3$: C 61.29, H 8.08, N 30.63; found: C 61.06, H 8.04, N 30.57. This reaction was repeated using an ether solution of pyrrolyllithium (0.100 mol) together with TMED (0.200 mol) and the product hydrolyzed with water and worked up to give N,N′-dimethyl-1-pyrrolylcarbamidine 1.30 g (10%). As well, starting materials were recovered.

(*k*) A solution of pyrrolyllithium (0.100 mol) in ethyl ether (40 ml) and TMED (0.200 mol) was treated at about −20°C with methyl thiocyanate (7.30 g, 0.100 mol) in ether (40 ml) over ½ h, and stirred at this temperature a further 1 h before the usual work-up. Vacuum distillation gave two products. The first was 1,1′-dipyrrolyl ketimine (3.97 g, 25%), bp 84–88°C/1 Torr, mp 47–48.5°C (petroleum bp 30–50°C); uv (ethanol): 238 nm (ε 17 800): ir (KCl): 3240, 1660 cm^{-1}; nmr ($CDCl_3$) τ: 2.34 (1H, b s, NH), 2.92 (2H, t, αH), 3.70 (2H, t, βH). *Anal.* calcd. for $C_9H_9N_3$: C 67.91, H 5.70, N 26.40; found: C 68.03, H 5.79, N 26.26. The second product was 1,1′-dipyrrolyl *N*-methylthioketimine (5.69 g, 28%), bp 105–110°C/1 Torr, mp 41–42°C (petroleum, bp 30–50°C); uv (ethanol): 239 nm (ε 9300), 296 nm (ε 11 400); ir: 1640, 1625 cm^{-1}; nmr ($CDCl_3$) τ: 3.80 (2H, t, αH), 3.71 (2H, t, βH), 7.32 (3H, s, —SCH_3). *Anal.* calcd. for $C_{10}H_{11}N_3S$: C 58.53, H 5.40, N 20.84, S 15.59; found: C 58.50, H 5.51, N 20.38, S 15.66.

11. Reduction of Compound ***1***

A mixture of N,N′-dicyclohexyl-1-pyrrolylcarbamidine (**1**) (3.22 g, 0.012 mol) and lithium aluminum hydride (0.88 g, 0.024 mol) in ethyl ether (200 ml) was refluxed for 26 h. The mixture was cooled in ice and hydrolyzed with water-saturated ether (200 ml). The organic solution was filtered, washed with water, and dried ($MgSO_4$). After filtration and solvent removal, the residue was vacuum distilled to give N,N′-dicyclohexylformamidine (1.38 g, 56%), bp 120–121°C/1 Torr, mp 102–104°C (lit. (26) mp 106°C). Other physical properties were consistent with this structure.

Pyrrole chemistry. XVII. Alkylation of the pyrrolyl ambident anion

NAM-CHIANG WANG, KANG-ER TEO, AND HUGH J. ANDERSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received May 19, 1977

NAM-CHIANG WANG, KANG-ER TEO, and HUGH J. ANDERSON. Can. J. Chem. **55**, 4112 (1977).

A series of experiments were carried out to find optimum conditions for C- and N-alkylation of the pyrrolyl ambident anion. While almost total C-alkylation could be obtained, isolation of a single alkylation product was not feasible. However, N-alkylation of pyrrole and several 2-substituted pyrroles was readily achieved by phase transfer catalysis with primary alkyl halides.

NAM-CHIANG WANG, KANG-ER TEO et HUGH J. ANDERSON. Can. J. Chem. **55**, 4112 (1977).

On a effectué une série d'expériences afin de trouver les conditions optimales pour la C- et la N-alkylation de l'anion ambivalent pyrrolyle. Alors que l'on peut obtenir une C-alkylation presque totale, il n'est pratiquement pas possible d'isoler un seul produit d'alkylation. Toutefois la N-alkylation du pyrrole et de plusieurs pyrroles substitués en position 2 peut être réalisée par une catalyse de transfert de phase avec des halogénures d'alkyles primaires.

[Traduit par le journal]

In the course of our investigation of the acylation of the pyrrolyl ambident anion under various conditions (1) it seemed desirable to use the information gained to establish the simplest possible preparative methods for *C*- and *N*-alkylpyrroles. It has been necessary to extend earlier work by others as well as to repeat some of it under conditions comparable to those of our acylations.

The review by Shevelev (2) has related, among many other reactions, most of the known alkylation experiments on the pyrrolyl and indolyl ambident anions to the 'hard and soft acids and bases principle' (3). Thus alkylation of the pyrrolyl and indolyl salts of the hardest cations give the lowest N/C ratio.

The work of Hobbs *et al.* (4) has established that the order of increasing N/C ratio for allyl, crotyl, and benzyl halides is $Li^+ < Na^+ < K^+ < NR_4^+$, with the hardest ion, Li^+, giving most C-substitution, as expected. The even harder Mg^{2+} of Grignard reagents leads to almost exclusive C-substitution by allyl bromide (5). The saturated alkyl is harder than the allyl group and gives a higher N/C ratio under comparable conditions (6). Nevertheless, the amount of N-alkylation is very small with Grignard reagents (7).

Another factor is that the N/C ratio changes with the changing polarity of aprotic solvents. For example, the change from ethers to arenes and alkanes in the reaction of pyrrolylpotassium with allyl halides caused a decrease from 4:1 to 1:6 in the N/C ratio (4). The stepwise addition of the strongly coordinating dipolar aprotic solvent, hexamethylphosphoric triamide (HMPA), to the tetrahydrofuran solution of indolylmagnesium halide caused a regular increase in the N/C ratio of methylation products (8). In ethyl ether and tetrahydrofuran (THF), pyrrolylmagnesium bromide gave almost entirely C-methylation, but in pure HMPA gave only N-methylation (5). This hard coordinating agent strongly associates with the hard metal and separates the ion pair.

In an attempt to establish an experimentally convenient approach to preparative N-alkylation (Table 1) we first added 2 mol equiv. of HMPA to the ethyl ether solution of 1 mol equiv. of pyrrolylmagnesium bromide. While a rise in temperature and the appearance of a white precipitate was observed, there was no N-methylation with methyl iodide nor any significant change in the distribution of C-substituted products. Although our results were similar to those of Reinecke *et al.* (8), at lower ratios of HMPA to Grignard reagent we did not obtain in the pyrrole series the complete change to N-methylation they observed in the indole series. Because alkylation in pure HMPA required preparation of the Grignard reagent in ether and replacement of it by HMPA (5), this was not considered a satisfactorily simple approach to the preparation of *N*-alkylpyrroles.

Griffin and Obrycki (9) found little change in

TABLE 1. Methylation of pyrrolylmagnesium bromide

Ratio HMPA / Pyrrolyl–MgBr	1-Methyl (%)	2-Methyl (%)	3-Methyl (%)	2,3-Dimethyl (%)	2,5-Dimethyl (%)	2,3,5-Trimethyl (%)	N/C* ratio

4:1	49	Trace	Trace	—	—	—	99:1

*About 30–40% of unchanged pyrrole was recovered from each reaction.

the small N/C ratio when pyrrolylmagnesium bromide in ethyl ether reacted with methyl iodide, bromide, sulfate, phosphate, or *p*-toluenesulfonate. However, using the softer allyl group, Papadopoulos and Tabello (6) obtained a greater N/C ratio for alkali metal salts of pyrrole with allyl *p*-toluenesulfonate than with allyl bromide. Thus, the harder leaving group does seem to have an effect under favorable conditions.

Reinecke *et al.* (8) had found that the addition of 2 mol equiv. of HMPA before treatment with methyl iodide permitted observation of decreasing N/C ratios for indolylmagnesium chloride, bromide, and iodide in THF solution. We added 2 mol equiv. of HMPA of pyrrolylmagnesium bromide and found it possible to observe that while no N-methylation took place with methyl iodide, there was a substantial proportion with methyl sulfate and *p*-toluenesulfonate. That is, the harder the alkylating agent the more the N-attack, provided the Mg is coordinated with a strongly polar aprotic reagent. We have also used tetramethylethylenediamine (TMED) in this way to observe the N/C ratios in some acylations (1).

It is not easy to alter the Grignard reaction to obtain nearly all N-alkylation by changes in solvent, complexing agent, or alkylating agent. The traditional use of alkali metal salts for N-alkylation requires anhydrous conditions and considerable care. One simple approach appeared to be the use of phase transfer catalysis which has recently been used successfully to N-alkylate indole and to benzylate pyrrole (10). The only other methods available require the formation of the relatively expensive thallium(I) salt of pyrrole (11) or the use of potassium hydroxide – dimethyl sulfoxide (12).

The phase transfer catalysis method makes use of the very soft quaternary ammonium salt of the ambident anion. The choice of a suitable tetraalkylammonium cation enables transfer of its ion pair with the pyrrolyl anion from the aqueous phase into an organic one of low polarity where it can react with the alkyl halide (13) at the harder (N) centre.

Our results for alkylations of pyrrole itself are recorded in Table 2. In each example the product was isolated by distillation and was found to show a ^{1}Hmr spectrum free of C-alkylated product except for the allyl halide reaction. There the ^{1}Hmr spectrum integration showed both 1- and 2-allylpyrroles in a ratio of about 1:4. So, once again the softer allyl halide tended to give a lower N/C ratio than did the alkyl halides (10*b*). The results were of preparative utility for primary alkyl halides, and did not require the alkyl iodides used by others (11, 12). They were not as satisfactory for the secondary (isopropyl) halide, and failed for the tertiary (*tert*-butyl) halide in common with the other methods (11, 12). For reasons that are not clear, butyl bromide gave superior yields to butyl chloride. Iodides are generally not satisfactory in the phase transfer method (13) as they give the softest alkylating reagent. The harder reagents, methyl sulfate and methyl *p*-toluenesulfonate, were more successful than methyl, ethyl, or butyl iodides.

The phase transfer method was also satisfactory for the methyl sulfate methylation of pyr-

TABLE 2. Phase transfer alkylation of pyrrole

Alkylating agent	Pyrrole isolated	% yield	Boiling or melting range (°C/Torr) Present study	Lit. (ref.)

2-Pyrrolecarbonitrile	1-Methyl-2-pyrrolecarbonitrile	76	35–37/0.5	86–88/11 (17*d*)

roles having an electron withdrawing group at position-2. However, 2-methylpyrrole gave a poor yield of 1,2-dimethylpyrrole (see Table 3).

While alkylation of the pyrrole Grignard gives entirely C-substituted products, it can be seen from Table 1 that the method is not suitable for the preparation of 2- or 3-methylpyrrole. Most authors found (5, 7, 9) that the C-alkylated product was a mixture from which no single component was easily obtained in a yield of preparative value, or that the overall yield was low (14). No simple modification of the procedure has improved this situation so far. It appears that 2- and 3-alkylpyrroles are still best prepared through reduction of the corresponding acylpyrroles as suggested by Skell and Bean (15).

Preparation of the Grignard reagents from 2- and 3-methylpyrroles and 2,5-dimethylpyrrole and their reactions with methyl iodide helped to confirm the structures of the methylation products as well as to confirm that only C-methylation occurred in each case.

Experimental

Instruments and conditions were as described in ref. 19. Analysis of reaction mixtures was carried out on a Varian 1520B gas chromatograph equipped with a 12 ft column packed with 30% Carbowax 20M on Chromosorb W (80–100 mesh) with helium as carrier gas. Each product was dried, the volume reduced to a fixed volume, and a 1 ml sample retained for analysis as described in ref. 1. The rest of the solution was used for isolation and identification of products.

Pyrrolylmagnesium Bromide

This compound was prepared as described in ref. 1. All Grignard reagents were prepared and reacted under dry nitrogen.

Reaction with Methyl Iodide

Pyrrolylmagnesium bromide (0.400 mol) in absolute ether (800 ml) was cooled in ice, and methyl iodide (113 g, 0.800 mol) in absolute ether (100 ml) was added slowly with stirring. The reaction mixture was stirred overnight at room temperature, cooled in ice, and cold water added until the product was distributed between two layers. After two further ether extractions of the aqueous layer, the combined extracts were washed twice with water, flushed with nitrogen, and dried (K_2CO_3).

The dried product was reduced to 500 ml and analyzed by gas chromatography using authentic samples of pyrrole: 1-, 2-, and 3-methylpyrrole; 2,3- and 2,5-dimethylpyrrole; and 2,3,5-trimethylpyrrole for comparison. Distillation enabled separation into: (*a*) unreacted pyrrole, bp 129–131°C/760 Torr; (*b*) a mixture of 2- and 3-methylpyrrole, bp 147–149°C/760 Torr; (*c*) a mixture of 2,3- and 2,5-dimethylpyrrole, bp 65–67°C/10 Torr; and (*d*) a mixture of 2,3-, 2,5-dimethylpyrrole and 2,3,5-trimethylpyrrole, bp 72–75°C/10 Torr. Percentages are listed in Table 1. These fractions were used as well to compare nmr (and ir of fractions (*a*) and (*d*)) spectra with authentic samples. The physical properties of these compounds are given by Hinman and Theodoropulos (18*a*).

Reactions with Methyl Iodide in the Presence of HMPA

A solution of hexamethylphosphoric triamide (21.5 g, 0.120 mol) in absolute ether (10 ml) was added slowly to the pyrrolylmagnesium bromide (0.040 mol) in absolute ether (50 ml) at room temperature. The reaction mixture was refluxed 30 min, then cooled in ice. The reaction with methyl iodide (5.68 g, 0.040 mol), work-up, and analysis are described above, except that an earlier fraction, 1-methylpyrrole, bp 113–114°C, was collected and identified.

Results of experiments using varying proportions of HMPA are given in Table 1.

Reactions with Methyl p-Toluenesulfonate and Methyl Sulfate in the Presence of HMPA

These reactions were carried out, worked up, and analyzed as before. The results are given in Table 1.

Reaction of 2-Methylpyrrolylmagnesium Bromide with Methyl Iodide

The Grignard reagent was prepared from 2-methylpyrrole (0.040 mol) and reacted with methyl iodide (0.04 mol) in the manner described for pyrrole. Work-up and analysis was as before, giving 2,5-dimethylpyrrole (0.55 g, 17%), 2,3-dimethylpyrrole (0.43 g, 11%) and 2,3,5-trimethylpyrrole (0.33 g, 8%).

Reaction of 3-Methylpyrrolylmagnesium Bromide with Methyl Iodide

The Grignard reagent from 3-methylpyrrole (0.0070 mol) reacted with methyl iodide (0.0070 mol) gave, after the usual treatment, 2,3-dimethylpyrrole (0.13 g, 22%) and 2,3,5-trimethylpyrrole (0.17 g, 24%).

Reaction of 2,5-Dimethylpyrrolylmagnesium Bromide with Methyl Iodide

The Grignard reagent from 2,5-dimethylpyrrole (0.010 mol) reacted with methyl iodide (0.010 mol) gave, after the usual treatment, 2,3,5-trimethylpyrrole (0.22 g, 20%).

Typical Phase Transfer Catalysis Alkylation

A 50% aqueous solution of sodium hydroxide (5 ml) was added to a solution containing pyrrole (0.67 g, 0.010 mol), butyl bromide (1.5 g, 0.011 mol), and tetrabutylammonium bromide (0.32 g, 0.0010 mol) in methylene chloride (10 ml) with external cooling. The mixture was then stirred and gently refluxed for 20 h. The resulting mixture was diluted with water and extracted with methylene chloride. The combined extracts were washed with 2 *M* HCl, water, saturated brine solution, and dried ($MgSO_4$). The solvent was removed *in vacuo* at a temperature <40°C. A crude yield of brown liquid (1.14 g, 93%) was obtained. The crude product was then distilled at reduced pressure to give pure 1-butylpyrrole (1.03 g, 84%); the bp (Table 2) was in accord with the literature (16*a*) and its pmr and mass spectrum in agreement with the structure.

See Table 2 for other alkylations.

Reactions of 2-substituted pyrroles were carried out similarly. (Table 3). Some alkylations were checked for yield on a 10 × scale.

Stereospecific syntheses of the α-patchoulene and α-cedrene skeletons from a common intermediate

PIERRE DESLONGCHAMPS, JACQUES LAFONTAINE, LUC RUEST, AND PIERRE SOUCY

Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 28, 1977

PIERRE DESLONGCHAMPS, JACQUES LAFONTAINE, LUC RUEST, and PIERRE SOUCY. Can. J. Chem. **55**, 4117 (1977).

The synthesis of the cyclopropane diketone **3** and its specific conversion into the tricyclic enedione **4** (cedrene skeleton) under kinetic control and into the tricyclic enedione **5** (patchoulene skeleton) under thermodynamic control is reported.

PIERRE DESLONGCHAMPS, JACQUES LAFONTAINE, LUC RUEST et PIERRE SOUCY. Can. J. Chem. **55**, 4117 (1977).

On rapporte la synthèse de la dicétone cyclopropanique **3** et sa transformation spécifique en ènedione tricyclique **4** (squelette du cédrène) sous contrôle cinétique et en ènedione tricyclique **5** (squelette du patchoulène) sous contrôle thermodynamique.

The sesquiterpenes α-cedrene and α-patchoulene are known to possess the structures **1** (1) and **2** (2) respectively (Scheme 1). If both structures are rewritten and represented by formulas **1***A* and **2***A*, it is interesting to note that α-cedrene and α-patchoulene have rings A and B identical (except for the configuration of the secondary methyl group) and that they differ by the attachment of one of the bonds of ring C. Ring C is attached to C-1 in cedrene and to C-5 in α-patchoulene. Both structures differ also by the position of the methyl group in ring C which is at C-8 in **1***A* and at C-10 in **2***A*. This analysis led us to imagine a synthetic route which could potentially produce both skeletons via a single intermediate. We wish to report the synthesis of the cyclopropane diketone **3**, a common intermediate lacking only the methyl group of ring C, and its specific conversion into the tricyclic enediones **4** (cedrene skeleton) or **5** (patchoulene skeleton) respectively.

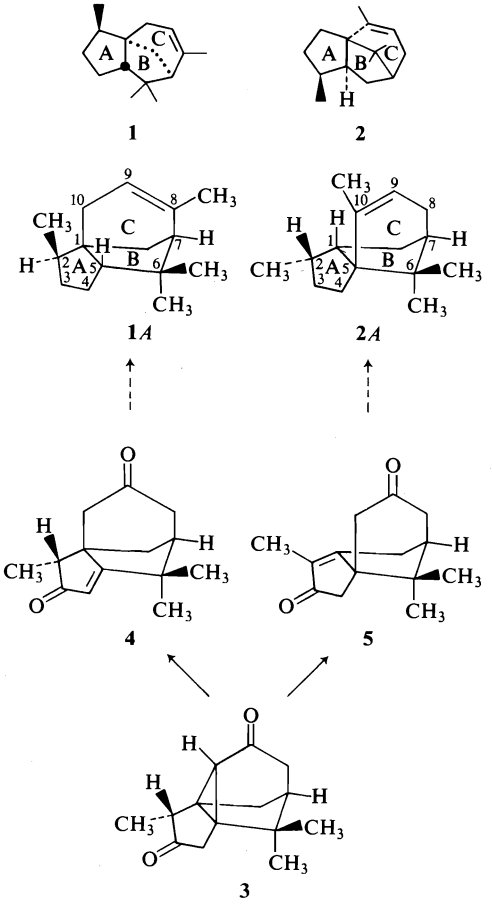
Synthesis of the Cyclopropane Diketone 3

The synthetic route chosen to build **3** is described in Scheme 2. Both epimeric diacetate anhydrides **10***A* (R = H, R′ = OAc) and **10***B* (R = OAc, R′ = H) have been obtained pure and were individually transformed into **3**. The key steps from **10** are the formation of the tetrasubstituted olefins (**10** → **12**), the Arndt–Eistert homologation of the side chain (**12** → **16**), and the formation of the cyclopropane intermediates (**16** → **19**) (3) which were then converted into **3** by oxidation of the cyclopropane alcohols **20** and **21**. The details of these transformations which occurred in good yield in both epimeric series are described in the Experimental. The pyrolysis of the epimers **11** (*A* and *B*) was carried at 200–210°C under nitrogen at atmospheric pressure and this interesting elimination reaction proceeded well in both cases.[1]

The epimeric mixture (at carbon-2) **9** is known; it is one of the intermediates in the synthesis of α-cedrene carried out by Stork and Clarke (7). In their original synthesis, alkylation of the β-ketoester **6** with benzyl α-bromopropionate gave **7** (X = $OCH_2C_6H_5$) which was then converted (into the methyl ketone **8**) in five operations by the successive transformation of the benzyl ester group into a carboxylic acid (**7**, X = OH), an acid chloride (**7**, X = Cl), a diazoketone (**7**, X = CHN_2), an α-chloroketone (**7**, X = CH_2Cl), and a methyl ketone (**8**).

We have repeated this sequence of reactions and have obtained only one epimer (at carbon-6)

[1]This reaction does not proceed by elimination of acetic acid (Scheme 3) to give the intermediate **22** which could then undergo a retroene decarboxylative elimination (4), since the pyrolysis of **11** (COOH = COOD) did not give **12** (X = D) containing a deuterium. It is therefore either a direct elimination which could occur via an eight-membered transition state **23** (5) or an indirect one, via internal anhydride formation **24** followed by β-lactone **25** and loss of CO_2 (6).



SCHEME 1

of diketone **8**. Treatment of that pure epimer of **8** with potassium *tert*-butoxide in *tert*-butanol gave a mixture of epimers **9**.

We have found that the same mixture of epimers **9** could be obtained in two steps from the β-ketoester **6**. Alkylation of **6** with 3-bromo-2-butanone gave an epimeric mixture (at carbon-6) of diketone **8** which was then converted into the same mixture of epimers **9**.

The reduction of crude **9** with sodium borohydride in ethanol followed by hydrolysis with aqueous potassium hydroxide and treatment with acetic anhydride in the presence of *p*-toluenesulfonic acid in benzene, gave a crystalline mixture of the epimers **10** which were separated by fractional crystallization.

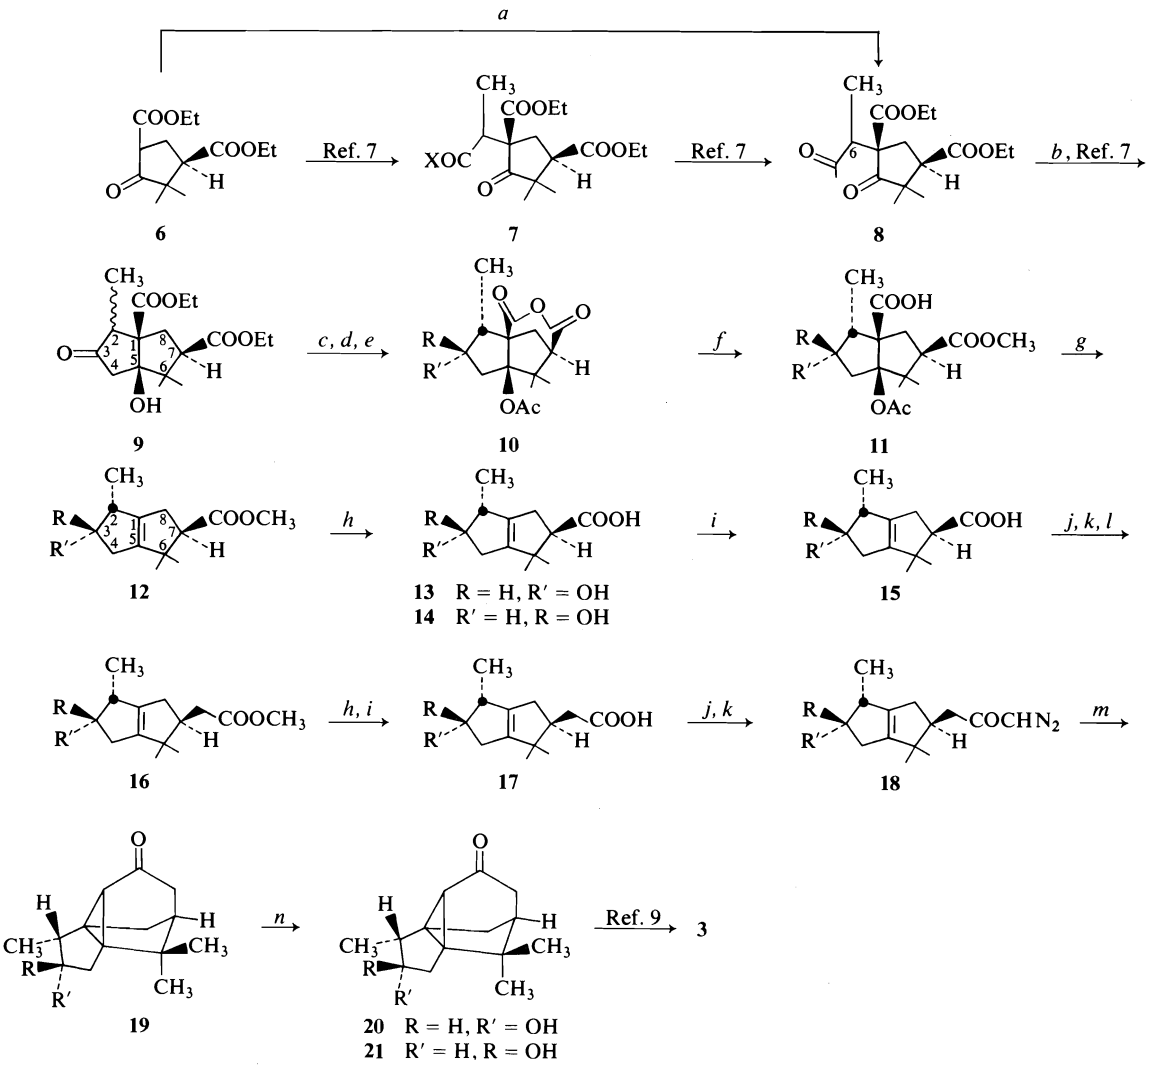
Configuration of Epimers 10A and 10B

With the epimer **10***A*, a nuclear Overhauser effect (8) was not observed between the secondary methyl group and the proton H_3 (Scheme 4). This result was taken as evidence that the secondary acetate group is *cis* to the secondary methyl group. In the case of the epimer **10***B*, a 12% increase in the intensity of the signal for the proton H_3 was observed by irradiation of the secondary methyl group. This result was taken as evidence that the secondary methyl group is *trans* to the secondary acetate group in **10***B*.

The following series of transformations (Scheme 4) constitute a chemical proof that compounds **10***A* and **10***B* are epimeric at carbon-3 only. Basic hydrolysis of **10***B* followed by treatment with diazomethane gave the crystalline diol diester **26** which was then oxidized by the chromium trioxide – pyridine reagent (9) to give the ketoalcohol diester **27**. Reduction of **27** with sodium borohydride in methanol gave a mixture of the dihydroxy dimethyl esters **26** (66%) and **28** (34%) which were separated by preparative thin-layer chromatography. Oxidation of **28** with the chromium trioxide – pyridine reagent gave back **27**. Finally, basic hydrolysis of **26** and **28** followed by acetylation gave the epimers **10***B* and **10***A* respectively. The fact that the epimers **20** and **21** (Scheme 2) are both converted to the same cyclopropane diketone **3** by oxidation with the chromium trioxide – pyridine reagent further confirms that compounds of the *A* and the *B* series have different configurations at carbon-3 only.

The relative configurations of the secondary methyl and acetate groups of ring A with the anhydride and the tertiary acetate groups in compounds **10** could be determined by proton nmr and infrared spectroscopic analysis. The signal of the hydrogen at carbon-3 appears at a much lower field in **10***A* (5.41 δ) than in **10***B* (4.84 δ) indicating that this hydrogen must be *cis* to the anhydride function in **10***A* (Scheme 4) and *trans* in **10***B*. It appears reasonable to assume that the carbonyl group of an anhydride function properly oriented could have a deshielding effect (10). The secondary methyl groups have virtually the same chemical shift in both epimers (**10***A* = 1.02 δ and **10***B* = 1.08 δ) and the value corresponds to that expected for a methyl group not subject to strong deshielding or shielding effects. In support of this assignment, the secondary methyl group of norcedrene dicarboxylic acid anhydride (**29**)[2] appears at 1.34 δ (11). Thus the methyl group cannot be *cis* to the anhydride function in **10***A* and **10***B*.

[2]We are grateful to Professor Gilbert Stork for his generous gift of norcedrene dicarboxylic acid anhydride.



Series *A*: R = H, R' = OAc Series *B*: R' = H, R = OAc

(*a*) LiH, DME; 3-bromo-2-butanone; (*b*) *t*-BuOK, *t*-BuOH; (*c*) $NaBH_4$, EtOH; (*d*) KOH, H_2O; (*e*) $(CH_3CO)_2O$, *p*-toluenesulfonic acid; (*f*) CH_3ONa, CH_3OH; (*g*) pyrolysis, 200–210°C; (*h*) NaOH, H_2O; (*i*) $(CH_3CO)_2O$, pyridine; (*j*) oxalyl chloride, pyridine, benzene; (*k*) CH_2N_2, ether; (*l*) Ag_2O, CH_3OH; (*m*) copper, benzene (3); (*n*) NaOH, H_2O, THF.

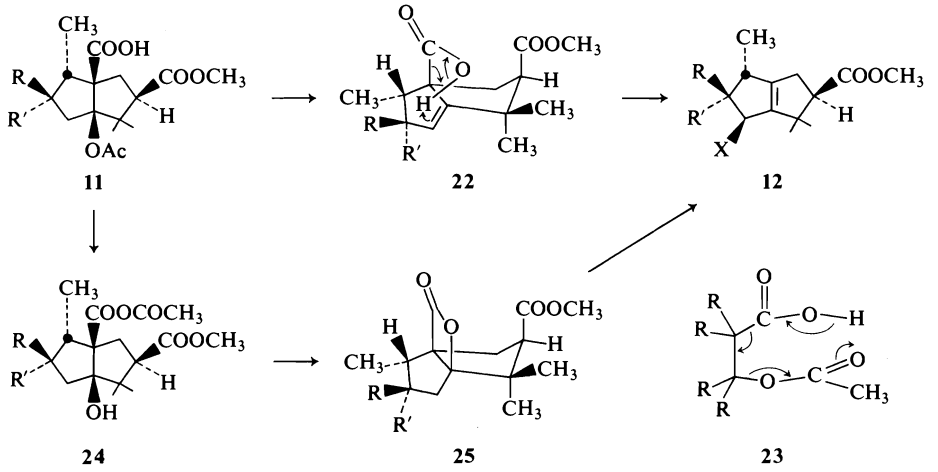
SCHEME 2

A study of the hydroxyl absorption by infrared spectroscopy at high dilution of compounds **26**, **27**, and **28** indicates clearly that the hydroxyl groups are *cis* in **26** and *trans* in **28**. Compound **26** showed hydrogen bonded hydroxyl groups only (3460 and 3515 cm^{-1}) while the isomer **28** had both bonded and nonbonded hydroxyl frequencies (3470 and 3650 cm^{-1}). Ketone **27** was also studied as a model and it showed only bonded hydroxyl group frequency (3470 cm^{-1}).

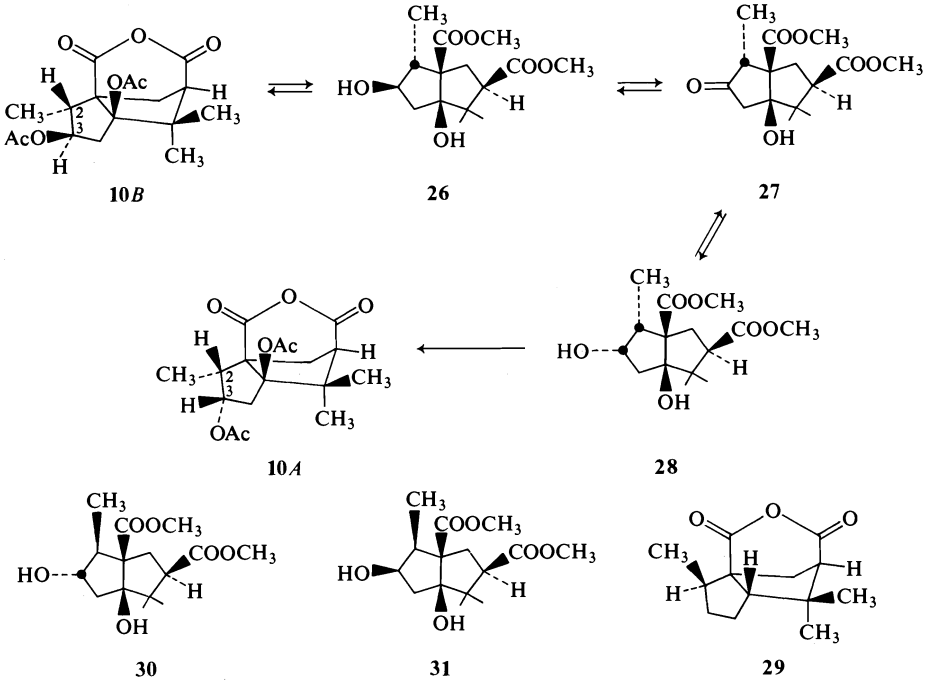
These results indicate that the alternative structures **30** and **31** for **26** and **28** can be eliminated.

Reactivity of the Cyclopropane Diketone 3

Treatment of the tetracyclic diketone **3** with three equiv. of sodium methoxide in methanol



SCHEME 3

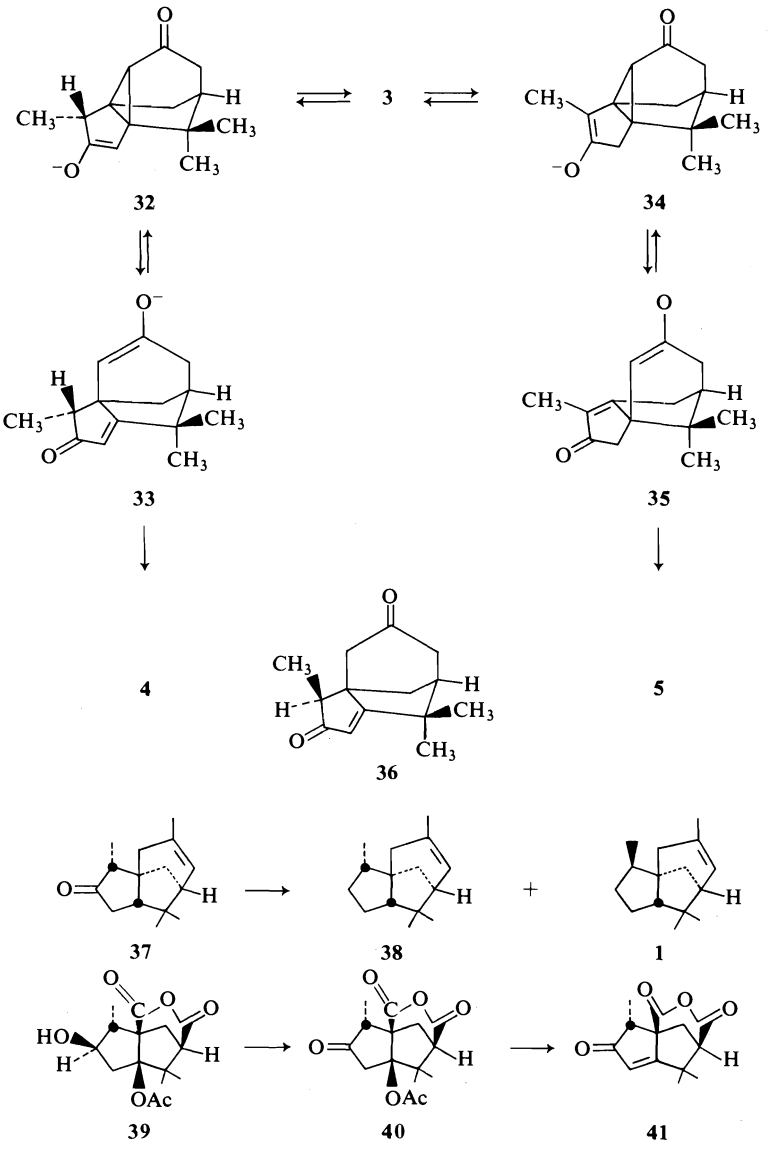


SCHEME 4

at room temperature for a period of 20 min gave a single product which was identified as the tricyclic enedione **4**[3] (12). When the same reaction was carried out for a period of 12 h, a single new substance was formed which was identified as the isomeric enedione **5**. Clearly, **4** is a kinetic product while **5** is the result of a reaction under thermodynamically controlled conditions.

These interesting results can be rationalized in the following way. It is reasonable to assume that enolization of **3** should be faster at the less hindered carbon-4 (Scheme 5), generating the kinetic enolate **32** which would then undergo a cyclopropane ring opening via a retro Michael addition reaction to give the tricyclic enolate **33** which yields **4** on protonation.

[3]With a catalytic amount of sodium methoxide, the same product **4** was obtained, but the reaction takes 68 h.



SCHEME 5

Formation of the other isomer **5** clearly indicates that **4** is in equilibrium under basic conditions with the tetracyclic dione **3** although the equilibrium is much in favor of **4**. It also indicates that **3** can also enolize at the more hindered carbon-2, although at a lower rate than at carbon-4, to give the more substituted enolate **34** which fragments to give the tricyclic enolate **35** which gives **5** on protonation.

The isomerization of **4** into **5** represents an interesting rearrangement which occurs via a cyclopropane intermediate **3** through a Michael – retro Michael addition reaction mechanism (12, 13).

It is in principle possible that the enedione **4** could possess the isomeric structure **36**. However, we believe that it is very unlikely that **4** could have completely isomerized to **36**. Demole *et al.* (14) have shown that the Wolff–Kischner reduction of **37** under equilibrating conditions gave a mixture of *epi*-α-cedrene **38** (65%) and α-cedrene (**1**) (35%) (Scheme 5).

During the course of this work, the pure tricyclic enone anhydride **41** was also prepared

(Scheme 5). Basic hydrolysis of **10***B* under mild conditions gave the alcohol **39** which was oxidized by the chromium trioxide – pyridine reagent to give crude ketoacetate **40**. Attempted crystallization of **40** resulted in the formation of pure enone **41**.

The conversion of **5** into α-patchoulene as well as the transformation of **4** into α-cedrene was not investigated.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Vapor-phase chromatographic (vpc) analyses were carried out on a Varian aerograph instrument model 90-P. Proton nmr spectra were recorded on a Varian A-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The mass spectra were taken on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de microanalyse, Université de Sherbrooke, and by Dr. C. Daessle, Organic Microanalyses, Montréal. Anhydrous magnesium sulfate was used as the drying agent in working up reactions. Low boiling petroleum ether (bp 30–60°C) was used.

Benzyl Ester **7** *(X = $OCH_2C_6H_5$)*

Following the experimental procedure of Stork and Clarke (7), the β-ketoester **6** (43 g, 0.17 mol) was alkylated with benzyl α-bromopropionate. Distillation gave the benzyl ester **7** (X = $OCH_2C_6H_5$) (33 g, 75%); bp 125°C/1.5 Torr (lit. (7) bp 132–133°C/0.01 Torr); ir ν_{max} ($CHCl_3$): 3300 and 1725 cm^{-1}; nmr ($CDCl_3$) δ: 7.26 (5H, s, C_6H_5), 5.02 (2H, m, $CH_2C_6H_5$), 4.0 (4H, q, 2 OCH_2CH_3), and 1.6–0.6 (15H, 5 CH_3).

Diester Diketone **8**

(a) From Benzyl Ester **7** *(X = $OCH_2C_6H_5$)*

Following the experimental procedure of Stork and Clarke (7), the benzyl ester **7** (X = $OCH_2C_6H_5$) (25 g, 0.06 mol) gave the carboxylic acid **7** (X = OH) (10 g, 53%); mp 113–114°C (lit. (7) mp 113–115°C); ir ν_{max} ($CHCl_3$): 3250 (br) and 1725 cm^{-1}; nmr ($CDCl_3$) δ: 4.25 (4H, q, J = 6 Hz, 2 OCH_2CH_3), 1.44–1.18 (12H, m), and 0.92 (3H, s, CH_3—C_5).

The carboxylic acid **7** (X = OH) (5 g, 15 mmol) was then transformed into **7** (X = CH_2Cl) (2.2 g, 44%); mp 72–73°C (lit. (7) mp 72–73°C); ir ν_{max} ($CHCl_3$): 1715 cm^{-1}; nmr ($CDCl_3$) δ: 4.22 (4H, q, J = 6 Hz, 2 OCH_2CH_3), 4.22 (2H, s, CH_2Cl), 1.4–1.1 (12H, 4 CH_3), and 0.95 (3H, s, 1 CH_3—C_5).

Compound **7** (X = CH_2Cl) (2.2 g, 6 mmol) was finally converted into the diester diketone **8** (1.8 g, 91%); mp 68–69°C (from petroleum ether) (lit. (7) mp 55–60°C); ir ν_{max} ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 4.15 (4H, q, J = 6 Hz, 2 OCH_2CH_3), 2.08 (3H, s, CH_3CO), 1.6–1.0 (12H, m, 4 CH_3), and 0.82 (3H, s, 1 CH_3—C_5).

(b) From β-Ketone Ester **6**

The β-ketone ester **6** (150 g, 0.60 mol) in dry dimethoxyethane (450 ml) was added to a suspension of lithium hydride (4.88 g, 0.61 mol) in dry dimethoxyethane (600 ml). After refluxing for 12 h under nitrogen, the mixture was decanted and the lithium hydride residue was washed with dry dimethoxyethane. To the combined dimethoxyethane solution was added 3-bromo-2-butanone (95.4 g, 0.63 mol) in dry dimethoxyethane (30 ml) and the mixture heated at reflux for 50 h under nitrogen. The solution was evaporated *in vacuo* and the solid removed by filtration. The filtrate was diluted with ether, washed with 10% aqueous sodium carbonate and water, and dried over sodium sulfate. The solvents were evaporated and the resulting oil was purified by chromatography on Florisil to yield the diester diketone **8** (121 g, 64%); ir ν_{max} ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 4.15 (4H, q's, OCH_2CH_3), 2.16 and 2.08 (3H, 2 s's (ratio 1:1), CH_3CO), and 1.45–0.84 (15H, m's, 5 CH_3).

Ketoalcohol Diester **9**

Following the experimental procedure of Stork and Clarke (7), the diketone diester **8** (34.7 g, 0.106 mol) was added to a cold solution (0°C) of potassium *tert*-butoxide (from 12.8 g, 0.33 mol, of potassium in 650 ml *tert*-butanol). The stirred solution was allowed to come to room temperature over 50 min, and then poured into a mixture of ether and water. The aqueous phase was extracted twice with ether and the combined ether phase was washed with a saturated sodium chloride solution. Drying and evaporation of the solvent yielded the ketoalcohol diester **9** as an oil (24.7 g, 71%) which was not further purified; ir ν_{max} ($CHCl_3$): 3450 and 1725 cm^{-1}; nmr ($CDCl_3$) δ: 4.15 (4H, q's, OCH_2CH_3) and 1.48–0.80 (15H, m's, 5 CH_3).

The same reaction was carried out with the pure epimer **8** (mp 68–69°C) and it gave the same epimeric mixture of the ketoalcohol diester **9**.

Diacetate Anhydrides **10***A and* **10***B*

A solution of crude ketoalcohol diester **9** (170 g, 0.52 mol) in absolute ethanol (200 ml) was added slowly to a suspension of sodium borohydride (31.4 g, 0.85 mol) in absolute ethanol (1.3 ℓ). After 4 h at 0°C, the mixture was acidified with dilute hydrochloric acid to pH 5. The mixture was concentrated and then extracted several times with ether. Drying and evaporation of the solvent gave an oily residue of crude diol diester (159 g, 93%). The crude diol diester (165 g, 0.506 mol) was heated at reflux with potassium hydroxide (123 g, 2.19 mol) in water (600 ml). After cooling, the solution was extracted with ether, the aqueous phase was acidified with dilute hydrochloric acid to pH 5, saturated with sodium chloride, then extracted several times with ether. Drying and evaporation of the solvent gave the diol diacid as an oil (110 g, 85%). A solution of the crude diol diacid (110 g, 0.405 mol), acetic anhydride (600 ml), and *p*-toluenesulfonic acid (800 mg) was heated at 60–70°C for 24 h. The acetic anhydride was removed *in vacuo* and the residue dissolved in ether. The organic phase was washed several times with water, dried, and evaporated to yield a viscous oil. Crystallization from chloroform gave the mixture of diacetate anhydrides **10***A* and **10***B* (36 g, 26%). Fractional crystallization from chloro-

form–pentane (1:2) afforded the diacetate anhydrides **10***A* and **10***B* in a ratio of 1:2.

*Diacetate Anhydride **10A***: mp 215–216°C (from chloroform–pentane); ir ν_{max} ($CHCl_3$): 1815, 1768, and 1740 cm^{-1}; nmr ($CDCl_3$) δ: 5.41 (1H, m, H_3), 2.08 (3H, s, CH_3CO), 2.00 (3H, s, CH_3CO), 1.37 (3H, s, CH_3—C_6), 1.17 (3H, s, CH_3—C_6), and 1.02 (3H, d, J = 7 Hz, CH_3—C_2); ms *m/e*: 338 (M^+). *Anal.* calcd. for $C_{18}H_{22}O_7$: C 60.35, H 6.51; found: C 59.98, H 6.35.

*Diacetate Anhydride **10B***: mp 158–160°C (from chloroform–pentane); ir ν_{max} ($CHCl_3$): 1835, 1790, and 1760 cm^{-1}; nmr ($CDCl_3$) δ: 4.84 (1H, q, J = 7.5 Hz, H_3), 2.06 (3H, s, CH_3CO), 2.03 (3H, s, CH_3CO), 1.38 (3H, s, CH_3—C_6), 1.16 (3H, s, CH_3—C_6), and 1.08 (3H, d, J = 7 Hz, CH_3—C_2); ms *m/e*: 338 (M^+). *Anal.* calcd. for $C_{18}H_{22}O_7$: C 60.35, H 6.51; found: C 59.68, H 6.30.

*Diacetate Anhydride **10A** from Diol Diester **28***

A solution of diol diester **28** (33 mg, 0.11 mmol) in tetrahydrofuran and sodium hydroxide (*N*, 0.33 ml, 0.33 mequiv.) was heated at reflux for 10 h. The solution was concentrated by evaporation *in vacuo* and extracted with ether. The aqueous phase was acidified with dilute hydrochloric acid (*N*) and extracted several times with ether. Drying and evaporation of the organic phase gave a product (crude diol diacid) which was dissolved in acetic anhydride (5 ml) containing *p*-toluenesulfonic acid (1 mg). This solution was heated at reflux for 6 h and evaporated to dryness and the product obtained was dissolved in ether. The organic phase was washed with water, dried, and evaporated to dryness to give the diacetate anhydride **10***A* (22 mg, 60%); mp 215–216°C.

*Diacetate Anhydride **10B** from Diol Diester **26***

Using the above experimental procedure, the diol diester **26** (34 mg, 0.11 mmol) was converted into the diacetate anhydride **10***B* (27 mg, 70%); mp 158–160°C.

*Acid Ester **11A***

The diacetate anhydride **10***A* (10.0 g, 30 mmol) in dry methanol (100 ml) was added to a solution of sodium (690 mg, 0.030 mol) in methanol (100 µl). The mixture was stirred at room temperature for 1 h, acidified with dilute hydrochloric acid to p*H* 6 and extracted several times with chloroform. The organic phase was washed with water, dried, and evaporated to give acid ester **11***A* (10.2 g, 93%); mp 111.5–112.5°C (from ether–pentane); ir ν_{max} ($CHCl_3$): 3500 (br), 1732, and 1698 cm^{-1}; nmr ($CDCl_3$) δ: 9.99 (1H, COOH), 5.47 (1H, m, H_3), 3.73 (3H, s, OCH_3), 2.08 (3H, s, CH_3CO), 1.98 (3H, s, CH_3CO), 1.28 (3H, s, CH_3—C_6), 0.97 (3H, s, CH_3—C_6), and 0.92 (3H, d, J = 7 Hz, CH_3—C_2); ms *m/e*: 328 (M^+ − 42). *Anal.* calcd. for $C_{18}H_{26}O_8$: C 58.38, H 7.02; found: C 58.43, H 6.96.

*Acid Ester **11B***

Using the above experimental procedure, the diacetate anhydride **10***B* (5.0 g, 15.0 mmol) was converted into acid ester **11***B* (5 g, 92%); mp 171–172°C (from chloroform–pentane); ir ν_{max} ($CHCl_3$): 3500 (br), 1732, and 1702 cm^{-1}; nmr ($CDCl_3$) δ: 10.34 (1H, COOH), 4.63 (1H, m, H_3), 3.73 (3H, s, OCH_3), 2.06 (3H, s, CH_3CO), 1.97 (3H, s, CH_3CO), 1.39 (3H, s, CH_3—C_6), 0.96 (3H, d, CH_3—C_2), and 0.93 (3H, s, CH_3—C_6); ms *m/e*: 328 (M^+ − 42). *Anal.* calcd. for $C_{18}H_{26}O_8$: C 58.38, H 7.02; found: C 57.95, H 6.92.

*Ester Acetate **12A***

The acid ester **11***A* (2.0 g, 5.4 mmol) was heated under nitrogen in a distillation apparatus and a mixture of an oil and acetic acid distilled at 200–210°C. The acetic acid was evaporated *in vacuo* and the oily ester acetate **12***A* was purified by successive microdistillations (1.38 g, 96%); ir ν_{max} ($CHCl_3$): 1747 cm^{-1}; nmr ($CDCl_3$) δ: 5.59 (1H, m, H_3), 3.71 (3H, s, CH_3O), 2.07 (3H, s, CH_3CO), 1.26 (3H, s, CH_3—C_6), 0.95 (3H, d, J = 7.5 Hz, CH_3—C_2), and 0.89 (3H, s, CH_3—C_6); ms *m/e*: 235 (M^+ − 31) and 223 (M^+ − 43). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.67, H 8.27; found: C 67.47, H 8.40.

*Ester Acetate **12B***

Using the above experimental procedure, the acid ester **11***B* (2.0 g, 5.4 mmol) was transformed into the oily acetate ester **12***B* (1.4 g, 97%); ir ν_{max} ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 5.08 (1H, m, H_3), 3.71 (3H, s, CH_3O), 2.05 (3H, s, CH_3CO), 1.23 (3H, s, CH_3—C_6), 1.10 (3H, d, J = 7.0 Hz, CH_3—C_2), and 0.91 (3H, s, CH_3—C_6); ms *m/e*: 235 (M^+ − 31). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.67, H 8.27; found: C 67.68, H 8.26.

*Alcohol Acid **13***

A solution of acetate ester **12***A* (3.35 g, 0.013 mol) and sodium hydroxide (*N*, 27 ml, 0.027 mol) in water (15 ml) was heated at reflux for 2 h. After cooling and extracting with ether, the aqueous phase was acidified to p*H* 4 with dilute hydrochloric acid, saturated with sodium chloride, and extracted several times with ether. Drying and evaporation of the solvent yielded the alcohol acid **13** as a viscous oil (2.68 g, 100%); ir ν_{max} ($CHCl_3$): 3600, 3500 (br), and 1702 cm^{-1}; nmr ($CDCl_3$) δ: 7.25 (1H, br, COOH), 4.65 (1H, m, H_3), 1.25 (3H, s, CH_3—C_6), 1.01 (3H, d, J = 7 Hz, CH_3—C_2), and 0.95 (3H, s, CH_3—C_6); ms *m/e*: 210 (M^+).

*Alcohol Acid **14***

Using the above experimental procedure, the acetate ester **12***B* (3.31 g, 13.0 mmol), gave the alcohol acid **14** (2.2 g, 84%); mp 157–158°C (from acetone); ir ν_{max} ($CHCl_3$): 3600, 3500 (br), and 1702 cm^{-1}; nmr ($CDCl_3$) δ: 5.25 (1H, br, COOH), 4.32 (1H, m, H_3), 3.12 (1H, t, J = 8.5 Hz, H_7), 1.25 (3H, s, CH_3—C_6), 1.08 (3H, d, J = 7 Hz, CH_3—C_2), and 0.96 (3H, s, CH_3—C_6); ms *m/e*: 210 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.57, H 8.57; found: C 68.39, H 8.76.

*Acetate Acid **15A***

The alcohol acid **13** (2.68 g, 0.012 mol) was dissolved in a mixture of acetic anhydride (19.5 ml) and pyridine (19.5 ml). After 3 h at room temperature, the mixture was cooled at 0°C and methanol (19.5 ml) was added dropwise. The reaction mixture was left to warm up to room temperature (1 h) and it was diluted with ether. The organic phase was washed several times with dilute hydrochloric acid and water. Drying and evaporation of the solvent yielded an oil which gave pure acetate acid **15***A* (2.25 g, 70%); mp 151–153°C (from dichloromethane–ether–pentane); ir ν_{max} ($CHCl_3$): 3600, 3500 (br), 1724, and 1707 cm^{-1}; nmr ($CDCl_3$) δ: 10.88 (1H, br, COOH), 5.61 (1H, m, H_3), 2.07 (3H, s, CH_3CO), 1.28

(3H, s, CH_3—C_6), 1.0 (3H, s, CH_3—C_6), and 0.95 (3H, d, J = 7 Hz, CH_3—C_2); ms *m/e*: 193 ($M^+ - 59$) and 192 ($M^+ - 60$). *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.64, H 7.99; found: C 66.57, H 8.23.

*Acetate Acid **15B***

Using the above experimental procedure, the alcohol acid **14** (3.0 g, 14 mmol) was converted into acetate acid **15*B*** (2.52 g, 70%); mp 105–107°C (from dichloromethane – petroleum ether); ir ν_{max} ($CHCl_3$): 3600, 3500 (br), 1727, and 1707 cm^{-1}; nmr ($CDCl_3$) δ: 12.65 (1H, br, COOH), 5.15 (1H, m, H_3), 3.20 (1H, m, H_7), 2.07 (3H, s, CH_3CO), 1.27 (3H, s, CH_3—C_6), 1.09 (3H, d, J = 7.5 Hz, CH_3—C_2), and 1.02 (3H, s, CH_3—C_6); ms *m/e*: 193 ($M^+ - 59$) and 192 ($M^+ - 60$). *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.64, H 7.99; found: C 66.45, H 8.23.

*Acetate Ester **16A***

A solution of acetate acid **15*A*** (1.08 g, 4.3 mmol) in pyridine (0.88 ml, 10.9 mmol) and anhydrous benzene (100 ml) was added dropwise during 1.5 h to a cooled solution (0°C) of oxalyl chloride (0.768 ml, 9.0 mmol) in anhydrous benzene (72 ml). The reaction mixture was left for 1.5 h at room temperature. After filtration, the solution was slowly added to a vigorously stirred cold (≃ −30°C; Dry Ice – acetone bath) solution of diazomethane (≃15 mg of CH_2N_2/ml) in ether (250 ml). The reaction mixture was left for 1 h at room temperature and the solvent was removed by evaporation *in vacuo* to yield a crude diazoketone (1.33 g, ≃100%) which was not further purified; ir ν_{max} ($CHCl_3$): 3110, 2110, 1720, and 1630 cm^{-1}.

A solution of the crude diazoketone (1.32 g, 4.3 mmol) in anhydrous methanol (70 ml) containing silver oxide (600 mg, 2.4 mequiv.) was heated to reflux during 12 h under nitrogen atmosphere. The solution was then filtered through Celite and evaporated to dryness. Chromatography with Florisil gave the pure oily acetate ester **16*A*** (818 mg, 68%); ir ν_{max} ($CHCl_3$): 1738 cm^{-1}; nmr ($CDCl_3$) δ: 5.58 (1H, m, H_3), 3.70 (3H, s, OCH_3), 2.07 (3H, s, CH_3CO), 1.06 (3H, s, CH_3—C_6), 0.95 (3H, d, J = 7.5 Hz, CH_3—C_2), and 0.83 (3H, s, CH_3—C_6); ms *m/e*: 221 ($M^+ - 59$) and 220 ($M^+ - 60$). This compound was found to decompose slowly at room temperature.

*Acetate Ester **16B***

Using the above experimental procedure, the acetate acid **15*B*** (1.16 g, 4.6 mmol) was converted into the corresponding diazoketone (1.26 g, ≃100%); ir ν_{max}: 3110, 2110, 1720, and 1630 cm^{-1}.

The crude diazoketone (1.26 g, 4.6 mmol) was then transformed into the oily acetate ester **16*B*** (842 mg, 65.4%); ir ν_{max} ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 5.11 (1H, m, H_3), 3.70 (3H, s, OCH_3), 2.05 (3H, s, CH_3CO), 1.09 (3H, d, J = 6.5 Hz), 1.03 (3H, s, CH_3—C_6), and 0.85 (3H, s, CH_3—C_6); ms *m/e*: 221 ($M^+ - 59$) and 220 ($M^+ - 60$). This compound was found to decompose slowly at room temperature.

*Acetate Acid **17A***

A solution of acetate ester **16*A*** (2.05 g, 7.3 mmol) in sodium hydroxide (0.5 *N*, 40 ml) was heated at reflux during 2 h. After cooling, the aqueous solution was extracted with ether, acidified with dilute hydrochloric acid to p*H* 5, saturated with sodium chloride, and extracted several times with ether. Drying and evaporation of the organic phase gave the corresponding alcohol acid (1.28 g, 78%); mp 111.5–112.5°C (from acetone – petroleum ether); ir ν_{max} ($CHCl_3$): 3640, 3500 (br), and 1705 cm^{-1}; nmr ($CDCl_3$) δ: 5.80 (1H, br, COOH), 4.64 (1H, m, H_3), 1.07 (3H, s, CH_3—C_6), 1.0 (3H, d, J = 8 Hz, CH_3—C_2), and 0.84 (3H, s, CH_3—C_6); ms *m/e*: 224 (M^+). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.99; found: C 69.34, H 8.80.

A solution of the alcohol acid (1.00 g, 4.4 mmol) in acetic anhydride (13.2 ml) and pyridine (13.2 ml) was left for 2.5 h at room temperature. The mixture was cooled at 0°C and then methanol (13.2 ml) was added dropwise. The reaction mixture was left to warm up at room temperature (1 h) and it was diluted with ether. The organic phase was washed several times with dilute hydrochloric acid and water. Drying and evaporation of the solvent yielded an oil which gave pure acetate acid **17*A*** (944 mg, 80%); mp 91–92.5°C (from ether – petroleum ether); ir ν_{max} ($CHCl_3$): 3500 (br), 1725, and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 10.25 (1H, br, COOH), 5.61 (1H, m, H_3), 2.07 (3H, s, CH_3CO), 1.09 (3H, s, CH_3—C_6), 0.95 (3H, d, J = 7.5 Hz, CH_3—C_2), and 0.84 (3H, s, CH_3—C_6); ms *m/e*: 207 ($M^+ - 59$) and 206 ($M^+ - 60$). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.65, H 8.33; found: C 67.35, H 8.39.

*Acetate Acid **17B***

Using the above experimental procedure, the acetate ester **16*B*** (1.67 g, 6.0 mmol) gave the corresponding alcohol acid (1.07 g, 80%); mp 119–120°C (from acetone – petroleum ether); ir ν_{max} ($CHCl_3$): 3500 (br) and 1708 cm^{-1}; nmr ($CDCl_3$) δ: 7.50 (1H, br, COOH), 4.15 (1H, m, H_3), 1.05 (3H, d, J = 6.5 Hz, CH_3—C_2), 1.05 (3H, s, CH_3—C_6), and 0.85 (3H, s, CH_3—C_6); ms *m/e*: 224 (M^+). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.99; found: C 69.34, H 8.80.

This crystalline alcohol acid (775 mg, 3.4 mmol) was then converted into the acetate acid **17*B*** (885 mg, 95%); mp 90–91°C (from ether–pentane); ir ν_{max} ($CHCl_3$): 3500 (br) and 1715 (br) cm^{-1}; nmr ($CDCl_3$) δ: 11.93 (1H, br, COOH), 5.14 (1H, m, H_3), 2.07 (3H, s, CH_3CO), 1.12 (3H, d, J = 7.0 Hz, CH_3—C_2), 1.07 (3H, s, CH_3—C_6), and 0.88 (3H, s, CH_3—C_6); ms *m/e*: 207 ($M^+ - 59$) and 206 ($M^+ - 60$). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.65, H 8.33; found: C 67.42, H 8.20.

*Diazoketone **18A***

The acetate acid **17*A*** (300 mg, 1.13 mmol) dissolved in a mixture of pyridine (0.264 ml, 3.1 mmol) and anhydrous benzene (60 ml) was added dropwise during a period of 2 h to a cooled (0°C) solution of oxalyl chloride (0.228 ml, 2.7 mmol) in benzene (48 ml) under nitrogen atmosphere. The mixture was left at room temperature for 1 h. After filtration, the solution was slowly added to a vigorously stirred, cold (≃ −30°C, Dry Ice – acetone bath), solution of diazomethane (≃15 mg of CH_2N_2/ml) in ether (120 ml). The reaction mixture was left at room temperature for 1 h and evaporation of the solvent *in vacuo* yielded the crude diazoketone **18*A*** (320 mg, 100%) which was not further purified because of its instability; ir ν_{max} ($CHCl_3$): 2120, 1740, and 1640 cm^{-1}; nmr ($CDCl_3$) δ: 5.58 (1H, m, H_3), 5.40 (1H, s, $COCHN_2$), 2.08 (3H, s, CH_3CO), 1.07 (3H, s, CH_3—C_6), 0.93 (3H, d, J = 7 Hz, CH_3—C_2), and 0.84 (3H, s, CH_3—C_6).

Diazoketone 18B

Using the above experimental procedure, the acetate acid **17***B* (560 mg, 2.1 mmol) was converted into the crude diazoketone **18***B* (609 mg, ≃100%); ir ν_{max} ($CHCl_3$): 2120, 1740, and 1640 cm^{-1}; nmr ($CDCl_3$) δ: 5.33 (1H, s, $COCHN_2$), 5.05 (1H, m, H_3), 2.05 (3H, s, CH_3CO), 1.06 (3H, d, J = 7 Hz, CH_3—C_2), 1.03 (3H, s CH_3—C_6), and 0.84 (3H, s, CH_3—C_6).

Cyclopropane Acetate 19A

A solution of the crude diazoketone **18***A* (340 mg, 1.2 mmol) in anhydrous benzene (60 ml) containing copper (Fisher Co., 1.14 g) was heated at reflux during 3.75 h under a nitrogen atmosphere. The solution was filtered under Celite and evaporated to dryness. The crude product was purified by chromatography with Florisil to yield the oily cyclopropane acetate **19***A* (186 mg, 61%) which was not purified further because of its instability; ir ν_{max} ($CHCl_3$): 1730 and 1680 cm^{-1}; nmr ($CDCl_3$) δ: 5.10 (1H, m, H_3), 2.07 (3H, s, CH_3CO), 1.14 (3H, s, CH_3—C_6), 1.03 (3H, s, CH_3—C_6), and 0.93 (3H, d, J = 7.5 Hz, CH_3—C_2); ms *m/e*: 262 (M^+); vpc one peak at 9.5 min (5 ft, ¼ in., SE-30-5% on Chromosorb W, 200°C).

Cyclopropane Acetate 19B

Using the above experimental procedure, the crude diazoketone **18***B* (609 mg, 2.1 mmol) was converted to the oily cyclopropane acetate **19***B* (216 mg, 40%), after chromatography; ir ν_{max} ($CHCl_3$): 1725 and 1680 cm^{-1}; nmr ($CDCl_3$) δ: 5.07 (1H, m, H_3), 2.02 (3H, s, CH_3CO), 1.12 (3H, d, J = 8 Hz, CH_3—C_2), 1.10 (3H, s, CH_3—C_6), and 1.01 (3H, s, CH_3—C_6); ms *m/e*: 262 (M^+); vpc one peak at 12.6 min (5 ft, ¼ in., SE-30-5% on Chromosorb W, 181°C).

Cyclopropane Alcohol 20

A solution of crude cyclopropane acetate **19***A* (314 mg, 1.2 mmol) in tetrahydrofuran (15 ml), sodium hydroxide (*N*, 1.2 ml, 1.2 mmol), and water (3 ml) was heated at reflux for 2.5 h. The solution was concentrated by evaporation *in vacuo* and diluted with water (10 ml). It was then extracted several times with ether. Drying and evaporation of the organic phase yielded the cyclopropane alcohol **20** (240 mg, 75%); mp 118–119°C (from ether – petroleum ether); ir ν_{max} ($CHCl_3$): 3620, 3450, 1684, and 1667 cm^{-1}; nmr ($CDCl_3$) δ: 4.31 (1H, m, H_3), 1.12 (3H, s, CH_3—C_6), 1.02 (3H, s, CH_3—C_6), and 0.99 (3H, d, J = 7.2 Hz, CH_3—C_2); ms *m/e*: 220 (M^+). *Anal.* calcd. for $C_{14}H_{20}O_2$: C 76.33, H 9.15; found: C 75.56, H 8.91.

Cyclopropane Alcohol 21

Using the above experimental procedure, the crude cyclopropane acetate **19***B* (204 mg, 0.8 mmol) was converted into the cyclopropane alcohol **21** (165 mg, 96%); mp 120.5–121.5°C (from dichloromethane–ether); ir ν_{max} ($CHCl_3$): 3620, 3440, and 1675 cm^{-1}; nmr ($CDCl_3$) δ: 4.26 (1H, m, H_3), 1.09 (3H, s, CH_3—C_6), 1.04 (3H, d, J = 6 Hz, CH_3—C_2), and 0.99 (3H, s, CH_3—C_6); ms *m/e*: 220 (M^+). *Anal.* calcd. for $C_{14}H_{20}O_2$: C 76.33, H 9.15; found: C 75.94, H 8.97.

Cyclopropane Diketone 3

(a) From Cyclopropane Alcohol 20

Chromium trioxide (88 mg, 0.924 mmol) was added to a solution of pyridine (145 mg, 1.85 mmol) in dry dichloromethane (7 ml) and the mixture was stirred at room temperature for 15 min. A solution of cyclopropane alcohol **20** (33 mg, 0.154 mmol) in dichloromethane (5 ml) was added and the mixture was stirred for 15 min at room temperature. The solution was decanted and the residue was washed with dichloromethane. The organic phase was evaporated, ether was added, and the solution was filtered through Celite. Evaporation of the solvent gave cyclopropane diketone **3** (30 mg, 90%); mp 97–98°C (from ether – petroleum ether); ir ν_{max} ($CHCl_3$): 1750 and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 2.93–1.45 (9H, m's), 1.18 (3H, d, J = 8 Hz, CH_3—C_2), 1.15 (3H, s, CH_3—C_6), and 1.09 (3H, s, CH_3—C_6); ms *m/e*: 218 (M^+); vpc one peak at 9.8 min (5 ft, ¼ in., SE-30-5% on Chromosorb W, 175°C). *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found: C 76.71, H 8.06.

(b) From Cyclopropane Alcohol 21

Using the above experimental procedure, the cyclopropane alcohol **21** (100 mg, 0.46 mmol) was converted into the cyclopropane diketone **3** (92 mg, 90%); mp 97–98°C.

Tricyclic Enedione 4

A solution of the cyclopropane diketone **3** (33 mg, 0.15 mmol) in dry methanol (5 ml) containing sodium methoxide (30 mg, 0.45 mmol) was left at room temperature during 20 min. The solution was concentrated by evaporation *in vacuo*, diluted with water (10 ml), and acidified with dilute hydrochloric acid. The aqueous phase was extracted several times with ether. Drying and evaporation of the organic phase gave the tricyclic enedione **4** (33 mg, ≃100%); mp 160.5–162°C (from dichloromethane–ether); ir ν_{max} ($CHCl_3$): 1710 and 1630 cm^{-1}; nmr ($CDCl_3$) δ: 5.83 (1H, s, H_4), 3.05–1.08 (8H, m's), 1.24 (6H, s, $(CH_3)_2$—C_6), and 1.13 (3H, d, J = 7.5 Hz, CH_3—C_2); uv λ_{max} (EtOH): 237 nm (ε = 39 800); ms *m/e*: 218 (M^+); vpc one peak at 10.8 min (5 ft, ¼ in., SE-30-5% Chromosorb W, 175°C). *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found: C 76.71, H 8.06.

If a catalytic amount of sodium methoxide (2 mg) is used, the tricyclic enedione **4** was obtained after 68 h of reaction time.

