Received July 9, 1976

STEVEN J. RETTIG, JAMES TROTTER, W. KLIEGEL, and D. NANNINGA. Can. J. Chem. **55**, 1 (1977).

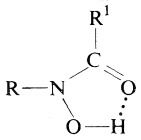
Crystals of difluoroboron *N*-methylacethydroxamate are monoclinic, $a = 5.097(1)$, $b = 10.653(2)$, $c = 11.520(2)$ Å, $\beta = 103.57(2)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.056 and R_w of 0.077 for 988 reflections with $I \geq 3\sigma(I)$. The structure features a planar five-membered BO_2CN ring. Bond lengths (corrected for libration) are: B—F, 1.374(3) and 1.381(3), O—B, 1.496(3) and 1.497(3), O—N, 1.349(2), O—C, 1.346(2), C—N, 1.298(3) and 1.458(3), and C—C, 1.468(3) Å.

STEVEN J. RETTIG, JAMES TROTTER, W. KLIEGEL et D. NANNINGA. Can. J. Chem. **55**, 1 (1977).

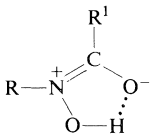
Les cristaux du *N*-méthylacethydroxamate de difluorobore sont monocliniques, $a = 5.097(1)$, $b = 10.653(2)$, $c = 11.520(2)$ Å, $\beta = 103.57(2)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de R de 0.056 et de R_w de 0.077 pour 988 réflexions avec $I \geq 3\sigma(I)$. La structure comprends un plan cycle BO_2CN à cinq membres. Les longueurs de liasons (corrigées pour la libration) sont: B—F, 1.374(3) et 1.381(3), O—B, 1.496(3) et 1.497(3), O—N, 1.349(2), O—C, 1.346(2), C—N, 1.298(3) et 1.458(3), and C—C, 1.468(3) Å.

Introduction

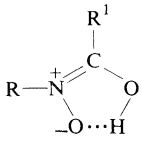
The formulae **1***a–c*, describing the different tautomeric and mesomeric forms of an isolated molecule of hydroxamic acid with intramolecular chelate type hydrogen bonding, have been discussed for hydroxamic acid and its anions (1–10), and may be summarized in **1***d*, which features chelation of the proton by a bidentate zwitterionic ligand. Replacement of the proton by a metal cation should allow fixation of this structure which is otherwise difficult to establish due to the formation of both inter- and intramolecular hydrogen bonds (4).



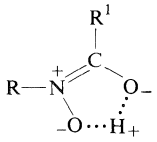
1*a*



1*b*



1*c*



1*d*

Metal hydroxamates are well known (11–15), but structural formulations are (as with hydroxamic acid or hydroxamate anions) still subject to some controversy (6, 15). Spectroscopic data do not provide sufficient information for a definitive formulation. Evidence for at least partial C—N double bond and C—O single bond character is mainly given by X-ray crystallographic studies of organotin (16–18), iron (19), and zinc (20) complexes of hydroxamic acids and a nickel thiohydroxamate (15, 21). Chelated protons are also easily displaced by "pseudo-metal" cations (22) X_2B^+ which are well established (23–27) as remarkable acceptors in the formation of chelate complexes. The bidentate dianionic ligand in **1***d* should be well suited for the synthesis of boron chelates and in fact hydroxamic acids and their *N*-substituted derivatives readily form X_2B-chelates **2** (8, 9, 26, 28–31).[1] The uv spectrum of the anion **3** suggests the presence of C=N double bonding (8, 9) whereas for a cyclic thiohydroxamate the thione form, analogous to **2***a*, is favored but not unambiguously proven (30).

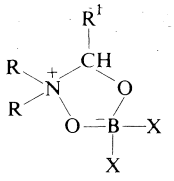
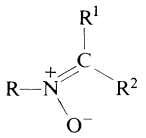
[1]W. Kliegel and D. Nanninga, unpublished results.

With the assumption that a betainic structure **4***a* represents the best formal description of the chelates **2***a–d*, the study of complexes of *N*-substituted[2] hydroxamic acids with electron-accepting boron compounds seemed very useful. One of the simplest molecules of this type is the *N*-methylacethydroxamate of the extremely electron-deficient difluoroborenium ion (**2** or **4**, R = R′ = Me, X = F). The ir spectrum of *N*-methylacethydroxamic acid (**1**, R = R′ = Me) (32) displays an absorption around 1625 cm^{-1} which can be assigned to C=O of the hydroxamic or to C=N of the hydroximic form (33). In the difluoroboron chelate **2** or **4***a* this band is shifted to a higher frequency (about 1675 cm^{-1}) into the region of $C{=}N^+$ vibrations of iminium salts, which is a general effect (34) associated with quaternization of a C=N group. The iminium structure **2***b–d* or **4***a* is also supported by the ^{1}H-nmr spectrum, which shows a low field shift of the *N*-methyl protons at δ = 3.70 ppm which can be compared with the values for *N*-methyl protons in nitrones **6** (R = Me) of 3.70 ppm. (δ (ppm) for *N*-methyl protons in *N*-methyl-C-...-nitrones: (*a*) -*tert*-butyl-, 3.65;[3] (*b*) -phenyl-, 3.86 (35); (*c*) -phenyl-, 3.83; -*p*-tolyl-, 3.80; -methyl-C-phenyl-, 3.65; -methyl-C-*p*-tolyl-, 3.65 (36).)



5



6

Formally **4***a* can be derived by the elimination of R—H from the boron-nitrogen betaine **5** (26, 37), the structure of which has been confirmed by X-ray analysis of the diphenylboron derivative (38). Structure **5** may also be regarded as a formal reduction derivative of **4***a*. Definitive information on the boron-nitrogen betaine character of **4***a* could be expected from an analysis of bond distances. To this end an X-ray crystallographic analysis of difluoroboron *N*-methylacethydroxamate has been undertaken.

[2]In *N*-unsubstituted hydroxamates (R = H) the position of the proton within the complex is unclear (21).

[3]W. Kliegel, unpublished results.

Experimental

2,2-Difluoro-4,5-dimethyl-1,3-dioxa-4-azonia-2-boranata-cyclopent-4-ene

Boron trifluoride – diethyl ether complex (1.42 g, 10 mmol) was added to a solution of 0.45 g (5 mmol) of *N*-methylacethydroxamic acid (39) in 20 ml of anhydrous diethyl ether. A white solid, which had precipitated during 30 min of refluxing, was filtered off after the solution had been allowed to stand at room temperature for 10 h. After recrystallization from ethyl acetate/diethyl ether or chloroform/ethyl acetate 0.53 g (77%) of colourless crystalline material, mp 91 °C, was obtained. *Anal.* calcd. for $C_3H_6BF_2NO_2$: C 26.32, H 4.42, B 7.90, N 10.23; found: C 26.31, H 4.25, B 7.53, N 10.26; ir (1/300 KBr) 1675 cm^{-1} (C=N); ^{1}H-nmr (60 MHz, $CDCl_3$/TMS) δ (ppm) 2.53 (s, 3, C—CH_3), 3.70 (s, 3, N—CH_3).

X-Ray Crystallographic Analysis

Crystals suitable for X-ray analysis were obtained by recrystallization from chloroform/ethyl acetate. The crystal chosen for study was mounted with a^* parallel to the goniostat axis and had dimensions of *ca.* 0.4 × 0.2 × 0.3 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 18 reflections measured on a diffractometer with Cu K_α radiation. Crystal data are:

$C_3H_6BF_2NO_2$ f.w. = 136.9

Monoclinic, $a = 5.097(1)$, $b = 10.653(2)$, $c = 11.520(2)$ Å, $\beta = 103.57(2)°$, $V = 608.0(2)$ Å^3, $Z = 4$, $\rho_c = 1.4954(5)$ g cm^{-3}, $F(000) = 280$ (22 °C, Cu K_α, $\lambda = 1.54178$ Å, $\mu = 14.1$ cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, Cu K_α (nickel filter and pulse height analyser), and a θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ, with 10 s background counts being measured at each end of the scan. Data were measured to 2θ = 146° (minimum interplanar spacing 0.81 Å). The intensity of the check reflection, measured every 50 reflections throughout the data collection, remained constant to with ±4%. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 1223 independent reflections measured, 230 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement but were included in the structure factor calculations.

The structure was solved by direct methods. Eight sets of signs for 168 reflections with $|E| \geq 1.50$ were determined by a computer program which uses Sayre relationships in an iterative procedure (40). One set of signs was outstanding in that it converged in six cycles to a set having the highest consistency index, 0.72, with 84 positive and 84 negative signs. The positions of the nine nonhydrogen atoms were easily located among the 13 highest peaks on an *E*-map calculated from this set of signs.

Two cycles of isotropic followed by two cycles of anisotropic full-matrix least-squares refinement of the nonhydrogen atoms gave $R = 0.085$. An electron density difference map calculated at this point gave the coordinates of the six hydrogen atoms which were included in all subsequent cycles of refinement with isotropic thermal parameters. The entire structure was refined for six cycles giving a final R of 0.056 and R_w of 0.077 for 978 reflections with $I \geq 3\sigma(I)$ (15 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 4.1×10^{-8}. The scattering factors of ref. 41 were used for the nonhydrogen atoms and those of ref. 42 for the hydrogen atoms. Anomalous scattering factors from ref. 43 were used for the nonhydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^o \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^o is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

Near the end of the refinement it became apparent that there may be some ambiguity in the identification of the ring carbon and nitrogen atoms. A parallel refinement with C(1) and N interchanged was carried out. The ratios of the final R and R_w values (for all 993 observed planes) are 1.068 and 1.038 respectively. Hamilton's test (44) indicates that this ratio is significant at a confidence level of >99.5%, indicating correct assignment of C(1) and N and also that these atoms are most likely not disordered. The behavior of the thermal parameters of C(1) and N upon interchange of scattering factors further supports this conclusion. The mean values of U_{ii} (from the parallel refinements mentioned above) for C(1) and N as shown in Fig. 1 are 5.22 and 5.87 Å^2 and when interchanged are 4.75 and 6.56 Å^2 respectively. On the final cycle of refinement the mean parameter shift was 0.05σ and no parameter shift was greater than 0.26σ. The mean error in an observation of unit weight was 1.913. The final positional and thermal parameters appear in Tables 1 and 2 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the nonhydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (45) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0011 Å^2. The rms ΔU_{ij} value for the entire molecule treated as a rigid-body is 0.0034 Å^2. This

[4]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

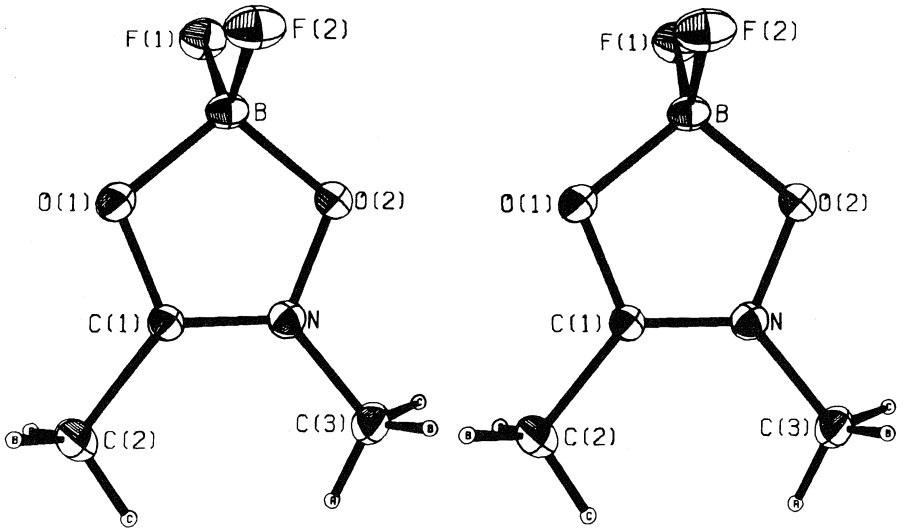


FIG. 1. A stereo view of the difluoroboron *N*-methylacethydroxamate molecule. 50% ellipsoids are shown for the nonhydrogen atoms. Hydrogen atoms have been assigned artificially small temperature factors for clarity.

value indicates some independent motion of the atoms but the derived rigid-body parameters are otherwise physically reasonable.

The appropriate bond distances have been corrected for libration (46, 47), using shape parameters q^2 of 0.08 for all atoms involved. The bond distances not involving hydrogen atoms were also corrected for independent motion based on the ΔU_{ij} (48, 49). Corrected bond lengths appear in Table 3 along with the uncorrected values.

Results and Discussion

Figure 1 shows a general view of the difluoroboron *N*-methylacethydroxamate molecule with the crystallographic numbering scheme and Fig. 2 shows the packing arrangement viewed down *a**. Bond angles are listed in Table 4 and deviations of atoms from the least-squares mean plane defined by the five-membered BO_2CN ring are given in Table 5. The corrected bond distances will be employed throughout the discussion.

The crystal structure (Fig. 2) consists of discrete molecules of difluoroboron *N*-methylacethydroxamate. The shortest nonbonded intermolecular distance not involving hydrogen (F(1)...C(1) $(1 + x, y, z) = 2.961(2)$ Å) corresponds to a normal van der Waals contact. In view of recent comments on the importance of weak hydrogen bonds (50), the geometry of three such C—H...F interactions appears in Table 6. These weak intermolecular C—H...F interactions may be responsible for a close intramolecular contact between H(2*c*) and H(3*a*) (2.22(6) Å), both of which interact with the same fluorine atom (see Table 6).

The five-membered BO_2CN ring is essentially, but not rigorously ($\chi^2 = 10.7$), planar with all five ring atoms lying within ±0.004 Å of the mean plane (see Table 5). The substituent atoms C(2) and C(3) are both significantly displaced from the mean plane of the BO_2CN ring, by −0.082(4) and −0.028(3) Å respectively.

In contrast to the organotin (16–18) and iron (19) hydroxamates in which the metal–oxygen bond from C—O is significantly longer than that from N—O, the O—B bonds in difluoroboron *N*-methylacethydroxamate, 1.496(3) and 1.497(3)

Å, are essentially equal in length. The O—B distances are somewhat longer than those of 1.485(3) and 1.490(3) Å in the related molecule (benzoylacetonato)difluoroboron (51), the difference possibly being due to σ-hybridization effects arising from angular constraints at boron imposed by the different chelate ring sizes (5- *vs.* 6-membered rings). The O—B—O angle in the present structure is 101.9(2)° *vs.* 111.4° in (benzoylacetonato)difluoroboron. The B—F bond lengths (Table 3) do not differ significantly from one another and their mean value of 1.378 Å compares well with the unique distance of 1.376(2) Å in (benzoylacetonato)difluoroboron (51).

The C—N and N—O bonds are shorter and the C—O bond longer than those in all other hydroxamate chelates cited (15–20) as well as in acethydroxamic acid hemihydrate (52). The C—N and N—O distances of 1.298(3) and 1.349(2) Å are similar to corresponding bond lengths of 1.29–1.30 and 1.33–1.37 Å in the *cis*- and *trans*-nickel(II) thiohydroxamate complexes (21). The C—N distance is shorter than that in pyridine-*N*-oxide (53) (1.34 Å) and about the same as that in the dimethylformamide complex $SbCl_5.HCON(CH_3)_2$ (54) (1.29(1) Å), in which at least partial C=N double bond character is assumed. The N—O distance of 1.349(2) Å compares well with the N—O distance of 1.35(2) Å in pyridine-*N*-oxide (53). The C—O distance of 1.346(2) Å is comparable to phenolic C—O distances. The C(1)—C(2) bond length of 1.468(3) Å is shorter than the value of 1.51 Å expected for a $C(sp^2)$—$C(sp^3)$ single bond. Other bond distances in the molecule are as expected.

In view of the equivalence of the two O—B bond distances and their covalent character as deduced from the bond lengths, the overall structure of difluoroboron *N*-methylacethydroxamate appears to be best described by the resonance forms **4***a* and **4***b*. The C—N and C—O bond lengths indicate bond orders of approximately 1.75 and 1.25 respectively, thus the overall structure may be thought of as a 3:1 hybrid of **4***a* and **4***b*, *i.e.* the B–N betainic form **4***a* is the most important contributor to the structure.

TABLE 6. C—H...F interactions*

D—H...A	H...A (Å)	D...A (Å)	∠DHA (deg)	∠XAH (deg)
C(3)—H(3*c*)...F(1)[1]	2.67(4)	3.355(3)	128(3)	108(1)
C(3)—H(3*a*)...F(2)[2]	2.53(4)	3.358(4)	150(3)	138.8(8)
C(2)—H(2*c*)...F(2)[2]	2.69(5)	3.636(4)	169(3)	108.1(9)

*Superscripts refer to atoms at positions: [1] $x-1, 1/2-y, z-1/2$; [2] $-x, 1/2+y, 1/2-z$. The H...F...H angle at F(2) is 50(1)°.

[Traduit par le journal]

Introduction

The type specific capsular polysaccharide of type XXVII *Streptococcus pneumoniae* (pneumococcus) has been reported to contain glucose, galactose, rhamnose, and glucosamine (1) as well as 7.02% acetyl, 3.12% phosphorus (2), and 8.7% pyruvic acid (3). However, the relative amounts, sequence, and linkages of the monosaccharides and the locations of the other substituents are unknown. A number of cross-reactions of anti-XXVII serum have been recorded (4–7) but the only structural bases that could be deduced from these was the common presence of pyruvic acid in the type XXVII polysaccharide and in the cross-reacting polysaccharides. The present paper reports the results of a structural study of the type XXVII polysaccharide as part of a continuing program on structure–specificity relations in polysaccharide antigens of bacteria.

Results and Discussion

The type XXVII polysaccharide was from the collection of pneumococcal polysaccharides prepared by Brown (2). Table 1 gives the results of analysis of this product; the constituents, reported as percent of hydrolysed material, accounted for 91.7% of the polysaccharide on an anhydrous basis.

Elemental analysis of the type XXVII polysaccharide showed twice as much nitrogen as could be accounted for by the glucosamine content (N, calculated from glucosamine, 1.33%; found, 2.7%). The absence of amino acids in hydrolysates precluded protein or peptides as the source of this extra nitrogen, but the initial clue as to its identity was found in the ^{13}C nmr spectrum of the polysaccharide. An outstanding feature of this spectrum (Fig. 1) was the high intensity resonance at 55.1 ppm. The observation that this signal was three times the intensity of the signals from three equivalent methyl-carbons at 18.1, 23.4, and 25.6 ppm (for assignments see below), suggested a structure with

three carbons of identical electronic environment. Choline is such a compound, and its ^{13}C nmr spectrum exhibits a triplet at 55.0, 55.2, and 55.4 ppm attributed to the trimethylammonium carbons. Thus, the resonance at 55.1 ppm in the spectrum of the type XXVII polysaccharide was assigned tentatively to the trimethylammonium carbons of choline. Confirmation of the presence of choline in acid hydrolysates of the polysaccharide was obtained on thin-layer chromatograms (8) by Dragendorff's reagent (9) and by quantitative analysis (10) that showed a choline content of 13.1%.

The identification of choline, not previously reported as a constituent of the type XXVII polysaccharide, was cause for concern that the preparation was contaminated by C-substance that is known to contain choline (11–13): however, ribitol, *N*-acetyl-D-galactosamine, and *N*-acetyldiaminotrideoxyhexose, the other major components of C-substance (12, 14, 15) were not present. Furthermore, the amount of choline (13.1%) and its stoichiometric relation with the other components (Table 1) indicated that it could not have arisen from a minor contaminant. Finally, the type XXVII polysaccharide gave a single precipitin band on immunodiffusion against homologous antiserum (Fig. 2) and showed a cross-reaction with myeloma proteins specific for phosphorylcholine (16); the resulting spur formation where the precipitin bands merge (Fig. 2*A*) indicated partial identity of reaction (complete cross-over of the bands would have indicated non-identity). Thus, the myeloma proteins and *some* of the homologous antibody proteins had reacted with a common determinant in the polysaccharide. Confirmation that this determinant was phosphorylcholine was given by the ability of that compound to dissolve the precipitin bands formed with the myeloma protein (Fig. 2*B*).

Evidence that the choline was bound to the type XXVII polysaccharide through a phosphodiester linkage was provided by inhibition studies of the homologous precipitin reaction. Table 2 shows the results of inhibition by phosphorylcholine and choline in homologous precipitations of type XXVII and type VIII. While both phosphorylcholine and choline were good inhibitors of the type XXVII system, it was clear from the inhibition at the two lowest concentrations that phosphorylcholine was the better inhibitor. The lack of inhibition in the type VIII homologous precipitation showed that the results for type XXVII were indeed specific and were not caused by non-specific, ionic dissociation of the precipitated complex.

The ^{13}C nmr spectrum (Fig. 1) provided other information in addition to the detection of choline: the methyl carbon region between 15

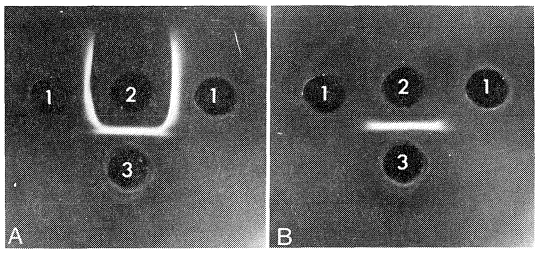

FIG. 2. Immunodiffusion of pneumococcal type XXVII polysaccharide against homologous antiserum and myeloma proteins specific for phosphorylcholine. 5.0	21.0	−0.8
20.0	20.7	−2.9

and 30 ppm showed four distinct resonant frequencies. These were assigned to rhamnose *C*-methyl at 18.1 ppm (17), to *N*-acetyl methyl at 23.4 ppm (18), and to pyruvic acid *C*-methyl at 25.6 ppm, the last being made by comparison with the ^{13}C nmr spectrum of methyl 4,6-*O*-carboxyethylidene-α-D-galactopyranoside (19) that showed a *C*-methyl resonance at 26.4 ppm. The equivalent intensities of these three signals and the triple-strength intensity of the choline methyl carbon peak showed that rhamnose, *N*-acetyl glucosamine, pyruvic acid, and choline were present in equimolar amounts in the polysaccharide. The smaller signal at 20.8 ppm in the ^{13}C nmr spectrum might be attributed to the methyl carbons of *O*-acetyl groups (20); however, neither the structural nor serological significance of *O*-acetyl groups was assessed because of the relatively small amount and the uncertainty in detecting their serological role in the presence of the major determinants, pyruvate and phosphorylcholine.

Methylation studies provided information about some of the linkages in the polysaccharide. Complete methylation was difficult to achieve, probably because of the pyruvate and phosphorylcholine substituents. However, three major components were detected by gas–liquid chromatography of the partially methylated alditol acetates. The three derivatives, identified by gas chromatography – mass spectrometry (21), were 1,3,5-tri-*O*-acetyl-2,4,6-tri-*O*-methyl galactitol, 1,4,5-tri-*O*-acetyl-2,3,6-tri-*O*-methyl glucitol, and 1,2,4,5-tetra-*O*-acetyl-3-*O*-methyl rhamnitol in a ratio of 1:1:0.6. Two smaller components were identified as 1,4,5-tri-*O*-acetyl-2,3-di-*O*-methyl rhamnitol and 1,3,4,5-tetra-*O*-acetyl-2-*O*-methyl rhamnitol. The sum of all rhamnitol derivatives was equal to an equimolar ratio with respect to the galactitol and glucitol derivatives. These results indicated that glucose and galactose were present as 1→4 and 1→3 linked units, respectively. The presence of 3-*O*-methyl rhamnitol as a major component indicated that rhamnose was disubstituted at C-2 and C-4, and was either a branch point or the site of a non-sugar substituent. As no products representing a non-reducing terminal unit were detected, it was concluded that the polysaccharide was not branched. Reported difficulty in methylation of phosphorylated sugars, and problems of phosphate migration during methylation (22), provide a probable interpretation of the rhamnose derivatives that were found. Thus, the 3-*O*-methyl rhamnitol and the smaller quantities of the 2,3-di-*O*-methyl and 2-*O*-methyl derivatives could have arisen from a 1→4 linked rhamnose residue that bore a phosphorylcholine group at C-2. Dephosphorylation would account for the 2,3-di-*O*-methyl and a 2→3 phosphate migration would yield the 2-*O*-methyl rhamnitol. Each of these reactions would be expected to occur to some extent under the strongly basic conditions of methylation. This interpretation was supported by oxidation of the dephosphorylated polysaccharide by periodate as described below.

The conditions under which the three non-sugar substituents, pyruvic acid, choline, and phosphate, could be removed from the polysaccharide provided information about their modes of linkage. Hydrolysis by acid (0.01 *N* hydrochloric at 100 °C) released pyruvic acid but choline and phosphate were stable. Gel chromatography showed that depyruvylation caused some degradation by hydrolysis of either glycosidic bonds or phosphodiester linkages between sugar units. Incubation of the depyruvylated product with alkaline phosphatase did not release phosphate, thus eliminating the latter alternative. Alkaline hydrolysis (0.01 *N* sodium hydroxide at 100 °C) released choline, but pyruvate and phosphate were stable. This lability of choline and stability of phosphate has been observed with phosphorylcholine groups in C-substance (12).

Dephosphorylation of the native type XXVII polysaccharide by 48% hydrofluoric acid at

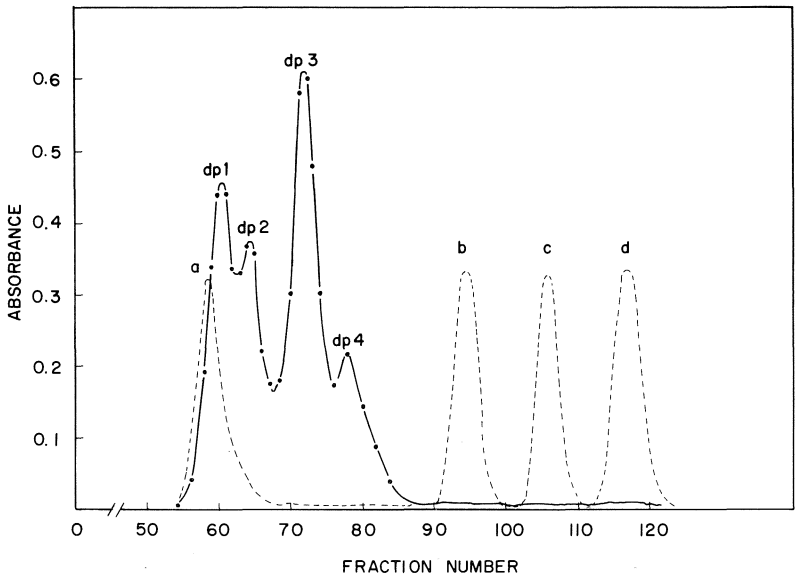

FIG. 3. Bio-Gel P-2 chromatography of dephosphorylated pneumococcal type XXVII oligosaccharides (●—●, phenol-sulfuric assay) and standards [---, (*a*) blue dextran, (*b*) 3-*O*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-L-rhamnose, (*c*) 2-acetamido-2-deoxy-D-glucose, (*d*) D-galactose].

4 °C (23) yielded a mixture of oligosaccharides that was resolved by gel filtration in Bio-Gel P-2 (Fig. 3). The major component (dp 3) was a tetrasaccharide that contained equimolar proportions of glucosamine, galactose, glucose, rhamnose, and pyruvate but no choline or phosphate. Oxidation of this by periodate, followed by reduction and hydrolysis, yielded glucosamine, galactose, pyruvic acid, glycerol, and 4-deoxyerythritol. The last was identified by gas chromatography – mass spectrometry of its triacetate as compared with a standard obtained from 4-*O*-β-D-glucopyranosyl-L-rhamnose (24) by the same sequence of reactions. The 4-deoxyerythritol could have arisen only from a 4-*O*-substituted rhamnose residue in the dephosphorylated tetrasaccharide and the point of linkage in the linear polymer was thereby established. Furthermore, as the rhamnose in the polysaccharide was not susceptible to periodate before dephosphorylation and yielded mainly 3-*O*-methyl rhamnose on methylation, the phosphorylcholine was located at the C-2 hydroxyl of this sugar. Oxidation of the dephosphorylated tetrasaccharide by periodate also contributed information about the sequence of sugars. The glycerol in the hydrolysate after reduction must have come from glucose, the only sugar other than rhamnose to be oxidized. The glucose must therefore have been the nonreducing terminal unit in the oligosaccharide; a 1→6 linked glucose residue that would also have given rise to glycerol was ruled out because the results of methylation showed that glucose was 4-*O*-linked in the repeating unit. Similarly, galactose was 3-*O*-substituted in the repeating unit (methylation results) and could not represent the reducing end of the tetrasaccharide because it would then have been susceptible to oxidation by periodate. Degradation of the native polysaccharide described below gave a glucosaminylgalactose disaccharide that located the amino sugar as being attached glycosidically (1→3) to galactose. The tetrasaccharide sequence was therefore glucosyl-glucosaminyl-galactosyl-rhamnose.

The evidence so far showed that in the repeating unit glucose and galactose were glycosidically monosubstituted, and rhamnose was substituted by a glycosidic bond at the 4-*O*-position and by phosphorylcholine at the 2-*O*-position. Thus glucosamine was the only residue that could bear the pyruvate substituent. As the pyruvate was stable in alkali it must have been present as a ketal bridging the 3,4, 3,6, or 4,6 hydroxyls with the latter most likely for steric reasons. The presence of pyruvate and glycosidic attachment of the adjacent sugar residue to the

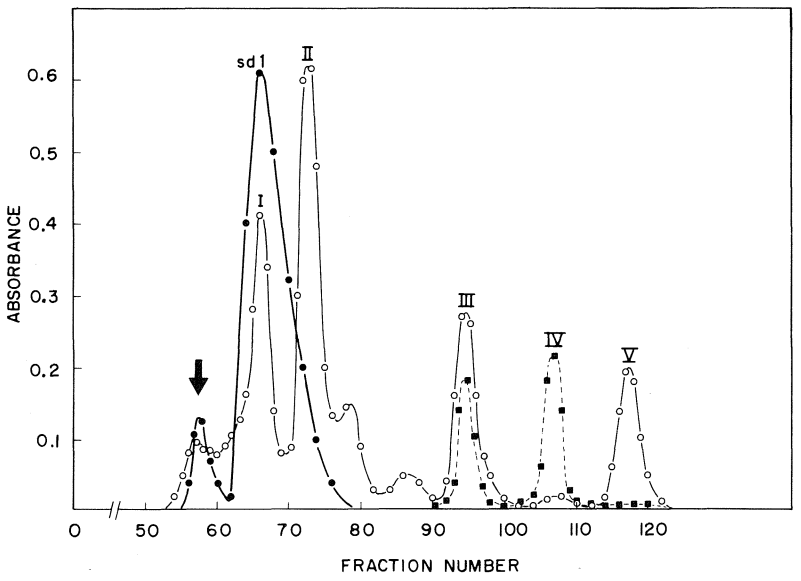

FIG. 4. Bio-Gel P-2 chromatography of hydrolysates (*a*) and (*b*) of periodate oxidized, reduced, pneumococcal type XXVII polysaccharide. Hydrolysate (*a*) ●—●; hydrolysate (*b*) ○—○ (phenol–sulfuric) and ■---■ (amino sugar). The arrow indicates the void volume.

remaining hydroxyl would mean that glucosamine was fully substituted in the native polysaccharide. In support of this, it was noted that no methyl ethers of glucosamine were identified in the methylation analysis.

Confirmation of the foregoing deduction was obtained by the following degradations. The native polysaccharide, when oxidized by periodate, consumed 1 mol of oxidant per 4 mol of monosaccharide. Analysis of the products after reduction and hydrolysis showed that all the glucose had been oxidized and had given rise to erythritol; a direct confirmation of the methylation study showing that glucose was monosubstituted glycosidically at the 4-*O*-position. Periodate oxidation of the 85% depyruvylated polysaccharide (0.01 *N* hydrochloric acid, 60 min, 100 °C) gave the same results as the native polysaccharide. Thus, depyruvylation did not expose a glycol group and the possibility that pyruvate was linked in glucosamine as a 3,4-ketal was ruled out.

The periodate-oxidized, reduced, native polysaccharide was subjected to mild hydrolysis (25) under two sets of conditions: (*a*) 1 *N* hydrochloric acid at 23 °C for 24 h, (*b*) 0.1 *N* hydrochloric acid at 100 °C for 1 h. The products of these partial hydrolyses were separated by elution from Bio-Gel P-2 (Fig. 4). Hydrolysis (*a*) gave a single oligosaccharide (peak sd 1, Fig. 4) in about 90% yield. This product contained equimolar amounts of glucosamine, galactose, rhamnose, erythritol, phosphate, choline, and pyruvate. It was therefore an erythritol glycoside of a trisaccharide that represented the intact repeating unit of the polysaccharide with erythritol in the position of the oxidized glucose residue. Further periodate oxidation, reduction, and hydrolysis of this non-reducing erythritol glycoside resulted in the loss of erythritol with the concomitant appearance of glycerol. However, when the compound was depyruvylated (0.01 *N* hydrochloric acid at 100 °C for 1 h) and then exposed to periodate, erythritol disappeared as before but there was also loss of glucosamine that corresponded quantitatively with the amount of depyruvylation. Because depyruvylation of the native polysaccharide did not expose glucosamine to periodate as it did in the erythritol glycoside, it was concluded that glucosamine formed the other non-reducing terminal unit in the latter. Thus, the oxidation of glucosamine in the depyruvylated erythritol glycoside must have occurred at adjacent hydroxyl groups, one of which was exposed by the hydrolysis of the oxidized polysaccharide, the other by the subsequent depyruvylation. The most likely interpretation was that glucosamine was 3-*O*-linked

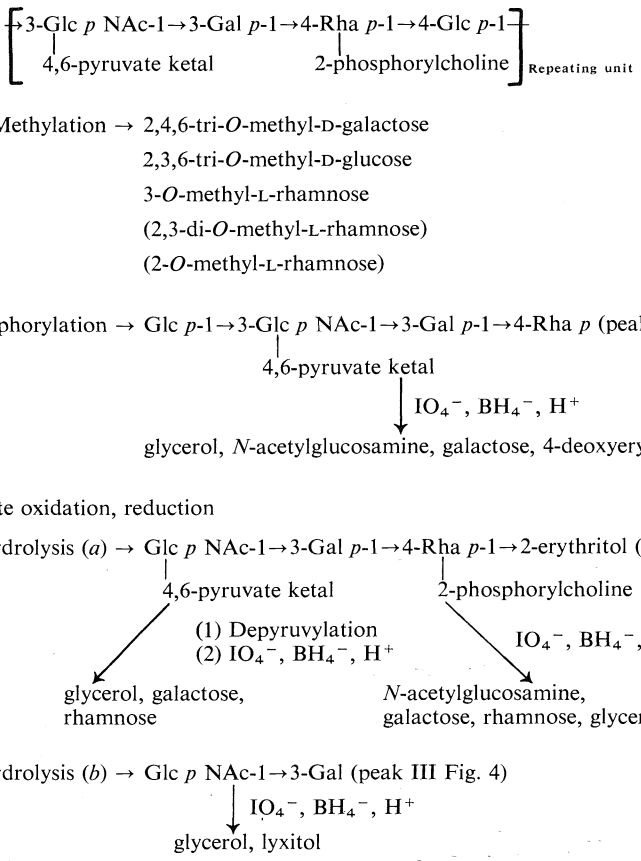

FIG. 5. Structural analysis of pneumococcal type XXVII polysaccharide.

in the polysaccharide and carried a 4,6-pyruvate ketal. The alternative of a 4-*O*-linked glucosamine with a 3,6-pyruvate ketal was considered unlikely on steric grounds, nor have 3,6-pyruvate ketals been found in polysaccharides.

Hydrolysis (*b*) of the oxidized, reduced polysaccharide gave a mixture that was resolved into five components (peaks I–V, Fig. 4). Peaks IV and V contained *N*-acetylglucosamine and galactose respectively. Peak III was a disaccharide composed of *N*-acetylglucosamine and galactose. Borohydride reduction converted the galactose moiety to galactitol showing that the compound was a glucosaminyl-galactose. Periodate oxidation, reduction, and hydrolysis yielded glycerol and lyxitol. Clearly, the glycerol came from the non-reducing terminal *N*-acetylglucosamine and the lyxitol must have arisen from oxidation (at the C_1—C_2 glycol) of a 3-*O*-linked galactopyranose residue. The characterization of this disaccharide, together with the identification of the reducing and non-reducing terminal residues in the tetrasaccharide from dephosphorylation as rhamnose and glucose respectively, unequivocally established the sequence in the repeating unit. The results of this structural analysis are summarized in Fig. 5.

The relative susceptibilities of the sugars in the polysaccharide to oxidation by chromium trioxide were investigated to permit assignment of anomeric configurations to the glycosidic bonds (26–28). It was necessary to depyruvylate and dephosphorylate the polysaccharide so that a sufficient number of acetyl groups could be introduced for extractability into chloroform after the oxidation. Even though this caused some depolymerization, enough glycosidic bonds were left intact to permit a clear interpretation of the results. Thus, glucosamine, glucose, and rhamnose were oxidized and their glycosidic linkages were therefore in the β-configuration. The galactose was not oxidized so its glycosidic linkage was α.

The enantiomorphic forms of glucose and

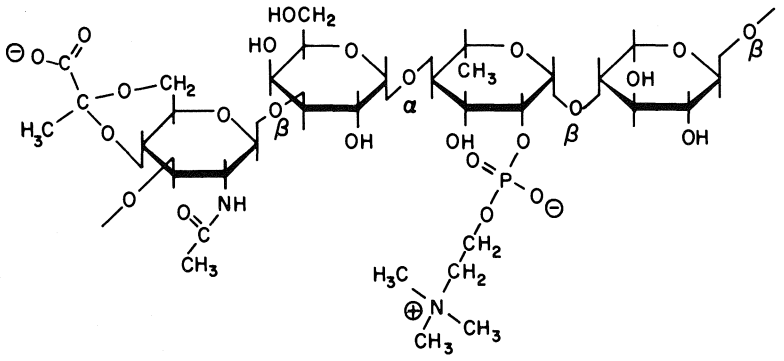

FIG. 6. The repeating unit of pneumococcal type XXVII capsular polysaccharide. The configuration at the asymmetric carbon of the pyruvate ketal has not yet been determined.

galactose were established as D by the susceptibility of these two sugars to enzymic oxidation by their specific oxidases. If it is assumed that the glucosamine is also D, a reasonable assumption because the L-form has not been found in nature, then the enantiomorphic form of rhamnose may be deduced from the specific rotation of the polysaccharide ($[\alpha]_D$ +53.2°) (2). This rotation may be regarded as the sum of rotations of the four constituent sugars in the anomeric configuration given above. For the corresponding methyl glycosides these are: β-D-glucopyranoside −34.2°, α-D-galactopyranoside +179.3°, β-D-glucosamine −44°, and β-L-rhamnopyranoside +95.4° for a total contribution of (196.5°)/4 = +49.1°. The corresponding calculated rotation using the value for β-D-rhamnopyranoside is +5.7°. It was therefore concluded that rhamnose was present as the L-enantiomer and the full structure of the repeating unit is shown in Fig. 6.

Experimental

Biological Materials

The pneumococcal type XXVII capsular polysaccharide and type specific anti-XXVII and anti-VIII horse sera were generously provided by Dr. Kenneth Amiraian, New York State Department of Health, Albany, New York. Mouse serum from BALB/c mice bearing plasmacytoma MOPC603, as the source of myeloma proteins specific for phosphorylcholine, was a gift from Dr. N. M. Young of these laboratories.

^{13}C Nuclear Magnetic Resonance

The spectrum of the type XXVII polysaccharide (100 mg in 1.0 ml D_2O) was measured in a 12 mm tube at 30 °C on a Varian XL-100 spectrometer at 25.16 MHz. Spectra were obtained using a pulsed Fourier transform mode with complete proton decoupling. Chemical shifts are reported as parts per million downfield relative to an external tetramethylsilane standard. The ^2H resonance of the D_2O provided the field frequency lock. Spectra of phosphorylcholine and of methyl 4,6-*O*-carboxyethylidene-α-D-galactopyranoside (19) in D_2O were determined in 10 mm tubes on a Varian CFT-20 spectrometer.

Immunodiffusion

Double diffusion studies (29) were done at 4 °C in plastic petri plates (1.5 × 5 cm) containing 1% agarose in 0.8% sodium chloride solution. The precipitin bands (Fig. 2) were allowed to form during 4 days. The plate was then flooded with 5 ml of aqueous phosphorylcholine (5 mg/ml). Disappearance of the precipitin bands specific for phosphorylcholine determinants was complete in 3 h (Fig. 2*B*).

Quantitative Precipitins

The relative amounts of antigen and antiserum used for inhibition studies were those at maximum precipitation. The system used was 0.5 *M* sodium bicarbonate, p*H* 7.5 (100 µl), undiluted antiserum (100 µl), antigen (25 µg in 100 µl water), and varying amounts of inhibitor in water (200 µl). Mixtures were incubated at 4 °C for 5 days after which the precipitates were washed twice with 0.1 *M* sodium bicarbonate, p*H* 7.5 (1.0 ml), and dissolved in 0.1 *N* sodium hydroxide for estimation of protein (30).

Other Analytical Methods

For analysis of neutral sugars the polysaccharide was hydrolysed by *N* hydrochloric acid at 100 °C for 10 h. The hydrolysate was neutralized (Dowex 1-X8, HCO_3^- form) and concentrated by evaporation under diminished pressure at 40 °C. Sugars were separated by thin-layer chromatography on silica gel 60 in ethyl acetate:isopropanol:acetic acid:water, 3:5:1:1, and analysed by a micromodification (31) of the phenol – sulfuric acid method (32) with the minor but significant change that the silica gel was simply pelletized by centrifugation before absorbances were measured.

Alditols from studies on periodate oxidation and their methyl ethers from methylations were analysed by gas–liquid chromatography with a Hewlett-Packard Model 402 gas chromatograph. The glass U-tube columns (150 × 0.3 cm) were packed with 3% ECNSS-M on 80–100 mesh Gas-Chrom Q (33) which was also used in a Finnigan Model 9500 gas chromatograph-3100D mass spectrometer when that system was used to identify products (21).

TABLE 3. Characterization of partially methylated alditols

Alditol	T_R*	*m/e*	Molar ratio
1,4,5-Tri-*O*-acetyl-2,3-di-*O*-methyl rhamnitol	1.00	117, 203	0.2
1,3,4,5-Tetra-*O*-acetyl-2-*O*-methyl rhamnitol	1.54	117	0.2
1,2,4,5-Tetra-*O*-acetyl-3-*O*-methyl rhamnitol	1.88	189, 203	0.6
1,3,5-Tri-*O*-acetyl-2,4,6-tri-*O*-methyl galactitol	2.26	45, 117, 161, 233	1.0
1,4,5-Tri-*O*-acetyl-2,3,6-tri-*O*-methyl glucitol	2.53	45, 117, 233	1.0

*Retention times relative to that of 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl glucitol.

Analyses for amino sugars and amino acids were done on an automatic amino acid analyzer following hydrolysis by 3 *N* hydrochloric acid at 100 °C for 10 h. Phosphate (34), pyruvic acid (35), and choline (10) were assayed by published procedures. Acetyl was determined as acetic acid by gas chromatography on Chromosorb 102 with propionic acid as an internal standard.

Methylation

Because of its limited solubility in dimethyl sulfoxide the type XXVII polysaccharide (5 mg) was acetylated prior to methylation. The acetylation and methylations by the Hakomori (36) and Purdie and Irvine (37) methods were as described by Choi and Meyer (38). Two methylations by the Hakomori procedure gave incomplete methylation as shown by hydroxyl absorption in the infrared and by a multiplicity of components after hydrolysis. The partially methylated polysaccharide was therefore remethylated with methyl iodide:methanol (1:1) and silver oxide (37). The product, recovered by extraction with chloroform and methanol, was dissolved in 80% aqueous methanol and deionized (mixed resin column: Rexyn 101 (H^+) and Dowex 1 (OH^-)). Infrared spectroscopy showed only minor hydroxyl absorption, and three major components were present after hydrolysis. The methylated polysaccharide was hydrolysed, first in 2.5% methanolic hydrogen chloride at 100 °C for 20 h, then in 2 *N* hydrochloric acid at 100 °C for 6 h. The hydrolysis products were reduced ($NaBH_4$), acetylated, and analysed by gas chromatography – mass spectrometry (21). The characterization of the partially methylated alditols is detailed in Table 3.

Hydrolysis of Substituent Groups

(i) Acid Hydrolysis

The type XXVII polysaccharide (8 mg) was dissolved in 0.01 *N* hydrochloric acid (8.0 ml) and the solution was heated at 100 °C. At intervals the solution was cooled and aliquots (100 and 400 µl) were removed, the former for analysis of free pyruvic acid (35). The other aliquot was neutralized (4 µl of *N* sodium hydroxide) and incubated 5 days with alkaline phosphatase (100 µl, 0.1% solution in 0.5 *M* Tris, p*H* 10.3), after which 200 µl was assayed for free choline (10) and 300 µl was assayed for free phosphate (34).

(ii) Alkaline Hydrolysis

The same quantities and conditions used for acid hydrolysis were employed for hydrolysis of the polysaccharide in 0.01 *N* sodium hydroxide. Release of pyruvic acid, choline, and phosphate were monitored as described above.

(iii) Dephosphorylation

A solution of the polysaccharide (10 mg) in 48% hydrofluoric acid kept at 4 °C for 3 days was neutralized with sodium carbonate and insoluble sodium fluoride was removed by centrifugation. The supernatant was deionized (mixed resin, Rexyn 101 (H^+) and Dowex 1-X8 (OH^-)) and freeze dried. The product recovered (8 mg) was free of both phosphate and choline.

Periodate Oxidation

Periodate oxidations, borohydride reductions, and hydrolysis of the products were done by standard procedures (25). In brief, oxidations were done with 0.01 *M* sodium metaperiodate in the dark at room temperature for 50 h; consumption of oxidant was monitored spectrophotometrically (39). Oxidized products were reduced with sodium borohydride and hydrolysed with *N* hydrochloric acid at 100 °C for 10 h. Components in these hydrolysates were analysed by thin-layer chromatography and by gas–liquid chromatography after further reduction and acetylation to alditol acetates. Glucosamine was determined colorimetrically (40). Results are given in the preceding section.

Isolation of Oligosaccharides

(i) From Dephosphorylation

Dephosphorylated oligosaccharides (8 mg) were eluted from Bio-Gel P-2 (minus 400 mesh, 120 × 1.2 cm) with 0.1 *M* pyridine acetate buffer, p*H* 6.0. Fractions (0.85 ml) were monitored by the phenol – sulfuric acid method (32) and the elution pattern is shown in Fig. 3. Fractions containing only peak dp 3 were combined and freeze dried to yield a product shown to be a tetrasaccharide as described above.

(ii) From Periodate Oxidation

Portions (10 mg) of periodate-oxidized, borohydride-reduced, polysaccharide were hydrolysed (*a*) by *N* hydrochloric acid (5 ml) at room temperature for 24 h, (*b*) by 0.1 *N* hydrochloric acid (5 ml) at 100 °C for 1 h, neutralized (0.5 *N* sodium hydroxide), and fractionated on Bio-Gel P-2 as described above. Fractions were monitored for neutral sugars as in (*i*) and for amino sugars by a modified Elson–Morgan assay (40). The elution patterns are shown in Fig. 4. Hydrolysis (*a*) gave only one component (sd 1) apart from a small peak at the void volume. Analysis and further degradation studies as described above and summarized in Fig. 5 showed this to be an erythritol glycoside of a trisaccharide. Hydrolysis (*b*) gave 5 components on elution from Bio-Gel P-2 (peaks I–V, Fig. 4). Peaks IV and V were identified by chromatography as *N*-acetylglucosamine and galactose, respectively. Peak III, as described above, was shown to be the disaccharide, Glc *p* NAc 1→3 Gal. Peaks I and II from this elution were not examined further.

Chromium Trioxide Oxidations

The polysaccharide (5.5 mg) was depyruvylated and dephosphorylated as described above. The deionized product (3 mg) was reduced ($NaBH_4$), acetylated, and divided into three equal portions for oxidations of 0, 1, and 2 h as described by Laine and Renkonen (28). After hydrolysis the glucosamine contents were determined colorimetrically (40); neutral sugars were analysed directly by thin-layer chromatography and as alditol acetates by gas–liquid chromatography with addition of inositol as internal quantitative standard. The results showed a 75% loss of glucosamine and the almost total loss of glucose and rhamnose in the 2 h oxidations; galactose was not affected.

Enzymic Oxidations

An hydrolysate of the polysaccharide was incubated separately with D-glucose oxidase and D-galactose oxidase (Glucostat and Galactostat reagents, Worthington). Thin-layer chromatography failed to show glucose and galactose.

Acknowledgements

The authors gratefully acknowledge the generosity of Dr. Kenneth Amiraian, New York State Department of Health, Albany, N.Y., for donations of polysaccharide and antisera. The mouse myeloma antiserum specific for phosphorylcholine was provided by Dr. N. M. Young of these laboratories. The methyl 4,6-*O*-carboxyethylidene-α-D-galactopyranoside was a gift from Dr. P. A. J. Gorin, National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, and Dr. I. C. P. Smith of these laboratories determined the ^{13}C nmr spectrum. Finally, we are grateful for the skilled technical assistance of Mr. F. P. Cooper with methylations and gas chromatography – mass spectrometry and Mr. H. Seguin with microanalysis.

Molecular inclusions in the paraffin layers of the nickel cyanide *n*-alkylamine systems

Y. MATHEY, R. SETTON, AND C. MAZIERES

Laboratoire de Physicochimie Minérale, Université de Paris Sud, 91405 Orsay, France

Received May 10, 1976

Y. MATHEY, R. SETTON, and C. MAZIERES. Can. J. Chem. **55**, 17 (1977).

The layered $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4$ acts as a host structure for amines, yielding $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4,xC_nH_{2n+1}NH_2$ (with $0 \leq x \leq 0.4$ and $12 \leq n \leq 16$) which are easily prepared by various procedures including solid–solid reaction. The guest can be removed and re-included; it can be replaced by aromatics. Phase transitions of the clathrate (with amines as guest) occur in the range 55–85 °C, obviously related to the transitions previously observed in the parent compound $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4$.

Y. MATHEY, R. SETTON et C. MAZIERES. Can. J. Chem. **55**, 17 (1977).

La préparation et les caractéristiques de composés d'inclusion $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4$, $xC_nH_{2n+1}NH_2$ avec $0 \leq x \leq 0.4$ et $12 \leq n \leq 16$ sont décrites. Les molécules d'amines incluses dans les couches paraffiniques du système peuvent être déplacées puis réinsérées. L'inclusion d'aromatiques, dans le même système, a été réalisée. L'existence de deux transitions pour le clathrate d'amines dans l'intervalle 55–85 °C est interprétée en relation avec le comportement de la structure d'accueil $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4$.

The method of preparation which was given (1) after the original description by Weiss (2) of the nickel cyanide *n*-alkylamine compounds always leads to products for which the $RNH_2/Ni(CN)_2$ ratio (with $R = C_nH_{2n+1}$) can vary between 1 (parent compound) and about 1.20. A moderate heating (2 h at 100 °C, for instance) yields the parent compound $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4$ which has already been described (1–3).

The ease of formation of the Ni cyanide *n*-alkylamines compounds will first be demonstrated; then, using *n*-dodecylamine as an example, it will be shown that the excess of amine molecules is not held by superficial adsorption but rather as the guest in a true layered inclusion compound conveniently described as $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4,xC_nH_{2n+1}NH_2$)with $0 \leq x \leq 0.4$. The process of inclusion is progressive and reversible but a point exists beyond which the polymeric cyanide host structure breaks down. Furthermore, the same type of compound can exist with aromatic hydrocarbons as the included species.

Experimental

Preparation

The compounds $Ni(C_nH_{2n+1}NH_2)_2Ni(CN)_4,xC_nH_{2n+1}NH_2$ (which will hereafter be noted $NiNiC_n,xC_n$) have been prepared with normal alkylamines with $n = 12$ to 16.

In the case of *n*-dodecylamine (given as an example), one of the following three preparations can be used; all of them leading to a light violet product. (*A*) 'Quasi-anhydrous' nickel cyanide was prepared by dehydrating the hydrated cyanide at 160 °C; 0.5 mol of the yellow powder thus obtained was suspended in dry hexane and refluxed for 2 h with 0.65 mol of $n\text{-}C_{12}H_{25}NH_2$. The solid was then filtered, washed with hexane and dried.[1] (*B*) Freshly prepared hydrated cyanide $Ni(H_2O)_2Ni(CN)_4 \cdot yH_2O$ (0.5 mol) (4) was added to 65 ml of a 10 *M* solution of *n*-dodecylamine in hexane and the mixture refluxed, filtered, washed, and dried as above. (*C*) A mixture of 0.65 mol of solid $C_{12}H_{25}NH_2$ and 0.5 mol of quasi-anhydrous nickel cyanide was gently heated until it suddenly changes from yellow to light violet indicating coordination of the amine on the available Ni sites.

Analysis

Nickel was estimated by EDTA complexometry (5). Thermogravimetric analysis (TGA) gave the total amine content and hence *x*. These results were in good agreement with those calculated from elementary analysis using the hypothesis of one Ni to each two CN groups (Table 1).

Note

The maximum value of *x* found was 0.4; this value did not seem to depend on the mode of preparation. However, the use of excess quantities of amine led to much larger values of *x* (up to $x = 4$) but X-ray diffraction and infrared absorption showed that the compounds thus obtained were no longer of the $NiNiC_n,xC_n$ type here described.

[1]This method of preparation is analogous to that given by Walker and Hawthorne (1) in which the excess amine is removed by heating to yield the stoichiometric parent compound $NiNiC_n$ in its form I (3).

TABLE 1. Elementary analysis results

	Ni		C		N		H	
x*	Calcd.	Found	Calcd.	Found	Calcd.	Found	Calcd.	Found
0	19.8	19.8	56.8	56.1	14.2	13.7	9.2	9.2
0.15	18.9	18.8	57.7	57.3	13.9	13.8	9.4	9.4
0.35	17.9	17.4	58.9	58.7	13.5	13.3	9.7	9.7

*Content included dodecylamine.

Physical Properties

X-Ray diffraction patterns were obtained by reflexion, on a diffractometer ($\lambda K_{\alpha 1}Cu$); ir spectra were obtained on Nujol mulls or KBr pellets; thermal analyses were obtained in air on samples ranging from 10–15 mg (TGA) to a few micrograms (DTA).

Results

Whatever the value of x (between 0 and 0.4) or n (between 12 and 16) the compounds are light violet powders. A part of the X-ray diffraction pattern of the $NiNiC_{12}$, $\sim 0.4C_{12}$ compound is compared to the diffractogram given by form I of the parent $NiNiC_{12}$ compound in Fig. 1. Thermal treatment of the compounds singles out

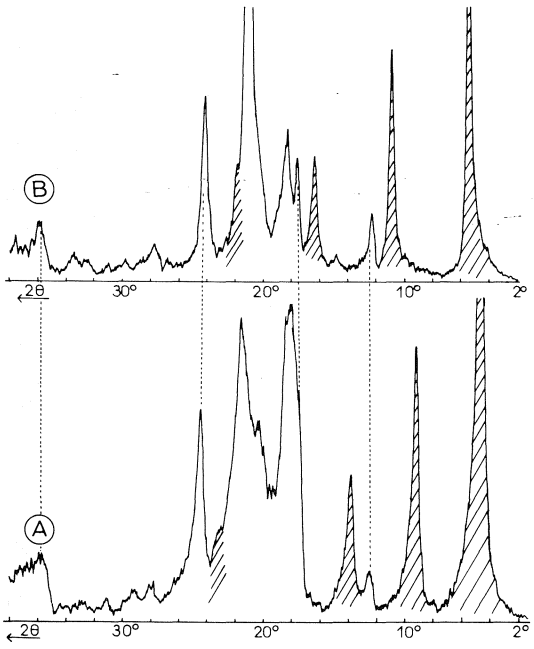

FIG. 1. X-Ray diffractogram ($\lambda K_{\alpha 1}Cu$) of (*A*) $NiNiC_n$, xC_n inclusion compound, for $n = 12$ and $x \approx 0.4$; (*B*) $NiNiC_{12}$, the parent compound (form I). The shading refers to the first category of lines (see text) In *A*, the 4th harmonic (around 19°) is occulted by other reflections. The lines of the second category are shown linked in the two diagrams.

TABLE 2. Maximum values (in Å) observed for the largest interplane distance in $NiNiC_n,xC_n$ with $12 \leq n \leq 16$ and $x \approx 0.4$

	d (Å)	
n	$NiNiC_n$	$NiNiC_n,xC_n$
12	16.2	19.3
13	17.1	20.5
14	18.0	21.2
15	18.9	22.3
16	19.7	23.2

three categories of lines: (*i*) The first line (smallest value of the diffraction angle) and its harmonics, with intensities strongly enhanced by preferential orientation of the powder on the holder. The corresponding value of the interlayer spacing is slightly dependent on the value of x and differs with n. It is always greater than that of the corresponding parent compound but tends discontinously to this latter value during the heat treatment (Table 2); an incomplete heat treatment leads to two phases. (*ii*) A few lines whose positions do not depend on n and which are not much affected by the heat treatments. They correspond to distances very close to those characteristic of the polymeric nickel cyanide plane already met in $NiNiC_n$. (*iii*) Some strong lines which are not linked with the value of n and are considerably modified by the heat treatment.

The ir spectra obtained on as-prepared and heat-treated compounds are quite similar but, in the latter case, the spectrum is less complex, particularly in the extension vibrations ν(C—C) and ν(C—N) of the $C_nH_{2n+1}NH_2$ chain and ν(N—H) of the NH_2 group; also the very intense ν(C≡N) vibration splits (2162 and 2156 cm^{-1}).

The different methods of physical analysis show that below 85 °C, modifications occur without any loss of mass; above this threshold, loss of mass occurs leading to $NiNiC_n$ (I) with $x = 0$. Depending on the previous thermal his-

tory, three types of thermograms can thus be distinguished:

Heating to 75 °C (maximum)

The DTA curve of Fig. 2*A* shows a first endotherm starting at 55 °C and another rather weaker one at about 65 °C. The reverse signals can be observed on cooling and the cycle is reproducible any number of times. There is no loss of mass from the sample; X-ray diffraction pattern and ir spectra of the sample at room temperature show no variations.

Heating to 85 °C

At room temperature no loss of mass or any modification of the ir spectrum are observed after a first heating to 85 °C, but the X-ray diffraction pattern is permanently modified with the largest value of *d*, the interplanar distance, changing from 19.30 to 19.05 Å. Similarly, the DTA curve shows a significant reduction of the first endotherm (Fig. 2*A'*). Identical thermograms are obtained during further heating cycles limited to a maximum temperature of 85 °C.

Heating to Beyond 85 °C

This entails decomposition and leads to $NiNiC_{12}$ (I) whose characteristics have already been described (3) (Fig. 2*B*). It is important to note that the removal of the excess amine is still, in a way, reversible since *x* can be increased again through the action of a solution of $n\text{-}C_{12}H_{25}NH_2$ in hexane. The products thus obtained, corresponding to the formula $NiNiC_{12}$, $x'C_{12}$, are analogous to those obtained by procedures *A*, *B*, or *C*, with the value of x' independent of the previous value of *x*. Also in this case, there exists a limiting value of x' beyond which profound modifications of the system occur. Thus, the products obtained from $NiNiC_{12}$ and a quantity of amine equivalent to $x' = 4$ correspond to the expected formula but their characteristics are quite different from those described above. X-Ray diffraction yields a value of 24.9 Å and the ir spectrum shows two peaks for $\nu(C{\equiv}N)$ at 2152 and 2123 cm^{-1}, both intense, two for $\nu_{as}(N{-}H)$ at 3334 and 3316 cm^{-1} and two for $\nu_s(N{-}H)$ at 3270 and 3254. The product is identical to that described in the Note in Experimental section.

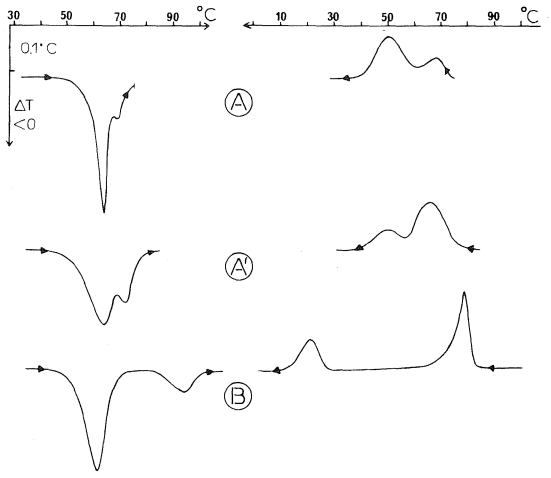

FIG. 2. Differential thermal analysis. (*A*) Of $NiNiC_n$, xC_n with $x \approx 0.4$. First heating and cooling cycle. if $t < 75$ °C, this cycle is reproducible. (*A'*) After a first heating to 85 °C, this cycle is reproducible if $t_{max} \leq 85$ °C. (*B*) After a first heating to 100 °C (2 h). The thermogram is that of the parent compound.

Discussion

The analogy between the X-ray diffraction pattern and the ir spectra of $NiNiC_n$ and $NiNiC_n,xC_n$ (particularly with regard to the structure in the Ni planes) as well as the analogy of the DTA curves suggests that the excess amine of $NiNiC_n,xC_n$ (with $0 \leq x \leq 0.4$) leaves most of the crystalline lamellar structure of the parent compound unchanged. Apparently, the excess molecules are trapped between the layers, and this both modifies the interlayer spacing and increases the complexity of organization of the paraffinic system. Since the coordinated and non-coordinated alkyl chains are identical and must probably both be in their fully extended *trans* conformation, the axes of the mean repulsion cylinder are likely to be parallel so as to obtain closest packing in the interlayer spacing. Furthermore, since the increase in the interlamellar distances with *n* (when $x \approx 0.4$) is slightly greater than that observed for the parent compound (Table 2), the angle between the chains and the cyanide planes must have been slightly increased. The problem of the structural relationship between the various parts of the lattice has not, however, yet been solved owing to the lack of single-crystal data (3).

The thermal evolution of $NiNiC_{12},xC_{12}$ can be interpreted as follows: at about 75 °C the system of planes and chains settles irreversibly with d_{max} changing from 19.30 to 19.05 Å. When this more compact $NiNiC_{12},xC_{12}$ is heated once again from room temperature, a first transition occurs at about 55 °C, strikingly similar to the I → II transition of the parent compound (3).

The second transition, starting at about 65 °C, could be homologous to the II → III transition which, in $NiNiC_{12}$, occurs at 85 °C. The decrease in the transition temperature could be the result of an increase in freedom of the terminal CH_3 groups.

The $NiNiC_n,xC_n$ system therefore shows the following properties: reproducibility of the spectral and structural properties, possibility of obtaining x values between ~ 0.4 and 0, decomposition leading to the parent compound $NiNiC_n$, possibility of regeneration. These features are characteristic of an inclusion compound in which the parent lattice plays the role of a host structure. For $n = 12$, the maximum value of x seems to be about 0.4; beyond this value, the Ni—CN bonds in the polymeric cyanide phase break down, as shown by the profound modifications of the ir spectra in which two intense ν(C—N) bands appear separated by 30 cm^{-1}. In other words, an excess of amine seems to lead to $[Ni(RNH_2)_x]^{2+}[Ni(CN)_4]^{2-}$ but the structural relationship between the square planar anions and the bulky cations has not yet been ascertained.

A similarity can be drawn between the host structure and that of the Hofmann clathrate (6) $Ni(NH_3)_2Ni(CN)_4,2C_6H_6$. This has led us to attempt the inclusion of aromatics: (*1*) With benzene, for $n \leq 12$ one can obtain $NiNiC_n$, xC_6H_6 but the stability of this compound is low even at room temperature. In fact benzene seems to diffuse into and out of the $NiNiC_n$ structure. Naphthalene and anthracene can be included, their diffusion out being slow enough to permit observation of their inclusion. (*2*) If one tries to regenerate $NiNiC_{12},x'C_{12}$ by reacting $NiNiC_{12}$ with $C_{12}H_{25}NH_2$ dissolved in benzene (instead of hexane), the inclusion of the amine doesn't occur. The extreme ease with which benzene apparently diffuses into the structure probably prevents the bulkier amine molecules from penetrating between the layers. (*3*) The stability of the aromatic inclusion compounds can be markedly improved by adjusting the size of host site to that of the included molecule, thus, anthracene can be better included in $NiNiC_8$ than in $NiNiC_{12}$. The differences in the uv spectrum of the aromatic molecules brought about by inclusion suggest that the distribution and orientation in the aliphatic chains could be studied along the lines of the numerous results (7) obtained following the work of Shpolskii (8) in this field.

1,2,3,4,7,8,9,10-Octahydrodicyclohepta[*de*,*ij*]naphthalene and 2,7-dimethylpyrene: a short novel synthesis

DAVID E. LAYCOCK,[1] ROSEMARY J. WAIN,[2] AND ROBERT H. WIGHTMAN[3]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received July 12, 1976

DAVID E. LAYCOCK, ROSEMARY J. WAIN, and ROBERT H. WIGHTMAN. Can. J. Chem. **55**, 21 (1977).

The preparation of two tetracyclic benzenoid hydrocarbons is described using a four step synthesis involving 'aromatization' of a Diels–Alder dianhydride adduct.

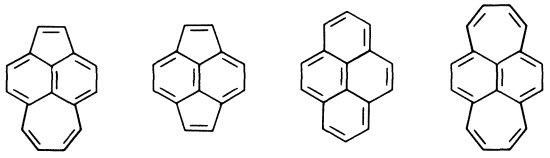
DAVID E. LAYCOCK, ROSEMARY J. WAIN et ROBERT H. WIGHTMAN. Can. J. Chem. **55**, 21 (1977).

On décrit la préparation de deux hydrocarbures benzénoïdes tétracycliques qui se font par l'intermédiaire d'une synthèse en quatre étapes impliquant 'l'aromatisation' d'un adduit dianhydride de Diels–Alder.

[Traduit par le journal]

Introduction

Bis-annelation of the naphthalene nucleus via the peri positions has led to some interesting tetracyclic polyunsaturated hydrocarbons including acepleiadylene **1** (1), pyracylene **2** (2) and pyrene **3** (3). These compounds have received much chemical (1, 4) and theoretical (5–7) attention to ascertain their degree of 'aromatic' character. The next higher homologue 'dipleiadiene' **4** has not yet been synthesized (for synthesis of a similar system, see ref. 8) although it has received considerable theoretical attention (9, 10). One approach to **4** would seem to be via its octahydro derivative **8** and this manuscript describes a short synthetic route for this compound as well as an interesting rearrangement by-product, 2,7-dimethylpyrene **9**.



1 **2** **3** **4**

Fischer *et al.* have reported the only synthesis of **8** in a lengthy sequence starting with benzosuberone and involving ten steps with a 7% overall yield (11). Our synthesis outlined in Scheme 1 can provide the compound quickly in four steps from cycloheptanone despite one very low yield step. Interestingly, the sequence also provides a source of 2,7-dimethylpyrene **9** for which there is only one reported synthesis with an acceptable yield (12).

Results and Discussion

1,2,3,4,7,8,9,10-Octahydrodicyclohepta[de,ij]-naphthalene

The synthesis of **8** was based on the observation that mono Diels–Alder adducts of maleic anhydride and bicyclic dienes could be converted directly to benzenoid hydrocarbons in yields of 60–70% by heating with phosphorus pentoxide (13). This procedure has been used previously by us to synthesize a series of bis *meta*-annelated benzenoid hydrocarbons (14).

A substantial improvement over reported yields (~50%) of 1-chlorocycloheptene **5** (15) from cycloheptanone was achieved by modifications in the work-up (see Experimental). The product should be used immediately after distillation but can be stored under nitrogen atmosphere in the cold (0 °C) and dark. Conversion to the diene **6** was accomplished with potassium *tert*-butoxide in tetrahydrofuran at 70 °C as reported by Bottini *et al.* (16). The method is a distinct improvement over the original procedure of Ball and Landor (15) both in yields and experimental ease. We have found that cmr provided an easy and direct verification of the absence of double bond isomers noted by previous workers

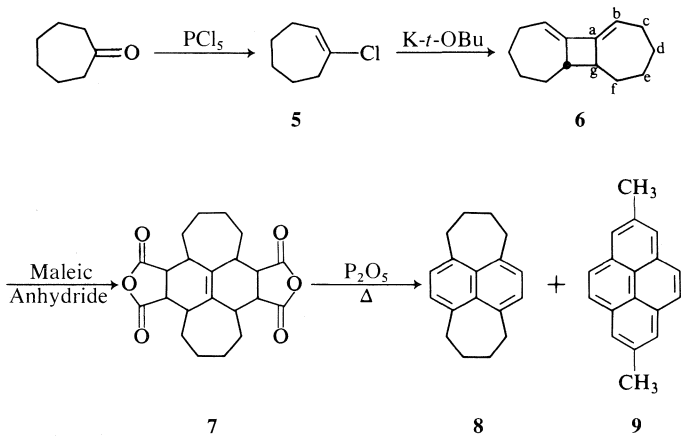

SCHEME 1

(15, 16). The presence of only seven lines in the spectrum must indicate the required (symmetrical) product. The *anti* configuration for **6** indicated on the formula is based on assignments from chemical degradations of **6** (17), a Woodward–Hoffman conrotatory [2 + 2] dimerization of the cycloallene proposed as the intermediate between compounds such as **5** and **6** (16, 18), and possible pmr evidence (19). It should be possible to confirm this stereochemical assignment by cmr if the other isomer of **6** could be obtained (20).

The dianhydride **7** was obtained as described by Ball and Landor (15) although we were never able to achieve the yields nor, consistently, the sharp melting points reported by the earlier workers. This may be due to mixtures of conformational/configurational isomers such as have been reported for similar products (21). Nonetheless the reaction product when foamed and dried gave spectral data (ir, nmr, ms) consistent with the proposed structure and gave products identical to the crystalline material when subjected to the final reaction conditions. Upon heating the dianhydride **7** with phosphorus pentoxide at 360 °C an orange hydrocarbon-soluble solid was obtained in 13% yield which was disappointingly low when compared to our previous experiences (14). Gas–liquid chromatographic analysis of this product indicated two major components which were easily separated and purified by column chromatography on alumina to yield **8** with petroleum ether elution and **9** from the benzene fraction.

Various attempts were made to improve the yield of the Diels–Alder/aromatization sequence. Cycloadditions with the diene **6** were investigated using ethylene, acrylic acid, dimethylacetylene dicarboxylate, and tetracyanoethylene (22) as dienophiles with no useful derivatives obtained. Attempted conversion of the dianhydride to hydrocarbon products using bis triphenylphosphine nickel dicarbonyl (23), Pd/C at 350 °C (14), or lead tetraacetate with dimethyl sulfoxide in pyridine (24) were also unsuccessful.

2,7-Dimethylpyrene

At first glance the formation of **9** bears some similarity to reported pyrolytic (500 °C) rearrangement of benzcycloheptadiene to methylnaphthalene (25). However, treatment of **8** at 360 °C or with phosphorus pentoxide at 360 °C returned essentially quantitative amounts of starting material with no evidence for **9**. Perhaps this result offers some clue to the mechanism of the 'oxidative decarboxylation' reaction with phosphorus pentoxide.

Experimental

General Details

All reactions were carried out under nitrogen. Melting points were obtained on a Fisher-Johns melting point apparatus. Refractive indices were taken on an Officine Galileo Di Milano (Jo. 50532) refractometer. Analytical glc data were obtained on a Hewlett Packard F&M 402 instrument using ¼ in. × 6 ft columns packed with 5% SE54 on Chromosorb W, an oven temperature of 225 °C, and flow rate of nitrogen at 70 ml/min. Infrared spectra were recorded on a Perkin-Elmer 237B spectrophotometer. Ultraviolet spectra were obtained in 95% EtOH on a Perkin-Elmer Coleman-124 spectrophotometer. ^{13}C nmr data were obtained on a Varian XL-100 (100 MHz) instrument and proton nmr spectra were recorded on a Varian T-60 (60 MHz) instrument; all values are recorded in ppm (δ) with reference to TMS. All nmr were taken in $CDCl_3$ with 1% TMS. Low resolution mass spectra were carried out at Trent University in Peterborough.

1-Chlorocycloheptene (5) (15)

Cycloheptanone (225 g, 1.8 mol) was added dropwise to phosphorus pentachloride (454 g, 2.2 mol) over 3 h at 0 °C. The reaction mixture was then poured on ice (1000 g) and after 1 h extracted with methylene chloride (3 × 200 ml); the combined organic layers were washed with water (2 × 200 ml), dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. Distillation of the resulting oil yielded 1-chlorocycloheptene, 196 g (79%) as a clear colourless oil; bp 54–59 °C/14 torr, η_D^{20} 1.4840 (lit. (26) bp 75 °C/26 torr, η_D^{21} 1.4844); nmr 5.95 (1H, t, olefinic C*H*), 2.5 (2H, m, CH_2 α to CCl), 2.1 (2H, m, allylic CH_2), 1.6 (6H, m, other CH_2).

Tricyclic Diene (6) (16)

Freshly distilled 1-chlorocycloheptene (**5**) (196 g, 1.5 mol) was added dropwise over 1 h to a stirred dispersion of potassium *tert*-butoxide (370 g, 3.3 mol) in 1 litre dry THF at 66–70 °C. After 2 h at this temperature the mixture was poured into 1 litre of water and extracted with ether (3 × 200 ml); the combined ether extracts were washed with water (1 × 200 ml), dried, filtered, and evaporated to give a reddish oil. Upon distillation the diene **6** was obtained, as a clear colourless oil, 67 g (49%), bp 150–162 °C/14 torr (lit. (15, 16) 142 °C/14 torr, 123–137 °C/4 torr); η_D^{20} 1.5408; nmr 5.8 (2H, m, olefinic C*H*), 2.6–0.9 (18H, m, other *H*); ir 1660 cm^{-1} (C=C); uv λ_{max} (ε) 260 (17 500), sh 270, sh 254 nm; ^{13}Cmr (±0.2 ppm), 145.8 (C_a), 118.2 (C_b), 48.7 (C_g), 33.4 (C_e), 30.9 (C_c), 29.7 (C_f or C_d), 28.9 (C_d or C_f).

Dianhydride 7 (15)

Freshly distilled diene **6** (29.0 g, 0.154 mol) and maleic anhydride (58 g, 0.465 mol) were refluxed in dry benzene (200 ml) for 8 h. Removal of benzene *in vacuo* followed by trituration with ether furnished a residual yellow oil which, after repeated evaporations with acetone, yielded yellow foam, 16.5 g (28%). A small portion could be crystallized in benzene – petroleum ether (60–100 °C) as needles mp 263–267 °C, softening at 230 °C (lit. (15) 267 °C); ir 1760, 1850 cm^{-1} (anhydride); ms *m/e* 384 (M^+); nmr 3.3 (4H, m, C*H* α to C=O), 2.9–2.4 (4H, m, allylic C*H*), 2.3–1.2 (16H, m, other *H*).

Substituted Naphthalene (8) and 2,7-Dimethylpyrene (9)

Dry powdered dianhydride **7** (15 g, 0.039 mol) was mixed thoroughly with phosphorus pentoxide (15.0 g, 0.15 mol) and placed in a long Pyrex tube with a Hickman still attached. The apparatus was then placed vertically in a furnace at 360 °C for 15 min. Orange crystals were recovered from the still and chromatographed on an alumina column. Elution with petroleum ether gave clear colourless needles, recrystallized from hexane to yield **8**, 0.5 g (6%): mp 143 °C (lit (11) 143 °C); glc 6.5 min; nmr 7.0 (4H, s, aromatic *H*), 3.15 (8H, m benzylic CH_2), 2.0 (8H, m, other CH_2).

Subsequent elution with benzene furnished, after recrystallization from hexane, 2,7-dimethylpyrene **9**, 0.3 g (4%), as clear colourless crystals: mp 233 °C (lit. 12, 27) 234 °C, 238 °C); glc 8.75 min; nmr 7.95 (8H, s, ring *H*'s), 2.75 (6H, s, CH_3's); ms *m/e* 230 °C (M^+); uv λ_{max} (ε) 247 (20 000), 267 (5900), 277 (9500), sh 237 nm.

Gas phase ion equilibria studies of the proton in hydrogen sulfide and hydrogen sulfide – water mixtures. Stabilities of the hydrogen bonded complexes: $H^+(H_2S)_x(H_2O)_y$

KENZO HIRAOKA AND PAUL KEBARLE

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2E1

Received July 6, 1976

KENZO HIRAOKA and PAUL KEBARLE. Can. J. Chem. **55**, 24 (1977).

The temperature dependence of the equilibria $(n,n+1)$ $H^+(H_2S)_n + H_2S \rightleftharpoons H^+(H_2S)_{n+1}$ was measured for $n = 1$ to 5 in a pulsed electron beam mass spectrometer with a high pressure ion source. The $\Delta H_{n+1,n}$ values obtained were (2,1) 15.4, (3,2) 9.1, (4,3) 8.4, (5,4) 6.7 kcal/mol. Possible structures of the clustered ions are proposed.

Addition of water vapor leads to mixed cluster ions such as $H^+(H_2S)_x(H_2O)_y$, with $x + y$ from 1 to 6, observed as the ion source temperature was decreased to -100 °C. The temperature dependence of the equilibria for the exchange reactions $H^+(H_2S)(H_2O) + H_2O \rightleftharpoons H^+(H_2O)_2 + H_2S$, $H^+(H_2S)(H_2O)_2 + H_2O \rightleftharpoons H^+(H_2O)_3 + H_2S$, and the association reaction $H^+(H_2S)(H_2O) + H_2S \rightleftharpoons H^+(H_2S)_2(H_2O)$ were also measured. For all ions measured, the hydration process is energetically more favorable than the solvation by H_2S.

KENZO HIRAKOA et PAUL KEBARLE. Can. J. Chem. **55**, 24 (1977).

La relation qui existe entre la température et l'équlibre $(n,n+1)$ $H^+(H_2S)_n + H^+(H_2S)_{n+1}$ a été mesurée pour $n = 1$ jusqu'à 5 dans un spectromètre de masse avec un faisceau d'électrons pulsés et une source ionique à haute pression. Les valeurs de $\Delta H_{n+1,n}$ obtenues sont (2,1) 15.4, (3,2) 9.1, (4,3) 8.4, (5,4) 6.7 kcal/mol. On propose des structures possibles pour les ions agglomérés.

L'addition de vapeur d'eau conduit à des ions mixtes sous forme d'agglomérats tels que $H^+(H_2S)_x(H_2O)_y$ où $x + y$ varie de 1 à 6; on peut observer ces ions lorsque la température de la source ionique est abaissée jusqu'à -100 °C. Les relations entre la température et l'équilibre pour les réactions d'échange $H^+(H_2S)(H_2O) + H_2O \rightleftharpoons H^+(H_2O)_2 + H_2S$, $H^+(H_2S)(H_2O)_2$ $H_2O \rightleftharpoons H^+(H_2O)_3 + H_2S$ et pour la réaction d'association $H^+(H_2S)(H_2O) + H_2S \rightleftharpoons H^+(H_2S)_2(H_2O)$ ont aussi été mesurées. Pour tous les ions mesurés, le processus d'hydratation est plus favorisé, au point de vue énergétique, que la réaction de solvatation par H_2S.

[Traduit par le journal]

Introduction

Several years ago, a study of the gas phase equilibria of the proton in water, methanol, dimethyl ether (1) and mixtures thereof (2) was made in this laboratory. This study provided thermochemical information giving special insights in the solvation processes and suggested possible structures of the hydrogen bonded clusters.

The present work deals with hydrogen sulfide and mixtures of hydrogen sulfide and water. A number of spectroscopic studies of hydrogen bonding to the sulfur atom in solution have been reported (3). However, few thermochemical data were obtained by this method. Lowder *et al.* (4) estimated the energy of hydrogen bonding in $H_2S....HSH$ in the gas phase from quantitative infrared intensity measurements as 1.7 ± 0.3 kcal/mol. This can be compared with the energy of hydrogen bonding of water $H_2O...OH_2$ which is ~ 5 kcal/mol (5). Apart from a qualitative study of Hopkins and Bone (6), no quantitative information on the hydrogen bonding in ionic species like $(H_2S...H...SH_2)^+$ etc. has been published. In order to investigate the intrinsic hydrogen bonding ability of hydrogen sulfide, we studied the equilibrium reaction of the proton in hydrogen sulfide and mixtures of hydrogen sulfide and water in methane carrier gas.

Experimental

The high pressure ion source mass spectrometer with which the measurements were done was described earlier (7). Only a brief account of the procedures followed will be given here.

The 2000 V ionizing electron beam (10^{-8} Å) was pulsed 'on' for 10–100 μs and 'off' for 2–4 ms. The ions escaping from the field free ion source into an evacuated region were magnetically mass analyzed and collected in a multichannel analyzer as a function of their arrival time after the electron pulse.

The $H^+(H_2S)_n + H_2S \rightleftharpoons H^+(H_2S)_{n+1}$ measurements were done with CH_4 gas at a pressure of 4 torr containing known small amounts of H_2S (50 to 600 mtorr). The CH_4 gas (Linde UHP) was further purified by passing it through a Dry Ice – acetone-cooled trap containing molecular sieve 5 Å. Downstream of this trap, H_2S (Matheson C.P. Grade) was added to the CH_4 stream through a calibrated capillary. The mixed gas was passed in slow flow through the thermostated ion source.

For the measurements of equilibria of the mixed cluster ions of H_2S and H_2O, only a very small amount of H_2O (< 1 mtorr) needed to be introduced since more than a few mtorr of water easily converted all mixed cluster ions to fully hydrated ions. This made it difficult to determine the water pressure directly. We had to determine the water pressure by measuring the equilibrium ion intensities of $H^+(H_2O)_n$ and $H^+(H_2O)_{n+1}$ and using the expression:

$$p = \frac{I_{n+1}}{I_n} \times \frac{1}{K_{n,n+1}}$$

The equilibrium constants $K_{n+1,n}$ were obtained in this laboratory before (7, 8). The water concentration resulting from this procedure is accurate to only some 20–50%. This introduces a similar error in the equilibrium constants for the exchange reactions $H^+SW + W \rightleftharpoons H^+W_2 + S$ and $H^+SW_2 + W \rightleftharpoons H^+W_3 + S$ (where S stands for H_2S and W for H_2O).

The cluster ions H^+S_n and H^+W_n, and mixed cluster ions $H^+S_xW_y$ were the major ions observed in the mixed H_2S, water experiment with some minor ions such as CHS^+, CH_3S^+, $CH_3SH_2^+$, $C_2H_5SH_2^+$, $C_3H_5SH_2^+$, and $C_3H_7SH_2^+$. The total of the minor ions was less than 1% of the total ions. The minor ions might be produced from the impurities, possibly mercaptans present in the hydrogen sulfide gas, by reaction of the primary ions of methane with hydrogen sulfide. No investigation was made of the mechanism by which these ions were formed.

Results and Discussion

The experimentally obtained van't Hoff plots for the reactions $(n,n+1)$ $H^+(H_2S)_n + H_2S = H^+(H_2S)_{n+1}$ are shown in Fig. 1 together with the corresponding results for water which are given for comparison.

An examination of the dependence of the equilibrium constants on the H_2S pressure was made at all the temperatures shown in the van't Hoff plots. One example of these determinations is given in Fig. 2 for the reaction (1,2).

(1,2) $\quad H^+(H_2S) + H_2S \rightleftharpoons H^+(H_2S)_2$

The results show that the equilibrium constants are independent of H_2S pressure in the experimentally covered pressure range, where the pressure changes by a factor of five to six.

The van't Hoff plots for the exchange reactions $H^+SW + W \rightleftharpoons H^+W_2 + S$ and $H^+SW_2 + W \rightleftharpoons H^+W_3 + S$, and the addition reaction

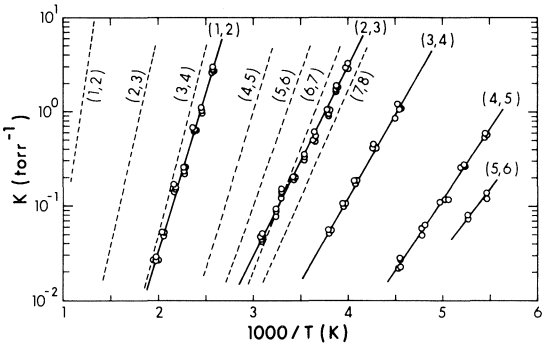

FIG. 1. van't Hoff plots for the reactions $H^+(H_2S)_n + H_2S \rightleftharpoons H^+(H_2S)_{n+1}$ $(n,n+1)$. (---) plots for the reaction $H^+(H_2O) + H_2O = H^+(H_2O)_{n+1}$, refs. 7 and 8.

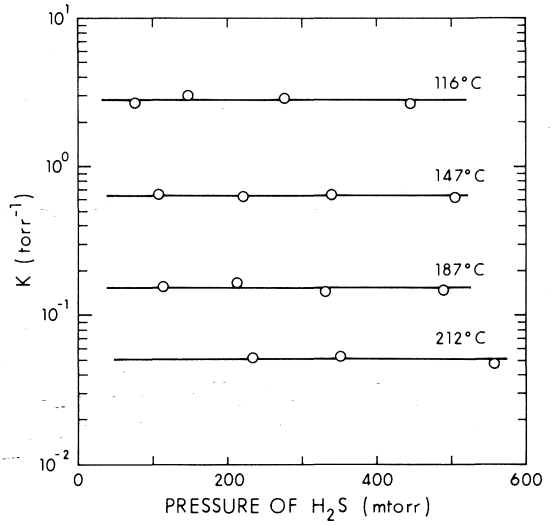

FIG. 2. Pressure dependence of the equilibrium constant $K_{1,2}$ for the reaction $H^+(H_2S) + H_2S \rightleftharpoons H^+(H_2S)_2$.

$H^+SW + S \rightleftharpoons H^+S_2W$ are shown in Fig. 3. The corresponding ΔH^0, ΔG^0, and ΔS^0 values are summarized in Fig. 4 and Table 1. Included are results obtained earlier for pure protonated water (7, 8). Some of the values shown in Fig. 4 are marked by an asterisk. Such values were obtained not by direct measurement of the equilibrium but by the application of thermodynamic cycles. This was done for cases where the direct measurement of the equilibrium was difficult.

The van't Hoff plots for pure hydrogen sulfide were shown in Fig. 1. The vertical distance between two adjacent van't Hoff lines taken at some $(1/T)$ is proportional to the free energy difference. Big gaps between two van't Hoff lines

TABLE 1. Thermochemical data from protonated clusters in equilibria; hydrogen sulfide, hydrogen sulfide – water mixture[a]

Reaction	$-\Delta H^0$	$-\Delta G^0$	$-\Delta S^0$
	(1) Addition Reaction		
$H^+S + S \rightleftharpoons H^+S_2$	15.4±0.5	8.1±0.4	24.4±1.5
$H^+S_2 + S \rightleftharpoons H^+S_3$	9.1±0.5	2.8±0.1	20.9±2.1
$H^+S_3 + S \rightleftharpoons H^+S_4$	8.4±0.5	1.0±0.2	24.5±1.8
$H^+S_4 + S \rightleftharpoons H^+S_5$	6.7±0.3	−0.7±0.2	24.7±1.4
$H^+S_5 + S \rightleftharpoons H^+S_6$[b]	~6.1[b]	~−1.1[b]	(24)
$H^+SW + S \rightleftharpoons H^+S_2W$	13.3±0.4	6.8±0.2	21.7±1.3
	(2) Exchange Reaction		
$H^+SW + W \rightleftharpoons H^+W_2 + S$	6.7±1	7.1±0.5	−1.2±2
$H^+SW_2 + W \rightleftharpoons H^+W_3 + S$	5.9±1	6.3±0.6	−1.3±2

[a]All values are in kcal/mol, ΔG^0 values for 300 K, ΔS^0 in eu, standard state 1 atm. Only data from directly measured equilibria are shown. Data for related reactions can be obtained from thermodynamic cycles as shown in Fig. 4. S and W are hydrogen sulfide and water.
[b]The values ΔH^0 and ΔG^0 are estimated by assuming $-\Delta S^0 = 24$ eu and ΔG measured at a different temperature.

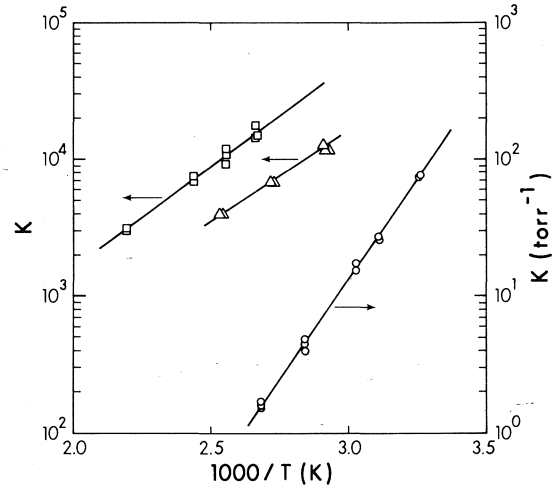

FIG. 3. van't Hoff plots for hydrogen sulfide (S) and water (W): Exchange reactions: $H^+SW + W \rightleftharpoons H^+W_2 + S$ (□) and $H^+SW_2 + W \rightleftharpoons H^+W_3 + S$ (△). Association reaction $H^+SW + S \rightleftharpoons H^+S_2W$ (○).

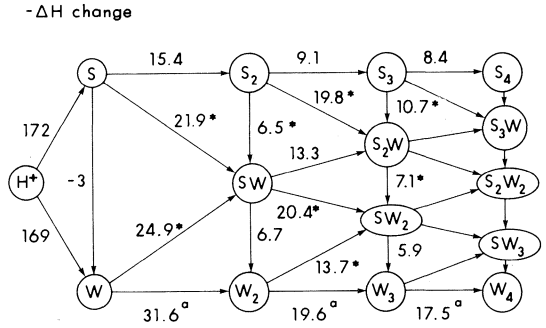

FIG. 4. Enthalpy changes for addition and exchange reactions of protonated clusters containing hydrogen sulfide (S) and water (W). The value corresponds to $-\Delta H$ (kcal/mol). The proton is omitted from the clusters. Values with an asterisk were obtained indirectly from cycles involving directly measured values. The pure water values taken from refs. 7 and 8 are indicated with the superscript [a].

thus indicate a big drop of stability towards dissociation of one molecule. Easily noticed in Fig. 1 is a big gap between (1,2) and (2,3). This is followed by a smaller gap between (2,3) and (3,4) and a big gap again between (3,4) and (4,5).

A similar pattern can be observed in Fig. 5 which shows the measured enthalpy changes for the $(n,n+1)$ reactions in function of n. A decrease of $\Delta H_{n+1,n}$ with n is observed as is generally the case for ion clusters. The results of Fig. 5 show that the decrease is not regular. The fall off between the first three interactions $\Delta H_{2,1}$, $\Delta H_{3,2}$ and $\Delta H_{4,3}$ is rather smooth, then an appreciable decrease occurs between $\Delta H_{4,3}$ and $\Delta H_{5,4}$ followed by an only small decrease to $\Delta H_{6,5}$. This means that the first incoming molecule reacts most strongly, relatively strong interactions occur also for the second and third molecule, while the next two molecules, *i.e.* fourth and fifth, experience weaker interactions. This pattern of interactions is qualitatively very similar to the changes observed earlier for the proton hydrates $H^+(H_2O)_n$, except that the binding energies for the H_2S clusters are very much lower. For the proton hydrates the stability decrease between $H_3O^+(H_2O)_3$ and $H_3O^+(H_2O)_4$ was very much less pronounced than the stability decrease observed between $H_3S^+(H_2S)_3$ and $H_3S^+(H_2S)_4$ observed in the present results. In the earlier studies (1, 2, 7, 8), it was concluded that the Eigen

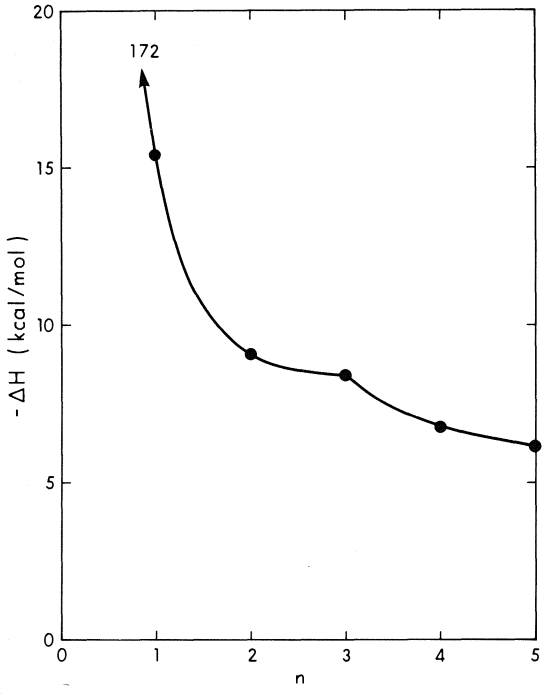

FIG. 5. Plot of experimental $-\Delta H_{n,n+1}$ *vs.* n for the reactions $H^+(H_2S)_n + H_2S \rightleftharpoons H^+(H_2S)_{n+1}$. The number 172 is the proton affinity of hydrogen sulfide obtained in this laboratory (14).

structure (9) $H_3O^+(H_2O)_3$ does not have a really special prominence. It is therefore interesting to compare the water and hydrogen sulfide systems and also examine why the Eigen-type structure should show relatively greater stability in the H_2S system. (The Eigen type structure, H_3S^+-$(H_2S)_3$ is shown in Fig. 6.)

Yamabe *et al.* (10) have examined the electronic structure of H_3S^+ by *ab initio* MO calculations (STO 3G). Their results predict that H_3S^+ has C_{3v} structure with an HSH angle of 94°. The calculated net positive charges on H and S are 0.150 and 0.550 respectively. Comparable calculations for H_3O^+ by Almlöf and Wahlgren (11) predict an HOH angle of 117° and net positive charges on H and O of 0.328 and 0.015 respectively. Thus nearly all the positive charge in H_3O^+ is on the hydrogens. The near planarity of this molecule may be considered to be a consequence of the H^+ repulsions. H_3S^+ is quite different with much more charge on the sulfur atom, consequent smaller hydrogen repulsions and pyramidal structure. The above differences may be considered to largely reflect the higher electronegativity of the oxygen atom. The dipole

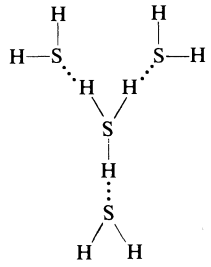

FIG. 6. Structure of cluster $H_3S^+(H_2S)_3$.

moments of H_2S and H_2O are 1.1 and 1.8 D respectively. Considering the much smaller partial positive charges on the H atoms in H_3S^+, the smaller permanent dipole of H_2S and the greater bulkiness of the S atom one has no trouble understanding that the $H^+(H_2S)_n$ clusters are held much more weakly than the corresponding water clusters. The shorter bonds in the water clusters lead to a fairly efficient positive charge transfer from the 'inner' hydrogen atoms of the H_3O to the outer hydrogen atoms in the water molecules of the Eigen structure. This charge dispersal, which is characteristic of 'strong hydrogen bonds', is achieved by a small amount of electron transfer from the outer molecules to the H_3O and by a considerable internal polarization of the outer water molecules. For this reason bonding of the $H_3O(H_2O)_3^+$ to an additional water molecule *i.e.* $-\Delta H_{4,5}^0$ and $-\Delta G_{4,5}^0$ is not weakened appreciably. In the $H_3S(H_2S)_3^+$ system positive charge transfer to the periphery should be much smaller because of the weaker hydrogen bonding, *i.e.* longer bonds with attendant big decrease in electron transfer and polarization. In addition to this comes the smaller permanent dipole of H_2S. Therefore the large drop off at the (4,5) stage is expected. Other solvents with weak bonding abilities have been also observed to show distinct drop off the enthalpy and free energy change after completion of the first shell. For example recent measurements of the solvation of the proton by hydrogen (12) and methane (13) gas showed breaks after the completion of the first 'shell' that were even more distinct than that observed for the hydrogen sulfide system.

Figure 4 shows the enthalpy changes for addition and exchange reactions of protonated clusters containing hydrogen sulfide and water. The proton affinity of hydrogen sulfide is 3 kcal/mol higher than that of water (14). Since the chemical bonding ability of sulfur is much lower,

the slightly better accommodation of the proton by H_2S should be mostly due to the higher polarizability of the H_2S. This slight edge of H_2S is lost when the interactions occur at larger distances and for reasons outlined above the interactions with water when more than one molecule is present are more favorable. Thus we see from Fig. 4 that the addition of one H_2S molecule to H_3S^+ brings only 15.4 kcal/mol exothermicity while the addition of a water molecule ($S \rightarrow SW$) brings a whole 21.9 kcal/mol. The exchange reaction $H^+S_2 + W \rightleftharpoons HSW^+ + S$ is exothermic by $\sim$6.5 kcal while the further exchange $HSW^+ + W \rightleftharpoons HW_2{}^+$ releases an additional $\sim$6.7 kcal/mol. These and the other data in Fig. 4 graphically show how H_2S rapidly becomes a less desired species as the clusters grow. Thus the very weak bonding of H_2S in an acidic aqueous solution is foreshadowed by these results.

It is interesting to compare the present pair for $H^+(H_2O)_n$ and $H^+(H_2S)_n$ with the $H^+(NH_3)_n$ and $H^+(PH_3)_n$ systems for which results were obtained earlier (15, 16). The bonding in the phosphine system was found (16) to be much weaker than that in the ammonia system. This is a result that could have been expected for reasons very similar to those pointed out in the present work for the water and hydrogen sulfide systems. A further analogy could have been expected, namely that the relative drop off in stability between inner- and outer-shell should have been more pronounced for the phosphine system. This, however, was not observed (16). While there is a significant drop off in stability between $NH_4{}^+(NH_3)_4$ and $NH_4{}^+(NH_3)_5$ the change for the corresponding phosphine species seems to be small and continuous (16). The reasons for this result are not very clear.

Photoisomerization of 1-triphenylmethylcyclopentadiene. Di-π-methane rearrangement to 5,6,6-triphenylbicyclo[3.1.0]hex-2-ene

STEFAN WEIGL AND JOHN WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 4, 1976

STEFAN WEIGL and JOHN WARKENTIN. Can. J. Chem. **55**, 29 (1977).

Triphenylmethylcyclopentadiene exists as a mixture of isomers, the minor and major components of which are shown to be 1-triphenylmethylcyclopentadiene (**1**) and 2-triphenylmethylcyclopentadiene (**2**), respectively.

Direct irradiation of a mixture of **1** and **2** led to formation of 5,6,6,-triphenylbicyclo[3.1.0]hex-2-ene (**3**) via rearrangement of **1**. Acetophenone-sensitized irradiation of the same mixture gave **3** as well as a two component mixture of photodimers of **1** and/or **2**. Results are interpreted in terms of the di-π-methane rearrangement mechanism.

STEFAN WEIGL et JOHN WARKENTIN. Can. J. Chem. **55**, 29 (1977).

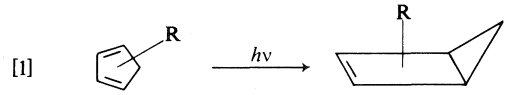
Le triphénylméthylcyclopentadiène existe sous forme de mélange d'isomères; les composants mineurs et majeurs sont respectivement le triphénylméthyl-1 cyclopentadiène (**1**) et le triphénylméthyl-2 cyclopentadiène (**2**).

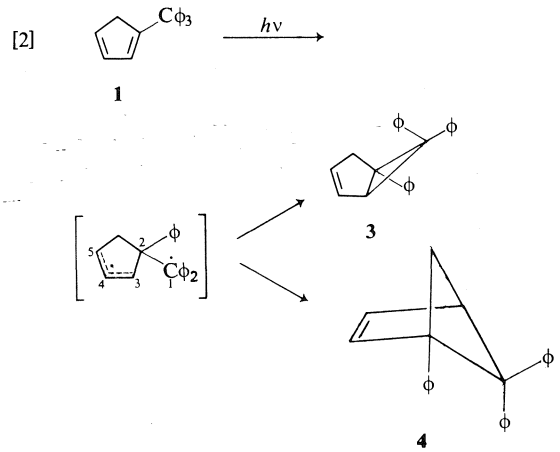
L'irradiation directe d'un mélange de **1** et de **2** conduit à la formation de triphényl-5,6,6 bicyclo[3.1.0] hexène-2 (**3**), par l'intermédiaire d'un réarrangement de **1**. Une irradiation sensibilisée par l'acétophénone du même mélange conduit à **3** ainsi qu'à un mélange à deux composants des photodimères de **1** et/ou **2**. On interprète les résultats en terme d'un mécanisme de réarrangement di-π-méthane.

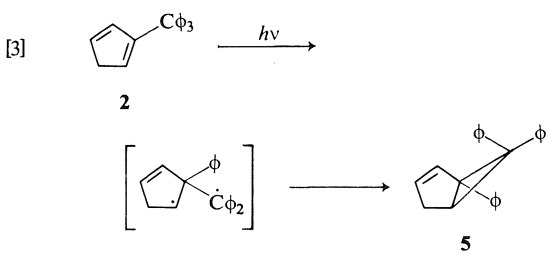
[Traduit par le journal]

Introduction

There are many potential photoreactions of the triphenylmethylcyclopentadiene system. First, monosubstituted cyclopentadienes are interconverted by thermal [1,5]-sigmatropic hydrogen migration and are obtained as mixtures of isomers (1–6), any one or all of which could be photolabile. Second, all three possible isomers have the endocyclic di-π-methane system of cyclopentadiene itself but, in the cases of 1- and 2-triphenylmethylcyclopentadienes, **1** and **2**, respectively, there is an additional di-π-methane system consisting of a double bond of the diene moiety and a phenyl group. Potential photoproducts, therefore, include four triphenylmethylbicyclo[2.1.0]pent-2-enes from the known electrocyclic reaction of the diene singlet (6, 7), eq. 1, two bicyclo[3.1.0]hex-2-enes from di-π-methane rearrangement[1] with phenyl migration, eqs. 2 and 3, and a bicyclo[2.1.1]hex-2-ene from







a variant (unprecedented) of that rearrangement, eq. 2. Finally, some of the potential photopathways might require either the singlet or the triplet excited state of the precursor.

[1]Photochemical rearrangement of systems having a single sp^3-hybridized carbon flanked by two π-systems (*e.g.* vinyl and phenyl) has been named *di-π-methane rearrangement* by Zimmerman and co-workers, who first recognized its generality (8).

In this paper we report the identities of the isomers present in triphenylmethylcyclopentadiene and the structure and origin of the photorearrangement product.

Methods, Results, and Discussion

Isomers of Triphenylmethylcyclopentadiene

Riemschneider and Nehrin (9), as well as Werner *et al.* (10) had established that **1** and **2** are the major isomers in triphenylmethylcyclopentadiene mixtures and the equilibrium ratio had been established at 3.8:1 (10). However, neither group was able to establish whether **1** or **2** is the predominant isomer. We speculated that the large trityl group might slow Diels–Alder reaction of **1** more than that of **2**. That postulate turned out to be correct, for treatment of the mixture of **1** and **2** with tetracyanoethylene (**6**) led to rapid consumption of the major isomer only, with formation of 5,5,6,6-tetracyano-2-triphenylmethylbicyclo[2.2.1]hept-2-ene (**7**). Long reaction times led to total conversion of dienes to **7**, presumably by prior rearrangement of **1** to **2**, followed by reaction with **6**. Thus, the major component in the mixture of **1** and **2** is isomer **2**. Methylcyclopentadiene also contains more 2- than 1-isomer at equilibrium but the ratio is only 1.20:1 (2, 4). Since this ratio is opposite in sense to that expected from a hyperconjugative effect of the methyl group (4), and since the effect of replacing the methyl group with the larger triphenylmethyl group is to increase the fraction of 2-substituted diene in the equilibrium mixture, we suggest that the reason for the predominance of 2-alkyl cyclopentadienes over the 1-isomers has to do with greater steric hindrance in the latter.

The pmr spectrum of the cyclopentadiene portion of **2** was assigned with the aid of decoupling and the data are gathered in Table 1.

TABLE 1. Nuclear magnetic resonance spectra of **1** and **2**

Nucleus	Chemical shift (δ)[a] **1**	**2**	J(Hz)[b]
H_1	—	6.08	$J_{1,3} = 1.40$
H_2	6.05–6.40[c]	—	$J_{1,4} = 2.05$
H_3	6.05–6.40[c]	6.20	
H_4	6.05–6.40[c]	6.33	$J_{3,4} = 5.29$
H_5	2.89	3.03	$J_{1,5} = 1.83$[d], $J_{4,5} = 1.85$[d]
C_1	154.2[e]	130.1[e]	$J_{3,5} = 0.92$[d]
C_2	128.3[e]	152.4[e]	
C_3	132.7[e]	136.9[e]	
C_4	131.3[e]	131.9[e]	
C_5	44.5[e]	40.6[e]	
C_6	62.2[e]	60.9[e]

[b] Determined by decoupling, except where otherwise indicated.
[c] Not resolved from other signals in the vinyl region.
[d] Estimated by computer simulation of the vinylic signals.
[e] Assignments based on relative intensities and the known isomer ratio (**2**:**1** = 4.5), as well as by analogy, using methylcyclopentadiene spectra as models (11).

Identity of Photoproduct ***3***

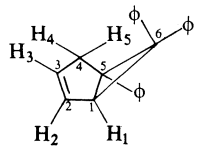
The structure of the photorearrangement product followed from molecular weight and composition data (see Experimental) and from its spectra. A cyclopropane ring was inferred from ir bands at 3.25 and 9.80 μm (12). The uv spectrum (cyclohexane, max 275 (350); plateaus 267 (850), 260 (1205) and 227 nm (ε 20 153)) is similar to that of 6,6-diphenylbicyclo[3.1.0]hex-2-ene (13) (uv, cyclohexane, max 276 (700); plateaus 268 (1145), 260 (1560), and 227 nm (ε 12 800)) and indicated that the cyclopropane ring bears two or more phenyl substituents. Particularly useful in the structure elucidation were the ^{1}H and ^{13}C nmr spectra (Table 2). Off-resonance decoupling of the ^{13}C spectrum showed that the four high-field signals must be attributed to two quaternary, one tertiary, and one secondary carbon. Decoupling of the ^{1}H spectrum showed that the methine proton resonating at 3.21 δ is coupled weakly (1.5 Hz) to the methylene protons. That feature rules out the isomeric 1,6,6-triphenylbicyclo[3.1.0]hex-2-ene (**5**), in which the methine and methylene protons would be vicinally coupled. Model bicyclo[3.1.0]hex-2-enes show approximately 7 Hz coupling to one of the methylene protons and 0–2 Hz coupling to the other (14, 15). In the case of accidental magnetic equivalence of the methylene protons, one would expect the vicinal coupling constant to the cyclopropyl proton to be of 3–4 Hz magnitude. Clearly, the observed spectrum is not compatible with structure **5** but does fit **3**.

Bicyclo[2.1.1]hexene system **4** can be ruled out, not only on the basis of the ir and uv data cited above but also on the basis of the ^{1}H spectrum, in which one would expect to see strongly differentiated methylene protons.

Photochemistry

Direct irradiation of a solution of **1** and **2** in benzene (see Experimental) yielded **3** cleanly, with 45% conversion. Chromatographic separation of unreacted starting material revealed that the latter was depleted in isomer **1** (**2**:**1** $\geqslant$ 10).

TABLE 2. Nuclear magnetic resonance spectra of **3**



Nucleus	Chemical shift (δ)[a]	*J*(Hz)
H_1	3.21 q[b]	$J_{1,2} = 2.0, J_{1,3} \simeq 0.0$
H_2	5.91 m	$J_{1,4} = J_{1,5} = 1.5$
H_3	5.19 m	$J_{2,3} = 5.5, J_{2,4} = J_{2,5} = 2.0$
H_4, H_5	2.83 q[b]	$J_{3,4} = J_{3,5} = 2.0$

[d]C_2 and C_3 signals mixed in with aromatics.

Control experiments showed that **1** and **2** elute together from the column that was employed and that the chromatographic process itself did not alter the ratio (**2**:**1** ≃ 4.5) in an unirradiated sample. The simplest explanation for the change in isomer ratio as a result of irradiation is that **1** is more reactive than **2** in the di-π-methane rearrangement. The fact that only one product (**3**) was detectable suggests that **2** does not undergo any photorearrangement on direct irradiation, with the possible exception of [1,3]-sigmatropic shifts which would interconvert it with **1**.

Formation of **3** can be interpreted in terms of the di-π-methane rearrangement (8, 16). The process is most easily visualized in terms of diradical intermediates [1] although such pictures do not necessarily represent actual minima on the potential energy surface but are more likely points on the energy surface of a concerted process (8, 16, 17). The fact that **4** is not obtained is understandable because the 1,5-overlap required to reach it is expected to be poor, relative to 1,3-overlap required in the transition state leading to **3** (eq. 2, arbitrary numbering in bracketed structure). A diradical representation is also useful for rationalizing the inefficient di-π-methane rearrangement of **2**, for which an unconjugated, as opposed to an allylic, radical site develops along the reaction coordinate [2].

Acetophenone sensitized reaction of **1** and **2** led to **3** and two other major products. Although the latter were not separated from each other, analyses and osmometric molecular weight determination of the mixture indicated that they are dimers of **1** and/or **2**. A melting point determination on a microscope-equipped hot stage showed two crystalline solids melting at 199 and 234 °C, respectively.

Sensitized photodimerization of cyclopentadiene to form both the *exo* and *endo* (4 + 2) cycloadducts as well as a (2 + 2) cycloadduct has been reported (18) and sensitized addition of cyclopentadiene to alkenes, such as *cis*- and *trans*-but-2-ene is also well known (19). Formation of dimers from use of a triplet sensitizer in the present case was therefore expected and the interesting results are, first, that only two of the many possible dimers can be detected and, second, that **3** is formed. The former result can be attributed to the large steric requirements of the trityl groups which would make for exceedingly crowded transition states for some potential cycloadditions. The latter result implies that both the singlet and the triplet excited states of **1** undergo the di-π-methane rearrangement. Sensitized reaction must involve the triplet, for the sensitizer absorbs nearly all of the light and the products include dimers typical of triplet diene reactions. Unsensitized rearrangement could also involve the triplet as the rearranging species but, if that were the case, dimers should be formed in that reaction also. We conclude that the singlet of **1** undergoes rearrangement more rapidly than intersystem crossing, that the triplet of **1** undergoes the same rearrangement in competition with intermolecular cycloadditions, and that neither excited state of **2** rearranges. Presumably, the triplet of **2** also adds to **1** and/or **2**.

Generalizations concerning structure–multiplicity relationships for the di-π-methane rearrangement have been proposed by Zimmerman and co-workers (8, 17). They proposed that an unconstrained system (*e.g.* one having at least one of the π-moieties capable of causing geometric change via rotation) is capable of fast deactivation of its triplet excited state. That deactivation stops (or slows) rearrangement and such a system therefore rearranges from the singlet state only. A constrained di-π-methane, being unable to deactivate as rapidly after intersystem crossing, does rearrange from the triplet state. It may or may not rearrange to the same product from the singlet state, depending on what other singlet reactions are possible.

At least one example has been reported of a

system which undergoes di-π-methane rearrangement from both the singlet and the triplet manifolds (20). Compound **1** appears to be another system which behaves in that way.

We do not have an explanation for the apparent failure of **1** and/or **2** to form bicyclo[2.1.0] hex-2-enes [1] in the direct irradiation. For the case of **1**, the alternative di-π-methane reaction may simply be faster but that rationale is an unlikely one for the case of **2**, which does not undergo di-π-methane rearrangement. One possibility is that some or all of the substituted bicyclo[2.1.0]hex-2-enes [1] are simply too labile, thermally, to accumulate to detectable concentration levels.

Experimental

Triphenylmethylcyclopentadienes (1 and 2)

Treatment of cyclopentadienyl magnesium bromide, prepared from cyclopentadiene (10.0 g, 0.15 mol) and a slight excess of ethylmagnesium bromide, with triphenylchloromethane (26.0 g, 0.095 mol) as described in the literature (3) afforded a mixture of **1** and **2** (11.5 g, 40%), mp 197–199 °C after crystallization of the crude product from benzene. The pmr spectrum consisted of signals at δ 2.89 (m), 3.03 (m), 6.08 (m), 6.10–6.39 (m), and 7.15 (s). Integration of the signals at 2.89 and 3.03 δ, attributable to **1** and **2**, respectively, gave the ratio **2**:**1** = 4.5.