Tricyclic Enedione 5

A solution of the cyclopropane diketone **3** (70 mg, 0.32 mmol) in methanol (10 ml) containing sodium methoxide (50 mg, 0.92 mmol) was left at room temperature during 12 h. The solution was concentrated by evaporation *in vacuo*, diluted with water (10 ml), and acidified with dilute hydrochloric acid. The aqueous phase was extracted several times with ether. Drying and evaporation of the organic phase gave the tricyclic enedione **5** (70 mg, ≃100%); mp 96.0–96.5°C (from dichloromethane–ether–pentane); ir ν_{max} ($CHCl_3$): 1705 and 1665 cm^{-1}; nmr ($CDCl_3$) δ: 3.20–1.75 (9H, m's), 1.69 (3H, t, J = 2 Hz (homoallylic coupling), CH_3—C_2), 1.29 (3H, s, CH_3—C_6), and 0.89 (3H, s, CH_3—C_6); uv λ_{max} (EtOH): 243 nm (ε = 36 000); ms *m/e*: 218 (M^+); vpc one peak at 8.6 min (5 ft, ¼ in., SE-30-10% Chromosorb W, 178°C). *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H H 8.31; found: C 76.77, H 8.11.

Diol Ester 26

A solution of diacetate anhydride **10***B* (1.0 g, 3.0 mmol) in tetrahydrofuran (30 ml) and sodium hydroxide (*N*,

15 ml, 15.0 mequiv.) was heated to reflux for 72 h. The solution was concentrated by evaporation *in vacuo* and extracted with ether. The aqueous phase was acidified with dilute hydrochloric acid and extracted several times with ether. After drying and evaporation of the solvent, it was dissolved in ether and a large excess of diazomethane in ether was added. Evaporation of the solvent gave the diol diester **26** (777 mg, 96%); mp 124–126°C (from dichloromethane–ether); ir ν_{max} ($CHCl_3$): 3540 (br), 1720, and 1695 cm^{-1}; nmr ($CDCl_3$) δ: 4.97 (1H, s, OH), 3.78 (3H, s, OCH_3), ≃3.75 (1H, m, H_3), 3.72 (3H, s, OCH_3), 1.14 (3H, s, CH_3—C_6), 1.02 (3H, d, J = 7 Hz, CH_3—C_2), and 0.78 (3H, s, CH_3—C_6); ms *m/e*: 300 (M^+). *Anal.* calcd. for $C_{15}H_{24}O_6$: C 59.98, H 8.05; found: C 60.02, H 7.99.

Ketoalcohol Diester 27

(a) From Diol Diester 26

Chromium trioxide (352 mg, 3.6 mmol) was added to a solution of pyridine (580 mg, 7.2 mmol) in dry dichloromethane (20 ml) and the mixture was stirred at room temperature for 30 min. A solution of the diol diester **26** (180 mg, 0.6 mmol) in dichloromethane (20 ml) was added and the mixture was stirred at room temperature for 20 min. The solution was decanted and the residue was washed with dichloromethane. The organic phase was evaporated, ether was added, and the solution was filtered through Celite. Evaporation of the solvent gave the ketoalcohol diester **27** (154 mg, 88%); mp 68–70°C (from ether–pentane); ir ν_{max} ($CHCl_3$): 3450, 1735, and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 5.37 (1H, s, OH), 3.87 (3H, s, OCH_3), 3.73 (3H, s, OCH_3), 3.33–1.28 (6H, m's), 1.17 (3H, s, CH_3—C_6), 1.07 (3H, d, J = 7 Hz, CH_3—C_2), and 0.76 (3H, s, CH_3—C_6); ms *m/e*: 298 (M^+). *Anal.* calcd. for $C_{15}H_{22}O_6$: C 60.39, H 7.43; found: C 59.61, H 7.08.

(b) From Diol Diester 28

Using the above experimental procedure, the diol diester **28** (22 mg, 0.073 mmol) was converted into the ketoalcohol diester **27** (18 mg, 81%); mp 68–70°C.

Diol Diester 26 and 28 from Ketoalcohol Diester 27

A solution of ketoalcohol diester **27** (133 mg, 0.44 mmol) in methanol (5 ml) was added to a solution of sodium borohydride (34 mg, 0.88 mmol) in methanol (5 ml) and the mixture was left at 0°C for 2 h. The mixture was then acidified with dilute hydrochloric acid to p*H* 6 and concentrated by evaporation *in vacuo*. The resulting solution was extracted several times with dichloromethane. After drying and evaporation of the solvent, two products were obtained and separated by thin-layer chromatography on silica gel. The more polar product was identified as the diol ester **26** (56 mg); mp 124–126°C. The less polar product was identified as the diol diester **28** (34 mg); mp 127–128°C (from dichloromethane–ether); ir ν_{max} ($CHCl_3$): 3620, 3450, 1720, and 1690 cm^{-1}; nmr ($CDCl_3$) δ: 5.08 (1H, s, OH), 4.36 (1H, m, H_3), 3.81 (3H, s, OCH_3), 3.72 (3H, s, OCH_3), 2.93–2.12 (7H, m's), 1.13 (3H, s, CH_3—C_6), 1.04 (3H, d, J = 7 Hz, CH_3—C_2), and 0.73 (3H, s, CH_3—C_6); ms *m/e*: 300 (M^+). *Anal.* calcd. for $C_{15}H_{24}O_6$: C 59.98, H 8.05; found: C 60.21, H 8.05.

Alcohol Anhydride 39

A solution of diacetate anhydride **10***A* (1.5 g, 4.5 mmol) in tetrahydrofuran (50 ml), sodium hydroxide (*N*, 14 ml, 14.0 mequiv.) was heated at reflux for 12 h. The solution was concentrated by evaporation *in vacuo* and extracted with dichloromethane. The aqueous phase was acidified with dilute hydrochloric acid and extracted several times with ether. Drying and evaporation of the organic phase gave a product (diacid) which was dissolved in acetic anhydride (50 ml) and heated at reflux for 20 min. Evaporation of the solvent gave the alcohol anhydride **39** (1.10 g, 84%); mp 165–167°C (from acetone); ir ν_{max} ($CHCl_3$): 3480, 1810, 1760, and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 3.93 (1H, m, H_3), 1.98 (3H, s, CH_3CO), 1.37 (3H, s, CH_3—C_6), 1.10 (3H, s, CH_3—C_6), and 1.07 (3H, d, J = 7 Hz, CH_3—C_2); ms *m/e*: 237 (M^+ − 59) and 236 (M^+ − 60). *Anal.* calcd. for $C_{15}H_{20}O_6$: C 60.80, H 6.80; found: C 60.48, H 6.77.

Tricyclic Enone Anhydride 41

Chromium trioxide (599 mg, 6.0 mmol) was added to a solution of pyridine (949 mg, 1.2 mmol) in dry dichloromethane (20 ml) and the mixture was stirred at room temperature for 30 min. A solution of the alcohol anhydride **39** (272 mg, 1.0 mmol) in dichloromethane (30 ml) was added and the mixture was stirred for 20 min at room temperature. The solution was decanted and the residue was washed with dichloromethane. The organic phase was evaporated, ether was added, and the solution was filtered through Celite. Evaporation of the solvent gave crude **40** as shown by nmr (no olefinic hydrogen) which by attempted crystallization gave the tricyclic enone anhydride **41** (212 mg, ≃100%); mp 156–160°C (from dichloromethane–ether); ir ν_{max} ($CHCl_3$): 1815, 1770, 1730, and 1635 cm^{-1}; nmr ($CDCl_3$) δ: 6.03 (1H, s, H_4), 3.35 (2H, m's), 2.3 (2H, m's), 1.44 (6H, s, $(CH_3)_2$=C_6), and 1.15 (3H, d, J = 7.5 Hz, CH_3—C_2); uv λ_{max} (EtOH): 235 nm (ε = 34 950); ms *m/e*: 234 (weak, M^+) and 190 (M^+ − 44).

Individual rate constants of methyl radical reactions in the pyrolysis of dimethyl ether

ANDREW M. HELD, KIM C. MANTHORNE, PHILIP D. PACEY, AND HOWARD P. REINHOLDT

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 1, 1977

ANDREW M. HELD, KIM C. MANTHORNE, PHILIP D. PACEY, and HOWARD P. REINHOLDT. Can. J. Chem. **55**, 4128 (1977).

Dimethyl ether was pyrolyzed in a flow system at 10 to 80 Torr and 1005 K. The average concentration of CH_3 radicals in the reactor was measured by ultraviolet absorption spectroscopy. Product yields were measured by gas chromatography. The system was simulated using a computer program, taking into account the warm-up of the entering gas and the occurrence of secondary reactions. Rate constants were varied to find values consistent with experimental observations. The limiting, high pressure rate constant for the recombination of CH_3 was estimated to be $10^{10.15\pm0.5}$ ℓ mol^{-1} s^{-1}. Estimated rate constants for the reactions

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3 \text{ and } CH_3 + CH_2O \rightarrow CH_4 + CHO$$

were $10^{7.12\pm0.2}$ ℓ mol^{-1} s^{-1} and $10^{7.5\pm0.4}$ ℓ mol^{-1} s^{-1}, respectively.

ANDREW M. HELD, KIM C. MANTHORNE, PHILIP D. PACEY et HOWARD P. REINHOLDT. Can. J. Chem. **55**, 4128 (1977).

On a effectué la pyrolyse de l'éther diméthylique dans un système à flux entre 10 et 80 Torr à 1005 K. On a mesuré la concentration moyenne des radicaux CH_3 dans le réacteur par spectroscopie d'absorption ultraviolet. On a mesuré les rendements de produits par chromatographie en phase gazeuse. On a simulé le système en faisant appel à un programme d'ordinateur en tenant compte de la période de réchauffement du gaz qui entre et de l'existance de réactions secondaires. On a fait varier les constantes de vitesse pour trouver des valeurs en accord avec les observations expérimentales. On a estimé que la constante de vitesse à la limite de hautes pressions pour la recombinaison des radicaux CH_3 est de $10^{10.15\pm0.5}$ ℓ mol^{-1} s^{-1}. On a estimé que les constantes de vitesse des réactions

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3 \text{ et } CH_3 + CH_2O \rightarrow CH_4 + CHO$$

sont respectivement de $10^{7.12\pm0.2}$ ℓ mol^{-1} s^{-1} et $10^{7.5\pm0.4}$ ℓ mol^{-1} s^{-1}.

[Traduit par le journal]

This paper reports measurements of the rate constants at 1005 K for two types of methyl radical reactions, the recombination reaction (see Table 1 for list of reactions),

[6] $$2CH_3 \rightarrow C_2H_6$$

and the abstraction reactions, particularly the reaction with dimethyl ether,

[5] $$CH_3 + C_2H_6O \rightarrow CH_4 + C_2H_5O$$

Abstraction reactions involving methyl radicals are of interest because several studies have reported curvature of the Arrhenius plots (1–3). With one exception (1), however, these studies have not reported direct measurements of the rate constants, but, instead, measurements relative to the rate constant of reaction 6.

Since the early work of Ingold and Lossing (4), there have been only two measurements of the rate constant of reaction 6 at high temperatures (>500 K). Clark, Izod, and Kistiakowsky (1) used mass spectrometry to follow the disappearance of methyl radicals in a shock tube at 1120 to 1400 K; Glanzer, Quack, and Troe (5) used ultraviolet absorption spectroscopy at similar temperatures. The rate constants measured differed by a factor of three. Knowledge of the temperature dependence of this reaction is important, both because the reaction is used as a reference reaction for studying abstractions, like [5], and because the temperature dependence provides a sensitive test for theoretical treatments of recombination reactions. Most Rice–Ramsperger–Kassel–Marcus (RRKM) calculations, which place the activated complex atop a rotational barrier at a point on the reaction coordinate with potential energy near its maximum value, predict a strong increase in rate with increasing temperature (5). Theories which place the critical configuration at lower energies, such as the adiabatic open channel (5), minimum state density (6), or maximum free energy theo-

ries (7), predict little or no temperature dependence.

In this work reactions 5 and 6 were studied in the pyrolysis of dimethyl ether. Methyl radical concentrations were measured by ultraviolet absorption spectroscopy; product concentrations, by gas chromatography. In an earlier gas chromatographic study (2), it was shown that reaction 6 was the only major source of C_2H_6; the rate constant, k_6, has been determined herein from measurements of the concentration of CH_3 and of the rate of formation of C_2H_6. Reaction 5 is believed to be the main source of CH_4 in the early stages of pyrolysis (2); k_5 has been determined herein from $[CH_3]$ and the rate of formation of CH_4.

Higher temperatures have been used than in the earlier work to increase ultraviolet absorption by CH_3 to a measureable level. The rate constant of the initiation reaction,

[1] $$CH_3OCH_3 \rightarrow CH_3 + OCH_3$$

determined in the earlier work from yields of C_2H_6, the main termination product, has been redetermined at these higher temperatures. Because of the higher temperatures, overall reaction rates and conversions were greater and secondary reactions of the products became significant. Interpretation of the experiments has been assisted by a computer simulation, taking into account secondary reactions and the temperature profile in the reactor. It has been possible to place limits on the rate constant of one secondary reaction,

[9] $$CH_3 + CH_2O \rightarrow CH_4 + CHO$$

Experimental

The experimental system was described previously (8), except for the changes that follow.

Dimethyl ether (Matheson, 99.87%) was degassed and allowed to flow at a controlled rate through a 1 cm inside diameter quartz reactor, heated externally by a nichrome wire resistance furnace. Temperatures were measured using a moveable Pt – Pt–15% Rh thermocouple in a 2 mm inside diameter quartz tube attached to the outside of the reactor. By a method described previously (9), average reaction temperatures were calculated.

Light from a McKee-Pedersen MP-1035 deuterium lamp was focussed and directed along the axis of the reactor. A portion of the light entered a McKee-Pedersen MP-1018A monochromator, which had been altered by decreasing the height of the entrance slit and covering all but a 3 mm diameter circle of the parabolic mirror behind this entrance slit. These alterations ensured that light from the side walls of the reactor could not reach the grating and the R372 photomultiplier. The slit function of the altered monochromator was studied using the 253.7 nm line from an Hg lamp. With the 1.6 mm slit width used, the slit function could be fitted to within 1% of the peak height by a Gaussian curve with full width at half height of 1.44 nm.

In most experiments, samples of product gases were injected directly into an on-line gas chromatograph. In some experiments, products were collected and analyzed on an external gas chromatograph. Columns and detectors have been described previously (2).

Results

Curves *a* and *b* of Fig. 1 are traces of a photomultiplier signal as a function of wavelength for experiments in which 10 Torr of dimethyl ether was passed through the reactor at temperatures of 850 and 1002 K, respectively. The curvature of the upper trace was caused by the optical system, as the dimethyl ether absorption continuum was found to be featureless at these wavelengths and the methyl radical concentration would be too small to contribute. The extra dip in curve *b* was interpreted as being caused by absorption by CH_3.

This interpretation was tested in several ways. Curve *c* of Fig. 1 shows the shape of the CH_3 peak calculated for the conditions of these experiments using a computer program[1] based on the theoretical model of Glanzer *et al.* (10). This model was shown (10) to match observations of the CH_3 spectrum at room temperature and at 1400 K. The computer program has also been used to calculate the extinction coefficient (2730 ℓ mol^{-1} cm^{-1}) at the absorption maximum and the oscillator strength (7.0×10^{-3}) of the main band (214.3 to 220.0 nm) for the conditions of this work.

Over 100 traces, like *b* in Fig. 1, have been made; peak heights have been calculated by comparing heights at the absorption maximum (216.5 nm) and minima (214.3 and 220.0 nm) with traces, like *a* in Fig. 1, at the same pressure but at 800 to 900 K. Average CH_3 concentrations in the reactor, calculated from peak heights, the extinction coefficient, and the length of the hot zone of the reactor, were reproducible, with standard deviations of about 10%.

Radical concentrations have also been calculated from peak areas and the oscillator strength; the average ratio of the CH_3 concentrations obtained by the two methods was 0.99 ± 0.11. When the band was traced with narrow slits,

[1]Copies of this and other original computer programs are available from the authors on request.

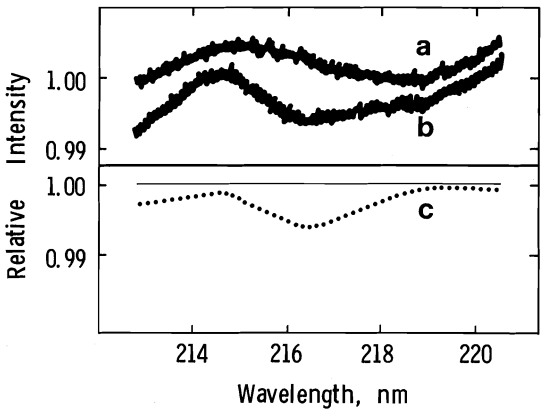

FIG. 1. Recorder traces of photomultiplier output with 10 Torr of $(CH_3)_2O$ in the reactor at 850 K (*a*) and 1002 K (*b*). Trace *a* has been raised 0.002 units for clarity. Curve *c* shows the theoretically predicted spectrum of CH_3 for the condition of curve *b*.

the characteristic double peak of the CH_3 spectrum appeared, as was reported previously (8). Variation of the pressure at room temperature indicated that absorption by dimethyl ether obeyed the Beer–Lambert law. Because the concentration of CH_3 varied along the reactor, there was no straightforward way of testing this law for this species.

Ethylene was found to absorb near 216 nm. At 1000 K, 10^{-5} mol ℓ^{-1} of C_2H_4 contributed an absorption dip from 214 to 220 nm of 0.5%. During pyrolysis experiments, average C_2H_4 concentrations in the reactor were kept at least an order of magnitude less than this to minimize interference.

Over 300 gas chromatographic analyses have been performed for reactor pressures from 10 to 80 Torr at reactor temperatures from 1000 to 1012 K.[2] H_2, CH_4, C_2H_6, and C_2H_4 were determined in most cases, CO and C_2H_6O in a few. As in previous work (2), C_2H_4 appeared to be formed mainly from an impurity; it will be given limited weight in subsequent discussions. The similarity of analyses performed with the D_2 lamp on and off showed that photochemical reactions were not significant.

Logarithms of the rates of formation of CH_4, H_2, and C_2H_6 are shown as a function of reactor residence time at 10 and 80 Torr reactor pressure in Figs. 2 and 3, respectively. Spectroscopically

[2]Tables of data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

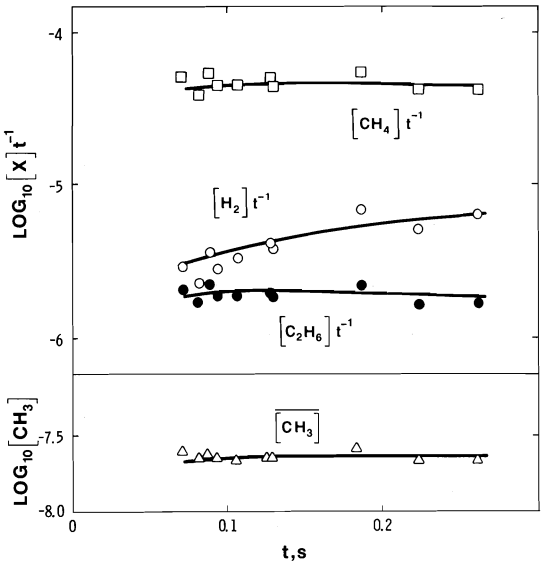

FIG. 2. Logarithms of the rates of formation of CH_4, H_2, and C_2H_6 (mol ℓ^{-1} s^{-1}) and of the average concentrations of CH_3 (mol ℓ^{-1}) as a function of reactor residence time at 1005 K and 10 Torr. Points are experimental; lines were predicted by the computer simulation.

determined average concentrations of methyl radicals are also shown.

Discussion

Computer Simulation

A computer simulation was used to assist in interpreting the experiments. The program, modelled after one described in ref. 11, integrated the rate equations for the system using a Runge–Kutta–Gill procedure. The reactions taken into account (numbered consistently with ref. 2) are listed in Table 1 with the corresponding rate constants.

Other reactions, as follows, were considered for inclusion in the program, but were estimated to make little contribution and were omitted. Alternative reactions of CH_3O and of C_2H_5 were considered in ref. 2 and shown to be negligible. Reactions of CH_2OCH_3 radicals were shown (2) to be possible minor contributors to termination at 784 K; because of the higher activation energy of reaction 4 compared to reaction 5, CH_2OCH_3 termination reactions would be even less able to compete with reaction 6 at higher temperatures. The recombination alternative to reaction 16 was not included, as acetaldehyde has not been observed as a product of dimethyl ether pyrolysis. Rates of the reverses of the reactions in Table 1 (except [−6] and

TABLE 1. Reactions and rate constants used in computer simulation

	Reaction	Log k at 1005 K (ℓ mol^{-1} s^{-1} or s^{-1})	E_A (kcal mol^{-1})	Sources or references
[1]	$C_2H_6O \rightarrow CH_3 + CH_3O$	See Table 2	77.	This work, 2

[a]Assumed to follow automatically whenever the respective radical was formed.
[b]Assumed pressure dependent.

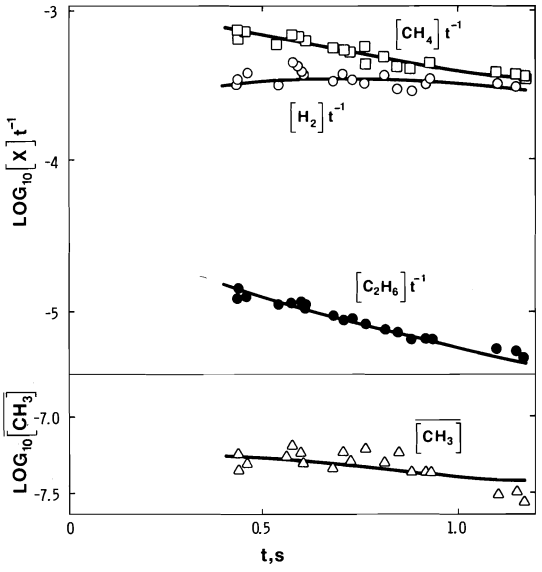

FIG. 3. Logarithms of the rates of formation of CH_4, H_2, and C_2H_6 (mol ℓ^{-1} s^{-1}) and of the average concentrations of CH_3 (mol ℓ^{-1}) as a function of reactor residence time at 1007 K and 80 Torr. Points are experimental; lines were predicted by the computer simulation.

[−15]) were calculated using thermochemistry (13) and were found to be negligible. Other reactions, such as the unimolecular decomposition of CH_2O or addition of radicals to C_2H_4 or CH_2O, could be eliminated by considering rate constants and thermochemistry in the literature (18, 22). Surface reactions were neglected because no effect of surface to volume ratio was observed in ref. 2.

The concentration of CH_3 was assumed to be zero at the reactor entrance and was allowed to relax toward its steady state value as the reaction progressed. At 10 Torr the relaxation time for this process was found to be 7% of the shortest experimental residence time. Use of the steady state assumption throughout the reactor would have led to an error in predicted product yields and average CH_3 concentration of about 7%. Because of their smaller concentrations, the corresponding relaxation times for H and CHO were at least an order of magnitude faster, justifying the use of the steady state assumption for these species.

To observe reaction rates which were as close as possible to the initial rates, faster reagent flow rates were used in these experiments than in ref. 2. As a result the reagent would have proceeded farther down the reactor before it was heated to the same temperature as the reactor wall. This problem has been considered by Mulcahy and Pethard (23), who described the average temperature of the gas, T_x, a distance x from the furnace entrance by the formula

$$[20] \quad T_x = T_s - 0.82(T_s - T_0) \times \exp(-3.658Ktx/R^2L)$$

where T_s and T_0 are the temperatures of the wall and the entering gas, respectively; K is the thermal diffusivity; t, the residence time; R, the tube radius; and L, the length of the furnace. The thermal diffusivity was estimated from the thermal conductivity (24) and heat capacity (22) of the similar molecule, ethanol, to be $3 \times 10^{-3}[C_2H_6O]^{-1}$ cm^2 s^{-1}. Temperatures within the reactor were calculated from eq. 20. Rate coefficients at each distance, x, could be calculated using the activation energies in Table 1. The rate equations were then integrated. This modification required changes in k_1 and k_6 of up to 10%.

Mulcahy and Pethard (23) have also considered the errors that arise because the flow velocity has a parabolic profile instead of the plug flow profile assumed by our program. For a first order reaction occurring at the conditions of this work, the error would be 0.5%. Although not all reactions in the present system are first order, these errors have been neglected.

Reactions -6, 17, 18, and 19 did not affect the simulations, even when increased by an order of magnitude. They could have been omitted. Reactions 13, 15, and -15 were only significant at the higher pressures.

The computer simulation was initially attempted using values of k_{12} from ref. 9, but this model predicted greater concentrations of C_2H_4 than observed at 80 Torr and long residence times. To correct this, k_{12} was reduced, although reducing k_{13}, increasing k_3 and k_{10}, or including reactions to remove C_2H_4 would have had a similar result.

The value of k_9 was chosen to give agreement with observed H_2 concentrations at 10 and 20 Torr.

Reaction 16 was a minor contributor to chain termination at high pressures and long residence times. The value of k_{16} was chosen to match the downward slopes of Figs. 2 and 3. This could also have been accomplished by adjusting k_{11}.

The rates of reactions 1, 5, and 6 were then varied at each pressure to match the $[CH_4]/t$, $[C_2H_6]/t$, and $[\overline{CH_3}]$ observations. The results for 10 and 80 Torr are shown as the solid lines in Figs. 2 and 3. Agreement at the other pressures used was also within experimental uncertainty. The coefficients, k_1, k_5, and k_6, used at each pressure, are shown in Table 2. Both k_1 and k_6 generally increase as pressure increases, as expected for dissociation–recombination reactions in their pressure dependent region. Values of k_5 were almost independent of pressure, as expected.

TABLE 2. Rate constants determined by computer simulation

Pressure (Torr)	$k_1 \times 10^2$ (s^{-1})	$k_5 \times 10^{-7}$ (ℓ mol^{-1} s^{-1})	$k_6 \times 10^{-9}$ (ℓ mol^{-1} s^{-1})
10	1.7±0.4	1.31±0.10	3.5
20	1.6±0.6	1.20±0.20	4.1
40	2.8±1.1	1.24±0.28	4.2
60	4.4±2.3	1.33±0.28	4.6
80	4.9±2.3	1.57±0.45	6.1

The rate constants in Table 1 were varied by factors of two in various combinations to find the sensitivity of k_1, k_5, and k_6 to changes in the model. Uncertainties in k_1, k_5, and k_6 determined in this way were combined with estimates of the scatter of the data. Uncertainties in the extinction coefficient and the thermal diffusivity, which have a similar effect at all pressures, were not included at this point.

The uncertainties in k_1, shown in Table 2, were greater than in the earlier work (2), because of the greater conversions. Using the experimentally determined Arrhenius parameters from ref. 2 ($\log A = 15.2$, $E_A = 77$ kcal mol^{-1}), the high pressure rate constant at 1005 K would be predicted to be 3.1×10^{-2} s^{-1}, within the uncertainty limits of the high pressure values in Table 2.

Recombination Reaction

The acceptable ranges for k_6 are shown, plotted as a function of the logarithm of pressure, by the vertical bars in Fig. 4. Curve *a* was calculated from the equilibrium constant (from Table 1) and from the RRKM model[3] used by Clark and Quinn (25) to reproduce their data for k_{-6} at 838 K. Curve *b* was calculated by the method of van den Bergh (26), using reduced Kassel curves and a collision efficiency for deactivation of excited C_2H_6 of 0.29. This model, with a smaller collision efficiency for deactivation by argon, was fitted to the data of Glanzer *et al.* (5) at 1350 K. Both curves can be seen to be somewhat steeper than, though compatible with, the pressure dependence observed in this work.

Extrapolating the data of this work to high

[3]State densities and sums were calculated using a program by W. L. Hase and D. L. Bunker, Quantum Chemistry Program Exchange, No. 234, Indiana University, Bloomington, IN, U.S.A.

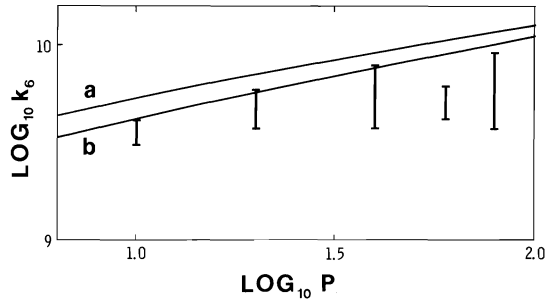

FIG. 4. Dependence of k_6 (ℓ mol^{-1} s^{-1}) on reactor pressure (Torr). The vertical bars show the range of values compatible with the present experiments for a fixed extinction coefficient. Curve *a* was calculated from the theoretical treatment of ref. 25; *b*, from ref. 26.

pressures would place too much emphasis on the less reliable 40 and 80 Torr results. Instead, comparisons have been made with curves *a* and *b*, which are based on more extensive and precise results. The experimental values of k_6 were, on the average, seven tenths of the values from curve *b*. If this proportion were retained, the limiting high pressure rate constant, $k_{6,\infty}$, for this work would be 1.4×10^{10} ℓ mol^{-1} s^{-1}, compared to the value, 2×10^{10} ℓ mol^{-1} s^{-1}, of curve *b*. By a similar comparison with curve *a*, again $k_{6,\infty}$ was found to be 1.4×10^{10} ℓ mol^{-1} s^{-1}. Values of k_6 from ref. 5 (the basis of curve *b*) depend directly on the extinction coefficient, whereas values from this work depend on its square. The uncertainty in the extinction coefficient quoted in ref. 5 was $\pm 30\%$. If the upper limit were taken, the values of $k_{6,\infty}$ from these sources would agree with each other and with most values measured at room temperature (27). The threefold disagreement between ref. 5 and the mass spectrometric measurements of refs. 1 and 4 would be narrowed but would not disappear. When the uncertainties in the extinction coefficient and the extrapolation are combined with the uncertainties in Fig. 4, we estimate that individual values of k_6 from the present work are reliable within about a factor of two and $k_{6,\infty}$ is reliable within a factor of three.

The present results tend to support the conclusion of Glanzer *et al.* that $k_{6,\infty}$ is no greater at high temperatures than at room temperature. The results then favour the adiabatic open channel or minimum state density theories.

Abstraction Reactions

Calculated values of k_5 were directly proportional to the extinction coefficient chosen, but almost independent of the thermal diffusivity. Uncertainties from other sources are shown in Table 2. This rate constant has not previously been measured individually, but only as the quotient $k_5 k_{6,\infty}^{-1/2}$. Calculating this quotient from Arrhenius parameters determined at 782–936 K in ref. 2 and taking $k_{6,\infty} = 1.4 \times 10^{10}$ ℓ mol^{-1} s^{-1} from this work led to a predicted value of k_5 at 1005 K of 1.36×10^7 ℓ mol^{-1} s^{-1}, in excellent agreement with the average, $1.33 \pm 0.14 \times 10^7$ ℓ mol^{-1} s^{-1}, from Table 2. Taking Arrhenius parameters from photolysis experiments at 407–523 K (28), a similar calculation led to $k_5 = 1.5 \times 10^6$ ℓ mol^{-1} s^{-1}, one ninth the observed value. Choice of a different source for $k_{6,\infty}$ would not have removed this difference. The difference cannot be caused by strong curvature of the Arrhenius plot for reaction 6, which has a similar rate constant at 300 K (27), 450 K (26), and high temperatures. Thus we conclude that reaction 5 exhibits a strongly curved Arrhenius plot.

Including the uncertainty in extinction coefficient, log k_5 would become 7.12 ± 0.2, in ℓ mol^{-1} s^{-1} units.

Values of k_9 of $3.0 (\pm 1.3) \times 10^7$ ℓ mol^{-1} s^{-1} were consistent with the observed H_2 yields. Including the uncertainty in the extinction coefficient, log $k_9 = 7.5 \pm 0.4$. Combining Arrhenius parameters for $k_9 k_{6,\infty}^{-1/2}$ from photolysis experiments at 357–453 K (15) and $k_{6,\infty}$ from this work led to a predicted value of k_9 of 4.5×10^6 ℓ mol^{-1} s^{-1} at 1005 K, one sixth of the experimental value. This reaction also appears to have a curved Arrhenius plot.

Since this article was submitted, a report (29) of a gas chromatographic study of dimethyl ether pyrolysis between 1063 and 1223 K has appeared. Extrapolation of the higher temperature data to 1005 K leads to the following predictions: $k_1 = 4.7 \times 10^{-2}$ s^{-1} at 1 atm, in satisfactory agreement with the present work; $k_9 = 2.5 \times 10^8$ ℓ mol^{-1} s^{-1}, almost an order greater than the present results. Reaction 9 merits further work.

THOMAS M. FYLES, CLIFFORD C. LEZNOFF, and JOHN WEATHERSTON. Can. J. Chem. **55**, 4135 (1977).

A 2% crosslinked divinylbenzene–styrene copolymer, incorporating trityl chloride groups (**2**) was used in the synthesis of insect sex attractants of Lepidoptera by a two-step alkyne coupling route. Polymer **2** reacted with the symmetrical diols, 1,8-octanediol and 1,10-decanediol, to give the monoblocked polymer-bound diols **5** and **6** respectively. Mesylation of **5** and **6** gave the polymer-bound monomesylates **7** and **8** which on coupling with lithioacetylide gave the polymer-bound terminal alkynes **9** and **10** respectively. Acid cleavage of **9** and **10** provide 9-decyn-1-ol and 11-dodecyn-1-ol respectively. A second coupling step was performed by lithiation of **9** and **10** with *n*-butyllithium or *tert*-butyllithium followed by treatment with *n*-butyl bromide or ethyl bromide to give polymer-bound internal alkynes, which on acid hydrolysis gave 9-tetradecyn-1-ol (**22**), 11-hexadecyn-1-ol (**23**), and 11-tetradecyn-1-ol (**24**). If **10** had been lithiated with *n*-butyllithium and coupled with ethyl bromide, some translithiation occurred to liberate *n*-butyl bromide which entered into the coupling reaction eventually giving a mixture of **23** and **24**. This problem was resolved by the use of *tert*-butyllithium in the lithiation step. Attempts were made to reduce polymer-bound internal alkynes stereoselectively to *cis*-alkenes with 9-borabicyclononane, diisobutylaluminum hydride, and catechol borane but all these reagents proved inadequate due to incomplete reduction, overreduction, hydrogenolysis of the alkyne from the polymer, and non-selectivity. Polymer-bound internal alkynes were quantitatively reduced exclusively to *cis* insect sex attractants using disiamylborane without concurrent overreduction or hydrogenolysis.

THOMAS M. FYLES, CLIFFORD C. LEZNOFF et JOHN WEATHERSTON. Can. J. Chem. **55**, 4135 (1977).

On a utilisé un copolymère divinylbenzène–styrène réticulé à 2% et incorporant des groupes chlorure de trityle (**2**) pour réaliser la synthèse de l'attirant sexuel du Lepidoptera en faisant appel à un schéma de couplage d'alcynes impliquant deux étapes. Le polymère **2** réagit avec les diols symétriques octanediol-1,8 et décanediol-1,10 pour conduire suivant le cas aux diols monobloqués **5** et **6** liés au polymère. La mésylation de **5** et **6** fournit les monomésylates **7** et **8** liés au polymère qui, par couplage avec l'acétylure de lithium, conduisent respectivement aux alcynes terminales **9** et **10** liés au polymère. Une scission acide de **9** et **10** conduit respectivement aux décyn-9 ol-1 et dodécyn-11 ol-1. Une nouvelle étape de couplage, effectuée par la lithiation de **9** et **10** avec le *n*-butyllithium ou le *tert*-butyllithium, suivie par un traitement avec le bromure de *n*-butyle ou le bromure d'éthyle conduit aux alcynes internes liés au polymère qui par hydrolyse acide fournissent le tétradécyn-9 ol-1 (**22**), l'hexadécyn-11 ol-1 (**23**) et le tétradécyn-11 ol-1 (**24**). Si l'on avait effectué la lithiation de **10** avec du *n*-butyllithium et si on l'avait couplé avec du bromure d'éthyle, il se serait produit un peu de translithiation pour libérer du bromure de *n*-butyle qui peut entrer éventuellement dans la réaction du couplage pour conduire à un mélange de **23** et de **24**. On a résolu ce problème par l'utilisation du *tert*-butyllithium dans l'étape de lithiation. On a effectué des essais pour réduire d'une façon stéréosélective les alcynes internes liés au polymère afin d'obtenir des alcènes *cis*; à cette fin on a fait appel au 9-borabicyclononane, à l'hydrure de diisobutylaluminium et au catéchol-borane mais tous ces réactifs s'avèrent inadéquats à cause soit d'une réduction incomplète, d'une réduction trop grande, d'une hydrogénolyse de l'alcyne du polymère ou à cause de la non-sélectivité. On a pu réduire quantitativement les alcynes internes liés au polymère et obtenir exclusivement les attractants sexuels des insectes *cis* en faisant appel au disiamylborane sans obtenir de réduction supplémentaire ou d'hydrogénolyse.

Introduction

Recently, we have reported the preparation of insect sex attractants (shown below) of Lepidop-

$$CH_3(CH_2)_mCH{=}CH(CH_2)_nOAc$$

cis

where $m = 1$–3 and $n = 6, 8$–10

tera on solid phases by an alkyne coupling route and by two different Wittig sequences (1, 2). The yields of reactions on solid phases, the use of symmetrical starting materials (3), the simplicity of solid phase reactions (4, 5), and the potential for synthesis in an automated procedure (6) showed distinct promise over solution phase methods, but several problems remained to be solved for the complete stereoselective synthesis of insect sex attractants (7) on solid phases. The use of expensive terminal alkynes in the coupling step can be construed as a disadvantage in both solid phase and solution methods of synthesis. Furthermore, in our previous syntheses on solid phases via the alkyne coupling route, the polymer-bound alkyne was cleaved from the polymer before stereoselective reduction to *cis* insect sex attractants was attempted. The stereoselective reduction was then achieved using 9-borabicyclononane (9-BBN) in solution (2, 8). A complete solid phase synthesis of *cis* insect sex attractants would require that the stereoselective *cis* reduction of an internal alkyne be accomplished directly on the polymer support. In this report we describe the synthesis of insect sex attractants on solid phases by a two-step alkyne coupling route using only acetylene and alkyl halides (9, 10). In addition, the stereoselective reduction of a polymer-bound alkyne to a polymer-bound *cis*-alkene by an examination of a variety of soluble reducing agents is described.

Results and Discussion

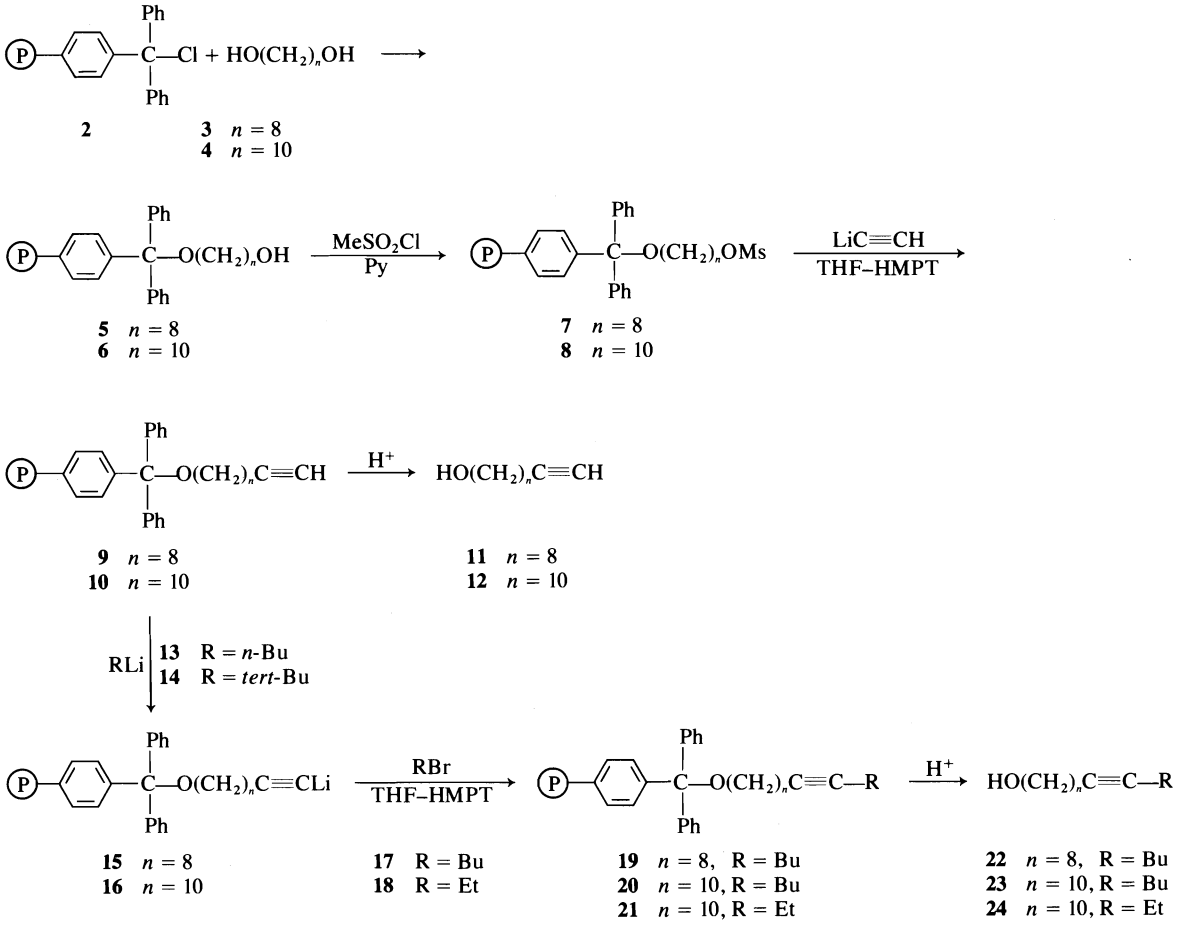
The Two-step Alkyne Route

A 2% crosslinked divinylbenzene (DVB)-styrene copolymer, incorporating trityl alcohol functional groups (**1**) (11, 12), was prepared by our direct lithiation method (12) and converted to a polymer-bound trityl chloride (**2**) (11, 12). Polymer **2** was treated with 1,8-octanediol (**3**) and 1,10-decanediol (**4**) for 48 h in pyridine at room temperature to give the monoprotected polymer-bound diols **5** and **6** respectively. Mesylation of **5** and **6** in benzene–pyridine (3:1) gave the polymer-bound symmetrical diol monomesylates **7** and **8** respectively. The amounts of diols bound to **5** and **6** and the yields of monomesylates derived from **7** and **8** were determined by acid cleavage as previously described (2) and are recorded in Table 1.

Monolithioacetylide can now be readily prepared in large quantities (13). Treatment of **7** and **8** with monolithioacetylide in tetrahydrofuran – hexamethylphosphoric triamide (THF–HMPT) (14) gave the polymer-bound terminal alkynes **9** and **10** respectively. Cleavage of **9** and **10** with HCl in dioxane as usual (2) gave 9-decyn-1-ol (**11**) and 11-dodecyn-1-ol (**12**) respectively in high conversion (Table 1) and some recovered **3** and **4** respectively. Lithiation of **9** with *n*-butyllithium (**13**) and **10** with **13** or *tert*-butyllithium (**14**) yielded the polymer-bound lithioalkynes **15** and **16** respectively. Coupling in THF–HMPT (14) of **15** with *n*-butyl bromide (**17**) and **16** with **17** or ethyl bromide (**18**) yielded the polymer-bound alkynes **19–21** respectively as shown in Scheme 1. Polymer-bound alkynes **19** and **21** had been previously prepared by a one-step alkyne coupling route from **7** and 1-lithio-1-hexyne and from **8** using 1-lithio-1-butyne respectively. Acid cleavage of **19–21** gave 9-tetradecyn-1-ol (**22**), 11-hexadecyn-1-ol (**23**), and 11-tetradecyn-1-ol (**24**) in high conversion from the symmetrical diols **3** and **4** (Table 1). All yields in Table 1 are calculated on products purified by preparative thin layer chromatography (tlc).

When a terminal alkyne is lithiated in a normal solution reaction (9, 10), equivalent amounts of *n*-butyllithium can be used to effect the lithiation. On polymer supports it is usually necessary to use excess reagents to drive reactions to completion and hence in our experiments on polymer **10**, excess **13** was used. Thus, in the coupling reaction of **16** with ethyl bromide (**18**), some excess **13** was present, which could and did exchange with **18** to give ethyllithium and some *n*-butyl bromide (**17**). The coupling of **16** prepared from *n*-butyllithium (**13**) with **18** thus led to a mixture of **20** and **21**, which on acid cleavage gave a mixture of the alkynols **23** and **24**. Analysis of this mixture, as their acetates, by high pressure liquid chromatography (hplc) showed that **24** was contaminated by about 15% of **23** (Table 2). The problem of translithiation was overcome by using *tert*-butyllithium (**14**) for the lithiation step and **24** could be prepared free of **23** (Table 2).

Conditions necessary for the conversion of **9**



SCHEME 1

and **10** to **22–24** according to Scheme 1 could be readily monitored by hplc analysis of crude **22–24** prepared via solid phases. In practice, the alkyne fraction, containing internal and sometimes terminal alkyne, was separated by preparative tlc from recovered diol and the alkyne fraction and converted to their acetates which were analyzed by hplc. By this method, the amounts of terminal alkyne in **22–24** could be accurately determined (Table 2).

cis Reductions of Polymer-bound Alkynes

Although we had previously reduced internal alkynes to *cis*-alkenes in solution by catalytic hydrogenation over a Lindlar-type catalyst (2), the results were not completely stereoselective in that less than 85% of the pure *cis* isomers were produced. In addition, the use of an *insoluble* palladium oxide catalyst would be incompatible with insoluble polymer supports in any attempt to reduce polymer-bound alkynes to *cis*-alkenes. It had been shown (2, 8) that internal alkynes can be reduced stereoselectively to *cis*-alkenes with *soluble* 9-BBN. After experimenting with a variety of soluble reducing agents (see below), disiamylborane (15) was found to be ideal for the job of reducing polymer-bound alkynes stereoselectively to polymer-bound *cis*-alkenes. Thus, the polymer-bound internal alkynes, **19** and **21**, that had been prepared, in fact, by the one-step alkyne coupling route (2), were treated with a large excess of 0.5 *M* disiamylborane ($(Sia)_2BH$) in THF at 0°C for 4 h. Protonolysis with acetic acid yielded the polymer-bound *cis*-alkenes **25** and **26**, which on acid cleavage and acetylation yielded, according to Scheme 2, *cis*-9-tetradecen-1-yl acetate (**27**) (10), the sex attractant of *Spodoptera frugiperda* (J. E. Smith), and *cis*-11-tetradecen-1-yl acetate (**28**) (16), the sex attractant of *Argyrotaenia velutinana* (Walker), in high

conversion (Table 3). Attractants **27** and **28** were examined by hplc and vapour phase chromatography (vpc) for isomeric purity about the double bond and were found to have *cis*:*trans* ratios of 99:1 and 90:10 respectively (Table 4).

Earlier attempts to reduce **21** to **26** using excess 9-BBN at 50°C gave complete reduction but some hydrogenolysis (cleavage from the polymer) occurred and the reduction was *not* completely stereoselective even though it was completely stereoselective in solution (Tables 3 and 4). Less vigorous conditions resulted in incomplete reduction of the alkyne (Table 4). Catechol borane (17) has been recently recommended for the stereoselective reduction of alkynes to *cis*-alkenes in solution, but treatment of **21** with catechol borane in dioxane under normal conditions (17) led to complete hydrogenation and hydrogenolysis to 1-tetradecanol, analyzed by hplc as its acetate (Table 4). In THF under reflux, however, only partial reduction of **21** to **26** occurred. In addition, some hydrogenolysis from the polymer took place and product **26** exhibited a *cis*:*trans* ratio of only 2:3 and hence reduction took place in a non-stereoselective manner (Tables 3 and 4). Diisobutylaluminum hydride (DIBAH) has been used for the stereoselective *cis* reduction of alkynes (18). Treatment of **21** in THF with a slight excess of 1 *M* DIBAH in hexane at room temperature overnight gave little reaction. With excess DIBAH at 60°C reduction to alkene was still incomplete. Under reflux conditions in benzene, reduction was complete, but hydrogenolysis from the polymer was also complete (Tables 3 and 4). In addition, some 1-tetradecanol, analyzed as its acetate was detected in the filtrate of the polymer, showing that overreduction had occurred. The reductions were not completely stereospecific in that **28** exhibited a *cis*:*trans* ratio of 85:15.

As shown in Table 3 the stereoselective reductions of **19** and **21** leading to **27** and **28** using $(Sia)_2BH$ are virtually quantitative. The analogous reaction in solution described by Holan and O'Keefe (15) proceeded very well in 90% yield but was not quite as good as described herein. We have noticed this phenomenon before in which polymer-bound reactions *appear* to be consistently 5–20% better than their solution analogs (2) although documentation and strict comparisons are difficult to make as, by their very nature, polymer-bound reactions are not

[c]The period of alkylation was 3–4 h.
[d]Solvent A is water–acetonitrile, 2:3, and solvent B is water–acetonitrile, 3:7.
[e]9-Decyn-1-yl acetate has a retention volume (V_T) of 9.3 ml.
[f]9-Tetradecyn-1-yl acetate has a V_T = 29.8 ml.
[g]11-Dodecyn-1-yl acetate has a V_T = 9.5 ml.
[h]11-Hexadecyn-1-yl acetate has a V_T = 25.6 ml.
[i]11-Tetradecyn-1-yl acetate has a V_T = 15.6 ml and is contaminated with 10% of 11-hexadecyn-1-yl acetate (V_T = 25.6 ml).
[j]11-Tetradecyn-1-yl acetate (V_T = 15.6 ml) is contaminated with 15% of 11-hexadecyn-1-yl acetate (V_T = 25.6 ml).

identical to their solution analogs in all respects. We make this observation because for this particular reduction a possible explanation is available. In the solution reaction the vinyl borane intermediate, hydrolyzed by protonolysis with acetic acid, yields boron-containing impurities which must be removed by treatment with hydrogen peroxide (15). In the analogous reductions of **19** and **21** leading to **25** and **26**, the boron-containing impurities are removed by simple filtration, as the desired products are bound to the insoluble support, and the products **27** and **28** are thus not subjected to treatment with hydrogen peroxide.

Elemental Analysis as a Diagnostic Tool for the Determination of Polymer-bound Products

We had previously stated that elemental analyses of polymer-bound products are unreliable guides to the purity of polymer-bound products (2), because, as in all reactions, side products are often obtained along with the desired product and hence polymer-bound products are unlikely to be pure. We prefer to base our yields of reactions on pure products isolated after cleavage from the polymer. Relles and Schluenz partially addressed this problem in discussing polymer-bound phosphine dichlorides (19). Firstly, they mention that elemental analysis of polymer-bound phosphorous is unreliable and irreproducible and, secondly, they quantify the amount of reagent bound to the polymer by the job it does and not by the phosphorous content of the polymer, which we feel is reasonable. In our own work in this paper, for example, elemental analysis of one batch of **8** for S (1.65%) shows a sulfur content corresponding to 0.52 mmol of 1,10-decanediol monomesylate/g, but acid cleavage yields only 0.29 mmol of 1,10-decanediol

[e]Yield if diol recovered from acid cleavage of 25 or 26 is recycled.
[f]Solution yield from ref. 10 is 30% based on 8-chloro-1-octanol.
[g]Isolated as their acetates.
[h]The reducing agent caused partial hydrogenolysis in these cases and products were isolated from the filtrate of the reduction of 19 or 21.

monomesylate/g of **8**. Indeed recycled polymer **1** contained 0.06 mmol S (0.2%)/g which indicates that a small amount of sulfur-containing product or impurities become permanently bound to the polymer, while a larger fraction of sulfur-containing impurities are washed out during the acid cleavage step or during the procedure used for cleaning recycled **1**.[3] Thus elemental analysis of **8** is an unreliable guide to the quantity of 1,10-decanediol monomesylate bound to **8**, but does, of course give a maximum possible value. On the other hand elemental analysis for N, of freshly prepared **1** exhibited 0.78 mmol N (1.1%)/g of **1**, while recycled **1** still showed 0.29 mmol N (0.41%)/g. Undoubtedly, the nitrogen comes from the *N,N,N'N'*-tetramethylethylenediamine used in the preparation of **1** (12), but the nature and consequences of these irreversibly bound polymer-bound nitrogen-containing impurities is unclear at this time. Recycled **1** also contains 0.42 mmol Cl (1.49%)/g of **1**, probably derived from the conversion of **1** to **2** with acetyl chloride, but possibly due to multiple cleavages with HCl in dioxane. Since we can separately analyze for benzylic and trityl chloride by the Volhard method (20) and for aliphatic chloride (2) using potassium *tert*-butoxide, and these methods show no residual chloride for recycled **1**, we feel that the residual chloride in recycled **1**[4] results from chloride bound to the phenyl rings of **1**. Perhaps the surprising aspect of these analytical results lies in the fact that these irreversibly bound impurities do not appear to affect the success of polymer-bound syntheses, although an understanding of these processes will make polymer-bound syntheses even more attractive.

Conclusions

A total stereoselective synthesis of *cis* insect sex attractants on solid phases has been achieved by a two-step alkyne coupling route using very inexpensive symmetrical diols, acetylene, and alkyl halides. Disiamylborane proved to be the

[3]Bio-Beads SX-2 were used in all reactions. Chemical analysis of the beads as purchased showed 0.91% Cl, 0.68% N, and 0.84% S, while washed beads still showed 0.73% Cl, 0.36% N, and 0.41% S. Thus, non-exhaustive washing procedures do not reduce all of the Cl, N, and S content of the initial polymer, which contribute to unreliable analyses at a later stage.

[4]Polymer **1** has been recycled over 25 times without degradation or significant loss of capacity to bind symmetrical diols.

TABLE 4. High pressure liquid chromatographic analysis[a] of insect attractants,[b] obtained by reduction of polymer-bound alkynes in THF overnight with an excess of various reducing agents at different temperatures

[a]Solvent B is used (see Table 2, footnote *d*).
[b]Obtained by cleavage of **25** or **26**, separated from starting diol, and acetylated for hplc or vpc analysis.
[c]This entry refers to **27**.
[d]These ratios were determined by vpc and hplc analysis. The retention volume (V_T) of *cis*-**27** is 24.2 ml, *trans*-**27** 26.2 ml, *cis*-**28** 26.0 ml, and *trans*-**28**, 27.4 ml.
[e]This and all lower entries in this column refer to **28**.
[f]Only a small excess of reducing agent was used.
[g]This reduction was done in dioxane.
[h]The remaining product was tetradecan-1-yl acetate produced by overreduction.
[i]In benzene.
[j]Complete hydrogenolysis from the polymer occurred and the product was isolated from the filtrate.

only effective reagent capable of converting a polymer-bound alkyne to a *cis* polymer-bound alkene in almost quantitative yield and high stereoselectivity. The polymer-bound products proved to be easier to purify and provided higher yields than reductions performed in solution. Elemental analysis cannot be used to provide quantitative information about polymer-bound products but can provide useful clues to possible side reactions and the presence of polymer-carried impurities.

Experimental

A Bausch and Lomb Abbé 3L refractometer was used to record the refractive indices. Infrared spectra were recorded on a Unicam SP1000 ir spectrophotometer as neat films between NaCl discs unless otherwise specified. Nuclear magnetic resonance spectra were recorded on a Varian EM360 spectrometer using deuteriochloroform as solvent and tetramethylsilane as internal standard. Mass spectra were recorded on a Perkin-Elmer-Hitachi RMU6E mass spectrometer. Silica gel was used for all thin and preparative layer chromatography. Fractions were extracted with ether in a Soxhlet extractor. Filtration was done under vacuum through sintered glass Buchner funnels. Filtration under an inert atmosphere was done as previously described (2). Microanalyses were performed by G. Gygli of Toronto.

Vapour phase chromatograms were run with a Perkin Elmer 990 instrument using a 15 ft × $\frac{1}{8}$ in. column of 10% Silar C on Gaschrom Q(60/80) at a temperature of 170°C and a nitrogen flow rate of 15 ml/min. High pressure liquid chromatograms were run with a Waters Associates Model 440 instrument, with an R-400 refractive index detector. A 30 × 0.4 cm reverse phase μ Bondapak C-18 column using water–acetonitrile mixtures as solvent was used at a flow rate of 1.0 ml/min. Spectral and analytical data are given for all new compounds and for known compounds where data are unreported.

Preparation of Polymer-bound Diol Monomesylates ***7*** *and* ***8***

The polymer-bound monomesylates **7** and **8** were prepared as previously described (2) except that benzene–pyridine, 3:1, was used as solvent instead of pure pyridine in the mesylation steps. This change gives a cleaner, less brown, polymer than previously described.

Preparation of Polymer-bound Terminal Alkynes ***9*** *and* ***10***

In a typical experiment, 10.8 ml (25 mmol) of a 2–3 *M* solution of *n*-butyllithium in 100 ml of dry THF was cooled in a Dry Ice – acetone bath under argon. Dry, acetone free, acetylene was bubbled into the solution for 0.5 h and the solution was stirred for a further 20 min at the Dry Ice bath temperature. To this solution 5 g of **7** or **8**, containing 0.25–0.35 mmol of diol monomesylate/g of polymer was added followed by the further addition of 100 ml of HMPT. The mixture was warmed to room temperature and stirred overnight. The black mixture was hydrolyzed with 20 ml of water. The polymer was filtered and washed with three 50 ml portions of ethanol, five 50 ml portions of water, three 25 ml portions of ethanol, and two 50 ml portions of benzene. The polymer, wet with benzene, was transferred to a thimble in a Soxhlet extractor in which molecular sieves (3A) had been placed in a second thimble or in the round bottom flask of the extractor, and the polymer was extracted with benzene for 4 h under reflux conditions. The polymer was washed

free of benzene with dry ether and dried *in vacuo* at 0.2 Torr for 0.5 h. The ir spectra of **9** and **10** exhibited a weak band at 3400 cm^{-1} (C≡C—H) and no absorptions at 1360 and 1180 cm^{-1} due to residual mesylate.

*Preparation of 9-Decyn-1-ol (**11**) and 11-Dodecyn-1-ol (**12**) and Their Acetates*

A suspension of 1.0 g of **9** in 40 ml of a 0.35 *M* HCl dioxane solution was stirred at room temperature for 48 h. The polymer residue was washed as previously described (12) and the filtrate diluted with water. As the product was somewhat soluble in water it was necessary to isolate the product from the aqueous solution in a liquid–liquid extractor using ether as the organic phase. The ether phase was dried over $MgSO_4$ and evaporated to yield 95 mg of crude material. Purification by preparative tlc (eluant, ether–benzene 2:3) afforded, from the slowest moving band (R_f, 0.15), 47 mg of recovered **3** and, from the faster moving band (R_f, 0.55), 34 mg of pure 9-decyn-1-ol (**11**), in 38% yield, as an oil; n_D^{25} 1.4851; ir: 3500 (O—H), 3400 (≡C—H), 2100 (C≡C) and 1050 cm^{-1} (C—O); nmr δ: 3.6 (t, 2, J = 7 Hz, CH_2OH), 2.2 (m, 2, $CH_2C{\equiv}C$), 1.9 (t, 1, J = 1.5 Hz, C≡C—*H*), and 1.7–1.2 (m, 12, $(CH_2)_6$). *Anal.* calcd. for $C_{10}H_{18}O$: C 77.87, H 11.76; found: C 76.98, H 11.88.

Acetylation of **11** with acetic anhydride in pyridine yielded 9-decyn-1-yl acetate as an oil; ir: 3400 (≡C—H), 2100 (C≡C), 1740 (ester C=O) and 1250 cm^{-1} (C—O); nmr δ: 4.0 (t, 2, J = 7 Hz, CH_2O), 2.2 (m, 2, $CH_2C{\equiv}C$), 2.0 (s, 3, CH_3CO), 1.9 (t, 1, J = 1.5 Hz, C≡C—*H*), and 1.8–1.2 (m, 12, $(CH_2)_6$); ms (70 eV) *m/e* (relative intensity): 196 (2.6) (M^+), 136 (10) ($M^+ - CH_3CO_2H$), 43 (100). *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.23, H 10.19.

Similarly (except that liquid–liquid extraction need not be used in this example), **10** yielded 61 mg of recovered **4** and 56 mg of 11-dodecyn-1-ol (**12**), in 43% yield, as an oil (lit. (21) $bp_{0.005}$ 83–86°C): n_D 1.4899 (lit. (21) n_D 1.4898); ir: 3500 (O—H), 3400 (≡C—H), 2100 (C≡C), and 1050 cm^{-1} (C—O); nmr δ: 3.6 (t, 2, J = 7 Hz, CH_2O), 2.2 (m, 2, $CH_2C{\equiv}C$), 1.9 (t, 1, J = 1.5 Hz, C≡C—*H*), and 1.8–1.2 (m, 16, $(CH_2)_8$).

Acetylation of **12** as before yielded 11-dodecyn-1-yl acetate as an oil; ir: 3400 (≡C—H), 2100 (C≡C), 1740 (ester C=O), and 1250 cm^{-1} (C—O); nmr δ: 3.6 (t, 2, J = 7 Hz, CH_2O), 2.2 (m, 2, $CH_2C{\equiv}C$), 2.0 (s, 3, CH_3CO), 1.8 (t, 1, J = 1.5 Hz, C≡C—*H*), and 1.8–1.2 (m, 16, $(CH_2)_8$); ms (70 eV) *m/e* (relative intensity): 224 (1) (M^+), 164 (9) ($M^+ - CH_3CO_2H$), and 43 (100). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.95, H 10.78; found: C 74.61, H 10.75.

*Preparation of Polymer-bound Internal Alkynes **19–21***

In a typical experiment, 1.25 g of **10**, containing 0.4 mmol of **12** was suspended in 20 ml of dry THF at 60–70°C under argon. The mixture was treated with *n*-butyllithium (**13**) (3.5 ml of a 0.5 *M* solution in hexane, 8 mmol) and stirred at 60–70°C for 0.5 h. To the suspension was added 5 ml of *n*-butyl bromide (**17**) and 20 ml of HMPT and the mixture was stirred for 4 h at 60–70°C. The polymer was filtered, washed successively with 10 ml portions of ethanol (three times), water (three times), ethanol (three times), dioxane (three times), and ether (three times), and air dried to give the polymer-bound internal alkyne **20**.

The polymer-bound alkynes did not exhibit absorptions at 2100–2200 cm^{-1} (C≡C) in their ir spectra.

The formation of **19–21** was achieved to some extent under a variety of conditions and reagents based on the above procedure. These variations are outlined in Table 2.

*Preparation of Alkyn-1-ols **22–24** and Their Acetates*

Acid cleavage of 1.0 g of **20** as previously described (12) and filtration and washing of the polymer as before gave a filtrate which was neutralized and evaporated to a mixture of salts and oil. Organic material was extracted with ether dried over $MgSO_4$ and evaporated to give an oil. Preparative tlc as before gave 59 mg of recovered **4** and 69 mg of 11-hexadecyn-1-ol (**23**) as an oil; n_D 1.4687; ir: 3500 (O—H) and 1050 cm^{-1} (C—O); nmr δ: 3.6 (t, 2, J = 8 Hz, CH_2O), 2.2 (m, 4, $CH_2C{\equiv}CCH_2$), 1.8–1.2 (m, 20, aliphatic H), and 0.9 (t, 3, J = 7.5 Hz, CH_3CH_2). *Anal.* calcd. for $C_{16}H_{30}O$: C 80.61, H 12.68; found: C 80.91, H 12.68.

Acetylation of **23** as before yielded 11-hexadecyn-1-yl acetate as an oil; n_D 1.4645; ir: 1740 (ester C=O) and 1250 cm^{-1} (C—O); nmr δ: 4.0 (t, 2, J = 8 Hz, CH_2O), 2.2 (m, 4, $CH_2C{\equiv}CCH_2$), 2.0 (s, 3, CH_3CO), 1.8–1.2 (m, 20 aliphatic H), 0.9 (t, 3, J = 8 Hz, CH_3CH_2); ms (70 eV) *m/e* (relative intensity): 280 (22) (M^+), 220(11) ($M^+ - CH_3CO_2H$), and 43 (100). *Anal.* calcd. for $C_{18}H_{32}O_2$: C 77.09, H 11.50; found: C 77.50, H 11.58.

The yields of **23** and the previously reported (2) **22** and **24** are recorded in Table 1. The yields of **22–24** relative to recovered **11** and **12** under different reaction conditions were determined by hplc analysis of their acetates as shown in Table 2.

*Preparation of Polymer-bound cis-Alkenes **25** and **26** Using Disiamylborane and Other Reducing Agents*

A suspension of 1.25 g of **21**, containing 0.3 mmol **24** of **21** was treated with 20 mmol of a 0.5 *M* THF solution of $(Sia)_2BH$. The mixture was stirred at −10 to 0°C under argon for 4 h, treated with 5 ml of acetic acid, and stirred for a further 0.5 h at 0–10°C. The polymer-bound *cis*-alkene **26** was filtered, washed with 15 ml portions of water (three times), ethanol (three times), dioxane (three times), and ether (three times), and air dried.

The formation of **25** and **26** was achieved to some extent under a variety of conditions using soluble reducing agents such as 9-BBN, catechol borane, and DIBAH based essentially on the procedure outlined above. The variations on the above conditions are outlined in Table 4.

*Preparation of cis-9-Tetradecen-1-yl and Acetate (**27**) and cis-11-Tetradecen-1-ol and Acetate (**28**)*

Insect attractants **27** and **28** were isolated as previously described (2) by acid cleavage of **25** and **26** respectively followed by acetylation. The yields of **27** and **28** prepared by different reduction methods are outlined in Table 3. The isomeric purity of **27** and **28** obtained under different reaction conditions was determined by hplc analysis given in Table 4.

Received May 19, 1977

JOHN W. BOVENKAMP, ROBERT Y. MOIR, and ROBERT A. B. BANNARD. Can. J. Chem. **55**, 4144 (1977).

Six related oxiranes (the *cis* and *trans* isomers derived from 3-methoxycyclopentene and from 3-methoxycyclohexene, as well as the oxiranes from the corresponding unsubstituted olefins) were each treated under the same conditions with an acidic solution containing charged and uncharged nucleophiles (chloride ion, water, and methanol). The corresponding perchloric acid catalyzed scissions were also carried out. Accurate and reproducible methods of product analysis for the reaction mixtures were developed. In this way, nucleophilic attacks upon different oxiranes were compared directly. Attacks by different nucleophiles upon the same oxirane, or by a single nucleophile upon different positions of the same oxirane, were compared in the very same solution. The results are considered to provide the most extensive demonstration of the effects of charge orientation yet available. The synthesis of some new isomeric 1,2,3-trisubstituted diols and dimethoxyalcohols are reported.

JOHN W. BOVENKAMP, ROBERT Y. MOIR et ROBERT A. B. BANNARD. Can. J. Chem. **55**, 4144 (1977).

Six oxirannes de même type (les isomères *cis* et *trans* du méthoxy-3 cyclopentène et du méthoxy-3 cyclohexène, aussi bien que les oxirannes provenant des oléfines non-substituées) sont traités individuellement dans les mêmes conditions par une solution acide contenant des nucléophiles chargés et non-chargés (ion chlorure, eau et méthanol). On réalise aussi les scissions correspondantes catalysées par l'acide perchlorique. On met au point des méthodes d'analyse précises et reproductibles des produits provenant du mélange réactionnel. De cette façon, les attaques nucléophiles sur les différents oxirannes sont comparées directement. Les attaques de différents nucléophiles sur le même oxiranne, ou par un seul nucléophile à différentes positions du même oxiranne, sont comparées dans la même solution. Les résultats semblent apporter la démonstration la plus marquée connue jusqu'à maintenant sur les effets d'orientation de charge. On rapporte la synthèse de quelques nouveaux diols trisubstitués-1,2,3 isomères et de diméthoxyalcools.

[Traduit par le journal]

The mechanism of oxirane[2] opening and the stereo- and regioselectivity of the nucleophilic addition have been topics of great interest (1–8). In these laboratories, we have expended a good deal of effort in this area due to our interest in conformational factors and the interaction of substituents in the cyclopentane and cyclohexane ring systems (see refs. 7–10 and references cited therein). In fact, it was the availability of compounds synthesized during these studies (for example most of **1–19**) (see Figs. 1*a* and 1*b*) which allowed us to proceed with the experiments described in this paper.