Reaction with Tetracyanoethylene (6)

A mixture of **1** and **2** (**2**:**1** ≃ 4.5) (0.500 g, 1.62 mmol) in dry benzene (8 ml) was added during 10 min to a stirring solution of **6** (0.209 g, 1.63 mmol) in dry benzene (7 ml), at 20 °C. After a further 20 min an aliquot was removed and the solvent was evaporated from it at reduced pressure. The pmr spectrum ($CDCl_3$) had, in addition to the signals listed below for **7**, a signal at 2.89 δ but none at 3.03 δ. An aliquot taken after 4 days did not absorb at 2.89 δ. Evaporation of the solvent from the main reaction mixture at that time afforded a residue which was recrystallized from benzene – petroleum ether to yield 0.576 g (82%) of **7** as colorless crystals: mp, decomposition at 206 °C; pmr ($CDCl_3$, δ) 2.38 (AB quartet, 2H, J_{AB} = 11.4 Hz, additional fine coupling, H_7), 3.95 (m, 1H, H_4), 4.44 (m, 1H, H_1), 6.13 (m, 1H, H_3), 7.05–7.40 (m, 15H); ^{13}C nmr ($CDCl_3$, δ, off resonance decoupled) 58.78 (d, C_1), 55.88 (d, C_4), 46.85 (s, C_5 or C_6), 47.98 (s, C_6 or C_5), 48.89 (t, C_7), 109.82, 111.47, 112.06, and 112.22 (s, CN), 63.39 (s, ϕ_3C). *Anal.* calcd. for $C_{30}H_{20}N_4$: C 82.54, H 4.62, N 12.84; found: C 82.23, H 4.85, N 12.99.

Direct Irradiation of 1 and 2

A Hanovia type L 450 W lamp was used in a water-cooled, quartz immersion apparatus fitted with magnetic stirrer and argon purging tubes. In a typical experiment, the mixture of **1** and **2** (2.05 g, 6.7 mmol) in 400 ml of cyclohexane (spectroquality, Matheson, Coleman and Bell) was irradiated for 12 h. The solvent was distilled off at reduced pressure and the orange residue was chromatographed on silica gel (Woelm, activity grade 1, 2.2 × 33 cm column) using CCl_4 as eluant. Product **3**, still contaminated with a trace of starting material, was further purified by preparative thin layer chromatography (silica gel, 50:50 hexane–cyclohexane). Crystallization from benzene gave **3** as colorless prisms: mp 108–109 °C; molecular ion (*m/e*) 308; ir (CCl_4 and CS_2) 3.27, 3.30, 13.21, 13.61, 13.87, 14.34, and 14.53 (strong), 3.24, 3.44, 6.28, 6.74, 9.38 and 9.80 (medium), 3.53, 7.04, 7.30, 7.48, 7.58, 7.67, 7.87, 8.62, 8.78, 9.94, 10.72, 10.87, 10.99, 11.11, 12.69, and 12.85 μm (weak). *Anal.* calcd. for $C_{24}H_{20}$: C 93.46, H 6.54, found: C 93.18, H 6.50. The nmr spectra of **3** are in Table 2.

Sensitized Irradiation of 1 and 2

The apparatus was the same as that described above except for a Pyrex sleeve around the lamp. A solution of **1** and **2** (10.0 g, 29.2 mmol) and freshly-distilled acetophenone (5.03 g, 41.8 mmol) in 500 ml of benzene was irradiated for 12 h. Vacuum distillation of the solvent and tlc of the residue showed four components, two of which were acetophenone and starting material (**1** and **2**). Column chromatography on neutral Alumina (80–200 mesh, Brockman, activity grade 1, 4.0 × 63 cm column) with hexane–cyclohexane (50:50) separated **1** and **2** (together) from the other components. A second component was eluted with 10% benzene – 90% hexane, and was followed by a fraction containing a third component contaminated with the second. That fraction was rechromatographed on a 2.2 × 55 cm column to yield pure third component.

Recrystallization of the second component from benzene gave colorless prisms of **3**, mp 108–109 °C, spectra as described above. Recrystallization of the third component from benzene gave granular crystals: mp 199–234 °C; mw (osmometric) 616, mw (ms) 616 (parent ion). Examination of the crystals with a microscope (Kofler hot stage) revealed two distinct types with sharp melting points of 199 and 234 °C.

Acknowledgments

The authors are grateful to Mr. Brian Sayer for the nmr spectra and to the National Research Council of Canada for financial support.

La formation de biphénylènes par pyrolyse de mélanges de précurseurs de benzynes

ANDRÉ MARTINEAU ET DON C. DEJONGH[1]

Département de chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Reçu le 25 mai 1976

ANDRÉ MARTINEAU et DON C. DEJONGH. Can. J. Chem. **55**, 34 (1977).

Nous décrivons une nouvelle méthode d'obtention des biphénylènes substitués sur un cycle. La pyrolyse en phase gazeuse de mélanges de précurseurs de benzynes appropriés est utilisée pour ces synthèses. La rencontre de deux benzynes provenant de sources différentes conduit à la formation des dits biphénylènes. Les divers composés sont sublimés dans un courant d'azote, puis entraînés dans une colonne de quartz non garnie, chauffée extérieurement par un four.

La pyrolyse simultanée de la ninhydrine et de l'anhydride tétrachlorophtalique (rapport molaire 2:1), à 800 °C, donne le tétrachloro-1,2,3,4 biphénylène avec un rendement de 31%. La pyrolyse du mélange anhydride phtalique – anhydride méthyl-4 phtalique, à 850 °C, conduit à la formation du méthyl-2 biphénylène (rapport molaire 9:1) (16%).

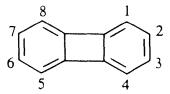
ANDRÉ MARTINEAU and DON C. DEJONGH. Can. J. Chem. **55**, 34 (1977).

A new method of forming biphenylenes substituted on one ring is described using gas-phase pyrolysis of mixtures of precursors of appropriate benzynes. The reaction of two benzynes coming from two different sources leads to the formation of the biphenylenes. The mixture of compounds is sublimed into a current of nitrogen and led into an unpacked quartz column heated externally by a furnace.

The simultaneous pyrolysis of ninhydrin and tetrachlorophthalic anhydride (molar ratio, 2:1) at 800 °C gives 1,2,3,4-tetrachlorobiphenylene in a 31% yield. The pyrolysis of a mixture of phthalic anhydride and 4-methylphthalic anhydride at 850 °C leads to the formation of 2-methylbiphenylene (molar ratio, 9:1) (16%).

Introduction

Plusieurs méthodes d'obtention des biphénylènes sont connues dans la littérature; trois d'entre elles sont retenues pour l'intérêt qu'elles ont suscité chez plusieurs chercheurs. La première méthode fut proposée par Lothrop. Il obtint le biphénylène (**1**) par distillation du diiodo-2,2′ biphényle sur de l'oxyde cuivreux (1). Par la suite, certains biphénylènes substitués ont été obtenus par cette méthode (2–7).

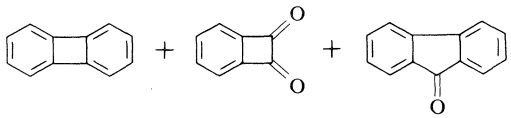


1

La deuxième méthode concerne la substitution électrophile sur le biphénylène. Un grand nombre de biphénylènes nouveaux ont pu être obtenus de cette façon (3, 8–10). Il faut cependant noter que les règles de substitutions ne permettent que la synthèse de certains biphénylènes.

Vers 1965, certains chercheurs ont commencé à préparer le benzyne dans la phase gazeuse par pyrolyse à haute température de produits simples. Brown et Solly ont fait la pyrolyse en phase gazeuse de l'indanetrione (**2**) dans une colonne de quartz garnie d'hélices de Pyrex (11, 12). À 600 °C sous une pression de 0.2 torr, ils ont obtenu le biphénylène avec un rendement de 40%; le biphényle, le naphtalène, le fluorène, le phénanthrène, l'anthracène et le triphénylène furent aussi présents. La même pyrolyse à 500 °C a conduit à la formation du biphénylène (17%), de la benzocyclobutènedione (**3**) (11%) et de la fluorènone (**4**) (1.2%) [1].

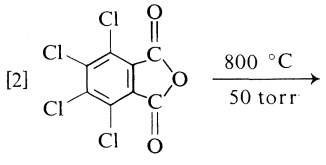
[1] 
2



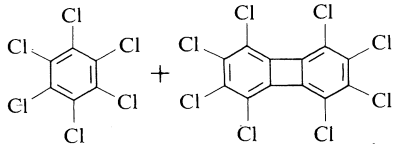
1 (17%) **3** (11%) **4** (1.2%)

[1]A qui toute demande d'information devra être adressée.

D'autre part, Cava *et al.* ont entrepris la pyrolyse des anhydrides phtalique (**5**), tétrachlorophtalique (**6**) et tétrabromophtalique (13). Les pyrolyses furent faites dans un courant d'azote, les anhydrides étant entraînés sur un fil de Nichrome chauffé à 800 °C. Pour la pyrolyse de l'anhydride phtalique (**5**), un rendement de biphénylène situé entre 10 et 15%, basé sur l'anhydride non récupéré (33% récupéré), fut obtenu. La pyrolyse de l'anhydride tétrachlorophtalique (**6**) dans les mêmes conditions a conduit à la formation de l'hexachlorobenzène (**7**) (34%) et de l'octachlorobiphénylène (**8**) (30%), éq. 2. Enfin, la pyrolyse de l'anhydride tétrabromophtalique n'a conduit qu'à la formation de l'hexabromobenzène (20%).



6

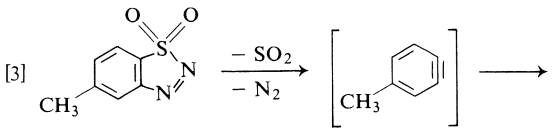


7 (34%) **8** (30%)

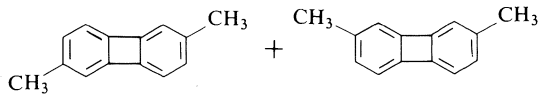
Brown et coll. ont aussi fait la pyrolyse de l'anhydride phtalique (14, 15). Leur pyrolyse a été faite dans une colonne non garnie, à 760 °C, sous une pression de 0.3 torr, et a conduit à la formation du biphénylène (9%), du triphénylène (1.5%) et de petites quantités de naphtalène, de biphényle et de fluorène; 71% du produit de départ a été récupéré. A 830 °C, dans les mêmes conditions, le rendement de biphénylène monte à 17% et les produits mineurs sont presque absents.

La pyrolyse de certains anhydrides phtaliques substitués a été faite et les biphénylènes correspondants ont été obtenus (15). Ainsi furent obtenus le dichloro-2,6 (15%), le tétrachloro-2,3,6,7 (6.5%), le tétrachloro-1,4,5,8 (4%), l'octachloro (**8**) (26%) et le tétraméthyl-2,3,6,7 (3%) biphénylène. D'autre part, parmi les composés polycarbonylés, la pyrolyse de l'anhydride *o*-sulfobenzoïque (15) a été faite. A 730 °C, dans une colonne garnie de tubes de quartz, le biphénylène a été obtenu; un rendement de 5.5% a été calculé.

On trouve dans la littérature d'autres préparations de biphénylènes par pyrolyse de composés précurseurs de benzyne ou du diradical-2,2′ biphényle (16–21). Par exemple, la pyrolyse du dioxyde-1,1 de méthyl-5 benzothiadiazole (**9**) conduit à la formation des diméthyl-2,6 (**10**) et diméthyl-2,7 (**11**) biphénylènes (17), [3]. Aussi, Adger *et al.* ont fait la pyrolyse de benzotriazines-1,2,3 (21). Ils pensaient obtenir les benzazètes correspondants, mais ont obtenu le biphénylène.



9



10 **11**

Fields et Meyerson ont fait la pyrolyse de plusieurs anhydrides aromatiques et hétérocycliques, dans le benzène et la pyridine (22). La formation de produits formés par réaction des benzynes avec le solvant a été constatée.

Parmi les différentes méthodes énumérées jusqu'ici impliquant la pyrolyse en phase gazeuse, on remarque que toutes impliquent la décomposition d'un seul composé à la fois. Ceci a pour effet de conduire à la formation du biphénylène, quand le produit de départ n'est pas substitué, et, dans le cas contraire, à la formation de biphénylènes substitués symétriquement sur les deux cycles.

Partant de ce que l'obtention des différents biphénylènes se fait par un intermédiaire benzyne, nous nous sommes proposés d'obtenir certains biphénylènes substitués sur un cycle par pyrolyse de mélange de diverses sources de benzyne et de benzynes substitués.

Partie théorique

Notre démarche nous a d'abord conduit à examiner deux sources de benzyne: les pyrolyses de l'anhydride phtalique (**5**) et de la ninhydrine (**12**) ont été faites à différentes températures avec notre appareillage. Nous avons ensuite entrepris la pyrolyse de deux anhydrides phtaliques substitués; dans un premier cas, les halogènes sont utilisés comme substituants et, dans l'autre, un groupement aliphatique. Ainsi, les pyrolyses des

anhydrides tétrachlorophtalique (**6**) et méthyl-4 phtalique (**13**) ont été faites pour examiner leur comportement individuel avec la chaleur. En dernier lieu, la pyrolyse d'un mélange composé de ninhydrine et d'anhydride tétrachlorophtalique a été entreprise d'une part et, d'autre part, la pyrolyse du mélange anhydride phtalique – anhydride méthyl-4 phtalique. La pyrolyse se produit dans un courant d'azote; les produits sont condensés dans une série de trappes refroidies et, par la suite, sont analysés dans la plupart des cas par cpg.

Sources de benzyne

Nous avons décidé de réexaminer le comportement de l'anhydride phtalique (**5**) avec la chaleur dans les conditions dictées par notre appareillage. La pyrolyse du composé **5** a été faite à différentes températures. Les produits obtenus à 825 °C sont des traces de naphtalène et de fluorène, le biphénylène (5%) et de l'anhydride phtalique récupéré. Ceci représente le meilleur rendement de **1** que nous ayions obtenu à partir de **5** seul. Donc nos résultats montrent des rendements de biphénylène assez faibles. L'augmentation de la température de pyrolyse fait se consommer plus de produit de départ, sans pour autant augmenter de façon appréciable les rendements de **1**. D'autre part, les rendements de **1** sont plus petits que ceux obtenus (15%) par Cava *et al.* à 800 °C avec le fil de Nichrome (13).

Comme deuxième source de benzyne, nous avons examiné la pyrolyse de la ninhydrine (**12**). On trouve dans la littérature la pyrolyse du composé **12** sous sa forme déshydratée (indanetrione-1,2,3 (**2**)), (11, 12). Nous avons tout de même pyrolysé le composé **12**, en supposant que la déshydratation se ferait "in situ" et que l'eau ainsi formée ne gênerait pas la formation du biphénylène.

A 700 °C, le composé **1** uniquement est obtenu (40%), tandis qu'à 800 °C, c'est encore le seul produit obtenu mais son rendement diminue (32%). Lorsque la pyrolyse est faite à 600 °C, deux produits sont présents: le composé **1** avec un rendement de 19%, inférieur à ce qu'il est à 700 °C, et la benzocyclobutènedione (**3**) (39%). Dans chacun des cas, aucun produit de départ n'est récupéré. Ceci est en accord avec les résultats obtenus par Brown et Solly (11, 12).

Sur la base de ces résultats, il ressort que la ninhydrine (**12**) est un meilleur précurseur de benzyne que l'anhydride phtalique (**5**) dans le cas de notre appareillage. De plus, la pyrolyse du composé **12** se fait à des températures plus basses et avec une efficacité plus grande, si l'on tient compte du produit de départ récupéré. Etant donné ces résultats, le plus grand intervalle de température dans lequel le composé **12** se pyrolyse peut être une variable importante dans la pyrolyse de mélanges.

Pyrolyse des anhydrides substitués

La pyrolyse de l'anhydride tétrachlorophtalique (**6**) est déjà connue dans la littérature (13, 15). Dans un premier cas, un fil de Nichrome chauffé à 800 °C est utilisé (13). Les produits obtenus sont l'hexachlorobenzène (**7**) et l'octachlorobiphénylène (**8**) avec des rendements respectifs de 34% et 30%. Dans un autre cas, la pyrolyse a été faite à 700 °C avec une colonne de quartz garnie (15). Les mêmes produits sont obtenus; des rendements respectifs de 31% et 26% ont été calculés pour les composés **7** et **8**. Avant de faire la pyrolyse de mélange impliquant la ninhydrine et l'anhydride tétrachlorophtalique, nous avons voulu refaire la pyrolyse du composé **6** pour vérifier si les mêmes produits sont obtenus dans les conditions dictées par notre appareillage.

La pyrolyse du composé **6** a été faite à 800 °C. Les produits obtenus les plus importants sont l'hexachlorobenzène (**7**, 44%) et l'octachlorobiphénylène (**8**, 32%). Les produits mineurs sont le pentachlorobenzène (3%) et le décachlorobiphényle (3%).

Un deuxième anhydride substitué a été examiné; le choix de l'anhydride méthyl-4 phtalique (**13**) a été fait. Nous voulions voir si la différence des substituants pouvait faire varier les conditions d'obtention des biphénylènes substitués sur un cycle. La démarche entreprise pour l'anhydride tétrachlorophtalique a été utilisée à nouveau. Une pyrolyse du composé **13** seul a été faite pour voir si le biphénylène correspondant était obtenu. Le choix de la température a été fait par analogie avec les résultats obtenus pour les pyrolyses des composés **5** et **6**.

Ainsi, la pyrolyse de l'anhydride **13** a été faite à 825 °C. A cette température, une grande partie du produit de départ est récupérée. Le diméthylbiphénylène a, d'autre part, été obtenu. La pyrolyse du dioxyde-1,1 de méthyl-5 benzothiadiazole (**9**) passe par le même intermédiaire, méthyl-4 benzyne, que dans notre cas et conduit à la formation des composés **10** et **11** (17). Sur

cette base, nous supposons que ces deux isomères sont aussi présents dans nos produits de pyrolyse. De plus, le diméthylfluorène a été obtenu. Sur la même base que précédemment, nous présumons que trois isomères sont présents. Aucune détermination des quantités de produits n'a été faite, puisque le but de cette pyrolyse était de voir si le biphénylène attendu était formé. Cependant, on remarque en plus d'une grande récupération du produit de départ qu'on obtient d'après le chromatogramme, une quantité relativement grande de diméthylbiphénylène. Les quantités relatives de diméthylfluorène sont plus petites.

Compte tenu que les biphénylènes désirés ont été formés, nous avons été encouragés à faire les pyrolyses de mélanges. Les températures utilisées, 800 °C pour le composé **6** et 825 °C pour l'anhydride **13**, serviront de base pour les pyrolyses de mélanges.

Pyrolyse des mélanges

Notre première préoccupation dans la pyrolyse des mélanges est de trouver les conditions de température maximales pour l'obtention des biphénylènes substitués sur un cycle. Concernant la synthèse du tétrachloro-1,2,3,4 biphénylène (**14**), nous nous sommes basés sur les résultats obtenus pour les pyrolyses des composés seuls. Les rendements élevés du biphénylène dans la pyrolyse de la ninhydrine à 700 et 800 °C, et l'absence de l'anhydride tétrachlorophtalique récupéré dans la pyrolyse de ce dernier à 800 °C, nous ont conduits à faire la pyrolyse du mélange de ces composés à 800 °C. Des pyrolyses qualitatives ont cependant été faites pour s'assurer de la validité de notre choix. Des quantités relatives maximums du composé **14** sont obtenues pour des températures de pyrolyse de 750 et 800 °C. On note cependant à 750 °C la présence de l'anhydride tétrachlorophtalique dans les produits de pyrolyse; à 800 °C, aucune quantité de composé **6** n'est récupérée. La pyrolyse quantitative du mélange des composés **6** et **12** a donc été faite à 800 °C (voir tableau 1).

Une investigation sur le rendement du composé **14** en fonction des proportions relatives de chacun des composés de départ a été faite. Des mélanges de composés **6** et **12** ont été pyrolysés à 800 °C avec des rapports molaires respectifs de 1:2, de 1:3 et de 1:9; les résultats sont résumés dans le tableau 1. Parmi les produits obtenus, les plus importants sont le biphénylène (**1**) et le tétrachloro-1,2,3,4 biphénylène (**14**). Les produits mineurs sont le tétrachloro-1,2,3,4 naphtalène (**15**), l'octachlorobiphénylène (**8**) et le décachlorobiphényle. Ces produits sont en accord avec les résultats attendus (schéma 1).

Uniquement les rendements des produits **1** et **14** ont été calculés. Bien qu'aucune détermination précise de la quantité de tétrachloro-1,2,3,4 naphtalène (**15**) n'ait été faite, elle est apparue environ six fois plus petite que la quantité de produit **14**, indépendamment du rapport des composants du mélange.

On note que le rendement de biphénylène augmente avec la quantité de ninhydrine initialement pesée. D'autre part, on constate que le rendement de tétrachloro-1,2,3,4 biphénylène (**14**) ne varie pas avec le pourcentage de ninhydrine employée.

On note dans la pyrolyse d'un même mélange, un certain écart dans la reproductibilité des résultats. Nous sommes portés à croire que le facteur responsable de ces différences est la sublimation individuelle des composés formant le mélange. La synthèse du tétrachloro-1,2,3,4 biphénylène implique la rencontre de benzynes provenant de sources différentes et une variation dans la sublimation aura un effet sur les rendements des produits obtenus. Cet effet est dû à ce que les composés formant le mélange ne se subliment pas à la même température.

Quand nous avons entrepris la pyrolyse d'un mélange conduisant à la formation du méthyl-2 biphénylène (**16**), nous nous sommes d'abord intéressés à la température à laquelle il faudrait pyrolyser ce mélange. La ninhydrine (**12**) s'étant avérée une meilleure source de benzyne que l'anhydride phtalique dans nos pyrolyses préliminaires, nous avions pensé l'utiliser à nouveau dans la pyrolyse impliquant l'anhydride méthyl-4 phtalique (**13**). Le choix de la température pour la pyrolyse du mélange ninhydrine – anhydride méthyl-4 phtalique a été fait sur la base des résultats obtenus pour les pyrolyses des composés seuls. La présence satisfaisante des diméthylbiphénylènes dans les produits de la pyrolyse du composé **13** à 825 °C et le rendement important de biphénylène (32%) dans la pyrolyse du composé **12** à 800 °C nous ont conduits à pyrolyser le mélange de ces deux composés à 825 °C.

En se basant sur les résultats obtenus dans la section précédente, la quantité de ninhydrine employée dans une première pyrolyse a été mise

TABLEAU 1. Pyrolyses du mélange ninhydrine (**12**) – anhydride tétrachlorophtalique (**6**)*

SCHÉMA 1

au double de celle de l'anhydride. L'analyse des produits de pyrolyse a montré la présence d'une faible quantité de méthyl-2 biphénylène. Aucune étude quantitative n'a été faite dans ce cas. Nous avions noté, au cours de la pyrolyse, que l'anhydride **13** se sublimait en premier et que le composé **12** (après déshydratation "in situ") se sublimait beaucoup plus tard. Cette observation expliquait en quelque sorte pourquoi si peu de méthyl-2 biphénylène avait été formé.

TABLEAU 2. Pyrolyse du mélange anhydride phtalique (**5**) – anhydride méthyl-4 phtalique (**13**)*

*Ces pyrolyses ont été faites à 850 °C sous une pression de 0.2 torr avec un débit d'azote de 90 ml/min.
†Ces rendements sont basés sur les quantités d'anhydride phtalique non récupérées.
‡Ces rendements sont basés sur les quantités d'anhydride méthyl-4 phtalique non récupérées.
§Les temps de rétention du fluorène, formé dans les pyrolyses conduisant au benzyne (11, 12, 15) et de **16** se recouvrent sur plusieurs colonnes.

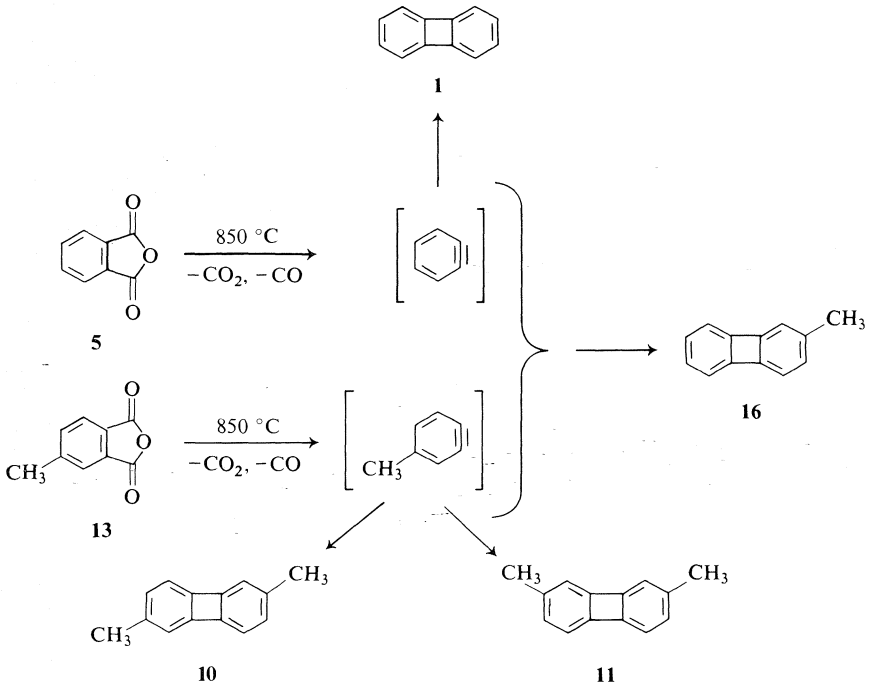

SCHÉMA 2

Les contraintes de la sublimation des produits de départ nous ont conduits à remplacer la ninhydrine dans le mélange par l'anhydride phtalique. De nouvelles conditions de température ont dû être choisies. Les grandes quantités de produit de départ récupéré dans les pyrolyses séparées des anhydrides **5** et **13** à 800 et 825 °C nous ont amenés à penser que la pyrolyse devrait se faire à une température supérieure; une température de 850 °C a été choisie. On avait constaté, dans la pyrolyse du composé **5** à 850 °C, que le rendement de biphénylène était le même que celui obtenu à 825 °C; de plus, la quantité d'anhydride récupéré avait grandement diminué en passant d'une température à l'autre.

La pyrolyse du mélange anhydride phtalique – anhydride méthyl-4 phtalique a été faite à 850 °C et les deux anhydrides ont été pesés pour qu'un rapport molaire de ceux-ci soit de 3:1 respectivement; les résultats sont résumés dans le tableau 2. Les produits obtenus sont le biphénylène (**1**), le méthyl-2 biphénylène (**16**) et un mélange de diméthyl-2,6 (**10**) et diméthyl-2,7 (**11**) biphénylènes. Certaines quantités des deux produits de départ ont été récupérées. Les produits sont en accord avec les résultats attendus (schéma 2).

Dans cette dernière pyrolyse la quantité de diméthylbiphénylène est relativement grande par rapport à celle du méthyl-2 biphénylène. C'est pourquoi nous avons fait une pyrolyse où les

deux composants du mélange sont présents dans un rapport molaire de 9:1. Les mêmes produits sont obtenus mais avec des rendements différents; les résultats sont résumés dans le tableau 2.

Conclusions

La synthèse des biphénylènes substitués sur un cycle implique la rencontre de benzynes provenant de sources différentes. Partant de ce fait, il est important que les deux produits de départ entrent dans la zone de pyrolyse en même temps, comme mis en évidence avec la pyrolyse du mélange impliquant l'anhydride méthyl-4 phtalique. Quand la ninhydrine est employée pour l'obtention du méthyl-2 biphénylène, le trop grand écart dans les températures de sublimation des deux produits fait que ceux-ci entrent successivement dans la zone de pyrolyse. De ce fait, la différence des températures de sublimation des produits formant le mélange est plus importante que le rendement des produits attendus dans les pyrolyses individuelles.

D'autre part, on a pu remarquer avec les résultats obtenus pour les pyrolyses de chaque mélange que dans le premier cas, le rendement du biphénylène substitué sur un cycle ne dépend pas du rapport molaire des deux composants du mélange et que dans l'autre cas, ce rendement varie avec le rapport molaire des deux anhydrides de départ. Nous pensons que le facteur important est l'efficacité de la source de benzyne à se fragmenter dans la zone de pyrolyse. En effet, dans le cas où la ninhydrine est employée, la fragmentation efficace de cette dernière fait que la concentration de benzyne présent dans la zone de pyrolyse est grande même si peu de ninhydrine est employé. Dans le cas où l'anhydride phtalique est utilisé, il faut une quantité plus grande de ce dernier pour que la même quantité de benzyne obtenue avec une quantité moindre de ninhydrine soit présente dans la zone de pyrolyse.

Somme toute, la méthode que nous avons décrite comporte des avantages et des désavantages. Les principaux avantages de notre méthode sont qu'elle utilise comme source de benzynes des produits commerciaux facilement accessibles et que la synthèse des biphénylènes substitués sur un cycle se fait en une étape. Pour ces raisons, si l'on considère en plus les rendements, notre méthode est plus avantageuse que celle proposée par Lothrop (1, 2). Un des principaux désavantages de la méthode est qu'il nous est impossible d'utiliser des anhydrides phtaliques dont le substituant se décompose pendant la pyrolyse; ainsi les anhydrides portant un groupement nitro ne pourront être utilisés.

Les contraintes de notre montage font que seulement 1 à 2 g de mélange peuvent être pyrolysés à la fois. Ainsi l'obtention d'une grande quantité de produit nécessite plusieurs pyrolyses. Pourtant, nous n'avons pas essayé de construire un appareillage à plus grande échelle.

En conclusion, ce travail a permis d'obtenir des biphénylènes substitués sur un cycle et a permis d'ouvrir la voie pour de nouvelles synthèses de biphénylènes.

Partie expérimentale

Les spectres de masse ont été pris à basse résolution sur un appareil Hitachi modèle RMU-6D vendu par la compagnie Perkin-Elmer et/ou un appareil de la compagnie Associated Electrical Industries (A.E.I.) modèle MS-902.

Les points de fusion ont été mesurés à l'aide d'un appareil Buchi et/ou Mel-Temp; les valeurs rapportées ne sont pas corrigées.

Les spectres de résonance magnétique nucléaire du proton ont été pris sur un spectromètre Brucker de 90 MHz, modèle WH-90 fonctionnant par transformée de Fourier.

Les spectres ultraviolets ont été enregistrés sur un appareil Cary, modèle 14 et/ou 17.

Les analyses par chromatographie en phase gazeuse (cpg) ont été faites par un appareil de la compagnie Hewlett-Packard modèle 5750. Cet appareil contient deux colonnes et est muni d'un système de programmation de température. Dans la plupart de nos analyses, une colonne de cuivre mesurant 9 pieds de longueur par 0.25 po de diamètre est utilisée. Le garnissage de la colonne consiste en du SE-54, 10%, sur Chromosorb W. Une programmation de 6 °C/min de 90 à 270 °C est utilisée. Dans certains cas, une colonne mesurant 6 pieds de longueur, contenant du SE-30, 10%, sur Chromosorb W a été nécessaire. La programmation employée est la même que précédemment.

Produits

L'anhydride phtalique provient de la compagnie Matheson, Coleman et Bell. Avant son utilisation, il a été purifié par cristallisation dans un mélange benzène–éthanol. La ninhydrine a été achetée de la compagnie Pierce Chemical; les anhydrides tétrachlorophtalique et méthyl-4 phtalique proviennent de la compagnie Eastman Kodak; après vérification de leur pureté, ils ont été utilisés comme tels.

Montage et procédure

Le montage pour la pyrolyse et la procédure ont déjà été décrits précédemment (23). Le produit ou le mélange de produits est d'abord sublimé dans un courant d'azote, puis entraîné sous forme vapeur dans une colonne de quartz de ~60 cm, dont la zone chauffée par un four extérieur mesure 30 cm. La vitesse d'entrée du produit dans la zone chauffée est réglée par un débitmètre. Un vide de l'ordre de 0.1 torr est maintenu. Les produits

formés sont condensés dans une série de trappes. La colonne et les trappes sont par la suite lavées. La solution provenant du lavage est concentrée, placée dans un ballon jaugé de 25 ml et le volume total est amené jusqu'à la ligne de jauge. Les produits obtenus sont dans la plupart des cas séparés par cpg. Leurs rendements sont déterminés en comparant les surfaces sous la courbe du chromatogramme des produits de pyrolyse avec les surfaces des pics de composés standards de concentrations connues.

Sources de benzynes

Dans les pyrolyses de l'anhydride **5** et de la ninhydrine, le chloroforme et l'acétone ont été utilisés pour le lavage des trappes. Les analyses de la solution de chaque pyrolyse ont été faites par cpg en utilisant une colonne de SE-54, 10% sur Chromosorb W mesurant 9 pieds. Une programmation de 6 °C/min à partir de 90 jusqu'à 270 °C a été utilisée.

Dans la pyrolyse de l'anhydride phtalique, le chromatogramme montre la présence de trois produits dont deux d'entre eux sont l'anhydride phtalique et le naphtalène; ils ont été identifiés par leur spectre de masse (24, 25) et par leur temps de rétention qui sont identiques à ceux d'échantillons commerciaux.

Le troisième produit, un solide jaune, a été identifié comme étant le biphénylène. Le spectre de masse obtenu donne la fragmentation suivante: *m/e* (%) 153(13.7), 152(100), 151(15.1), 150(11.7), 126(6.4), 76(14.9), 75(5.7), 74(4.8), 63(9.4) (litt. (26) *m/e* (%) 153(14.0), 152(100.0), 151(18.0), 150(10.0), 126(7.1), 76(9.1), 75(4.9), 74(4.5), 63(6.0)). Un spectre ultraviolet qualitatif a été enregistré et les absorptions suivantes ont été obtenues: λ_{max} (MeOH) nm 239, 247, 327, 330, 339, 348 et 358 (litt. (3) (EtOH) 239, 248, 326, 330, 339, 343, 348, et 358). Une trace de fluorène a aussi été détectée.

Dans la pyrolyse de la ninhydrine à 700 et 800 °C, uniquement le biphénylène a été obtenu; il a été identifié par ses spectres de masse et ultraviolet. A 600 °C, en plus du biphénylène, est présente la benzocyclobutènedione. Le spectre de masse de ce dernier donne les pics suivants: *m/e* (%) 133(1.6), 132(16.3), 105(8.0), 104(78.3), 78(5.4), 77(12.4), 76(100.0), 75(10.1), 74(16.3), 73(7.7), 50(45.7). Le spectre ultraviolet qualitatif du même composé donne les absorptions suivantes: λ_{max} (MeOH) 224, 247, 284, 291, 299 (litt. (12) 225, 286, 292, 301; litt. (27) 220, 286, 292, 301).

Pyrolyse des anhydrides substitués

Pyrolyse de l'anhydride tétrachlorophtalique

Dans la pyrolyse de l'anhydride tétrachlorophtalique, le benzène et l'acétone ont été utilisés comme solvants pour le lavage des trappes. L'analyse de la solution de pyrolyse par cpg a été faite sur une colonne de SE-54, 10%, sur Chromosorb W mesurant 9 pieds, dans les mêmes conditions de programmation que précédemment.

Le chromatogramme obtenu montre la présence de deux produits dont l'hexachlorobenzène; pf 227 °C (litt. (28) pf 230 °C). Le spectre de masse d'un échantillon de ce composé a été enregistré à 70 eV; il est comparable à celui trouvé dans la littérature (29). Une série de pics dont les valeurs de *m/e* sont situées entre 282 et 292 correspond à l'ion moléculaire et ses pics isotopiques. Le calcul des intensités relatives des pics isotopiques de l'ion moléculaire montre que le composé possède 6 atomes de chlore (30). Le même calcul fait pour les ions fragments indique la perte respective de 1, 2 et 3 atomes de chlore.

Le second produit est le pentachlorobenzène; pf 85 °C (litt. (31) pf 86 °C). Le spectre de masse de ce composé, un solide de couleur blanche a été pris à 70 eV. Une série de pics dont les valeurs sont situées entre 248 et 256 correspond à l'ion moléculaire et ses pics isotopiques. Le calcul des intensités relatives des pics isotopiques de l'ion moléculaire montre que le composé possède 5 atomes de chlore (30). Les autres séries de pics correspondent à la perte respective de 1, 2, 3 et 4 atomes de chlore.

La prise de spectres de masse du mélange de pyrolyse, en fonction de la température, nous a permis de détecter la présence de l'octachlorobiphénylène et du décachlorobiphényle.

Par la suite, nous avons fait la sublimation du mélange des produits de pyrolyse. Après avoir chauffé le mélange à 90 °C sous la pression atmosphérique, une première fraction contenant l'hexachlorobenzène et le pentachlorobenzène a été recueuillie. Le poids de cette fraction a été déterminé et les quantités respectives de chacun des composés ont été trouvées par calcul du rapport des surfaces sous la courbe du chromatogramme. Le résidu a été par la suite sublimé à 120 °C sous une pression de 0.6 torr; une deuxième fraction contenant l'octachlorobiphénylène et le décachlorobiphényle a été recueuillie.

Le spectre de masse de la deuxième fraction à 70 eV montre la présence d'une série de pics entre *m/e* 424 et 434 ainsi qu'entre *m/e* 494 et 506. L'intensité relative des deux massifs varie avec le temps indiquant la présence de deux produits. Le spectre ultraviolet de cette fraction donne les absorptions suivantes: λ_{max} (dioxanne) nm 224, 243, 265, 278, 288, 302, 324, 333, 350, 370, 392, 425, 450. Le spectre ultraviolet de l'octachlorobiphénylène est donné dans la littérature (13): λ_{max} (dioxanne) 225, 243, 268, 279, 290, 354, 375, 393, 428, 452. De même le spectre ultraviolet du décachlorobiphényle est connu (32): λ_{max} (isooctane) nm 280, 292, 301.

Les quantités relatives de l'octachlorobiphénylène et du décachlorobiphényle ont été calculées par spectrométrie de masse à 11 eV. La méthode consiste à enregistrer des spectres de masse du mélange à 11 eV à partir du moment de son introduction dans l'appareil jusqu'à disparition presque complète des pics de chaque composé; l'étape suivante consiste à faire un graphique donnant l'intensité des ions en fonction du temps et ceci pour chaque produit. Etant donné que le nombre d'atomes de chlore dans chaque molécule est différent, nous avons additionné les intensités de tous les pics formant chaque massif pour fin de comparaison. Le rapport des quantités respectives est de 9:1 pour l'octachlorobiphénylène et le décachlorobiphényle respectivement.

Pyrolyse de l'anhydride méthyl-4 phtalique

La pyrolyse de l'anhydride méthyl-4 phtalique a été faite à 825 °C, avec un débit d'azote de 90 ml par min, sous une pression de 0.3 torr. Le benzène et l'acétone ont été utilisés comme solvants pour le lavage des trappes. Les analyses de cpg ont été faites en utilisant une colonne de SE-54, 10% sur Chromosorb W; les conditions de programmation sont les mêmes que précédemment.

Le chromatogramme montre la présence de trois produits. Le premier composé est l'anhydride méthyl-4 phtalique; son pf est de 88 °C (litt. (33) pf 88.5–89 °C). Le spectre de masse de ce composé pris à 20 eV montre trois pics; *m/e* (%) 162(23.3), 118(100), 90(27.8). Le spectre de masse pris à 70 eV donne la fragmentation suivante:

m/e (%) 163(1.8), 162(16.1), 119(8.8), 118(100.0), 91(5.6), 90(67.1), 89(48.4), 88(0.6), 87(1.1), 86(1.6), 85(1.2), 77(0.6), 76(0.2), 75(1.2), 74(2.4), 73(0.5), 64(6.3), 63(22.1), 62(9.6), 61(2.9), 51(4.2), 50(7.9).

Le deuxième produit est le diméthylbiphénylène. Un spectre de masse de ce produit a été enregistré à 70 eV: *m/e* (%) 181(14.3), 180(100.0), 179(30.0), 178(24.4), 177(7.0), 176(8.7), 166(11.1), 165(58.5), 164(4.2), 163(6.6), 162(6.3), 90(18.8), 89(27.2), 88(9.8), 87(5.6), 86(3.5), 64(3.9), 63(15.7), 62(5.9). Le spectre de rmn montre un singulet à δ 2.15 ppm (6H) et un singulet élargi à δ 6.50 (6H). Le spectre de rmn du diméthyl-2,7 est connu dans la littérature (34); les protons des groupes méthyle apparaissent à δ 2.12 ppm, tandis que les protons aromatiques apparaissent à δ 6.50 ppm. Nous croyons que les deux isomères sont présents et que la grande symétrie de ceux-ci ne nous permet pas de les différencier dans le mélange par la spectroscopie de rmn.

Le troisième composé a été identifié comme étant le diméthylfluorène par son spectre de masse et par analogie avec les pyrolyses de composés similaires trouvées dans la littérature (11, 12, 15) (trois isomères sont attendus). Le spectre de masse de ce composé a été enregistré à 70 eV: *m/e* (%) 195(17.3), 194(100.0), 193(15.0), 192(5.3), 191(7.5), 190(3.0), 189(9.0), 180(23.3), 179(95.5), 178(35.3), 177(7.5), 176(8.3), 166(3.8), 165(12.8), 164(3.0), 163(3.8), 162(3.0).

Pyrolyse des mélanges:

Pyrolyse du mélange ninhydrine – anhydride tétrachlorophtalique

Dans la pyrolyse des mélanges ninhydrine – anhydride tétrachlorophtalique, le benzène et l'acétone ont été utilisés comme solvants pour le lavage des trappes. Les analyses par chromatographie en phase gazeuse ont été faites en utilisant une colonne de SE-54, 10% sur Chromosorb W mesurant 9 pieds de longueur.

Des pyrolyses qualitatives de mélanges ont été faites à différentes températures selon la procédure décrite plus haut. L'analyse des chromatogrammes obtenus pour chaque pyrolyse par comparaison des surfaces sous la courbe montre que la température de choix est 800 °C.

Dans les pyrolyses quantitatives, le chromatogramme obtenu par injection d'une quantité de chaque solution montre la présence de trois produits; leur temps de rétention respectif est de 18.7, 28.7 et 32.4 min. Le second composé est présent en faible quantité; donc, après identification des trois composés uniquement les rendements des deux autres produits ont été déterminés (voir tableau 1).

Le premier composé a été identifié comme étant le biphénylène par ses spectres de masse et ultraviolet. Le second composé, un solide blanc, a été identifié comme étant le tétrachloro-1,2,3,4 naphtalène. Le point de fusion d'un échantillon collectionné du chromatographe en phase gazeuse est voisin de celui trouvé dans la littérature: 196 °C (litt. (35) pf 200–201 °C); le spectre de masse de ce composé montre une série de pics entre *m/e* 264 et 270 qui correspond à l'ion moléculaire et ses pics isotopiques. Trois autres séries de pics sont obtenus par perte successive de 1, 2 et 3 atomes de chlore. Enfin, il y a deux séries de pics débutant à *m/e* 132 et 97 correspondant à $(M)^{++}$ et $(M - Cl_2)^{++}$.

Le troisième composé est le tétrachloro-1,2,3,4 biphénylène; pf 175 °C (litt. (36) pf 176 °C). Son spectre de masse a été enregistré à 70 eV. Une série de pics entre *m/e* 288 et 294 correspond à l'ion moléculaire et ses pics isotopiques. Un calcul de l'intensité relative de cette série de pics montre que le composé contient quatre atomes de chlore: trouvé, *m/e* (%) 288(80.0), 290(100.0), 292(47.0), 294(10.3), calculé (30), *m/e* (%), 288(77.16), 290(100.0), 292(48.60), 294(10.50). Le reste du spectre a la même allure que celui du tétrachloro-1,2,3,4 naphtalène; les trois séries de pics suivant l'ion moléculaire correspondent respectivement à $(M - Cl)^+$, $(M - 2Cl)^+$ et $(M - 3Cl)^+$. Les deux dernières séries correspondent à $(M)^{++}$ et $(M - 2Cl)^{++}$. Un spectre ultraviolet qualitatif du même composé a été enregistré: λ_{max} (MeOH) nm 256 ép., 263, 335, 352 ép, 355, 371, (litt. (36) λ_{max} (EtOH) nm 258 ép., 265, 339, 353 ép, 357, 375).

Pyrolyse du mélange anhydride phtalique – anhydride méthyl-4 phtalique

Au départ, des pyrolyses qualitatives de mélange impliquant la ninhydrine et l'anhydride méthyl-4 phtalique ont été faites. Après avoir remarqué la formation d'une faible quantité de méthyl-2 biphénylène, nous avons abandonné la pyrolyse de ce mélange. Aucune étude quantitative n'a été faite dans ce cas. Par la suite, nous avons remplacé la ninhydrine par l'anhydride phtalique.

Dans la pyrolyse du mélange anhydride phtalique – anhydride méthyl-4 phtalique, le benzène et l'acétone ont été utilisés comme solvants pour le lavage des trappes. L'analyse des produits de pyrolyse a été faite par chromatographie en phase gazeuse, utilisant une colonne de 6 pieds contenant du SE-30, 10% sur Chromosorb W. La programmation de température est la même qu'utilisée précédemment. Les rendements des produits sont donnés dans le tableau 2.

Le chromatogramme montre la présence de cinq produits dont les temps de rétention respectifs sont de 14.8, 17.8, 18.4, 20.8 et 23.0 min. Les deux premiers ont été identifiés comme étant les deux anhydrides de départ (le premier étant l'anhydride phtalique). Les spectres de masse et les temps de rétention mesurés correspondent à ceux d'échantillons commerciaux. Le troisième produit est le biphénylène; il a été identifié par ses spectres de masse et ultraviolet. Le cinquième produit est le diméthylbiphénylène; il a été identifié par ses spectres de masse et de rmn. Comme dans la pyrolyse de l'anhydride méthyl-4 phtalique, nous supposons que deux isomères sont présents.

Le dernier produit est le méthyl-2 biphénylène (**16**): spectre de masse (70 eV), ion moléculaire, *m/e* (%) 166(100.0). Un spectre rmn a été enregistré dans le $CDCl_3$: **16**, δ 2.15 (s, 3H), 6.5–7.0 ppm (m, 7H). Il y a un recouvrement des pics du composé **16** et du fluorène, trouvé également en petite quantité dans notre pyrolyse de l'anhydride phtalique (**5**) ainsi que dans d'autres pyrolyses de **2** (11, 12) et de **5** (15). Il est possible de distinguer ces deux produits dans un mélange des deux par moyen du spectre rmn: le fluorène, δ 3.76 (s, 2H) et 7.2–7.7 ppm (m, 8H). Le spectre uv de **16** formé dans cette pyrolyse s'accorde bien avec celui de la littérature (8): λ_{max} (EtOH) nm 242, 250, 298, 343, 361.

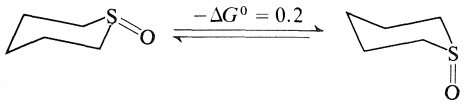
^{1}H and ^{13}C nmr results for 1,2-oxathiane 2-oxide and eight derivatives are reported. It is concluded that these molecules have a high preference for chair forms with axial S=O groups, even when a sterically bulky group such as phenyl is substituted in a *syn*-axial orientation to the exocyclic oxygen.

G. W. BUCHANAN, N. K. SHARMA, F. DE REINACH-HIRTZBACH et T. DURST. Can. J. Chem. **55**, 44 (1977).

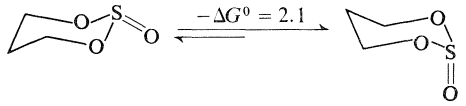
On rapporte des données de rmn ^{1}H et ^{13}C pour l'oxyde-2 d'oxathianne-1,2 et pour huit de ses dérivés. On en conclut que ces molécules ont une grande préférence pour des formes chaises avec des groupes S=O axiaux même lorsqu'un groupe stériquement encombrant tel que le phényle est substitué dans une orientation *syn*-axiale par rapport à l'oxygène exocyclique.
[Traduit par le journal]

Introduction

In recent years there has been considerable interest in the stereochemistry of 6-membered organic heterocycles containing the S=O function. For thiane oxide it has been established (1) that the preferred conformation is a chair in which there is a slight preponderance (0.2 kcal/mol) of the form in which the S=O is axial.



When heteroatoms with lone pairs of electrons are introduced into the ring, adjacent to the S=O group, the equilibria become more biased toward the axial S=O forms. In the case of trimethylene sulfite, this preference has been estimated to be *ca.* 2.1 kcal/mol (2), although no direct measure of $-\Delta G^0$ for the parent compound has been possible since its ^{1}H nmr spectrum is temperature independent from -150 to $+150\,^{\circ}C$.



On the basis of dipole moments (2), ^{1}H nmr (3) and ^{13}C nmr (4), substitution of potentially axial CH_3 groups at both C-4 and C-6 of the sulfites is deemed to alter the ring conformation such that non-chair forms, or chairs with equatorial S=O functions, can contribute.

Compounds intermediate between the thiane oxides and the trimethylene sulfites, namely the 1,2-oxathiane 2-oxides (sultines) have, by contrast, received rather little attention. To date, the only report has been that of Harpp and Gleason (5) who found that the ^{1}H spectrum of 1,2-oxathiane 2-oxide is temperature independent from -90 to $+150\,^{\circ}C$. They concluded that the molecule adopts a chair conformation with a considerable preference for the form having an axial S=O moiety (*ca.* 2 kcal/mol).

For all these systems the ^{1}H nmr spectra are difficult to analyze completely, and thus the structural information available is somewhat limited. Recently it has been demonstrated that ^{13}C nmr offers an attractive alternative for the study of sulfur heterocycles (4, 6–8) since the spectra are first order and the chemical shift differences are an order of magnitude greater than those in the ^{1}H spectra. We now report the

TABLE 1. ^{1}H spectral data of 1,2-oxathiane 2-oxides*

Compound	Area of adsorption (assignment)
1,2-Oxathiane 2-oxide (**1**)	1.5–2.2 (4e, 5a, 5e); 2.2–3.0 (3a, 3e, 4a); 3.6–3.8 (6e); 4.3–4.7 (6a)
3-Methyl-1,2-oxathiane 2-oxide (**2**)	1.08 (CH_3); 1.4–2.2 (4e, 5a, 5e); 2.2–3.0 (3a, 4a); 3.3–3.8 (6e); 4.0–4.6 (6a)
4-Methyl-1,2-oxathiane 2-oxide (**3**)	1.0 (CH_3); 1.3–1.9 (5a, 5e); 2.3–2.8 (3a, 3e, 4a); 3.75–4.0 (6e); 4.4–4.7 (6a)
5-Methyl-1,2-oxathiane 2-oxide (**4**)	0.87 (CH_3); 1.6–2.4 (4e, 5a); 2.6–3.0 (3a, 3e, 4a); 3.6–3.8 (6e); 4.0–4.5 (6a)
6-Methyl-1,2-oxathiane 2-oxide (**5**)	1.22 (CH_3); 1.45–2.0 (4e, 5a, 5e); 2.3–2.8 (3a, 3e, 4a); 4.5–4.9 (6a)
6-Phenyl-1,2-oxathiane 2-oxide (**6**)	1.2–2.2 (4e, 5a, 5e); 2.5–2.9 (3a, 3e, 4a); 5.37 (6a); 7.3 (phenyl)
6,6-Dimethyl-1,2-oxathiane 2-oxide (**7**)	1.25 (CH_3-equatorial); 1.57 (CH_3-axial); 1.6–1.9 (4e, 5a, 5e); 2.3–2.8 (3a, 3e, 4a)
cis-6-Methyl-6-phenyl-1,2-oxathiane 2-oxide (**8**)	1.90 (CH_3); ~2.25 (4e, 5a, 5e); ~2.75 (3a, 3e, 4a); 7.2 (5H)
trans-6-Methyl-6-phenyl-1,2-oxathiane 2-oxide (**9**)	1.58 (CH_3); 1.7–3.2 (all other ring H); 7.1–7.5 (5H)

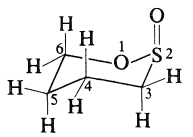
*0.05–0.10 *M* solutions in $CDCl_3$.

results of an examination of 1,2-oxathiane 2-oxide and eight derivatives, using ^{1}H and ^{13}C nmr, which permits some detailed conformational conclusions.

Results and Discussion

(a) ^{1}H Spectra

Table 1 contains a summary of the ^{1}H data for the nine compounds examined. A discussion of part of the 100 MHz ^{1}H spectrum of **1** has been published (5). The axial C-6 proton is the



1

most deshielded (δ = 4.42) due to the well known (9–13) *syn*-axial deshielding effect of the sulfinyl oxygen. This proton exhibits an 11.5 Hz vicinal coupling with the *trans*-diaxial H on C-5, indicative of a chair-type geometry. The C-4 axial hydrogen is also deshielded relative to its equatorial counterpart for the same reason as the axial C-6 hydrogen, and to a similar extent. The close spatial relationship between the S=O group and the C-4 and C-6 axial hydrogens was verified by the observation that these hydrogens underwent the largest downfield shift, *ca.* 8 ppm, upon addition of approximately 0.5 equiv. of $Eu(FOD)_3$.

The chemical shift differences referred to above were observed for all the monosubstituted 1,2-oxathiane 2-oxides which we have thus far been able to isolate. On the basis of these observations and the ^{13}C spectra discussed below, the preferred conformations of these compounds (**2**–**6**) are chair forms having the substituent in an equatorial and the S=O in the axial position.

The proton spectrum of 6,6-dimethyl-1,2-oxathiane 2-oxide (7) showed two methyl signals at 1.25 and 1.57 ppm, assigned to the equatorial and axial methyl groups respectively. The chemical shift difference between the CH_3 groups of **6** (0.32 ppm) is somewhat smaller than for the CH_3 groups of the corresponding sulfite **10** (3), but considerably larger than that in the sulfite **11** which has an equatorial S=O bond (3). On this basis, **7** is suggested to have a conformation similar to that of **10**. The methyl proton assignments in **7** were confirmed by $Eu(FOD)_3$ studies which showed downfield shifts of *ca.* 3.0 and 1.5 ppm for the δ = 1.57 and the δ = 1.25 resonances respectively upon addition of 0.3

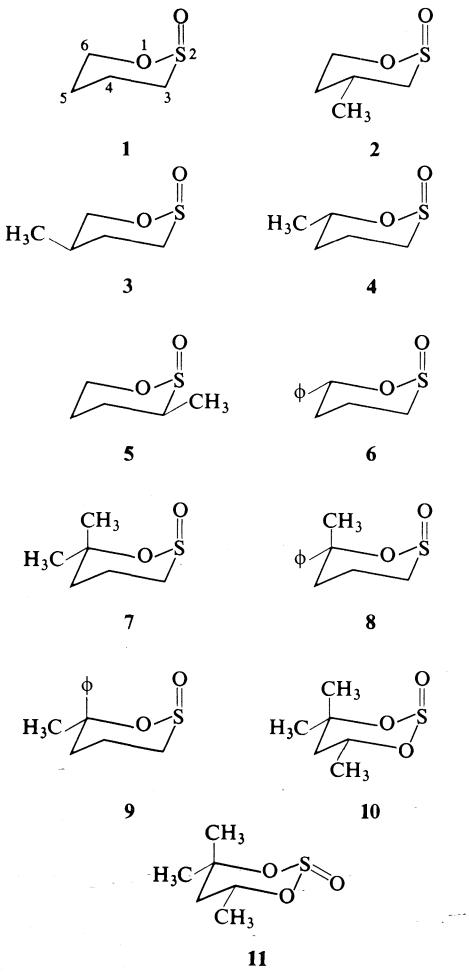


FIG. 1. Structures and numbering scheme for compounds discussed in the text.

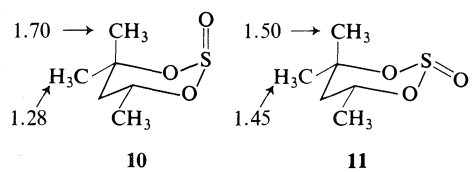
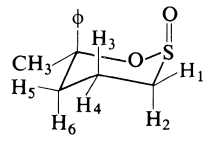
equiv. of the shift reagent, indicating that the $\delta = 1.57$ resonance arises from the axial methyl.

Examination of the data for the 6-methyl-6-phenyl isomers **8** and **9** suggests that **8** exists mainly in the chair form having both the S=O and the CH_3 axial. For **9**, the CH_3 group is shielded by 0.32 ppm relative to **8**, resulting from the removal of the deshielding *syn*-axial S=O --- CH_3 interaction present in **8**. Interestingly in **8** the phenyl protons appear as a singlet at



$\delta = 7.2$ whereas in **9** a multiplet in the range 7.1–7.5 ppm is found. In 2-phenyl-1,3-dithiane which contains an axial phenyl group (14) resolved *ortho* aromatic protons are also observed. Further evidence for the existence of **9** in a chair with axial S=O is obtained from the effect of addition of *ca.* 0.3 equiv. of $Eu(FOD)_3$. The protons most affected (downfield shift of *ca.* 4 ppm) are those in the *ortho* aromatic position. The axial proton (H_3) was next most affected (downfield shift of *ca.* 3 ppm) as expected on the basis of its *syn*-axial relation to the S=O, assuming the exocyclic oxygen to be the site of complexation (3). Furthermore, the lanthanide



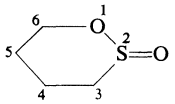
shifted spectrum of **9** permitted measurement of several of the coupling constants. In addition to large geminal couplings (13.0 and 14.5 Hz for J_{12} and J_{56} respectively), J_{23} and J_{36} are 11.0 Hz which typify axial–axial couplings in chair forms and are similar to values found in related molecules such as sulfites (3). Smaller couplings (3.0–6.5 Hz) are noted for interactions involving equatorial protons as expected on the basis of dihedral angle considerations. Of course it can be argued that the shift reagent perturbs the geometry of the substrate and renders conformational conclusions somewhat tenuous. Nevertheless, it seems clear that the lanthanide complexed system **9** exists in a chair with axial S=O and we thus can suggest that the geometry of the free substrate is similar.

(b) ^{13}C Spectra

^{13}C chemical shifts for compounds **1**–**9** are presented in Table 2. Assignments have been made using results for model compounds (4, 7), well-established trends of alkyl substitution (15), selective ^1H decoupling, and single frequency off resonance (SFORD) decoupling experiments.

For **1** it is interesting to compare the ring carbon shifts with those for trimethylene sulfite **12** and the two chair forms of thiane oxide **13** and **14**. Not surprisingly (15, 16), the C-5 shift of **1** is near that of C-5 of **12** and C-4 of **13** and **14**. Also, C-6 of **1** resonates at a similar position

TABLE 2. ^{13}C chemical shifts of 1,2-oxathiane-2-oxides (δ_c from TMS ± 0.1)*



Compound	Substituent	Position C-3	C-4	C-5	C-6	CH_3	C-quat.	C-*o*	C-*m*	C-*p*
1	—	49.5	13.6	24.5	58.5

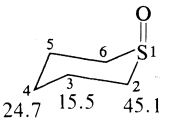
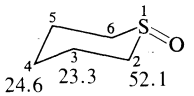
12



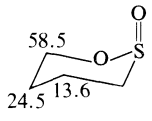
13



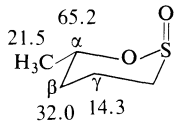
14

to C-4,6 of **12** (4). Notably C-4 of **1** is highly shielded (δ = 13.6) which reflects its *gauche*-γ relationship to the exocyclic oxygen atom (4). An equatorial S=O bond as in **14** is manifested by the absence of the upfield γ shift and the effect is pronounced (7–9 ppm) for both sulfites and sulfoxides (4, 7). Thus the ^{13}C data for **1** are supportive of a chair conformation with an axial S=O function.

For the mono-CH_3 derivatives **2**, **3**, and **4**, several pieces of evidence favor the concept of chair forms with equatorial CH_3 groups and axial S=O bonds. Initially, the alkyl substituent effects on the ring carbon shifts are similar to those in the related sulfites (4) where the corresponding chair forms are likely. For example in **4**, the introduction of the CH_3 at C-6 deshields C-6 by +6.7 ppm (α effect), C-5 by +7.5 ppm (β effect), and C-4 by +0.7 ppm (*trans*-γ effect) relative to **1**.

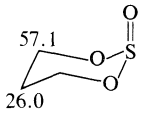


1

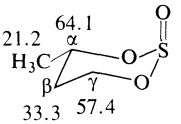


4

Comparing the corresponding sulfites **12** and **15**, the results are +7.0, +7.3, and +0.3 ppm for the α, β, and *trans*-γ effects respectively.



12

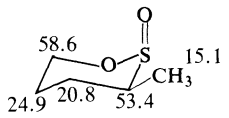


15

Small deshielding γ-effects for **2** (+0.6 ppm) and **3** (+0.5 ppm) relative to **1** again reflect the introduction of equatorial CH_3's into the ring. If the CH_3 groups were axial, pronounced shielding effects (4–6 ppm) would be expected at the γ-carbons (17, 18).

Finally, the close correspondance in the CH_3 shifts for **2**, **3**, and **4** with **15** and other sulfites (4) with equatorial methyl groups support this argument.

Results for the 3-CH_3 derivative **5** also indicate a chair geometry with axial S=O and equatorial CH_3. Compared to **2**, **3**, and **4**, the CH_3 group is shielded by *ca.* 6 ppm, due to its *gauche*-γ

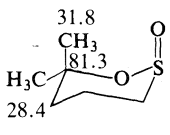


5

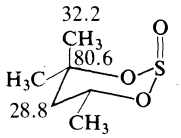
relationship to the exocyclic oxygens. Also the small deshielding *trans*-γ effect at C-5 (+0.4 ppm) relative to **1** is consistent with the *trans*-γ shifts noted in **2**, **3**, and **4**.

Comparison of the ring carbon shieldings for the 6-phenyl compound **6** with the 6-CH_3 system **4** reveals a marked similarity at the C-3, 4, and 5 positions. Thus for **6** a chair form with an equatorial phenyl group is dominant. The deshielding effect at C-6 (+4.7 ppm) relative to **4** is a consequence of the two β carbons of the aromatic ring.

Compound **7** exhibits a *gauche*-γ upfield shift of 2.2 ppm at C-4 relative to **1** which is indicative of a substantial contribution from a pure axial CH_3 at C-6. It is interesting to compare the C-6 shift and the gem-CH_3 shifts of **7** with a related sulfite **10** which is mainly a chair form with an axial S=O bond (4). Clearly there is marked



7

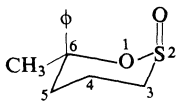


10

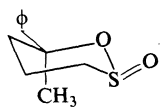
similarity in the data suggesting like geometries for **7** and **10**. The deshielding of the axial CH_3's in these compounds compared to their equatorial counterparts may be attributed to a 'δ' interaction with the axial S=O function (4, 19) or to the anisotropic property of the S=O moiety (20).

With the exception of C-6, the ring carbon chemical shifts for **8** are within 1 ppm of those for **7** which can be taken to indicate similar ring conformations. The deshielding at C-6 of **8** relative to **7** is no doubt a consequence of the β deshielding influence of the *ortho*-aromatic carbons. By contrast the CH_3 of **8** is shielded by 1.3 ppm relative to the axial CH_3 of **7**. This is presumably a manifestation of the minor γ interactions of the CH_3 with the *ortho*-aromatic carbons.

Compound **9**, if it were in a chair form with an axial S=O would have the structure **9***a*. An alternate possibility is that ring reversal might occur to render **9***b*. If this were the case, the



9*a*



9*b*

C-4 resonance of **9** should be deshielded by 7–9 ppm compared to **8**, using the previous results for trimethylene sulfites (4) and thiane oxides (7) as analogies since there is a marked influence of S=O stereochemistry on γ-carbon shieldings. This large deshielding is not found and accordingly **9***b* seems unlikely.

Examination of the shift data for **8** and **9** in Table 2 reveals a marked similarity in the shieldings and accordingly similar chair conformations of these molecules can be suggested. If **9** were to adopt a twist shape then all the ^{13}C shifts would be expected to go upfield (21) and such a trend is not observed.

The only somewhat puzzling feature of the spectrum of **9** is the 2.3 ppm deshielding of the methyl resonance relative to **8**. We can offer no clear rationale for this finding other than to note that the CH_3 is *trans*-coplanar to a γ sulfur atom. Recently (22) deshielding *trans*-γ shifts have been reported for CH_3's *trans* and γ to oxygen atoms, when both the CH_3 and the O are bonded to quaternary sites.

In conclusion, it is clear that ^1H and ^{13}C nmr are useful complementary tools for the study of 1,2-oxathiane 2-oxide stereochemistry. Our results indicate a pronounced tendency for these molecules to adopt chair forms with axial S=O functions.

Experimental

Spectra

The ^{13}C chemical shifts were obtained using a Varian XL-100-12 nmr spectrometer in the Fourier transform mode via previously described procedures (23). Over the concentration range employed (0.05–0.10 *M* solutions) the ^{13}C shifts vary less than ±0.1 ppm. ^1H spectra were obtained on a Varian T-60 spectrometer using TMS as an internal reference for the $CDCl_3$ solutions. The $Eu(FOD)_3$ experiments on **9** were carried out using a Varian HA-100 nmr spectrometer and CD_2Cl_2 as solvent.

Nuclear magnetic resonance studies. XXX.[1] Hydrogen–deuterium exchange in bicyclo[3.2.1] and -[2.2.2]octenes through allylic and vinylic anions

A. K. CHENG AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 26, 1976

A. K. CHENG and J. B. STOTHERS. Can. J. Chem. **55**, 50 (1977).

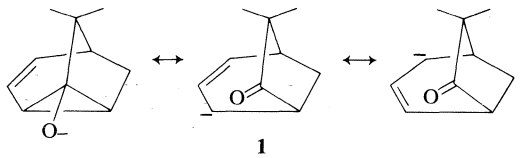
Bicyclo[3.2.1]oct-2-ene undergoes hydrogen–deuterium exchange through allyl and vinyl carbanionic intermediates under strongly basic conditions, *tert*-BuO^-/*tert*-BuOD at 185 °C. Only allylic exchange had been observed in previous studies with *tert*-BuO^-/DMSO. Since the 2-*tert*-butoxybicyclo[3.2.1]octanes are stable under these conditions an addition–elimination sequence cannot account for exchange at C-3. The relative rates of exchange at C-2, -3, and -4, and the stereoselectivity at the allylic site were determined by ^2H nmr. For comparison, the rate of olefinic exchange in bicyclo[2.2.2]octene was also measured.

A. K. CHENG et J. B. STOTHERS. Can. J. Chem. **55**, 50 (1977).

Dans des conditions basiques fortes impliquant le *tert*-BuO^-/*tert*-BuOD à 185 °C, le bicyclo-[3.2.1]octène-2 subit des échanges hydrogène–deutérium par l'intermédiaire de carbanions allyliques et vinyliques. On avait observé uniquement des échanges allyliques dans des études antérieures avec le *tert*-BuO^-/DMSO. Puisque les *tert*-butoxy-2 bicyclo[3.2.1]octanes sont stables dans ces conditions, on ne peut pas faire appel à une séquence d'addition–élimination pour expliquer l'échange en position C-3. On a déterminé, par rmn du ^2H, les vitesses relatives d'échanges en positions C-2, C-3 et C-4 et la stéréosélectivité au site allylique. Pour fins de comparaison, on a aussi déterminé la vitesse de l'échange des protons oléfiniques du bicyclo-[2.2.2]octène.

[Traduit par le journal]

In earlier work on the behavior of bicyclic ketones in a strongly basic medium, *tert*-butoxide/*tert*-butyl alcohol at 185 °C, we had found that the α,α-dimethyl derivatives of bicyclo-[2.2.2]octenone, bicyclo[3.2.1]oct-2-en-6-one and its Δ^3 isomer undergo hydrogen–deuterium exchange at both olefinic carbons (1). Since these ketones are interconvertible through the common β-enolate **1**, exchange at one of the olefinic centres is readily explicable in terms of the allylic nature of this intermediate. Exchange at the second olefinic carbon, however, requires a different mechanism, perhaps by direct exchange through a vinyl carbanion with a possible activating effect arising from the neighboring carbonyl group. To shed further light on the nature of these processes we have examined the reactivity of bicyclo[3.2.1]oct-2-ene (**2**) and bicyclo-[2.2.2]octene (**3**) under the same conditions to compare their behavior with that of the ketones. The [3.2.1] olefin has been studied previously (2) as a model system for assessing long range π participation in the anion formed from bicyclo-[3.2.1]octadiene. The monoene, with *tert*-butoxide/dimethyl sulfoxide as the base, was found to exhibit only allylic exchange. A comparison of the behavior of this olefin in these two media has proved interesting and we wish to present our results in this paper. Through the use of ^2H nmr spectra, the relative rates of exchange and the stereoselectivity at the allylic methylene site were readily measured in a straightforward fashion.



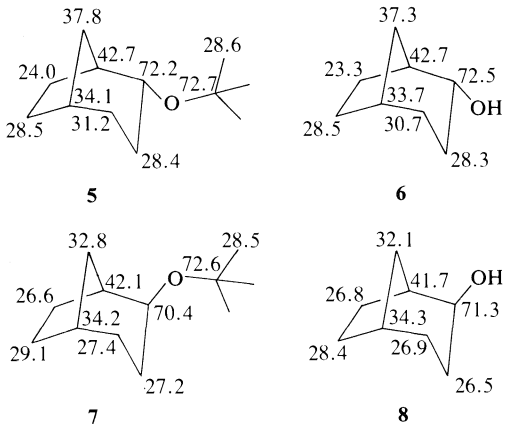
1

Experimental

Materials

With one exception, the compounds employed in this study have been described in the literature and samples were synthesized having essentially the same physical constants. Bicyclo[3.2.1]oct-2-ene (**2**) was obtained from 3-chlorobicyclo[3.2.1]oct-2-ene by Birch reduction (3). This chloroolefin had been prepared by reaction of bicycloheptene with dichlorocarbene followed by reduction with lithium aluminum hydride (4). Epoxidation of **2** with *m*-chloroperbenzoic acid in methylene chloride at room temperature (5) afforded *exo*-2,3-epoxy-**2** (6) in more than 80% yield. Bicyclo[2.2.2]octene (**3**) was pre-

[1]For part XXIX, see ref. 17 and for part XXVIII see ref. 18.



pared by Wolff–Kishner reduction of the corresponding enone which was available from earlier studies (7).

2-tert-Butoxybicyclo[3.2.1]octanes

To a solution of 1 g of *endo*-tricyclo[3.2.1.$0^{2,4}$]oct-6-ene (**4**) (8), in 15 ml of dry *tert*-butyl alcohol was added *p*-toluenesulfonic acid (80 mg) and the temperature raised to 60 °C. After stirring for 4 days, the reaction mixture was cooled and poured into water. Our synthesis was adapted from that reported for methanol addition (9). The product, isolated by pentane extraction, was analyzed by gc on a 15% DEGS column at 90 °C and found to contain three major components in a ratio of 6:2:2, constituting >95% of the total. Hydrogenation of the product in ether at 45 psi over PtO_2 afforded a 2:1 mixture of two compounds, separable by preparative gc on a 15% Carbowax 20M column. The proton spectra of each contained a sharp singlet at 1.15 ppm (9H, $(CH_3)_3C$) and a broad multiplet near 3.4 ppm (1H, $-CH(OR)-$) with no absorption at lower field. The ^{13}C spectrum of the minor product in $CDCl_3$ contained 10 signals which were assigned to the individual carbons in *endo*-2-*tert*-butoxybicyclo[3.2.1]octane as shown in **5** by comparison with the results for **6**, measured in $CDCl_3$ (10); the latter are in reasonable agreement with those recently reported (11) for an unspecified solvent. The ^{13}C spectrum of the major product **7** similarly accorded well with that for *exo*-bicyclo[3.2.1]octan-2-ol (**8**) (10, 11).

Precise mass measurements for the two products gave the following results: *Mol. wt.* calcd. for $C_{12}H_{22}O$: 182.1669; found for **5** (*m/e*): 182.1670; found for **7** (*m/e*): 182.1662.

Spectra

Proton spectra of each of the compounds included in this study were obtained to confirm their identity and purity. These spectra were recorded with a Varian HA-100 spectrometer which was also used for the spin decoupling experiments. ^2H and ^{13}C spectra were obtained with a Varian XL-100-15 system operating in the Fourier transform mode at 15.4 and 25.2 MHz, respectively. The determination and integration of the ^2H spectra have been described previously (12); the precision of the computer-fitted integration data is judged to be 1%. Total deuterium content for each sample was measured with a Varian M-66 instrument; a MAT 311A was used for the precise mass measurements of ethers **5** and **7**.

Exchange Experiments

The general procedure followed was essentially as described previously (12). Typically, the olefin (ether) was added to the base, prepared by dissolving potassium metal in *tert*-butyl alcohol-*O-d*, (99% deuterated and <0.005 *M* in water) to give a solution with a molar ratio of substrate: base:alcohol of 1:4:40, 1.2 *M* in *tert*-BuO^-. Aliquots were placed in glass tubes under nitrogen which were sealed after degassing. After heating at 185 ± 3 °C for various times, the tubes were opened and the products recovered by pentane extraction. Preparative gc was used to isolate samples for analysis.

Results

Following the method used for our examination of the bicyclic ketones (1), samples of **2** dissolved in *tert*-butoxide/*tert*-butyl alcohol-*O-d* were heated in sealed tubes for varying periods of time at 185 °C. After recovery of the olefin, the deuterium content of each sample was determined by mass spectrometry. The results are collected in Table 1, from which it is apparent that up to four deuterium atoms were incorporated. The ^2H spectrum of each sample clearly showed that four sites are involved in the exchange processes and the relative ^2H content at each site was measured by integration using the curve fitting technique described previously (12). These data are included in Table 1. The assignments for the individual signals were made from proton spectra of the olefin and the corresponding epoxide.

The ^2H spectra of the samples of **2**-d_x contained two signals at higher field, 0.53 ppm apart, the allylic methylene deuterons, and two at 3.52 and 4.06 ppm from the highest field signal, the olefinic nuclei. In the proton spectrum of **2**, the lowest field absorption (δ 5.79) was essentially a 'triplet' with spacings of ~8 Hz, and each component broadened by long range coupling. The more shielded of the olefinic patterns at δ 5.26 was essentially a doublet ($J \sim 8$ Hz) of multiplets. Thus, H-2 is the less shielded. To identify the *exo*- and *endo*-4-protons, the ^1H spectrum of the *exo*-epoxide of **2** was examined with varying amounts of the shift reagent, $Eu(fod)_3$, added. As the shift reagent concentration increased, absorption patterns attributable to six nonequivalent protons were shifted sufficiently to permit assignment through spin-decoupling experiments. With 0.74 equiv. of $Eu(fod)_3$, the epoxy protons exhibited the largest shifts to δ 17.15 and 16.89 and the other patterns were: a doublet, $J \sim 11$ Hz, at δ 12.22, a doublet of doublets, $J \sim 4.5$ and 16 Hz, at δ 9.48, an

ill-defined quartet, δ 8.99, and a doublet of multiplets at δ 6.14 having the large J of 16 Hz. Spin-decoupling showed that the 16 Hz coupling was common to the δ 6.14 and 9.48 patterns, thereby identifying the 4-protons, since a geminal coupling of ~16 Hz and substantial shifts in the presence of Eu(fod)$_3$ were expected for these nuclei. The absorption giving the larger relative shift must arise from the *exo*-proton. Irradiation of the lowest field signal changed the quartet at δ 8.99 into a triplet, showing it to arise from H-1. The remaining doublet, δ 12.22, was assigned to the *syn*-8-proton, whose geminal coupling of 11 Hz agreed well with several model systems, and was shown to be coupled to a proton near 5.3 ppm. With this information, a sample of **2**-d_x from the 200 h base treatment was converted to the *exo*-epoxide and its ^{2}H spectrum recorded. The relative intensities of the four signals showed that the shielding order is the same as in the olefin. With Eu(fod)$_3$, the more intense of the two methylene signals exhibited the larger shift showing that *exo*-deuteration at C-4 is preferred. Thus the assignments of the four signals in the ^{2}H spectra of the olefins were completed.

From the deuterium incorporation results (Table 1) for the runs up to 220 h, first-order rate constants for exchange at the four sites were estimated to be: C-2, 3.3×10^{-7}; C-3, 2.1×10^{-7}; *exo*-C-4, 7.2×10^{-7} and *endo*-C-4, 3.9×10^{-7} s^{-1}.

Since exchange at the olefinic sites could occur through an addition–elimination sequence, the stability of the *tert*-butoxy ethers potentially involved in this process was of interest. A sample of *exo*-2-*tert*-butoxybicyclo[3.2.1]octane (**7**) was treated for 221 h under the same conditions employed for the olefin exchange studies. A gas chromatogram of the product was identical to that of the starting material indicating the presence of a single component having a retention time different from that of bicyclo[3.2.1]octene, and the proton spectrum showed no change from that of the starting material. Similarly, a 72:28 mixture of the *exo*- and *endo*-2-*tert*-butoxybicyclo[3.2.1]octanes was unchanged after treatment for 221 h. Thus the observed exchange at C-3 cannot involve addition–elimination.

In the manner described for **2**, samples of bicyclo[2.2.2]octene (**3**) were subjected to the exchange conditions for various times. The deuterium contents of the **3**-d_x samples thus obtained were measured by mass spectrometry and these data are given in Table 2. No species containing three deuterium atoms were observed and examination of the ^{2}H spectrum of **3**-d_x from the longest reaction time showed only olefinic absorption. From the mass spectrometric data a first-order rate constant for deuterium incorporation at C-2 (or C-3) can be estimated as 5.6×10^{-7} s^{-1}.

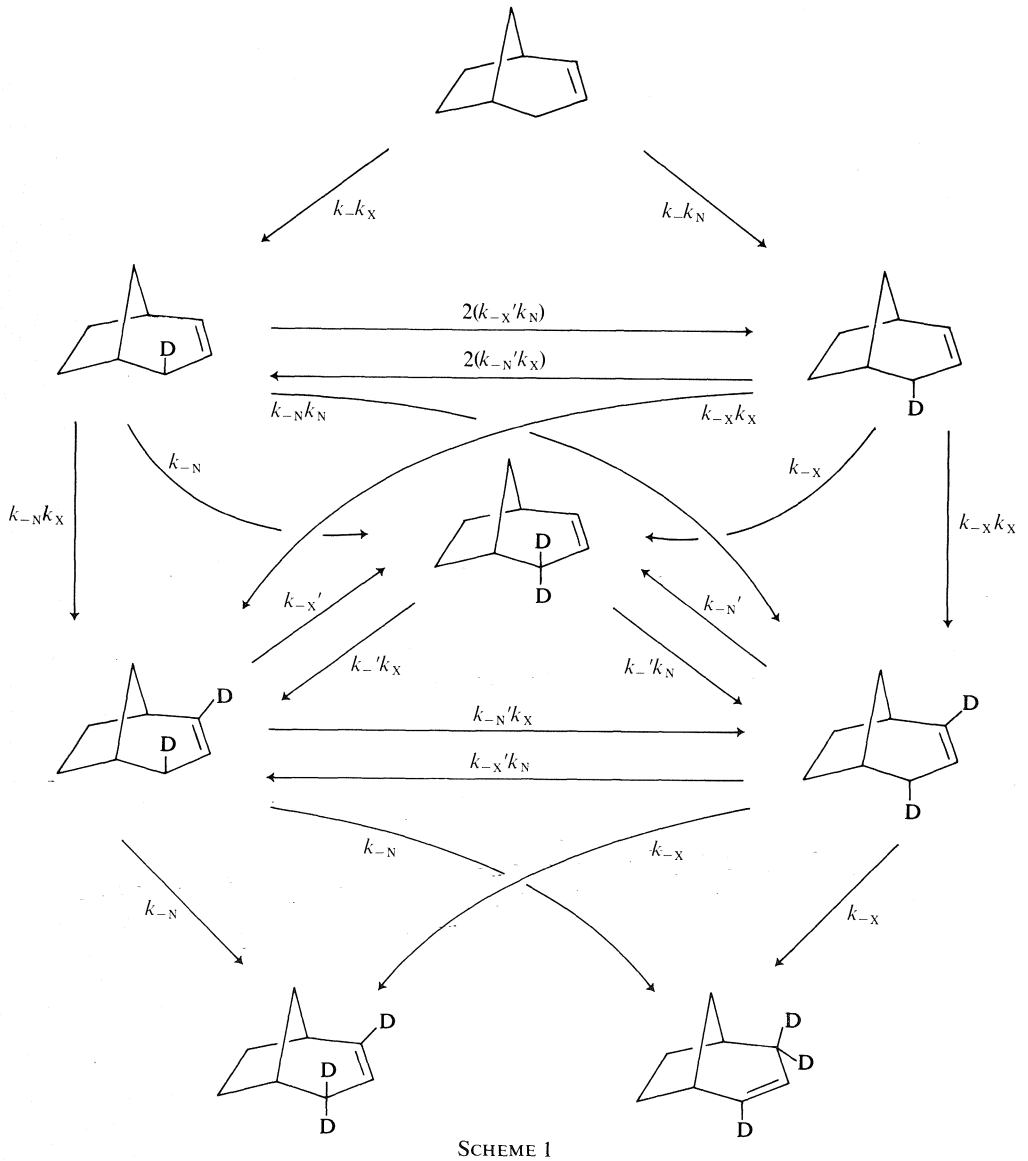
Discussion

The striking feature of the present results for the [3.2.1] olefin **2** compared to the earlier data (2) is the finding of exchange at C-3 at a rate nearly comparable to that exhibited for the process proceeding through an allylic carbanion. In the earlier study, with *tert*-butoxide – dimethyl sulfoxide as the base–solvent system, only allylic exchange was observed. A crude comparison of the total exchange rates in the two systems may be made from first-order plots of the disappearance of nondeuterated material *vs.* time which gives $k_1 = 2 \times 10^{-7}$ s^{-1} in *tert*-BuO$^-$/DMSO at 60 °C and $k_1 = 1.7 \times 10^{-6}$ s^{-1} in *tert*-BuO$^-$/*tert*-BuOD at 185 °C. Although the temperature difference is 125 °C, the overall rates differ by less than an order of magnitude. As noted above, the observed rate of deuterium incorporation at C-3 (2×10^{-7} s^{-1}) is approximately 50% of that observed for the *endo*-allylic site (3.9×10^{-7} s^{-1}). Unfortunately the ratio of *exo*:*endo* incorporation for **2** in *tert*-BuO$^-$/DMSO was not determined. In fact, the mass spectrometric results reported (2) indicate no species with more than two deuterium atoms. This indicates that the *exo*:*endo* ratio of protonation of the allylic anion is much higher than that found in *tert*-BuO$^-$/*tert*-BuOD, assuming that *exo*-protonation (deuteration) of the anion is the preferred process as seems usual in these systems. It may be noted that pronounced differences in *exo*/*endo* protonation upon quenching the corresponding dienyl anion with ROH and with DMSO have been reported (13).

This contrast in behavior of **2** in the two base–solvent systems could be the result of a number of factors. Perhaps the simplest explanation would be an addition–elimination process in *tert*-BuO$^-$/*tert*-BuOD which would be much less likely in *tert*-BuO$^-$/DMSO. However, the stability of **5** and **7** under the reaction conditions preclude this notion. Another possibility could be a marked difference in the intramolecularity of the exchange processes in the two media since it has been shown that the extent of intramolecularity (internal return) in *tert*-BuO$^-$/*tert*-BuOD at 200 °C can be much less than that found for similar substrates in *tert*-BuO$^-$/DMSO (14). Unfortunately, this suggestion cannot be tested experimentally for **2** but it seems unlikely that this can be the sole factor responsible for the lack of observable exchange at C-3. This would require a major difference in the extent of intramolecularity for the two (or more) exchange processes in *tert*-BuO$^-$/DMSO, *e.g.* allylic and vinylic exchange. The higher temperature may be responsible for the C-3 exchange observed in *tert*-BuO$^-$/*tert*-BuOD. If C-3 exchange is 10 times slower than allylic exchange in DMSO compared with a difference of 2–3 in *tert*-BuOD, one can estimate that an activation enthalpy difference ($\Delta\Delta H^{\neq}$) of 3–4 kcal/mol for the allylic and vinylic exchange processes could render C-3 exchange unobservable at the lower temperature for the reaction times chosen, all other factors being equal. However, other factors may not be equal since the stabilities of the localized and delocalized carbanions may differ in the two solvents. The change from a nonpolar protic to a polar aprotic solvent tends to diminish the stability of a localized carbanion, to judge from pK_a values (15) and this feature may preclude C-3 exchange in DMSO.

It is interesting that exchange at the olefinic carbons in bicyclo[2.2.2]octene (**3**) is *ca.* 3 times faster than that at C-3 in **2**. Presumably there is greater *s* character in the C—H bond in **3** than in **2** which would render the olefinic hydrogens in **3** more acidic. It may be noted that the rate of olefinic exchange in 3,3-dimethylbicyclo[2.2.2]-oct-5-en-2-one is much faster than that for **3**, by a factor of ~100 at C-5 and even more at C-6 at 185 °C. In fact, measurements at lower temperatures will be required to obtain these rate constants for the ketone. Clearly, the polarity of the carbonyl group markedly accelerates olefinic exchange. We have presented ^{13}C data which indicates an appreciable polarization of the double bond by the carbonyl group in the ketone (16).

While the ^{2}H assays for the individual sites of exchange in **2** (Table 1) permit one to estimate rate constants for the appearance of deuterium at these sites, it would be useful to check their relative magnitudes and to determine the rate constant for direct exchange at C-2. The observed deuterium incorporation at C-2 can arise through a combination of allylic and vinylic exchange. The available pathways for allylic exchange can be set out as in Scheme 1 in terms of the rate constants for *exo*- and *endo*-proton abstraction, k_{-X} and k_{-N}, respectively, and the ratio, *R*, of *exo*:*endo* protonation (deuteration). In this scheme, the following abbreviations are used: $k_- = (k_{-X} + k_{-N})$; $k_X = 1/(1 + 1/R)$; $k_N = 1/(1 + R)$ and the primed *k*'s include a factor



SCHEME 1

k_D/k_H for a primary kinetic isotope effect on the abstraction process. To reduce the complexity of the Scheme, only one enantiomer for A, B, C, D, and E are shown but the rate expressions include the contributions of A′, B′, C′, D′, and E′. These rate equations were numerically integrated using the MIMIC simulation language of the CDC computer and data for ^2H incorporation at C-4 were generated. A good fit with the experimental values was obtained with rate constants of 8.3×10^{-7} s^{-1} and 3.6×10^{-7} s^{-1} for *exo*- and *endo*-proton abstraction, respectively, and a ratio of 2.3 for the *exo*:*endo* deuteration (k_X/k_N). The calculated ^2H content at C-2 was lower than that observed, as expected, since direct vinyl exchange also leads to ^2H incorporation, as observed for C-3. Expansion of the MIMIC analysis to include vinyl exchange at C-2 gave a rate constant of 1.6×10^{-7} s^{-1} which compares favorably with the value of 2.1×10^{-7} s^{-1}, noted earlier for C-3 exchange, indicating no striking reactivity difference between the two olefinic sites.

DAVID JOHN HARRIS, M. T. THOMAS, VICTOR SNIECKUS, NOGA FRIEDMAN, KJELD SCHAUMBURG, KENNETH B. TOMER, and OLE BUCHARDT. Can. J. Chem. **55**, 56 (1977).

Thermolysis of 3,5,7-triphenyl-1,2(4*H*)-diazepine (**1**) gives, besides the known 2,4,6-triphenylpyridine (**2**), 3,5,6-triphenyl-1,2(4*H*)-diazepine (**3**) and 3,5,6-triphenyl-1,2(1*H*)-diazepine (**4**) whose structures are deduced on the basis of spectroscopic and chemical evidence. Neat thermolysis of **1** and the related 5-(*p*-methoxyphenyl)-3,7-diphenyl-1,2(4*H*)-diazepine (**24***a*) and 5-(*p*-chlorophenyl)-3,7-diphenyl-1,2(4*H*)-diazepine (**24***c*) gives only the corresponding pyridine derivatives **2**, **26***a*, and **26***c* in low yields. Photolysis of **1** in ethanol affords the somewhat unstable 3,5,7-triphenyl-1,2-diazabicyclo[3.2.0]hepta-2,6-diene (**21**) which upon thermolysis undergoes cycloreversion to **1** and upon hydrolysis provides 3,5-diphenylpyrazole (**23**) and acetophenone. In contrast, photolysis of **1** as well as of **24***a* and **24***c* in acetone results in the formation of the pyridine (**26***a*, **26***c*) and pyrazole (**25***a*, **25***c*) derivatives respectively in low yields. Irradiation of 5-(*p*-dimethylaminophenyl)-3,7-diphenyl-1,2(4*H*)-diazepine (**24***d*) under these conditions gives the photo-oxygenation product **24***e*. The observed thermolysis and photolysis results of **1** are compared and contrasted with those reported for the closely related 4,4-dimethyl-3,7-diphenyl-1,2(4*H*)-diazepine (**16**).

DAVID JOHN HARRIS, M. T. THOMAS, VICTOR SNIECKUS, NOGA FRIEDMAN, KJELD SCHAUMBURG, KENNETH B. TOMER et OLE BUCHARDT. Can. J. Chem. **55**, 56 (1977).

La thermolyse de la triphényl-3,5,7 (4*H*)-diazépine-1,2 (**1**) conduit, en plus de la triphényl-2,4,6 pyridine (**2**) qui est connue, à la triphényl-3,5,6 (4*H*)-diazépine-1,2 (**3**) et à la triphényl-3,5,6 (1*H*)-diazépine-1,2 (**4**) pour lesquelles on a déduit les structures en se basant sur des données spectroscopiques et chimiques. Les thermolyses en phase liquid de **1** et de la *p*-méthoxyphényl-5 diphényl-3,7 (4*H*)-diazépine-1,2 (**24***a*) et de la *p*-chlorophényl-5 diphényl-3,7 (4*H*)-diazépine-1,2 (**24***c*) qui lui sont reliées conduisent uniquement aux dérivés pyridiniques correspondants **2**, **26***a* et **26***c*, avec de faibles rendements. La photolyse de **1** dans l'éthanol conduit au triphényl-3,5,7 diaza-1,2 bicyclo[3.2.0]heptadiène-2,6 (**21**) qui est assez instable et qui par thermolyse subit une cycloréversion pour conduire à **1** et qui par hydrolyse fournit le diphényl-3,5 pyrazole (**23**) et l'acétophénone. Par opposition, les photolyses de **1** ainsi que de **24***a* et de **24***c* dans l'acétone conduisent respectivement à la formation de pyridines (**26***a* et **26***c*) et de dérivés pyrazoles (**25***a* et **25***c*), avec de faibles rendements. L'irradiation de la *p*-diméthylaminophényl-5 diphényl-3,7 (4*H*)-diazépine-1,2 (**24***d*) dans de telles conditions conduit à un produit de photo-oxygénation **24***e*. On compare les résultats observés pour la thermolyse et la photolyse **1** avec ceux rapportés pour la diméthyl-4,4 diphényl-3,7 (4*H*)-diazépine-1,2 (**16**) qui a une structure très analogue; on note qu'ils sont en opposition.

[Traduit par le journal]

The ready accessibility of 1,2(4*H*)-diazepines (**1**) from the reaction of hydrazine with pyrylium (2) and thiapyrylium (3) salts invited the investigation of their thermal and photochemical behaviour as part of our continuing interest in the chemistry of seven-membered heterocyclic systems (1, 4). Studies concerning the photochemistry of acyclic azines (5), pyrazoles (6), and pyrazolines (7) and, in particular, other simple and condensed diazepines (8) and the thermolysis of acyclic azines (9) and diazepines (10, 11) have been recently reported.

[1]This work was initiated independently in both laboratories. Decision for a cooperative project was reached in order to avoid duplication of results.

[2]Part IV in the series "The chemistry of seven-membered heterocyclic systems"; for previous paper, see ref. 1.

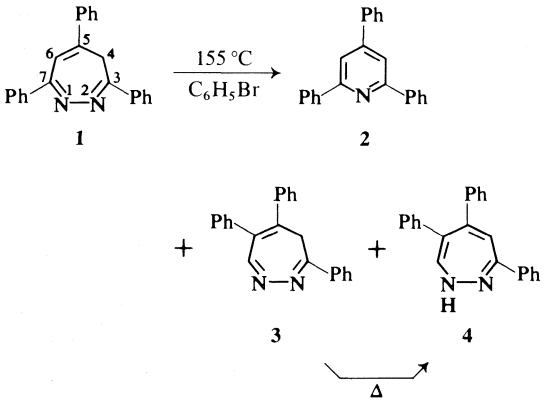
Thermolysis

The thermolysis of 3,5,7-triphenyl-1,2,(4*H*)-diazepine (**1**) in refluxing bromobenzene followed by preparative layer chromatography yielded 2,4,6-triphenylpyridine (**2**) (2.5%) and two new isomeric 1,2-diazepines which are assigned structures **3** (14%) and **4** (19%) respectively on the basis of the following evidence (Scheme 1).

The ir, uv, and the mass spectral fragmentation pattern of **3** are very similar to those of **1** (2). Comparison of the nmr spectra of **1** and **3** clearly shows that in both compounds a methylene group is present with a large chemical shift difference between the two geminal protons. In **1**, δ 4.16 and 2.41 (2, 12); in **3**, δ 4.63 and 2.0. For both methylene groups, $J_{gem} = 11 \pm 1$ Hz. Furthermore, both compounds behave similarly under temperature variation: for **1**, $\Delta G^{\ddagger}$(343 K) = 17.6 kcal/mol, $T_c = 366$ K; for **3**, the exchange-broadened doublets observed at 305 K become sharp doublets at 273 K and a value of $T_c = 370$ K may be estimated. Reference to the recently determined X-ray crystal structure of the diazepinium picrate **5** (13) is useful in the analysis of the large chemical shift difference between the C_4-geminal protons in **1** and therefore in **3**.[5] The 1,2(4*H*)-diazepine conformation is such (*cf.* **5**) that H_B is close to and almost coplanar with the C_3 and C_5 phenyl groups whereas H_A is not. A rough estimate of the ring current effect based on the model of Haigh and Mallion (16) predicts a difference in shielding



SCHEME 1

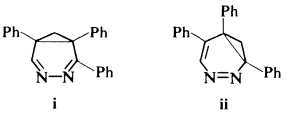
[5]There are valid arguments that (*a*) the conformation of the protonated form **5** and **1** are similar (14) and (*b*) the conformation of a (4*H*)-diazepine in the solid state and in solution should be comparable (13, 15).

$\delta_B - \delta_A \approx 2$ ppm which is in qualitative agreement with the observed values (*vide supra*). A further consequence of the conformational representation **5** is the expected larger coupling between H_6 and H_B than between H_6 and H_A due to the coplanarity of the atoms H_6–C_6–C_5–C_4–H_B. In agreement with this expectation, we have found previously (2, 12) that the low-field methylene proton (H_B) in **1** exhibits $J = 2.4$ Hz while the high-field methylene proton (H_A) shows $J = 1.6$ Hz.

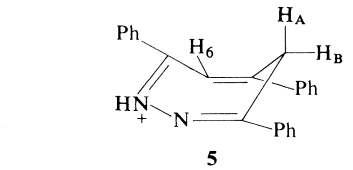
The above analysis leads to the deduction that the thermolysis product must exhibit a structure which embodies a methylene group flanked by two phenyl-bearing sp^2-carbons within a 1,2(4*H*)-diazepine framework. This rules out a number of mechanistically reasonable structures (see below) and leaves for examination the two possible formulations, **3** and **6**. Structure **6** would be expected to show long range coupling between the C_5-methylene and H_7 similar to the ABX coupling pattern observed for compound **1** (δ (H_6) 6.45) (2, 12). Since no such absorption and pattern was observed, structure **6** is eliminated[6] and therefore the 3,5,6-triphenyl-1,2(4*H*)-diazepine structure **3** is assigned to the thermolysis product. The spectrum of **3** recorded after addition of Eu(DPM)$_3$ shift reagent showed a sharp singlet at δ 7.56. This downfield shift, independent of other signals, is assigned to the C_7-proton and is undoubtedly due to coordination of europium at N_1 by analogy with rhodium coordination of **1** (19).[7]

The ir spectrum of the other new thermolysis product (**4**) shows the presence of NH (ν_{max} 3425 cm^{-1}) and the mass spectrum exhibits the base

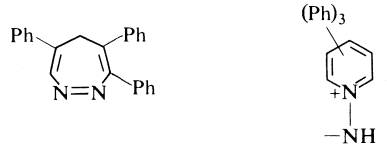
[6]It may be expected that **6** should exist predominantly in its corresponding valence isomer form **i** on the basis of several independent studies on such diazanorcaradienes (11*a*, 17). Structure **i** and, incidentally, **ii** and **12** (Scheme 2), the potential valence isomers of **3** and **1** respectively are eliminated since they should all show typically high field absorption due to the cyclopropane protons (δ < 2, J_{gem} = 3–6 Hz) (18).



[7]The methylene signal of **3** was also influenced by the addition of Eu(DPM)$_3$: H_A was shifted strongly downfield while H_B was almost unaffected which is again reasonable if binding of the shift reagent at N_1 is assumed (*cf.* **5**). A similar effect on the methylene protons of **1** was observed.

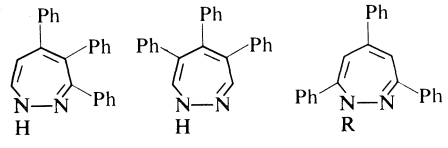


5



6 7

peak at m/e 321 ($M^+ - 1$). The nmr spectrum portrays, besides absorption for the aromatic protons at δ 7.9–6.85 (m, 16H), a doublet at δ 6.72 (J = 3 Hz) and a broad singlet at δ 8.9. A D_2O exchange experiment collapsed the signal at δ 6.75 into a sharp singlet and removed the broad NH signal at δ 8.9. This observation rules out a 1-iminopyridinium ylide type structure (**7**)[8] and directs consideration of a 1,2(1*H*)-diazepine formulation possessing a hydrogen at C_7. In 3,4,5-triphenyl-1,2(1*H*)-diazepine (**8**), $J_{6,7}$ substantially larger than 3 Hz would be expected. In 4,5,6-triphenyl-1,2(1*H*)-diazepine (**9**), NH-prototropy should make H_3 and H_7 equivalent with an identical chemical shift and coupling constant to NH.[9] The observed spectrum rules out both of these possibilities. There remain structures **4** and **10**, R = H for consideration. In previous work, we have observed that, in general, 3,5,7-triphenyl-1,2(1*H*)-diazepines (*e.g.* **10**, R = Me, CO_2Et, COMe) show $J_{4,6}$ = 1.5–2.0 Hz (3, 4). Since the D_2O exchange experiment resulted in the observation of a sharp singlet for C_7—H with a line width of less than 0.8 Hz, **10**, R = H is eliminated and structure **4** is assigned to this thermolysis product. That the C_4—H signal in **4** falls under the envelope of the phenyl absorption is also reasonable on the basis of our previous observations (3, 4).



8 9 10

[8]In addition, ylide **7** would not be expected to be stable in refluxing bromobenzene (14, 20).

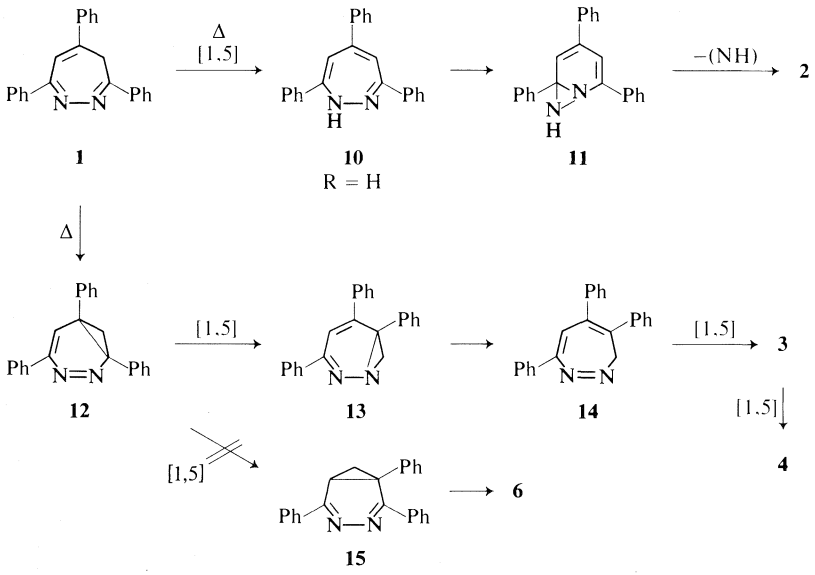
[9]We have observed this phenomenon recently in the irontricarbonyl complex of the parent 1,2(1*H*)-diazepine (21).

The interrelationship of **3** and **4** was established by thermolysis of **3** which gave **4** as the exclusive product. It was also shown that **4** was stable under these conditions and that refluxing **1** for an extended period of time led to increased amounts of **4** at the expense of **3**. The conversion of **3** into **4** provides supportive chemical evidence and may be viewed as a thermally allowed [1,5]-sigmatropic shift (see Scheme 2). Interconversion of other structures which have been discussed, *e.g.* **6** → **4**, could only proceed by a more complicated series of rearrangements.

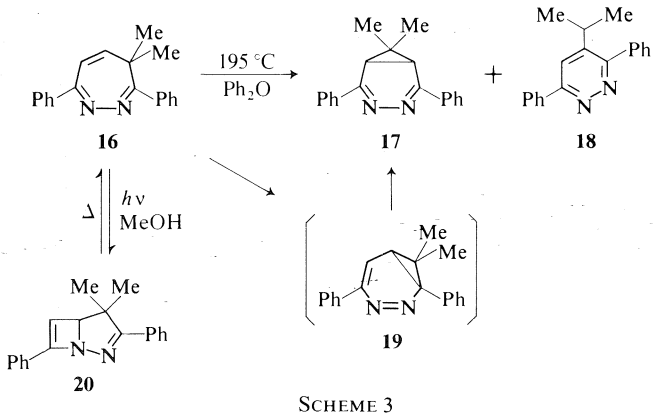
Neat thermolysis (220 °C) was also performed on **1** to give 2,4,6-triphenylpyridine (**2**) as the only isolable product. Furthermore, these conditions were applied to 5-(*p*-methoxyphenyl)- and 5-(*p*-chlorophenyl)-3,7-diphenyl-1,2(4*H*)-diazepines, **24***a* and **24***c* respectively and led to the formation of the corresponding pyridine derivatives, **26***a* and **26***c* in low yields (see Experimental).

The mechanism for the formation of products from the thermolysis of **1** is given in Scheme 2. The formation of 2,4,6-triphenylpyridine (**2**) may be viewed as proceeding by a [1,5]-sigmatropic hydrogen shift to the 1,2(1*H*)-diazepine **10**, R = H followed by valence isomerization to **11** and loss of the elements of (NH). [1,5]-Sigmatropic shifts have been observed in a related 1,2-diazepine (15) and are more widely documented in azepines derivatives (22). Valence isomerization of **10**, R = H into **11** and thence rearrangement to **2** (possibly via the intermediate *N*-iminopyridinium ylide, *cf.* **7**) is expected to be facile on the basis of previous thermolysis results of 1-substituted 1,2(1*H*)-diazepines (**10**, R = Me, etc.) (11*b*, 14). The 5,6-dihydro derivative of **1** also yields the pyridine **2** presumably by an oxidative process (10). The formation of **3** and **4** may be described by the sequence of valence isomerizations and [1,5]-sigmatropic shifts (intermediates **12**–**14**) shown in Scheme 2 although a radical mechanism is not excluded.

Contrasting significantly with our results are those reported by Zimmerman and Eberbach on the thermolysis of the closely related dimethyl-1,2(4*H*)-diazepine **16** which gave diazanorcaradiene (**17**) and pyridazine (**18**) products (Scheme 3) (11*a*). Clearly, an identical valence isomerization step, **16** → **19** and **1** → **12** may be invoked to rationalize the thermolysis results of **1** and **16** respectively. However, whereas **19** then



SCHEME 2



SCHEME 3

may directly proceed to **17** by a C-to-C [1,5]-sigmatropic shift ('walk' rearrangement (11*a*)), intermediate **12** avoids the analogous pathway to **15** in favor of a C-to-N [1,5]-sigmatropic shift to **13** which then continues via **14** to product. In both cases, **1** and **16**, no evidence is available to distinguish between a concerted or non-concerted process. If a concerted process is operative, their different behavior may be a consequence of perturbation on the MO correlation diagrams and thus on the energy requirements caused by the absence of symmetry (N-atoms) and presence or lack of electronic effects (C_5-phenyl in **12**) (23). If a non-concerted process applies, there may be expected to be little difference in stability of the two hypothetical dipolar or diradical species from **12** en route to **13** or **15**. On the other hand, there should be a distinct preference in **19** for C—C cleavage of the cyclopropane ring at the more highly substituted and congested side, a rationalization which is consistent with the observed formation of **17**.[10] It may also be noted that the C–C [1,5]-sigmatropic shift, **19** → **17** is favored over the alternate C–N shift for steric reasons.

Photolysis

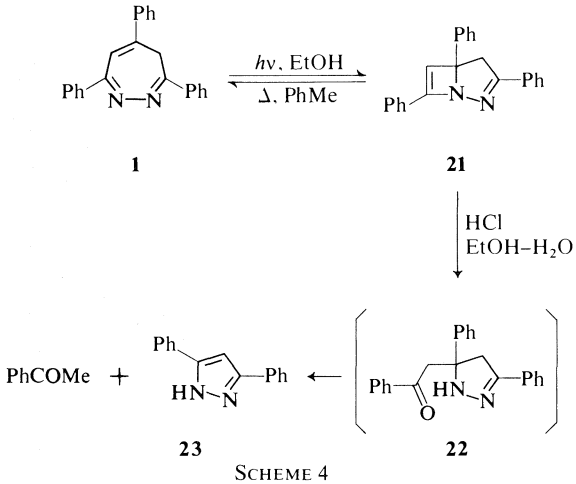
When 3,5,7-triphenyl-1,2(4*H*)-diazepine (**1**) was irradiated in ethanol with a Pyrex-filtered immersion lamp, a single, somewhat unstable

[10]Compound **18** probably arises from **17** (11*a*).

product was isolated to which the 3,5,7-triphenyl-1,2-diazabicyclo[3.2.0]hepta-2,6-diene structure **21** is assigned on the basis of the following evidence (Scheme 4). Its 60 MHz nmr spectrum consists of a multiplet at δ 7.1–7.8 due to the aromatic protons, a singlet at δ 6.4 assigned to the vinyl hydrogen, and an AB quartet at δ 3.8 and 3.2 (J = 17.5 Hz) attributed to the C_4 methylene protons. Since no allylic coupling between the vinyl proton signal and the methylene absorption was evident (confirmed by 100 MHz nmr), the structural possibility resulting from the alternate photochemical electrocyclic closure of **1** is eliminated.

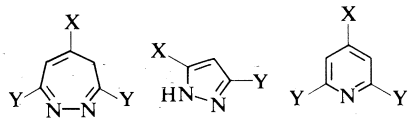
Chemical confirmation of structure **21** was obtained as follows. Upon reflux in toluene solution, the photoisomer underwent partial thermal reversion to a 2:1 mixture of **1**:**21**. Such cycloreversions have been observed in the analogous case **20** → **16** (Scheme 3) (11*a*) and other closely related systems (8*a*). In further support of structure, brief treatment of **21** with ethanolic hydrochloric acid gave acetophenone and 3,5-diphenylpyrazole (**23**). This reaction most likely occurs through the intermediacy of 5-phenacyl-3,5-diphenyl-2-pyrazoline (**22**), which has been shown to undergo fragmentation to the same two products upon acid treatment (24).

Irradiation of the readily available (2) compounds **24***a* and **24***b* under conditions similar to those employed for **1** gave crude material whose nmr spectra exhibited peaks consistent with diazabicyclo[3.2.0]heptadiene structures analogous to **21** (see Experimental). However, attempted purification of these products resulted in mixtures of at least eight components (tlc analysis) which were not characterized. Finally, photolysis of **24***c* yielded a complex reaction mixture containing no detectable bicyclic isomer (nmr analysis).



SCHEME 4

When the parent diazepine (**1**) was irradiated (253.7 nm) in acetone solution, the same pyrazole derivative (**23**) as well as 2,4,6-triphenylpyridine (**2**) were isolated in low yields. Under these conditions, but longer irradiation times, the 5-*p*-methoxyphenyl- and 5-*p*-chlorophenyl-1,2-(4*H*)-diazepines, **24***a* and **24***c* afforded the corresponding pyrazole (**25***a* and **25***c*) and pyridine (**26***a* and **26***c*) derivatives respectively.[11] In neither case was there observed a significant build up of the respective diazabicyclo[3.2.0]-heptadiene derivatives. The pyrazoles **25** and pyridines **26** are known compounds and were fully characterized by comparison with authentic samples synthesized independently (see Experimental). Since it is known that *N*-substituted pyrazoles undergo photochemical rearrangement (6), the stability of the NH-pyrazole **23** to our irradiation conditions was tested. It was shown that **23** is stable to prolonged irradiation in acetone solution.

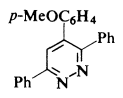


24 **25** **26**

a, X = *p*-$MeOC_6H_4$, Y = Ph
b, X = *p*-$MeOC_6H_4$, Y = *p*-MeC_6H_4
c, X = *p*-ClC_6H_4, Y = Ph
d, X = *p*-$Me_2NC_6H_4$, Y = Ph
e, X = *p*-Me(CHO)NC_6H_4, Y = Ph

Photolysis of **24***d* in acetone did not produce rearranged products but resulted instead in photo-oxidation to give the *N*-formyl derivative **24***e*. Structure **24***e* was assigned on the basis of spectral evidence. Its ir spectrum exhibits amide

[11] An additional minor product from the photolysis of **24***a* could not be obtained in pure form (contaminated with **26***a* even after several preparative tlc separations) but it was definitely shown *not* to be the pyridazine **iii** by independent synthesis (25). Compound **iii** could arise by a valence isomerization analogous to **1** → **12** followed by [CH_2] loss.



iii

carbonyl absorption at 1675 cm^{-1} and its mass spectrum shows the correct molecular ion at *m/e* 379. In comparison with the starting material (**24***d*), the nmr spectrum of **24***e* shows the loss of one N-Me group and the appearance of a singlet at δ 8.70 readily assigned to a formyl proton. Whereas compound **24***d* shows two-proton absorption at δ 6.80 due to the *ortho* hydrogens of the *p*-dimethylaminophenyl group, in **24***e* this multiplet is shifted under the aromatic proton envelope (δ 8.10–7.10) as expected on the basis of the deshielding influence of the N—CHO function.

The photochemical formation of the diazabicyclo[3.2.0]heptadiene **21** (Scheme 4) may be expected to occur by an allowed 4π electrocyclization and has direct parallel, in contrast to the thermolysis results (*vide supra*), with the photolysis of **16** to give **20** (Scheme 3) (11*a*). These reactions represent additions to an expanding list of cases which involve electrocyclization of azabutadiene units within diverse molecular frameworks (8*a*).[12]

The results obtained by irradiation in acetone may be mechanistically interpreted by reference to the reaction of **1** to produce 3,5-diphenylpyrazole (**23**) and 2,4,6-triphenylpyridine (**2**). The formation of compound **23** may be explained by postulating the intermediacy of **21** (Scheme 4) which undergoes loss of phenyl acetylene to form product. Precedence for such fragmentation is available (11*b*). The pyridine derivative **2** may arise by a photosensitized [1,3]-sigmatropic hydrogen shift to form the 1,2(1*H*)-diazepine **10**, R = H which suffers thermal ring contraction and [NH] loss in a manner similar to that already postulated (Scheme 2). Finally, the transformation **24***d* → **24***e* may be interpreted as an acetone photosensitized oxygenation, a reaction which has been widely documented for tertiary amines in the recent literature (27).

Experimental

General Methods

Melting points were measured on a Mel-Temp apparatus or a Reichert mp Microscope and are uncorrected. Microanalyses were performed by the microanalysis department at the University of Copenhagen. Infrared spectra were determined with Beckman IR-10 and Perkin-Elmer 337 spectrophotometers. Ultraviolet spectra were obtained on a Perkin-Elmer 137 spectrophotometer. Routine nmr spectra were recorded on a Varian T-60 spectrometer with Me_4Si as internal standard. For comparison and interpretation purposes, the nmr spectra of **1–4** were obtained in frequency sweep mode at 32 °C on the Varian HA-100 spectrometer equipped with a Spectra 100 system. Integration was performed on averaged spectra. Samples were prepared in C_6D_5Br (25 mg/400 μl). For shift reagent experiments, **3** was dissolved in $CDCl_3$–CCl_4 (1:4), $Eu(DPM)_3$ was added, and the solution was subjected to filtration. The filtrate was subsequently diluted with additional solvent while the dependence of the signals was followed. Starting concentrations: [**3**] = 0.135 *M*; $[Eu(DPM)_3] = 9.0 \times 10^{-2}$ *M*. Variable temperature spectra of **3** were determined on the Varian A-60A spectrometer using $CDCl_3$ for $T = -40$ to $+50$ °C and C_6D_5Br for the $T = +30$ to $+125$ °C temperature ranges. Mass spectra were recorded on an AEI MS902 spectrometer.