Although several papers deal with the scission of 3-substituted cyclohexene or cyclopentene oxides (see, for example, refs. 7, 8, and 11–15), these report almost exclusively either the attack of a charged nucleophile in an inert solvent or the acid or base catalyzed opening by the solvent. In several instances, the effect of the 3-substituent on stereo- and regioselectivity has been studied by comparing nucleophilic scissions which have been conducted under widely varying conditions. Although these interpretations are useful in a qualitative sense, the derivation of quantitative

[1]Present address: Defence Research Establishment Ottawa, Ottawa, Ont., Canada K1A 0Z4.

[2]For the remainder of this paper oxiranes will be designated as epoxides or cycloalkene oxides. These designations have been in use for many decades.

b R = $COCH_3$; cyclohexane series
c R = H; cyclopentane series
d R = $COCH_3$; cyclopentane series

FIG. 1*a*. Structures of the 1,2-di- and 1,2,3-trisubstituted cycloalkanes. To conserve space, the unsubstituted ring methylenes are not shown.

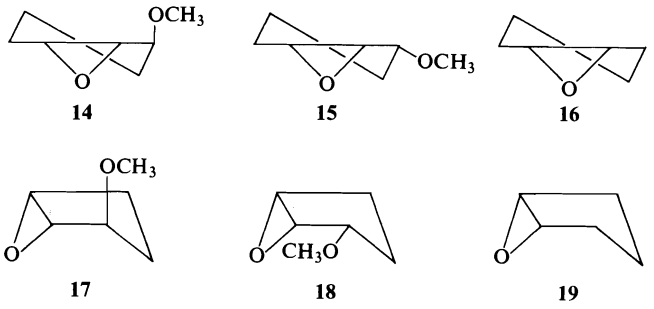

FIG. 1*b*. Oxirane structures.

data from which direct comparisons are possible demands careful standardization of experimental conditions.

In this paper are described the results obtained when the six epoxides **14–19** are subjected to scission under the same reaction conditions (2.43°C) in 50 wt.% aqueous methanol containing hydrochloric acid. A comparison is thus possible for charged and uncharged nucleophiles in terms of the presence and orientation of the 3-methoxyl substituent as well as in terms of the five- and six-membered ring systems.[3] The corresponding scissions using perchloric acid as the catalyst were also carried out.

Many years ago, Parker and Isaacs (1) strongly emphasized the need to carry out accurate product analyses in epoxide scission reactions. This requirement has clearly been met in this paper. In Table 1 are given the product analyses found in the cyclohexane series, while the corresponding figures for the cyclopentane series are found in Table 2.

Immediately apparent from Table 1 is the profound effect of the orientation of the methoxyl substituent on the proportion of chlorohydrin produced. In the scission of *trans*-3-methoxycyclohexene oxide (set 2), the total amount of chlorohydrin formed is 12.9%. Almost four times as much chlorohydrin (46.5%) is formed from the *cis* isomer under the same conditions (set 6). Less chlorohydrin is formed from cyclohexene oxide than from the *cis*-3-methoxycyclohexene oxide (compare sets 8 and 4; 5.2:7.2 respectively). A similar trend is found in the cyclopentane series (Table 2). As observed and discussed

[3]A number of papers have dealt with the comparison of charged and neutral nucleophiles in straight chain epoxides (1). In fact as early as 1929, Brönsted *et al.* (16) compared the attack of chloride ion and water upon ethylene oxide under acidic conditions.

TABLE 1. Composition of the reaction mixtures from cyclohexene oxides[a,b,c]

Set	Reagent concentrations (*M*)	Percent scission at epoxide carbons 1 and 2

[a]Initial ionic strength for each experiment was 0.215 *M*. Epoxide concentration was initially 0.06 *M* in all runs. The solvent was a 50:50 wt. % solution of methanol and water. Reaction temperature was 2.43°C.

[b]The percentages in parentheses are calculated using the assumption that the ratio of water to methanol scission is not significantly affected by whether the acid used is hydrochloric or perchloric. This assumption was shown to be true in two ways. First, in sets 1 (perchloric) and 2 (hydrochloric) (both sets analyzed by glc), the ratio of water to methanol scission product was 51.9:48.1 and 50.9:49.1 respectively. Also in Table 2, set 10 (perchloric acid) and set 11 (hydrochloric acid) were analyzed by glc and again the methanol–water product ratios were close (44.8 in set 10 and 44.4 in set 11). Secondly, the percentages of diol in sets 8 and 9 were calculated to be 51.4 and 45.5 from the methanol to water scission ratio of set 7. These were very close to the values of 51.0 and 45.1 found by sodium periodate oxidation.

[c]When the methanol and water scission figures are given in parenthesis, the amount of chlorohydrin formed was determined by the amount of hydrochloric acid consumed (all titrations carried out in triplicate).

[d]In the glc determinations, all of the peaks were well separated except in set 2 where the peaks for **4***a* and **1***a* completely overlapped. However, **4***a* could be obtained from the difference between the amount of hydrochloric acid consumed and the value found for **3***a*. This allowed the calculation of **1***a*. Two complete product analyses determinations were carried out for set 2. The values for set 1 were so close (on a percentage basis) to those of set 2 that only one determination was done.

[e]Average of three determinations.

previously for single nucleophilic scissions (7), a small but significant amount of minor isomer (C-2 scission) is formed from *trans*-3-methoxycyclohexene oxide **14** while no minor isomer formation was detected for the corresponding *cis* oxide **15**. As for single nucleophilic scissions, the very interesting reversal in minor isomer formation between the cyclohexane and the cyclopentane series is also found under the present conditions. In the cyclohexane series, C-2 attack is observed in the *trans* but not in the *cis* oxide while the reverse is found in the cyclopentane series. This phenomenon has been interpreted previously in terms of transition state geometries (8).

The most interesting comparisons in this type of study are those from which the energetics of the transition states may be deduced. Second- and third-order differences are the significant quantities in such a study and the main advantage of our approach is the accuracy with which these differences may be obtained. Nucleophilic attacks upon *different oxides* were performed as nearly as possible under exactly the same conditions of solvent, temperature, and ionic strength. Attacks by *different nucleophiles* upon the same oxide, or by a single nucleophile upon *different positions* of the same oxide, were compared in the very same solution. Finally, the comparisons made in this paper of different rates of reaction

[b]Two determinations.
[c]Four determinations.

are based upon analytical results only and are free from the errors inherent in kinetic measurements. Although a high order of accuracy was achieved in the free energy differences discussed below, likely more convincing is the fact that the conclusions reached are supported by the obviously substantial and significant differences in product composition reported in Tables 1 and 2.

In the reaction of a nucleophile N_1 with an epoxide E_1, several ground state energies remain in the expression [1] for the free energy[4] of the transition state ${F_{1,1}}^{\ddagger}$:

$$[1]\quad {F_{1,1}}^{\ddagger} = \Delta {F_{1,1}}^{\ddagger} + {F^0}_{E_1} + {F^0}_{H^+} + {F^0}_{N_1}$$

If we wish to compare attack of N_1 at carbons C-1 and C-2 of the same epoxide, then we have the familiar Curtin–Hammett equation (17)

$$[2]\quad \Delta^2 F^{\ddagger} = {F_{1,1}}^{\ddagger}(\text{C-1}) - {F_{1,1}}^{\ddagger}(\text{C-2}) = \Delta {F_{1,1}}^{\ddagger}(\text{C-1}) - \Delta {F_{1,1}}^{\ddagger}(\text{C-2})$$

In a previous paper (7), we have applied this equation to the results of oxide scissions under varied conditions of temperature and solvent composition.

[4]The symbol F is used in these papers for the Gibbs' free energy in order to avoid confusion with the symbol G used in conformational analysis for the free energy due to *gauche* effects.

If E_2 represents a second oxide which reacts with nucleophile N_1 and we wish to compare it with the attack of the same nucleophile on the first oxide, then

$$[3]\quad \Delta^2 F^{\ddagger} = {F_{2,1}}^{\ddagger} - {F_{1,1}}^{\ddagger} = (\Delta {F_{2,1}}^{\ddagger} - \Delta {F_{1,1}}^{\ddagger}) + ({F^0}_{E_2} - {F^0}_{E_1})$$

Equation 3 is only useful if one can gain some idea of the differences in the standard ground state free energies (${F^0}_{E_2}$ and ${F^0}_{E_1}$) of the two oxides. Because the theoretical explanation of these $\Delta^2 F^{\ddagger}$ values is complex, the discussion has been left to the paper on the kinetics of the reactions.

Ground state energies may be removed in another way, which leads to the most interesting conclusions of this paper. If we consider the reaction of two nucleophiles, N_1 and N_2, upon two epoxides, E_1 and E_2, then

$$[4]\quad \Delta^3 F^{\ddagger} = ({F_{2,2}}^{\ddagger} - {F_{2,1}}^{\ddagger}) - ({F_{1,2}}^{\ddagger} - {F_{1,1}}^{\ddagger}) = (\Delta {F_{2,2}}^{\ddagger} - \Delta {F_{2,1}}^{\ddagger}) - (\Delta {F_{1,2}}^{\ddagger} - \Delta {F_{1,1}}^{\ddagger})$$

by subtraction involving the appropriate eqs. 1. In [4] all ground state energies have disappeared. The second-order difference $\Delta^3 F^{\ddagger}$ has an immediate physical meaning. It is a measure of the

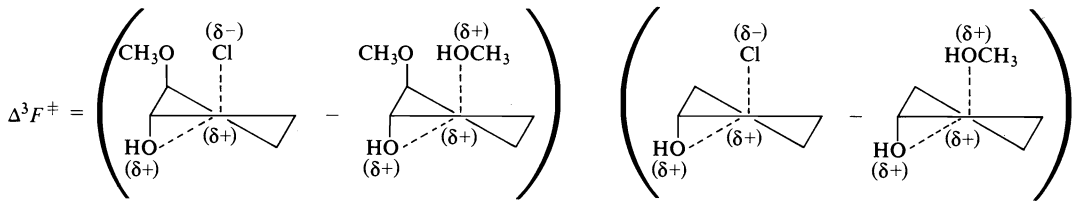

FIG. 2. The physical picture (it is the free energies of these transition states in the cyclopentane series which are being compared) of $\Delta^3F^{\ddagger}$ for one set of transition states in the cyclopentane series.

difference in the ability of two oxides to discriminate between two nucleophiles.[5] Thus in Fig. 2, $\Delta^3F^{\ddagger}$ represents the difference in the free energies of the transition states for chloride and methanol attack on position-1 of *trans*-3-methoxycyclopentene oxide as compared with the difference of the corresponding transition states in the scission of unsubstituted cyclopentene oxide.

The calculation of the values of $\Delta^3F^{\ddagger}$ from the product analysis data of Tables 1 and 2 is complicated by the fact that methanol and chloride attack the oxides in reactions of different apparent kinetic orders.

As pointed out by Lamaty *et al.* (6) for ethylene oxide, the equation for chlorohydrin (C) formation is given by

$$[5] \qquad \frac{dC}{dt} = \frac{1}{K}k_c[E][H^+][Cl^-]$$

where K is the equilibrium constant for the protonation of the epoxide (E). The corresponding equation for the product due to methanol attack (M) is

$$[6] \qquad \frac{dM}{dt} = \frac{1}{K}k_m[E][H^+]$$

Now $[Cl^-] = A_0 + S_0 - C$, where A_0 is the initial concentration of hydrochloric acid and S_0 is the concentration of sodium chloride. On dividing [5] by [6] we obtain

$$[7] \qquad \frac{k_c}{k_m}dM = \frac{dC}{A_0 + S_0 - C}$$

Integration of [7] gives

$$[8] \qquad \frac{k_c}{k_m} = \frac{1}{M}\ln\left\{\frac{A_0 + S_0}{A_0 + S_0 - C}\right\}$$

When the reaction is complete, then A_f, the final acidity, is equal to $A_0 - C_f$ and [8] becomes

$$[9] \qquad \frac{k_c}{k_m} = \frac{1}{M_f}\ln\left\{\frac{A_0 + S_0}{A_f + S_0}\right\}$$

Consider the most complicated case where $\Delta^3F^{\ddagger}$ (Cl^- vs. MeOH; epoxide **14** (set 2) vs. epoxide **16** (set 8) (Table 1)) is calculated for position-1 attack on an epoxide where position-2 is also attacked. For epoxide **14**, let the amount of chlorohydrin formed by position-1 attack be C_1 and by position-2 attack be C_2. Also let M_1 and M_2 represent the products due to methanol attack at positions-1 and -2 respectively. Thus, the rate constants for position-1 attack on **14** are

$$[9a] \qquad k_{c_1} = \frac{C_1}{C_1 + C_2}k_c$$

and

$$[9b] \qquad k_{m_1} = \frac{M_1}{M_1 + M_2}k_m$$

From [4]:

$$[10] \qquad \Delta^3F^{\ddagger} = \left(-RT\ln\frac{k_{c_1}h}{KT} + RT\ln\frac{k_{m_1}h}{KT}\right) - \left(-RT\ln\frac{0.5k_c'h}{KT} + RT\ln\frac{0.5k_m'h}{KT}\right)$$

The prime refers to values for the unsubstituted oxide **16**. Substitution of [9*a*] and [9*b*] into [10] results in

$$[11] \qquad \Delta^3F^{\ddagger} = RT\ln\frac{k_c'}{k_m'} - RT\ln\left(\frac{k_c}{k_m}\frac{C_1}{(C_1 + C_2)}\frac{(M_1 + M_2)}{M_1}\right)$$

[5]The theoretical analysis leading to [3] and [4] is subject to an error caused by partition at 'hidden' intermediates. Such an intermediate may be thought of as occupying a notch in the reaction profile, and the size of the resulting error as a function of the difference in height of the two sides of the notch, reaching a maximum when the two sides are equal in height. The error is negligible for intermediates such as protonated epoxides. At the time of writing, it is believed (3*c*, 6, 10, 18) that the error caused by ion-dipole or ion-pair intermediates is negligible for substitutions at secondary centres in highly nucleophilic solvents, and to some extent at least the errors will cancel in comparative studies like the present. Nevertheless, the large effect of barely perceptible valleys in the reaction profile near the rate-limiting transition state must be kept in mind in all applications of the Curtin–Hammett theory (19).

TABLE 3. Relative abilities of epoxides to discriminate between pairs of nucleophiles in acid catalyzed scissions[a,b] (symbols and relations from [4])

Epoxide E_2	Epoxide carbon attacked	Nucleophiles N_1	Nucleophiles N_2	$\Delta^3F^{\ddagger}$ (kcal/mol)[b]

		H_2O	MeOH	−0.15
trans-3-Methoxy[d] (**17**)	1	Cl^-	MeOH	0.61
		H_2O	MeOH	+0.05
cis-3-Methoxy[d] (**18**)	1	Cl^-	MeOH	−0.32
		H_2O	MeOH	−0.06
	2	Cl^-	MeOH	−0.55
		H_2O	MeOH	+0.14

[a]Reaction conditions are in footnote *a*, Table 1. The values of the initial and final acidities used in these calculations were obtained from titrations carried out in triplicate.
[b]Values of $\Delta^3F^{\ddagger}$ are calculated from [12] and [13]. The standard deviation in $\Delta^3F^{\ddagger}$ is approximately 0.01 kcal (depending on the example being considered). The average standard error (as a percent of the actual value) in the product analysis determinations was 1.34. The value of $\Delta^3F^{\ddagger}$ for position-1 attack on the *cis* epoxide **15** can vary from −0.22 to −0.27 kcal depending on which of sets 4, 5, or 6 are used for the *cis* oxide or whether set 8 or 9 is used for the unsubstituted oxide. This range shows that there is some error in the replacement of sodium perchlorate by hydrochloric acid and sodium chloride at the moderate ionic strength of 0.215 *M*; however, a higher ionic strength results in less chlorohydrin formation.
[c]E_1 is cyclohexene oxide (set 8).
[d]E_1 is cyclopentene oxide (set 13).

Substituting [9] into [11] and rearranging gives

$$[12]\quad \Delta^3F^{\ddagger} = -RT\ln\left\{\frac{\dfrac{C_1}{M_1(C_1+C_2)}\ln\dfrac{A_0+S_0}{A_f+S_0}}{\dfrac{1}{M_f'}\ln\dfrac{A_0'+S_0'}{A_f'+S_0'}}\right\}$$

The equations required when only one epoxide carbon is attacked ($C_2 = 0$) or when no sodium chloride is added ($S_0 = 0$) can be obtained directly from [12].

The calculation of $\Delta^3F^{\ddagger}$ for water versus methanol attack is much simpler. Since all of the products obtained from the perchloric acid catalyzed runs are of the same kinetic order, then $\Delta^3F^{\ddagger}$ can be calculated using [4] from product analysis only. Thus for water versus methanol attack upon position-1 for epoxides **14** vs. **16** (sets 1 and 7), eq. 4 becomes

$$[13]\quad \Delta^3F^{\ddagger} = -RT\ln((W_1/M_1)(M_1'/W_1'))$$

The calculated values of $\Delta^3F^{\ddagger}$ (see Table 3) indicate the ability of the substituted epoxides to discriminate between pairs of nucleophiles as compared to that of the corresponding unsubstituted epoxides. Other comparisons may be made by suitable combinations of the entries. From the table, it is seen that cyclopentene oxide discriminates between chloride ion and methanol, or between water and methanol, by about the same amount compared to cyclohexene oxide. In terms of yields, the differences of −0.14 and −0.15 kcal/mol are significant (compare set 8 (Table 1) with set 13 (Table 2)).

The most important result of Table 3 is the clear demonstration of the large variation in polar effects with orientation. In Fig. 3, comparison of **20** and **21** shows how unfavourable a *syn*-1,3-diaxial orientation of chloride and methoxyl (in **20**) is in comparison with the similar orientation of the two methoxyl groups (in **21**). The *gauche* arrangement of the same groups is only moderately less unfavourable to attack by chloride (compare **24** and **25**). In both these examples, it is not possible to distinguish between field effects and the effects of hydrogen bonding of the incoming methanol with the methoxyl substituent (in **21** and **25**); however, even though hydrogen bonding between 1,2 and *cis*-1,3 substituents has been shown to be important (9, 20 and references cited therein) under certain conditions, the extent to which bonding

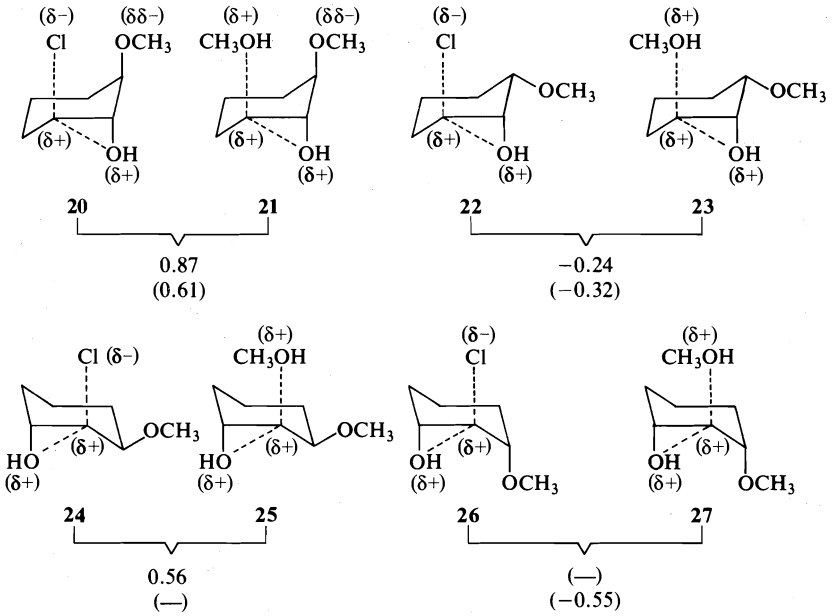

FIG. 3. Effect of dipole orientation on the relative selectivities of epoxides towards nucleophiles. (*1*) Values of Δ^3F^+ with respect to unsubstituted epoxides are given in kcal/mol, the values for the corresponding cyclopentane compounds being given in parentheses (see [4] and Table 3). NOTE: The numbers do not represent the difference in free energy between the transition states shown. Instead, for example, the non-parenthetical number joining **20** and **21** implies that introduction of a methoxyl group at the *trans*-3-position in cyclohexene oxide has made attack by chloride ion more unfavourable by 0.87 kcal/mol with respect to attack by methanol, than it was in cyclohexene oxide itself. (*2*) The transition states **20, 21, 24,** and **25** are obtained from the *trans* epoxides while those for **22, 23, 26,** and **27** are obtained from the *cis* epoxides. (*3*) For examples of the corresponding cyclopentane transition states, see Fig. 2. These distorted twist conformations and the orientation of the substituents in them has been presented in ref. 8.

takes place in strongly hydrogen bonding solvents is difficult to ascertain. In fact, Tichý (21) has concluded that, in a hydroxylic solvent, internal hydrogen bonding in the *trans*-1,2-amino alcohols studied by him does not play an important role.

That the field effects are certainly large is beautifully shown by the comparisons in which hydrogen bonding cannot have the same relative importance. In the anticlinal arrangement of nucleophile and substituent shown in **22** and **23**, or still more in the *anti* arrangement of **26** and **27** (Fig. 3), the electrical situation (of nucleophile versus substituent) has been reversed, and in agreement with this both are more favourable to attack by chloride than by methanol, in comparison with the unsubstituted oxides which lack the methoxyl dipole. The results strongly support the correctness of the chair-like[6] transition states pictured in Fig. 3 and thus is in agreement with the proposal made earlier (8) that the transition state of the nucleophilic attack on protonated epoxides is more similar to the products than to the reactants.[7,8]

In specifically comparing the results in Fig. 3 for the cyclohexane series (non-parenthetical values) with those of the cyclopentane series (parenthetical values), it is seen that for **20** vs. **21**, the value of 0.61 for the cyclopentane transition states would seem to indicate a deviation from

[6]Paulsen and Koebernick (22) have recently shown for the ground state that a 1,3-diaxial interaction must be large indeed in order to cause the cyclohexane ring to predominate in the boat conformation.

[7]This assumption has more recently (11) been applied in the nucleophilic attack on epibromonium ions.

[8]The residual contribution (not cancelled in the comparisons) of ordinary conformational *A*, *Z*, and *G* effects (17) to the Δ^3F^+ differences given in Table 3 and in Fig. 3 is essentially zero in the comparisons **22–23** and **26–27** and negligible in the comparison **24–25** (difference of two similar steric *gauche* effects). Since the charge-related and hydrogen bonding effects must be larger in the comparison **20–21** than in **24–25** it follows from the values given, that the ordinary *A*, *Z*, and *G* contributions to the differences **20–21** (Fig. 3) must be small also and perhaps negligible.

TABLE 4. The effect of ionic strength on the amount of chlorohydrin formed from cyclohexene oxide[a] (**16**)

	Concentration of reagents (*M*)			
Identification	HCl	$NaClO_4$	NaCl	% chlorohydrin
a	0.015	0.0	0.0	9.4
b	0.03	0.0	0.0	16.2
c	0.015	0.03	0.0	7.8
d[b]	0.015	0.2	0.0	5.2
e[c]	0.015	0.165	0.035	16.1

[a]Solvent in all entries was methanol–water (50:50 wt. %) and the concentration of cyclohexene oxide was 0.06 *M*.
[b]Set 8 of Table 1.
[c]Set 9 of Table 1.

the *syn*-1,3-diaxial arrangement of substituent and nucleophile; however, the size of the interaction remaining would indicate that the deviation is small. The difference between **22** and **23** for the two series is small and thus indicates that the orientation of the methoxyl dipole is not significantly different in the two series. In comparing the transition states for position-1 attack on the *cis* epoxide for the cyclopentane equivalents of **22** and **23** with that for position-2 attack (cyclopentane equivalents of **26** and **27**), it is seen that the methoxyl dipole stabilizes the transition state for chloride attack (relative to that for methanol scission at position-2) by 0.23 kcal/mol. The results presented here are in total agreement with the transition states proposed previously to explain isomer distributions for chloride attack on the four positions of the *cis*- and *trans*-3-methoxycyclopentene oxides (8). It appears that the results of Table 3 provide the most extensive demonstration of the effect of charge orientation yet available.

In Table 4 are figures showing how the yield of chlorohydrin can be controlled by the opposing mass law and ionic strength effects. For example, adding 0.2 mol/ℓ of $NaClO_4$ to the reaction solution (a vs. d) nearly halves the amount of chlorohydrin formed. The synthetic usefulness of such a relationship is readily apparent. A similar effect has been observed previously for much simpler epoxides (16, 23).

Table 5 compares the relative rates of attack upon the six epoxides studied by methanol and by water. The trend from the *trans* to unsubstituted to *cis* oxide is the same in both the cyclohexane and the cyclopentane systems. This behaviour is intelligible in terms of the dipole effect discussed above if (as expected) the positive charge on the nucleophilic oxygen in the transition state is less dispersed for methanol than for water. Another

TABLE 5. Comparison of methanol and water scission in the six epoxides

Epoxide	% scission by methanol[a]
trans-3-Methoxycyclohexene oxide	48.1
Cyclohexene oxide	45.8
cis-3-Methoxycyclohexene oxide	43.4
trans-3-Methoxycyclopentene oxide	55.2
Cyclopentene oxide	52.8
cis-3-Methoxycyclopentene oxide	50.4

[a]These figures are obtained from the perchloric acid catalyzed scissions listed in Tables 1 and 2. The remainder of the reaction product is that due to scission by water.

factor must be invoked to explain the constant 7% difference (Table 5) between corresponding members of the cyclohexane and cyclopentane series, the simplest explanation being that a difference in 'size' of the two reagents had different effects in the two series. In our solvent, which is 50% by weight aqueous methanol (or 36 mol% methanol), methanol is the better nucleophile with each of the epoxides studied. Newall and Eastham (24) have already pointed this out using ethylene oxide as the substrate. Interpolation of their results to the conditions of Table 5 suggests that ethylene oxide would show 44% scission by methanol, close to the value (46%) reported here for cyclohexene oxide.

All of the compounds required for this study from the cyclohexane series have been previously reported (7, 10 and references therein) except for the acetates **3***b* and **4***b* (see Table 6). In the cyclopentane series, the epoxides and chlorohydrins had been previously reported (8); however, several compounds in this series remained to be synthesized. The isomeric diols **5***c* and **6***c* were obtained from epoxides **17** and **18** respectively by acid catalyzed scission with water. The epoxide **17** gave **5***c* free of its isomer but the epoxide **18**

[a]This sample contained a small accurately determined amount of its isomer **10***d* (see Experimental).

gave a mixture of the diols with **6***c* predominating (93:7). The required diol **6***c* could be obtained pure by fractional distillation. This is in contrast to the situation in the cyclohexane series where **5***a* and **6***a* do not even begin to separate upon extensive fractional distillation and **5***a* must be obtained pure by conversion of the mixture of diols to the dibenzoates and recrystallization to purity (25).

The acid catalyzed scission of **17** with methanol gives the dimethoxy alcohol **1***c* free of its isomer. On opening **18** under the same conditions a mixture of **10***c* and **12***c* is obtained (90:10). Pure **10***c* was obtained after several tedious fractionations while the best that could be obtained for **12***c* was a mixture containing 83% of this isomer. The 11 cyclopentane acetates needed for the product analysis (**1***d*, **3***d*, **5***d*–**13***d*) have not been reported previously and their properties and elemental analyses are given in Table 6.

Experimental

Melting points were determined using a precision melting point apparatus (26) with calibrated Anschütz thermometers. Elemental analyses were conducted by the Alfred Bernhardt Microanalytisches Laboratorium of West Germany. Gas–liquid chromatographic (glc) analyses were carried out using a Jarrell-Ash (model 700) analytical gas chromatograph equipped with a strontium-90 detector and a Texas Instruments recorder (model FWS (Int.)) with a mechanical integration unit. The two principal columns used were: (*A*) a 6 ft by $\frac{1}{4}$ in. diameter (outside diameter) copper column packed with Embacel (60/100 mesh) impregnated with neopentyl glycol sebacate (10%) and (*B*) a 12 ft by $\frac{1}{4}$ in. diameter (outside diameter) aluminum column packed for half its length with 4% diethylene glycol sebacate and the other half with 4% silicone fluid QF-1 both on Chromosorb G (70/80 mesh, AW, DMCS treated). Column *A* was used to analyze compounds in the cyclohexane series, whereas column *B* was used to analyze compounds in the cyclopentane series as well as in all of the product analysis work.

Compounds Prepared Previously

The preparation of compounds used in this work, when not reported here, can be found in earlier papers (7, 8, 10 and references cited therein). Epoxides **14** and **15** and **17** and **18** were each free of their respective isomers and had a purity of better than 99.9%. The unsubstituted epoxides **16** and **19** were purer than 99.9 and 99.5% respectively.

Preparation of Acetates

The physical properties of newly prepared acetates are reported in Table 6. They were synthesized using essentially the same procedure as that described below for **5***d*.

(±)-1,2-Di-O-acetyl-3-O-methyl-(1,3/2)-1,2,3-cyclopentanetriol (5d)

To 1.05 g (7.9 mmol) of **5***c* in a round-bottom flask containing a stirring bar was added 3.27 g of acetic anhydride containing a drop of concentrated sulfuric acid. The solution which initially became hot was stirred at room temperature overnight. Water (8 ml) was added, the mixture was heated to 70°C for 15 min, and after being cooled was neutralized with sodium bicarbonate. The mixture was extracted with ether (3 × 25 ml). The combined extracts were dried with anhydrous magnesium sulphate, filtered, and the solvent removed to leave a light yellow oil. On distillation in a Späth tube, a clear colourless oil was obtained (1.55 g, 90%) at an air bath temperature of 80–86°C (4 Torr).

Preparation of Alcohols

(±)-1-O-Methyl-(1,3/2)-1,2,3-cyclopentanetriol (5c)

trans-3-Methoxycyclopentene oxide **17** (8.00 g, 0.070 mol) was added to water (20 ml) containing perchloric acid (three drops). The two phase system was stirred vigorously while being heated at 53°C. After 15 min, a

homogeneous solution resulted. After heating for a further 3 h at 53°C, the solution was neutralized (solid sodium bicarbonate), the bulk of the water removed at room temperature *in vacuo*, and the last traces of water were removed by azeotropic distillation with absolute ethanol. The resultant viscous oil was dissolved in ether and the solution was decanted from the small amount of precipitate. The solvent was removed *in vacuo* leaving a light yellow oil which was subjected to a Späth bulb distillation. A colourless viscous oil (7.89 g, 85%) (n_D^{25} 1.4755) was obtained at 87–100°C/0.02 Torr which gave a single peak by glc. *Anal.* calcd. for $C_6H_{12}O_3$: C 54.54, H 9.15; found: C 54.43, 54.38, H 9.08, 9.01.

(±)-1-O-Methyl-(1,2/3)-1,2,3-cyclopentanetriol (6c)

The *cis* epoxide **18** (10.0 g, 0.0878 mol) was treated with water (24 ml) containing three drops of perchloric acid in the manner described in the synthesis above for **5***c*. Unlike the *trans* isomer, the *cis* epoxide is soluble in the aqueous solutions. After work-up as for the synthesis of **5***c*, a clear, colourless, viscous oil was obtained (11.56 g, 99%). The crude oil showed two peaks on the glc with the minor peak having the same retention time as the diol (**5***c*) obtained from the *trans* epoxide. A small amount of this mixture was set aside for determination of the isomer percentages. (It was later shown by glc that 6.7% of the crude mixture was **5***c* while the remainder was **6***c*. This figure was obtained using the method of McNair and Bonelli (27), in which the glc areas were adjusted using correction factors obtained from a mixture of known composition.) The remainder was subjected to a careful fractionation using the Späth apparatus. After two fractionations, 4.67 g of **6***c* (bp 68–77°C/0.02 Torr; n_D^{25} 1.4757) was obtained free of its slightly higher boiling isomer. *Anal.* calcd. for $C_6H_{12}O_3$: C 54.54, H 9.15; found: C 54.45, 54.50, H 9.25, 9.16.

(±)-1,3-Di-O-methyl-(1,3/2)-1,2,3-cyclopentanetriol (1c)

trans-3-Methoxycyclopentene oxide (8.00 g, 0.0702 mol) was dissolved in methanol (20 ml) containing one drop of concentrated sulfuric acid. The solution was stirred at room temperature for 9 h, refluxed for 15 min, cooled, and neutralized with solid sodium bicarbonate. After removal of the methanol *in vacuo*, the residual clear colourless oil was distilled using the Späth apparatus. The first fraction (0.93 g, 8–9 Torr, bp ca. 60°C) was unreacted epoxide. The remainder (6.55 g, 64%) distilled at a bath temperature of 67–78°C/0.03 Torr and gave a single peak by glc (n_D^{25} 1.4523). *Anal.* calcd. for $C_7H_{14}O_3$: C 57,51, H 9.65; found: C 57.32, 57.38, H 9.46, 9.49.

(±)-1,3-Di-O-methyl-(1,2/3)-1,2,3-cyclopentanetriol (10c) and Its Isomer (12c)

cis-3-Methoxycyclopentene oxide **18** (10.03 g, 0.088 mol) was dissolved in methanol containing three drops of concentrated sulfuric acid. The solution was refluxed for 2.5 h, then neutralized with solid sodium bicarbonate. The oil obtained on removal of the methanol was dissolved in ether and dried (magnesium sulfate). On removal of the ether from the dried filtrate, a clear mobile oil was obtained (12.6 g, 98%).

This oil was shown by glc to contain three peaks: major peak (**10***c*), minor peak (**12***c*), and a trace impurity. A small sample of this mixture was shown later to contain 89.5% **10***c* and 10.5% **12***c*. These values were obtained after correcting the glc areas using correction factors obtained from a mixture of known composition (method of McNair and Bonelli (27)). After three careful Späth bulb fractionations of the crude oil, pure **10***c* was obtained (3.33 g, bp 65–77°C/9 Torr; n_D^{25} 1.4487). *Anal.* calcd. for $C_7H_{14}O_3$: C 57.51, H 9.65; found: C 57.35, 57.44, H 9.82, 9.68.

The minor isomer (**12***c*) and the unidentified impurity were in the higher boiling fractions. These were subjected to repeated fractionations in an attempt to obtain pure **12***c*. Eventually 0.30 g of a mixture (bp 64–70°C/9 Torr) was obtained which contained 83.2% **12***c*, 12.6% **10***c*, and 4.2% unidentified impurity. (In obtaining these figures, the glc peak areas for the minor (**12***c*) and major (**10***c*) isomers were corrected by adding a known amount of pure major isomer to a known amount of the mixture.) *Anal.* calcd. for $C_7H_{14}O_3$: C 57.51, H 9.65; found: C 57.28, 57.33, H 9.55, 9.55.

Standard Reaction Conditions for Epoxide Scissions

The epoxide scission reactions were conducted in a reaction vessel kept in an insulated Sargent bath maintained at 2.43 ± 0.005°C which contained a mixture of water and ethanol. A second bath was maintained at 22.0°C and it was at this temperature that the reaction solutions were made up (taking into account the contraction of the reaction solutions from 22.0°C to 2.43°C). The solvent for all the reactions was a 50:50 wt.% solution of methanol and water.

The required weight of epoxide was sealed into a thin walled glass bulb and placed in the reaction vessel in contact with the breaking tip of the end of a glass rod. The reaction solution was then pipetted in, a dilatometer[9] was attached to the reaction vessel, and equilibrated in the bath. The bulb was broken by tapping the glass rod, the mixture was stirred, and the solution was transferred into the dilatometer by the application of compressed air to an opening in the top of the reaction vessel.

Analysis of the Epoxide Scission Products

The main method used in the determination of the product composition was glc. This method is capable of giving the total composition of the reaction mixture. Two other methods which can account for only part of the reaction mixture and which can not distinguish between positional isomers were used as a check. These were periodate oxidation (to determine the amount of 1,2-diols formed) and the determination of the decrease in acidity during the reaction (to obtain the amount of chlorohydrin formed).

Product Analysis Using Gas–Liquid Chromatography

The retention times of the isomeric alcohols formed from **14** were too uniform for facile analysis. Therefore reaction products in the cyclohexane series were acetylated to provide the more readily separable derivatives. The reaction products in the cyclopentane series were also acetylated except for those formed from **18** in which the retention times of the isomeric acetates were unsuitably

[9]A manuscript which reports and discusses the kinetic results is being prepared. The main use of the dilatometer for the purpose of this paper was to indicate completion of the reaction.

close for quantitative analysis.[10] These were analyzed as mixtures of the alcohols which were well separated. Column *B* was used in the product analysis work. The only reaction mixture in which overlap between peaks occurred was that which resulted from opening the epoxide **14** with hydrochloric acid. In this case the acetates **4***b* and **1***b* completely overlapped; however, the percent of **4***b* (and consequently **1***b*) could be calculated from the amount of hydrochloric acid consumed and the percent of **3***b*.

All product analysis using the glc method were carried out as described below for the scission of **17** (0.06 *M* at 2.43°C) in aqueous methanol (50:50 wt.%; 0.15 *M* HCl; 0.065 *M* $NaClO_4$). From the hydrochloric acid titration, it was known that 15.7% of chlorohydrin had formed in the reaction. Also, from the corresponding run with perchloric acid, 37.8% of diol was expected and thus 46.5% of methanol scission product should be present. A mixture of this composition was weighed out and dissolved in 30 ml of the same solution that the epoxide had been reacted with to give a solution containing a total concentration of 0.0605 *M* of the alcohols. The solution of known composition and 30 ml of the epoxide scission solution were then treated in exactly the same manner as described below.

Solid sodium bicarbonate was added to neutralize the hydrochloric acid and the bulk of the solvent was then removed *in vacuo* (0.1 Torr). When the volume was reduced to 2–3 ml, two 50 ml portions of absolute ethanol were added and the residual water was removed by azeotropic distillation *in vacuo*. The residual oil was dissolved in chloroform and separated from the solid by filtration. After removal of the solvent, 5 ml of acetic anhydride was added to the residual mixture of the alcohols and the solution was heated under reflux for 4 h. The acetic anhydride and acetic acid were removed by successive addition and removal (at 0.1 Torr) of three 10 ml portions and then two 3 ml portions of absolute ethanol. The slightly yellowish oil was dissolved in chloroform (1.5 ml) and analyzed by glc. From the known mixture 0.384 g of acetates were obtained while 0.366 g were obtained from the epoxide scission solution. The peak areas of both mixtures were obtained by integration and the areas were then corrected with the factors obtained from the solution of known composition by the method of McNair and Bonelli (27). The diacetate or the major diacetate (when two were formed) was the compound which was assigned a correction factor of 1.0000.

In this manner the composition of the scission product of **17** was found to be 47.2% **1***c*, 37.1% **5***c*, and 15.7% **3***c*. A duplicate set gave values of 46.5% **1***c*, 37.7% **5***c*, and 15.9% **3***c*. The average value of 15.8% **3***c* agrees remarkably well with the amount of chlorohydrin calculated from hydrochloric acid consumption (15.7%). Also the average amount of diol **6***c* was 37.4% which was very close to that predicted (37.8%) from the amount of diol determined with the same epoxide when perchloric acid was used. The results of the product analysis are listed in Tables 1 and 2.

A Check of the Product Analysis Method Using Sodium Periodate Oxidation

The glc method of product analysis was checked for sets 8 and 9 (Table 1) by determining the amount of diol formed from cyclohexene oxide using sodium periodate oxidation. The procedure used was that of Dyer (28) with one modification. Since the sodium periodate reacts at a non-negligible rate with aqueous methanol, it was necessary to vary the volume of the solvent added to the blank with the expected concentration of diol in the reaction solution. That is, enough solvent was added to the blank so that the initial concentration of periodate was equal to that of the reaction solution after all of the diol had reacted. This method worked well since the reaction of the diol with the sodium periodate solution was rapid.

A check of the above method with a known mixture of the alcohols **7***a*, **8***a*, and **9***a* (in a ratio of 40.1:9.4:50.6 respectively; total molarity 0.0601) in aqueous methanol (50:50 wt.%) (0.015 *M* HCl) gave a value which was within 0.2% of the actual value of **9***a*. For set 8, the amount of cyclohexene oxide opened by water was determined to be 51.0 and for set 9 it was 45.1. These values compare very favourably with the values 51.4 and 45.5 respectively found by the glc method.

[10]For a detailed discussion of the retention time behaviour in these compounds see ref. 9.

COMMUNICATION

Hydrogen/deuterium selectivity in the infrared laser photolysis of chloroethylene[1]

A. GANDINI, C. WILLIS, AND R. A. BACK

PIE Group, Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 15, 1977

A. GANDINI, C. WILLIS, and R. A. BACK. Can. J. Chem. **55**, 4156 (1977).

The decomposition of chloroethylene to acetylene and hydrogen chloride induced by focused radiation from a CO_2 laser has been shown to be H/D isotopically selective at low pressures. As the pressure is reduced below 1 Torr, C—Cl bond scission appears to increase at the expense of molecular fragmentation and gives rise to radical processes which are isotopically non-selective.

A. GANDINI, C. WILLIS et R. A. BACK. Can. J. Chem. **55**, 4156 (1977).

On a montré que la décomposition du chloroéthylène en acétylène et acide chlorhydrique, provoquée par l'irradiation focalisée d'un laser à CO_2, est sélective vis-à-vis les isotopes H/D à des pressions faibles. En dessous de 1 Torr, la rupture de la liaison C—Cl devient un processus alternatif important par rapport à la fragmentation moléculaire et amorce des reactions radicalaires qui ne possèdent pas de sélectivité isotopique.

We wish to report some preliminary findings on the photolysis of chloroethylene and its monodeuterated homologues induced by infrared radiation from a high-power CO_2 TEA laser. This technique has been the subject of several recent reviews (1–3).

The gas-phase decomposition of chloroethylene has been studied under a variety of conditions (4–9). While in shock-tube pyrolysis (4, 5) molecular dehydrochlorination predominates ($CH_2{=}CHCl \rightarrow C_2H_2 + HCl$), the flash and steady-state ultraviolet photolyses (6–9) lead to two primary modes of fragmentation, viz. molecular dehydrochlorination and C—Cl bond rupture ($CH_2{=}CHCl \rightarrow C_2H_3 + Cl$), the latter process yielding ethylene as the major product. Berry (9) has thoroughly discussed the various aspects related to the photochemistry of this compound.

Chloroethylene was degassed on a vacuum line; only traces of acetylene were detected as impurity by glc analysis. A mixture of α- and β-monodeuterochloroethylenes was prepared by the photochemical addition of hydrogen chloride to monodeuteroacetylene. Mass spectra of the purified product at 13 eV gave the following composition: 8% chloroethylene, 6% dideuterochloroethylenes, and 86% monodeuterochloroethylenes. The line-tunable laser used, a Lumonics model 103, gave ~5 J pulses of 250 ns duration at 0.6 Hz. Reactions were conducted in cylindrical Pyrex cells, 40 to 50 mm id and 60 to 90 mm long, provided with NaCl windows. While for most of this work the laser beam was focused into the cell with a 50 mm focal length Ge lens, the effect of the unfocused beam (power density ~2 MW cm^{-2}) was also tested. The reaction progress was followed by mass spectrometry and by taking infrared spectra of the cell contents. Yields were determined at the end of each run by separating the residual reactants (chloroethylenes) at 113 K from the products (acetylene, HCl, and ethylene) and measuring their pressure ratio. The two fractions were then analysed by mass spectrometry and occasionally by glc. Isotopic ratios were measured before, during, and at the end of the reaction from mass spectra obtained at 10–13 eV.

Figure 1 shows the portion of the infrared spectra relevant to this study of both chloroethylene and the synthesized monodeuterochloroethylene mixture. From previously reported spectra (10–12) of individual homologues, the relative proportion of α and β derivatives in our mixture was estimated as approximately 1:1. Irradiation of 50 to 500 Torr of chloroethylene with various laser lines (focused and unfocused) produced appreciable yields of acetylene and HCl, as already reported (13).

At low chloroethylene pressures (<2 Torr) it

[1]NRCC No. 16344.

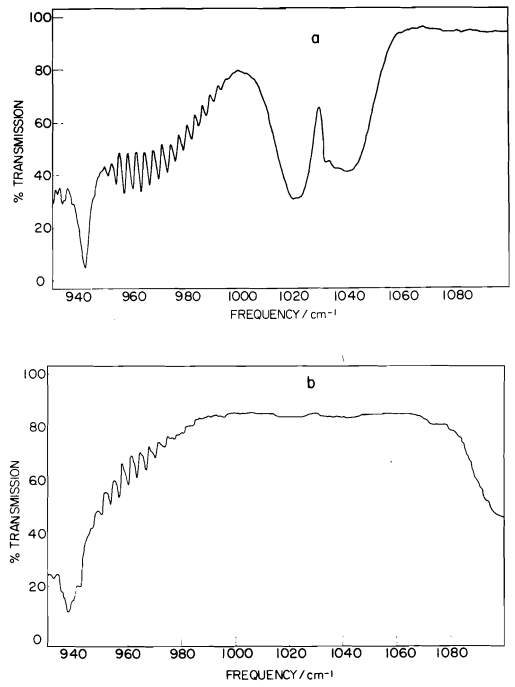

FIG. 1. Low-resolution infrared spectra of: (*a*) chloroethylene, 55 Torr; (*b*) mixture of monodeuterated chloroethylenes (see text), 40 Torr (the slight absorption around 1020 and 1040 cm^{-1} is due to 8% chloroethylene impurity). Optical path length 80 mm.

was possible to focus the beam without causing electrical breakdown, and decomposition was always observed provided the line selected matched an absorption feature of the substrate. As shown in Fig. 1, marked differences exist between the spectrum of chloroethylene and that of its monodeuterated homologues, suggesting that isotopically selective decomposition from mixtures of these two gases might be feasible. A mixture containing approximately equal amounts of chloroethylene and chloroethylenes-d_1 was therefore prepared and tested with different laser lines. Some of the results obtained are given in Table 1. Selective decomposition at 1041.34 and 1045.04 cm^{-1}, lines absorbed only by chloroethylene, produced enrichment in the deuterium content of the reactants. Conversely, selective decomposition at 1090.04 cm^{-1} resulted in deuterium enrichment in the products; the only absorbing molecule was α-deuterochloroethylene (10–12), and because β-deuterochloroethylene is transparent to that line, only about one half of the deuterium-containing substrate was in fact exposed to decomposition. The experiment at 1090.04 cm^{-1} with chloroethylene alone (No. 6, Table 1) clearly shows that no thermal reactions were induced in these systems if the substrate did not absorb the laser radiation. Focusing of the laser beam in the cell at substrate pressures higher than about 2 Torr resulted in electrical breakdown with abundant decomposition into acetylene (or acetylene-d_1) and HCl (or DCl) and no isotopic selectivity from H/D-containing mixtures.

The data in Table 1 show a decrease in selectivity with decreasing pressure, an unexpected result since in other systems the opposite has been observed (14–16). This gradual loss of selectivity with decreasing pressure was accompanied by the appearance of progressively larger proportions of ethylene (and to a minor degree of higher alkenes and alkynes) among the products. Thus, as the pressure is reduced, a second channel for decomposition, the homolytic cleavage of the C—Cl bond (6–9), becomes available to the vibrationally excited chloroethylenes and competes more and more successfully with the molecular elimination channel (final column, Table 1). While the activation energy for the latter process is 69 ± 3 kcal mol^{-1} (5), which is equivalent to about 23 photons of CO_2 radiation, the threshold energy required for C—Cl bond rupture in chloroethylene is about 90 kcal mol^{-1} ($\equiv D(C_2H_3—Cl)$ (17)), i.e., for this channel to become operative 7 more CO_2 photons must be absorbed by the chloroethylene molecule. The observation that bond scission becomes increasingly important as the pressure is reduced indicates that collisional deactivation is affecting the energy content of the decomposing molecules. The lifetime of molecules excited above the threshold for molecular elimination must be long enough to allow absorption of the additional photons required for bond scission, and in effect the decomposition must proceed from an assembly of molecules with a distribution of energies determined by the competition between absorption of laser radiation, collisional deactivation, and decomposition.

The onset of the second decomposition channel does not constitute a loss of primary isotopic selectivity, but the subsequent radical reactions involving the substrate are nonselective and thus cause a decrease in enrichment. Ways of circumventing this problem include the addition of radical scavengers and the reduction of pulse energy. These and other studies on the effect

A. G. McINNES, D. G. SMITH, J. L. C. WRIGHT, and L. C. VINING. Can. J. Chem. **55**, 4159 (1977).

Three new metabolites have been isolated from cultures of *Streptomyces caeruleus* and are related to caerulomycin, a known antibiotic metabolite of this organism now designated caerulomycin A. The structures of two of the new compounds, caerulomycins B and C, are shown to be 3-hydroxy-4-methoxy- and 3,4-dimethoxy-2,2′-dipyridyl-6-(*E*)-aldoxime.

A. G. McINNES, D. G. SMITH, J. L. C. WRIGHT et L. C. VINING. Can. J. Chem. **55**, 4159 (1977).

On a isolé trois nouveaux métabolites à partir de milieux de cultures des *Streptomyces caeruleus*; ces métabolites sont reliés à la caerulomycine, un métabolite antibiotique connu de ces organismes, qui est maintenant désigné sous le nom de caerulomycine A. Les structures de deux des nouveaux composés, les caerulomycines B et C, sont les hydroxy-3 méthoxy-4 et diméthoxy-3,4 dipyridyl-2,2′ aldoxime-6-(*E*).

[Traduit par le journal]

Streptomyces caeruleus, first described by Baldacci (1), belongs to a small group of alkaline-dependent actinomycetes investigated by Taber (2, 3). Cultures grown in starch-Czapek medium produce an antibiotic, caerulomycin, isolated in 1959 by Funk and Divekar (4), and henceforth referred to as caerulomycin A to distinguish it from a similarly named antibiotic, cerulomycin, isolated at approximately the same time from *Actinomyces caerulescens* (5). We have found that addition of 1 m*M* L-tryptophan to the medium modifies the *S. caeruleus* fermentation so that the product isolated is not the expected caerulomycin A, but a mixture of two related metabolites which are named caerulomycins B and C. Subsequent examination of cultures grown on unsupplemented starch-Czapek medium showed that the caerulomycin A that they produced was accompanied by small amounts of caerulomycins B and C as well as a fourth product which we refer to as caerulomycin D.

The structure of caerulomycin A was deduced from chemical and spectral evidence (6) to be 4-methoxy-2,2′-dipyridyl-6-(*E*)-aldoxime (**1***a*), and has been confirmed by synthesis (7). In this paper we present evidence that caerulomycins B and C have structures **2** and **3***a*, respectively. Caerulomycin D is a glycosidic derivative of 3,4-dihydroxy-2,2′-dipyridyl-6-(*E*)-aldoxime.[2]

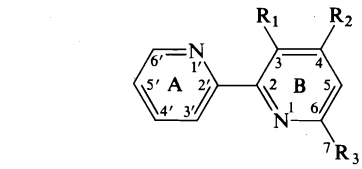
Isolation

Procedures described for the isolation of **1***a* from culture filtrates (4, 6) were modified to allow the recovery of only the ether-soluble basic fraction. High vacuum sublimation of the crude extract from cultures grown on starch-Czapek medium gave **1***a* mixed with small amounts of other caerulomycins, from which it was freed by several crystallizations from ethanol. Fractional crystallization of the unsublimed residue gave caerulomycin D. Caerulomycin C was the least soluble product but crystallized slowly from ethanol. It could be obtained pure by fractional crystallization of the crude caerulomycin mixture. This latter procedure applied to the crude extract from cultures grown in L-tryptophan-supplemented medium gave only caerulomycins B and C. In cultures grown on the unsupplemented medium caerulomycin B was a very minor component and could be separated only by preparative partition chromatography. Chromatography also provided an alternative and more satisfactory separation of the other three metabolites.

Properties

The molecular formulae of caerulomycins B and C were established by mass spectral and elemental analysis as $C_{12}H_{11}N_3O_3$ and $C_{13}H_{13}N_3O_3$. Caerulomycin B, but not C, gave a positive test for phenolic groups by coupling to stabilized diazonium salts. As with **1***a* (6), caerulomycin C could be converted to a monoacetate (**3***c*, ν_{max} 1760 cm^{-1}, δ 2.22 ppm) using a mild acetylating procedure, and to a nitrile (**3***b*, ν_{max} 2240 cm^{-1}) by eliminating the acetoxy group under more vigorous conditions. The mass spectra of caerulomycins B and C, like those of **1***a*, contained significant ion peaks corresponding to the loss of hydrogen, methyl, water, methoxyl, and aldoxime fragments. Caerulomycin C showed an initial loss of 30 mass units to generate an ion with *m/e* 229 equivalent to M^+ for **1***a* and giving rise to a similar series of fragment ions. In particular these included a second loss of 30 mass units and low abundance ions at *m/e* 155 (dipyridyl) and 78 (pyridyl). The spectrum of caerulomycin B lacked the *m/e* 155 ion but the peak at *m/e* 78 was relatively intense. The infrared spectra of the metabolites and their derivatives contained strong absorption bands in the same regions as those of 2,2′-dipyridyl and **1***a* (6). Also like 2,2′-dipyridyl and **1***a*, caerulomycins B and C gave a deep-red color in the presence of ferrous salts. The color given by 2,2′-dipyridyl is due to the complex Fe-$[(C_{10}H_8N_2)_3]^{2+}$ in which the pyridyl rings are *cis* coplanar (9), and steric hindrance due to substituents at the 3,3′- (10) or 6,6′-positions (11, 12) is known to partly or completely inhibit complex formation. In 2,2′-dipyridyl itself, both crystalline (13, 14) and in solution (9, 15, 16), the two rings are *trans* coplanar.



1*a*	R_1 = H	R_2 = OCH_3	R_3 = CH=NOH

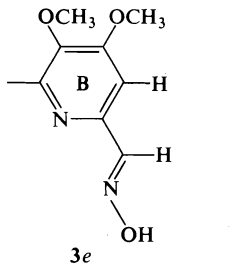
3*d*



3*e*

2,2′-Dipyridyl (16) and **1***a* (4) show three principal absorbing bands in the ultraviolet region, with maxima at approximately 230, 260, and 280 nm. These bands are present in the spectrum of caerulomycin B, but the maxima are shifted to longer wavelengths by 13–48 nm, as would be predicted with the introduction of a hydroxyl group into a pyridine ring at position 3 (17). By hydrogen bonding to nitrogen of the adjacent ring this group should also maintain the *trans* coplanar conformation. Caerulomycin C and its derivatives show only two major ultraviolet absorption bands with maxima close to 230 and 260 nm. However, it is known that substitution of H-3 and H-3′ in 2,2′-dipyridyl shifts the weaker 280 nm band hypsochromically to the extent that it merges with that at 260 nm, and the shift is attributed to the steric effect of the substituents increasing the interplanar angle between the rings (16). These properties suggest that the two new metabolites contain a 2,2′-

*H-3′, H-4′, H-5′, and H-6′ form an AMXY sub-spectrum which was analyzed with the Varian spin simulation program on a 620L data system associated with the model XL-100 spectrometer. The coupling constants for this system, and $J_{3,5}$ of **1***b*, are not given since they agreed within experimental error (±0.1 Hz) with values already reported for 2,2′-dipyridyl (20) and **1***a* (6).

†Nuclear Overhauser enhancement measurements for **3***a* were as follows: H-5 {4-OCH_3} 30%; H-7 {=NOH} 12%.

dipyridyl residue substituted at the 3- or 3′-position.

^{1}*H Nuclear Magnetic Resonance Spectra*

Proton assignments were confirmed by spin-decoupling experiments (19) and nuclear Overhauser enhancement (nOe) studies (20), while spectral simulation techniques were used to obtain relevant parameters from complex subgroups (see footnote to Table 1).

The ^{1}Hmr spectra of 2,2′-dipyridyl (9, 15, 18) in a variety of solvents including DMSO-d_6 (21), and the spectrum of **1***a* in $CDCl_3$ (6), have been reported. Known substituent effects in 2-substituted pyridines (22) account for spectral differences between **1***a* and its nitrile derivative (**1***b*). Thus H-3 and H-5 of **1***b* were deshielded by about 0.2 and 0.4 ppm, and signals for the oxime group of **1***a* at δ 8.22 and δ 11.72 ppm were absent. Signals corresponding to the ring A, oxime, and methoxyl hydrogens of **1***a* were also present in the ^{1}Hmr spectra of **2** and **3***a* (Table 1). Indeed, the spectra of **3***a* and **1***a* differed in only three respects. In the former the H-3 signal was replaced by one for a methoxyl group (δ 3.76), the H-5 resonance at δ 7.49 was a singlet, and H-3′ (δ 7.69) was shielded relative to the corresponding hydrogen of **1***a*.

In the *trans* coplanar conformation of 2,2′-dipyridyl, H-3 is close to the nitrogen atom of the adjacent ring and is deshielded by approximately 1.4 ppm as a result of contributions from the diamagnetic anisotropy of the neighbouring ring and dipolar fields associated with the nitrogen atom (9, 16). The remaining hydrogens are unaffected, and their chemical shifts are similar to those of pyridine (23). Introduction of a bulky substituent at C-3 would cause a conformational change (16) and so reduce the deshielding (particularly that associated with nitrogen) at H-3′. Thus, the upfield shift of H-3′ in caerulomycin C agrees with evidence from ultraviolet absorption and mass spectra, and indicates that this metabolite possesses a methoxyl substituent at C-3 and has structure **3***a*. Confirming this conclusion, irradiation at the resonance frequency of the low-field methoxyl group (δ 3.98) of **3***a* caused a 30% nOe of the H-5 singlet at δ 7.49. No nOe was obtained by irradiating the other methoxyl resonance at δ 3.76. Thus, the lone aromatic hydrogen is adjacent to the methoxyl group which has a chemical shift identical to that of the methoxyl substituent of **1***a*.

The ^{1}Hmr spectrum of the nitrile **3***b* was similar to that of **3***a* except that it contained no signals for an oxime group, and exhibited deshielding effects comparable to those noted in **1***b*. Of particular importance, the lone hydrogen at δ 7.49 in **3***a* was shifted by 0.47 ppm to δ 7.96 in **3***b*, which was similar to the deshielding of H-5 (δ 7.35 to δ 7.75) accompanying the conversion **1***a* to **1***b*. Thus, the substitution pattern at the 4-, 5-, and 6-positions of **1***a* is retained in **3***a*, and this in turn requires that the additional methoxyl group in **3***a* be attached to C-3.

Irradiation at the resonance frequency of the OH proton in **3***a* caused a 12% nOe of the H-7 signal, thus establishing an (*E*) configuration for the oxime group. Similar experiments showed that H-5 and H-7 do not contribute to each other's relaxation, which indicates that the oxime group is oriented as in partial structure **3***d* rather than **3***e*. A previous study using a different approach (6) established that the oxime group of **1***a* had an (*E*) configuration.

^{13}*C Nuclear Magnetic Resonance Spectra*

Further support for the proposed structure of caerulomycin C came from examination of the

†The signals for the acetyl group in this compound appeared at 19.2 and 167.9 ppm.

^{13}C nmr data in Tables 2 and 3 which list the proton noise decoupled (pnd) and high resolution (hr) spectral results. Assignments were aided by off-resonance decoupling (ord) experiments (23) and by the use of 2,2′-dipyridyl as a model compound. Apart from providing supporting evidence for the structure of caerulomycin C, these data are required for the structural elucidation[2] of caerulomycin D and for biosynthetic studies on ^{13}C-labeled **1***a*, now in progress, which rely upon correct interpretation of ^{13}C nmr spectra.

Assignment of resonances for 2,2′-dipyridyl and the ring-A carbons of **1***a* and **1***b* was straightforward, the ^{13}C—H spin–spin coupling data in Table 3 being similar to those observed for pyridine (24, 25) and 2-substituted pyridines (25, 26, 27). Typical deshielding by the directly bonded methoxyl substituent (28) and three-bond coupling to the methoxyl hydrogens (**1***a*, $^3J_{CH} \approx 3$ Hz; **1***b*, bm due to additional coupling with[2] H-5) identified C-4. Signals for ring-B carbons bonded to hydrogen (C-3, C-5) were assigned from differences in residual couplings in proton ord spectra. As expected, dehydration of the oxime was accompanied by considerable deshielding of C-5 (≈11 ppm), and to a lesser extent C-3 (≈3 ppm). Thus the oxime substituent in 2-pyridine aldoxime shields C-3 by 3.9 ppm but does not affect[3] C-5, whereas the nitrile group in 2-cyanopyridine (8) deshields both C-3 (4.7 ppm) and C-5 (3.3 ppm). Conversion to a nitrile also increased the spin–spin coupling between C-5 and H-5 from 165.2 to 171.8 Hz, in contrast to coupling between C-3 and H-3 which changed little. In **1***a* C-3 was also long-range coupled to H-5 ($^3J_{CH}$ 3.8 Hz), and C-5 to H-3 ($^3J_{CH}$ 3.6 Hz) and one additional hydrogen ($^nJ_{CH}$ 3.6 Hz). However, in **1***b* C-3 was still long-range coupled to H-5 whereas C-5 was coupled only to H-3 ($^3J_{CH}$ 3.8 Hz). Thus, the additional splitting in the C-5 resonance of **1***a* must have been due to H-7.

In the hr ^{13}C nmr spectrum of **1***a* one of the resonances due to the quaternary carbons C-2 and C-6 was a sharp singlet (δ_c 156.9); the other was a doublet (δ_c 153.4) with a spacing of 5.3 Hz. Since the latter signal was a sharp singlet in **1***b* it was assigned to C-6, because geminal coupling of H-7 to C-6 would be removed in the nitrile. The singlet at δ_c 156.9 was, therefore, assigned to C-2. The resonances for C-6 and C-2 in **1***b* appeared at δ_c 133.5 and δ_c 158.4, respectively, because conversion of the oxime to a nitrile would cause considerable shielding of C-6 (≈20 ppm) and a slight deshielding (≈1 ppm) of C-2. In pyridine-2-aldoxime C-2 is deshielded by 2.6 ppm and C-6 shielded by 0.4 ppm (28), whereas for 2-cyanopyridine C-2 is shielded by 16.3 ppm and C-6 deshielded by 1.1 ppm.[3]

Finally, the carbons of the oxime and nitrile groups (C-7) gave characteristic resonances at δ_c 148.8 and δ_c 117.3 (28[3]) and the methoxyl carbons at δ_c 55.5 (**1***a*) and δ_c 56.3 (**1***b*). The hr spectra showed that both the oxime carbon ($^3J_{CH}$ 7.7 Hz) and the nitrile carbon ($^3J_{CH}$ 3.8 Hz) were long-range coupled to H-5.

The ^{13}C nmr spectra of **3***a* and **3***b* were similar to those of **1***a* and **1***b*, with resonances at δ_c 148.5 and 117.1 ppm for the oxime and nitrile carbons. Five signals had chemical shifts and multiplicities in hr spectra that permitted them to be assigned to ring-A carbons. Of the two methoxyl groups in each compound (**3***a*, δ_c 56.0, δ_c 61.0; **3***b*, δ_c 56.9, δ_c 61.2) one had a chemical shift close to that of the methoxyl group in **1***a* (δ_c 55.5) or **1***b* (δ_c 56.3). Other differences were associated with the ring-B carbons and attributable to changes induced by the extra methoxyl

group. Many of the chemical shift trends and coupling characteristics noted for the ring-B carbons of **1***a* and **1***b* were observed in **3***a* and **3***b*.

The carbon bonded to hydrogen in ring B of **3***a* had a similar chemical shift to that of C-5 in **1***a* and both were almost equally deshielded upon conversion to the nitriles **3***b* and **1***b*. These conversions were also accompanied by similar increases in the $^1J_{CH}$ values. Furthermore the single aromatic proton in ring B was coupled to the oxime ($^3J_{CH}$ 9.2 Hz) and nitrile ($^3J_{CH}$ 3.6 Hz) carbons of **3***a* and **3***b* just as H-5 was coupled to these groups in **1***a* and **1***b*. In addition two ring-B quaternary carbons of **3***a* and **3***b* had similar spectral characteristics to C-6 and C-2 of **1***a* and **1***b*. One (δ_c 148.2) in **3***a* was geminally coupled to H-7 ($^2J_{CH}$ 5.6 Hz), whereas the corresponding carbon in **3***b* (δ_c 127.8) was characteristically shielded ($\approx$20 ppm) by the conversion of the oxime to a nitrile group. The other (δ_c 152.8) in **3***b* was slightly but typically deshielded relative to the corresponding carbon (δ_c 151.0) in **3***a*. Low intensity signals for the remaining carbons which bear methoxyl groups in **3***a* (δ_c 143.8, δ_c 159.4) and **3***b* (δ_c 146.5, δ_c 159.7) were easily recognized from their chemical shifts and from the broad multiplets which they gave in hr spectra as a result of coupling to the methoxyl hydrogens and a poor signal/noise ratio. The resonance at lowest field could be assigned to C-4 as the alternative would require the C-3 methoxyl to possess unreasonable shielding characteristics. The combined observations are, therefore, consistent only with the assignments given in Table 3, and with caerulomycin C having structure **3***a* and caerulomycinonitrile C structure **3***b*.

Caerulomycin C monoacetate must have structure **3***c*. In the ^{1}Hmr spectra, absence of an OH signal and a slight downfield shift of the resonances for H-5 and H-7 are the only differences from **3***a*. The ^{13}C spectrum of **3***c* was also similar to that of **3***a* apart from the presence of acetoxyl methyl (δ_c 19.2) and carbonyl (δ_c 167.9) signals, and a downfield shift of the oxime carbon resonance to δ_c 156.2.

It was also apparent from ^{1}Hmr evidence (Table 1) that replacement of the C-3 methoxyl group of **3***a* by a hydroxyl substituent in caerulomycin B was the only structural difference between the two metabolites. Thus caerulomycin B has structure **2**. Hydrogen bonding of this hydroxyl group with the nitrogen atom in ring A of **2** not only accounts for the low-field chemical shift of the hydroxyl proton (δ 14.62) but, in stabilizing the *trans* coplanar conformation of the dipyridyl ring system, ensures that H-3′ is deshielded as in **1***a*. Lack of material prevented ^{13}C nmr data being obtained for this metabolite.

Experimental

Melting points were measured on a hot stage and are uncorrected. Ultraviolet and infrared spectra were recorded with Unicam model SP 8000 and Perkin-Elmer model 237 spectrophotometers. Mass spectra were obtained with a Consolidated Electrodynamics Corporation model 110-B double-focusing spectrometer operated in the electrical mode. ^{1}H nuclear magnetic resonance spectra were obtained with a Varian Associates model HA-100 spectrometer. ^{13}C nuclear magnetic resonance spectra (25.16 MHz) were recorded with a Varian Associates model XL-100-15 pulsed Fourier transform spectrometer.

Isolation of Caerulomycins

Cultures of *Streptomyces caeruleus* were grown as described by Funk and Divekar in starch-Czapek medium (4), or in this medium supplemented with L-tryptophan at 1 m*M* concentration. The filtered broth was extracted with three half-volumes of ether and basic products were separated by extraction from the ether into *N* hydrochloric acid. They were recovered, after addition of excess sodium bicarbonate, by filtration and by back-extraction from the filtrate with ether. The crude residue from starch-Czapek cultures was sublimed at 105–130°C under high vacuum and the sublimate (mp 168–171°C) was recrystallized several times from ethanol to give caerulomycin A, mp 176–177°C.

Repeated recrystallization from ethanol of the unsublimed residue, collecting only the crop of fine colorless needles which formed immediately upon cooling, gave caerulomycin D, mp 241–242°C.

When a hot ethanolic solution of the crude caerulomycin from starch-Czapek medium was allowed to cool to room temperature the crop of needles deposited was a mixture of caerulomycin A with a smaller amount of caerulomycin D. The mother liquor slowly deposited a second crop of crystals consisting mainly of caerulomycin C (**3***a*). Recrystallization yielded colorless prisms, mp 208–210°C; λ_{max} in methanol at 229 and 263 nm (log ε 4.13 and 3.96); ν_{max} in potassium bromide at 3160, 1585, 1560, 1490, 1360, 1245, 1200, 1065, 995, 851, 800, and 712 cm^{-1}; *m/e* at 259 (15%), 258 (14%), 242 (100%), 229 (13%), 228 (10%), 214 (21%), 199 (14%), 155 (14%), 105 (17%), and 78 (31%). Accurate mass measurement of M$^+$, *m/e* 259.0952 (calcd. for $C_{13}H_{13}O_3N_3$: 259.09579); found: C 60.39, H 5.05, N 16.12 (calcd. for $C_{13}H_{13}O_3N_3$: C 60.23, H 5.01, N 16.21). Fractional crystallization in this manner of the extract from cultures grown on starch-Czapek medium containing L-tryptophan did not yield a first crop of needles. Caerulomycin C (25 mg/ℓ) separated slowly from the solution and was removed. When the mother liquor was concentrated caerulomycin B (**2**, 15 mg/ℓ) crystallized as feathery needles. These were sublimed in high vacuum at 110°C and recrystallized from methanol to give needles, mp 215–217°C; λ_{max} (log ε) in

ethanol at 249 (4.19), 273 (4.01) inflexion, 328 (3.75); ν_{max} in potassium bromide at 3250, 3160, 1565, 1472, 1374, 1280, 1200, 1165, 1050, 1040, 970, and 710 cm^{-1}; *m/e* at 245 (100%), 229 (67%), 228 (93%), 200 (22%), 171 (19%), 144 (22%), 105 (45%), 79 (26%), and 78 (42%). Accurate mass measurement of M^+ gave *m/e* 245.0797 (calcd. for $C_{12}H_{11}O_3N_3$: 245.0800).