Irradiations were carried out as follows:

Method A: A solution of the sample was placed in a water-cooled (25–35 °C) Pyrex container and photolysis was performed using a Hanovia Q-700 medium pressure mercury arc as internal light source.

Method B: Irradiations were carried out in quartz or Vycor vessels placed centrally in a Rayonet Photochemical Reactor equipped with RUL-2537 Å lamps and cooled internally (15–20 °C) by a cold-finger condenser.

All solvents were dried and distilled before use. Thin layer chromatography was carried out with Merck silica gel GF 254 and column chromatography was effected with Merck silica gel (0.05–0.2 mm). Preparative tlc was performed with Merck PF 254-336 silica gel using 20 × 100 cm plates coated with a 1.5–2.0 mm layer of adsorbent. Fractions were scraped from the plates and isolated by extraction with $CHCl_3$ in a Soxhlet apparatus.

Thermolysis of 3,5,7-Triphenyl-1,2(4H)-diazepine (1) in Bromobenzene

A solution of **1** (2, 3) (1.0 g) in bromobenzene (30 ml) was refluxed under a nitrogen atmosphere for 9 days. The solvent was removed under reduced pressure and the residue was subjected to preparative tlc using ethyl acetate – benzene (5:95) as eluent. Two successive elutions gave the following fractions:

(*a*) Starting material (**1**): 550 mg (55%).

(*b*) *2,4,6-Triphenylpyridine (2)*: 25 mg (2.5%) identified by comparison with an authentic sample (28).

(*c*) *3,5,6-Triphenyl-1,2(4H)-diazepine (3)*: 136 mg (14%); mp 163–164 °C (EtOH); ir ν_{max} (KBr) 1593, 1270, 1200, 925 cm^{-1}; uv λ_{max} (EtOH) 274 (ε 29 400), 312 (sh, 12 200), 360 (6 900) nm; nmr ($CDCl_3$) δ 8.13 (m, 2H), 7.82 (m, 2H) and 7.08–7.53 (m, 12H) aromatic H, 4.63 (br d, 1H, C_4-H_A), 2.0 (br d, 1H, C_4–H_B); mass spectrum *m/e* 322 (M^+). *Anal.* calcd. for $C_{23}H_{18}N_2$: C 85.68, H 5.63, N 8.69; found: C 85.50, H 5.69, N 8.55.

(*d*) *3,5,6-Triphenyl-1,2(1H)-diazepine (4)*: 190 mg (19%), mp 209–210 °C (EtOH–H_2O); ν_{max} (KBr) 3425, 1600, 1495, 1460, 900 cm^{-1}; uv λ_{max} (EtOH) 244 (ε 27 200) 285 (19 000) nm; nmr (C_6D_5Br) δ 6.72 (d, 1H, J = 3 Hz, H_7), 6.9–7.45 and 7.8–8.0 (m, 15H, aromatic H), 8.9 (br s, 1H, exchangeable with D_2O, NH); mass spectrum *m/e* 322 (M^+), 321 (100%). *Anal.* calcd. for $C_{23}H_{18}N_2$: C 85.68, H 5.63, N 8.69; found: C 85.11, H 5.76, N 8.40.

When a solution of **1** (1.9 g) in bromobenzene (30 ml)

[12]The mechanistic details of 1-azabutadiene → azetine electrocyclization are under study by CNDO calculations by Prof. J. P. Snyder, University of Copenhagen (personal communication, May, 1974; see also ref. 26).

was refluxed under nitrogen for 36 days and the crude reaction mixture was processed and separated by preparative tlc as described above, there was obtained compound **4** (250 mg, 25%) as the major product in addition to minor amounts (< 5% each) of starting material and compound **3**.

*Thermolysis of 3,5,6-Triphenyl-1,2(4H)-diazepine (**3**) in Bromobenzene*

Compound **3** (25 mg) in bromobenzene (2 ml) was refluxed under a nitrogen atmosphere for 4 days. Thin layer chromatography (ethyl acetate – benzene, 5:95) showed the complete disappearance of starting material and the formation of *3,5,6-triphenyl-1,2(1H)-diazepine* (**4**) as the only product.

*Thermolysis of 3,5,6-Triphenyl-1,2(1H)-diazepine (**4**) in Bromobenzene*

Compound **4** (25 mg) in bromobenzene (2 ml) was refluxed under nitrogen for 4 days after which time starting material was completely recovered.

*Neat Thermolysis of 1,2(4H)-diazepines **1**, **24b**, and **24c***
*3,5,7-Triphenyl-1,2(4H)-diazepine (**1**)*

Compound **1** (246 mg) was pyrolyzed in a sealed evacuated tube at 220 °C (Wood's metal bath) for 1.5 h. The resulting dark brown oil was subjected to column chromatography (CH_2Cl_2 eluent to give 19 mg (8%) of *2,4,6-triphenylpyridine* (**2**) and 82 mg of recovered **1**. The pyridine **2** was identified by mp and mixture mp comparison with an authentic sample (28).

Pyrolysis of **1** at 220 °C for 4 h (complete disappearance of starting material by tlc) resulted in the formation of 25% of **2**. Numerous minor products evidenced by tlc were in insufficient quantities for isolation.

*5-(p-Methoxyphenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24a**)*

Compound **24***a* (2) (240 mg) was pyrolyzed under the first set of conditions described for **1** above to give 23 mg (10%) of 4-(*p*-methoxyphenyl)-2,6-diphenylpyridine (**26***a*), identified by mp and mixture mp comparison with an authentic sample (29) prepared by a literature method (28), and 85 mg of recovered **1**.

*5-(p-Chlorophenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24c**)*

Pyrolysis of compound **24***c* (2, 3) (240 mg) as described for **1** above (1.5 h) gave 19 mg (10%) of 4-(*p*-chlorophenyl)-2,6-diphenylpyridine (**26***c*) and 83 mg of recovered **1**. Compound **26***c* was identified by mp and mixture mp comparison with an authentic sample (30) synthesized by a literature procedure (28).

*Photolysis of 3,5,7-Triphenyl-1,2(4H)-diazepine (**1**) in Ethanol*

A solution of **1** (300 mg) in ethanol (250 ml) was irradiated for 4 h according to *Method A* outlined in General Methods. The photolysate was carefully taken to dryness *in vacuo* at room temperature and the residue was recrystallized from benzene – petroleum ether (60–90 °C) to give 200 mg (67%) of *3,5,7-triphenyl-1,2-diazabicyclo[3.2.0]hepta-2,6-diene* (**21**), mp 161–163 °C; uv λ_{max} (EtOH) 254 (ε 25 700) nm; nmr ($CDCl_3$) δ 7.1–7.8 (m, 15H, aromatic H), 6.4 (s, 1H, C_6-H), 3.8 (d, 1H, J = 17.5 Hz) and 3.2 (d, 1H, J = 17.5 Hz), CH_2; mass spectrum *m/e* 322 (M^+). *Anal.* calcd. for $C_{23}H_{18}N_2$: C 85.68, H 5.63, N 8.69; found: C 84.36, H 5.73, N 8.34.

Reproducibility of the above experimental conditions was found to be somewhat problematic. On several occasions, attempts to isolate **21** by evaporation of solvent *in vacuo* resulted in complex mixtures of products which no longer contained **21** (nmr evidence) even though tlc of the photolysate showed that it was the major constituent. See also photolysis of **24***a* and **24***b* below.

*Photolysis of 5-(p-Methoxyphenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24a**) in Ethanol*

A solution of **24***a* (200 mg) in ethanol (250 ml) was irradiated according to *Method A* until no more starting material was present (tlc). Evaporation to dryness under reduced pressure gave material whose nmr spectrum ($CDCl_3$) is consistent with *5-(p-methoxyphenyl)-3,7-diphenyl-1,2-diazabicyclo[3.2.0]hepta-2,6-diene*: δ 6.75–7.8 (m, 14H, aromatic H), 6.35 (s, 1H, C_6-H), 3.68 (d, 1H, J = 17.5 Hz) and 3.15 (d, 1H, J = 17.5 Hz), CH_2, 3.65 (s, 3H, OCH_3). Attempted recrystallization from benzene – petroleum ether (60–90 °C) resulted in extensive decomposition (tlc analysis).

*Photolysis of 5-(p-Methoxyphenyl-3,7-di-(p-methylphenyl)-1,2(4H)-diazepine (**24b**) in Ethanol*

Irradiation of **24***b* (2) and work-up was carried out as described for compound **24***a* to give crude material whose nmr spectrum ($CDCl_3$) was consistent with *5-(p-methoxyphenyl)-3,7-di-(p-methylphenyl)-1,2-diazabicyclo[3.2.0]hepta-2,6-diene*: δ 6.7–7.7 (m, 12H, aromatic H), 6.3 (s, 1H, C_6—H), 3.73 (d, 1H, J = 17.5 Hz) and 3.2 (d, 1H, J = 17.5 Hz), CH_2, 3.65 (s, 3H, OCH_3), 2.3 (s, 6H $2 \times CH_3$). Attempted recrystallization from ether – petroleum ether resulted in decomposition to at least eight new products (tlc analysis).

*Thermolysis of Compound **21***

A solution of **21** (30 mg) in toluene (5 ml) was refluxed for 24 h and then evaporated to dryness *in vacuo*. Nuclear magnetic resonance examination of the crude material showed the presence of compounds **21** and **1** in a ratio of 1:2.

*Hydrolysis of Compound **21***

A solution of **21** (50 mg) in ethanol (50 ml) containing concentrated hydrochloric acid (1 ml) was refluxed for 3 h. The solvent was removed under reduced pressure and the resulting residue was treated, in part, with 2,4-dinitrophenylhydrazine solution to give *acetophenone 2,4-dinitrophenylhydrazone*, mp 148 °C, shown to be identical by mp, mixture mp, and ir spectral comparison with an authentic sample. The remaining portion of the residue was recrystallized from ether to give *3,5-diphenylpyrazole* (**23**), identified by nmr and mass spectral and tlc comparison with an authentic sample (31).

*Photolysis of Compounds **1**, **24a**, **24c**, and **24d** in Acetone*
*3,5,7-Triphenyl-1,2(4H)-diazepine (**1**)*

A solution of **1** (200 mg) in anhydrous degassed acetone (200 ml) was irradiated in a quartz tube under nitrogen for 19 h according to *Method B* (General Methods). The solvent was removed *in vacuo* and the resulting oil was subjected to column chromatography to give in order of elution (eluent): 16 mg (8.5%) of *2,4,6-triphenylpyridine* (2) (methylene chloride), 72 mg (36%) of **1** (methylene chloride – ether, 9:1), and 24 mg (20%) of *3,5-diphenylpyrazole* (**23**) (ether).

Compound **1** was found to be stable under the following photochemical conditions (Rayonet apparatus): methylene chloride, 350 nm, 16 h; acetonitrile, 253.7 nm, 12 h; benzene, 253.7 nm, benzophenone sensitization, 24 h.

*Photochemical Stability of 3,5-Diphenylpyrazole (**23**)*

Irradiation of **23** (100 mg) in dry acetone (70 ml) for 24 h under nitrogen using *Method B* resulted in high yield recovery of starting material.

*5-(p-Methoxyphenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24a**)*

Irradiation (Vycor) of **24***a* (1.0 g) for 286 h in anhydrous acetone (500 ml) according to *Method B* gave, after chromatography (benzene eluent), 31 mg (13%) of *4-(p-methoxyphenyl)-2,6-diphenylpyridine* (**26***b*), 10 mg (1%) of *5-(p-methoxyphenyl)-3-phenylpyrazole* (**25***b*), and 500 mg (50%) of starting material. Compound **26***b* was characterized as indicated above while **25***b* was identified by comparison (mp and mixture mp) with an authentic sample prepared by a known method (31).

*5-(p-Chlorophenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24c**)*

A solution of compound **24***c* (1.0 g) was irradiated (*Method B*, Vycor) in anhydrous acetone (500 ml) for 262 h and processed as described for **24***a* above to give 31 mg (12%) of *4-p-chlorophenyl-2,6-diphenylpyridine* (**26***c*) and 10 mg (1%) of *5-(p-chlorophenyl)-3-phenylpyrazole* (**25***c*) in addition to 400 mg of recovered starting material (**24***c*). The pyridine (**26***c*) (30) and pyrazole (**25***c*) (32) derivatives were characterized by mp and mixture mp comparison with authentic samples synthesized independently by the methods of Dimroth and Wolf (28) and Widman (32) respectively.

*5-(p-Dimethylaminophenyl)-3,7-diphenyl-1,2(4H)-diazepine (**24d**)*

A solution of **24***d* (3) (500 mg) in anhydrous acetone (600 ml) was irradiated (*Method B*, quartz) for 24 h. Chromatography gave the following fractions in order of elution (eluent): 127 mg (25%) of starting material (ether – methylene chloride, 5:95), 43 mg (9%) of compound **24***e* (ether – methylene chloride, 10:90). Recrystallization from ethanol gave pure **24***e*, mp 190–191 °C; ir ν_{max} (CH_2Cl_2) 1675 cm^{-1}; nmr ($CDCl_3$) δ 8.70 (s, 1H, CHO), 8.10–7.10 (m, 14H, aromatic H), 6.75 (br s, 1H, C_6-H), 4.45 (br d, 1H, J = 12 Hz, C_4-H_A), 3.40 (s, 3H, CH_3), 2.70 (br d, 1H, J = 12 Hz, C_4-H_B); mass spectrum *m/e* 379 (M^+). *Anal.* calcd. for $C_{25}H_{21}N_3O$: C 79.13, H 5.58, N 11.07; found: C 78.66, H 5.28, N 10.74.

A three-coordinate complex of mercury: crystal structure of bis(iodo-*N*,*N*-diethyldithiocarbamatomercury(II))

CHUNG CHIEH

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received July 9, 1976

CHUNG CHIEH. Can. J. Chem. **55**, 65 (1977).

Reaction of mercuric iodide with *N*,*N*,*N*′,*N*′-tetraethylthiuramdisulfide (TETD), $Et_2N-\overset{\overset{S}{\|}}{C}-S-S-\overset{\overset{S}{\|}}{C}-NEt_2$, gave bis(iodo-*N*,*N*-diethyldithiocarbamatomercury(II)) and diiodo-*N*,*N*,*N*′,*N*′-tetraethylthiuramdisulfidemercury(II). The crystal of the former was monoclinic with $a = 7.645(3)$, $b = 7.787(4)$, $c = 18.005(7)$ Å and $\beta = 102.08(4)°$. The space group was $P2_1/c$, with two dimeric molecules per unit cell. Diffractometer measured intensities of 1727 observed reflections were used to determine the structure; the final *R* factor being 0.059. The mercuric ion was three-coordinated with two Hg—S distances of 2.422(4) and 2.644(4) Å and one Hg—I distance of 2.641(1) Å. The dimer had a centre of symmetry and formed an eight-membered ring.

CHUNG CHIEH. Can. J. Chem. **55**, 65 (1977).

La réaction de l'iodure mercurique avec le disulfure de *N*,*N*,*N*′,*N*′-tétraéthylthiourame (TETD) $Et_2N-\overset{\overset{S}{\|}}{C}-S-S-\overset{\overset{S}{\|}}{C}-NEt_2$, conduit aux bis(iodo *N*,*N*-diéthyldithiocarbamatomercure(II)), $Et_2-N-C-S-S-C-N-Et_2$, et au diiodo *N*,*N*,*N*′,*N*′-tétraéthylthiouramdisulfure de mercure(II). Les cristaux de premier sont monocliniques avec $a = 7.645(3)$, $b = 7.787(4)$, $c = 18.005(7)$ Å et $\beta = 102.08(4)°$. Le groupe d'espace est $P2_1/c$ et comporte deux molécules dimères par maille. On a utilisé les intensités mesurées à l'aide d'un diffractomètre pour 1727 réflexions observées pour déterminer la structure; le facteur final *R* est de 0.059. L'ion mercurique est tricoordonnée avec deux distances Hg—S de 2.422(4) et 2.644(4) Å et une distance Hg—I de 2.641(1) Å. Le dimère a un centre de symétrie et forme un cycle à huit chaînons.

[Traduit par le journal]

Introduction

Disulfuram has been used for the treatment of chronic alcoholism at a dose of 0.5 g per day. The chemical abstract name for the compound is tetraethylthioperoxydicarbonic diamide; however, it is better known as tetraethylthiuram disulfide (TETD),

$$Et_2NCS-SCNEt_2 \quad (1).$$

There has been a considerable interest in the interaction of heavy metal ions with biologically active compounds (2, 3). The interactions of TETD with mercurials are being studied. Reaction of TETD with methylmercury chloride gave bis(*N*,*N*-diethyldithiocarbamato)mercury-(II), $(Et_2NCS_2)_2Hg$, and methyl *N*,*N*-diethyldithiocarbamatomercury(II), $(Et_2NCS_2)HgMe$. The former was also obtained as a product in the reaction of TETD with mercuric chloride in chloroform–ethanol (1:1 by volume) mixed solution. Both α- and β-forms of $(Et_2NCS_2)_2Hg$ were obtained and X-ray diffraction data confirmed that they had the structures as reported by Iwasaki (4). The structure of Et_2NCS_2HgMe had been reported (5). The reactions of TETD with mercuric bromide and mercuric iodide also gave two kinds of products in each case. Compounds of HgX_2.TETD were obtained for X = Br and I. Their gross structures were obtained by X-ray diffraction methods. Further refinements are now being carried out. The existence of compounds of this type was claimed through nmr studies (6). Another compound obtained in the reaction of TETD with HgI_2 had cell constants similar to those of $(Et_2NCS_2)HgMe$ (5) and it was originally thought that they not only had similar formula but also similar structure, with CH_3 and I playing the same role. However the Raman spectrum of them, Fig. 1 and Fig. 5 of ref. 5, were quite different and the structure determination was carried out. It revealed that the compound had the empirical formula (Et_2NCS_2)-

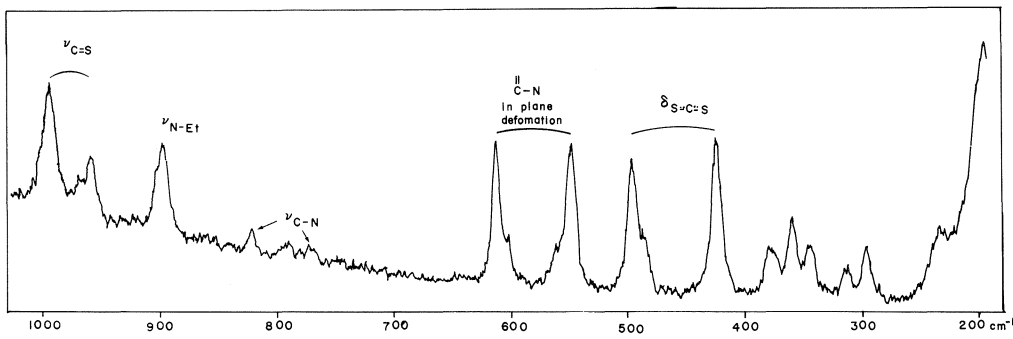

FIG. 1. Raman spectrum of bis(iodo-*N*,*N*-diethyldithiocarbamatomercury(II)) and partial assignments.

HgI which is similar to $(Et_2NCS_2)HgMe$; however, the two structures were different.

Experimental

The room temperature stable red form of mercuric iodide was purchased from Fisher Scientific Co., and tetraethylthiuram disulfide from Sigma Chemical Company, St. Louis, Missouri. The solvents used were standard reagent grade chemicals. Raman spectra of solids were obtained by Dr. S. Y. Tang on a Jarrel-Ash 25-100 spectrometer with argon ion laser excitation.

Several methods of preparation had been tried. For $((Et_2NCS_2)HgI)_2$, the following method was found to be the best. To 20 ml ethanolic solution of 0.235 g HgI_2, 20 ml chloroform solution of 0.154 g TETD were added. There was a small amount of small deep yellow square plates formed when the solutions were mixed. These small plates were identified as HgI_2.TETD as mentioned in the Introduction. The mixture was covered and left at room temperature for 3 days. Then, it was placed in a cool room (0 °C) and partly covered only to allow slow evaporation. After a week, the solution was reduced to about 0.5 ml. Yellow hexagonal prismatic crystals were obtained after filtration. A few square plate-like crystals were visible even to the naked eye. Due to the presence of a mixture, elemental analysis was not performed.

Crystals grown from the reactions described above were subjected to X-ray diffraction studies. Cell constants and space group were determined from photographic measurements; however, the former were refined by least-squares methods based on the 2θ values of 30 reflections measured on a G.E. XRD-6 diffractometer.

Crystal Data

$C_5H_{10}HgINS_2$ fw = 475.7

Monoclinic, $a = 7.645(3)$, $b = 7.787(4)$, $c = 18.005(7)$ Å, $\beta = 102.08(4)°$, $V = 1048.1$ Å^3, $\rho_0 = 3.00(1)$, $Z = 4$, $\rho_c = 3.014$, μ(Mo-K$_\alpha$) = 182.9 cm^{-1}; mp = 136 °C, space group $P2_1/c$.

Crystallographic Measurement

The crystal used for intensity measurement was a hexagonal prism with cross sections and length of 0.10 and 0.12 mm respectively. It was mounted with a^* along the φ axis of the goniostat. Intensities of 3052 independent reflections with $2\theta < 60°$ (Zr-filtered Mo-K$_\alpha$ radiation) were measured using θ–2θ scan method at room temperature (25 ± 3°). The scan speed was 2°/min and the 2θ range was $\pm(0.9 + 0.41 \tan\theta)$. Stationary background counts of 10 s each were taken at the limits of scan. Four standard reflections (104, 040, 202, 011) which had values evenly spread around the φ-circle were measured after each 100 reflections. The intensities of these reflections showed a fluctuation of ±2% during data collection. Of the reflections collected, 1727 had net intensities greater than $2\sigma_{(I)}$ were considered as observed. Majority of the unobserved reflections had 2θ greater than 45°. No absorption correction was made; however, the crystal used was uniform in dimension μR(Mo-K$_\alpha$) = 1.10, and the intensity of reflection 200, which had $\chi = 90°$, showed very little variation when φ was varied. Lorentz and polarization corrections were applied and only the observed reflections were used in the structure analyses.

Solution and Refinement

The structure was solved by the heavy-atom method and refined by full-matrix least-squares. The solution was straightforward and the refinement was smooth. The atomic scattering curves were taken from ref. 7 with dispersion corrections made for Hg and I atoms. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ where $w = (60 - |F_o| + 0.005F^2)^{-1/2}$ in the final stage of refinement. This weighting scheme gave lighter weight for both strong and weak reflections than the medium intense reflections; the variation of $\Sigma w\Delta F^2/n$ *vs.* ranges of F_o was small. An extinction coefficient of Zachariasen type was included in the 92-variable refinements. In the last cycle of refinement, the shifts of parameters were less than a quarter of their standard deviations. The difference Fourier showed some ripples around the mercury atom but was otherwise featureless. The final R $(= \Sigma(|F_o| - |F_c|)/\Sigma F_o)$ and weighted R_w $(= (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$ were 0.059 and 0.051 respectively. The atomic coordinates and temperature factors are listed in Table 1.[1]

Results and Discussion

The crystal consists of dimeric molecules as shown in Fig. 2. The dimer has a centre of inversion which coincides with the centre of

[1]Photocopies of the table of structure factors may be obtained at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

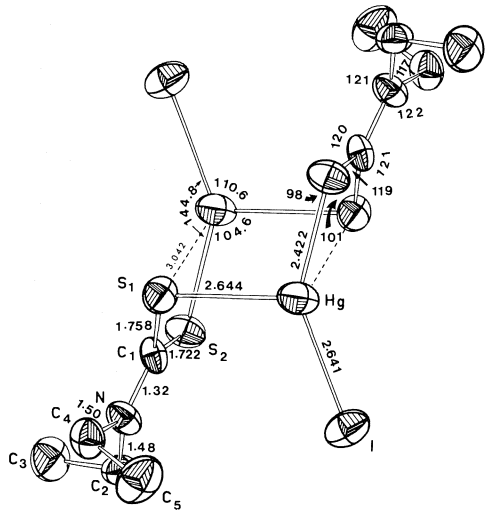

FIG. 2. Molecular structure with atomic labels and important bond distances and angles. The esd's are: σ_{Hg-I}, 0.001; σ_{Hg-S}, 0.004; σ_{C-S}, 0.015; and $\sigma_{C-C \text{ or } C-N}$, 0.02 Å. For the angles, the esd depends mainly on the centre atom: σ_{Hg}, ~0.1, σ_S, ~0.5 and $\sigma_{C \text{ or } N}$, ~0.7°.

symmetry of the space group $P2_1/c$; therefore, atoms of only half of the diagram are labelled. The important bond lengths and angles are also given separately in the two halves of the dimer. Around the mercuric ion, three bond lengths are noted: one Hg—I, 2.641(1), and two Hg—S distances of 2.644(4) and 2.422(4) Å. However, there is an additional short Hg...S contact of 3.042(4) Å. The mercury atom is coplanar with the three coordinated atoms, plane *5* of Table 2. It is interesting to compare with the coordination of Hg in diiodo-*N*,*N*,*N'*,*N'*-tetramethylthiuram-disulfidemercury(II), $HgI_2(S_2CNMe_2)_2$, in which there are two almost equal Hg—I distances of 2.661(2) and 2.654(2) Å. However, the two Hg—S distances of 2.651(7) and 2.882(7) Å are significantly different (8). The mercury atom is 0.305 ± 1 Å out of the plane containing the two iodine and the short-distant sulfur atoms.

Grdenic (9) derived the following mercury radii: van der Waals radius, 1.50; ionic radius, 1.04; digonal covalent radius, 1.30; and tetrahedral covalent radius, 1.48 Å. No three coordinated covalent radius was available, probably due to the fact that three coordinated mercury is not common; however the anions HgX_3^- (X = Cl, Br, and I) have a coordination number of 3 for mercury atom and the anion is planar (9). In particular, for HgI_3^- the three Hg—I distances are 2.71, 2.71, and 2.65 Å (average 2.69 Å)

TABLE 1. Final parameters (esd's) × 10^5 for Hg, I, and S, but × 10^4 for N and C, $\pm|x,y,z;x,\frac{1}{2}-y,\frac{1}{2}+z|$

2,3	2.3
2,4	2.7
2,5	99.3
3,4	4.9

and the three I—Hg—I angles are 123.3, 123.6, and 112.8° (10). Taking the single-bond covalent radius for I as 1.33 Å (11), the trigonal radius for mercury is then 1.36 Å. By taking into account the influence of the electronegativity difference (12) (Schomaker–Stevenson coefficient = 0.03), the mean value for trigonal radius is then 1.38 Å. The single-bond covalent radius for sulfur is 1.04 Å (11). The sum of trigonal mercury radius and single-bond sulfur covalent radius is 2.42 Å which agrees very well with the shortest Hg—S distance, 2.422 Å, found for the title compound. The lengthening of the other Hg—S distance, 2.644 Å, may be due to the fact that S_1 is in close contact with another mercury atom. The Hg—I distance of 2.641(1) Å is slightly shorter than those found for HgI_3^- ion. The three bonds are not evenly spread in space around the mercury atom with angles of 144.8°, 110.6°, and 104.6°, of which the sum is 360°. From the above discussion, it can be concluded that the mercury atom is three-coordinated. The additional short Hg...S contact, 3.042 Å, is less than the sum of van der Waals radii for Hg and S, 3.35 Å, but this type of interaction is not uncommon in crystal structures (9, 13). It is true that in coordination compounds, the mercury atom is either linearly two- or tetrahedrally four-coordinated (14). This tendency still remains in the present compound as the angle between the shortest Hg—S and Hg—I bonds is 144.8°, much greater than 120°. Perhaps intramolecular forces prevent Hg...S_1 contact to be closer than 3.04 Å.

The part of  in the ligand, diethyldithiocarbamate, is usually found to be planar (4). The equations for mean planes of various parts of the molecule are listed in Table 2. The unlabelled mercury atom is almost coplanar with labelled dithiocarbamate, excluding

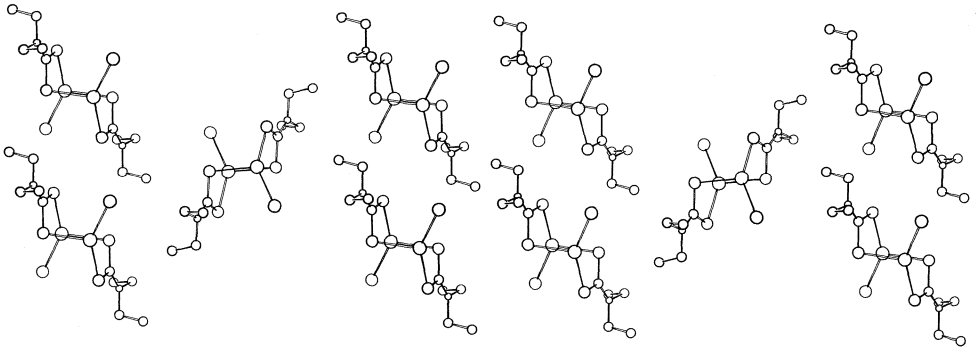

FIG. 3. Stereoscopic view of the molecular packing in bis(iodo-*N*,*N*-diethyldithiocarbamatomercury-(II)). Atoms are represented by the size of the ring in descending order of Hg > I > S > C > N. The direction of viewing is from *a* axis.

the terminal CH_3 groups. When Hg^{2+} is included in the mean plane calculation, the maximum displacement from the plane is only 0.11 Å. When Hg^{2+} is excluded from the least-squares plane calculation, the deviation becomes −0.3 Å. The planarity of  and the short N—C distance of 1.32(2) Å suggest that partial double bond character exists between N and C_1.

Absorption bands in the range from 560 to 608 cm^{-1} were assigned to C—N in plane deformation in ref. 15 for similar compounds; the band at 615 cm^{-1}, Fig. 1, was assigned accordingly. The band caused by $\nu_{(C-N)}$, usually found for other compounds, is very weak. Assignments for bands in the region between 200 and 400 cm^{-1} are very difficult. Coleman, Koenig, and Shelton gave all kinds of composite contributions for bands in this region for tetramethylthiuram disulfide (15). Meić studied the vibrational spectra of CH_3HgI and CD_3HgI as well as other halo-complexes and assigned a band at 173 cm^{-1} for $\nu_{(Hg-I)}$ (16). Two very strong Raman bands at 173 and 139 cm^{-1} were observed for $((Et_2NCS_2)HgI)_2$. The one at 139 cm^{-1} was 30 times as strong as the strongest band of Fig. 1, and ten times stronger than the band at 173 cm^{-1}. It was anticipated that the stretching mode of Hg—I be a strong band in Raman and a shift in frequency was also expected due to a change from two- to three-coordinated mercury; therefore, the band at 139 cm^{-1} could be assigned to $\nu_{(Hg-I)}$.

A packing diagram is shown in Fig. 3. The viewing direction is from the *a*-axis. All intermolecular distances are van der Waals type. The mercuric ion has no further close contact other than the one indicated in Fig. 2. The next closest intermolecular distance between mercury and iodine atoms is 3.5 Å. The dimers interlock into one another and this may be responsible for the hardness of the crystals.

Synthesis and electron spin resonance studies of a Co(II) complex with a tetradentate macrocyclic Schiff base ligand

AMIKAM REUVENI, VINCENZO MALATESTA,[1] AND BRUCE R. MCGARVEY

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 4, 1976

AMIKAM REUVENI, VINCENZO MALATESTA, and BRUCE R. MCGARVEY. Can. J. Chem. **55**, 70 (1977).

The synthesis, physical properties, and electron spin resonance of frozen solutions of $CoTAAB(NO_3)_2$ (TAAB = tetrabenzo[*b,f,j,n*] [1,5,9,13]tetraazacyclohexadecine) are reported. The spin Hamiltonian parameters were elucidated by simulation of spectra assuming axial g and ^{59}Co hyperfine tensors and including nuclear quadrupole and Zeeman contributions. Electron spin resonance spectra in solvents such as methanol, acetone, and dimethylformamide are typical for a low spin complex ($S = 1/2$) and are nearly identical with $|A_{\parallel}| \gg |A_{\perp}|$ and $g_{\perp} \gg g_{\parallel}$. In pyridine and quinoline a complex with a molar ratio solvent/ligand of 1:1 is formed with the solvent which gives $|A_{\parallel}| \approx |A_{\perp}|$ and $g_{\perp}$ much closer to $g_{\parallel}$. In strong Lewis bases, such as piperidine, a 2:1 complex is formed and no esr signal is found. Evidence is presented to show that these 2:1 complexes with strong Lewis bases are $S = 1/2$ complexes with a low lying $S = 3/2$ state that is partially populated at room temperatures. This behaviour is accounted for in terms of a theory derived for a $^2A_1$ ground state with a low lying quartet state which could become the ground state in strong basic solvents.

AMIKAM REUVENI, VINCENZO MALATESTA et BRUCE R. MCGARVEY. Can. J. Chem. **55**, 70 (1977).

On rapporte la synthèse, les propriétés physiques et les résonances paramagnétiques électroniques de solutions surgelées de $CoTAAB(NO_3)_2$ (TAAB = tétrabenzo[*b,f,j,n*] [1,5,9,13]-tétraazacyclohexadécine). On a élucidé les paramètres du hamiltonien de spin par simulation de spectres en faisant l'hypothèse que g est axial, en utilisant des tenseurs hyperfins pour ^{59}Co, et en incluant des contributions nucléaires quadrupolaires et de Zeeman. Les spectres de résonance paramagnétique électronique dans des solvants tels que le méthanol, l'acétone et la diméthylformamide sont typiques pour un complexe de spin bas ($S = 1/2$); ils sont pratiquement identiques et $|A_{\parallel}| \gg |A_{\perp}|$ et $g_{\perp} \gg g_{\parallel}$. Dans la pyridine et la quinoléine il y a formation d'un complexe avec un rapport molaire solvant-ligand de 1:1 qui donne $|A_{\parallel}| \approx |A_{\perp}|$ et $g_{\perp}$ beaucoup plus proche de $g_{\parallel}$. Dans des bases de Lewis fortes, telles que la pipéridine, il y a formation d'un complexe 2:1 et on ne trouve aucun signal rpe. On présente des données pour montrer que ces complexes 2:1 avec des bases de Lewis fortes sont des complexes $S = 1/2$ avec un état $S = 3/2$ peu élevé et qu'un peuplement partiel à température de la pièce. On tient compte de ce comportement en termes d'une théorie dérivée d'un état fondamental $^2A_1$ avec un état quadruplet peu élevé qui peut devenir l'état fondamental dans les solvants basiques forts.

Introduction

Planar low spin Co(II) complexes of the types CoN_4, CoN_2O_2, and CoS_4 have been the subject of many esr studies. The theory for the spin Hamiltonian parameters for these d^7 complexes was the subject of a recent study (1) which showed that contributions of low-lying quartet states to the magnetic parameters could be significant for some systems. Most of the esr studies on frozen solutions (see references in ref. 1) have involved low symmetry complexes and have proven of little value since the three principal g and A values could not be assigned unambiguously to the molecular axes. A few single crystal studies have appeared (2–7). Most of these complexes can bond to Lewis bases to form five- and six-coordinated species. Several of the five-coordinated complexes have demonstrated the ability to bond reversibly to molecular oxygen.

Transition metal complexes of the tridentate, tribenzo[*b,f,j*][1,5,9]triazacycloduodecine, abbreviated TRI, **1**, and tetradentate, tetrabenzo-[*b,f,j,n*][1,5,9,12]tetraazacyclohexadecine, abbreviated TAAB, **2**, have been made (8–11) by the condensation of *o*-aminobenzaldehyde in the presence of different metal ions.

2

We report here the synthesis of Co(II)TAAB-$(NO_3)_2 \cdot H_2O$, its isolation for the first time, and an esr study of the Co(II)TAAB^{2+} complex in frozen solutions of various solvents and Lewis bases. The TAAB ligand is similar to the porphyrin and phthalocyanine ligands in that it is a planar, conjugated tetradentate ligand with a fourfold symmetry axis. It differs from the porphyrin, phthalocyanine, and most planar tetradentate ligands studied in that it is neutral in charge. We therefore will expect to find the complex with the fifth and sixth coordination sites occupied by either a polar solvent molecule or the anions required for charge balance.

Experimental

Synthesis of Co(II)TAAB$(NO_3)_2 \cdot H_2O$

The synthesis follows that used by Melson and Busch (8) except that care is taken to keep oxygen out by degassing all solvents and carrying out all steps under prepurified N_2. A solution of 2.9 g (0.024 mol) of *o*-aminobenzaldehyde (freshly prepared by the method of Smith and Opie (12)) in 40 ml of ethanol was heated and stirred. While the *o*-aminobenzaldehyde solution was under reflux, a solution of 1.75 g of $Co(NO_3)_2 \cdot 6H_2O$ in 30 ml of absolute ethanol was added. The color of the solution changed from pale yellow to reddish brown and within 15–20 min it turned green and a precipitate began forming. After refluxing for 5 h the solution was cooled and filtered. The dark green solid was washed with chilled ethanol and ether. The green solid was recrystallized from acetonitrile to give dark green crystals which analyzed as CoTAAB$(NO_3)_2 \cdot H_2O$. Calculated for $C_{28}H_{20}N_6O_6$-$Co \cdot H_2O$: C 54.82, H 3.61, N 13.70, Co 9.61. Found: C 54.30, H 3.29, N 13.63, Co 9.63.

Physical Measurements

Electron spin resonance spectra were taken with a Varian E-12 spectrometer. All spectra were taken at X-band at liquid nitrogen temperatures using a finger-Dewar. Infrared absorption spectra were obtained using a Beckman IR-12 spectrophotometer. Electron Ionization mass spectra were obtained at various temperatures up to 270 °C using a Varian-MAT CH5 spectrometer. Magnetic susceptibilities of methanol and piperidine solutions were measured using the nmr shift technique (13). Magnetic susceptibilities of powder (in air) were measured by Professor A. B. P. Lever of York University using the Faraday method at temperatures from 82 K to room temperature. Nuclear magnetic resonance spectra were taken using a JEOL C68JEL Spectrometer. Chemical analysis was done by Galbraith Laboratories Inc., Knoxville, Tenn.

Results

Properties of CoTAAB$(NO_3)_2$

CoTAAB$(NO_3)_2$ is soluble in water. Addition of concentrated solutions of $HClO_4$ or HBr to the water solution produced green precipitates which are presumed to be the corresponding perchlorate and bromide salts. When O_2 was bubbled through an HBr solution of the bromide a red–brown solid resulted whose ir was identical to that of [CoTAABBr_2]Br reported by Cummings and Busch (11). The synthesis of Co-TAABBr_2 directly from $CoBr_2$ was attempted yielding a green precipitate whose esr in acetone was identical to the bromide produced from the nitrate and which oxidized to [CoTAABBr_2]Br, but a suitable recrystallization solvent was not found so no analysis was attempted.

In the reaction between $Co(NO_3)_2$ or $CoBr_2$ with *o*-aminobenzaldehyde considerable amounts of cobalt remain in the ethanol solution. Evaporation of this green filtrate under vacuum yields a light green solid. Examination of this solid by tlc reveals it to be a mixture. Frozen solution esr spectra of acetone solutions give only the signal found for CoTAAB$(NO_3)_2$. Magnetic susceptibility measurements reveal a much larger susceptibility than that found for CoTAAB$(NO_3)_2$ suggesting the presence of a high spin complex. Finally acetone and ethanol solutions of this solid turn brown within minutes after exposure to air while similar solutions of CoTAAB$(NO_3)_2$ oxidize much more slowly. Cummings and Busch (11) have shown that under similar preparative conditions, but in the presence of oxidizing agents, a mixture of Co(TRI)$_2X_3$ and Co-TAABX_3 is produced. We presume, therefore, that a main constituent of the ethanol solution after reflux is a Co(TRI)$_2^{2+}$ compound since this complex is octahedrally coordinated and would be expected to be high spin. This would account for the high susceptibility and our failure to detect any other esr signals at liquid nitrogen temperatures.

The ir spectrum of CoTAAB$(NO_3)_2$ is similar to that reported by Cummings and Busch (11) for [CoTAAB$(NO_3)_2$]NO_3 except only three bands attributable to NO_3^- are found at 1365, 1310, and 1031 cm^{-1}. The first two are obviously asymmetric stretches and the 1031 cm^{-1} is the

symmetric stretch. Since these frequencies are those normally found in ionic nitrates we can conclude that neither nitrate ion is really coordinated to the cobaltous ion. Electron ionization mass spectra, between 100 and 270 °C, of $CoTAAB(NO_3)_2$ did not give the m/e peak at 412 attributed by Cummings and Busch (11) to $(TAAB)^+$.

The magnetic susceptibilities at 298 K of methanol and piperidine solutions were found from nmr measurement of these solutions in a concentric double tube with TMS in the annulus (13). (Calibration was made with acetone, methanol, and carbon tetrachloride, respectively, in the inner tube.) The susceptibility of the methanol solution was found to be 1.67 ± 0.05 B.M., a value very close to that expected for an $S = 1/2$ state (1.73 B.M.). The piperidine solution gave a susceptibility of 2.25 ± 0.05 B.M., indicating a presence of an $S > 1/2$ state.

The magnetic susceptibility of powdered $CoTAAB(NO_3)_2$ has been measured between 82 and 298 K and is given in Table 1. Ligand and anion corrections were calculated from Pascal's constants (14). The effective magnetic moment increases with temperature to a value at room temperature considerably larger than that expected for an $S = 1/2$ system with the g values found for the complex from the esr studies. Attempts to fit the data to a simple model assuming a ground state doublet and an excited quartet state were made, but no satisfactory fit of all the data could be made. It seems reasonable, however, that the only way to account for these results is to assume some population at room temperature of excited states with a spin higher than 1/2. The same may be said for the piperidine solution of the complex.

TABLE 1. Magnetic susceptibilities of $CoTAAB(NO_3)_2$ powder at various temperatures

T (K)	μ_{eff} (B.M.)	χ_M (cgs × 10^6)

263.2	2.50	2950
298.2	2.65	2950

Electron Spin Resonance

The esr results were fitted to the spin Hamiltonian

$$[1]\quad \mathcal{H} = \beta[g_{\parallel}H_zS_z + g_{\perp}(H_xS_x + H_yS_y)] + A_{\parallel}S_zI_z + A_{\perp}(S_xI_x + S_yI_y) + Q'[I_z^2 - \tfrac{1}{3}I(I+1)] - g_N\beta_N\mathbf{H}\cdot\mathbf{I}$$

where symbols have their usual meaning. The esr studies were all done in frozen solutions involving $CoTAAB(NO_3)_2$ in most cases (esr of the powdered compound gave a very broad line). Spectra of the perchlorate and bromide salts in acetone and methanol were identical to the nitrate. The solvents used for making the frozen solutions could be divided into three groups according to the spin Hamiltonian parameters observed: (*i*) Solutions in methanol, acetone, and dimethylformamide which gave $|A_{\parallel}| \gg |A_{\perp}|$, and $g_{\perp} \gg g_{\parallel}$. (*ii*) Solutions in pyridine and quinoline which gave $|A_{\parallel}| \approx |A_{\perp}|$, $g_{\perp}$ much closer to $g_{\parallel}$ than in (*i*). (*iii*) Solutions in piperidine, aliphatic amines, pyrrolidine, and morpholine which gave no esr spectrum at all.

The magnetic parameters were obtained by comparing the experimental spectra with simulated spectra obtained from a computer program which numerically integrates over expressions for the resonance fields predicted by the spin Hamiltonian given in eq. 1, solved to second order. Forbidden transitions ($\Delta m_I = \pm 1, \pm 2$) were included with the allowed transitions

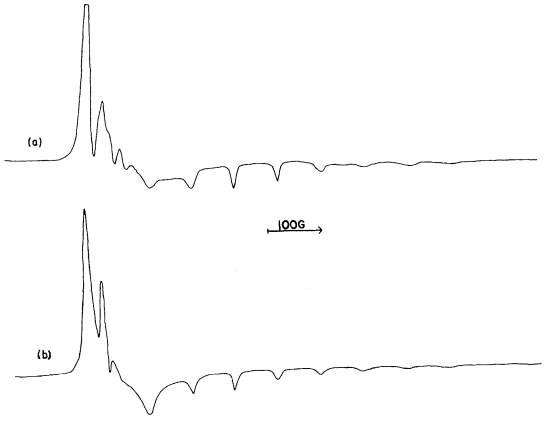

FIG. 1. (*a*) Electron spin resonance spectrum of a frozen solution of $CoTAAB(NO_3)_2$ in dimethylformamide. (*b*) Simulated spectrum of the dimethylformamide solution.

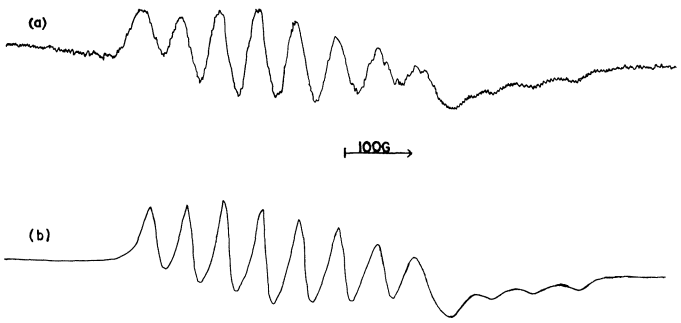

FIG. 2. (*a*) Electron spin resonance spectrum of a frozen solution of $CoTAAB(NO_3)_2$ in pyridine. (*b*) Simulated spectrum of the pyridine solution.

($\Delta m_I = 0$) (15) in the calculation. A Lorentzian line shape was assumed and it was found necessary to assume a different line width for each hyperfine line to get good agreement between calculated and experimental spectra. Our program for frozen solution spectra appears to be different from most reported programs in that it calculates the derivative directly rather than numerically differentiating an absorption curve.

Figure 1(*a*) shows a spectrum of a frozen solution of $CoTAAB(NO_3)_2$ in DMF. The lower trace (*b*) is the simulated spectrum. Figure 2 shows, similarly, a spectrum of a frozen solution of the complex in pyridine. The magnetic parameters for different frozen solutions are given in Table 2.

Addition of pyridine stepwise to a solution of $CoTAAB(NO_3)_2$ in acetone gives a complete conversion to the pyridine-type spectrum at a molar ratio of 1:1, indicating that the spectrum observed in pyridine is of a complex formed by addition of one pyridine molecule to $CoTAAB^{2+}$. A similar experiment using piperidine gives complete disappearance of the acetone esr spectrum at a molar ratio of 2:1, indicating the formation of a complex having two molecules of piperidine. Addition of acetone to the residue obtained after evaporation of a piperidine solution of $CoTAAB(NO_3)_2$ restores the acetone esr signal. This indicates that the reaction between piperidine and the complex is reversible in nature and that the disappearance of the esr spectrum in piperidine is not due to some irreversible process such as oxidation which converts Co(II) to diamagnetic Co(III). The nmr spectrum of $CoTAAB(NO_3)_2$ in piperidine shows an upfield shift of all piperidine lines relative to the neat solvent with the NH line shifted most. The lines are also slightly broadened. Further shifts and broadening occur in mixed piperidine–CD_3COCD_3 solvents. These nmr shifts indicate that the piperidine complex is paramagnetic with a much shorter spin relaxation time than the $S = 1/2$ complex in pyridine or acetone. The only reasonable explanation for the lack of an esr spectrum and the nmr shifts is to postulate either an $S = 3/2$ ground state for the piperidine complex or a low lying $S = 3/2$ state that is close enough in energy to produce a very short electronic T_1 making esr detection at liquid N_2 temperatures impossible. The latter explanation is favored by the nmr susceptibility measurements.

TABLE 2. Spin Hamiltonian parameters for $CoTAAB(NO_3)_2$ in frozen solutions[a]

Solvent	$g_\parallel$	$g_\perp$	$A_\parallel$[b]	$A_\perp$[b]
Acetone	2.0259	2.2762	75.3	12.9
Methanol	2.0275	2.2720	75.3	12.3
Dimethyl formamide	2.0244	2.2772	75.8	12.1
Pyridine	2.0562	2.1949	59.4	58.3
Quinoline	2.0547	2.1968	60.5	59.4

[a] Q' was found to be $-0.00015\ cm^{-1}$.
[b] Values in $10^{-4}\ cm^{-1}$.

Discussion

The spin Hamiltonian parameters fit the theoretical equations for an $^2A_1$ ground-state, where in the case of axial symmetry we have, by perturbation methods (1), for an electron in a d_z^2 orbital:

$$[2] \quad g_\parallel = g_e + 2c_3^2 - 3c_1^2$$

$$[3] \quad g_\perp = g_e + \tfrac{2}{3}c_3^2 - 6c_1^2 + 6c_1$$

TABLE 3. Computed parameters for $CoTAAB(NO_3)_2$ using perturbation and exact equations

	Perturbation calculation				Exact calculation				
Solvent	c_1	c_3	P^a	K^a	c_1	c_3	P^a	K^a	K(ave)^b
Methanol	0.045	0.125	206.0	−32.5	0.047	0.118	235.5	−19.6	−24.3
Pyridine	0.030	0.168	228.7	−51.3	0.033	0.109	227.9	−40.7	−47.5

[a]In 10^{-4} cm^{-1}.
[b]See ref. 1, p. 2509.

$$[4] \quad A_{\parallel} = K + P\left\{\frac{4}{7} - \frac{4}{7}c_3 - \frac{6}{7}c_1 + \frac{2}{63}{c_3}^2 + \frac{15}{7}{c_1}^2\right\}$$

$$[5] \quad A_{\perp} = K + P\left\{-\frac{2}{7} + \frac{45}{7}c_1 + \frac{2}{7}c_3 + \frac{4}{21}{c_3}^2 - \frac{57}{14}{c_1}^2\right\}$$

$$[6] \quad \begin{cases} c_1 = \xi/\Delta(^2B_1) \\ c_3 = \xi/\Delta(^4B_1) \end{cases}$$

$$[7] \quad P = g_e g_N \beta_e \beta_N \langle r^{-3} \rangle$$

K is the Fermi contact interaction, ξ is the spin–orbit interaction constant for one d electron. $\Delta(^2B_1)$ is the energy difference between the $^2B_1$ state and the ground state and $\Delta(^4B_1)$ is defined likewise. These equations can serve to obtain c_1 and c_3 from the g-values and P and K from $A_{\parallel}$ and $A_{\perp}$. In this case we can also solve exactly for the magnetic parameters. The results of these exact calculations are given in eqs. 48–56 of ref. 1. Table 3 gives values for methanol and pyridine frozen solutions obtained by using both methods of calculation.

Table 1 of ref. 1 contains a large number of results of such calculations for axial complexes of Co(II) with porphyrins and phthalocyanines, our values are within the range of values given there. It was found (1) that in the range $c_1 < 0.05$ it was necessary to take $A_{\parallel} > 0$ and $A_{\perp} < 0$ in order to obtain P in the expected range, this choice of signs was also used here.

The $CoTAAB(NO_3)_2$ forms three types of complexes with the solvents investigated here. In acetone, methanol, and dimethylformamide the ground state is a doublet. In piperidine, where two solvent molecules are attached to the planar $CoTAAB^{2+}$, there is obviously a low-lying $S = 3/2$ state, which is partially populated. It is close enough in energy to the ground state to result in an electronic T_1 too short to allow observation of esr spectra even at 77 K. The magnetic susceptibility measured in the solution and the paramagnetic shifts observed in the nmr spectrum of the complex are strong indications that there is indeed a paramagnetic species here which is not a pure $S = 1/2$ state. The magnetic susceptibility of the powdered complex is about the same as that measured in the piperidine solution, suggesting an arrangement in the solid where molecules are stacked such that the fifth and sixth coordination sites are occupied by nitrogen atoms from adjacent molecules. That the species in piperidine is indeed a reversibly formed complex and not a product of some irreversible chemical change is manifested by retrieving the acetone-complex on redissolving in acetone the residue left after evaporating the piperidine from its solution. The pyridine-complex, which is formed with one solvent molecule is apparently an intermediate case between the acetone-type complex and the piperidine-type one. The low-lying quartet state is closer to the $S = 1/2$ ground state than in the acetone complex but still farther than in the piperidine case so that esr spectra (with different magnetic parameters) could be observed.

Excess volumes of an alcohol + methylethylketone

KALLURU S. REDDY AND PULIGUNDLA R. NAIDU
Sri Venkateswara University Chemical Laboratory, Tirupati 517502, India

Received August 11, 1976

KALLURU S. REDDY and PULIGUNDLA R. NAIDU. Can. J. Chem. **55**, 76 (1977).

Excess volume data for mixtures of 1-propanol, 1-butanol, 1-pentanol, and 1-hexanol with methylethylketone were determined at 303.15 and 313.15 K. These volumes are negative with 1-propanol and increasingly positive with the higher homologs, suggesting that the structure-making effect of the ketone outweighs the structure-breaking effect in the first mixture of the series while the structure-breaking effect dominates in the other three mixtures. Further, the temperature coefficient of V^E was found to be positive in all four mixtures.

KALLURU S. REDDY et PULIGUNDLA R. NAIDU. Can. J. Chem. **55**, 76 (1977).

On a déterminé, à 303.15 et à 313.15 K, les données concernant les volumes d'excès pour des mélanges de propanol-1, de butanol-1, de pentanol-1 et d'hexanol-1 avec la butanone-2. Ces volumes qui sont négatifs avec le propanol-1 augmentent d'une façon algébrique lorsque l'on passe aux homologues supérieurs; ces résultats suggèrent que l'effet de formation de structure de la cétone contrebalance l'effet de brisure de structure dans le premier mélange de la série alors que l'effet de brisure de structure domine dans les trois autres mélanges. De plus on a trouvé que le coefficient de température de V^E est positif dans les quatre mélanges.

[Traduit par le journal]

Introduction

These measurements were made as part of a study of excess volumes of alcohol solutions containing a ketone as a common component (1). The systems studied include: 1-propanol, 1-butanol, 1-pentanol, and 1-hexanol with methylethylketone. An attempt has been made to interpret the results on the basis of structure-breaking and structure-making effects of the common solvent, methylethylketone.

Experimental

The dilatometer used for measuring excess volumes was similar to that described by Rao and Naidu (2). The mixing cell contained two bulbs of two different capacities and were connected through a U-tube having mercury to separate the two components. One end of the bulb was fitted with a capillary (1 mm id) and the other end of the second bulb was fixed with ground glass stopper. The V^E values were accurate to ± 0.003 cm^3 mol^{-1}.

The alcohols were purified by the method described by Rao and Naidu (2). Methylethylketone was dried over potassium carbonate for 3 days, then boiled for 2 h and distilled (3). The purity of methylethylketone was checked by comparing the values of density ρ with that reported in the literature $\rho^{303.15} = 0.79443$ g cm^{-3} (lit. (4) 0.79452 g cm^{-3}).

Results

Excess volume data[1] determined at 303.15 and 313.15 K are presented in Figs. 1 to 4. These results may be expressed by an emperical equation of the form

$$[1] \quad \frac{V^E}{X_A X_B}\ \text{cm}^3\ \text{mol}^{-1} = a_0 + a_1(X_A - X_B) + a_2(X_A - X_B)^2$$

The values of a_0, a_1, and a_2 obtained by method of least-squares are given in Table 1 along with the standard deviation $\sigma(V^E)$.

Discussion

The values of V^E are negative for the mixture 1-propanol and methylethylketone at 303.15 and 313.15 K. The negative values for V^E suggest

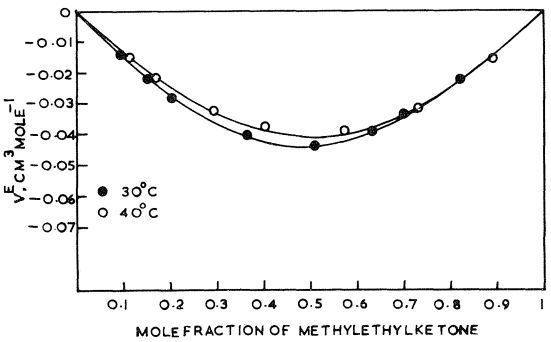

FIG. 1. Plot of V^E as a function of composition for methylethylketone and 1-propanol system.

[1]Complete set of actual experimental data is available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 1. Standard deviation $\sigma(V^E)$ and values of the constants in eq. 1

System	Temperature (K)	a_0	a_1	a_2	$\sigma(V^E)$ ($cm^3\ mol^{-1}$)
Methylethylketone + 1-propanol	303.15	−0.1709	0.0122	0.0118	0.001
Methylethylketone + 1-butanol	303.15	0.0598	0.0283	0.0156	0.002
Methylethylketone + 1-pentanol	303.15	0.1615	0.0662	−0.0960	0.004
Methylethylketone + 1-hexanol	303.15	0.3133	0.0051	0.1721	0.002
Methylethylketone + 1-propanol	313.15	−0.1897	0.0030	0.0614	0.006
Methylethylketone + 1-butanol	313.15	0.1218	0.0157	−0.0206	0.002
Methylethylketone + 1-pentanol	313.15	0.2170	0.0132	0.0802	0.005
Methylethylketone + 1-hexanol	313.15	0.3073	−0.0683	−0.0031	0.006

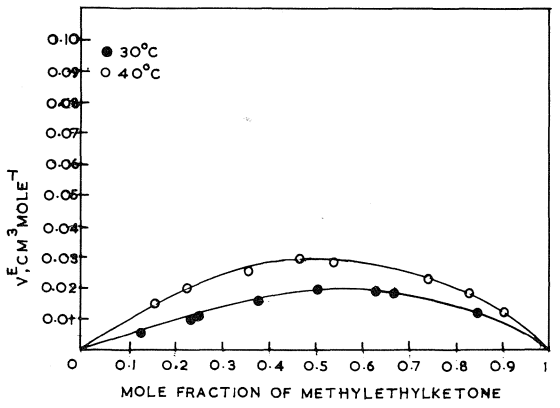

FIG. 2. Plot of V^E as a function of composition for methylethylketone and 1-butanol system.

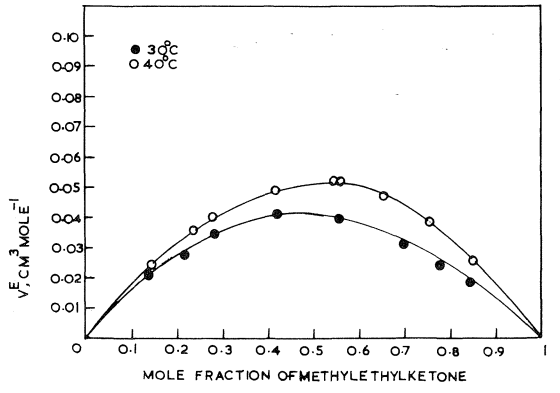

FIG. 3. Plot of V^E as a function of composition for methylethylketone and 1-pentanol system.

that the structure-making effect, hydrogen bond formation between the components, outweighs the structure-breaking effect. V^E is positive for the mixtures of 1-butanol, 1-pentanol, and 1-hexanol with methylethylketone at 303.15 and

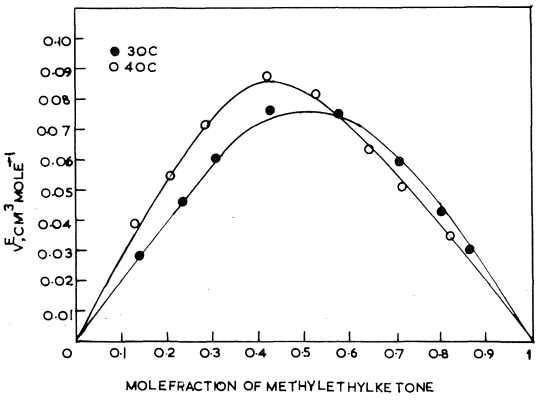

FIG. 4. Plot of V^E as a function of composition for methylethylketone and 1-hexanol system.

313.15 K. In these systems the structure-breaking effect is dominant over structure-making effect.

The algebraic values of V^E of the four systems fall in the order:

1-propanol < 1-butanol < 1-pentanol < 1-hexanol

This order is similar to that observed in the earlier work (1). This shows that the individual alcohol behaves in the same way towards the two ketones.

Finally, a comparison between V^E values determined at 303.15 and 313.15 K shows that V^E becomes more positive with increase in temperature in the four mixtures.

Pulsed nuclear magnetic resonance study of deuteron lineshapes in clathrate hydrates[1]

JOHN A. RIPMEESTER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received June 28, 1976

JOHN A. RIPMEESTER. Can. J. Chem. **55**, 78 (1977).

D nmr lineshape information was obtained from the echo response following a pair of phase shifted pulses using a method first proposed by Clark. In this manner the D quadrupole coupling constant and asymmetry parameter for D_2O in *p*-dioxane·$17D_2O$ were found to be 217 kHz and 0.10 at 63 K. The D nmr lineshape for ethylene oxide-d_4·$7H_2O$ shows that at 17 K the guest molecules are held rigidly in their cages. At higher temperatures the doublet lineshape collapses to a broad structureless line characteristic of molecules for which the reorientational modes vary from cage to cage.

JOHN A. RIPMEESTER. Can. J. Chem. **55**, 78 (1977).

On a obtenu de l'information sur les formes des lignes de D rmn à partir de la réponse écho qui peut être dérivée en une paire de pulsations déplacées en phase et utilisant une méthode qui avait été développée originalement par Clark. On a trouvé, de cette manière, que la constante de couplage quadrupolaire D et que le paramètre d'asymétrie du D_2O dans le complexe *p*-dioxanne·$17D_2O$ sont de 217 kHz et de 0.10 à 63 K. La forme des lignes D rmn de l'oxyde d'éthylène d_4·$7H_2O$ montre qu'à 17 K, les molécules hôtes sont tenues rigidement dans leurs cages. A des températures plus élevées la forme des lignes du doublet disparait et devient une ligne large sans structure, caractéristique de molécules pour lesquelles des modes de réorientation varient d'une cage à l'autre

[Traduit par le journal]

Introduction

In the study of clathrate hydrates, selective deuteration of either guest or host molecules has been used extensively to separate the respective contributions to the ^1H nmr spectrum (1). Relatively little use has been made of D nmr lineshape information, presumably because of experimental difficulties in recording the weak, very broad D nmr spectral lines.

In this publication it is shown that a method first suggested by Clark (2), in which the resonance line is swept while the free induction decay (FID) is integrated, can also be applied to very wide D nmr powder spectra. For such lines, which can be ~300 kHz wide, the FID decays in a time of the same order as the instrument recovery time, and the lineshape can be obtained by integrating the echo response of the spin system to a pair of phase shifted pulses as the magnetic field is swept.

In the following sections the principle of the method is described, some experimental details are given, and results of the technique as applied to two clathrate hydrate systems are discussed.

[1]NRCC No. 15567. Presented at the 58th Annual Meeting of the Chemical Institute of Canada, Toronto, Ontario, 1975.

Theory

The quadrupolar Hamiltonian in a coordinate frame rotating at the Larmor frequency ω can be written as (4)

$$[1] \qquad \mathcal{H} = \Delta\omega\hbar\boldsymbol{I}_z + a\hbar\boldsymbol{I}_z^2$$

where $\Delta\omega = \omega_0 - \omega$ and

$$a\hbar = \frac{3eQV_{zz}}{4I(2I-1)}$$

where Q is the nuclear quadrupole moment and V_{zz} is the electric field gradient in the direction of the external magnetic field. The response of the spin system to rf pulses can be obtained from (3)

$$[2] \qquad S(t) = \mathrm{Tr}\,[\rho(t)\boldsymbol{I}_+]$$

where $\rho(t)$ is the density matrix in the rotating frame and $\boldsymbol{I}_+ = \boldsymbol{I}_x + i\boldsymbol{I}_y$. The equilibrium density matrix in the high temperature, high field approximation is proportional to I_z, and becomes I_y after rotation by a sufficiently intense 90° pulse about the rotating frame x axis. After a second pulse of length $t = \theta/\gamma H_1$, where H_1 is the rf field strength, and shifted in phase with respect to the first by an angle ϕ at time τ, the spin system response can be found from

[3] $$S(t) = \mathrm{Tr}\{\exp[(-i/\hbar)\mathscr{H}(t-\tau)]\boldsymbol{R} \times \exp[(-i/\hbar)\mathscr{H}\tau]\boldsymbol{\rho}(0)\exp[(i/\hbar)\mathscr{H}\tau]\boldsymbol{R}^{-1} \times \exp[(i/\hbar)\mathscr{H}(t-\tau)]\boldsymbol{I}_+\}$$

with

$$\boldsymbol{R} = \exp(i\phi\boldsymbol{I}_z)\exp(-i\theta\boldsymbol{I}_y)\exp(-i\phi\boldsymbol{I}_z)$$

For $I = 1$, this expression can be evaluated to give

[4] $$S(t) = e^{-i2\phi}\cos\{\Delta\omega(t-2\tau)\}\{F(t) \times \cos\theta(1-\cos\theta) - \sin^2\theta F(t-2\tau)\} + \cos\Delta\omega t\{\cos\theta(1+\cos\theta)F(t) + \sin^2\theta F(t-2\tau)\}$$

Equation 4 is similar to the expression found by Metzger and Gaines (4) for the two pulse response of two half integral spins tightly coupled by the nuclear dipolar interaction. Here $F(t)$ is the Fourier transform of the lineshape function

[5] $$F(t) = \int_{-\infty}^{\infty} f(\Delta\omega)\cos\Delta\omega t\, d\Delta\omega$$

$F(t-2\tau)$, the echo response, consists of two FID's back to back centred at $t = 2\tau$ if relaxation effects are neglected. If both ϕ and θ for the second pulse are 90°

[6] $$S(t) = F(t-2\tau)\{\cos\Delta\omega(t-2\tau) + \cos\Delta\omega t\}$$

If the spin echo signal is then integrated using the boxcar integrator, the boxcar response will be

[7] $$V(\Delta\omega) = K\int_{t'}^{t''} F(t-2\tau) \times \{\cos\Delta\omega(t-2\tau) + \cos\Delta\omega t\}\, dt$$

Here K is a constant to take into account the gain of the integrator. If the entire spin echo is integrated, the limits of integration t' and t'' can be expanded to $-\infty$ and $+\infty$, respectively. On expanding expression 7 one gets

[8] $$V(\Delta\omega) = K(1+\cos 2\Delta\omega\tau) \times \int_{-\infty}^{\infty} F(t-2\tau)\cos\Delta\omega t\, dt$$

It can be seen that the boxcar response is proportional to the absorption line intensity at $\Delta\omega$. The entire absorption line shape can therefore be obtained by plotting $V(\Delta\omega)$ as $\Delta\omega$ is swept through resonance. According to eqs. 6 and 8 both the spin echo amplitude and the boxcar response are modulated. Often, by judicious choice of the pulse spacing τ, the modulating $\cos 2\Delta\omega\tau$ term can be made to vary with $\Delta\omega$ much more rapidly than the spin echo fine structure information, and the modulated absorption line shape envelope can still provide lineshape information.

Time averaging can be used to good advantage to remove the modulation. Instead of averaging successive scans, the usual time averaging technique, the resonance line is scanned only once and m successive boxcar output signals are added.

At constant sweep rate, the signal is sampled at constant intervals of $\Delta\omega$, say $\Delta'\omega$. The averaged signal will then be

[9] $$V(m\Delta'\omega) = K\sum_{n=1}^{m}(1+\cos 2n\Delta'\omega\tau) \times \int_{-\infty}^{\infty} F(t-2\tau)\cos 2n\Delta'\omega\tau\, dt$$

If m and τ are adjusted so that $2m\Delta\omega\tau = \pi$ the $\cos 2\Delta\omega\tau$ modulation will be averaged out. Naturally the signal response will be averaged over the interval $m\Delta'\omega$.

Experimental Methods

Pulsed D nmr measurements were performed at 9.2 MHz using a Bruker SXP spectrometer. D quadrupole echoes were generated using $90°_{x}$–τ–$90°_{90°}$ pulse sequences. The H_1 field amplitude was about 60 G, and the FID could be observed after a recovery time of 20–25 μs measured from the center of the rf pulse. The quadrupole echoes centred at a time $t = 2\tau$ were integrated using a Bruker B-KR Z15 pulse gated (boxcar) integrator. Time averaging was effected using a Digital Equipment Corporation PDP 8-L computer.

The experimental conditions used to obtain each spectrum can be summarized by specifying τ, the pulse spacing, $\Delta t = t'' - t'$, the integrator gate width, T_c, the integrator time constant, m (eq. 9), the number of successive integrator responses added, N_t, the total number of points taken to define the spectrum and t, the total time taken to accumulate each spectrum. In addition, each spectrum could be subjected to one or more cycles of digital smoothing.

The clathrate hydrate samples were the same as used in other studies (5, 6).

Results and Discussion

p-Dioxane forms a clathrate hydrate in which the *p*-dioxane guest molecules occupy the large structure II cages (5). The water molecules making up the clathrate cages form a fully hydrogen bonded network, with each water molecule bonded to four others (7).

The right portion of Fig. 1*a* shows half of the

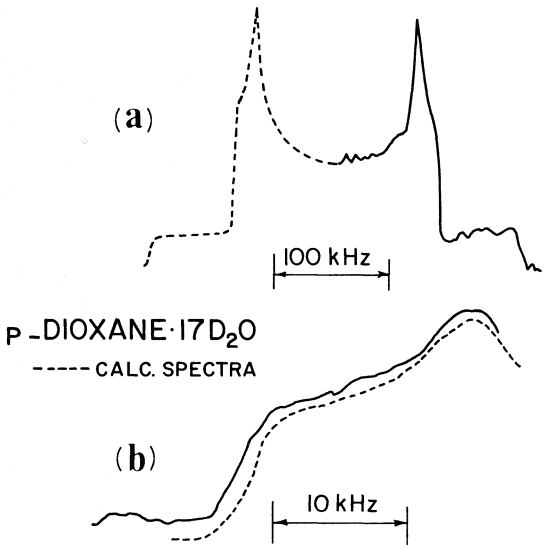

FIG. 1. Experimental and calculated D nmr lineshapes for *p*-dioxane·17D_2O (see text).

D nmr spectrum for *p*-dioxane·17D_2O recorded at 63 K. The total time taken to obtain the spectrum was 30 min, with the other experimental parameters as follows: $N_t = 225$, $\tau = 220$ μs, $\Delta t = 300$ μs, $T_c = 1$ ms, $m = 8$. The spectrum is a typical spin 1 powder doublet with fine structure in the vicinity of the singularity due to a non-zero asymmetry parameter (8). This fine structure is illustrated in Fig. 1*b* where the spectral region near the singularity was recorded on an expanded scale. The recording time was 20 min, with $N_t = 100$, $m = 12$, and the remaining parameters the same as for Fig. 1*a*.

The dashed portions of Fig. 1 (*a*) and (*b*) were calculated (8) using a quadrupole coupling constant of 217 kHz and an asymmetry parameter of 0.10. Internuclear dipolar broadening was accounted for by folding the powder pattern with a Gaussian function using a broadening parameter of 1.6 kHz. As structure II clathrate hydrates have three inequivalent sites for the O atoms of the water molecules (7), the parameters characterizing the *p*-dioxane·17D_2O spectrum must be average values. Not surprisingly, the D nmr parameters for the deuteriohydrate are nearly the same as those obtained for D_2O ice I_h (9); for OD bonds parallel to the *c* direction the quadrupole coupling constant and asymmetry parameter were 213.3 kHz and 0.100, and for the non-*c* bonds the values were 216.4 kHz and 0.100 (the last value assumed).

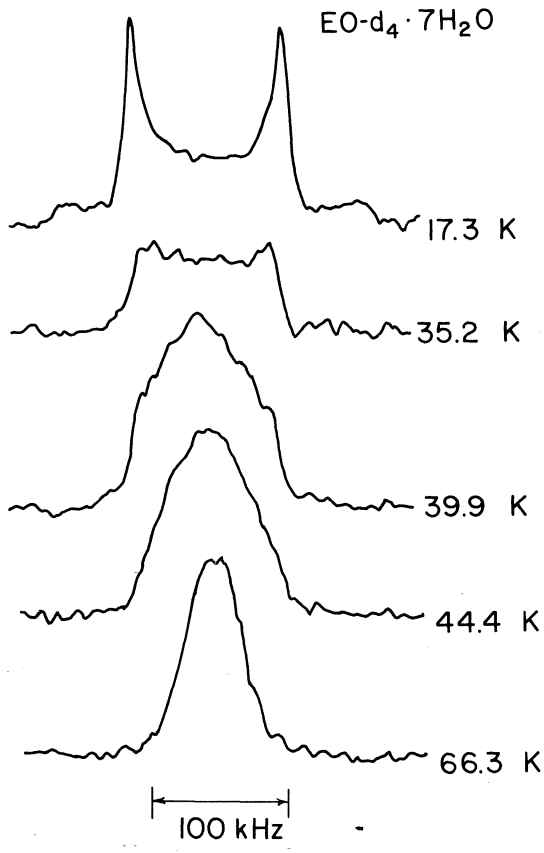

FIG. 2. D nmr lineshapes obtained for ethylene oxide-d_4·7H_2O at various temperatures.

Figure 2 shows a number of D spectra obtained for ethylene oxide-d_4·7H_2O, a structure I clathrate hydrate (10). From the exact composition of the hydrate, EO·6.89H_2O (11), about 90% of the EO molecules are in the large structure I cage, the remainder in the smaller cage (12).

The 17.3 K spectrum is again a typical powder doublet from which a quadrupole coupling constant of 163 kHz for the deuterons in EO-d_4 can be derived. The total accumulation time for this spectrum was 50 min with the other experimental parameters $N_t = 200$, $\tau = 220$ μs, $\Delta t = 300$ μs, $T_c = 1$ ms, $m = 30$. The other spectra were obtained under identical conditions but in a much shorter time, 10 min. The doublet structure can be seen to collapse with rise of temperature from 17.3 to 40 K, the spectrum at the highest temperature being a broad featureless line. This disappearance of fine structure corresponds to the onset of slow guest molecule reorientations which were also observed in this

temperature range by dielectric and CW ^{1}H nmr methods (13). The width and shape of the D nmr line at 66.3 K indicate that the EO molecules reorient about axes which vary from cage to cage, and that, in general, the motions are not random.

The lineshapes presented here illustrate the relative ease with which D nmr spectra may be recorded using a pulsed nmr spectrometer, even for very wide powder spectra. It should be possible to obtain good results with this technique provided that T_2 is constant for all components of the spectrum so that the degree of refocusing is the same for all the spins.

JAMES OEHLDRICH et JAMES M. COOK. Can. J. Chem. **55**, 82 (1977).

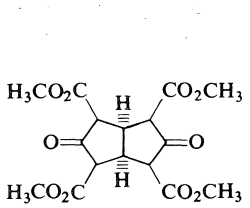
La réaction de l'acide β-cétoglutarique avec le benzile en présence de KOH en milieu éthanolique conduit à l'adduit 1:1, **7**. L'hydrolyse et la décarboxylation partielle conduisent au monoacide **8**; il avait été rapporté par erreur dans une référence antérieure que cet acide avait la structure **5**.

[Traduit par le journal]

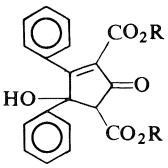
In 1968 Weiss and Edwards (1) reported that reaction of aliphatic or alicyclic 1,2-dicarbonyl compounds with dimethyl β-ketoglutarate provided 1:2 adducts of the type represented by tetramethyl bicyclo[3.3.0]octane-3,7-dione-2,4,-6,8-tetracarboxylate **1**. We have investigated the analogous reaction of dimethyl-β-ketoglutarate with aromatic α-diketones. This procedure yielded 1:1 adducts (2–4) of type **2** instead of compounds having the 1:2 stoichiometry observed in aliphatic or alicyclic cases (1, 2). This reaction of aromatic α-diketones has been extended to phenanthrenequinone which also gave adducts of 1:1 stoichiometry (5).

In the course of this work we have had occasion to reexamine the reaction of benzil **3** with β-ketoglutaric acid **4**, which was first carried out by Japp and Lander (6). These authors reported that this condensation furnished a 1:1 adduct, which was formulated as **5** because of its conversion to the monoketone **6** by treatment with hydroiodic acid. The monoketone **6** had been prepared by another route (7).

In our laboratory, benzil **3** was stirred with β-ketoglutaric acid **4** in alcoholic potassium hydroxide under the conditions reported by Japp and Lander (6). Upon acidification of the potassium salt isolated from this reaction, followed by treatment with ethanol to remove excess benzil, a new compound (mp 248–250 °C) was obtained which appeared to be the diacid **7** ($C_{19}H_{14}O_6$). Esterification of this substance with methanolic



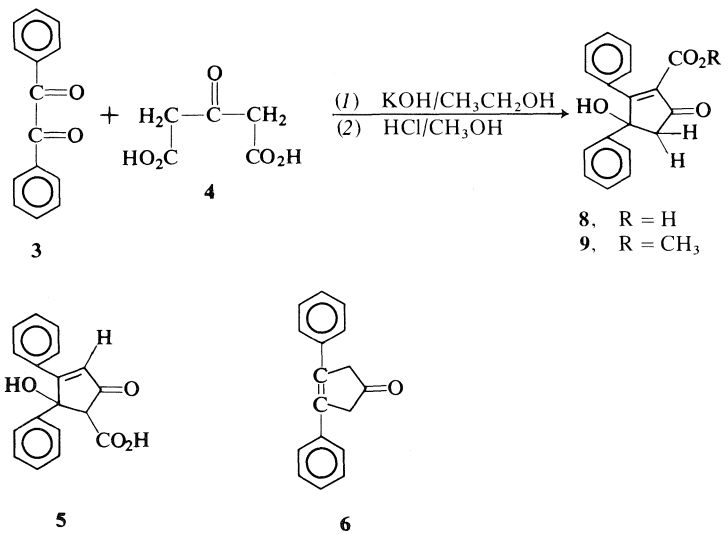
1



2, R = CH_3
7, R = H

hydrogen chloride furnished dimethyl-4-hydroxy-3,4-diphenylcyclopent-2-enone-2,5-dicarboxylate **2**, identical in all respects with an authentic sample prepared by the procedure outlined in refs. 2, 3, and 4.

Decarboxylation of the diacid **7** in hot glacial acetic acid provided the monoacid **8** (mp 167–168 °C); the structure of which was incorrectly reported to be **5** by Japp and Lander (6). The nmr spectrum of this acid did not contain a signal in the vinyl region; this observation suggested structure **8** for this compound. This was confirmed by the appearance of two overlapping singlets (representing two protons) at δ 2.99 and 3.01 in the spectrum, which are clearly due to the



3 4 8, R = H 9, R = CH_3 5 6

SCHEME 1

methylene protons of the monoacid **8**. This signal for α-methylene protons is not possible for the structure **5** reported in 1897 by Japp. The electron impact mass spectra of the diacid **7** and the monoacid **8** are very similar, a fact which indicates that thermal decarboxylation of **7** to **8** occurs readily, as would be anticipated. Esterification of the monoacid in methanolic hydrogen chloride gave the ester **9** (142–144 °C) in 92% yield. The nmr spectrum of this ester also contained a signal for the α-methylene protons (δ 2.97). We would therefore like to propose structure **8** for the monoacid instead of structure **5** reported earlier (6) for this compound.

β-Keto acids are quite difficult to isolate in good yield; however, presumably the strain which occurs when **7** is decarboxylated through the high energy cyclopentadiene intermediate precludes facile decarboxylation and allows isolation of this diacid.

Experimental

Microanalyses were performed (UWM) on an F & M Scientific Corporation Carbon, Hydrogen, Nitrogen Analyzer model 185. Melting points were taken on a Thomas Hoover apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded on Varian T-60 and HA-100 spectrometers. Infrared spectra were taken on a Beckman Acculab-1 instrument; ultraviolet spectra were recorded on a Cary 17 spectrophotometer and mass spectra were taken on a Finnigan 1015 or AEI MS902 instrument.

Analytical tlc plates used were E. Merck-Brinkmann uv active silica gel on plastic. The spray reagent was composed of 2,4-dinitrophenylhydrazine, ethanol, and sulfuric acid. The citrate–phosphate buffer (p*H* 6.8) was prepared by dissolving $Na_2HPO_4 \cdot 7H_2O$ (11.67 g) and citric acid (3.68 g) in water (900.00 ml).

4-Hydroxy-3,4-diphenylcyclopent-2-enone-2,5-dicarboxylic Acid, 7

Benzil (11.5 g, 0.05 mol) and 3-ketoglutaric acid (7.5 g, 0.05 mol) were dissolved in a small amount of warm ethanol. A prefiltered solution of potassium hydroxide (8.5 g, 0.15 mol), water (10 ml), and ethanol (50 ml) was added. The mixture was stirred for 1 h after which time a white solid precipitated. The precipitate was filtered and washed with a small amount of ethanol; the crystals were then dissolved in the smallest amount of water possible and the resulting solution was acidified to p*H* 1 with 6 *M* H_2SO_4. White crystals (11.5 g, 68%) formed and were filtered from the solution, washed with water, and dried *in vacuo*: mp 248–250 °C with decomposition; ir (KBr) 3300 (br OH), 1727 (C=O), and 1673 cm^{-1} (enol form of β-keto acid); nmr (DMSO-d_6) δ 2.74 (1H, s), 7.60 (10H, m); mass spectrum *m/e* 294(25), 277(19), 276(87), 250(20), 234(54), 232(28), 220(20), 208(20), 206(21), 205(33), 203(29), 202(25), 191(22), 278(33), 249(20), 131(21), 129(39), 106(43), 105(100), 103(25), 102(46), 101(25), 91(54), 89(21), 78(41), 77(100), 76(31). (Molecular ion not observed, $M^+ - CO_2$ was found.) *Anal.* calcd. for $C_{19}H_{14}O_6 \cdot 3H_2O$: C 58.16, H 5.14; found: C 58.38, H 5.03.

Dimethyl 4-Hydroxy-3,4-diphenylcyclopent-2-enone-2,5-dicarboxylate, 2

The diacid **7** (0.5 g, 1.48 mmol) was dissolved in methanolic hydrogen chloride (20 ml). This solution was stirred for 24 h and the solvent was then evaporated under reduced pressure. The crystals (0.51 g, 94%) were recrystallized from benzene: mp 138–140 °C, ir (KBr) 3480 (OH) and 1745 cm^{-1} (ester C=O), M^+ at *m/e* 366; nmr identical with that reported by White (4*b*). *Anal.* calcd. for $C_{21}H_{18}O_6$: C 68.85, H 4.95; found: C 69.00, H 5.06.

*4-Hydroxy-3,4-diphenylcyclopent-2-enone-2-carboxylic Acid, **8***

The diacid **7** (0.50 g, 1.48 mmol) was dissolved in hot glacial acetic acid and diluted with enough hot water to cause the solution to become turbid. This mixture was allowed to cool to room temperature and crystallize. The crystals (0.31 g, 71%) were recrystallized from benzene; mp 167–168 °C, ir (KBr) 3400 (OH), 1685 (acid C=O), and 1675 cm^{-1} (enol form of β-keto acid), nmr (acetone-d_6) δ 2.99, 3.01 (2H, overlapping signal, methylene protons) 5.78 (1H, s, OH, D_2O exchangeable), 7.25 (10H, m, aryl protons); mass spectrum *m/e* 294(36), 277(25), 276(97), 234(63), 232(27), 206(29), 205(37), 203(27), 202(21), 191(21), 178(30), 129(38), 105(100), 103(30), 91(44), 78(40), 77(96), 76(21). *Anal.* calcd. for $C_{18}H_{14}O_4$: C 73.46, H 4.79; found: C 73.17, H 4.56.

*Methyl 4-Hydroxy-3,4-diphenylcyclopent-2-enone-2-carboxylate, **9***

The monoacid **8** (0.25 g, 0.85 mmol) was placed in methanolic hydrogen chloride (10 ml) and stirred for 24 h. The solvent was then evaporated under reduced pressure. The crystals (0.24 g, 92%) were recrystallized from methanol: mp 142–144 °C, ir ($CHCl_3$) 3600 (OH) and 1735 cm^{-1} (ester C=O); nmr ($CDCl_3$) δ 2.97 (2H, s, methylene protons), 3.66 (3H, s, OCH_3), 3.85 (1H, s, OH, D_2O exchangeable), 7.20 (10H, m, aryl protons). *Anal.* calcd. for $C_{19}H_{16}O_4$: C 74.01, H 5.23; found: C 73.92, H 4.98.

The reaction of diphenylethylenes with boron trifluoride and water[1]

STANLEY BYWATER AND DENIS J. WORSFOLD

Chemistry Division, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received July 9, 1976

STANLEY BYWATER and DENIS J. WORSFOLD. Can. J. Chem. **55**, 85 (1977).

The concentrations have been measured of carbenium ions formed when diphenylethylene and diphenylpropene react with boron trifluoride and water in methylene chloride solution. With both these olefins it appeared necessary that two boron trifluoride molecules should be present for every water molecule to form the carbenium ion. Also the ionic species formed showed a very high degree of ionic dissociation. Diphenylethylene rapidly formed the cyclized dimer, and as a side reaction formed some triphenylmethylcarbenium ions. The diphenylpropene gave a diphenylcarbenium ion that appeared stable, but the accompanying anion was thought to be unstable and rearranged to a more stable form which disrupted the dependences on the concentrations of original reactants.

STANLEY BYWATER et DENIS J. WORSFOLD. Can. J. Chem. **55**, 85 (1977).

On a mesuré les concentrations d'ions carbénium qui sont formés lorsque le diphényléthylène et le diphénylpropène réagissent avec le trifluorure de bore et l'eau en solution dans le chlorure de méthylène. Avec ces deux oléfines, il semble nécessaire que deux molécules de trifluorure de bore soient présentes pour chaque molécule d'eau si l'on veut former un ion carbénium. De plus les espèces ioniques formées présentent un très haut degré de dissociation ionique. Le diphényléthylène forme rapidement un dimère cyclique et une réaction secondaire forme aussi des ions triphénylméthylcarbénium. Le diphénylpropène conduit à l'ion diphénylcarbénium qui semble stable mais il nous est apparu que l'anion qui l'accompagne est instable et qu'il se réarrange pour donner une forme plus stable; ce réarrangement brise la dépendance sur les concentrations des réactifs originaux.

[Traduit par le journal]

1,1-Diphenylethylene (DPE) has been used by several authors in model systems of cationic polymerization. Its basic reactions in these systems parallel those found with other monomers, but with the simplifying factor that only a reversible dimerization occurs. Evans *et al.* (1–3) studied principally the kinetics of these systems in benzene, whereas Sigwalt and co-workers (4, 5) took advantage of the relatively high concentrations of the diphenylcarbenium ion formed in methylene chloride solution to make a spectroscopic study of the active centres. The uv spectra obtained at low temperatures were complex, and three forms of active centre were suggested.

An attempt has been made here to use this system to describe the behaviour of boron trifluoride and water as a catalyst–cocatalyst system in the initiation reaction of cationic polymerizations of olefins by spectroscopic measurements of the carbenium ion concentration. Because of the activity of this catalyst, however, the subsequent cyclization reaction found for this monomer complicates the system. Some work has also been done using 1,1-diphenylpropene (DPP) for which the reaction goes no further than the initiation reaction, subsequent dimerization or cyclization is negligible.

[1]NRCC No. 15585.

Experimental

All reactions were done in all-glass appartus, with break seals separating reactants, and glass covered breakers. The reaction vessel contained 1 cm quartz uv cells with removable 9 mm quartz blocks to convert them at will to 1 mm cells. All manipulations were made under a vacuum of 10^{-3} P. The monomers were treated with butyl lithium. The solvent was methylene chloride, dried over calcium hydride after treatment with sulphuric acid and fractional distillation.

No attempt was made to have rigorously dry systems as water was added to most reactions. The residual water in the DPE systems was estimated to be less than 10^{-4} *M* as judged from spectra observed in systems where no water was added and the intercept on the abscissa of Fig. 3. Then solid DPP was more difficult to dry, and the residual water level appeared somewhat higher.

All reactions were carried out at 20 °C, unless otherwise stated. Concentrations of ions in methylene chloride solution were determined from the optical spectra at λ_{max} = 436 nm for DPE and 438 nm for DPP, using extinction coefficients of 35 000 as determined from H_2SO_4 solutions. Values of extinction coefficients between 35 000 and 39 000 are reported in the literature for

DPE. The absorption of DPP dissolved in H_2SO_4 was very similar to that of DPE in the same solvent having maxima at 319 and 434 nm attributable to the diphenylethylcarbenium ion. The maxima were displaced slightly in methylene chloride under our reaction conditions.

Results and Discussion

When DPE is added to a solution of BF_3 in methylene chloride in the presence of small amounts of water at 20 °C, the characteristic uv spectrum of the diphenylcarbenium ion is observed, although the shorter wavelength band is obscured by excess DPE. If lower temperatures are used, however, the spectrum is complicated by auxilliary peaks which were attributed by Sigwalt and co-workers (5) to complexes between DPE and the ions. To avoid this complication measurements were confined to 20 °C.

At 20 °C, however, due to the great reactivity of this Friedel–Crafts catalyst the presence of the final product of the reaction, the cyclic dimer (3-methyl-1,1,3-triphenylindane), leads to the formation of some triphenylcarbenium ions. This reaction has been noted previously with perchloric acid catalysis (6). Hence, very soon after the start of the reaction, the uv spectrum of the diphenylcarbenium ion is replaced slowly by that of the triphenylcarbenium ion. It is, however, possible by measuring a series of spectra to extrapolate back to zero time to get the initial diphenylcarbenium ion spectrum (Fig. 1). In Fig. 2 is plotted the disappearance of the monomer in a typical experiment, measured by vpc, together with the concentrations of the diphenyl- and triphenylcarbenium ions. The sole product found was the cyclic dimer, identified by vpc and tlc by comparison with an authentic sample. The product which produced the spectrum characteristic of triarylcarbenium ions could not be isolated or identified because of its very low concentration.

Difficulty was found in establishing proper equilibrium between BF_3 in the vapour phase and that in solution in the 1 mm optical cell, particularly as the initial stages of the reaction were important. This led to undesirable irreproducibility of the results. From the optical density at zero time it was possible to calculate the concentration of carbenium ions as a function of concentration of BF_3, H_2O, and DPE. At a fixed concentration of the BF_3 and DPE, the concentration of the carbenium ion was found to increase as the water concentration was increased to a maximum near a 2:1 ratio of BF_3–H_2O and

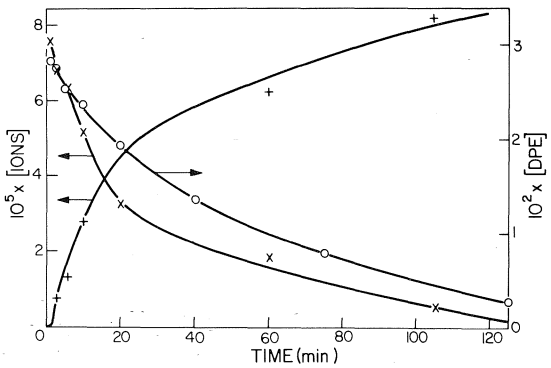

FIG. 2. Changes of concentration with time of DPE (○), diphenylcarbenium ion (×) and, triphenylcarbenium ion (+). Reaction conditions as in Fig. 1.

then to decrease (Fig. 3). If the BF_3 concentration was varied, a non-linear relationship was found as in Fig. 4 with very low ion concentrations formed when the BF_3 concentration was less than that of the water. The dependence on the DPE concentration was quite small under the conditions chosen, a forty-fold increase in $[DPE]_0$ caused only a four-fold increase in carbenium ion concentration.

At 20 °C the concentration of carbenium ions was small compared with the water concentration if the BF_3 was in excess. Initiation of the reaction at −30 °C led to much higher carbenium ion concentrations but the spectrum at this temperature showed the extra absorption band at 520 nm described by Sigwalt and co-workers (4). On cooling of these solutions to −70 °C, the total absorption increased, corresponding to a carbenium ion concentration approaching that

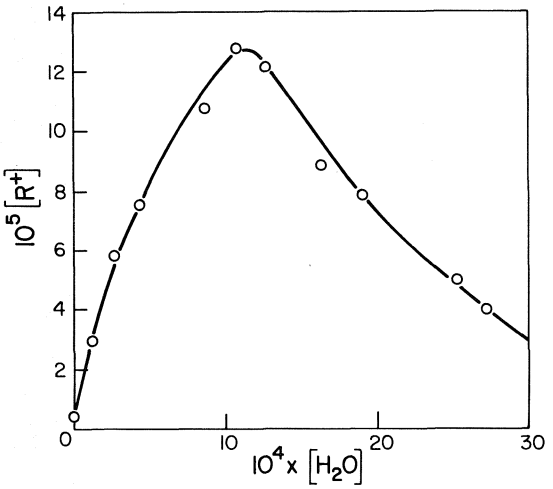

FIG. 3. Initial concentrations of diphenylcarbenium ions formed in reaction of DPE with BF_3 at varying added H_2O concentrations. $[DPE]_0 = 2.84 \times 10^{-2}$ *M*, $[BF_3]_0 = 2.56 \times 10^{-3}$ *M*, 20 °C.

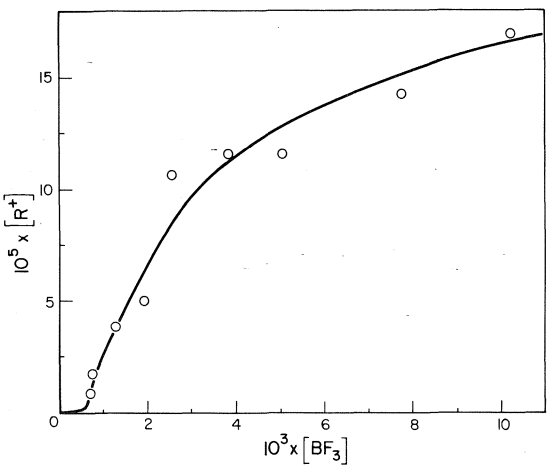

FIG. 4. Initial concentrations of diphenylcarbenium ions formed in reaction of DPE with H_2O and varying BF_3 concentrations. $[DPE]_0 = 2.84 \times 10^{-2}$ *M*, $[H_2O]_0 = 8.3 \times 10^{-4}$ *M*, 20 °C.

of the added water. Subsequent warming of the solutions to 0 °C and then to 20 °C caused a reduction in ion concentration; disappearance of the 520 nm band and finally spectral evolution of the type shown in Fig. 1. Despite the complications at low and high temperatures, the large differences in absorption at different temperatures suggest a temperature dependent equilibrium between BF_3, H_2O, DPE, and carbenium ions. At 20 °C carbenium ion formation was unfavoured, and the concentration of ions was in the range 10^{-5}–10^{-4} *M*. If the dissociation constant of the carbenium salt was similar to that of triphenylcarbenium salts in solvents with dielectric constant comparable to that of methylene chloride, *i.e.*, in the region $K_D = 2 \times 10^{-4}$ *M* (7), a concentration of salt of 5×10^{-5} *M* would be 80% dissociated into free ions.

Boron trifluoride as a catalyst has been studied extensively by Eastham and co-workers (8–10). In the system BF_3/H_2O, it was shown that the presence of both $BF_3 \cdot H_2O$ and excess BF_3 was necessary for catalytic activity to be evident. If it is assumed that the catalytic activity is reflected be the concentration of carbenium ions, the dependence of the carbenium ion concentration on H_2O and BF_3 shown in this study is in agreement with that found by Eastham. Negligible concentrations of carbenium ions would be expected until appreciable amounts of free BF_3 are present in solution. This condition requires $[BF_3]_0 \geqslant [H_2O]_0$ where the subscript zero refers to *added* concentrations. In this range the concentration of $BF_3 \cdot 2H_2O$ can be neglected with respect to the concentrations of BF_3 and $BF_3 \cdot H_2O$ according to the measurements of Clayton and Eastham (9).

The overall equation describing this scheme is

$$BF_3 \cdot H_2O + BF_3 + M \overset{K}{\rightleftharpoons} R^+ + A^-$$

where M = DPE, R^+ = the carbenium ion, and A^- the corresponding anion. Because of the high degree of ionic dissociation and the comparatively small concentration of carbenium ion, the carbenium ion concentration would be *approximately* governed by the equation

$$[R^+]^2 = aK\,[H_2O]_0([BF_3]_0 - [H_2O]_0)[M]_0$$

when $[BF_3]_0 \gg [H_2O]_0$, *a* is the fraction of the total free BF_3 that is in solution and in equilibrium with that in the vapour phase. The above equation predicts a maximum concentration of carbenium ions will occur when $[BF_3]_0 = 2[H_2O]_0$. It will become increasingly inaccurate as $[H_2O]_0$ approaches $[BF_3]_0$ due to the neglect of the presence of $BF_3 \cdot 2H_2O$. Overestimation of the carbenium ion concentration will result when $[H_2O]_0$ is greater than about 75% of $[BF_3]_0$ (9).

The dependence of $[R^+]$ on [M] should be a simple half power. The dependence found was lower than this which raises the possibility of preliminary complexing between DPE and BF_3 or $BF_3 \cdot H_2O$. Total complexing would give zero

order in [M] under the present conditions where DPE is in large excess. This is not the case and so an equilibrium would have to exist. Complexes between other Friedel–Crafts reagents and aromatic hydrocarbons have been demonstrated, also between BF_3 and olefins at low temperatures (11, 12).

Neglecting this deviation, the term aK has been calculated from the data obtained and was found to be a constant with a fairly large random error, $aK = 0.245 \pm 0.087$. The value of a is not known but from results of Clayton and Eastham (9) must be about 0.3 for the reaction vessels used.

A similar study was made using DPP as the monomer at 20 °C. It is reasonable to assume that the extra species formed with DPE leading to new spectral bands are associated with the presence in this system of the dimer cation. A monomer which would only form monomer cations might therefore show simpler behaviour. No dimerization could, in fact, be detected with DPP by tlc, and glc indicated less than 1% in 24 h. Only the main absorption band at 438 nm corresponding to the diphenylethylcarbenium ion was observed. Several days elapsed before noticeable changes in peak shape became apparent. It was also found that on lowering the temperature of the reaction mixture, although there was a great increase in optical density, the shape of the absorption band remained unchanged. Conversely, on re-warming the solution, the absorption decreased markedly. No longer wavelength band appeared at low temperatures as it did with DPE.

The concentration of ions formed was considerably lower with DPP than with DPE. In contrast with the DPE system, a 1 cm cell could be used to measure the absorption, and a cell was constructed incorporating a stirrer that circulated the solvent through the cell to improve the equilibrium between the liquid and vapour phases. Several additions of BF_3 were made to each reaction mixture of given water concentration.

It was found, as with DPE, that when the concentration of BF_3 was less than that of the water, little or no carbenium ion was formed. When a small excess of BF_3 was added, the absorption appeared instantly, but would then decrease with a half life time of about 10 min. The final value was the measured value. On adding more BF_3 a point would come when there was no decrease with time, and the absorption remained constant for this BF_3 concentration. The reaction mixture also became a little cloudy, particularly on standing, although it would tend to clear at higher $BF_3 : H_2O$ ratios.

The equilibrium carbenium ion concentration was measured as a function of the concentration of reactants. Although the results were in some ways similar to those found for DPE, there were some marked differences. Once again, for a fixed $[BF_3]_0$, $[R^+]$ went through a maximum with increasing water concentration (Fig. 5), but except at low $[BF_3]_0$, this maximum did not correspond to $[BF_3]_0 = 2[H_2O]_0$. The dependence on $[DPP]_0$ was far closer to a half power than for DPE. In addition it was not found possible to fit the results to the equation which was satisfactory for the DPE results. There were gross systematic variations in the constants aK found. Empirically a better constant was found by substituting the term $([BF_3]_0 - [H_2O])$ in the equation for $[R^+]$ by $([BF_3]_0 - 2[H_2O]_0)$. It should be noted that with DPE the diphenylmethylcarbenium ion concentrations had to be found by extrapolation to zero time. On the other hand, in the DPP experiments it was possible to allow sufficient time for steady values to be obtained. This could be taken to imply that in the DPP experiments the system was closer to

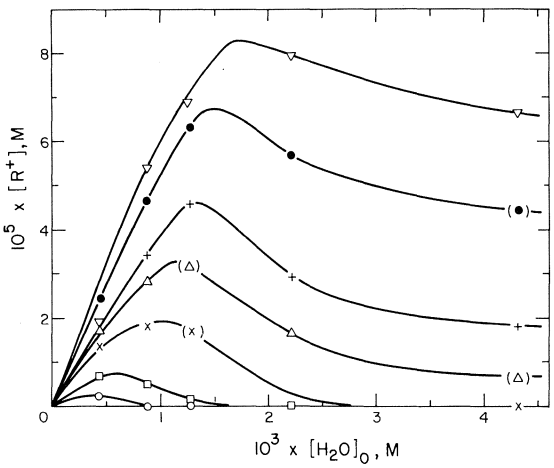

FIG. 5. Steady state concentrations of diphenylcarbenium ions formed in the reaction of DPP with BF_3 at varying added H_2O concentrations. $[DPP]_0 = 2.8 \times 10^{-2}$ *M*, $[BF_3]_0$ = ○, 0.639; □, 1.28; ×, 2.56; △, 3.83; +, 5 11; ●, 7.67; ▽, 10.22×10^{-3} *M*. Points in parentheses interpolated.

true equilibrium. Alternatively the DPP experiments could be affected by reactions described later associated with the cloudiness developed in the systems.

Confirmation of the high degree of dissociation into free ions was sought by conductance measurements. A reaction vessel incorporating both a conductivity cell and an optical cell was used, and incremental additions of BF_3 were made to vary the carbenium ion concentration. The ion concentration was in the range 10^{-5} to 10^{-4} *M*. Difficulty was again experienced maintaining an equilibrium between the vapour and solution in such a complex apparatus. The degree of ionic dissociation over this range was over 0.9, assuming $\Lambda_0 = 89$ ohm^{-1} cm^2 by extrapolation to infinite dilution, and a very approximate K_D of 4×10^{-4} *M* was found. This is in the range found for triphenylcarbenium salts, but in such a complex system it is uncertain whether such a calculation is legitimate.

A further test of the high degree of ionic dissociation was made by adding the salt Bu_4NBF_4 to a reaction mixture which normally would be expected to have a concentration of carbenium ions of 1.34×10^{-5} *M*. When the concentration of ammonium salt was 2.1×10^{-3} *M*, the absorption due to the carbenium ion could not be measured, but at a concentration of 2.3×10^{-4} *M* salt, the ion gave a small absorption (*ca.* 8×10^{-7} *M*). This is in agreement with a high degree of ionic dissociation. Although the tetrafluoroborate salt added is not necessarily a true common-ion salt, as it is in such large excess, its presence would cause the effective proton acid to be HBF_4 instead of $BF_3 \cdot H_2O$. Thus on the usual assumption that the free cation and its ion-pair have nearly identical absorptions, addition of a large excess of tetrafluoroborate would cause a drastic reduction in absorption as the total carbenium ion concentration is reduced to the small equilibrium concentration of ion-pairs. Had the carbenium ions been present largely in the form of ion-pairs, only a small reduction in absorption would have been observed as the free carbenium ions were removed from solution.

The differences between the dependences of the carbenium ion concentration on the reactants in the DPE and DPP systems is suggested to be associated with the formation of the cloudiness in the latter system as it came to equilibrium. Typical reactions that occur are described by Eastham and co-workers for the reaction of triphenylcarbinol with BF_3. The triphenylcarbenium ion formed and the BF_3OH^- ion rearranged to fluoroborate ions and H_3BO_3, with the boric acid precipitating (13),

$$3Ph_3COH + 7BF_3 \rightarrow 3Ph_3CB_2F_7 + B(OH)_3$$

The anions expected to be formed initially in solution in the DPP system resemble closely those in the triphenylcarbinol case, and the reaction might follow the same course. This is in accord with the decline in the carbenium ion absorption found when BF_3 is added initially in excess to the DPP + water solution. The resultant 1,1-diphenylpropylfluoroborate could be expected to have a constant of formation (*K*) from DPP and its acid component different from the original BF_3OH^- compound, and hence give a different carbenium ion concentration.

Attempts to isolate boric acid from the DPP system failed, as the precipitate was not crystalline as was that found with triphenylcarbinol, so it is probable that these secondary reactions are more complex in this case. Nevertheless a similar rearrangement to a fluoroborate ion is probable. At lower temperatures (-30 °C , it is possible to eliminate the initial decline in the carbenium ion concentration, but difficulties caused by heterogeneity still occurred.

It has been suggested here that an equilibrium is established between this Friedel–Crafts reagent, olefins, and the carbenium ion. Because of the high degree of ionic dissociation, the dependence of the carbenium ion concentration appears as a half power of the effective reagents. In studies of kinetics of systems using this type of catalyst–cocatalyst system, such half powers do not appear, and linear dependences are found (8–10). This indicates that equilibrium is not established in these reactions between the ion and the reactant, so that the formation of the ion is the rate determining process.

With DPE, the initial rapid formation of the carbenium ion is studied as it is comparatively shortlived. If however, the ion is longlived as is the ion formed by DPP, secondary reactions of the counter ion take place in this catalyst system and complicate the dependences on the reactants.

Mössbauer spectra of ^{57}Fe probe atoms in the spinel $Co_{2.94}Fe_{0.06}S_4$ indicate the existence of a magnetic transition at $T_{tr} \approx 95$ K in the parent phase Co_3S_4. The spectrum observed below T_{tr} consists of a six-line magnetic spectrum and a two-line quadrupole spectrum. Above T_{tr} the six-line spectrum collapses to a single line superposed on the two-line quadrupole spectrum. Consideration of the Mössbauer parameters and of the area ratio of the component spectra suggests that the atomic occupancy of the spinel lattice is $[Co_{0.968}Fe_{0.032}][Co_{0.986}Fe_{0.014}]_2S_4$, the Fe atoms having preference for the tetrahedrally coordinated cation sites.

F. W. D. WOODHAMS et OSVALD KNOP. Can. J. Chem. **55**, 91 (1977).

Les spectres Mössbauer du ^{57}Fe dans la spinelle $Co_{2.94}Fe_{0.06}S_4$ témoignent de l'existence d'une transition magnétique à $T_{tr} \approx 95$ K dans la phase mère Co_3S_4. Au-dessous de T_{tr} on observe un spectre magnétique à six composantes superposé à un doublet quadrupolaire, tandis qu'au-dessus de T_{tr} les six composantes du spectre magnétique fusionnent, ce qui produit une bande unique superposée au spectre quadrupolaire. Les valeurs des paramètres Mössbauer et le rapport de l'aire du spectre magnétique à celle du spectre quadrupolaire suggèrent une répartition des atomes du Co et du Fe sur le réseau spinelle suivant $[Co_{0.968}Fe_{0.032}][Co_{0.986}Fe_{0.014}]_2S_4$, les atomes Fe préférant des sites à coordinence tétraèdrique.

Only a very limited amount of work has been done to determine the nature of the spin states of the Co atoms at the A and B sites in the spinel Co_3S_4. Heidelberg *et al.* (2) stated the magnetic susceptibility (in 10^{-6} emu/g) of the sulfide to be 3.4 and independent of temperature between 300 and 800 K,[2] while Lotgering (footnote 1 of ref. 4) found a small temperature dependence: 3.1 (700 K), 3.6 (295 K), 4.6 (77 K), and 6.9 (20 K). It is not clear whether this represents spontaneous magnetic behaviour from ions with a small spin, or Pauli-paramagnetic behaviour (*cf.* Co_9S_8 and pentlandite, ref. 1). There was no evidence in the susceptibility data (*cf.* also ref. 5) to indicate the onset of magnetic order. Bouchard *et al.* (6) measured the resistivity of Co_3S_4 between -180 and $+150$ °C and found that the resistivity increased with temperature; the room-temperature value was small, 3×10^{-4} ohm cm. From this they concluded that Co_3S_4 is metallic. The existence of metallic conduction is not inconsistent with spontaneous magnetic behaviour. Goodenough (7) has shown that if the strength of the interaction between neighbouring atoms, as measured by the parameter b, is such that $b_c < b < b_m$, then both spontaneous magnetism and metallic conduction are observed (*cf.* the pyrite CoS_2, ref. 8). Goodenough himself concluded from the magnetic and electrical properties that Co_3S_4 was a Pauli paramagnet but that the small temperature dependence of χ indicated a narrow conduction band and thus $b \approx b_m$, *i.e.* close to the border between metallic with a localized spin and metallic with no localized spin. Locher (4) has suggested that the Co atoms at the A sites might be present as Co^{1+} ($3d^8$), which would be qualitatively consistent with the observed low χ values. His suggestion is based on a comparison of the nmr spectra of ^{59}Co in the metallic spinel $CuCo_2S_4$ and in Co_3S_4. It was estimated that $2.5 \pm 1.5\%$ of the Co atoms in $CuCo_2S_4$ were in the A sites; these and the Co(A) atoms in Co_3S_4 showed a zero quadrupole interaction, while the splitting at 77 K at Co(B) was closely similar in both sulfides. In Co_3S_4 the

[1]For Part X, see ref. 1.

[2]Serres (3) reported 1.27×10^{-6} emu/g for natural linnéite between 19 and 115 °C.

change in the splitting from 295 to 77 K was small compared with $CuCo_2S_4$.

Replacing some of the Co in Co_3S_4 by ^{57}Fe offers the possibility of utilizing this nuclide as a Mössbauer probe to investigate the behaviour of the Fe atoms in the host structure and, indirectly, the magnetic properties of the Co_3S_4 matrix. In this paper we describe the results of such Mössbauer experiments with $Co_{2.94}Fe_{0.06}S_4$, *i.e.* at 2% replacement of Co by Fe.

Experimental

A sample of $Co_{2.94}{}^{57}Fe_{0.06}S_4$ was prepared by direct synthesis from high-purity elements in an evacuated, sealed silica-glass tube. The ^{57}Fe content of the iron powder was about 92%; the powder was freshly reduced with H_2 before use. On completion of reaction the sulfide was kept at 500 °C for 24 h. The cooled mass was then reground under acetone, resealed, and annealed at 600 °C/6 days → 550 °C/2 days → 400 °C/1 day followed by cooling with the furnace. A sample of Co_3S_4 was prepared for comparison (600 °C/24 h; reground, 600 °C/4 days → 550 °C/2 days → 400 °C/1 day → room temperature). Overexposed X-ray powder photographs contained only lines of the spinel phase. The patterns were identical with those reported in ref. 9.

Mössbauer spectra of the Fe-containing sample at temperatures between 10 K and ambient were obtained with a conventional constant-acceleration transducer system coupled to a 400-channel multichannel analyzer, operated in its multiscaler mode. The source used was ^{57}Co in Pd and had an initial strength of 25 mCi. Calibration of the spectrometer was carried out using an enriched ^{57}Fe foil and the calibration data given by Stevens and Preston (10). The low-temperature spectra were obtained with the source and absorber mounted in a vertical configuration in a commercial liquid-helium cryostat (Oxford Instrument Company Ltd.). This cryostat maintained the source temperature at that of the main refrigerant (He or N_2) but allowed the absorber temperature to be maintained at any temperature between that of the main refrigerant and ambient. The absorber temperature was measured with a AuFe/chromel thermocouple and the desired temperature was maintained with a proportional temperature controller coupled to a small heating coil mounted close to the absorber. The temperature stability was better than ± 0.5 K throughout the period required to obtain a spectrum.

All chemical shifts quoted in this paper are relative to metallic iron at room temperature.

Results and Discussion

A representative selection of the Mössbauer ^{57}Fe spectra is shown in Figs. 1 to 3. Below 80 K the spectra consisted of two components: a six-line magnetic spectrum (6LMS) and superposed on this a two-line quadrupole spectrum (2LQS) typical of Fe atoms not ordered magnetically, in sites of symmetry lower than cubic. The presence of a 6LMS at only 2% replacement of the Co by Fe is an immediate indication that the structure of the sulfide is magnetically ordered and that the Co atoms participate in the ordering. Thus Co_3S_4 must fall within Goodenough's region $b_c < b < b_m$.

As the temperature of the sample was increased from 10 K the splitting of the 6LMS decreased, until at 93 K the six lines overlapped to such an extent that only a broad envelope was observed. Above 97 K the 6LMS collapsed to a single line superposed on the 2LQS, the net result being that only a broad, non-Lorentzian-shaped resonance line appeared. This would fix the magnetic transition temperature T_{tr} at about 95 K. Thus in demonstrating the existence of magnetic ordering and in yielding an estimate of T_{tr} the ^{57}Fe probe provides information concerning the behaviour of *cobalt* atoms in Co_3S_4.

Spectra below T_{tr} were fitted by least-squares to a model comprising a 6LMS and a 2LQS. As lines 3 and 4 of the 6LMS were not well resolved from the 2LQS, constraints had to be applied to obtain a sensible fit: the areas of the six lines were constrained in the ratio 3:2:1:1:2:3, the ratio appropriate for an unmagnetized absorber, the widths of the pairs of lines 1–6, 2–5, and 3–4 were constrained to be equal, and the relative positions of lines 3 and 4 were fixed with respect to lines 1 and 6 using the known ratio of the magnetic moments of the excited and ground states. No constraints were applied to the two lines of the 2LQS. This model will be referred to as model *a*.