Chromatography

Caerulomycins A, B, C, and D were separated qualitatively by thin-layer chromatography (tlc) on silica gel HF_{254} (Merck & Co., Darmstadt) using as solvent either a mixture of benzene – acetic acid – water (42:24:1) giving R_f values of 0.09, 0.05, 0.24, and 0.16, respectively, or a mixture of benzene–diethylamine (50:3) saturated with 10% aqueous ammonia giving R_f values of 0.39, 0.35, 0.31, and 0.21, respectively. Alternatively, the metabolites could be separated by circular chromatography on formamide-treated paper with benzene as mobile phase. The R_f values were 0.65, 0.57, 0.26, and 0.28, respectively. Caerulomycin zones were detected as quenching areas under light of 254 nm, and as red to purple areas after the plates had been sprayed with aqueous ferrous sulfate.

For the preparative separation of caerulomycins a column (90 × 2.6 cm) of Sephadex LH20 (Pharmacia, Uppsala) was equilibrated with the solvent system benzene – ethyl acetate – acetic acid – water (1:12:4:12). Crude caerulomycin (500 mg) in upper phase (5 ml) was applied and the column irrigated with upper phase while fractions (20 ml) were collected. Caerulomycins, eluted in the sequence B, A, D, C, were collected in fractions 24–29, 34–40, 42–103, and 140–142, respectively.

Caerulomycin C Monoacetate (3c)

Caerulomycin C (20 mg) was dissolved in acetic anhydride (3 ml) and kept at room temperature for 24 h. Ice was added to hydrolyze excess reagent and the solution evaporated *in vacuo* at 45°C. The product crystallized slowly from ether – petroleum ether (bp 60–80°C) as feathery needles (19 mg), mp 102–103°C; λ_{max} (log ε) in ethanol at 229 (4.13) and 265 (4.02) nm; λ_{max} in potassium bromide at 1760 cm^{-1}; M^+ at *m/e* 301.1063 (calcd. for $C_{15}H_{15}N_3O_4$: 301.1064).

Caerulomycinonitrile C (3b)

Caerulomycin C (25 mg) was heated under reflux with acetic anhydride (5 ml) for 3 h. The cooled solution was diluted with water and evaporated at 45°C *in vacuo* to a tan solid which crystallized from ethanol as colorless needles (16 mg), mp 114–116°C; λ_{max} (log ε) in ethanol at 227 (4.67) and 260 (3.81) nm; ν_{max} in chloroform at 2240 cm^{-1}; M^+ at *m/e* 241.0849 (calcd. for $C_{13}H_{11}N_3O_2$: 241.0851).

Details of the synthesis of the tridentate tris chelating ligand dimethyl(*N*,*N*-dimethylethanolamino)(1-pyrazolyl)gallate and the preparation and physical properties of the binuclear transition metal complexes incorporating this ligand are given. Crystals of bis-μ-pyrazolyl(*N*(1),*N*(2))-bis[dimethyl(*N*,*N*-dimethylethanolamino)(1-pyrazolyl)gallato(*N*(2),*O*,*N*)copper(II)] are monoclinic, $a = 12.018(2)$, $b = 10.390(1)$, $c = 13.568(3)$ Å, $\beta = 100.04(6)°$, $Z = 2$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.045 and R_w of 0.058 for 2460 reflections with $I \geq 3\sigma(I)$. The centrosymmetric binuclear molecule features copper atoms having distorted square pyramidal coordination geometry. Three of the basal positions are occupied by the oxygen, pyrazolyl nitrogen, and amino nitrogen atoms of the tridentate tris-chelating ligand. The two remaining sites are occupied by bridging pyrazolyl groups, which provide a basal nitrogen atom to one copper atom and an apical nitrogen atom to the second copper centre. The gallium atoms have distorted tetrahedral coordination geometry. Important bond lengths (corrected for libration) are: Cu—O, 1.981(3), Cu—N(basal), 1.953(3)–2.143(4), Cu—N(apical), 2.173(3), Ga—O, 1.907(3), Ga—N, 1.991(4), and Ga—C, 1.962(7) and 1.977(7) Å.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **55**, 4166 (1977).

On rapporte les détails de la synthèse du ligand tridentate et trichélatant diméthyl(*N*,*N*-diméthyléthanolamino)(pyrazolyl-1)gallate et la préparation et les propriétés physiques de complexes binucléaires de métaux de transition incorporant ce ligand. Les cristaux du bis-μ-pyrazolyl(*N*(1),*N*(2))-bis[diméthyl(*N*,*N*-diméthyléthanolamino)(pyrazolyl-1)gallato(*N*(2),*O*,*N*)-cuivre(II)] sont monocliniques, $a = 12.018(2)$, $b = 10.390(1)$, $c = 13.568(3)$ Å, $\beta = 100.04(6)°$, $Z = 2$, groupe d'espace $P2_1/c$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.045 et de R_w de 0.058 pour 2460 réflexions avec $I \geq 3\sigma(I)$. La molécule binucléaire centrosymétrique comporte des atomes de cuivre dont la géométrie de coordination correspond à une pyramide carrée déformée. Trois des positions de base sont occupées par l'oxygène, l'azote du pyrazolyle et l'azote du groupe amino du ligand trichélatant et tridentate. Les deux autres sites sont occupés par les groupes pyrazolyles formant le pont; ils fournissent un atome d'azote de la base d'un des atomes de cuivre et un atome d'azote apical du second atome de cuivre. La géométrie de coordination des atomes de gallium correspond à un tétraèdre déformé. Les longueurs des liaisons importantes (corrigées pour la libration) sont: Cu—O, 1.981(3), Cu—N(base), 1.953(3)–2.143(4), Cu—N(apical), 2.173(3), Ga—O, 1.907(3), Ga—N, 1.991(4) et Ga—C 1.962(7) et 1.977(7) Å.

[Traduit par le journal]

Introduction

As part of an expanding investigation of pyrazolyl and related derivatives of gallium and aluminum, novel anionic tridentate chelating ligands have been synthesized and their coordinating abilities studied. Neutral dimeric molecules (1–4) and transition metal complexes derived from symmetrical anionic bidentate chelating ligands (5–8) have been reported. The present account describes the synthesis of the anionic ligand, dimethyl(*N*,*N*-dimethylethanolamino)-(1-pyrazolyl)gallate, $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]^-$, and its coordination properties with respect to the transition metal ions Co(II),

Ni(II), Cu(II), and Zn(II). The resulting binuclear transition metal complexes have distorted square pyramidal coordination geometry about the transition metal atoms. These atoms are bridged by two pyrazolyl groups and end-capped with the tridentate ligands.

Experimental

Air sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately after distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Pyrazole (K and K Laboratories) and sodium hydride (Alfa Inorganic) were used as supplied. *N,N*-dimethylethanolamine was refluxed over anhydrous $CaSO_4$ and distilled prior to use. Gallium trimethyl was prepared as previously described (9).

Sodium Dimethyl(N,N-dimethylethanolamino)(1-pyrazolyl)gallate, $Na^+[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]^-$

$$[1]\quad NaH + N_2C_3H_4 \xrightarrow[N_2\ atm]{THF} Na^+N_2C_3H_3^- + H_2$$

$$[2]\quad Na^+N_2C_3H_3^- + Me_3Ga \xrightarrow[N_2\ atm]{THF} Na^+Me_3Ga(N_2C_3H_3)^-$$

$$[3]\quad Na^+Me_3Ga(N_2C_3H_3)^- + Me_2NCH_2CH_2OH \xrightarrow[N_2\ atm,\ reflux]{THF} Na^+[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]^- + CH_4$$

Trimethyl gallium (4.28 g, 37.3 mmol) in THF was added to sodium pyrazolide (37.3 mmol) (made from sodium hydride (0.894 g, 37.3 mmol) and pyrazole (2.54 g, 37.3 mmol) in THF) in the same solvent. *N,N*-dimethylethanolamine (3.32 g, 37.3 mmol) was added to the resulting solution and on refluxing a slow evolution of methane occurred. The course of the reaction was monitored by ^1H nmr as well as by visual observation of gas evolution. The product solution exhibits a Ga–*Me* proton resonance 0.1 ppm to lower field than that from the starting material. There was a gradual appearance of the new signal at the expense of the original signal in the Ga–*Me* region of the spectrum. The reaction was complete after refluxing for 24 h. Aliquots of the resulting clear solution of the ligand were used in further experiments since attempts to isolate the sodium salt from the THF solution were not successful.

Attempted Preparation of $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]_2M$ (M = Co, Ni, Cu, Zn)

The experimental procedure is very similar for each case and can be illustrated by the preparation of the cobalt derivative. The transition metal starting materials for all of the preparations are listed in Table 1.

An aliquot of the ligand solution prepared above and containing $Na^+Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)^-$

TABLE 1. Analytical data for $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2M]_2$ complexes

Compound	Color	Melting point (°C)	Transition metal precursor	Analysis						Electronic spectra	
				Found (%)			Calculated (%)				
				C	H	N	C	H	N	ν_{max} (cm^{-1})	ε
M = Co	Purple	158–159	$CoCl_2$	37.8	5.8	18.4	37.8	5.8	18.4	20 325(sh)	177
										18 939(sh)	225

(2.06 g, 7.43 mmol) was reacted with cobalt chloride, $CoCl_2$ (0.482 g, 3.71 mmol), dissolved in THF. A white precipitate (NaCl) formed and the color of the solution changed from pink to purple immediately. The precipitate was allowed to settle and the clear solution siphoned off prior to removal of the solvent. The resulting purple solid was recrystallized from benzene. The purple crystals were collected, washed with benzene, and subjected to physical measurements (see Table 1). Elemental analysis and mass spectral data show that instead of the expected mononuclear octahedral complex, the purple solid is a binuclear cobalt complex having the formulation $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Co]_2$, **1** (M = Co).

The nickel reaction produced, in addition to the green binuclear complex listed in Table 1, small amounts of orange and lilac crystalline materials. These were characterized by elemental analyses and mass spectrometry. The orange compound proved to be identical to the previously characterized (5, 6, 8) compound $[Me_2Ga(N_2C_3H_3)_2]_2Ni$. The lilac compound is a new complex having the formulation $[MeGa(N_2C_3H_3)_3]_2Ni$. The latter has since been synthesized in larger quantities by an alternate route and will be described in a forthcoming publication together with other compounds incorporating the tris-chelating anionic ligand $MeGa(N_2C_3H_3)_3^-$.

All four transition metal complexes are relatively stable in air as solids but solutions are rapidly oxidized on exposure to air. These oxidations may involve attack at the 'vacant' sixth coordination sites on the transition metals.

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 80–100°C. Data for the cobalt complex appear in Table 2.[1] Proton nmr spectra were recorded on Varian T60 and XL100 instruments, ir spectra on a Perkin-Elmer 457 spectrophotometer, and electronic absorption spectra (solutions) on a Cary 14 spectrometer using 1.0 cm solution cells.

X-Ray Crystallographic Analysis of Bis-μ-pyrazolyl(N(1),N(2))-bis[dimethyl(N,N-dimethylethanolamino)-(1-pyrazolyl)gallato(N(2),O,N)copper(II)]

The crystal chosen for study was mounted with (0, −1, 1) normal to the goniostat axis and had dimensions of ca. 0.09 × 0.45 × 0.64 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares on 2 sin θ/λ values for 30 reflections measured on a diffractometer with CuK_α radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{24}H_{44}Cu_2Ga_2N_{10}O_2$ fw = 771.20
Monoclinic, a = 12.018(2), b = 10.390(1), c = 13.568(3) Å, β = 100.04(6)°, V = 1668.2(6) Å^3, Z = 2, ρ_c = 1.535 g cm^{-3}, $F(000)$ = 788, $\mu(CuK_\alpha)$ = 37.7 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with nickel-filtered CuK_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4 deg min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts of 10 s were measured at each end of the scan. Data were measured to 2θ = 140°. The intensities of the check reflections, measured every 40 reflections throughout the data collection, decreased uniformly to final values that were 0.85 times the initial values. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (10, 11). Transmission factors ranged from 0.201 to 0.720. Of the 3165 independent reflections measured, 2472 (78%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count.

The structure was solved by direct methods (12). The positions of the metal atoms, the oxygen atom, and two nitrogen atoms were located on the E-map. Two cycles of full-matrix least squares refinement of the coordinates and isotropic thermal parameters of these five atoms gave R = 0.292. A difference map calculated at this point gave the position of the remaining non-hydrogen atoms. The non-hydrogen atoms were refined for two cycles with isotropic thermal parameters, then for two cycles with anisotropic thermal parameters, reducing R to 0.058. All 22 hydrogen atoms were located on a subsequent difference map and were included in the refinement with isotropic thermal parameters. The entire structure (270 variables) was refined for four cycles giving a final R of 0.045 and R_w of 0.058 for 2460 reflections with $I \geq 3\sigma(I)$ (12 reflections, which had $|F_o| - |F_c| > 3\sigma(F)$, were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections, but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 3165 reflections R = 0.059 and R_w = 0.066.

A correction for secondary extinction was approximated by basing the least squares refinement on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 9.2 × 10^{-8}. The scattering factors of ref. 13 were used for the non-hydrogen atoms and those of ref. 14 for the hydrogen atoms. Anomalous scattering factors from ref. 15 were used for the Ga, Cu, O, and N atoms. The weighting scheme, $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.07σ, the largest shift (0.84σ) being associated with the y coordinate of H(9c). The mean error in an observation of unit weight was 1.381. The final positional and thermal parameters appear in Tables 3 and 4,[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation

[1]The structure factor table and Tables 2 (mass spectral data), 4 (thermal parameters), 5*b*, and 6*b* (bond lengths and angles involving hydrogen) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(T), libration (L), and screw (S) motion (16) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least squares analysis) is 0.0030 Å^2. Analyses were successful for the 28 atom group consisting of Ga, Cu, O, N(1)–N(4), C(1)–C(7), and their symmetry related counterparts (rms ΔU_{ij} = 0.0059 Å^2) and the N(5) and Ga tetrahedra (rms ΔU_{ij} = 0.0019 and 0.0029 Å^2, respectively).

The appropriate bond distances have been corrected for libration (17, 18), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 5 along with the uncorrected values. Changes in the bond angles were not significant; thus only the uncorrected bond angles appear in Table 6.

X-Ray film data indicate that the cobalt and nickel complexes are isomorphous with the copper complex.

Results and Discussion

The mass spectra of the binuclear transition metal complexes indicate high thermal stability. Signals due to the parent ions were observed in all cases. The major peaks in the mass spectrum of the cobalt complex (listed in Table 2[1]) provide an example of the fragmentation patterns observed. The isotopic patterns of the individual signals are in good agreement with those predicted from the isotopic distribution of metal atoms (^{69}Ga, 60%; ^{71}Ga, 40%; ^{59}Co, 100%). A further indication of the stability of the binuclear complexes is the presence of $M(N_2C_3H_3)_2M$ fragments, which can only arise after several fragmentation losses. The proton nmr spectrum of the diamagnetic zinc complex $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Zn]_2$ in C_6D_6 is consistent with a binuclear structure as found in the solid state for the copper complex. There are two unique equal intensity Ga–*Me* resonances at high field, as would be expected from the nonequivalent positions of these methyl groups in the structure. The N–*Me* resonances, although not as clearly resolved due to overlapping with the N—CH_2— signal, again occur at different positions in the spectrum as predicted from the solid state structure of the copper complex. The remainder of the spectrum was complicated by overlapping of signals but the overall integration gave the different protons in their expected intensity ratios.

The ir spectra of the four complexes are very similar and all display strong Ga—C symmetric and asymmetric stretching frequencies in the 530–540 and 570–580 cm^{-1} regions of the spectrum, respectively.

The visible spectra of the Co, Ni, and Cu complexes in benzene each consisted of one broad asymmetric absorption band. These are listed in Table 1 along with extinction coefficients. No assignment is attempted at this time but a magnetic moment study indicates that the compounds are high spin complexes. This is expected for five-coordinate complexes of this type involving N and O donor atoms (19). The cobalt complex, $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Co]_2$, gave a μ_{eff} value of 4.22 per cobalt ion at 298 K (corrected for ligand and metal diamagnetism). This is consistent with the presence of three unpaired electrons in a high spin

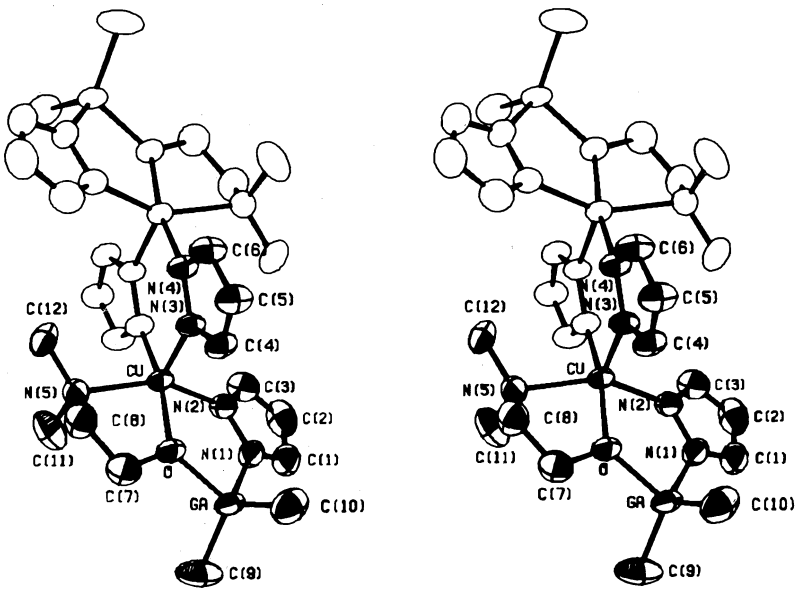

FIG. 1. A stereo view of the bis-μ-pyrazolyl(*N*(1),*N*(2))-bis[dimethyl(*N*,*N*-dimethylethanolamino)(1-pyrazolyl)gallato(*N*(2),*O*,*N*)copper(II)] molecule. Fifty percent ellipsoids are shown for the non-hydrogen atoms, hydrogen atoms are omitted for clarity.

cobalt(II) ion having square pyramidal coordination geometry.

In previous studies (6–8), symmetric anionic ligands of the type $Me_2Ga(N_2C_3H_3)_2^-$ have been synthesized and their chelating properties towards transition metal ions studied. Substitution of pyrazole by a different active hydrogen compound in step 3 (see Experimental section) of the preparation of these ligands has led to a wide variety of asymmetric ligands of potentially higher denticity. The present study involves utilization of the active hydrogen compound *N*,*N*-dimethylethanolamine in step 3 of the ligand synthesis. This compound was of interest since it is known to react readily with Me_3Ga (20) to give the five-coordinate gallium complex $[Me_2NCH_2CH_2OGaMe_2]_2$, and thus should react easily with $Me_3GaN_2C_3H_3^-$ as in step 3. The ligand expected from this reaction, $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]^-$, may interact with transition metal ions in a number of ways as shown in **2**. The ligand may act a triden-

*Primed atoms at $1 - x, 1 - y, 1 - z$.

tate tris-chelating system, **2***a*; as a bidentate ligand to the metal atom M while coordinating back to the gallium (via the amino nitrogen atom) giving five-coordinate gallium as found in $[Me_2NCH_2CH_2OGaMe_2]_2$ (20), **2***b*; or (less likely) as a bidentate system via the pyrazolyl and amino nitrogen atoms, **2***c*. In the latter case the available lone electron pair on oxygen could then give some type of intermolecular association by donating to a second gallium atom, indicated by the dotted lines in **2***c*.

The X-ray crystallographic study of **1** (M = Cu) shows that the ligand is acting as a tridentate tris-chelating system as in **2***a* but that it is too bulky to enable accommodation of two ligands around the transition metal atom. Rather than the mononuclear complexes envisaged, the products isolated were binuclear complexes of the general formula $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2M]_2$, which have two mononuclear $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]M$ fragments bridged by two pyrazolyl ($N_2C_3H_3$) groups. The formation of these compounds must involve decomposition of the ligand as this is the only source of pyrazolyl moieties. It is possible that once one ligand has been accommodated, a second ligand linked to the transition metal via its pyrazolyl nitrogen atom is unable to coordinate further and loses '$Me_2Ga(OCH_2CH_2NMe_2)$', which immediately forms the known dimer

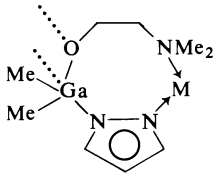
2*b*



2*c*

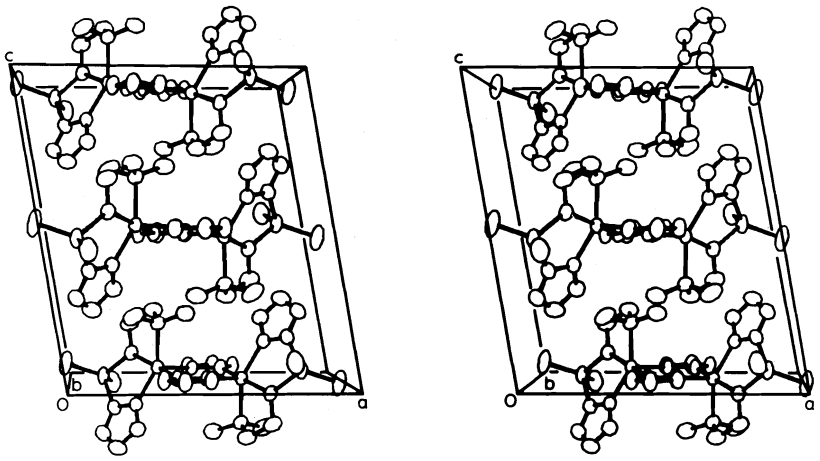


FIG. 2. The crystal structure of bis-μ-pyrazolyl(*N*(1),*N*(2))-bis[dimethyl(*N*,*N*-dimethylethanolamino)-(1-pyrazolyl)gallato(*N*(2),*O*,*N*)copper(II)] viewed along *b*.

$[Me_2NCH_2CH_2OGaMe_2]_2$ (20). This product occurred as a white residue obtained during recrystallization procedures and was identified by its characteristic mass spectrum. The resulting transition metal fragments then dimerize to give the observed binuclear transition metal products, **1**.

The crystal structure of the copper complex $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Cu]_2$ (Fig. 2) consists of discrete centrosymmetric binuclear molecules separated by normal van der Waals distances. The coordination geometry about copper in distorted square pyramidal with the copper atom displaced 0.362 Å toward the apical atom from the mean plane of the basal atoms. Three of the basal positions are occupied by the amino nitrogen, oxygen, and pyrazolyl nitrogen atoms of the tris-chelating ligand. The two remaining sites are occupied by the bridging pyrazolyl nitrogen atoms, which provide a basal atom to one copper atom and an apical atom to the second copper centre. The steric constraints imposed by ring formation are primarily responsible for distortion of the copper coordination group. The basal group itself is markedly non-planar. Bond angles at the copper atom between the apical and basal atoms range from 93.2(1) to 110.1(1)° and within the basal group *cis* angles range from 80.8(1) to 92.9(1)° while the *trans* angles are 148.6(2) and 166.0(1)°. The Cu—O and Cu—N bond lengths all lie within the normal range of distances observed for such bonds. The two basal Cu—N (pyrazolyl) distances (1.953(3) and 2.023(4) Å) are significantly different, the shorter distance being part of the less strained central $Cu_2(N_2C_3H_3)_2$ grouping, which was indicated by the mass spectrum to be a stable fragment. The apical Cu—N (pyrazolyl) bond (2.173(3) Å) is also part of this central grouping and is only 0.03 Å longer than the basal Cu—N (amino) bond (2.143(4) Å), which is lengthened by steric repulsion between the C(12) methyl group and one of the bridging pyrazolyl groups (H(12c)...N(3)′ = 2.51(9) and H(12c)...N(4)′ = 2.52(9) Å).[2]

The gallium atom has tetrahedral coordination geometry, distorted by the angle of 90.0(1)° in the five-membered chelate ring. The opposite angle, C(9)—Ga—C(10), is correspondingly expanded to 121.3(4)°. The bond lengths involving gallium are close to those in related molecules (1, 2–5, 7, 20–23).

The molecular framework consists of a system of nine fused rings, five of which are crystallographically unique. Torsion angles in the non-planar rings are listed in Table 7. The central Cu_2N_4 ring, situated about the molecular inversion centre, is significantly non-planar and has a flattened chair conformation. The Cu...Cu′ distance across this ring is 3.991(1) Å. The pyrazolyl ring that is fused to the central Cu_2N_4 ring is rigorously planar within experimental error ($\chi^2 = 0.24$) but both copper atoms are considerably displaced from the pyrazolyl mean plane (−0.1462(6) and 0.4158(6) Å for Cu and

[2]Here and elsewhere in this report primed atoms are related to those whose coordinates are listed in Table 3 by the molecular centre of symmetry at (1/2, 1/2, 1/2).

TABLE 7. Intra-annular torsion angles (deg)

Bond	Observed	Bond	Observed
Ga—O	−1.8(1)	Cu—O	−11.3(3)
O—Cu	2.2(1)	O—C(7)	−12.1(5)
Cu—N(2)	−2.0(2)	C(7)—C(8)	41.4(5)
N(2)—N(1)	1.3(3)	C(8)—N(5)	−47.4(4)
N(1)—Ga	0.2(2)	N(5)—Cu	31.4(3)
Cu—N(3)	16.8(2)		
N(3)—N(4)	−20.6(3)		
N(4)—Cu′	15.5(3)		

Cu′, respectively). As a result, the coordination about both N(3) and N(4) is significantly distorted from planarity (N(3) and N(4) are displaced 0.040(3) and 0.122(4) Å from their respective NCCu planes). The angle between normals to the mean planes of the Cu_2N_4 and N(3)N(4) pyrazolyl rings is 9.8°. The ethanolamine chelate ring (CuOC(7)C(8)N(5)) adopts a typical puckered conformation while the chelate ring (CuOGaN(1)N(2)) is nearly planar (mean and maximum deviations of atoms from the weighted least squares mean plane being 0.011 and 0.030(3) Å (for O), $\chi^2 = 136$). The $CuOGaN_2$ ring is also fused to a planar ($\chi^2 = 0.86$) pyrazolyl ring and as before the metal atoms are significantly displaced from the mean plane of the pyrazolyl ring (Cu by 0.0953(6) and Ga by 0.1313(6) Å) and the nitrogen coordination groups are not rigorously planar (N(1) being 0.041(4) Å from the GaNC plane and N(2) being 0.026(4) Å from the CuNC plane). The angle between normals to the $CuOGaN_2$ and N(1)N(2) pyrazolyl ring mean planes is 4.3°.

The trigonally coordinated oxygen atom lies 0.135(3) Å off the plane of its substituents and the Cu...Ga distance is 3.397(1) Å. The bond lengths and angles in the remainder of the molecule (see Tables 5 and 6) are generally as expected.

Acknowledgments

We thank the National Research Council of Canada for financial support and the University of British Columbia Computing Centre for assistance. We are grateful to Mr. J. Nip for mass spectra, Mr. P. Borda for C, H, N analyses, Dr. S. Chan for nmr spectra, and to Mr. R. Morrison for the magnetic susceptibility measurement.

L-Proline derivatives of gallium trimethyl and gallium triethyl: crystal and molecular structure of L-prolinatodimethylgallium

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received July 8, 1977

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **55**, 4174 (1977).

Crystals of L-prolinatodimethylgallium are orthorhombic, $a = 10.624(2)$, $b = 10.567(4)$, $c = 8.2268(6)$ Å, $Z = 4$, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.029 and R_w of 0.035 for 1109 reflections with $I \geq 3\sigma(I)$. Details of the preparation and physical properties of L-prolinatodimethylgallium and L-prolinatodiethylgallium are given. The crystal structure of L-prolinatodimethylgallium consists of molecules each linked to two others by weak Ga—O bonds (2.695(3) Å) and N—H...O hydrogen bonds (N...O = 2.901(4) Å) to form a chain-like polymeric structure extending along the *b* axis. The gallium atom is five-coordinate and has distorted trigonal bipyramidal geometry. Important bond lengths are: Ga—O (axial), 2.044(3) and 2.695(3); Ga—N, 2.035(3); and Ga—C, 1.942(5) and 1.958(5) Å.

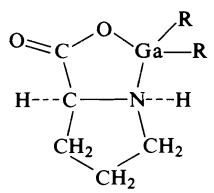
KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **55**, 4174 (1977).

Les cristaux du L-prolinatodiméthylgallium sont orthorhombiques, $a = 10.624(2)$, $b = 10.567(4)$, $c = 8.2268(6)$ Å, $Z = 4$, groupe d'espace $P2_12_12_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.029 et R_w de 0.035 pour 1109 réflexions avec $I \geq 3\sigma(I)$. On donne des détails concernant la préparation et les propriétés physiques de L-prolinatodiméthylgallium et de L-prolinatodiéthylgallium. La structure cristalline du L-prolinatodiméthylgallium est formée de molécules qui sont toutes liées avec deux autres par des liens Ga—O qui sont faibles (2.695(3) Å) et des liens hydrogènes N—H...O (N...O = 2.901(4) Å) pour former une structure en chaîne ressemblant à un polymère s'étendant le long de l'axe *b*. L'atome de gallium est pentacoordonné et possède une géométrie trigonale bipyramidale déformée. Les longueurs de liaisons importantes sont: Ga—O (axiale), 2.044(3) et 2.695(3); Ga—N, 2.035(3) et Ga—C, 1.942(5) et 1.958(5) Å.

[Traduit par le journal]

Introduction

Gallium trialkyls react readily with compounds containing 'active hydrogen', eliminating alkane to yield products containing either four- or five-coordinate gallium (1–11). These products are often associated and frequently occur as dimers. The present study involves the reaction of gallium trimethyl and gallium triethyl with the active hydrogen compound L-proline. The crystal structure of one of the products, L-prolinatodimethylgallium (**1**, R = Me), has been determined. This work is part of a continuing investigation of organogallium compounds in which the gallium atom is potentially five-coordinate.



1

Experimental

All solvents were dried and distilled before use. Reactions involving gallium trialkyls were initiated in a glove box filled with dry nitrogen, with subsequent handling under a blanket of dry nitrogen or on a high vacuum line. Gallium trimethyl (12) and gallium triethyl (13) were prepared as previously described. L-Proline was used as supplied (Sigma Chemical Corporation).

L-Prolinatodimethylgallium

This compound was prepared by reacting gallium trimethyl (1.657 g, 14.44 mmol) with L-proline (1.610 g, 14.00 mmol) in refluxing benzene. The reaction mixture, initially milky in appearance, cleared as the reaction proceeded. At the completion of the reaction, when methane evolution had ceased, a clear benzene solution remained. Upon cooling this solution slowly to room temperature, large colorless crystals of the desired product were

deposited. The crystals were collected and dried. *Anal.* calcd. for $C_5H_8NO_2{\cdot}GaMe_2$: C 39.31, H 6.55, N 6.55; found: C 39.60, H 6.80, N 6.40.

L-Prolinatodiethylgallium

This compound was prepared by the reaction of gallium triethyl (2.540 g, 16.21 mmol) with L-proline (1.864 g, 16.21 mmol) in refluxing benzene. When evolution of ethane ceased, marking the completion of the reaction, the benzene solution was slowly cooled to room temperature yielding crystals of the desired product. The crystals were collected and dried. *Anal.* calcd. for $C_5H_8NO_2{\cdot}GaEt_2$: C 44.68, H 7.45, N 5.79; found: C 44.66, H 7.58, N 5.88.

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 80–100°C. Proton nmr spectra of $CDCl_3$ solutions were obtained on Varian T60 and XL100 instruments and ir spectra were recorded on a Perkin-Elmer 457 spectrophotometer as Nujol mulls.

X-ray Crystallographic Analysis of L-Prolinatodimethylgallium

The crystals chosen for study were mounted with b parallel to the goniostat axis and had dimensions of ca. 0.17 × 0.35 × 0.40 and 0.17 × 0.23 × 0.49 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares on 2 sin θ/λ values for 38 reflections measured on a diffractometer with CuK_α radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_7H_{14}GaNO_2$ fw = 213.9

Orthorhombic, $a = 10.624(2)$, $b = 10.567(4)$, $c = 8.2268(6)$ Å, $V = 923.6(6)$ Å^3, $Z = 4$, $\rho_c = 1.538$ g cm^{-3}, $F(000) = 440$, $\mu(CuK_\alpha) = 40.2$ cm^{-1}. Absent reflections: $h00$, $h \neq 2n$, $0k0$, $k \neq 2n$, and $00l$, $l \neq 2n$ define uniquely the space group $P2_12_12_1$ (D_2^4, No. 19).

Intensities were measured with nickel-filtered CuK_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. 10 s background counts were measured at each end of the scan. Data were measured to 2θ = 160°. The intensities of the check reflections, measured every 40 reflections throughout the data collection, decreased slowly and uniformly to values which were 0.94 times the initial values then dropped rapidly to 0.70 times the initial values. Data collected during the rapid drop in intensity of the check reflections were recollected using a second crystal. Intensities of the check reflections for the second crystal remained constant to within ±1% for this stage of the data collection. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (14, 15). Transmission factors ranged from 0.358 to 0.572 for crystal I and from 0.279 to 0.591 for crystal II. Of the 1180 independent reflections measured, 1117 (95%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count.

The structure was solved by direct methods (16, 17). All reflections with $|E| \geq 1.35$ were phased without the use of symbol phases. After tangent formula phase refinement (18) an E-map gave the positions of all 11 non-hydrogen atoms. Two cycles of full-matrix least squares refinement of the non-hydrogen atoms with isotropic temperature factors gave $R = 0.075$. Refinement with anisotropic temperature factors reduced R to 0.052. The coordinates of 10 of the 14 hydrogen atoms were determined from an electron density difference map calculated at this point. The remaining hydrogen atom positions were taken from subsequent difference maps. The entire structure (hydrogen atoms with isotropic thermal parameters) was refined for six cycles giving a final R of 0.029 and R_w of 0.035 for 1109 reflections with $I \geq 3\sigma(I)$ (8 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections, but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 1180 reflections R = 0.032 and $R_w = 0.037$.

A correction for secondary extinction was approximated by basing the least squares refinement on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $6.2(9) \times 10^{-8}$. The scattering factors of ref. 19 were used for the non-hydrogen atoms and those of ref. 20 for the hydrogen atoms. Anomalous scattering factors from ref. 21 were used for the non-hydrogen atoms. The weighting scheme, $w = 1.0$ if $|F_o| < 20.0$, $w = (20.0/|F_o|)^2$ if $|F_o| \geq 20.0$, and $w = 0.38$ for the unobserved reflections, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

The absolute configuration is fixed by the known chirality of the C(2) centre. As a result of coordination to gallium the proline nitrogen atom becomes chiral as well. The chirality of both centres (C(2) and N) is S. On the final cycle of refinement the mean parameter shift was 0.15σ and the largest shift (1.5σ) was associated with a hydrogen atom. The mean error in an observation of unit weight was 0.5172. A final difference map showed maximum fluctuations of ±0.75 e Å^{-3} near the gallium atom and ±0.24 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (22) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least squares analysis) is 0.0021 Å^2. Analysis of the entire molecule (rms $\Delta U_{ij} = 0.0044$ Å^2) yielded physically reasonable rigid-body parameters.

The appropriate bond distances have been corrected for libration (23, 24), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values. Corrected bond

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

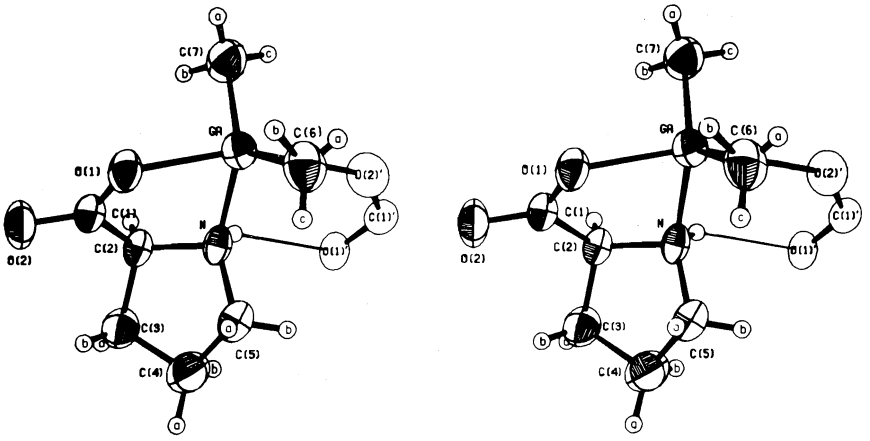


FIG. 1. A stereo view of the unique part of the L-prolinatodimethylgallium structure. Fine line represents a hydrogen bond. 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

angles differ by less than 0.1° from the uncorrected values in Table 4.

Results and Discussion

Figure 1 shows a general view of the unique part of the structure with the crystallographic numbering scheme and Fig. 2 shows the structure viewed down the crystallographic *c* axis. Torsion angles defining the conformations of the five-membered rings are given in Table 5.

The crystal structure of L-prolinatodimethylgallium (Fig. 2) features an unusual chain-like association of monomer units extending along the *b* axis. Each molecular unit is linked to two others (related by the screw axis parallel to *b*) by two weak Ga—O bonds (2.695(3) Å) and two N—H...O(1)[$1 - x$, $1/2 + y$, $1/2 - z$] hydrogen bonds (N...O = 2.901(4), H...O = 2.27(5) Å, N—H...O = 137(4)°) to form a linear polymer which contains five-coordinate gallium atoms. Non-bonded distances between the parallel chains correspond to normal van der Waals interactions. Other five-coordinate gallium species consist of discrete molecular units; four of these are binuclear (9, 10, 25) while one is polynuclear (26) and one is mononuclear (27, 28).

The gallium atom has distorted trigonal bipyramidal coordination geometry. The equatorial positions are occupied by the nitrogen and two methyl carbon atoms and the axial sites by oxygen atoms. As in related compounds (9, 10, 25–28) the angles at the gallium atom are distorted from 'ideal' values by steric constraints imposed by chelate ring formation. The angle between axial substituents is 157.7(1)°, axial–equatorial angles range from 77.2(1) to 103.4(2)°, and the angles between the equatorial substituents range from 111.5(2) to 129.9(3)°. The gallium atom is displaced 0.2109(5) Å toward O(1) from the NC(6)C(7) plane.

The Ga—O(1) and Ga—C bond lengths are consistent with corresponding distances in the

other five-coordinate gallium structures (all of which have trigonal bipyramidal coordination geometry). The equatorial Ga—N bond (2.035(3) Å) is longer than those in $C_{24}H_{72}Ga_8N_{12}O_2$ (26) (1.949(3) and 1.999(3) Å) and the axial Ga—O(2)′ distance (2.695(3) Å) is the longest Ga—O bond yet observed. In most of the other five-coordinate gallium structures studied one of the axial bonds is relatively long, for example: Ga—O = 2.469(3) Å in the salicylaldehydatodimethylgallium dimer (10) and Ga—N = 2.779(3) Å in the polycyclic cage compound $C_{24}H_{72}Ga_8N_{12}O_2$ (26).

The conformation of the chelate ring is qualitatively equivalent to that in the related molecule L-prolinatodiphenylboron (29), the mean deviation between corresponding torsion angles being 3.3°. The steric and electronic differences between the tetrahedral boron and trigonal bipyramidal gallium complexes lead to small, but possibly significant, geometrical differences in the L-proline moieties. The C(1)—O(1) and C(1)—O(2) distances in the two complexes (1.300(3) and 1.219(3) Å for the boron and 1.283(5) and 1.232(5) Å for the gallium complex) reflect the relative weakness of the axial Ga—O(1) bond with respect to the B—O(1) bond as well as the effect of weak

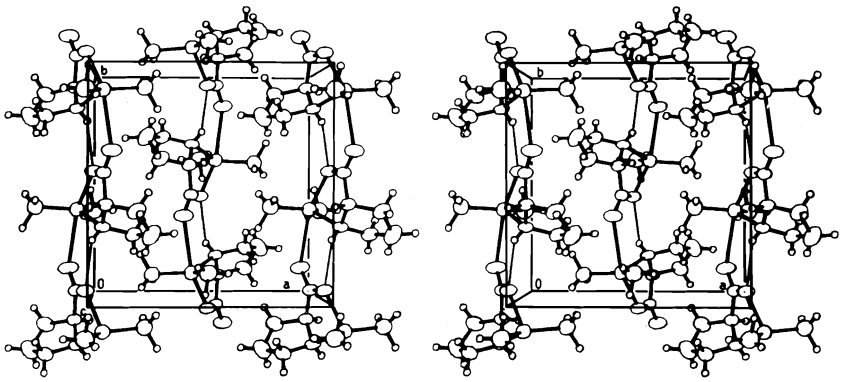

FIG. 2. The crystal structure of L-prolinatodimethylgallium viewed down *c*. Fine lines represent hydrogen bonds.

coordination of the carbonyl oxygen atom, O(2), to the gallium atom.

The strongest signals in the mass spectra of the two L-prolinatodialkylgallium compounds were due to the parent ion minus one alkyl group. No signals with higher mass than the parent monomer ion were observed. In view of the weak association of monomer units in the solid (for the methyl derivative) the monomeric constitution in the gas phase is not surprising. Salicylaldehydatodimethylgallium was found to be monomeric in the gas phase but in the solid dimerizes through the formation of two weak Ga—O bonds (10). The parent monomer ion was only observed for the diethyl derivative, and then only at about 2% of the intensity of the strongest peak in the spectrum. The absence or low intensity of parent ion signals is common in this type of organogallium compound (2, 8). Other strong signals in the mass spectrum were due to $C_4H_8N{\cdot}GaR_2^+$, $C_4H_8N{\cdot}GaR^+$, GaR_2^+, Ga^+, and $C_4H_8N^+$ ions. The relative intensities of the peaks in the doublet signals of gallium containing ions agreed well with those predicted from the isotopic distribution of the metal atoms [^{69}Ga(60%), ^{71}Ga(40%)].

The proton nmr spectra of the two complexes in $CDCl_3$ solution showed similar patterns with the alkyl groups on gallium at high field and the L-prolinato proton resonances to lower field. The spectrum of L-prolinatodimethylgallium displayed the Ga–*Me* resonance as a sharp singlet, and a sharp triplet–quartet pattern was observed for the Ga–*Et* protons in L-prolinatodiethylgallium. These observations are somewhat surprising considering the different environments of the two methyl groups on gallium in the solid state structure of L-prolinatodimethylgallium.

The infrared spectra show strong Ga—C symmetric and asymmetric stretching vibrations in the 500–600 cm^{-1} region of the spectrum. In the dimethyl gallium compound these occur at 546 and 597 cm^{-1}, respectively, and in the diethyl gallium compound they are shifted to 516 and 563 cm^{-1}, respectively.

The preparation and absolute configuration of *trans*-2-aminocyclopentanol enantiomers

ALEX A. BARR, IRENA FRENCEL,[1] AND J. BARRY ROBINSON[2]

Faculty of Pharmacy, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 20, 1977

ALEX A. BARR, IRENA FRENCEL, and J. BARRY ROBINSON. Can. J. Chem. **55**, 4180 (1977).

A method is reported for the resolution of (±)-*trans*-2-benzylaminocyclopentanol using D- or L-dibenzoyltartaric acid as the resolving agent. Debenzylation of the enantiomeric bases gives the enantiomeric *trans*-2-aminocyclopentanols. These compounds have been converted to their quaternary ammonium acetate ester derivatives and the absolute configuration assigned by comparison of the ord spectra with the spectra of the appropriate cyclohexane derivatives.

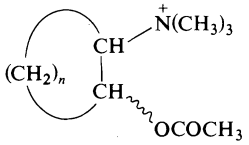
ALEX A. BARR, IRENA FRENCEL et J. BARRY ROBINSON. Can. J. Chem. **55**, 4180 (1977).

On rapporte une méthode pour la résolution en antipodes optiques du (±)-benzylamino-2 cyclopentanol *trans* qui fait appel aux acides D- ou L-dibenzoyltartariques comme agent de résolution. La débenzylation des bases énantiomères conduit aux amino-2 cyclopentanols *trans* énantiomères. On a transformé ces composés en ester d'ammonium quaternaire et on a attribué leur configuration par comparaison de leur spectre ord avec les spectres des derivés appropriés de cyclohexane.

[Traduit par le journal]

Several distinct receptor types (preganglionic autonomic, postganglionic parasympathetic, somatic motor) have been identified as specific binding sites for the chemically simple molecule acetylcholine. However, the conformation of the acetylcholine molecule which becomes bound to each of these binding sites cannot currently be defined and one of the several possible approaches to this problem involves the synthesis of rigid and/or semirigid analogues of acetylcholine, of known stereochemistry, followed by evaluation of these compounds as acetylcholine-like agonists. (For a recent review, see ref. 1.)

The 1,2-disubstituted cycloalkanes of structure **1** have proved useful in such studies relating stereochemistry of the molecule to its acetylcholine-like pharmacological activity. Thus, the muscarinic agonist activity is found in the



1 ($n = 1$–4)

(±)-*trans* isomers in the cyclohexane (**1**, $n = 4$) (2–4), cyclobutane (**1**, $n = 2$) (5), and cyclopropane (**1**, $n = 1$) (6–8) series. It is also the (±)-*trans* isomer which is a substrate for the enzyme acetylcholinesterase (acetylcholine hydrolase E.C. 3.1.1.7) in this series (3, 6, 9).

Within the cyclohexane and the cyclopropane series of compounds, the *trans* isomer has been resolved and both the muscarinic agonist activity and the enzyme catalyzed hydrolysis activity have been shown to be either a stereoselective (2–4) or a stereospecific phenomenon (6, 7).

Within the cyclopentyl series of compounds (**1**, $n = 3$), the relationships between stereochemistry and biological activity have not been as clearly demonstrated. An early preparation of (±)-*cis*- and (±)-*trans*-2-dimethylaminocyclopentylacetate methiodide (**1**, $n = 3$) (10) suggested that the (±)-*cis* isomer was a superior substrate for the enzyme acetylcholinesterase than either the (±)-*trans* isomer or acetylcholine. Subsequent studies of the muscarinic agonist activity among this series of compounds demonstrated the (±)-*cis* isomer to be only a weak partial agonist whereas the (±)-*trans* isomer was a more potent pure muscarinic agonist (11).

The above results stimulated a reinvestigation of the biological activity of the (±)-*cis* and (±)-*trans* isomers of the cyclopentyl series (**1**, $n = 3$). Enzyme substrate activity was found to be resident in the (±)-*trans* isomer only and we were thus further led to attempt the preparation

[1]Present address: Polish Academy of Science, Poznan, Poland.

[2]Author to whom correspondence should be addressed.

of the enantiomers of *trans*-2-dimethylaminocyclopentyl acetate methiodide and to determine the absolute configuration of each enantiomer. This study is the subject of the present communication. The biological data (enzyme activity and muscarinic agonist activity studies) will be the subject of a separate communication.

Synthesis

The preparation of (±)-*cis*- and (±)-*trans*-2-dimethylaminocyclopentyl acetate methiodide (**1**, $n = 3$) was accomplished using a previously reported method (10), the structure and stereochemistry of the products being checked, where appropriate, by infrared and proton magnetic resonance techniques. The physical properties of the products agreed well with reported literature data.

Although resolution of (±)-*trans*-2-aminocyclopentanol has been previously reported (12) using tartaric acid as the resolving agent, the requirement for performing all crystallizations at an elevated temperature was found to lead to poor control of the resolution process. In the present work, (±)-*trans*-2-benzylaminocyclopentanol was resolved using separately D- and L-dibenzoyltartaric acid. Decomposition of the stereoisomeric salts followed by hydrogenation of the extracted bases using palladium-on-charcoal gave the enantiomeric *trans*-2-aminocyclopentanols from which the enantiomeric *trans*-2-dimethylaminocyclopentyl acetate methiodides were separately prepared using conventional methods.

Absolute Configuration of the Enantiomers of *trans*-2-Dimethylaminocyclopentyl Acetate Methiodide

The absolute configuration of (−)-*cis*-2-dimethylaminocyclohexyl acetate methiodide has been previously established as (1*R*,2*S*) by unambiguous synthesis from (1*S*,2*R*)-(−)-*cis*-2-hydroxycyclohexane carboxylic acid (2). A similar method was also employed for the absolute configuration of (1*R*,2*R*)-(−)-*trans*-2-dimethylaminocyclohexyl acetate methiodide (4) and these conclusions were independently confirmed by circular dichroism studies of the cuprammonium complexes of the appropriate aminoalcohols (13).

In the present study the absolute configuration of the enantiomers of *trans*-2-dimethylaminocyclopentyl acetate methiodide was determined

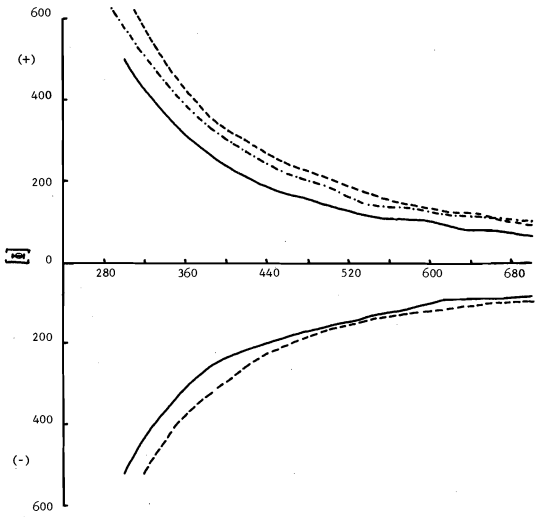


FIG. 1. Optical rotatory dispersion spectra in aqueous solution of 2-dimethylaminocycloalkyl acetate methiodide enantiomers: (—) *trans*-cyclopentyl derivatives; (--) *cis*-cyclohexyl derivatives; (-·-) *trans*-cyclohexyl derivative.

by comparison of the optical rotatory dispersion spectra of each of the enantiomers (recorded in aqueous solution between 700 and 250 nm) with the similarly recorded spectra of (1*S*,2*S*)-(+)-*trans*-, (1*R*,2*S*)-(−)-*cis*-, and (1*S*,2*R*)-(+)-*cis*-2-dimethylaminocyclohexyl acetate methiodide. Plain positive rotatory dispersion curves were shown by (1*S*,2*S*)-(+)-*trans*-2-dimethylaminocyclohexyl acetate methiodide, (1*S*,2*R*)-(+)-*cis*-2-dimethylaminocyclohexyl acetate methiodide and (+)-*trans*-2-dimethylaminocyclopentyl acetate methiodide (Fig. 1), thus indicating that they all possess the same absolute configuration at the C_1-atom (potential chromaphoric group). Thus, (+)-*trans*-2-dimethylaminocyclopentyl acetate methiodide has the (1*S*,2*S*) absolute configuration.

Experimental

All melting points were obtained using a Thomas-Hoover Uni-melt apparatus and are uncorrected. Infrared spectra were recorded on a Beckman IR-8 spectrophotometer and ^{1}Hmr spectra were recorded on a Varian T-60 spectrometer using CCl_4 as solvent and tetramethylsilane as external standard. Optical rotatory dispersion (ord) spectra were recorded on a Jasco ORD/UV-5 optical rotatory dispersion recorder. Combustion analyses were by Microanalysis Laboratory Ltd., Toronto.

(±)-2-Chlorocyclopentanone, (±)-2-dimethylaminocyclopentanone, (±)-*cis*- and (±)-*trans*-2-dimethylaminocyclopentanol, (±)-*cis*- and (±)-*trans*-2-dimethylaminocyclopentyl acetate and their methiodide salts were all prepared by known methods (10). Physical properties

were consistent with literature values and spectral properties were consistent with the proposed structures.

(±)-*cis*-2-Dimethylaminocyclopentyl acetate methiodide had mp 178.5–180°C (lit. (10) mp 177–178°C, (11) mp 176–177°C). *Anal.* calcd. for $C_{10}H_{20}INO_2$: C 38.35, H 6.44; found: C 38.4, H 6.5.

(±)-*trans*-2-Dimethylaminocyclopentyl acetate methiodide had mp 167–168°C (lit (10, 11) mp 166–167°C). *Anal.* calcd. for $C_{10}H_{20}INO_2 \cdot \frac{1}{2}H_2O$: C 37.3, H 6.5; found: C 37.25, H 6.5.

(±)-trans-2-Benzylaminocyclopentanol

To cyclopentene oxide (24.5 g) was added benzylamine (33.75 g) and water (5 ml) and the solution refluxed during 5 h. Water (50 ml) was added and the solution extracted with ether (5 × 50 ml), the extracts dried (Na_2SO_4), filtered, and evaporated. The residue was fractionally distilled, the fraction bp 110–113°C/0.1 Torr being collected. The product (33 g, 67%) crystallized on standing at room temperature overnight, mp 60–63°C; ^{1}Hmr ($CDCl_3$) δ: 7.33 (s, 5H, aromatic protons), 3.65–4.0 (m, with superimposed singlet at δ 3.8, total of 3H, C_2 methine proton and benzylic protons), 2.3–3.1 (m, 3H, C_1 methine proton, OH and NH, latter two displaced by D_2O), 1.1–2.2 (m, 6H, ring methylenes).

Resolution of (±)-trans-2-Benzylaminocyclopentanol

(±)-*trans*-2-Benzylaminocyclopentanol (54.5 g, 0.28 mol) was dissolved in absolute ethanol (300 ml) and added to a solution of dibenzoyl-D-tartaric acid monohydrate (mp 87–89°C) (113 g, 0.3 mol) in absolute ethanol (700 ml). The solution was allowed to stand at room temperature overnight and then at 4°C for a further 24 h. The crystals which deposited were collected and recrystallized three times from absolute ethanol to yield white needle crystals, mp 169–170°C; $[\alpha]_D^{20}$ −74° (*c* 0.16, ethanol), unchanged on further recrystallization. The product was dissolved in water, the solution made alkaline with KOH solution and extracted with chloroform (5 × 50 ml). The extracts were dried (Na_2SO_4), filtered, and the solvent evaporated. The residue was recrystallized from an acetone – petroleum ether (40–50°C) mixture to yield (−)-*trans*-2-benzylaminocyclopentanol (13.2 g) mp 74–75°C; $[\alpha]_D^{20}$ −52° (*c* 1.525, ethanol).

A sample of *trans*-2-benzylaminocyclopentanol enriched in the (+)-enantiomer was obtained by basification and extraction of the mother liquors from the above tartrate salt crystallizations. Reaction of this product with dibenzoyl-L-tartaric acid and crystallization as above yielded a salt, mp 169–170°C, $[\alpha]_D^{20}$ +75° (*c* 0.13, EtOH), from which (+)-*trans*-2-benzylaminocyclopentanol (7.3 g) was obtained, mp 76–77°C; $[\alpha]_D^{20}$ +59° (*c* 1.58, EtOH).

(−)-trans-2-Aminocyclopentanol

(−)-*trans*-2-Benzylaminocyclopentanol (6 g) was dissolved in ethanol (200 ml) and palladium-on-charcoal (2 g, 10%) added. The mixture was shaken over hydrogen at 20 lb/in.^{2} at room temperature until uptake of gas ceased. The reaction mixture was filtered, the filtrate acidified (HCl), and the solution evaporated to dryness under reduced pressure. The solid residue was recrystallized from an ethanol–ether mixture to yield white platelike crystals (3.5 g, 81%), mp 161–163°C; $[\alpha]_D^{20}$ −34.8° (*c* 1.6, H_2O) (lit (12) mp 155–156°C; $[\alpha]_D^{20}$ −29° (*c* 6.6, no solvent stated)). The above hydrochloride salt was dissolved in water, the solution made alkaline (KOH solution) and extracted with chloroform. The extracts were dried (Na_2SO_4), filtered, and the solvent evaporated. The residue was fractionally distilled, the fraction bp 104°C/8 Torr being collected as a viscous liquid which slowly solidified on standing; $[\alpha]_D^{20}$ −33.3° (*c* 1.7, EtOH) (lit. (12) bp 116–117°C/13 Torr; $[\alpha]_D^{20}$ −38° (concentration and solvent not stated)).

(+)-trans-2-Aminocyclopentanol

This compound was prepared in a similar manner as above but using (+)-*trans*-2-benzylaminocyclopentanol and had bp 100°C/8 Torr; $[\alpha]_D^{20}$ +36° (*c* 1.1, EtOH); hydrochloride salt, mp 160–162°C; $[\alpha]_D^{20}$ +32.2° (*c* 0.9, H_2O) (lit. (12) bp 116–117°C/13 Torr; $[\alpha]_D^{20}$ +38° (*c* 5.5, solvent not stated); hydrochloride salt, mp 155–156°C; $[\alpha]_D^{20}$ +29.3° (*c* 6.6, solvent not stated)).

(−)-trans-2-Dimethylaminocyclopentanol

(−)-*trans*-2-Aminocyclopentanol (2.75 g) was dissolved in formic acid (20 ml, 98%) and formaldehyde (20 ml, 40%) added and the solution warmed on a steam bath overnight. The reaction mixture was cooled, acidified with HCl, and concentrated to half volume under reduced pressure. The mixture was made alkaline (NaOH, 20% w/v) and continuously extracted with chloroform. The extracts were dried (Na_2SO_4), filtered, and the solvent evaporated. The residue was distilled, the fraction bp 90–93°C/10 Torr being collected (2 g); $[\alpha]_D^{20}$ —37°C (*c* 1.1 EtOH); ir and ^{1}Hmr spectra were identical to those of an authentic sample of (±)-*trans*-2-dimethylaminocyclopentanol.

(+)-trans-2-Dimethylaminocyclopentanol

The material was prepared in a similar manner from (+)-*trans*-2-aminocyclopentanol and had bp 90–93°C/10 Torr, $[\alpha]_D^{20}$ +40.5° (*c* 0.8, EtOH), and ir and ^{1}Hmr spectra identical to those of an authentic sample of the racemate.

(−)-trans-2-Dimethylaminocyclopentyl Acetate

This was prepared from (−)-*trans*-2-dimethylaminocyclopentanol by the method reported for the cyclohexane analogue (2). The product had bp 83–86°C/15 Torr, $[\alpha]_D^{20}$ −37.7° (*c* 0.76, EtOH), and spectral characteristics identical to those of the racemate.

(+)-trans-2-Dimethylaminocyclopentyl Acetate

This compound was prepared in a similar manner as above but using (+)-*trans*-2-dimethylaminocyclopentanol and had bp 83–85°C/15 Torr, $[\alpha]_D^{20}$ +43° (*c* 0.7, EtOH), and spectral characteristics identical to the racemate.

(−)-trans-2-Dimethylaminocyclopentyl Acetate Methiodide

Prepared from (−)-*trans*-2-dimethylaminocyclopentyl acetate by the method reported for the cyclohexane analogue (2), the product had mp 203–205°C. $[\alpha]_D^{20}$ −29.4° (*c* 0.61, EtOH). *Anal.* calcd. for $C_{10}H_{20}INO_2$: C 38.35, H 6.44; found: C 38.33, H 6.29.

(+)-trans-2-Dimethylaminocyclopentyl Acetate Methiodide

Prepared in a similar manner as above but using (+)-*trans*-2-dimethylaminocyclopentyl acetate, the product had mp 202–205°C, $[\alpha]_D^{20}$ +28° (*c* 1.14, EtOH). *Anal.* calcd. for $C_{10}H_{20}INO_2$: C 38.35, H 6.44; found: C 38.28, H 6.26.

Optical Rotatory Dispersion Spectra

The ord spectra of the quaternary ammonium ester salts (Fig. 1) were recorded in aqueous solution (approximately 5% w/v) using 1 cm path length cells.

^{13}C magnetic resonance studies 70.[1] The behavior of bicyclo[2.2.2]octenone under strongly basic conditions. A competition between retro Diels–Alder and Haller–Bauer cleavages

A. K. CHENG AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 17, 1977

A. K. CHENG and J. B. STOTHERS. Can. J. Chem. **55**, 4184 (1977).

As a test for possible competitive α- and β-enolization in bicyclic ketones the behavior of bicyclo[2.2.2]octenone in *t*-BuO$^-$–*t*-BuOH at 185°C has been examined. The major reaction (~90%) involves Claisen condensation followed by retro Diels–Alder elimination of ethylene and Haller–Bauer cleavage. All acidic and phenolic components, accounting for 90% of the product, have been identified and characterized, primarily by their ^{13}Cmr spectra.

A. K. CHENG et J. B. STOTHERS. Can. J. Chem. **55**, 4184 (1977).

Afin de développer une méthode permettant d'évaluer des énolisations α et β en compétition dans les systèmes de cétones bicycliques, on a examiné le comportement de la bicyclo[2.2.2]-octénone en présence de *t*-BuO$^-$/*t*-BuOH à 185°C. La réaction principale (~90%) implique une condensation de Claisen suivie par une réaction de rétro Diels–Alder provoquant l'élimination d'éthylène et une coupure de Haller–Bauer. On a identifié et caractérisé tous les composants acides et phénoliques qui représentent 90% des produits; cette identification a été principalement effectuée par rmn du ^{13}C.

[Traduit par le journal]

It is well-established that proton abstraction from ketones can occur at positions more remote from the carbonyl group than the α-carbons to generate β-enolates in a variety of systems (1–3) and even γ-enolates in a few cases (1*a*, 4). Such enolates are potentially useful for synthesis since skeletal rearrangements can occur by protonation at sites other than that of the initial proton abstraction. It is therefore of interest to define the scope and limitations of these β- and γ-enolizations more precisely. One particular feature which merits attention is the possibility of remote enolization competing with α-enolate formation since a successful competition would enhance the synthetic utility of the former significantly. With few exceptions, the generation of β- and γ-enolates has been investigated with systems either lacking α-protons or having α-protons at bridgeheads thus generally rendering enolization difficult if not precluding it because of Bredt's rule. A notable exception is the isocamphanone–camphor system (1*a*) for which it was found that β-enolization dominated in terms of product composition since the α-enolates which are undoubtedly formed did not undergo Claisen condensation or other side reactions to appreciable extents; ketone recoveries were ~80%. Similarly β-enolization dominates in the cases of the bicyclo[3.2.1]octanones (3, 4*c*, 5); although these α-enolize at bridgehead carbons the resulting α-enolates are hindered, as are the available carbonyl sites and Claisen condensation was not observed (3, 4*c*, 5). From these earlier studies, we have shown that the α,α-dimethyl derivatives of bicyclo[2.2.2]octanone and bicyclo-[3.2.1]octan-6-one are interconvertible via β-enolization (3, 5) albeit very slowly. However, the corresponding derivatives of bicyclo[2.2.2]octenone (**1**), bicyclo[3.2.1]oct-2-en-6-one, and its Δ^3 isomer are readily isomerized (5) under typical β-enolization conditions, *t*-BuO$^-$–*t*-BuOH, 185°C. Since the half-life for equilibration of the latter ketones is a few hours, it was felt that this system would be suitable for examination of competitive α- and β-enolization. Since the [3.2.1] skeleton was expected to be the more stable from our results for the α,α-dimethyl derivatives (5), **1** was chosen for study and we wish to present the results in this paper. The major path involved Claisen condensation followed by retro Diels–Alder and Haller–Bauer cleavage. These products were identified largely by ^{13}Cmr spectroscopy; these data are presented and discussed.

Experimental

The general procedure described previously (3) was

[1]For part 69 see ref. 8.

employed for the reaction of **1** (6) but the nature of the reaction products necessitated changes in the work-up. After cooling, the individual reaction tubes were opened and the contents poured into water and ether. The ethereal layer was extracted 5 times with 20% sodium hydroxide solution and all aqueous solutions were combined. After acidification, the acidic reaction products were extracted with methylene chloride and the methylene chloride aliquots were combined and reextracted with 10% sodium carbonate solution. Acidification of the latter afforded the carboxylic acid products. A pure sample of the major component of this mixture was obtained by recrystallization from pentane–ether, mp 125–126°C. While the majority of the phenolic product was isolated by evaporation of the methylene chloride solution, some phenol was also present in the original 'neutral' mixture obtained by evaporation of the ether solvent. Gas chromatographic (gc) analyses were done with FFAP or diethylene glycol succinate (DEGS) columns. Preliminary gc analysis of the carboxylic acid fraction indicated that examination of these components as their methyl esters would be better. Consequently the total carboxylic acid fraction was esterified with diazomethane in the usual fashion. Analysis with FFAP columns revealed the presence of three major components in a ratio of 20:4:1; these were readily separated by preparative gc. The individual esters were characterized by their ir, uv, mass, ^{1}H, and ^{13}C spectra. Similarly, the products obtained by hydrogenation over PtO_2 and over Pd/C were identified and characterized. Hydrolyses to the parent carboxylic acids were also carried out in most cases. Precise mass measurements were obtained for most of these esters and acids. The phenolic product was a single compound, mp 56.5–57.5°C, and was found to be identical with authentic 2-phenylphenol by mixture melting point, ir, mass, ^{1}H, and ^{13}C spectra; ^{13}Cmr ($CDCl_3$) δ: 152.4(C-1), 128.2(C-2), 130.3(C-3), 120.8(C-4), 129.1(C-5), 115.9(C-6), 137.2(C-1, phenyl) 129.1(C-2, 3, 5, 6, phenyl), 127.7(C-4, phenyl). The neutral fraction, constituting $<10\%$ of the total product, was found to contain at least seven components on a DEGS column. One of these, present in distinctly larger amount than the others, exhibited the same retention time as **1**. Complete extraction of 2-phenylphenol from the neutral fraction was never realized but its retention time on the DEGS column was very long, more than 2 h longer than those of the other components. The combined yield of the isolated carboxylic acids and phenol was ca. 75%.

Hydrogenation Experiments

In an initial experiment, a pure sample of the major carboxylic acid (100 mg) was dissolved in ether containing PtO_2 (40 mg) and hydrogenated at 4 atm for 4 h. Proton and ^{13}C spectra showed the absence of olefinic and aromatic unsaturation in the product, while gc analysis on a 10% FFAP column after esterification revealed the presence of two components in essentially equal amounts. These were subsequently shown to be the methyl esters of the 4-cyclohexylmethylcyclohexanecarboxylic acids. An analogous hydrogenation using Pd/C was found to be much slower, but with the methyl ester of the major carboxylic acid (90 mg) in methanol containing 10% Pd/C (20 mg) hydrogenation occurred at 1 atm in 19 h to afford a 60:40 mixture of two compounds subsequently identified as the methyl esters of the 4-benzylcyclohexanecarboxylic acids **6** and **7**. After separation of these esters by gc on a 15% FFAP column, each was hydrolyzed to the parent acid by refluxing in 12% aqueous sodium hydroxide solution overnight. Acid **6** whose ester had the shorter retention time, melted at 93.5–94.5°C. Precise mass calcd. for $C_{14}H_{18}O_2$: 218.1306; found: 218.1311. Acid **7** melted at 87–8°C (lit. (7) 79–80°C); precise mass found: 218.1310. Similar hydrogenation experiments with the total acid product, after esterification, afforded the same two materials, establishing the isomeric nature of the three acids.

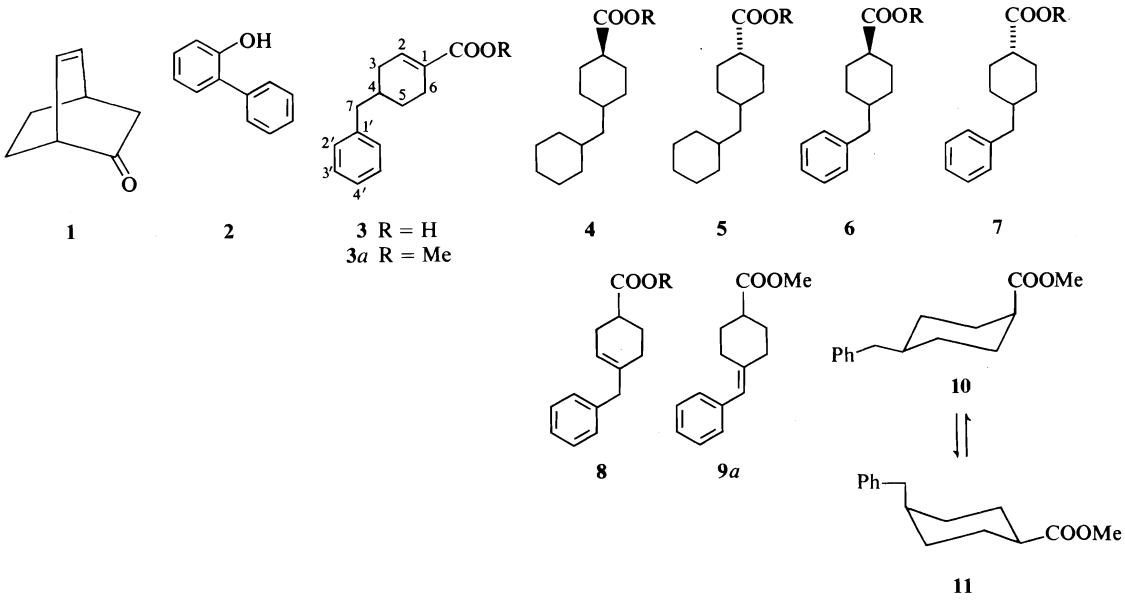
Spectra

The ^{13}C spectra were obtained with a Varian XL-100-15 system operating in the Fourier transform mode at 25.2 MHz with square-wave modulated decoupling or single frequency off-resonance decoupling at 100 MHz. The samples were examined as 5–10% (w/v) solutions in $CDCl_3$ and the data have an estimated precision of ± 0.05 ppm. Proton spectra were recorded with Varian T60 and XL-100 instruments using the same solutions.

Results

Preliminary experiments using our usual isolation procedure (3) quickly revealed the necessity for modifications. Initially the neutral fractions were relatively small indicating the presence of substantial proportions of acidic products. Acidification of the aqueous alkaline layer followed by methylene chloride extraction gave a product containing two major fractions with markedly different retention times on gc analysis. These were readily separated by reextraction of the methylene chloride solution with sodium carbonate solution. Evaporation of the methylene chloride furnished a low melting solid **2** (mp 56–57°C) which exhibited only sp^2 absorption in its ^{13}Cmr spectrum. Its precise mass, 170.0727, compared favorably with that calculated for $C_{12}H_{12}O$, 170.0731, and its infrared spectrum indicated the presence of hydroxyl absorption. Comparison of its physical properties (ir, ^{1}Hmr, ^{13}Cmr) and gc analysis with those for authentic 2-phenylphenol showed **2** to be identical with the latter.

The acidic product, soluble in Na_2CO_3 solution, was found by gc analysis to contain three components; samples of the major acid were isolated by recrystallization from pentane–ether. This acid (**3**) was examined by nmr spectroscopy. Its proton spectrum contained a complex multiplet centred at 7.2 ppm arising from six nuclei. The characteristic carboxyl proton absorption was evident at 10.40 ppm and a doublet due to two protons appeared at 2.61 ppm ($J \sim 7$ Hz). The infrared spectrum exhibited absorption characteristic of carboxylic acids and of aryl



rings, with the carbonyl absorption at 1675 cm^{-1}. The ^{13}C spectrum exhibited signals typical of a phenyl group: 140.3(C-1), 129.1(C-2, 6), 128.3 (C-3, 5), and 126.0(C-4) ppm as well as the signals for a trisubstituted double bond: 141.7(CH) and 129.8 ppm. The carbonyl absorption appeared at 172.9 ppm. In the higher field region, methylene signals occurred at 23.7, 27.9, 32.3, and 42.4 ppm with a lone methine signal at 34.5 ppm. These data are consistent with the formulation of acid **3** as 4-benzylcyclohexene-1-carboxylic acid and a precise mass determination of 216.1133 agreed nicely with that calculated for $C_{14}H_{16}O_2$, 216.1149. Esterification with diazomethane furnished the methyl ester (**3***a*) which exhibited a similar ^{13}Cmr spectrum to that for **3** and its carbonyl absorption in the infrared occurred at 1705 cm^{-1}.

Preliminary attempts to hydrogenate the double bond of **3** over PtO_2 yielded a product totally lacking aryl and olefinic absorption in the ^1H and ^{13}C spectra. Esterification with diazomethane followed by gc analysis showed this product to contain two components in approximately equal amounts which were separable by preparative gc. Both esters **4***a* and **5***a* exhibited nine saturated carbon signals, four of which had twice the intensity of the others, in addition to the carbonyl and methoxyl absorptions near 176 and 51 ppm, respectively. The shieldings of ester **4***a*, having the shorter retention time, tended to be higher than those for **5***a*. The presence of four equivalent pairs of carbons confirmed that these esters contained a plane of symmetry. With Pd/C as catalyst, the hydrogenation of **3** proceeded sluggishly whereas with **3***a* a smooth conversion to a 2:3 mixture of two nonconjugated esters (**6***a*, **7***a*) was realized. These esters, after isolation by preparative gc, exhibited carbonyl absorption at 1727 and 1720 cm^{-1}, respectively, and both gave ^{13}C spectra containing signals characteristic of a phenyl group, a COOMe function, and five saturated carbon peaks, two of which had twice the intensity of the other three. As before, ester **6***a* with the shorter retention time had the somewhat more shielded carbon nuclei. Hydrolysis of each of these esters furnished samples of the corresponding acids as crystalline compounds. Acid **6** melted at 93–94°C while **7** melted at 87–88°C. The melting point for *trans*-4-benzylcyclohexanecarboxylic acid (**7**) has been reported (6) as 79–80°C but the earlier work did not describe a rigorous purification. We conclude that the earlier value refers to a sample contaminated with a small amount of the *cis* isomer **6**.

With these results in hand, attention was turned to characterization of the mixture of acids isolated by extraction with Na_2CO_3 solution. Initially, the mother liquors depleted in **3** were examined. Esterification with diazomethane furnished a mixture of three esters having distinctly different retention times upon gc analysis; that with the longest time was **3***a*. Hydrogenation of the mixture over PtO_2 and Pd/C gave the same

products as those found from the experiments with **3***a*. Thus the two unknown compounds differ from **3***a* only in the location of the double bond. Ester **8***a*, having the shortest retention time, exhibited carbonyl absorption at 1725 cm^{-1} in the infrared and λ_{max} of 250 nm (ε = 180) in the ultraviolet. The latter may be compared with the values of 260 nm (210) found for **3***a*. The ^{13}C spectrum of **8***a* contained, in addition to the phenyl and COOMe signals, those for a trisubstituted double bond, 121.1(CH) and 137.0 ppm, four methylene signals, 25.5, 27.3, 27.8, and 44.2 ppm, and a lone methine carbon at 39.3 ppm. These data indicate **8***a* to be the methyl ester of 1-benzylcyclohexene-4-carboxylic acid. This is supported by the appearance of a two-proton singlet at 3.20 ppm in the proton spectrum of **8***a* ascribable to a methylene group which is allylic and benzylic. The ^{13}C methylene signal at 44.2 ppm also strongly suggests the presence of a benzylic methylene carbon, tending to rule out the remaining double bond isomer having a trisubstituted olefinic bond. The third carboxylic acid (**9**) was found to be the latter isomer on the basis of the following observations. For the methyl ester in the ultraviolet spectrum, λ_{max} was 290 nm (400) and the proton spectrum contained, in addition to a five-proton multiplet at 7.20 ppm for the phenyl ring, a one-proton singlet at 6.23 ppm. These features are consistent with a styryl fragment. As in the cases of **3***a* and **8***a*, the ^{13}C spectrum for **9***a* consisted of four phenyl signals, those for a trisubstituted double bond, 123.3 (CH) and 138.0 ppm, four methylene signals, 27.8, 29.7, 30.4, and 35.8 ppm, and a methine carbon absorbing at 42.9 ppm. The absence of a methylene carbon near 44 ppm is good evidence against the presence of a benzylic methylene group. Thus the structures of the carboxylic acid products are **3**, **8**, and **9**. Precise mass measurements for all of the esters described above were obtained as well as the ^{13}C spectra. These data are tabulated in Table 1 together with the corresponding results for most of the carboxylic acids.

A series of runs for 5, 20, and 40 h reaction times were carried out and the product distribution was assessed by gc analysis. The product for the longer intervals was essentially unchanged from the results obtained for the shortest reaction periods. At least 90% of the product was in the acidic fractions with the total carboxylic acid fraction equal to the yield of phenol **2**. The neutral fraction constituted less than 10% of the

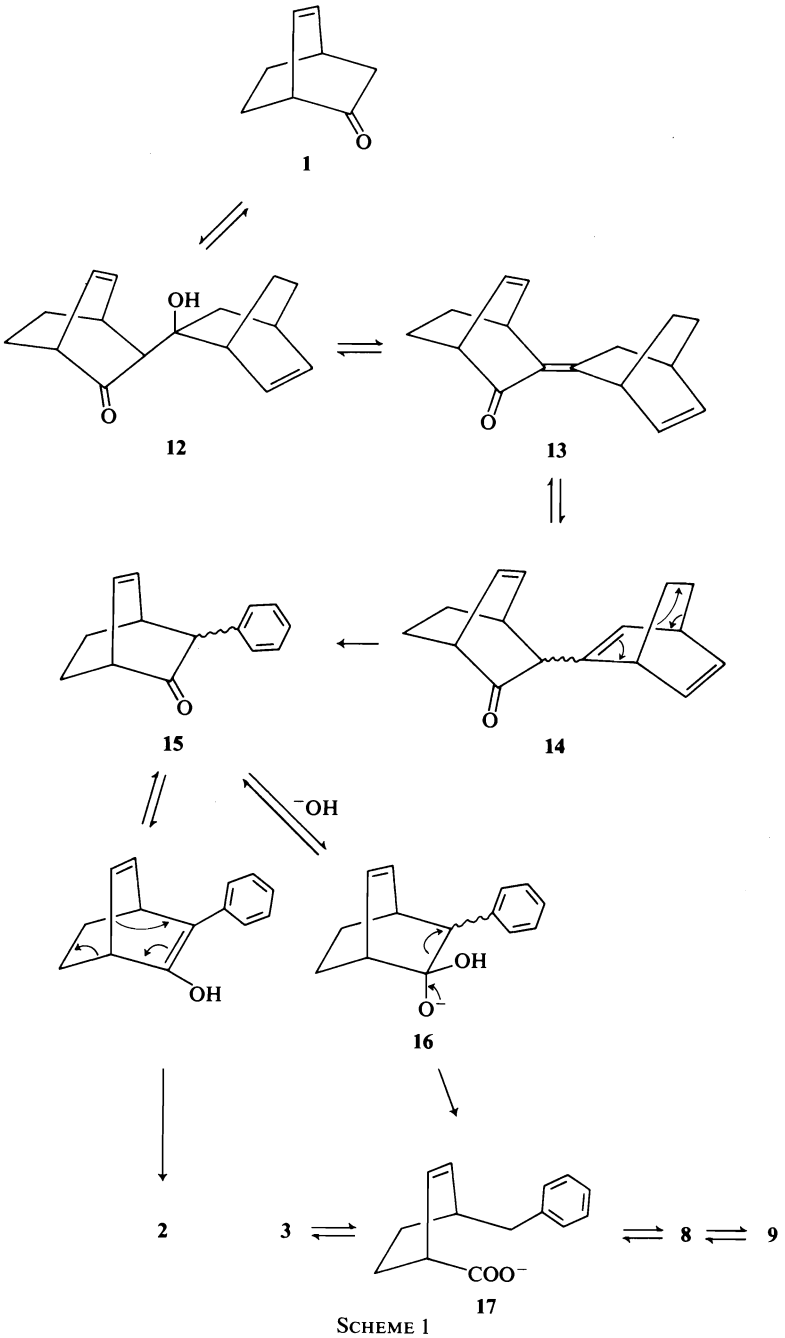
material and was found to contain at least seven components by gc analysis. The three carboxylic acids were produced in a ratio of approximately 20:4:1 for **3**, **8**, and **9**, respectively. Although traces of a fourth acidic component constituting $<1\%$ of the acid fraction were detected by gc, this material was not isolated.

Discussion

The assignments for individual carbons listed in Table 1 follow from straightforward considerations. The carboxyl and methoxyl signals appear in characteristic regions while the phenyl absorptions are similarly readily identified, although the assignments for the *ortho* and *meta* carbons may be interchanged. The upfield shift for the carboxyl carbon in **3** relative to the others is a clear indication of its conjugated nature. The lack of a benzylic methylene signal in the spectrum of **9***a* near 44 ppm has already been noted as strong support for the assigned structure rather than that for the isomeric **8***a*. The slightly increased shieldings found for **4***a* vs. **5***a* and **6***a* vs. **7***a* point to the stereochemical assignments of *cis* vs. *trans*. In these cases, the *trans* isomers exist essentially as single conformations with both substituents in equatorial orientations. However, the *cis* isomers populate two axial–equatorial conformers, e.g. **10** and **11** for **6***a* but **10** should predominate since the conformational free energy of the carbomethoxyl group is smaller than that expected for the benzyl group, or, for **4***a*, the cyclohexylmethyl group. For **7***a*, the less shielded of the two methine carbon signals was assigned to C-1 because of its similarity to the corresponding signals in the spectra of methyl cyclohexanecarboxylate and its *trans*-4-*t*-butyl derivative, i.e. 43.4 vs. 43.1 and 43.4 ppm, respectively. Similar considerations led to the distinction between the C-2 and C-3 signals for **7***a*. In the *cis* isomer **6***a* each of these nuclei is expected to absorb at higher field because of the axial substituents and the listed assignments follow this reasoning. For **4** and **5**, as well as the corresponding methyl esters, specific methylene assignments presented a greater problem. For **5** and **5***a*, comparisons with the results for **7** and **7***a* pointed to the listed assignments for C-2(6) and C-3(5). For the *cis* isomers **4** and **4***a* these centres would be expected to be shielded. Some support for these methylene carbon assignments for the disubstituted cyclohexane ring is provided by the occurrence of two methylene signals, each due to two carbons, at 26.5 and 33.7 ppm in the spectra of **4**, **4***a*, **5**, and **5***a*; these are most readily assigned to C-3′(5′) and C-2′(6′) respectively, in the monosubstituted cyclohexane ring. These carbons may be expected to be essentially independent of the orientation of the cyclohexylmethyl group in these isomers. The assignments for C-3 and -5 for **9***a* followed from the fact that C-3, *cis* with respect to the phenyl ring, will be the more shielded, but the C-2 and -6 signals cannot be unequivocally distinguished.

The generation of the products obtained upon treatment of **1** with *t*-BuO^-–*t*-BuOH at 185°C is readily explained as shown in Scheme 1. The Claisen product **12** can reversibly dehydrate to **13** which will be in equilibrium with minor amounts of **14**. (Only one of the possible four isomers of **13** is included in the scheme for simplicity.) Irreversible loss of ethylene in a retro Diels–Alder reaction leads to **15**, the enol form of which can undergo a second retro Diels–Alder loss of ethylene to produce **2**. Hydroxide ion, formed from the dehydration step, attacking the carbonyl group of **15** leads to **16** with Haller–Bauer cleavage to generate **17** irreversibly. From the product distribution, **15** is partitioned approximately equally to **2** and **17**. Double bond migration to **3** is strongly favored by the formation of the conjugated system. Although **9** is also conjugated, it was found to be the minor component in the carboxylic acid mixture presumably because of steric destabilization arising from the close approach of the phenyl ring to the C-3 methylene group in a planar conjugated arrangement. Because of the symmetry of the system, **8** can be generated in two ways, increasing its probability of formation. Since the proportions of the three acids are independent of reaction time the observed ratios must represent the equilibrium concentrations. Presumably trace quantities of **17** may be present, as suggested by a small unidentified peak in gas chromatograms of the acid fraction.

Clearly Claisen condensation occurs readily in this system. Although this could be anticipated, the condensation is a series of equilibria and β-enolization of **1** to the more stable [3.2.1] skeleton could indeed occur in competition. The retro Diels–Alder process, however, is irreversible and clearly upsets the condensation equilibria by generating **15**. It follows, therefore, that β-



SCHEME 1

enolization is much slower and the retro Diels–Alder reaction removes **1** from the reaction mixture too rapidly for significant rearrangement via a β-enolate. Since, with few exceptions, the retro Diels–Alder process requires elevated temperatures, a successful competition between α- and β-enolization may be realized at significantly lower temperatures. Experiments to test this suggestion are under investigation.

A.W. ADDISON, NAR S. DALAL, YUMIKO HOYANO, SYTZE HUIZINGA, and LARRY WEILER. Can. J. Chem. **55**, 4191 (1977).

Dihydro-TCNDQ was prepared from biphenyl. The dianion salts of TCNDQ with alkali metal and tetraalkylammonium counter ions were prepared and characterized by their nmr and uv-visible spectra. Solutions of these dianions undergo two one-electron oxidations at −0.31 and −0.15 V in DMF. The electrochemistry is complicated by a second chemical process involving the monoanion $TCNDQ^{\cdot-}$. This was postulated to involve a dimerization of $TCNDQ^{\cdot-}$ and this process was also implicated in the analysis of the uv-visible spectra of this anion. The $TCNDQ^{\cdot-}$ anion has a solution esr spectrum of over 25 lines which have been analyzed by a computer simulation of the spectrum.

A. W. ADDISON, NAR S. DALAL, YUMIKO HOYANO, SYTZE HUIZINGA et LARRY WEILER. Can. J. Chem. **55**, 4191 (1977).

On a préparé le dihydro-TCNDQ à partir du biphényle. On a pu préparer et caractériser par leurs spectres rmn et uv-visible les sels dianioniques du TCNDQ avec des ions de métaux alcalins ou de tétraalkylammonium comme contre ions. Des solutions de ces dianions subissent deux oxydations monoélectroniques à −0.31 et −0.15 V dans le DMF. L'électrochimie est compliquée par un deuxième processus chimique impliquant le monoanion $TCNDQ^{\cdot-}$. On a postulé que ce processus implique une dimérisation du $TCNDQ^{\cdot-}$ et on a aussi impliqué ce processus dans l'analyse du spectre uv-visible de cet anion. L'anion $TCNDQ^{\cdot-}$ a un spectre rpe en solution comprenant plus de 25 lignes qui ont pu être analysées par une simulation du spectre par ordinateur.

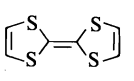
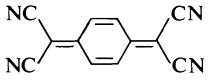
Introduction

In the past few years there has been a great deal of interest in the synthesis and study of organic charge transfer complexes. Much of this interest arises from the novel transport properties of these materials, for example TTF·TCNQ (For a recent review of this field see ref. 1). A number of groups has been involved in the synthesis of new donors and acceptors to prepare

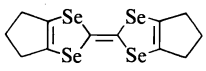


TTF



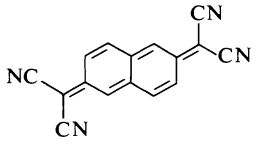
TCNQ

additional solid complexes and also to lead to a better understanding of the electronic properties of these materials. A range of donors has been prepared, the most promising of which appears to be HMTSF (2). However, none of the complexes of these donors has room temperature



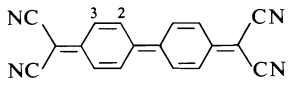
HMTSF

electrical conductivities substantially above that of TTF·TCNQ which is the original organic metal (3). Thus attention has turned to the synthesis of new acceptors. A number of studies have shown that substitution on the basic TCNQ skeleton usually produces an adverse effect on the conductivities of charge transfer solids with these acceptors (4, 11). Hence one is forced to investigate acceptors with a carbon skeleton different from that of TCNQ. The only successful venture in this area has been the preparation of TNAP (5) and its complex with TTF (6).



TNAP

An obviously attractive new acceptor would be tetracyanodiphenoquinodimethane (TCNDQ). The reduction potentials of the corresponding quinone (7) indicate that this basic carbon



TCNDQ

skeleton is an excellent two electron acceptor. Unfortunately, attempts to prepare TCNDQ have led only to formation of a polymeric material (8*a*, *b*).[1] However, we have recently been able to prepare a number of salts of the anions of TCNDQ and study their physical properties.

Experimental

Visible and uv absorption spectra were obtained on Cary-14 and 17D instruments, and ^{1}H nmr spectra on a Varian Associates T60 spectrometer, with chemical shifts (δ) reported vs. internal TMS. Infrared spectra were obtained with a Perkin-Elmer 700, mass spectra from an AEI MS-9 spectrometer operating at 70 eV, and esr spectra on a Varian E3 instrument, calibrated with a ^{1}H nmr probe. Fluorescence spectra were recorded on an Aminco-Bowman instrument, at 0.5 mm slit widths, wavelength-calibrated with a mercury emission lamp.

Electrochemistry was performed at 25.0 ± 0.2°C with a three electrode cell, using apparatus incorporating a PAR-173 potentiostat and PAR-176 *i*/*E* converter. A Beckman rotating platinum disc electrode was used for dc polarography, and also served as a stationary electrode for cyclic voltammetry. Current vs charge plots were obtained by integration (McKee–Pedersen MP-1012A integrator) of the anodic current, and using the current and its integral as inputs for an X–Y recorder. The supporting electrolyte was G. F. Smith Chemical Co. polarographic grade tetraethylammonium perchlorate, dried *in vacuo* over P_4O_{10}. The reference electrode was a Ag|$AgClO_4$ (0.01 *M*), TEAP (0.1 *M*), CH_3CN half-cell, the potential of which we have measured as being 0.30 V positive of the sce, both in CH_3CN/TEAP at 25°C. Acetonitrile was distilled off P_4O_{10} under nitrogen before use, dimethylformamide was vacuum-distilled off P_4O_{10} or CaH_2, and 9,10-diphenylanthracene was recrystallized from acetonitrile, while other reagents were used as received.

4,4′-Biphenyldiacetonitrile (2)

Biphenyl was bisbromomethylated with HBr and paraformaldehyde in ca. 30% yield according to the procedure of Reynolds and Durham (9). This was converted into the bisnitrile (**2**) in ca. 90% yield by displacement of the bromide with NaCN in aqueous ethanol – dioxane (9). 4,4′-Biphenyldiacetonitrile (**2**) was characterized by the following data: mp 182–185°C (lit. (9) mp 185–187°C); ir ($CHCl_3$): 2280 cm^{-1}; nmr ($CDCl_3$) δ: 3.77 (s, 4H) 7.30 and 7.51 (AB quartet, J = 8 Hz, 8H).

Dimethyl 4,4′-Biphenyl-α,α,α′,α′-tetracyanodiacetate (3)

A mixture of freshly prepared sodium methoxide (56.5 mmol from 1.30 g of sodium) and 5.04 g (21.7 mmol) of bisnitrile (**2**) from above in ca. 300 ml of toluene was refluxed under nitrogen for 0.5 h to yield a clear solution. Then 25.4 g (283 mmol) of dimethyl carbonate were added and this mixture was refluxed for an additional 3 h. The solvents were then distilled from the reaction mixture until the temperature of the distillate reached 100°C. Finally, ca. 50 additional millilitres of toluene were distilled from the reaction mixture. The reaction mixture was cooled in ice and treated with 4.0 g (65 mmol) of cyanogen chloride in 20 ml of toluene. This mixture was heated to reflux for 1.5 h. Most of the solvents were distilled off and the residue was poured into a mixture of dilute aqueous acid and CH_2Cl_2. The aqueous layer was extracted with CH_2Cl_2 and the extracts were combined, washed with water, dried ($MgSO_4$), filtered, and the solvents removed to yield 9 g of crude product. This crude material was recrystallized from CH_2Cl_2–MeOH to yield 7.1 g (85%) of compound **3**: mp 160–162°C; ir ($CHCl_3$): 2280, 1770 cm^{-1}; nmr ($CDCl_3$): 3.90 (s, 6H), 7.7 (br s, 8H); ms *m*/*e* (relative intensity): 398 (0.3), 354 (2), 332 (6), 321 (8), 310 (6), 306 (12), 296 (8), 295 (10), 282 (12), 281 (11), 276 (21), 256 (16), 232 (35), 217 (100), 190 (70), 152 (20). *Anal.* calcd. for $C_{22}H_{14}N_4O_4$: C 66.32, H 3.54, N 14.07; found: C 66.18, H 3.61, N 14.14.

4,4′-Biphenyl-α,α′-dicyanodiacetonitrile (Dihydro-TCNDQ) (1)

(*a*) Chromatography of diester **3** on silica gel produced varying yields of dihydro-TCNDQ (1).

(*b*) Diester **3** (4 g, 0.010 mol) was dissolved in 10 ml of dioxane and 45 ml of 10% aqueous KOH. This solution was heated to 70°C for about 15 min, cooled to room temperature, and acidified with 6 *N* HCl to p*H* 2. The acid mixture was extracted with CH_2Cl_2. The extracts were combined, dried ($MgSO_4$), filtered, and the solvents evaporated to yield 2.3 g (82%) of purple solid, mp 172–179°C (lit. (8*a*) mp 176–181°C); ir ($CHCl_3$): 2260, 1495, 990 cm^{-1}; nmr ($CDCl_3$) δ: 5.1 (s, 2H), 7.6 (s, 8H).

Salts of the Dianion TCNDQ^{2-}

(*a*) Solutions of M_2^+ TCNDQ^{2-} were prepared by dissolving dihydro-TCNDQ (**1**) in an aqueous solution of NaOH or KOH, or by dissolving **1** in acetonitrile and treating with slightly more than 2 equiv. of NaH or KH. These solutions tended to oxidize quite rapidly; however, a trace of $NaBH_4$ stabilized the solutions for spectroscopic characterization, which included uv (CH_3CN) λ_{max}: 377 (5.1 × 10^4) and nmr (CD_3CN) δ: 6.83 (d, J = 8 Hz, 4H) and 7.22 (d, J = 8 Hz, 4H).

(*b*) The bistetraethylammonium and bistetra-*n*-butylammonium salts of TCNDQ^{2-} were prepared from the diester **3** or **1** by first forming solutions of the sodium salt of TCNDQ^{2-}. These solutions were obtained by dissolving **3** or **1** in aqueous NaOH, taking precautions to exclude oxygen. The solutions of TCNDQ^{2-} were filtered and treated with 2–3 equiv. of the tetraalkylammonium hydroxide, also in water. The bistetraalkylammonium salts precipitated in yields of 60–80%. The bistetraethylammonium TCNDQ^{2-} salt had mp ca. 70°C and resisted efforts at purification. However, the bistetra-*n*-butylammonium TCNDQ^{2-} salt was recrystallized from ethanol–water (1:3) to yield pure salt, mp 155–160°C; nmr (CD_3CN) δ: 1.1 (br t, J = 7 Hz, 24H) 1.6 (br m, 32H), 3.2 (br t, J = 8 Hz, 16H), 6.9 (d, J = 8 Hz, 4H), 7.3 (d, J = 8 Hz, 4H). *Anal.* calcd. for $C_{50}H_{80}N_6$: C 78.48, H 10.54, N 10.98; found: C 78.19, H 10.50, N 10.77.

[1]L. D. Pedersen and L. Weiler. Unpublished results.

Sodium Salt of TCNDQ$^{\cdot-}$

Poly-TCNDQ was prepared from dihydro-TCNDQ (**1**) and then converted into crude NaTCNDQ as outlined by Hertler (*8a*). This crude material was purified by continuous Soxhlet extraction with CH_3CN. Evaporation of the acetonitrile solution gave a black solid which could not be combusted in an elemental analysis. The solid was characterized by solution uv-visible and esr spectra. The solid also has an intense single esr line at $g = 2.0035$.

Results and Discussion

Synthesis of Dihydro-TCNDQ and its Anions

Dihydro-TCNDQ (**1**) was prepared as outlined in Fig. 1. Biphenyl was converted into 4,4′-biphenyldiacetonitrile (**2**) using the method of Reynolds and Durham (9). The anion of nitrile **2** was reacted with dimethyl carbonate followed by cyanogen chloride to yield dimethyl 4,4′-biphenyl-α,α,α′,α′-tetracyanodiacetate (**3**) according to the procedure of Sandman and Garito (10). Diester (**3**) was hydrolyzed and decarboxylated to yield dihydro-TCNDQ (**1**) by silica gel chromatography or by hydrolysis in aqueous base. A number of attempts to directly oxidize dihydro-TCNDQ (**1**) to TCNDQ were unsuccessful (8, 10).[1] Thus we turned to the preparation of the various salts of TCNDQ to study the metathetical reactions of these salts with salts of donors (D), for example eq. 1 (11).

[1] $M^+TCNDQ^- + D^+X^- \rightarrow D{\cdot}TCNDQ + MX$

$(M^+)_2TCNDQ^{2-} + D^{2+}(X^-)_2 \rightarrow D{\cdot}TCNDQ + 2MX$

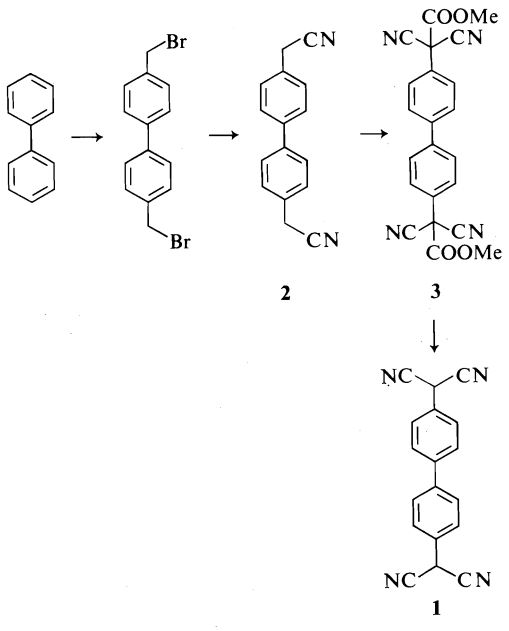


FIG. 1. Preparation of dihydro-TCNDQ (**1**).

The dianions of TCNDQ were prepared by deprotonation of dihydro-TCNDQ (**1**) with a variety of potassium and sodium bases to give $(M^+)_2TCNDQ^{2-}$. These salts were characterized by their nmr spectra and uv-visible spectra. The proton nmr spectrum of **1** in $CDCl_3$ has a two-proton singlet at δ 5.05 and an eight-proton singlet at δ 7.58. The nmr spectrum of the sodium salt of $TCNDQ^{2-}$ in acetonitrile shows an AB quartet at δ = 6.83 and 7.22 (J = 8 Hz). The disappearance of the signal at δ 5.05 in **1** and the upfield shift of the aromatic protons is consistent with the formation of $TCNDQ^{2-}$. As a result of our esr and molecular orbital (mo) studies (*vide infra*) we assign the signal at δ 6.83 to the protons on C-3. The mo calculations indicate that this carbon has a greater electron density than C-2 in the dianion. In addition the doublet at δ 6.83 in $TCNDQ^{2-}$ broadens noticeably when air is passed through the solution. This is attributed to formation of the radical anion $TCNDQ^-$ and the larger spin density on C-3 (*vide infra*) would lead to preferential broadening of this signal. This effect is reversed by the addition of $NaBH_4$.

Dihydro-TCNDQ (**1**) was converted into a polymer of TCNDQ with a number of oxidizing agents.[1] Treatment of the polymer with sodium iodide yielded crude NaTCNDQ (*8a*) which was purified via Soxhlet extraction with acetonitrile. This material was characterized as the radical ion salt, NaTCNDQ, by esr and uv-visible spectroscopy (*vide infra*).

Redox Chemistry of Anions of TCNDQ[2]

The TCNDQ redox system is not straightforward in its electrochemical behaviour, which is typified by the cyclic voltammagram in Fig. 2. Of three oxidation processes observable for $TCNDQ^{2-}$, in voltammetry the first two yield equivalent anodic currents, while the peak-to-peak potential separation of the lowest potential process (55–65 mV) is suggestive of an $n = 1$ redox step (13). With regard to this first oxidation process, it was also observed that (*i*) the voltammetric peak current function ($i_pc^{-1}v^{-1/2}$) in DMF is within 10% of that observed for the 1ē reduction (14) of 9,10-diphenylanthracene in DMF; (*ii*) the value of $n^{1/2}$ obtained from complementary voltammetry and chronoamperom-

[2]Abbreviations: TBA, tetra(*n*-butyl)ammonium; TEAP, tetraethylammonium perchlorate; DMF, *N*,*N*-dimethylformamide; rpe, rotating platinum electrode.

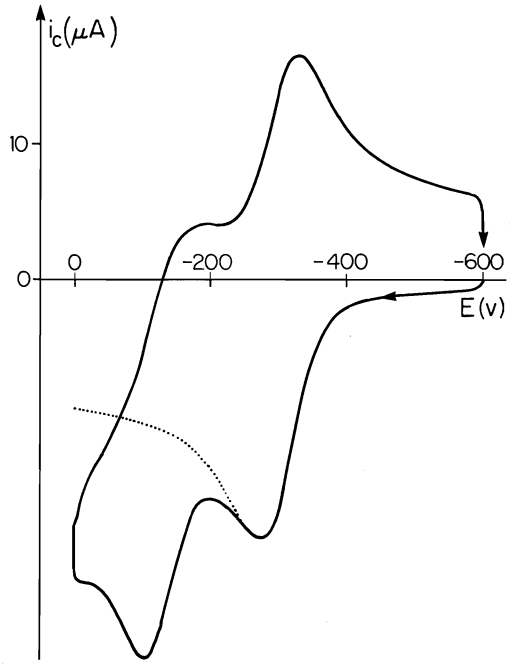

FIG. 2. Cyclic voltammagram of 0.23 mM $(TBA)_2$-(TCNDQ) in DMF–TEAP (0.1 M) at Pt-disc electrode, scan rate 0.167 V s^{-1}. The dashed curve is the extrapolated current decay of the first anodic peak (12).

etry at the same electrode (15) is 0.89 if reversibility is assumed; (*iii*) at the rpe (Fig. 3), good linearity of the $i_L:\omega^{1/2}$ plot (16) demonstrated the first oxidation to be diffusion controlled, while (*iv*) the ratio of the polarogram's slope at $E = E_{1/2}$ to the limiting current, $di/(i_L\, dE)$, was

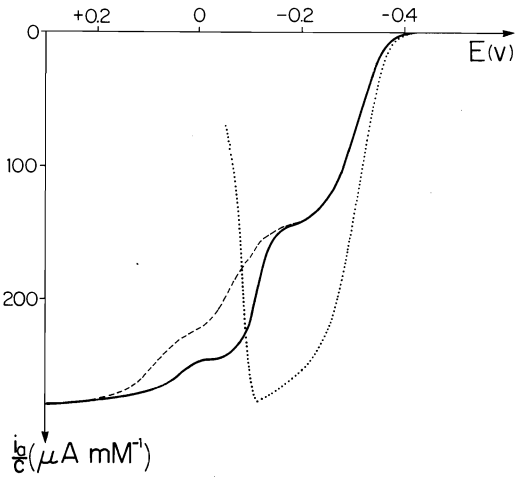

FIG. 3. Concentration-normalised rpe polarograms of $(TBA)_2(TCNDQ)$ at 30 revolutions s^{-1}: (*a*) 0.44 mM in DMF (—); (*b*) 2.0 mM in DMF (--); (*c*) 2.01 mM in CH_3CN) (· ·). Supporting electrolyte, 0.1 M TEAP.

close (9.9 V^{-1}) to the value (9.7 V^{-1}) expected for an $n = 1$ Nernstian process;[3] and (*v*) the limiting current was equivalent to that observed for the $n = 1$ 9,10-diphenylanthracene reduction. The $n = 1$ assignment was finally confirmed coulometrically (*vide infra*), and allows computation of the diffusion coefficient (Table 1) of $TCNDQ^{2-}$. As expected, the value is lower than that of TCNQ, while the $D\eta$ products (4.0×10^{-8} g cm s^{-2}) agree well with each other for the two solvents used, in which the redox process may be written as

$$TCNDQ^{2-} \rightleftharpoons TCNDQ^{\cdot-} + \bar{e}$$

The third oxidation step is resolved best in rpe polarography, which shows the second oxidation to be coupled with it, in the sense that the sum of the limiting currents of these second two waves is equal to the limiting current for the $TCNDQ^{2-} \rightarrow TCNDQ^{\cdot-}$ oxidation. This indicates that the oxidation of (nominally) $TCNDQ^{\cdot-}$ proceeds via two parallel pathways under our experimental conditions, to the product, nominally neutral TCNDQ. Precipitation (Fig. 3) of product on the electrode renders the system intractible with respect to more detailed electrochemical study, although observed dependences of the potentials of the second and third redox steps on $TCNDQ^{2-}$ concentration and on rpe rotation rate reiterate the non-Nernstian nature of the polarograms obtained for these oxidations, which are therefore observed only as steady-state results in a kinetically controlled system. The data of Table 1 are therefore derived by extrapolation to zero concentration and rotation rate where applicable. The two idealised processes

$$TCNDQ + \bar{e} \rightarrow TCNDQ^{\cdot-}$$

and

$$TCNDQ^{\cdot-} + \bar{e} \rightarrow TCNDQ^{2-}$$

are therefore separated by a potential difference (150–200 mV) considerably less than that for

[3]The usual relationship between current and potentia on a reversible polarogram

$$E = E^0 + \frac{RT}{nF} \ln\left(\frac{i_L - i}{i}\right)$$

on differentiation yields

$$\frac{di}{d\Delta} = -\frac{nF i_L e^{nF\Delta/RT}}{RT(1 + e^{nF\Delta/RT})^2}$$

where $\Delta = E - E^0 = E - E_{1/2}$ for $D_0 = D_R$. At $E = E_{1/2}$, the slope of the polarogram is $di/dE = -i_L nF/4RT$.

TABLE 1. Redox properties of TCNDQ and TCNQ[a]

[b]± 10%, computed from voltammetric peak currents (14).
[c]Oxidation of species.
[d]Lowest estimated limit; becomes more positive as concentration is increased.
[e]Reduction of species at Pt electrode (cyclic voltammetry).

TCNQ (17), but similar to that reported (7) for the structurally related 1,8-diphenoquinone. This is presumably a result of the increased delocalisation of, and thereby decreased coulombic interaction between, successive electrons added to the binuclear system.

From the measured potentials, a disproportionation constant can be calculated for the idealised reaction:

$$2TCNDQ^{\dot{-}} \rightleftharpoons TCNDQ + TCNDQ^{2-}$$

at a total TCNDQ concentration in the 1 m*M* region, $K = 2 \times 10^{-3}$, in 0.1 *M* TEAP. Hence the small potential difference between the successive process contains the implication that it is not possible to prepare solutions which contain pure $TCNDQ^{\dot{-}}$ without $TCNDQ^{2-}$ and/or TCNDQ present in these solvents.

Electrosynthesis of $TCNDQ^{\dot{-}}$ via anodic coulometry of $TCNDQ^{2-}$ was therefore performed firstly at the $E_{1/2}$ of the $TCNDQ^{2-}$/$TCNDQ^{\dot{-}}$ couple. Electrooxidation of 102 μmol of $(TBA)_2$(TCNDQ) at a platinum mesh anode at −0.31 V in 42 ml acetonitrile–TEAP resulted in the essentially linear current vs. charge plot shown in Fig. 4, intersecting the *q*-axis at 48 μF (0.47 F mol^{-1}). An rpe polarogram showed the solution to be 50 ± 5% through the first oxidation stage. Electrooxidation of 101 μmol of $(TBA)_2$(TCNDQ) in DMF–TEAP at +0.25 V was associated with the consumption of 1.93 F mol^{-1}, as judged from extrapolation of the *i* vs. *q* plot to $i = 0$. The orange solution eventually deposited a white precipitate of the (probably polymeric) neutral TCNDQ.

Electronic Spectra of Anions of TCNDQ

During electrooxidation of $TCNDQ^{2-}$ to $TCNDQ^{\dot{-}}$, the yellow solutions of the dianion became orange. A series of electrooxidation steps were carried out on a 2.3×10^{-5} *M* solution, in DMF–TEAP, and yielded the absorption spectral changes depicted in Fig. 5. The 377 nm band of $TCNDQ^{2-}$ decreased in intensity, and a structured band system appeared in the 500–550 nm region, with the spectra exhibiting an isosbestic point at 411 nm. The results obtained suggest that *both* $TCNDQ^{2-}$ and $TCNDQ^{\dot{-}}$ have absorption maxima near 375 nm, the latter with what we have deduced to be an approximately twofold decrease in intensity (Table 2). It would thus seem that the aromatic rings of $TCNDQ^{2-}$ and $TCNDQ^{\dot{-}}$ behave as electronically independent systems on the time scale of electronic absorption spectroscopy, which contrasts with our esr results below. That is, both results can be interpreted in terms of a twisted geometry with minimum interaction between the rings. Figure 6 shows that the dianion is luminescent in solution. The emission, which maximizes at 420 nm, is excited by the strong absorption in the 370 nm region, while its high intensity evidences that it is indeed fluorescence, and that a singlet ground state for $TCNDQ^{2-}$ is thereby confirmed.

When the 2.77 m*M* solution of $(TBA)_2$-TCNDQ in CH_3CN–TEAP was oxidized to

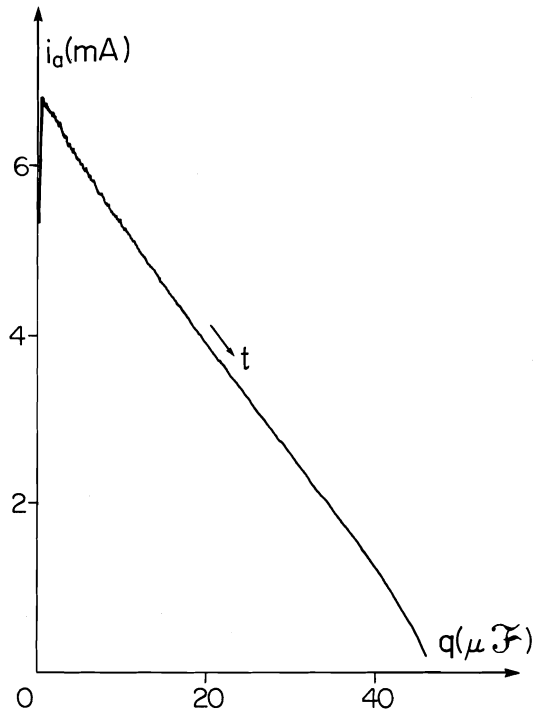

FIG. 4. Current vs. charge output from electrooxidation of $TCNDQ^{2-}$ in CH_3CN–TEAP at $E = E_{1/2}$ for first oxidation step. The current is capacitively damped.

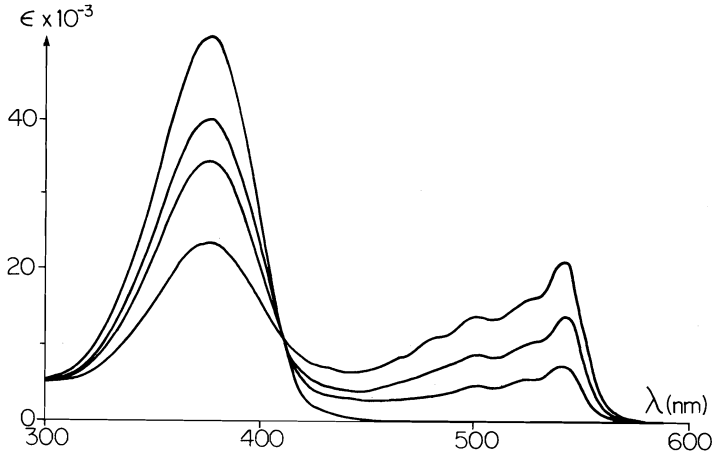

FIG. 5. Spectral changes accompanying electrooxidation of a DMF–TEAP solution of $(TBA)_2$-(TCNDQ) (2.3×10^{-5} *M*) to the radical anion, $TCNDQ^{\dot{-}}$. Decreasing absorbances near 370 nm correspond to approximately 0%, 40%, 65%, 90% oxidized respectively, as judged from application of the Nernst equation and the results of Fig. 4 to the reaction mixture at the attained potentials.

$E = E_{1/2}$, to form the $TCNDQ^{\dot{-}}/TCNDQ^{2-}$ equilibrium mixture, the acetonitrile solution showed the absorption band at ca. 375 nm and the structured band with $\varepsilon_{app} = 4200$ at 536 nm. When this solution was diluted with acetonitrile, the apparent molar absorptivity in the 375 nm region decreased, and the apparent molar absorptivity at 536 nm increased, to $\varepsilon = 73\,000$ when $[TCNDQ^{\dot{-}}] \simeq 6 \times 10^{-7}$ *M*. This concentration dependence is very suggestive of a self-association (e.g. dimerization) of the radical anion, with $TCNDQ^{\dot{-}}$ being the species exhibiting the structured absorption in the 500–550 nm region. Figure 5 shows, indeed, that electrosynthesized solutions of $TCNDQ^{\dot{-}}$ in DMF–TEAP also do not obey Beer's law, the apparent molar absorptivity at 540 nm again decreasing with increasing concentration of $TCNDQ^{\dot{-}}$. A similar phenomenon has been observed in the electronic spectrum of $TCNQ^{\dot{-}}$ in solution (17*b*), and we have previously observed strong self-association of organic radical ions in solution spectroelectrochemical studies (18). Furthermore, this postulate is consistent with our observations that (*i*) the peak voltammetric current function, $i_pC^{-1}v^{-1/2}$, for the second anodic maximum increases with decreasing scan rate, *v*, and (*ii*) the first oxidation step for $TCNDQ^{2-}$ has a peak current ratio $i_{p,c}/i_{p,a}$ greater than unity (19).

[a]0.1 *M* in TEAP.
[b]At a total TCNDQ anionic species concentration of 2.3×10^{-5} *M* of which 50% is monoanionic, 50% dianionic. Apparent ε given.

Finally, we have compared the electronic absorption spectra of TCNDQ with a number of related compounds given in Table 2. Ionization of H_2-TCNQ to yield the dianion of $TCNQ^{2-}$ produces a bathochromic shift of ca. 80 nm and indicates a strong interaction between the ring and substituents in a fully planar $TCNQ^{2-}$ ion. Phenylmalononitrile and H_2-TCNDQ on the other hand show much smaller bathochromic shifts on ionization. This would indicate that the dicyanomethylene groups in the anion of phenylmalononitrile and $TCNDQ^{2-}$ are not in the plane of the benzene ring. Also it is clear that the $TCNDQ^{2-}$ system is not fully planar (also *vide supra*). Twisting about the central CC bond and the exocyclic CC bonds is probably due to a

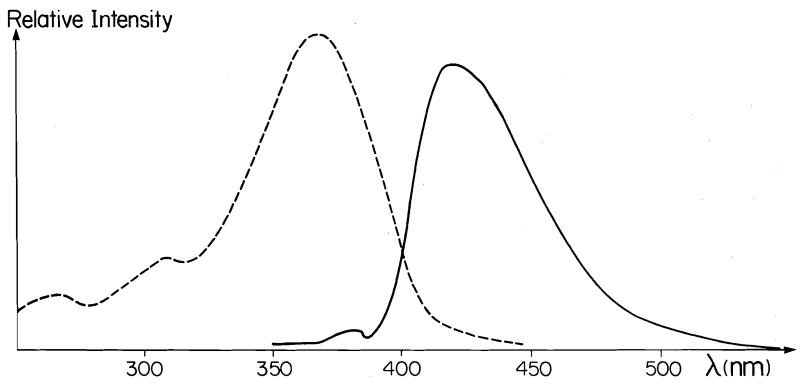

FIG. 6. Fluorescence emission (—) and excitation (--) spectra of a $\sim 2 \times 10^{-6}$ *M* solution of $(TBA)_2$-(TCNDQ) in acetonitrile. Spectra uncorrected for instrument spectral response.

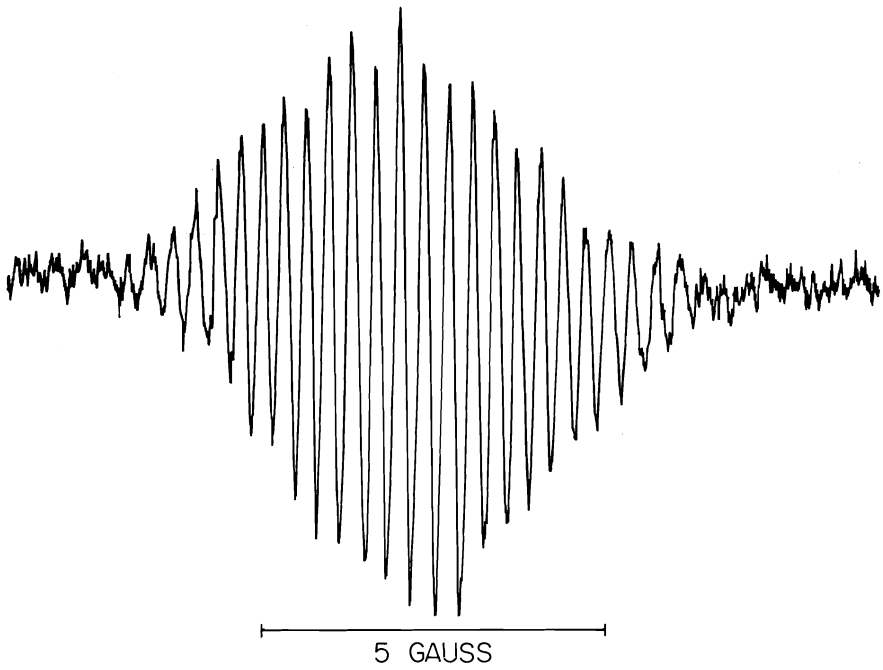

FIG. 7. Electron spin resonance spectrum of $TCNDQ^{\dot{-}}$ in DMF.

combination of steric and electrostatic effects. The bathochromic shift of the long wavelength band from $TCNDQ^{2-}$ to $TCNDQ^{\dot{-}}$ is also seen in the TCNQ anions. But the shift is much smaller in the former anions and again this is consistent with the proposal that the substituents are not conjugated in the TCNDQ system to the same extent that they are in the TCNQ system.

Electron Spin Resonance Spectra of $TCNDQ^{\dot{-}}$

The solution esr spectrum of other acceptor radical anions (20) and donor radical cations (18, 21) have been extremely useful in characterizing these species and studying aggregation (17*b*) and exchange (22) processes in solution. The esr spectrum of $TCNDQ^{\dot{-}}$ in DMF is shown in Fig. 7. The spectrum consists of over 25 lines with $g = 2.0032 \pm 0.0005$ in acetonitrile. The esr spectrum of $TCNQ^{\dot{-}}$ has over 45 lines and $g = 2.0026$ (20*a*). In acetonitrile solutions, the $TCNDQ^{\dot{-}}$ spectrum shows an asymmetry which has not been analyzed as yet. Spectra in acetone often show some signal broadening, possibly due to an exchange phenomenon. The *g* value is free-

electron like and consistent with the formulation of $TCNDQ^{\dot{-}}$ as a π radical anion.

A computer simulation of the spectrum agrees with the observed spectrum when $a_N = 0.7$ G, $a_{H_2} = 0.7$ G, and $a_{H_3} = 1.1$ G. Because of the complexity of the spectrum, small changes in these calculated values of the hyperfine constants might occur in a more detailed analysis of the spectrum. Although these values are consistent with the proposed structure of the radical anion, there is a difficulty in assigning the proton hyperfine couplings. In the radical anion of 4,4′-dinitrobiphenyl the assignments are $a_{H_2} = 0.20$ G and $a_{H_3} = 1.23$ G (23). However, the esr of the radical anion of 4,4′-dicyanobiphenyl is assigned as $a_{H_2} = 1.82$ G and $a_{H_3} = 0.30$ G (24). The difficulty in making these assignments has been stressed by Rieger and Fraenkel (23, 24); in addition, they suggest that a_{H_2} and a_{H_3} are mainly dependent on the electronegativity of the substituents at the 4 and 4′ positions (23). The dicyanomethylene group is probably between the nitro and cyano groups in electronegativity and this is reflected in the values of a_{H_2} and a_{H_3} in $TCNDQ^{\dot{-}}$ being between those of 4,4′-dinitrobiphenyl and 4,4′-dicyanobiphenyl. We have assigned a_{H_2} and a_{H_3} in TCNDQ on the basis of our extended Hückel calculations for the radical anion (*vide infra*).

It is well known that the McConnell relation, $a_H = Q_{CH}\rho_C$(25) is followed for a large number of organic π radicals. We have used the extended Hückel method of Hoffmann (26) to calculate the spin densities in $TCNQ^{\dot{-}}$ and $TCNDQ^{\dot{-}}$. From the calculated spin density in $TCNQ^{\dot{-}}$ and the observed proton hyperfine coupling, $a_H = 1.44$ G (27) we calculate a value of $Q = -24.4$ G, in good agreement with the values of Q obtained for other organic π radicals (28*a*). Using this value of Q and the calculated spin density[4] of $TCNDQ^{\dot{-}}$ we obtained $|a_{H_2}| = 0.86$ G and $|a_{H_3}| = 1.10$ G. Thus we suggest that the largest proton hyperfine coupling (1.1 G) be assigned to a_{H_3} and the smaller coupling (0.7 G) be assigned to a_{H_2}. This simple McConnell relation applies to neutral π radicals. Several workers have developed methods to include the effect of excess charge on the couplings in anions and cations (28*b*). However, this effect is usually small for anions and our value of Q calculated from the $TCNQ^{\dot{-}}$ spectrum partially corrects for this effect.

In addition, one can calculate the nitrogen hyperfine constants using the relation formulated by Rieger and Fraenkel (24) for cyano substituted π radicals. This relation is

$$a_N = \pm 29.7\ \rho_N{}^{\pi} \mp 13.3\ \rho_{C'}{}^{\pi}$$

The calculated nitrogen hyperfine coupling is 1.43 G in $TCNQ^{\dot{-}}$ compared with an observed value of 1.02 G (27). Similarly, the calculated nitrogen hyperfine coupling is 1.04 G in $TCNDQ^{\dot{-}}$ compared with an observed value of 0.7 G. In both cases the calculated value is about 50% higher than the observed a_N.

The observed esr spectrum is consistent with the formation of the $TCNDQ^{\dot{-}}$ radical anion and its serves to characterize the ion in solution. The assignment of the esr spectrum, although tentative, does allow us to probe the electronic nature of the highest occupied mo(homo) in $TCNDQ^{\dot{-}}$. As we have shown earlier, the homo in $TCNQ^{\dot{-}}$ is very important in understanding the conductivity (30) and solid state packing (31) in TCNQ salts. Our calculations indicate that the homo in $TCNDQ^{\dot{-}}$ has the same symmetry as that of $TCNQ^{\dot{-}}$. This is consistent with the observed esr spectrum and augurs well for the potential use of this acceptor.

The solid esr spectrum of powder NaTCNDQ has a very strong single line at $g = 2.0035$. This solid's esr signal is similar to that of the alkali metal salts of TCNQ (32).

[4]This calculation assumes a planar geometry for the radical anion and that the central double bond in TCNDQ is slightly longer than the other double bonds. The remaining bond lengths and angles were taken from those in TCNQ (29).

Phase-transfer catalyzed formation of cyanohydrin ethers and acetates[1]

JOHN M. MCINTOSH

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received July 4, 1977

JOHN M. MCINTOSH. Can. J. Chem. **55**, 4200 (1977).

In the presence of an allylic bromide, aldehydes, but not ketones, react with cyanide ion under phase-transfer catalysis to give cyanohydrin allyl ethers which can be converted to ketones. Other alkylating agents and nucleophiles give different results. Replacing the allylic bromide with acetic anhydride leads to cyanohydrin acetates.

JOHN M. MCINTOSH. Can. J. Chem. **55**, 4200 (1977).

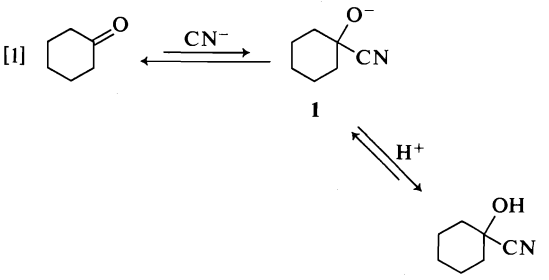
En présence d'un bromure allylique, les aldéhydes mais non les cétones réagissent avec l'ion cyanure par catalyse de transfert de phase pour fournir des éthers mixtes d'allyl et de cyanohydrine qui peuvent être transformés en cétones. Des agents alkylant et des nucléophiles autres donnent des résultats différents. Le remplacement du bromure allylique par de l'anhydride acétique conduit aux acétates de cyanohydrine.

[Traduit par le journal]

Recently we have become interested in the interaction of nucleophiles with aldehydes and ketones under the influence of phase-transfer catalysis. This interest stems from our observations of 1,4-addition of various sulfur nucleophiles to conjugated aldehydes (1). In order to assess the generality of these reactions, we turned our attention to a well-studied nucleophile, cyanide ion, and we report here some of the interesting results observed.

The simplest reaction between carbonyl compounds and cyanide ion is an addition reaction leading to cyanohydrins. This process is known to be reversible and proceeds under general base catalysis (2). When an aqueous solution of potassium cyanide was stirred vigorously with a methylene chloride solution of cyclohexanone, 3-pentanone, or mesityl oxide, no cyanohydrin formation could be detected either with or without the addition of a catalytic amount of triethylbenzylammonium chloride (TEBAC). One possible rationale for this result was that the high p*H* of the cyanide solution did not permit protonation of the intermediate oxyanion **1** (eq. 1). Thus reversal of addition would occur. Conducting the reaction using tributylamine catalyst and an aqueous solution of hydrocyanic acid did lead to an equilibrium amount of **2**, but the possibility that this reaction did not involve phase-transfer catalysis led us to consider other alternatives for trapping **1**.

[1]



1 **2**

In this regard, the work of Cazes and Julia (3) is of interest. They have shown that preformed cyanohydrins derived from aldehydes can be alkylated with allylic halides under phase-transfer conditions. The products can be transformed into ketones via a [2,3] sigmatropic rearrangement. They point out that, under their conditions, the cyanohydrin may dissociate forming cyanide ion, and, in fact, they report minor amounts of allylic cyanide as by-products. It appeared to us that if cyanide ion was attacking the carbonyl ion in our reaction, allylic halides might trap **1** by an irreversible alkylation leading to products analogous to those observed by Cazes and Julia. The success of the reaction would depend on a preferential attack on the carbonyl group, rather than the well-known (4) attack at sp^3-hybridized carbon which would lead to nitriles.

Results and Discussion

Stirring a methylene chloride solution of butanal (**3***b*) and allyl bromide (**4***a*) with an

[1]Presented in part at the Annual Conference, Chemical Institute of Canada, Montreal, June 1977.

aqueous solution of potassium cyanide in the absence of a catalyst led to a rapid disappearance of the aldehyde, but only water soluble aldol-type oligomers of undetermined structure were produced. Incorporation of 4 mol% of TEBAC led to a smooth reaction to give cyanohydrin ether **6** (eq. 2). Repetition of this reaction using

[2] 
a variety of aliphatic aldehydes led to comparable results (Table 1). The only other products observed were unreacted starting materials and the previously mentioned water-soluble material. The latter material was obtained only when aldehydes possessing appreciable water solubility were employed (runs 1, 2, 4). All reactions were run on a 0.05 molar scale, using equimolar amounts of **3** and **4** and 1.5 equiv. of cyanide. When benzaldehyde (**3***e*) was used, small amounts of benzoin were also obtained (5). Noteworthy in all these examples is the near absence of allylic cyanides as determined by glc analysis of the crude reaction mixture. The ease with which compounds of type **5** can be obtained makes Cazes and Julia's ketone synthesis much more attractive.

Extension of the reaction to related systems led to unexpected results. Whereas replacing **4***a* with other primary allylic or benzylic bromides afforded the expected products, the less reactive allylic chlorides were completely inert (runs 9, 10) and only the water-soluble oligomers were obtained. The same result was obtained using 1-bromobutane (**4***d*) as the trapping reagent. Replacing the aldehydes with representative ketones (runs 11, 12) again changed the reaction and only allyl cyanide could be detected. The ketones could be quantitatively recovered after completion of the reaction. Thus it appears that the increased steric congestion present in ketones serves either to reduce the equilibrium amount of **1** or retards its reaction with **4** to a point where the desired reaction is very slow.

To examine this point in more detail, a more reactive trapping reagent was required and we turned our attention to the use of acetic anhydride. When the reaction of this with **3** was carried out in the usual fashion, a vigorous exotherm occurred, and only highly coloured products could be isolated. However, by carrying out the reaction at 0°C with slow addition of the organic reagents, a smooth conversion to the cyanohydrin acetate could be achieved (Table 2). In this case, a representative ketone (run 4) also gave the expected product although excess cyanide and acetic anhydride are required. Thus it appears that the failure of the reaction of ketones and **4***a* is due to an inefficient reaction between **1** and **4***a*. In view of the very rapid hydrolysis of acetic anhydride by aqueous cyanide solution, these reactions are quite remarkable. The current interest in cyanohydrin esters as synthetic pyrethroids (6) makes these latter reactions of some practical interest.

The reaction of conjugated carbonyl compounds with cyanide ion can occur either by 1,2- or 1,4-addition. Our previous work using sulfur nucleophiles (1) had led to products derived from 1,4-addition, although 1,2-addition may well be an undetected equilibrium side reaction. Very recent work by Liotta *et al.* (7) has shown that, using crown ether-catalyzed solid–liquid phase transfer conditions in the presence of a suitable proton source, 1,4-addition of cyanide ion to conjugated ketones can occur. The contrast between these results and those of Evans *et al.* (8) using silyl cyanides is noteworthy. Thus, we attempted to apply our conditions to this reaction.

Three different products can be envisaged (Scheme 1) depending on the mode of the initial cyanide attack. When crotonaldehyde or 2-cyclohexenone were reacted with cyanide ion and **4***a* (Table 1, runs 13, 14) under the usual conditions, only polymers were formed. However, the reac-

tion of **3***i* with acetic anhydride did lead to a clean formation of the ester **19** derived from 1,2-addition of cyanide. Under the same conditions **3***h* was recovered quantitatively from the reaction.

We have also briefly investigated three other nucleophilic species which were chosen to obtain a less basic aqueous solution and thus minimize the formation of aldol-type polymers. When aqueous sodium azide was employed with **3***a* and **4***a*, no reaction of any kind occurred. However, the use of potassium thiophenoxide or thiolacetate led cleanly to the formation of the allylic sulfides **14** and **15**, with complete recovery of the carbonyl component (Table 1, runs 16–18). None of the previously described (9) attack on methylene chloride was observed. The contrast between the reaction of thiolacetate with **3***i* in the presence of **4***a* (formation of **15**) and in the absence of **4***a* (formation of **20**) (1) indicates how delicately balanced these reactions are.

14 **15** **20**

Finally, it should be noted that simple Michael acceptors do not effectively trap anions **1**, presumably due to a ready reversal of the reactions under the alkaline conditions. Thus, neither acrylonitrile nor ethyl acrylate afforded any useful products. We are currently investigating other variations of these reactions and the application of the products to synthesis. We will report on these in due course.

Experimental

Nuclear magnetic resonance spectra were recorded on a JEOL C60 HL spectrometer in deuterochloroform and are reported in parts per million downfield from TMS as internal standard. Infrared spectra were determined on a Beckman IR 12 instrument in chloroform solution. The drying agent used was anhydrous sodium sulfate and solvents were removed at reduced pressure. Gas chromatographic analyses were performed on either an F & M Model 720 or Hewlett-Packard Model 5750 instrument utilizing a 10 ft × 0.25 in. 20% SE 30 on Chromosorb W column. Mass spectra were determined on a Varian MAT CH 5-DF in the electron-impact mode. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto.

General Procedure for Compounds 5–13

A solution of 4 g (0.06 mol) of potassium cyanide in 10 ml of distilled water was added to 20 ml of methylene chloride in a 100 ml round bottom flask fitted with a magnetic stirrer and reflux condenser. Four mol% (500

[a]In $CDCl_3$ solution; tabulation follows the order: chemical shift (δ), multiplicity, number of protons, coupling constant.

mg) of TEBAC was added, the stirrer was started, and a mixture of the carbonyl compound (0.05 mol) and allylic bromide (0.05 mol) was added all at once through the condenser. A mild exotherm was noted. (Within 2 h, the phases had reversed, the aqueous phase being on top.) The reaction was stirred at ambient temperature or reflux (see Table 1) until glc analysis of the organic phase showed no further reaction was occurring. The phases were separated, the organic phase washed with 15 ml of water and evaporated. Ether was added to the residue to precipitate the catalyst. The ether solution was dried, filtered, and evaporated and the residue distilled to afford the products shown in Table 1. In the cases of **5** and **6** especially, considerable high-boiling material was left after distillation. Physical constants and spectral and analytical data for new compounds are given in Tables 3 and 4.[2]

[2]Copies of Table 4 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Reactions using other nucleophiles or alkylating agents were run in exactly the same manner.

*General Procedure for Compounds **16–19***

A solution of 4 g (0.06 mol) of potassium cyanide in 10 ml of water was added to 10 ml of methylene chloride in a 100 ml three-necked round bottom flask fitted with a magnetic stirrer, addition funnel, and reflux condenser. Four mol% (500 mg) of TEBAC was added and the flask was cooled to 0°C in an ice bath. The stirrer was started and a mixture of 0.05 mol of each of the carbonyl compound and acetic anhydride in 15 ml of methylene chloride was added dropwise with stirring over a period of 20 min at 0°C. Stirring was continued at 0°C for 20 min and then at ambient temperature until glc indicated no further change in the composition of the mixture. Work-up was then effected in the same way as before and the products shown in Table 2 were isolated by distillation. Physical constants and spectral and analytical data for new compounds are given in Tables 3 and 4.

In the case of cyclohexanone, the yields given in Table

2 were obtained using 0.1 mol of cyanide and 0.1 mol of acetic anhydride.

Crystal and molecular structure of hexamethylcyclotriphosphazene, $(NPMe_2)_3$

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received July 5, 1977

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **55**, 4206 (1977).

Crystals of hexamethylcyclotriphosphazene are monoclinic, $a = 12.084(2)$, $b = 13.426(1)$, $c = 15.488(2)$ Å, $\beta = 102.92(2)°$, $Z = 8$, space group $C2/c$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.045 and R_w of 0.060 for 1922 reflections with $I \geq 3\sigma(I)$. The six-membered phosphazene ring is slightly nonplanar and has a distorted chair conformation. Important molecular dimensions (bond lengths are corrected for libration) are: P—N, 1.599(2)–1.612(2), P—C, 1.796(3)–1.823(4) Å, N—P—N, 115.7(1)–117.9(1), P—N—P, 122.1(1)–122.9(1), and C—P—C, 101.8(2)–103.1(2)°.

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 4206 (1977).

Les cristaux de l'hexaméthylcyclotriphosphazène sont monocliniques: $a = 12.084(2)$, $b = 13.426(1)$, $c = 15.488(2)$ Å, $\beta = 102.92(2)°$, $Z = 8$, groupe d'espace $C2/c$. La structure a été résolue par des méthodes directes et a été affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.045 et de R_w de 0.060 pour 1922 réflexions avec $I \geq 3\sigma(I)$. Le cycle a six chaînons du phosphazène n'est pas complètement planaire et assume une conformation chaise déformée. Les dimensions moléculaires importantes (longueurs de liaisons corrigées pour les librations) sont: P—N, 1.599(2)–1.612(2), P—C, 1.796(3)–1.823(4) Å, N—P—N, 115.7(1)–117.9(1), P—N—P, 122.1(1)–122.9(1) et C—P—C, 101.8(2)–103.1(2)°.
[Traduit par le journal]

Introduction

Hexamethylcyclotriphosphazene has been known for some time (1*a*), but its structure has not been determined. The X-ray crystallographic analysis of $(NPMe_2)_3$ has been prompted by the recent structure determinations of the methylphosphazenes $(NPMe_2)_{5-8}$ (2–5) in addition to the previously known structure of $(NPMe_2)_4$ (6). The structure of $(NPMe_2)_3$ is also of interest in relation to those known for other homogeneously substituted cyclotriphosphazenes $(NPX_2)_3$, where X = F (7–10), Cl (10–14), Br (15–18), C_6H_5 (19), $1/2[O_2C_6H_4]$ (20, 21), OC_6H_5 (22), NMe_2 (23), NCS (24), and $1/2[2,2'$-$OC_6H_4C_6H_4O]$ (25).