The Mössbauer parameters obtained from these computer fits are given in Table 1. The parameter ε of the 6LMS is the difference in the splitting between lines 1–2 and 5–6. The fits of model *a* to the 10, 60, and 70 K spectra (Fig. 1) are acceptable except in the region of the resonance positions of the 2LQS lines. Moreover, there is a very noticeable difference in the widths and the intensities of the two component lines of the 2LQS, a feature to which we shall return below.

We assign the two spectra on the assumption that they arise from ^{57}Fe atoms substituting for Co atoms in the A and B sites of the spinel structure. However, the assignment is not straightforward, as it cannot be made directly from the area ratio R of the two spectra, $R =$ (area of 6LMS)/(area of 2LQS). The value of R at 10, 60, and 70 K is about 1.2, whereas a value of 2 would be expected if the 6LMS originated

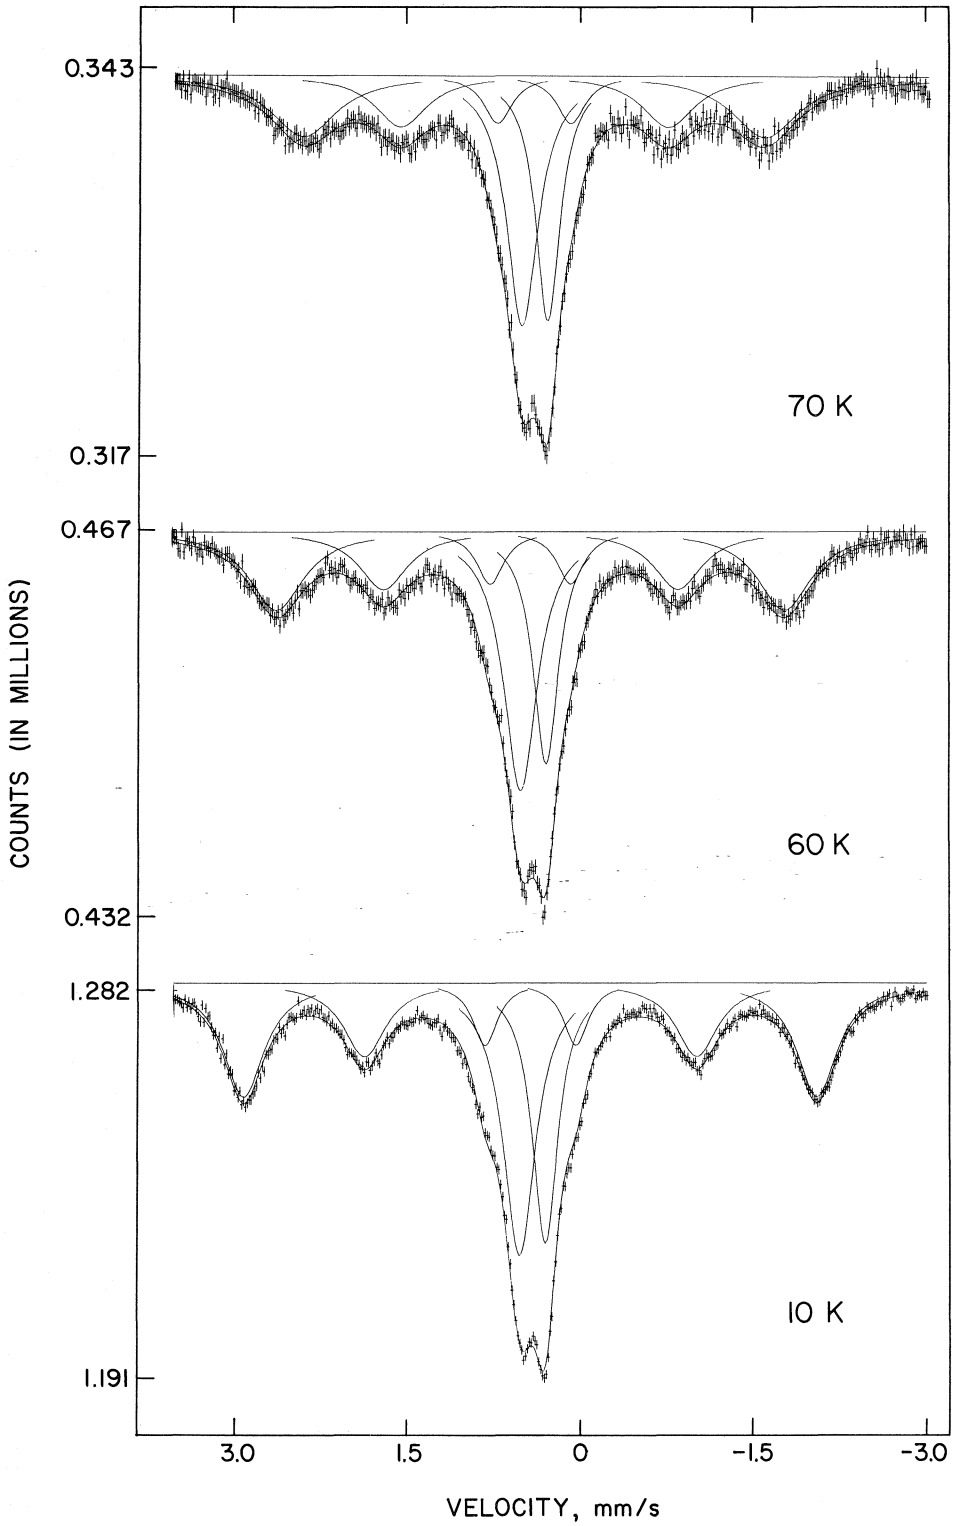

FIG. 1. Mössbauer ^{57}Fe spectra of $Co_{2.94}{}^{57}Fe_{0.06}S_4$ at 10, 60 and 70 K fitted to model *a* (see text).

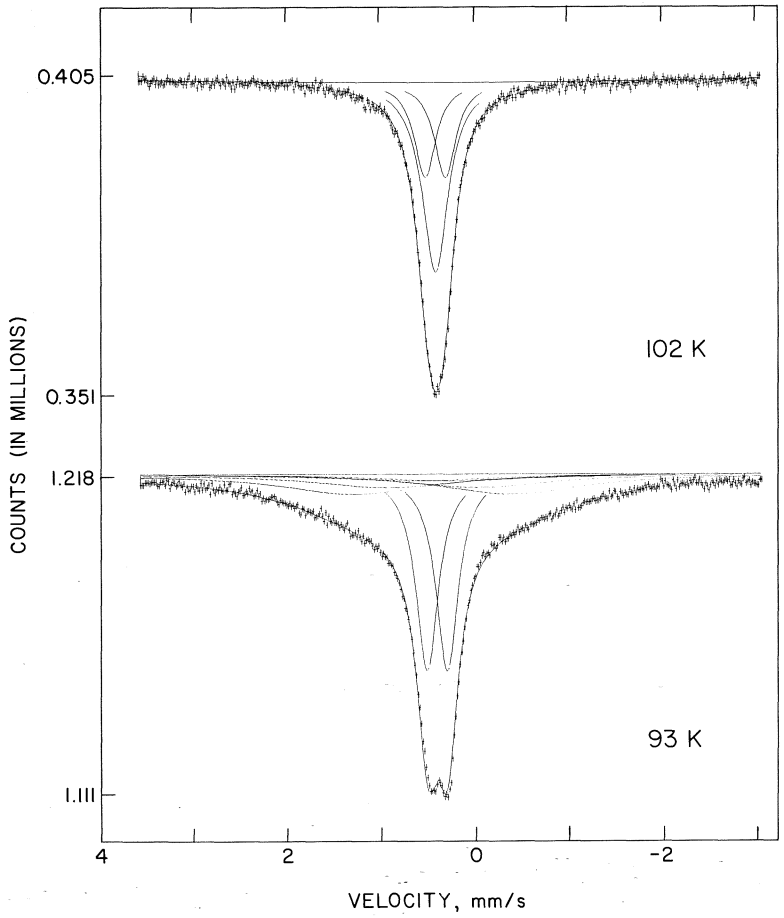

FIG. 2. Mössbauer ^{57}Fe spectra of $Co_{2.94}{}^{57}Fe_{0.06}S_4$ below (93 K) and above (102 K) the magnetic transition temperature $T_{tr} \approx 95$ K, fitted to model *b*.

from Fe(B), and 0.5 if from Fe(A), assuming the Fe atoms to be distributed at random over the A and B sites. The observed ratio is too small to be considered as a 2:1 ratio reduced by differences in the recoil-free fractions of the ^{57}Fe atoms at the two sites, or by vacancies at the A sites. It must then be due to a marked preference of Fe atoms for one type of site. Assignment of the two spectra has therefore been made from a consideration of the quadrupole splittings and the important observation that there is no, or at least only a very small, hyperfine magnetic field at one of the sites.

The fact that $\varepsilon = 0$, within experimental error, indicates that there is either no electric field gradient (EFG) at the Fe atom that gives rise to the 6LMS, or if there is, then the angle between the hyperfine magnetic field and the principal axis of the EFG is close to arc cos $(1/\sqrt{3})$. The 2LQS has an essentially temperature-independent quadrupole splitting of about 0.22 mm/s.

The symmetry at the A site is $\bar{4}3m$–T_d, so that no EFG is expected except for a contribution from disordered local environments of an Fe(A) due to other probe atoms (see below). The symmetry at a B site is $\bar{3}m$–D_{3d}, so that here an EFG is expected giving a non-zero quadrupole splitting; indeed, a non-zero nmr quadrupole interaction has been previously reported (4) at Co(B) in pure Co_3S_4 at 295 and 77 K. On this basis we assign the 6LMS observed below T_{tr} as arising from Fe atoms in the tetrahedrally coordinated A sites, and the 2LQS from Fe atoms in the trigonally distorted octahedral B

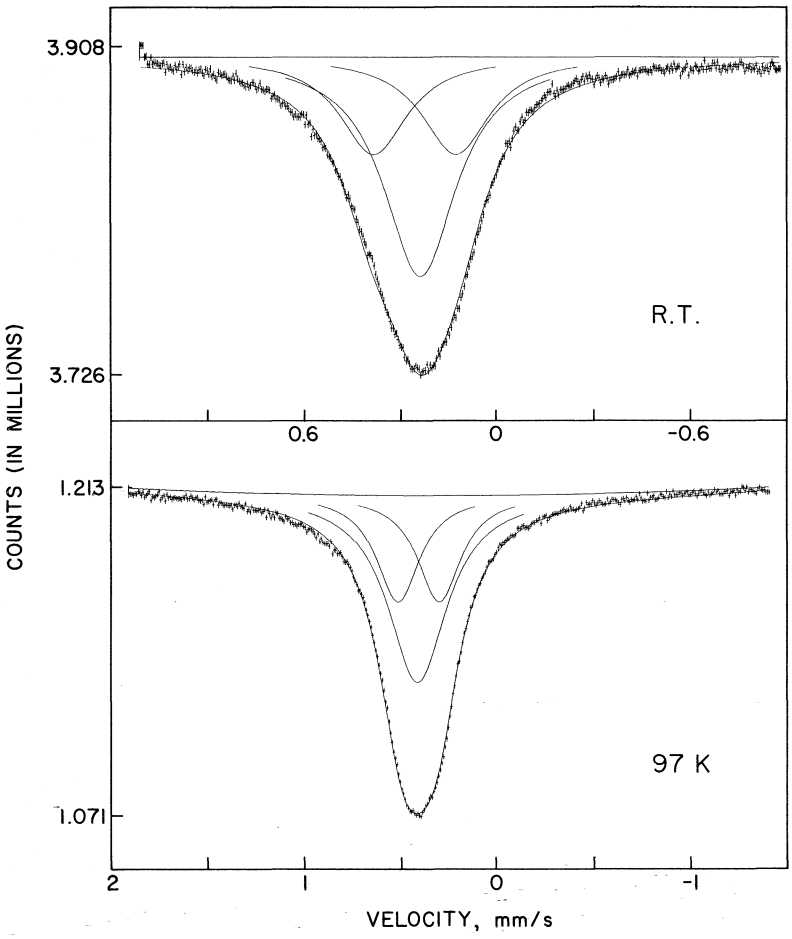

FIG. 3. Mössbauer ^{57}Fe spectra of $Co_{2.94}{}^{57}Fe_{0.06}S_4$ at 97 K and room temperature using a narrow velocity sweep. The spectra are fitted to model *b* with additional constraints (see text and Table 1). Note the different velocity scales.

sites. The site occupancy should thus be formulated as $[Co_{0.968}Fe_{0.032}][Co_{0.986}Fe_{0.014}]_2S_4$, the probe atoms preferring the A sites.[3]

An unusual feature is the closeness of the chemical shifts at Fe(A) and Fe(B) at all temperatures (Table 1). These shifts are, however, close to the measured chemical shifts in other sulfides containing Fe in tetrahedral sites (*cf.* Fig. 4 of ref. 11). The similarity of the room-temperature shifts at Fe(A) in $Co_{2.94}Fe_{0.06}S_4$ and in Fe_3S_4, 0.26(2) mm/s (12), is paralleled by the similarity of the shortest M(A)—S distances in these two spinels, 2.18(5) and 2.15(2) Å, respectively (13).

The magnitude of the hyperfine magnetic field *B* at Fe(A), extrapolated to 0 K, is about 16 T and thus much smaller than that observed in other Fe sulfides. For example, the field at both Fe(A) and Fe(B) in Fe_3S_4 is 31 T (12), while in troilite, FeS, it is 31 T at room temperature (14) and in orthorhombic cubanite, $CuFe_2S_3$, it is about 33 T (15, 16); in chalcopyrite, $CuFeS_2$, the value is about 37 T at 77 K (15). Since the similarity of δ[Fe(A)] in $Co_{2.94}Fe_{0.06}S_4$ and Fe_3S_4 would lead us to expect that covalency effects might be comparable in the two sulfides, the smallness of *B* in $Co_{2.94}Fe_{0.06}S_4$ might be

[3]A similar preference of Fe for tetrahedrally coordinated sites is observed in natural (untreated) pentlandite, $(Fe, Ni)_{9\pm\delta}S_8$ (11).

taken as evidence that the moment localized at the A site is much less than it is in Fe_3S_4. This would be consistent with the metallic nature of Co_3S_4, the small dependence of its χ on temperature, and with $b \approx b_m$.

The appearance of the 2LQS below T_{tr} shows that the Fe atoms that give rise to this spectrum do not participate in the magnetic order. This is entirely consistent with the proposed assignment that the 2LQS arises from Fe(B) atoms, if they have a low-spin $S = 0$ t_{2g}^6 configuration. The chemical shift of the 2LQS at room temperature, 0.250(5) mm/s, is reasonably close to that of the pyrite FeS_2, 0.305(3) mm/s (17), which is known to contain Fe atoms with an $S = 0$ configuration in an octahedral coordination of sulfur atoms. The shift is smaller than that observed at Fe(B) in Fe_3S_4, 0.55(2) mm/s (12). This is not surprising, as the configuration of Fe(B) in Fe_3S_4 has been suggested by Spender *et al.* (18) to be intermediate between high-spin ferric and high-spin ferrous; the low-spin d^6 Fe(B) configuration in $Co_{2.94}Fe_{0.06}S_4$ is more highly covalent than Fe in the high-spin states and yields a correspondingly smaller δ. Support for this is found in the observed Fe(B)—S distances. In Fe_3S_4, the shortest Fe(B)—S distance, 2.46(1) Å, is noticeably larger than the comparable Co(B)—S distance in Co_3S_4, 2.27(3) Å (*cf.* ref. 13), and the Fe—S distance in pyrite, 2.26 Å. The quadrupole splitting, ~0.22 mm/s at room temperature, is smaller than that of cubic FeS_2, 0.613(4) mm/s, (17), so that any lattice and molecular-orbital contributions are less than in pyrite.

The 2LQS below T_{tr} is similar in appearance to the ^{57}Fe spectrum of the pyrite $Co_{0.98}Fe_{0.02}S_2$ at 91 K that we have previously analyzed in detail (8). That spectrum was shown to be due to a supertransferred hyperfine magnetic field of about 0.6 to 0.7 T at the Fe sites in addition to the quadrupole interaction. The fact that a similar spectrum is observed at Fe(B) in $Co_{2.94}Fe_{0.06}S_4$ is not particularly surprising.

In the 93 K spectrum, which was the highest-temperature magnetic spectrum still showing a resolved quadrupole spectrum (Fig. 2), the hyperfine magnetic field at Fe(A) has decreased to such an extent that only a broad envelope of the collapsed 6LMS is seen. To obtain a sensible fit to this spectrum additional constraints were necessary. The widths of all six lines of the 6LMS were now constrained to be equal and the relative line

positions to be consistent with those of a pure magnetic interaction; the two lines of the 2LQS were constrained to have equal areas and widths. As Fig. 2 shows, this model, model *b*, gave a satisfactory fit. The ratio R again turned out to be close to the value of 1.2 observed in the well-resolved low-temperature spectra.

Above T_{tr} the area ratio R and Δ had to be constrained to values extracted from the low-temperature spectra; the two lines of the quadrupole doublet were constrained to have equal line widths and areas (Table 1). In the room-temperature spectrum the velocity sweep was small and it was possible to obtain a reasonable fit without constraining Δ. This resulted in a somewhat higher Δ value.

Some comment is justified concerning the absence of any measurable quadrupole splitting in the 6LMS and the appreciable, and unequal, line widths of the 6LMS components, which show an increase with increasing temperature as the hyperfine magnetic field at Fe(A) decreases. This line-width behaviour is an indication that either there are a number of hyperfine magnetic fields or there is a hyperfine-field distribution, leading to a number of closely overlapping six-line spectra. Examination of the Co_3S_4 structure shows that a Co(A) atom is surrounded by four Co(A) atoms at 4.07 Å, at the corners of a regular tetrahedron, and by twelve Co(B) atoms at 3.90 Å, at the corners of a regular truncated tetrahedron. The frequency of 4Co(A) + 12Co(B) environments of the Fe(A) atoms in $Co_{2.94}Fe_{0.06}S_4$, assuming an Fe(A):Fe(B) ratio of 1.2 but a random distribution over the A and B sites, will be 0.742, *i.e.* 74.2% of the Fe(A) atoms will have only Co atoms as their nearest metal-atom neighbours out to a distance of 6 Å. A 10% fraction of the Fe(A) atoms will have 1Fe(A) + 3Co(A) + 12Co(B) as their nearest metal-atom neighbours, and 12.4% will have 4Co(A) + 1Fe(B) + 11Co(B). As the magnetic moments of the Fe(A), Co(A), and Co(B) atoms will almost certainly be different, and non-zero,[4] these three environments of Fe(A) atoms will be expected to give three different hyperfine magnetic fields at Fe(A). If more distant metal-atom neighbours are included a *distribution* of magnetic fields at Fe(A) will result.

The second and third of the Fe(A) environments just enumerated are non-cubic if the charges on the Fe and Co atoms are different, and will give rise to an EFG at Fe(A). However, the resulting quadrupole splitting is difficult to estimate from a point-charge lattice sum because of the uncertainty in assigning effective charges to the metal atoms and in the absence of an estimate of the shortest Fe—Fe distances. Moreover, the principal axis of the Fe(A)—$Co(A)_3$-$Fe(A)_1$ tetrahedron is the threefold axis passing through the two Fe atoms. If the hyperfine magnetic field is parallel to a crystallographic axis (*i.e.* to an edge of the unit cell or to a $\bar{4}$ axis), the angle of the field with the threefold axis of the tetrahedron, and thus with the principal axis of the EFG, is arc cos $(1/\sqrt{3})$. Then if the effective charges on the Fe(A) and Co(A) atoms were similar, the q_{latt} contribution from any such tetrahedron to Δ would be close to zero. The EFG in the Fe(A)—$Co(B)_{11}Fe(B)_1$ truncated tetrahedron does not have axial symmetry; the Fe(A)—Fe(B) vector is 29.5° off the nearest threefold axis. The q_{latt} contribution to Δ from this environment is not likely to be large. These considerations explain why Δ is not resolved in the 6LMS and why it is almost certainly 'swamped' by the range of hyperfine magnetic fields expected at Fe(A). Further evidence for this conclusion is available from the spectra obtained above T_{tr}: the single line arising from Fe(A) atoms is not noticeably broadened.

It is interesting to note that the recently reported (19) room-temperature spectrum of the paramagnetic phase of the spinel $Fe_{1.06}Cr_{1.94}S_4$ consisted of a singlet and a quadrupole doublet having the same δ and an area ratio of 70:30. The appearance of the doublet was explained by formulating the site occupancy as $[Fe^{2+}_{0.94}Fe^{3+}_{0.06}][Fe^{2+}_{0.03}Cr^{3+}_{0.97}]_2S_4$, in which case the Fe^{2+}(A) atoms would occur in the structure either surrounded by $12Cr^{3+}$ or by $11Cr^{3+}$ + $1Fe^{2+}$ nearest-neighbour B atoms, in an abundance ratio of 69:26. The observed Δ produced at an Fe^{2+}(A) atom by the $11Cr^{3+}$ + $1Fe^{2+}$ environment was 0.73 mm/s. Since the authors considered a distribution $[Fe^{2+}][Fe^{3+}_{0.03}Cr^{3+}_{0.97}]_2S_4$ unlikely on the grounds that the M(B) atoms would have equal charge and practically equal ionic radii and hence would not produce an EFG at Fe(A), the spectrum was taken as experimental evidence of a preference of the Fe^{2+} ions for B sites in sulfospinels.

[4]The magnetic moment of Fe(B) is zero, see above.

Our results support this conclusion to the extent that the Fe(B) atoms in $Co_{2.94}Fe_{0.06}S_4$ have a t_{2g}^6 configuration, $S = 0$; the effective ionic radii for 6-coordination of Fe^{2+}_{LS} and Co^{3+}_{HS} are closely similar (20).

Acknowledgments

We wish to thank Dr. C.-H. Huang for the preparation of the two samples and to the National Research Council of Canada for a grant in aid of research to one of us (O.K.).

JOHN R. JONES and RICHARD FUCHS. Can. J. Chem. **55**, 99 (1977).

The accelerating effect of added dimethyl sulfoxide on the rate of hydroxide-catalyzed ionization of chloroform in water has been examined in terms of the solvation of reactants and transition state. Enthalpies of solution of chloroform in water, DMSO, and mixtures of the two have been measured. From these, together with enthalpies of activation for the detritiation of chloroform, and enthalpies of transfer of hydroxide ion from water to aqueous DMSO mixtures, transition state enthalpies of transfer have been calculated. The reaction is accelerated by small concentrations of DMSO because of increased transition state solvation, but by large DMSO concentrations due to reduced solvation of hydroxide ion. Transition state solvation is unlike that of the reactants, but resembles that expected for CCl_3^- ion.

JOHN R. JONES et RICHARD FUCHS. Can. J. Chem. **55**, 99 (1977).

L'addition de diméthylsulfoxyde dans l'eau augmente la vitesse d'ionisation, catalysée par les ions hydroxyles, du chloroforme; on a étudié cet effet d'accélération en termes de solvatation des réactifs et d'état de transition. On a aussi mesuré les enthalpies de solution du chloroforme dans l'eau, dans le DMSO et dans des mélanges des deux. A partir de ces données et à l'aide des enthalpies d'activation pour la détritiation du chloroforme et des enthalpies de transfert de l'ion hydroxyle de l'eau vers des mélanges aqueux de DMSO, on a calculé les enthalpies de l'état de transition du transfert. La réaction est accélérée par des faibles concentrations de DMSO parce qu'il y a augmentation dans la solvatation de l'état de transition; toutefois dans le cas de concentrations élevées de DMSO, l'accélération est due à une solvatation réduite de l'ion hydroxyle. La solvatation de l'état de transition ne ressemble pas à celle des réactifs mais ressemble plutôt à celle attendue pour l'ion CCl_3^-.

[Traduit par le journal]

Dimethyl sulfoxide – water mixtures containing a fixed concentration of hydroxide ions (usually 0.010 *M*) are finding increasing use in physical organic chemistry (1). Many reactions are greatly accelerated in such media (2) which have also been used to study the acidities of weak acids (3) and kinetic hydrogen isotope effects (4).

In analyzing the effects of changing the composition of the reaction medium on reaction rates it is necessary to be able to assess the importance of solvent – solute interactions. This can best be done by taking a reaction of well defined mechanism and varying the nature of the substrate. Unfortunately, in many kinds of chemical reactions there are severe limitations on the choice of substrate. This restriction probably applies less to the ionization of carbon acids than most other types of reaction and we have recently shown (5) how a carbonyl-activated carbon acid (D-α-methyl-α-phenylacetophenone) responds to changes in medium composition. Such an analysis requires enthalpies of activation in a series of dimethyl sulfoxide – water mixtures, and corresponding heats of solution for the substrate. The present paper is concerned with a different type of carbon acid (chloroform) for which data of the first kind are available (6). We have consequently measured heats of solution for chloroform in water, dimethyl sulfoxide, and mixtures of the two, as well as for deuteriated chloroform in a particular medium as it is implicit in the analysis of the data that the heats of solution are not subjected to isotope effects.

The hydroxide-catalysed rate of detritiation of chloroform in water has a value of 0.165 l mol^{-1} s^{-1}, somewhat higher than that observed

[1]Work at the University of Houston was supported by the Robert A. Welch Foundation Grant E-136.

for acetone (0.0024) (7) and acetophenone (0.0054) (8). This suggests a pK_a *ca.* 20, and on this basis the rate acceleration upon addition of dimethyl sulfoxide should, if expressed in terms of a log $k - H_-$ relationship (9), result in a slope of 0.4–0.45. The much higher value near unity (6) is unlike that of other carbon acids, and probably occurs because the process of ionization of chloroform is accompanied by little charge delocalization and solvent reorganization.

Experimental

Materials

Reagent grade dimethyl sulfoxide was purified by a previously reported procedure (10). Mixtures with deionized water were prepared by weight. Reagent grade chloroform (stabilized with 0.75% ethanol) was stored over 4A molecular sieves to remove water and ethanol. The dried chloroform was examined by gas chromatography (DC-710 on Chromosorb W). No remaining ethanol was found under conditions which will detect less than 0.1%. Deuteriated chloroform was commercially available and of 99.8% isotopic purity.

Calorimetry

The procedure employed was the same as that outlined previously (11). The accuracy of the ΔH_s measurements is ± 0.10 kcal mol^{-1} in water and the most highly aqueous solvent mixtures and ± 0.05 kcal mol^{-1} in the other solvents. The values of ΔH_s reported are averages of 3–6 determinations in the concentration range of 3–10 $\times$ 10^{-3} *M*. No effect of concentration on ΔH_s was observed.

Results and Discussion

The measured enthalpies of solution (ΔH_s) in water, dimethyl sulfoxide, and mixtures of the two solvents are listed in Table 1. These slowly increase until a maximum is reached at mole fraction DMSO of 0.17. The value of ΔH_s for deuteriated chloroform in a medium of mole fraction DMSO equal to 0.13 is, within experimental error, equal to that obtained for chloroform itself. It is reasonable to assume that the identity of values is carried over to the other solvent mixtures and to tritiated chloroform.

Single ion enthalpies of transfer (from water to DMSO–water mixtures) for hydroxide ion can be calculated using the extrathermodynamic assumption $\Delta H_{tr}(Ph_4P^+) = \Delta H_{tr}(Ph_4B^-)$ (11, 12). The absolute values of ΔH_{tr} for anions are dependent on the accuracy of the assumption, but the relative values of $\Delta H_{tr}(OH^-)$ and ΔH_{tr}^{ts} are independent of the assumption (12). The enthalpy of transfer of chloroform is obtained from the enthalpies of solution: $\Delta H_{tr} = \Delta H_s(S) - \Delta H_s(H_2O)$. The sum of the two enthalpies of transfer ($\sum\Delta H_{tr}$(reactants)) together with changes in the measured enthalpies of activation (6) ($\Delta H_{tr}^{\neq} = \Delta H^{\neq}(S) - \Delta H^{\neq}(H_2O)$) can be used to derive the transition state enthalpy of transfer for the ionization of chloroform $\Delta H_{tr}^{ts} = \sum\Delta H_{tr}$(reactants) + $\Delta H_{tr}^{\neq}$. The results (Table 2) indicate that in the more aqueous solvent mixtures (up to DMSO mole fraction 0.13) the enthalpies of transfer for chloroform and hydroxide ion are small, with both species being slightly better solvated than in water. Further increase in the concentration of dimethyl sulfoxide however brings about a considerable change, the hydroxide ion becoming increasingly desolvated and chloroform solvation remaining approximately constant. In other words the initial rate acceleration is brought about by increasing transition state solvation but subsequent rate increases arise mainly from hydroxide ion desolvation.

Although the results are not directly comparable with those for the ionization of D-α-methyl-α-phenylacetophenone (5) (where because of solubility difficulties mixtures of higher mole fraction dimethyl sulfoxide had to be used) it appears that the loss of transition state solvation with increasing DMSO concentration is smaller in chloroform ionization. Recent findings (13) on hydroxide-catalysed isotopic exchange of molecular deuterium indicate that the loss of transition state solvation with increasing [DMSO] approaches that of hydroxide ion. The dependence of enthalpies of transfer of the transition state on structure is to be expected, as has been well established for stable ions. In the ionization of chloroform the available evidence (5, 14) suggests that the transition state is very product-like ($\bar{C}Cl_3 \ldots \overset{+}{H}\bar{O}H$). It is interesting therefore that ΔH_{tr}^{ts} resembles ΔH_{tr} for the iodide ion (11) (Table 2) with the difference that at mole fractions dimethyl sulfoxide in excess of 0.13 the transition state values become less exothermic.

This suggests that the transition state is a 'harder' anion than iodide, *i.e.* is less polarizable, with more localized charge and probably better solvated by water than dimethyl sulfoxide. This would be expected for a species resembling CCl_3^-.

The above analysis is based entirely on considerations of enthalpy changes. This would seem to be a good approximation as the results of Margolin and Long (14) show that the enthalpy of activation for the detritiation of chloroform decreases by 3 kcal mol^{-1} in going from water to a medium of mole fraction dimethyl sulfoxide 0.13 with but a small (3.4 eu) decrease in the entropy of activation. However, for media of still higher dimethyl sulfoxide content $\Delta S^{\neq}$ rapidly decreases. Consequently our interpretation of the results in these solutions is less firmly based.

Kinetic studies of Dakin oxidation of *o*- and *p*-hydroxyacetophenones[1]

M. B. HOCKING AND J. H. ONG

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received May 20, 1976

M. B. HOCKING and J. H. ONG. Can. J. Chem. **55**, 102 (1977).

Rates of oxidation of aqueous *o*-, and *p*-hydroxyacetophenone with alkaline hydrogen peroxide to yield catechol and hydroquinone, respectively, have been followed spectrophotometrically. Both ketones showed smooth pseudo first-order behaviour, the *ortho* isomer yielding rate constants in the range 2.6 to 6.6 × 10^{-2} min^{-1} at 0 °C, and the *para* isomer of 0.73 to 7.10 × 10^{-2} min^{-1} at 35 °C for the concentrations of hydrogen peroxide and base used. The order in hydrogen peroxide was, unexpectedly, found to be 1.4. A simple test established that this fractional order was probably not the result of hydrogen peroxide involvement in simultaneous first- and second-order processes of differing rates. Other plausible pathways to explain this are proposed.

M. B. HOCKING et J. H. ONG. Can. J. Chem. **55**, 102 (1977).

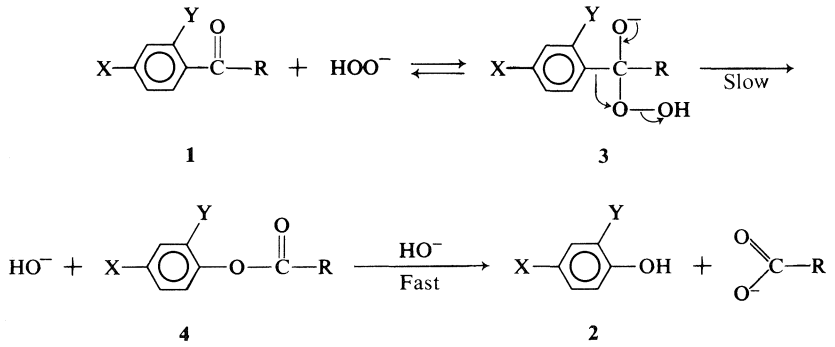
L'oxydation, par le peroxyde d'hydrogène en solution alcaline aqueuse, de l'*ortho* et de la *para*-hydroxyacétophénone conduit au catéchol et à l'hydroquinone; on a déterminé les vitesses de ces réactions d'une façon spectrophotométrique. Les deux cétones présentent un comportement régulier du pseudo premier ordre, pour les concentrations de peroxyde d'hydrogène et de base utilisées, les constantes de vitesse de l'isomère *ortho* sont de l'ordre de 2.6 à 6.6 × 10^{-2} min^{-1} à 0 °C alors que celles de l'isomère *para* devient de 0.73 à 7.10 × 10^{-2} min^{-1} à 35 °C. On a trouvé d'une façon inattendue que l'ordre en peroxyde d'hydrogène est de 1.4. Un test simple a établi que cet ordre fractionnel n'est probablement pas dû à l'implication du peroxyde d'hydrogène dans des processus simultanés du premier et du second ordre de vitesse différentes. On propose d'autres chemins plausibles pour expliquer ces résultats.

[Traduit par le journal]

Introduction

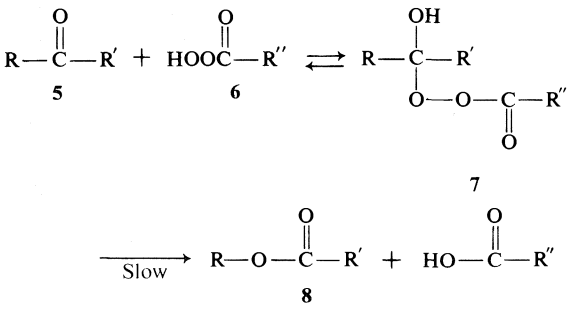
Dakin oxidation (1) as a means to obtain a predictable variety of hydroxylated aromatic nuclei (**2**) from appropriate *ortho*- or *para*-hydroxylated aldehydes or ketones (**1**) has been known for many years (1) but no experimentally well-supported mechanism has yet been presented. The reaction path which is generally accepted (2, 3) as a plausible description of the process is given in Scheme 1. The ionic basis is founded on the resemblance of this reaction to the Baeyer–Villiger oxidation of bis-aromatic ketones **5** with peracids (4), which is experimentally well documented by evidence which includes isolated intermediates and rearrangement products.

These general conclusions may be made from the extensive mechanistic experiments concerning the Baeyer–Villiger reaction. The migratory aptitude is greatest for groups R or R′ best able to

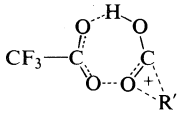


SCHEME 1

[1]Presented at the First Chemical Congress of the North American Continent, Mexico City, Nov. 30, 1975.



stabilize a positive charge (5–8), although vinyl (4, pp. 117 and 18; 9) and cyclopropyl (10) groups have been shown to migrate in preference to methyl. Migration proceeds with retention of configuration (11–13). ^{18}O labelling of the carbonyl carbon in the substrate **5** gives ^{18}O in the carbonyl of the ester **8** (14, 15). A migration cage **9** has been proposed for the group R (16), with a highly negative $\Delta S^{\ddagger}$ of -30 to -45 eu (5, 17–19), and it is accepted that no free (electron deficient) oxygen species or carbonium ion is



formed during the rearrangement process (16, 20). The collapse of **8** to products is acid-catalyzed and is the rate-determining step of the process (6).

That the initial step of Dakin oxidation is via nucleophilic attack of the ketone carbonyl by hydroperoxide anion is plausible and well accepted (2, 3, 21). The alkaline solution present has led to the adoption of hydroxyl ion as the leaving group coincident to migration. In contrast, the acidic solutions of Baeyer–Villiger oxidations involve departure of a carboxylate anion, which being a delocalized, 'softer' anion than hydroxide is much more acceptable as a leaving group than the highly localized hydroxyl ion, and specifically in this type of reaction (21, p. 120; 22, 23).

From a stereochemical point of view, as from leaving group considerations, there are contrasting aspects to the two processes. A hydroxyphenonium ion is the intermediate or transition state required by the currently held Dakin mechanism, which dictates phenolate migration with inversion of configuration. Unfortunately configurational changes cannot be observed with Dakin reaction substrates, but with the Baeyer–Villiger reaction where configurational changes are observable retention has been demonstrated, probably via a closely associated three-center transition state (24).

While a very strong electron-donating substituent such as OH (or $-O^-$) is required on the aromatic nucleus for Dakin oxidation to occur at all (25, 26), Baeyer–Villiger reactions have been shown to proceed with migration of acyl aromatic groups (24, pp. 242 and 243; 27).

With all these contrasting features, it is evident that the mechanism for the Dakin reaction cannot simply be adopted from an analogy with the Baeyer–Villiger oxidation, but to have any real hope of understanding must be experimentally examined using the conditions required for the Dakin reaction itself.

Experimental

Melting points were determined at calibration immersions using thermometers calibrated against National Bureau of Standards thermometers. Melting points and boiling points are not corrected. Ultraviolet spectra were obtained on a Cary Model 17 spectrophotometer at room temperature and nmr spectra on a Perkin-Elmer R12A spectrometer at 37 °C. p*H* measurements were taken using a Fisher Accumet Model 310 p*H* meter calibrated at measuring temperature in p*H* 11.10 buffer using a high p*H* electrode (type H5586-1, Canlab).

Materials

Commercial *p*-hydroxyacetophenone was purified by recrystallization from water followed by sublimation at 160 °C/0.5 torr, white crystals mp 109–110 °C (lit. (28) mp 109–110 °C). The cut of redistilled *o*-hydroxyacetophenone used boiled at 120–122 °C/15 torr (lit. (29) bp 106–107 °C/17 torr) and was a pale yellow oil which gave only one peak on glc 25% SE 30 on Chromosorb G, AW-DMCS, column temperature 115 °C. All inorganic salts, ethylenediamine tetraacetic acid (EDTA), and hydrogen peroxide used were reagent grade materials. The strength of the initial batch of 30% hydrogen peroxide was accurately determined by titration (30) to be 9.62 *M*, about 1% above labelled, and the strength was periodically checked both during use and on changing to a new lot number. Hydrogen peroxide was briefly sparged with nitrogen before use. Quadruply distilled water, the second stage from alkaline $KMnO_4$ in Pyrex and the third and fourth stages from quartz ware (conductance 0.8×10^{-6} S), purged with nitrogen (to avoid radical interference from dissolved oxygen) was employed in the kinetic runs.

Hydroquinone monoacetate was prepared by acetylation of hydroquinone with acetic anhydride in aqueous sodium carbonate at 0 °C according to the method of Olcott and incorporating the improvements of Bunton and Hellyer (31). When the reaction was complete, diester was filtered off and the filtrate was extracted with ether. The ether extracts were dried (Na_2SO_4) and the ether evaporated. The residual solid obtained gave a low

yield of monoester on trituration with 60–90 °C petroleum ether (PE). Recrystallization several times from 60–90 °C PE yielded colourless plates mp 57–59 °C (lit. (31) mp 62–63 °C); 60 MHz nmr (37 °C, CCl_4, internal TMS) δ 2.21 (s, 3H), 7.60 (d, 4H), 5.75 (br s, 1 H), *m/e* 152 (m^+) was observed.

Competitive Oxidation/Hydrolyses

The oxidation of *p*-hydroxyacetophenone (136 mg; 1 mmol) in 2.6 ml of 0.375 *M* sodium hydroxide in water, with 214 mg of 30% hydrogen peroxide at 37 °C was followed by the loss of the ketone methyl and the appearance of acetate ion methyl in repetitive nmr spectra. No other methyl was observed.

p-Hydroxyacetophenone (136 mg) was then oxidized competitively while hydroquinone monoacetate (152 mg; 1 mmol) was hydrolyzed in 5.2 ml of 0.375 *M* sodium hydroxide in water with the addition of 214 mg of 30% hydrogen peroxide. By nmr, the relative changes in peak height *vs.* time, which had previously been checked by integration and found to be a reliable measure of concentration at the scanning rates used, were recorded (Table 1).

Alternate Oxidizing Agents

tert-Butylhydroperoxide reacted only very slowly with *p*-hydroxyacetophenone in dilute aqueous sodium hydroxide or sodium hydroxide – sodium acetate at room temperature so that proton nmr examination at intervals during 2 days showed only *tert*-butylhydroperoxide methyl and acetyl methyl protons, with only a trace of *tert*-butanol and acetate ion. Heating the same initial compositions 3 days at 85 °C still gave only a small acetate ion peak, even though small amounts of acetone (32) and *tert*-butanol were produced.

Hydrogen disulfide (33) could not be induced to react with *p*-hydroxyacetophenone in 0.2 *M* Na_3PO_4 in water at room temperature or on heating at 60 °C for 5 h, when monitored in the same way as the *tert*-butylhydroperoxide experiments.

Kinetic Preliminaries

Buffer selection was guided by the 11.65 pK_a of hydrogen peroxide at 25 °C (34) together with the requirement of a high hydroperoxide anion concentration. Solutions of 2.5 g of sodium and potassium carbonates or phosphates in 50 ml of water gave p*H* readings at 20 °C of 11.8 and 12.6 for the change in anion, and each dropped 0.05, 0.04, 0.04, and 0.03 p*H* units for each 10 ml addition of water. Addition of hydrogen peroxide to these solutions showed noticeable spontaneous peroxide decomposition, probably from traces of iron or manganese in the buffer salts. This could not be cured by use of the highest purity reagents available, by adsorptive pretreatment of the solutions with MgO, or by solution passage through 'Chelex 100' chelating resin[2] (35), and could only be reduced somewhat by the addition of small amounts of the standard peroxide stabilizers Na_2SnO_3, $Na_4P_2O_7$, or 8-hydroxyquinoline. It could, however, be prevented for a period of 2 h or more by the addition of 20–30 mg of EDTA.

Using proton nmr to follow directly ketone loss during the reaction failed because the initial concentrations required for analysis were sufficiently high that the temperature could not be held constant. Gravimetric determinations by either bromination or lead salt formation were insufficiently reproducible and were tedious. Gas–liquid chromatographic determination of ketone directly from the aqueous reaction solutions using a flame ionization detector gave problems with time measurement and was less accurate than uv. Ultraviolet determination of the ketone directly from the aqueous kinetic solutions was not possible because of interference by broad buffer absorption, but three extractions with chloroform of acidified blank samples saturated with NaCl gave quantitative recovery of ketone for absorbance measurement without interference.

Kinetic Runs

For a typical run a solution of 1–3 × 10^{-4} mol of the hydroxyacetophenone, 2.5 g of Na_2CO_3 or $Na_3PO_4 \cdot 12H_2O$, and ~10^{-5} mol EDTA in 40 ml H_2O in an alkaline hydrogen peroxide pretreated (30) new polyethylene flask, was equilibrated in a thermostatted water bath. To this was added 10 ml of previously thermally-equilibrated 30% hydrogen peroxide, usually corresponding to more than 100× excess. To follow the progress of the reaction, 5 ml aliquots of the reaction solution were transferred to 25 ml glass vials and were then rapidly chilled in a dry ice – acetone bath and acidified to p*H* 1 with HCl or $HClO_4$ (*p*- and *o*-ketone respectively), which effectively stopped the reaction. In this way, duplicate experimental samples extracted and analyzed immediately or after up to 2 h refrigerated storage gave agreement of ketone concentrations within 1.0%.

Quenching by sparging with SO_2 or addition of sodium sulfite was found to be too slow acting and produced significant heat. It was also a procedure which did not allow monitoring of peroxide disappearance.

For runs with *p*-hydroxyacetophenone, the chloroform extracts of the chilled acidified and salted aliquots were scanned in the region of 268 nm (λ_{max} for the ketone) to follow the loss in optical density and to determine the rate of ketone loss (*e.g.* Table 2). Product hydroquinone was further oxidized under the reaction conditions used, and did not interfere spectrophotometrically. Duplicate samples from a single run were reproducible in ketone concentrations to within 0.5%, and pseudo first-order rate constants of whole kinetic runs were reproducible to better than 1% (Table 1).

For runs with *o*-hydroxyacetophenone, aliquots satu-

40	0.10325

*Na_2CO_3 (2.500 g) in total solution volume of 50 ml, p*H* before H_2O_2 addition = 11.8.

rated with NaCl generated a yellow colour which, it was suspected, might interfere with the ketone analysis; therefore, the chilled aliquots were simply extracted with chloroform to recover unreacted ketone and the loss of optical density of the peak at 253 nm was followed. Blank tests with known amounts of ketone established that the extraction procedure was quantitative and reproducible without salting. Catechol, the oxidation product was relatively stable under the extraction conditions at 0 °C and was seen in the $CHCl_3$ phase by a peak at λ_{max} 277.5 nm and a shoulder at 282.5 nm. Its presence did not interfere with the ketone determination. In this way duplicate sample runs gave pseudo first-order rate constants reproducible to better than 4% for $1\frac{1}{2}$ half-lives, and better than 6% for whole kinetic runs.

Hydrogen peroxide concentration and p*H* were monitored during the course of several of the kinetic runs and neither changed significantly. For hydrogen peroxide typical results, when oxidizing *p*-hydroxyacetophenone (41.3 mg) titres of 10 ml of 30% H_2O_2 (reaction concentration, 1.92 *M*) in 0.13 *M* Na_3PO_4 (40 ml) KI/thiosulfate (0.0994 *M*) with aliquots taken initially and after 15, 75, and 135 min, were 9.92; 10.10, 9.98 (duplicate); 9.96; and 9.69, 9.92 ml (duplicate), respectively. While nitrogen purging of the water used and brief nitrogen sparging of the hydrogen peroxide eliminated any significant interference of oxygen-induced radical formation in the initial rates, in prolonged runs a rate enhancement occurred when spontaneous peroxide decomposition was observed.

Results and Discussion

Kinetic study of any system comprising substituted phenols and hydrogen peroxide has to contend with the formation of phenoxy radicals and secondary products, either of which may interfere. This may be minimized, allowing useful kinetic interpretation if the reaction being studied is fast and only the 'initial rate' data are considered. Experiments aimed at reducing this type of interference here by use of the alternative oxidizing agents *tert*-butylhydroperoxide and hydrogen disulfide only succeeded in generating small amounts of *tert*-butanol and acetone (a rearrangement product (32)) from the former and no reaction with the latter.

With the proper choice of buffer, absolute and relative concentrations, and temperature oxidation of *p*-hydroxyacetophenone with alkaline hydrogen peroxide was kinetically well-behaved yielding smooth concentration *vs.* time curves. From these, an initial rate test using the general expression $dx/dt = k[\text{ketone}]^n$ gave 0.971 for the order of the reaction, *n* (first 10 min). Runs 1 and 2 (Table 3) followed through $2\frac{1}{2}$ half-lives gave pseudo first-order rate constants of 7.10×10^{-2} min^{-1} and 7.14×10^{-2} min^{-1}, agreement to within 0.6% and also, from the different initial ketone concentration, confirmation of first-order behaviour with respect to ketone. Even to $4\frac{1}{2}$–5 half-lives, the rate constants for the same runs showed less than 7% deviation from each other, kinetically very predictable behaviour (Fig. 1), but the first-order plots became slightly concave-down curves.

A decrease in the initial peroxide concentration in order to determine the effect on rate accentuated the concavity observed in the later stages of runs 1 and 2 (see Table 3, runs 4 and 5).

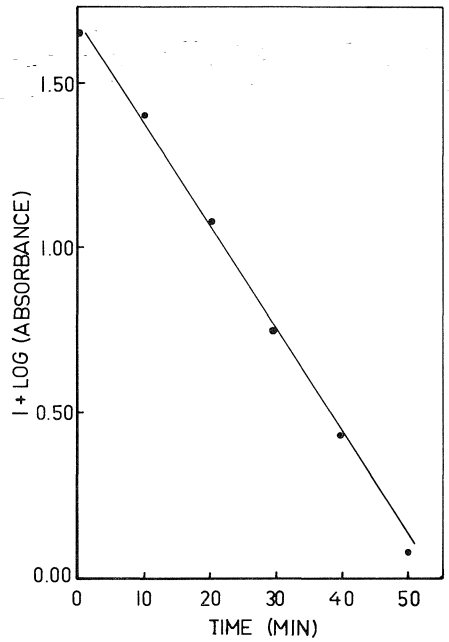

FIG. 1. Loss of *p*-hydroxyacetophenone with time, when oxidized with hydrogen peroxide in the presence of Na_2CO_3, $LiNO_3$, and EDTA at 35 °C (run 2, Table 3).

*Oxidized in 0.4630 M Na_2CO_3 (2.50 g Na_2CO_3 in 40+ ml of water, plus reagents tabulated, giving in all cases a total solution volume of 50 ml). pH before H_2O_2 addition = 11.8.
†Solutions with 1.923 and 0.962 M H_2O_2 present gave pH readings of 9.9 and 10.5 respectively.
‡$LiNO_3$ (250 mg, 0.0725 M) was also present in these runs as part of salt effect study.
§Reaction followed for 70 min but curvature was evident in kinetic plots at times greater than shown (see Experimental and Discussion).

While the rate of initial ketone loss with time was slower for smaller (~41:1 $[H_2O_2]$:[*p*-ketone]) excesses of hydrogen peroxide present, this initial rate was found to increase as the run progressed, possibly an indication of kinetic influence by the products of the reaction. The more than 100 molar excess of hydrogen peroxide normally used was probably instrumental in oxidizing the initial product (hydroquinone) before it could exert kinetic influence in most runs.

The much more significant result emerging when the hydrogen peroxide concentration was varied was that the pseudo first-order rate constant obeyed the relation $k_{obs} = k[H_2O_2]^{1.4}$ (Fig. 2), where $k = 2.82 \times 10^{-3}$ min^{-1} $mol^{-1.4}$. Thus, the Dakin oxidation is clearly not first-order in hydrogen peroxide. The mechanism currently accepted requires at least some modification to yield an acceptable pathway consistent with this.

If the Dakin reaction is assumed to proceed via a purely ionic route, Scheme 2 is one way in which the observed order in hydrogen peroxide may be rationalized. Hydroperoxide anion attack on the carbonyl carbon of **10** is straightforward (20, p. 218; 36), and the process of peroxy anion displacement by **11** has been invoked for *p*-cyanobenzoic acid hydrolysis in the presence of hydrogen peroxide, with the comment it is expected that this type of process "... will increase in importance... at higher pH values". (37). Hydrotrioxide intermediates like **12** have also been observed, for example benzaldehyde hydrotrioxide has been shown to have a half-life

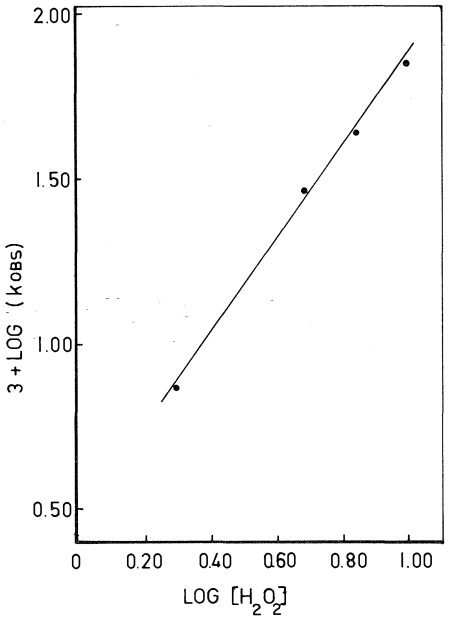

FIG. 2. Order in hydrogen peroxide from Dakin oxidation of *p*-hydroxyacetophenone at 35 °C.

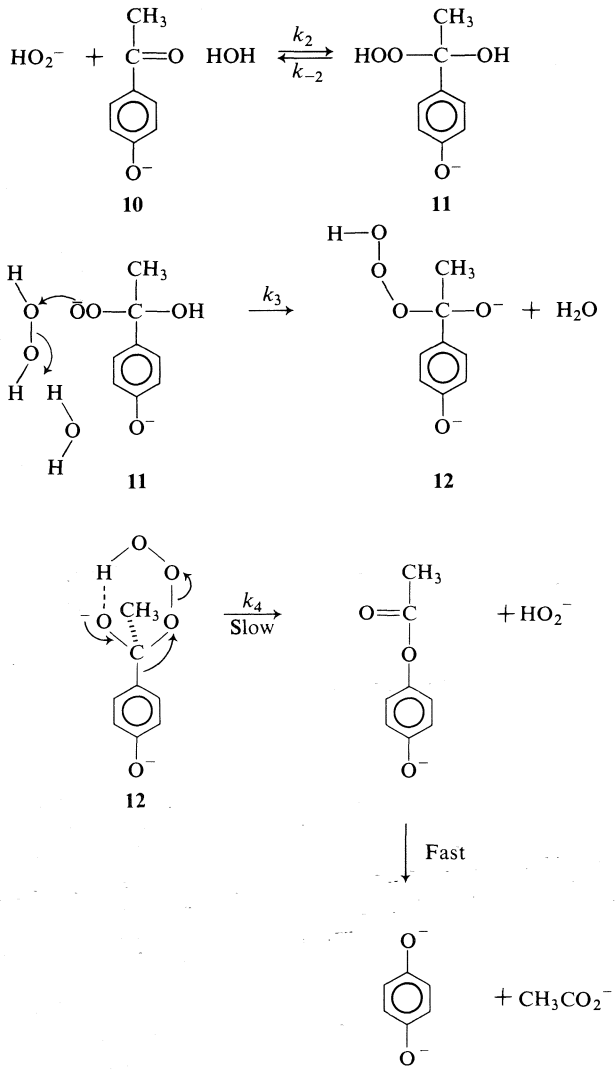
of 400 s at 12 °C (38). For more than a first-order dependence on hydrogen peroxide, hydrotrioxide decomposition must be the slow step of the sequence.

Theoretical considerations too support the proposed pathway. A readily polarizable hydroperoxide anion (39) presents a more energetically favourable leaving group (38) to the hydrotrioxide intermediate **12**, than hydroxide



SCHEME 2. Proposed pathway to incorporate $[H_2O_2]$[1,4] in Dakin oxidation kinetics

$$H_2O_2 + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} HO_2^- + HB$$

ion does to the alternative intermediate **3**. Also, the much less stable hydrotrioxide intermediate **12** favours significant progression of hydroperoxide anion departure prior to phenyl migration, facilitating the slow step of the reaction.

Even though mildly alkaline competitive oxidation/hydrolyses could be readily followed (Table 1), final step ester hydrolysis under the kinetic reaction conditions was found to be extremely fast. At 35 °C, by nmr, using 0.1 to 0.5 *M* buffer concentrations, the ester was completely hydrolyzed before it could be placed in the spectrometer. The possibility of mechanistic ester intermediacy in the Dakin reaction, therefore, could not be ruled out.

From the slow step of the sequence

$$\text{Rate} = k_4\,[\mathbf{12}]$$

and invoking a series of pre-equilibria between starting ketone and **12**, this becomes

$$\text{Rate} = \frac{k_4 k_3 k_2 k_1}{k_{-3} k_{-2} k_{-1}} [H_2O_2]^2[\mathbf{10}]\frac{[B]}{[BH]}$$

§Value calculated for this temperature from the three values experimentally determined at higher temperatures.

This simplifies to

$$\text{Rate} = k'[H_2O_2]^2[\mathbf{10}]\frac{[B]}{[BH]}$$

where

$$k' = \frac{k_4k_3k_2k_1}{k_{-3}k_{-2}k_{-1}}$$

For a constant [B]/[BH],

$$\text{Rate} = k''[H_2O_2]^2\,[\mathbf{10}],$$

where $k'' = k'[B]/[BH]$. With a large excess of hydrogen peroxide

$$\text{Rate} = k_{obs}\,[\mathbf{10}]$$

where $k_{obs} = k''[H_2O_2]^2$ and is the pseudo first-order rate constant with respect to ketone experimentally observed.

The possibility that the fractional order in hydrogen peroxide might be the consequence of competing reactions involving terms first-order and second-order in hydrogen peroxide was examined by letting $k_{obs} = k_x[H_2O_2] + k_y[H_2O_2]^2$. Rearranging, this gives

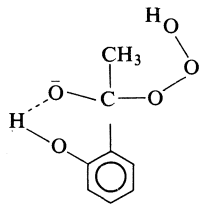
$$\frac{k_{obs}}{[H_2O_2]} = k_x + k_y[H_2O_2]$$

Plotting the data on coordinates [H_2O_2] *vs.* $k_{obs}/[H_2O_2]$ gave a scatter diagram, suggesting that this was not the explanation for the observed fractional order in hydrogen peroxide. Kinetic information from the *p*-ketone was insufficient to permit further speculation on the reason for this fractional order.

The enthalpy of activation for the oxidation of *p*-hydroxyacetophenone calculated from observed rates at 40, 35, and 25 °C (Table 4), was 65.7 kJ/mol (15.7 kcal/mol) and the entropy change, −16.3 eu. While these values are not readily interpreted mechanistically (22, p. 121; 40) they fall between the values for nucleophilic displacement of iodide from methyl iodide, $\Delta S^{\ddagger} = -10$ eu, and the more crowded neopentyl iodide, $\Delta S^{\ddagger} = -20$ eu (41).

o-Hydroxyacetophenone was found to oxidize about 180 times faster than the *p*-isomer (Table 5), which required decreasing the reaction temperature to 0 °C to allow the same kinetic methods to be used. Similarly faster *ortho* than *para* ketone oxidation has been observed for chloramine oxidation of hydroxyacetophenones (42), and for the Baeyer–Villiger oxidation of nitroacetophenones (24).

For a large excess of hydrogen peroxide, good pseudo first-order plots were obtained for the rate of disappearance of *o*-hydroxyacetophenone up to 2–3 half-lives. However, decreasing the

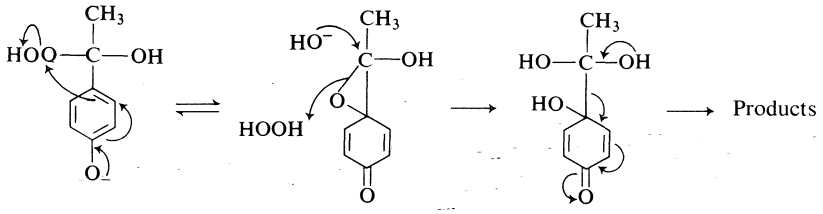


13

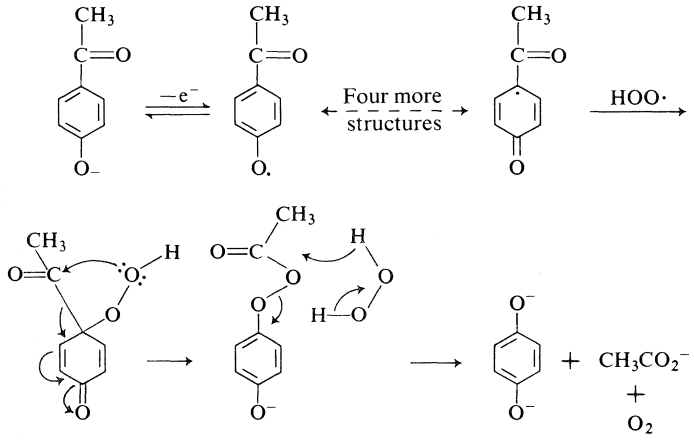
initial hydrogen peroxide concentration gave a more significant deviation from first-order linearity than seen for the *p*-ketone. Since catechol is not nearly as readily oxidized as hydroquinone under these conditions,[3] and since it has been found to be catalytically active for oxidations with hydrogen peroxide (43), it is possible that catechol or its oxidation products were responsible for the more significant kinetic interference found with the *o*-ketone.

o-Hydroxyacetophenone is more susceptible to hydroperoxide anion attack than *para* because of intramolecular hydrogen bonding. For the phenyl migration step, the phenonium ion requires the phenyl group to be perpendicular to the bond between the migration origin and the migration terminus (44) requiring rupture of the hydrogen bond in **13**, and consequent loss of stabilization energy of the order of 5 kcal (45) in the process. Thus, if phenyl migration was the rate determining step, the *ortho* isomer would be expected to react more slowly than the *para*.

Because *o*-hydroxyacetophenone was found to react faster than the *para* isomer possibly a variant of Scheme 2 operates to account for this, or other alternatives may be operating for both ketones. A spirocyclic epoxide intermediate (46) (Scheme 3) or a resonance-stabilized phenolate radical intermediate (Scheme 4), such as has been invoked by Kratzl for air oxidation of phenols in the presence of amine–copper complexes (47), are other less likely possibilities under consideration. Further synthetic and electron spin resonance experiments are underway to attempt to identify and isolate if possible, key intermediates in this system to better establish the pathway involved.



SCHEME 3. Proposed involvement of a spirocyclic epoxide intermediate in Dakin oxidation.



SCHEME 4. Suggested involvement of a phenolate radical intermediate in Dakin oxidation.

Reaction of $[n\text{-}Bu_4N]_2[Re_4(CO)_{16}]$ with $AgBF_4$ in acetonitrile affords the compound $[(CH_3CN)_3Re(CO)_3][BF_4]$. The latter crystallizes in monoclinic space group $P2_1/c$ with unit cell dimensions $a = 11.021(5)$ Å, $b = 11.136(5)$ Å, $c = 12.980(6)$ Å, $\beta = 96.906(25)°$, and four molecules per unit cell. Data were collected by counter methods and the structure was refined using least-squares procedures to give $R = 0.041$. The rhenium cation is approximately octahedrally coordinated by six facially arranged ligands. The mean rhenium–nitrogen distance is 2.13 Å, and the mean rhenium–nitrogen–carbon angle in the coordinated acetonitrile is 174.7°.

LILLIAN Y. Y. CHAN, E. E. ISAACS et W. A. G. GRAHAM. Can. J. Chem. **55**, 111 (1977).

La réaction de $[n\text{-}Bu_4N]_2[Re(CO)_{16}]$ avec $AgBF_4$ dans l'acétonitrile conduit à un composé $[(CH_3CN)_3Re(CO)_3][BF_4]$. Ce dernier cristallise sous forme monoclinique avec un groupe d'espace $P2_1/c$ avec des dimensions de maille $a = 11.021(5)$ Å, $b = 11.136(5)$ Å, $c = 12.980(6)$ Å, $\beta = 96.906(25)°$ et il y a quatre molécules par maille. On a récolté les données par la méthode des compteurs et la structure a été affinée par la méthode des moindres carrés jusqu'à une valeur de $R = 0.041$. Le cation rhénium est coordonné approximativement d'une façon octaédrique par six ligands arrangés d'une façon faciale. La distance moyenne rhénium/azote est de 2.13 Å et l'angle moyen rhénium–azote–carbone dans l'acétonitrile coordonné est de 174.7°.

Introduction

A number of polynuclear rhenium carbonyl anions are known through the work of Kaesz and co-workers (1–3). The electrochemistry of these species has been little investigated and it seemed to us that the oxidation of the tetranuclear anion $[Re_4(CO)_{16}]^{2-}$ (1) might lead to the formation, via rhenium–rhenium bond formation, of new neutral polynuclear carbonyls of rhenium. However, this expectation was not fulfilled under the conditions of our experiments. Using silver tetrafluoroborate in acetonitrile, the product was $[(CH_3CN)_3Re(CO)_3][BF_4]$. We describe here this unexpected reaction, and, more importantly, the crystal structure of the product.

Experimental

Preparation of $[(CH_3CN)_3Re(CO)_3][BF_4]$

To 10 ml of an acetonitrile solution of $[n\text{-}Bu_4N]_2[Re_4(CO)_{16}]$ (1) (0.25 g, 0.15 mmol), $AgBF_4$ (0.8 g, 5.1 mmol) was added and the mixture stirred for 24 h. The initial red color was lost as the solution became colorless with the deposition of Ag metal. The solution was filtered through Celite and the solvent removed *in vacuo*. The brown residue was washed with several portions of water and then dried by pumping overnight. Two recrystallizations from dichloromethane–heptane afforded 0.2 g (58% yield) of product. *Anal.* calcd. for $C_9H_9N_3O_3ReBF_4$: C 22.50, H 1.89, N 8.75; found: C 22.56, H 2.14, N 8.49; mp 171–173 °C.

The conductivity measurement performed on a 3.5×10^{-3} *M* nitromethane solution gave a value of 104.5 ohm^{-1} cm^2 mol^{-1}.

The crystals for the X-ray determination were obtained by slow recrystallization from acetone–ethanol.

Crystal Structure

Preliminary X-ray studies of single crystals of the compound with Weissenberg and precession photographs showed the systematic absences *h0l*, $l = 2n + 1$, and *0k0*, $k = 2n + 1$, which indicate the monoclinic space group $P2_1/c$. A single crystal was ground to a sphere (diameter 0.155 mm) for diffractometer use. The lattice parameters and their estimated standard deviations were obtained at 22 °C as $a = 11.021(5)$ Å, $b = 11.136(5)$ Å, $c = 12.980(6)$ Å, and $\beta = 96.906(25)°$, by a least-squares refinement using 2θ values for 12 high-angle reflections that had been accurately centered on a Picker automatic FACS 1 diffractometer (Mo $K_{\alpha 1}$ radiation, $\lambda = 0.70926$ Å). The observed density by flotation is 2.03 g cm^{-3}, in good agreement with that calculated, 2.02 g cm^{-3}, for four molecules per unit cell.

Intensity data were collected using graphite monochromated Mo K_α radiation ($\mu = 82.20$ cm^{-1}) and the θ–2θ scan method (2° base width, 2° min^{-1} scan rate, 20 s background counts at each scan limit). The intensity data were reduced using the procedure of Doedens and Ibers (4) with a *p* factor of 0.03. The independent Re atom was recovered from a Patterson map and a difference Fourier map based on the Re atom position revealed all of the remaining non-hydrogen atoms. Following several cycles

of full-matrix least-squares refinement using isotropic thermal parameters, anisotropic thermal parameters were allowed for rhenium, oxygen, and fluorine (as indicated from a difference map) whereupon the *R* value dropped to 4.8%. Examination of the structure factors at this stage showed extinction effects, and a secondary extinction parameter was introduced in the refinement. Finally, refinement converged at $R_1 = 4.1\%$ and $R_2 = 3.9\%$. A final electron density difference map showed no peaks or troughs exceeding ± 0.6 electrons $Å^{-3}$.[1]

The scattering factors used were taken from Cromer and co-worker (5) with anomalous dispersion included for the rhenium atom. Table 1 lists atomic positions and thermal parameters, and Table 2 the interatomic distances and angles. A drawing of the $[(CH_3CN)_3Re(CO)_3][BF_4]$ structure is shown in Fig. 1, with a packing diagram in Fig. 2.

[1]Photocopies of the table of structure factors may be obtained at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Results and Discussion

The reaction of $[n\text{-}Bu_4N]_2[Re_4(CO)_{16}]$ with $AgBF_4$ in acetonitrile solution resulted in the formation of the title compound, a process which can be represented by the following equation:

$$[n\text{-}Bu_4N]_2[Re_4(CO)_{16}] + 6AgBF_4 + 12CH_3CN \rightarrow 4[(CH_3CN)_3Re(CO)_3][BF_4] + 6Ag + 4CO + 2n\text{-}Bu_4NBF_4$$

The infrared spectrum in dichloromethane shows two strong carbonyl stretching bands at 2052 and 1951 cm^{-1}, the latter of greater half width. These are clearly the A_1 and E modes expected for the facial (C_{3v}) isomer. In addition, the solid state infrared spectrum (KBr disc) showed weak bands at 2315 and 2290 cm^{-1} due to the coordinated acetonitrile ligands.

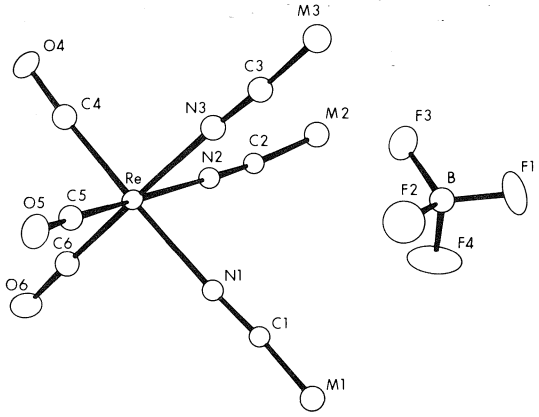

FIG. 1. The structure of $[(CH_3CN)_3Re(CO)_3][BF_4]$. Methyl groups are represented by M.

The preparation of the hexafluorophosphate salt of $[(CH_3CN)_3Re(CO)_3]^+$ has been reported by Reimann and Singleton (6) who obtained it in almost quantitative yield by reaction of $Re(CO)_5Br$ with $AgPF_6$ in acetonitrile. Their method would be preferred for synthesis of salts of this cation in terms of the ease of availability of starting materials.

The structure consists of discrete cations and anions with no unusual non-bonded contacts. It is interesting to note the ligands about the rhenium atom together with the BF_4^- group are so arranged that there is an approximate three-fold axis passing through the two moieties. The bond angles at rhenium deviate slightly from octahedral, averaging 88.3° for OC—Re—CO and 83.9° for CH_3CN—Re—$NCCH_3$.

The average N—C—CH_3 angle is 174.7°, and the average N—CCH_3 and NC—CH_3 distances of 1.14 and 1.46 Å, respectively, are essentially the same as those in the free ligand (7). The average Re—N bond length in $[(CH_3CN)_3Re(CO)_3]^+$ is 2.13 Å. Using a value of 1.52 Å as the covalent radius of Re(I), a figure derived from the reported Re(I)—Cl distance of 2.51 Å (8), the predicted Re(I)—N distance is 2.22 Å; this might be considered reasonable agreement, if

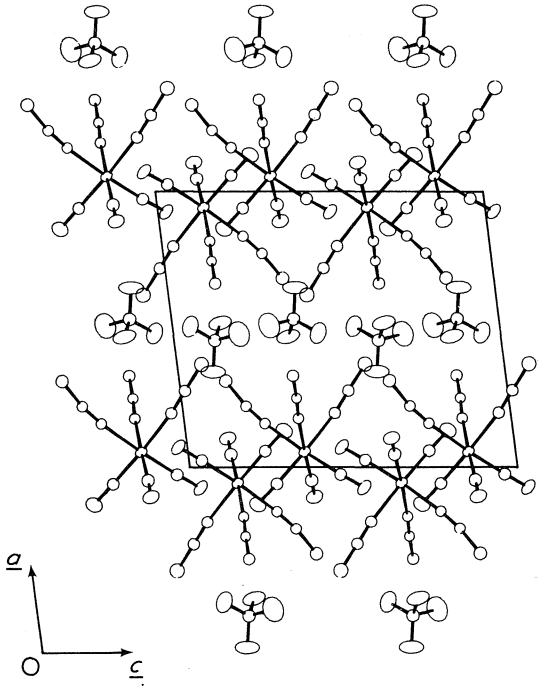

FIG. 2. Packing diagram and unit cell for $[(CH_3CN)_3Re(CO)_3][BF_4]$, shown in projection along the *b* axis.

allowance is made for uncertainties in the choice of appropriate covalent radii for both N and Re(I) in the circumstances. In acetonitrile complexes of copper(II), the Cu(II)—N bond length is 1.96–1.97 Å (9); if an adjustment is made for the larger size of Re(I) (1.52 Å *vs.* 1.28 Å) (10), one estimates Re(I)—N as 2.22 Å. This may indicate a stronger ligand–metal interaction in the $[(CH_3CN)_3Re(CO)_3]^+$ cation than in the Cu(II) complexes. It is of interest that the Re(V)—N distance in $[ReBr_4—O(CH_3CN)]^-$ was 2.31 Å (10), which was taken to indicate a very weak interaction between rhenium and the acetonitrile ligand relative to the same Cu(II) complexes.

The average Re—CO distance of 1.91 Å is comparable to other reported terminal Re—CO values, *e.g.*, 1.95 Å in $Ph_2SiH_2Re_2(CO)_8$ (11), 1.91 Å in $[Re_4(CO)_{16}]^{2-}$ (1), and 1.85 Å in $(\eta\text{-}C_5H_5)_2Re_2(CO)_5$ (12).

Magnetic susceptibilities between 80 and 300 K and ^{57}Fe Mössbauer parameters between 4.2 and 295 K are reported for $Fe(SO_3F)_2$. These data have been analysed via a crystal field model including spin–orbit and spin–spin coupling. The compound is trigonally distorted by an elongation along the [111] axis of the FeO_6 octahedron, and the ground state is the orbital doublet $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$. The quadrupole coupling constant e^2qQ is positive, and no rhombic distortion could be detected. The electronic spectrum shows a splitting of the ^5E_g excited level, presumably by a dynamic Jahn–Teller effect, and $10Dq \simeq 8000\ cm^{-1}$. Attempts to fit a low-temperature magnetic perturbation Mössbauer spectrum using a pseudo-spin Hamiltonian were only partially successful, but suggest that the **g** tensor is highly anisotropic with $g_{\parallel} \gg g_{\perp}$, and that the internal hyperfine field is small. Spin relaxation in $Fe(SO_3F)_2$ is fast at all temperatures down to 4.2 K and in applied magnetic fields of up to 5.0 *T*.

JOHN R. SAMS, ROBERT C. THOMPSON et TSANG BIK TSIN. Can. J. Chem. **55**, 115 (1977).

On rapporte les susceptibilités magnétiques, entre 80 et 300 K, et les paramètres de Mössbauer du ^{57}Fe, entre 4.2 et 295 K, dans $Fe(SO_3F)_2$. On a analysé ces données par l'intermédiaire d'un modèle de champ de cristal impliquant des couplages spin–orbite et spin–spin. Le composé est déformé d'une façon trigonale par une élongation le long de l'axe [111] de l'octaèdre FeO_6 et l'état fondamental est l'orbitale sous forme de doublet $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$. La constante de couplage quadrupolaire e^2qQ est positive et on n'a pas pu détecter aucune distorsion rhombique. Le spectre électronique montre une coupure de l'état excité ^5E_g qui est probablement dû à un effet Jahn–Teller dynamique et $10Dq \simeq 8000\ cm^{-1}$. Les essais pour ajuster une perturbation magnétique à basse température du spectre de Mössbauer en faisant appel à un hamiltonien pseudo-spin n'ont connu que des succès partiels; ils suggèrent toutefois que le tenseur **g** est hautement anisotropique avec $g_{\parallel} \gg g_{\perp}$ et que le champ hyperfin interne est petit. La relaxation de spin du $Fe(SO_3F)_2$ est rapide à toutes les températures jusqu'à 4.2 K et dans des champs magnétiques appliqués jusqu'à 5.0 *T*.

[Traduit par le journal]

Introduction

In a recent study (1, 2) of some octahedrally coordinated high-spin iron(II) complexes, $Fe(pyO)_6(ClO_4)_2$ (pyO = C_5H_5NO) was found to have an unusual orbital ground state. The $Fe(pyO)_6^{2+}$ cation is distorted by a trigonal elongation along the [111] direction of the octahedron, and the ground state is the $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$ orbital doublet. A detailed fit of the temperature dependence of the Mössbauer quadrupole splitting in terms of a crystal field model which included spin–orbit and spin–spin coupling, showed that the axial crystal field splitting $3Ds$ was 455 cm^{-1} (2), with the ground doublet separated by 110 cm^{-1} from the next lowest lying spin–orbit-split state.

One of the most interesting features of this complex is that it is the only known example of an octahedral paramagnetic iron(II) derivative in which the spin–lattice relaxation rate at low temperatures is slow compared to the nuclear Larmor precession frequency. Thus, at temperatures below 30 K the two lines of the Mössbauer spectrum broaden asymmetrically, signaling the onset of paramagnetic hyperfine splitting (1, 2). Mössbauer measurements at 4.2 K in applied magnetic fields ranging from 1 to 50 kG have unequivocally confirmed the existence of slow spin relaxation in the complex (3). These measurements also established that any Jahn–Teller-induced rhombic splitting of the ground doublet must be less than 15 cm^{-1}.

For purposes of comparison we were interested in studying another trigonally distorted octahedral iron(II) complex. In particular, we wished to know if the existence of a ground doublet well isolated from all higher lying states is generally to be expected for a trigonally elongated complex, and if this could be in-

fluencing the spin relaxation rate. The ir spectrum of $Fe(SO_3F)_2$ (4) shows clearly that the anion maintains C_{3v} symmetry even though the ν_2 band is shifted upwards by 147 cm^{-1} compared to its position in $CsSO_3F$ (5), indicating significant cation–anion interaction. This means that the metal–anion coordination must involve terdentate fluorosulphate groups with all three oxygen atoms coordinated in an equivalent manner. Thus the structure of $Fe(SO_3F)_2$ is presumably of the terdentate bridging type proposed for $Co(SO_3F)_2$ (6), and should involve a trigonal distortion of the Fe—O_6 octahedron. $Fe(SO_3F)_2$ therefore seemed an attractive compound to investigate, and this paper reports detailed measurements of its susceptibility and Mössbauer spectra over wide ranges of temperature.

Experimental

Iron(II) fluorosulphate was prepared as described previously (4), and its identity and purity were confirmed by chemical analysis and ir spectroscopy. Electronic spectra over the range 5–33 kK were obtained on samples mulled in Nujol and hexachlorobutadiene, using a Cary model 14 spectrophotometer. Magnetic susceptibility and ^{57}Fe Mössbauer spectra were measured as fully described elsewhere (2). The Doppler velocity scale was calibrated with a metallic iron foil absorber, and isomer shifts are quoted relative to the centroid of the iron foil spectrum.

Results

Magnetic moments of $Fe(SO_3F)_2$ between 78 and 300 K and Mössbauer parameters between 4.2 and 295 K are given in Tables 1 and 2, respectively. The μ_{eff} values are in the range expected for a high-spin iron(II) complex. It will be noted that the values increase initially with decreasing temperature, pass through a maximum and then decline at low temperature. Similar behaviour was found for $Fe(pyO)_6(ClO_4)_2$, whereas for two similar solvates having tetragonal distortions and orbital singlet ground states, μ_{eff} decreased monotonically with decreasing temperature (2).

The electronic spectrum of $Fe(SO_3F)_2$ consists of a broad band, similar in appearance to that observed for $FeSiF_6.6H_2O$ (7), with a principal absorption at 8800 cm^{-1} and a broad shoulder at approximately 7100 cm^{-1}.

The Mössbauer isomer shift δ is very high, the usual range for octahedral $S = 2$ iron(II) complexes at *ca.* 80 K being 1.1–1.3 mm s^{-1}. The only other high-spin iron(II) compounds which show comparable shifts are the fluorides FeF_2 (8), $CsFeF_3$ (9), and Rb_2FeF_4 (10). As a general rule, high isomer shifts are associated with high ionicity. Using either the Walker–Wertheim–Jaccarino (11) model, or its modified form given by Danon (12), the derived electron configuration for the Fe^{2+} ion in $Fe(SO_3F)_2$ is $3d^{6.00}$ $4s^{0.00}$. The temperature dependence of δ presumably arises from a second-order Doppler shift, and is not chemically significant.

The quadrupole splitting $|\Delta E_Q|$ of $Fe(SO_3F)_2$ is much smaller than that of FeF_2 (8) where the ground state is essentially an orbital singlet (13), but somewhat larger than those of the other anhydrous iron(II) dihalides, all of which are trigonally distorted with doublet ground states (14–17). $|\Delta E_Q|$ for $Fe(SO_3F)_2$ also shows a strong temperature dependence, a point we shall return to below.

The Mössbauer spectrum of the compound remained a sharp symmetric doublet down to 4.2 K, and there was no indication of either

magnetic ordering or of the asymmetric line broadening found for $Fe(pyO)_6(ClO_4)_2$. Thus it is clear that in the absence of an applied magnetic field the electronic spin relaxation in $Fe(SO_3F)_2$ is fast compared to the nuclear precession frequency, so that the internal field sensed by the nucleus is zero.

Discussion

As suggested above, the fact of C_{3v} symmetry for the SO_3F^- ion in $Fe(SO_3F)_2$ strongly suggests an Fe—O_6 octahedron which is either undistorted or distorted along the threefold (C_3) axis, since a tetragonal distortion along the C_4 axis of the octahedron would be expected to result in a lowering of the anion symmetry to C_s. Of course the ir data cannot differentiate between D_{3h} and O_h symmetries for the cation because the anion symmetry would be identical in either case. The Mössbauer data are definitive on this point, however, since a pure $^5T_{2g}$ state cannot show a quadrupole splitting. Thus the cation must have symmetry lower than O_h.

In view of the small $|\Delta E_Q|$ values observed, it might be thought that the crystal field distortion may be too small to be sensed by ir spectroscopy, and that the ir data do not in fact rule out a tetragonal distortion. Indeed, it is sometimes assumed (18) that a small $|\Delta E_Q|$ necessarily implies a small distortion for octahedral Fe^{2+} ions. This view completely ignores the fact that an orbital doublet ground state will produce a quadrupole splitting roughly half that produced by a singlet ground state, and that no matter how large the distortion $|\Delta E_Q|$ will never be much greater than 2 mm s^{-1} for a doublet state. This is an important point. For an octahedral high-spin iron(II) complex a quadrupole splitting substantially larger than 2 mm s^{-1} is conclusive proof of an orbital singlet ground state. On the other hand, if the quadrupole splitting is less than *ca.* 2 mm s^{-1} two possibilities exist: either the orbital ground state is a singlet and the crystal field splitting is very small, or the ground state is a doublet. Only by detailed analysis of the temperature dependence of ΔE_Q over a wide range of T can these cases be distinguished, as we now describe.

Orbital Ground State

For simplicity we consider only those iron 3*d* orbitals transforming as t_{2g}, and ignore the higher lying e_g orbitals. In the presence of an axial crystal field the threefold degeneracy of the t_{2g} subset is partially lifted to produce a singlet and a doublet, separated by $3Ds$. The nature of these orbital states depends upon the symmetry of the axial field (*i.e.*, the choice of quantization axis). For a tetragonal distortion the singlet is $|xy\rangle$ and the doublet ($|xz\rangle$, $|yz\rangle$). However, if the distortion is along the trigonal axis the singlet is $|z^2\rangle$ and the doublet $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$. In both cases the singlet lies lower if the distortion corresponds to a compression along the quantization axis, and higher for an elongation along this axis. If there is a rhombic field as well, the doublet will be split by $12Dr$. Each of these orbital states also has a fivefold spin degeneracy which will be split by the spin–orbit coupling.

If we assume there is no rhombic distortion, and we shall see that this is a good approximation for $Fe(SO_3F)_2$, then there are four possible orbital ground states. A knowledge of the sign of the quadrupole coupling constant e^2qQ will eliminate two of these possibilities, since for the $|z^2\rangle$ and ($|xz\rangle$,$|yz\rangle$) states e^2qQ will be negative, whereas it is positive for the other two states.

A Mössbauer spectrum of $Fe(SO_3F)_2$ recorded at 195.3 $\pm$ 0.1 K in the presence of a longitudinal applied magnetic field of 5.0 T revealed that e^2qQ was positive, and the asymmetry parameter η of the electric field gradient (EFG) tensor was nearly or exactly zero. (As discussed elsewhere (1, 2), this measurement was made at elevated temperature to avoid any possible ambiguity which might arise from induced magnetization in the specimen due to spin polarization by the applied field.) The fact that $\eta \simeq 0$ is consistent with the absence of a significantly large rhombic distortion, whilst $e^2qQ > 0$ limits the possible ground states to $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle), (\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$ or $|xy\rangle$.

Both the ir data and the fact that ΔE_Q does not exceed 2.0 mm s^{-1} favour the former ground state. However, in order to establish this unequivocally, we have attempted to fit the temperature dependence of ΔE_Q, using the crystal field model described below, for both these ground states. With $|xy\rangle$ taken to be the ground state we were not able to obtain a satisfactory representation of the observed ΔE_Q *vs.* T behaviour, for any reasonable choice of parameter values. With the doublet ground state on the other hand, a very satisfactory fit of the data was achieved (*vide infra*), which thus establishes that

the orbital ground state is in fact the $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$ doublet. Thus, the Fe—O_6 octahedron in $Fe(SO_3F)_2$ is distorted by a trigonal elongation along the [111] axis, and the point-group symmetry of the iron environment is effectively D_{3h}.

Crystal Field Parameters

The value of $10Dq$ for $Fe(SO_3F)_2$ should be obtainable from its electronic spectrum. For a regular octahedral complex the spectrum should consist of a single absorption, at an energy $10Dq$, arising from the $^5T_{2g} \rightarrow {}^5E_g$ transition. The structure observed here (principal band at 8800 cm^{-1} and shoulder at 7100 cm^{-1}) suggests a splitting of the excited level by some 1700 cm^{-1}. As discussed above the distortion of this complex from regular O_h symmetry is trigonal in nature, and since such a distortion cannot lift the degeneracy of the ^5E_g level, this cannot be the cause of the band splitting.

A similar situation exists for $FeSiF_6.6H_2O$ which contains trigonally distorted $[Fe(H_2O)_6]^{2+}$ octahedra. The spectrum of this compound consists of a principal band at 10 300 cm^{-1} with a shoulder at 8700 cm^{-1}, and the band splitting in this case has been attributed to the removal of the excited state degeneracy by a dynamic Jahn–Teller effect (7). If one assumes that the band splitting in $Fe(SO_3F)_2$ is also due to this effect, the value of $10Dq$ for the complex must be about 8000 cm^{-1} (approximate centre of the absorption band). This value is not unreasonable when compared with previously measured $10Dq$ values of 7650 cm^{-1} for $Co(SO_3F)_2$ (6) and 7340 cm^{-1} for $Ni(SO_3F)_2$ (19).

The effects of the noncubic part of the crystal field together with spin–orbit and spin–spin splitting can be treated via the Hamiltonian

$$[1] \quad \mathcal{H} = Ds(\hat{L}_z^2 - 2) + Dr(\hat{L}_+^2 + \hat{L}_-^2) - \lambda[\hat{L}_z\hat{S}_z + \tfrac{1}{2}(\hat{L}_+\hat{S}_- + \hat{L}_-\hat{S}_+)] - D\sigma(\hat{S}_z^2 - 2)$$

where the $\hat{L}_i$ and $\hat{S}_i$ are orbital and spin angular momentum shift operators, respectively, Ds and Dr the axial and rhombic field splitting parameters, and λ and $D\sigma$ the spin–orbit and spin–spin coupling constants. The cubic field term has been omitted from [1] because in our calculations we ignore the e_g orbitals, and $\mathcal{H}$ operates only on a basis set of 15 t_{2g} wave functions. We have shown elsewhere (2) that this appears to be a valid truncation if $10Dq \gtrsim 9000$ cm^{-1}. Although we estimate $10Dq$ for $Fe(SO_3F)_2$ to be only ~ 8000 cm^{-1}, this approximation is retained here. (The reason for doing this is simply that it allows one to truncate the 25×25 matrices which one would otherwise need to diagonalize to 15×15 matrices, thereby reducing the computation time by a factor of nearly three.) The basis sets used were

$$\sqrt{1/2}(|2,2\rangle - |2,-2\rangle)|M_s\rangle$$
$$\sqrt{1/2}(|2,1\rangle \pm |2,-1\rangle)|M_s\rangle$$

for tetragonal symmetry, and

$$|2,0\rangle|M_s\rangle$$
$$(\sqrt{2/3}|2,\pm 2\rangle \mp \sqrt{1/3}|2,\mp 1\rangle)|M_s\rangle$$

for trigonal symmetry, where we have used the notation $|L,M_L\rangle|M_s\rangle$, M_L being the z component of the total orbital angular momentum L, and $M_s = 0, \pm 1, \pm 2$ the z component of spin angular momentum.

For particular choices of Ds/λ, Dr/λ, and $D\sigma/\lambda$ the 15×15 matrix was diagonalized to obtain the eigenvalues ε_i/λ and corresponding eigenvectors $|i\rangle$. These quantities were then used to calculate quadrupole splittings and magnetic moments as described in detail previously (2). The only change from our earlier procedure is that the numerical factor appearing in eq. 8 of ref. 2 has been altered from 4.1 to 4.5, as suggested recently by König *et al.* (20).

In fitting the Mössbauer data, since the EFG at Fe has effectively axial symmetry ($\eta \simeq 0$), we have set $Dr = 0$. The remaining parameter values were refined by least-squares techniques. As mentioned above, we were unable to obtain a satisfactory fit using an orbital singlet ground state. The main difficulty here was that in order to fit the approximate magnitude of ΔE_Q one must use quite small values of Ds, and this in turn leads to a much more pronounced temperature dependence than that observed experimentally. No reasonable choices of λ and $D\sigma$ could rectify this problem. For the doublet ground state, the Mössbauer quadrupole splittings are adequately fitted by the crystal field model using the following parameter values: $Ds = 96$ cm^{-1}, $\lambda = -90$ cm^{-1}, and $D\sigma = 22$ cm^{-1}. In treating the magnetic moment data we employed these same values of Ds, λ, and $D\sigma$, and fitted the μ_{eff} *vs.* T curve merely by adjusting the orbital reduction factor κ. The value of κ so found was 0.95. Figure 1 compares the experi-

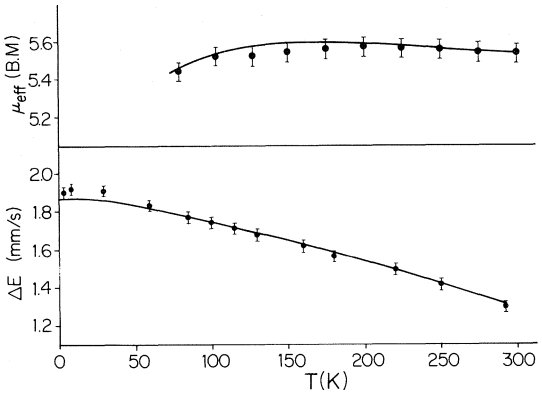

FIG. 1. Comparison of observed and calculated effective magnetic moments (upper) and quadrupole splittings (lower) as functions of temperature for $Fe(SO_3F)_2$. The parameters used to compute the theoretical curves are given in the text.

mental ΔE_Q and μ_{eff} data with theoretical curves computed from these parameter values.

The *Ds* value found for $Fe(SO_3F)_2$ is somewhat larger than those reported for $FeCl_2$ (48 cm^{-1}), $FeBr_2$ (58 cm^{-1}), and FeI_2 (61 cm^{-1}) (15, 17), all of which have orbital doublet ground states. The larger distortion here is perhaps not surprising in view of the polyatomic nature of the anion. Inclusion of the spin–spin coupling term, $D\sigma(\hat{S}_z^2 - 2)$, is necessary to account for the behaviour of ΔE_Q at temperatures below *ca.* 80 K. If this term is omitted from the Hamiltonian [1] the theoretical ΔE_Q values decrease rather than increase as the temperature is lowered from 80 to 4.2 K. The magnitude of $D\sigma$ for $Fe(SO_3F)_2$ is very similar to those obtained for other high-spin Fe^{2+} complexes (2).

The λ and κ values found here are slightly lower than one might expect. In view of the very high isomer shift of $Fe(SO_3F)_2$ which suggests high ionicity, values of these parameters closer to the free-ion values ($\lambda_0 = -103\ cm^{-1}$, $\kappa_0 = 1.00$) would appear more reasonable. We suspect the low values we obtain may be more artificial than real, and perhaps result from our neglect of the iron e_g orbitals in the crystal field model used. This omission appears to have no significant effect on the results for tetragonally distorted complexes (2), presumably because under D_{4h} symmetry E_g goes over into $A_{1g} + B_{1g}$ and there is no mixing with the ground term. However, the E_g term remains degenerate under D_{3h} (trigonal distortion) and there is now a symmetry-allowed mixing with the E_g component of T_{2g}. Clearly any effect on κ and λ is not very large, and we feel that more elaborate calculations employing a full basis set of 25 spin–orbit wavefunctions are hardly justified.

Spin Relaxation and Magnetic Hyperfine Interaction

As noticed above, electronic spin relaxation in $Fe(SO_3F)_2$ at 4.2 K in zero magnetic field is fast relative to the nuclear precession frequency, so that the Mössbauer spectrum remains a symmetric doublet under these conditions.

The *d* orbital energy level diagram for the compound, obtained from the eigenvalues calculated in the crystal field treatment above, is shown in Fig. 2. This diagram is similar in appearance to that of $Fe(pyO)_6(ClO_4)_2$ (3), for which spin–lattice relaxation is slow. In particular, the ground spin–orbit-split doublet in $Fe(SO_3F)_2$ lies 96 cm^{-1} below the next lowest lying state, compared to 110 cm^{-1} in $Fe(pyO)_6(ClO_4)_2$. In both cases the ground state is effectively isolated at 4.2 K ($kT \simeq 2.9\ cm^{-1}$) and there will be no mixing with higher levels. We have shown (3) that a ground state of this type

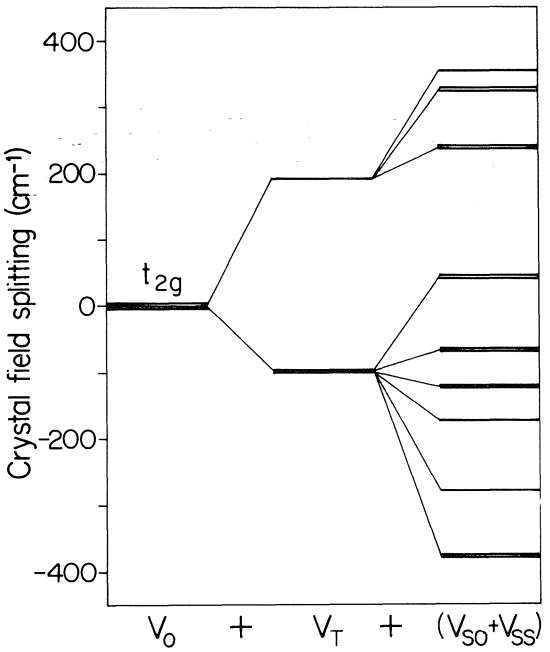

FIG. 2. Energy level diagram for the t_{2g} subset of ferrous 3*d* orbitals in $Fe(SO_3F)_2$, obtained by fitting the temperature dependence of the quadrupole splitting via the crystal field model described in the text. The effects of the trigonal distortion (V_T), spin–orbit coupling (V_{so}), and spin–spin coupling (V_{ss}) are shown.

can be accurately treated as a Kramer's doublet, and that the magnetic properties of such a state in the presence of an applied field $\boldsymbol{H}$ can be described in terms of a pseudo-spin ($S = \frac{1}{2}$) Hamiltonian,

$$[2] \quad \mathscr{H} = \beta \boldsymbol{H} \,.\, \mathsf{g} \,.\, \boldsymbol{S} + \boldsymbol{I} \,.\, \mathsf{A} \,.\, \boldsymbol{S} - g_n \beta_n \boldsymbol{I} \,.\, \boldsymbol{H} + \mathscr{H}_Q$$

where β and β_n are the Bohr and nuclear magnetons, respectively, g_n the nuclear g-factor and $\mathscr{H}_Q$ the nuclear quadrupole coupling Hamiltonian. The first three terms in [2] describe respectively the electronic Zeeman interaction, the magnetic hyperfine interaction between the nuclear spin $\boldsymbol{I}$ and electron spin $\boldsymbol{S}$, and the direct nuclear Zeeman interaction with the external field. Thus, in principle, Mössbauer measurements on such a system at 4.2 K in large applied fields enable one to deduce the components of both the g and A tensors and the magnitude of the internal hyperfine field.

The spectrum shown in Fig. 3 was obtained at 4.2 K with an applied longitudinal magnetic field of 5.0 T, and is unusual from several points of view. Rather than a well-resolved hyperfine pattern of six or more lines, one sees only two comparatively featureless absorption envelopes. These envelopes have very different intensities, and their small widths suggest that the internal magnetic field along the trigonal axis is quite small.

Because of these unusual features we have made a great effort to fit the spectrum using the Hamiltonian of [2]. From our previous experience with $Fe(pyO)_6(ClO_4)_2$ (3) and the predictions of Griffith (21), we expected a highly anisotropic g tensor with $g_\parallel \gg g_\perp \simeq 0$. Therefore most of the theoretical spectra calculated employed one of the following sets of g values: $g_\perp = 0$, $g_\parallel = 9$; $g_\perp = 0.5$, $g_\parallel = 9$; $g_\perp = 0.8$, $g_\parallel = 9$; $g_\perp = 1$, $g_\parallel = 9$; and $g_\perp = 2$, $g_\parallel = 8$. However, several other seemingly less realistic sets of values were also tried, including $g_\perp = g_\parallel = 2$ and sets with $g_\perp > g_\parallel$. For a given combination of g values the A tensor components $A_\perp$ and $A_\parallel$ were systematically varied, and spectra were calculated in both slow and fast relaxation limits (3) in attempting to simulate the observed spectrum. Altogether, more than 300 spectra were generated, but in no case were we able to obtain a really satisfactory fit. One of the main difficulties was in trying to reproduce the relative intensities of the two absorption envelopes.

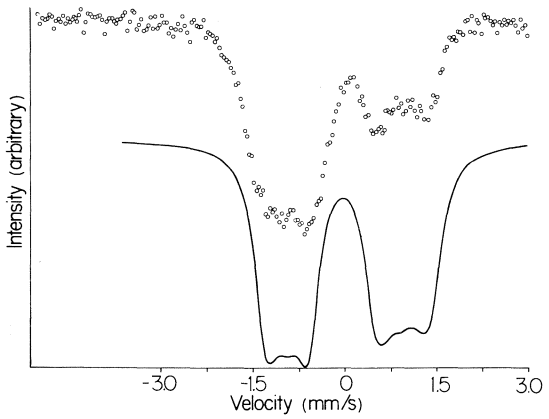

FIG. 3. ^{57}Fe Mössbauer spectrum of $Fe(SO_3F)_2$ at 4.2 K in a longitudinal applied magnetic field of 5.0 T. The solid line is a theoretical spectrum computed from the $S = 1/2$ pseudo-spin Hamiltonian, using parameter values given in the text and a fast relaxation limit. The velocity scale is relative to the centroid of the zero-field spectrum

The solid line shown in Fig. 3 represents our most successful attempt at simulating the widths and shapes of the two envelopes, but the intensities are clearly wrong. This spectrum, computed in the fast relaxation limit, employs the parameters: $g_\perp = 1$, $g_\parallel = 9$, $A_\perp = +1.50$ mm s^{-1}, $A_\parallel = +0.78$ mm s^{-1}, and ΔE_Q and Γ values obtained from the zero-field spectrum. Although these parameter values should not be taken too seriously in view of the inadequacies of the fit, certain rather firm conclusions did emerge during the course of our calculations. Firstly, it appears necessary to use a very anisotropic g tensor with $g_\parallel \gg g_\perp$ as expected (3, 21). Spectra computed with isotropic g values or with $g_\perp > g_\parallel$ were far less successful. Secondly, the easy axis of magnetisation is parallel to the z axis of the EFG, and the hyperfine field along this axis is apparently small ($\gtrsim 6T$) and positive. Thirdly, in almost all cases spectra computed in the slow relaxation limit showed substantially more fine structure than did the fast relaxation spectra, and in order to duplicate the rather featureless character of the measured spectrum it seems necessary to use the fast relaxation limit. Thus, at 4.2 K spin relaxation in $Fe(SO_3F)_2$ remains fast even in the presence of a large applied field.

The rather marked difference between theoretical and experimental intensity ratios of the two absorption envelopes remains a mystery, and we are not able to offer a satisfactory explanation at this time. The zero-field spectra rule

out the possibility of an anisotropy of the recoilless fraction, and this would not be expected to be important in a highly ionic compound at 4.2 K in any case. Preferential orientation of the crystallites also seems highly improbable. Spectra at 4.2 K in zero applied field were recorded for three different samples of $Fe(SO_3F)_2$, and in each instance the intensities and areas of the two lines were identical within experimental error.

Conclusions

The present study has shown that $Fe(SO_3F)_2$ is distorted by an elongation along the C_3 axis of the Fe—O_6 octahedron, with a trigonal field splitting $3Ds$ of about 290 cm^{-1}. The $10Dq$ value is about 8000 cm^{-1}, and there appears to be substantial Jahn–Teller splitting of the ^5E_g level. The quadrupole coupling constant is positive and the electric field gradient has effectively axial symmetry, consistent with a nearly degenerate $[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle),(\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$ orbital doublet ground state. The trigonal axis of the crystalline field, the z axis of the EFG and the easy axis of magnetisation are colinear, and the hyperfine field along this axis is apparently small. Spin relaxation in the complex is fast relative to the ^{57}Fe nuclear precession frequency at all temperatures down to 4.2 K and in applied magnetic fields of up to 5.0 T.

Electrophilic additions of iodonium nitrate to unsaturated substrates

J. WILLIAM LOWN AND ALUMMOOTTIL V. JOSHUA[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 14, 1976

J. WILLIAM LOWN and ALUMMOOTTIL V. JOSHUA. Can. J. Chem. **55**, 122 (1977).

Iodonium nitrate (generated by reaction of iodine chloride with silver nitrate in chloroform–pyridine) reacts with a variety of unsaturated substrates to form the following: 1,4-conjugate addition products of the type alkenyl pyridinium nitrates; alkyliodopyridinium nitrates; products of aromatic iodination of both phenols and anilines; substituted benzodihydrofurans; tetrahydrofurans and tetrahydropyrans; polycyclic bridged ethers; lactones; thiazolines.

J. WILLIAM LOWN et ALUMMOOTTIL V. JOSHUA. Can. J. Chem. **55**, 122 (1977).

Le nitrate d'iodonium (formé par réaction du chlorure d'iode avec le nitrate d'argent dans le chloroforme et la pyridine) réagit avec un grand nombre de substrats non-saturés pour former ceux qui suivent: des produits d'addition conjugué-1,4 du type nitrate d'alkényl pyridinium; des nitrates d'alkyliodopyridinium; des produits d'iodation aromatique des phénoles et d'anilines; des benzodihydrofurannes substitués; des tétrahydrofurannes et des tétrahydropyrannes; des éthers polycycliques pontés; des lactones; des thiazolines.

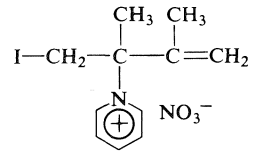
[Traduit par le journal]

In previous publications we reported on the chemical versatility of the addition reactions of the pseudo halogen iodonium nitrate (1–3). For example, iodonium nitrate (generated by reaction of iodine chloride with silver nitrate in chloroform–pyridine solution) readily undergoes addition to alkenes to form (*i*) iodoalkyl nitrates, (*ii*) iodoalkylpyridinium nitrates, or (*iii*) alkenylpyridinium iodides (1, 3). With olefinic alcohols, iodonium nitrate affords (*iv*) hydroxyiodoalkyl nitrates, (*v*) hydroxyiodoalkylpyridinium nitrates, or (*vi*) three, four, and five membered cyclic ethers depending on the substrate and the reaction conditions (2). It was established that these electrophilic additions proceed via a discrete pyridine complex $(I{\cdot}2Py)^+NO_3^-$ (in which the iodine is bonded to the nitrogens of the pyridine rings), *trans*-stereospecifically and often regiospecifically (1).

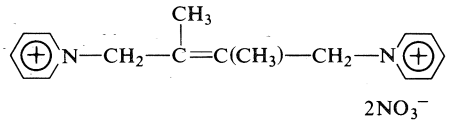
In a continuation of our investigations we report several further examples of the synthetic utility of this reagent.

Reactions with Conjugated Systems

2,3-Dimethyl-1,3-butadiene reacts with iodonium nitrate to afford the 1,2-addition product *N*-[3-(4-iodo-2,3-dimethyl)but-1-enyl]pyridinium nitrate **1** in 60% yield and compound **2**, the product of 1,4-conjugate addition, in 5.5% yield. The sole formation of the pyridinium salt is consistent with the observation that this is the major type of product obtained when a stabilized (*e.g.* allylic) cation intermediate is involved (1). The nmr spectrum of **1** was consistent with a 1,2-addition since it showed the terminal vinylic protons. Product **2** is envisaged as arising from 1,4-addition followed by displacement of the allylic iodine by pyridine. Alkenyl pyridinium salts of the general type represented by **1** and **2** were found to possess significant oral antidiabetic properties which will be reported elsewhere.



1

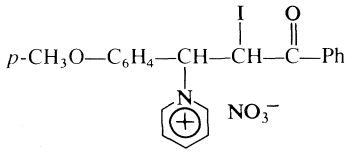


2

Iodonium nitrate is generally unreactive towards α,β-unsaturated ketones and esters unless activated by electron-releasing substituents. Thus chalcone is recovered unchanged on treatment with iodonium nitrate. In contrast, *p*-methoxychalcone **3** did react to afford the iodopyridinium nitrate **4** as the sole product in 91% yield.

[1]NRCC scholarship holder 1974–1975.

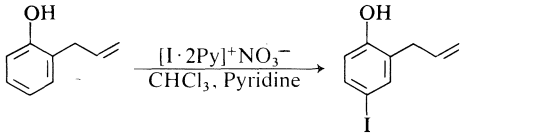
3



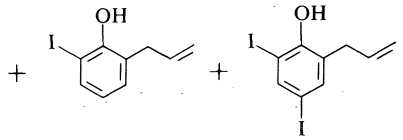
4

Reactions with Phenols and Anilines

Reaction of 2-allylphenol **5** with 1 mol equiv. of iodonium nitrate did not give the expected double bond addition product, but instead gave the aromatic iodination products **6**, **7**, and **8** together with the corresponding amount of pyridinium nitrate. With 2 equiv. of iodonium nitrate the diiodinated product **8** was obtained in 74.5% yield.

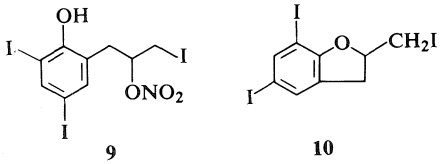


5 6



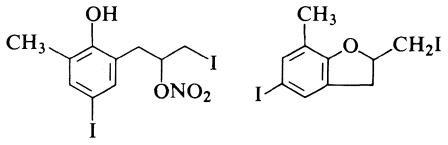
7 8

In the reaction between allylphenols and iodonium nitrate no addition to the double bond takes place until all the available positions *ortho* and *para* to the hydroxy group are substituted with iodine; subsequently addition occurs readily. Thus 2-allylphenol on reaction with 3 equiv. of INO_3 in chloroform–pyridine gave **9** in 13% yield and a substituted benzo[*b*]furan **10**. The regiochemistry of **9** is evident from the nmr



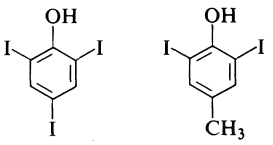
9 10

spectrum which showed characteristic absorptions for the $—CH_2I$ and $—CHONO_2$ groups at δ_{TMS} 3.33 and 5–5.5 respectively. The same type of products, **11** and **12**, were isolated from the addition of iodonium nitrate to 2-allyl-6-methylphenol in almost the same ratio (15% and 33.5% respectively).



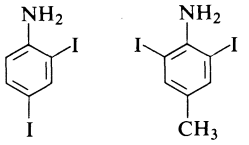
11 12

Phenol reacted with 3 mol equiv. of INO_3 to give 2,4,6-triiodophenol **13** in 94% yield. Similarly, *para*-cresol afforded a 90% yield of 2,6-diiodo-4-methylphenol **14** with 2 equiv. of INO_3.



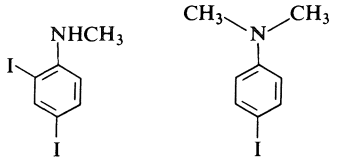
13 14

Aromatic primary amines react with INO_3 to give the corresponding iodinated products in low yield. This reaction is accompanied by tar formation probably due to oxidation of the amino group. It was also observed that a maximum of two iodine atoms can be introduced. Thus aniline with 3 equiv. of INO_3 gave 2,4-diiodoaniline **15** in 46% yield and *para*-toluidine



15 16

gave the corresponding diiodo compound **16** in 23% yield. Reactions of secondary and tertiary aromatic amines with INO_3 are cleaner and the iodinated products are obtained in good to excellent yields. For example, *N*-methylaniline with an excess of INO_3 gave a 78% yield of 2,4-diiodo-*N*-methylaniline **17**. In the case of *N*,*N*-dimethylaniline the reaction was regiospecific in that only the *para* iodinated product **18** was formed in 94.5% yield.



17 18

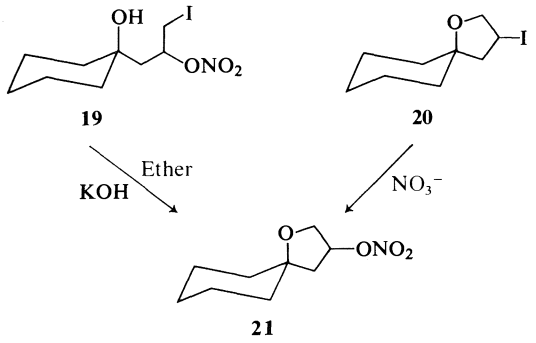
Only two of the three available *ortho* and *para* positions in aromatic 1°- and 2°-amines can be substituted with INO_3 in contrast to phenol. This may be due to the deactivation of the ring as a result of the introduction of the two iodine atoms. Steric factors may also play a role (*cf.* aniline and *N,N*-dimethylaniline).

This convenient method compares favorably with alternative methods of aromatic iodination. For example, iodine will only react with aromatic amines because the iodide precipitates as a salt; otherwise an oxidizing agent must be added to oxidize the iodide ion to iodine (4–6). Iodine chloride has also been used and tends to be a better iodinating agent (4). Recently another route to aromatic iodination has been developed using thallium trifluoroacetate and potassium iodide but tends to be more specialized in its applications (7).

Additions to Olefinic Alcohols

The behavior of neighbouring groups in electrophilic addition (4) of pseudo-halogens is often unpredictable. For example, whereas participation and subsequent migration of phenyl group have been observed in the addition of bromine (9), iodine chloride, iodine isocyanate, iodine azide (10), and bromine azide (11) to triphenylpropene, no participation by hydroxy group occurs in the addition of iodine isocyanate to 1,1-dimethylallyl alcohol (10, 11). Therefore we examined the reaction of iodonium nitrate with unsaturated substrates bearing potential neighbouring groups.

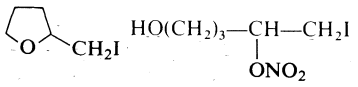
Reaction of 1-allylcyclohexanol with INO_3 in chloroform–pyridine gave a normal addition product **19**. The Markovnikov nature of the



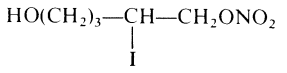
19 **20** **21**

addition was evident from the nmr spectrum which showed absorptions at δ 3.4 (d) and 5.23 (quintet) characteristic of $—CH_2I$ and $—CHONO_2$ (3). In addition to compound **19**, a spiro ether was isolated in 10% yield which proved to be **21** and not the expected product **20**. This was confirmed by the base-catalyzed cyclization of **19** to the spiro ether **21** which was characterized by its nmr and ir spectra and elemental analysis. The formation of spiro ether **21** in the addition of INO_3 to 1-allylcyclohexanol is explicable on the basis of the scheme outlined for the reaction of INO_3 with hex-5-en-3-ol (2).

Olefinic compounds which can give rise to five- or six-membered cyclic structures by neighbouring group participation in the addition of electrophilic reagents are generally expected to follow this path in preference to other reaction pathways as exemplified by the formation of five-membered cyclic ethers (12, 13) and lactones (14) in the electrophilic addition of iodine to pent-4-en-1-ol and 4-pentenoic acid respectively. Addition of INO_3 in chloroform–pyridine to pent-4-en-1-ol gave as the major product 2-iodomethyltetrahydrofuran **22** in 60% yield. In addition a small amount (6%) of isomeric hydroxyiodoalkyl nitrates **23** and **24** was produced in a ratio of approximately 9:1 as determined by comparing the intensities of $CHONO_2$



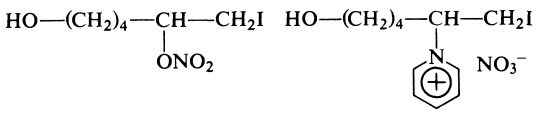
22 **23**



24

and $—CH_2ONO_2$ absorptions in the nmr spectrum. The ir spectrum showed intense hydroxy and nitrate absorptions. The structure of **22** was evident from the nmr and ir spectra. The ir spectrum showed no hydroxyl absorption. The cyclic ether and the iodonitrate esters were readily separable by chromatography on Florisil.

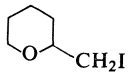
As the distance between the olefinic centre and the neighbouring hydroxy group increases, the propensity for participation decreases, as evi-



25 **26**

denced by the addition of INO_3 to hex-5-en-1-ol. The major products isolated were the hydroxy-iodoalkyl nitrate **25** and the pyridinium salt **26** formed in 21% and 39% yields respectively corresponding to regiospecific Markovnikov addition.

The cyclic ether 2-iodomethyl tetrahydropyran **27** was also formed in 17% yield. The behavior of pent-4-en-1-ol and hex-5-en-1-ol towards INO_3 is consistent with their behaviour towards bromine and iodine in that their propensity for

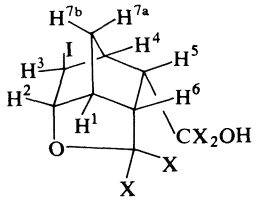


27

participation by a neighbouring hydroxyl group decreases if the resulting cyclic structure is six-membered rather than five-membered (13).