Experimental

Hexamethylcyclotriphosphazene was prepared by standard methods (1*b*). Crystals suitable for X-ray analysis were obtained by recrystallization from methylene chloride – toluene. The crystal chosen for study was mounted with a^* parallel to the goniostat axis and had dimensions of ca. 0.78 × 0.11 × 0.49 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by least squares on 2 sin θ/λ values for 36 reflections measured on a diffractometer with Cu K_α radiation ($\lambda = 1.5418$ Å). Crystal data (at 22°C) are:

$C_6H_{18}N_3P_3$ fw = 225.15

Monoclinic, $a = 12.084(2)$, $b = 13.426(1)$, $c = 15.488(2)$ Å, $\beta = 102.92(2)°$, $V = 2449.1(6)$ Å^3, $\rho_m = 1.21$ (flotation in aqueous KI), $Z = 8$, $\rho_c = 1.221$ g cm^{-3}, $F(000) = 960$, μ(Cu K_α) = 40.9 cm^{-1}. Absent reflections: hkl, $h + k \neq 2n$ and $h0l$, $l \neq 2n$. Space group $C2/c$ (C_{2h}^6, No. 15).

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. 10 s background counts were measured at each end of the scan. Data were measured to $2\theta = 160°$. The intensities of the check reflections, measured every 50 reflections throughout the data collection, decreased uniformly to values which were 0.91 times the initial values. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (26, 27). Transmission factors ranged from 0.160 to 0.622. Of the 2686 independent reflections measured, 1931 (72%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.03S)^2$ with S = scan count and B = time averaged background count.

The structure was solved by direct methods (28). The positions of all the non-hydrogen atoms were determined from an E-map. Two cycles of full-matrix least squares refinement of the coordinates and isotropic thermal parameters of the non-hydrogen atoms, followed by two cycles with anisotropic thermal parameters, gave $R = 0.067$. The positions of all 18 hydrogen atoms were given

by an electron density difference map calculated at this point. The entire structure (including hydrogen atoms with isotropic thermal parameters) was refined for six cycles giving a final R of 0.045 and R_w of 0.060 for 1922 reflections with $I \geq 3\sigma(I)$ (9 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections, but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 2686 reflections $R = 0.063$ and $R_w = 0.064$.

A correction for secondary extinction was approximated by basing the least squares refinement on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $3.2(9) \times 10^{-8}$. The scattering factors of ref. 29 were used for the non-hydrogen atoms and those of ref. 30 for the hydrogen atoms. Anomalous scattering factors from ref. 31 were used for the non-hydrogen atoms. The weighting scheme, $w = 1.0$ if $|F_o| < 20.0$, $w = (20.0/|F_o|)^2$ if $|F_o| \geq 20.0$, and $w = 0.09$ for the unobserved reflections, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.04σ and no shift was greater than 0.32σ. The mean error in an observation of unit weight was 0.9013. The final positional and thermal parameters appear in Tables 1 and 2 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (32) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least squares analysis) is 0.0016 Å^2. Analysis of the entire molecule as a rigid body was unsuccessful, but each of the phosphorus tetrahedra was found to behave as a rigid body (rms $\Delta U_{ij} = 10$, 14, and 17×10^{-4} Å^2 for P(1), P(2), and P(3) respectively).

The appropriate bond distances have been corrected for libration (33, 34), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values. Corrected bond angles differ by less than 0.1° from the uncorrected values in Table 4.

Results and Discussion

Figure 1 shows a general view of the molecule with the crystallographic numbering scheme and Fig. 2 shows the packing arrangement viewed down a^*. Torsion angles in the six-membered ring are listed in Table 5. The mean structural parameters for $(NPMe_2)_3$ are compared with those of the methylphosphazenes, $(NPMe_2)_{4-8}$, and the homogeneously substituted cyclotriphosphazenes, $(NPX_2)_3$, in Table 6.[2]

The crystal structure (Fig. 2) consists of well-separated molecules of hexamethylcyclotriphosphazene. The shortest intermolecular H...H and N...H contacts (2.43(8) and 2.70(4) Å respectively) correspond to normal van der Waals interactions.

At each phosphorus atom in the molecule, the two P—N and the two P—C distances are equal within experimental error. Small, but significant, differences in bond lengths and angles at the three independent phosphorus atoms result in a small distortion of the molecule from threefold symmetry which is probably a result of packing forces. The six-membered P_3N_3 ring is slightly, but significantly, non-planar, and has a distorted chair conformation; the mean and maximum

deviations from the weighted least squares mean plane are 0.043 and 0.162(3) Å (N(2)).

Small deformations of P_3N_3 rings from planarity have been ascribed to intra- and intermolecular steric effects (12, 18, 19). In $(NPMe_2)_3$, the sum of the two independent mean ring angles is 0.6° less than the maximal 240°, and the resulting torsion angles (Table 5) would allow some steric relief of the methyl–methyl repulsion. The data of Table 6 suggest that there may also be an electronic effect. Electronegative substituents are known to decrease P—N bond lengths, as exemplified by the increase from 1.570 Å in $(NPF_2)_3$ to 1.605 Å in $(NPMe_2)_3$, the longest yet found in a trimeric phosphazene. There is evidently a related effect on angles, the N—P—N angle decreasing in the series F (119.6°) > Cl > Br > Ph > OPh > Me > NMe_2 (116.7°), in which the methyl group falls into the position expected chemically. The effect probably depends on the migration of bonding electron density which results from changes in the effective electronegativity of phosphorus.

In the larger cyclic methylphosphazenes, the steric constraints imposed by the six-membered

A study of the Osterberg–Sarkar–Kruck method for evaluating free metal and free ligand concentrations in solutions of complex equilibria

ROGER GUEVREMONT AND DALLAS L. RABENSTEIN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 21, 1977

ROGER GUEVREMONT and DALLAS L. RABENSTEIN. Can. J. Chem. **55**, 4211 (1977).

The method developed by Osterberg, Sarkar, and Kruck for obtaining the concentrations of free ions in solutions of complex equilibria from p*H* titration data has been studied to establish the conditions under which the method gives accurate values for free ligand and free metal concentrations in systems containing a variety of complexes, including protonated, hydroxy, mixed ligand, and polynuclear complexes. Simulated titration data have been used so that the true values of free ligand and free metal concentrations would be known. Calculation procedures are described for each step in the data evaluation, including procedures for extracting information about the stoichiometry of the complexes from the unique information provided by this method. The effect of various systematic and random errors is also considered.

ROGER GUEVREMONT et DALLAS L. RABENSTEIN. Can. J. Chem. **55**, 4211 (1977).

On a étudié la méthode développée par Osterberg, Sarkar et Kruck pour obtenir, à l'aide de données de titrations de p*H*, les concentrations en ions libres dans des solutions impliquant des équilibres complexes afin d'établir les conditions où la méthode fournit des valeurs précises pour les concentrations de ligands libres et de métaux libres dans des systèmes contenant une variété de complexes incluant des complexes des ligands protonés, hydroxylés et mixtes, et des complexes polynucléaires. On a utilisé des données de titrations simulées de façon à connaitre les valeurs réelles des concentrations de ligands libres et de métaux libres. On décrit des méthodes de calcul pour chacune des étapes dans l'évaluation des données incluant des méthodes pour extraire de l'information concernant la stoechiométrie des complexes à partir d'informations uniques fournies par cette méthode. On considère aussi l'effet de diverses erreurs systématiques et de celles dues au hasard.

[Traduit par le journal]

Introduction

Of the methods for determining the stability constants of metal complexes, those based on potentiometry with the glass electrode are used the most frequently and generally are considered to yield the best results. Several procedures can be used for extracting the stability constants from the experimental data, which usually consist of a series of p*H* titration curves for several combinations of the metal and ligand concentrations. If there are no protonated, deprotonated, hydroxy, or polynuclear complexes, the Bjerrum method (1) is the method of choice. However, if such species do form the stability constants are usually calculated by one of several elaborate computer-based evaluation methods, of which the more widely used are LETAGROP (2), GAUSS (3), SCOGS (4), and STEW (5).

Each of these computation methods makes use of the three mass balance equations for each experimental point.

$$[1] \quad C_H = [H] - [OH] + \sum q\beta_{pqr}\,[M]^p[H]^q[L]^r$$

$$[2] \quad C_M = [M] + \sum p\beta_{pqr}\,[M]^p[H]^q[L]^r$$

$$[3] \quad C_L = [L] + \sum r\beta_{pqr}\,[M]^p[H]^q[L]^r$$

where β_{pqr} and $\beta_{pqr}[M]_p[H]_q[L]_r$ are the stability constant and concentration, respectively, of the species $M_pH_qL_r$. In outline, the procedures generally involve systematic adjustments in the stability constants to minimize the function defined by eq. 4.

$$[4] \quad U = \sum(C_H^{exp} - C_H^{calc})^2$$

where the summation is over all experimental points. C_H^{calc} is obtained at each experimental point by first choosing a model for the solution equilibria and guessing values for the stability constants in this model. The guesses are substituted into eqs. 2 and 3, which are then solved simultaneously at each experimental point for [M] and [L]. These values and the guesses for the stability constants are then substituted into eq. 1 to give C_H^{calc}. Once U has been calculated for this set of stability constants, the constants are adjusted and the entire set of calculations is

repeated. This procedure is continued until U is apparently minimized. If the true minimum of the residual function has been found, the resulting stability constants are those which 'best' fit the experimental data, according to the criteria of least sum of the squares of the residuals, for the chosen model. Usually the stoichiometry of the complexes which form is not known, and this entire procedure is repeated with several models. Clearly, the values calculated for [M] and [L] at each experimental point, and thus the stability constants, depend on the model. It is disconcerting that different models can result in equivalent 'best' fits for the same chemical system.

Recently, a pH titration method has been described in which the free metal ion and the free ligand can be calculated simultaneously throughout the central titration of an appropriately designed set of titrations (6–8). This method is appealing in that the concentrations are obtained directly from the experimental data, without assuming any hypothesized collection of species for that system. The calculation of stability constants then reduces to a linear least-squares problem using any of the mass balance equations. If the stoichiometries of the complexes are not known, it still is necessary to postulate a model. It is to be expected, however, that fewer models will fit the data because the free ligand and free metal concentrations are known and not derived from the model.

We have undertaken a critical examination of this approach, to establish the conditions under which it gives accurate values for the free metal and free ligand concentrations in systems containing a variety of complexes. Our approach has been to analyze simulated titration data, so that the true values of free metal and free ligand concentration would be known. In addition, since this method provides information not available in the study of complex systems by other data evaluation procedures, we also consider ways in which this information can be used to provide guidance in the selection of a model.

Overview of the Method

The basic relationships in this method for determining the concentrations of free ions in solutions of complex equilibria[1] are

$$[5]\quad \mathrm{p[L]} = \mathrm{p[L]}_0 - \int_{\mathrm{p}H_0}^{\mathrm{p}H} \left(\frac{\mathrm{d}C_\mathrm{H}}{\mathrm{d}C_\mathrm{L}}\right)_{C_\mathrm{M},\mathrm{p}H} \mathrm{dp}H$$

$$[6]\quad \mathrm{p[M]} = \mathrm{p[M]}_0 - \int_{\mathrm{p}H_0}^{\mathrm{p}H} \left(\frac{\mathrm{d}C_\mathrm{H}}{\mathrm{d}C_\mathrm{M}}\right)_{C_\mathrm{L},\mathrm{p}H} \mathrm{dp}H$$

where C_H is the concentration of titrable proton, C_L and C_M are the total analytical concentrations of ligand and metal, and [L] and [M] are their free concentrations. For systems containing more components, equations analogous to [5] and [6] can be written for each component in the solution. For simplicity let us only consider the component L, remembering that the discussion is applicable to every component in the system.

The quantity $\mathrm{p[L]}_0$ is the negative logarithm of the concentration of free L at some initial pH_0. A pH_0 is usually chosen at which no complex is formed, and consequently $[\mathrm{L}]_0$ is equal to (or may be calculated from) C_L. The integral of $(\mathrm{d}C_\mathrm{H}/\mathrm{d}C_\mathrm{L})_{C_\mathrm{M},\mathrm{p}H}$ is evaluated from pH_0 to the pH at which p[L] is to be evaluated.

One experimental method for obtaining $(\mathrm{d}C_\mathrm{H}/\mathrm{d}C_\mathrm{L})_{C_\mathrm{M},\mathrm{p}H}$ as a function of pH is with a series of titrations where the total concentration of L is varied, while all the other components are at constant concentration. At a given pH, C_H is extracted from each of the titrations. The derivative $(\mathrm{d}C_\mathrm{H}/\mathrm{d}C_\mathrm{L})_{C_\mathrm{M},\mathrm{p}H}$ is the change in C_H with C_L, measured at C_L of the middle titration. In exactly this way the derivative at each pH throughout the titration is calculated. The values of $(\mathrm{d}C_\mathrm{H}/\mathrm{d}C_\mathrm{L})_{C_\mathrm{M},\mathrm{p}H}$ are then integrated from pH_0 to a given pH, and p[L] at that pH is calculated from [5]. The experiment is designed in such a way that, given a system of composition C_L and C_M, referred to as the composition of the middle titration, each component is in turn selectively varied. The FICS method will then provide [L] and [M] as a function of pH, for a solution of that overall composition.

The stability constants of the complexes are calculated by a linear least-squares fit of the [L] and [M] data into the mass balance equations. Any one mass balance is completely sufficient unless a given complex does not contain any of that particular component.

In the following section, the calculation procedures at each step in the method are considered.

Calculation Procedures in the FICS Method

C_H Calculations

The total concentration of titrable proton is

[1]For convenience, we will name this method FICS, for free ion concentrations in solution.

calculated from the relation

$$[7] \qquad C_H = (NTP \times C_L) + C_A - C_B$$

where NTP is the number of titrable protons on the ligand in the form used to prepare the solutions, and C_A and C_B are concentrations of added acid and base. Calculation of $(dC_H/dC_L)_{C_M,pH}$ requires that C_H be known at specific and closely spaced pH values throughout the series of titrations. Since this is difficult experimentally, some manipulation of the data is necessary. We have used a simple linear interpolation between data points. The linear interpolation is limited in that, first it does not use the entire body of data as a unit, and therefore does not have the smoothing potential which curve fitting procedures might have, and second it will bias the data in some cases. A bias to large C_H will result if the C_H vs. pH curve is concave upward, and to low C_H's if the curve is concave downward. However we have found that the linear interpolation provides very good estimates of C_H at the required pH's when data points are taken at pH intervals of 0.1 units or less. Efficient use of the experimental data requires that the pH interval used in the FICS procedure be approximately equal to that of the data.

The Derivative, $(dC_H/dC_L)_{C_M,pH}$

The reliability of the derivative depends strongly on several factors: (*1*) the accuracy of C_H, (*2*) the degree of curvature of the C_H vs. C_L function, (*3*) the number of titrations of varying C_L, and (*4*) the extent to which the concentrations of components other than C_L remain constant.

In Fig. 1 are plots of C_H vs. C_L at various pH values for a system containing a diprotic ligand and complexes ML, ML_2, ML_3, and $H_{-1}ML_2$, where $H_{-1}ML_2$ might be a hydroxy complex. The important characteristics to note are that C_H may vary over several orders of magnitude, under conditions of excess metal concentration C_H may be small, and there may be extreme curvature in the function of C_H vs. C_L.

The design of the experiment must avoid problems arising from the above factors. The quantity C_H has error associated with it, and if the absolute value of C_H is small the experimental data may not be sensitive enough to reflect the true behaviour of C_H with change in C_L. In this situation the derivative cannot have much significance. This will occur in systems where C_L is low, and in those containing excess metal.

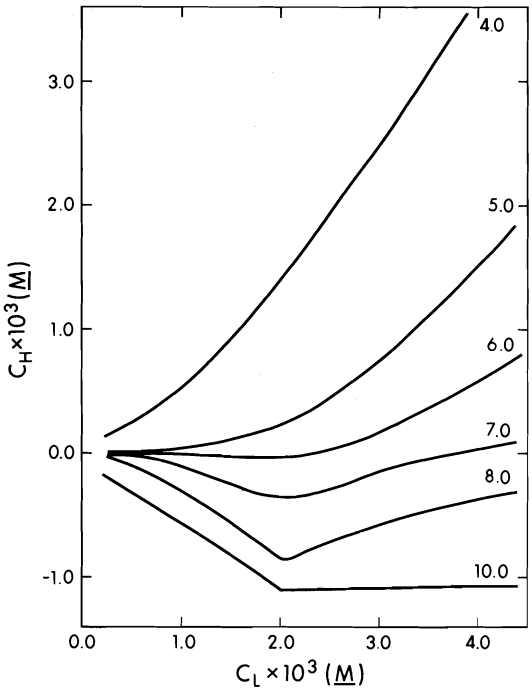

FIG. 1. C_H vs. C_L for a system containing a diprotic ligand and complexes ML, ML_2, ML_3, and $H_{-1}ML_2$. The overall ligand protonation constants are 1.0×10^6 and 1.0×10^{10}. The formation constants of the complexes are 1.0×10^6, 1.0×10^{11}, 1.0×10^{15}, and 1.0×10^4 respectively. C_M was constant at 1.0×10^{-3} M (see Tables 1 and 3).

Each point on a C_H vs. C_L plot represents data from a separate titration, and the numbers of points are therefore necessarily small. This imposes the requirement that the range of C_L be chosen so that C_H varies linearly with C_L. If this condition is met only two titrations are necessary, and more will provide increasingly reliable results. Reasonable random error is acceptable since a linear least-squares fit will tend to give better derivatives than the limit of accuracy of C_H might indicate possible. A linear variation in C_H with C_L can be achieved experimentally if the ligand to metal ratio is higher than the stoichiometric ligand to metal ratio of predominating complexes. The range of C_L must not be so wide as to extend into regions of curvature of the C_H vs. C_L function.

With a small number of data points, a least-squares polynomial fit will not solve the problem of curvature of C_H with C_L. First, if the function of C_H vs. C_L is in fact linear with ran-

dom error superimposed, the polynomial may try to fit even those errors. Second, if the function is nonlinear, it is not likely as simple as a polynomial of low degree, and systematic distortion of the actual relation will occur.

The Integral $\int_{pH_0}^{pH} \left(\frac{dC_H}{dC_L}\right)_{C_M,pH} dpH$

The values of $(dC_H/dC_L)_{C_M,pH}$ and $(dC_H/dC_M)_{C_L,pH}$ usually fall within the range $\pm n$, where n is the number of protons on the fully protonated ligand. Figure 2 shows the variation in these derivatives as a function of pH for the same system considered in Fig. 1.

The concentrations of free ligand and free metal at a particular pH are calculated by integrating the functions shown from pH_0 to that pH. We have chosen to evaluate the integral numerically from the tabulated function $(dC_H/dC_L)_{C_M,pH}$ using the trapezoid rule. This procedure, used at 0.1 pH intervals, gave as good accuracy as in most cases is appropriate. Alternatively, the entire set of $(dC_H/dC_L)_{C_M,pH}$ can be fit to a polynomial (7), and the integral evaluated by simple calculus.

All the series of simulated titration data presented in this paper were treated in exactly the manner described in the previous sections. Examples of free ligand and free metal concentrations derived using FICS are shown in Tables 1 and 2. Table 1 contains known and derived [L] and [M] corresponding to the system already referred to in Figs. 1 and 2. Table 2 presents results from which can be seen the effect of dilution on [L] and [M]. This is discussed in a later section on errors.

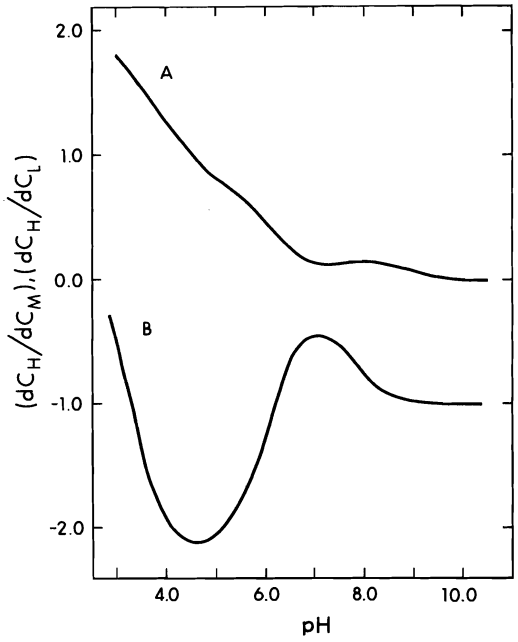

FIG. 2. $(dC_H/dC_L)_{C_M,pH}$, A, and $(dC_H/dC_M)_{C_L,pH}$, B, as a function of pH for the system of complexes defined in the legend of Fig. 1. $C_M = 1.0 \times 10^{-3}$ M, $C_L = 4.0 \times 10^{-3}$ M (see Tables 1 and 3).

Formation Constants

The FICS method provides free ligand and free metal concentrations as a function of pH. Formation constants can be extracted from a linear least-squares fit to the mass balance of each component in solution. The quantity U is minimized.

$$[8] \quad U = \sum(C_L - ([L] + \sum r\beta_{pqr}[M]^p[H]^q[L]^r))^2$$

In all the examples presented in this paper we have used a Gaussian elimination followed by matrix inversion to solve the simultaneous equations. Each mass balance is treated separately and no constants are given as knowns. The mass balance for protons, C_H, has not been used since weighting of the data would be necessary. For simplicity in this work, the mass balances for ligand and metal are shown as $\sum$[L] and $\sum$[M].

Some estimate of the accuracy of the FICS method is necessary. The simplest, though not the most reliable quantity, is the goodness of the fit of the model to the known total analytical concentrations of ligands and metals. The experimental values of [L] and [M] and the formation constants are inserted into [8] and the standard deviation of the fit is $[U/(n-1)]^{1/2}$, where n is the number of experimental points. The relative standard deviation of the fit, in percent, is used in this work.

The standard deviation calculation is limited in that it does not give any indication of the accuracy of the [L] and [M] data, rather it only estimates the fit of the hypothesized model to that data. For this reason a study of the evaluation of [L] and [M] by the FICS method using simulated titration data, where [L] and [M] are accurately known, is particularly important.

The suitability of a model describing the composition of complex species existing in solution may be checked several ways. It is expected that a good hypothesis will give a low standard deviation of the fit, and that the constants derived from one mass balance will agree

TABLE 1. Known free ligand and free metal concentrations and those calculated by FICS[a]

	Free ligand		Free metal	
pH	Known	Calculated	Known	Calculated
4.0	1.204×10^{-5}	1.202	3.414×10^{-5}	3.419
5.0	1.250×10^{-4}	1.246	2.732×10^{-7}	2.746
6.0	5.792×10^{-4}	5.732	4.314×10^{-9}	4.389
7.0	1.055×10^{-3}	1.044	7.151×10^{-10}	7.262
8.0	1.422×10^{-3}	1.415	1.959×10^{-10}	1.971
9.0	1.844×10^{-3}	1.836	2.463×10^{-11}	2.474
10.0	1.980×10^{-3}	1.973	2.498×10^{-12}	2.510

[a]For a system containing a diprotic ligand and the complexes ML, ML_2, ML_3, and $H_{-1}ML_2$. The known constants and those derived from these values are given in Table 3. The following conditions were used in the simulation: C_M = 0.90, 0.95, 1.00, 1.05, and 1.10×10^{-3} M with $C_L = 4.00\times10^{-3}$ M and C_L = 3.6, 3.9, 4.1, and 4.4×10^{-3} M with $C_M = 1.00\times10^{-3}$ M. The middle titration is $C_M = 1.00\times10^{-3}$ M and $C_L = 4.00\times10^{-3}$ M.

TABLE 2. The effect of dilution on free ligand and free metal concentrations calculated by FICS[a]

	Titrant	Free ligand		Free metal

10.0	7.201	4.882×10^{-4}	5.474	4.092×10^{-15}	3.039

[a]For a system containing a triprotic ligand and the complexes HML, HML_2, and ML_2. The known constants and those derived from these values are given in Table 3. The titration conditions were: C_M = 0.99, 1.0, and 1.01×10^{-3} M with $C_L = 3.0\times10^{-3}$ M, and C_L = 2.99 and 3.01×10^{-3} $M$with $C_M = 1.00\times10^{-3}$ M. The middle titration is $C_M = 1.00\times10^{-3}$ M and $C_L = 3.00\times10^{-3}$ M.
[b]Initial volume was 300 ml.

with those derived from another. The constants which are known, for example, ligand protonation constants, must be derived correctly from the data. The existence of some species may be questioned if small or negative formation constants are produced, or if the agreement of values based on different mass balances is poor.

The next section will deal directly with the problem of assigning a model to the system.

A Model for Metal–Ligand Interactions

Titration methods do not in general provide information from which the model, or the types of complexes in a system, can be derived. In this respect, FICS has an advantage over other methods. Using [H], [L], and [M] the concentrations of proton, ligand, and metal whose chemical situation has not been determined (ΔC_H, ΔC_L, and ΔC_M) can be calculated. For example, given the total ligand concentration C_L, and the free ligand concentration [L], ΔC_L equals C_L − [L]. If the pH and protonation constants are known,

$$[9]\quad \Delta C_L = C_L - ([L] + \beta_1[H][L] + \beta_2[H]^2[L])$$

for a diprotic ligand.

Figure 3 is a combined plot of ΔC_H, ΔC_L, and ΔC_M for a system containing a triprotic ligand and complexes H_2ML, HM_2L, and M_2L_2.

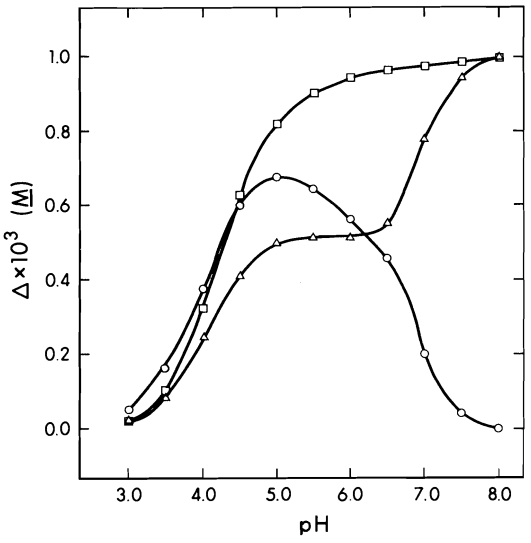

FIG. 3. ΔC_H, ○, ΔC_L, △, and ΔC_M, □, for a system containing a triprotic ligand and complexes H_2ML, HM_2L, and M_2L_2. See text for details of calculation.

Three distinct areas can be seen. (*1*) Below p*H* 3.5 there is a region where ΔC_H is about twice as large as ΔC_L and ΔC_M. (*2*) Near p*H* 6.0 ΔC_M is about twice as large as ΔC_H or ΔC_L. (*3*) Above p*H* 6.0 ΔC_H becomes zero and ΔC_L and ΔC_M are equal. Based upon (*1*) a complex of type H_2ML would be expected to minimize ΔC_H, ΔC_L, and ΔC_M if its concentration is about 1×10^{-4} *M* at p*H* 3.5. Using [H], [L], and [M] from p*H* 3.0 to 3.5, a formation constant of 1.2×10^{19} for H_2ML was calculated.

Figure 4 is a plot of ΔC_H, ΔC_L, and ΔC_M, where these quantities are calculated using the estimated value of the formation constant for H_2ML. For example

$$[10] \quad \Delta C_L = C_L - ([L] + [HL] + [H_2L] + [H_3L] + [H_2ML])$$

where $[H_2ML]$ equals $\beta_{H_2ML}[H]^2[M][L]$. If the series of species included in [10] completely accounts for all the ligand in solution, ΔC_L will be zero. This appears to be the case in the region near p*H* 3. However, in the p*H* region 4 to 5 a complex forms which contains approximately equal amounts of proton and ligand, and a larger amount of metal. A complex of the type HM_2L may best account for the observed ΔC_H, ΔC_L, and ΔC_M. This was not evident in Fig. 3 for the same p*H* range. Using [H], [L], and [M] data from p*H* 3 to 6, constants for H_2ML and HM_2L were found to be 1.02×10^{19} and 9.98×10^{17}

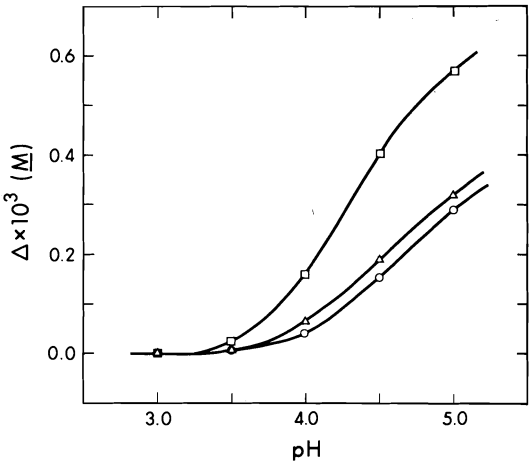

FIG. 4. ΔC_H, ○, ΔC_L, △, and ΔC_M, □, as in Fig. 3, except that the complex H_2ML is accounted for in the calculation of ΔC_H, ΔC_L, and ΔC_M. An estimated value of 1.2×10^{19} for β_{H_2ML} was used in the calculation.

respectively. Figure 5 is a plot of ΔC_H, ΔC_L, and ΔC_M using these estimated constants. The other major complex in solution must contain no protons, and equal numbers of ligands and metals. Inclusion of the species M_2L_2 yielded formation constants of 1.00×10^{21}, 9.97×10^{15}, 9.97×10^{9}, 9.93×10^{18}, 1.03×10^{18}, and 1.01×10^{17} for H_3L, H_2L, HL, H_2ML, HM_2L, and M_2L_2 respectively from the ligand mass balance and

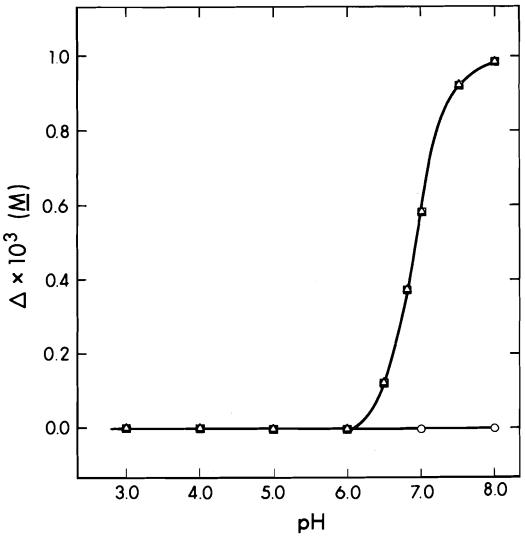

FIG. 5. ΔC_H, ○, ΔC_L, △, and ΔC_M, □, as in Fig. 3, except that the complexes H_2ML and HM_2L are accounted for in the calculation of ΔC_H, ΔC_L, and ΔC_M. Estimated values of 1.02×10^{19} and 9.98×10^{17} were used for β_{H_2ML} and β_{HM_2L}.

9.98×10^{18}, 1.00×10^{18}, and 1.01×10^{17} for H_2ML, HM_2L, and M_2L_2 respectively from the metal mass balance.

The Effect of Error on the FICS Method

This discussion will be limited to error introduced through the experimental procedure. The size of error due to the nature of data handling of the FICS method can be seen in Tables 1 and 2. The systems of simulated titrations were designed to be experimentally feasible, but without the error associated with the actual experiment. There has been no attempt to show that FICS can produce perfect [L]'s and [M]'s because this would require a set of titrations which could never actually be performed. At this point we will introduce those systematic and random errors which are inherent to the real experiment. The error in [L] and [M] will then include uncertainty arising from both sources, the FICS data handling and the imposed experimental error.

Dilution Error

Three separate types of error are introduced by dilution. First, in the experiments designed for the evaluation of $(dC_H/dC_L)_{C_M,pH}$, C_L is not constant but varies as titrant is added. This is easily compensated for in the evaluation by using C_L exactly as it is found at that pH, based upon volume of titrant added to that point. Each pH will have a unique set of C_L's through which the derivative is evaluated.

The second and third dilution problems are related to dilution of components other than C_L, and cannot be corrected in the data handling process. During a set of titrations designed to give the derivative $(dC_H/dC_L)_{C_M,pH}$, the C_M will vary through dilution. Assuming that all the titrations have equal dilution to a given pH, the derivative will be evaluated at a C_M different from C_M at pH_0.

The third type of error is implied above. All the titrations do not have equal dilution to a given pH, and consequently, at each pH, C_M will be different for the different titrations. The term $(dC_H/dC_L)_{C_M,pH}$ explicitly requires that the change in C_H with C_L be measured at constant pH and C_M.

These problems contribute significant error to the free ion concentrations. Table 2 shows [L] and [M] for a system containing a triprotic acid and complexes HML, HML_2, and ML_2. With a total dilution of 7.201 ml titrant into 300 ml, the free ligand concentration at pH 10.0 had about 10% error and the free metal concentration about 25%. Without dilution the error in [L] and [M] was only 0.5%. Table 3 summarizes formation constants derived from these two sets of free ion concentration data.

Error introduced by dilution cannot be corrected once the data have been taken. On the other hand, it is possible to experimentally ensure that C_M remains constant throughout a set of titrations, either by eliminating dilution by use of coulometric titration, or by simultaneous addition of titrant and a concentrated metal solution. We have found the latter, using computer operated instrumentation, to be a practical solution to this problem.

Error in pH Measurement

Unlike other pH titration methods, the FICS procedure does not require that the hydrogen ion concentration or the hydrogen ion activity be known to get accurate free ion concentrations for ligands and metals. The pH is merely a reference scale on which to first evaluate $(dC_H/dC_L)_{C_M,pH}$, and to finally integrate this quantity from pH_0 to pH. Its numerical value is not required in any stage of the calculation of [L] and [M]. However, the pH does enter into the calculation of formation constants.

If the electrodes are standardized using NBS activity buffers, then [L] and [M] are known at a series of p_aH values. The formation constants are calculated using the sets of p_aH, [L], and [M], and consequently are of a mixed activity, concentration type. If the electrodes are calibrated for H^+ concentration, the [L] and [M] are correct at those concentrations, and the derived β's are concentration formation constants.

The FICS method requires only that the pH electrode standardization be internally consistent and serious systematic error is avoided. Random errors in individual measurements will exist, however. These will give rise to exactly the same type of error as random errors in C_H, and will therefore be discussed in that section.

Error in the Initial Free Ligand and Free Metal Concentrations

The FICS method requires that [L] and [M] be known at pH_0, imposing restrictions which contradict many of the experimental requirements discussed above. In most cases complexation is only negligible at low pH, where protons successfully compete for ligand. Under these con-

TABLE 3. Actual formation constants and those calculated from p[M] and p[L] values obtained by the FICS method

Complex system	Formation constants

9.0	3.34×10^{-11}	2.74	2.57	2.50	2.47
10.0	3.39×10^{-12}	2.78	2.60	2.54	2.51

[a]See Table 1 for the model and the known free ligand and free metal concentrations.
[b]Correct $p[L]_0 = 6.470$ and $p[M]_0 = 3.131$ at $pH_0 = 3.00$.
[c]$p[L]_0$ and $p[M]_0$ assuming no complexation has occurred at pH_0.

ditions, C_H at pH_0 is large. This leads to difficulty in those regions of the pH titration where C_H is small. As the size of C_A and C_B (concentrations of added acid and base) increases, C_H loses significance at correspondingly larger values.

Table 4 illustrates the effect of error in $p[L]_0$ and $p[M]_0$ on [L] and [M] derived for the system

considered in Table 1. The far left column is the set of [L] and [M] calculated using $p[L]_0$ and $p[M]_0$ based upon the (incorrect) assumption that no interaction between ligand and metal has occurred. The error in [L] and [M] is significant.

The problem may be corrected by an iteration where (*1*) the $p[L]_0$ and $p[M]_0$ are calculated assuming no complexation and used in the FICS procedure to estimate p[L] and p[M], (*2*) the formation constants are then estimated, and (*3*) new $p[L]_0$ and $p[M]_0$ calculated on the basis of the calculated constants. Tables 4 and 5 show the effect of this iteration. Each $p[L]_0$ and $p[M]_0$ are based upon the [L], [M], and formation constants of the previous column. Each iteration gives better [L] and [M] values, and more reliable formation constants.

The method will fail if too much metal and ligand are complexed at pH_0, or if the complexes forming at low p*H* are not known. In these cases the titrations must be repeated beginning at lower pH_0. The C_H vs. C_L and C_H vs. C_M plots indicate the p*H* at which the complex starts to form; if no complex forms the slope of the C_H vs. C_L plot will equal the average protonation number of the ligand at that p*H* while that of the C_H vs. C_M plot will be zero.

Random Error

All measurements have some uncertainty associated with them. In order to evaluate the effects of random error on the FICS method we have imposed random noise of various magnitudes on the titration data. The experimental data are C_H as a function of p*H*. We will therefore restrict discussion to error in C_H, since an error in p*H* is equivalent to an error in C_H.

Two approaches have been considered, first a random error based on the absolute magnitude of C_H and, second, a random error of constant magnitude. It must be noted here, however, that error seldom is totally random, and conclusions based on studies of random errors are only qualitative in nature.

Table 6 summarizes results of the FICS method used on the system considered in Table 1, where random errors proportional to the size of C_H have been imposed on the titration data. The constants derived from the [L] and [M] from Table 6 are shown in Table 7. Considerable error develops in [L] and [M] when the random errors are larger than 0.5% of C_H. Similar con-

TABLE 5. Effect of systematic error in $p[L]_0$ and $p[M]_0$ on formation constants[a,b]

clusions result from the consideration of random error in C_H of a constant magnitude.

Several words of caution are appropriate. Systematic errors are considerably more serious than random errors. Therefore a systematic error of magnitude comparable to the random errors considered in Tables 6 and 7 will not give results as good as the results in Tables 6 and 7 indicate. In addition it must be kept in mind that the ligand to metal ratio, and so on, used in the simulated data, was chosen with all those factors discussed in the section on calculations given careful consideration. Conclusions arrived at in this section on errors cannot be applicable to situations where C_H is unnecessarily small, or severe curvature in the function of C_H vs. C_L exists.

Conclusions

The FICS method has several important advantages over most pH titration methods for the study of complex equilibria. The method provides free ion concentrations directly from the experiment. Moreover, they are derived for each component individually, that is, independent of the other components, and independent of the numerical value of the hydrogen ion

concentration. In contrast to most other methods, FICS derives free ligand and free metal concentrations completely independent of any preconceived model of interactions which may be occurring in solution. The free ligand and free metal concentrations are accurate even if a model for the system is never found.

The FICS procedure has been tested extensively on simulated titration data, and is applicable to systems containing a variety of species. Examples include hydroxy, protonated, polynuclear, and mixed ligand complexes. No attempt has been made to show that FICS will give completely exact [L] and [M]; rather, attention has been focused on each step of the procedure to find the most practical and reliable experimental method to use with FICS. In this respect it was found that situations where C_H is small and where the curvature of C_H vs. C_L is large must be avoided. Systems containing an excess of ligand appear to be most favorable. Under these conditions a series of relatively simple manipulations of the experimental data will give accurate free ion concentrations.

The availability of free ligand and free metal concentrations presents excellent possibilities for the logical deduction of the complexes existing in solution. For this purpose, the quantities ΔC_H, ΔC_L, and ΔC_M have been introduced, and applied to the deduction of a model from simulated titration data. Considerable information concerning the model is also potentially available from plots such as those in Figs. 1 and 2.

The results in this paper indicate, however, that proper use of this method requires careful design of the experiment. For example, significant error can result from dilution due to the systematic violation of the theoretical requirements of the FICS method. The requirement that $p[M]_0$ and $p[L]_0$ be known at pH_0 can be satisfied even though some complexation has occurred at pH_0 by use of an iterative procedure. This makes it possible to avoid extremely low pH values where precise measurement of pH, and thus C_H, can be difficult.

We have used the methods described in this paper in a study of the zinc complexes of aspartic acid and glutamic acid. The theoretical requirement that C_M and C_L remain constant for the evaluation of $(dC_H/dC_L)_{C_M,pH}$ and $(dC_H/dC_M)_{C_L,pH}$ has been satisfied by the addition of the required amount of a concentrated metal or a concentrated ligand solution with each addition of titrant. The results are in excellent agreement with literature values and will be presented in a future publication on the chemistry of these systems.

MICHAEL J. KRECH, STANLEY JAMES W. PRICE, and HENRY J. SAPIANO. Can. J. Chem. **55**, 4222 (1977).

The heat of formation of bromopentafluorobenzene has been determined through the use of the direct combustion method which has been applied to hexafluorobenzene, octafluorotoluene, and iodopentafluorobenzene. While a platinum lined bomb is normally used for these types of compounds a steel bomb had to be adopted in this work. The combustion of bromopentafluorobenzene in the steel bomb yields CO_2, CF_4, F_2, Br_2, and BrF_3. With a ten-fold excess of oxygen, the average CO_2 to CF_4 molar ratio is 7.29 ± 0.07. A material balance was obtained for carbon, fluorine, and bromine. The value of $\Delta H_{f298}^0(C_6F_5Br, g) = -711.6 \pm 16.7$ kJ mol^{-1} (-170.1 ± 4.0 kcal mol^{-1}) has been combined with $\Delta H_{f298}^0(C_6F_5, g) = -387.4$ kJ mol^{-1} (-92.6 kcal mol^{-1}) and $\Delta H_{f298}^0(Br, g) = 111.7$ kJ mol^{-1} (26.7 kcal mol^{-1}) to obtain a value for $D[C_6F_5—Br]$ of 435.9 kJ mol^{-1} (104.2 kcal mol^{-1}).

MICHAEL J. KRECH, STANLEY JAMES W. PRICE et HENRY J. SAPIANO. Can. J. Chem. **55**, 4222 (1977).

On a déterminé l'enthalpie de formation du bromopentafluorobenzène par l'utilisation de la méthode de combustion directe qui a été appliquée à l'hexafluorobenzène, à l'octafluorotoluène et à l'iodopentafluorobenzène. Alors qu'une bombe couverte de platine est généralement utilisée pour ce type de composé, on a adopté une bombe en acier dans le présent travail. La combustion du bromopentafluorobenzène dans la bombe d'acier conduit à la formation de CO_2, de CF_4, de F_2, de Br_2 et de BrF_3. Si on utilise 10 fois la quantité nécessaire d'oxygène, le rapport molaire moyen de CO_2 sur CF_4 est de 7.29 ± 0.07. On a obtenu une bonne balance de matériel pour le carbone, le fluor et le brome. On a combiné la valeur de $\Delta H_{f298}^0(C_6F_5Br, g) = -711.6 \pm 16.7$ kJ mol^{-1} (-170.1 ± 4.0 kcal mol^{-1}) avec la valeur de $\Delta H_{f298}^0(C_6F_5, g) = -387.4$ kJ mol^{-1} (-92.6 kcal mol^{-1}) et $\Delta H_{f298}^0(Br, g) = 111.7$ kJ mol^{-1} (26.7 kcal mol^{-1}) pour obtenir une valeur de 435.9 kJ mol^{-1} (104.2 kcal mol^{-1}) pour $D[C_6F_5—Br]$.

[Traduit par le journal]

Introduction

To date no thermodynamic study for the heat of formation of C_6F_5Br has been reported. The combustion of C_6F_5X (X = F, H, CH_3, Cl, OH) has been determined by Cox and co-workers (1, 2). These studies involve the placement of fluoro compounds in polyester film bags. To ensure complete combustion hydrogen containing organic materials were added to the crucible. An alternate and successful approach involves open dish combustion under anhydrous conditions and without any auxiliary materials (3–5). This method has been adopted for the combustion of bromopentafluorobenzene through the use of a steel crucible in a steel bomb.

Experimental

Materials

(i) Bromopentafluorobenzene

C_6F_5Br obtained from the Imperial Smelting Corporation was purified by fractional distillation. The final product had the following physical properties (the values in parentheses are those reported by the manufacturer (6)): bp = 137°C (137°C), $n_D^{25} = 1.4483$ (1.4483). Analysis by gas chromatography (6 ft × $\frac{1}{8}$ in. od Durapak *n*-octane/Porasil C, 100–200 mesh, N_2 carrier, 60 cm^3/min, column temperature 120°C, flame ionization detection) showed the presence of a minor impurity which was found to represent a maximum of 0.05% of the sample.

Vapour pressure measurements were taken over the range 10–75°C using the same modified Ramsay–Young system previously employed for C_6F_6 (3), $C_6F_5CF_3$ (4), and C_6F_5I (5). Over 50 vapour pressure measurements were made over three independent runs. The data may be represented by

$$[1] \quad \log_{10} P\,(\text{cm}) = 7.2304 - 2278.4/T + 0.1142 \log_{10} T$$

The resulting heat of vaporization and average heat capacity differences (vapour − liquid) are $\Delta H_{298}{}^{0} = 43.05 \pm 0.21$ kJ mol^{-1} and $\langle \Delta C_p \rangle_{10.75°C} = 0.954$ J deg^{-1} mol^{-1}.

(ii) CO_2, CF_4, F_2, BrF_3, BrF_5

CO_2, CF_4, and F_2 were obtained from the Matheson Chemical Company and were used without further purification. BrF_5 and BrF_3 were obtained from the Air Products Chemical Company and Fluorchem Ltd., respectively. Both were stored as received in monel steel cylinders under their own vapour pressure. Before use the liquids were distilled into Pyrex traps and vacuum distilled. The vacuum distillation system used had taps equipped with Teflon barrels and Viton-O-rings and all joints and glass stopcocks were greased with halocarbon grease.

(iii) Bromine

Reagent A.C.S. bromine was dried over phosphorous pentoxide and vacuum distilled. A middle fraction was collected and stored under its own vapour pressure in a Pyrex tube.

(iv) Sodium Thiosulphate

Sodium thiosulphate pentahydrate (12.5 g) was dissolved in 1 ℓ of water that had been recently boiled and cooled. A few drops of chloroform were added as a preservative and the resulting solution was standardized with potassium iodate (7).

(v) Potassium Iodide

Reagent grade potassium iodide was used without further purification.

Apparatus and Calorimetric Procedure

The apparatus and procedure used for the main combustion process were identical to those used for C_6F_6 (3), C_7F_8 (4), and C_6F_5I (5). The sole exception was the use of a Parr model 1004 C steel bomb and steel crucible that contained the liquid C_6F_5Br.

The rate of loss of C_6F_5Br from the steel crucible in which it was weighed was 0.0207 mg s^{-1}. The time between weighing the crucible containing the liquid and closing the bomb was such that less than 0.04% of the total sample was lost by evaporation. The correction for the evaporation is estimated to be accurate to better than ±3%. The error generated by the correction procedure should therefore be less than ±0.001%.

Analysis of Reaction Products

The analytical procedures for CO_2, CF_4, and F_2 have been described elsewhere (3–5). Br_2 was either weighed and/or reduced with KI and titrated with standardized 0.05 *N* sodium thiosulphate. Quantitative analysis of BrF_3 was based on determination of F^- using a fluoride specific ion electrode in conjunction with an Orion 701 digital p*H* meter. Mass spectra were obtained using a Varian MAT CH5-DF spectrometer controlled by an INCOS computer system. Fluorine nmr spectra were obtained on a nmr JELCO C60 HL spectrometer and are reported in ppm with trifluoroacetic acid used as an internal standard. A Bauch and Lomb Spectronic 20 colorimeter was used to determine iron with 1,10-phenanthroline. Standards containing Fe(II) and Fe(III) were used. Both the ferrous and ferric iron were determined simultaneously. Only the ferrous complex absorbs at 515 nm and both complexes have identical absorption at 396 nm (the amount being additive) (8).

Results and Discussion

Preliminary combustions done in the platinum lined bomb resulted in the formation of a dark red to yellow–brown solid indicating possible formation of PtF_4. A noticeable loss in weight of the platinum crucible was observed after each combustion. Spot tests showed that platinum(IV) ions were formed (9).

Combustions were then extended to test the suitability of a steel bomb. It has been observed that combustion in this bomb with fluoroaromatic compounds produced the formation of a green coloration inside the bomb (10). This was shown to be iron(II) and iron(III) fluorides (9). A determination of the amount of Fe(II) and Fe(III) fluorides after combustion of C_6F_5Br was tested. A spectrophotometric determination (8) was used and the amount of iron fluorides found after combustion was 1.7 ± 0.01 mg. The correction to the heat of formation of C_6F_5Br caused by the formation of FeF_2 and FeF_3 would be less than 3.3 ± 0.5 kJ mol^{-1} per experiment. All subsequent combustions were therefore carried out using the steel bomb and steel crucible.

The combustion of C_6F_5Br led to the formation of products that were identified as CO_2, CF_4, F_2, Br_2, and BrF_3.

CO_2, CF_4, and F_2 were identified in the same manner as reported for the products of combustion of C_6F_6 (3), C_7F_8 (4), and C_6F_5I (5). Quantitative analysis of these products was carried out by gas chromatographic procedures similar to those previously used (3–5). In this study two types of columns were used. The first column was a 6 ft × ¼ in. od silica gel column (25°C, He carrier, 15 cm^3/min). Uncorrected retention times for O_2, CF_4, and CO_2 are 1 min 30 s, 3 min 12 s, and 12 min 36 s, respectively. In the first five runs in Table 1, the CO_2/CF_4 ratio was found through the use of this column. Calibrations were carried out using O_2–CF_4 and O_2–CO_2 mixtures. Use of pure CF_4 leads to a response factor that is low by 4.6%. The CO_2 calibration is uneffected. The net result is that, if the relative factor determined with pure CF_4 and CO_2 is used, a value for $\Delta H_{f298}{}^{0}(C_6F_5Br, g)$ is obtained that is about 17 kJ mol^{-1} too high.

*Molar ratio.
†From F_2 and BrF_3.
‡Runs 1 to 7 glass trap used to collect liquid products, runs 8 to 13 steel trap used to collect liquid products.
§Additional typical data (see ref. 19 for notation); ΔE, ign/J = 10.1, E(J) $(-\Delta t_c)$/J = −12 850.3, $\Delta E_c^0/M$(compound)/J g^{-1} = −8656.3.

The second column which was a 6 ft × $\frac{1}{4}$ in. od Porapak Q column (25°C, He carrier, 48 cm^3/min) was used to determine the CO_2/CF_4 ratio for the remaining runs. Uncorrected retention times for O_2, CF_4, and CO_2 are 1 min 3 s, 1 min 54 s, and 4 min 57 s, respectively. An improved separation between oxygen and tetrafluoromethane occurred using this column. Use of pure CF_4 leads to a response factor that is low by only 1%.

Condensable products (at −80°C) were collected in either a glass or stainless steel trap. To ensure all products volatile at 25°C were removed from the combustion bomb, the system was flushed with ultra high pure oxygen for 2 h and the bomb was then evacuated through the trap. The cold trap was allowed to come to room temperature. Two immiscible liquids were observed. The major portion (lower phase) had a characteristic colour of free bromine and the upper phase had a colorless to gray–yellow colour. Since a carbon balance had already been established the possibility of any halo-carbon products were unlikely and the fact that all the bromine oxides (11) are unstable at room temperature indicated that the remaining products would be halogen or interhalogen compounds such as Br_2, BrF, BrF_3, and BrF_5. BrF has not been isolated as of yet but there are indications that it does exist through spectroscopic studies.

By simple vacuum distillation the liquids were easily separated. The more volatile substance was dark red in colour and appeared to be free bromine. This was confirmed by mass spectral analysis using a MAT CH5 mass spectrometer. Major peaks were obtained at m/e 162, 160, and 158 with a peak height ratio of close to 1:2:1. In addition peaks of approximately equal height (about 7% of the m/e = 160 peak height) were observed at m/e = 81 and 79. Since the molecular constituents in order of increasing volatility at 25°C are BrF_3, Br_2, BrF_5, and BrF, any BrF_5 and/or BrF would have been collected in the 'bromine' fraction. In addition to the mass spectral analysis this fraction was tested by adding water to the distilled sample. If any halogen fluorides were present they would have reacted with water to form a complex mixture of HF, HBr, $HBrO_3$, Br_2, and O_2 (12). Fluoride analysis of this solution with a specific fluoride ion electrode proved to be negative.

Based on colour and volatility it appeared possible that the remaining liquid was BrF_3. The

*All values in this column are based on $\Delta H_{f298}^0(C_6F_5,g) = -387.4$ kJ mol^{-1} (-92.6 kcal mol^{-1}) determined from the kinetic value of $D(C_6F_5—I)$ and $\Delta H_{f298}^0(C_6F_5I,g) = -557.7 \pm 12.6$ kJ mol^{-1} (-133.3 ± 3.0 kcal mol^{-1}).
†Based on the kinetic value of $D(C_6F_5I)$ and differences in AP values.
‡Kinetic value.

liquid was distilled under vacuum into a carefully dried quartz capillary tube while the tube was immersed in liquid nitrogen. The capillary was then sealed under vacuum and removed for subsequent nmr fluorine analysis. The fluorine nmr analysis indicated a singlet peak corresponding to liquid BrF_3 at -55.2 ppm (literature value -54.3 ppm (13)) relative to trifluoroacetic acid.

The amount of Br_2 was analyzed by either weighing the sample collected in a small ampoule and/or by iodometric analysis (7). The BrF_3 was reacted with KI solution and analyzed for fluoride using the corresponding specific ion electrode. In three runs the BrF_3 fraction was also determined directly by weighing this fraction. Good agreement was obtained between specific ion and gravimetric determination.

From the material balance shown in Table 1 along with the average CO_2/CF_4 molar ratio, reaction 2 may be written to represent the combustion of bromopentafluorobenzene. However, as will be discussed later, it is unlikely that free bromine exists in the bomb.

$$[2]\quad C_6F_5Br + 5.276O_2 \rightarrow 5.276CO_2 + 0.724CF_4 + 0.923F_2 + 0.086BrF_3 + 0.457Br_2$$

In treating a complex mixture of products possible interactions between the compounds must be taken into account. No detectable heat of mixing was observed when F_2, O_2, CF_4, and CO_2 were mixed under anhydrous conditions (5).

However, a correction of -130 ± 13 kJ mol^{-1} is required for the interaction between Br_2, F_2, and BrF_3. Approximately -68.2 kJ mol^{-1} of this correction is due to reaction 3.

$$[3]\quad \tfrac{1}{2}F_2\,(g) + \tfrac{1}{2}Br_2\,(l) \rightleftharpoons BrF\,(g)$$

With the excess F_2 present the equilibrium should be far to the right (14). It should be noted that during the slow bleeding of the bomb over a period of 20 h to recover the combustion products for analysis, the BrF equilibrium shifts to the left resulting in quantitative conversion of BrF to Br_2 and F_2. In an all-metal system (steel traps) the reaction may be somewhat inhibited as indicated by the apparent slight shortfall in bromine recovery (Table 1). The shortfall was always accompanied by the appearance of a light yellow coloration in the F_2 absorbing solution in the bubbler.

In carrying out the thermochemical calculations the following heats of formation have been used: CO_2 (g), -393.512 kJ mol^{-1} (15); CF_4 (g), -933.0 kJ mol^{-1} (16); and BrF_3 (g), -255.60 kJ mol^{-1} (12).

Based on the preceding data and an estimated correction to standard state of 5.5 kJ mol^{-1}, $\Delta H_{f298}^0(C_6F_5Br, g) = -711.6 \pm 5.6$ kJ mol^{-1} with a standard deviation of 5.6 kJ mol^{-1}. However, when the uncertainty in the auxiliary experiments are taken into account the overall limit must be set at about ± 16 kJ mol^{-1}.

Defining $D(C_6F_5—X)$ as ΔH_{298}^0 for the reaction

$$[4]\quad C_6F_5X,g \rightarrow C_6F_5,g + X,g$$

and using the value for $\Delta H_{f298}^0(C_6F_5,g)$ as -387.4 ± 12 kJ mol^{-1} (5) and $\Delta H_f(Br,g) =$

111.7 kJ mol^{-1} (17) and the present determined value of $\Delta H_{f298}{}^{0}(C_6F_5Br,g) = -711.6 \pm 16.7$ kJ mol^{-1} will yield a value of $D(C_6F_5—Br)$ to be 435.9 kJ mol^{-1}.

In Table 2 a comparison is made between $D(C_6F_5X)$ values based on thermochemical methods and appearance potential methods (18). Agreement of the present value of $D(C_6F_5—Br)$ with the value estimated from the AP studies is well within the combined error limits.

Tris(*tert*-butyl)phosphine and tri(*o*-tolyl)phosphine form 1:1 complexes with mercury(II) halides and with mercury(II) thiocyanate. Physicochemical measurements, i.e. conductance, molecular weight determinations, infrared and Raman spectra indicate a dimeric structure of C_{2h} skeletal symmetry. The Hg—X and Hg—P stretching frequencies for all complexes have been assigned.

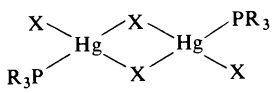
ELMER C. ALYEA, SHELTON A. DIAS, RAM G. GOEL et WILLIAM O. OGINI. Can. J. Chem. **55**, 4227 (1977).

La tris(*tert*-butyl)phosphine et la tris(*o*-tolyl)phosphine forment des complexes 1:1 avec les halogénures et le thiocyanate de mercure(II). Des mesures physicochimiques comme la conductivité, les déterminations de poids moléculaire et les spectres infrarouges et Raman indiquent que les complexes existent sous forme dimère avec une symétrie de squelette C_{2h}. On a fait l'attribution des fréquences de vibration Hg—X et Hg—P pour tous les complexes.

[Traduit par le journal]

Introduction

Mercury(II) salts are known (1) to form complexes with tertiary phosphines in the $HgX_2:PR_3$ ratios of 1:2, 1:1, 2:3, 2:4, and 3:2. Of these, the complexes of the type $(R_3P)_2HgX_2$ are the best characterized (1–7). The complex $(Ph_3P)_2Hg(SCN)_2$ has been shown by an X-ray diffraction study (6) to have a tetrahedral structure. A similar structure has been assigned (5) for the halide complexes $(Ph_3P)_2HgX_2$ on the basis of their infrared spectra in the low frequency region. Although the complexes of the type $(R_3P)HgX_2$ have been studied by several workers (1, 3, 7–10), their structures have not been well established. The complexes $(R_3P)HgX_2$ where X = halide and R = alkyl were found to be dimeric in solution and the dimeric *trans* structure as shown below was assigned by analogy with the structure established for the complex $(Et_3As)HgI_2$ by preliminary crystallographic analysis (1).



After the completion of this work, a preliminary report (11) on the crystal structures of the complexes $(R_3P)HgCl_2$ (R = Me, Et, or Ph) and $(Ph_3As)HgCl_2$ has appeared, which shows that the structures of the 1:1 complexes are markedly influenced by the nature of the phosphine. The complexes $(Ph_3P)HgCl_2$ and $(Ph_3As)HgCl_2$ are isostructural and consist of the expected chlorine-bridged centrosymmetric dimeric molecules. However, the complexes $(Me_3P)HgCl_2$ and $(Et_3P)HgCl_2$ have polymeric structures containing five-coordinate mercury atoms. Likewise, the crystal structure (12) of the complex $(Ph_3As)Hg(SCN)_2$ unexpectedly shows a trigonal coordination around mercury with two additional Hg---NCS contacts defining a distorted trigonal bipyramid geometry. A similar structure has also been suggested (8) for the complex $(Cy_3P)Hg(SCN)_2$[1] on the basis of a vibrational spectral study but an X-ray single-crystal analysis (13*a*) has established the structure as polymeric with trigonal pyramidal geometry at each mercury atom. Similarly, a recent X-ray single-crystal determination (14) has established that $(Ph_3P)Hg(NO_3)_2$ forms infinite chains via bridging nitrato groups; the coordination geometry about mercury may be described as very distorted tetrahedral or as distorted square pyramidal (if an additional weak Hg—O bond is included). In contrast, the crystal structure (13*b*) of $(Cy_3P)Hg(NO_3)_2$ is quite different, the molecule being dimeric with each mercury atom having a distorted square pyramidal coordination geometry.

[1] Cy_3P is tricyclohexylphosphine.

In order to evaluate the role of steric effects in metal complexes of tertiary phosphines we have undertaken a study of metal complexes of tertiary phosphines containing bulky substituents (13, 15–17). Recent studies (15*b*, 18) have clearly shown that the steric requirements of the substituents on phosphorus have a marked effect on the stereochemistry and the chemical reactivity of metal complexes of phosphorus ligands. In a previous paper (15*a*) we reported on the tris(*tert*-butyl)phosphine complexes of zinc(II) and cadmium(II). Herein we report on the synthesis, characterization, and vibrational spectra of tris(*tert*-butyl)phosphine and tri(*o*-tolyl)phosphine complexes of mercury(II) halides and mercury(II) thiocyanate.

Results and Discussion

Reaction of tris(*tert*-butyl)phosphine with mercury(II) halides or with mercury(II) thiocyanate in 2:1 mole ratio, in an aprotic solvent such as ether or dichloromethane, gave 1:1 complexes instead of the possible 2:1 complexes. The reaction of mercury(II) salts with tri(*o*-tolyl)phosphine also gave 1:1 complexes. Since less bulky tertiary phosphines such as tricyclohexylphosphine (8) and triphenylphosphine (5–7, 10) form both 1:1 and 2:1 complexes with mercury(II), the formation of only 1:1 complexes in the present work is evidently due to the large steric requirements of tris(*tert*-butyl)- and tri(*o*-tolyl)phosphines. A measure of the steric requirement of the phosphine ligands in terms of a "cone angle" has been proposed by Tolman (18). He estimated cone angles for $(o\text{-tolyl})_3P$, $Bu_3{}^tP$, Cy_3P, and Ph_3P to be 194°, 182°, 170°, and 145° respectively, using CPK molecular models. A crystallographic study (17) on the complex $[Bu_3{}^tPH][(Bu_3{}^tP)NiBr_3]$ showed that the Ni—$PBu_3{}^t$ cone angle is 180 ± 2°. X-ray structural studies (13) of several complexes have established that Tolman's estimates for the cone angle of PCy_3 (originally calculated as 179 ± 10°) are in good agreement with the observed range of experimentally derived cone angles.

The melting points, analytical, conductance, and molecular weight data for the complexes prepared in this work are given in Table 1. The conductance data clearly show that all the complexes behave as nonelectrolytes in nitromethane or dimethylsulfoxide. The molecular weight data for the tris(*tert*-butyl)phosphine complexes show their dimeric constitution in 1,2-dichloroethane. The molecular weights of the tri(*o*-tolyl)phosphine complexes could not be determined due to their insolubility in any solvent suitable for molecular weight measurements.

The infrared and Raman spectral data for the halide complexes in the region below 400 cm^{-1}, in the solid state, together with their assignments are shown in Tables 2 and 3. From a comparison of these infrared data with the infrared data reported for the $(Ph_3P)HgX_2$ complexes (5) it is clearly evident that the infrared frequencies associated with the vibrations involving the metal–halogen bonds in the complexes of tris(*tert*-butyl)phosphine, tri(*o*-tolyl)phosphine, and triphenylphosphine complexes are very similar. Thus, there can be little doubt that the mercury(II) halide complexes of tris(*tert*-butyl)-phosphine, tri(*o*-tolyl)phosphine, and triphenyl-phosphine are structurally similar.

A dimeric *trans*-tetrahedral structure of C_{2h} skeletal symmetry (*vide supra*) should give rise to only one infrared active and one Raman active frequency due to the stretching of the terminal mercury–halogen bonds. The Raman spectrum for each complex listed in Tables 2 and 3 showed only one band that can be assigned to the terminal mercury–halogen stretching frequency. Like the corresponding infrared frequency, this frequency is progressively decreased to lower wave numbers as X is changed from Cl to Br to I. For the chloride and the bromide complexes a Raman band due to a bridged Hg—X stretching mode is also observed. The Raman spectra of the tris(*tert*-butyl)phosphine complexes also show a strong band in the 123–110 cm^{-1} region. A similar Raman band is observed for the tri(*o*-tolyl)phosphine complexes in the 138 to 122 cm^{-1} region. Since no band is observed in these regions in the Raman spectra of the free phosphines, the above mentioned Raman bands are most likely due to the Hg—P stretching frequencies. As shown by the far infrared data (5) for tetrahedral $(Ph_3P)_2HgX_2$ complexes, the Hg—X bending frequencies are expected in the region below 80 cm^{-1}. Thus the combined infrared and Raman data for the present complexes are in complete accord with a dimeric tetrahedral structure of C_{2h} skeletal symmetry.

The assignments for the Raman bands in the region below 100 cm^{-1} cannot be made with certainty without polarization measurements.

Unfortunately, attempts to obtain Raman spectra in solution were not successful due to lack of solubility of the complexes in suitable solvents. The remaining Raman bands listed in Tables 2 and 3 are due to the internal vibrations of the coordinated phosphines.

In spite of several studies on tertiary phosphine complexes of mercury(II) little information is available on the Hg—P stretching frequencies. From the far-infrared spectral study (5) of the $(Ph_3P)_2HgX_2$ complexes the Hg—P stretching frequencies have been assigned in the range of 137 to 98 cm^{-1}. In a recent report (19) on trimethylphosphine complexes of mercury(II), the Hg—P stretching frequencies for the complexes $(Me_3P)HgX_2$ where X = halide or pseudohalide have been assigned in the 364 to 342 cm^{-1} region. Since the metal–phosphorus stretching frequencies (20) for the Ni(II) and Pd(II) complexes $(R_3P)_2MX_2$ have been found to be below 200 cm^{-1}, we believe that the assignments for the Hg—P stretching frequencies for the trimethylphosphine complexes of mercury(II) are erroneous. Our assignments for the Hg—P stretching frequencies for the tris(*tert*-butyl)-phosphine and the tri(*o*-tolyl)phosphine complexes are thus consistent with those for the $(Ph_3P)_2HgX_2$ complexes. Further support for

the proposed assignments is provided by the Raman data for the tertiary phosphine complexes of the halides of the main group elements. The In—P symmetric frequency for the complex $(Me_3P)_2InCl_3$ has been found (21) to be at 135 cm^{-1} by a single-crystal Raman polarization study. The Sn—P symmetric stretching frequency for the complex *trans*-$SnCl_4(PMe_3)_2$ has been reported (22) to be at 146 cm^{-1}. It is worth noting that the Hg—P stretching frequencies for the tris(*tert*-butyl)phosphine complexes as well as the tri(*o*-tolyl)phosphine complexes show a progressive decrease as X is changed from Cl to Br to I. A similar trend has been observed (15*a*) for the Zn—P and Cd—P stretching frequencies of the complexes with tris(*tert*-butyl)-phosphine.

The observed infrared and Raman frequencies due to the internal vibrations of the SCN groups for the complexes $(Bu_3^tP)Hg(SCN)_2$ and $[(o\text{-tolyl})_3P]Hg(SCN)_2$, in the solid state, are given in Table 4. By comparing these frequencies with the frequencies reported (23) for N-bonded, S-bonded, and bridged SCN groups, it can be concluded that both complexes contain S-bonded and/or bridging SCN groups. The observation of three ν(CN) frequencies for each compound suggests that each complex contains both S-bonded and bridging SCN groups. The infrared and Raman data for both compounds in the low frequency region, shown in Table 5, are also consistent with the presence of both S-bonded and bridging SCN groups. The infrared spectra of both complexes show medium to weak bands at ca. 270 and 250 cm^{-1}. Strong to medium bands in these regions are also observed in the Raman spectra. By comparison of these bands with the reported (24) infrared and Raman frequencies for $Hg(SCN)_2$ they can be assigned to the terminal Hg—SCN stretching

frequencies. For both compounds another infrared band is observed at ca. 170–180 cm^{-1}. Since this band is not observed for the free phosphines it can be assigned to a bridging Hg—SCN stretching frequency. The assignment of this band to a Hg—SCN bending frequency can be ruled out because the Hg—SCN bending frequency for $Hg(SCN)_2$ is reported (24) to be at 148 cm^{-1}. The Raman spectra for both $(Bu_3{}^tP)Hg(SCN)_2$ and $[(o\text{-tolyl})_3P]Hg(SCN)_2$ show a strong band in the 120–112 cm^{-1} region. Following the assignments for the halide complexes, this band can be assigned to the Hg—P stretching frequency.

Although the Raman spectrum of neither compound could be examined in solution, the infrared measurement for the $(Bu_3{}^tP)Hg(SCN)_2$ complex in chloroform solution, in the ν(CN) spectral region, showed no change in the ν(CN) frequencies. It therefore appears that the solid state molecular geometry of this compound is maintained in solution. A dimeric formulation is compatible with the solution molecular weight determination and the assigned structures of the halides. The solid state infrared and Raman spectral bands assignable to thiocyanato modes for the $[(o\text{-tolyl})_3P]Hg(SCN)_2$ complex are nearly identical to those found for $(Cy_3P)Hg(SCN)_2$ (note that three Raman bands are observed in the ν(CN) region). The latter complex has a polymeric structure involving one thiocyanato bridge linking trigonal pyramidal mercury atoms (13*a*).

The proton nmr spectra for the tris(*tert*-butyl)phosphine complexes in dichloromethane show a doublet shifted downfield (δ = 1.63–1.65 ppm; $^3J_{P-H}$ = 15.0 Hz) as compared with the chemical shift of the free phosphine (δ = 1.30 ppm; $^3J_{P-H}$ = 10.0 Hz). A similar downfield shift (ca. 0.05 ppm) occurs for the methyl resonance in DMSO-d_6 solution of the tri(*o*-tolyl)phosphine complexes.

Experimental Section

Chemicals

Tri(*o*-tolyl)phosphine was prepared according to literature methods (25, 26), or obtained from Pressure Chemicals; other commercial samples were very impure. Tris(*tert*-butyl)phosphine was synthesized as previously described (16). Mercury(II) halides were obtained from Alfa Inorganics, Inc. $Hg(SCN)_2$ was prepared by a reported method (24). Solvents were purified and dried following standard procedures.

General Procedures

All operations involved in the preparation and purification of tris(*tert*-butyl)phosphine complexes were carried out either in a dry-box under an atmosphere of oxygen-free dry nitrogen or under vacuum. Elemental analyses were performed by M-H-W Laboratories, Garden City, Michigan. Molecular weights were measured with a Hitachi-Perkin-Elmer 115 osmometer. Melting points, conductance, infrared, Raman, and nmr spectra were measured as reported previously (16).

Preparation of Tris(tert-butyl)phosphine Complexes

(*a*) Tris(*tert*-butyl)phosphine (2.20 mmol) was added with stirring to a solution of mercury(II) halide (1.00 mmol) in 25 ml ether. The white solid formed was filtered off and recrystallized from a mixture of dichloromethane and petroleum ether. Yield: ca. 80%. The filtrate was concentrated to give a viscous liquid, which was found to be unreacted tris(*tert*-butyl)phosphine as shown by its ^1H nmr spectrum.

(*b*) A solution of 2.20 mmol Bu_3^tP in 10 ml dichloromethane was added with stirring to a suspension of 1.01 mmol $Hg(SCN)_2$ in 20 ml dichloroethane. A clear solution was formed after stirring for 6 h; upon concentrating the solution and adding petroleum ether to the concentrated solution the white $(Bu_3^tP)Hg(SCN)_2$ was precipitated. Recrystallization from dichloromethane yielded colourless needle-shaped crystals. Yield: 75%.

Preparation of Tri(o-tolyl)phosphine Complexes

(*a*) A 1.00 mmol solution of tri(*o*-tolyl)phosphine in 25 ml diethyl ether was slowly added to a stirred solution of 1.00 mmol mercury(II) halide in 25 ml diethyl ether (acetone for the bromide). After $\frac{1}{2}$ h reflux, the white precipitate was collected by filtration, washed with several portions of diethyl ether, and recrystallized from nitromethane or ethanol. The same products were obtained using excess $(o\text{-tolyl})_3P$. Yield: ca. 90%.

(*b*) A warm solution of 1.00 mmol tri(*o*-tolyl)phosphine in 30 ml ethanol was added dropwise to a stirred suspension of 1.00 mmol $Hg(SCN)_2$ in 30 ml of ethanol. The reaction mixture was refluxed for $\frac{1}{2}$ h and the white crystalline product collected by filtration. After washing with ethanol, recrystallization was effected from *n*-propanol. Yield: 96%.

Constituents of *Nauclea diderrichii*. Part IX. Conversion of sweroside to naucledal and 3-epinaucledal

JOHN PURDY AND STEWART MCLEAN

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received July 4, 1977

JOHN PURDY and STEWART MCLEAN. Can. J. Chem. **55**, 4233 (1977).

The aglucone of sweroside has been converted to naucledal and its epimer, 3-epinaucledal; the structure and stereochemistry of these products have been established through analysis of their nmr spectra. The course of the rearrangement has been studied and the intermediacy of a ring-opened isomer, seconaucledal, has been demonstrated. The relative amounts of naucledal and 3-epinaucledal produced from seconaucledal depend on the conditions of the cyclization.

JOHN PURDY et STEWART MCLEAN. Can. J. Chem. **55**, 4233 (1977).

On a transformé l'aglycone de la swéroside en naucléda l et en son épimère l'épi-3 naucléda l; on a pu établir la structure et la stéréochimie de ces produits par une analyse de leur spectra rmn. On a étudié l'évolution du réarrangement et on a démontré l'existence d'un isomère à cycle ouvert, le seconaucléda l, comme intermédiaire. Les quantités relatives de naucléda l et d'épi-3 naucléda l qui se forment à partir du seconaucléda l dépendent des conditions de la cyclisation.
[Traduit par le journal]

One of the neutral materials extracted from the bark of *Nauclea diderrichii* was a colorless syrup, the principal component of which was assigned the name naucledal (1). Although a homogeneous sample could not be obtained and the material appeared to be rather unstable, sufficient spectroscopic data could be obtained to allow the assignment of structural formula I to naucledal as a working hypothesis.

The secoiridoid glucoside, sweroside, has been assigned formula **1***a*, the structure and configuration of which appear to be on secure grounds (2). Examination of this structure led us to propose that a route to a product of formula I should be available through the aglucone (**1***b*) and a rearranged intermediate, II. In a preliminary report (3) we have shown that this transformation could, indeed, be carried out and that naucledal can be assigned the structure and relative configuration **2**. We now report on the details of this conversion.

Aliquots of a solution of the crystalline aglucone **1***b* (4) in pyridine-d_5 were subjected to a range of reaction conditions in which the amounts of water and acid added to the solution and the temperature were varied. The progress of the reaction was followed by nmr spectroscopy. Signals appropriate for the intermediate II (which we shall refer to as seconaucledal) and the product I appeared at rates that were markedly dependent on the reaction conditions; signals attributed to other reaction products, generally

formed in smaller amounts, were also observed, and the composition of the reaction mixture depended on its history. The conditions that appeared optimum for the formation of I (aqueous pyridine at 100°C) were then applied on a preparative scale. Removal of the solvent *in vacuo* and chromatography of the residue afforded in 64% yield a product that closely resembled natural naucledal in spectroscopic and tlc behavior.

It became apparent, however, that neither the material obtained from the *Nauclea* extract nor

*Coupling constants established by spin–spin decoupling.
†See formula I for complete numbering system. The sample contained ~60% of **3** and ~40% of **2** (see Experimental). Assignments were made after subtracting the spectrum of **2** (see Table 1).
‡These multiplets appear to overlap completely the multiplets associated with **2**; the resolution of the signals suggests that the characteristics of those from **2** are very similar to those from **3**.

the rearrangement product from **1***b* was a single homogeneous substance, but consisted of a mixture of isomers that could not be completely separated. It was necessary, therefore, to use the close similarity of the ir spectra of the materials and a signal-to-signal comparison of their nmr spectra to judge the identity of components. It is desirable to reserve the name naucledal for the principal isomer obtained in the original isolation (1).

The rearrangement conditions described above produced material that corresponded most closely to the material isolated from *N. diderrichii*. The nmr spectrum showed that it consisted mainly of naucledal, but that an epimer was also present in smaller amounts. Examination of the original spectra showed that this epimer was also present in the material from *N. diderrichii*. The rearranged material afforded a crystalline oxime that was also a mixture of stereoisomers, but gave satisfactory results on microanalysis.

The material obtained from sweroside was then used to assign the structure and configuration of **2** to naucledal from a detailed examination of its 220 MHz nmr spectrum. The key data were the values of 11 and 10 Hz assigned to the coupling constants between the proton at C-2 and those at C-7 and C-3, respectively; details of the analysis are shown in Table 1. It was found that when the aglucone **1***b* was stirred in water with silica gel, naucledal and the epimer observed previously were again produced, but the product was much richer in the epimer (~60%), and a similar detailed examination of the 220 MHz nmr spectrum of this component was carried out. The analysis, which establishes that the molecule is an isomer of **2**, is recorded in Table 2. The proton at C-2 still shows the 11 Hz coupling to the C-7 proton, but its coupling to the C-3 proton is now 4 Hz. It follows that the compound is 3-epinaucledal, **3**. A careful examination of the nmr spectra of various product mixtures reveals the presence of other signals that can reasonably

be attributed to C-2 epimers of **2** and **3**, but the concentration of these isomers was never high enough to allow a thorough analysis of their spectra.

That naucledal, the dominant stereoisomer under conditions where equilibrium is approached, has the configuration of **2** with no axial substituents is in accord with expectations based on thermodynamics. It follows that mixtures rich in 3-epinaucledal, **3**, are formed under conditions where kinetic control is more important. It may be noted, however, that the antiviral natural product, elenolic acid, is structurally related to naucledal, but its stereochemistry corresponds to that of 3-epinaucledal, **3** (5). Moreover, Kelly and Schletter obtained isomerically pure methyl elenolate by a rearrangement similar in design to ours and apparently carried out under conditions very similar to those in which we obtained **2** as the dominant product.

The interconversion of **2** and **3** requires a retro-Michael reaction to afford an intermediate such as II, related to (if not identical with) the intermediate implicated in their formation from **1***b*. As was noted earlier, there is spectroscopic evidence for the presence of such an intermediate in some of the mixtures produced by rearrangement. In fact, under some conditions the intermediate, seconaucledal, appeared to be the principal product obtained from **1***b* and it could be methylated with diazomethane and acetylated with acetic anhydride. It was not possible to obtain any of these compounds in a sufficiently pure state for satisfactory characterization, but some spectroscopic data could be collected. These data, particularly from the nmr spectra, indicate that the intermediate exists, at least predominantly, as a single isomer. Some evidence bearing on the configuration of the double bonds at C-2 and C-8 was observed. In the related case of vallesiachotamine and its geometrical isomer, homoallylic coupling between the methyl group corresponding to C-4 and the proton at the site corresponding to C-7 was observed only in the isomer in which these two carbon centres were *trans* related (6). The absence of such coupling in seconaucledal and its derivatives provides evidence, albeit weak since only one isomer was observed, for placing the methyl and aldehyde groups in a *trans* relationship. The configuration at C-9 is even less secure, but under the conditions used to observe the ir spectrum, the values obtained for the stretching frequencies of the hydroxyl and carbonyl groups, as well as the shape of the spectroscopic envelopes they produce and their behavior on dilution, indicate that the hydroxyl is hydrogen-bonded to the lactone carbonyl. Formula **4** is thus the best available representation of the molecule. It may be noted, however, that while acetylation of seconaucledal appears to produce a single enol acetate, diazomethane converts it to a crude product which exhibits two distinct singlets characteristic of methyl ethers as well as smaller peaks that may also be associated with methyl ethers; it appears, therefore, that at least two isomeric enol ethers are formed, but it is possible that isomerization has occurred during their formation and isolation.

The conversion of sweroside to naucledal and 3-epinaucledal has allowed us to establish the structure and stereochemistry of the products and to identify them as constituents of *N. diderrichii*. It is, moreover, gratifying to find evidence that the rearrangement did, indeed, follow the predicted path through an intermediate of the anticipated type. However, more careful examination of the nature and behavior of seconaucledal raises questions about details of its role in the rearrangement. The C-9 hydroxyl group in **4** appears to have the wrong orientation for the required Michael addition at C-3, but this is a relatively minor point, since ready isomerization at this enolic centre can be anticipated. Of more significance is the apparent stability of the intermediate under a number of reaction conditions. As has been stated previously, the aglucone **1***b* rearranged rapidly to a mixture of **2** and **3** in hot aqueous pyridine. In dry pyridine, the intermediate **4** formed rapidly but was converted to ring-closed material very slowly, and under these conditions, it could be observed that the ratio of **3** to **2** in the product was highest in the early stages of ring closure. In pyridine containing an added acid, the intermediate again formed rapidly, but either failed to undergo ring closure or did so at a rate slower than that of reactions leading to its degradation.

These results can be best explained by postulating that **2** and **3** are not, in fact, formed from **4** by a simple Michael addition. The data from the reaction in dry pyridine suggest that the C-9 hydroxyl group is not an effective Michael donor (either for stereochemical reasons or because the lone-pair electrons are too delocalized). However, water catalyzes the ring closure, and it is

logical to propose that it does so by acting as a Michael donor itself and converting the unsaturated aldehyde to the aldol **5** (or its epimer); it is the hydroxyl group produced in this way that adds to C-9 in the Michael fashion and the subsequent elimination of a molecule of water leads to **2** (or **3**). In the presence of an acid, the unsaturated aldehyde in **4** remains unhydrated; in accord with this is the common observation that aldols undergo very ready dehydration in acidic media. The relative amounts of **2** and **3** formed when kinetic control is important may reflect factors influencing the stereochemistry of the hydration of **4** as well as those governing the cyclization process; when equilibration can occur, the thermodynamic arguments remain unchanged. Undoubtedly, we are describing only a portion of a larger and more complex equilibrium, but in the local area of interest, these proposals can explain all of the observations.

Experimental

Melting points were determined on a Thomas-Kofler micro hot stage. Infrared spectra were obtained on a Perkin-Elmer 337 spectrometer with samples dissolved in chloroform; the wavelengths (μm) of significant peaks are reported. A Unicam SP 1800 ultraviolet spectrometer was used; the solvent was methanol and the wavelengths (nm) of absorption peaks are reported. Routine nmr spectra (60 MHz) were obtained on a Varian T-60 spectrometer with samples dissolved in chloroform-*d* (containing tetramethylsilane) unless otherwise indicated; chemical shifts are reported on the τ scale and are followed in parentheses with an indication of the signal multiplicity (initial letter), the coupling constants (*J* in Hz) if determined, and the number of protons associated with the signal; in the spectra of impure samples the characteristics of complex signals could not be assigned with confidence, but rough values are quoted for completeness. The 220 MHz spectra were determined at the Canadian 220 MHz NMR Centre with a Varian HR-220 spectrometer; the results are reported in Tables 1 and 2. Samples rich in naucledal or 3-epinaucledal (see below) were dissolved in chloroform-*d* (containing tetramethylsilane); signals characteristic of the component of interest were identified by as many characteristics as possible: relative area, the change in relative areas with change in composition, and decoupling techniques. The circular dichroism measurement was made with a Roussel-Jouan Dichrographe II.

Sweroside Aglucone (1b)

Sweroside, isolated from local *Lonicera tatarica*, was cleaved with almond β-D-glucosidase according to the method of Linde and Ragab (4) and the aglucone was obtained as crystals, mp 121–123°C. The mp and spectroscopic data were in accord with literature values (4).

Rearrangement Reactions

Preliminary studies were carried out with solutions of the aglucone **1***b* in pyridine-d_5 (5 to 10 mg in 0.1 ml) containing variable amounts of water and acid (HCl or $MeSO_3H$). The nmr spectra of solutions at various temperatures were recorded and time-dependent changes were observed; of particular value for identifying components and judging their relative concentrations were the distinctive methyl doublets and the signals associated with the aldehyde groups and the β-proton of the alkoxyacrylate groups (see below). Typical results were the following.

(*i*) A solution of **1***b* in pyridine-d_5 containing 10% of water was heated to 105–110°C. The nmr spectrum was recorded at hour intervals for 6 h. After 1 h, signals associated with naucledal (~70%), seconaucledal (~20%) and 3-epinaucledal (~10%) were observed and only traces of the aglucone appeared to be present. Subsequent spectra showed little change in product composition.

(*ii*) A solution of **1***b* in dry pyridine-d_5 was heated to 105–110°C. After 3 h the aglucone had been converted to seconaucledal (~50%) and about equal amounts of naucledal and 3-epinaucledal. The composition of the reaction mixture then changed slowly with time, with the amount of naucledal increasing at the expense of the other components, and after about 1 day the composition corresponded to that produced in (*i*) above.

(*iii*) A solution of **1***b* in pyridine-d_5 containing 10% of a solution of 50% aqueous methanesulfonic acid was observed at room temperature. Signals associated with seconaucledal increased steadily with time at the expense of the aglucone. Complete conversion required about 2 days. No signals associated with naucledal or its epimer were observed, even when the solution was heated.

Preparative Scale

Naucledal (2)

A solution of sweroside aglucone (**1***b*, 70 mg) in 1 ml of 10% aqueous pyridine was heated at 100–110°C under nitrogen for 3 h. The solution was allowed to cool and the solvent was removed by evaporation under reduced pressure; addition of benzene to the residue and evaporation was then carried out repeatedly to ensure the complete removal of solvent. Preparative tlc on deactivated silica gel with elution by methylene chloride – acetone (9:1) led to a single band (R_f 0.3) which provided a yellow oil (45 mg) that was identical in all significant respects with the material obtained from *N. diderrichii* (1) (tlc, ir, uv, nmr, and ms); circular dichroism λ (MeOH) ($[\theta]_{max}$) 283 (10 550), 309 (−3690). Examination of its nmr spectrum showed that this material consisted of naucledal (**2**, ~90%) and 3-epinaucledal (**3**, ~10%) with traces of other epimers (see Tables 1 and 2). A sample was converted to a crystalline oxime, mp 175–183°C. *Anal.* calcd. for $C_{10}H_{13}O_4N$: C 56.86, H 6.20, N 6.63; found: C 56.90, H 6.31, N 6.68.

3-Epinaucledal (3)

The sample richest in **3** was prepared by stirring a solution of the aglucone **1***b* (20 mg) in 1 ml of water with silica gel (0.2 g, 70–230 mesh) for 24 h at room temperature. The silica gel was removed by filtration, washed with methanol, and the washings were combined with the aqueous solution. Evaporation under reduced pressure then afforded a yellow oil (20 mg) which consisted of **3** (~60%) and **2** (~40%) and traces of isomers (see Tables 1 and 2).

Seconaucledal

A solution of the aglucone **1***b* (34 mg) in 1 ml of pyridine containing about 0.1 ml of 40% aqueous

methanesulfonic acid was left at room temperature for 2 days and then heated to 70°C for 1 h. A further 20 ml of pyridine was added, and the volume of the solution was reduced to about 1 ml by distillation under reduced pressure to remove water. About 20 ml of dry ether was added and pyridinium salts were removed by filtration. The solvent was then removed on the rotary evaporator to provide crude seconaucledal as a gummy residue (32 mg). This material could not be purified satisfactorily because of its instability; under some conditions it readily cyclized to naucledal and 3-epinaucledal. Spectroscopic data: ir: 2.80, 3.0 (b, unchanged on dilution), 3.70, 5.92, 6.00, 6.22; uv: 245, 282 (shoulder); in base 285, reversed by acid; nmr: 0.78 (b s, 1), 1.4 (b, 1), 2.35 (m, 1), 3.20 (q, J = 7; 1, coupled to 7.95), 5.4–6.2 (complex, 2), 6.9–7.3 (m, 1), 7.7–8.2 (complex, 2), 7.95 (d, J = 7; 3, coupled to 3.20).

When seconaucledal was treated with an excess of diazomethane in ether at 0°C, a mixture of products, including some cyclized material, was obtained; peaks of equal height at 6.20 and 6.35 in the nmr spectrum indicated the presence of two methyl ethers; small satellite peaks were also observed. By preparative tlc on silica gel (9:1 methylene chloride – acetone elution), a single methyl ether was isolated, but this could not be purified further. Spectroscopic data: ir: 5.88, 6.22; nmr: 0.71 (b s, 1) 2.79 (d, J = 2; 1), 3.40 (q, J = 7; 1), ~7.9 (complex, 2), 8.00 (d, J = 7; 3).

When seconaucledal was treated with an excess of acetic anhydride and pyridine and the crude product from the standard isolation procedure was subjected to tlc on silica gel (9:1 methylene chloride – acetone elution), an impure acetate was obtained. Attempts at further purification were not fruitful (tlc on silica gel deactivated by water led to the formation of naucledal and seconaucledal). Spectroscopic data: ir: 5.61, 5.88, 5.92, 6.12, 6.20; nmr: 0.64 (b s, 1), 1.90 (d, 1), 3.31 (q, J = 7; 1), ~5.8 (complex, 3), 7.6–8.2 (complex, 2), 7.82 (s, 3), 7.93 (d, J = 7; 3).

Acknowledgments

We thank Dr. A. Grey for the 220 Hz nmr spectra and Dr. H. Boucher for the circular dichroism measurements. This research was supported by the National Research Council of Canada.

Synthesis of proctolin, a pharmacologically active pentapeptide in insects

ALVIN NEIL STARRATT AND BRIAN ELLMAN BROWN

Agriculture Canada, Research Institute, University Sub Post Office, London, Ont., Canada N6A 5B7

Received June 20, 1977

ALVIN NEIL STARRATT and BRIAN ELLMAN BROWN. Can. J. Chem. **55**, 4238 (1977).

The synthesis of the pentapeptide H-Arg-Tyr-Leu-Pro-Thr-OH by the mixed anhydride procedure and by the pentafluorophenyl ester method is described. This synthetic peptide is identical to proctolin, a myotropic substance isolated from the cockroach, *Periplaneta americana* (L.).

ALVIN NEIL STARRATT et BRIAN ELLMAN BROWN. Can. J. Chem. **55**, 4238 (1977).

On décrit la synthèse du pentapeptide H-Arg-Tyr-Leu-Pro-Thr-OH par la procédure à anhydride mixte ainsi que par la méthode de l'ester pentafluorophényle. Ce peptide synthétique est identique à la proctoline, une substance myotropique isolée à partir de l'insecte *Periplaneta américana* (L.).

[Traduit par le journal]

Recently we reported the isolation of the myotropic substance proctolin from the cockroach, *Periplaneta americana* (L.), and its identification as H-Arg-Tyr-Leu-Pro-Thr-OH (1, 2).[1] Proctolin is a peptide of neural origin occurring in highest titre in nerves innervating the viscera (4). This peptide evokes contraction of the visceral musculature at threshold concentrations of about 10^{-9} *M*. Pharmacological and other lines of evidence suggest that proctolin functions as an excitatory neuromuscular transmitter in insect visceral muscle (4, 5). Although most of our studies have been limited to *P. americana*, it has been shown that proctolin occurs in a wide variety of insects (6). The synthesis of proctolin was undertaken to confirm the assigned structure and to provide sufficient material for further studies of its physiological role.

Proctolin was first synthesized in a stepwise manner by the mixed anhydride procedure using conditions for racemization-free coupling (7). The overall route is shown in Scheme 1. Reaction with the wrong moiety of the mixed anhydride can occur to a significant extent during coupling of amino acids to proline by this method (8). Therefore, to avoid a poor yield at the tripeptide stage and difficulties in purification expected from a synthesis commencing with the C-terminal amino acid of proctolin, we began by coupling Boc-Leu-OH to H-Pro-OMe. Treatment of the products with hydrogen chloride – acetic acid to remove the *tert*-butoxycarbonyl group yielded crystalline H-Leu-Pro-OMe·HCl. This substance was also obtained by the pentafluorophenyl ester method of coupling. Sequential addition of N-protected H-Tyr(Bzl)-OH and H-Arg(NO_2)-OH yielded the tetrapeptide, Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OMe. The acid from alkaline hydrolysis was coupled to H-Thr-OBzl by the mixed anhydride procedure and, with similar results, by the use of diphenylphosphoryl azide (9). Hydrogenolysis removed all the protecting groups yielding H-Arg-Tyr-Leu-Pro-Thr-OH which after purification was shown to be chromatographically, electrophoretically, and pharmacologically identical to natural proctolin (2).

Starting from threonine, the sequential synthesis of proctolin was also accomplished by the pentafluorophenyl ester method (10, 11) as outlined in Scheme 2. In some cases, the pentafluorophenyl esters were prepared immediately before the coupling step and used without purification. This did not appear to result in lower yields or products that were more difficult to purify. Occasionally, samples of the pentafluorophenyl ester of Boc-Arg(NO_2)-OH were partially converted during handling and storage to a less polar substance, probably a lactam analogous to that obtained when synthesis of the *p*-nitrophenyl ester of Z-Arg(NO_2)-OH was attempted (12). A significant amount of this substance was not observed, however, in samples of freshly prepared, crude ester. After removal of the *tert*-butoxycarbonyl group of the pentapeptide derivative with hydrogen chloride – acetic acid, other protecting groups were removed in one operation by catalytic hydrogenolysis. Puri-

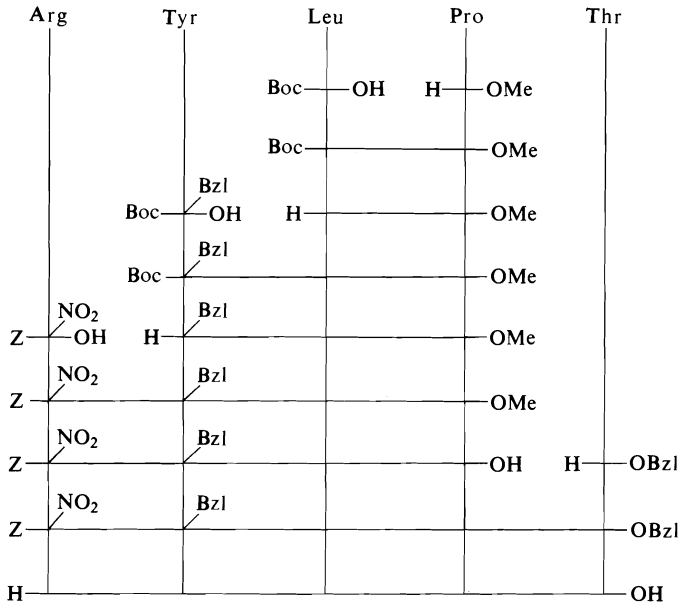
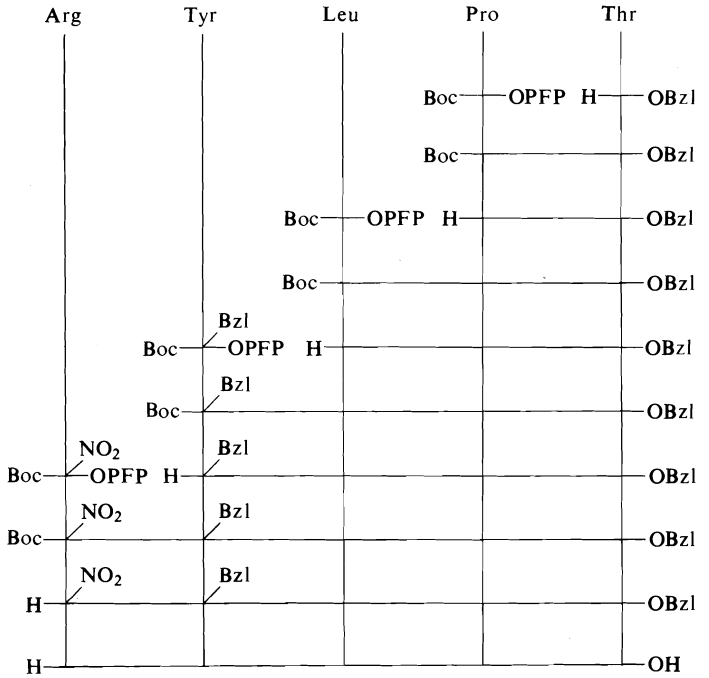


SCHEME 1

fication by ion-exchange chromatography and gel filtration yielded pure proctolin.

Peptides can usually be synthesized rapidly and efficiently by repeated addition of an excess of either the amino acid pentafluorophenyl esters or the mixed anhydrides to the peptide chain without purification of the intermediates (8, 11, 13). Proctolin has been synthesized in this manner by both methods. Although by-products were formed in each case during the coupling of Boc-



SCHEME 2

Arg(NO_2)-OH, the mixed anhydride procedure appeared to produce superior results in our hands. For the early steps in the synthesis of proctolin it is more convenient to use the pentafluorophenyl ester method since chain-lengthening can begin at the C-terminal end.

As well as confirming the structure of proctolin, the syntheses have furnished sufficient material for further physiological studies. In addition, intermediates useful in the synthesis of proctolin analogs have been characterized.

Experimental

The L-amino acids and derivatives used as starting materials were purchased from Pierce or Sigma Chemical Co. Dimethylformamide, dioxane, and tetrahydrofuran were passed through columns of basic alumina before use. The purity of amino acid and peptide derivatives was checked by thin-layer chromatography on Kieselgel DF-5 (Camag) plates using chloroform–methanol – acetic acid (85:10:5.5) and chloroform–methanol (19:1, 9:1, or 4:1). Spots were detected by use of ninhydrin and uv illumination. Melting points were determined on a Kofler hot stage and are uncorrected. Microanalyses were performed by Dr. C. Daessle, Montreal, and the amino acid analysis was carried out by the Amino Acid Analysis Laboratory, Chemistry and Biology Research Institute, Agriculture Canada, Ottawa.

Extracts containing completely protected peptides were washed successively with 1 *N* $KHCO_3$, water, 1 *M* citric acid, and water. In the case of products obtained by the pentafluorophenyl ester method, extracts were treated with *N*,*N*-diethylethylenediamine (11) prior to washing to remove unreacted active ester. All extracts were dried over magnesium sulfate and solvent was removed under reduced pressure at 30–35°C.

Removal of the tert-Butoxycarbonyl Group

The *tert*-butoxycarbonyl derivative was dissolved in 1.1 *N* hydrogen chloride in acetic acid. After approximately 30 min at room temperature, the reagent was removed under reduced pressure at 30–35°C.

Preparation of Pentafluorophenyl Esters

Pentafluorophenyl esters were prepared from *N*-protected amino acids by the method of Kisfaludy *et al.* (10).

H-Leu-Pro-OMe·HCl

(a) Mixed Anhydride Method

Isobutyl chloroformate (0.65 ml) was added to a solution of Boc-Leu-OH (1.15 g) and *N*-methylmorpholine (0.55 ml) in tetrahydrofuran (4 ml) at −15°C. The mixture was stirred for 2 min and then a cold solution of H-Pro-OMe·HCl (0.82 g) and *N*-methylmorpholine (0.55 ml) in dimethylformamide (3 ml) was added. After stirring for 1 h at approximately −15°C, the temperature was raised to 0°C and 2.5 *M* $KHCO_3$ added until a basic reaction was obtained. The solution was stirred for 30 min at 0°C, 75% saturated salt solution was then added, and the product was extracted into ethyl acetate. The extract was washed and dried and the solvent removed, yielding the crude product. Removal of the *tert*-butoxycarbonyl group and crystallization of the product from anhydrous ether – methanol yielded H-Leu-Pro-OMe·HCl (825 mg, 60%), mp 176–178°C (lit. (14) 177°C).

(b) Pentafluorophenyl Ester Method

N-Methylmorpholine (142 μl) was added to H-Pro-OMe·HCl (182 mg) in dioxane (5 ml) and the mixture was stirred for 10 min. Then Boc-Leu-OPFP (275 mg) was added and stirring was continued for 30 min. The solvent was removed and the product dissolved in ethyl acetate, washed, and dried. Removal of the *tert*-butoxycarbonyl group and crystallization of the product yielded H-Leu-Pro-OMe·HCl (220 mg, 71%), mp 182–183°C.

Boc-Tyr(Bzl)-Leu-Pro-OMe

Isobutyl chloroformate (285 μl) was added to a solution of Boc-Tyr(Bzl)-OH (881 mg) and *N*-methylmorpholine (260 μl) in tetrahydrofuran (3 ml) at −15°C. After 2 min a solution of H-Leu-Pro-OMe·HCl (470 mg) and *N*-methylmorpholine (185 μl) in dimethylformamide (2 ml) was added. The mixture was stirred for 1 h at approximately −15°C, unreacted mixed anhydride was destroyed, and the product was isolated as described for the preparation of Boc-Leu-Pro-OMe by the mixed anhydride method. Recrystallization of the product from ethyl acetate – light petroleum (60–80°C) yielded Boc-Tyr(Bzl)-Leu-Pro-OMe (725 mg, 72%), mp 91–93°C; $[\alpha]_D$ −43° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{33}H_{45}N_3O_7$: C 66.53, H 7.61, N 7.05; found: C 66.82, H 7.40, N 7.09.

H-Tyr(Bzl)-Leu-Pro-OMe·HCl

Removal of the *tert*-butoxycarbonyl group of Boc-Tyr(Bzl)-Leu-Pro-OMe and recrystallization of the product from anhydrous ether – methanol yielded H-Tyr(Bzl)-Leu-Pro-OMe·HCl, mp 128–134°C; $[\alpha]_D$ −48° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{28}H_{38}N_3O_5Cl$: C 63.20, H 7.20, N 7.90; found: C 62.74, H 7.27, N 8.28.

Z-Arg(NO$_2$)-Tyr(Bzl)-Leu-Pro-OMe

Isobutyl chloroformate (54 μl) was added to a solution of Z-Arg(NO_2)-OH (158 mg) and *N*-methylmorpholine (49 μl) in tetrahydrofuran (2 ml) at −15°C. After 2 min a solution of H-Tyr(Bzl)-Leu-Pro-OMe·HCl (170 mg) and *N*-methylmorpholine (35 μl) in dimethylformamide (2 ml) was added. The mixture was stirred for 1 h at −15°C, unreacted mixed anhydride was destroyed, and the product isolated as described for the preparation of Boc-Leu-Pro-OMe by the mixed anhydride method. Recrystallization from ethyl acetate yielded Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OMe (206 mg, 78%), mp 101–104°C; $[\alpha]_D$ −38° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{42}H_{54}N_8O_{10}$: C 60.70, H 6.55, N 13.48; found: C 60.83, H 6.44, N 13.65.

Z-Arg(NO$_2$)-Tyr(Bzl)-Leu-Pro-OH

To a solution of Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OMe (328 mg) in methanol (4 ml) was added 0.5 *N* NaOH (2 ml). After 3.5 h at room temperature in a nitrogen atmosphere, the methanol was removed *in vacuo*. Water was added, the solution acidified with 1 *N* HCl, and the product extracted into ethyl acetate. Removal of the solvent yielded Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OH (255 mg, 78%). Thin-layer chromatography ($CHCl_3$–MeOH, 4:1) of the gummy material showed a single major spot, R_f 0.15, and traces of more polar material.

H-Thr-OBzl·HCl

This compound, mp 127–128°C (lit. (15) 125–126°C) was prepared by the method of Maclaren (16).

Boc-Pro-Thr-OBzl

Boc-Pro-OPFP (2.52 g) in dioxane (2 ml) was added to a mixture of H-Thr-OBzl·HCl (1.61 g) and *N*-methylmorpholine (868 μl) in dioxane (20 ml). After stirring for 1 h at room temperature, the solvent was removed *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed and dried. Recrystallization of the product from ether–hexane gave Boc-Pro-Thr-OBzl (2.24 g, 84%), needles, mp 88–90°C; $[\alpha]_D$ −54° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{21}H_{30}N_2O_6$: C 62.05, H 7.44, N 6.89; found: C 62.00, H 7.49, N 6.66.

H-Pro-Thr-OBzl·HCl

Removal of the *tert*-butoxycarbonyl group of Boc-Pro-Thr-OBzl (2.17 g) and recrystallization of the product from anhydrous ether – methanol yielded H-Pro-Thr-OBzl·HCl (945 mg, 52%), mp 134–135°C; $[\alpha]_D$ −60° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{16}H_{23}N_2O_4Cl$: C 56.05, H 6.76, N 8.17; found: C 55.63, H 7.07, N 8.26.

Boc-Leu-Pro-Thr-OBzl

Boc-Leu-OPFP, prepared from Boc-Leu-OH (346 mg) and used without purification, in dioxane (4 ml) was added to a mixture of H-Pro-Thr-OBzl·HCl (512 mg) and *N*-methylmorpholine (198 μl) in dioxane (5 ml). After stirring for 20 min at room temperature, water was added and the product was extracted into ethyl acetate. Recrystallization of the product (634 mg) from ether–hexane gave Boc-Leu-Pro-Thr-OBzl (140 mg), mp 68–70°C; $[\alpha]_D$ −89° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{27}H_{41}N_3O_7$: C 62.41, H 7.95, N 8.09; found: C 62.11, H 8.18, N 8.51.

Boc-Tyr(Bzl)-Leu-Pro-Thr-OBzl

Boc-Tyr(Bzl)-OPFP (687 mg) in dioxane (3 ml) was added to a mixture of H-Leu-Pro-Thr-OBzl·HCl (486 mg), obtained by hydrolysis of the *tert*-butoxycarbonyl derivative, and *N*-methylmorpholine (140 μl) in dioxane (5 ml). After stirring for 20 min at room temperature the product was isolated. Addition of hexane to an ether solution of this material precipitated Boc-Tyr(Bzl)-Leu-Pro-Thr-OBzl (372 mg), mp 73–75°C; $[\alpha]_D$ −61° (*c* 1.0, MeOH). *Anal.* calcd. for $C_{43}H_{56}N_4O_9$: C 66.82, H 7.30, N 7.25; found: C 66.97, H 7.43, N 7.68.

Removal of the *tert*-butoxycarbonyl group yielded noncrystalline H-Tyr(Bzl)-Leu-Pro-Thr-OBzl·HCl.

H-Arg-Tyr-Leu-Pro-Thr-OH (Proctolin)

(a) From Z-Arg(NO₂)-Tyr(Bzl)-Leu-Pro-OH

(*1*). Isobutyl chloroformate (14 μl) was added to a stirred solution of Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OH (99 mg) and *N*-methylmorpholine (13 μl) in tetrahydrofuran (1 ml) at −15°C. After 2 min, a solution of H-Thr-OBzl·HCl (21 mg) and *N*-methylmorpholine (9 μl) in dimethylformamide (1.5 ml) was added and stirring was continued for 1 h. Unreacted mixed anhydride was destroyed and the product was isolated. Chromatography on a Kieselgel plate with chloroform–methanol – acetic acid (85:10:5.5) indicated the presence of a major product at R_f 0.61 and two minor products at R_f 0.49 and 0.40. For removal of the protecting groups, the crude peptide was dissolved in acetic acid – water (9:1) and 5% palladium-on-barium sulfate (1.5 times the weight of peptide derivative) added. The flask was flushed with nitrogen and hydrogen was bubbled slowly through the reaction mixture for approximately 24 h at room temperature. The solution was filtered and the solvent removed *in vacuo* yielding crude peptide (59 mg) indicated by bioassay (1) to contain 50 mg (89%) of proctolin.

(*2*). Diphenylphosphoryl azide (31 μl) in dimethylformamide (1.3 ml) was added to a stirred mixture of Z-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OH (99 mg) and H-Thr-OBzl·HCl (35 mg) in dimethylformamide (2 ml) at 0°C. Triethylamine (37 μl) was added and the mixture stirred at 0°C for 4.7 h and then at room temperature for 13 h. After addition of saturated salt solution, the product was extracted into ethyl acetate and the extract was washed and dried. Thin-layer chromatography indicated that the product consisted of the same components as obtained by the mixed anhydride method. Hydrogenolysis as described above yielded crude peptide shown by bioassay to contain 65 mg (84%) of proctolin.

(b) From H-Tyr(Bzl)-Leu-Pro-Thr-OBzl·HCl

Boc-Arg(NO_2)-OPFP, prepared from Boc-Arg(NO_2)-OH (255 mg) and used without purification, was dissolved in dioxane (3 ml) and added to a solution of H-Tyr(Bzl)-Leu-Pro-Thr-OBzl·HCl (358 mg) and *N*-methylmorpholine (62 μl) in dioxane (5 ml). After stirring for 1 h at room temperature and removal of the solvent, the residue was dissolved in ethyl acetate and the solution was washed and dried. The *tert*-butoxycarbonyl group was removed and the product partly purified by precipitation from methanol with ether. Thin-layer chromatography on Kieselgel with chloroform–methanol (4:1) indicated the presence of one major component, R_f 0.36, and several minor components. Hydrogenolysis of the hydrochloride as described above yielded crude peptide shown by bioassay to contain 250 mg (82%) of proctolin.

Purification of Proctolin

Crude proctolin was purified by ion-exchange chromatography (Rexyn 101, NH_4^+ form) and gel filtration (Sephadex G-15) as employed in the isolation of proctolin (1). The purified synthetic proctolin was homogeneous by paper and thin-layer chromatography and by high voltage paper electrophoresis and was chromatographically, electrophoretically, and pharmacologically identical to natural proctolin (2). Amino acid analysis of an acid hydrolysate (18 h at 110°C with constant boiling HCl in a sealed evacuated tube) showed the following molar ratio of amino acids: Arg, 0.97; Leu, 1.0; Pro, 0.99; Thr, 0.93; Tyr, 0.95

Comparison of the Mixed Anhydride and Pentafluorophenyl Ester Methods for Synthesis of Proctolin

Starting with H-Leu-Pro-OMe·HCl (4 mmol), the protected tetrapeptide Boc-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-OMe was prepared by the mixed anhydride method as described above with the exception that a 1.4-fold excess of mixed anhydride was used at each stage (13). The product of each coupling was checked by tlc and used without further purification for the subsequent step. Hydrolysis of the ester and coupling of the product to H-Thr-OBzl (small excess) yielded Boc-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-Thr-OBzl. After removal of the pro-

tecting groups, the overall yield of proctolin as determined by bioassay was 35%.

Similarly, beginning with H-Thr-OBzl·HCl (4 mmol), proctolin was synthesized by the pentafluorophenyl ester method as described above with the exception that a 1.5-fold excess of the Boc-amino acid pentafluorophenyl ester was used at each step and intermediates were not purified (11). Chromatography of the resulting protected pentapeptide, Boc-Arg(NO_2)-Tyr(Bzl)-Leu-Pro-Thr-OBzl, on Avicel with *n*-butanol – acetic acid – water (4:1:1) and on Kieselgel with *n*-butanol – acetic acid – ethyl acetate – water (1:1:1:1) showed the presence of one major ninhydrin-positive spot. After removal of the protecting groups, the overall yield of proctolin by this method as determined by bioassay was 40%.

Received June 24, 1977

A. OKAGAWA and S. G. MASON. Can. J. Chem. **55**, 4243 (1977).

Transients in angular light scattering and turbidity of dilute suspensions of nearly monodisperse spheroidal particles undergoing simple shear flow have been investigated by combining Rayleigh–Debye light scattering theory for single dielectric particles with fluid mechanical theory for the orientation distributions of particle assemblies in shear flow. Applying shear to an initially isotropic suspension causes the orientation distributions and thus the angular scattering coefficients to oscillate. Various geometrical arrangements are considered with a view to selecting those that will maximize such rheo-optical effects.

By calculating the optical scattering cross section of a single particle, the turbidity of a suspension is obtained; like the scattering coefficient, it undergoes oscillations that are damped by (*1*) the inevitable spread in particle shape and volume in real systems, (*2*) shear-induced particle interactions, and (*3*) rotary Brownian motion. The rates of damping, expressed as relaxation times, are considered for the three mechanisms acting alone or in concert.

Preliminary measurements of the turbidity of dilute suspensions of hardened human red blood cells confirm this general pattern of behavior. Apart from their intrinsic interest, such rheo-optical effects can be used to determine a number of useful properties of dispersions.

A. OKAGAWA et S. G. MASON. Can. J. Chem. **55**, 4243 (1977).

On a étudié les espèces de transition qui se produisent dans la diffusion de la lumière angulaire et la turbidité de suspensions diluées de particules sphéoridales presque monodispersées subissant un écoulement cisaillé simple; ces études ont été effectuées en combinant la théorie de la diffusion de la lumière de Raleigh–Debye pour des particules diélectriques simples avec la théorie de mécanique des fluides pour les distributions de l'orientation de groupements de particules subissant un écoulement cisaillé. L'application d'un cisaillement à une suspension initialement isotrope provoque une oscillation des distributions d'orientation et, donc, aussi des coefficients de diffusion angulaire. On a considéré divers arrangements géométriques afin de choisir ceux qui maximisent de tels effets rhéo-optiques.

En calculant la section droite de diffusion optique d'une particule simple, on obtient la turbidité de la suspension; on note que la turbidité subit, comme le coefficient de diffusion, des oscillations qui sont atténuées par: (*1*) l'inévitable dispersion de forme et de volume des particules dans le système réel; (*2*) les interactions de particules induites par le cisaillement et (*3*) par le mouvement rotatoire Brownien. On considère les taux d'atténuation, exprimés sous forme de temps de relaxation, pour les trois mécanismes agissant individuellement ou ensemble.

Des mesures préliminaires de turbidité de suspensions diluées de cellules rouges durcies de sang humain confirment ce comportement général. En plus de leur intérêt intrinsèque, on peut utiliser de tels effets rhéo-optiques pour déterminer un certain nombre de propriétés utiles des dispersions.

[Traduit par le journal]

Introduction

Many macroscopic properties of flowing suspensions depend on the motions of the individual particles and especially their rotations and the resulting orientations. Elsewhere the rheological (1) and electrical (2) properties have been examined. In this paper we consider optical properties, specifically angular light scattering and turbidity.

In the past the most commonly measured rheo-optical effect has been streaming birefringence, used to determine particle (or molecular) size and configuration in colloidal sols and polymer solutions (3–5). On the other hand, light scattering, while widely used in quiescent fluids, has received relatively little attention in streaming systems except by Diesslhost and Freundlich (6) and Heller, Peterlin, and co-workers (7–11), the latter workers deducing the statistical configuration of flowing macromolecules in dilute solutions. More re-

cently angular scattering (12) and turbidity (13, 14) measurements on dilute suspensions of human erythrocytes have been made in simple shear flow; the turbidity measurements (13, 14) exhibited damped oscillations from which it was inferred that cell shapes, size, and orientations could be determined.

In this paper we establish the theoretical foundations of the periodic optical properties of flowing dispersions by combining angular light scattering theory with that for the rotational motion of dilute and nearly monodisperse dispersions of spheroids in simple shear flow, and offer some corroboratory experimental evidence, which goes beyond that in refs. 13 and 14.

In our theory we assume that particles are much larger than the light wavelength and that their refractive index is close to that of suspending medium so that Rayleigh–Debye scattering theory (15) applies. Various geometrical arrangements of incident and scattered light beams relative to the flow field are considered with a view to optimizing the rheo-optical effects. The particle rotations and the resulting orientations in dilute suspensions are then expressed in various coordinate systems using the theory previously developed (1) for transient orientation distributions of spheroids. We thus show that the various angular scattering coefficients and the turbidity undergo oscillations, usually damped, with a frequency twice that of the particles rotating about the vorticity axis of the flow.

In our experiments, like some of those in ref. 13, dilute suspensions of hardened (i.e., rigid) red blood cells, which are biconcave discs, have been used to model oblate spheroids for which shape all of the numerical calculations from the theory are given. However, all of the light scattering equations are equally valid for prolate spheroids, including spheres. For reasons that will be seen later, some of the relations are purely formal in nature, while others (i.e., those dealing with relaxation times) are based on orientation distribution functions and are not applicable directly to light scattering. However, sufficient detail is given so that the theory can be readily used for numerical calculations of a variety of systems and geometries extending beyond those for which calculated or measured data are presented.

Angular Light Scattering

Light Scattering by Single Spheroids

When a particle of maximum linear dimension l suspended in a fluid is exposed to linearly polarized light of wavelength λ, the light may be absorbed and scattered by the particle; in this treatment we limit consideration to systems that do not absorb light, i.e., the optical dielectric constant (or refractive index) is not complex; we also assume that the particles are optically isotropic. When $l > \lambda$ and the particle refractive index n_B is close to that of the medium n_A, Rayleigh–Debye scattering occurs (15) for which the basic condition is

$$kl(m^2 - 1) \ll 1 \qquad [1]$$

where $k = 2\pi/\lambda$ is the wave number and $m = n_B/n_A$. The light scattering for this case is given by summation of the scattering by each volume element of the particle, which we take to be a spheroid whose surface is

$$\frac{x_1'^2}{a^2} + \frac{x_2'^2}{b^2} + \frac{x_3'^2}{b^2} = 1 \qquad [2]$$

where a, b are the semi-axes ($a \lessgtr b$ for oblate and prolate spheroids, and $a = b$ for a sphere) of revolution and the Cartesian coordinate system X_i' is fixed in the particle with X_1' on the axis of revolution. When the particle is placed in linearly polarized light of intensity I_0 directed along one of the Cartesian coordinate axes fixed in space as shown in Fig. 1, the scattered light intensity I_s at the scattering angle θ_0, ϕ_0 (the spherical polar coordinates for the scattered light with X_k as the polar axis) is given (15) by

$$I_s = \frac{I_0 V^2 k^4 (m^2 - 1)^2 (1 - \sin^2\theta_0 \sin^2\phi_0) R(\theta_0, \beta)}{16\pi^2 r^2} \qquad [3]$$

where $V = 4\pi ab^2/3$ and r is the distance from the particle to the light detector. The form factor $R(\theta_0, \beta)$ depends upon particle volume V, its shape, and orientation, and is given by

$$R(\theta_0, \beta) = \left[\frac{3(\sin u - u\cos u)}{u^3}\right]^2 \qquad [4]$$

where

$$u = 2kb \sin \tfrac{1}{2}\theta_0 [\sin^2\beta + (a/b)^2 \cos^2\beta]^{1/2} \qquad [5]$$

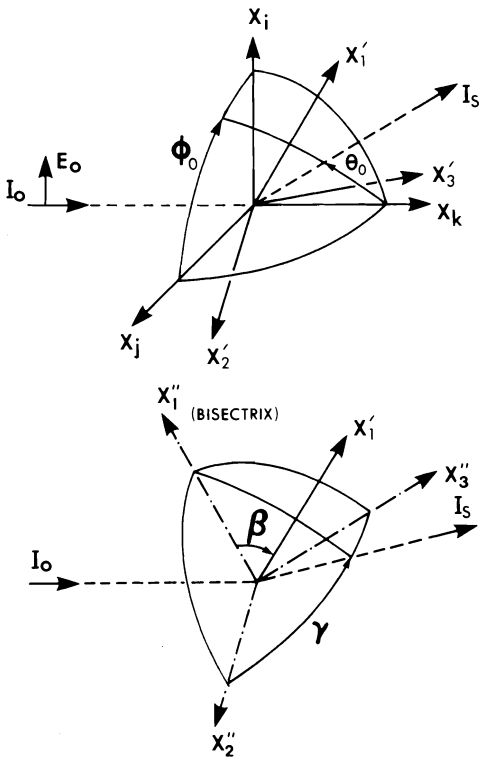

FIG. 1. Various coordinate systems for light scattering by a single spheroid whose axis of revolution is along X_1'. Top: The incident light I_0 polarized in the direction of X_i (indicated by E_0) is directed along X_k axis. The direction of the scattered light I_s is expressed by the spherical polar coordinates θ_0, ϕ_0 (relative to the incident light beam as polar axis). The numbering of $i, j, k = 1, 2, 3$ is determined by the geometrical arrangement of the optical and flow systems. Bottom: The orientation of X_1' relative to the Cartesian coordinates X_1'', X_2'', X_3'' is given by the spherical coordinates β, γ with the bisectrix (the axis bisecting the backward direction of incident beam I_0 and I_s) as the polar axis which is taken as X_1''.

where the orientation of particle is expressed by the spherical polar coordinates β and γ when the bisectrix (the axis which bisects the angle between I_0 and I_s in the plane containing them) is taken as the polar axis (Fig. 1, bottom). Since u is a function only of β, thus all particles of a given β have the same scattering pattern. It is usual to define the relative scattering intensity $I_r = I_s/I_s$ ($\theta_0 = 0$), so that from [3]

$$[6] \qquad I_r = (1 - \sin^2\theta_0 \sin^2\phi_0)R(\theta_0, \beta)$$

Thus I_r like $R(\theta_0, \beta)$ is also a function of the particle volume, shape, and orientation for a given scattering angle θ_0, ϕ_0.

Spheroids in the Simple Shear Flow

We now consider a single isolated spheroid when the fluid medium undergoes slow simple shear flow with velocity components v_i relative to the Cartesian coordinates X_i fixed in space

$$[7] \qquad \begin{aligned} v_1 &= v_2 = 0 \\ v_3 &= Gx_2 \end{aligned}$$

G being the velocity gradient (Fig. 2, top). The axis of revolution of the spheroid, whose orientation θ_1, ϕ_1 is now expressed relative to the polar axis X_1, rotates periodically in a fixed spherical elliptic orbit given by Jeffery's equations (1, 16):

$$[8a] \qquad \tan\theta_1 = \frac{C r_e}{(r_e^2 \cos^2\phi_1 + \sin^2\phi_1)^{1/2}}$$

$$[8b] \qquad \tan\phi_1 = r_e \tan(2\pi t/T + \kappa)$$

where $r_e = a/b$ is the axis ratio, C and κ are the orbit constant and phase angle respectively, and T is the period of one complete rotation about the vorticity axis X_1 given by

$$[9] \qquad T = 2\pi(r_e + r_e^{-1})/G$$

Since the particle rotates periodically with a frequency which is shape- but not size-dependent, I_r will vary periodically (but with twice the frequency of rotation because of fore–aft symmetry) in phase with the particle with an amplitude depending upon both the shape r_e and volume V of the particle and the geometrical arrangement of the optical system. As a guide for optimizing the measurement of I_s (and its oscillations), a number of geometries have been considered, all of which are experimentally realizable. These fall into two groups; one in which the bisectrix and the other in which the incident light coincide with one of the fixed coordinate axes X_i of the flow field. This classification yields six geometries as shown in Fig. 2, which we examine in detail below. In all cases, the incident and scattered light beams and their bisectrices are taken to lie on one of the X_iX_j planes and the electric field of the incident beam is normal to this plane (i.e., $\phi_0 = 0°$) so that

$$[10] \qquad I_r = R(\theta_0, \beta)$$

It thus becomes more convenient to express the particle orientation as β, γ the transformation equations of which from θ_1, ϕ_1, and θ_0 for the six cases are as listed in Table 2. In group I (Fig. 2, left), we consider scattering in the X_1X_2-plane with X_1 as bisectrix (I-A), in the X_2X_3-plane with X_2 as bisectrix (I-B), and in the X_2X_3-plane with X_3 as bisectrix (I-C). Since the bi-

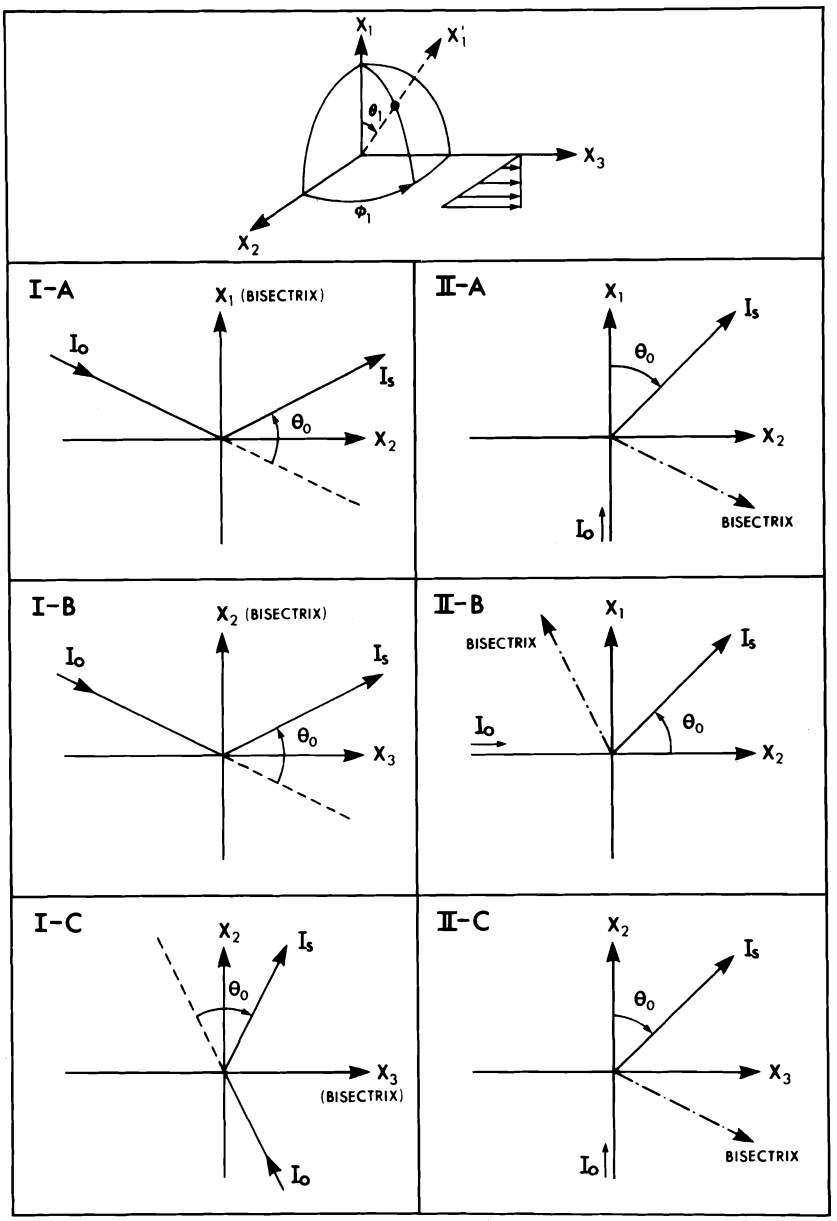

FIG. 2. Various feasible geometrical arrangements. In group I (A–C), the bisectrix between I_0 and I_s coincides with one of the space-fixed coordinate axes X_i, whereas in group II (A–C), I_0 itself coincides with one of X_i. I_s is considered only in the plane X_iX_j with the polarization of I_0 normal to this plane. At the top of the figure the spherical polar coordinates θ_1, ϕ_1 of the spheroidal axis are shown relative to the simple shear flow given by [7].

sectrix is the polar axis for β, γ and coincides with the Cartesian space coordinates X_i, the transformations are straightforward. For I-A, $\beta = \theta_1$ and $\gamma = \phi_1$, the variations of β and γ are thus identical to [8], whereas those of β and γ for the other two cases in group I depends upon the orbit constant C such that $\tan \gamma$ is limited to $\pm Cr_e$ for I-B and $\pm C$ for I-C.

On the other hand, in group II (Fig. 2, right) where the scattering is considered in the X_1X_2-plane with I_0 along the X_1 axis (II-A), in the X_1X_2-plane with I_0 along the X_2 axis (II-B), and

II-B	$\frac{\cos\frac{\theta_0}{2} - C\sin\frac{\theta_0}{2}\cos T^*}{[1 + C^2\{\cos^2 T^* + r_e^2\sin^2 T^*\}]^{1/2}}$	$\frac{Cr_e\sin T^*}{\sin\frac{\theta_0}{2} + C\cos\frac{\theta_0}{2}\cos T^*}$
II-C	$\frac{C\{r_e\cos\frac{\theta_0}{2}\sin T^* - \sin\frac{\theta_0}{2}\cos T^*\}}{[1 + C^2\{\cos^2 T^* + r_e^2\sin^2 T^*\}]^{1/2}}$	$C\{r_e\sin\frac{\theta_0}{2}\sin T^* + \cos\frac{\theta_0}{2}\cos T^*\}$

[a]Calculated from [8] and the transformation equations in columns 2 and 3.
[b]$T^* = (2\pi t/T) + \kappa$.

in the X_2X_3-plane with I_0 along the X_2-axis (II-C), the transformations of θ_1, ϕ_1 to β, γ are more complicated and are functions of the scattering angle θ_0 (Table 1). The particle rotations expressed in terms of β and γ are also listed in the last two columns of Table 1.

Dilute Suspensions

If a suspension of identical spheroids is so dilute that there is no secondary scattering (i.e., by one particle from that scattered from another) the total scattering from the assembly is given by the summation, which from [10] becomes:[1]

$$[11]\qquad \overline{R(\theta_0, \beta)} = \int_0^{2\pi}\int_0^{\pi} R(\theta_0, \beta)p_t(\beta, \gamma)\,d\beta\,d\gamma$$

where $p_t(\beta, \gamma)\,d\beta\,d\gamma$ is the fraction of particles oriented in the interval $d\beta\,d\gamma$ at β, γ. We have previously shown theoretically for spheroids (1) and confirmed experimentally for rods and discs that behave like prolate ($r_e > 1$) and oblate ($r_e < 1$) spheroids (17) that, in an initially randomly oriented (or isotropic) dilute suspension of non-interacting spheroids when each particle retains its original orbit constant C and phase angle κ in flow [7], the time-dependent orientation probability distribution $p_t(\theta_1, \phi_1)$ is (1)

[1]Symbols with an overbar designate instantaneous number averages.

$$[12] \qquad p_t(\theta_1, \phi_1) = \frac{\sin \theta_1}{4\pi(\cos^2 \theta_1 + \chi^2 \sin^2 \theta_1)^{3/2}}$$

where

$$[13a] \qquad \chi^2 = \chi_1 \sin^2 \phi_1 + \chi_2 \sin \phi \cos \phi + \chi_3 \cos^2 \phi_1$$

$$[13b] \qquad \chi_1 = \tfrac{1}{2}[1 + r_e^{-2} + (1 - r_e^{-2}) \cos (4\pi t/T)]$$

$$[13c] \qquad \chi_2 = (r_e^{-1} - r_e) \sin (4\pi t/T)$$

$$[13d] \qquad \chi_3 = \tfrac{1}{2}[1 + r_e^2 + (1 - r_e^2) \cos (4\pi t/T)]$$

The transformation of $p_t(\theta_1, \phi_1)$ to $p_t(\beta, \gamma)$ can be made through the identity:

$$[14] \qquad p_t(\theta_1, \phi_1)\, d\theta_1\, d\phi_1 = p_t(\beta, \gamma)\, d\beta\, d\gamma$$

with the result:

$$[15] \qquad p_t(\beta, \gamma) = \frac{\sin \beta}{4\pi(F_1 \sin^2 \beta + F_2 \sin \beta \cos \beta + F_3 \cos^2 \beta)^{3/2}}$$

where F_1, F_2, and F_3 are explicit functions (the details of whose derivations like those in Table 1 are straightforward and hence omitted) of r_e, θ_0, γ, and t listed for all six cases in Table 2. Substituting [15] into [11], $\overline{R(\theta_0, \beta)}$ can be obtained by numerical integration over all possible orientations.

To illustrate, numerical integrations have been made for initially isotropic suspensions of oblate spheroids of $r_e = 0.4$, $b = 4.25$ μm with $n_B = 1.40$ in a fluid of $n_A = 1.44$, so that $(m^2 - 1) = 0.054$ and thus satisfying [1], which are exposed to linearly polarized incident light of $\lambda = 632.8$ nm in vacuum; these physical properties correspond closely to the experimental system described later. The calculated relative scattering intensities at various θ_0 over a semi-rotation $0 \leq t \leq T/2$ for the six geometries (Fig. 2) are shown in Fig. 3. Cases I-A and II-B exhibit only small amplitudes of oscillation in I_r during rotation whereas the other four cases clearly show appreciable amplitudes of frequency $2/T$. The scattering intensities at $t/T = 0.25$ are greater for cases I-B and II-A and lower for I-C and II-C than for random orientations (i.e., at $t = 0$ and $T/2$).

It is immediately clear from those calculations that geometries I-A and II-B are not suitable for studying particle orientation phenomena for this system, whereas the others are. At this stage it is not possible to generalize on the most suitable geometry to be used except to state that it will depend on (*1*) particle volume and shape, (*2*) the refractive indices n_A, n_B, and (*3*) the use of which the measurements are made. As will be seen in the following section the much simpler geometry used in turbidity measurements (and generally considered an anathema to most angular light scattering) is especially convenient for the oblate spheroids considered here.

Turbidity

Undamped Oscillations

The attenuation of light transmitted through a suspension of particles is given by the Beer–Lambert law (15)

$$[16] \qquad T_0 = I_t/I_0 = \exp(-\nu d)$$

where I_t is the transmitted intensity over the path length d and T_0 is the transmittance. The attenuation coefficient ν is the absorption coefficient when light is absorbed or the turbidity when it is scattered; as stated earlier only the latter case is considered here. Since we neglect secondary scattering, strictly speaking [16] is limited to low concentrations when only the linear term of the Taylor expansion is valid, i.e.,

$$[17] \qquad T_0 = 1 - \nu d$$

The turbidity ν (of dimension $[L]$) is a measure of the total energy removed from the primary beam by scattering, and can be written as

$$[18] \qquad \nu = N\overline{C_{sca}}$$

where N is the particle number concentration and $\overline{C_{sca}}$ (of dimension $[L^2]$) is the mean particle scattering cross section.

For a spheroid at θ_1, ϕ_1 (polar axis X_1) exposed to incident light directed along the X_2-axis and polarized in the X_1-direction (Fig. 4),

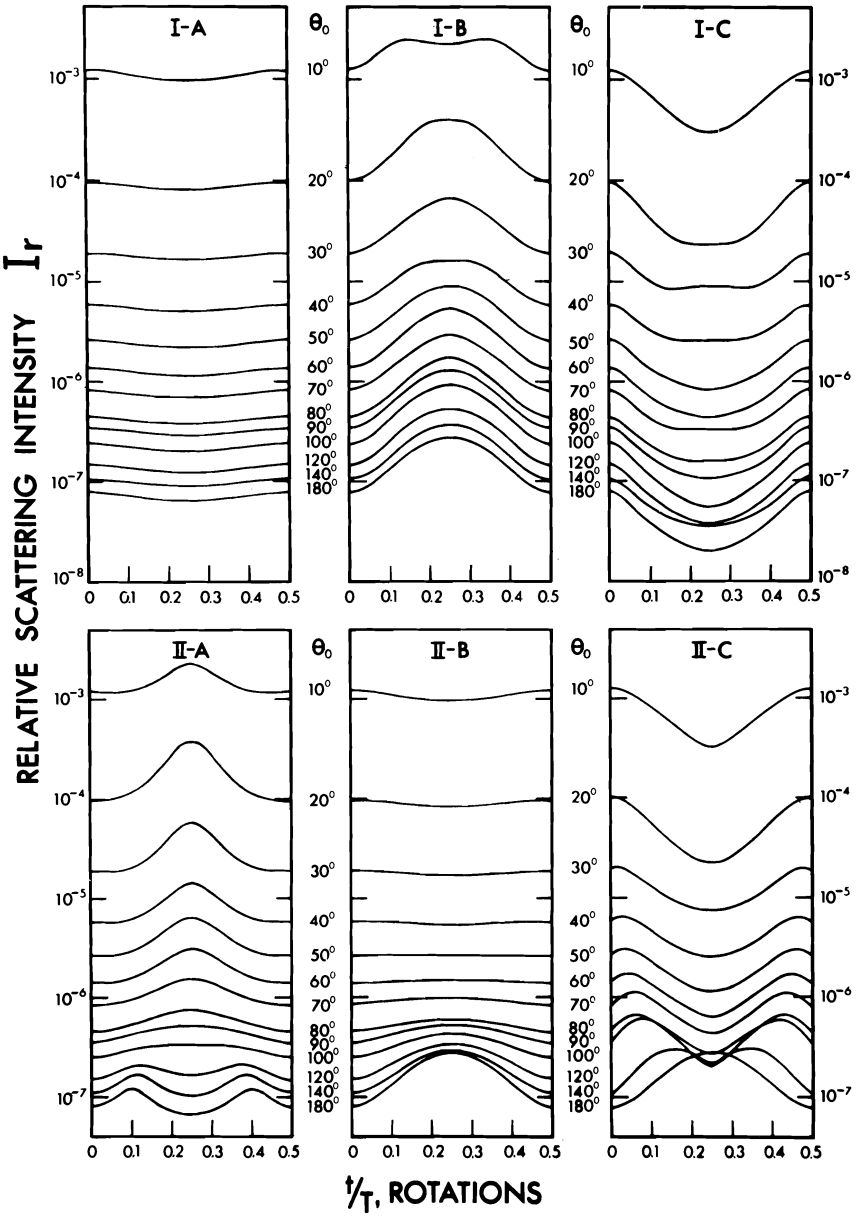

FIG. 3. Oscillation of relative scattering intensities I_r of a dilute suspension of oblate spheroids over a half-rotation in shear flow, for the various geometrical arrangements in Fig. 2 for $r_e = 0.4$ ($a = 1.2$ μm, $b = 4.25$, and $V = 91$ μm^3), $n_A = 1.44$, $n_B = 1.40$, and $\lambda = 632.8$ nm. The values at $t/T = 0$ and 0.5 are for random particle orientations and for a given θ_0 are identical for all cases. Equation 11 was integrated numerically using $p_t(\beta, \gamma)$ given by [15] and the values of F_i listed in Table 2.

scattering occurs over all values of θ_0, ϕ_0, the angular coordinates for the scattered light with X_2 taken as the polar axis. The scattering cross section is thus (15)

$$[19] \quad C_{sca} = \int_0^{2\pi} \int_0^{\pi} (I_s/I_0)\, r^2 \sin\theta_0 \, d\theta_0 \, d\phi_0$$

where I_s is given by [3], so that

$$[20] \quad C_{sca} = \frac{1}{16\pi^2} \int_0^{2\pi} \int_0^{\pi} V^2 k^4 (m^2 - 1)^2 (1 - \sin^2\theta_0 \sin^2\phi_0) R(\theta_0, \beta) \sin\theta_0 \, d\theta_0 \, d\phi_0$$

However, the angles β, γ of the bisectrix for a given θ_1, ϕ_1 vary with the scattering angles θ_0, ϕ_0 via the geometrical relations:

$$[21a] \quad \cos\beta = \cos\theta_1 \cos\tfrac{1}{2}\theta_0 \sin\phi_0 + \sin\theta_1 \cos\phi_1 \sin\tfrac{1}{2}\theta_0 - \sin\theta_1 \sin\phi_1 \cos\tfrac{1}{2}\theta_0 \cos\phi_0$$

$$[21b] \quad \tan\gamma = \frac{\sin\theta_1 (\cos\phi_1 \cos\tfrac{1}{2}\theta_0 \cos\phi_0 + \sin\phi_1 \sin\tfrac{1}{2}\theta_0)}{\cos\tfrac{1}{2}\theta_0 \sin\phi_0 \cos\beta - \cos\theta_1}$$

C_{sca} of a single particle can be conveniently compared with the geometrically projected area S_{13} on the plane normal to the incident beam (i.e., on the X_1X_3-plane) to yield the 'scattering efficiency':

$$[22] \quad Q_{sca} = C_{sca}/S_{13}$$

For a spheroid given by [2]

$$[23] \quad S_{13} = \pi ab[1 - \sin^2\theta_1 \cos^2\phi_1(a^2 - b^2)/a^2]^{1/2}$$

When $\theta_1 = 0$, $S_{13} = \pi ab$; and when $\theta_1 = 90°$, $\phi_1 = 0°$, $S_{13} = \pi b^2$; for an oblate spheroid ($r_e < 1$) these cases correspond to viewing it along the X_2-axis edge-on and face-on, respectively. Figure 5 shows numerical values of Q_{sca} for various orbit constants C for the oblate spheroids used in computing Fig. 3 when shear flow given by [7] is applied for a half-rotation starting at $\phi_1 = 0$ (i.e., $\kappa = 0$). When $C = 0$, (i.e., $\theta_1 = 0°$) the particle spins about its axis of revolution so that there is no change in C_{sca} and and S_{13}. When, on the other hand, $C = \infty$ (i.e., $\theta_1 = 90°$) it faces the incident light near $t = 0$ and $T/2$, and orients edge-on at $t = T/4$ so that Q_{sca} passes through a minimum and a maximum and like I_r oscillates with frequency $2/T$. It may appear paradoxical that the particle scatters more light when it is oriented edge-on to the incident light (when S_{13} is least) than when face-on (S_{13} greatest). This is confirmed by the experiments described below. From [22], $Q_{sca} = 1$ means that all of the light beam falling on the particle is removed by scattering. However, it is seen in Fig. 5 that Q_{sca} is often >1; this results from the disturbance of the light beam in regions away from the surface of the particle.