Reactions with Bicyclic Olefinic Alcohols

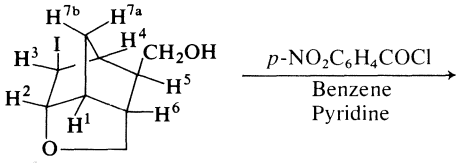
The behavior of bicyclic olefinic alcohols towards INO_3 was examined. It was anticipated that in such rigid ring systems ring closure by the neighbouring hydroxy group would be preferred to other modes of reaction namely addition and/or rearrangement, provided the participating group has the correct stereochemistry and the resulting ring system is stable. The three isomeric 5-norbornene-2,3-dimethanols namely, *endo-cis*-5-norbornene-2,3-dimethanol, *exo-cis*-5-norbornene-2,3-dimethanol, and *trans*-5-norbornene-2,3-dimethanol were synthesized according to literature procedures (15, 16). Reaction of *endo-cis*-5-norbornene-2,3-dimethanol with iodonium nitrate in chloroform–pyridine gave a cyclized product **28***A* in 74% yield and a



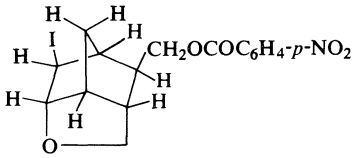
28
A X = H
B X = D

stoichiometric amount of pyridinium nitrate. Similarly addition of INO_3 to the deuterated analog (>95% deuterium) gave the corresponding cyclic ether **28***B*. Structural assignments for **28***A* and **28***B* are based on nmr and ir spectra and elemental analysis. Assignments of the various absorptions in the nmr spectra were made by comparison with other models (17–21) and extensive decoupling.

Reaction of iodonium nitrate with *trans*-5-norbornene-2,3-dimethanol in chloroform–pyridine gave the cyclized product **29** in 86% yield together with a corresponding amount of pyridinium nitrate. Compound **29** contained only one hydroxyl group as shown by the formation of a mono *para*-nitrobenzoyl derivative **30** in 70% yield, which was characterized by its nmr and ir spectra and elemental analysis.

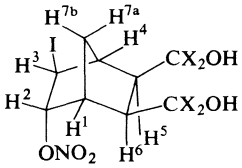


29



30

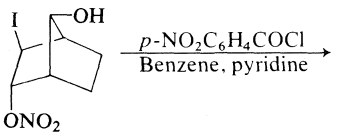
Reaction of *exo-cis*-5-norbornen-2,3-dimethanol with INO_3 gave a mixture of products from which the major product **31** was isolated in 40%



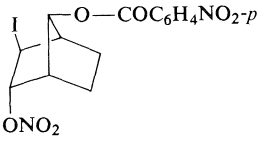
31
A X = H
B X = D

yield by chromatography on Florisil. The ir spectrum showed intense absorption at 1630 cm^{-1} indicating the presence of a ONO_2 group. The assignments of the various absorptions in the nmr spectrum were made by extensive decoupling and by comparison of the spectrum with that of **31***B* prepared from the deuterium analog. Thus the nmr spectrum of **31***B* showed δ 5.5 (q, 1H, H^2, $J_{2,3}$ = 2.8 Hz; $J_{1,2}$ = 2 Hz); 3.82 (t, 1H, H^3, $J_{2,3} = J_{3,7a}$ = 2.8 Hz). The methylene signal of the hydroxylmethyl groups in **31***A* appeared as a multiplet at δ 3.3–4.

Anti-7-norbornenol (19), on reaction with INO_3 in chloroform–pyridine gave **32** as the sole product indicating a preference for addition. Compound **32** was characterized as its *para*-nitrobenzoyl derivative **33**. *syn*-7-Norbornenol



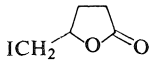
32



33

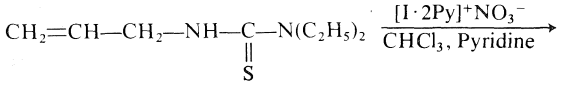
(24) reacted more slowly than **32** with INO_3 to give a mixture of several products as shown by the nmr spectrum of the crude reaction products, which could not be separated and characterized.

Like the hydroxyl group, the carboxyl group can also participate in INO_3 additions if such participation can lead to five- or six-membered ring structures (14, 25). An example is provided by the addition of INO_3 to 4-pentenoic acid which gave the iodolactone **34** together with a stoichiometric amount of pyridinium nitrate. Compound **34** has also been obtained in the addition of iodine and iodine cyanide to 4-pentenoic acid.

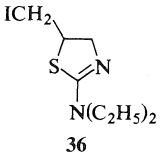


34

An example of participation by a neighbouring sulfur is provided in the addition of INO_3 to the allylthiourea **35** which gave a cyclized product assigned the thiazoline structure **36**. The more



35



36

quantitative aspects of these reactions of iodonium nitrate are discussed in the following paper (31).

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The ir spectra were recorded on a Perkin-Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The ^1H nmr spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in appropriate deuterated solvents with tetramethylsilane as standard. Line positions are reported in ppm from the reference. Noise decoupled ^{13}C nmr spectra were obtained at 25.15 MHz in 12 mm spinning tubes on a Varian HA-100-15 instrument. Mass spectra were determined on an Associated Electrical Industries MS-9 double focussing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography.

The gc analyses were performed with an Aerograph model A-700 gas chromatograph. The lc analyses were made with a Waters Associates model ALC-100 liquid chromatograph. Microanalyses were carried out by Mrs. D. Mahlow of this department.

General Procedure for the Reaction of Iodonium Nitrate with Unsaturated Substrates

Silver nitrate, 6.8 g (0.04 mol) was dissolved in a mixture of 50 ml of anhydrous chloroform and 15 ml of anhydrous pyridine. Iodine monochloride, 6.5 g (0.4 mol) in 20 ml of dry chloroform, was added dropwise to the stirred solution. The silver chloride produced was collected and washed with a mixture of 10 ml of chloroform and 10 ml of pyridine. A 0.04 mol quantity of the unsaturated substance was added all at once to the yellow filtrate. The mixture was stirred at room temperature for 3 h, then poured into an excess of ether and chilled. The resulting precipitate was collected and the filtrate concentrated *in vacuo*. The oil obtained was taken up in 50 ml of ether and washed with 50 ml of 5% cold hydrochloric acid to remove pyridine and then with 25 ml of cold water to remove any remaining pyridinium salt. If the ether solution was colored with iodine, it was washed with 20 ml of 5% sodium thiosulfate solution and then with 20 ml of water. The ether layer was dried ($MgSO_4$) and evaporated *in vacuo*. Further purification of the iodonitrate ester so obtained was effected by distillation under reduced pressure.

The ether insoluble residue, after washing several times with ether, was extracted with a 50:50 mixture of ethanol–isopropanol and filtered. Ether was added to the filtrate dropwise until the solution turned cloudy. The solution contained in a small beaker was placed in a larger beaker containing a little ether; the large beaker was covered with plastic film and kept in the refrigerator overnight. The resulting precipitate was collected and washed with ether containing a little ethanol and then with ether to

afford the iodopyridinium nitrate. In a few instances, when the iodopyridinium salt was difficult to purify and very dark in color (contamination with iodine and tarry materials), the purification was carried out by chromatography on silica gel, eluting with $CHCl_3$, 5% CH_3OH in $CHCl_3$ (v/v), 10% CH_3OH in $CHCl_3$ (v/v), and 30% CH_3OH in $CHCl_3$ (v/v), the iodopyridinium salt being collected with the last mixture of solvents.

Reaction of Iodonium Nitrate with 2,3-Dimethyl-1,3-butadiene in Chloroform–Pyridine

To a solution of iodonium nitrate (0.04 mol) in 60 ml of chloroform and 25 ml of pyridine was added 3.28 g (0.04 mol) of 2,3-dimethyl-1,3-butadiene all at once. The mixture was stirred at room temperature for 3 h, then poured into an excess of ether and chilled. The resulting precipitate was collected. Evaporation of the filtrate *in vacuo* did not give any identifiable material.

The ether insoluble residue after washing several times with ether was extracted with ethanol at room temperature and filtered. Ether was added dropwise to the filtrate till it turned cloudy. Crystallization by the method discussed before gave 8.4 g (60%) of *N-[3-(4-iodo-2,3-dimethyl)-butenyl]pyridinium nitrate* **1**; mp 106–108 °C. *Anal.* calcd. for $C_{11}H_{15}N_2O_3I$: C 37.73, H 4.32, N 8.00; found: C 37.70, H 4.03, N 7.91. The nmr spectrum δ_{TMS} ($(CD_3)_2SO$) 1.67 (s, 3H, CH_3—C=C), 2.03 (s, 3H, CH_3—C(—)=N$^+$(=)—), 4.3 (s, 2H, —CH_2I), 5.28 (s, 1H, one olefinic hydrogen), 5.41 (m, 1H, other olefinic hydrogen), 8.2–9.3 (m, 5H, pyridine hydrogens).

The ethanol insoluble residue was extracted with hot methanol and filtered. Addition of ether and filtration gave 0.8 g (5.5%) of *N,N'-[1,4-(2,3-dimethylbut-2-enyl)]dipyridinium dinitrate* **2** mp 261–263 °C (dec.). *Anal.* calcd. for $C_{16}H_{20}N_4O_6$: C 52.97, H 5.49, N 15.38; found: C 52.43, H 5.51, N 15.33. The nmr spectrum δ_{TMS} ($(CD_3)_2SO$) 1.82 (s, 6H, 2—CH_3), 5.4 (s, 4H, —CH_2—N$^+$(=)—), 7.9–8.8 (m, 10H, Py).

Reaction with p-Methoxychalcone

A similar reaction between iodonium nitrate (0.40 mol) and *p*-methoxychalcone (0.04 mol) in chloroform–pyridine afforded *N-[1-(2-iodo-2-benzoyl-1-para-methoxyphenyl-ethyl)]pyridinium nitrate* **4** mp 178–179 °C (dec.) in 91% yield. *Anal.* calcd. for $C_{21}H_{19}N_2O_6I$: C 49.79, H 3.75, N 5.53; found: C 49.73, H 3.72, N 5.57.

General Procedure for the Reaction of Iodonium Nitrate with Phenols and Anilines.

The procedure was similar to that described above. Addition of the reaction mixture to an excess of ether resulted in the precipitation of an equivalent amount of pyridinium nitrate which was collected. The filtrate was concentrated *in vacuo* and the residual oil taken up in ether. The ether extract was washed with water, sodium thiosulfate solution, and then with water. Evaporation *in vacuo* after drying ($MgSO_4$) gave the iodinated compound. Purification was effected either by crystallization from a suitable solvent or chromatography on Florisil. Addition to 2-allylphenol gave 4,6-diiodo-2-allylphenol **8** in 74.5% yield. *Mol. Wt.* calcd. for $C_6H_8OI_2$: 385.8664; found (ms): 385.8688. Infrared ν_{max} ($CHCl_3$) 3845 (OH), 1633 (C=C) cm^{-1}; nmr δ_{TMS} ($CDCl_3$) 7.8 (d, 1H, H^3, $J_{3,5}$ = 2 Hz), 7.4 (d, 1H, H^5, $J_{5,3}$ = 2 Hz), 5.5–6.3 (m, 1H, C*H*=CH_2), 5.4 (s, 1H, —OH), 4.8–5.3 (m, 2H, =CH_2), 3.4 (d, 2H, —CH_2—).

Similarly phenol gave 2,4,6-triiodophenol (26) **13** in 94% yield; 4-methylphenol gave 2,6-diiodo-4-methylphenol **14** (27) in 90% yield, aniline gave 2,4-diiodoaniline **15** (28) in 46% yield, 4-methylaniline gave 2,4-diiodo-*N*-methylaniline **16** (29) in 23% yield, and *N,N*-dimethylaniline gave 4-iodo-*N,N*-dimethylaniline **18** (30) in 95% yield. *N*-methylaniline afforded 2,4-diiodo-*N*-methylaniline **17** in 78% yield. *Mol. Wt.* calcd. for $C_7H_7NI_2$: 358.8660; found (ms): 358.8662. Infrared ν_{max} ($CHCl_3$) 3405 (NH) cm^{-1}; nmr δ_{TMS} ($CDCl_3$) 7.85 (d, 1H, H^3, $J_{3,5}$ = 2 Hz), 7.4 (q, 1H, H^5, $J_{5,3}$ = 2 Hz, $J_{5,6}$ = 8.5 Hz), 6.27 (d, 1H, H^6, $J_{5,6}$ = 8.5 Hz), 6.2 (brs, 1H, —NH—), 2.83 (s, 3H, CH_3).

General Procedure for the Reaction of Iodonium Nitrate with Unsaturated Alcohols

The procedure in chloroform–pyridine was similar to that discussed before. When the reactions were carried out in chloroform–*sym*-collidine the following procedure was adopted. The reaction mixture was added to sufficient ether to precipitate the collidinium salt. The precipitate was collected and the ethereal layer was washed several times successively with (*a*) cold hydrochloric acid (5%) saturated with sodium chloride, (*b*) saturated aqueous sodium chloride, (*c*) sodium bicarbonate (5%) saturated with sodium chloride until neutral, and finally (*d*) saturated sodium chloride solution containing sodium thiosulfate. The ether layer was dried ($MgSO_4$) and concentrated *in vacuo*. The residual oil was distilled under reduced pressure. The iodopyridinium salts were purified by the crystallization procedure described before.

Hex-1-en-3-ol with INO_3 gave an isomeric mixture of 3-hydroxy-1-iodohex-2-yl nitrate and 3-hydroxy-2-iodohex-1-yl nitrate bp 90 °C/0.1 torr in a yield of 34%. *Anal.* calcd. for $C_6H_{12}NO_4I$: C 24.95, H 4.2, N 4.85; found: C 24.95, H 4.2, N 4.85. This product was formed together with a 16% yield of the corresponding iodopyridinium salt.

1-Allylcyclohexanol similarly gave 4-hydroxy-4,4-pentamethylene-1-iodobut-2-yl nitrate **19** in 55% yield. *Mol. Wt.* calcd. for $C_9H_{16}NO_3I$: 329.0124; found (ms): 329.0113. This product was formed together with a 15% yield of the corresponding iodopyridinium salt and 10% of the spiro ether **21**.

2-Allylphenol with INO_3 gave 3-(2-hydroxy-3,5-diiodo)phenol-1-iodoprop-2-yl nitrate **9** in 13% yield. *Mol. Wt.* calcd. for $C_9H_8NO_4I_3$: 574.7587; found (ms): 574.7598. The nmr δ_{TMS} ($CDCl_3$) 5.0–5.5 (2H, m, —$CHONO_2$), 3.33 (2H, m, —CH_2I), 3.1 (m, 2H, —CH_2—), 7.45, 7.9 (2d, 2H, aromatic protons, J = 2 Hz). In addition was formed 2-iodomethyl-5,7-diiodobenzo-[*b*]2,3-dihydrofuran **10** in 33% yield. *Mol. Wt.* calcd. for $C_9H_7OI_3$: 511.7631; found (ms): 511.7631. The nmr δ_{TMS} ($CDCl_3$) 3.1–3.5 (4H, m, —CH_2I), 4.9 (m, 1H, —CH—O), 7.4, 7.75 (2d, 2H, aromatic protons, J = 1 Hz).

Similarly 2-allyl-6-methylphenol gave 3-(2-hydroxy-5-

iodo-3-methyl)phenyl-1-iodoprop-2-yl nitrate **11** in 15% yield. *Mol. Wt.* calcd. for $C_{10}H_{11}NO_4I_2$: 462.8778; found (ms): 462.8773. The nmr δ_{TMS} ($CDCl_3$) 5.2 (1H, quint, J = 6 Hz, —$CHONO_2$), 3.33 (2H, m, —CH_2I), 2.2 (s, 3H, CH_3), 3.1 (m, 2H, CH_2), 7.4 (s, 2H, aromatic hydrogens). In addition was formed 2-iodomethyl-5-iodo-6-methylbenzo[*b*]2,3-dihydrofuran **12** in 33.5% yield. *Mol. Wt.* calcd. for $C_{10}H_{10}OI_2$: 399.8822; found (ms): 399.8828. The nmr δ_{TMS} ($CDCl_3$) 3.33 (2H, m, —CH_2I), 3.04 (m, 2H, —CH_2—), 7.3 (s, 2H, aromatic protons), 4.8 (m, 1H, —CH—O), 2.14 (s, 3H, —CH_3).

Base-catalyzed Cyclization of 1-Iodo-4-hydroxy-4,4-pentamethylenebut-2-yl Nitrate

To a stirred solution of 7.1 g (0.0215 mol) of 1-iodo-4-hydroxy-4,4-pentamethylenebut-2-yl nitrate **19** in 50 ml of ether was added 2.25 g (0.04 mol) of powdered potassium hydroxide. The mixture was stirred at room temperature overnight and then filtered. The ether solution was washed with 25 ml portions of water twice and dried ($MgSO_4$). Removal of the ether *in vacuo* gave 3.8 g (88%) of *5,5-pentamethylenetetrahydrofuran-3-yl nitrate* **21**, which was purified by distillation under reduced pressure; bp 66–67 °C/0.07 torr. *Anal.* calcd. for $C_9H_{15}NO_4$: (mol. wt. 201.1001) C 53.72, H 7.46, N 6.97; found: (M, ms, 201.0995) C 53.97, H 7.43, N 6.82. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.57 (br s, 10H, cyclohexane ring hydrogens), 1.9–2.15 (m, 2H, —CH_2—), 4.7 (m, 2H, —CH_2—O), 5.5 (m, 1H, —CH—ONO_2). The ir spectrum ν_{max} (liquid film), 1630, 1275 cm^{-1} (—ONO_2).

Addition of Iodonium Nitrate to Pent-4-en-1-ol in Chloroform–Pyridine

To a solution of iodonium nitrate (0.02 mol) in 30 ml of chloroform and 12.5 ml of pyridine was added 1.55 g (0.018 mol) of pent-4-en-1-ol; the mixture was stirred at room temperature for 3 h and then poured into an excess of ether and chilled. The precipitated pyridinium nitrate was collected and the filtrate concentrated *in vacuo*. The residual oil was taken up in ether and washed successively with 40 ml of cold 5% hydrochloric acid, 25 ml of water, 25 ml of 5% sodium thiosulfate solution, and finally with 25 ml of water. The ether layer was dried ($MgSO_4$) and concentrated *in vacuo*. The residual oil was chromatographed on 75 g of Florisil and eluted with petroleum ether – chloroform (9:1) and then with chloroform–methanol (9:1). Evaporation of the first fraction gave 2.29 g (60%) of *2-iodomethyltetrahydrofuran* **22**. The nmr spectrum δ_{TMS} ($CDCl_3$) 3.25 (d, 2H, —CH_2—I, J = 6 Hz), 1.5–2.3 (m, 4H, 2 —CH_2—), 3.6–4.1 (m, 3H, —CH—O, —CH_2—O).

Evaporation of the second fraction gave a mixture of *5-hydroxy-1-iodopent-2-yl nitrate* **23** and *5-hydroxy-2-iodopent-1-yl nitrate* **24**, 0.3 g (6%).

Addition of Iodonium Nitrate to Hex-5-en-1-ol in Chloroform–Pyridine

The reaction was carried out by the general procedure described before. The oil obtained on evaporation of the dried ($MgSO_4$) ether solution was chromatographed on Florisil and eluted with petroleum ether – chloroform (1:1) and then with chloroform–methanol (9:1). Evaporation of the first fraction gave 0.7 g (17%) of *2-iodomethyltetrahydropyran* **27**. The nmr spectrum δ_{TMS} ($CDCl_3$) 3.23 (s, 2H, —CH_2—I), 0.8–2.5 (m, 6H, 3 —CH_2—), 3.1–3.7 (m, 2H, —CH_2—O), 3.9–4.25 (m, 1H, —CH—O).

Evaporation of the second fraction gave 1.115 g (21%) of *6-hydroxy-1-iodohexyl nitrate* **25**.

The ether insoluble residue was extracted with ethanol and a small amount of ether added. The precipitated pyridinium nitrate was collected and more ether added to the filtrate. The resulting oil was separated by decantation and the excess solvents removed *in vacuo* to afford 2.6 g (39%) of *N-[2-(6-hydroxyl-1-iodohexyl)]pyridinium nitrate* **26** as an oil.

Addition of Iodonium Nitrate to endo-cis-5-Norbornene-2,3-dimethanol in Chloroform–Pyridine

Reaction of iodonium nitrate (0.03 mol) in 40 ml of chloroform and 20 ml of pyridine with 4.16 g (0.027 mol) of *endo-cis*-5-norbornene-2,3-dimethanol (15, 16) at room temperature for 2½ h and work-up by the usual procedure gave the cyclic ether **28***A*. Yield 5.58 g (74%). Purification was effected by recrystallization from ether–hexane; mp 54.5–55.5 °C. *Anal.* calcd. for $C_9H_{13}O_2I$: (mol. wt. 279.9961) C 38.56, H 4.64; found: (279.9971, ms) C 37.87, H 4.68. The nmr spectrum δ_{TMS} ($CDCl_3$) see text. The ir spectrum ν_{max} ($CHCl_3$) 3620, 3450 cm^{-1} (—OH). Similarly reaction of *endo-cis*-5-norbornene-2,3-dimethanol-d_4 with iodonium nitrate gave **28***B* (70%).

Addition of Iodonium Nitrate to trans-5-Norbornene-2,3-dimethanol in Chloroform–Pyridine

Reaction of iodonium nitrate (0.02 mol) in 30 ml of chloroform and 15 ml of pyridine with 2.772 g (0.018 mol) of *trans*-5-norbornene-2,3-dimethanol (15, 16) at room temperature for 3 h and work-up by the usual procedure gave 4.315 g (86%) of the cyclic ether **29**. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.5–2.7 (m, 6H, H^1, H^6, H^5, H^4, H^7, H^{7a}), 3.65 (d, 1H, CH—I, $J_{3,7a}$ = 2.3 Hz), 4.73 (d, 1H, CH—O, $J_{1,2}$ = 5 Hz). The ir spectrum ν_{max} (liquid film) 3400 cm^{-1} (—OH).

para-Nitrobenzoylation of Cyclic Ether 29

To a solution of 0.650 g (2.32 mmol) of **29** and 0.237 g (3 mmol) of pyridine in 25 ml of anhydrous benzene was added a solution of 0.431 g (2.32 mmol) of *para*-nitrobenzoyl chloride in 10 ml of anhydrous benzene dropwise and the mixture stirred at room temperature overnight. The precipitated pyridinium chloride was collected and the filtrate washed with 20 ml of 5% sodium bicarbonate solution and then with 20 ml of water. Removal of the solvent *in vacuo* after drying ($MgSO_4$) gave an oil which was crystallized from benzene–hexane to afford 0.7 g (70%) of the *para*-nitrobenzoyl derivative **30**; mp 105–105.5 °C. *Anal.* calcd. for $C_6H_{16}NO_5I$: C 44.75, H 3.73, N 3.26; found: C 45.13, H 3.74, N 3.29. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.7–2.85 (m, 6H, H^1, H^6, H^5, H^4, H^7, H^{7a}), 3.7 (d, 1H, CH—I, J = 2 Hz), 3.8 (d, 2H, —CH_2—O, J = 2 Hz), 4.33 (d, 2H, —CH_2—O—C(=O)—, J = 8 Hz), 4.8 (d, 1H, CH—O, J = 4.5 Hz), 8.35 (m, 4H, aromatic hydrogens). The ir spectrum ν_{max} ($CHCl_3$) 1735 cm^{-1} (C=O), 1530 cm^{-1} (—NO_2).

Addition of Iodonium Nitrate to exo-cis-5-Norbornene-2,3-dimethanol in Chloroform–Pyridine

The reaction was carried out as before with iodonium

nitrate (0.02 mol) in chloroform–pyridine and the olefinic alcohol, 2.772 g (0.018 mol). The oil obtained after evaporation of the dried ($MgSO_4$) solution was chromatographed on Florisil and eluted with chloroform, chloroform–methanol (19:1), and chloroform–methanol (9:1). Evaporation of the last fraction gave 2.45 g (40%) of the adduct, **31***A*, which was recrystallized from chloroform–hexane; mp 86–88 °C. *Anal.* calcd. for $C_9H_{14}NO_5$: C 31.5, H 4.08, N 4.08; found: C 31.38, H 3.99, N 3.75. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.5–2.6 (m, 6H, H^1, H^6, H^5, H^4, H^{7a}, H^{7b}), 6.2 (s, 2H, 2 —OH), 3.3–4.0 (m, 5H, 2 $—CH_2—O$, —CH—I), 5.5 (m, 1H, *CH*—ONO_2). The ir spectrum ν_{max} ($CHCl_3$) 3600, 3430 cm^{-1} (—OH), 1637 (O—NO_2).

Similarly reaction of 1.386 g (9 mmol) of *exo-cis*-5-norbornene-2,3-dimethanol-d_4 with iodonium nitrate (0.01 mol) in chloroform–pyridine and work-up by the method described above gave 1.13 g (36%) of the adduct **31***B*. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.5–2.6 (m, 6H, H^1, H^6, H^5, H^4, H^{7a}, H^{7b}), 3.82 (t, 1H, —CH—I), 5.5 (m, 1H, —CH—ONO_2).

Addition of Iodonium Nitrate to anti-7-Norbornenol in Chloroform–Pyridine

The reaction was carried out according to the general procedure. Thus reaction of iodonium nitrate (0.01 mol) and 0.99 g (0.9 mmol) of *anti*-7-norbornenol (23) gave 2 g (74.3%) of *anti*-7-hydroxy-*exo*-3-iodo-*endo*-norborn-2-yl nitrate **32**. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.2–2.5 (m, 4H, $—CH_2—$), 2.2 (s, 1H, —OH), 2.6 (m, 2H, H^1, H^4), 3.6 (d, 1H, —CH—I, J = 3 Hz), 4.8 (m, 1H, —C*H*—OH), 5.6 (m, 1H, —CH—ONO_2). The ir spectrum ν_{max} ($CHCl_3$) 3600 cm^{-1} (—OH), 1637, 1275 cm^{-1} (—ONO_2).

*para-Nitrobenzoylation of Adduct **32***

The reaction was carried out as described before. Thus from 1 g (3.344 mmol) of adduct **32** and 0.625 g (3.344 mmol) of *para*-nitrobenzoyl chloride was formed 0.77 g (51.4%) of *anti-7-para-nitrobenzoyloxy-exo-3-iodo-endo-norborn-2-yl nitrate*, **33**; mp 119, 120 °C (benzene–hexane). *Anal.* calcd. for $C_4H_{13}N_2O_7$: C 37.5, H 2.9, N 6.25; found: C 38.06, H 2.94, N 5.88. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.45–2.25 (m, 4H, 2 $—CH_2—$), 2.9 (m, 2H, H^1, H^4), 3.75 (d, 1H, —CH—I, J = 3 Hz), 5.6 (m, 2H, *CH*—ONO_2, —*CH*—O—C(=O)—). The ir spectrum ν_{max} ($CHCl_3$) 1733 cm^{-1} (>C=O), 1645 cm^{-1} (ONO_2), 1525 (—NO_2).

Addition of Iodonium Nitrate to 4-Pentenoic Acid in Chloroform–Pyridine

The addition was carried out as described before. Thus reaction of iodonium nitrate (0.04 mol) in 60 ml of chloroform and 25 ml of pyridine with 3.6 g (0.036 mol) of 4-pentenoic acid and work-up by the usual procedure gave 4.9 g (60%) of 5-iodomethylbutyrolactone, **34**. Purification was effected by chromatography on Florisil and elution with chloroform. *Anal.* calcd. for $C_5H_7O_2I$: (mol. wt. 225.9491) C 26.56, H 3.10, I 56.2; found: (225.9486, ms) C 27.01, H 3.18, I 58.28. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.7–2.8 (m, 4H, 2 $—CH_2—$), 3.4 (t, 2H, $—CH_2I$, J = 4 Hz, 6.5 Hz), 4.6 (m, 1H, —CH—O). The ir spectrum ν_{max} (liquid film) 1775 cm^{-1} (>C=O).

Addition of Iodonium Nitrate to 3-Allyl-1,1-diethyl-2-thiourea in Chloroform–Pyridine

To a stirred solution of iodonium nitrate (0.02 mol) in 40 ml of chloroform and 15 ml of pyridine was added 3.49 g (0.02 mol) of 3-allyl-1,1-diethyl-2-thiourea all at once. An exothermic reaction took place and the color changed to dark brown. The mixture was stirred at room temperature for 3 h, then poured into an excess of ether and chilled. The resulting residue was collected, washed several times with ether, extracted with cold methanol, filtered, and reprecipitated with ether. The residue was chromatographed on 100 g of silica gel and eluted with benzene–methanol (85:15). Evaporation of the eluate gave an oily residue (3.3 g) which solidified slowly on standing to give *2-diethylamino-5-iodomethyl-2-thiazoline*, **36**. *Mol. Wt.* calcd. for $C_8H_{15}N_2SI$: 298.0001; found (ms): 298.0003. The nmr spectrum δ_{TMS} $(CD_3)_2SO$ 1.03 (t, 6H, 2 $CH_3—CH_2—$, J = 6.5 Hz), 3.3–4.6 (m, 9H, $—CH_2—$, CH_2I, 2 $—N—CH_2—$, —CH—). The ir spectrum ν_{max} ($CHCl_3$) 1597–1625 (—C=N—).

Kinetics and energetics of the addition of iodonium nitrate to unsaturated systems

J. William Lown and Alummoottil V. Joshua[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 17, 1976

J. William Lown and Alummoottil V. Joshua. Can. J. Chem. **55**, 131 (1977).

The stereochemistry of the products of addition of iodonium nitrate to a series of cycloalk-2-en-1-ols indicates that the intermediate iodonium ion is formed *cis* to the neighbouring hydroxyl in the case of five-, six-, and seven-membered cyclic alkenols and *trans* to the hydroxyl in the case of cycloct-2-en-1-ol. The rates and Arrhenius parameters for the second-order additions of iodonium nitrate to these and other unsaturated substrates have been determined. An α-hydroxy group enhances the rate of addition over the corresponding alkene when the iodonium ion is formed *cis* to the hydroxyl and has the opposite effect when it is formed *trans* to the hydroxyl. This evidence for neighbouring hydroxyl group participation in additions of iodonium nitrate is in contrast to the known chemistry of iodine isocyanate and iodine azide. The effects of structural changes of the substrate on the kinetic and energetic parameters in iodonium nitrate additions are discussed and compared with those of other pseudo-halogens.

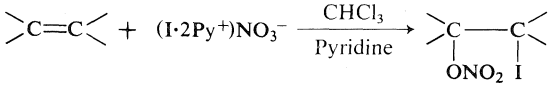
J. William Lown et Alummoottil V. Joshua. Can. J. Chem. **55**, 131 (1977).

La stéréochimie des produits d'addition du nitrate d'iodonium à une série de cycloalcène-2 ols-1 indique que l'ion iodonium intermédiaire est formé en position *cis* par rapport au groupement hydroxyle voisin dans le cas des alkanols cycliques à cinq, six et sept chaînons et *trans* par rapport au groupe hydroxyle dans le cas du cyclooctène-2 ol-1. On a déterminé les vitesses et les paramètres d'Arrhénius pour les additions du second ordre du nitrate d'iodonium à ces substrats insaturés et à d'autres substrats. Un groupe hydroxyle en α augmente la vitesse d'addition par rapport à l'alcène correspondant lorsque l'ion idononium se forme *cis* par rapport à l'hydroxyle et présente l'effet opposé quand il est formé *trans* par rapport à l'hydroxyle. Ces indications concernant la participation du groupe hydroxyle voisin à l'addition du nitrate d'iodonium est en opposition avec la chimie connue de l'isocyanate d'iode et de l'azoture d'iode. On discute des effets produits par des changements structuraux dans le substrat sur les paramètres cinétiques et énergétiques des additions de nitrate d'iodonium et on les compare avec ceux d'autres pseudo-halogènes.

[Traduit par le journal]

Introduction

In previous papers we have explored the chemical behavior of iodonium nitrate, particularly in electrophilic additions to a wide range of unsaturated substrates (1–4). Iodonium nitrate (generated by the reaction of iodine chloride with silver nitrate in chloroform–pyridine) like



other pseudohalogens has all the characteristics of an electrophilic reagent which is consistent with the qualitative observation that electron-donating groups facilitate the reaction while electron-withdrawing groups considerably retard or even arrest it (1, 2).

But iodonium nitrate differs from the other pseudohalogens in that in this reagent the iodine is complexed to two pyridine groups through nitrogen (1, 2). The effect of this complexation may alter its relative electrophilicity compared to other iodine containing pseudohalogens such as iodine isocyanate, iodine chloride, and iodine azide depending on the electronic and steric environments in the olefinic substrate. It was also observed that iodonium nitrate in both chloroform–pyridine and chloroform–*sym*-collidine added to suitable olefinic substrates gives cyclized and/or addition products depending upon the structure of the substrate (2, 3). These results were in contrast to the known chemistry of iodine isocyanate (5) and iodine azide (6). Also, addition of INO_3 to cyclohex-2-en-1-ol gives products derived from intermediate iodonium ions which are formed *cis* to the hydroxyl group, signifying some compensating interaction

[1]NRCC scholarship holder 1974–1975.

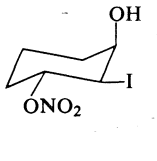
between the iodine and hydroxyl group (3) (see below).

Therefore we undertook a kinetic study of the addition of iodonium nitrate to olefins of varying nucleophilic character to allow comparison with other pseudo-halogens and with a view to obtaining thermodynamic evidence for neighboring group participation and for the stereodirectional character of these electrophilic additions.

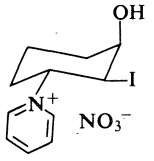
Results and Discussion

Stereochemical Directing Influence of Neighboring Hydroxyl Groups in the Addition of Pseudohalogens to Cycloalk-2-en-1-ols.

Addition of iodonium nitrate to cyclohex-2-en-1-ol in chloroform–pyridine gave an iodonitrate ester **1** in 36% yield and the iodopyridinium nitrate **2** in 29% yield. Examination of the appropriate coupling constants in the nmr spectrum of **1** showed it to be 3-hydroxy-2-iodocyclohexyl nitrate with the stereochemistry shown in which the hydroxy group is axial. Assuming both the iodonitrate ester and the iodopyridinium salt are formed from the same intermediate iodonium ion, structure **2** is proposed for the salt. Parallel reaction of iodonium



1

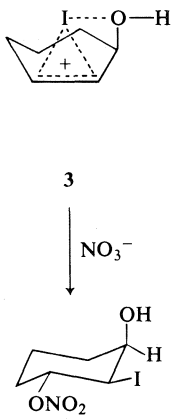


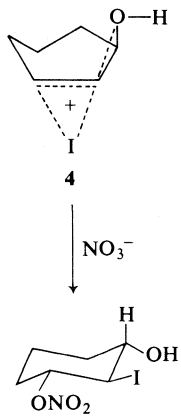
2

nitrate in chloroform–*sym*-collidine with cyclohex-2-en-1-ol gave **1** in 55% yield (3).

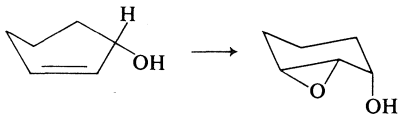
The stereochemistry of the two possible products favors an intermediate of type **3** and proves that the iodonium ion is formed *cis* to the hydroxyl group. This is in agreement with the observed stereochemistry of epoxidation of cyclohex-2-en-1-ols in which the oxirane ring is formed *cis* to the hydroxy group (7, 8). Apparently the epoxidation reagent becomes associated in some way with the hydroxy group in the molecule prior to attacking the double bond and is therefore constrained to approach the latter from the side of the ring which bears the hydroxy group.

The above result prompted us to investigate the stereochemical directing influence of hydroxy groups in the addition of other pseudohalogens to cyclohex-2-en-1-ol and also in the addition

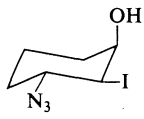




of iodonium nitrate to cycloalk-2-en-1-ols of various ring sizes.



Reaction of iodine azide with cyclohex-2-en-1-ol produced an unstable adduct in 86% yield. The ir spectrum of the adduct showed strong absorption at 2100 cm^{-1} indicating the presence of an azide group in the molecule. The nmr spectrum showed the following significant absorptions: δ_{TMS} ($CDCl_3$) 4.3 (q, 1H, —CH—I, J = 8.5 Hz and 2.5 Hz), 3.7–4.15 (m, 2H, —C*H*—OH and —CH—N_3). On the basis of the nmr spectrum structure **5** is assigned to the

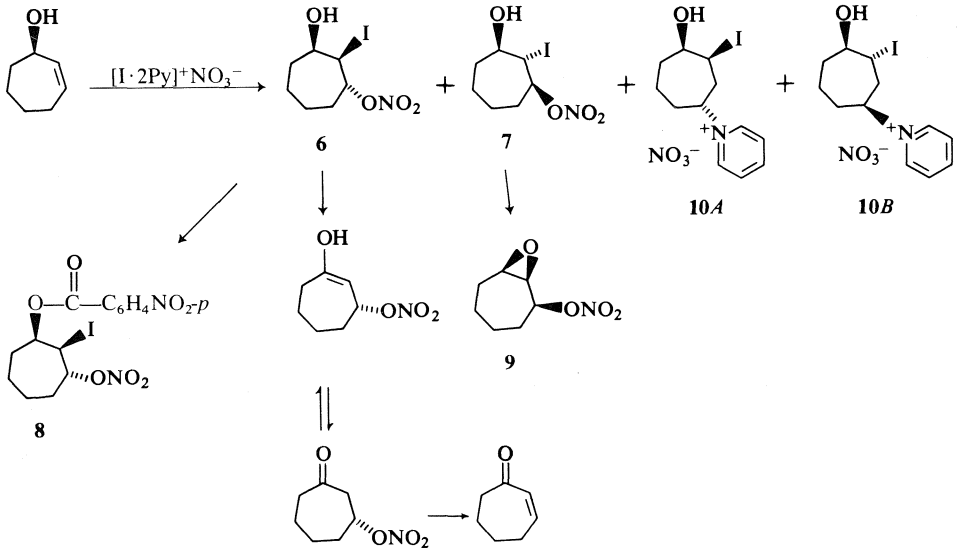


5

adduct, which is derived from an intermediate iodonium ion formed *cis* to the hydroxy group.

Addition of iodine monochloride to cyclohex-2-en-1-ol gave a product in about 90% yield, but no stereochemical information could be gathered from the nmr spectrum.

Cyclohept-2-en-1-ol (9) with iodonium nitrate produced four products. The two iodonitrate esters were formed in a combined yield of 59% and in a ratio of approximately 80:20 (obtained by comparing the nmr intensity of —CH—I of the major product with the total intensity of —CH—ONO_2 at δ_{TMS} ($CDCl_3$) 5.2–5.6). The major product is assigned structure **6** in which the iodine is *cis* to the hydroxyl group, and the



SCHEME 1

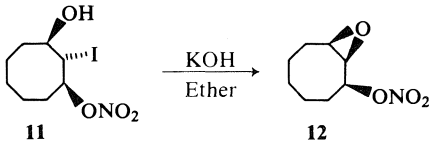
minor product as **7**. The major product had the —CH—I absorption in the nmr spectrum at δ_{TMS} ($CDCl_3$) 4.57 (q), with coupling constants of 2.25 Hz and 6.75 Hz. The nmr spectrum of the cycloheptene – iodonium nitrate adduct showed absorptions at δ_{TMS} ($CDCl_3$) 4.33 (sextet, 1H, —CH—I, $J_{a,a}$ = 7 Hz, $J_{a,e}$ = 5 Hz), and 5.36 (sextet, 1H, —CH—ONO_2, $J_{a,a}$ = 7 Hz, $J_{a,e}$ = 3.5 Hz). This indicates that in **6** the hydroxy group is pseudo-axial and iodine and nitrate groups equatorial. Esterification of the hydroxyl group with *para*-nitrobenzoyl chloride in the presence of pyridine allowed separation of the major product as a crystalline derivative **8** which had in the nmr spectrum absorptions at δ_{TMS} ($CDCl_3$) 4.77 (q, 1H, CH—I, J = 2.5 Hz and 6.5 Hz), 4.96 (m, 1H, —CH—O), and 5.5 (m, 1H, —CH—ONO_2). Treatment of the mixture of iodonitrate esters with potassium hydroxide in ether produced cycloheptenone as the major product by elimination of both hydrogen iodide and nitric acid from **6** and another compound which is assigned the epoxy nitrate structure **9** derived from **7** by base-catalyzed cyclization. The transformations are illustrated in Scheme 1.

The iodopyridinium nitrate salts **10***A* and **10***B* were formed in 27% and 8% yields respectively. They were easily separated by fractional crystallization from ethanol.

Reaction of iodonium nitrate with cyclooct-2-en-1-ol in chloroform–pyridine gave an iodonitrate ester in 60% yield. No iodopyridinium nitrate was isolated in this case. The reaction was considerably slower and traces of cyclooctenol could be detected in the reaction mixture even after 24 h.

The assignment of structure **11** to the iodonitrate ester is based on a comparison of the coupling constants in the nmr spectrum of **11** with those in the spectrum of the cyclooctene – iodonium nitrate adduct. Thus the nmr spectrum of **11** showed absorptions at δ_{TMS} ($CDCl_3$) 4.43 (t, 1H, —CHI, J = 9 Hz), and 5.3 (sextet, 1H, —CH—ONO_2, J = 9 Hz and 4.5 Hz). The corresponding coupling constant $J_{CHI-CH-ONO_2}$ in the spectrum of 2-iodocyclooctyl nitrate was 10 Hz. A coupling constant of 9 Hz indicates a *trans* configuration of iodine and hydroxyl groups.

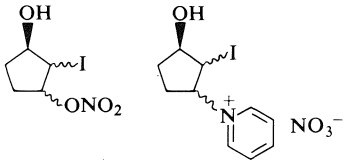
Treatment of adduct **11** with potassium hydroxide in ether gave a cyclized product assigned as the epoxy nitrate **12** on the basis of nmr and ir spectra and mass spectral fragmentation pattern.



11 **12**

Cyclopent-2-en-1-ol (17) with iodonium nitrate in chloroform–pyridine produced an iodonitrate ester **13** in 52% yield and the corresponding iodopyridinium nitrate **14** in 22% yield. No stereochemical information could be gathered from the nmr spectra of the products and comparison with that of the cyclopentene – iodonium nitrate adducts. Treatment of the iodonitrate ester with base did not produce any cyclized product. This may indicate that the iodonium ion is formed *cis* to the hydroxy group.

The second-order rate constants and thermodynamic factors for the addition of iodonium nitrate to a range of selected unsaturated substrates were determined by estimation of unreacted iodonium nitrate with thiosulfate at



13 **14**

appropriate intervals. The kinetic data support an addition of iodonium ion *cis* to the hydroxyl group in the case of cyclopent-2-en-1-ol (see below).

In electrophilic epoxidation reactions cyclohept-2-en-1-ol gave a mixture of *cis* and *trans*-3-hydroxycycloheptene oxides in a ratio of 2:1 (9, 10). On the other hand, cyclooct-2-en-1-ol (18) gave the *trans* isomer stereospecifically (11). No information is available on the stereochemistry of epoxidation cyclopent-2-en-1-ol.

A comparison of the relative yields of iodonitrate esters and iodopyridinium salts for olefinic alcohols and alkenes of comparable structure (3) reveals that in general introduction of the hydroxy function results in a marked increase in the proportion of the iodopyridinium salt relative to that of the iodonitrate. This suggests that the hydroxy function contributes to the increased stabilization of the intermediate iodonium ion rather than to its inductive destabilization. This finding is born out by the kinetic results.

Figure 1 represents a typical standard and weighted least-squares plot for the determination of second-order rate constants for the addition of iodonium nitrate to various substrates.

The second-order rate constants at 0 °C for

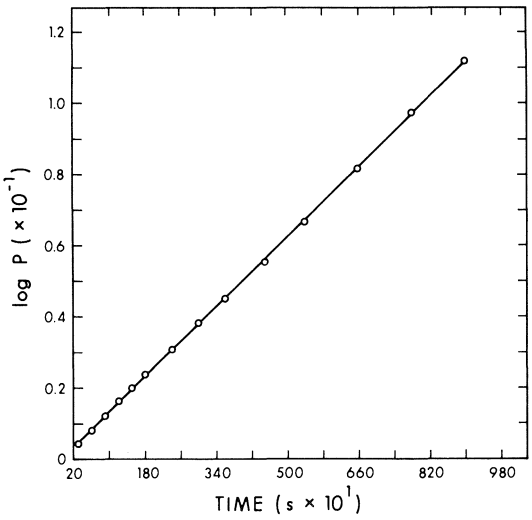


FIG. 1. Plot of log P against time (s) for the addition of iodonium nitrate to cyclooct-2-en-1-ol at 37 °C in 70% chloroform and 30% pyridine.

the reaction of iodonium nitrate with some cyclic olefins and the corresponding olefinic alcohols (hydroxy group in the α-carbon atom) along with their concentrations are given in Table 1. For the monocyclic olefins the order of increasing rate of reaction is cyclooctene < cycloheptene < cyclohexene < cyclopentene. Norbornadiene is approximately 2.5 times as

TABLE 1. Second-order rate constants, k (l mol^{-1} s^{-1}), for the addition of iodonium nitrate at 0 °C in 70% chloroform and 30% pyridine

Substrate	k
Cyclopentene	$7.96 \pm 0.06 \times 10^{-3}$
Cyclopent-2-en-1-ol	$1.12 \pm 0.01 \times 10^{-2}$
Cyclohexene	$7.08 \pm 0.12 \times 10^{-3}$
Cyclohex-2-en-1-ol	$1.17 \pm 0.01 \times 10^{-2}$
Cycloheptene	$4.24 \pm 0.04 \times 10^{-3}$
Cyclohept-2-en-1-ol	$9.50 \pm 0.27 \times 10^{-3}$
Cyclooctene	3.36×10^{-4}*
Cyclooct-2-en-1-ol	2.21×10^{-5}*
Norbornylene	$3.24 \pm 0.06 \times 10^{-3}$
Norbornadiene	$8.14 \pm 0.07 \times 10^{-3}$
Hex-1-ene	$3.09 \pm 0.03 \times 10^{-3}$
Allyl alcohol	$9.04 \pm 0.17 \times 10^{-3}$
But-3-en-1-ol	$7.44 \pm 0.06 \times 10^{-3}$
Pent-4-en-1-ol	$3.98 \pm 0.02 \times 10^{-3}$
Hex-5-en-1-ol	$2.83 \pm 0.03 \times 10^{-3}$
Z-Hex-3-en-1-ol	$4.18 \pm 0.05 \times 10^{-2}$
Hex-1-en-3-ol	$7.71 \pm 0.14 \times 10^{-3}$
3-Methylbut-3-en-1-ol	$3.95 \pm 0.10 \times 10^{-2}$
3,3-Dimethylbut-1-ene	$1.12 \pm 0.03 \times 10^{-3}$

*Obtained by extrapolation to 0 °C.

reactive as norbornylene towards iodonium nitrate.

The effect of an α-hydroxy group in the monocyclic olefin systems on the rate of reaction is also evident. In the five-, six-, and seven-membered cyclic systems, where the iodonium ion is formed *cis* to the hydroxyl group, the alcohols are more reactive than the corresponding olefins, whereas with the eight-membered case where the iodonium ion is formed *trans* to the hydroxyl the reverse situation obtains. Since the only product of reaction of cyclooct-2-en-1-ol with iodonium nitrate corresponds to addition of the iodonium ion *trans* to the hydroxyl group, the rate ratio between cyclooctene and cyclooct-2-en-1-ol = 15.5 provides an estimate of the combined statistical, steric hindrance, and inductive withdrawal effects of the α-hydroxyl in the absence of neighboring group rate enhancement. By contrast cyclohex-2-en-1-ol is some 15.5 × 1.5 ≈ 23 times as reactive as cyclohexene and cyclopent-2-en-1-ol is some 15.5 × 1.4 ≈ 22 times as reactive as cyclopentene. Both cases indicate rate enhancement due to the neighboring hydroxyl group. Cyclohept-2-en-1-ol represents an intermediate situation leading to addition both *cis* and *trans* to the hydroxyl group with the former favored by at least a factor of 4.

The order of decreasing reactivity for the linear unsubstituted olefinic alcohols is allyl alcohol > but-3-en-1-ol > pent-4-en-1-ol > hex-5-en-1-ol. The rate constant for hex-5-en-1-ol is comparable with that for hex-1-ene indicating that the hydroxy group does not have any profound influence on the reaction rate when it is far removed from the reaction centre. The rate constants for the other three olefinic alcohols show that the stabilization of the intermediate iodonium ion by the hydroxy group is a maximum when it is α to the olefinic center and that the effect decreases as the distance between the hydroxy group and the olefinic center increases, whereas for bromination in methanol, water, acetic acid, and trifluoroacetic acid and for iodination in water the reverse has been observed (12, 13). The drastically reduced extent of hydroxy participation for bromination in trifluoroacetic acid solvent has been attributed to hydrogen bonding between the solvent and the hydroxy substituent which reduces its nucleophilicity and hence its effectiveness as a neighboring group (12). The results for addition of

TABLE 2. Rate coefficients for the addition of halogens and iodonium nitrate to olefinic alcohols, k (l mol^{-1} min^{-1})

bromine, iodine, and iodonium nitrate are summarized in Table 2.

For the determination of activation parameters, both log k and log k/T were plotted against $1/T$. This gave good Arrhenius-type plots. A representative example of a standard and weighted least-squares plot is given in Fig. 2. The E_a values (see Table 3) are larger than those for the addition of iodine in hexane to cyclohexene (5.3 kcal mol^{-1}) and for the addition of iodine monobromide to cyclohexene in carbon tetrachloride (8.2 kcal mol^{-1}) (16). On the other hand $\Delta S^{\neq}$ values are comparatively lower for the addition of iodonium nitrate than for the addition of sulfenyl chloride (14) or bromine (15). This may indicate that in this bimolecular reaction, there is no large increase in polarity in the transition state compared to the reactants. This is not unexpected since the reacting pseudohalogen itself is considerably polarized as $[I{\cdot}2Py]^+NO_3^-$.

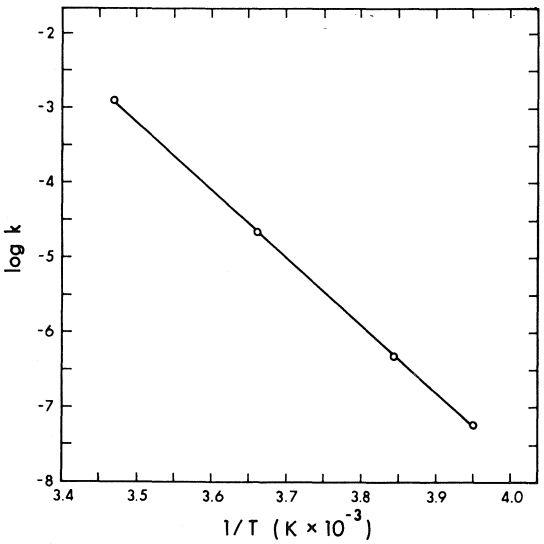

FIG. 2. Plot of log k against $1/T$ for the addition of iodonium nitrate to cyclohept-2-en-1-ol in 70% chloroform and 30% pyridine.

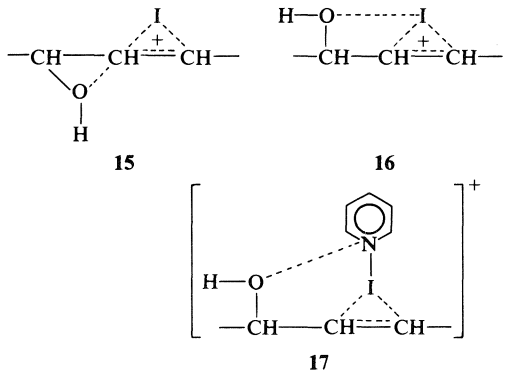
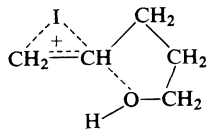
For the linear olefinic alcohols the E_a and $\Delta H^{\neq}$ values increase steadily from allyl alcohol to pent-4-en-1-ol whereas the $\Delta S^{\neq}$ values show a tendency to become less negative. This may suggest that the transition state for allyl alcohol is more favored both by energetics and entropically than those for its higher homologues. This signifies considerable stabilization of the intermediate iodonium ion by the neighbouring hydroxy group. This enhanced stabilization afforded the iodonium ion by the hydroxy group can be envisaged in a number of ways; participation to carbon **15**, participation to iodine **16**, or participation to the slightly positively charged pyridine nitrogen which may be still attached to the iodine in the transition state **17**. Since no



such interaction to carbon or halogen has been observed in the iodination and bromination of allyl alcohol (13), the participation may be to the nitrogen as in **17**.

It was also observed that pent-4-en-1-ol with

iodonium nitrate gives a substantial amount of cyclized product. Hex-5-en-1-ol behaved similarly, although to a lesser extent. This result signifies considerable participation to the carbon by the hydroxy group in the transition state. Thus it is reasonable to assume that in allyl alcohol and but-3-en-1-ol, the hydroxy group stabilizes the iodonium ion by participation to nitrogen, whereas in pent-4-en-1-ol and hex-4-



18

en-1-ol, the stabilization is by participation to carbon. In the latter two compounds participation to nitrogen will be unfavorable entropically.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The ir spectra were recorded on a Perkin-Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The nmr spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in appropriate deuterated solvents with tetramethylsilane as standard. Line positions are reported in ppm from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focussing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography.

The gc analyses were performed with an Aerograph model A-700 gas chromatograph. The lc analyses were made with a Waters Associates model ALC-100 liquid chromatograph. Microanalyses were carried out by Mrs. D. Mahlow of this department.

Materials

Chloroform and pyridine were freshly distilled. All olefinic substrates were fractionally distilled before use and purities were determined by gas chromatography on a Varian Autoprep instrument. The iodonium nitrate–pyridine complex required for kinetic studies was prepared as follows. A solution of iodonium nitrate in chloroform–pyridine was prepared in the usual way. The solution was poured into an excess of anhydrous ether with stirring. The precipitated solid was collected and washed several times with ether. The product was recrystallized several times from anhydrous acetonitrile or acetonitrile–ether. It was not possible to remove all silver salts from the complex because of their solubility in acetonitrile. An approximate purity of 95% was achieved by this method.

The presence of silver salts was shown not to interfere with the reaction by studying kinetics with samples of complex containing different amounts of silver salts.

General Procedure for the Reaction of Iodonium Nitrate with Unsaturated Substrates

The procedure in chloroform–pyridine was similar to that discussed before (1). When the reactions were carried out in chloroform–*sym*-collidine the following procedure was adopted. The reaction mixture was added to sufficient ether to precipitate the collidinium salt. The precipitate was collected and the ethereal layer was washed several times successively with (*a*) cold hydrochloric acid (5%) saturated with sodium chloride, (*b*) saturated aqueous sodium chloride, (*c*) sodium bicarbonate (5%) saturated with sodium chloride until neutral, and finally (*d*) saturated sodium chloride solution containing sodium thiosulfate. The ether layer was dried ($MgSO_4$) and concentrated *in vacuo*. The residual oil was distilled under reduced pressure. The iodopyridinium salts were purified by the crystallization procedure described before (4).

Allyl alcohol gave an isomeric mixture of (*a*) 3-hydroxy-1-iodo-2-propyl nitrate and (*b*) 3-hydroxy-2-iodo-1-propyl nitrate in 30% yield, bp 78 °C/0.15 torr. *Anal.* calcd. for $C_3H_4NO_4I$: N 5.8; found: N 5.7. The nmr (*a*) 5.15 (0.8H, m, $—CHONO_2$), 3.42 (1.6H, d, J = 6 Hz, $—CH_2I$), 3.3 (s, 1H, OH); (*b*) 4.35 (0.2H, m, —CHI), 4.83(0.4H, t, J = 6Hz, 7 Hz, $—CH_2ONO_2$), 3.95 (m, 2H, CH_2OH). In addition were formed the corresponding pyridinium nitrates in 23% yield, mp 48–52 °C. *Anal.* calcd. for $C_8H_{11}N_2O_4I$: C 29.45, H 3.4, N 8.6; found: C 30.2, H 3.18, N 8.8. The nmr (*a*) 4.1 (1.5H, d, J = 5 Hz, $—CH_2I$), 3.85 (m, 2H, CH_2OH), 5.83 (s, 1H, OH); (*b*) 4.5–5.41 (m, pyr).

1,1-Dimethylallyl alcohol gave 3-hydroxy-2-iodo-3-methyl-1-butyl nitrate in 20% yield, bp 70 °C/0.15 torr. *Anal.* calcd. for $C_5H_{10}NO_4I$: C 21.8, H 3.65, N 5.00; found: C 22.1, H 3.7, N 4.55. 2,3-Epoxy-1-iodo-3-methylbutane was also produced, bp 52 °C/6 torr in 5% yield. *Anal.* calcd. for C_5H_9OI: C 28.3, H 4.3; found: C 28.5, H 4.2. The corresponding pyridinium salt was also formed in 40% yield.

Hex-1-en-3-ol gave an isomeric mixture of (*a*) 3-hydroxy-1-iodo-2-hexyl nitrate and (*b*) 3-hydroxy-2-iodo-1-hexyl nitrate in 34% yield, bp 90° C/0.1 torr. *Anal.* calcd. for $C_6H_{12}NO_4I$: C 24.95, H 4.2, N 4.85; found: C 24.95, H 4.2, N 4.7. The nmr (*a*) 4.95 (0.5H, m, $CHONO_2$), 3.47 (1H, d, J = 6 Hz, $—CH_2I$), 0.97 (m, 3H, CH_3), 1.5 (m, 4H, $2—CH_2$); (*b*) 4.4 (0.5H, m, CHI), 4.87 (1H, d, J = 7.5 Hz), 2.43 (s, 1H, OH), 3.0, 3.9 (m, 1H, C*H*OH). In addition was formed the corresponding pyridinium salt *N*-[1-(3-hydroxy-2-iodohexyl)]pyridinium nitrate in 16% yield, mp 80–85 °C. *Anal.* calcd. for $C_{11}H_{17}N_2O_4I$: C 35.9, H 4.65, N 7.61; found: C 36.15, H 4.7, N 7.2. Also formed was the corresponding 3-iodo-2-propyloxetan, bp 72 °C/2 torr in 11% yield (in the reaction in *sym*-collidine). *Anal.* calcd. for $C_6H_{11}OI$: C 31.9, H 2.9; found: C 31.75, H 4.75.

Hex-5-en-3-ol gave an isomeric mixture of 3-hydroxy-1-iodo-2-hexyl nitrate and 3-hydroxy-2-iodo-1-hexyl nitrate in 10% yield, bp 65 °C/0.1 torr. *Anal.* calcd. for $C_6H_{12}NO_4I$: N 4.85; found: N 5.0. In addition was found *N*-[3-(5-ethyltetrahydrofurfuranyl)]pyridinium nitrate in 20% yield, bp 60 °C/1 torr. *Anal.* calcd. for $C_6H_{11}NO_4$: N 8.7; found: N 8.1.

2-Cyclohexenol gave 3-hydroxy-2-iodo-cyclohexyl ni-

trate, bp 90 °C/0.05 torr in 36% yield. *Anal.* calcd. for $C_6H_{10}NO_4I$: C 25.1, H 3.5, N 4.9; found: C 25.3, H 3.4, N 4.2. The nmr 4.48 (1H, q, $J_{1,2} = 8.5$ Hz, $J_{2,3} = 2.5$ Hz, CHI), 5.4 (1H, m, —$CHONO_2$), 1.78 (m, 4H, $2CH_2$), 2.3 (m, 3H, —CH_2, OH), 3.8 (m, 1H, —*CH*OH). The pyridinium salt, *N*-[1-(3-hydroxy-2-iodocyclohexyl)]pyridinium nitrate, mp 166–168 °C, was found in 29% yield. *Anal.* calcd. for $C_{11}H_{15}N_2O_4I$: C 36.1, H 4.1, N 7.65; found: C 36.1, H 4.8, N 8.0.

2-Cyclopentenol gave 3-hydroxy-2-iodocyclopentyl nitrate, mp 46–47 °C in 52% yield. *Anal.* calcd. for $C_5H_8NO_4I$: C 21.98, H 2.93, N 5.13; found: C 21.97, H 2.98, N 5.04. The nmr 4.33 (1H, t, $J = 4.5$ Hz, —CHI), 5.6 (1H, m, —CH—ONO_2), 1.7–2.8 (m, 5H, 2—CH_2, OH), 3.83 (s, 1H, C*H*OH, $J = 5$ Hz). *N*-[1-(3-Hydroxy-2-iodocyclopentyl)]pyridinium nitrate, mp 137–139 °C was formed in 22% yield. *Anal.* calcd. for $C_{10}H_{13}N_2O_4I$: C 34.1, H 3.69, N 7.96; found: C 34.14, H 3.68, N 7.91.

2-Cycloheptenol gave 3-hydroxy-2-iodocycloheptyl nitrate in 59% yield. *Mol. Wt.* calcd. for $C_7H_{12}NO_4I$: 300.9811; found (ms): 300.9811. The nmr 4.57 (1H, q, $J = 2.25$ Hz, 6.75 Hz, CHI), 5.5 (1H, m, $CHONO_2$), 1.5–2.5 (m, 9H, $4CH_2$, OH), 3.76 (m, 1H, CHO). *N*-[1-(3-Hydroxy-2-iodocycloheptyl)]pyridinium nitrate, mp 148 °C, was formed in 59% yield. *Anal.* calcd. for $C_{12}H_{17}N_2O_4I$: C 37.9, H 4.47, N 7.37; found: C 37.92, H 4.89, N 7.22.

1-Hexene gave 1-iodo-2-hexyl nitrate, bp 80 °C/0.5 torr, in 41% yield. *Anal.* calcd. for $C_6H_{12}NO_3I$: C 26.39, H 4.42, N 5.12; found: C 26.35, H 4.79, N 4.73. The nmr 4.9 (1H, m, $CHONO_2$), 3.35 (2H, d, $J = 5.5$ Hz, CH_2I), 1.3 (m, 9H, $3CH_2$—CH_3). *N*-[2-(1-Iodohexyl)]pyridinium nitrate was formed in 42% yield as an oil.

3,3-Dimethyl-1-butene gave 2-iodo-3,3-dimethyl-1-butyl nitrate, bp 55 °C/0.2 torr, in 26% yield. *Anal.* calcd. for $C_6H_{12}NO_3I$: C 26.39, H 4.42, N 5.12; found: C 26.37, H 4.80, N 4.70. The nmr 4.17 (1H, m, CHI), 4.8 (2H, m, CH_2ONO_2) 1.15 (s, 9H, —$C(CH_3)_3$). *N*-[1-(2-Iodo-3,3-dimethylbutyl)]pyridinium nitrate, mp 133 °C, was formed in 49% yield. *Anal.* calcd. for $C_{11}H_{17}N_2O_3I$: C 35.90, H 4.65, N 7.50; found: C 36.10, H 4.70, N 4.60.

3,4-Dimethyl-1-hexene gave an isomeric mixture of 1-iodo-3,4-dimethyl-2-hexyl nitrate and 2-iodo-3,4-dimethyl-1-hexyl nitrate bp 93–97 °C/0.5 torr, in 75% yield. *Anal.* calcd. for $C_8H_{16}NO_3I$: C 31.90, H 5.35, N 4.65; found: C 32.30, H 5.60, N 4.67. The nmr 4.8 (1H, m, CHI), 5.0 (2H, m, $CHONO_2$), 3.4 (1.4H, m, CH_2I), 4.4 (0.6H, m, CH_2ONO_2), 0.8–2 (m, 13H, 2—CH—, —CH_2—, $3CH_3$).

Cyclopentene gave 2-iodocyclopentyl nitrate, bp 40 °C/0.5 torr, in 54% yield. *Anal.* calcd. for $C_5H_8NO_3I$: C 23.35, H 3.11, N 5.45; found: C 23.48, H 3.19, N 5.42. The nmr 4.2 (1H, m, —CHI), 5.4 (1H, m, —$CHONO_2$), 2.0 (m, 6H, $3CH_2$—). *N*-(2-Iodocyclopentyl)pyridinium nitrate was also formed as an oil in 9% yield. *Anal.* calcd. for $C_{10}H_{13}N_2O_3I$: C 35.73, H 3.89, N 8.33; found: C 34.13, H 3.96, N 8.94.

Cyclohexene formed 2-iodocyclohexyl nitrate, bp 113 °C/1.3 torr, in 60% yield. *Anal.* calcd. for $C_6H_{10}NO_3I$: C 26.58, H 3.72, N 5.16; found: C 26.84, H 3.87, N 4.98. The nmr 4.17 (1H, m, —CH—I), 5.15 (1H, m, —CH—ONO_2), 1.7 (m, 8H, 4—CH_2—). *N*-(2-Iodocyclohexyl)-pyridinium nitrate, bp 145–150 °C, was formed in 40% yield. *Anal.* calcd. for $C_{11}H_{15}N_2O_3I$: C 37.73, H 4.32, N 8.00; found: C 37.77, H 4.80, N 7.97.

Cycloheptene gave 2-iodocycloheptyl nitrate, bp 113 °C/1.3 torr, in 60% yield. *Anal.* calcd. for $C_7H_{12}NO_3I$: C 29.50, H 4.21, N 4.91; found: C 29.93, H 4.52, N 4.84. The nmr 4.33 (1H, m, —CHI), 5.36 (1H, m, —$CHONO_2$), 1.5–2.4 (m, 10H, 5—CH_2). *N*-(2-Iodocycloheptyl)pyridinium nitrate, bp 140–142 °C, was also formed in 40% yield. *Anal.* calcd. for $C_{12}H_{17}N_2O_3I$: C 39.60, H 4.67; found: C 39.82, H 4.87.

Cyclooctene similarly gave 2-iodocyclooctyl nitrate, bp 97 °C/0.02 torr, in 79% yield. *Anal.* calcd. for $C_8H_{14}NO_3I$: C 33.62, H 4.90, N 4.90; found: C 32.71, H 5.08, N 4.37. The nmr 4.3 (1H, m, —CHI), 5.4 (1H, m, —$CHONO_2$), 1.1–2.3 (m, 12H, $6CH_2$—). *N*-(2-Iodocyclooctyl)pyridinium nitrate, bp 152–153 °C, was formed in 5.5% yield. *Anal.* calcd. for $C_{13}H_{19}N_2O_3I$: C 41.27, H 4.03, N 7.41; found: C 41.36, H 4.99, N 7.36.

Norbornene gave 2-iodonorborn-3-yl nitrate, bp 83 °C/0.3 torr, in 60% yield. *Anal.* calcd. for $C_7H_{10}NO_3I$: C 29.70, H 3.56, N 4.95; found: C 30.55, H 3.50, N 4.33. The nmr 3.75 (1H, m, —CH—I), 5.5 (1H, m, —$CHONO_2$), 1.3–2.8 (m, 8H, 2—CH—, 3—CH_2—). Nortricyclanyl iodide was also produced in 40% yield, bp 40 °C/0.15 torr. Molecular ion 220.

Norbornadiene gave tricyclo[2.2.1.$0^{2,6}$]-5-iodohept-3-yl nitrate, bp 75 °C/0.08 torr, in 64% yield. *Anal.* calcd. for $C_7H_8NO_3I$: C 29.92, H 2.87, N 4.93; found: C 30.05, H 3.18, N 5.05. The nmr 4.25 (1H, m, —CHI), 5.03 (1H, m, —$CHONO_2$), 1.75, 2.5 (m, 6H, 4—CH—, —CH_2).

1,5-Hexadiene gave 6-iodohex-1-en-5-yl nitrate, bp 62 °C/0.35 torr, in 85% yield. *Anal.* calcd. C 26.59; H 3.72, N 5.16; found: C 26.51, H 3.34, N 4.89. The nmr 4.9 (1H, m, —$CHONO_2$), 3.35 (2H, d, $J = 5.5$ Hz, —CHI), 2.0 (m, 4H, $2CH_2$), 5.5, 5.6 (m, 3H, —CH=CH_2).

Treatment of Cyclohept-2-en-1-ol Iodonium Nitrate Adducts with Potassium Hydroxide in Ether

A solution of 2.5 g (8.3 mmol) of the adducts in 50 ml of ether was stirred with 0.6 g of powdered potassium hydroxide for 3 h. Work-up according to the procedure described before gave 1 g of cyclohept-2-en-1-one and a small amount of 2,3-epoxycyclohept-1-yl nitrate **9**. Separation was achieved by chromatography on Florisil and elution with benzene–hexane (50:50). Evaporation of the first fraction gave the epoxy nitrate. The nmr spectrum δ_{TMS} ($CDCl_3$) 0.8–2.5 (m, 8H, 4—CH_2—), 3.2 (m, 2H, 2—CH—O), 5.25 (m, 1H, —CH—ONO_2). The ir spectrum ν_{max} ($CHCl_3$) 1630 cm^{-1}, 1270 cm^{-1} (ONO_2), 1310, 960 cm^{-1}  .

Evaporation of the second fraction gave cyclohept-2-en-1-one, which was identical with an authentic sample.

para-Nitrobenzoylation of 3-Hydroxy-3-iodocycloheptyl Nitrate

To a solution of 2 g (6.63 mmol) of adducts **6** and **7** and 0.79 g (0.01 mol) of pyridine in 30 ml of anhydrous benzene was added a solution of 1.245 g (0.00663 mol) of *para*-nitrobenzoyl chloride in 10 ml of benzene dropwise and the mixture stirred for 3 h. Work-up by the usual procedure gave an oil which was crystallized from benzene–hexane to afford 1.5 g (50%) of *3-para-nitrobenzoyloxy-2-iodocycloheptyl nitrate*, **8** mp 103–104 °C. *Anal.* calcd. for $C_{14}H_{15}N_2O_7I$: C 37.34, H 3.33, N 6.22; found: C 37.4, H 3.41, N 6.25. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.7–2.5 (m, 8H, 4—CH_2—), 4.77 (q, 1H,

—CH—I, J = 2.5 Hz), 4.96 (m, 1H, —CH—O), 5.5 (m, 1H, —CH—ONO_2), 8.27 (m, 4H, aromatic hydrogens). The ir spectrum ν_{max} ($CHCl_3$) 1730 cm^{-1} (>C=O), 1640 (—ONO_2), 1530 (—NO_2).

Treatment of 3-Hydroxy-2-iodocyclooctyl Nitrate with Potassium Hydroxide in Ether

To a solution of 2 g (6.35 mmol) of 3-hydroxy-2-iodocyclooctyl nitrate in 50 ml of ether was added 0.56 g (0.01 mol) of powdered potassium hydroxide. The mixture was stirred at room temperature for 3 h. Work-up by the usual procedure gave 1 g (84%) of 2,3-epoxycyclooctyl nitrate, **12**. Purification was achieved by chromatography on Florisil and elution with benzene–hexane (50:50). The nmr spectrum δ_{TMS} ($CDCl_3$) 1.1–2.4 (m, 10H, 5—CH_2—), 2.88 (q, 1H, H^3), 3.08 (t, 1H, H^2, J = 4 Hz), 5.63 (sextet 1H, —CH—ONO_2, J = 5 Hz, 3.33 Hz). The ir spectrum ν_{max} ($CHCl_3$) 1640 cm^{-1} (ONO_2), 1280 cm^{-1}. (). The mass spectrum, *m/e* 141 ($M - NO_2$), 125 ($M - ONO_2$).

Addition of Iodine Azide to Cyclohex-2-en-1-ol

This reaction was carried out by the procedure of Hassner and Teeter (19). Thus the reaction of 3.92 g (0.04 mol) of cyclohex-2-en-1-ol with iodine azide generated from 5.2 g (0.08 mol) of sodium azide and 9.8 g (0.06 mol) of iodine monochloride in 70 ml of anhydrous acetonitrile at 0 °C for 24 h and work-up by the usual procedure gave 9.2 g (86%) of 3-hydroxy-2-iodo-1-azidocyclohexane, **5**, as a dark brown oil. The nmr spectrum δ_{TMS} ($CDCl_3$) 1–2.5 (m, 6H, 3—CH_2—), 2.85 (s, 1H, —OH), 3.9 (m, 2H, —C*H*—OH, —CH—N_3), 4.3 (q, 1H, —CH—I, $J_{1,2}$ = 9.5 Hz, $J_{2,3}$ = 2.5 Hz). The ir spectrum ν_{max} (liquid film) 3425 cm^{-1} (—OH), 2100 cm^{-1} (—N_3).

Addition of Iodine Monochloride to Cyclohex-2-en-1-ol

To a stirred solution of 8.1 g (0.05 mol) of iodine monochloride in 60 ml of anhydrous acetonitrile at 0 °C was added a solution of 3.92 g (0.04 mol) of cyclohex-2-en-1-ol in 10 ml of anhydrous acetonitrile and the mixture stirred at 0–5 °C for 24 h. The solution was added to 50 ml of saturated sodium bisulfite solution and the mixture extracted with 50 ml of ether. Removal of the solvent *in vacuo* after drying ($MgSO_4$) gave 9.4 g (90%) of the adduct as a dark brown oil. The nmr spectrum δ_{TMS} ($CDCl_3$) 1.2–2.6 (m, 7H, 3—CH_2—, —OH), 3.2–3.8 (m, 3H, —CH—I, —CH—Cl, —C*H*—OH). The ir spectrum ν_{max} (liquid film) 3420 cm^{-1} (—OH).

Estimation of Iodonium Nitrate

Iodonium nitrate can be estimated quantitatively with thiosulfate. The reaction may be formulated as:

$$2Na_2S_2O_3 + INO_3 \rightarrow NaI + NaNO_3 + Na_2S_4O_6$$

The method is as follows:

A known volume of iodonium nitrate solution in chloroform–pyridine (70:30) is thoroughly shaken with an excess of a known volume of standard sodium thiosulfate solution. The completion of the reaction between sodium thiosulfate and iodonium nitrate is indicated by the change in color of the iodonium nitrate solution from light yellow to colorless (*ca.* 15–20 s). The excess of sodium thiosulfate is then determined by titration with standard iodine solution using starch as the indicator. The titre values were quite reproducible within experimental limits. The end point is indicated by the first appearance of the blue color. It was found that the color faded gradually.

In some additions, where cyclization (*e.g.* pent-4-en-1-ol, hex-5-en-1-ol) or rearrangement (*e.g.* norbornylene) occurs, pyridinium nitrate (Py·HNO_3) is an additional product in the reaction. It was found that the titre values were unchanged in the presence of added pyridinium nitrate.

Stoichiometry of the Reaction

The stoichiometry of the addition reactions was shown to be 1:1 by allowing a known excess of iodonium nitrate in chloroform–pyridine to react with a known amount of *e.g.* cyclohexene to completion and then determining the excess of iodonium nitrate by the method described above.

Kinetic Measurements

All kinetic studies were done in chloroform–pyridine (70:30 v/v) at temperatures between −20.5 to 45 °C. Chloroform and pyridine were freshly distilled. The progress of the reaction was followed by the rate of disappearance of iodonium nitrate. An accurately weighed amount of olefin was made up to 50 ml with chloroform–pyridine (70:30) at the temperature at which kinetic measurements were made. The olefin solution and the iodonium nitrate solution (50 ml) were equilibrated at the desired temperature. The two solutions were mixed thoroughly. Portions (5 ml) of the reaction mixture were withdrawn at intervals and the unreacted iodonium nitrate was estimated by the method described before. Whenever possible the kinetics were followed up to 80–85% of the reaction except at very low temperatures where they were followed up to 50–60%.

In all the kinetic runs a slight excess (10–25%) of iodonium nitrate was used. The initial concentration of iodonium nitrate was determined by titrating 5 ml of the stock solution. This was checked by titrating a sample after completion of the reaction. Good agreement was observed within experimental error.

A typical kinetic run may be represented as follows:

Time (min)	I_2* (ml)	Time (min)	I_2* (ml)
5	1.3	50	11.9
10	2.85	60	13.6
20	5.45	80	16.4
30	7.8	100	18.8
40	9.9	120	20.7

*I_2 ≡ excess thiosulfate.

Determination of Rate Constants

The second-order rate constants for the addition of iodonium nitrate to various olefinic substrates were determined by plotting log P against time: $P = (c_b^0 \times c_a)/(c_a^0 \times c_b)$, where c_a^0 = initial concentration of iodonium nitrate, c_b^0 = initial concentration of unsaturated substrate, c_a and c_b are concentrations of iodonium nitrate and olefin respectively at any given time.

Good second-order plots (straight lines) were obtained up to about 80–85% of the reaction: k = Slope $(2.303/c_a^0 - c_b^0)$.

Hydroxyl proton resonances of methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides and their derivatives in dimethyl sulfoxide solution[1]

YÔTARO KONDO AND KEISUKE KITAMURA[2]

Department of Agricultural Biochemistry, Tottori University, Tottori 680, Japan

Received June 7, 1976

YÔTARO KONDO and KEISUKE KITAMURA. Can. J. Chem. **55**, 141 (1977).

Proton magnetic resonance spectra of methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides (**1** and **10**) and their mono-substituted derivatives are determined in dimethyl sulfoxide solution. Assignments of the hydroxyl group resonances of **1** and **10** are confirmed by means of INDOR techniques. It is shown that the position of the hydroxyl substituent of the mono-substituted derivatives of **1** and **10** can be determined by using the coupling constants $J_{H-C-O-H}$. It is proposed that the vicinal diols of **1** and **10** give 1:1 associations with dimethyl sulfoxide molecules, and the C—H and O—H bonds at position 2 of the mono-substituted derivatives of **1** are approximately *anti*.

YÔTARO KONDO et KEISUKE KITAMURA. Can. J. Chem. **55**, 141 (1977).

On a déterminé les spectres rmp, dans des solutions de diméthylsulfoxyde, des *O*-benzylidène-4,6-α- et β-D-glucopyrannosides de méthyle (**1** et **10**) et de leurs dérivés monosubstitués. L'attribution des résonances des groupes hydroxyles de **1** et de **10** a pu être confirmée en faisant appel à des techniques INDOR. On montre que la position d'un substituant hydroxyle des dérivés monosubstitués de **1** et de **10** peut être déterminée en faisant appel aux constantes de couplage $J_{H-C-O-H}$. On croit que les diols vicinaux de **1** et de **10** donnent des associations 1:1 avec les molécules de diméthylsulfoxyde et que les liaisons C—H et O—H en position 2 des dérivés mono-substitués de **1** sont approximativement *anti*.

[Traduit par le journal]

It is well known that the pmr spectra of alcohols (1, 2) and carbohydrates (3–9) in dimethyl sulfoxide (DMSO) solution display well resolved signals of the hydroxyl groups and that the derived coupling constants $J_{H-C-O-H}$ provide valuable information on configuration and conformation of these compounds (2–9).

This communication describes assignments of the vicinal diols in the pmr spectra of methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides in dimethyl sulfoxide solution and characterization of 'isolated' hydroxyl groups of their mono-substituted derivatives.

The pmr spectrum of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) in DMSO-d_6, together with the INDOR spectra, are shown in Fig. 1. The signals of the hydroxyl groups appeared at τ 4.85 and 5.04 as doublets (J = 4.5 and 6.5 Hz, respectively) which disappeared on addition of D_2O. The signal of H-1 occurred at τ 5.37 as a doublet ($J_{1,2}$ = 3.8 Hz). The signals of the hydroxyl groups at C-2 and C-3 were assigned by using INDOR (internuclear double resonance) techniques (10–13).

Six different INDOR spectra are shown in Fig. 1. Monitoring the frequency of line 1 and varying the INDOR frequency gave rise to three pairs of 'negative–positive' peaks (spectrum 1), whereas that of line 2 gave rise to three pairs of 'positive–negative' peaks (spectrum 2) in the same region of τ 6.20–6.60. Monitoring lines 3 and 4 (spectra 3 and 4) resulted in responses in the same region of τ 6.50–6.80. When the H-1 peaks (lines 5 and 6) were monitored, perturbation patterns similar to the INDOR spectra 3 and 4 were observed at frequencies corresponding to the H-2 proton. These indicate that peaks 3, 4, 5, and 6 come from the H-2 resonance. Accordingly, the doublet at higher field (τ 5.04) was assigned to the 2-OH resonance and another doublet at lower field (τ 4.85) to the 3-OH.

The pmr and INDOR spectra of methyl 4,6,-*O*-benzylidene-β-D-glucopyranoside (**10**) in DMSO-d_6 are shown in Fig. 2. The signals of two hydroxyl groups occurred as overlapped pair doublets at τ 4.67 (J = 5.0 Hz) and 4.70 (J = 3.5 Hz). The signal of H-1 appeared at τ 5.75 as a doublet ($J_{1,2}$ = 7.8 Hz). Assignment of the

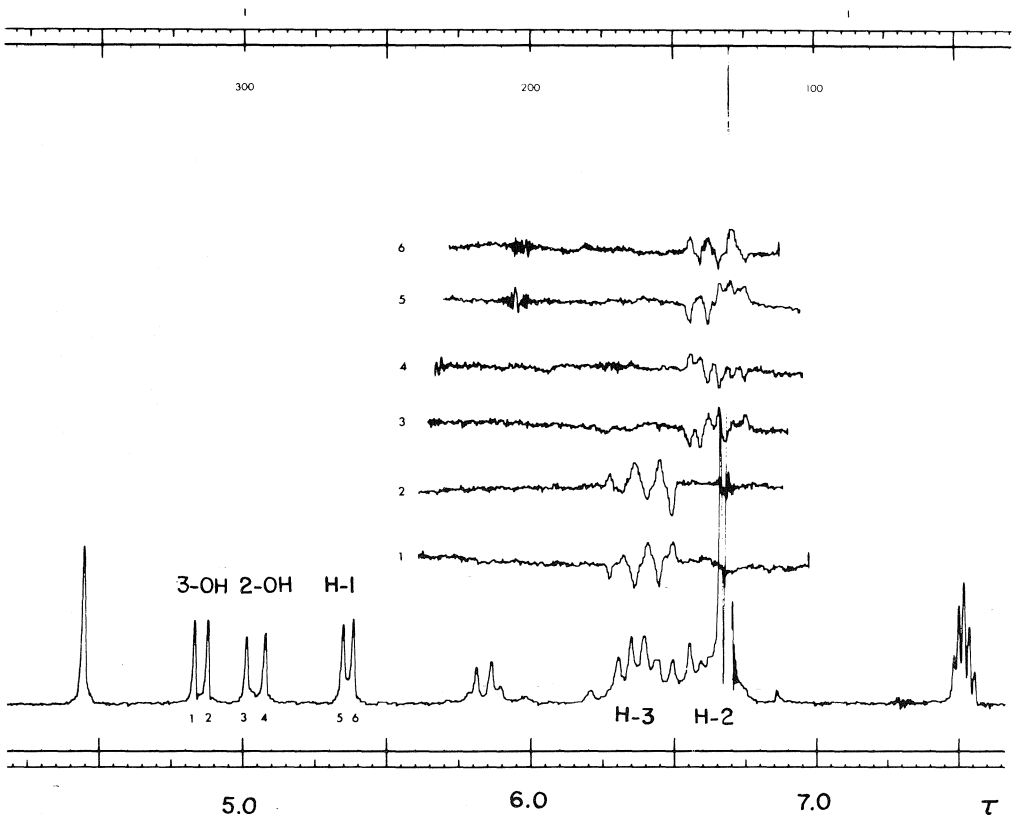

FIG. 1. Proton magnetic resonance and INDOR spectra of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) in DMSO-d_6.

hydroxyl groups at C-2 and C-3 was facilitated by combined use of INDOR and double-resonance techniques.

When lines 1 and 2 were monitored, perturbations were observed (spectra 1 and 2) at the same frequencies as when lines 4 and 5 were monitored (spectra 4 and 5). It follows that the doublet at lower field (τ 4.67) was due to the 2-OH resonance and hence, by inference, that the doublet to higher field (τ 4.70) must be due to the 3-OH. The perturbations observed in Fig. 2, obtained by monitoring transition 3 must, then, arise from the H-3 resonance. These assignments were confirmed by double-resonance experiments (Fig. 2). On irradiation of the H-2 resonance at the region 7, the 2-OH doublet at lower field collapsed to a singlet, whereas irradiation of H-3 at the region 6 changes the 3-OH doublet at higher field to a sharp singlet. The 2-OH signal in compound **1** appeared at higher field as compared with that in compound **10**. This large up-field shift (0.37 ppm) may be caused by the shielding of the axial methoxyl group in compound **1**, indicating the axial methoxyl group has a strong influence on the neighboring hydroxyl group rather than the equatorial methoxyl group.

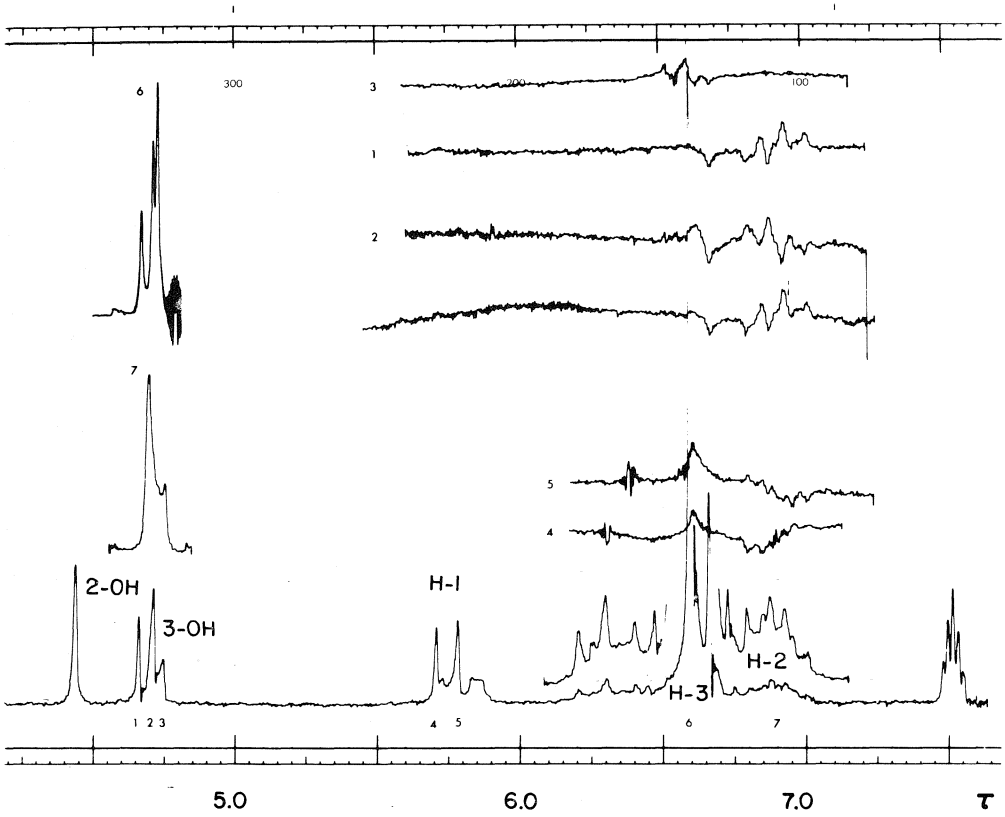

FIG. 2. Proton magnetic resonance and INDOR spectra of methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (**10**) in DMSO-d_6.

It is noteworthy that H–O–C–H(2) couplings are larger than H–O–C–H(3) in vicinal diols of both anomers **1** and **10**. Provided that a similar correlation holds for 'isolated' hydroxyl groups of mono-substituted derivatives of compounds **1** and **10**, this relationship may be useful for determination of the position of the substituents in compounds **1** and **10**. To confirm this, we selected mono-substituted (acetyl, benzoyl, methyl, and benzyl) derivatives of compounds **1** and **10**. The coupling constants $J_{H-C-O-H}$ for these compounds are presented in Tables 1 and 2. For mono-substituted derivatives (**2–9**) with α-D-configuration, the coupling constants of positions 2 and 3 were found to be 7.0–8.0 and 5.0–5.3 Hz, respectively, while compounds **11–18** with β-D-configuration showed coupling constants of 5.5–6.0 and 4.5–5.2 Hz for the 2- and 3-OH signals, respectively. This shows that in these mono-substituted derivatives, the coupling constants at position 2 of the α- and β-D-anomers are larger than those at position 3, in agreement with the results obtained with the original diols **1** and **10**. Consequently, it is possible to predict directly the location of the substituents in a series of mono-substituted derivatives of **1** and **10** from the coupling constants of 'isolated' hydroxyl groups.

*Unresolved.

It is interesting to note that H–O–C–H(2) couplings in the α-D-anomers **6–9** (7.0–8.0 Hz) are especially large. This indicates that the C—H and O—H bonds are approximately an *anti*-conformation, because it is well known that Karplus type of relation for H–C–C–H system is also applicable for H–O–C–H system and the coupling constants are larger for *anti*-conformers than *gauche* (9, 14).

Casu *et al.* (5) postulated 1:1 and 2:1 complex models (Fig. 3 *a* and *b*, respectively) for the complex formation of DMSO molecules with a vicinal diol. Inspection of molecular models of the association of compounds **1** and **10** with DMSO offers an explanation for their observed difference in the coupling constants. In a 2:1 association, the DMSO molecule that is sufficiently far from the glucosidic methoxyl moiety in **1** and **10**, has little influence on the geometry of the seven-membered ring, so that a significant change of the coupling constants of hydroxyl groups would not be expected to be caused by the configurational change at C-1. However, a considerable difference in coupling constants at position 2 and 3 was observed for the α- and β-D-anomers **1** and **10**. This observation may be explained by the steric hindrance of the glucosidic methoxyl group in a 1:1 association to the neighboring DMSO molecule at C-2. This effect is expected to be especially significant in the α-D-anomer with the axial methoxyl group. Accordingly, 1:1 associations of DMSO molecules with vicinal diols of methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides are responsible for the difference in the coupling constants.

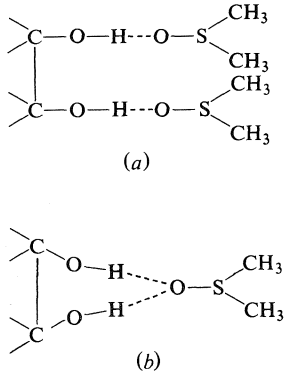

FIG. 3. Association of a vicinal diol with DMSO molecules.

Experimental

Proton magnetic resonance spectra were measured on a Hitachi–Perkin-Elmer 90 MHz spectrometer with tetramethylsilane as an internal reference. The solutions used contained 30 mg of compound in 0.4 ml DMSO-d_6. Chemical shifts were measured at the 800 Hz sweep-width and coupling constants obtained directly from the spectra recorded at the 400 Hz or 200 Hz sweep-widths. INDOR spectra were measured on a Varian HA-100D spectrometer which was modified as reported by van Deursen (13), *i.e.*, an additional oscillator was used for irradiation.

The sugar derivatives used were prepared by the literature procedures (15).

Aliphatic diazo compounds. X. The reaction of α-diazoacetophenone with methanolic sodium methoxide[1]

PETER YATES AND R. J. MAYFIELD

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 8, 1976

PETER YATES and R. J. MAYFIELD. Can. J. Chem. **55**, 145 (1977).

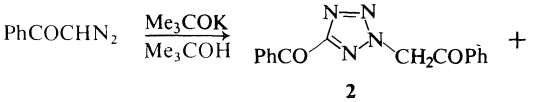
The reaction of α-diazoacetophenone (**1**) with methanolic sodium methoxide in dilute solution gives 3-benzoyl-5-hydroxy-4-phenylpyrazole (**4**), 3-benzoyl-4-hydroxy-5-phenylpyrazole (**5**), 3-benzoyl-5-methoxy-4-phenylpyrazole (**9**), 3-benzoyl-4-phenylpyrazole (**6**), 5-benzoyltetrazole (**7**), 3,6-dibenzoyldihydro-*s*-tetrazine (**10**), *cis*- and *trans*-β-benzoyl-α-phenylacrylic acid, acetophenone, methyl benzoate, and benzoic acid. The pyrazoles **4**, **5**, and **9** are considered to arise via reaction of **1** to give α-methoxyacetophenone followed by further reaction of the anion of the latter with **1**. Evidence in accord with this view was obtained by a study of the products formed when **1** was treated with methanolic sodium methoxide in the presence of 2-methoxy-4′-methylacetophenone. Acetophenone is considered to arise by reduction of **1** via phenylglyoxal 2-monohydrazone (**37**); condensation of **1** with the enolate ion derived from acetophenone then can give the pyrazole **6**, while condensation of **1** with **37** could give the tetrazole **7**.

PETER YATES et R. J. MAYFIELD. Can. J. Chem. **55**, 145 (1977).

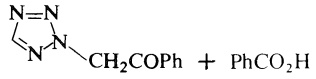
La réaction de l'α-diazoacétophénone (**1**) avec une solution diluée de méthylate de sodium dans le méthanol conduit au benzoyl-3 hydroxy-5 phényl-4 pyrazole (**4**) au benzoyl-3 hydroxy-4 phényl-5 pyrazole (**5**), au benzoyl-3 méthoxy-5 phényl-4 pyrazole (**9**), au benzoyl-3 phényl-4 pyrazole (**6**), au benzoyl-5 tétrazole (**7**), au dibenzoyl-3,6 dihydro *s*-tétrazine (**10**), aux acides β-benzoyl α-phénylacrylique *cis* et *trans*, à l'acétophénone, au benzoate de méthyle et à l'acide benzoïque. On considère que les pyrazoles **4**, **5** et **9** proviennent d'une réaction de **1** conduisant à l'α-méthoxyacétophénone dont l'anion réagirait par la suite avec **1**. On a obtenu des données en accord avec ces vues par une étude des produits formés lorsque l'on traite **1** avec une solution méthanolique de méthylate de sodium en présence de méthoxy-2 méthyl-4′ acétophénone. On considère que l'acétophénone provient d'une réduction de **1** par l'intermédiaire de la monohydrazone du phénylglyoxal-2 (**37**); la condensation de **1** avec l'ion énolate dérivé de l'acétophénone conduit alors au pyrazole **6** alors que la condensation de **1** avec **37** donne le tétrazole **7**.

[Traduit par le journal]

Treatment of a 0.1 *M* solution of α-diazoacetophenone (**1**) with 0.15 *M* potassium *tert*-butoxide in *tert*-butyl alcohol has been shown to give 5-benzoyl-2-phenacyltetrazole (**2**), a dimer of **1**, in good yield (1). The only other products formed are 2-phenacyltetrazole (**3**) and benzoic acid, which are considered to arise by cleavage of **2**.



2



3

In contrast, treatment of a 5 *M* solution of **1** in methanol with 7 *M* methanolic sodium methoxide has been found to give an exceedingly complex product mixture that includes the pyrazoles **4**–**6**, the tetrazole **7**, and the N_5 compound **8***a* or **8***b*, together with methyl benzoate and benzoic acid (2) (Table 1).

We now report on an investigation of the reaction of **1** and sodium methoxide in dilute solution that has shed further light on the reactions of α-diazo ketones with bases.[2]

Products and their Identification

The products obtained were compounds **4**–**7**, methyl benzoate and benzoic acid, and five

[1]For paper IX, see ref. 1.

[2]A preliminary study of the reaction of **1** with methanolic sodium methoxide of intermediate concentration has been carried out previously (3).

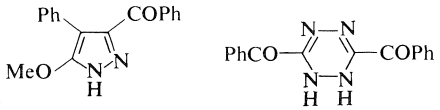
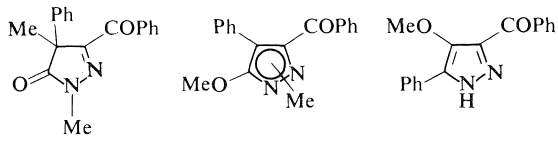
compounds not previously detected from the reaction in concentrated solution (Table 1). Although acetophenone was not isolated from the reaction in concentrated solution, it has been isolated from the reaction mixture obtained on treatment of **1** with aqueous sodium hydroxide (3).



9 **10**

11 **12**

The pyrazole **9** was identified by comparison with an authentic sample obtained, together with the dimethylation products **13** and **14**, by methylation of the sodium salt of **4** with methyl iodide in dimethyl sulfoxide. In order to determine whether the product mixtures from the reaction of **1** with sodium methoxide also contained **15**, the methyl ether of **5**, this was prepared by methylation of **5** with diazomethane. The pmr spectra of the neutral fractions from the reaction of **1** with sodium methoxide failed to show the presence of **15**.



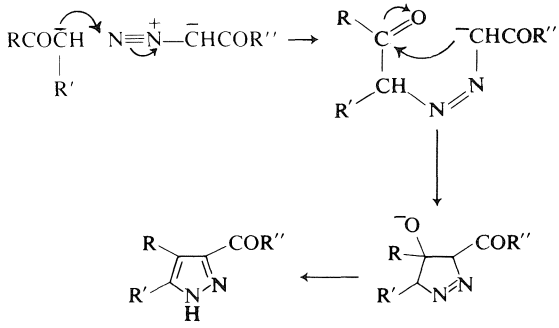
13 **14** **15**

The dihydrotetrazine **10**[3] has previously been obtained from **1** by treatment with potassium hydroxide in dimethyl sulfoxide (4). It was obtained in the present work in one run only, when a reaction of **1** was carried out with very dilute methanolic sodium methoxide and the reaction mixture became neutral during the course of the reaction, suggesting that it is a product of the reaction of **1** with methanolic sodium methoxide but is not normally observed because of its own base sensitivity (*vide infra*).

The lactol **11** of *cis*-β-benzoyl-α-phenylacrylic acid was identified by comparison with an authentic sample (5). The corresponding *trans* acid, **12**, was isolated as its methyl ester which was also identified by comparison with an authentic sample (5).

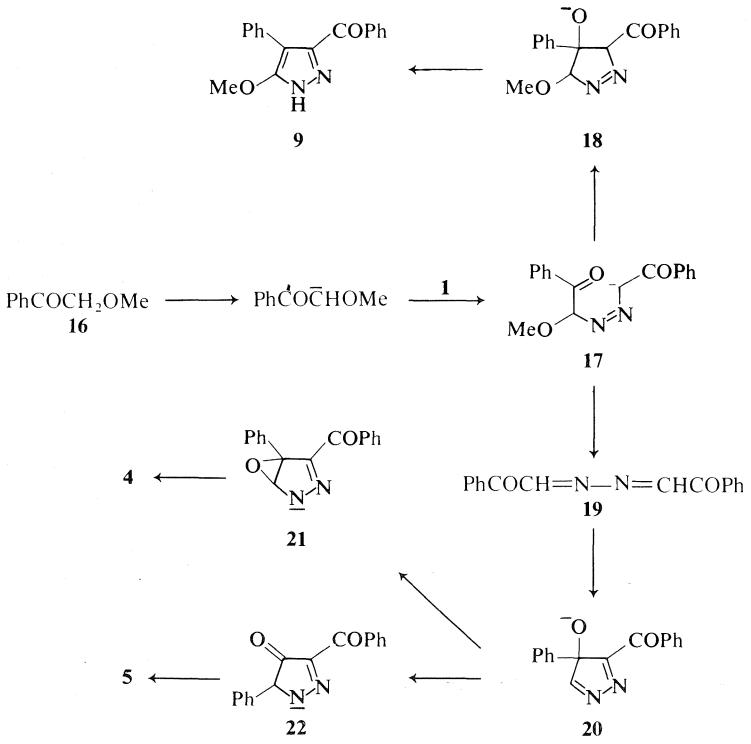
Formation of Pyrazoles

Pyrazoles are known to be formed on treatment of α-diazo carbonyl compounds with



SCHEME I

[3]This is either the 1,2- or 1,4-dihydro compound (4).



SCHEME 2

enolate ions, a reaction that can readily be interpreted as involving initial terminal addition (3) of the enolate ion to the α-diazo carbonyl compound, followed by aldol condensation and dehydration (*cf.* ref. 6) (Scheme 1).

The occurrence of acetophenone in the reaction mixture from **1** and methanolic sodium methoxide clearly suggests that the pyrazole **6** arises by the condensation of **1** with acetophenone as in Scheme 1, as has previously been suggested for the reaction in aqueous base (3).

The other pyrazoles formed, *i.e.*, **4**, **5**, and **9**, are all in a higher oxidation state than **6**, and their formation via Scheme 1 from **1** and an enolate ion in a higher oxidation state than that of acetophenone seems likely. In the case of the methoxypyrazole **9**,[4] the route in Scheme 1 could involve the condensation of **1** with the enolate ion of α-methoxyacetophenone (**16**)[5] to give **17**, and the conversion of this to **9** via **18** (Scheme 2). When **16** was added to the initial solution of **1** and methanolic sodium methoxide, the yield of **9** was considerably increased. Furthermore, there was an increase in the yields of the two hydroxypyrazoles **4** and **5**.[6] Thus the intermediacy of α-methoxyacetophenone is implicated in the formation of all three of the pyrazoles, **4**, **5**, and **9**. To account for this we propose that **17** is converted to the azine **19**, which undergoes base-catalyzed cyclization to **20**, which gives **4** and **5**, via **21** and **22**, respectively (Scheme 2).

These pathways together with the pathway via **18** to **9** account for the circumstance that, while both the 5-hydroxypyrazole **4** and the corresponding 5-methoxypyrazole **9** are formed, the 4-hydroxypyrazole **5** is not accompanied by the corresponding 4-methoxypyrazole, **15**.[7] Scheme 2 also accounts for the following observations made when 2-methoxy-4′-methyl-

[4]The observation that a 5-methoxypyrazole of type **9** is formed in the reaction of an α-diazo ketone with methanolic sodium methoxide was first made by Dr. A. L. Crowther in the case of α-diazopinacolone (P. Yates, A. L. Crowther, and P. A. Gilbert, unpublished results).

[5]The origin of α-methoxyacetophenone is discussed subsequently.

[6]We thank Dr. R. G. F. Giles for the original observation of this effect.

[7]The possibility that **9** and **15** were both formed but that **15** preferentially underwent further reaction was excluded by the observation that both **9** and **15** are stable under the reaction conditions.

acetophenone (**23**) was added to the initial solution of **1** and methanolic sodium methoxide. From the weak acid fraction was obtained a crystalline mixture of the hydroxypyrazoles **24** and **25**. The pmr spectrum of the mixture showed two overlapping singlets at δ 2.35 and 2.39 (11:9). Baeyer–Villiger oxidation of the mixture followed by hydrolysis gave a 1:1 mixture of the carboxylic acids **26** and **27**, together with a mixture of phenol and *p*-cresol (1:1). From the acid fraction of the original reaction mixture was obtained a mixture of the two hydroxypyrazoles **28** and **29**. The pmr spectrum of the

34

35

mixture showed two overlapping singlets at δ 2.23 and 2.30 (11:4). Baeyer–Villiger oxidation of the mixture followed by hydrolysis gave a mixture of carboxylic acids considered to be **30** and **31**, together with a mixture of phenol and *p*-cresol (2:1). From the neutral fraction of the original reaction mixture was obtained a single 5-methoxypyrazole, **32**; the presence of the isomeric 5-methoxypyrazole, **33**, could not be detected. The assignment of structure **32** to the methoxypyrazole is based on comparison of its pmr spectrum with the spectra of **9** and **15** and of the mixture of **32** and **33** obtained by methylation of the 11:4 mixture of hydroxypyrazoles **28** and **29** (see Table 2). These results are readily accommodated in terms of Scheme 2. Thus, the terminal adduct **34** formed from **1** and the anion of **23** can give the single 5-methoxypyrazole **32** and the azine **35**, which can give **24**, **25**, **28**, and **29** via two analogues of **20**.

Formation of N_4 Compounds and Other Products

5-Benzoyltetrazole (**7**) was isolated from the product mixtures formed on treatment of **1** with both concentrated and dilute methanolic sodium methoxide. Its structural relationship to 2-phenacyl-5-benzoyltetrazole (**2**) the major product from the reaction of **1** with potassium *tert*-butoxide in *tert*-butyl alcohol suggested that it might arise via cleavage of **2**. However, treatment of **2** with methanolic sodium methoxide led not to **7** but to 5-benzoyl-2-methyltetrazole (**36**). This is in interesting contrast to its reaction with potassium *tert*-butoxide and *tert*-butyl alcohol which gives 2-phenacyltetrazole (**3**) (1). Presumably cleavage to give **36** is inhibited in this case by enolate anion formation at the methylene group.

With the exclusion of **2** as the source of **7** in methanolic sodium methoxide, we propose that the formation of **7** involves base-catalyzed reaction of **1** with phenylglyoxal 2-monohydrazone (**37**), itself formed by reduction of **1** by methanolic sodium methoxide; the resulting intermediate, **38**, could then form **7** by cyclization to **39** followed by elimination of acetophenone (Scheme 3). The latter could also arise via Wolff–Kishner reduction of **37**. In these terms the formation of **7** requires that the base also be a reducing agent.

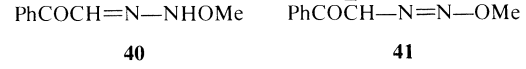
[b]First order approximation: J = 7.5 and 2 Hz.

The other type of N_4 product, **10**, has not been observed previously in the reaction of **1** with methanolic sodium methoxide; as mentioned above, this might be due to the fact that it usually reacts further under the basic reaction conditions. In order to investigate this possibility the reaction of **10** with dilute methanolic sodium methoxide was investigated. All of the products isolated were also obtained from the reaction of **1** with dilute methanolic sodium methoxide. However, the relative product yields suggest strongly that **10** is not a major intermediate in the reaction of **1** with sodium methoxide, nor a major source of compounds other than methyl benzoate in that reaction. This follows from the very much greater yield of methyl benzoate in the case of the reaction of **10** with sodium methoxide.

The cleavage product, methyl benzoate, could also arise by attack of methoxide ion on either **1** itself or on **40**, its adduct with methanol (*i.e.*, a protonation product of the terminal adduct **41**) (3). The formation of benzoic acid is attributable to hydrolysis of methyl benzoate by hydroxide ion produced from water formed, for example, in the formation of the pyrazoles **6** and **9**. The putative intermediate, α-methoxyacetophenone (**16**), could also arise from **41**; protonation of this on carbon would give **42**, which could give **16** either directly by loss of nitrogen or by a displacement reaction with methoxide ion. The adduct **42** could serve as a further source of methyl benzoate.



40 **41**

42

It is recognized that the mechanistic proposals made here are speculative; however, the multiplicity of the reactions involved makes it difficult to delineate definitively the origin of all the products, particularly since these may often arise by more than one pathway.[8]

[8]A discussion of some additional mechanistic proposals and ancillary experimental results are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Experimental

Solutions in organic solvents were dried over anhydrous magnesium sulfate. Chromatographic columns were packed in petroleum ether (bp 60–70 °C); the mixture to be separated was pre-absorbed on the column material and the resulting powder was placed as a thin band on top of the column. Melting points are uncorrected. Infrared spectra were recorded with chloroform as solvent, unless otherwise specified; pmr spectra were recorded with deuterochloroform as solvent. Known compounds were identified by mp and mixture mp determinations, and by spectroscopic and vpc comparison with authentic samples.

*Reaction of α-Diazoacetophenone (**1**) with Methanolic Sodium Methoxide*

(*i*) A solution of **1** (1.32 g, 9.0 mmol) in anhydrous methanolic sodium methoxide (0.4 *M*, 450 ml), was boiled under reflux for 5.5 h. The resulting mixture was separated into acid (soluble in aqueous 5% $NaHCO_3$), weak acid (soluble in aqueous 3% KOH), and neutral fractions. The *acid fraction* (0.40 g) was triturated with petroleum ether – ether (1:1) and the resulting pale yellow precipitate was filtered to give **4** (0.12 g, 11%), mp 246–248 °C. The filtrate was stripped of solvent and treated with an ethereal solution of diazomethane. Evaporation of solvent left a pale yellow oil whose pmr spectrum showed methyl benzoate (δ 3.90 (s)) to be the major component, accompanied by smaller amounts of the two *N*-methyl derivatives of 5-benzoyltetrazole (**7**) (δ 4.28 (s) and 4.40 (s)). In another run the residue obtained on removal of the solvent was examined by vpc (10 ft, 10% SE 30), and ir and pmr spectroscopy, which showed the presence of benzoic acid and **7**. The *weak acid fraction* (0.26 g) was treated with warm benzene to yield a pale brown precipitate of **5** (0.065 g, 6%), mp 206–208 °C. The *neutral fraction* (0.48 g) was chromatographed on alumina. Elution with ether – petroleum ether (4–10% v:v) gave a mixture of acetophenone (0.070 g, 7%) and methyl benzoate (0.010 g, 1%) as determined by vpc (SE 30). Unchanged α-diazoacetophenone (0.090 g) was eluted subsequently. Elution with ether – petroleum ether (10–25% v:v) afforded small amounts of unidentified products. Elution with methanol–ether (2% v:v) yielded 3-benzoyl-5-methoxy-4-phenylpyrazole (**9**) (0.050 g, 4%) as a yellow glass, which on crystallization from ether – petroleum ether gave yellow prisms, mp 143–144 °C.

(*ii*) A solution of **1** (1.00 g, 6.8 mmol) in anhydrous methanolic sodium methoxide (0.01 *M*, 17.5 ml) was boiled under reflux. An aliquot (2 ml), taken after a reaction time of 6.25 h, deposited on cooling in dry ice – methanol red-brown needles of **10** (0.005 g), mp 182–183 °C (lit. (4) mp 182–183 °C). After this reaction time the mixture was found to have p*H ca.* 6.5. A further amount of methanolic sodium methoxide was added to bring the concentration to 0.025 *M*. The mixture was boiled for a further 47 h, and then cooled (dry ice – ethanol). A further quantity of **10** (0.004 g), mp 179–181 °C, was deposited. The reaction mixture was separated into acid, weak acid, and neutral fractions; these were shown to contain **4**, benzoic acid, **7**, and α-diazoacetophenone.

(*iii*) To a boiling solution of methanolic sodium methoxide (0.4 *M*, 100 ml) was added dropwise over a 7 h period, a solution of **1** (2.92 g, 0.020 mol) in anhydrous methanol (100 ml). Heating was continued at 45–50 °C for a further 22 h. The *acid fraction* (0.90 g) was triturated with ether – petroleum ether (1:1) to give **4** (0.30 g, 11%), mp 246–248 °C. The filtrate was stripped of solvent, and the residue was chromatographed on silica gel. The first fraction was eluted with ether – petroleum ether (13–25% v:v) and afforded benzoic acid (0.07 g, 3%), mp 121–122 °C. Elution with ether – petroleum ether (25–35% v:v) yielded a pale yellow oil (0.28 g) that was a mixture. 5-Benzoyltetrazole (**7**) (0.075 g, 4%) was isolated by a combination of fractional crystallization and precipitation as its silver salt from a hot aqueous solution of the oil. On cooling the aqueous solution a cream solid precipitated, which on crystallization from benzene–cyclohexane gave the lactol form of *cis*-β-benzoyl-α-phenylacrylic acid (**11**) (0.15 g, 6%) as colorless plates, mp 122–123 °C (lit. (5) mp 123–124 °C). Methylation of **11** with an ethereal solution of diazomethane gave methyl *cis*-β-benzoyl-α-phenylacrylate as a viscous oil. The *weak acid* (0.60 g) and the *neutral fractions* (1.09 g) were shown to contain **5**, **7**, acetophenone, methyl benzoate, and unchanged α-diazoacetophenone as in (*i*).

(*iv*) A solution of α-diazoacetophenone (2.92 g) in anhydrous methanolic sodium methoxide (0.4 *M*, 200 ml) was boiled under reflux for 23.5 h. The *acid fraction* (0.48 g) was triturated with warm ether – petroleum ether (1:1), to give **4** (0.18 g, 7%), mp 245–247 °C. The filtrate was stripped of solvent, and the residue was treated with ethereal diazomethane. Removal of the ether left a viscous yellow oil, which was chromatographed on silica gel. The first fractions eluted with ether – petroleum ether (5% v:v) gave methyl benzoate. Elution with ether – petroleum ether (20% v:v) yielded the methyl ester of *trans*-β-benzoyl-α-phenylacrylic acid (**12**) (0.01 g) as a viscous oil that partially crystallized. Elution with ether – petroleum ether (25–30% v:v) gave the methyl ester of *cis*-β-benzoyl-α-phenylacrylic acid (**11**) (0.13 g) as a viscous pale yellow oil. The final fractions were eluted with ether – petroleum ether (30–35% v:v) to give 5-benzoyl-1-methyltetrazole (0.09 g) as a colorless oil that slowly crystallized. The *weak acid* (0.68 g) and *neutral fractions* (0.71 g) contained the same products as the corresponding fractions in *iii*. In another run with 0.2 *M* methanolic sodium methoxide and 0.2 *M* α-diazoacetophenone, 3-benzoyl-4-phenylpyrazole (**6**), mp 197–198 °C, was isolated from the neutral fraction.