The mean value $\overline{C_{sca}}$ for an infinitely dilute suspension can be obtained from the orientation probability $p_t(\theta_1, \phi_1)$ using the relation

$$[24] \quad \overline{C_{sca}} = \int_0^{2\pi} \int_0^{\pi} C_{sca}\, p_t(\theta_1, \phi_1)\, d\theta_1\, d\phi_1$$

Values of $\overline{C_{sca}}$ calculated from [12], [20], and [24] for an initially random suspension of oblate spheroids of the system used in Figs. 3 and 5, and for the geometry of Fig. 4, are shown in Fig. 6. Since $p_t(\theta_1, \phi_1)$ is a periodic function of frequency $2/T$ (1), $\overline{C_{sca}}$ oscillates in synchronism and with constant amplitude reaching a minimum at $t = T/4$ when there is a preferred face-on orientation towards the X_2-axis (1), and a maximum at $t = 0$, $T/2$ when there is a preferred edge-on orientation and (as with a single particle) vice-versa for S_{13} (Fig. 6).

Damped Oscillations

The oscillations described above are modified by various factors not yet considered. Thus, direct measurements of particle orientation distributions (17) have shown that the oscillations decay with a characteristic relaxation time τ during which the amplitude is reduced to $1/e$ of its initial value.

The damping results from various mechanisms

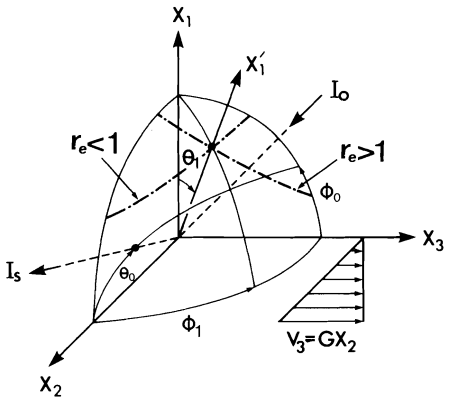

FIG. 4. Coordinate system for calculating the scattering cross section of a spheroid in the simple shear flow $v_3 = Gx_2$. The incident light beam is polarized in the X_1-direction and directed along the X_2-axis. The direction of the scattered light is expressed by the spherical angles θ_0, ϕ_0 (X_2 as polar axis) and the orientation of the axis of revolution of the spheroid by θ_1, ϕ_1 (X_1 as polar axis). The broken lines are the spherical elliptical orbits given by [8a] for oblate ($r_e < 1$) and prolate ($r_e > 1$) spheroids for arbitrarily chosen C's.

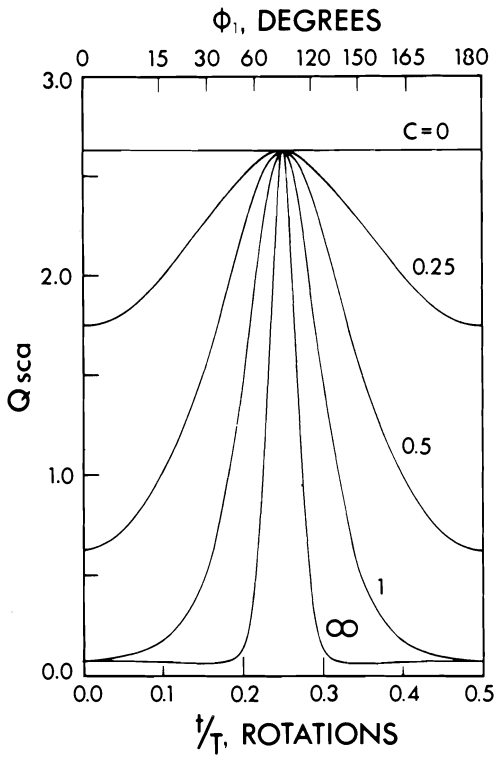

FIG. 5. Scattering efficiency Q_{sca} of a single oblate spheroid from the same system as in Fig. 3 rotating in simple shear flow at various orbit constants C for an initial $\phi_1 = 0$, $\kappa = 0$. When $C = 0$, the spheroid spins about its own axis, and is thus steadily oriented edge-on to the incident light so that Q_{sca} is constant. When $C = \infty$, it orients face-on at $t/T = 0$ and 0.5, but edge-on at $t/T = 0.25$ so that Q_{sca} alternates between a minimum and a maximum and vice-versa for S_{13} (see text). Thus when $0 < C \leq \infty$ Q_{sca}, like I_r (Fig. 3), oscillates with a frequency $2/T$.

(1, 17), but principally (*1*) variations in particle shape r_e, (*2*) shear-induced two-particle interactions, and (*3*) rotary Brownian motion, each with its own τ_i. Taking the effects to be additive the net τ for orientation distributions can be expressed[2]

$$[25] \qquad \frac{1}{\tau} = \frac{1}{\tau_1} + \frac{1}{\tau_2} + \frac{1}{\tau_3}$$

which can be rewritten in the dimensionless form

$$[26] \qquad T/\tau = b_1 + b_2 N + b_3 G^{-1}$$

[2]Equation 25 is based primarily on the redistribution of κ, i.e., 'rotational phase mixing' (18). Strictly speaking the equation should include a τ_4^{-1} for changes in orbit constants C [8*a*] due to shear-interactions; on the time and concentration scales for the systems considered here (1, 17) T/τ_4 is effectively zero.

TABLE 2. Equations for F_1, F_2, and F_3. See [15]

Geometry (Fig. 2)	F_1	F_2	F_3
I-A	$\chi_1 \sin^2\gamma + \chi_2 \sin\gamma\cos\gamma + \chi_3\cos^2\gamma$	0	1
I-B	$(\chi_1 - 1)\sin^2\gamma + 1$	$\chi_2 \sin\gamma$	χ_3
I-C	$(\chi_3 - 1)\sin^2\gamma + 1$	$\chi_2 \sin\gamma$	χ_1
II-A	$\left(\chi_3 \sin^2\frac{\theta_0}{2} + \cos^2\frac{\theta_0}{2}\right)\sin^2\gamma + \chi_2 \sin\frac{\theta_0}{2}\sin\gamma\cos\gamma + \chi_1\cos^2\gamma$	$2(\chi_3 - 1)\sin\frac{\theta_0}{2}\cos\frac{\theta_0}{2}\sin\gamma + \chi_2 \sin\frac{\theta_0}{2}\cos\gamma$	$\chi_3\cos^2\frac{\theta_0}{2} + \sin^2\frac{\theta_0}{2}$
II-B	$\left(\chi_3\cos^2\frac{\theta_0}{2} + \sin^2\frac{\theta_0}{2}\right)\cos^2\gamma + \chi_2\cos\frac{\theta_0}{2}\sin\gamma\cos\gamma + \chi_1\sin^2\gamma$	$2(1 - \chi_3)\sin\frac{\theta_0}{2}\cos\frac{\theta_0}{2}\cos\gamma - \chi_2\sin\frac{\theta_0}{2}\sin\gamma$	$\chi_3\sin^2\frac{\theta_0}{2} + \cos^2\frac{\theta_0}{2}$
II-C	$\left(\chi_1\sin^2\frac{\theta_0}{2} + \chi_2\sin\frac{\theta_0}{2}\cos\frac{\theta_0}{2} + \chi_3\cos^2\frac{\theta_0}{2}\right)\sin^2\gamma + \cos^2\gamma$	$(\chi_1 - \chi_3)\sin\theta_0\sin\gamma + \chi_2\cos\theta_0\sin\gamma$	$\chi_1\sin^2\frac{\theta_0}{2} - \chi_2\sin\frac{\theta_0}{2}\cos\frac{\theta_0}{2} + \chi_3\sin^2\frac{\theta_0}{2}$

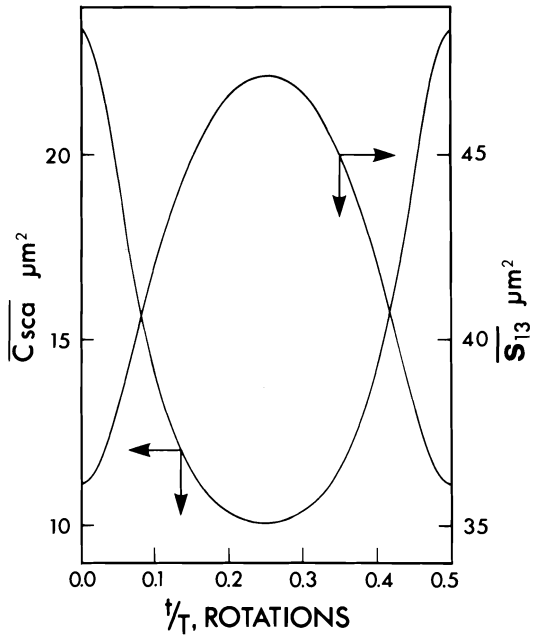

FIG. 6. Mean scattering cross section $\overline{C_{sca}}$ and mean projected area $\overline{S_{13}}$ for an initially isotropic dilute suspension of the system used in Figs. 3 and 5, when subjected to the simple shear flow shown in Fig. 4. The values were obtained by numerical integration of [24] using [20] with $p_t(\theta_1, \phi_1)$ given by [12], and show that $\overline{C_{sca}}$ and $\overline{S_{13}}$ behave oppositely, but with both oscillating with frequency $2/T$.

where b_1 is a known constant for spheroids and b_2 and b_3 are thus far calculable only for prolate spheroids ($r_e \gg 1$) (1, 17, 19), although for oblate spheroids ($r_e < 1$) they may be roughly estimated by analogy.

It is obvious that similar relations should apply to the damping of any orientation dependent property but, of course, with different values for the parameters b_i. However, the period of oscillation $T/2$ should be the same for all since it is determined by the particle rotation about the vorticity axis, is given by [9] using the mean value $\bar{r}_e$ (1), and is independent of V.

Considering now $\overline{C_{sca}}$ (or more generally I_r), damped oscillations of frequency $2/\overline{T}$ with a characteristic τ determined by $\bar{r}_e$ and $\overline{V}$ and their distributions should occur. The simplest general case to consider is that for which the distributions of r_e and V are independent, with the probability distribution $g(r_e, V)$ given by the product

$$[27] \qquad g(r_e, V) = g_1(r_e)g_2(V)$$

where $g_1(r_e)$ and $g_2(V)$ are the respective probability densities. The mean scattering cross section is then given by the formal relation:

$$[28] \quad (\overline{C_{sca}})_\sigma = \int_0^\infty \int_0^\infty \overline{C_{sca}}\, g_1(r_e)\, g_2(V)\, dr_e\, dV$$

where the subscript σ designates the spread in r_e, and $\overline{C_{sca}}$ is given by [24]; analogous equations will exist for I_r. In many situations, however, [27] will not apply and $g(r_e, V)$ will be more complicated and, indeed, may not be known; when it is, however, the optical properties can be calculated numerically by the use of equations given above.

We illustrate by numerically calculating $(\overline{C_{sca}})_\sigma$ for system considered in Figs. 3, 5, and 6, for simplicity taking $\tau_2^{-1} = \tau_3^{-1} = 0$ and particles of identical volume, but with a non-zero τ_1^{-1} resulting from a Gaussian distribution in r_e:

$$[29] \quad g_1(r_e) = \frac{1}{\sqrt{2\pi}\,\sigma_e} \exp\left[\frac{-(r_e - \bar{r}_e)^2}{2\sigma_e^2}\right]$$

where σ_e (= 0.07 (17.5%) corresponding to the experimental system) is the standard deviation in r_e.

As expected (Fig. 7), the calculated $(\overline{C_{sca}})_\sigma$ undergoes damped oscillations of frequency $2/T$ with the relative amplitude $A(t)$ at each quarter rotation decreasing nearly exponentially (although the scale in Fig. 7 is linear) from which $\tau_1/T = 0.875$. This is surprisingly close to the value (0.89) from the damped oscillations in orientation distribution using the earlier confirmed theory (1, 17) (see [30] below). At this stage of our knowledge this agreement between the two sets of τ_1 may be fortuitous because of the numerical values of r_e and σ_e selected for illustrations; however, the agreement in frequency, as already stated, is not. For the sake of brevity we will employ numerical values of b_1 based on the optical data presented in the experimental part which follows.

Experimental Part and Discussion

Methods

For turbidity measurements, suspensions of hardened human red blood cells (mean diameter 8.6 μm, thickness 2.5 μm) were used as convenient models of nearly mono-disperse oblate spheroids (20). They were suspended in aqueous glycerol (75% by volume) with a small amount of dissolved $SnCl_2$ to eliminate sedimentation. The density and viscosity of the medium were 1.29 g/ml and 0.125 Pa s, respectively. Particle concentrations determined by a hemacytometer ranged from 2×10^7 to 4×10^8 cells/ml corre-

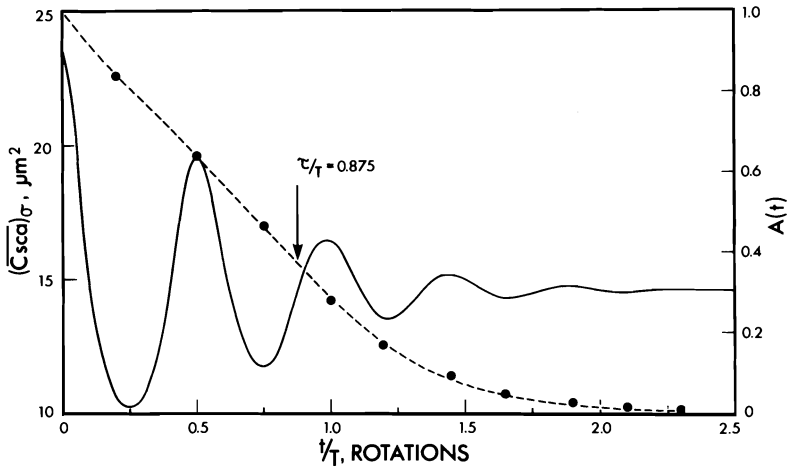

FIG. 7. Values calculated by numerical integration of [28] for the suspension considered in Figs. 3 to 6, but with a spread in r_e given by [29] with $\overline{r_e} = 0.4$, $\sigma_e = 0.07$, and $\tau_{2,3}^{-1} = 0$. The damping of the relative amplitude $A(t)$ whose values were determined at each peak and valley of $(\overline{C_{sca}})_\sigma$ is shown by the broken line yielding $\tau_1/T = 0.875$.

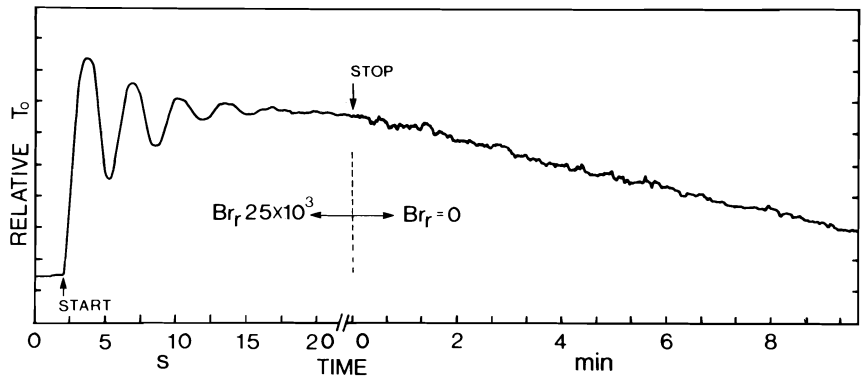

FIG. 8. Typical example of a recorder trace of the transmitted light intensity (arbitrary scale) for a suspension of hardened human red blood cells at $N = 4 \times 10^8/ml^{-1}$ and $G = 2.6\ s^{-1}$ over the interval marked START to STOP when damped oscillations occurred. The fluctuations in the decaying I_t after stopping shear appeared to be enhanced; this is due mainly to the expanded time scale.

sponding to volume fractions of 1.7×10^{-3} to 3.6×10^{-2} when the average volume of red blood cells is taken as 88 μm^3 (20). The refractive indices were $n_A = 1.44$ and $n_B = 1.40$, respectively, so that $m = 1.03$. The suspension was then placed between two parallel optically polished glass discs of diameter 12.7 cm separated by a gap of 1.6 mm, with the bottom one rotated at an adjustable constant angular velocity (21).

The turbidity was measured across the discs (i.e., along the X_2-axis) using a He–Ne laser (Spectra Physics Model 124A, $\lambda = 632.8$ nm with a beam diameter of 1.1 mm) and a power meter (Coherent Radiation Laboratory, Model 212) whose output was chart-recorded (Keithley Instruments, Model 370). All measurements were made in a constant temperature room at 21 ± 1°C.

Results and Discussion

A typical example of the changes in light transmission is given in Fig. 8. When shear was applied T_0 initially increased rapidly to a maximum and then experienced damped oscillations, with superimposed (and apparently random) fluctuations, which became more evident as the oscillations became smaller. When flow was stopped, T_0 decreased monotonically and asymptotically approached the initial value at $t = 0$.

The damped oscillations of T_0 parallel the theoretical calculation shown in Fig. 7, remembering ([16] to [18]) that a decrease in $\overline{C_{sca}}$corre-

[a]For these systems $\overline{TG} = 16.9 \pm 0.6$ when measured from the period of oscillation of T_0 as in Figs. 7 and 8.
[b]From intercepts $(T/\tau)_{G^{-1}=0}$ in Fig. 9 using [34].
[c]From slopes in Fig. 9 using [34].

sponds to an increase in T_0 and vice-versa. The periods of oscillation, which should correspond to $\overline{T}/2$, were measured from those tracings. As expected the product TG was found to be independent of N and G, and for some 50 measurements yielded $\overline{TG} = 16.9 \pm 0.6$; from [9] this yields a mean equivalent spheroidal axis ratio $\overline{r_e} = 0.44$, a value that compares reasonably well with $\overline{r_e} = 0.38 \pm 0.07$ obtained by direct microscopic observations of $\overline{TG}$ on a different sample of the rotating cells (20).

The amplitude $A(t)$ of the oscillations was generally found to decay nearly exponentially. Taking the height of the first peak as $A(0) = 1$, τ was determined as in Fig. 7. The dimensionless relaxation times τ/T thus obtained are listed in Table 3. Their reciprocals, which can be regarded as damping coefficients, are plotted against G^{-1} for various concentrations in Fig. 9 where it is seen that they vary linearly in accord with [26]. The slopes give b_3 and the intercepts at $G^{-1} = 0$, which correspond to orthokinetic conditions (22) when the effect of rotary Brownian motion are negligible (i.e., the rotary Brenner number $Br_r = \infty$ (22)), yield $b_1 + b_2N$ (Table 3). The intercepts $(T/\tau)G^{-1} = 0$ are linear with N (Fig. 9, top) from which, using [26], $b_1 = 0.68$ and $b_2 = 1.22 \times 10^{-7}$ ml^{-1}.

Using the analytic expression for b_1 of *orientation distributions* derived in ref. 1 for a distribution of r_e's given by [29] is:

$$[30] \qquad b_1 = \frac{\sqrt{8}\pi\sigma_e(1 - \overline{r_e}^2)}{\overline{r_e}(\overline{r_e}^2 + 1)}$$

and inserting the experimental value of b_1 for damping of transmission coefficients, $\sigma_e = 0.05$ for $\overline{r_e} = 0.44$. This is somewhat lower than the value (0.07) obtained by the direct microscopic measurements (20); however, in view of the differences to be expected in b_1 derived from optical measurements and those given for orientation distributions by [30], the fact our samples and those of Goldsmith and Marlow (20) were different, and that $g_1(r_e)$ and $g_2(V)$ are not strictly independent for blood cells (20), the agreement in the σ_e's is considered satisfactory. In the absence of a theory of two-body shear-interactions for oblate spheroids (1), it is premature to comment on our experimental value of b_2.

We now consider the effects of rotary Brownian motion which determines τ_3 in [25] by a relation of the type (17)

$$[31] \qquad \tau_3^{-1} \simeq \alpha D_r$$

where α is a parameter yet to be determined and D_r the rotary Brownian diffusion coefficient normal to X_1', which for an oblate spheroid ($r_e < 1$) is given by (23)

$$[32] \qquad D_r = \frac{k_0 T_1 r_e^2}{4\eta V(1 - r_e^4)}\left[1 + \frac{1 - 2r_e^2}{r_e\sqrt{1 - r_e^2}}\tan^{-1}\frac{\sqrt{1 - r_e^2}}{r_e^2}\right]$$

k_0 being the Boltzmann constant, T_1 the absolute temperature, and η the medium viscosity. The parameter $\alpha = 6$ for orientation distributions at $Br_r = G/2D_r = 0$ (i.e., at $G = 0$) (23). For finite, but very large Br_r, α is estimated to be proportional to r_e^4 for phase mixing (24) when $r_e \gg 1$. If an analogy can be made for oblate spheroids ($r_e < 1$) we may write

$$[33] \qquad \alpha = 6r_e^{-4}$$

For the system used in our experiments, $D_r = 5.2 \times 10^{-5}$ s^{-1}, so that from [31] the calculated $\tau_3 = 120$ s whereas the experimental τ_3 obtained from the measured mean value of $\overline{b_3} = 1.04$ s^{-1} (Table 3) is 16 s. At $G = 0$ (as in the last portion of Fig. 8 where the decay was due to rotary Brownian motion restoring random orientation) the measured $\tau_3 = 4 \times 10^2$ s and the calculated τ_3 from [31] and [32] with $\alpha = 6$ (23) is 3.2×10^3 s. In both cases the measured τ_3's are approxi-

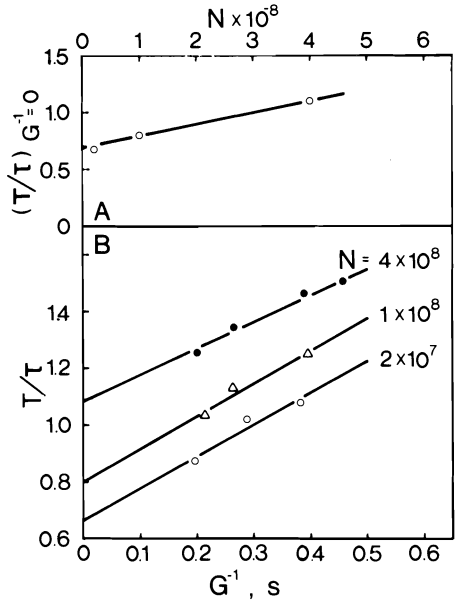

FIG. 9. Measured damping coefficients T/τ vs. G^{-1} at various N ml^{-1} (part *B*). The intercepts $(T/\tau)G^{-1} = 0$ vs. N are plotted in the upper half. From these plots of the experimental data, the constants b_i in [26] were evaluated (see Table 3 and text).

mately one order of magnitude smaller than those calculated. However, in view of the approximations that are inherent in applying [26] and [31] to turbidity data the difference between two values is not unreasonable.

The fluctuations, or scintillations (13), which are superimposed on the traces to T_0 (Fig. 9), are considered to be experimentally significant, and are not merely electronic noise and other random disturbances: it is significant that at $Br_r = \infty$ they, like the oscillations in T_0, can be perfectly reproduced on reversing flow (25) and for this reason cannot be random. On the other hand, at $Br_r = 0$, when Brownian motion predominates and one is dealing with purely perikinetic conditions (22), the scintillations are random. It is our belief that for $0 \leq Br_r \leq \infty$ they arise from statistical fluctuations in the number of particles sampled by the finite volume (1.5×10^{-3} ml) of the light beam; since only a small fraction of the total number are in orientations near maximum C_{sca}, the fluctuation in T_0 can be shown to be significant, e.g., 2.5% of T_0 at $N = 10^8$ (13).

Concluding Remarks

The theory and the preliminary experimental results presented here demonstrate some of the potentials of rheo-optical measurements in determining distributions of size and shape, especially when the particles scatter (rather than absorb) light and are reasonably monodisperse. Some related observations are the following:

(*1*) Damped oscillations in T_0 can occur with particles that absorb light, e.g., with hardened red blood cells like those used here but rendered absorbing by coating them with silver (25), under which conditions all of the light on a particle is removed from the beam and hence, as the analogue of [18],

$$[34] \qquad \nu = N\overline{S_{13}}$$

However, the oscillations in T_0 are now in phase with those of $\overline{S_{13}}$ instead of being 90° out of phase (as in Fig. 6), and thus show an initial drop to a minimum instead of rising to a maximum (as in Fig. 8). Q_{sca} is now a maximum when the cell is face-on to the beam, and a minimum when edge-on as expected intuitively.

(*2*) When σ_e becomes very large $\tau/T < 1/4$ and oscillations will not occur, i.e., the system is overdamped (1). Under these conditions monotonic changes of T_0 and I_r may be expected as we have already observed with highly heterodisperse suspensions of guanine (26) and kaolin (27) platelets, but with both systems recovering the original values on stopping shear as random orientations are restored by the appreciable D_r. Further complications undoubtedly arose from the optical anisotropy (birefringence) of the guanine crystals (26).

Further development of the theory (including a consideration of particles that are deformable in a flow) and of instrumental methods that incorporate a number of the geometries described in Fig. 2 have been planned or made and will be reported later. Additional optical phenomena which may prove fruitful for similar theoretical and experimental investigations are streaming dichroism and optical rotatory dispersion when Br_r is much greater, as in classical streaming birefringence studies (3).

Acknowledgements

The authors wish to thank Mr. K Sarantidis for assistance in the light transmission measurements, and Drs. H. L. Goldsmith and M. M. Frojmovic for preparation of the erythrocyte suspensions.

Received June 6, 1977

LEWIS A. SLOTIN, DENIS R. LAUREN, and ROSS E. WILLIAMS. Can. J. Chem. **55**, 4257 (1977).

Several polypeptides have been synthesized which contain the alternating sequence lysyl-X, where X = gly, L-ala, D-ala, L-val, L-leu, and L-phe. The polypeptides have been characterized by gel filtration (molecular weight) and by circular dichroism spectroscopy (secondary structure).

LEWIS A. SLOTIN, DENIS R. LAUREN et ROSS E. WILLIAMS. Can. J. Chem. **55**, 4257 (1977).

Nous avons synthétisé plusieurs polypeptides qui contiennent la séquence alternée lysyl-X, ou X = gly, L-ala, D-ala, L-val, L-leu et L-phe. Les polypeptides ont été caractérises par des filtrations sur gel (poids moléculaire) et par des spectres du dichroisme circulaire (structure secondaire).

Introduction

The nuclei and chromosomes of eukaryotic organisms contain significant amounts of protein and nucleic acid. Many of the proteins are basic or cationic in nature and constitute a class of proteins known as the histones. Because of their cationic character these proteins interact strongly with cellular DNA (deoxyribonucleic acid) and have thus been postulated to play an integral role in chromosomal architecture and a smaller role in cellular regulation (1).

The nature of the association between these cationic proteins and cellular DNA may be simply electrostatic or may be coupled to a more complex sequence-dependent recognition process (2). In order to elucidate the role which the structure of the protein plays in these interactions, a number of synthetic models containing basic amino acids have been utilized (3–7). As an example, the homopolymers poly-(L-lysine) and poly-(L-arginine) have been used to study DNA – cationic protein interactions (3, 4). In order to extend the study of these latter model systems the synthesis, characterization, and DNA interaction study of a series of sequential lysine–glycine polypeptides has been reported (8). To continue in this approach the sequential polymers

poly-(L-lysgly)

poly-(L-lys-L-ala)

poly-(L-lys-D-ala)

poly-(L-lys-L-val)

poly-(L-lys-L-leu)

poly-(L-lys-L-phe)

have been synthesized.

In this paper we describe the synthesis of the monomer blocks used for the preparation of the polymers and the polymerization conditions used. The secondary structure and conformational mobility of the polypeptides has also been examined by circular dichroism (cd) spectroscopy.

Materials and Methods

All chemicals were of reagent grade and were used directly unless otherwise noted.

Optical rotations were measured on a Perkin-Elmer polarimeter Model 141 in a 1 dm microcell. Methanol (MeOH) or glacial acetic acid (HOAc) were used as solvents as noted. Melting points were taken on a Fisher-Johns melting point apparatus (heated block) and are uncorrected. Combustion analyses were determined on a Perkin-Elmer CHN analyzer, model 240. Amino acid analyses were done on a Beckman automatic analyzer, model 120. Amino acid hydrolyses were carried out in 6 *N* HCl at 110°C for 24 h.

Circular dichroism spectra were taken on a calibrated (9) Cary spectropolarimeter, model 61, in quartz cells (path length 0.05 cm). Reported ellipticities are based upon the lysine concentration (as determined by amino acid analysis). Ultraviolet spectra were taken on a Cary 14

recording spectrophotometer in quartz cells (path length 1 cm).

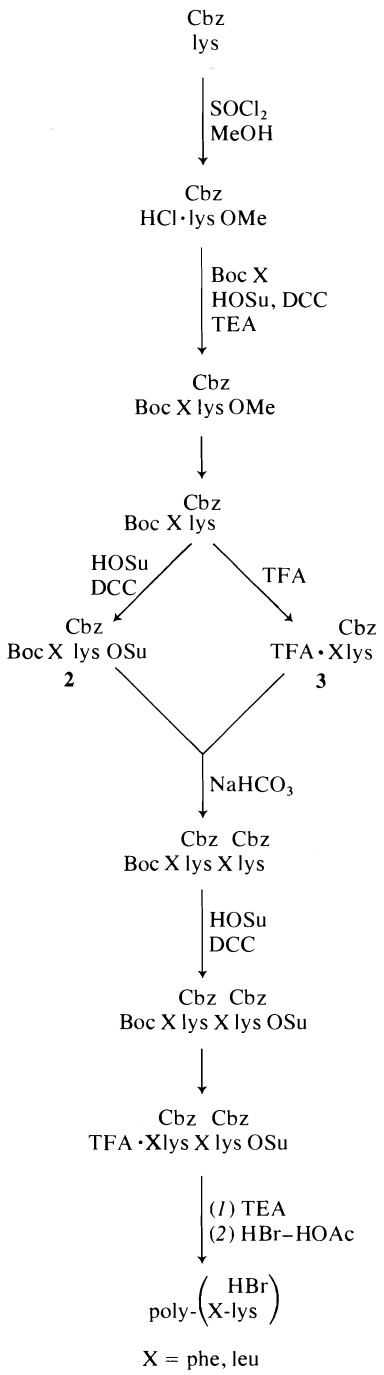
N^{ε}-Benzyloxycarbonyl(Cbz)-L-lysine was purchased from Pierce Chemicals, Rockford, Illinois. N^{α}-*tert*-Butyloxycarbonyl (Boc)-N^{ε}-Cbz-L-lysine, N^{α}-*tert*-Boc-phenylalanine, and N^{α}-*tert*-Boc-leucine monohydrate were purchased from Beckman Instruments Co., Palo Alto, California. L-Alanine was purchased from Bion Biochemicals, Oakville, Ontario, D-alanine from Nutritional Biochemicals Corporation, Cleveland, Ohio, and glycine from British Drug House, England. *N*-Hydroxysuccinimide (HOSu) and dicyclohexylcarbodiimide (DCC) were obtained from Fluka AG, Buchs, Switzerland.

N^{α}-*tert*-Boc-leucine monohydrate was rendered anhydrous by repeated dissolution in and evaporation from anhydrous benzene. Triethylamine (TEA) was distilled from *p*-toluenesulfonyl chloride and stored under nitrogen atmosphere. Dicyclohexylamine (DCHA) was distilled prior to use. Dimethylformamide (DMF) was purified by treatment with barium oxide, filtration, and vacuum distillation. Dimethoxyethane (DME) was purified by distillation from lithium aluminum hydride. Pyridine was purified by distillation from *p*-toluenesulfonyl chloride and then lithium aluminum hydride. Trifluoracetic acid (TFA) was purified by distillation from phosphorous pentoxide.

Polymer molecular weight (mw) distributions were established on the unblocked polymers by dialysis against 2% aqueous HOAc in Spectrapor dialysis tubing (#3 mw cutoff, 3500; #1 mw cutoff, 6000–8000; and #2 mw cutoff, 12 000 – 14 000) which had been pretreated as directed (sodium sulfide and dilute sulfuric acid). Dialyses were performed at room temperature for 18 h. Polymer molecular weights were also estimated by thin layer gel filtration on Sephadex G-100 (sodium phosphate, 0.002 *M*; sodium chloride, 0.05 *M*; p*H* 7.0) using ribonuclease, chymotrypsinogen, and ovalbumin as standards (10, 11). Detection was by trinitrobenzene – sulfonic acid treatment of a paper replica (12).

Monomer Preparation

The monomers used for the synthesis of the polypeptides were prepared according to the procedures outlined in Schemes 1 and 2. Elemental analyses, specific rotations ($[\alpha]_D$), and melting points are given in Tables 1[5,6] and 2. The general procedure for the preparation of Cbz
t-Boc-X-lys-dipeptides (Scheme 1) may be exemplified by the synthesis of N^{α}-*t*-Boc-phenylalanine-N^{ε}-Cbz-L-lysine DCHA salt. N^{ε}-Cbz-L-lysine (50 g, 0.18 mol) was suspended in anhydrous methanol (600 ml) and the mixture cooled in a Dry Ice – acetone bath. Thionyl chloride (42.4 ml, 0.59 mol) was added dropwise over 0.5 h with rapid stirring. Upon completion of addition the reaction clarified. The solution was then warmed to 0–5°C and stirred overnight during which time the temperature rose to ambient. The solvent was removed *in vacuo*

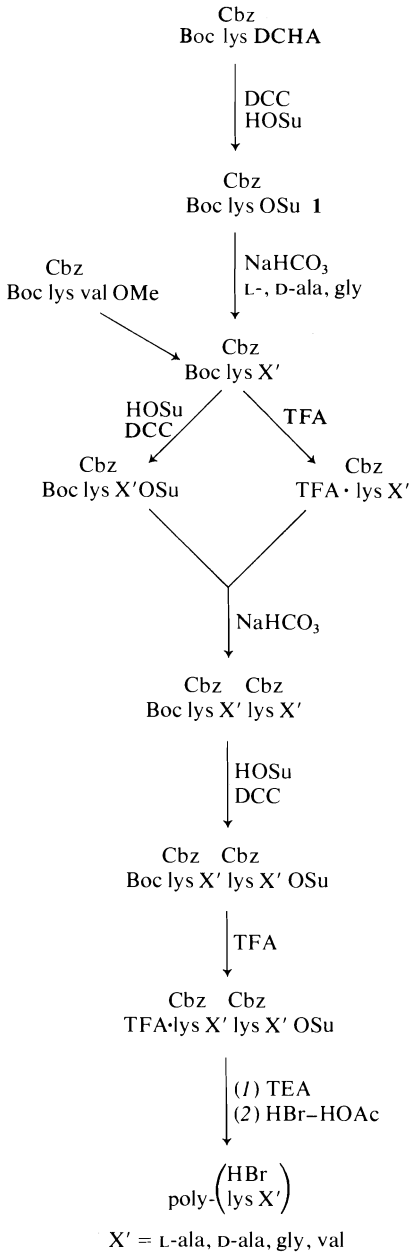


SCHEME 1

below 30°C and methanol–benzene (1:1, 400 ml) added and evaporated. The process was repeated three times. The residue was shaken with acetone (600 ml) and Cbz
HCl·lysOMe (50 g) collected by filtration. *t*-Boc-phenyl-

[5]All elemental analyses were within acceptable limits (C ±0.2%, H ±0.2%, N ±0.3%).

[6]Copies of Table 1 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



SCHEME 2

Cbz
alanine (45.5 g, 170 mmol) and HCl·lysOMe (56 g, 170 mmol) were dissolved in DME–DMF (2:3, 250 ml) and cooled in ice. *N*-Hydroxysuccinimide (19.5 g, 170 mmol) and triethylamine (23.6 ml, 170 mmol), followed by a cooled (0–5°C) solution of dicyclohexylcarbodiimide (DCC) in DME–DMF (2:3, 100 ml), were added. After stirring overnight, during which time the temperature reached ambient, the mixture was filtered and the precipitated dicyclohexylurea washed with cold methylene chloride (3 × 1 ℓ). The filtrate and washings were combined and concentrated *in vacuo*. The residue was dissolved in ethyl acetate (2 ℓ), filtered, and the filtrate washed successively with 0.1 *N* HCl (cold, 2 ℓ), 5% sodium bicarbonate (cold, 2 ℓ), and water (cold, 4 ℓ). The organic layer was dried over sodium sulfate, filtered, and evaporated *in vacuo*. The residue, *t*-Boc-
Cbz
phelysOMe (72.5 g, 79%) was recrystallized from ethyl acetate – petroleum ether (30–60°C).

Cbz
t-BocphelysOMe (40 g, 74 mmol) was dissolved in DME (300 ml) and cooled to 0–5°C. Cold 1 *N* NaOH (74 ml) was added and the temperature allowed to reach ambient over a period of 2 h. Cold (0–5°C) sodium bicarbonate (5%, 1 ℓ) was added and the mixture cooled in ice and then acidified to p*H* 2 with cold 1 *N* HCl. The aqueous solution was extracted with ethyl acetate (3 × 1 ℓ) and the organic phase dried over sodium sulfate and evaporated to dryness *in vacuo*. The product was taken up in ether (1 ℓ) and dicyclohexylamine (15.9 ml, 81 mmol) added. The solution was refluxed on a steam bath for 2 h, cooled to room temperature, and shaken overnight on a mechanical shaker. The DCHA salt was collected by filtration and washed with petrol (30–60°C) (yield 71%).

Cbz
t-BocleulysDCHA salt was prepared in a similar manner from *t*-Bocleu and HCl·lysOMe (yield 50%).

The general procedure for the preparation of *t*-
Cbz
Boclys-X dipeptides (Scheme 2) was identical to the re-
Cbz
ported (8) synthesis of N^{α}-*t*-BoclysglyDCHA from N^{α}-*t*-
Cbz
BoclysOSu and glycine in aqueous sodium bicarbonate
Cbz
(yield 91%). The couplings of N^{α}-*t*-BoclysOSu with L- and D-alanine were performed in an analogous fashion (yields: L 73%; D 63%). The dipeptide *t*-Boclysval was pre-
Cbz
pared from *t*-Boclys and HCl·valOMe by coupling with DCC in the presence of hydroxysuccinimide, hydrolysis of the methylester on DME–NaOH(aq.), and isolation of the acidic product (yield 90%).

The general procedure for the preparation of *t*-Boc-
Cbz Cbz Cbz Cbz
X-lys-X-lys or *t*-Boc-lys-X-lys-X tetrapeptides is exempli-
Cbz Cbz
fied by the synthesis of *t*-Boc-phe-lys-phe-lys and is as
Cbz
follows: N^{α}-*t*-Boc-phe-lysDCHA (15 g, 21.1 mmol) was dissolved in cold (0–5°C) ethyl acetate (250 ml). Cold (0–5°C) 0.1 *N* HCl (230 ml, 23 mmol) was added and the mixture stirred vigorously at 0–5°C for 10 min. The free acid was extracted into ethyl acetate (3 × 300 ml), dried over sodium sulfate, and filtered. The filtrate was divided into two equal fractions (*A* and *B*) and each was concentrated to dryness *in vacuo*. The residue from *A* was converted to its succinimide ester by dissolution in cold (0–5°C) DME–pyridine (95:5, 50 ml) followed by the addition of *N*-hydroxysuccinimide (1.2 g, 10.55 mmol) and DCC (2.28 g, 10.55 mmol). The mixture was stirred at 0–5°C for 6 h, filtered, and the filtrate concentrated

to dryness *in vacuo*. The residue from *B* was treated with TFA–CH_2Cl_2 (1:1, 40 ml) and let stand at room temperature for 1 h. Excess ether was added and the solution concentrated *in vacuo*. The residue was triturated with ether until the TFA was removed. The residue was dissolved in *p*-dioxane (150 ml) and added to the succinimide ester from *A*. Water (50 ml) was added and the solution cooled (0–5°C). Sodium bicarbonate (1.77 g, 21.1 mmol) was added and the solution stirred at 0–5°C for 6 h. The product was extracted into ethylacetate (4 × 400 ml), dried over sodium sulfate, filtered, and concentrated to dryness *in vacuo*. The residue was recrystallized from ethyl acetate (5.17 g) (60%). The tetrapeptides (yields in parentheses) *t*-Boc-lys-val-lys-valDCHA (an uncharacterized oil 70%), *t*-Boc-leu-lys-leu-lysDCHA salt (54%), *t*-Boc-lys-L-ala-lys-L-ala (76%), *t*-Boc-lys-D-ala-lys-D-alaDCHA salt (83%), and *t*-Boc-lys-gly-lys-glyDCHA salt (75%) were prepared in a similar manner from *t*-Boc-lysvalDCHA, *t*-Boc-leu-lysDCHA, *t*-Boc-lys-L-alaDCHA, *t*-Boc-lys-D-alaDCHA, and *t*-Boc-lys-glyDCHA respectively.

Activation and Polymerization of the Monomer Blocks

N-Hydroxysuccinimide esters of the blocked peptides were prepared by coupling the free acid (liberated from its DCHA salt where necessary) with *N*-hydroxysuccinimide using DCC in ice cold DME–pyridine (95:5, v/v). After reaction (6 h at 0°C) the urea was filtered off and the solution evaporated. The residue was thoroughly dried and treated with an excess of TFA and methylene chloride (1:1, v/v) (approx. 10 ml/g) at room temperature for 2 h. The TFA salt was precipitated by addition of 10–20 volumes of ether by decantation. The product was transferred to a centrifuge tube (50 ml) in methylene chloride and the solvent evaporated by a stream of nitrogen.

The TFA–succinimide ester (approximately 1 g) was suspended in cold (0–5°C) DME to make the solution 1 *M* in monomer. Triethylamine (3 mol equiv./mol of monomer) was added and the mixture stirred rapidly with a glass rod. The polymerization was allowed to proceed in a desiccator ($CaCl_2$) at room temperature overnight after which the gel or viscous solution which resulted was diluted with DME to give a monomer concentration of 0.5 *M*. The polymerization was allowed to continue for an additional 6 days. The polymeric material was precipitated by addition of 10 volumes of acidified water (1 drop concentrated HCl per litre) and then recovered by centrifugation. The polymer was rewashed and then the precipitate washed first with isopropanol

(3 × 20 ml) and then with ether (3 × 20 ml). The residue was then dried *in vacuo* over calcium chloride at room temperature overnight.

Blocking Group Removal

Benzyloxycarbonyl (Cbz) blocking groups were removed from all polymers with saturated HBr – acetic acid (15). The hydrobromide salt was isolated by precipitation with ether. The HBr – acetic acid treatment was repeated in order to ensure complete removal of all blocking groups. The ether-insoluble salt was then washed with isopropanol–ether (1:10, 20 ml, 2×) and then dried *in vacuo* over $CaCl_2$. The extent of blocking group removal after the two HBr – acetic acid treatments could be estimated for all but the phenylalanine containing polymer by the residual benzyloxycarbonyl (Cbz) absorption at 254 nm (aqueous solution, approximately 2 mg/ml (ε_{254} 200 (16)). In all cases greater than 98% of all blocking groups were estimated to have been removed.

Isolation of High Molecular Weight Polymeric Material

Isolation of polymeric material was accomplished using Spectrapor 1 (mw cutoff 6000–8000) dialysis sacs except for the $(lysval)_n$ sample which was isolated using Spectrapor 3 (3500 mw cutoff). Dialyses of 50 ml volumes (polypeptide concentration approx. 50 mg/ml) were performed against 3.5 ℓ of 2% aqueous acetic acid for 4 h at room temperature followed by further dialysis against a fresh 2% aqueous acetic acid solution (3.5 ℓ) overnight. The contents of the sacs were then passed through Millipore filters (0.45 μ) and lyophillized.

Results and Discussion

Synthesis of Monomers and Polypeptides

The routes for the synthesis of the monomers and their polymerization are given in Schemes 1 and 2. The N^{α}-*t*-Boc-X-N^{ε}-Cbz-lysDCHA dipeptides (Scheme 1) were synthesized by coupling the N^{α}-*t*-Boc-X amino acid with HCl·N^{ε}-Cbz-lysOMe in the presence of dicyclohexylcarbodiimide and *N*-hydroxysuccinimide. Hydrolysis of the methyl ester, followed by treatment of the resulting acid with dicyclohexylamine (DCHA), gave the dipeptide DCHA salts. For the synthesis of the N^{α}-*t*-Boc-N^{ε}-Cbz-lys-X DCHA dipeptides (Scheme 2) the *N*-hydroxysuccinimide active esters **1** were coupled with D- or L-alanine or glycine in aqueous sodium bicarbonate solutions via a backing-off procedure (17). In both cases activation via the *N*-hydroxysuccinimide ester was used to minimize racemization (18, 19). The dipeptide Boclysval was prepared from Boclys(Cbz) and HClvalOMe by coupling with DCC, hydrolysis of the methyl ester and isolation of the acidic product. The DCHA salts could be obtained from the acidic products in good yields and were easily characterized compounds (Table 2). Conversion of the dipeptides into their corresponding tetrapeptides was accomplished by converting one half the material into the corresponding succinimide ester, **2**, while the other half was treated with trifluoroacetic acid to remove the N^{α}-*tert*-butyloxycarbonyl blocking group. The trifluoroacetate salt, **3**, was then coupled with **2** in the presence of triethylamine. Except for N^{α}-*t*-Boc-leu-N^{ε}-Cbz-lys-leu-N^{ε}-Cbz-lysDCHA and corresponding valine tetrapeptide all the tetrapeptides gave satisfactory combustion analyses. The leucine tetrapeptide, however, consistently gave a low carbon analysis. To further substantiate its structure, a molecular weight determination by end group titration (14) was determined to be within 1.5% of the calculated value and the product also had a leucine–lysine ratio of 0.98. N^{α}-*t*-Boc-N^{ε}-Cbz-lys-val-N^{ε}-Cbz-lys-val-DCHA was an oil which resisted all attempts at crystallization and its acid was used directly for the polymerization.

The choice of the tetrapeptide as the minimum size of monomer to be used in the polymerizations was determined by a comparison of the yields of unblocked polymeric material obtained from the polymerizations of phenylalanine-lysine di- and tetrapeptides respectively (Table 3). Dimethoxyethane was chosen as the polymerization solvent because higher yields of unblocked high molecular weight material were obtained when the polymerization of the TFA salt of phe-N^{ε}-Cbz-lys-phe-N^{ε}-Cbz-lysOSu was compared in DMF, DMSO, and DME (Table 3).

For the polymerization of other tetrapeptides, their acids were activated by conversion to their succinimide esters since it has been shown that good yields of polymeric material could be obtained using these esters (20–24). The *t*-Boc blocking group was removed and the resulting active ester trifluoroacetate (TFA) used for polymerization in dimethoxyethane (DME) solution. During polymerization the monomer concentration was kept high (~ 1 *M*) in order to reduce the formation of cyclic and low molecular weight material. After isolation the polymers were treated twice with HBr – acetic acid to ensure complete removal of all the benzyloxycarbonyl groups as evidenced by uv absorption at 254 nm. The resulting hydrobromide salts were isolated in good yields (30–50% yield based upon the amount of monomer used). Unblocked polymeric materials were finally

TABLE 3. Effects of monomer size and polymerization solvent on the preparation of high molecular weight poly-(L-lys-L-Phe)[a]

Monomer[c]	Polymerization solvent	Unblocked polymer	% retained 3500 mw	% retained 6000–8000 mw	% retained < 12 000 mw
Cbz TFAphelysOSu	DMF[b]	Poly-(L-lys-L-phe)	—	6	3
Cbz Cbz TFAphelysphelysOSu	DMF[b]	Poly-(L-lys-L-phe)	38	15	12
	DMF	Poly-(L-lys-L-phe)	34	14	6
	DME	Poly-(L-lys-L-phe)	59	33	23
	DMSO	Poly-(L-lys-L-phe)	31	13	7

[a]Dialyses were performed using dialysis tubing (Spectrapor 3, 1, and 2, nominal mw cutoff of 3500, 6000–8000 and 12 000 – 14 000 respectively). Percentages retained by the dialysis sacs were determined by dialyzing the polypeptide solutions (approx. 4 mg/ml) against 2% aqueous acetic acid for 18 h at room temperature and are based on the lysine concentration in solution before and after dialysis.
Cbz
[b]Polymerization in the presence of 0.01 mol equiv. of chain terminator HCl·lysOMe.
[c]All optically active amino acids are of the L configuration unless noted otherwise.

TABLE 4. Percentage retained on dialysis of the unblocked polypeptides and molecular weights of lysine-X polypeptides

Polymer	% retained by Spectrapor 1 dialysis sac[a]	Molecular weight[b]
Poly-(L-lys)	—	33 000 (78 000–8 200)
Poly-(L-lys-gly)	49	8 700 (21 700–2 300)
Poly-(L-lys-L-ala)	51	16 500 (33 500–4 100)
Poly-(L-lys-D-ala)	45	7 800 (21 500–1 800)
Poly-(L-lys-L-val)	10[c]	< 2 000 (5 400– < 2 000)
Poly-(L-lys-L-leu)	71	6 000 (13 200–2 200)
Poly-(L-lys-L-phe)	33	3 200 (9 500– < 2 000)

[a]Percentages retained by the dialysis sac were determined as noted in Table 3.
[b]Measured by gel filtration of the unblocked polypeptide on Sephadex G-100 in 0.002 *M* sodium phosphate, 0.05 *M* sodium chloride, p*H* 7.0 (10, 11). Ribonuclease, chymotrypsinogen, and ovalubumin were used as standards. Molecular weights were unaffected by increasing the sodium chloride concentration to 0.15 *M*. The molecular weight was taken as mid-point of a spot detected on paper replica by trinitrobenzenesulfonic acid – borate buffer treatment. Ranges are given in parentheses.
[c]Dialysis was done using Spectrapor 3 (3500 mw cutoff).

isolated by dialysis against dilute acetic acid (Table 4) and stored as lyophilized powders in a desiccator.

Previous reports have described the preparation of a high molecular weight poly-(L-lys-L-phe) (25) via the tetrapeptide monomer but little experimental detail and no characterization of the monomer blocks was reported. In addition a poly-(L-lys-L-ala) sample has been synthesized earlier by an alternate approach (26).

Polypeptide Molecular Weights

Molecular weight determinations of the unblocked polymeric material obtained by dialysis were checked by gel filtration on Sephadex G-100 (10, 11) (Table 4). This allowed us to determine the molecular weight distribution of each of the polymers. It should be noted the values obtained for poly-(L-lys-L-val), poly-(L-lys-L-leu), and poly-(L-lys-L-phe) may not be truly representative of their actual molecular weights. It is possible that these hydrophobic polymers interact with the gel employed or adopt non-globular-like conformations and thus reduce their mobility relative to the globular standards employed. Either effect would lead to molecular weight values much lower than reality.

Circular Dichroic Spectra

Circular dichroic spectra have been used to investigate the conformation of polypeptides and proteins (27). Circular dichroic spectra of polypeptides in the various standard conformations are available (28–30) and comparison of these with the circular dichroic spectra of the sequential lysine-X polypeptides would indicate which, if any, of the standard conformations the synthetic polypeptides adopt.

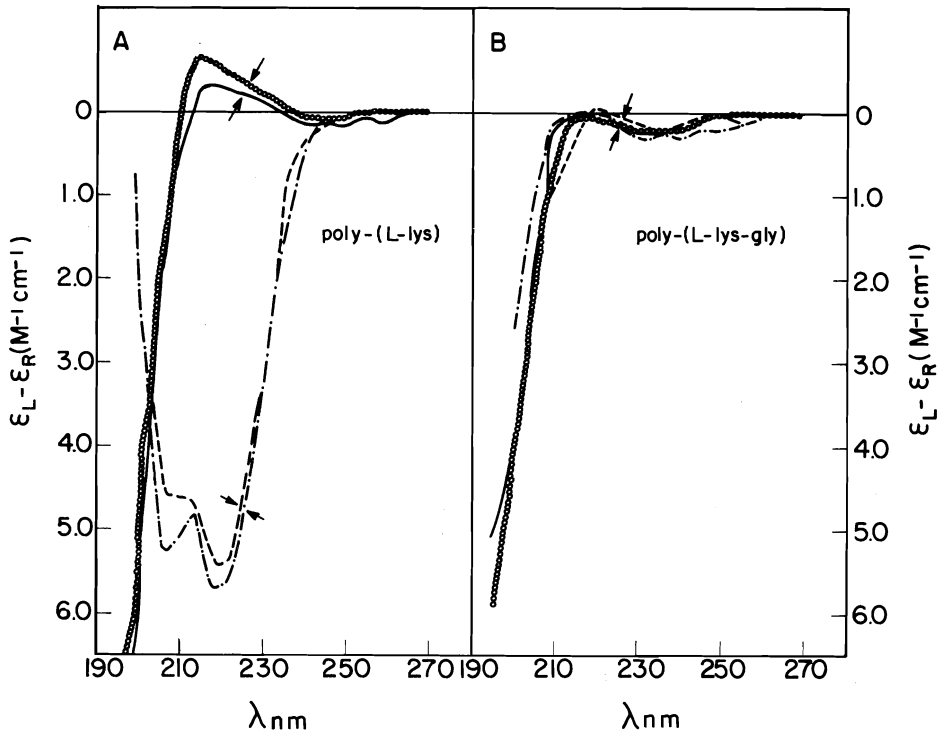

FIG. 1. Circular dichroic spectra of the unblocked poly-(L-lys) (A) and poly-(L-lysgly) (B) isolated by dialysis against dilute acetic acid (Spectrapor 1): (○) p*H* 7.0, 0.14 *M* KF; (—) p*H* 7.0, 1.0 *M* KF; (---) p*H* 12.0, 0.14 *M* KF; (-·-) p*H* 12.0, 1.0 *M* KF; arrows indicate wavelengths where ellipticities listed in Table 5 were taken.

Circular dichroic spectra under differing conditions of p*H* (7 and 12) and salt concentrations (0.14 and 1.0 *M*) have been taken of each of the polypeptides (Figs. 1–3). The ellipticities at specific wavelengths and based upon molar concentration of lysine are presented in Table 5.

The spectrum of poly-(L-lys) (Fig. 1A), at low and high salt (p*H* 7.0), is characteristic of an extended or disordered conformation (31–33) or 3_1 helix (34) and shows a slight decrease in ellipticity at 215 nm upon increasing the salt concentration from 0.14 to 1.0 *M* (35). When the p*H* of the solution was changed to 12 in order to neutralize the side chain charges, the poly-(L-lysine) conformation shifted to that of the α helix with the concomitant production of intense negative bands at 225 and 208 nm (36).

The conformation of poly-(L-lys-gly) (Fig. 1B) is one of a random coil over the complete salt and p*H* ranges examined. This is in accord with the poly-(L-lys-gly) synthesized from the dipeptide monomer and reported earlier (8). Thus poly-(L-lys-gly) would appear to be very flexible, lacking the rigidity observed in poly-(L-lys).

The spectrum of poly-(L-lys-L-ala) (Fig. 2A) at low salt and neutral p*H* is essentially the same as that seen for poly-(L-lys) (Fig. 1A). At neutral p*H* and high salt the poly-(L-lys-L-ala) polymer shows a slight tendency towards α-helix formation or random coil formation (34) either of which may be attributed to a greater charge separation making the electrostatic shielding of the salt more effective than that observed with poly-(L-lys). At p*H* 12 where the side chain charges are neutralized, poly-(L-lys-L-ala) adopts the typical α-helical conformation with the maximum ellipticities centered at 220 and 208 nm. Changing the salt concentration from 0.14 to 1.0 *M* at this p*H* had no effect. This conformational assignment is consistent with optical rotatory dispersion studies reported for poly-(L-lys-L-ala) of similar size (26) and closely resembles a series of poly-(L-lys-L-ala) random copolymers (37). Poly-(L-lys-L-ala-L-ala) (38) and poly-(L-lys-L-ala-L-ala-L-ala) (39, 40) show de-

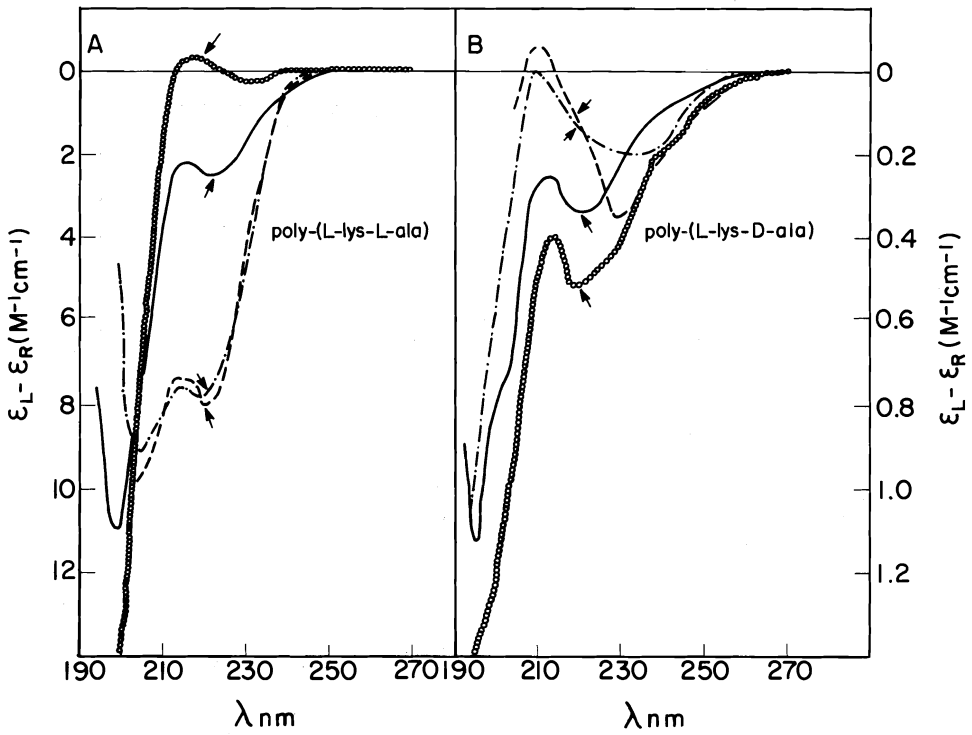

FIG. 2. Circular dichroic spectra of the unblocked poly-(L-lys-L-ala) (A) and poly-(L-lys-D-ala) (B) isolated by dialysis against dilute acetic acid (Spectrapor 1); symbols and details as in Fig. 1.

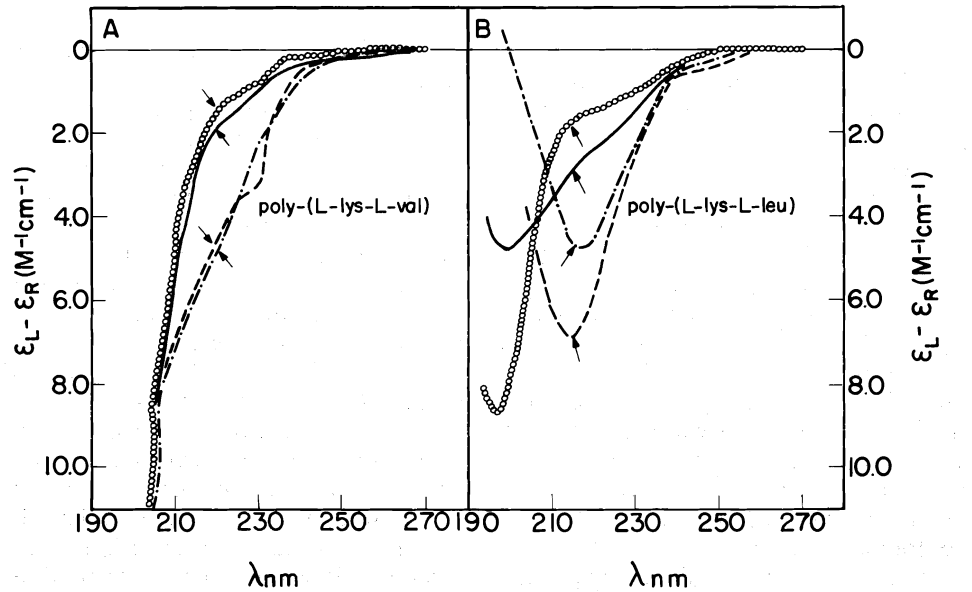

FIG. 3. Circular dichroic spectra of the unblocked poly-(L-lys-L-val) (A) and poly-(L-lys-L-leu) (B) isolated by dialysis against dilute acetic acid (Spectrapor 3 and Spectrapor 1 respectively); symbols and details as in Fig. 1.

TABLE 5. Circular dichroic ellipticities

		$\varepsilon_L - \varepsilon_R$[a]			
		0.14 *M* KF		1.0 *M* KF	
	λ (nm)	p*H* 7	p*H* 12	p*H* 7	p*H* 12.0
Poly-(L-lys)	225	+0.34	−4.90	+0.25	−5.17
Poly-(L-lys-gly)	225	−0.19	−0.13	−0.19	−0.13
Poly-(L-lys-L-ala)	220	+0.05	−8.34	−2.95	−8.18
Poly-(L-lys-D-ala)	220	−0.53	−0.18	−0.34	−0.18
Poly-(L-lys-L-val)	220	−1.48	−4.68	−1.91	−4.56
Poly-(L-lys-L-leu)	215	−1.67	−7.01	−2.95	−4.70
Poly-(L-lys-L-phe)	220	+1.31	−1.44	+0.50	−0.15

[a]The calculations of $\Delta\varepsilon$ ($\varepsilon_L - \varepsilon_R$) are based upon the number of moles of lysine in solution (approximately 2–4 × 10^{-3} *M*) as determined by hydrolysis and amino acid analysis. Spectra were first taken at p*H* 7 in Tris-HCl buffer, 0.01 *M*, at the salt concentrations noted. The solutions were then adjusted to p*H* 12 with concentrated sodium hydroxide (1 *N*) and the spectra measured. All polymeric materials used were obtained by dialysis of the unblocked polypeptides against dilute acetic acid.

finite tendencies towards α-helical conformations in conditions of low salt and neutral p*H* but this may be attributed to a more effective separation of positive charge than is possible with poly-(L-lys-L-ala).

The spectrum of poly-(L-lys-D-ala) (Fig. 2B) suggests that the polymer exists in a random coil conformation under all the salt and p*H* ranges examined. This is similar to that obtained for poly-(L-lys-gly) (Fig. 1B) and, thus, indicates this polypeptide is very flexible. There does appear to be a bathochromic shift of the negative band at 220 nm to 230 nm upon increasing the p*H* from 7.0 to 12.0 which is not seen in the poly-(L-lys-gly) spectrum. However, structural assignments based upon completely L-amino acid systems as references may not be applicable and final conclusions as to the solution conformation of poly-(L-lys-D-ala) must await further examination of more relevant models.

Poly-(L-lys-L-val) (Fig. 3A) is predominantly in a random coil conformation at low and high salt at neutral p*H*. Increasing the p*H* from 7.0 to 12.0 increases the ellipticity at 220 nm (Table 5), suggestive of a slight contribution from a β-like conformation.

Poly-(L-lys-L-leu) (Fig. 3B) is predominantly in a random coil conformation at low salt and neutral p*H*. Increasing the salt concentration did not affect the cd significantly but at p*H* 12 (low and high salt) the spectrum was characteristic of a β-structure. Random copolymers of poly-(L-lys-L-leu) show a similar tendency towards random coil conformation at low salt and neutral p*H* with the transition to a β-structure as the p*H* is raised (41, 42). However, in a series of random copolymers where the mole fraction of L-leucine went from 0 to 0.41, there was an apparent transition to α-helical conformation upon raising the p*H* above 9.8 at low salt (41).

At p*H* 12.0 and 0.14 *M* KF the spectrum of poly-(L-lys-L-phe) (Fig. 4) resembles that generated by a polypeptide adopting a β-structure and is similar in shape but weaker in intensity to that

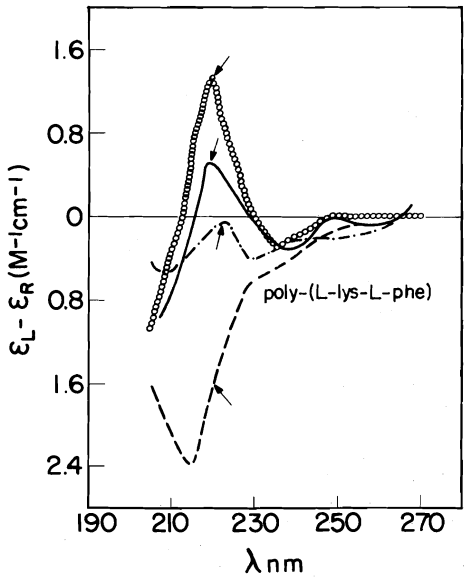

FIG. 4. Circular dichroic spectra of the unblocked poly-(L-lys-L-phe) isolated by dialysis against dilute acetic acid (Spectrapor 1); symbols and details as in Fig. 1.

reported by Seipke *et al.* (25). At neutral p*H* and 0.14 or 1.0 *M* salt the spectrum shows a slightly positive ellipticity centered at 220 nm which is in direct contrast to the reported cd spectrum of the Seipke copolymer in which a slightly negative ellipticity is evident at 225 nm. The spectrum recorded here (Fig. 4) more closely resembles the reported cd of a 1:1 random poly-(lys,phe) (43, 44). It is possible that the spectral differences among the various polypeptide preparations arise from a considerable difference in apparent molecular weights (70 000 vs. 3200), a phenomena which has been previously observed in the cd spectra of poly L-lysines of varying sizes (45). Although the spectrum resembles that generated by a β-structured polypeptide the assignment of one of the standard secondary conformations based upon the spectral appearance in the 215–220 nm region becomes quite difficult due to the contribution of the π–π^* transition of the phenylalanine chromphore (46).