*3-Benzoyl-5-methoxy-4-phenylpyrazole (**9**)*

To a stirred solution of the sodium salt of **4** (0.38 g) in dimethyl sulfoxide (5 ml) was added dropwise a solution of methyl iodide (0.30 g) in ether (5 ml). After addition was complete, stirring was continued for 0.5 h, the mixture was poured into water, and then extracted with ether. The ethereal extract was washed with aqueous 5% KOH and water, and dried. Evaporation of the ether left a viscous oil (0.24 g), which was chromatographed on alumina. Elution with ether – petroleum ether (10–15% v:v) afforded **13** as a pale yellow viscous oil (0.10 g); λ_{max} (CCl_4) 6.05, 7.60, 7.82, 9.40, 10.68, 10.86 μm; δ 3.87 (s, 3H), 4.00 (s, 3H), 7.0–7.4 (m, 8H), 7.73 (d of d, 2H). Elution with ether – petroleum ether (40–50% v:v) gave **14** as cream crystals (0.04 g); λ_{max} (CCl_4) 5.76, 6.05, 8.10, 9.85, 10.82, 11.10 μm; δ 1.95 (s, 3H), 3.52 (s, 3H), 7.25–7.6 (m, 8H), 8.13 (d of d, 2H). Elution with ether gave **9**

(0.05 g, 24%) which, after recrystallization from ether – petroleum ether, was obtained as pale yellow prisms, mp 145–146 °C; λ_{max} 3.00, 3.05–3.25, 6.09, 7.05, 7.70, 9.32, 9.75, 10.96 μm; δ 4.03 (s, 3H), 7.1–7.4 (m, 8H), 7.67 (d of d, 2H). *Anal.* calcd. for $C_{17}H_{14}N_2O_2$: C 73.36, H 5.07, N 10.07; found: C 73.19, H 5.15, N 9.97.

*3-Benzoyl-4-methoxy-5-phenylpyrazole (**15**)*

A solution of **5** (0.50 g, 1.9 mmol) in anhydrous ether was treated with an ethereal solution of diazomethane (10 ml, 2.56 mmol). The resulting mixture was stirred at 5–10 °C for 6 h and then allowed to stand at room temperature for a further 18 h. The reaction mixture was extracted with aqueous 3% KOH and the ethereal layer was separated and dried. Evaporation of the ether left a viscous colorless oil which was chromatographed on alumina. Elution with ether – petroleum ether gave small quantities of several unidentified compounds. Elution with methanol–ether (2% v:v) gave an oil that slowly crystallized. Recrystallization from benzene–cyclohexane afforded **15** (0.22 g, 42%) as colorless needles, mp 143–144.5 °C; λ_{max} 3.00, 3.15–3.40, 6.08, 7.28, 9.90, 11.00 μm; δ 3.60 (s, 3H), 7.3–7.5 (m, 6H), 7.8–8.1 (m, 4H). *Anal.* calcd. for $C_{17}H_{14}N_2O_2$: C 73.36, H 5.07, N 10.07; found: C 73.52, H 5.04, N 9.84.

Reaction of α-Diazoacetophenone with α-Methoxyacetophenone and Methanolic Sodium Methoxide

To a stirred solution of sodium methoxide in anhydrous methanol (5.5 *M*, 6.5 ml) was added dropwise a solution of α-diazoacetophenone (4.90 g, 0.034 mol) and α-methoxyacetophenone (4.70 g, 0.031 mol) in anhydrous methanol (5.5 ml). The mixture was kept at 0 °C during the addition and allowed to stand at room temperature for 1 h after completion of the addition. The *acid fraction* was treated with a little warm ether to give a precipitate of **4** (0.63 g, 7%)[9], mp 248–250 °C. The filtrate was stripped of solvent to give a pale yellow oil (0.25 g) that slowly crystallized. Its pmr and ir spectra showed that it consisted mainly of benzoic acid and **7**. The *weak acid fraction* was triturated with a small amount of hot benzene to give **5** (0.50 g, 5.5%)[9], mp 206–208 °C. The *neutral fraction* was obtained as a yellow-orange glass (5.7 g) that slowly crystallized on standing at room temperature for several days. Its pmr spectrum exhibited a singlet at δ 3.93 besides aromatic proton signals. It was chromatographed on silica gel. Elution with ether – petroleum ether mixtures (0–35% v:v) afforded some biphenyl (shown to be present as an impurity in the α-methoxyacetophenone used in this experiment), a small amount of methyl benzoate, and small quantities of yellow oils. Elution with ether – petroleum ether (40% v:v) gave **9** (2.20 g, 24%)[9] as a pale yellow glass that slowly crystallized. Recrystallization from ether – petroleum ether yielded pale yellow prisms, mp 145–146 °C.

*2-Methoxy-4′-methylacetophenone (**23**)*

A solution of *p*-tolylmagnesium bromide in anhydrous ether (350 ml) was prepared from magnesium (8.8 g) and *p*-bromotoluene (61.6 g). Methoxyacetonitrile (21.3 g) in anhydrous ether (50 ml) was slowly added to the cooled (ice–salt bath), well stirred Grignard solution and, after completion of the addition, the mixture was allowed to stand at room temperature for 2 h. The complex was decomposed by the addition of water (200 ml), cracked ice, and cold 12 *N* sulfuric acid (100 ml). The solution was extracted with ether, and the extract was dried and stripped of solvent to give a colorless liquid. Distillation gave **23** (32 g, 54%), bp 83–88 °C/0.15 torr (lit. (7) bp 127 °C/3.0 torr); λ_{max} (film) 5.90, 6.24, 8.10, 8.32, 8.85, 12.30 μm; δ 2.37 (s, 3H), 3.35 (s, 3H), 4.45 (s, 2H), 7.18 (d, 2H, J = 8 Hz), 7.80 (d, 2H, J = 8 Hz).

*Reaction of α-Diazoacetophenone with **23** and Methanolic Sodium Methoxide*

α-Diazoacetophenone (4.05 g, 0.028 mol) and **23** (4.50 g, 0.027 mol) in anhydrous methanol (5.5 ml) were added dropwise to a stirred solution of methanolic sodium methoxide (5.5 *M*, 6.5 ml), which was kept at 0 °C. After the addition the mixture was allowed to stand at room temperature for 1 h and then poured into water. The *acid fraction* (0.67 g) was triturated with warm ether – petroleum ether (1:1) to give a yellow solid (0.38 g), mp 195–207 °C, which could not be purified by recrystallization. Its pmr spectrum (DMSO-d_6) exhibited overlapping singlets at δ 2.23 and 2.30 (ratio 11:4) in addition to aromatic proton signals, assigned to 3-benzoyl-5-hydroxy-4-(*p*-tolyl)pyrazole (**28**) and 5-hydroxy-4-phenyl-3-(*p*-toluyl)pyrazole (**29**), respectively. The filtrate was evaporated to dryness and treated with an ethereal solution of diazomethane. The resulting yellow oil was shown to consist mainly of methyl benzoate and methyl *p*-toluate (major product) by pmr spectroscopy and vpc. The *weak acid fraction* (1.16 g) was digested with warm benzene and the resulting solution allowed to stand for several hours to give a yellow-brown solid (0.51 g), mp 191–194 °C. Its pmr spectrum showed overlapping singlets at δ 2.35 and 2.39 (ratio 11:9) in addition to aromatic proton signals, and these were assigned to 3-benzoyl-4-hydroxy-5-(*p*-tolyl)pyrazole (**24**) and 4-hydroxy-5-phenyl-(3-*p*-toluyl)pyrazole (**25**), respectively. The *neutral fraction* (4.92 g) was chromatographed on alumina. Elution with ether – petroleum ether (10% v:v) afforded a mixture of bi-*p*-tolyl and methyl benzoate; the former was present as an impurity in the starting material **23**. Elution with ether – petroleum ether (10–12% v:v) gave unchanged **23** (0.16 g). Elution with ether – petroleum ether (20–25% v:v) gave a yellow oil (1.44 g) that slowly crystallized. Recrystallization from ether–hexane afforded pale yellow prisms of 3-benzoyl-5-methoxy-4-(*p*-tolyl)pyrazole (**32**), mp 126–127 °C; λ_{max} 3.00, 3.20, 6.10, 6.72, 7.75, 9.30, 11.00 μm; δ 2.25 (s, 3H), 4.04 (s, 3H), 6.8–7.4 (m, 7H), 7.67 (d of d, 2H). *Anal.* calcd. for $C_{18}H_{16}N_2O_2$: C 73.95, H 5.52, N 9.58; found: C 74.01, H 5.47, N 9.38.

*Baeyer–Villiger Oxidation of the Mixture of **24** and **25***

To a solution of glacial acetic acid (2.0 ml) and concentrated H_2SO_4 (1.0 ml) was added the mixture of **24** and **25** (0.20 g). The solution was cooled to 0 °C, 40% peracetic acid (0.3 ml) was added, and the mixture was stirred at room temperature for 24 h. It was then poured into excess water to give a fawn solid; λ_{max} (Nujol) 5.85 μm. This was dissolved in aqueous KOH (10 ml) and the solution was boiled under reflux for 2 h. This was acidified and steam distilled. The distillate was acidified and extracted with several portions of ether. The extract was dried and stripped of solvent to give a colorless oil

[9]Calculated on the basis of the conversion of 1 mol of **1** to 1 mol of pyrazole.

(0.03 g) that possessed a distinct phenolic odor. Infrared and nmr spectroscopy and vpc analysis of the oil showed it to be a *ca.* 1:1 mixture of phenol and *p*-cresol. The steam involatile components of the above mixture were isolated by extraction with ether. The ethereal extract was dried and stripped of solvent to give a fawn solid (0.06 g); λ_{max} (Nujol) 3.0–4.8, 5.98, 8.05, 10.30, 12.15 μm; this ir spectrum was identical with that of a 1:1 mixture of 4-hydroxy-5-(*p*-tolyl)pyrazole-3-carboxylic acid (**26**) and 4-hydroxy-5-phenylpyrazole-3-carboxylic acid (**27**).

*4-Hydroxy-5-(p-tolyl)pyrazole-3-carboxylic Acid (**26**)*

To a stirred solution of anhydrous methanolic sodium methoxide (5 *M*, 20 ml) at room temperature was added dropwise a mixture of methyl *p*-tolylacetate (2.20 g, 13.4 mmol) and ethyl diazoacetate (1.60 g, 14.0 mmol). After addition was complete, the mixture was stirred for an additional 1 h. The reaction mixture was diluted with water (5 ml) and boiled under reflux for 2 h. The resulting dark-brown solution was neutralized with dilute HCl, poured into aqueous 5% $NaHCO_3$ (150 ml), and extracted with ether. The aqueous layer was acidified and extracted with several portions of ether. The ethereal extract was dried and stripped of solvent to give an orange-brown gum, which after several washings with boiling cyclohexane solidified to an orange-brown solid (0.95 g), which was chromatographed on silica gel. Elution with ether – petroleum ether (30% v:v) afforded **26** (0.50 g, 17%) as a cream solid, mp 221–222 °C (dec.); λ_{max} (Nujol) 3.04, 3.0–4.8, 6.00, 8.05, 10.30, 12.15 μm. *Anal.* calcd. for $C_{11}H_{10}N_2O_3$: C 60.54, H 4.62, N 12.84; found: C 60.53, H 4.68, N 12.79.

*4-Hydroxy-5-phenylpyrazole-3-carboxylic Acid (**27**)*

Compound **27** was prepared from anhydrous methanolic sodium methoxide (5 *M*, 20 ml), methyl phenylacetate (3.00 g, 20.0 mmol), and ethyl diazoacetate (2.30 g, 20.0 mmol) by the procedure described above for the preparation of **26**. The orange-brown crude solid product (1.50 g) was chromatographed on silica gel; elution with ether – petroleum ether (60–80% v:v) gave **27** (0.53 g, 13%) as a cream solid, mp 212–213 °C (dec.); λ_{max} (Nujol) 3.00, 3.0–4.8, 5.98, 10.30 μm. *Anal.* calcd. for $C_{10}H_8N_2O_3$: C 58.82, H 3.95, N 13.72; found: C 58.96, H 4.13, N 13.60.

*Baeyer–Villiger Oxidation of the Mixture of **28** and **29***

The mixture of **28** and **29** (0.15 g) was oxidized with glacial acetic acid (2 ml), concentrated H_2SO_4 (1 ml), and peracetic acid (0.3 ml) by a procedure similar to that described above. When poured into water, the reaction mixture gave a fawn precipitate, which was dried; λ_{max} (Nujol) 3.08, 3.24 (br), 5.80, 7.94, 8.34 μm. This was subjected to alkaline hydrolysis followed by steam distillation as described above. The steam distillate was acidified and extracted with ether. The ethereal extract was dried and stripped of solvent to give a colorless oil (0.025 g) with a distinct phenolic odor. Infrared and pmr spectroscopy and vpc showed the oil to be a 2:1 mixture of phenol and *p*-cresol. The steam involatile constituents were obtained as a fawn solid (0.055 g); λ_{max} 3–4, 5.90 μm. This is considered to be a mixture of **30** and **31**, but attempts to separate the components were unsuccessful.

*Methylation of the Mixture of **28** and **29***

Sodium methoxide (0.019 g, 0.36 mmol) was added to a solution of the mixture of **28** and **29** (0.10 g, 0.36 mmol) in dimethyl sulfoxide (5 ml). The resulting orange solution was treated dropwise with a solution of methyl iodide (0.051 g, 0.36 mmol) in dimethyl sulfoxide (2 ml). The mixture was stirred at room temperature for 2 h, when the orange color had faded to a pale yellow color. It was poured into aqueous 3% KOH and extracted with ether. The ethereal layer was washed with several portions of water, dried, and stripped of solvent to give a mixture of **32** and **33** as a viscous oil (0.04 g) that slowly crystallized (mp 80–90 °C); δ 2.25 and 2.28 (overlapping s (11:4), 3H), 4.03 (s, 3H), 6.9–7.7 (m, 9H).

*Reaction of **2** with Methanolic Sodium Methoxide*

Compound **2** (0.100 g) was dissolved in anhydrous methanolic sodium methoxide (0.3 *M*, 20 ml), and the solution was boiled under reflux for 3.5 h. The reaction mixture was poured into water, and the aqueous solution was neutralized and extracted with ether. The ethereal extract was dried and stripped of solvent to give a colorless oil (0.084 g); δ 3.90 (s), 4.48 (s) and 6.30 (s) (ratio 7:11:12), 7.5–7.8 (m), 8.00 (d of d) and 8.37 (d of d) (ratio 5:8). The oil was chromatographed on silica gel. Elution with ether – petroleum ether (5% v:v) gave methyl benzoate (0.01 g, 20%). Elution with ether – petroleum ether (40–50% v:v) afforded **36** (0.02 g, 30%) as a colorless oil; after crystallization from ether – petroleum ether this had mp 41–43 °C (lit. (8) mp 45.4–46 °C); λ_{max} 6.00, 6.30, 7.35, 10.90 μm; δ 4.48 (s, 3H), 7.5–7.7 (m, 3H), 8.37 (d of d, 2H). The final fraction from the column was eluted with ether – petroleum ether (50% v:v) and gave unchanged **2** (0.04 g).

Isotope effect studies of the decomposition of 2-propanol on hafnium(IV) oxide

IAN M. HOODLESS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received July 6, 1976

IAN M. HOODLESS. Can. J. Chem. **55**, 153 (1977).

The catalytic decomposition of 2-propanol on hafnium dioxide has been investigated over the temperature range 355–397 °C by a micropulse reactor technique. The major reaction is one of dehydration to propene but dehydrogenation also occurs to a small extent. Isotope effect measurements with deuterio-2-propanols indicate that the rate-limiting step in dehydration involves cleavage of the β-carbon–hydrogen while in the dehydrogenation reaction it is cleavage of the α-carbon–hydrogen bond.

IAN M. HOODLESS. Can. J. Chem. **55**, 153 (1977).

On a étudié, à des températures allant de 355–397 °C et utilisant une technique de réacteur micropulsé, la décomposition catalytique du propanol-2 sur le dioxyde d'hafnium. La réaction principale conduit au propène par déshydratation; il y a toutefois une petite quantité de déshydrogénation. Des mesures d'effets isotopiques à l'aide de deutériopropanols-2 indiquent que l'étape déterminante dans la déshydratation implique le bris du lien carbone-β hydrogène alors que dans la réaction de déshydrogénation, l'étape déterminante implique le bris du lien carbone-α hydrogène.

[Traduit par le journal]

Introduction

The mechanism of the catalytic decomposition of secondary alcohols on metal oxide surfaces has been the subject of numerous studies. Dehydration and dehydrogenation are the predominant modes of decomposition but there is still some controversy in regard to the identification of the rate-determining step in these reactions. Desorption of one of the products, the ketone in the case of dehydrogenation and water in the case of dehydration, has been proposed by some workers as the rate-controlling stage while others favour the surface reaction of the adsorbed alcohol as rate controlling (1). One method of investigation of the rate-determining stage in a reaction is by kinetic isotope effect measurements; the present paper describes the application of this method to the investigation of 2-propanol decomposition on a HfO_2 catalyst. HfO_2 is an insulator oxide and previous work (2) has indicated that it catalyses both the dehydration and dehydrogenation of 2-propanol.

Experimental

The decomposition of 2-propanol was investigated by a micropulse reactor technique. The reactor was a 10 mm diameter Pyrex-glass tube containing the powdered catalyst mounted on a sintered glass disc sealed across the tube. Pulses of the alcohol (2 μl each) were injected into a preheated helium carrier-gas stream and passed over the catalyst; the reaction products and unreacted alcohol emerging from the reactor were collected in a trap, cooled with liquid nitrogen, before being admitted to a Pye series 104 gas chromatograph. Quantitative analysis for 2-propanol, acetone, and propene was carried out using a 6 ft column of 10% Carbowax 20M on Chromosorb G at 85 °C and a katharometer as detector. A trapping time of 4 min was employed in all the experiments; tests in which the trapping time was increased by a factor of six did not lead to an increased recovery of products or the alcohol. The general procedure was that at a particular reaction temperature the catalyst would be subjected to approximately twenty pulses of the alcohol; typically pulses 1–4 would be 2-propanol, pulses 5–7, a deuterio-alcohol, pulses 8–10, 2-propanol and so on. The time interval between pulses was approximately 15 min. On the basis of the results over the whole temperature range the mean error in the estimation of propene is 10%, while that for acetone is 13%.

Materials

The catalyst samples were HfO_2 (special grade, Alfa Inorganics Incorporated) and had a surface area of approximately 0.4 $m^2\ g^{-1}$, as measured by the BET method using krypton as the adsorbate. Prior to any alcohol pulses the catalysts were conditioned in the reactor by annealing at 500 °C for 4 h in the helium carrier-gas stream. The reactants were Spectranalyzed 2-propanol (Fisher Scientific Company) and the deuterio-alcohols (Merck, Sharp and Dohme); 2-propanol-d_1 ($(CH_3)_2CHOD$) and 2-propanol-d_6 ($(CD_3)_2CHOH$) had a minimum isotopic purity of 99 atom% D while for 2-propanol-2d_1 ($(CH_3)_2CDOH$) it was 98 atom% D.

Results

The decomposition of 2-propanol was investigated over the temperature range 355 to 397 °C. The predominant reaction was dehydration of the alcohol to propene; small amounts of acetone and propane were also formed. In comparative experiments over the same temperature range but in the absence of the catalyst, no decomposition of the alcohol was detected.

The kinetics of the dehydration reaction were briefly examined on four samples of the catalyst and with varying reactant–catalyst contact times. Plots of conversion to propene against reciprocal space velocity obtained by varying the amount of catalyst at a constant flow rate (Fig. 1) or by varying the carrier-gas flow rate (Fig. 2) are shown. The results are consistent with zero-order kinetics, which have frequently been reported (1*c*) for this type of reaction. Furthermore, since the curves pass through the origin, product desorption is unlikely to be the rate-controlling process (3). In independent experiments we have shown that water does inhibit the reaction; injections of 2 μl of water on to the catalyst prior to the alcohol injections reduced the subsequent propene production only with the first alcohol pulse. Apparently the time interval between alcohol injections is sufficient to permit the desorption of water from the catalyst at these reaction temperatures. The limited temperature range investigated does not permit accurate evaluation of the activation energy for the dehydration reaction but the present results yield a value of 32 kcal mol^{-1}. The extent of conversion to acetone is too small to enable identification of the kinetics or the determination of the activation energy for this reaction.

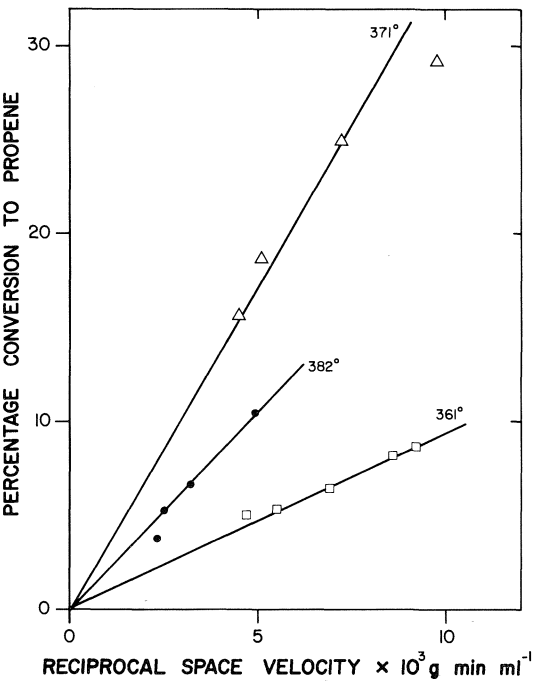

FIG. 2. Dehydration of 2-propanol over HfO_2. Space velocity was varied by flow rate: □, catalyst wt. = 0.42 g; ●, catalyst wt. = 0.166 g; △ (1 μl alcohol injections), catalyst wt. = 0.338 g.

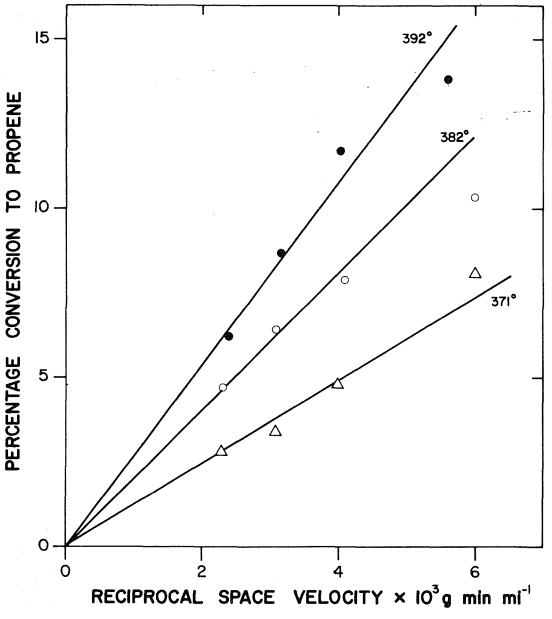

FIG. 1. Dehydration of 2-propanol over HfO_2. Space velocity was varied by catalyst weights (0.166 g, 0.230 g, 0.284 g, and 0.42 g).

Substitution of deuterium for hydrogen leads to significant changes in the degree of conversion of alcohol. Some results for one catalyst sample are given in Table 1 and a more complete set of results for two catalyst samples is shown in Fig. 3 as a plot of the ratio of the fractional conversions of the alcohol and deuterio-alcohols as a function of temperature. With 2-propanol-d_6 the propene yield is reduced while the acetone yield is reduced with 2-propanol-2d_1 as the reactant; the substitution of deuterium in the hydroxyl group does not appear to affect

the rate of either the dehydration or the dehydrogenation reactions.

Discussion

The present work has shown that there is a significant kinetic isotope effect in the production of propene when there is deuterium substitution at the β-hydrogens of the alcohol and in the production of acetone when the deuterium substitution is at the α-hydrogen. These observations rule out desorption of acetone in the case of dehydrogenation and desorption of water in the case of dehydration as being the rate-determining steps in the reactions under the present experimental conditions. The magnitude of the isotope effect for the acetone formation compares favourably with some recent studies of the same reaction on a predominantly dehydrogenating catalyst. Nondek and Sedláček (6) have compared the rate constants for the reaction of 2-propanol, 2-propanol-d_1, and 2-propanol-2d_1 on a chromia catalyst. With 2-propanol-2d_1 and a reaction temperature of 350 °C they obtained an isotope effect of 1.94 which compares with a value of 2.1_4 obtained by extrapolation of the present results. As with the present work, substitution of deuterium in the hydroxyl group had no significant influence on the reaction rate. This observation contrasts with that obtained using molten indium as a catalyst for 2-propanol dehydrogenation; at a reaction temperature of 460 °C substitution of deuterium in the hydroxyl group gives rise to a significant isotope effect (7). With a basic oxide transfer of the hydrogen, presumably as a proton, from the hydroxyl group to the catalyst would more easily be achieved and hence the rate-limiting step would be fission of the α-carbon–hydrogen bond.

The isotope effect observed in formation of propene from 2-propanol-d_6 is somewhat unusual in that, over the temperature range under investigation, it appears to be temperature independent; a value of 1.5_2 is obtained for the magnitude of the effect. A simplified model (8) for the calculation of isotope effects gives

$$[1]\quad \frac{k_H}{k_D} = \left(\frac{m_D}{m_H}\right)^{1/2} \frac{h\nu_D}{h\nu_H} \times e^{(h\nu_H - h\nu_D)/2RT} \frac{1 - e^{-h\nu_H/RT}}{1 - e^{-h\nu_D/RT}}$$

where k_H/k_D is the kinetic isotope effect, m_H and m_D are the reduced masses of the normal and deuterated substrates and ν_H and ν_D are the frequencies of the stretching vibrations of the C—H and C—D bonds undergoing reaction. The model assumes that the C—H and C—D bonds in question are completely broken in the activated complex. At moderate temperatures eq. 1 can be approximated to

$$[2]\quad \frac{k_H}{k_D} = e^{(h\nu_H - h\nu_D)/2RT}$$

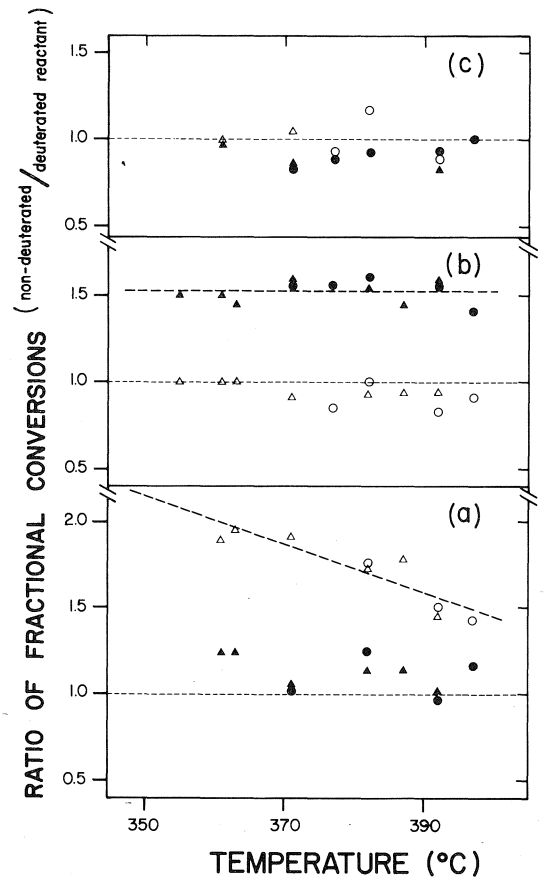

FIG. 3. Isotope effect (fractional conversion of 2-propanol/fractional conversion of deuterated 2-propanol) as a function of temperature for decomposition of 2-propanol; (*a*) 2-propanol-2d_1, (*b*) 2-propanol-d_6, (*c*) 2-propanol-d_1. Shaded symbols are for conversion to propene and open symbols for conversion to acetone; ▲/△, catalyst wt. = 0.42 g: ●/○, catalyst wt. = 0.23 g.

Comparison of the ir spectra of 2-propanol and 2-propanol-d_6 shows that the insertion of deuterium in the methyl group reduces its C—H stretching frequencies by 738 cm^{-1}. Substitution of this value in eq. 2 gives a value of 2.26 for the isotope effect at a reaction temperature of 375 °C and the decrease in the value of k_H/k_D over the interval 350–400 °C is less than 4%. Such a small temperature dependence could be obscured by errors in the experimental determination of the isotope effect. Because of the model employed, the values from eq. 3 correspond to a maximum possible isotope effect and the relatively low value obtained in the present work could indicate incomplete bond fission in the transition state.

The mechanism of the dehydration of alcohols on oxides, particularly alumina, has been extensively investigated and Pines and Manassen (9) have proposed that tertiary alcohols are dehydrated via a carbonium ion mechanism while primary and secondary alcohols are dehydrated via a concerted mechanism. In the latter case a transition state involving two-point attachment of the alcohol to the catalyst surface would be anticipated and the isotope effect would be lower than that predicted by eq. 3. The transition state would involve the weakening of the C_α—O and C_β—H bonds of the alcohol and the rate and extent of this bond loosening is important in identifying the detailed reaction mechanism. If the weakening of the C_α—O and C_β—H bonds proceeds to approximately equal extents in the transition state an E2-like mechanism applies, while a marked weakening of only one of the bonds in the transition state is characteristic of an E1-like mechanism. This aspect of the reaction mechanism has been investigated by Knözinger and co-workers (4, 5, 10) using isotope effect measurements. They conclude that with increasing reaction temperature there is a trend from an E2- to an E1-like mechanism. A similar trend is observed with increasing acidic nature of the catalyst. In one such study the dehydration of 2-propanol, 2-propanol-d_1, and 2-propanol-d_6 was investigated on some oxide catalysts at a reaction temperature of 300 °C (5). Substitution of deuterium in the hydroxyl group led to an increase in the isotope effect from 1.01 to 1.47 for the catalyst sequence Al_2O_3, ZrO_2, TiO_2, SiO_2 while the reverse trend from an isotope effect of 1.44 to 1.04 was observed for deuterium substitution at the β-carbon. Comparison of this study with the present results suggests that the dehydration reaction on HfO_2 occurs by a predominantly E2-type mechanism.

Analysis of heat capacities for weak electrolytes (or 'almost strong' electrolytes) in terms of the various solute species is shown to require allowance for the thermal effects associated with the shift of the association or dissociation equilibrium when the temperature changes during a calorimetric measurement. This shift of equilibrium state is related to changes in the equilibrium constant and activity coefficient with temperature, as expressed by thermodynamic equations we have derived. These equations have been applied to aqueous $MgSO_4$ and HIO_3 to obtain the contributions of the solute species to the apparent molal heat capacities, which are then analyzed to yield heat capacities of $MgSO_4$ (aq, undiss.) and HIO_3 (aq, undiss.) and ΔC_p^0 values for the association reactions of the ions to form these species.

EARL M. WOOLLEY et LOREN G. HEPLER. Can. J. Chem. **55**, 158 (1977).

L'analyse des capacités calorifiques des électrolytes faibles (ou des électrolytes presque forts) en termes des diverses espèces solutées démontre que l'on doit faire appel à des facteurs thermiques associés avec le déplacement de l'équilibre d'association ou de dissociation quand la température change durant une mesure calorimétrique. Ce déplacement de l'état d'équilibre est relié à des changements, avec la température, de la constante d'équilibre et de coefficient d'activité tel qu'exprimés par les équations thermodynamiques que nous avons dérivés. On a appliqué ces équations au $MgSO_4$ et HIO_3 en solutions aqueuses pour obtenir les contributions des espèces solutées aux capacités calorifiques molales apparentes qui ont ensuite été analysées pour obtenir les capacités calorifiques de $MgSO_4$ (aqueux et non-dissocié) et de HIO_3 (aqueux et non-dissocié) et les valeurs de ΔC_p^0 pour les réactions d'association des ions pour former ces espèces.

[Traduit par le journal]

Introduction

It has been known for a long time that heat capacities are useful or even essential for various important thermodynamic calculations. Also, it has gradually become apparent that theoretical analysis of heat capacities can lead to knowledge of the microscopic properties of various systems. For specific applications of these generalities to solutions, the quantities that are usually desired are the partial molal heat capacities of solute species at infinite dilution. In principle, these desired partial molal heat capacities can be obtained from results of heat capacity measurements on solutions of finite concentration, with results of the measurements expressed as apparent molal heat capacities, which are then extrapolated to infinite dilution.

There are no special problems associated with data treatment for nonelectrolytes or for those electrolytes that are completely dissociated in the usual moderately dilute concentration range of the heat capacity measurements. But there are significant unresolved problems in the treatment of experimental results for weak electrolytes or for 'almost strong' electrolytes that are partly associated in the concentration range of the heat capacity measurements. In this paper we show how to analyze measured heat capacities (expressed as apparent molal heat capacities) to obtain heat capacities of the undissociated species and the sum of the heat capacities of the ions. We illustrate the method by application to heat capacities for aqueous magnesium sulfate and iodic acid at 298 K, followed by brief discussion of other systems.

Method of Data Analysis and Results

We are here concerned with analysis of heat capacities of solutions in which there is an equilibrium between ions and a neutral species as in

[1] $$M^{n+}(aq) + X^{n-}(aq) \rightleftharpoons MX(aq, undiss.)$$

[1]On leave from Department of Chemistry, Brigham Young University, Provo, Utah, U.S.A.

The measured heat capacities are to be analyzed in terms of contributions from the various solute species, partly along the lines previously described by Perron, Desnoyers, and Millero (1). It is also necessary to consider the thermal effects associated with the shift of the equilibrium represented by equation 1 when the temperature increases during a measurement of heat capacity. This shift of equilibrium state is related to the change in the equilibrium constant with temperature and also to the change of activity coefficient with temperature.

Letting $C_p^{\,s}$ and $C_p^{\,w}$ represent the heat capacity of a solution of molality m that contains 1 kg of water and the heat capacity of 1 kg of pure water, respectively, we express the experimental apparent molal heat capacity ϕ_C^{exp} as

$$[2] \qquad \phi_C^{exp} = (C_p^{\,s} - C_p^{\,w})/m$$

The heat capacity of a solution that contains $M^{n+}(aq)$, $X^{n-}(aq)$, and MX(aq, undiss.) in equilibrium with each other can be expressed as

$$[3] \qquad C_p^{\,s} = (dH_{sp}/dT) + (dH_r/dT)$$

in which subscripts sp and r indicate contributions to the total enthalpy from the solute *sp*ecies (and their interactions with solvent and each other) and from the *r*eaction represented by eq. 1. Combination of eqs. 2 and 3 leads to

$$[4] \quad \phi_C^{exp} = [(dH_{sp}/dT) + (dH_r/dT) - C_p^{\,w}]/m$$

We now define the contribution to the apparent molal heat capacity from the solute species as

$$[5] \qquad \phi_C^{sp} = [(dH_{sp}/dT) - C_p^{\,w}]/m$$

and combine with eq. 4 to obtain

$$[6] \qquad \phi_C^{sp} = \phi_C^{exp} - [(dH_r/dT)/m]$$

We shall later express ϕ_C^{sp} as a sum of contributions from the various solute species and thence obtain some desired partial molal heat capacities, but first we evaluate (dH_r/dT) so that we can obtain ϕ_C^{sp} values from the experimental results represented here by ϕ_C^{exp}.

The thermodynamic equilibrium constant for the reaction represented by eq. 1 is

$$[7] \qquad K_f = a_{MX}/a_M a_X$$

in which we have omitted charges on M^{n+} and X^{n-}. This equilibrium constant can also be expressed in terms of the fraction of ions associated, the mean activity coefficient of free ions, and the activity coefficient of undissociated MX (represented by α, $\gamma_\pm^{\,i}$, and γ^u, respectively):

$$[8] \qquad K_f = \alpha\gamma^u/(1 - \alpha)^2 m(\gamma_\pm^{\,i})^2$$

We take the activity coefficient of the neutral MX to be unity and express the activity coefficient of the ions in terms of the stoichiometric (experimental) mean activity coefficient ($\gamma_\pm^{\,st}$) as

$$[9] \qquad \gamma_\pm^{\,i} = \gamma_\pm^{\,st}/(1 - \alpha)$$

to obtain

$$[10] \qquad K_f = \alpha/m(\gamma_\pm^{\,st})^2$$

and thence

$$[11] \qquad \alpha = K_f m(\gamma_\pm^{\,st})^2$$

Differentiation of α with respect to temperature (at constant molality) leads to

$$[12] \quad d\alpha/dT = 2K_f m(\gamma_\pm^{\,st})^2(d \ln \gamma_\pm^{\,st}/dT) + m(\gamma_\pm^{\,st})^2 K_f(d \ln K_f/dT)$$

We now substitute $-\bar{L}_2/2RT^2$ for $d \ln \gamma_\pm^{\,st}/dT$ and $\Delta H_r^{\,0}/RT^2$ for $d \ln K_f/dT$ to obtain

$$[13] \quad d\alpha/dT = K_f m(\gamma_\pm^{\,st})^2(\Delta H_r^{\,0} - \bar{L}_2)/RT^2 = \alpha(\Delta H_r^{\,0} - \bar{L}_2)/RT^2$$

The quantity (dH_r/dT) in eq. 6 can be expressed as

$$[14] \quad dH_r/dT = (dH_r/d\alpha m)(d\alpha m/dT) = m\Delta H_r(d\alpha/dT)$$

in which ΔH_r represents the molar enthalpy of the association reaction. Combination of eqs. 13 and 14 with 6 now leads to

$$[15] \quad \phi_C^{sp} = \phi_C^{exp} - m\Delta H_r K_f(\gamma_\pm^{\,st})^2 \times (\Delta H_r^{\,0} - \bar{L}_2)/RT^2 = \phi_C^{exp} - \alpha\Delta H_r(\Delta H_r^{\,0} - \bar{L}_2)/RT^2$$

Note that ΔH_r represents the enthalpy of the association reaction at the molality of the heat capacity measurement while $\Delta H_r^{\,0}$ represents the standard state (infinite dilution) enthalpy of the same reaction. Our procedure for obtaining ΔH_r values from $\Delta H_r^{\,0}$ and other information is given in Appendix I.

Now that we have eq. 15 to permit evaluation of ϕ_C^{sp} from experimental results expressed as ϕ_C^{exp} at various molalities, we can proceed to relate ϕ_C^{sp} to ϕ_C values for the various solute species as follows.

The contribution of electrically neutral MX (aq, undiss.) to ϕ_C^{sp} is represented by $\phi_{C(MX)}$, an initially unknown quantity that is taken to be independent of concentration. Similarly, the sum of the contributions of $M^{n+}(aq)$ and $X^{n-}(aq)$ to ϕ_C^{sp} is represented by $\phi_{C(M^{n+},X^{n-})}$. It is now possible to express ϕ_C^{sp} in terms of these quantities and α as

$$[16]\quad \phi_C^{sp} = \alpha\phi_{C(MX)} + (1-\alpha)\phi_{C(M^{n+},X^{n-})}$$

Extended Debye–Hückel theory leads to

$$[17]\quad \phi_{C(M^{n+},X^{n-})} = \phi^0_{C(M^{n+},X^{n-})} + A_C[(1-\alpha)m]^{1/2} + B_C(1-\alpha)m$$

in which A_C is known and B_C is an empirical parameter. Substitution of eq. 17 in eq. 16 and rearrangement leads to

$$[18]\quad \left[\frac{\phi_C^{sp} - (1-\alpha)\phi^0_{C(M^{n+},X^{n-})} - (1-\alpha)^{3/2}A_C m^{1/2}}{\alpha}\right] = \phi_{C(MX)} + B_C\left[\frac{(1-\alpha)^2 m}{\alpha}\right]$$

A graph of the term in brackets on the left side of this equation *vs*, the term in brackets on the right side should lead to a straight line. The intercept of this line will give us the desired value of $\phi_{C(MX)}$ while the slope will give the parameter B_C that is of no immediate interest to us.

To make use of eq. 18, we must have a value of $\phi^0_{C(M^{n+},X^{n-})}$. Because we are here concerned with solutes that are incompletely dissociated into $M^{n+}(aq)$ and $X^{n-}(aq)$ in the concentration range of the heat capacity measurements, we cannot obtain the desired $\phi^0_{C(M^{n+},X^{n-})}$ values by straightforward extrapolation of ϕ_C^{exp} (or even ϕ_C^{sp}) to zero concentration. Instead, we make use of heat capacity results for other electrolytes involving M^{n+} and X^{n-} ions whose heat capacities can be extrapolated to zero concentration without troublesome complications due to association or dissociation reactions. We illustrate this procedure as follows for both magnesium sulfate and iodic acid.

Combination of ϕ_C^0 values for aqueous $MgCl_2$ (2), NaCl (2, 3), and Na_2SO_4 (2, 4) and similar combination of ϕ_C^0 values for $MgCl_2$ (2), KCl (2, 3), and K_2SO_4 (2) lead to $\phi^0_{C(Mg^{2+},SO_4^{2-})} = -293$ J K^{-1} mol^{-1}. Similarly, combinations of ϕ_C^0 values for aqueous (HCl (3), KCl (2, 3), KIO_3 (4)) and (HBr (3), KBr (2, 3), KIO_3 (4)) lead to $\phi^0_{C(H^+,IO_3^-)} = -74$ J K^{-1} mol^{-1}.

For further specific application of our data treatment procedure to magnesium sulfate, we use the following auxiliary thermodynamic quantities. Sillén and Martell (5) and Pitzer (6) have reviewed various evaluations of K_f; we select $K_f = 200$. Sillén (5), Larson (7), and Leung and Millero (8) have all reported results of various evaluations of ΔH_r^0; we select $\Delta H_r^0 = 1.2$ kcal mol^{-1} = 5.0 kJ mol^{-1}. Stoichiometric activity coefficients from Pitzer (6) and from Millero and Masterton (9) are in good agreement with each other. Self-consistent heats of dilution and related quantities (ϕ_L^{exp} and $\bar{L}_2$) are from ref. 10 and Harned and Owen (11). We have used results of our measurements (4) of heat capacities (expressed as ϕ_C^{exp}) of aqueous magnesium sulfate.

A graph for magnesium sulfate based on eq. 18 (also using eqs. 15 and I-8) is shown in Fig. 1, from which we obtain $\phi^0_{C(MgSO_4)} = -168$ J K^{-1} mol^{-1} (= −40 cal K^{-1} mol^{-1}). We estimate that the *total* uncertainty in this value is about ±15 J K^{-1} mol^{-1} or ±4 cal K^{-1} mol^{-1}. Combination of this $\phi^0_{C(MgSO_4)}$ for undissociated $MgSO_4$ with $\phi^0_{C(Mg^{2+},SO_4^{2-})} = -293$ J K^{-1} mol^{-1} cited earlier leads to $\Delta C_p^0 = 125$ J K^{-1}

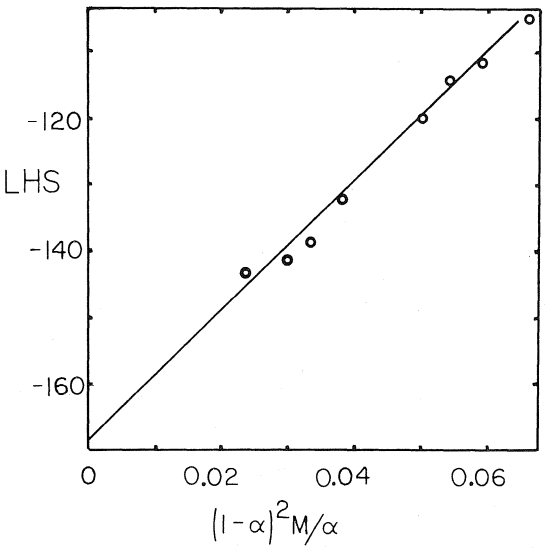

FIG. 1. Plot of the left hand side of eq. 18 for $MgSO_4$, yielding $\phi^0_{C(MgSO_4)} = -168$ J K^{-1} mol^{-1} and $B_C = 930$.

mol^{-1} (= 30 cal K^{-1} mol^{-1}) for the association reaction represented by eq. 1.

Several years ago Helgeson (12) and Marshall (13) carefully analyzed equilibrium results to obtain information about this ΔC_p^0. Helgeson (12) reported ΔC_p^0 = 19 cal K^{-1} mol^{-1} as an average value for a wide temperature range, while Marshall (13) reported ΔC_p^0 = 3 cal K^{-1} mol^{-1} for 25 °C and ΔC_p^0 = 25 cal K^{-1} mol^{-1} as an average value for the temperature range 0–200 °C. Uncertainties in all of these values based on d ln $K/dT = \Delta H^0/RT^2$ and $d\Delta H^0/dT = \Delta C_p^0$ are large.

More recently, Perron *et al.* (1) have reported ΔC_p^0 = 85 J K^{-1} mol^{-1} for the association reaction represented by eq. 1. Because our eq. 15 had not yet been derived, they made no distinction between ϕ_C^{exp} and ϕ_C^{sp}. Furthermore, there appear to be inconsistencies between $\phi^0_{C(Mg^{2+},SO_4^{2-})}$ values used in their eqs. 9–13.

For iodic acid (HIO_3) we use K(ionization) = 0.157 and thence K_f = 1/0.157 = 6.37 from the results of Pethybridge and Prue (14), from whom we also obtain activity coefficients. Further activity coefficients have been based on the work of Goldman, Bates, and Robinson (15). For the enthalpy of ionization we have ΔH^0_{ioniz} = −2.4 kcal mol^{-1} from earlier reviews (16) and therefore use ΔH_r^0 = 2.4 kcal mol (= 10.0 kJ mol^{-1}). Because there are no reliable ϕ_L^{exp} values for aqueous iodic acid known to us, we use eq. I-5 with ϕ_L^i based on the Debye–Hückel theory and the ion size parameter from Pethybridge and Prue (14) to obtain the connection between ΔH_r^0 and ΔH_r values and the $\bar{L}_2$ values needed for application of eq. 15 to ϕ_C^{exp} values (4) to obtain ϕ_C^{sp} values.

A graph for iodic acid based on eq. 18 (also using eq. 15 and I-5) is shown in Fig. 2, from which we obtain $\phi^0_{C(HIO_3)}$ = −40 J K^{-1} mol^{-1} (= −10 cal K^{-1} mol^{-1}). We estimate that the *total* uncertainty in this value is about ±8 J K^{-1} mol^{-1} or ±2 cal K^{-1} mol^{-1}. Combination of this $\phi^0_{C(HIO_3)}$ for undissociated HIO_3 with $\phi^0_{C(H^+,IO_3^-)}$ = −74 J K^{-1} mol^{-1} cited earlier leads to ΔC_p^0 = 34 J K^{-1} mol^{-1} for the association reaction represented by eq. 1 or to ΔC_p^0 = −34 J K^{-1} mol^{-1} (= −8 cal K^{-1} mol^{-1}) for the ionization of HIO_3(aq, undiss.). We know of no results with which to compare this value, but we note that is is of "reasonable" magnitude as compared to "similar" reactions (16).

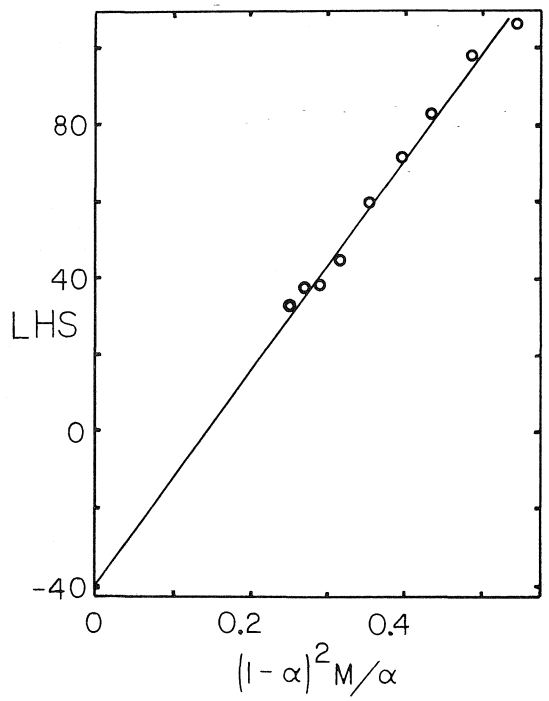

FIG. 2. Plot of the left hand side of eq. 18 for HIO_3, yielding $\phi^0_{C(HIO_3)}$ = −40 J K^{-1} mol^{-1} and B_C = 274.

Discussion

The magnitude of the hitherto unrecognized difference between ϕ_C^{exp} and ϕ_C^{sp} depends on the concentration range of the heat capacity measurements and on the various thermodynamic quantities that appear in eq. 15. For magnesium sulfate and iodic acid solutions treated here, the difference between ϕ_C^{exp} and ϕ_C^{sp} ranges from less than 1 to 22 J K^{-1} mol^{-1}. Thus the distinction between ϕ_C^{exp} and ϕ_C^{sp} should not be ignored for these solutes.

For quite strong electrolytes that are fully dissociated in the practical concentration range of heat capacity measurements there is no need or opportunity for the treatment described here. For much weaker electrolytes, such as acetic acid, there is again no need for the treatment described here. In this case it is possible to obtain ΔC_p^0 for association of H^+ with Ac^- or dissociation of HAc by way of combination of results of heat capacity measurements on solutions of acetic acid, sodium acetate, sodium chloride, and hydrochloric acid. It is only for 'intermediate' electrolytes, such as magnesium sulfate and iodic acid, that a treatment such as the one described here is needed.

It should be noted that eq. 15 cannot be applied to very weak electrolytes for which $\alpha \cong 1$, due to complications associated with eq. 9. Instead, it is proper to consider [1′]

[1′] $\quad HX(aq, undiss.) \rightleftharpoons H^+(aq) + X^-(aq)$

We now define α' as the fraction of HX dissociated. Following the procedure given earlier in this paper, with $\gamma_\pm \cong 1$ (or calculated from the Debye–Hückel theory) and small α', we obtain

$$[15'] \quad \phi_C^{sp} \cong \phi_C^{exp} - [\alpha'(\Delta H^0_{ioniz})^2]/2RT^2$$

in which ΔH^0_{ioniz} represents the standard enthalpy of ionization of HX(aq). The term in brackets is very small so that ϕ_C^{exp} can be attributed to HX(aq, undiss.) in straightforward fashion as stated in the paragraph above.

NOTE ADDED IN PROOF:

In considering the dimensional consistency of eq. 14 (and some other equations) it is necessary to remember that we are concerned with the heat capacity of a solution that contains 1 kg of solvent. We therefore express dH_r/dT in terms of energy K^{-1} (kg solvent)$^{-1}$, which is consistent with expressing $m\Delta H_r(d\alpha/dT)$ in terms of (mol solute) (kg solvent)$^{-1}$ energy (mol solute)$^{-1}$ K^{-1}.

Appendix I

We first consider a solution of magnesium sulfate of stoichiometric molality m. The concentrations of Mg^{2+} and SO_4^{2-} ions are both $(1 - \alpha)m$ and the concentration of undissociated $MgSO_4$ is αm. Dilution of the ions in this solution to $m = 0$ is represented by

[I-1] $$Mg^{2+}[(1 - \alpha)m] + SO_4^{2-}[(1 - \alpha)m] \rightleftharpoons Mg^{2+}(m = 0) + SO_4^{2-}(m = 0)$$

The enthalpy change for this dilution is $-\phi_L^i[(1 - \alpha)m]$, where ϕ_L^i is the relative apparent molal enthalpy of the ions at the indicated molality of ions. We also write

[I-2] $$Mg^{2+}(m = 0) + SO_4^{2-}(m = 0) \rightleftharpoons MgSO_4(m = 0) \qquad \Delta H_r^0$$

for the standard state formation of $MgSO_4$(aq, undiss.). Next we have

[I-3] $$MgSO_4(m = 0) \rightleftharpoons MgSO_4(\alpha m)$$

for the change in concentration of undissociated $MgSO_4$ from zero concentration to the concentra-

tion represented by αm. The enthalpy of this process is represented by $\phi_L{}^u$. Combination of the three equations above and the corresponding enthalpies leads to

[I-4] $$Mg^{2+}[(1 - \alpha)m] + SO_4{}^{2-}[(1 - \alpha)m] \rightleftharpoons MgSO_4(\alpha m)$$

and

[I-5] $$\Delta H_r = \Delta H_r{}^0 - \phi_L{}^i[(1 - \alpha)m] + \phi_L{}^u(\alpha m)$$

To eliminate $\phi_L{}^i$ from eq. I-5, we consider three processes similar to those above, but now for an amount of solution of stoichiometric molality m such that the solution contains 1 mol of magnesium sulfate and therefore $(1 - \alpha)$ mol of Mg^{2+}, $(1 - \alpha)$ mol of $SO_4{}^{2-}$, and (αm) mol of undissociated $MgSO_4$. The corresponding enthalpies will be $-(1 - \alpha)\phi_L{}^i[(1 - \alpha)m]$, $\alpha\Delta H_r{}^0$, and $\alpha\phi_L{}^u(\alpha m)$. Combination of equations and enthalpies for these three processes leads to

[I-6] $$(1 - \alpha)Mg^{2+}[(1 - \alpha)m] + (1 - \alpha)SO_4{}^{2-}[(1 - \alpha)m] + \alpha MgSO_4(\alpha m) \rightleftharpoons Mg^{2+}(m = 0) + SO_4{}^{2-}(m = 0)$$

and the corresponding *exp*erimental enthalpy of dilution represented by

[I-7] $$-\phi_L{}^{exp} = -(1 - \alpha)\phi_L{}^i[(1 - \alpha)m] - \alpha\Delta H_r{}^0 - \alpha\phi_L{}^u$$

Finally, we combine eqs. I-5 and I-7 with $\phi_L{}^u = 0$ to obtain

[I-8] $$\Delta H_r = (\Delta H_r{}^0 - \phi_L{}^{exp})/(1 - \alpha)$$

Equation I-7 above is equivalent to equations used by earlier investigators (7, 8, 17) of the thermodynamics of ion pair formation.

Rearrangements involving alkoxycarbonyl group migration between nitrogen and oxygen. III. Reactions of modified isoquinoline Reissert compounds with aldehydes

M. D. ROZWADOWSKA

Institute of Chemistry, Adam Mickiewicz University, Grunwaldzka 6, 60–780 Poznań, Poland

Received June 8, 1976

M. D. ROZWADOWSKA. Can. J. Chem. **55**, 164 (1977).

The condensation reaction of modified Reissert compounds with aldehydes was investigated. In the reaction of the *N*-ethoxycarbonyl Reissert analog **1***b*, ethoxycarbonyl group migration takes place and carbonates of 1-isoquinolylphenylcarbinols (**2***b*, *c*) are formed. No alkoxycarbonyl group migration was observed in the case of the dihydro-Reissert derivative **6**, but the cyclic urethane **7** and the amide **8** were obtained.

M. D. ROZWADOWSKA. Can. J. Chem. **55**, 164 (1977).

On a examiné la réaction de condensation de composés de Reissert modifiés avec des aldéhydes. Dans la réaction de l'analogue *N*-éthoxycarbonylé de Reissert (**1***b*), il y a migration du groupe éthoxycarbonyle et formation de carbonates de l'isoquinolyl-1 phénylcarbinoles (**2***b*, *c*). On n'observe aucune migration du groupe alkoxycarbonyle dans le cas du dérivé dihydro-Reissert **6** mais on obtient l'uréthane cyclique **7** et l'amide **8**.

[Traduit par le journal]

Introduction

Rearrangement reactions involving acyl group migration are well known, and have been the subject of several reviews (1–4). They are common in acylated 1,2-amino alcohols, where an intramolecular mechanism with a 5-membered cyclic intermediate hydroxyoxazolidine is postulated. Significant contributions to the elucidation of the mechanism of this reaction are due mainly to Fodor and co-workers (5, 6) and to Welsh (7).

These migrations are reversible and p*H*-dependent. It has been well established that in acidic conditions N → O migration occurs, whereas in alkaline solutions the opposite O → N takes place. The structure of the products is determined by the direction of ring opening in the intermediate hydroxyoxazolidine. The cleavage of either C—N or C—O bonds furnishes the *O*-acyl or *N*-acyl derivatives, respectively. In acidic media the positive nitrogen attracts the bonding electrons giving rise to an *O*-acyl amine. In alkaline conditions the C—O bond, being more polarized, is broken and an *N*-acyl alcohol is formed. This can be considered as a general rule and is applicable to most of the acylated aliphatic amino alcohols. There are, however, exceptions. For instance, in reaction of Reissert compounds with aldehydes N → O acyl migration takes place in strongly alkaline conditions (8, 9). The aromatization of the system is postulated as the driving force for this transformation.

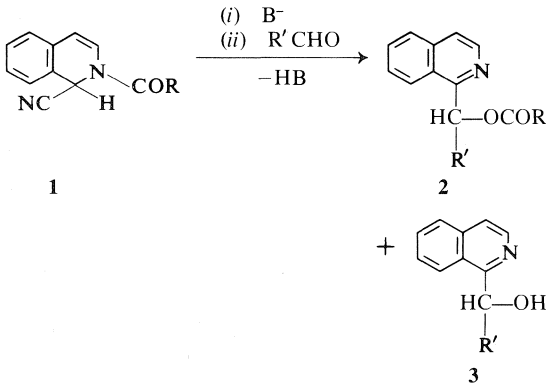
In connection with our studies of alkoxycarbonyl group migration (10, 11), this reaction was chosen, but modified *N*-ethoxycarbonyl and dihydro-Reissert compounds were used.

Results and Discussion

The name 'isoquinoline Reissert compounds' has been reserved for 1-cyano-2-benzoyl-1,2-dihydroisoquinolines (8, 9). However, some modified Reissert compounds have been prepared. Thus 1,2,3,4-tetrahydro derivatives, called 'dihydro-Reissert compounds' have been described (9, 12–15), and others, having acetyl (9, 16), sulfonyl (17), alkoxycarbonyl (9, 18, 19), carbamoyl (20), and phosphate (21) substituents in the place of benzoyl group are also known.

Reissert compounds are easily converted into their conjugate bases, which are valuable intermediates in organic synthesis (8, 9). In condensation reactions with aldehydes, these compounds (**1***a*) are transformed into secondary alcohols, or their esters, containing a 1-isoquinolyl or 2-quinolyl group bonded to the carbinol carbon atom (Scheme 1, **2**, **3**) (9, 21, 23–26).

In the course of this reaction the acyl group is shifted from nitrogen to oxygen in alkaline solution. However, an example was described by Popp *et al.* (18) in which migration of the alkoxycarbonyl group was not observed in this

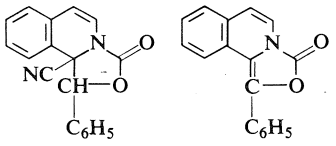


1 2 3

a, $R = C_6H_5$
b, $R = OC_2H_5$, $R' = C_6H_5$
c, $R = OC_2H_5$, $R' = C_6H_3(OCH_2O)$

SCHEME 1

process. This involved the reaction of *N*-alkoxycarbonyl analogs of Reissert compounds with benzaldehyde in which the anions were generated by the action of *n*-butyllithium at −40 °C. As a result the cyclic urethane **4** was formed in moderate yield. This difference can be easily ex-



4 **5**

plained, when one considers that the oxyanion *C* (Scheme 2) can alternatively lose alkoxide and give the product **4**. When the reaction was carried out using sodium hydride in *N*,*N*-dimethylformamide, the authors were able to isolate the carbinol **3***b* with 47% yield, although in one case **5** was isolated and easily hydrolized by base to **3***b*.

It was of interest to see whether there is a general tendency for *N*-alkoxycarbonyl Reissert compounds to form a cyclic urethane in reactions with aromatic aldehydes and not the fully aromatic isoquinoline formed by the rearrangement–elimination process. Therefore *N*-ethoxycarbonyl-1,2-dihydroisoquinaldonitrile (**1***b*) was prepared from isoquinoline, potassium cyanide and ethyl chloroformate, and reacted with aromatic aldehydes using two different reaction conditions. Treatment of **1***b* with benzaldehyde in a two-phase catalytic system according to the Makosza method (27) described by Jończyk (22), using triethylbenzylammonium chloride (TEBA) as a phase-transfer agent, resulted, depending on the time of the reaction, in either of the two compounds **2***b* or **3***b*, or both of them. When the reaction time was 30 min the ethyl carbonate of 1-isoquinolylphenylcarbinol (**2***b*) was formed in high yield (96%). After 24 h the hydrolysis product of **2***b*, 1-isoquinolylphenylcarbinol (**3***b*), was isolated in 91% yield. With times varying from 30 min to 24 h mixtures of **2***b* and **3***b* were obtained.

Reaction with piperonal in the place of benzaldehyde gave carbonate **2***c* or carbinol **3***c* depending on the reaction time.

When the reaction of **1***b* and benzaldehyde was carried out with sodium hydride in DMF at −40 °C, carbonate **2***b* was obtained almost quantitatively.

The structure of carbonates **2***b* and **2***c* was established on the bases of elemental analysis, spectral data (ir, nmr, uv, ms), and chemical transformations. All these data are in accordance with structures **2***b*, *c* except for one: compounds **2***b* and **2***c* do not show basic properties in that they are not soluble in aqueous solutions of acids. Table 1 lists the pK_a values (measured in methylcellosolve) of several compounds related to the carbonates. As expected, carbinols **3***b*, *c* exhibit pK_a values (4.1) similar to that of the parent isoquinoline (3.85). The values for carbonates **2***b*, *c* (approximately 2.1) are comparable with that of *N*-ethoxycarbonylquinaldonitrile (**1***b*) (approximately 2.1).

On the other hand, carbonate **2***b* under the action of hydrogen chloride in dry ether forms a crystalline hydrochloride which on dissolution in aqueous solvents is hydrolized to the free base.

Because of the diverse behaviour of these compounds a careful analysis of their spectra seemed to be necessary.

A strong absorption band in the carbonyl frequency region, centered at 1745 cm^{-1}, is pres-

TABLE 1. pK_a values of carbonates **2***b*, *c* and related compounds

Compound	pK_a

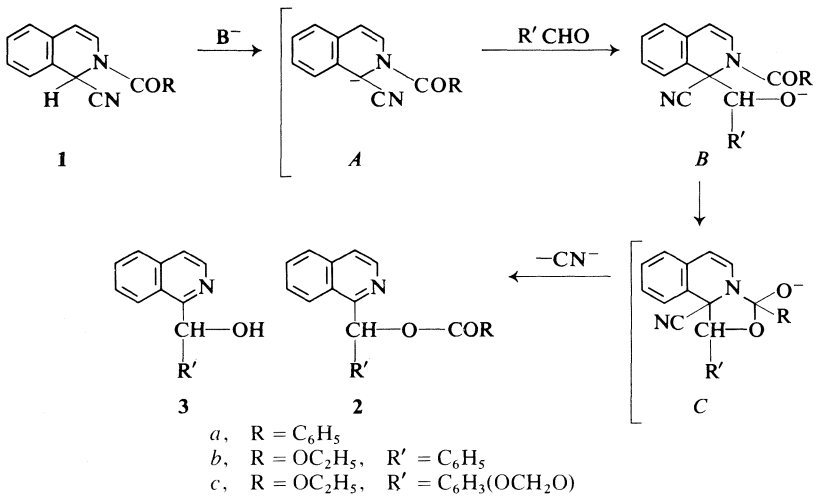
Carbonate **2***b*	~2.1
Carbonate **2***c*	~2.1
Carbinol **3***b*	~4.1
Carbinol **3***c*	~4.1
Isoquinoline	~3.85



SCHEME 2

ent in the ir spectra of carbonates **2***b*, *c*, which if compared with the spectrum of the starting *N*-ethoxycarbonylisoquinaldonitrile (**1***b*) is shifted 20 cm^{-1} to shorter wavelength. This position corresponds better to the carbonate absorption (1750 cm^{-1}) described in the literature (28) than to a disubstituted urethane (1720 cm^{-1}) (28).

The nmr spectra of 1,2-dihydroisoquinolines exhibit signals characteristic of olefinic protons, giving rise to an AB quartet located in the region between 5.95–6.9 δ with a coupling constant $J = 8$ Hz (15, 29). As is evident from Table 2, the *N*-ethoxycarbonyl Reissert analog **1***b* shows such a quartet centered at 6.0 δ and 6.9 δ, with $J = 8$ Hz. Neither in the spectra of carbonates **2***b*, *c* nor in those of carbinols **3***b*, *c* is an absorption present around 5.95–6.9 δ (except for a sharp singlet near 6 δ, corresponding to two methylenedioxy group protons in **2***c* and **3***c*). On the other hand, the C_3 proton in the spectra of these compounds, as in spectra of other isoquinoline derivatives, appears as a doublet at *ca.* 8.6 δ with $J = 6$ Hz.

Other spectral evidence that suggests a fully aromatic system for carbonates **2***b*, *c* can be seen from their uv spectra which are practically superimposable with those of the corresponding carbinols **3***b*, *c* and isoquinoline, but which differ significantly from that of the starting Reissert compound **4***b* (see Experimental).

In their mass spectra the two carbonates show the common feature of the initial loss of ethoxycarbonyl and carbonate groups (73 and 89 mass units respectively) followed by the substituent attached to the C_1 carbon atom giving rise to the isoquinoline fragment ion (129-1 *m/e*) (30). In the mass spectra of carbinols the molecular ion is also the parent. The second most intense peak is that at 129 mass units, which corresponds to the isoquinoline ion.

Reduction of **2***b* with sodium borohydride yielded carbinol **3***b*, also obtained by alkaline hydrolysis of **2***b*. Reaction of **3***b* with ethyl chloroformate under Gadamer–Knoch conditions yielded **2***b*.

In view of the spectral and experimental results, the structures **2***b*, *c* for the carbonates formed in the reaction of 2-ethoxycarbonylisoquinaldonitrile (**1***b*) with aromatic aldehydes seem to be confirmed.

The mechanism of this reaction is shown in Scheme 2. In the first step the attack of the carbanion *A* on the carbon atom of the aldehyde carbonyl takes place. The resulting oxyanion *B* then undergoes rearrangement (via *C*) with simultaneous release of the cyanide ion, giving the final product **2***a*.

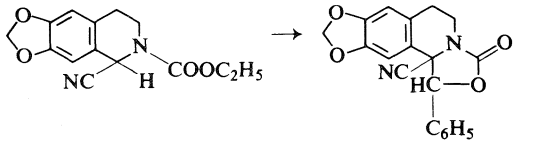
Taking into consideration the observations made on the reaction of *N*-alkoxycarbonyl Reissert analogs with aldehydes, one comes to a conclusion that this reaction may proceed via three different mechanisms, giving rise to three different intermediates (**2**, **4**, **5**) formed on the route from Reissert compound **1** to 1-isoquinolylphenylcarbinol (**3**). These mechanisms probably show the same initial course, involving the formation of oxyanion *C* (see Scheme 2) which can then be transformed to either carbonate **2***b*, *c*

due to alkoxycarbonyl group migration and elimination of the cyanide ion, or to the cyclic urethane **4** or **5** by the loss of alkoxide ion. Formation of **5** requires the additional elimination of a molecule of hydrogen cyanide.

It is evident from the results presented in this paper as well as from those reported by Popp *et al.* (18) that the course of this reaction and thus the structure of the products depend on the experimental conditions. Factors such as type and amount of base used for the generation of the anion, solvent, temperature, and time of reaction seem to have a significant influence on the direction of this process. A more detailed study must, however, be undertaken in order to examine the relation between experimental conditions and the course of this reaction.

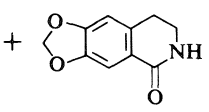
The reaction of dihydro isoquinoline Reissert compounds in which formation of their anions is needed, such as alkylation and acylation have been investigated in two cases (14, 15). The behaviour of these compounds in condensation reactions with aldehydes has not been examined.

In connection with our interest of alkoxycarbonyl group migration, 2-ethoxycarbonyl-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinaldonitrile (**6**) was synthesized and subjected to reaction with benzaldehyde in a two-phase catalytic system with TEBA as catalyst. When acetonitrile was used as solvent two compounds were isolated: the cyclic urethane **7** and dihydroisocarbostiril **8**, while in benzene only **7** was formed.



6

7



8

In the ir spectra of **7** and **8** strong absorption bands are present in the carbonyl region, centered at 1760 and 1660 cm^{-1} respectively, while in the spectrum of **8** an additional broad band around 3200 cm^{-1} suggests N—H stretching vibrations.

The nmr spectra of **7** and **8** (Table 2) do not exhibit the resonances characteristic of ethoxy group protons, but rather a singlet at 5.36 δ in the

spectrum of **7** may be attributed to the proton attached to the C_α carbon atom.

Further support for **7** and **8** as correct structures was adduced from their mass spectra. Both compounds show molecular ions and the base peak (200 *m/e*) in the spectrum of **7** is probably derived from the 6,7-methylenedioxy-3,4-dihydroisoquinaldonitrile ion, formed from **7** by the cleavage of bonds between nitrogen and the urethane carbonyl and between the C_1 and C_α carbon atoms.

The molecular ion in the spectrum of **8** is at the same time the base peak. The loss of 29 mass units ($NHCH_2$) provides the fragment *m/e* 162, which in turn appears to lose a molecule of carbon monoxide giving rise to an ion *m/e* 134.

6,7-Methylenedioxy-1-oxo-1,2,3,4-tetrahydroisoquinoline (**8**) is probably formed from **7** via dihydroquinaldonitrile and subsequent displacement of nitrile by hydroxide ion.

Two conclusions may be drawn from the reactions described above. First, no alkoxycarbonyl group migration is observed in the reaction of dihydro-Reissert compounds with aldehydes, even under conditions when this group migrates readily in normal Reissert compounds. Secondly, there seems to be a general tendency of the alkoxycarbonyl group to lose alkoxide ion from the intermediate oxyanion *C* (Scheme 2) and form a stable 5-membered carbamate.

Experimental

Melting points were determined on a Kofler block and are uncorrected. The ir spectra were determined in chloroform solution using 0.1 mm cells and a ~0.2 *M* sample concentration on a Unicam SP 200G spectrophotometer. The uv spectra in 96% ethanol were recorded on a Specord UV–VIS spectrophotometer. The nmr spectra were measured on a Varian Associates A-60 spectrometer with TMS as an internal standard. Sample concentrations were approximately 19% w/v in $CDCl_3$. Chemical shifts are given in δ units. The mass spectra were obtained on a Jeol MS 100-D instrument. Only those signals of use in structure assignment are given in this paper. The pK_a values were measured in methylcellosolve on a Radiometer Titrigraph Module PMA 943. Purity of all compounds prepared was checked by tlc on alumina plates (Woelm, neutral).

2-Ethoxycarbonyl-1,2-dihydroisoquinaldonitrile (1b)

To a vigorously stirred mixture of 0.05 mol of iso quinoline (freshly distilled from zinc dust) and 0.15 mol of potassium cyanide in 60 ml of water was added 0.1 mol of ethyl chloroformate over a period of 1 h with ice cooling. The temperature was allowed to rise to room temperature and stirring was continued overnight. The mixture was then extracted with benzene and the organic layer washed with water, dilute HCl, water, dilute NaOH, and water again, then dried. Evaporation of the solvent left a dark oil (7.8 g) which was passed through silica gel (MN, 100–200 mesh ASTM). Benzene eluted 6.5 g (57%) of a colorless oil, that solidified, mp 82–85 °C. After recrystallization from ether–hexane mp 83–85 °C; uv λ_{max} 285 nm (ε 12 000); ir 1725 (urethane C=O), 1620 cm^{-1} (C=C); nmr 1.33 (t, J = 7 Hz, 3H, -OCH_2 -CH_3), 4.36 (q, J = 7 Hz, 2H, -O-CH_2-CH_3), 6.0 (d, J = 8 Hz, 1H, C_4-H), 6.38 (br s, 1H, C_1-H), 6.95 (d, J = 8 Hz, 1H, C_3-H), 6.75–7.5 δ (m, 4H, aromatic); ms *m/e* 228 (M^+, 32%), 155 ($M - COOC_2H_5$, 16%), 129 ($M - COOC_2H_5 - CN$, 100%). *Anal.* calcd. for $C_{13}H_{12}O_2N_2$ (228): C 68.42, H 5.26, N 12.28; found: C 68.35, H 5.44, N 12.12.

Condensation of the Reissert Analog 1b with Aromatic Aldehydes

(1) In a Two Phase System Using TEBA as Phase-transfer Agent

Compound **1***b* (1.27 g, 5.57 mmol), 3 ml of benzene, 50% NaOH (2.3 ml), TEBA (45 mg), and freshly distilled benzaldehyde (0.69 ml, 7.28 mmol) were stirred at room temperature for 30 min. The mixture was diluted with water and extracted with benzene. The organic layer was washed with dilute HCl, and water, dried, and the solvents evaporated *in vacuo*. Carbonate **2***b* (1.65 g, 96%) was obtained as a colorless oil which crystallized from ethanol: mp 93–94.5 °C; uv λ_{max} 324 (4080), 311 (3440), 286 (4160), 274 (5040), 261 (3760), 255 nm (ε 3000); ir 1745 cm^{-1} (carbonate C=O); nmr 1.23 (t, J = 7 Hz, 3H, -O-CH_2-CH_3), 4.23 (q, J = 7 Hz, 2H, -O-CH_2-CH_3), 7–8.45 (m, 11H, aromatic + C_α-H), 8.7 δ (d, J = 6 Hz, 1H, C_3-H); ms *m/e* 307 (M^+, 29%), 234 ($M - COOC_2H_5$, 61%), 218 ($M - OCOOC_2H_5$, 100%), 128 ($M - C_1$ – substituent, 36%). *Anal.* calcd. for $C_{19}H_{17}O_3N$ (307): C 74.26, H 5.54, N 4.65; found: C 74.20, H 5.55, N 4.39.

Hydrochloride of 2b—HCl gas was bubbled through a solution of carbonate **2***b* in ether for 5 min. A white solid precipitated in quantitative yield that was recrystallized from anhydrous methanol, mp around 100 °C; ir (KBr) 3450 and 1640 (water of crystallization), 3100–2500 ($^+$N—H), 1750 cm^{-1} (carbonate C=O). *Anal.* calcd. for $C_{19}H_{17}O_3N \cdot HCl \cdot H_2O$ (361.5): C 63.07, H 5.53, N 3.87; found: C 63.02, H 5.51, N 3.68.

Treatment of **1***b* (880 mg, 4 mmol) with piperonal (675 mg, 4.5 mmol) with the same reaction conditions afforded 1.24 g of an oil, which after chromatography on alumina (Woelm, neutral, activity grade II°) yielded 440 mg (32%) of carbonate **2***c*, which, crystallized from ether–hexane, mp 98–100 °C; uv λ_{max} 321 (4960), 308 (4640), 285 (8480), 275 (7600), 259 (4320), 252 nm (ε 3840); ir 1745 cm^{-1} (carbonate C=O); nmr 1.26 (t, J = 7 Hz, 3H, -O-CH_2-CH_3), 4.2 (q, J = 7 Hz, 2H, -O-CH_2-CH_3), 5.9 (s, 2H, -O-CH_2-O-), 6.66–8.35 (m, 9H, aromatic + C_α-H), 8.63 δ (d, J = 6 Hz, 1H, C_3-H); ms *m/e* 351 (M^+, 18%), 278 ($M - COOC_2H_5$, 34%), 262 ($M - OCOOC_2H_5$, 100%), 128 ($M - C_1$ – substituent, 21%). *Anal.* calcd. for $C_{20}H_{17}O_5N$ (351): C 68.37, H 4.81, N 3.98; found: C 68.11, H 4.99, N 3.89.

When this reaction was carried out in the same conditions, but over 24 h carbinols **3***b* or **3***a* were obtained in yields of 91 and 48%, respectively.

Carbinol 3b—**3***b* mp 107–109 °C (lit. (26) mp 108.5–109.5 °C); uv λ_{max} 320 (4080), 308 (3280), 282 (4240),

271 (5200), 261 (4800), 254 nm (ε 4000); ir 3500–3150 cm^{-1} (carbinol OH); nmr 6.0 (br, 1H, exchangable with D_2O, OH), 6.35 (s, 1H, C_α-H), 7.2–8.2 (m, 10H, aromatic), 8.55 δ (d, J = 6 Hz, 1H, C_3-H); ms *m/e* 235 (M^+, 100%), 218 (M − OH), 129 (M − C_6H_5CHO).

Carbinol 3c—**3***c* mp 91–93 °C; uv λ_{max} 320 (4640), 307 (4160), 282 (7520), 272 (6720), 259 (6380), 251 nm (ε 3040); ir (KBr) cm^{-1} 3350–3150 (carbinol OH); nmr 6 (br, 1H, exchangable with D_2O, OH), 5.9 (s, 2H, -O-CH_2-O-), 6.30 (s, 1H, C_α-H), 6.6–8.2 (m, 8H, aromatic), 8.6 δ (d, J = 6 Hz, 1H, C_3-H); ms *m/e* 279 (M^+, 100%), 262 (M − OH, 12%), 129 (M − C_1 − substituent, 95%). *Anal.* calcd. for $C_{17}H_{13}O_3N$ (279): C 73.11, H 4.66, N 5.02; found: C 73.05, H 4.70, N 4.91.

(2) In Dimethylformamide with Sodium Hydride

To a solution of **1***b* (456 mg, 2 mmol) and of benzaldehyde (206 mg, 2 mmol) in 6 ml of DMF cooled to −40 °C was added with stirring 96 mg (2 mmol) of 50% sodium hydride in oil dispersion in one portion. This mixture was stirred at −40 to −30 °C for 1 h, and then at room temperature overnight. Ice (12 g) was added and the mixture was extracted with ether. The ethereal solution was washed with water, dilute HCl, and water. Drying and evaporation of the solvent gave a residue (600 mg), which was purified by the filtration through alumina to yield carbonate **2***b* (590 mg, 96%).

Sodium Borohydride Reduction of Carbonate 2b

A methanolic solution of carbonate **2***b* (154 mg, 0.5 mmol) was treated with sodium borohydride (33 mg, 1 mmol) at room temperature with stirring overnight. After the usual work-up was isolated 80 mg (68%) of carbinol **3***b*.

Base-catalyzed Hydrolysis of Carbonate 2b

2*b* (170 mg, 0.55 mmol) was dissolved in acetonitrile (0.5 ml) and 0.8 ml of 50% NaOH was added. The mixture was stirred overnight. Water was added and the mixture extracted with benzene. The combined organic layers were extracted with dilute HCl, the acidic solution neutralized, and extracted with ether. Work-up resulted in 80 mg (61.5%) of pure carbinol **3***b*.

Carbonates **2***b*, *c* are resistant toward acid-catalyzed hydrolysis.

Reaction of Carbinol 3b with Ethyl Chloroformate

Carbinol **3***b* (130 mg, 0.55 mmol) was dissolved in 6.5 ml of ether and three portions of reagent, consisting of 0.5 ml of 50% KOH and 0.15 ml of ethyl chloroformate each, were added to the mixture at 1 h intervals. Stirring was continued for 20 h at ambient temperature. The organic layer was separated, washed with water and dilute HCl, dried, and the solvent evaporated to yield carbonate **2***b* (140 mg, 82%).

2-Ethoxycarbonyl-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinaldonitrile (6)

To a vigorously stirred mixture of 6,7-methylenedioxy-3,4-dihydroisoquinoline (32) (320 mg, 1.8 mmol) in methylene chloride (2.5 ml) and sodium cyanide (271 mg, 4.5 mmol), in 2.5 ml of water was added gradually ethyl chloroformate (0.68 ml, 3.7 mmol) in 1.25 ml of methylene chloride. Stirring was continued overnight, then the organic layer was separated and washed with water, dilute HCl, water, dilute NaOH, and water. Removal of the solvent yielded a yellow oil (500 mg) which was chromatographed on alumina (Woelm, neutral, activity II°). Benzene eluted 355 mg of a colorless oil, that crystallized from ether–hexane giving 150 mg (30%) of crystals, mp 103–105 °C; ir 1710 cm^{-1} (carbamate C=O); nmr 1.33 (t, J = 7 Hz, 3H, -O-CH_2-CH_3), 4.31 (q, J = 7 Hz, 2H, -O-CH_2-CH_3), 6.0 (s, 3H, C_1-H + -O-CH_2-O-), 6.66–6.78 δ (m, 2H, aromatic); ms *m/e* 274 (M^+, 45%), 274 (M − HCN, 45%), 200 (M − $HCOOC_2H_5$, 68%), 174 (M − HCN − $COOC_2H_2$, 100%). *Anal.* calcd. for $C_{14}H_{14}O_4N$ (274): C 61.31, H 5.10, N 10.21; found: C 61.63, H 5.19, N 10.07.

Reaction of Dihydro-Reissert Analog 6 with Benzaldehyde

Compound **6** (210 mg, 0.76 mmol), 1.5 ml of benzene, 0.3 ml of 50% NaOH, 0.1 ml (1 mmol) of benzaldehyde, and TEBA (8 mg) were stirred at room temperature for 30 min in an argon atmosphere. A little water and ether was added, causing precipitation of a white solid which was filtered off, washed with water and ether, dried, and recrystallized from ethyl acetate. Fine crystals (117 mg) were collected; mp 221–222.5 °C (sealed capillary). The remaining filtrate (water–ether) was separated and the aqueous layer extracted three times with ether. The combined ether extracts were worked-up in the usual manner, giving an additional 100 mg of carbamate **7**. Total yield 217 mg (79%); ir 1760 cm^{-1} (carbamate C=O); nmr 5.36 (s, 1H, C_α-H), 6.0 (s, 2H, -O-CH_2-O-), 6.6, 6.7 (2s, 2H, aromatic), 7.6 δ (s, 5H, aromatic); ms *m/e* 334 (M^+, 24%), 200 (M − CO − PHCHO, 100%). *Anal.* calcd. for $C_{19}H_{14}O_4N_2$ (334): C 68.25, H 4.19, N 8.38; found: C 68.28, H 4.28, N 8.37.

When in the same reaction, acetonitrile was used as solvent, and the products were worked-up by extraction with ether, a mixture of two compounds was obtained. They were separated by column chromatography on alumina (Woelm, neutral, activity II°). Benzene eluted 120 mg of urethane **7**, while ether eluted compound **8** (110 mg, overall yield 73%).

Compound **8** after crystallization from ethyl acetate showed mp 185.5–186.5 °C (lit. (33) mp 185–186 °C); ir 3200–2900 (br, N—H), 1660 cm^{-1} (amide C=O); nmr 6.0 (s, 2H, -O-CH_2-O-), 6.68, 7.5 δ (2s, 2H, aromatic); ms, *m/e* 191 (M^+, 100%), 162 (M − CHNH, 89%), 134 (M − CHNH − CO, 78%). *Anal.* calcd. for $C_{10}H_9O_3N$ (191): C 62.82, H 4.71, N 7.32; found: C 62.63, H 4.73, N 7.30.

Gas phase competitive anionic cleavage of esters[1]

M. COMISAROW

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 30, 1976

M. COMISAROW. Can. J. Chem. **55**, 171 (1977).

The gas phase reaction of deuteriomethoxide with methyl benzoate and with methyl trifluoroacetate yields the corresponding carboxylate anions and not protiomethoxide ion. These results are opposite to what would be expected based upon the known reactions in solution of anions with esters. The reasons for the different behavior between the gas phase and the solution phase are discussed.

M. COMISAROW. Can. J. Chem. **55**, 171 (1971).

La réaction en phase gazeuse du deutérométhylate avec le benzoate de méthyle et le trifluoroacétate de méthyle conduit aux anions carboxylates correspondants et non pas à l'ion protiométhylate. Ces résultats sont en opposition avec ceux que l'on pourrait attendre en se basant sur les réactions connues en solution des anions avec les esters. On discute des raisons pour le comportement différent entre la phase gazeuse et la phase en solution.

[Traduit par le journal]

It is well known that the base catalyzed hydrolysis of carboxylic acid esters usually proceeds via the acyl cleavage $B_{AC}2$ mechanism; the alkyl cleavage $B_{AL}2$ mechanism only occurring in special cases (1). The same mechanistic preference holds for base catalyzed alcoholysis (1). For instance, the reaction of methoxide in methanol with methyl benzoate at 100 °C yields exchanged methyl benzoate 430 000 times faster than it yields dimethyl ether (1). This communication reports an investigation using ion cyclotron resonance techniques (2) of the gas phase reaction of methoxide ion with some carboxylic acid methyl esters[2] and shows that in the *gas phase*, the reaction products are strikingly different from those observed *in solution*.

When deuteriomethoxide ion **1**, formed by dissociative electron capture by deuteriomethyl nitrite (4), is reacted in the gas phase with methyltrifluoroacetate **2**, trifluoroacetate ion **3**, is the only product of the reaction as shown by pressure dependence studies and double resonance experiments.[3,4]

$$[1]^{5}\quad \underset{\substack{\mathbf{1}\\ m=34}}{CD_3O^-} + \underset{\mathbf{2}}{CF_3COCH_3} \xrightarrow{k_{carboxylate}} \underset{\substack{\mathbf{3}\\ m=113}}{CF_3CO^-} + CD_3OCH_3$$

Similarly, methyl benzoate **4**, reacts with deuteriomethoxide ion to yield only benzoate anion **5**.

[1]Reported at 57th Canadian Chemical Conference, Regina, Saskatchewan, June 3–5, 1974.

[2]The reaction of alkoxide ions with formate esters yields clustered alkoxide ions (3).

[3]The reactions were carried out on a home-built 'drift cell' ICR spectrometer of conventional design. A dynamic pressure balance was maintained in the cell by bleeding in the reagents via separate inlet systems while pumping on the vacuum system with an ion pump. Double irradiation in the source region of the drift cell was used for double resonance experiments. The techniques used are well described in ref. 2.

[4]Typical pressures of the reagents were CD_3ONO, 10^{-6} torr; ester, 10^{-6} to 5×10^{-5} torr.

[5]All ion structures and the structures of the neutral products are presumed.

$$[2]^5\quad \underset{\underset{m=34}{\mathbf{1}}}{CD_3O^-} + \underset{\mathbf{4}}{C_6H_5\overset{\overset{O}{\|}}{C}OCH_3} \xrightarrow{k_{carboxylate}} \underset{\mathbf{5}\ m=121}{C_6H_5\overset{\overset{O}{\|}}{C}O^-} + CD_3OCH_3$$

Under the experimental conditions,[4] no protiomethoxide ion, **6**, was observable with either the trifluoroacetate or benzoate systems and from the estimated maximum possible yield of protiomethoxide, the rate of the alkoxide-forming reaction 3 may be estimated to be *at least* thirty times *slower* than the corresponding carboxylate-forming reaction 1 or 2.

$$[3]^5\quad \underset{\underset{m=34}{\mathbf{1}}}{R\overset{\overset{O}{\|}}{C}OCH_3} + {}^-OCD_3 \xrightarrow{k_{alkoxide}} \underset{\mathbf{6}\ m=31}{R\overset{\overset{O}{\|}}{C}OCD_3} + {}^-OCH_3$$

$$R = CF_3, C_6H_5$$

The enthalpy change, ΔH_1, for reaction 1 can be determined from the thermodynamic cycle

$$\begin{array}{ccc} CF_3\overset{\overset{O}{\|}}{C}OCH_3 + {}^-OCD_3 & \xrightarrow{\Delta H_1} & CF_3\overset{\overset{O}{\|}}{C}O^- + CH_3OCD_3 \\ \downarrow \Delta H_a & & \uparrow \Delta H_c \\ CF_3\overset{\overset{O}{\|}}{C}O\cdot + \cdot CH_3 + {}^-OCD_3 & \xrightarrow{\Delta H_b} & CF_3\overset{\overset{O}{\|}}{C}O^- + \cdot CH_3 + \cdot OCD_3 \end{array}$$

where ΔH_a is the methyl–oxygen bond strength in methyltrifluoroacetate **2**, ΔH_c is minus the methyl–oxygen bond strength in dimethyl ether, and ΔH_b is the difference in electron affinities between methoxide radical and trifluoroacetate radical;

$$\Delta H_b = EA(CH_3O\cdot) - EA(CF_3COO\cdot)$$

Assuming[6]

$$\Delta H_a = -\Delta H_c$$

yields

$$\Delta H_1 = \Delta H_b$$

Therefore

$$\begin{aligned}\Delta H_1 &= EA(CH_3O\cdot) - EA(CF_3COO\cdot)\\ &= 32.5 \text{ (ref. 5)} - 103.4 \text{ (ref. 6)}\\ &= -70.9 \text{ kcal}\end{aligned}$$

Reaction 2 may similarly be estimated[7] to be exothermic by 53.8 kcal. Neglecting the secondary isotope effect, reaction 3 is, of course, thermoneutral.

The present results do not provide any direct evidence regarding the details of the molecular rearrangements which convert the reactants into products in the *gas phase* reactions 1 and 2. One possible mechanism, however, is that the deuteriomethoxide ion attacks the ester at the carbonyl carbon to form the tetrahedral intermediate, **7**, which then decomposes to products.

$$R-\underset{\underset{OCD_3}{|}}{\overset{\overset{O^-}{|}}{C}}-O-CH_3 \rightarrow RCOO^- + CD_3OCH_3$$

7

The formation of a tetrahedral intermediate has been suggested as the first step in the gas phase reactions of hydroxide ion and fluoride ion with formate esters (9). Another possible mechanism for the gas phase reactions 1 and 2 is S_N2 displacement upon the methyl group in the ester via the complex, **8** (9).

$$R-\overset{\overset{O}{\|}}{C}O^{\delta-}\cdots CH_3\cdots {}^{\delta-}OCD_3$$

8

The striking feature of the above results is the preference for carboxylate formation in the gas phase. In the case of methyl benzoate, the ratio $k_{carboxylate}/k_{alkoxide}$ is seven orders of magnitude

[6]This approximation could be in error by several kilocalories without changing any of the conclusions of this paper.

[7]Yamdagni and Kebarle (7) quote the difference between the O—H bond energy in benzoic acid and the electron affinity of benzoate radical as 23.7 kcal. Assuming that the O—H bond strength in benzoic acid is 110 kcal (8), estimation of the electron affinity of the benzoate radical would be 86.3 kcal.

greater in the gas phase than in methanol solution. Since the gas phase reaction yields the most exothermic products, the presence of the protic methanol solvent must be responsible for the observation of the formation of the thermoneutral products when the reaction of methoxide with methyl esters is carried out in solution. The change in product ratio when methanol solvent is 'added' to the gas phase systems can be explained by postulating a preferential stabilization by the protic methanol solvent of the transition state for the alkoxide-forming reaction, relative to the transition state for the carboxylate-forming reaction. Since *in solution* the alkoxide-forming reaction proceeds via the tetrahedral intermediate, **7**, in which negative charge is localized on one atom whereas carboxylate is formed via the transition state, **8**, in which the negative charge is spread out over three atoms, this preferential stabilization by the protic solvent is not surprising. Analogous considerations should apply to other (anion) – (acid derivative) reactions, and may explain why in solution the rate of the addition–elimination reaction is faster than many S_N2 reactions (10).

On the mechanisms of acid-catalyzed enolization and hydrogen isotope exchange of cyclic ketones

NICK HENRY WERSTIUK AND SUJIT BANERJEE

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 3, 1976

NICK HENRY WERSTIUK and SUJIT BANERJEE. Can. J. Chem. **55**, 173 (1977).

The acid-catalyzed hydrogen isotope exchange of norcamphor **1** in DOAc–DCl–D_2O is shown to follow the general theory (4) for exchange of a diastereotopic proton pair α to a carbonyl group. That is, the less reactive proton undergoes exchange via two channels. Through an analysis of a combination of the rate data for acid-catalyzed bromination and the pK_{BH+} values for a series of cyclic and bicyclic ketones, we establish that the reactivity order in the former is controlled by ketone basicity and not, as has been suggested previously, by angle strain developed in a very enol-like transition state.

NICK HENRY WERSTIUK et SUJIT BANERJEE. Can. J. Chem. **55**, 173 (1977).

Dans le cas du norcamphre **1**, on démontre que l'échange isotopique de l'hydrogène, catalysé par les acides dans le DOAc–DCl–D_2O, suit la théorie générale (4) de l'échange d'une paire de protons diastéréotopes en α d'un groupement carbonyle. Ceci implique que le proton moins réactif subit un échange par deux voies. Faisant appel à une analyse d'une combinaison des données concernant les vitesses pour la bromation catalysée par les acides et les valeurs de pK_{BH+} d'une série de cétone cyclique et bicyclique, on établit que l'ordre de réactivité dans le premier cas est contrôlé par la basicité de la cétone et non pas, comme il avait été suggéré antérieurement, par la tension d'angle développée dans un état de transition ressemblant beaucoup à un énol.

[Traduit par le journal]

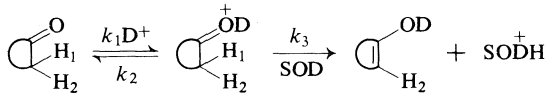
The generally accepted mechanism for acid-catalyzed enolization (exchange) of ketones, as described in Scheme 1 involves a rapid equilibrium protonation of the ketone B, and proton transfer from the conjugate acid BD^+ to produce enol E (1).



B BD^+ E

SCHEME 1

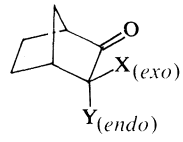
Up to the present, a diastereotopic proton pair H_1 (fast) and H_2 (slow) would have been expected to exchange by separate one-channel processes. Also, the implication in the literature is that the development of double bond character is advanced in acid-catalyzed enolization and it is greater than that developed in the base-catalyzed process (2, 3). Thus, it has been suggested (3) that bond-angle strain developed in a very enol-like transition state in the former, controls the order of reactivity[1] in a series of cyclic ketones.

As a continuation of our study on the enolization of bicyclic ketones (4, 5) we now establish that (*a*) acid-catalyzed hydrogen isotope exchange of a diastereotopic proton pair follows the general mechanism proposed previously (4), and (*b*) the range of reactivity in acid-catalyzed enolization of cyclic and bicyclic ketones primarily results from a variation of pK_{BH^+} with ketone structure.

That acid-catalyzed exchange in norcamphor **1** is describable by the theory documented for base-catalyzed exchange (4) is established by the data in Table 1. That the less reactive proton exchanges via two channels is determined by the fact that $(k_{exo}/k_{endo})^{D\rightarrow H} = 29$ (entries 5 and 6). The intrinsic selectivity factor s is obtained from either the H → D ($i = 5.4$, $s = 191$) or D → H ($i = 5.4$, $s = 186$) exchange data.[2]

[1]The range of reactivity for acid-catalyzed enolization in the series of cyclobutanone, cyclopentanone, cyclohexanone, and cycloheptanone (1:150:743:101) (3) is much greater than that for base-catalyzed enolization (15:9.9:1.0:1.7) (6).

[2]Theory (4) predicts that $(k_{exo}/k_{endo})^{H\rightarrow D} = si/(i+1)$, and $(k_{exo}/k_{endo})^{D\rightarrow H} = s/(i+1)$, where s = intrinsic selectivity, $i = i_{exo} \simeq i_{endo}$, $k_{H\rightarrow D}(endo)/k_{D\rightarrow H}(endo) = i_{solv}$ (solvent isotope effect) and $k_{H\rightarrow D}(exo)/k_{D\rightarrow H}(exo) = i_{exo} \times i_{solv}$. From entries 3 and 6, $i_{solv} \simeq 1.99$, and from entries 2 and 5, $i_{exo} \times i_{solv} = 10.65$. Therefore the K.I.E. $i = 5.4$ at 100 °C.



1*a* X = Y = H
b X = D, Y = H
c X = Y = D
d X = H, Y = D

To establish whether acid-catalyzed enolization (exchange) is sensitive to torsional or bond-angle strain effects in the transition state, we utilized data that were available in the literature (Table 2). Bank and co-workers (8) have shown that the rates of base-catalyzed isomerization (*tert*-BuO^-, DMSO) of the exocyclic olefins correlate with torsional strain energy differences between transition state and ground state. Furthermore, they have established that angle strain factors are of major importance in endocyclic olefin isomerization. Schriesheim and co-workers (6, 7) have shown that the rates of base-catalyzed bromination of the corresponding ketones correlate with the rates of isomerization of the corresponding exocyclic olefins, thereby establishing that torsional strain effects are important in determining the reactivity order in base-catalyzed enolization.

We have utilized Bank's isomerization data to estimate the importance of torsional and bond-angle strain effects on the rates of acid-catalyzed enolization. Thus a plot of $\log k^{acid}_{bromination}$ (Table 2) *vs.* $\log^{exo\rightarrow endo}_{isomerization}$ (8)[3] reveals no obvious

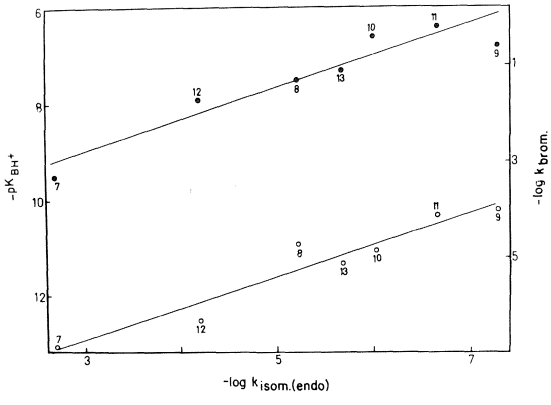


FIG. 1. Correlation of $\log k^{acid}_{bromination}$ (○) and pK_{BH^+} (●) with $\log k^{exo\rightarrow endo}_{isomerization}$. Numbers refer to entries in Table 2.

[3]The available *exo* → *endo* isomerization rate data (8) are not included in Table 2.

TABLE 1. Rate constants for acid-catalyzed exchange

[d]This work in 90% HOAc – 10% 2.00 *N* HCl at 40.0 °C. Rates converted to conditions in footnote *b* by comparison with cyclohexanone.
[e]This work in 90% DOAc – 10% 2.08 *N* DCl at 40.0 °C. Rates corrected for solvent isotope effect (based on norcamphor) and converted to the conditions in footnote *b*, by comparison with cyclohexanone.
[f]Estimated from a plot of pK_{BH^+} *vs.* $\nu_{C=O}$ (9).

correlation (correlation coefficient 0.46)[4], whereas a linear relationship (correlation coefficient 0.96) exists between $\log k^{acid}_{bromination}$ and $\log k^{exo \rightarrow endo}_{isomerization}$ (Fig. 1). Consequently, the reactivity of the ketones in the present series is controlled by bond-angle strain effects rather than by torsional strain factors.

For the process

$$B \underset{}{\overset{H^+}{\rightleftharpoons}} BH^+ \overset{k_3}{\longrightarrow} E$$

where B, BH^+, and E represent ketone, protonated ketone, and enol, respectively, and where protonation of the substrate follows the acidity function H_x,[5]

$$\log k_{obs} = \log k_3 + pK_{BH^+} - H_x$$

Since ketone pK_{BH^+} values are available (9), and the value for H_x is constant, the data (Table 2) establish that the deprotonation rate constant k_3 changes only minimally (a factor of 10). Consequently, we establish that ketone basicity, controlled by bond-angle strain effects as illus-

[4]To minimize the length of the text, the plot of $\log k^{acid}_{bromination}$ *vs.* $\log k^{exo \rightarrow endo}_{isomerization}$ is not included.

[5]Since the acidity function for protonation of these ketones has not been defined, we use H_x only in an illustrative sense.

trated in Fig. 1 by the plot of pK_{BH^+} *vs.* log $k^{endo \rightarrow exo}_{isomerization}$, determines the reactivity of the ketones towards acid-catalyzed enolization. Thus, it is clear that a deprotonation transition state in which unsaturation is highly developed *is not required* to account for the order of reactivity in cyclic ketones.

Received July 21, 1976

H. C. CLARK, P. L. FIESS, and C. S. WONG. Can. J. Chem. **55**, 177 (1977).

The reactions of *trans*-$[PtH(PEt_3)_2(acetone)]^+$ and *trans*-$[PtH(PEt_3)_2(CO)]^+$ with a variety of acetylenes are described. The geometries of the products with respect to the platinum centre and to the stereochemistry of the alkenyl group have been determined on the basis of their ^1H nmr parameters. For reactions with the cation containing acetone, and particularly from a variable temperature ^1H nmr study of its reaction with 2-butyne in the presence of water, the insertion pathway is shown to be entirely analogous to that for olefin insertion, involving an initial displacement of the *trans* ligand by acetylene, isomerization to a *cis*-like intermediate, migratory insertion rearrangement, and re-combination with an appropriate ligand to give either *cis* or *trans* platinum products. The insertion pathway with the carbonyl cation is dependent on the nature of the acetylene; for non-activated or weakly activated acetylenes insertion occurs via five-coordinate intermediates, but with strongly activated acetylenes, the same mechanism as with the acetone cation appears to occur, involving reversible loss of carbon monoxide.

H. C. CLARK, P. L. FIESS et C. S. WONG. Can. J. Chem. **55**, 177 (1977).

On décrit les réactions de $[PtH(PEt_3)_2(acétone)]^+$ *trans* et $[PtH(PEt_3)_2(CO)]^+$ *trans* avec divers acétylènes. On a déterminé, en se basant sur les paramètres de leurs spectres rmn du proton, les géométries des produits par rapport au platine et la stéréochimie des groupes alkényles. Pour les réactions avec le cation contenant l'acétone et particulièrement à partir d'une étude, par rmn du proton à température variable, de sa réaction avec le butyne-2 en présence d'eau on démontre que le chemin de l'insertion est complètement analogue à celui de l'insertion de l'oléfine et qu'il implique un déplacement initial du ligand *trans* par l'acétylène, une isomérisation impliquant un intermédiaire "*cis*", un réarrangement d'insertion migratoire et une recombinaison avec un ligand approprié pour donner des produits de platine soit *cis* soit *trans*. Le chemin d'insertion avec le cation carbonylé dépend de la nature de l'acétylène; pour des acétylènes non-activés ou faiblement activés, l'insertion se produit par des intermédiaires penta-coordonnés mais pour les acétylènes qui sont fortement activés, il semble que le mécanisme soit le même que celui du cation contenant l'acétone et qu'il implique une perte réversible du monoxyde de carbone.

[Traduit par le journal]

Introduction

There have been numerous reports in the literature of reactions involving the insertion of acetylenes in transition metal – hydrogen bonds (see, for example, ref. 1). While stable alkenyl products have been characterized, few investigations of the mechanism of such processes appear to have been conducted. This contrasts with the comparable insertions of olefins into metal–hydrogen bonds, which are of considerable importance in relation to the metal-catalyzed isomerizations and hydrogenations of olefins, and which have been extensively studied in recent years.

For Pt(II) hydrides, it has been demonstrated

[1]Present address: Department of Chemistry, University of Guelph, Guelph, Ont. Canada N1G 2W1.

that insertions proceed via a common mechanism in which the determining factor is the relative ease of displacement of the ligand *trans* to the hydridic hydrogen (2). Thus, for $-SnCl_3$ as a *trans* ligand which is not readily displaced, insertion proceeds via a five-coordinate intermediate (3). With —Cl, $-NO_3$, or acetone as readily displaceable *trans* ligands, such five-coordinate species occur only as transition states and insertion proceeds (4) by initial displacement of the *trans* ligand, isomerization of the resulting *trans* olefinic complex to its *cis* isomer, migratory rearrangement to the alkyl (or alkenyl) product, and finally recombination with a suitable ligand to give either the *cis* or *trans* product. Hence the nature of the *trans* ligand, in determining the relative stabilities of four- and five-coordinate species, controls the mechanistic pathway for insertion. Kinetic data (3, 4), the isolations (5, 6) of stable *trans*-hydrido(olefin)platinum(II) species, and the observation that, depending on the reaction conditions, both *cis* and *trans* platinum isomers of the alkenyl product may be obtained (7) with the formation of this *cis* isomer being kinetically controlled, all provide strong support for this general mechanism.

Most of the previous work described above relates to olefin insertions. Although qualitative studies have been conducted leading to the characterization of the alkenyl products formed by insertion with some acetylenes (3, 7), intermediates such as *trans*-hydrido(acetylene)platinum(II) species have not been identified. On the other hand, both cationic (8) and neutral (9) methylplatinum(II) acetylene complexes have been isolated as stable complexes, suggesting that comparable hydrido analogues should perhaps have a reasonable stability. Also, the presently available data do not indicate whether acetylenes, compared with olefins, have a greater or lesser preference for a five-coordinate versus a four-coordinate pathway for insertion. Again, the use of unsymmetrically substituted acetylenes, $R_1C{\equiv}CR_2$, in reactions with Pt(II) hydrides may provide much more detailed information about the actual migratory insertion step than is accessible from studies of olefin insertions.

Further data are therefore presented here concerning acetylene insertions in the Pt—H bond, particularly in terms of the stereochemical changes which occur at the platinum centre during the insertion process. In the following paper, the nature of the actual migratory insertion step is considered.

Experimental

Reactions were carried out in 50 ml round-bottomed flasks under standard conditions. Where gaseous acetylenes were used, standard vacuum techniques were employed to transfer slightly greater than equimolar amounts into the reaction mixture.

Infrared spectra were recorded using Nujol mulls between NaCl optics on a Perkin-Elmer 621 spectrometer. ^1H and ^{19}F nmr spectra were recorded on Varian T-60 and HA-100 spectrometers, with chemical shifts being reported relative to TMS and $CFCl_3$ (Freon 11) respectively. Melting points were recorded on a Thomas Hoover instrument. Microanalyses were carried out by Chemalytics Inc., Tempe, Arizona, and Midwest Microlab Ltd., Indianapolis, Indiana.

trans-Chlorohydridobis(triethylphosphine)platinum(II) was prepared using the procedure of Parshall (10), and *trans*-$PtH(CO)(PEt_3)_2^+PF_6^-$ following the method of Church and Mays (11).

Reactions with trans-$PtH(PEt_3)_2(acetone)^+PF_6^-$

Since common procedures were employed for numerous reactions, only typical experiments will be described. *trans*-Chlorohydridobis(triethylphosphine)platinum(II) (0.2 mmol) was dissolved in acetone and an acetone solution of silver hexafluorophosphate was added (0.2 mmol). The thick precipitate of silver chloride was removed by centrifugation and the resulting clear solution was diluted to 25 ml with acetone, in a 50 ml round-bottomed flask. The acetylene (0.2 mmol) was added with stirring, this usually being accompanied by a color change. After 5 min, pyridine (0.2 mmol) was added turning the solution to a pale yellow color. The solution was passed through a short florisil column (100–200 mesh) and then evaporated to dryness under vacuum. The resulting solid or oil was taken up in the minimum amount of methanol, and diethyl ether was added dropwise to induce crystallization of the alkenyl product. When gaseous acetylenes were being used, similar procedures were employed except that standard high vacuum techniques were used for transfers of acetylenes.

The products obtained in such reactions, together with characterization data, are described in Table 1.

Reaction of trans-$[PtH(PEt_3)_2(CH_3OH)]^+PF_6^-$ with $CH{\equiv}CCH_2CH_2OH$

A solution of *trans*-$[PtHCl(PEt_3)_2]$ (0.1 g, 0.21 mmol) in methanol (25 ml) was prepared in a 50 ml round-bottomed flask fitted with a magnetic stirring bar. 3-Butyne-1-ol (0.018 ml, 0.21 mmol) was added followed by silver hexafluorophosphate (0.053 g, 0.21 mmol) in methanol (5 ml). The thick white precipitate of silver chloride which formed rapidly was removed by centrifugation to give a clear pale yellow solution. This was through a short florisil column and then evaporated under reduced pressure to *ca.* one-third of its original volume. Diethyl ether (20 ml) was added to ensure crystallization of white crystalline *trans*-$[PtH\{\overline{CH_2CH_2O\ddot{C}CH_2}\}(PEt_3)_2]^+PF_6^-$; yield 92%; mp 128–130 °C. *Anal.* calcd. for $C_{16}H_{37}F_6OP_3Pt$: C 29.67, H 5.72; found: C 29.58, H 5.47.

Reactions of trans-$[PtH(PEt_3)_2(acetone)]^+PF_6^-$ with 2-Butyne over −60 to 32 °C Temperature Range in the Presence of Water

trans-$[PtHCl(PEt_3)_2]$ was dissolved in acetone-d_6 and

an equimolar amount of silver hexafluorophosphate in acetone-d_6 was added. The precipitated silver chloride was removed by centrifugation and the remaining clear solution was pipetted into an nmr tube. Sufficient water was added to provide an approximate H_2O:Pt ratio of 0.8:1. The solution was cooled to −60 °C and 2-butyne was added. After the ^1H nmr spectrum had been recorded, the temperature was raised to −30 °C, the spectrum re-run, and the process repeated at −20, −10, 0, and 32 °C.

Reactions with trans-PtH(CO)(PEt_3)$_2^+PF_6^-$

For qualitative observations of the rates of these reactions, 50 mg of the carbonyl salt was dissolved in 0.3 ml $CDCl_3$ in an nmr tube. A measured quantity of acetylene was then introduced (dimethylacetylenedicarboxylate, 15 µl; $CF_3C{\equiv}CC_6H_5$, 20 µl; C_4H_6, 15 µl; $C_6H_5C{\equiv}CC_6H_5$, 20 mg; $CH_3C{\equiv}CCOOCH_3$, 40 µl). The reaction was followed by nmr by monitoring the disappearance of the Pt–H signal and the formation of the product. The reaction time reported was the time after which no Pt—H signal was observed. The possible error in determining the reaction time is the interval of recording (may be as much as 12 h in slower reactions). Authentic samples of the products were prepared in larger quantities as described below.

Reaction with C_4F_6 was carried out in a sealed nmr tube. *trans*-PtH(CO)(PEt_3)$_2PF_6$ (105 mg) was dissolved in 0.3 ml $CDCl_3$. About 100 µl of C_4F_6 was condensed in and the tube sealed. On warming to room temperature, some C_4F_6 remained as a separate layer. The reaction was followed by periodically observing the ^1H nmr spectrum until the Pt—H signal had completely disappeared. Recrystallization of the product from acetone/ether yielded *cis*-Pt(PEt_3)$_2$($CF_3C{=}CHCF_3$)(CO)$^+PF_6^-$ (59%).

For the preparation of large quantities of the alkenyl products, *trans*-PtH(CO)(PEt_3)$_2PF_6$ was allowed to react with the appropriate acetylene in acetone solution for periods of time from 15 h to 2 days (heated to 54 °C when using $CF_3C{\equiv}CC_6H_5$). Solvent was removed under vacuum and the product recrystallized from methanol/ether. Yields with the various acetylenes were as follows: C_4H_6, 73%; $CH_3C{\equiv}CCOOCH_3$, 52%; $C_6H_5C{\equiv}CC_6H_5$, 78%; $CF_3C{\equiv}CC_6H_5$, 78%; $CH_3OOCC{\equiv}CCOOCH_3$, 49%. Characterization data are presented in Table 2.

Results and Discussion

The reactions which have now been investigated fall into two classes, the first of which is concerned with acetylenes interacting with *trans*-[PtH(PEt_3)$_2$(acetone)]$^+PF_6^-$. These reactions were all conducted in acetone, the Pt(II) cation being generated by the treatment of an acetone solution of *trans*-PtHCl(PEt_3)$_2$ with an equimolar amount of silver hexafluorophosphate. After removal of the precipitated silver chloride, treatment with the stoichiometric amount of acetylene (Table 1) gave the alkenyl insertion product according to *A*, reaction generally being complete in a matter of minutes. The products were isolated, following the addition of pyridine,

[*A*] *trans*-[PtH(PEt_3)$_2$(acetone)]$^+PF_6$ + $R_1C{\equiv}CR_2$ $\xrightarrow{py}$ *trans(cis)*- 
as the pyridine-cation. With only two exceptions

the yields are high (> 60%) and there is no indication of the formation of secondary products. The alkenyl derivatives are all air-stable, white crystalline materials with melting points in the 100–200 °C range.

The second group reactions is described by reaction *B*

[*B*] *trans*-[PtH(CO)$(PEt_3)_2$]$^+PF_6^-$ + $R_1C{\equiv}CR_2$
→ *trans*(*cis*)-[Pt(CO)(PEt_3)(alkenyl)]$^+PF_6^-$

These were all conducted in $CDCl_3$ as solvent, and of course did not require the addition of a neutral ligand such as pyridine for product isolation. Reactions in general were very slow, requiring periods of days or weeks and yields tended to be lower (49–78%) than for reactions with the acetone cation in [*A*]. The products are again all air-stable, crystalline solids with moderately high melting points.

Stereochemistry of Reaction Products

The nmr spectra of the products provided for the ready determination of the stereochemistry at platinum and also the disposition of substituents about the alkenyl C=C bond. The gross geometry about platinum was determined by examination of the P—CH_2—CH_3 signals (11–13). For a *trans* configuration at platinum, a 1:4:6:4:1 quintet was expected and observed. Coupling from the two methylene protons ($J(CH_2$–$CH_3)$ ~8 Hz) equivalent to virtual coupling (12, 14) from two equivalent phosphorus nuclei (J(P–CH_2–CH_3) ~ 8 Hz) produces an overlapping triplet of triplets forming the observed pattern. For a *cis* configuration a 1:2:2:2:1 quintet might be expected but a 1:3:4:4:3:1 sextet was observed. Coupling from the *cis* phosphorus nucleus is apparently too small to be observed and coupling from the other phosphorus is approximately twice that from the methylene protons (J(P–CH_2–CH_3) ~16 Hz; $J(CH_2$–$CH_3)$ ~8 Hz). The resulting overlap of the expected doublet of triplets should have produced the expected 1:2:2:2:1 quintet, but due to the strong *trans* influence of the pyridine ligand, the methyl resonance of the phosphine *trans* to pyridine is shifted about ~8 Hz producing the observed overlapping doublet of pentets.

These assignments could be confirmed by examination of the magnitude of the phosphorus coupling to the vinylic proton. For the *trans* isomer $^4J(P–H_v)$ ~1.5–4 Hz (15, 16). Where observable, this results in a splitting of the vinylic proton resonance into a triplet from virtual coupling to two equivalent phosphorus nuclei. For the *cis* isomer, coupling from the *cis* phosphorus atom is too small to be resolvable, so that the vinylic proton resonance is split into a doublet from coupling to only the *trans* phosphorus nucleus ($^4J(P–H_v)$ ~10 Hz) (7, 17).

The disposition of platinum and hydrogen in the alkenyl function may be determined from the magnitude of $^3J(Pr–H_v)$, for which it has been shown (7, 17–19) that the order observed is *trans* > *cis* ≫ geminal. However, it has also been found (16) that the value of $^3J(Pt–H_v)$ for a particular vinylic configuration varies considerably according to the *trans*-influence of the ligand *trans* to the vinylic group. Thus, for the complexes reported here (Table 3), when the configuration at platinum was *cis* (*i.e.* phosphines *trans* to the vinylic group), the ranges of values are $^3J(Pt–H_{v(trans)})$, 90–120 Hz; $^3J(Pt–H_{v(cis)})$, 35–60 Hz; $^3J(Pt–H_{v(gem)})$ 10–20 Hz. In those of our complexes with a *trans* configuration at platinum (*i.e.* pyridine *trans* to the vinylic group), the ranges are: $^3J(Pt–H_{v(trans)})$, 120–160 Hz; $^3J(Pt–H_{v(cis)})$, 80–105 Hz; and $^2J(Pt–H_{v(gem)})$, 25–30 Hz.

$COOCH_3$	$COOCH_3$	*cis*	5.89	60	10	

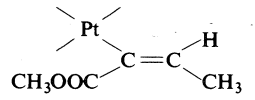
Consideration of the data in Table 3 shows that the products of reaction *A*, with few exceptions, had the *trans* configuration at the platinum centre. The only instances where *cis* isomers can be isolated as part or all of the product occurred where R_1 and R_2, and in some cases only R_1, was a strongly electron-withdrawing substituent, either $—COOCH_3$ or CF_3. It has been established (7) by variable temperature studies that *cis* isomers are the kinetically controlled products and the *trans* ones are thermodynamically more stable. This point is further verified by a variable temperature ^{1}H nmr study of the reaction of $PtH(PEt_3)_2(H_2O)^+PF_6^-$ and 2-butyne (see below). The nmr parameters of Table 3 also show that all the products have the *cis* arrangement of platinum and the vinylic hydrogen about the double bond.

For the products of symmetrically substituted acetylenes, the nmr parameters thus readily allow for the complete determination of stereochemistry. For products of other acetylenes, further analysis of their nmr spectra is necessary, although in all cases, the data of Table 3 show Pt and the vinylic proton to have the *cis* arrangement about the alkenyl double bond. Thus the proton nmr spectrum of the reaction product of *trans*-$[PtH(PEt_3)_2(acetone)]^+PF_6^-$ with methyl propiolate showed two vinylic proton resonances H_v(**A**) and H_v(**B**) at δ5.78 and δ6.12 respectively, indicating formation of two isomeric products **A** and **B**. For isomer **A**, a 1:3:3:1 quartet of triplets was observed, the quartet splitting of 7 Hz being consistent with coupling of a vinylic proton to a geminal methyl group. The triplet splitting of 3 Hz was attributable to virtual coupling to two phosphorus nuclei, *trans* to each other and *cis* to the vinylic group. Isomer **A** was thus assigned the vinylic configuration $—[(COOCH_3)C{=}CHCH_3]$. For isomer **B**, the observed 1:3:3:1 quartet arose from coupling (~1 Hz) of the vinylic proton to a *trans* methyl group, and coupling to ^{31}P was not resolved. This isomer was therefore assigned the configuration $[—(CH_3)C{=}CH(COOCH_3)]$. Irradiation experiments at the vinylic proton resonances indicated that the vinylic methyl resonances for **A** and **B** were at δ1.88 and δ1.97 respectively and hence obscured by the phosphine ethyl resonances. The $P—CH_2—CH_3$ resonance exhibited a 1:4:6:4:1 quintet at ~δ1.12 indicative of *trans* configurations of the phosphines in both isomers. Integration of the vinylic hydrogen resonances indicate a 5:1 ratio of **A** to **B**, and this was confirmed by the similar integration ratio found for the $—COOCH_3$ resonances at δ3.74 and δ3.59 respectively. Only for isomer **A** was coupling (4 Hz) observed between ^{195}Pt and $—COOCH_3$ which in this isomer is geminal.

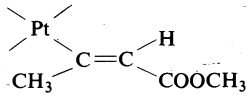
For the reaction product obtained with 1-

phenyl-1-propyne, the vinylic proton resonance appeared as a 1:3:3:1 quartet at δ6.59 with coupling to ^{195}Pt (^3J(Pt–H) = 74 Hz) giving rise to satellites of one quarter total intensity. The quartet splitting of 1.4 Hz is that expected for coupling to a *trans* methyl group and the configuration of the vinylic group was therefore assigned as [$(CH_3)C{=}CHC_6H_5$]. The methyl resonance appeared at δ2.25 as a broad 1:4:1 triplet due to coupling with ^{195}Pt (^3J(Pt–H) = 46 Hz); any splitting due to coupling to the vinylic proton was not well resolved. The phosphine P—CH_2—CH_3 resonance was a 1:4:6:4:1 pentet at δ1.12 indicative of *trans* phosphines.

The spectrum of the product obtained with methylphenylpropiolate shows the resonance for the vinylic proton as a broad triplet at δ6.80, with coupling to ^{195}Pt (^3J(Pt–H) = 92 Hz) giving rise to satellites of one-quarter total intensity. The triplet resonance and the magnitude of the splitting, 3 Hz, indicate a *trans* configuration of the phosphines about the platinum. The —$COOCH_3$ resonance appeared as a 1:4:1 triplet at δ3.74 due to coupling to ^{195}Pt. Such coupling has only been observed for configurations containing the Pt and —$COOCH_3$ attached to the same carbon atom (*e.g.* as described above, such coupling is observed for the configuration **1** but not for **2**

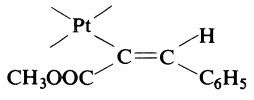


1



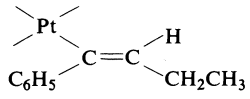
2

The product is therefore tentatively assigned configuration **3**.



3

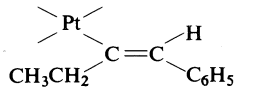
The vinylic insertion product of 1-phenyl-1-butyne gave a proton nmr spectrum showing two vinylic proton resonances at δ5.63 and 6.76, indicating the formation of two isomeric products, **A** and **B**, respectively. Satellites of one quarter intensity were observed for each isomer due to coupling to ^{195}Pt. For isomer **A**, the vinylic proton resonance appeared as a triplet of triplets, the larger triplet splitting of 7 Hz being attributable to coupling to a geminal ethyl (*i.e.* methylene) group so that the configuration **4** is assigned.



4

The smaller triplet of 1.5 Hz arises from coupling to the two equivalent, mutually *trans* phosphorus nuclei.

For isomer **B**, the vinylic proton resonance appears as a 1:4:6:4:1 pentet. Coupling to the methylene protons of a *trans* ethyl group ~1.5 Hz combined with coupling to the two mutually *trans* phosphines (~1.5 Hz) would lead to a pentet resonance. Isomer **B** is therefore assigned configuration **5**.



5

Integration of the vinylic resonances gave a ratio of **A**:**B** = 2:3.

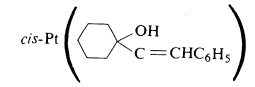
The product obtained from 1-phenyl-1-perfluoropropyne showed the presence of three CF_3 resonances in a 1:7:2 ratio at δ − 43.65, −43.95, and − 50.85 respectively in its ^{19}F nmr spectrum, indicating the presence of three isomeric products **A**, **B** and **C**. The **B** resonance at δ − 43.95 was a 1:4:1 triplet of doublets due to coupling to ^{195}Pt = 89 Hz. The chemical shift is that expected for a CF_3 group attached to the α-carbon, the doublet splitting of 9 Hz being due to coupling the phosphine *trans* to the vinylic group. The other phosphine in the *cis* position does not cause observable coupling. Resonance **B** is therefore attributable to *cis*-[Pt{$C(CF_3)$=CHC_6H_5}py$(PEt_3)_2$]$^+PF_6^-$. The **A** resonance at δ − 43.65, a singlet with one quarter intensity satellites (^3J(Pt–H) = 144 Hz), because of its very similar chemical shift, is assigned to the isomer, *trans*-[Pt{$C(CF_3)$=CHC_6H_5}py$(PEt_3)_2$]-PF_6. Vinylic proton resonances for these two isomers were not observed, but presumably were obscured by the broad phenyl resonance at δ7.3, but for **C** a vinylic proton resonance was observed as a quartet of triplets at δ5.92 with satellites of one quarter intensity due to ^{195}Pt coupling. The quartet splitting of 9.9 Hz is consistent with that expected for coupling of the vinylic proton to a geminal CF_3 group, and the further splitting into

triplets would be expected for coupling of the vinylic proton to two *cis* phosphorus nuclei (^4J(P–H) = 1.5 Hz). Product **C** is therefore identified as *trans*-[Pt{C(C_6H_5)=CHCF_3}py-(PEt_3)$_2$]$^+PF_6^-$. The ^{19}F nmr spectrum for this product showed a 1:6:10:7:7:10:6:1 octet at δ − 50.85, this resulting from coupling to ^{195}Pt(^4J(Pt–F) = 7 Hz), to two equivalent P nuclei *cis* to the vinylic group (^5J(P–F) = 3.5 Hz) and to the vinylic proton (^3J(H–F) = 9.9 Hz).

The ^{19}F nmr spectrum of the product obtained with 3,3,3-trifluoropropyne showed the CF_3 resonance as a 1:4:1 triplet of doublets at δ − 52.8. The triplet pattern is due to coupling to ^{195}Pt(^3J(Pt–F) = 69 Hz), the magnitude of which is consistent with other data given above for compounds containing both Pt and CF_3 on the α-carbon. The doublet splitting of 8 Hz is consistent with coupling to one *trans* phosphorus nuclei, thus indicating a mutually *cis* phosphine arrangement. This was confirmed by examination of the ^{1}H nmr spectrum in which the phosphine methyl resonance appeared as a characteristic 1:3:4:4:3:1 sextet at δ1.2. Also in the ^{1}H nmr spectrum, two vinylic proton resonances, H_v(**A**) and H_v(**B**), were observed at δ5.74 and 6.15 with coupling to platinum of 58 Hz and 101 Hz respectively. From the magnitudes of these couplings, assignments could thus be made of H_v(**A**) and H_v(**B**) to protons respectively *cis* and *trans* across the alkenyl bond with respect to platinum, as previously discussed. The H_v(**A**) resonance was a doublet flanked by satellites of one quarter intensity due to coupling to ^{195}Pt. The doublet splitting of 8 Hz arises from coupling to a *trans* phosphine, this again confirming the mutually *cis* arrangement of the two phosphines. As in other comparable cases (21), no coupling of the proton to the *trans* CF_3 group was observable. The H_v(**B**) resonance consisted of a doublet of quartets, flanked by satellites of one quarter intensity due to ^{195}Pt coupling. The quartet splitting of 2 Hz is consistent with coupling of the vinylic proton to a *cis* CF_3 across an alkenyl bond (20). The doublet splitting 16 Hz arises from coupling to the phosphorus *trans* to the alkenyl group.

For the reaction product obtained with phenylacetylene, two vinylic proton resonances, H_v(**A**) and H_v(**B**) in a 1:1 ratio, were observed at δ6.62 and 7.60 respectively. (The product was isolated as the carbonyl cation rather than as the pyridine analog, to avoid overlap of the second vinylic proton resonance with those of pyridine.) The resonance at δ6.62 was a doublet of triplets with satellites of one quarter intensity due to coupling to ^{195}Pt(^3J(Pt–H_v(**A**)) = 60 Hz; 72 Hz with pyridine as *trans* ligand.) The comparable coupling for H_v(**B**) was 17 Hz so that H_v(**A**) and H_v(**B**) were assigned to the *cis* and geminal protons respectively relative to platinum. Moreover the doublet splitting of both H_v(**A**) and H_v(**B**) of 18.5 Hz is fully consistent with coupling between *trans* protons on an alkenyl group. Both H_v(**A**) and H_v(**B**) resonances showed a triplet character due to couplings to two equivalent phosphines *cis* to the alkenyl group. This mutually *trans* geometry of the phosphines is also shown by the phosphine methyl resonance which appeared as the characteristic 1:4:6:4:1 pentet at δ1.12.

For the reaction product with 1-cyclohexanolphenylacetylene the vinylic proton resonance appeared as a broad 1:4:1 triplet at δ6.67 due to coupling with ^{195}Pt(^3J(Pt–H_v) = 100 Hz). The product is assigned the vinylic configuration



solely on the argument that in related vinylic products containing the =CHC_6H_5 group the vinylic proton resonance shows much the same chemical shift, whereas in cases where the phenyl group is on the α-carbon, this resonance is shifted to much higher field. The phenyl resonance is a broad multiplet centered at δ7.49, and the phosphine methyl resonance as a 1:4:6:4:1 pentet at δ1.01 characteristic of mutually *trans* phosphine ligands.

The reaction with CH≡CCH_2CH_2OH gave a product whose proton spectrum showed a triple hydride resonance at δ − 6.83, flanked by triplet satellites of one quarter intensity due to coupling with ^{195}Pt (^1J(Pt–H) = 616 Hz). The smaller triplet splitting of 18 Hz is indicative of coupling to two equivalent phosphines and this was confirmed by the characteristic 1:4:6:4:1 pentet resonance observed for the phosphine methyl protons at δ1.09. The α-alkoxy protons, —OCH_2R, appeared as a 1:4:1 triplet of triplets at δ5.65 (21) due to coupling to ^{195}Pt (^4J(Pt–H) = 15 Hz). The smaller triplet splitting of 4 Hz is consistent with coupling to the two protons on the β-carbon. The α-carbene protons, —CCH_2R appeared as a 1:4:1 triplet of triplets at δ3.22 due to coupling to ^{195}Pt (^3J(Pt–H) = 14 Hz), and

to the two protons on the adjacent carbon (^3J(H–H) = 1.5 Hz).

The reactions of acetylenes with the platinum(II) carbonyl cation gave products with the *trans*- geometry at platinum with non-activated acetylene or with mildly activated acetylenes, as is shown by the data of Table 4. Reactions with $CH_3C{\equiv}CCH_3$, $C_6H_5C{\equiv}CC_6H_5$, $CH_3C{\equiv}CCOOCH_3$, $CF_3C{\equiv}CC_6H_5$ gave only the *trans* isomers as products, but with more activated acetylenes such as $CH_3OOCC{\equiv}CCOOCH_3$ and $CF_3C{\equiv}CCF_3$, the *cis* isomers are the major products; from relative intensities in their nmr spectra, the relative amounts were, for $CH_3OOCC{\equiv}CCOOCH_3$, 12:1 (*cis*:*trans*) and for $CF_3C{\equiv}CCF_3$, no *trans* isomer was detected. Only for the unsymmetrical acetylenes $CH_3C{\equiv}CCOOCH_3$ and $CF_3C{\equiv}CC_6H_5$ does any question of the geometry of the vinylic group arise, since in all cases the ^3J(Pt–H) and ^4J(P–H) data clearly reveal both the *trans* (or *cis*) geometry at platinum as well as the *cis* arrangement of Pt and H about the C=C bond. For the product with $CF_3C{\equiv}CC_6H_5$, both the chemical shift (Table 4) for the CF_3 group and also the J(Pt–F) value of 111 Hz are indicative of a stereochemistry with CF_3 on the α-carbon. The product with $CH_3OOCC{\equiv}CCH_3$ showed, in its proton spectrum, a coupling of 6.9 Hz between the methyl and vinylic protons consistent with an arrangement containing the methyl group geminal to the vinylic hydrogen.

That the reactions of acetylenes with *trans*-$[PtH(PEt_3)_2(acetone)]^+PF_6^-$ proceed via the same route established previously (4, 6) for olefins is demonstrated by the ^{1}H nmr study of the reaction with 2-butyne in the presence of water. The presence of small amounts of water, which is a better donor than acetone, should allow species such as *trans*-$[PtH(PEt_3)_2(H_2O)]^+$ and its subsequent reaction products to be observed readily. Because of the close proximity of protons in the aquo ligand with the metal centre, they are extremely sensitive to changes in the metal coordination sphere, particularly to the ligand *trans* to the aquo ligand thus providing further information about the stereochemical course of the reaction. At −60 °C, the ^{1}H nmr spectrum (see Fig. 1) of this reaction mixture showed a broad resonance at δ7.10 clearly attributable to coordinated H_2O, in addition to the expected resonances for the phosphine protons, for free water, and for 2-butyne. At high field, in addition to the hydride signal of *trans*-$[PtH(PEt_3)_2(acetone)]^+$ (δ − 24.71, ^1J(PtH) = 1360 Hz, ^2J(PH) = 15 Hz), there was another signal at δ − 24.82 which was assigned to the hydridic hydrogen of *trans*-$[PtH(PEt_3)_2(H_2O)]^+$. At −30 °C, the signal of the coordinated water diminished in intensity, and a new resonance at δ2.21 developed with fine structure due to coupling to ^{195}Pt. This could be assigned to coordinated 2-butyne with ^3J(PtH) = 21 Hz in the species *trans*-$[PtH(PEt_3)_2(C_4H_6)]^+$ (step 1 in Scheme 1). Its hydride signal appears at δ − 12.06 with ^1J(PtH) = 1320 Hz, ^2J(PH) = 13 Hz. At −20 °C, all the resonances associated with *trans*-$[PtH(PEt_3)_2(acetone)]^+$, *trans*-$[PtH(PEt_3)_2(H_2O)]^+$ (δ6.72), and *trans*-$[PtH(PEt_3)_2(C_4H_6)]^+$ (δ2.16) could be observed, as well as new peaks at δ5.50 and δ7.20. The transient existence of the latter two peaks (see below) and the unusual low field of the latter lead us to assign them as the $-C(CH_3){=}CH(CH_3)$ and the coordinated water in *cis*-$[Pt(PEt_3)_2(CH_3C{=}CHCH_3)(H_2O)]^+$ (step 3 in Scheme 1). At 10 °C, isomerization of the *cis* vinyl complex to the *trans* isomer occurred (step 4 in Scheme 1) as is evidenced by the gradual disappearance of the resonance at δ7.20 and the simultaneous appearance of the resonance at δ6.18; the vinyl hydride signal also shifted to slightly higher field to δ5.32. These changes in positions of the resonances are in accordance with the greater *trans*-influence of PEt_3 compared with that of a vinyl group or of water. At 32 °C, the spectrum also showed the presence of *trans*-$[Pt(PEt_3)_2(cis\text{-}C(CH_3){=}CHCH_3)(C_4H_6)]^+$, ($H_v$5.32 with ^3J(PtH) = 90 Hz, and C_4H_6 δ1.91 with J(PtH) masked by the phosphine signals).

This experiment thus provides conclusive evidence for an insertion process (Scheme 1) which is initiated by acetylene displacement of the *trans* ligand, in this case water and acetone. The detection of the existence of the thermodynamically less stable *cis* product, *cis*-$[Pt(PEt_3)_2(cis\text{-}C(CH_3){=}CH(CH_3))(H_2O)]^+$, implies a *trans*-to-*cis* isomerization (step 2, Scheme 1) must have occurred. Interestingly, in this experiment we also observed interaction with a second acetylene unit in the formation of *trans*-$[Pt(PEt_3)_2(cis\text{-}(CH_3){=}CH(CH_3))(C_4H_6)]^+$.

Further evidence for this mechanism comes from the observation that the reaction of the hydrido cation with 3-butyne-1-ol gave the *trans*-hydrido carbene complex, the cyclic carbene resulting from rearrangement of the co-

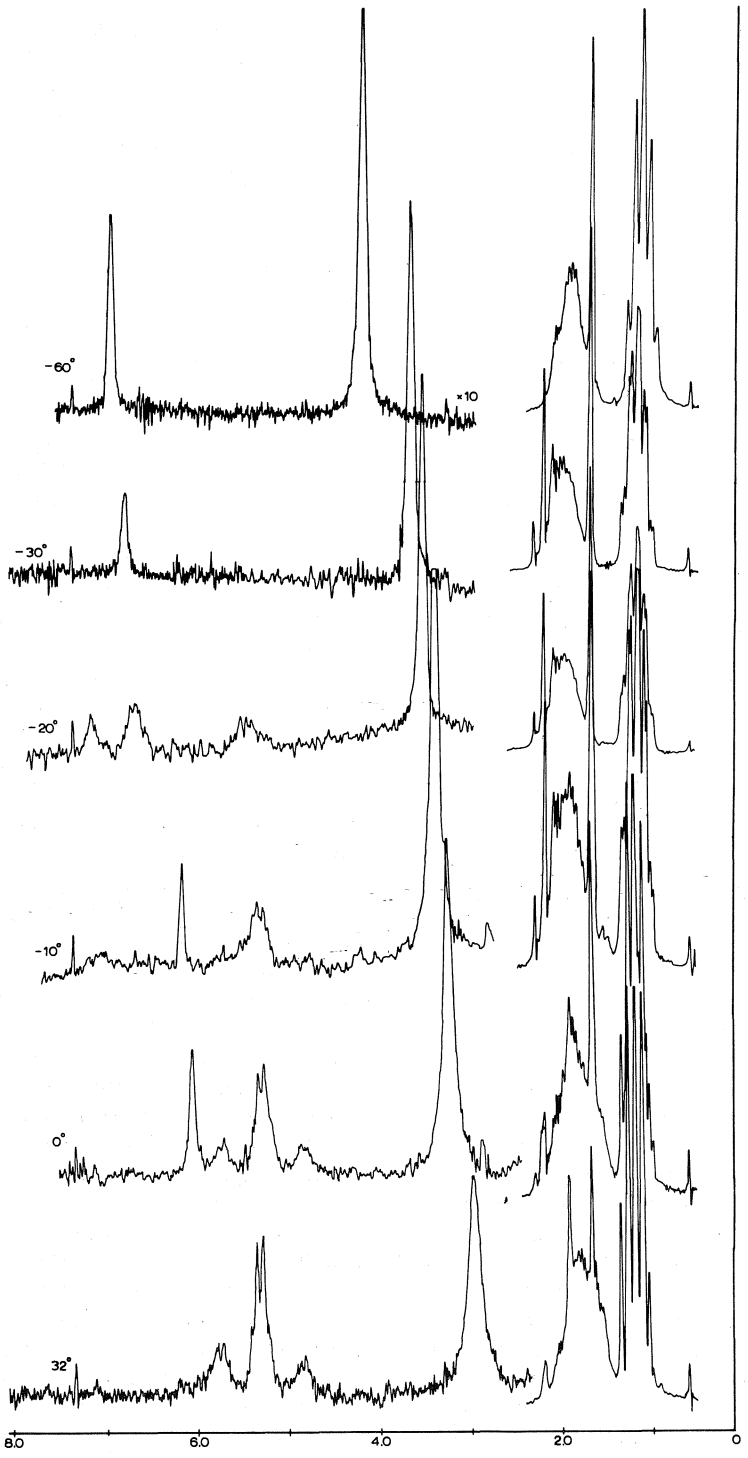

FIG. 1. Variable-temperature ^1H nmr spectrum of a CD_3COCD_3/H_2O solution containing *trans*-$[PtH(PEt_3)_2(acetone)]^+PF_6^-$ and 2-butyne.

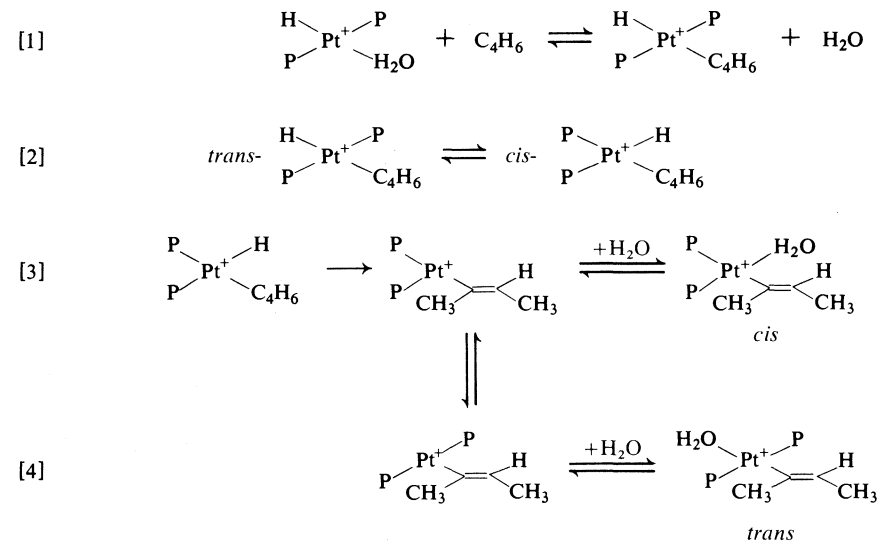
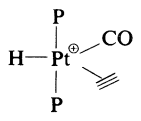


SCHEME 1. Proposed mechanism for the reaction of $PtH(PEt_3)_2(H_2O)^+PF_6^-$ with 2-butyne.

ordinated acetylene. It has previously been found that such carbene formation (for both cyclic and non-cyclic carbenes) occurs via co-ordinated acetylene intermediates for both Pt(II) (22), and rhodium(III) and iridium(III) systems (23).

In contrast, all currently available evidence indicates that the mechanism by which the carbonyl platinum(II) cation undergoes insertion with acetylenes (except for the highly activated perfluorobut-2-yne and dimethylacetylene dicarboxylate) must be described differently. Firstly, reactions with the hydrido(acetone)platinum cation require reaction times in the order of minutes, whereas hydrido(acetone)platinum cations takes days for their completion. Secondly, the reaction products with the hydrido(carbonyl) cation all retain CO as a ligand, and the final stereochemistry at platinum seems to depend on the nature of the acetylene employed. Hence, for reactions of non-activated or only weakly-activated acetylenes with the hydrido(carbonyl) cation where *trans* (at Pt) products are obtained, we conclude that five-coordinate, presumably trigonal bipyramidal intermediates (**6**) are involved,



6

With C_4F_6 and dimethylacetylene dicarboxylate, reactions with the hydrido(carbonyl) cation are slower than for the non-activated acetylenes, and *cis*-platinum alkenyl products, rather than *trans*, are formed. We therefore conclude that with these acetylenes, reaction may very well proceed via a four-coordinate cationic mechanism involving the displacement of CO from the coordination sphere by the acetylene. This interpretation is supported by our observation that *trans*-$PtH(PEt_3)_2(acetone)^+PF_6^-$ catalyzes the hydration of dimethylacetylene dicarboxylate in aqueous acetone solution to form dimethyloxosuccinate; *trans*-$PtH(CO)(PEt_3)_2^+PF_6^-$ shows the same catalytic effect when the reaction is carried out in an open atmosphere (under nitrogen purge), but the same compound is catalytically inactive in a closed atmosphere. This indicates that the active catalyst which is generated in an open atmosphere does not contain a CO ligand. We are currently studying further this interesting catalytic hydration reaction.

Again, therefore, as is the case for olefin insertion, the nature of the ligand *trans* to hydride largely determines the mechanistic course of the insertion process. A readily displaced *trans* ligand results in an insertion mechanism which proceeds via a four-coordinate intermediate, while a less readily displaced ligand such as CO requires the involvement of a five-coordinate

intermediate. However, the present results also indicate that the mechanistic pathway is also dependent on the nature of the acetylene. Because of the better coordinating ability of some acetylenes (*e.g.* C_4F_6) compared with olefins, the normally less readily displaced CO ligand may also be displaced in certain cases. Other than this, the behaviour of acetylenes towards insertion into platinum(II) hydrides and presumably other square planar d^8 metal hydrides is essentially the same as that of olefins.

T. G. ATTIG, H. C. CLARK, and C. S. WONG. Can. J. Chem. **55**, 189 (1977).

The reactions of platinum(II) hydrides, *trans*-$PtHXL_2$, where X = NO_3, Cl or CH_3OH, and L = PEt_3 or tricyclohexylphosphine, with disubstituted acetylenes, $R_1C{\equiv}CR_2$, have been examined under a variety of conditions. From spectroscopic parameters, the gross geometry at platinum as well as the geometry of the resulting alkenyl groups in the products have been determined. The observation that all alkenyl groups have a *cis* geometry is consistent with a migratory insertion step involving a four-centred transition state, in which the disposition of the acetylene relative to the Pt—H bond appears to be dependent on the Pt—H bond polarity. Evidence is presented to demonstrate that this polarity depends on several factors including solvent, and ligands on Pt(II). For L = tricyclohexylphosphine, the occurrence of a side reaction which competes with insertion and which leads to a Pt(0) acetylene complex is also demonstrated, and other interesting reactions are described.

T. G. ATTIG, H. C. CLARK et C. S. WONG. Can. J. Chem. **55**, 189 (1977).

On a étudié, dans diverses conditions, les réactions des hydrures de platine(II), $PtHXL_2$ *trans* (où X = NO_3, Cl ou CH_3OH et L = PEt_3 ou tricyclohexylphosphine) avec les acétylènes disubstitués $R_1C{\equiv}CR_2$. En se basant sur des paramètres spectroscopiques, on a déterminé, pour les produits, la géométrie globale au niveau du platine de même que la géométrie des groupes alkényles résultants. Le fait que tous les groupes alkényles possèdent une géométrie *cis* est en accord avec une étape d'insertion migratoire impliquant un état de transition à quatre centres dans lequel l'orientation de l'acétylène par rapport au lien Pt—H semble dépendre de la polarité du lien Pt—H. On présente des données pour démontrer que cette polarité dépend de plusieurs facteurs incluant le solvant et les ligands attachés au Pt(II). Pour L = tricyclohexylphosphine, l'existence d'une réaction secondaire qui est en compétition avec l'insertion et qui conduit à un complexe Pt(0) acétylène peut aussi être démontrée et on décrit d'autres réactions intéressantes.

[Traduit par le journal]

Introduction

In the preceding and earlier papers (1, 3), the mechanisms of insertion of olefins and acetylenes into the Pt—H bond of platinum(II) hydrides have been discussed with particular reference to the stereochemistry at the platinum centre. Evidence has been presented for a mechanistic pathway which may involve either four- or five-coordinate intermediates, the determining factors being the nature of the ligand *trans* to hydride in the original reactant and the coordinating ability of the organic substrate. This pathway brings the hydridic hydrogen and the coordinated unsaturate into *cis* positions with respect to each other, and it is from this arrangement that the alkyl or alkenyl product is thought to be formed. In the absence of any direct evidence, it has usually been assumed (4) that a simple four-centred transition state is involved. Recent semiempirical SCF-MO calculations (5) appear to be consistent with this, although unfortunately many of the models used for these calculations are inconsistent with recent experimental work (2, 6). The purpose of this paper is to present and discuss evidence concerning the nature of the actual insertion step and of the transition states that may be involved. The reactions of platinum(II) hydrides with disubstituted acetylenes are particularly valuable in this connection, in that their reaction rates can be conveniently followed, and also the nmr parameters of the resulting alkenyl derivatives allow their stereochemistry to be readily determined. It follows that the *cis* or *trans* geometry about the C=C alkenyl bond, and the locations of the acetylenic substituents on the α- and β-carbons of the alkenyl group, as well as the ligand and solvent effects on this stereochemistry, provide considerable information on the nature of the migratory insertion step.

Results and Discussion

In addition to the reactions described earlier (1), we have now investigated a substantial number of reactions of disubstituted acetylenes with platinum(II) hydrides. Table 1 gives details of some of the systems examined, the reaction conditions used and the yields and nature of the alkenyl products. The Pt(II) hydrides used contained either triethylphosphine or tricyclohexylphosphine as ligand, the latter introducing additional steric constraints due to its size and also placing greater electron density on Pt because of its higher basicity. Both cationic and neutral hydrides were used, the latter having either NO_3^- or Cl^- as anionic ligand.

As can be seen from Table 1, the yields of the alkenyl products are high, averaging about 70–75% with few exceptions. The reasonable assumption is therefore made that these are generally clean reactions with the alkenyl insertion compounds as the only major products. The rates of these reactions vary substantially. For triethylphosphine cationic hydrides, insertion is often complete in less than 30 min, in contrast to the reactions of neutral chlorides where complete insertion may require 24 h.

More electron-withdrawing substituents on the acetylene generally accelerate the insertion process.

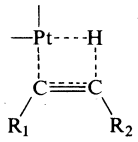
The arguments given below depend critically on the determination of the stereochemistry of each reaction product. For these Pt(II) alkenyl derivatives, such stereochemical determination can be achieved unambiguously on the basis of the observed nmr parameters, in terms both of *cis* or *trans* geometry about platinum and of the *cis* or *trans* disposition of Pt and H in the alkenyl group.

Consideration of ^3J(PtH) and ^4J(PH) data distinguishes clearly between the four isomeric possibilities. We have been able to prepare (7) the four possible isomers from the insertion of dimethylacetylene dicarboxylate with Pt(II) hydrides, and the data shown in Table 2, together with previously published values (8–11), allow a ready determination of stereochemistry. Additional information can also be obtained from the relative intensities of the P—CH_2CH_3 quintet signals (8, 12–14) and in favorable cases the couplings of Pt and P with protons on the α-carbon help to confirm stereochemistry. Table 1 contains the nmr data on which the

stereochemical conclusions are based. The question of kinetically or thermodynamically controlled products has been discussed in the preceding paper (1). We further note that although *cis*-to-*trans* isomerization (about the Pt centre) of the complexes in solution can be achieved by heating, no isomerization of the vinylic groups of the complexes shown in Table 2 has been observed even after heating in benzene at 70 °C for 3 days. It is, therefore, concluded that the geometry of the vinylic group is kinetically (rather than thermodynamically) controlled.[3]

In considering the nature of the insertion step, [1], two models may be proposed which rep-

[1] 
resent the extreme descriptions of the transition state. In the first model, the commonly held assumption is made that the Pt—H bond remains intact while the appropriate geometry of the transition state is attained. This suggests (but does not necessarily require) a four-centred transition state, **1**.



1

In all of the reactions described earlier (1), as well as those given in Table 1, the alkenyl groups have *cis* dispositions. Thus, in Table 1, for *trans* (at Pt) complexes, ^3J(PtH) is in the range 83–108.5 Hz and for *cis* (at Pt) complexes, the corresponding range is 38.6 to 61.8 Hz. These values taken in conjunction with the related ^4J(PH) values, and by comparison with the data of Table 2, confirm the *cis* stereochemistry for the alkenyl group. This is consistent with a four-centred transition state, although not proof of it. It is interesting that a recent theoretical study (5) of the ethylene–

[3]Intramolecular (C=C) isomerizations have been observed for several vinylic Rh(III) complexes (15). But their rearrangements corresponded to a *cis*-to-*trans* isomerization only and required up to 24 h reaction time. This result is, therefore, not in conflict with our conclusion that the *cis* geometry of the vinylic groups in our isolated products are kinetically controlled.

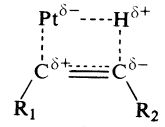
platinum hydride insertion, despite weaknesses in the choice of models, also suggests the likelihood of a four-centre transition state.

For a disubstituted acetylene inserting into Pt—H via such a transition complex, the disposition of the acetylenic substituents in the alkenyl product would then depend primarily on the polarity of the Pt—H bond. Since in the majority of products described in Table 1 the more electron-withdrawing acetylenic substituent is placed on the β-carbon, polarization of the transition state may be described by **2**.



2

However, our data show that there are three circumstances under which the reverse configuration of the alkenyl group with the more electron-withdrawing substituent on the α-carbon may be obtained.

Firstly, this occurs, for example, in the insertion (1) of $CH_3OOCC{\equiv}CCH_3$ or $CF_3C{\equiv}CC_6H_5$ with *trans*-$[PtH(PEt_3)_2(CO)]PF_6$. Since in these reactions CO remains on Pt during the insertion, a five-coordinate intermediate must be involved and in contrast to those cases involving a four-coordinate intermediate these ligands including CO must place much greater electron density into the platinum center.

Secondly, with tricyclohexylphosphine as

ligand, the alkenyl group tends (reactions 15 and 18 of Table 1) to have the stereochemistry with the more electron-withdrawing acetylenic substituent on the α-carbon. Thus from $CH_3C{\equiv}CCOOCH_3$ and *trans*-$[PtH(Pcy_3)_2(MeOH)]PF_6$ in dichloromethane a mixture of the two isomers is obtained, while with $CF_3C{\equiv}CC_6H_5$ the only product has CF_3 on the α-carbon. Since tricyclohexylphosphine is more basic than triethylphosphine (16), it will increase the electron density on platinum as did CO in the previous case. These two effects indicate that with ligands placing increased density on to platinum, a reversal of polarity may occur leading to formation of the other alkenyl isomer.

[2] $Pt^{\delta+}H^{\delta-} + RC{\equiv}CR' \rightarrow$  $\rightarrow$

R = $COOCH_3$, or CF_3

The third exceptional circumstance leading to this configuration of the alkenyl group appears to be caused by either an anion or solvent effect. An examination of Table 1 and of previous data (1) shows that for all neutral hydrido-complexes (*i.e.*, X = Cl or NO_3) the resulting alkenyl product always has the more electron-withdrawing acetylenic substituent on the β-carbon. On the other hand, for these neutral complexes the rate of formation of the insertion product does show some solvent dependence; $CH_3C{\equiv}CCOOCH_3$ and *trans*-$[PtHCl(PEt_3)_2]$ react completely within 24 h in methanol, 7 days in $CHCl_3$, but scarcely react at all in acetone, even over a period of 2 weeks. We have no obvious explanation for this unusual effect in acetone.

For cationic hydrido complexes, with methanol or DMSO as solvent, the same geometry of the alkenyl product is obtained as for the neutral complexes, but in acetone or methylene chloride, some of the alkenyl product has the reversed geometry with the more electron-withdrawing substituent on the α-carbon. Obviously, charge separation is less favoured in non-polar solvents, so that the Pt—H bond is less polarized, resulting in less selective insertions. The presence of coordinating anions may also play a role in affecting the polarity of the Pt—H bond, and we tentatively attribute this to an ion-pairing effect, $\overset{\delta-}{Pt}—\overset{\delta+}{H}—Cl^-$.

It is interesting that in protonation studies of $Pt(PPh_3)_2(CH_3C{\equiv}CC_6H_5)$, Shaw and coworkers report (9), without comment, the formation of the two alkenyl derivatives containing $Pt[C(CH_3){=}CHC_6H_5]$ and $Pt[C(C_6H_5){=}CHCH_3]$. From our results as described above, it is clear that by appropriate ligand and solvent changes the polarity of the Pt—H bond can be readily reversed so that the formation of one or other alkenyl isomer can be achieved in a controlled fashion.

The second model for the insertion step involves actual migration of the hydridic hydrogen to the coordinated acetylene. In its extreme form, it could be regarded as a stepwise process involving prior cleavage of the Pt—H bond. Such bond cleavage might be heterolytic or homolytic; the latter possibility will be considered in a later paper.

That facile Pt—H cleavage may occur in the course of such insertion reactions can be demonstrated from reactions 1 and 2 of Table 3. In particular, treatment of *trans*-$[PtH(Pcy_3)_2(MeOH)]PF_6$ with $CF_3C{\equiv}CCF_3$ or $H_3COOCC{\equiv}CCOOCH_3$ was found to be markedly solvent dependent. In dichloromethane the *cis*-alkenyl insertion product is obtained, but in a 1:8 dichloromethane:methanol mixture the platinum(0) acetylene complex, $(Pcy_3)_2Pt(RC{\equiv}CR)$, R = CF_3, or $COOCH_3$, is immediately precipitated. If this precipitate is not removed and more dichloromethane is added to the solvent mixture, the precipitate re-dissolves and the final product is the expected *cis*-alkenyl insertion derivative.

[a]As the CH_2Cl_2 solvate.
[b]79% keto, 21% enol.

Also, although *trans*-$[PtH(Pcy_3)_2(MeOH)]^+$ in methanol-*d* shows no H–D exchange over a 3 h period, when the above reaction with $H_3COOCC{\equiv}CCOOCH_3$ is carried out in a 1:1 mixture of CH_3OD and CH_2Cl_2 (the composition of the solvent mixture chosen so as to prevent actual precipitation of the Pt(0) acetylene complex) the *cis*-alkenyl insertion product has an 85% deuterium incorporation.

An obvious interpretation is that the insertion process occurs by a sequence of steps involving (*a*) reductive elimination of H^+ and formation of the Pt(0) complex, (*b*) rapid H–D exchange between the H^+ and the deuterated methanol solvent, (*c*) protonation of the coordinated acetylene to give the alkenyl 'insertion' product. The insertion 'step' is then the summation of a series of reactions and does not involve a four-centred transition state. It is by no means clear, however, that the conversion of the Pt(0) complex to the *cis*-alkenyl product involves protonation of the coordinated acetylene; it is at least equally probable that protonation involves reformation of the Pt—H bond and that insertion occurs *only* via a four centre transition state to give the *cis*-alkenyl product. This would also imply that in the majority of cases an equilibrium exists between the hydrido(acetylene)platinum(II) cation and the platinum(0) acetylene complex, and that the low solubility of the latter compound favors its precipitation in methanol-rich solvent mixtures.

[4] *trans*-$[PtH(Pcy_3)_2(MeOH)]PF_6$ + $RC{\equiv}CR \rightarrow$ *trans*-$[PtH(Pcy_3)_2(RC{\equiv}CR]PF_6$

[5] $[PtH(Pcy_3)_2(RC{\equiv}CR)]PF_6 \rightleftharpoons Pt(Pcy_3)_2(RC{\equiv}CR) + H^+ + PF_6^-$

[6] $[Pt(CR{=}CHR)(solvent)(Pcy_3)_2]PF_6$

Although the starting compound of equilibrium [5] has the *trans* configuration, this geometry at platinum is not necessarily regenerated in the protonation of the Pt(0) acetylene complex, nor does the product of [6] necessarily have the *trans* geometry.

This is consistent with other results given in Table 1 concerning acetylene insertions conducted in methanol-*d*. While none of these hydridoplatinum(II) species undergo H–D exchange themselves with methanol-*d*, the presence of acetylene does induce such exchange but only in some instances. As Table 1 indicates, for such systems with $CF_3C{\equiv}CC_6H_5$, $CF_3C{\equiv}CCF_3$, $CH_3C{\equiv}CCOOCH_3$, or $CH_3OOCC{\equiv}CCOOCH_3$, H–D exchange was essentially complete (*i.e.*, D incorporation into the alkenyl group better than *ca.* 90%) but for acetylenes such as $CH_3C{\equiv}CC_6H_5$, $C_6H_5C{\equiv}CC_6H_5$, or $CH_3C{\equiv}CCH_3$, no such exchange occurred (*i.e.*, D incorporation into the alkenyl group less than *ca.* 10%). Apparently, the generalization can be made that H–D exchange only occurs in those systems in which the acetylene has electron-withdrawing substituents. This can be explained in terms of the equilibria:

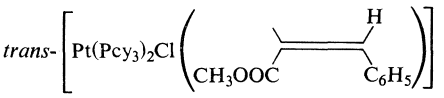
[7] *trans*-$[PtH(PR_3)_2X] + R_1C{\equiv}CR_2 \rightleftharpoons$ *trans*-$[PtH(PR_3)_2(R_1C{\equiv}CR_2)]X \rightleftharpoons Pt(PR_3)_2(R_1C{\equiv}CR_2) + H^+ + X^-$

The presence of acetylenic electron-withdrawing substituents assists in the stabilization of both hydridoacetylenic cations and of Pt(0) acetylene complexes, thus pushing the overall equilibria in the direction most favorable for H–D exchange with the methanol-*d* solvent. For the reactions described above involving tricyclohexylphosphine hydrido cations, not only are the acetylenes strongly electron-withdrawing, but also the low solubilities of the corresponding bis(tricyclohexylphosphine)acetyleneplatinum(0) complexes push the equilibria to the right favoring extensive H–D exchange. With regard to the actual insertion process then, such formation of Pt(0) acetylene complexes appears to represent only a side reaction which is relatively unimportant in terms of the mechanism of formation of alkenyl insertion products.

For the tricyclohexylphosphine complex a number of other interesting reactions were observed. With 2-butyne, in dichloromethane, reaction (see Table 3) with *trans*-$[PtH(Pcy_3)_2(MeOH)]PF_6$ gave the hydrido(acetylene) cation, *trans*-$[PtH(Pcy_3)(CH_3C{\equiv}CCH_3)]^+$. In the preceding paper (1), we reported that with triethylphosphine hydridoplatinum(II) species, the existence of the analogous hydrido(acetylene) cation could only be observed at low temperature. In the present case, presumably the steric bulk of the tricyclohexylphosphine ligands stabilize the hydrido(acetylene) species. Presum-

ably, also, insertion proceeds via the previously described mechanism involving an isomerization to the *cis*-platinum complex and insertion to the alkenyl product. Since platinum(II) species are known (19) with two tricyclohexylphosphine ligands in approximately *cis* positions, the bulk of the phosphine might well slow this *trans–cis* isomerization but not totally prevent it. The formation of a $Pt(Pcy_3)_2$(acetylene) complex and its recombination with H^+ possibly provide a route for the *trans*-to-*cis* isomerization of the $PtH(Pcy_3)_2$(acetylene) complex. If this is the case, then the inability of $CH_3C{\equiv}CCH_3$ to insert is because of its inability to form the Pt(0) acetylene complex. It is interesting also that reactions in methanol-rich solvent mixture of *trans*-$[PtH(Pcy_3)_2(MeOH)]^+$ with $CH_3C{\equiv}CC_6H_5$ and $CH_3C{\equiv}CCH_3$ gave only starting materials. This is consistent with the relatively low donor properties of these acetylenes and their inability to displace methanol from platinum.

In 1:8 dichloromethane methanol mixtures, the reaction of *trans*-$[PtH(Pcy_3)_2(MeOH)]PF_6$ with $C_6H_5C{\equiv}CCOOCH_3$ led to interesting products (Table 3). An approximately 25-fold excess of the latter acetylene was converted at room temperature to a mixture of **E** and **Z** isomers of $C_6H_5(CH_3O)C{=}CHCOOCH_3$, and $C_6H_5COCH_2COOCH_3$. The mode of formation of the latter compound as well as its abundance relative to the other purely organic products have yet to be determined. However, it is clear that the above two olefinic isomers result from the catalyzed addition of methanol and water to the acetylene. The platinum-containing catalyst is recovered as



with the final addition of NaCl. This catalyzed conversion of the acetylene therefore appears to be essentially quantitative other than the amount consumed in the Pt(II)-alkenyl formation. At the present stage, the efficiency of the original hydride as catalyst has yet to be determined and indeed the fact that the actual catalyst is the original hydride must be verified. Similar behaviour is observed for reactions with $CH_3C{\equiv}CCOOCH_3$, while using ethanol rather than methanol appears to lead to the ethoxy analogues. Work on these reactions is continuing. In this connection, it is interesting to note the formation of *trans*-$PtH[C(CF_3){=}C(OCH_3)(C_6H_5)(Pcy_3)_2$ from the reaction of the cationic hydride with $CF_3C{\equiv}CC_6H_5$ in methanol. This presumably results from nucleophilic attack on the coordinated acetylene and is comparable to the analogous reactions (18) of cationic methylplatinum(II) species.

Experimental

The general procedures and instrumentation employed in these studies have been described previously (see, for example, refs. 3, 8, and 11). Previously reported methods (17, 19) were used for the preparation of *trans*-$[PtHCl(PEt_3)_2]$ and *trans*-$[PtHCl(Pcy_3)_2]$. The source and method of purification for each acetylene were as follows: $CF_3C{\equiv}CC_6H_5$ was prepared and purified as described (20); $CH_3C{\equiv}CCOOCH_3$ was obtained by the methylation of tetrolic acid (Farchan) with methanol using sulfuric acid as catalyst and was purified by distillation under partial vacuum and characterized by nmr; $CF_3C{\equiv}CCF_3$ (PCR Inc.) was used without further purification; $CH_3C{\equiv}CC_6H_5$ and $CH_3OOCC{\equiv}CCOOCH_3$ (Aldrich) were distilled before using, and $PhC{\equiv}CPh$ was purified by recrystallization from methanol; 2-butyne was kindly provided by Dr. K. Yasufuku.

Preparation of Pt(alkenyl)Cl(PEt$_3$)$_2$ Derivatives

To a solution of 150 mg of *trans*-$PtHCl(PEt_3)_2$ in 1 ml of methanol was added two- to three-fold excess of acetylene. After 24 h, the solution was evaporated to dryness and the residue recrystallized from an appropriate solvent mixture ($CH_3C{\equiv}CC_6H_5$, ether/hexane; $CH_3C{\equiv}CCOOCH_3$, methanol/ether/hexane; $C_6H_5C{\equiv}CC_6H_5$, methanol; $CH_3OOCC{\equiv}CCOOCH_3$, methanol/ether/hexane; $CF_3C{\equiv}CC_6H_5$, methanol/pentane).

Preparation of trans-Pt(CH$_3$C=CHCH$_3$)Cl(PEt$_3$)$_2$

246 mg of *trans*-$PtHCl(PEt_3)_2$ in 9 ml of methanol was treated with 126 mg $AgPF_6$ in 1 ml of methanol. The white precipitate of AgCl was separated by centrifugation. Excess of 2-butyne (70 μl) was then added. After 1 h, the reaction mixture was quenched with an aqueous methanolic solution of NaCl. The solution was evaporated to dryness under vacuum, extracted with ether and passed through a short florisil column. Recrystallization in acetone/H_2O yield *trans*-$Pt(CH_3C{=}CHCH_3)Cl(PEt_3)_2$ as white crystals 220 mg (80%).

Preparation of cis-Pt(CF$_3$C=CHCF$_3$)X(PEt$_3$)$_2$ (X = Cl or NO$_3$)

C_4F_6 was passed into a solution of 150 mg of *trans*-$PtHX(PEt_3)_2$ in methanol for 5 min. Evaporation of the solvent after 3 h (X = Cl; ½ h for X = NO_3) gave white crystals which were recrystallized from methanol/ether/hexane (for X = Cl; CH_2Cl_2/ether for X = NO_3).

Preparation of Pt(alkenyl)NO$_3$(PEt$_3$)$_2$

To a solution of 150 mg of *trans*-$PtH(NO_3)(PEt_3)$ in 1 ml of methanol was added 1 equivalent of acetylene. After ½ h, the solution was evaporated to dryness

under vacuum and chromatographed through a florisil column with benzene. After evaporation to dryness under vacuum, the residue was recrystallized from an appropriate solvent mixture (for $CH_3C{\equiv}CCOOCH_3$, CH_2Cl_2/ether/hexane, for $CH_3OOCC{\equiv}CCOOCH_3$, methanol/ether/hexane; for $CH_3C{\equiv}CC_6H_5$, ether/hexane; for $CF_3C{\equiv}CC_6H_5$, methanol).

Preparation of $PtCl(CR_1{=}CHR_2)(Pcy_3)_2$

To a solution of 250 mg of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ (prepared from *trans*-$PtHCl(Pcy_3)_2$ as previously described (16)) in 5 ml CH_2Cl_2 was added 1 equivalent of acetylene. After being stirred for 1 h, a methanolic NaCl solution was added and the solvent was removed. The product was extracted with CH_2Cl_2, and precipitated as white crystals upon the addition of hexane or methanol.

Preparation of $PtCl(CF_3C{=}CHCF_3)(Pcy_3)_2$

In a thick-walled nmr tube containing 200 mg of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 0.5 ml CH_2Cl_2, were condensed 2 equivalents of hexafluoro-2-butyne at -196 °C. The tube was sealed and allowed to warm to room temperature and to stand for 12 h. After similar working with methanolic NaCl the white crystals of $PtCl(CF_3C{=}CHCF_3)(Pcy_3)_2$ were obtained upon addition of methanol.

Preparation of $Pt(Pcy_3)_2(CF_3C{\equiv}CCF_3)$

In a thick-walled nmr tube containing 200 mg (0.252 mmol) of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 0.25 ml CH_2Cl_2 and 1 ml CH_3OH was condensed 1.5 equivalents of hexafluoro-2-butyne at -196 °C and the tube sealed. After standing at room temperature for 1 day the tube was opened and the solution concentrated to afford 196 mg (81%) of white crystals of $Pt(Pcy_3)_2(CF_3C{\equiv}CCF_3)$; $\nu(C{\equiv}C)_{Nujol}$ 1727 cm^{-1}.

Preparation of $Pt(Pcy_3)_2(CH_3CO_2C{\equiv}CCO_2CH_3)$

To a solution of 100 mg (0.126 mmol) of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 1 ml CH_2Cl_2 and 10 ml CH_3OH were added 15.5 µl of dimethylacetylenedicarboxylate. After 5 min the product began precipitating from the solution as white crystals. Recrystallization from CH_2Cl_2–hexane afforded 91.7 mg (81%) of $Pt(Pcy_3)_2(CH_3CO_2C{\equiv}CCO_2CH_3)$ $\nu(C{\equiv}C)_{Nujol}$ 1768 cm^{-1}, ν(CO) 1677, 1693 cm^{-1}.

When CH_2Cl_2 is added to the reaction mixture, after precipitation of $Pt(Pcy_3)_2(CH_3CO_2C{\equiv}CCO_2CH_3)$, to redissolve the precipitate and the solution allowed to stir for 2 h, the vinylic product *trans*-$PtCl(C(CO_2CH_3){=}CHCO_2CH_3)(Pcy_3)_2$ is obtained after methanolic NaCl workup.

Preparation of $trans\text{-}PtCl(C(CO_2CH_3){=}CDCO_2CH_3)(Pcy_3)_2$

To a solution of 177 mg *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 1 ml CH_2Cl_2 and 2 ml CH_3OD were added 1 equivalent of dimethylacetylenedicarboxylate. After stirring for 1 h the reaction mixture was quenched with methanolic NaCl and worked up as above to afford 151 mg (85%) of *trans*-$PtCl(C(CO_2CH_3){=}CDCO_2CH_3)(Pcy_3)_2$ containing 85% deuterium on the β-carbon at the vinyl group as determined from relative intensities in its ^1H nmr spectrum.

Preparation of $trans\text{-}PtH(C(CF_3){=}C(OCH_3)(C_6H_5))(Pcy_3)_2$

To a solution of 295 mg of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 2 ml CH_2Cl_2 and 6 ml methanol was added 1 equivalent of $CF_3C{\equiv}CC_6H_5$. The solution was allowed to stir for 2 days during which the product slowly precipitated from the solution. The solution was concentrated slightly and the white crystals filtered to afford 329 mg (70%) of *trans*-$PtH(C(CF_3){=}C(OCH_3)(C_6H_5))(Pcy_3)_2{\cdot}CH_2Cl_2$. $\nu(Pt{-}H)_{Nujol}$ 2071 cm^{-1}.

Preparation of $[trans\text{-}PtH(CH_3C{\equiv}CCH_3)(Pcy_3)_2]PF_6$

A suspension of 236 mg of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 5 ml 2-butyne was stirred for 2 days. The white crystals were filtered to afford 223 mg (92%) of *trans*-$PtH(CH_3C{\equiv}CCH_3)(Pcy_3)_2PF_6$. $\nu(PtH)_{Nujol}$ 2206 cm^{-1}.

Reaction of $CH_3CO_2C{\equiv}CC_6H_5$ *with* $trans\text{-}PtH(Pcy_3)_2(CH_3OH)PF_6$ *in* CH_3OH

To a solution of 200 mg of *trans*-$PtH(Pcy_3)_2(CH_3OH)PF_6$ in 1 ml CH_2Cl_2, 10 ml CH_3OH, was added 4 ml of $CH_3CO_2C{\equiv}CC_6H_5$ and the solution was allowed to stir at room temperature for 4 days. The solvent was removed and the organic products were vaccum distilled from the residue at 88 °C to afford a mixture of methyl benzoylacetate and **Z** and **E** methylmethoxycinnamate.

Deuterium Exchange Experiments

trans-$PtH(PEt_3)_2(MeOD)PF_6$ was prepared by the addition of 1 equivalent of $AgPF_6$ to a solution of *trans*-$PtHCl(PEt_3)_2$ in methanol-*d*. After the removal of the AgCl, slight excess of acetylene was introduced. After 1 h the reaction mixture was evaporated to dryness and its nmr spectrum recorded in $CDCl_3$. The absence of an alkenyl proton signal in the product spectrum indicated exchange.

The exchange reactions of the nitrato and chloro complexes were carried out as described above for the preparation of the corresponding vinyl complexes except that methanol-*d* was used instead of methanol. The nmr spectrum was recorded in $CDCl_3$.

The silver–pyrazole electrode and its application to determine the stability of Cd(II), Zn(II), Ni(II), Co(II) pyrazole complexes

MARIE-JOSÉ BLAIS AND GUY BERTHON[1]

Laboratoire de Thermodynamique Chimique et Electrochimie de l'Université, 40, Avenue du Recteur Pineau, 86022 Poitiers, France

Received July 22, 1976

MARIE-JOSÉ BLAIS and GUY BERTHON. Can. J. Chem. **55**, 199 (1977).

The silver–pyrazole metal-complex electrode was investigated and used to determine free concentrations of pyrazole in the presence of Cd^{2+}, Zn^{2+}, Ni^{2+}, or Co^{2+} ion, under different pyrazole/divalent metal concentration ratios. The stability constants of the complexes formed between these ions and pyrazole were calculated.

MARIE-JOSÉ BLAIS et GUY BERTHON. Can. J. Chem. **55**, 199 (1977).

L'électrode métal-complexe argent–pyrazole a été étudiée et utilisée pour déterminer les concentrations de pyrazole à l'équilibre en présence des ions Cd^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, pour différents rapports de concentrations globales ligand/métal divalent. Les constantes de stabilité des complexes formés entre ces ions et le pyrazole ont été calculées.

Introduction

The proton ionisation constant of pyrazole is low (pK_a about 2.5 (1)) and hence its determination in solution is not easy by means of classical acid–base titration.

Indeed, two kinds of difficulties appear in such a case: the first arises from the closeness of the pK_a to the acidic pH limit of the solution, which reduces the possibility of accurate determination of the equivalence volume, even if the Gran procedure is used; the second is occasioned by the poor reproductibility of glass electrode measurements in the very acidic medium obtained at the end of the titration. In partially aqueous or non-aqueous solvents, the problem is still more complicated because of the necessary choice of an appropriate pH scale.

The usefulness of a selective electrode, which could be directly used as an indicator of pyrazole, is therefore evident.

In the present work, such an indicator is the Ag/Ag^+, pyrazole electrode.

First, we calculated the stability constants of the complexes formed between silver ion and pyrazole, which characterize the standard potential of this electrode. Then, we tested the reliance of the method by verifying its accuracy in some determinations of pyrazole in solutions of known titre.

Finally, we determined free concentrations of

pyrazole in the presence of Cd^{2+}, Zn^{2+}, Ni^{2+}, or Co^{2+} ion, and computed the stability constants of the complexes formed in these systems.

Theoretical Considerations

Let us consider the electrochemical equilibrium of a metal M with a solution including M^{z+} ions of this metal and a ligand A, which are liable to form complexes between themselves. They define the following electrode

[1] $$M/M^{z+},A$$

which is reversible to the metal ions.

The related potential may be expressed by

[2] $$E = E_M{}^0 + \frac{RT}{zF}\ln [M^{z+}]$$

or writing the free metal ion concentration in terms of

[3] $$E = E_M{}^0 + \frac{RT}{zF}\ln \frac{[M^{z+}]_T}{\sum_0^N \beta_n[A]^n}$$

where $[M^{z+}]_T$, [A], and β_n represent the total metal ion concentration, the free ligand concentration, and the stoichiometric stability constants, respectively.

If $[M^{z+}]_T$ is $\ll [A]_T$ then $[A] \simeq [A]_T$ and eq. 3 may be rearranged to give

[4] $$E = E^1 - \frac{RT}{zF}\ln \sum_0^N \beta_n[A]_T{}^n$$

Thus the electrode may be considered to be reversible to the ligand under consideration and may be used as a ligand indicator electrode.

From a practical point of view, one may consider a concentration cell of the type

[5] $$\underset{1}{M/M^{z+},A}//\underset{2}{M^{z+}/M}$$

the emf of which may be expressed by

[6] $$E_2 - E_1 = \frac{RT}{zF}\ln \frac{[M_2{}^{z+}]}{[M_1{}^{z+}]}$$

$$= \frac{RT}{zF}\ln \frac{[M_2{}^{z+}]\sum_0^N \beta_n[A]_T{}^n}{[M_1{}^{z+}]_T}$$

$$= \frac{RT}{zF}\ln \frac{[M_2{}^{z+}]}{[M_1{}^{z+}]_T} + \frac{RT}{zF}\ln \sum_0^N \beta_n[A]_T{}^n$$

If $[M_2{}^{z+}] = [M_1{}^{z+}]_T$, then

[7] $$E_1 = E_2 - \frac{RT}{zF}\ln \sum_0^N \beta_n[A]_T{}^n$$

From that last equation, it appears (on condition that $[M^{z+}]_T \ll [A]_T$ and the β_n constants are known for a known temperature, solvent and ionic strength) that the electrode

[8] $$M/[M(A)_{\bar{n}}]^{z+},A$$

can be used to determine any concentration of the ligand A, in the range of $[A]_T$ where the complexation of M with A is significant ($\bar{n} > 0$).

The Silver–Pyrazole Electrode

In order to determine the characteristic equilibrium constants of the silver–pyrazole electrode, the following cells were studied

[9] $$\underset{(0.5\,M)}{Ag/Ag^+,KNO_3}//\underset{(sat)}{KNO_3}//\underset{(sat)}{KCl/Hg_2Cl_2}–Hg$$

[10] $$Ag/[Ag(pyrazole)_{\bar{n}}]^+,\underset{(0.5\,M)}{pyrazole,KNO_3}//\underset{(sat)}{KNO_3}//\underset{(sat)}{KCl/Hg_2Cl_2}–Hg$$

The total silver concentration, C_{Ag}, was the same in eqs. 9 and 10, and remained always negligible in regard to that of pyrazole, C_A.

The temperature of the cells was controlled under the limits of 25 ± 0.05 °C.

Potential measurements were made by means of a Beckman Research pH-meter, the precision of which was ±0.05 mV. This apparatus was equipped with a Beckman silver electrode No. 39261 D7 and a Beckman calomel electrode No. 4970.

Determination of the Stability Constants of the Silver–Pyrazole System

A total silver concentration of 10^{-5} *M* was used, whereas the total concentrations of pyrazole varied from 10^{-3} to 3×10^{-2} *M*.

The formation constants obtained by means of the Leden method (8) are

$$\log \beta_1 = 2.110 \pm 0.005$$

$$\log \beta_2 = 4.235 \pm 0.005$$

which may be compared with 2.04 and 4.45 (7), that were determined in water–ethanol 20% solvent, at the ionic strength of 0.1 *M* KNO_3.

Testing of Applicability of the Electrode. Titration of Pyrazole Solutions

Equation 7, which may be rewritten in the form

[11] $$C_A = \frac{-\beta_1 + \sqrt{\beta_1^2 + 4\beta_2\left[\exp\left(\frac{E_{[9]} - E_{[10]}}{RT/F}\right) - 1\right]}}{2\beta_2}$$

and the previously determined values of β_1 and β_2 were used to determine a series of pyrazole concentrations in solutions which contained known concentrations of pyrazole. The comparison of known and calculated values is reported in the Table 1. The accuracy one obtained is generally better than 1%.

Application of Silver–Pyrazole Electrode to Determine Stability Constants of Complexes Formed by Cd(II), Zn(II), Ni(II), Co(II) Ions with Pyrazole

In those cases, we studied cells of the type [9] and

[12] $$Ag/[Ag(pyrazole)_{\bar{n}}]^+,\underset{(0.5\,M)}{pyrazole,M^{2+}},\underset{(sat)}{KNO_3}//\underset{(sat)}{KNO_3}//\underset{(sat)}{KCl/Hg_2Cl_2}–Hg$$

where C_{Ag} was always equal to 10^{-5} *M*.

An equation similar to [11] was used to analyze experimental emf data by calculating the free pyrazole concentrations [A] in the presence of a second metallic ion, and the average coordination number of the complexed metal then calculated from

[13] $$\bar{n}_M = \frac{C_A - [A]}{C_M}$$

These measurements were made for different ratios C_A/C_M in each system under consideration and are given in Fig. 1. Since, according to the results, none of the systems gave rise to polynuclear complexes, the calculation of the related stability constants was made from the pairs of ($\bar{n}$, [A]) values; first, graphically by the Fronaeus method (9) in order to determine the maximum degree of complexation in the investigated range of [A] concentrations (actually, the maximum value of $\bar{n}$ experimentally reached is determined by the appearance of precipitates of the complexes) and secondly, by means of a IRIS 45 CII computer, using a least-squares minimisation program (2).

The results are given in Table 2, where they may be compared to those earlier obtained by other authors from different methods (polarography, p*H*-metry) under several experimental conditions.

The agreement is generally satisfying and thus the accuracy of the constants we have calculated is rather good.

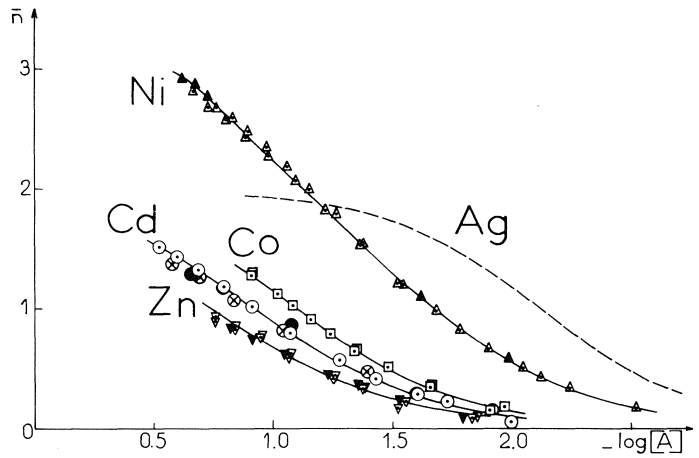

FIG. 1. Formation curves $\bar{n} = f(-\log [A])$ of the systems: Cd(II)–pyrazole ($C_{Cd} = 0.25\ M$ ○, $0.125\ M$ ⊗, $0.05\ M$ ●); Zn(II)–pyrazole ($C_{Zn} = 0.05\ M$ ▽, $0.04\ M$ ▼); Ni(II)–pyrazole ($C_{Ni} = 0.10\ M$ △, $0.05\ M$ ▲); Co(II)–pyrazole ($C_{Co} = 0.05\ M$ □). The averaged curves are drawn from the results of Table 2. The dashed line represents the formation curve of the Ag(I)–pyrazole reference system.

Conclusion

One can conclude from these results that the silver–pyrazole electrode is a suitable indicator of pyrazole. Practically, it is applicable from a concentration of pyrazole near $5 \times 10^{-3}\ M$ until relatively high values (about $1\ M$), under the experimental conditions defined here (25 °C, $\mu = 0.5\ M$ KNO_3).

Ozone yields from the Febetron radiolysis of oxygen – rare gas mixtures[1]

A. W. BOYD, O. A. MILLER, AND E. B. SELKIRK

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received June 25, 1976

A. W. BOYD, O. A. MILLER, and E. B. SELKIRK. Can. J. Chem. **55**, 203 (1977).

Ozone yields have been measured from the Febetron irradiation of mixtures containing 1–50 mol% oxygen and each of the five rare gases. The maximum values of $G(O_3)$ calculated using the energy absorbed only in the rare gas are obtained with the addition of less than 10% oxygen and are for: He, 16; Ne, 14; Ar, 11; Kr, 10; Xe, 12; each with an uncertainty of less than ±10%. On the addition of 0.2 mol% SF_6 these yields are reduced to 6, 5, 1, 2, and 2.5 respectively. These values are compared with those derived from ion and excited state yields and the contributions of subexcitation electrons.

A. W. BOYD, O. A. MILLER et E. B. SELKIRK. Can. J. Chem. **55**, 203 (1977).

On a mesuré les rendements en ozone obtenus par irradiation par le Febetron de mélanges contenant de 1 à 50 mol% d'oxygène et chacun des cinq gaz rares. On obtient les valeurs maximales de $G(O_3)$, calculées en utilisant uniquement l'énergie absorbée dans les gaz rares, lors de l'addition de moins de 10% d'oxygène et ces valeurs maximums sont de 16, He; 14, Ne; 11, Ar; 10, Kr; 12, Xe et dans chaque cas le facteur d'incertitude est moins que ±10%. Lors de l'addition de 0.2 mol% de SF_6, on réduit respectivement ces rendements à des valeurs de 6, 5, 1, 2 et 2.5. On compare ces valeurs avec celles obtenues à partir des rendements pour des états ioniques et excités et les contributions des électrons sous-excités.

[Traduit par le journal]

Introduction

The yields of ions and excited states and their reactions in irradiated rare gases are necessary to predict the radiolytic behaviour of mixtures of the rare gases with other materials. They are also important to the understanding of rare gas lasers. Values for many of these quantities are available: the total ion yields from W values; the ion distribution and energy from mass spectrometry; the reactions of ions and excited states from mass spectrometry, flowing afterglow, and beam techniques. The yields of the excited states are not readily determined experimentally in the pure gases. The present values are either calculated from binary collision theory (1, 2) or from partial excitation cross section measurements (3, 4). The two sets of values are not in agreement.

A possible method of obtaining excited state yields is from the measurement of the ozone yields in rare gas – O_2 mixtures. The yield of ozone in pure O_2 is well established (5) and there is good agreement between this value and the yields and reactions of the ions and excited states in oxygen (6). Combining the measured yields in the mixtures with the data for the pure components could then give values for the rare gas excited state yields.

We have therefore measured the yields of ozone from the irradiation of mixtures of each of the five rare gases with oxygen. We used the short intense pulses available from Febetrons because as we have shown, these result in a suppression of charge transfer to products or impurities (7). Previous measurements of these mixtures have been made using ^{60}Co γ-rays (8) but at the dose rates from these sources there is no contribution of ion neutralization to the ozone yield.

Experimental

The radiation source used is a Febetron 705. The oxygen – rare gas mixtures were contained in a single pass cell 16 cm long and 9 cm diameter with an electron window (0.025 cm thick, 6 cm diameter Al) at right angles to the optical path. The analyzing light was from a 300 W Xe arc and was dispersed by a 3/4 m Spex Czerny-Turner monochromator after passage through the cell. The ozone was measured at 254 nm and an interference filter with a transmission peak at 250 nm was used to eliminate scattered light from the monochromator.

Measurements were made both with and without a 0.005 cm thick 2.5 cm diameter Ta scattering foil placed ~1.5 cm in front of the electron beam window and within

[1]AECL No. 5628.

0.3 cm of the optical cell window. The average dose calculated from the yield of ozone $G(O_3) = 12.8 \pm 0.6$ (5) and its extinction coefficient $\varepsilon_{254nm} = 135\ cm^{-1}$ STP (9) and the observed optical density in pure O_2 was 0.2 Mrad/pulse with the foil and 0.5 Mrad/pulse without it.

Both Matheson UHP and CP grades of oxygen were found to give the same ozone yields. The rare gases were Matheson research purity. Substitution of Matheson purified grade for He and Ar did not change the observed yields. The sulphur hexafluoride was Matheson CP grade.

Results

The yields of ozone as a function of mol% oxygen in each of the five rare gases with and without the addition of 0.2 to 1 mol% SF_6 are shown in Figs. 1 to 3. These yields were determined using pressures of 50 to 220 kPa (375 to 1650 torr) and each one is the average of at least three measurements. They are based on $G(O_3) = 12.8$ in pure O_2 and $G(O_3) = 6.3$ in O_2 with 0.2 to 3 mol% SF_6 (5).

The values given $G(O_3)_{He}$, $G(O_3)_{Ne}$, etc. are the yields of O_3 due to energy absorbed only by the rare gas and were calculated as follows. The optical density (O.D.) of the O_3 observed in the mixture was first corrected by subtracting the O.D. of the O_3 resulting from energy absorbed in the O_2. This was assumed to be the O.D. of ozone obtained in pure O_2 under the same conditions multiplied by the mole fraction of O_2 in the mixture. The yield of ozone from the energy absorbed in the rare gas is then directly proportional to the ratio of the energy absorbed in the rare gas to the energy absorbed in pure O_2 with both gases at the same pressure. It is given by

$$G(O_3)_x = \frac{\text{Net O.D.}}{\text{O.D. pure } O_2} \times \frac{\text{Stopping power } O_2 \times \text{density } O_2}{\text{Stopping power X} \times \text{density X}} \times 12.8$$

The ratios (O_2/X) of stopping powers used are: He, 0.909; Ne, 1.05; Ar, 1.21; Kr, 1.38; Xe, 1.50 (10–12).

There appears to be no significant difference

between the yields of the two dose rates of 0.2 and 0.5 Mrad/pulse.

In all the O_2 rare gas mixtures and O_2 with SF_6 the ozone concentration as shown by the oscilloscope traces rose to a maximum value within 1–2 ms and remained constant at this value for several hundred milliseconds. In the rare gas – O_2 – SF_6 mixtures there was a fall-off in the ozone concentration over a period of 300–500 ms. The extent of this fall-off appeared to be greater in Xe and Kr mixtures than in Ar or Ne and was very small in mixtures with He.

Discussion

To provide a basis for the comparison of calculated excited state yields in the rare gases and those derived from the ozone yields, we shall first summarize the primary yields and the mechanism of ozone production in O_2 and list the yields and the reactions in the rare gases.

The following summary of O_2 radiolysis is taken from ref. 6.

The primary processes of ionization and excitation and their yields and energies are:

Processes	G	Threshold energy (eV)
$O_2 \rightsquigarrow O^+ + O + e$	1.22	18.8
$O_2 \rightsquigarrow O_2^+ + e$	2.06	12.08
$O_2 \rightsquigarrow O + O$	2.0	5.2

The ions and atoms thus formed may undergo the following reactions:

[1] $$O^+ + O_2 \rightarrow O_2^+ + O$$
$$k_1 = 2 \times 10^{-11}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

[2] $$O_2^+ + \text{e(or } O_2^- \text{ or } O_2^-(O_2)_n) \rightarrow O + O$$
$$k_2 \simeq 2 \times 10^{-6}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

[3] $$O + 2O_2 \rightarrow O_3 + O_2$$
$$k_3 = 3 \times 10^{-34}\ \text{cm}^6\ \text{molecule}^{-2}\ \text{s}^{-1}$$

[4] $$e + SF_6^- \rightarrow SF_6^-$$
$$k_4 = 2.4 \times 10^{-7}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

[5] $$O_2^+ + SF_6^- \rightarrow \text{Products (no O atoms)}$$
$$k_5 \simeq 2 \times 10^{-6}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

[6] $$O_2^- + O_3 \rightarrow O_3^- + O_2$$
$$k_6 = 3 \times 10^{-10}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

[7] $$O_2^+ + O_3^- \rightarrow O_2 + \text{products}$$
$$k_7 \approx 2 \times 10^{-6}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

With Febetron pulses because of the high ion concentration, reaction 6 cannot compete with reaction 2 so that each neutralization of a positive ion gives two O_3 molecules. However, because of the high value of k_4, only a small amount of SF_6 is needed to capture all the electrons and replace reaction 2 by reaction 5. At low dose rates in pure O_2 reaction 2 is replaced by reaction 6 and this like [5] results in no contribution to the O_3 yield from the neutralization.

The maximum calculated value of the ozone yield from the above processes and reactions is $G(O_3)_{calc} = 2(1.22) + 2(3.28) + 2(2.0) = 13$. This is reduced by $2(3.28 = 6.56$ on the addition of SF_6 or at low dose rates.

The measured and calculated values of ion and excited state yields in the rare gases are listed in Table 1. These can be divided into three categories. The first is the experimental ion pair yields which are well established and known within an uncertainty of less than $\pm 5\%$. The second category is the calculated values for all five gases of G_i and G_{ex} by Sato, Okazaki, and Ohno (2). These were obtained using binary collision theory in which several approximations are made. They provide the only reported results for excited state yields in Ne, Kr, and Xe. The third category comprises the calculations of Alkhazov (3) and Douthat (14) on He and of Eggarter (4) for Ar. For the comparison with our results we will of course use the experimental ion pair yields.

The rate constants for the reactions in the rare gas – O_2 mixtures are given in Table 2. The available rate data indicate that at concentrations of O_2 more than about 5%, all the rare gas ions react with O_2. The rate constants for the reactions to form the dimeric ion *e.g.*, [9], [15] are one to two orders of magnitude less than those for charge transfer to O_2 and neutralization of single rare gas atoms is a much slower process than formation of the dimeric ion. The rate constants listed for excited state reactions also indicate that these react only with O_2 at concentrations of the latter of 10% or more.

He–O_2

The maximum yields of ozone in He–O_2 mixtures calculated from the data in Tables 1 and 2 and the subexcitation electron contribution are compared with our experimental yields in Table 3.

The total energy of subexcitation electrons in He is estimated by Alkhazov (3) to be 15 eV. We have calculated the ionization and excitation of O_2 by these electrons using cross sections com-

[b]Ozone is produced as a result of the reactions listed and two or more of reactions 1 to 5.

piled by Kieffer (27) and the spectrum of the electrons calculated by Douthat (14). Over the energy range from 5 to 20 eV we assumed that the significant loss processes were ionization or dissociative excitation. Ionization was calculated to be less than 5% of neutral dissociation.

The yield of O_3 in the presence of SF_6 is reduced by the suppression of dissociative neutralization of O_2^+ and by inelastic collisions of the subexcitation electrons with the SF_6. There are several large resonances for the dissociative electron attachment to SF_6 in the region below 20 eV (28) and these should largely suppress dissociation of oxygen by these electrons.

The uncertainties in our experimental yields and in the calculated subexcitation electron contribution produce a wide range of excited state yields in He. Assuming the subexcitation contribution to $G(O_3)$ to be 2.8 ± 0.5 then $G(\text{He* T + S}) = 1.5 \pm 0.5$. It should be noted that excited state yields can also be derived from an energy balance. The energy available for excited state formation per 100 eV absorbed in He is $100 - [2.41(41.5) + 15]$. The first term in the brackets is the energy required for ionization, the second is that required for subexcitation electrons. Taking the average energy per excited state as 20 eV the yield is $G(\text{He*}) = 1.3$.

Ne–O_2

The maximum yields of ozone calculated from the data in Tables 1 and 2 and the subexcitation electron contribution for $Ne–O_2$ mixtures are compared with our experimental data in Table 4.

TABLE 4. Ozone yields in $Ne–O_2$ mixtures

Ion or excited state	Yield	Reaction[a]	$G(O_3)_{Ne}$ $Ne–O_2$	$G(O_3)_{Ne}$ $Ne–O_2–SF_6$
Ne^+	2.76	[13]	11.04	5.52

Ne* S	1.55	[15]	3.1	0
		Subtotal	14.28	5.52
Subexcitation electrons (See Discussion)			2.5	—
		Total	16.8	5.5
Experimental (Fig. 2)			13.7±0.6	5±1

[a]Ozone is produced as a result of the reaction listed and two or more of reactions 1 to 5.

The total energy of the subexcitation electrons is estimated to be the same as in He (29) but no spectrum for these is available. The value given is calculated assuming a spectrum similar to that for He. The contribution of these electrons to the production of O_2^+ is negligible.

It seems unlikely that the excited state yield in Ne is less than 1 and that the contribution of subexcitation electrons to the O_3 yield is less than 2. Using these minimum values the calculated yield is $G(O_3) = 15$ which is still significantly larger than the experimental value. A possible explanation of the discrepancy is that reaction 13 produces some O_2^+ at higher pressures. The value in Table 2 was measured at a total pressure of less than 0.3 kPa (22). Since the reaction is believed to proceed through the NeO_2^+ ion (30) the ratio of O_2^+ to O^+ could be pressure dependent.

Ar–O_2

The yields of ozone calculated from the data in Tables 1 and 2 and the subexcitation electrons in $Ar–O_2$ mixtures are compared with our experimental yields in Table 5.

The total energy of the subexcitation electrons was taken to be 15 eV and their spectrum was again assumed to have a shape similar to that in He.

The yield of the excited states in Ar below the ionization potential of O_2 from the O_3 yields is taken to be one-half the yield in the presence of SF_6 and is $G(\text{Ar* I}) = 0.5 \pm 0.1$ in good agreement with the yields calculated from the cross sections in ref. 4 and the slowing down spectrum in ref. 2. The calculation of $G(Ar^+)$ using the ionization cross sections of Ar and the slowing down spectrum in ref. 2 gave the same value as that calculated by Eggarter (4).

TABLE 5. Ozone yields in $Ar–O_2$ mixtures

TABLE 6. Ozone yields in $Kr–O_2$ mixtures

Ion or excited state	Yield	Reaction[a]	$G(O_3)_{Kr}$ $Kr + O_2$	$Kr + O_2 + SF_6$
Kr^+	4.11	[22]	8.22	0
Kr* S,T	1.87	[23]	3.74	3.74
		Total	11.96	3.74
Experimental (Fig. 3)			10.0±0.5	2.0±0.5

[a]Ozone is produced as a result of this reaction and two or more of reactions 1 to 5.

It can be seen that as with He the subexcitation electron contribution is necessary for good agreement between the calculated and experimental yields. The uncertainty in this contribution and the experimental uncertainty do not allow a precise value of $G(Ar^*\ II)$ to be derived from the measured $G(O_3)$ value.

$Kr–O_2$

The yields of ozone calculated from the data in Tables 1 and 2 for $Kr–O_2$ mixtures are compared with our experimental yields in Table 6. Although there will be some contribution from the subexcitation electrons to the ozone yield it should be smaller than the uncertainties in the calculated excited state yields or the measured ozone yield.

The excited state yields of ref. 2 again appear to be too high. We have assumed that reaction 23 is the sole pathway for the loss of energy of the excited states of Kr but this does not seem unreasonable in view of the rate constants found for reactions 11, 12, 14, 19, and 25. Our results indicate a total yield of $G(Kr^*) = 0.9 \pm 0.25$.

$Xe–O_2$

The yields of ozone calculated from the data in Tables 1 and 2 for $Xe–O_2$ mixtures are compared with our experimental yields in Table 7. The contribution of subexcitation electrons will be less than in $Kr–O_2$ mixtures.

Assuming all the excited states of Xe react as in [25] our results give a value of $G(Xe^*) = 1.3 \pm 0.2$.

Comparison with Reference 8

The yields of O_3 from irradiations of rare gas–oxygen mixtures at low dose rates (8) are compared with our data in Table 8. As we have discussed, the yield from dissociative neutralization is suppressed at these dose rates and they should be comparable to our values for mixtures with SF_6. A further correction needs to be made for the elimination of the contribution of the subexcitation yield by the SF_6. The difference between the values in the first and third columns is probably not much greater than the sum of the experimental uncertainties for Ar, Kr, and Xe. We have no explanation for the much greater differences for He and Ne.

TABLE 7. Ozone yields in $Xe–O_2$ mixtures

Ion or excited state	Yield	Reaction[a]	$G(O_3)_{Xe}$ $Xe + O_2$	$Xe + O_2 + SF_6$
Xe^+	4.56	[24]	9.12	0
Xe* S,T	1.9	[25]	3.8	3.8
		Total	12.92	3.8
Experimental (Fig. 3)			11.7±0.3	2.5±0.5

[a]Ozone is produced as a result of this reaction and two or more of reactions 1 to 5.

TABLE 8. Comparison with low dose rate yields

Rare gas	Low dose rate[a] (8)	$G(O_3)_{Kr}$ Febetron[b]	Corrected Febetron[c]
He	3.4	6	9
Ne	4.4	5	7.5
Ar	2.2	1	3
Kr	3.2	2	2–2.5
Xe	4.6	2.5	2.5–3.0

[a]These values have been corrected as discussed previously (5).
[b]These are for mixtures containing SF_6.
[c]The contributions of subexcitation electrons have been added to the measured Febetron values for mixtures containing SF_6.

Conclusions

The agreement between the experimentally determined yields of ozone in rare gas – O_2 mixtures due to energy absorbed in the rare gas and the values calculated from ion and excited state yields and subexcitation electrons is somewhat different for each rare gas.

In helium the value of the excited state yield is probably close to $G(He^* S + T) = 1.3$ and the agreement between the calculated and experimental ozone yields supports the rather large contribution we calculated due to subexcitation electrons.

In neon the minimum calculated value of $G(O_3)$ assuming four ozones per Ne^+ ion is significantly larger than the experimental value. Resolution of this discrepancy requires measurements of the pressure dependence of the products of the $Ne^+ + O_2$ reaction.

In argon as in helium, the excited state yields appear to be well known. The results support the importance of the contribution of subexcitation electrons to the O_3 yield and the suppression of this contribution by SF_6.

The excited state yields in Kr and Xe derived from our results can be compared only with the calculated values of Sato *et al.* (2). The differences between their values and ours may be due to inefficient energy transfer from the rare gas excited state to O_2 or to the difficulties of accurate yield calculations for these large atoms.

Acknowledgements

We are most grateful to Dr. C. Willis for many helpful discussions on the calculation of subexcitation electron yields. We also thank Drs. M. Bourène and J. LeCalvé for their comments.

The intra- and intermolecular copper(I) catalyzed couplings of vinyl Grignards. A facile synthesis of pleiadiene and a synthesis of a conjugated 14-membered ring system[1]

REGINALD H. MITCHELL,[2] BHUPENDRA N. GHOSE, AND MARY E. WILLIAMS

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received July 6, 1976

REGINALD H. MITCHELL, BHUPENDRA N. GHOSE, and MARY E. WILLIAMS. Can. J. Chem. **55**, 210 (1977).

Pleiadiene, **27**, can be efficiently prepared in 45% yield by copper catalyzed intramolecular coupling of the bis-Grignard reagent of 1,8-*trans*-(β-bromovinyl)naphthalene, **5**. Also obtained in 6% yield is the unsaturated 14-membered ring compound **28**. Whereas the bis(β-bromovinyl) compound **5** is readily available from 1,8-divinylnaphthalene, α-bromovinyl compounds are obtained from divinylbenzenes. On coupling the Grignard reagent from 1,4-bis(β-bromovinyl)-benzene, only linear dimeric products were obtained.

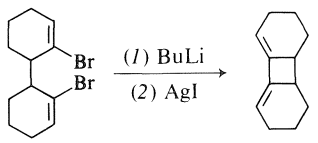
REGINALD H. MITCHELL, BHUPENDRA N. GHOSE et MARY E. WILLIAMS. Can. J. Chem. **55**, 210 (1977).

En effectuant un couplage intramoléculaire, catalysé par le cuivre, du réactif de Grignard double obtenu à partir du bis(β-bromovinyl)-1,8-*trans* naphtalène, **5**, on peut préparer d'une façon efficace le pléiadiène **27**, avec un rendement de 45%. On obtient aussi avec un rendement de 6% le composé **28** qui est insaturé et qui possède un cycle à 14 chaînons. Alors que le composé **5** peut etre obtenu facilement à partir du divinyl-1,8 naphtalène, les composés α-bromovinyliques ne peuvent être obtenus qu'à partir du divinylbenzène. Par couplage du réactif de Grignard obtenu à partir du bis(β-bromovinyl)-1,4 benzène, on obtient uniquement des produits dimères linéaires.

[Traduit par le journal]

Introduction

Extensive use (for a review see ref. 1) has been made of the copper induced coupling of acetylenes to diynes using the procedures known as the Glaser (2) and Eglinton (3) couplings. It is, however, only much more recently that the analogous coupling of vinyl compounds has been observed. In 1966 Whitesides *et al.* reported (4) that vinyllithium compounds on treatment with Cu(I) or Ag(I) coupled to give 1,3-dienes. This was extended in 1967 by Kauffman and Sahm (5) to include vinyl Grignard reagents and by Zweifel and Miller (6) in 1970 for vinyl alanes. Moreover, while the oxidative coupling of diacetylenes has been put to good use in the preparation of a whole variety of novel conjugated macrocyclic compounds (1, 7, 8), reports on the similar use of coupling of bis-vinyl derivatives are absent. Indeed there appears to be only one report (9) of a coupling of a bis-vinyl compound and in this the cyclobutane ring in **1** was formed. We decided



1

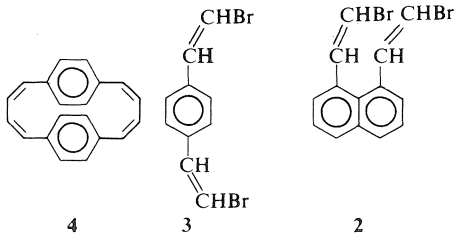
that in view of the extensive interest in large conjugated systems (for a review containing many pertinent examples see ref. 10) to investigate the feasibility of coupling vinyl derivatives to obtain such systems.

1,8-Bis(β-bromovinyl)naphthalene, **2**, had attraction as a test for the coupling reaction since the naphthalene nucleus directs the vinyl groups in the same region of space which should facilitate both intra- and intermolecular cyclization at the expense of linear polymer formation. On the other hand, 1,4-bis(β-bromovinyl)benzene, **3**, should be one of the hardest tests to apply since intramolecular cyclization is not

[1]Presented in preliminary form at the 30th Northwest Regional Meeting of the American Chemical Society, University of Hawaii, June 13, 1975.

[2]Author to whom correspondence should be addressed.

probable[3] and intermolecular cyclization is not going to be helped by the severe geometry requirements of the product, the known (12) paracyclophane derivative **4**. This paper reports the results of these tests.



4 3 2

Results and Discussion

I. Synthesis of Bromovinyl Compounds

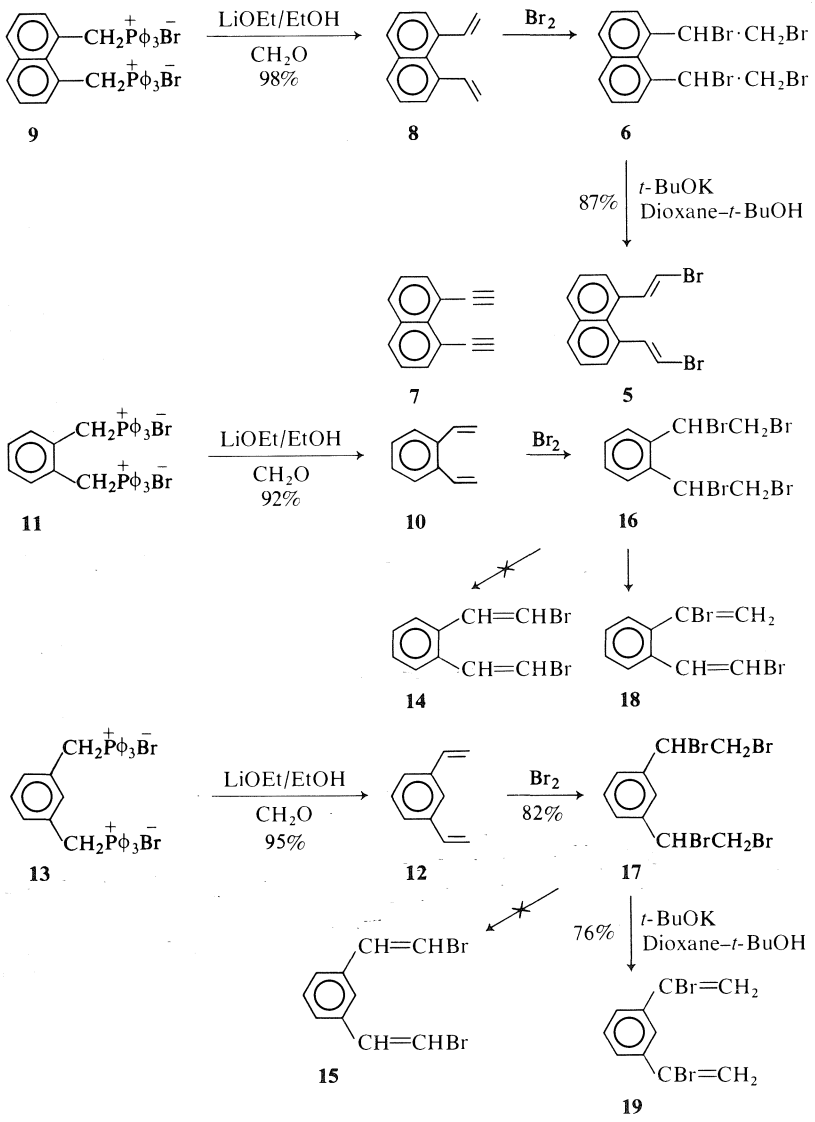
Mitchell and Sondheimer (7) reported that 1,8-bis(*trans*-β-bromovinyl)naphthalene, **5**, was obtained as a by-product in the dehydrobromination of the tetrabromide **6** to 1,8-diethynylnaphthalene (**7**). We have found that use of potassium *tert*-butoxide in *tert*-butyl alcohol – dioxane for short reaction times yields **5** as the major product, an average yield of 87% from **6** being obtained. The preparation of the precursor for **6**, 1,8-divinylnaphthalene, **8**, was achieved in 98% yield by using the Wittig reaction between the bis-phosphonium salt **9** and formaldehyde with lithium ethoxide as base rather than the much less convenient sodamide – liquid ammonia system previously reported (7). Further, the analogous reactions yielded 1,2-divinylbenzene **10** in 92% yield from **11**, and 1,3-divinylbenzene **12** in 95% yield from **13** using equally simple procedures. These were carried out since we hoped to generate both 1,2- and 1,3-bis(β-bromovinyl)benzene, **14** and **15** respectively from the tetrabromides **16** and **17** to provide further tests for our coupling reaction.

Raphael and co-workers (13) in 1964 reported that the unsymmetric bromide **18** is in fact formed from **16** on treatment with potassium *tert*-butoxide in *tert*-butyl alcohol. Since their aim was the preparation of 1,2-diethynyl benzene, we hoped that by variation of the base we could make the bis(β-bromide) **14** the major product. In fact that was not so. Indeed, the analogous tetrabromide **17** on treatment with a variety of bases gave the bis(α-bromide) **19** as the product.

[3]The smallest *p*-cyclophane derivative yet prepared is [6]paracyclophane (11).

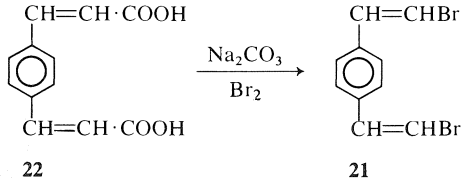
This suggests that the mechanism proposed by Raphael (13) for the dehydrobromination of **16** is not necessary, and a simple steric argument seems more likely. Removal of an α-H (necessary to form the β-bromides **5**, **14**, and **15**) becomes more difficult sterically as we go from the 1,3-benzene **17** to the 1,2-benzene **16** to the 1,8-naphthalene **6** and hence increased formation of β-bromide occurs in this order too. That there can be no doubt of the structures of the bromides **5**, **18**, and **19** follows from their ir and pmr spectra: **5** shows a strong 950 cm^{-1} band in its ir spectrum (*trans* —CH=CH—) and a coupling constant of $J = 14$ Hz for the doublet at τ 3.57 in its pmr spectrum, whereas **19** shows the 892 cm^{-1} band (—CBr=CH_2) and two doublets, $J = 2$ Hz each at τ 3.89 and 4.20. As Raphael (13) has reported, bromide **18** shows both ir bands and both types of doublets.

In order to overcome this problem we decided to investigate alternative routes to the 1,2-, 1,3-, and 1,4-bis(β-bromovinyl)benzenes. With the ready commercial availability of the corresponding benzene dialdehydes we were at first tempted by the Wittig reaction. Use of bromomethyltriphenylphosphonium bromide, however, proved fruitless, despite Kobrich's (14) successful use of this compound. The analogous chloromethyl salt did yield 1,4-bis(β-chlorovinyl)benzene **20** from terephthalaldehyde, albeit in low (20%) yield. However, it turned out that we were unable to convert this compound into its bis-Grignard reagent and hence preferred to seek an alternative source of the bromovinyl compounds. Bachman's (15) method, namely the decarboxylative dehydrobromination of α,β-dibromoacids seemed appropriate, since cinnamic acids can be readily formed from benzaldehydes, especially in light of the more recent paper by Wolinsky and Erickson (16). After following the procedure of Grovenstein and Lee (17) for the preparation of β-bromostyrene from cinnamic acid dibromide we found that we could obtain a better yield more conveniently by adding bromine to an aqueous solution of sodium cinnamate. This procedure also worked, albeit poorly (11% yield), to prepare 1,4-bis(β-bromovinyl)benzene, **21**, from *p*-benzene diacrylic acid, **22**, whereas attempted isolation of the dibromo-acids failed, probably because of low solubility in organic solvents. Use of pyridine or DMF as solvent (16), at least in our hands, did not appear to help. An analogous reaction produced very little of the 1,3-isomer **15**.



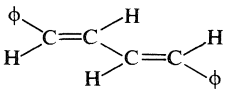
II. Coupling of β-Bromostyrene

Since Yoshino *et al.* (18) have shown that both *cis*- and *trans*-styryl Grignards are formed from either *cis*- or *trans*-β-bromostyrene, **23**, we decided in all couplings to use the mixture of isomers of β-bromovinyl compounds as prepared. Using Kauffman's method (5), namely



addition of the Grignard reagent to a cold (−50 °C) suspension of CuBr in tetrahydrofuran, and then warming to room temperature, a 65% yield of *trans-trans*-1,4-diphenylbuta-1,3-diene, **24**, could be isolated. Although Seyferth *et al.* (19) describe a method to prepare β-styryllithium in high yield, we found that coupling the resultant product led to both diene **24** and 1,4-diphenylbuta-1,3-diyne, **25**. When lithium/Br exchange was attempted using **23** and *n*-BuLi, diyne **25** was the sole isolated product. Seebach's (20) paper on lithium/Br exchange suggested that acetylene formation could be avoided by use of *tert*-butyllithium; this indeed was the case, how-

23



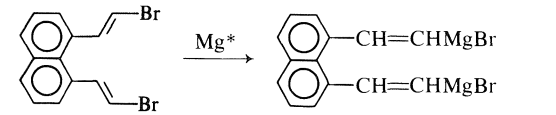
24

25

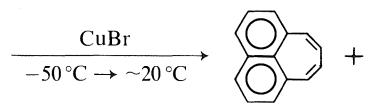
ever, the yield of the coupled diene **24**, was only 20%. We concluded therefore that simple coupling of the Grignard reagent was most fruitful.

III. Coupling of 1,8-Bis(β-bromovinyl)naphthalene. Synthesis of Pleiadiene and Cyclic Dimer

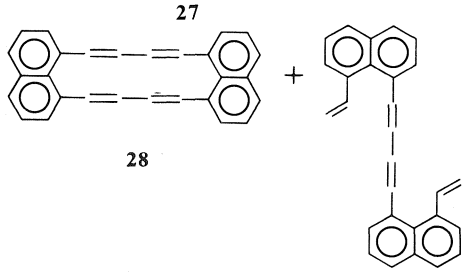
It quickly became obvious that ordinary Grignard quality magnesium was not active enough to react with the bis-bromovinylnaphthalene **5**. Since use of *n*- and *tert*-butyllithium and lithium itself failed to generate any vinyllithio-compounds from **5** (rather acetylenes were formed) we decided to activate the magnesium before use. Using the procedure of either Gilman and Kirby (21) (160 °C, I_2) or Rieke and Bales (22) (in which Mg is generated from $MgBr_2$ and K) sufficiently active Mg was formed so that immediate reaction occurred with the bis-bromide **5**. Coupling of bis-Grignard reagent **26** with CuBr and separation of the products by chromatography led to a 39–45% yield of pleiadiene, **27**, about 6% of the cyclic dimer **28**, and 1–2% of linear dimer **29**.



5 26



27

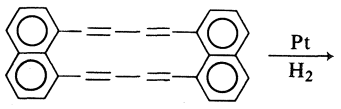


28 29

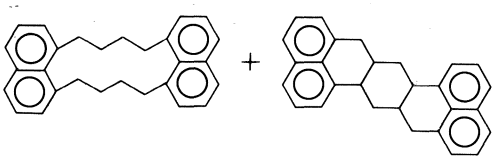
Pleiadiene (**27**) was readily recognized by its orange-red colour, mp, and pmr spectrum, all identical to that published (23). It has been synthesized by Boekelheide and Vick (24), Meinwald *et al.* (25), Shields *et al.* (23), and most recently by Pagni and co-workers (26) who claim the earlier syntheses to be lengthy and/or low yielding. We believe that the coupling procedure described is at least an equally facile synthesis of this interesting compound. The change of stereochemistry of the carbon–carbon double bonds in the cyclization is consistent with the work of Yoshino (18) noted above.

Structure of the Cyclic Dimer 28

The overall structure of dimer **28** (stereochemistry not indicated) follows from its mass spectrum, in which a clear molecular ion was observed at *m/e* 356. The structure was confirmed by hydrogenation, when one of the products showed uptake of 4 mol of hydrogen to give **30**. There was also obtained a heptacyclic transannular hydrogenation product of possible structure **31**, which showed a molecular ion at *m/e* 360, *i.e.* containing four hydrogen atoms less

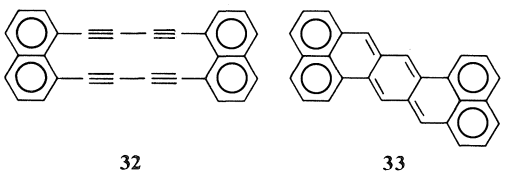


28



30 31

than **30**. These results are analogous to the case (7) for the hydrogenation of the tetraacetylene **32** in which **30** and a hexacyclic transannular product are formed. In both cases the resultant hydrogenation products are not very stable and



32 33

are rather difficult to characterize; several further conformers of **30** are capable of existence (for an analogous case see ref. 27) as are several isomers of **31**, and hence the pmr spectra of both

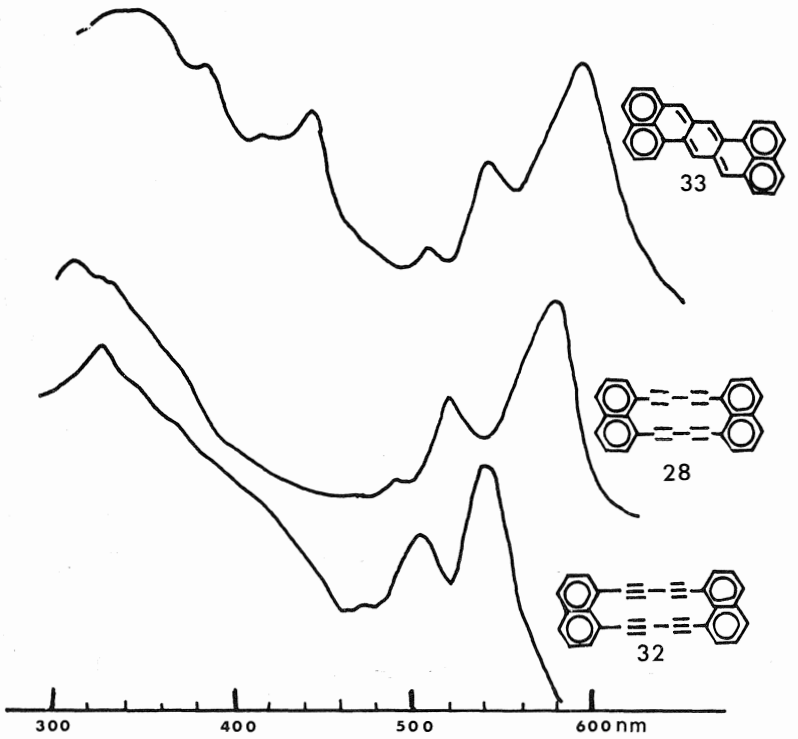


FIG. 1. The uv spectra of **33** (29), **32** (7), and **28**.

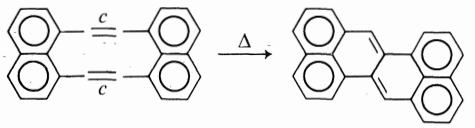
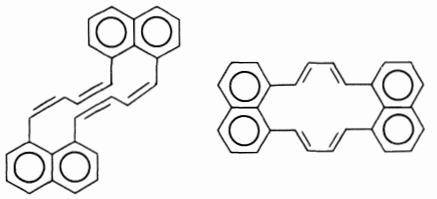
are complex. The uv spectra, however, are simple and consistent with the assigned structures and resemble that (7) of 1,8-diethylnaphthalene. The stereochemistry of **28** is more difficult to assign. The ir spectrum has only a very weak band at 970 cm^{-1}, the region associated[4] with *trans* —CH=CH— groups. Since all the protons occur as a broad band in the pmr spectrum (which is not resolved on cooling) coupling constants for the —CH=CH— protons cannot be obtained either. The uv spectra of **28**, the acetylene **32** (7), and heptazethrene, **33**, (29) are, however, all remarkably similar (see Fig. 1), and all three compounds give purple solutions. The acetylene **32** was too unstable to be isolated in the solid state (7), but both **28** and heptazethrene, **33**, form green crystals. Since no ir, mp, or pmr data are reported for **33**, it was at first thought that this was the product from the coupling reaction, especially in light of the report (30) that zethrene itself, **34**, is readily formed from the diene **35**.



35 **34**

However, the mass spectral evidence and the difference in stability reported for **33** from that found for **28** precludes that. Nevertheless, the similarities between the uv spectra of **28**, **32**, and **33** suggest that they have a very similar π-orbital structure. A *cis-cis*-isomer of **28**, namely **36**,



36 **37**

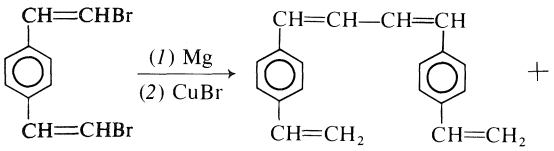
would not be planar or even nearly so, whereas a *trans-trans*-isomer, namely **37** could be, and hence is much more likely to give the observed uv spectrum which indicates that extensive delocali-

[4]By comparison, medium or strong ir bands in the 1000–940 cm^{-1} region are shown for *trans*-stilbene, *trans-trans*-1,4-diphenylbuta-1,3-diene, and many other examples (28).

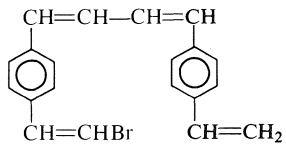
zation of the π-system occurs. In view of the limited stability of **28**, however, unless other isomers can be synthesized by an alternative route, it is unlikely that the stereochemistry question can be settled quickly.

IV. The Coupling of 1,4-Bis(bromovinyl)benzene

Activated magnesium readily formed the bis-Grignard reagent of **21** and coupling as previously described produced a mixture of yellow compounds from which the linear dimer **38** could be isolated in low (<5%) yield. The structure could be assigned on the basis of the mass



21 **38**



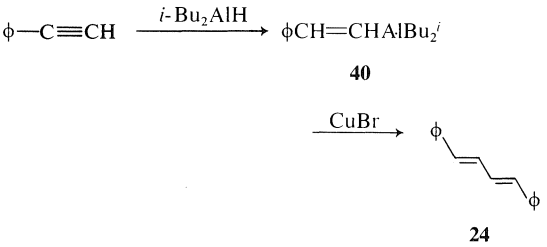
39

spectrum, the molecular ion at *m/e* 258, the pmr spectrum showing the presence of —CH=CH— protons at τ 2.9–4.2 as well as $=CH_2$ at τ 4.3–4.9, and strong ir bands at 1000 and 915 cm^{-1}. It is however, quite likely that more than one isomer is present. Mass spectroscopy also indicated that bromide **39** was formed in the reaction, presumably from the mono-Grignard reagent of **21**. However, we were unable to isolate any compound having the same molecular weight as the known (12) cyclic dimer **4**.

V. Coupling of Alanes

Since acetylenes are readily formed from bromovinyl compounds on treatment with strong base, and because vinylalanes are simple to prepare by addition of R_2AlH to the acetylene, we wondered if coupling the resultant vinylalane would be synthetically more useful than coupling the vinyl Grignard reagent.

Diisobutylaluminium hydride has been reported (31) to add to phenylacetylene in high yield to give diisobutylaluminiumstyryl **40**. When we added **40** to CuBr at −50 °C and then warmed to room temperature, we could only isolate diene **24** in low (6%) yield. This seemed surprising in view of Zweifel's (6) report of good yields from aliphatic-1-alkynes. When we applied



40 **24**

this procedure to 1,8-diethynylnaphthalene, **7**, we obtained a low yield of the previously obtained cyclic dimer **28**, linear dimer **29**, and no detectable pleiadiene, **27**.[5]

For the preparation of the cyclic dimer **28** coupling the alane does not appear to offer an advantage over coupling the Grignard reagent.

Conclusions

We have shown that both an inter- and intramolecular cyclization to yield a fully conjugated diene system are possible by coupling vinyl Grignard reagents with Cu(I), and in so doing have found a useful synthesis of pleiadiene, **27**. If a more general synthesis of β-bromovinyl compounds can be found, it is possible that the reaction can be extended to prepare other interesting examples of macrocyclic conjugated dienes, similar to **28**, of which there are very few reports.

A possible extension of this reaction is by the use of vinyl boranes. It was reported (32) in 1961 that alkyl boranes couple with $AgNO_3$. Despite the fact that Brown *et al.* (33) have reported that phenylacetylene forms a vinylborane with disiamylborane, no reports of the coupling of this compound have appeared. Very recently, however, Yamamoto *et al.* (34) have shown that dialkenyl chloroboranes couple with CH_3Cu to yield 1,3-dienes, at least in the case for those derived from alkyl-1-alkynes. Coupling of boranes derived from aryl-1-alkynes will form part of our next investigation into this area.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The pmr spectra were determined in $CDCl_3$ (unless otherwise stated) on a Perkin-Elmer R12A (60 MHz) or R32 (90 MHz) spectrometer

[5]As pointed out by a referee this is consistent with *cis*-addition of the elements of Al—H to the alkyne.

using tetramethylsilane as internal standard. Mass spectra were determined on a Hitachi–Perkin-Elmer RMU-7 or Finnigan 3300 mass spectrometer at 70 eV. The ir spectra were recorded on a Pye-Unicam SP1000 spectrophotometer and only major bands are reported. The uv spectra were recorded on a Cary 17 spectrophotometer. Microanalyses were performed by this department. All evaporations were carried out under reduced pressure on a rotary evaporator at *ca.* 40 °C. Extracts were dried with anhydrous sodium sulfate.

1,8-Divinylnaphthalene, **8**

A simpler procedure than that previously described (7) by one of us (R.H.M.) is rapid addition of a solution of lithium ethoxide (0.5 mol) in ethanol (150 ml) to a stirred solution of 1,8-bis(triphenylphosphoniomethyl)naphthalene dibromide, **9**, (7), (41.9 g, 50 mmol) and anhydrous formaldehyde (0.5 mol) in absolute ethanol (600 ml) at room temperature under N_2. After 3 h the volume was reduced by evaporation, and H_2O and pentane were added. The organic layer was washed, dried, and filtered through a short column of alumina (to remove any ϕ_3PO). Evaporation of the pentane filtrate yielded 8.12 g (98%) of pure product, identical to previous samples.

1,8-Bis(trans-β-bromovinyl)naphthalene, **5**

By shortening the reaction time of the literature procedure (7) from 24 h to 1 h the yield of the product (obtained by direct recrystallization from hexane) was increased from 28% to 87%.

1,2-Divinylbenzene, **10**

A solution of lithium ethoxide (0.25 mol) in ethanol (125 ml) was added with stirring under N_2 to a solution of *o*-bis(triphenylphosphoniomethyl)benzene dibromide, **11**, (35) (79 g, 0.10 mol) and formaldehyde (0.35 mol) in absolute ethanol (350 ml) at room temperature. After 3 h the volume of solvent was reduced by evaporation and H_2O and pentane were added. The organic extract was washed, dried, and filtered through a short column of alumina to remove any ϕ_3PO. Evaporation of the pentane yielded the product **10**, as a colourless oil, 11.9 g (92%); pmr τ (60 MHz) 2.5–3.3 (6H, m, Ar*H* + ArC*H*=), 4.51 (2H, dd, J = 18 and 2 Hz, *trans* —ArCH=C*H*—) and 4.80 (2H, dd, J = 11 and 2 Hz, *cis* —ArCH=C*H*—).

1,3-Divinylbenzene, **12**

(a) 1,3-Bis(triphenylphosphoniomethyl)benzene Dibromide, **13**

A solution of α,α′-dibromo-*m*-xylene (Aldrich, 66 g, 0.25 mol) and triphenylphosphine (144 g, 0.55 mol) in DMF (400 ml) was heated to 180 °C for 2 h with stirring and then allowed to cool. The product was removed by filtration. Evaporation of the filtrate to 50% (vol.) and addition of benzene precipitated a further quantity of product, 197 g in all (almost quantitative), mp 312–313 °C.

(b) The Wittig Reaction

A solution of lithium ethoxide (0.5 mol) in ethanol (250 ml) was added with stirring under N_2 to a solution of *m*-bis(triphenylphosphoniomethyl)benzene dibromide, **13**, (79 g, 0.10 mol), and formaldehyde (0.56 mol) in absolute ethanol (400 ml) at room temperature. After 2 h the volume of solvent was reduced by evaporation and H_2O and pentane added. The organic layer was washed, dried, and filtered through a short column of silica gel to give, after evaporation of the pentane, the product **12** as a colourless oil, 12.5 g (95%); pmr τ (60 MHz), 2.6–2.9 (4H, m, ArH), 3.39 (2H, dd, J = 11 and 17 Hz, Ar—C*H*=), 4.40 (2H, dd, J = 17 and 1 Hz, *trans* —ArCH=C*H*—) and 4.88 (2H, dd, J = 11 and 1 Hz, *cis* —ArCH=C*H*—).

1,3-Bis(α,β-dibromoethyl)benzene, **17**

Bromine (13 ml, 40 g, 0.25 mol) in CCl_4 (50 ml) was added dropwise to an ice cold solution of *m*-divinylbenzene, **12** (15.6 g, 0.12 mol), in CCl_4 (100 ml). After warming to room temperature the reaction mixture was poured into 10% $NaHSO_3$ solution. The organic layer was washed, dried, and evaporated to yield an oil which, on trituration with pentane at 0 °C, gave white crystals of product, 44.3 g (82%), mp 62–63 °C; pmr τ (60 MHz) 2.63 (4H, s, ArH), 4.90 (2H, dd, J = 10 and 7 Hz, ArC*H*Br—) and 5.8–6.1 (4H, m, —CH_2Br); ms correct M^+ for $C_{10}H_{10}Br_4$.

1,3-Bis(α-bromovinyl)benzene, **19**

A solution of *tert*-BuOK (Aldrich, 5.7 g, 50 mmol) in *tert*-butyl alcohol (75 ml) and dioxane (25 ml) was added over 30 min with stirring to a solution of the tetrabromide **17** (9.0 g, 20 mmol), in dioxane (100 ml) at room temperature. After a further 30 min, H_2O and ether were added. The organic layer was washed, dried, and evaporated and the residual oil was chromatographed on silica gel. Pentane first eluted the product **19** as a colourless oil, 4.4 g (76%); pmr τ (90 MHz) 2.2–2.8 (4H, m, ArH), 3.89 and 4.20 (2H each, d, J = 2 Hz, =CH_2); ir (neat) 1610 and 1478 (—C=C—), 1175 and 892 (—CBr=CH_2) and 800 and 705 cm^{-1} (1,3-benzene); ms correct M^+ for $C_{10}H_8Br_2$. *Anal.* calcd. for $C_{10}H_8Br_2$: C 41.71, H 2.80; found: C 41.73, H 2.77.

1,4-Bis(β-chlorovinyl)benzene, **20**

n-Butyllithium (Alfa, 35 mmol in 18 ml hexane) was injected into a stirred suspension of chloromethyltriphenylphosphonium chloride (Aldrich, 12.11 g, 35 mmol) in dry THF (200 ml) at −60 °C under N_2. After 10 min, terephthaladehyde (Aldrich, 2.35 g, 17.5 mmol) in dry THF (200 ml) was added keeping the temperature below −40 °C. The reaction mixture was then allowed to stir ~12 h without further cooling. After addition of water the aqueous phase was extracted with ether. The extracts were washed, dried, and evaporated. After chromatography of the residual solid on silica gel using pentane as eluant, the product **20** was obtained as a solid mixture of isomers, 1.39 g (20%). Crystallization from $CHCl_3$–hexane gave crystals of a single isomer mp 72–74 °C; pmr τ 2.35 (4H, s, ArH), 3.41 (2H, d, J = 8 Hz, ArC*H*=) and 3.80 (2H, d, J = 8 Hz, =CHCl); ir (KBr) 932 (m) (*trans* —CH=CHCl), 860 (vs), 852 (vs), 825 (vs), 728 (vs), and 670 (s) cm^{-1}; correct M^+ for $C_{10}H_8Cl_2$. *Anal.* calcd. for $C_{10}H_8Cl_2$: C 60.33, H 4.05; found: C 59.98, H 3.83.

The stereochemistry of the double bond is not assigned for this isomer since the ir band at 932 cm^{-1} indicates a *trans* CH=CHCl whereas the coupling constant, J = 8 Hz indicates a *cis* CH=CHCl.

β-Bromostyrene, **23**

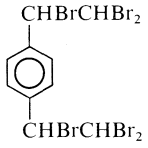
This was obtained in 60% yield using the method of Grovenstein and Lee (17) by treating cinnamic acid dibromide with aqueous sodium carbonate or more conveniently by adding bromine (1 mol) dropwise to a hot

(80 °C) solution of sodium cinnamate (1 mol, prepared by dissolving cinnamic acid and sodium carbonate in hot water) with good stirring. After cooling, the reaction was extracted with ether. The extract was washed, dried, and evaporated to yield a pale yellow oil consisting nearly entirely of β-bromostyrene by pmr comparison to an authentic sample (obtained above). Filtration through a short column of silica gel gave pure colourless product in about 85% yield.

1,4-Bis(trans-β-bromovinyl)benzene, ***21***

Bromine (5 ml, 92 mmol) was added dropwise with stirring at room temperature to a solution of *p*-benzene diacrylic acid, **22**, (36) (10.0 g, 46 mmol) and Na_2CO_3 (10 g, 94 mmol) in H_2O (500 ml). Vigorous bubbling ensued as the bromine colour was discharged and an off-white precipitate formed. The total reaction mixture was extracted with ether and the organic layer was washed, dried, and evaporated. Recrystallization of the resulting residue from benzene yielded almost white crystals of product, *ca.* 1.5 g (11% yield), mp 138–140 °C (lit. (37) mp 135 °C); pmr τ (60 MHz) 2.77 (4H, s, ArH), 2.91 (2H, d, J = 14 Hz, Ar*CH*=) and 3.28 (2H, d, J = 14 Hz, =CHBr); ir (KBr) 940 (*trans* —CH=CHBr), 770 and 725 cm^{-1}; ms correct M^+ for $C_{10}H_8Br_2$.

Concentration of the benzene mother liquors and addition of hexane precipitated the addition product of 2 mol of bromine to **21**, the hexabromide



mp 159–162 °C; pmr τ (60 MHz) 2.54 (4H, s, ArH), 4.03 (2H, d, J = 7 Hz, Ar—C*H*Br), and 4.64 (2H, d, J = 7 Hz, —$CHBr_2$); ms, M^+ 608, correct isotope pattern for $C_{10}H_8Br_6$ with subsequent stepwise loss of Br.

The Attempted Preparation of 1,3-Bis(trans-β-bromovinyl)-benzene ***15***

The reaction was carried out exactly as described above for the 1,4-isomer using *m*-benzene diacrylic acid (38). Chromatography of the resulting orange oil on silica gel using pentane as eluant gave a small amount of material which in its pmr spectrum showed peaks at τ (60 MHz) 2.81 (4H, bs, ArH), 2.92 (2H, d, J = 14 Hz, Ar*CH*=) and 3.32 (2H, d, J = 14 Hz, =C*H*Br), consistent with the structure of **15**.

Couplings of β-Bromostyrene, ***23***

(a) With Mg and then CuBr

β-Bromostyrene **23** (2.6 g, 14 mmol) and Mg turnings (0.36 g, 15 mmol) under N_2 in dry THF (50 ml) were heated under reflux for 6 h. The cooled black reaction mixture was then added dropwise over 30 min to a suspension of CuBr (dried over P_2O_5, 2.2 g, 15 mmol) kept at −60 °C under N_2. After the addition the resulting orange solution was allowed to warm to room temperature. It turned brown above −20 °C. After stirring overnight, H_2O and CH_2Cl_2 were added and the organic layer was washed, dried, and evaporated to yield a yellow residue which on crystallization from ethanol yielded *trans-trans*-1,4-diphenylbuta-1,3-diene, **24**, as plates, 1.0 g (65%), mp 152 °C (lit. (39) mp 152–152.5 °C). Identical pmr and ir spectra to those published (Aldrich *IV* 20C and 511E).

(b) With Li and then CuBr

The above reaction was repeated except that the vinyl lithium was prepared in ether at 0 °C under argon. The resulting oil from the coupling reaction contained the diene **24**, the diyne **25**, as well as many other products.

(c) With n-BuLi and then CuBr

A solution of *n*-BuLi (11 mmol in 5 ml hexane) was injected into a solution of β-bromostyrene (2.0 g, 11 mmol) in dry ether (50 ml) at 0 °C under N_2. After stirring for 1 h, this solution was added dropwise to a suspension of CuBr (1.6 g, 11 mmol) in dry ether (50 ml) kept at −60 °C under N_2. After stirring for 1 h the pale yellow solution was allowed to warm to room temperature (it turned brown above −10 °C). After addition of H_2O, the organic layer was washed, dried, and evaporated to yield a brown oil which on chromatography on silica gel using pentane as eluant yielded firstly unchanged bromide, **23** (30%) followed by crystals of 1,4-diphenylbuta-1,3-diyne, **25**, 0.3 g (27%), identical ir spectrum to that published (Aldrich 1257D).

(d) With tert-BuLi and then CuBr

A solution of β-bromostyrene (7.4 g, 40 mmol) in dry THF (50 ml) was added slowly to a solution of *tert*-BuLi (80 mmol) in pentane (100 ml) and dry THF (50 ml) kept at −78 °C. After 1 h, CuBr (5.7 g, 40 mmol) was added and then the reaction mixture was allowed to warm to room temperature. The volume of solvent was reduced and then H_2O and ether were added. The organic layer was washed, dried, and evaporated to yield a pale yellow solid. Recrystallization of this from ethanol yielded colourless plates of 1,4-diphenylbuta-1,3-diene, **24**, 0.82 g (20%) identical to previous samples.

Coupling of 1,8-Bis(β-bromovinyl)naphthalene, ***5***. *Synthesis of Pleiadiene*, ***27***, *and Cyclic Dimer* ***28***

1,2-Dibromoethane (1 ml) was added to a suspension of activated (21) Mg turnings (7.2 g, 30 mmol) in dry THF (100 ml) under N_2 at room temperature. After 15 min a portion of a solution of 1,8-bis(β-bromovinyl)naphthalene, **5**, (7.8 g, 20 mmol) in dry THF (75 ml) was added. The reaction started quickly and an orange colour developed. The remainder of **5** was added slowly and stirring continued for 2 h. The reaction mixture was then cooled to −78 °C and CuBr (7.0 g, 50 mmol) was added. The mixture was allowed to warm slowly to room temperature and was kept overnight. After addition of H_2O and ether the organic layer was washed, dried, and evaporated. The residue was then chromatographed on silica gel. Pentane first eluted a small amount of 1,8-divinylnaphthalene and as a second fraction an orange-red band. After evaporation of solvent and recrystallization from hexane this gave pleiadiene, **27**, 1.4–1.6 g (39–45%) as red crystals mp 91–92 °C (lit. (23) mp 91–92.5 °C) identical pmr spectrum to that published (23); ir (KBr) 3010 (—CH=CH—), 840, 775, 730 cm^{-1}. The third fraction eluted was any unchanged starting bromide **5**. Benzene–pentane (15:85) then eluted the yellow linear dimer **29**, *ca.* 50 mg (1.4%), mp 133 °C (dec.); pmr τ (60 MHz) 2.1–3.4 (18H, m, ArH and —*CH*=) and 4.30, 4.62, and 4.82 (4H, bs (some coupling), $=CH_2$); ir (KBr), 980 (s) (*trans* —CH=CH), 910 (m) ($=CH_2$), and 770 (s) cm^{-1}; ms *m/e*

(relative intensity), M^+ 358(5), 180(50), 179(100), 178(100), 165(100), under CH_4 chemical ionisation: $(MH)^+$ 359(19). The compound decomposes slowly on standing at room temperature.

Eluted next was the cyclic dimer **28**, as green crystals, 224 mg (6.3%) which formed a purple solution. Sometimes further chromatography on silica gel was necessary to purify this compound. Very careful recrystallization from hexane gave 94 mg (2.6%) of green crystals, mp 160–162 °C. On several occasions overheating or use of a different solvent produced dark tars; pmr τ (90 MHz, CD_2Cl_2) 2.1–3.7 (br signal, all protons, not resolved on cooling to −90 °C); ir (KBr) 970 (vw), 832 (m), 773 (s) cm^{-1}; uv (cyclohexane) λ_{max} (log ε_{max}) 578 nm (3.58), 534 (3.24), 497 (2.86), 332 (3.58), 316 (3.63), 305 (3.60), 279 (3.47), and 232 (4.28); (CH_2Cl_2) λ_{max} 582 nm, 536 and 500; (C_6H_5Cl) λ_{max} 592 nm, 545 and 510; ms *m/e* (relative intensity) (source temperature 170 °C) M^+ 356(17), 355(7), 354(10), 353(8), 352(5), 180(27), 179(71), 178(100), 177(20), 176(20), and 165(67), under $(CH_3)_3CH$ chemical ionization $(M + 1)^+$ 357(14). *Anal.* calcd. for $C_{28}H_{20}$: C 94.34, H 5.66; found: C 94.42, H 5.60. The compound can be stored unchanged at −20 °C. Eluted next, very close to the cyclic dimer, was a second green compound of unknown structure, ~20 mg, dec. *ca.* 250 °C, which gave a green solution having λ_{max} (cyclohexane) 592, 546, 506 nm. No molecular ions could be seen in the mass spectrum. The pmr and ir spectra were essentially the same as for **28**.

These results were not changed significantly by preparing the active magnesium from $MgBr_2$ and K (22).

Hydrogenation of the Cyclic Dimer 28

The cyclic dimer **28** (80 mg) and PtO_2 (30 mg) were stirred under an H_2 atmosphere in ethyl acetate (50 ml) for 30 min–2 h. Removal of catalyst and then solvent gave an oil which was chromatographed on silica gel, using pentane–benzene (5:1) as eluant. Eluted first was the product **30** as a yellow oil (~8 mg) which darkened on removal of solvent; pmr τ (60 MHz), 2.3–3.3 (12H, m, ArH); 6.6–7.2 (8H, m, ArCH_2—) and 7.6–8.4 (8H, m, —CH_2—); uv (Et_2O) λ_{max} (relative absorbance) 340 nm (0.07), 324 sh (0.24), 302 sh (0.92), 293 (1.00) and 279 sh (0.79); ms *m/e* (relative intensity) M^+ 364(100), 362(50), 360(47), with a very large number of much stronger cleavage peaks. This was immediately followed by a transannular product, *e.g.* **31**, ~5 mg as an oil; pmr τ 2.2–3.6 (12H, m, ArH) and 4.2–8.9 (12H, m, —CH, —CH_2); uv (ether) λ_{max} (relative absorbance) 300 nm (0.95), 293 (1.00), 280 sh (0.79) with a tail to 450 nm; ms *m/e* (relative intensity), M^+ 360(100), 358(22), 181(41), 180(46), and 179(71).

Coupling of 1,4-Bis(β-bromovinyl)benzene, 21

A few drops of 1,2-dibromoethane were added to a stirred suspension of activated (21) Mg (2.0 g, 8.3 mmol) in dry THF (50 ml) under N_2 at room temperature to which approximately one quarter of the dibromide **21** (1.30 g, 4.5 mmol) had been added. After 15 min stirring the colour of the reaction became yellowish and the remainder of the dibromide was added in dry THF (20 ml). After stirring overnight the yellow reaction mixture was added dropwise to a stirred suspension of CuBr (1.5 g, 10 mmol) in dry THF (100 ml) kept at −50 °C under N_2. The mixture was then allowed to warm slowly to room temperature. After 5 h, H_2O and ether were added, and the organic layer was washed, dried, and evaporated. The resulting bright orange solid (470 mg) was chromatographed on silica gel.

Pentane eluted first any unused starting bromide **21**, followed by the yellow linear dimer **38**, as a yellow solid from hexane, dec. with softening 140 °C; pmr τ (60 MHz) 2.5–2.9 (m, ArH), 2.9–4.2 (m, —CH=) and 4.3–4.9 (m, $=CH_2$); ir (KBr) 1000 and 915 ($=CH_2$), 868 and 822 cm^{-1}; ms *m/e* (relative intensity) M^+ 258(100) and 128(52). Later fractions contained the bromide **39** as indicated by its mass spectrum, molecular ions at *m/e* 338, 336. None of the known (12) cyclic dimer **4** could be detected.

Couplings of Alanes

(a) Derived from Phenylacetylene

i-Bu_2AlH (30 mmol) in hexane was added dropwise over 15 min to a solution of phenylacetylene (3 g, 29 mmol) in dry hexane (20 ml) under N_2. The mixture was then heated to 50 °C for 4 h when it became orange. After cooling, it was added dropwise with stirring to a suspension of CuBr (4.6 g, 32 mmol) in THF (50 ml) under N_2 kept at −50 °C. After 30 min the mixture was allowed to warm to room temperature. H_2O and ether were then added and the organic layer was washed, dried, and evaporated. The resulting solid was chromatographed on silica gel using pentane as eluant to yield the previously obtained diene **24**, 180 mg (6%).

(b) Derived from 1,8-Diethynylnaphthalene, 7

i-Bu_2AlH (50 mmol in hexane) was added to a solution of 1,8-diethynylnaphthalene, **7**, (7) (3.56 g, 20 mmol) in hexane (100 ml) at 0 °C under N_2. On warming to 50 °C the solution turned through yellow and red to brown. After 2 h the solution was cooled to −78 °C, and dry THF (50 ml) added followed by CuBr (7.2 g, 50 mmol). The reaction mixture was allowed to warm to room temperature and then H_2O and ether were added. The organic layer was washed, dried, and evaporated and the residue chromatographed on silica gel to give small amounts of the previously obtained linear **29** and cyclic dimers **28**, but no pleiadiene, **27**.

ROBERT J. CUSHLEY and BRUCE J. FORREST. Can. J. Chem. **55**, 220 (1977).

^{13}C spin–lattice relaxation studies on lecithin bilayers indicate a marked destabilization of the bilayer structure by incorporated vitamin E (*d,l*-α-tocopherol) and phytanic acid, phytanic acid causing the greatest perturbation.

Kinetic analysis of paramagnetic praseodymium infusion into the lecithin vesicles containing various phytyl compounds has been performed using ^{31}P nmr. Relative rates of Pr^{3+} leakage through the mixed lecithin – phytyl compound bilayer compared with pure lecithin (relative rate = 1.00) were: phytol = 7.8, vitamin E = 47.7, and phytanic acid = 2897.

ROBERT J. CUSHLEY et BRUCE J. FORREST. Can. J. Chem. **55**, 220 (1977).

Des études de relaxation spin–réseau du ^{13}C sur des couches doubles de lécithine indiquent qu'il se produit une déstabilisation importante de la structure de la couche double lors de l'incorporation de vitamine E (*d,l*-α-tocophérol) et d'acide phytanique; l'acide phytanique cause la plus grande perturbation.

Utilisant la rmn du ^{31}P, on a effectué des analyses cinétiques de l'infusion de praséodyme paramagnétique dans des ampoules de lécithine contenant divers composés phytylés. Les vitesses relatives de perte de Pr^{3+} à travers une couche double mixte de lécithine – composé phytylé, par rapport à la lécithine pure (vitesse relative = 1.00), sont: phytol = 7.8, vitamine E = 47.7 et acide phytanique = 2897.

Introduction

As part of our continuing study on the effects of branched chain compounds on the structure and stability of model membrane systems, we wish to report the effects of the incorporation of vitamin E (*d,l*-α-tocopherol) and phytanic acid into a model membrane. Previously, we had studied the effects of the intercalation of the related isoprenoid, phytol, 3,7,11,15-tetramethylhexadec-*trans*-2-en-1-ol (1). We found that, at 52 °C, the fluidity of the lecithin bilayer, as shown by ^{13}C T_1 relaxation times, increased greatly due to added phytol and the effect was lessened as the temperature was lowered and the gel–liquid crystalline transition temperature, T_m, was approached. Since any change in the packing of the lipid molecules may greatly alter the properties of the bilayer (2), the perturbation was interpreted in terms of the difficulty in accommodating the phytyl compound in an ordered bilayer structure.

In the present study the isoprenyl compounds phytanic acid and vitamin E have been incorporated into hen egg lecithin bilayers. Despite the obvious physiological importance of these two

phytyl compounds, very little is known of their effects at a molecular level. This is in direct contrast to the wealth of information concerning the interactions of cholesterol with membrane systems. To this end, we report herein the effects of incorporated vitamin E and phytanic acid on membrane structure and fluidity evidenced by ^{13}C nmr relaxation studies.

In addition, we have discovered a large permeability increase in the model membrane by means of lanthanide induced shifts (LIS) of the ^{31}P nmr signals which shows a strong correlation with the effects demonstrated by ^{13}C.

Experimental

Lecithin was extracted from fresh egg yolks by the method of Singleton *et al.* (3). Thin layer chromatographic analysis showed a single spot when developed with $CHCl_3$:MeOH:H_2O (65:25:4) and heated. Compounds were obtained from the following sources: *d,l*-α-tocopherol (vitamin E), Sigma Chemical Co.; phytanic acid (99.7%), Analabs; phytol, Aldrich Chemical Co.; praseodymium nitrate (99.9%), Alpha Inorganics.

Lecithin dispersions (10% w/v) were prepared by shaking the dry lipid with D_2O, in the case of the ^{13}C spectra, and with 0.05 *M* Tris buffer, p*H* 7.22 which was 0.05 *M* in KCl in the case of ^{31}P spectra. The dispersions were then sonicated under nitrogen on a Biosonik III probe-type sonicator until translucence (~10 min) while being cooled by a stream of cold water flowing through a jacket surrounding the sample. The vesicle preparations were then centrifuged and passed through a 0.22 μ Millipore filter to remove titanium fragments and to remove large liposomes. The resultant vesicle preparation was subsequently transferred under nitrogen to a 12 mm nmr tube and the nmr spectra were taken immediately.

Mixed vesicle preparations (3:1 mole ratio lecithin:phytyl compound) were prepared in a similar manner by first co-dissolving both components in chloroform followed by exhaustive pumping to obtain the dry mixture. Attempts to incorporate either vitamin E or phytanic acid into the bilayers at higher molar ratios were unsuccessful.

All ^{13}C spectra were determined at 25.2 MHz on a Varian XL-100-15 nmr spectrometer fitted with a TT 100 FT attachment using an internal ^{2}H field-frequency lock, and an 8K dataset, with external TMS as a reference. The sample temperature was kept constant at 11 ± 1 °C. Under these conditions, the vesicles remained stable throughout the course of the experiment. Due to the length of the T_1's to be measured, and in order to circumvent the required waiting period of five times T_1 between pulse sequences, the ^{13}C spin–lattice relaxation times were measured by the homospoil sequence of McDonald and Leigh (4). T_1's for several carbon atoms which were indicated to be < 200 ms were checked by the inversion-recovery method of Vold *et al.* (5) and were found to be in agreement with the homospoil determinations to within experimental error. The percentage error for each measurement is included in Table 1 and averages ±6%; occasionally duplicate runs showed variance in the two runs up to 10%. Thus, our confidence limit is set at ±10%. Therefore, if the variance exceeded the percentage error, the variance is reported in Table 1.

^{31}P spectra were determined at 33 °C using a Varian XL-100-15 spectrometer operating at 40.5 MHz fitted with a TT 100 FT attachment, using an external ^{19}F field-frequency lock and external H_3PO_4 (85%) as a reference. Unless otherwise indicated, running conditions were: data set = 2K zero-filled to 4K; digitizing rate = 2 kHz; pulse width = 10 μs; pulse delay = 0.5 s. Initial spectra were taken and a 150 μl portion of 0.1 *M* $Pr(NO_3)_3 \cdot 5H_2O$ in the aforementioned buffer solution was then added and subsequent spectra taken. Using 3 ml of vesicle solution gave a Pr^{3+} concentration of 0.005 *M*.

Results and Discussion

The ^{13}C spin–lattice relaxation times for egg lecithin, lecithin with 25 mol% incorporated vitamin E, and lecithin with 25 mol% incorporated phytanic acid are shown in Table 1. Assignments are taken from those made previously (1). At the concentrations used, resonances of the phytyl additives were not of sufficient intensity to allow an accurate determination of their relaxation times. An examination of the lecithin T_1's readily reveals a large increase in the fluidity of the lipid bilayer upon addition of the phytyl compounds.

Increases are observed in the relaxation times for each carbon along the lecithin hydrocarbon chain. For example, the T_1 of the main methylene envelope carbons increases from 0.30 to 0.55 s upon vitamin E incorporation, and to 0.81 s upon intercalation of phytanic acid, while the antepenultimate carbon experiences increases from 0.30 to 0.55 s and to 0.90 s for the lecithin – vitamin E, and lecithin – phytanic acid mixed bilayers, respectively. In like fashion, increases are also detected for the penultimate carbon from 0.66 to 0.80 and 1.75 s, and for the terminal carbon from 2.05 to 2.76 and to 2.98 s.

It has recently been pointed out by Seelig and Seelig (6) and Stockton *et al.* (7) that interpretation of ^{13}C T_1's is hampered by the fact that the order parameter, S_{mol}, and τ_c, the rate for segmental motion about individual C—C bonds, cannot be separated in the dipolar correlation time, τ, calculated from T_1 for purely dipolar relaxation

$$\tau = r^6/N\gamma_C{}^2\gamma_H{}^2\,\hbar^2 T_1$$

That is, the relaxation rate is determined by the anisotropy of motion as well as the rate of motion. Nevertheless, the concept of increased motional freedom due to separation of phos-

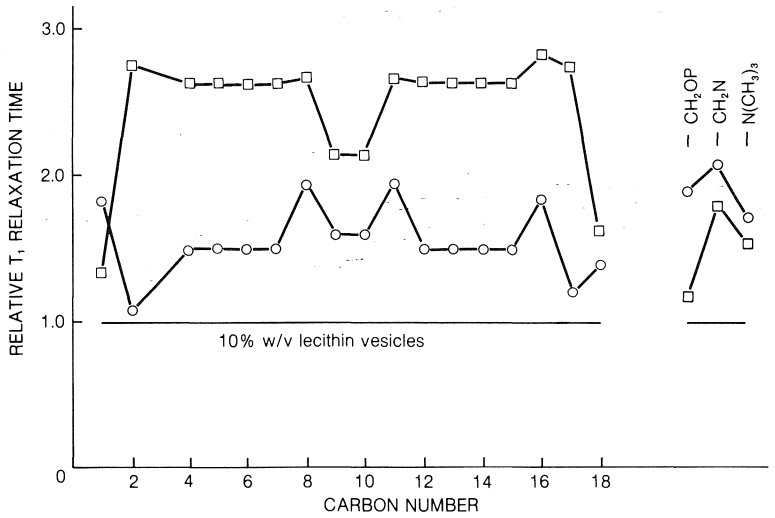

FIG. 1. Plot of the relative ^{13}C T_1 relaxation times for individual fatty acid carbons of lecithin and mixed lecithin – phytyl compounds in sonicated D_2O dispersions: □ 0.33 mol phytanic acid added; ○ 0.33 mol vitamin E added. The ^{13}C T_1 values for 10% w/v lecithin, column 2, Table 1 have been given the relative value of 1.00.

pholipid molecules in the bilayer will result in larger values for ^{13}C T_1's whether due to increased disorder ($< S_{mol}$), *i.e.*, greater excursions of the C—H dipole from the normal to the chain long axis, or increased rate of segmental motion, or both.

The amount of increase in relaxation time is more clearly evinced in Fig. 1. Figure 1 plots the observed ^{13}C T_1 values of lecithin with the incorporation of vitamin E and phytanic acid relative to the T_1 values obtained for egg lecithin alone (relative T_1 value = 1.00). As can be seen from the figure, large increases in T_1 for the hydrocarbon chain carbons of the order of 50–

100% are found for the incorporation of vitamin E and of the order of 150–200% for the incorporation of phytanic acid, even at 11 °C which is close to the transition temperature, $T_m = -5$–0 °C, for egg lecithin. Such increases in T_1, we believe, are a result of increased mobility along the entire acyl chain due to the necessary deviation from normal lipid packing. The deviations are caused by the difficulty in accommodating the highly branched compounds in an ordered bilayer arrangement.

London attractive forces between identical nonpolar molecules leads to an interaction potential of

$$U = -\frac{A\alpha^2}{r^6}$$

where A is a constant, α is the molecular polarizability, and r is the separation of the molecules. Since there is a highly distance dependent nature of the London forces between the hydrocarbon chains of a lecithin bilayer, the incorporation of phytol, α-tocopherol, or phytanic acid results in a large decrease in the interaction of adjacent lipid molecules for even a small expansion of the bilayer.

For the lecithin hydrophilic headgroup the order of T_1 increase is reversed; that is, vitamin E incorporation gives rise to greater increases in T_1 than determined for phytanic acid. The effect is particularly noticeable for the carbon atom adjacent to the choline phosphate moiety. The ^{13}C relaxation time for the choline CH_2—O—P is increased by only 17% by the incorporation of phytanic acid, while the T_1 value for CH_2—O—P is increased by 75% in the presence of vitamin E. The behavior of the headgroup carbons is explained by considering the depth each phytyl compound sits below the membrane surface.

We have previously provided firm evidence that phytol interjects further into the polar region of the lecithin bilayer than does, for instance, cholesterol (1). A linear electric field effect of the polar head groups of the lecithin bilayer was found for the unsaturated C2,C3 bond of intercalated phytol. An electric field calculation based on the surface dipole moment placed the midpoint of the C2,C3 double bond approximately 4.7 Å below the surface and the phytol hydroxyl close enough to hydrogen bond to the phosphate of the lecithin headgroup.

Since the ^{13}C relaxation time for the choline CH_2—O—P does not greatly increase upon incorporation of phytanic acid, in contrast to the effect of α-tocopherol, it is probable that the acid moiety is engaged in hydrogen bonding with the lecithin phosphate. Such an interaction would tend to anchor the carbon atoms of the lipid headgroup and decrease their motional freedom. A similar effect has been noted for the choline CH_2—O—P in mixed phytol–lecithin bilayers (1). Note that the effect is lessened as the trimethylammonium carbons are approached.

In direct contrast to the effect of vitamin E and phytanic acid, the intercalation of cholesterol does not cause any appreciable change in ^{13}C T_1 relaxation times of egg lecithin (8). Also, our own results indicate little effect upon ^{13}C T_1's due to the incorporation of up to 25 mol% of an unbranched C_{16} fatty acid, palmitic acid.

Monolayers of phytol, α-tocopherol, and phytanic acid occupy molecular areas of 55, 60, and 61 Å^2 per molecule at 0.5 dyn/cm, respectively (9). The disruptive effect of the branched phytyl chains of these molecules is understandable when a comparison of the aforementioned molecular areas is made with unbranched stearic acid which occupies 24 Å^2 per molecule (9). Cholesterol is known to form stable monolayers with molecular areas of approximately 40 Å^2 at a surface pressure of 0.5 dyn/cm.

Phytanic acid is expected to cause the greatest expansion of the bilayer not only because of steric factors, but also because the carboxyl moiety extends furthest into the hydrophilic region. In other words, the penetration into the plane of the lecithin headgroup further electrostatically interferes with the normal ionic interaction between the negative phosphate of one lecithin molecule for the now necessarily more distant trimethylammonium group of adjacent lipid molecules.

Although α-tocopherol has nearly the same area requirements as phytanic acid, it is not expected to penetrate as far into the hydrophilic region. With a single hydroxyl function on the bulky hydrophobic chromanol ring system vitamin E is expected to lie lower in the bilayer than phytanic acid or phytol and may parallel that occupied by incorporated cholesterol (10, 11). These authors have shown that the cholesterol hydroxyl is found at the position of the ester carbonyl. We calculate this to be some 7.5 ± 2 Å below the polar surface based on the X-ray data of Hitchcock *et al.* (12). The phytol

TABLE 2. Leak rates for lecithin and mixed lecithin vesicles determined by ^{31}P nuclear magnetic resonance

	^{31}P chemical shift[a] in absence of Pr^{3+} (ppm upfield from 85% H_3PO_4)	Decrease in 'inside' ^{31}P signal intensity upon Pr^{3+} addition (% total/min)	Relative rate	Half-life (day)
Lecithin	0.87	5.35×10^{-3}	1.00	6.5
Lecithin + phytol (25 mol%)	0.85	4.17×10^{-2}	7.79	0.83
Lecithin + vitamin E (25 mol%)	0.79	2.55×10^{-1}	47.66	0.14
Lecithin + phytanic acid (25 mol%)	0.91	15.50	2897	2.2×10^{-3}

[a]800 transients; pulse width = 10 μs (56° flip angle).

hydroxyl, on the other hand, resides some 0–2 Å from the surface based on the field effect measurements. The much larger steric effect of tocopherol *vs.* cholesterol, *vide supra*, would cause a disruptive expansion of the bilayer. Situated lower in the bilayer, vitamin E would not then be expected to interact with or anchor the lecithin headgroup. The large increase of 75, 108, and 71% for the relaxation times of the choline CH_2OP, $\overset{+}{N}CH_2$, and $\overset{+}{N}(CH_3)_3$ carbons, respectively, upon vitamin E incorporation, compared with increases of 17, 85, and 63% for the same three carbons when phytanic acid is added, is simply the consequence of decreased ionic interaction of adjacent lipid molecules due to the sterically induced increased separation with concomitantly decreased H-bonding of the vitamin E hydroxyl to phosphate.

Phytol, in spite of its relatively high position in the bilayer, is not expected to cause as large an electrostatic perturbation in the plane of the lipid headgroups as phytanic acid. In addition, the phytol monolayer area requirement of 55 $Å^2$ is not as large as that for phytanic acid or vitamin E. In summary, the foregoing provides a rationale that the destabilizing effect of the intercalation of isoprenoid compounds into phospholipid bilayer membranes increases in the order phytanic acid > α-tocopherol > phytol.

^{31}P *Nuclear Magnetic Resonance Results*

The permeability of lecithin vesicles can be correlated directly with the membrane fluidity as expressed by ^{13}C T_1 relaxation times. We have studied the effect of the incorporation of phytyl compounds on the permeability of lecithin vesicles using a lanthanide induced shift (LIS) ^{31}P nmr technique.

A number of recent studies have shown LIS of ^{1}H and ^{31}P nmr signals of phospholipid vesicles due to added lanthanide (13–16). The addition of Pr^{3+} results in a downfield shift for the outside phosphorus nuclei.

We have utilized the rate of disappearance of the 'inside' ^{31}P resonance signal to study the permeability changes in model membrane systems. Upon addition of the Pr^{3+} to preformed vesicles, the ^{31}P resonance of the nuclei on the outside of the bilayer is broadened slightly and shifted downfield (LIS) by approximately 8 ppm, while the 'inside' phosphorus resonance is shifted upfield very slightly (17) but remains sharp.

The rate of infusion of praseodymium across the bilayer is proportional to the rate of disappearance of the high field ^{31}P nmr signal. Plots of the disappearance of 'inside' ^{31}P resonance signal as paramagnetic Pr^{3+} crosses the bilayer *vs.* time are shown in Fig. 2.

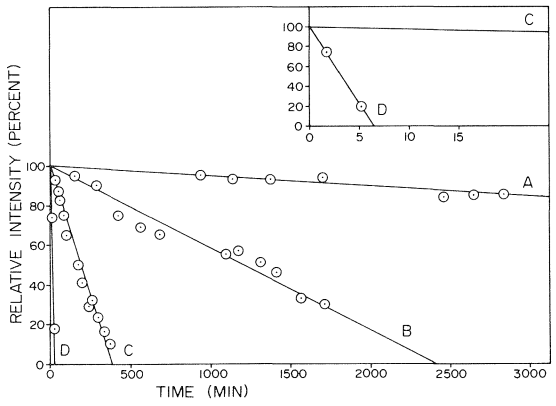

FIG. 2. Percent total of inside phosphorus nmr signal relative to its initial value *vs.* time for (*A*) egg lecithin alone + 0.005 *M* Pr^{3+}, (*B*) egg lecithin with 25 mol% incorporated phytol + 0.005 *M* Pr^{3+}, (*C*) egg lecithin with 25 mol% incorporated vitamin E + 0.005 *M* Pr^{3+}, (*D*) egg lecithin with 25 mol% incorporated phytanic acid + 0.005 *M* Pr^{3+}. Because of the extreme slope with phytanic acid, lines (*C*) and (*D*) are reproduced in the insert using an expanded time scale.

The kinetic data from Fig. 2 are quantified in Table 2 for egg lecithin alone, lecithin with incorporated phytol, lecithin with incorporated α-tocopherol (vitamin E), and lecithin with incorporated phytanic acid. The incorporation of 25 mol% phytol increases the vesicle leak rate by approximately 8 times, 25 mol% vitamin E by approximately 48 times, and 25 mol% phytanic acid by nearly 2900 times over the leak rate obtained with pure egg lecithin vesicles.

The half-life of the 'inside' resonance was calculated from the observed rates and is shown in Table 2, column 5. The addition of 25 mol% phytanic acid to the system is seen to decrease the half-life of the peak unaffected by paramagnetic Pr^{3+} from 6.5 days to about 3 min. Lesser, but significant, effects are seen with the incorporation of phytol and vitamin E which have half-lives of approximately 20 and 3 h, respectively. When 25 mol% palmitic acid was added, no change in the lecithin leak rate was detected.

Because of the potential physiological significance of the above results, a much lower amount of vitamin E (3 mol%) was incorporated. The permeability results still showed an increase of 300%.

In spite of the large increase in permeability, even in the presence of phytanic acid, the vesicles did not rupture. After the complete disappearance of the upfield 'inside' resonance due to Pr^{3+} entering the vesicles, sufficient EDTA was added to complex with all of the Pr^{3+} on the outside of the membrane resulting in reappearance of two ^{31}P resonances. In this case, the upfield peak was due to the 'outside' phosphorus nuclei of intact vesicles since Pr^{3+} inside the vesicles cannot form an EDTA complex.

The ^{31}P results parallel the ^{13}C T_1 relaxation studies on bilayers containing intercalated phytol (1) and ^{13}C studies of bilayers with incorporated vitamin E and phytanic acid reported here. The ^{13}C relaxation studies have shown an increase in the fluidity of the lipid bilayer caused by the intercalation of the branched chain compounds. The increased permeability to ions shown by ^{31}P nmr spectroscopy exactly parallels the order found for mobility increase *viz.* phytanic acid > vitamin E > phytol > lecithin alone.

Conclusion

On a molecular level, incorporation of vitamin E or phytanic acid disrupts the packing of the hydrocarbon region of phospholipid bilayers. In addition, penetration of the carboxyl function of phytanic acid into the plane of the lecithin headgroups causes a further disruption of the electrostatic attraction between adjacent lipid molecules. As we have demonstrated by ^{13}C spin–lattice relaxation measurements, large changes in the 'fluidity' of bilayer membranes can be caused by the incorporation of phytyl compounds.

In addition, the effect of intercalated vitamin E, phytol, and phytanic acid are shown to *increase* the permeability of phosphatidylcholine bilayers to Pr^{3+} by up to 2900 times. The incorporation of cholesterol is known to *decrease* the permeability of phospholipid bilayers to Na^+, K^+, Cl^-, and glucose (18) as well as showing increased order (7).

Several studies (19–22) have indicated that there exists a correlation between membrane 'fluidity' and the regulation of membrane bound co-operative enzymes. While it is possible that a definite level of membrane 'fluidity' is necessary for regulation, it is also probable that too great an increase in the 'fluidity' of biological membranes may lead to a loss of cell function and a failure of compartmentalization.

Thus, Lucy and Dingle (23) observed *in vitro* that the rapid hemolysis by added retinol of rabbit erythrocytes is inhibited by low concentrations of α-tocopherol, as well as other branched chain compounds such as 6-*O*-acetyl-α-tocopherol, squalene, ubiquinone-30, vitamin K_1, and phytol, while *N*,*N'*-diphenyl-*p*-phenylenediamine and hydroquinone were completely without effect. However, in higher concentrations, extensive hemolysis was produced by vitamin E and phytol themselves. This activity was deemed not to be caused by the redox system of α-tocopherol, but rather that it was a function of the isoprenoid side chain (23).

Furthermore, the accumulation of branched chain compounds has been associated with a number of disorders. Patients afflicted with Refsum's disease cannot α-oxidize and decarboxylate phytanic or similar branched chain fatty acids. The resultant buildup of these branched chain compounds in the nervous tissue has been linked with the observed degeneration which often leads to the complete disintegration of the myelin sheaths (24).

It is clear that the incorporation of phytyl compounds has a marked destabilizing effect on

phospholipid bilayers as shown by increased freedom of fatty acid chains, said effect also increasing abruptly their permeability.

The OH and NCH_2 proton signals of 1-(2′-hydroxythiobenzoyl)-2-methylpiperidine (**2**) are resolved into separate peaks assigned to four conformers (*EA*, *EB*, *ZA*, and *ZB*) in 220 MHz nmr spectra at −50 °C. All have a strong intramolecular OH· · ·S hydrogen bond. The *ZB* and *EB* conformers have the lowest and highest ground state energies, respectively. Exchanges between *A* and *B* conformers have a higher energy barrier than exchanges between *Z* and *E* isomers, but by +40 °C all four conformers interchange rapidly. The nature of all possible interchange processes is considered and a potential energy surface with respect to rotation about the Ph—C(S) and C—N bonds is presented. For the 4-methyl analogue of **2** low temperature nmr spectra exhibit two sharp OH signals arising from *A* and *B* conformers. For 2,6-dimethyl-4-(2′-hydroxythiobenzoyl)morpholine the *A*/*B* OH doublet of the *cis* dimethyl isomer can be distinguished from that of the *trans* isomer. Thus it is demonstrated that the intramolecularly hydrogen bonded OH proton is a good spectroscopic conformational probe. Nuclear magnetic resonance, ir, and uv data all indicate that in the 2,6-dimethylpiperidine analogue of **2** the CNC and Ph—C(S)N planes are perpendicular due to steric interference. Coplanarity of the phenyl ring with the thioamide group is attributed to a very strong intramolecular OH· · ·S hydrogen bond, in equilibrium with a proton transferred O· · ·H—S form in solution. This structure resembles the transition state for rotation in the most readily achieved exchange between conformers of **2**.

ADRIAN O. FULEA et PETER J. KRUEGER. Can. J. Chem. **55**, 227 (1977).

On a déterminé le spectre rmn à 220 MHz et à −50 °C de (l'hydroxy-2′ thiobenzoyl)-1 méthyl-2 pipéridine (**2**); on a pu en résoudre les signaux dus aux protons OH et NCH_2 en pics distincts attribués aux quatre conformères (*EA*, *EB*, *ZA* et *ZB*). Tous ces conformères présentent un pont hydrogène intramoléculaire OH· · ·S qui est très fort. Les conformères *ZB* et *EB* ont respectivement les énergies des états fondamentaux qui sont les plus basses et les plus élevées. Les échanges entre les conformères *A* et *B* ont une barrière d'énergie plus élevée que les échanges entre les isomères *Z* et *E*; toutefois à +40 °C les quatre conformères s'échangent rapidement. On considère la nature de tous les processus possibles pour ces échanges et on propose une surface d'énergie potentielle par rapport à la rotation autour des liens Ph—C(S) et C—N. Pour l'analogue de **2** méthylé en position 4, les spectres rmn à basse température montrent deux signaux OH intenses dérivant des conformères *A* et *B*. Dans le cas de la diméthyl-2,6 (hydroxy-2′ thiobenzoyl)-4 morpholine, on peut distinguer le doublet *A*/*B* du OH de l'isomère diméthyl-*cis* de celui de l'isomère *trans*. Ainsi on a pu démontrer que le proton OH lié par un pont hydrogène intramoléculaire est une bonne sonde spectroscopique conformationnelle. Des données de rmn, ir, et d'uv indiquent toutes que dans la diméthyl-2,6 pipéridine analogue de **2**, les plans CNC et Ph—C(S)N sont perpendiculaires l'un à l'autre dus à des interférences stériques. On attribue la coplanarité du cycle phényle avec le groupe thioamide à un lien hydrogène OH· · ·S intramoléculaire qui est très fort et qui est en équilibre, en solution, avec une forme H—S· · ·O dans laquelle le proton a été transféré. Cette structure ressemble à l'état de transition de rotation dans l'échange qui peut s'effectuer le plus facilement entre les deux conformères de **2**.

Introduction

In previous papers (1, 2) we have shown that 1-(2′-hydroxythiobenzoyl)piperidine and 4-(2′-hydroxythiobenzoyl)morpholine exist in two conformers (*A* and *B*) which arise because of different steric interactions between the 6′ aromatic proton and either one or both of the hetero-ring NCH_2 protons *trans* to the thiocarbonyl group. These conformers interchange rapidly on the nmr scale by ring inversion, and

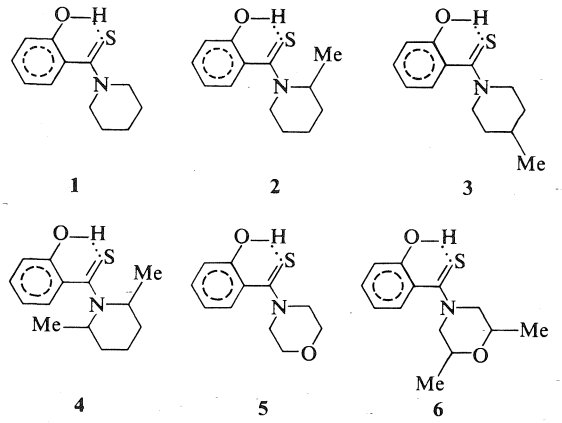
also by rotation around the C—N and Ph—C(S) bonds. The last two processes are slow at low temperatures.

Since these conformers play an important role in the elucidation of the origin of the magnetic non-equivalence of the NCH_2 protons in benzamides and thiobenzamides (3), we have now investigated *N*-(*o*-hydroxythiobenzoyl)piperidines and -morpholines in which the hetero ring is biased by one or more methyl groups, freezing the hetero-ring inversion over the temperature range investigated (+40 to −50 °C) and thus providing an opportunity to see both conformers separately in their nmr spectra.

Spectroscopic data on the compounds **1–6** are presented and discussed in this paper.



Compounds **1** and **5** are reference compounds for the study of the effect of methyl substitution on conformational dynamics. All of these compounds are characterized by a very strong intramolecular OH···S hydrogen bond. Furthermore, steric hindrance forces the aromatic ring out of planarity with the thioamide group.[5] The details of this have been investigated with a model which is in good agreement with experimental data.

Experimental

Compounds

Samples **1** and **5** were those used in previous investigations; **2**, **3**, **4**, and **6** are new compounds which were prepared by the Willgerodt–Kindler reaction (6) from *o*-hydroxybenzaldehyde, sulfur, and the appropriate methylated piperidine or morpholine, using pyridine as a solvent. A 3 h reflux period gave crystalline material with the characteristics described in Table 1. The 2,6-dimethylmorpholine used as starting material for the synthesis of **6** was a 60/30 = *cis*(ee)/*trans*(ae) mixture, from nmr. Microanalyses were carried out by Chemalytics, Inc., Tempe, Arizona, U.S.A.

Spectra

The 220 MHz ^1H nmr spectra were obtained at the Canadian 220 MHz NMR Centre, Sheridan Park, Ontario, under the direction of Dr. A. E. Grey. The 100 MHz spectra were obtained with a Varian HA-100 spectrometer, with the assistance of Mr. Lawrence Wong. Temperature calibrations for the latter were checked with methanol. An internal TMS reference was used in all cases.

Infrared spectra in solution, using matched 2 or 10 cm cells, were obtained with a Perkin-Elmer Model 621 spectrophotometer, and uv spectra with a Beckman Acta V spectrophotometer by Mrs. Marelle Bertram.

Calculations

Dreiding model dimensions and geometries are used throughout the discussion in this paper, with full recognition of their inherent limitations, particularly with respect to multiple angle deformations that may occur in sterically crowded molecules to relieve strain. The thioamide N atom was considered to be planar, and oriented for maximum π-electron overlap with the C=S group. The following thioamide group bond lengths were used:

$$(Ph)C—C(S) = 1.48 \text{ Å}$$
$$C=S = 1.68 \text{ Å}$$
$$C—N = 1.40 \text{ Å}$$

All non-bonded distances were calculated with the computer programme CART (7). While some distortion of the piperidine ring in compounds of this type has been established (1), it cannot be put on a quantitative basis at present, and this treatment does not take such dis-

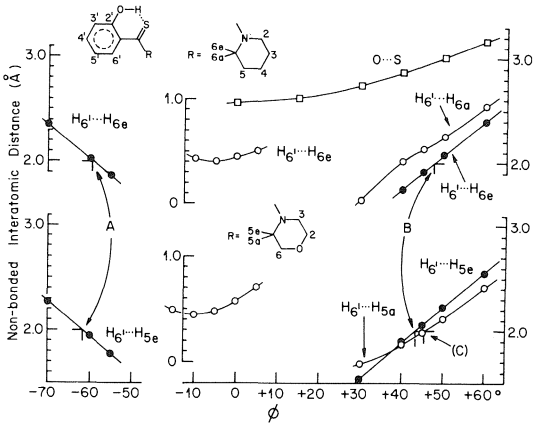


FIG. 1. Selected non-bonded H···H and O···S distances in the *A* and *B* conformers of *N*-(*o*-hydroxythiobenzoyl)morpholines and -piperidines, calculated from Dreiding model geometry, as a function of the phenyl ring rotational angle ϕ. For further details see text.

[5]The phenyl ring twist angle in benzamides and thiobenzamides has been discussed recently (4), and near planarity of the N atom in amides is well established (5).

tortion into consideration. *Greater planarity of the aromatic ring and the thioamide plane probably exists in these molecules than is deduced from the constrained models employed, but this does not alter the essential features of any conclusions, which are based on spectral observations.*

Results and Discussion

Geometry of Model Conformers

The $H_{6'}\cdots H_{6e}$ and corresponding $H_{6'}\cdots H_{5e}$ distances in **1** and **5** are shown in Fig. 1 as a function of the phenyl ring rotational angle (ϕ) out of the thioamide plane.[6] It would fall to less than 0.5 Å when $\phi = 0°$; comparison of this distance with twice the van der Waals radius of hydrogen (2.0 Å)[7] indicates that the phenyl ring must be rotated out of the thioamide plane.

In *ortho*-substituted *N*-thiobenzoylmorpholines and -piperidines with unsubstituted hetero rings we have previously found two conformers (*A* and *B*) arising out of hetero-ring inversion and its relation to the $H_{6'}\cdots H_{5e}$ steric interaction ($H_{6'}\cdots H_{6e}$ in piperidines), which requires extensive rotation of the phenyl ring out of the thioamide plane (1, 2). The ground state energies for *A* and *B* were found to differ by only 0.2 kcal/mol or less. Calculations based on Dreiding model geometries and assuming 'contact' of the $H_{6'}\cdots H_{5e}$ atoms in *N*-thiobenzoylmorpholines ($H_{6'}\cdots H_{6e}$ atoms in *N*-thiobenzoylpiperidines) at a distance of 2.0 Å[8] leads to twist angles ϕ_A and ϕ_B for the two conformers as listed in Table 2, along with other calculated geometric parameters. These are applicable to all the compounds under discussion, regardless of aromatic or hetero-ring substitution.

The data in Table 2 show, first of all, that substitution of a morpholine ring for piperidine introduces significant conformational changes. Secondly, the structural features calculated on the supposition that the phenyl ring will attempt to be as planar as possible with the thioamide group, being hindered only by the steric interference of an *ortho*-aromatic proton with one (or both) *anti* NCH_2 proton of the hetero ring, are very reasonable. Thus the first H···H 'contact' (d = 2.00 Å) when rotating the phenyl ring from $\phi = 90°$ toward planarity in compounds of the type **1** occurs when $\phi_A = 59.5°$ (in conformer *A*) and $\phi_B = 47.5°$ (in conformer *B*). In both cases the aromatic *o*-proton ($H_{6'}$) first touches the H_{6e} atom. In compounds of the type **5** (morpholine ring) $\phi_A = 61.5°$ and $\phi_B = 43.5°$, corresponding to 'contact' with H_{5e}, although it must be noted in the last case (see Fig. 1) that $H_{6'}\cdots H_{5a}$ 'contact' actually occurs *first* as ϕ decreases, leading to the definition of conformer *C* (as in Table 2) with $\phi_C = 45.5°$.[9] Since librations about the C—N bond would allow $H_{6'}$ to slip past H_{5a}, given the angle of approach, conformer *C* is not expected to play a role except perhaps at very low temperatures when librational amplitudes are reduced.

[6] The numbering system is summarized in Fig. 1.

[7] While the Pauling van der Waals radius of hydrogen is 1.2 Å, it has more recently been concluded that 1.0 Å is a more appropriate value (8). The hydrogen disks in Dreiding models therefore have 1.0 Å radii. Non-bonded atomic radii cannot be defined precisely in any event, and are frequently anisometric (9), so that contact distances depend on the angle between the bonds to the approaching atoms. For aromatic protons the consistent van der Waals radius appears to be 1.0 Å (9), and even closer H···H contacts have been reported in bicyclo[3.3.1]nonane (1.7 Å) (10) and in 1,8-bisdehydro[14]annulene (1.85 Å) (11). Large atoms in particular can lead to 'soft' contacts.

[8] This is the low value end of the 'contact range' recommended by Scheraga (12) for use in 'hard sphere potential' calculations of protein conformations.

[9] Previously estimated values of ϕ_A, ϕ_B and other structural parameters were based on direct measurements on Dreiding models; the values given in this paper supercede the earlier values.

TABLE 2. Geometric parameters calculated for conformers of *N*-(*o*-hydroxythiobenzoyl)piperidines and -morpholines[a]

Conformers		Hetero ring	
View along C=S bond[b]	View along (Ph)C—C(S) bond[c,d]	Piperidine (X = CH_2)	Morpholine (X = O)
(A) 		$\phi_A = 59.5°$ $d_{H...H_e} = 2.0$ Å $d_{H...H_a} > 2.0$ Å $d_{O...S} = 3.16$ Å $\Delta d = 0.09$ Å[e]	61.5° 2.0 Å >2.0 Å 3.18 Å 0.07 Å[e]
		0.18 Å decrease	0.26 Å decrease
(B) 		$\phi_B = 47.5°$ $d_{H...H_e} = 2.0$ Å $d_{H...H_a} = 2.0$ Å $d_{O...S} = 2.98$ Å $\Delta d = 0.27$ Å[e]	43.5° 2.0 Å 2.0 Å 2.92 Å 0.33 Å[e]
		$\phi_A - \phi_B = 12°$ $(\cos^2 \phi_B/\cos^2 \phi_A) = 1.8$	18° 2.3

[a]Using Dreiding model geometry, with a planar hetero-ring N atom. While these data are calculated for the *N*-(*o*-hydroxythiobenzoyl) compounds, the ϕ values determined by non-bonded H · · · H contact are also deemed applicable to all other *N*-thiobenzoylpiperidines and -morpholines.

[b]Hydrogen bond to thiocarbonyl S atom which is located directly behind thioamide C atom.

[c]H is the aromatic *o*-proton, H_a and H_e are the *anti* NCH_2 protons of the hetero ring, and ϕ is the dihedral angle between the phenyl ring and thioamide planes.

[d]When $\phi = 55.0°$ a torsion angle of 22.3° is required about the C—O bond for the COH···S atoms to lie in a plane. This corresponds to an ∠ OH···S of 145.8°.

[e]Sum of van der Waals radii of O and S atoms, minus calculated $d_{O...S}$.

Table 2 and Fig. 1 also show that O· · ·S distances are estimated to be 3.16 and 2.98 Å for conformers *A* and *B*, respectively, in the piperidine ring compounds, and 3.18 and 2.92 Å, respectively, in the morpholine ring compounds. These values are 0.07–0.33 Å shorter than the sum of the respective van der Waals radii ($r_O + r_S = 1.40 + 1.85 = 3.25$ Å), and such shortening on strong hydrogen bond formation is well known. Thus, O· · ·O and F· · ·F shortening of 0.25 Å has been documented for intermolecular OH· · ·O and FH· · ·F hydrogen bonds (13). For **1** and **5** in very dilute CCl_4 solution we have observed only minute traces of a 'free' fundamental OH stretching vibration in the infrared spectrum, but very intense and broad intramolecularly OH· · ·S bonded OH peaks displaced by 341 and 350 cm^{-1}, respectively. These attest to very strong hydrogen bonds, the hydroxyl proton being pushed into the S atom electron density as the aromatic ring attempts to achieve the maximum permissible co-planarity with the thioamide group. It is known that the effective radius of a hydrogen atom in a hydrogen bond is negligible (14). In 2-methylmercaptophenol the intramolecular O· · ·S distance is identical with that which we estimate for conformer *B* in the case of a morpholine ring, but the OH frequency shift due to intramolecular OH· · ·S hydrogen bonding is only 149 cm^{-1} (14*b*). From the data in Table 2 it is also expected that the acidity of OH_B will exceed that of OH_A, and the basicity of S_B will exceed that of S_A, for a given compound, due to the dependence of the conjugation on ϕ.

Hamilton and Ibers (15) consider that a good operational criterion for the existence of a hydrogen bond is H· · ·X shortening. Assuming a normal ∠COH and a normal OH bond distance, our model calculations show that the H· · ·S distance in the compounds under consideration falls from 2.23 Å at $\phi = 55°$ to 1.70 Å at $\phi = 0°$ (phenyl ring/thioamide group coplanar). Relative to the sum of the van der Waals radii ($r_H + r_S = 1.0 + 1.85 = 2.85$ Å), this corresponds to 'shrinkage' of 0.5–1.12 Å, which is in line with those of 0.9 and 1.4 Å noted for intermolecular OH· · ·O and OH· · ·F

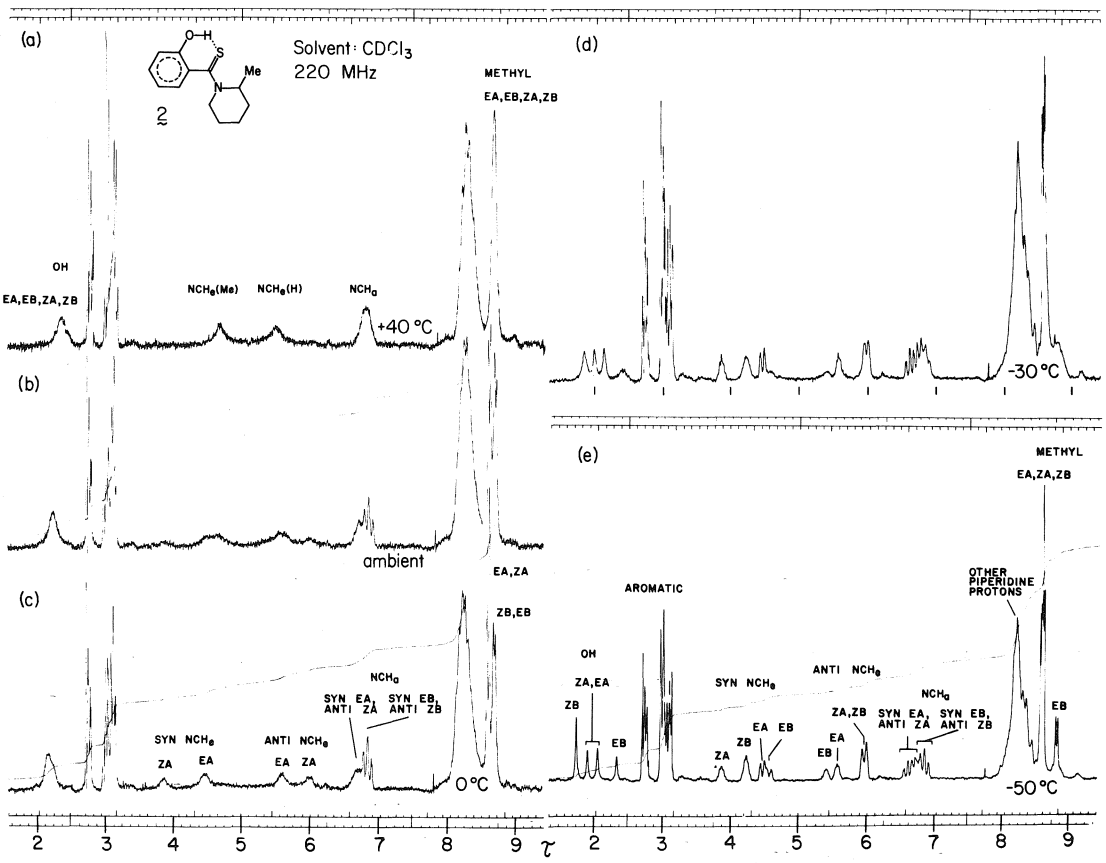

FIG. 2. 220 MHz ^1H nmr spectra of **2**.

hydrogen bonds, respectively (15). Unfortunately crystallographic data for compounds involving OH···S hydrogen bonds is quite meagre (16).

No reference is made to the $H_6\cdots H_{6a}$ and $H_6\cdots H_{5a}$ distances in Fig. 1 since they always exceed 2.0 Å when some other contact set in. As far as the *syn* NCH_2 protons are concerned, the following distances apply in our model: $S\cdots H_{2a} = 3.65$ Å, $S\cdots H_{2e} = 2.39$ Å (in piperidines); $S\cdots H_{3a} = 3.50$ Å, $S\cdots H_{3e} = 2.49$ Å (in morpholines). Distances below 2.85 Å are considered to correspond to 'soft' contacts here.

Conformers of 1-(2'-Hydroxythiobenzoyl)-2-methylpiperidine (2)

The 220 MHz nmr spectra of **2** in $CDCl_3$ at selected temperatures between +40 and −50 °C are given in Fig. 2, and expansions at two low temperatures in the most relevant regions in Fig. 3. Proton signal assignments are indicated in these figures. The most striking characteristic is the progressive resolution of the spectrum into distinctly separate OH and *syn* and *anti* NCH_2 (and NCHR) proton signals characterizing the *A* and *B* conformers of both the *Z* ('zusammen')[10] and *E* ('entgegen')[10] isomers as the temperature is lowered. These four conformers[11] are illustrated in Fig. 4 together with all possible interchange paths, the energy barriers being correlated with the schematic potential energy surface proposed in Fig. 5 to explain the experimental data.

Figure 4 classifies the interchange paths into

[10] *Z* and *E* have the methyl and thiocarbonyl groups on the same and opposite sides of the CN bond, respectively.

[11] Because the *Z* and *E* forms are not physically separable, reference will be made only to the *EA*, *EB*, *ZA*, and *ZB* forms as 'conformers'. These conformers can be interchanged by rotation around the formal single bonds C(S)—Ph and C—N. Each of these conformers has an enantiomer, but that is irrelevant for this study. Their existence might be demonstrated in a chiral solvent.

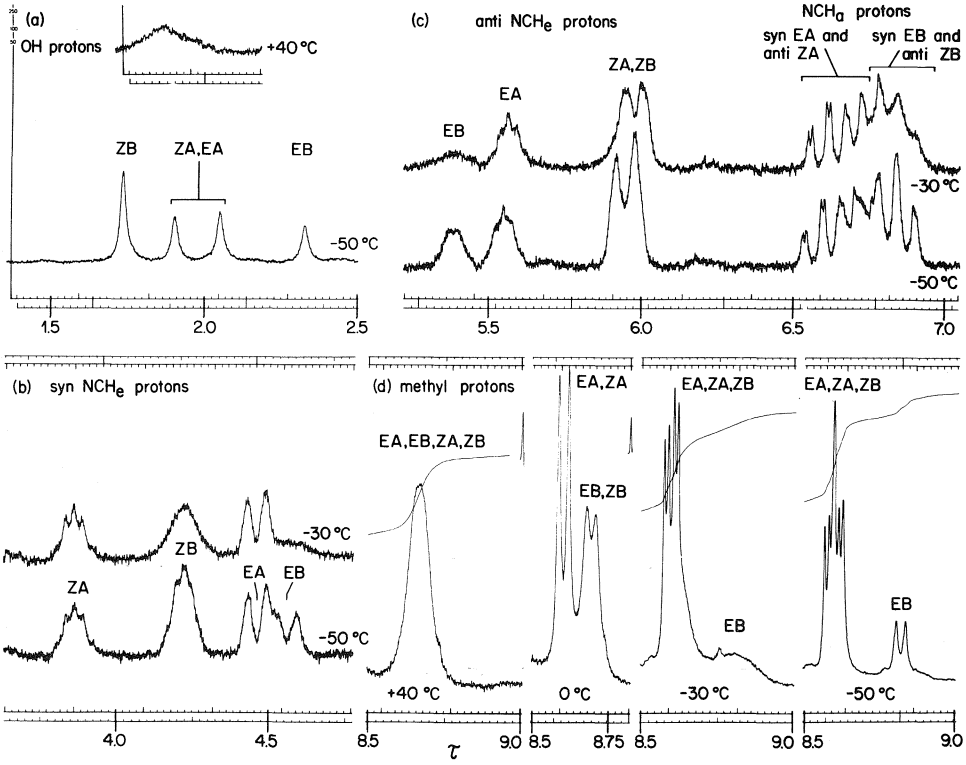

FIG. 3. Expanded scale 220 MHz ^{1}H nmr spectra of **2**: (*a*) OH protons, (*b*) *syn* NCH_e protons, (*c*) *anti* NCH_e and *syn* and *anti* NCH_a protons, and (*d*) methyl protons.

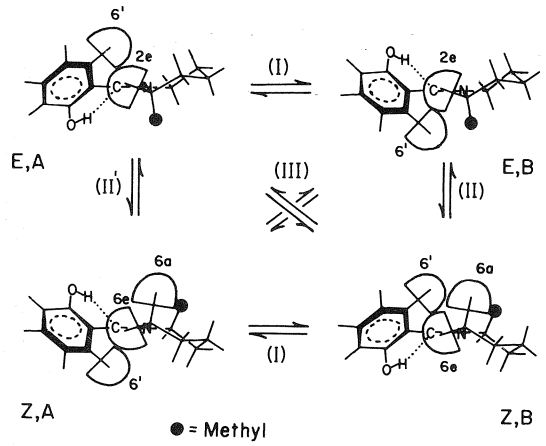

FIG. 4. The four conformers of **2** and their interchange paths, together with the energy barriers for interconversion correlated with the potential energy surface in Fig. 5. The thioamide plane is perpendicular to the paper and the thiocarbonyl S atom is directly behind the thioamide C atom. These sketches are based on photographs of Dreiding models, and selected H disks shown have a radius of 1 Å. For simplicity the methyl group is shown only as a dark circle.

the following processes, based on a comparison of equilibrium geometries for the four conformers calculated on the basis of thioamide group planarity and steric 'contact' between the aromatic *o*-proton and one (or both) *anti* NCH_2 protons of the hetero-ring:

(*I*) (*a*) Rotation about the Ph—C(S) bond ($\Delta\phi = \sim 107°$) and passage of the O atom past the S atom, and $H_{6'}$ past H_{2e} (or past H_{6e}, depending on the isomer involved), or (*b*) rotation about the Ph—C(S) bond in the opposite direction ($\Delta\phi = \sim 253°$) with passage of the O atom past H_{2e} (or H_{6e}), which would be even more difficult than (*a*).

(*II*), (*II'*) Co-operative rotation about the C—N bond ($\Delta\theta = \sim 180°$) and (*a*) about the Ph—C(S) bond ($\Delta\phi = \sim 95° - \sim 119°$) with passage of the O atom past the S atom, or (*b*) about the Ph—C(S) bond in the opposite direction ($\Delta\phi = \sim 241° - \sim 265°$), involving complete breaking of the conjugation of the phenyl ring with the thioamide group. Path (*a*) may be energetically preferable because of

the increased phenyl ring conjugation and the very strong OH· · ·S hydrogen bond stabilizing the planar transition state, as demonstrated later in this paper. This is an example of the 'gear effect' (17).

(*III*) Small angle rotation about the Ph—C(S) bond ($\Delta\phi = \sim 12°$) with maintenance of some conjugation of the phenyl ring with the thioamide group, and $\Delta\phi = \sim 180°$ rotation about the C—N bond.

The angles cited are based on our calculations for **1** and **5** described in the preceding section. Undoubtedly the real angles will be somewhat different, particularly in the case of **2**, but the calculated values are used throughout this discussion for illustrative purposes. Notwithstanding the above classification of pathways, all probably proceed via the energetically favourable 'saddle point' region in Fig. 5, *e.g.* even the $EA \rightleftarrows EB$ conversions which appear to involve no rotation about the C—N bond probably involve an intermediate state where sufficient rotation about this bond has occurred to permit the $H_{6'}$ atom to slip past H_{2e}. Librational motion about the C—N bond may provide the mechanism for this. Cooperative rotation about two bonds in amides has already received some consideration (18).

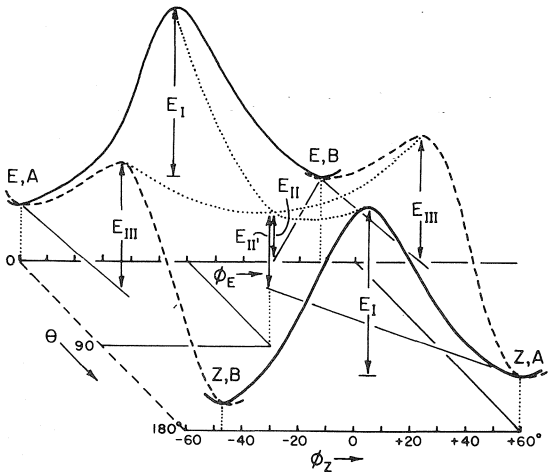

FIG. 5. Potential energy surface proposed for interconversion between all possible pairs of *ZA*, *ZB*, *EA*, and *EB* conformers. The angles θ and φ refer to rotation about C—N and Ph—C(S) bonds, respectively. The θ scale is compressed by a factor 2 relative to the φ scale. Only cuts through the surface are shown for Ph—C(S) rotation interchanging *E* and *Z* isomers, and for C—N rotation relating the $E,A \rightleftarrows Z,B$ and $E,B \rightleftarrows Z,A$ conformers. Tie lines (dotted lines) from the maxima in these cuts are joined to indicate the 'saddle point'.

The assignment of OH and CH proton peaks follows from their relative intensities at −50 °C, the manner in which they coalesce as the temperature is raised, and an assessment of steric plus other factors. The NCH_a signals account for half as many protons as the NCH_e signals; thus the methyl group is axial (19). The *syn* NCH_e proton signal is known to be downfield relative to the *anti* NCH_e signal (19). Further, the $NCH_e(H)$ proton signals are doublets due to coupling with the geminal axial protons, while the $NCH_e(CH_3)$ signals are multiplets due to coupling with the methyl protons. Molecular models show that conformer *EB* is the most sterically hindered conformer in the ground state, and hence its peak should have the lowest intensity. Thus all the *EB* signals can be assigned readily as indicated in the spectrum at −50 °C in Figs. 2*e* and 3. The methyl group signal for this conformer also appears well separated from that of the other three conformers.

The *syn* NCH_e proton doublet of conformer *EA* can be identified next, slightly downfield from the corresponding doublet in *EB*. At −30 °C the *EB* signals begin to broaden, together with the peaks for another conformer, whereas the peaks for the remaining two conformers (one of which is *EA*) are still sharp. Since the chemical shift difference between the *syn* NCH_e protons of *EA* and *EB* is the smallest of all the possible shift differences that can be formed for the four conformers, it follows that the process which interchanges $EB \rightleftarrows EA$ is *not* the one which begins to appear as rapid on the nmr scale at −30 °C (process *I*). Process *II* interchanging $EB \rightleftarrows ZB$ is envisaged as having a lower barrier than process *III* interchanging $EB \rightleftarrows ZA$ for reasons already mentioned, and this is proven later in this paper from the nmr spectra of **6**, where $A \rightleftarrows B$ interchange can be ruled out and coalescence similar to that observed for **2** must be due to $B \rightleftarrows B'$ interchange (where B' is the mirror image of *B*). The interchange $EB \rightleftarrows ZB$ thus remains as the one which first becomes rapid at −30 °C as the temperature is raised.

Taking the selective broadening at −30 °C into account, the OH and *syn* and *anti* NCH_e proton signals of the *ZB* conformer can be

assigned. This OH peak is the strongest of the four OH signals at −50 °C and has the largest chemical shift from TMS. The two central OH peaks of almost equal intensity are thus due to the *EA* and *ZA* conformers, but no specific assignment can be made. In order of increasing chemical shift at −50 °C, the OH protons therefore have the following chemical shifts from TMS (and relative intensities): *EB* = 1688 Hz (1.0); *EA*/*ZA* = 1749 Hz (1.7) and 1781 Hz (1.4); *ZB* = 1818 Hz (2.7). This means that the *EB* conformer is 0.43 kcal/mol less stable than the *ZB* conformer and the *EA*/*ZA* conformers are 0.20/0.28 kcal/mol less stable than *ZB*.

The remaining *syn* NCH_e multiplet (with the largest chemical shift in this group) must arise from *ZA*. The *anti* NCH_e multiplet that remains unidentified belongs to *EA*, and intensity considerations dictate that the *anti* NCH_e proton chemical shifts of the *ZB* and *ZA* conformers (doublet) must be identical. At −30 °C broadening due to the *ZB* contribution to this signal is already evident.

The axial proton signals are more overlapped. However, the broadening at −30 °C permits the identification of the *syn* and *anti* NCH_a proton signals of *EB* and *ZB*. The remaining NCH_2 peaks are assigned to a superposition of the *syn* and *anti* NCH_a signals of *EA* and *ZA*; these broaden at 0 °C and this shows that $\Delta E_{II'} > \Delta E_{II}$.

The commencement of selective broadening around −30 °C as the temperature is raised proves the following:

(*1*) The process *EB* ⇄ *ZB* is becoming rapid, and intermolecular hydrogen exchange processes are ruled out, as in this case all four OH signals should start to coalesce at the same temperature.

(*2*) Because

$$(\tau_{OH}^{EB} - \tau_{OH}^{ZB}) \gg |\tau_{OH}^{ZA} - \tau_{OH}^{EA}|$$

and yet the *EB* and *ZB* conformers interchange at a lower temperature, it follows that $\Delta E_{II'} > \Delta E_{II}$.

(*3*) The exchange *ZB* ⇄ *EB* takes place at a lower temperature than the exchange *EB* ⇄ *EA* in spite of the fact that for the NCH_e protons

$$(\tau_{anti}^{ZB} - \tau_{syn}^{EB}) \gg (\tau_{syn}^{EB} - \tau_{syn}^{EA})$$

which implies that the energy barrier for the latter exchange (ΔE_I) exceeds that for the former (ΔE_{II}).

The relative barrier heights $\Delta E_I > \Delta E_{III} > \Delta E_{II'} > \Delta E_{II}$ are therefore indicated, with the thermodynamic stability of isomers/conformers increasing in the order *E*,*B* < *E*,*A* ≈ *Z*,*A* < *Z*,*B*. These features are incorporated into Fig. 5. While the barriers for *ZA* ⇄ *ZB* and *EA* ⇄ *EB* exchange may be slightly different, they are both referred to here as ΔE_I; similarly those for *EB* ⇄ *ZA* and *EA* ⇄ *ZB* exchange are both labelled ΔE_{III}.

By 0 °C the OH peaks for all four conformers have already coalesced (Fig. 2*c*) and the NCH_e proton signals for the *EB* and *ZB* conformers have broadened to the extent that they are lost in the background. Broad signals are observed for the *syn* and *anti* NCH_e protons of the *EA* and *ZA* conformers, as well as a broad superimposed *syn* and *anti* NCH_a signal for these conformers. On the other hand, the *syn* and *anti* NCH_a signal of *EB* and *ZB* is *sharp* at τ = 6.85 ppm, as are the methyl doublets due to the conformer pairs *ZB*/*EB* and *EA*/*ZA*. These sharp features persist at 20 °C indicating that even at that temperature neither of the barriers ΔE_{III} or ΔE_I have yet been exceeded.

By 40 °C the signals for the OH, NCH_e(H), NCH_e(Me), NCH_a(H) and methyl protons are averaged to one signal each, respectively, for all four conformers (Fig. 2*a*). This means that at least one or both of the energy barriers ΔE_{III} and ΔE_I are now being exceeded by rapid exchange on the nmr scale, bearing in mind that co-operative θ,φ motion may mean that the full barrier heights ΔE_I and ΔE_{III} need never be attained (Fig. 5). Coalescence at 40 °C implies a barrier height of ~17 kcal/mol between *A* and *B* conformers of **2**.

Figure 6*a* shows the OH proton signals for **2** at 100 MHz over a temperature range. At low temperatures the four separate signals are still seen, corresponding to the number of conformers, proving that even at this lower field strength the OH group is a good spectroscopic probe in these compounds.

Conformers of 1-(2′-Hydroxythiobenzoyl)-4-methylpiperidine (3)

For **3** only two OH peaks are observed at 100 MHz at low temperatures, (Fig. 6*b*) in agreement with the expected number of conformers. The

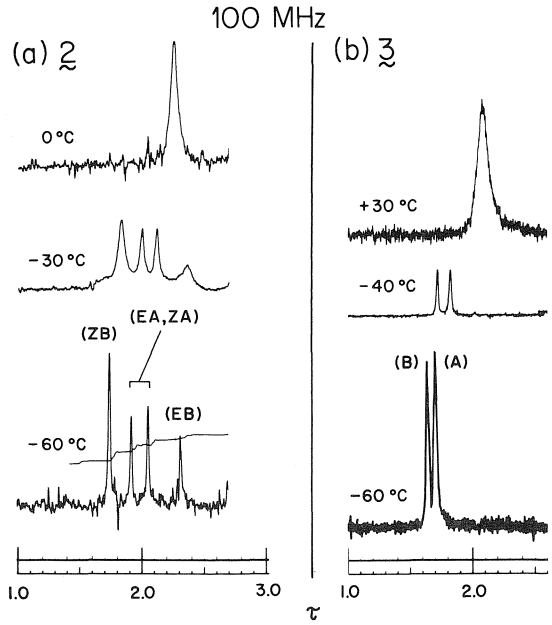

FIG. 6. 100 MHz ^{1}H nmr spectra of (*a*) **2** and (*b*) **3** in $CDCl_3$.

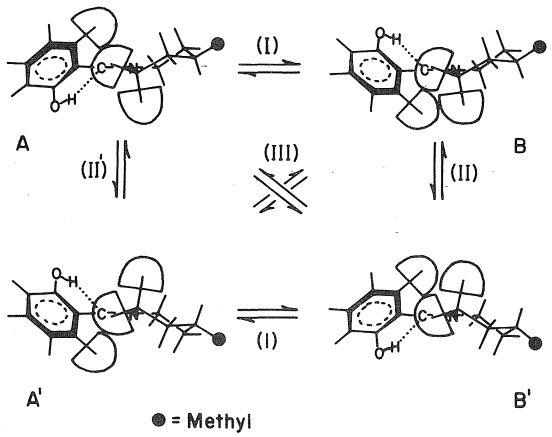

FIG. 7. The *A* and *B* conformers of **3** and their enantiomers *A'* and *B'*, respectively, together with all possible interconversion paths. For further details see caption to Fig. 4 and text.

complete conformational scheme for **3** is presented in Fig. 7. Here processes *II* and *II'* lead to the enantiomers *B'* and *A'* of the conformers *B* and *A*, respectively, and thus only two spectroscopically distinguishable forms of this molecule are expected in non-chiral solvents. The potential energy surface for conformational interconversion in **3** would resemble that presented in Fig. 5 except that it would have a vertical two-fold symmetry axis through the saddle point. At 100 MHz the OH signal splitting is the only evidence for the existence of two conformers of **3**, the hetero-ring protons giving only one signal for both *A* and *B* conformers.

Isomers of 2,6-Dimethyl-4-(2'-hydroxythiobenzoyl)morpholine (6)

The sensitivity of the OH proton to the *A* and *B*, and the *Z* and *E* conformers of **2** having been demonstrated, it was of interest to investigate the existence of *A* and *B* conformers in the *cis* and *trans* dimethyl compound **6**. The 220 MHz spectra of **6** at ambient temperature in $CDCl_3$ and CS_2 solution are shown in Fig. 8*d* and *e*, respectively. In $CDCl_3$ solutions the *syn* NCH_e and the *syn* and *anti* NCH_a proton signals differ in shape and in chemical shift for the *A* and *B* conformers, and the *syn* and *anti* methyl group protons are also distinguishable. From this $A \rightleftarrows B$ (process *I*) and $A' \rightleftarrows B$ (process *III*) exchanges can be ruled out, and $B \rightleftarrows B'$ and/or $A \rightleftarrows A'$ (processes *II* and *II'*) identified as being responsible for the broadening. The great similarity between the *syn* and *anti* NCH_a proton signal patterns for **6** and **2** at 20 °C suggests an identical process in the latter, and this has already been used in the assignment of its nmr signals. At the same temperature in CS_2 solution the *syn* NCH_e proton signals of **6** have merged, but the *syn* and *anti* NCH_a proton signals are still different in *A* and *B*.

From the spectrum of **6** in $CDCl_3$ at 20 °C a lower limit of $\Delta E > 17$ kcal/mol can be predicted for the barrier between *A* and *B* conformers, given that they still give separate *syn* and *anti* NCH_a peaks at this temperature. This barrier is probably $\Delta E_{III'}$ or related to it but lowered by passage through the saddle region in Fig. 5. In a compound like 2,6-dimethyl-4-(4'-nitrothiobenzoyl)morpholine an even higher barrier is expected because of increased 'stiffness' to rotation due to the higher C—N bond order.

The breadth, multiplicity, and temperature dependence of the OH peaks in **6** (Fig. 8*c*) are contrasted with the corresponding signals in **1** and **5**, which are shown on the same scale in Fig. 8*a* and *b*, respectively. Both **1** and **5** exhibit

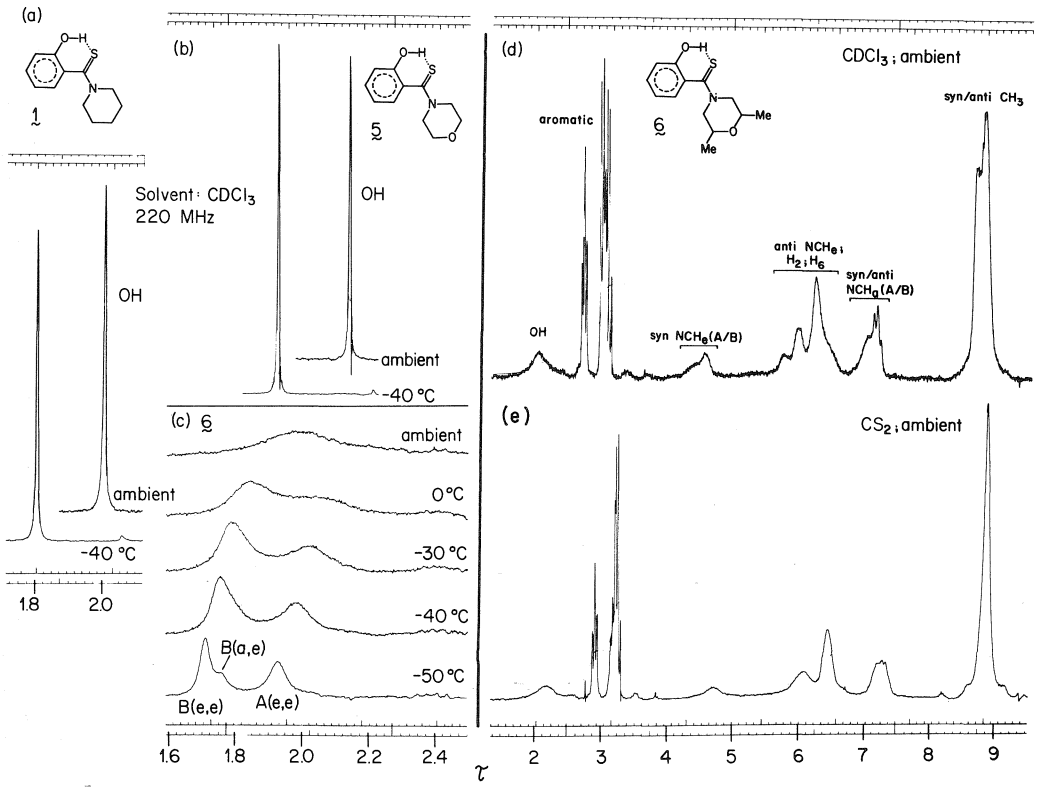

FIG. 8. 220 MHz ^{1}H nmr OH proton signals in (*a*) **1**, (*b*) **5**, and (*c*) **6**; (*d*) (*e*) nmr spectra of **6**.

only a single very sharp OH peak down to −40 °C. The chemical shifts $\tau_{OH}{}^{A}$ and $\tau_{OH}{}^{B}$ should each be approximately the same (if not identical) in **1** and **3**, and in **5** and **6**, as all the factors which can influence this chemical shift in a given conformer remain constant. Thus the shift differences $\tau_{OH}{}^{A} - \tau_{OH}{}^{B}$ should also be the same in **1** and **2**, and in **5** and **6**, respectively. The appearance of only a single peak in **1** and **5** implies that the interchange $A \rightleftarrows B$ by hetero-ring inversion is rapid on the nmr scale, over the temperature range investigated. For **2**, **3**, and **6** this process is frozen on the nmr scale by the biased hetero ring (or a rapidly equilibrating mixture of a major conformer like *A* and a minor conformer of type *B* with an axial methyl group exists).

The 220 MHz OH proton signals of **6** in $CDCl_3$ solution as a function of decreasing temperature are shown in Fig. 8*c*. By −50 °C three peaks are observed. The dominant peaks at 1777 and 1824 Hz from TMS are assigned to the *A* and *B* conformers of **6** with ee methyl groups, while the secondary peak at 1813 Hz arises from the *B* conformer of **6** with ea methyl groups. The latter reflect an ee/ae mixture in the 2,6-dimethylmorpholine used in the synthesis of **6** (see Experimental). The $\tau_{OH}{}^{ae}$ and $\tau_{OH}{}^{ee}$ signals of the *A* conformer may well overlap in Fig. 8*c*.

A smaller proportion of the ae isomer is also seen in the 300 MHz methyl proton signals of 2,6-dimethyl-4-(3′-nitrothiobenzoyl)morpholine (**7**) and (**6**) shown in Fig. 9*a* and *b*, respectively, together with assignments. The a methyl group in **7** now shows up as separate *syn* and *anti* doublets. In **6** the *o*-OH substituent introduces greater rigidity into the molecule and accentuates the difference between the *A* and *B* conformers. Thus at −11 °C the a methyl signals are now split. At −33 °C these signals have collapsed into single lines, but the *syn* e CH_3 signal shows splitting corresponding to the different chemical shifts of *A* and *B* conformers. The *anti* e CH_3 signals are clearly different for the *A* and *B* conformers at both of these temperatures.

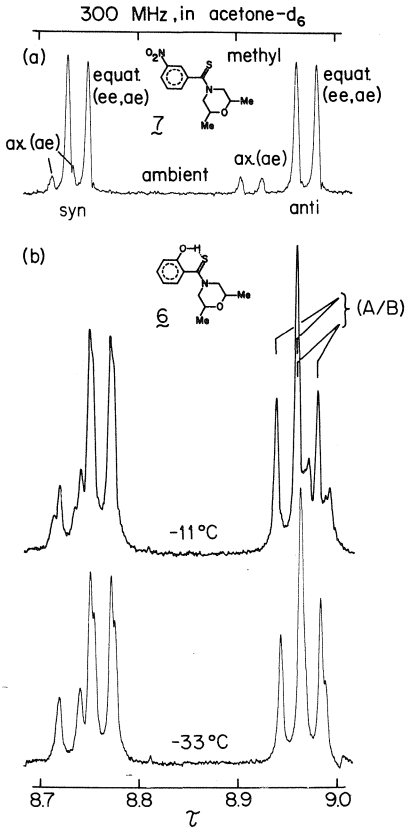

FIG. 9. 300 MHz ^{1}H nmr spectra of (*a*) **7** and (*b*) **6** in the methyl proton region.

1-(2′-Hydroxythiobenzoyl)-2,6-dimethylpiperidine (4): Phenolthione (C—O—H···S=C) and Enethiol-quinonemethide (C=O···H—S—C=C)

2,6-Dimethyl substitution of **1** produces **4**, which is radically different in structure from **2**. In the 220 MHz nmr spectrum of **4** (Fig. 10) both the chemical shift and the signal pattern of the NCH protons show that they are axial, and therefore both methyl groups must be equatorial. At all temperatures investigated the NCH_a protons have the same signal; also the two e CH_3 groups have the same signal. Molecular models indicate that the steric interactions cannot be accommodated in a structure like that of **2** (where the single methyl group is axial in all the conformers) and all spectral data are consistent with **4***a* (Scheme 1) in which the CNC plane is perpendicular to the Ph—C(S)—N plane. This would break the conjugation of the C—N bond and increase the Ph—C=S conjugation, with its planarity being favoured by a very strong intramolecular OH···S hydrogen bond. While another conformer can be envisaged by 180° rotation about the C—N bond, this involves steric H_6···Me interactions leading to an unpopulated high energy form. Rotation about the C—N bond to interchange these conformers is also bound to have a very high energy barrier because of the severe steric interactions in the planar transition state. We believe **4** to be the first amide in which N lone pair electrons are not conjugated with the C=X π-electrons because of mutual orthogonality in the molecular structure. Its ground state structure is a model for the transition state of process *II* in **2**, and the existence of **4** as a stable compound lends strong support to the hypothesis that this type of stabilized transition state is the most important in the low temperature interconversion of $Z \rightleftarrows E$ conformers in **2**.

All the compounds dealt with in this paper are white in colour, except **6** which is pale green, and **4** which is red. That provides further evidence of radically different electronic structure in the last one. Furthermore, in **4** the aromatic proton $H_{6'}$ is very much deshielded relative to the equivalent protons in all other *o*-OH thiobenzamides studied, such a low-field position being quite normal for a δ proton in a quinonemethide.

The OH signal of **4** is very broad in $CDCl_3$, conditions under which **1** and **5** give very sharp bands, and this is indicative of an exchange process. The infrared spectra of **4** in very dilute CCl_4 solution ($c < 10^{-3}$ *M*) provide further evidence as to its structure (Fig. 11). Compound **2** exhibits a very weak 'free' OH peak at 3613 cm^{-1} and an intense broad intramolecularly OH···S bonded band with a maximum ~3270 cm^{-1}, and all other *o*-hydroxythiobenzoylpiperidines and -morpholines are similar. Compound **4** has a trace of 'free' OH at 3616 cm^{-1}, with $\nu_{OH...S} < 3000\ cm^{-1}$ and overlapped by CH stretching bands, *and an intramolecularly hydrogen bonded SH···O band at 2250 cm^{-1}*. No absorption occurs in this region for any other related *o*-hydroxythiobenzamides, and 'free' SH groups normally absorb *weakly* in the range 2550–2600 cm^{-1}. We attribute all of these features to the equilibrium in Scheme 1.

The lack of double bond character in the C—N bond favours **4***b* and **4***d*, and the hydrogen

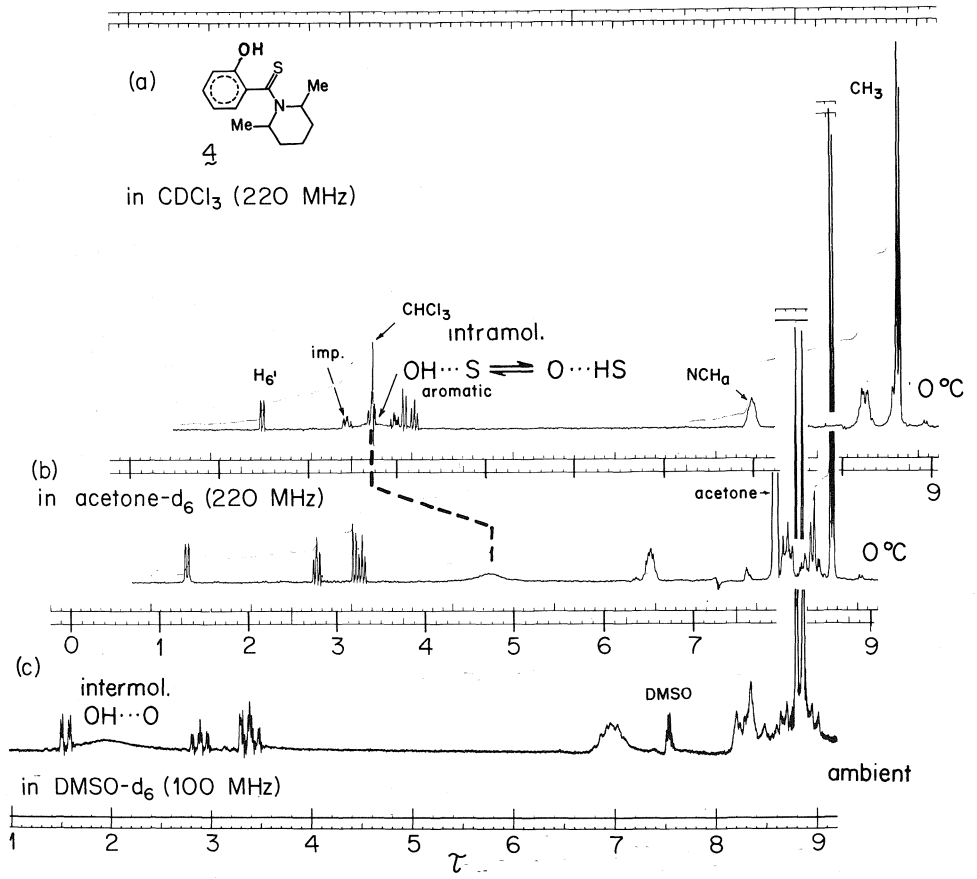

FIG. 10. ^1H nmr spectra of **4**.

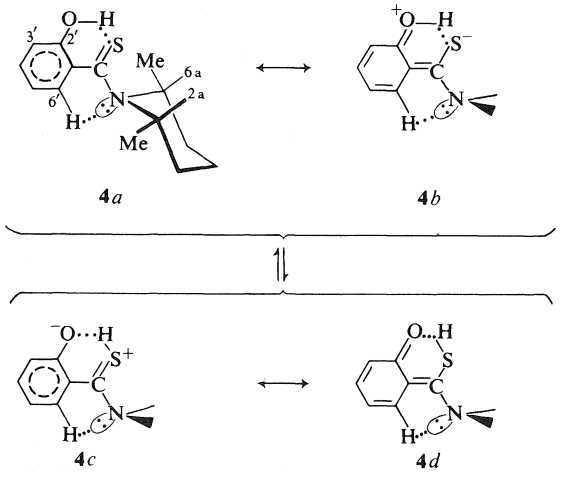

SCHEME 1

bonded proton moves in an unsymmetrical double minimum potential. The planarity of the 2′-hydroxythiobenzoyl moiety in the absence of steric interactions between $H_{6'}$ and H_{2e} lends strong support to the concept that non-planarity of the phenyl ring with the thioamide group which is normally found in *N*-thiobenzoyl-piperidines and -morpholines arises because of $H_{6'}\cdots H_{2e}$ interaction. Trace amounts of 'free' OH probably arise from rotation about the C—O bond, as opposed to rotation about the Ph—C(S) bond.

The intramolecular OH···S hydrogen bond in **4** has all the characteristics of a very strong hydrogen bond corresponding to a short O···S distance, not only in CCl_4 solution (Fig. 11) but also in KBr pellets (Fig. 12). Here the infrared spectra exhibit broad bands at 2750,

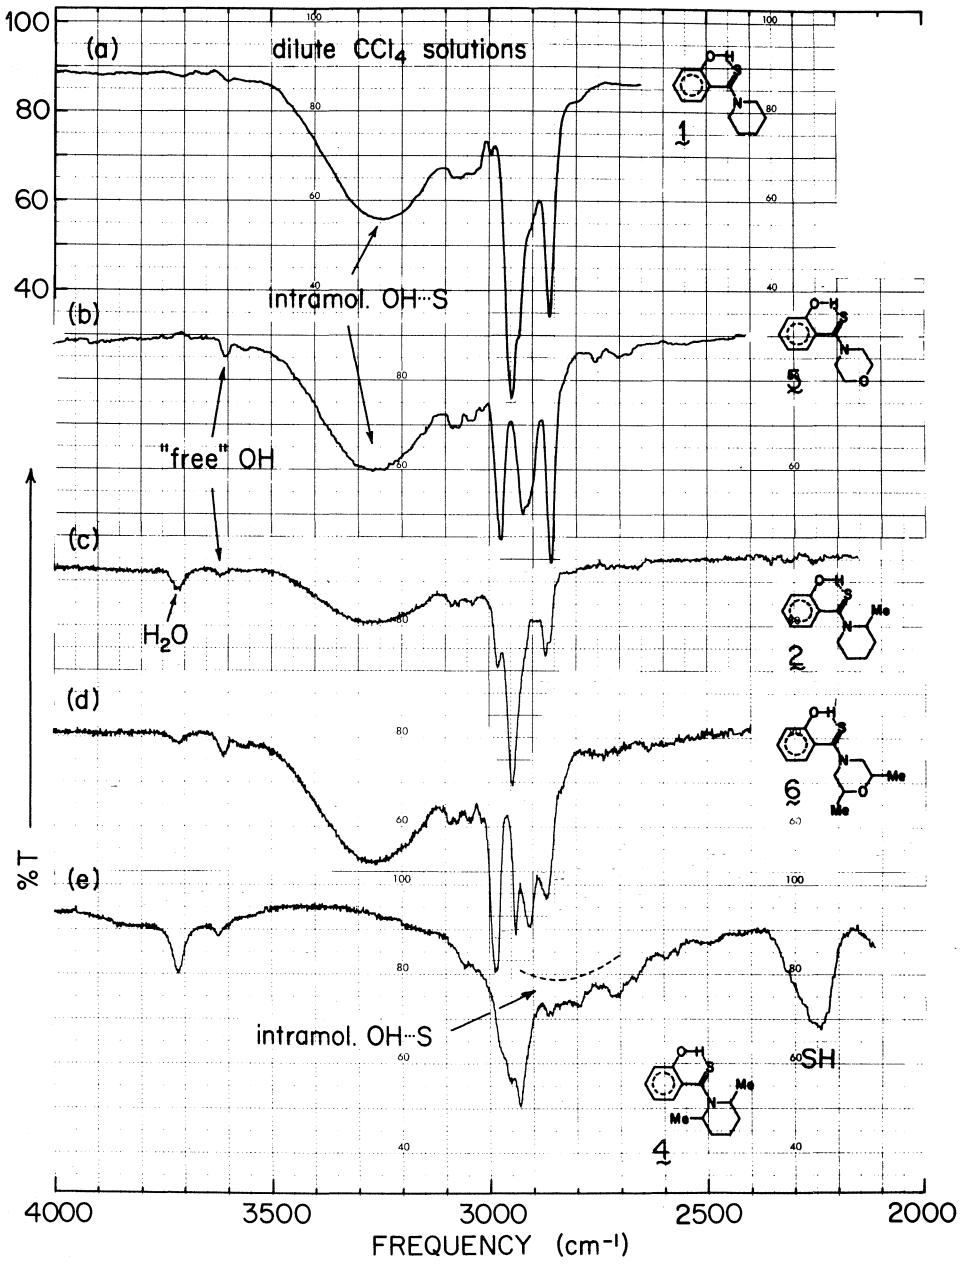

FIG. 11. Infrared spectra of *N*-(*o*-hydroxythiobenzoyl)morpholines and -piperidines in very dilute ($c < 0.003\ M$) CCl_4 solution.

2150, 1400 (?), and 970 cm^{-1}, similar to the "A", "B", "C", and "D" bands observed in strongly intermolecularly hydrogen bonded systems (20). These do not appear in the infrared spectra of KBr pellets of other *o*-hydroxythiobenzoylmorpholines (Fig. 12). Furthermore, the "A" and "B" bands have fine structure similar to that reported by Bellamy and Rogash (21) for strong hydrogen bonds in tautomeric 2-thiopyridone and 2-pyridone dimers. They interpreted the fine structure tentatively in terms of Fermi resonance of the ν_{XH} fundamental

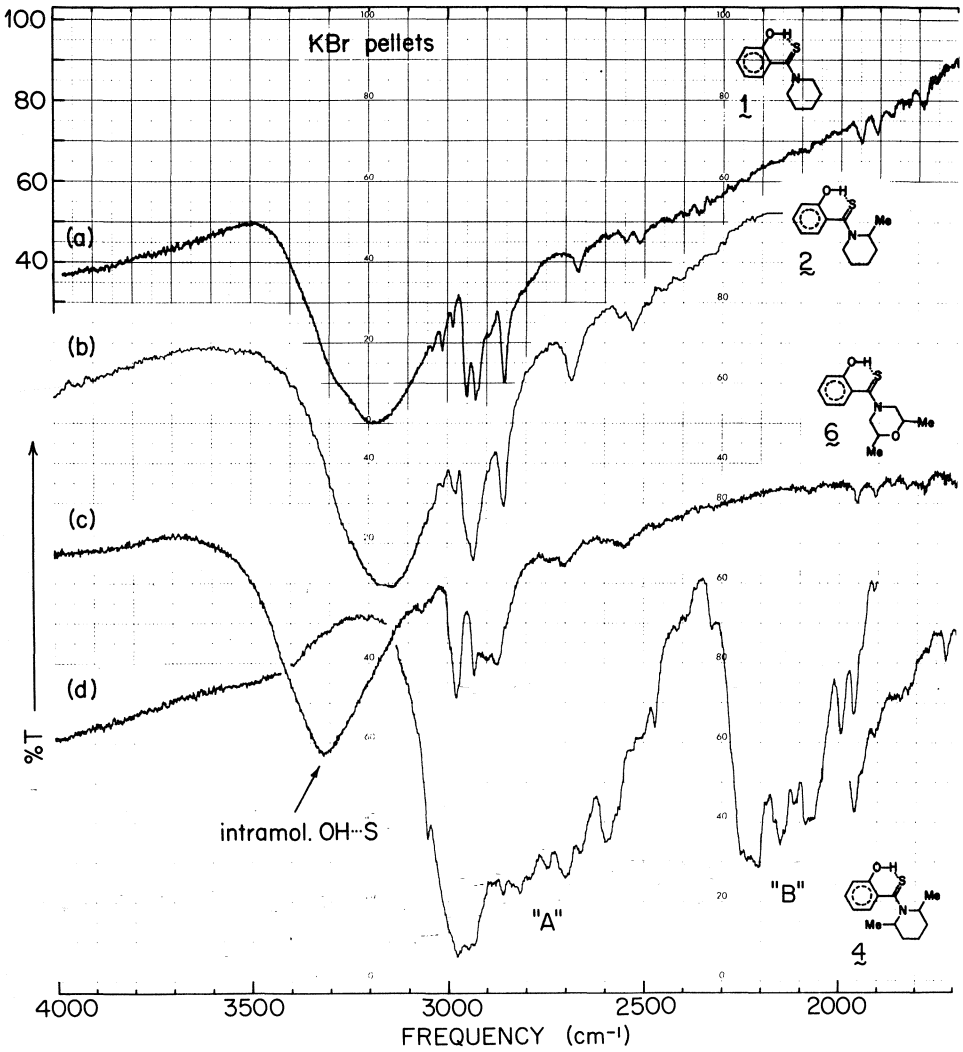

FIG. 12. Infrared spectra of *N*-(*o*-hydroxythiobenzoyl)morpholines and -piperidines in KBr pellets.

vibration with overtones and combinations of lower frequency fundamentals.

The uv spectrum of **4** is significantly different from that of **2**. The following absorption bands are observed in methanol (λ, nm; followed by ε, 1×10^4 l mol^{-1} cm^{-1}): **2**, 281 (1.3), 240 (0.71), 211 (1.7); **4**, 364 (0.80), 293 (0.72), 235 (0.76), 219 (1.4). Most normal *N*-thiobenzoylpiperidines exhibit a very weak $n \rightarrow \pi^*$ band near 350 nm, but it is too weak in **2** to be observed. The large ε value of the 364 nm band in **4** shows that it is due to a $\pi \rightarrow \pi^*$ and not an $n \rightarrow \pi^*$ transition, and its long wavelength (low energy) confirms the high degree of conjugation of the aromatic ring with the thiocarbonyl group, which are coplanar in **4**, but not in **2**.

The broad OH signals in the nmr spectra of **4** in $CDCl_3$ and acetone-d_6 (Fig. 10*a* and *b*; $\tau_{OH/SH}$ ~2.7 and ~4.8 ppm, respectively) reflect the intramolecular $OH\cdots S \rightleftarrows O\cdots HS$ proton transfer equilibrium, which is displaced more to the right in the latter solvent because of its higher dielectric constant.[12] The τ_{OH} signal at ~1.9 ppm in DMSO-d_6 solution (Fig. 10*c*) probably indicates that the intramolecular

[12]In aromatic thiols in $CDCl_3$ solution, τ_{SH} is around 6.5–6.7 ppm, dropping to 5.27 ppm in $O{=}C(SH)CH_3$ (22).

hydrogen bond has ruptured and has been replaced by a very strong intermolecular OH· · ·O bond to the solvent. In both acetone-d_6 and DMSO-d_6 the OH signal moves downfield with decreasing temperature, and the OH integral indicates the equivalent of more than one proton, which may indicate the involvement of traces of water in the hydrogen bonding equilibria.

Conclusions

(*1*) The proton in an intramolecular OH· · ·S hydrogen bond is shown to be a very sensitive conformational probe. To our knowledge this is the first observation of distinctly separate nmr OH signals arising from the *same* OH· · ·S bond, as modulated by different rotational isomeric and conformational geometries.

(*2*) The existence of *A* and *B* conformers in *o*-hydroxythiobenzoylpiperidines and -morpholines is well documented, and the geometrical parameters of these conformers are estimated from a model which is in good agreement with the experimental data.

(*3*) The structural characteristics of a thiobenzamide with no conjugation between the N lone pair electrons and the thiocarbonyl π-electrons is described for the first time, and it is shown to have an intramolecularly hydrogen bonded proton in an unsymmetrical double minimum potential.

(*4*) The complex and still poorly understood infrared "A", "B", "C", and "D" band systems which are well known for very strong intermolecular hydrogen bonds are also shown to arise from an intramolecular hydrogen bond in **4**.

(*5*) This investigation supports the hypothesis of Muller and Reiter (23) that the temperature dependence of the chemical shift of a hydrogen bonded proton can largely be explained by a change in the relative population of vibrational levels of the ν_σ (here $\nu_{O\ldots S}$) stretching mode (13*b*). This vibration lies around 100–200 cm^{-1} in the far infrared (24), and several excited states are expected to be appreciably populated even at low temperatures. The OH proton of **3** yields separate sharp signals for *A* and *B* conformers, respectively at −40 and −60 °C (Fig. 6) and no 'free' OH exists, since that would lead to a different chemical shift from that of OH_A· · ·S and OH_B· · ·S. Furthermore rapid exchange between hydrogen bonded and 'free' OH protons would collapse the hydrogen bonded peaks, which is not the case. The temperature dependence of the OH chemical shift for both conformers between −40 and −60 °C can be accounted for only by decreasing OH· · ·S distance (decreasing excitation of ν_σ) as the temperature decreases, and not by a shift in the hydrogen bonding equilibrium as previously considered (25).

The reaction of certain α-diazocarbonyl compounds with thiophosgene and ethyl chlorodithioformate[1]

PATRICIA DEMAREE, MARIE-CARMEN DORIA, AND JOSEPH M. MUCHOWSKI[2]

Research Laboratories, Syntex, S.A., Apartado Postal 10-820, Mexico 10, D.F.

Received July 27, 1976

PATRICIA DEMAREE, MARIE-CARMEN DORIA, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **55**, 243 (1977).

The reaction of thiophosgene with α-diazocarbonyl compounds produced mixtures of 1,2,3- and 1,3,4-thiadiazoles, in which the latter predominated, irrespective of whether the bis(α-diazoacyl)mercury derivatives or the free diazo compounds were used. In contrast, ethyl chlorodithioformate gave exclusively 1,3,4-thiadiazoles with α-diazocarbonyl compounds in the presence of triethylamine and only 1,2,3-thiadiazoles when the bis(α-diazoacyl)mercury derivatives were used.

PATRICIA DEMAREE, MARIE-CARMEN DORIA et JOSEPH M. MUCHOWSKI. Can. J. Chem. **55**, 243 (1977).

La réaction de thiophosgène avec les composés α-diazocarbonyles conduit à des mélanges de thiadiazoles-1,2,3 et 1,3,4; que l'on utilise des dérivés mercuriques du bis(α-diazoacyl) ou les composés diazos libres le dernier prédomine. Par opposition, le chlorodithioformate d'éthyle conduit uniquement à des thiadiazoles-1,3,4 par réaction avec les composés α-diazocarbonyles en présence de triéthylamine et uniquement à des thiadiazoles-1,2,3 lorsque l'on utilise des dérivés bis(α-diazoacyl) mercure.

[Traduit par le journal]

The reaction of diazoalkanes with thiocarbonyl compounds has been extensively studied (1–5), and diverse products, the nature of which depends on the structure of both reactants, are formed. For example, it has long been known (6, 7) that 1,3,4-thiadiazoles are produced from thiocarboxylic acid chlorides and diazoacetic esters or diazomethane. In addition, Ried and Beck (8) assigned the 1,2,3-structure to the thiadiazoles derived from thiophosgene and diazoketones, but it is now recognized (9) that the reported compounds were, in fact, members of the 1,3,4-series. Nevertheless, 1,2,3-thiadiazoles can arise from certain thioacyl halides, since it has recently been reported (2) that a mixture of 5-ethylthio-1,2,3-thiadiazole and 2-ethylthio-1,3,4-thiadiazole was obtained from ethyl chlorodithioformate and diazomethane. Both of the above types of thiadiazoles were required in connection with other studies and therefore the reaction of thiophosgene and ethyl chlorodithioformate with several diazoacetophenones and ethyl diazoacetate was examined under a variety of conditions.

When diazoacetophenone **1***a* (2 mol) was

2

a X = H
b X = Cl

reacted with thiophosgene (1 mol), a complex mixture, from which no pure chlorobenzoylthiadiazole **3***a* or **4***a* could be isolated, was obtained. The presence therein of at least one chlorothiadiazole was established, however, by the isolation of an ethylthiobenzoylthiadiazole, in 10% yield, after treatment of the mixture with ethanolic sodium ethyl mercaptide. The same compound was formed in considerably better yield (25%, see Table 1) from ethyl chlorodithioformate and bis(α-diazophenacyl)mercury **2***a*.

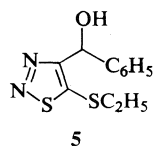
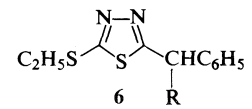
[b]See text and footnote 4.
[c]The ratio (3*b*):(4*b*) was 2:3 in the crude product as measured by nmr.
[d]The ratio (3*b*):(4*b*) was 1:6 in the crude product.
[e]The ratio (3*c*):(4*c*) was 1:6 in the crude product.
[f]Data taken from ref. 3. See text for structures of these thiadiazoles. Nuclear magnetic resonance analysis of the crude product indicated a 1:2.3 ratio of the 1,2,3- to the 1,3,4-isomers which was unchanged in the presence of triethylamine.

That this substance was 4-benzoyl-5-ethylthio-1,2,3-thiadiazole **3***d* was strongly supported by the characteristic (10, 11) mass spectrum[3] and conclusively established in the following manner. Sodium borohydride reduction of **3***d* gave an alcohol **5** which was different from that (**6***b*) synthesized by the aerial oxidation (12) of the anion derived from 1-ethylthio-5-benzyl-1,3,4-thiadiazole **6***a*. 2-Ethylthio-5-benzoyl-1,3,4-thiadiazole **4***d*, the ketone isomeric with **3***d*, could be prepared from diazoacetophenone and ethyl chlorodithioformate in the presence of triethylamine, and reduction of this compound with sodium borohydride produced the alcohol **6***b*.



5



6

a R = H
b R = OH

The reaction of 4-chlorodiazoacetophenone **1***b* and thiophosgene, with or without added triethylamine, gave a mixture of products in which

[3]It has been reported (10, 11) that the loss of N_2 from the molecular ion is characteristic of 1,2,3-thiadiazoles. Both **3***d* and **4***d* showed a peak due to the loss of 28 mass units from this ion and, therefore, it was not possible to distinguish between the two compounds on this basis in the absence of exact mass measurements. An examination of the other fragments of these spectra did, however, make a facile identification of **3***d* possible, because the mass spectrum of this compound showed two sequential losses of 28 mass units ($M^+ - N_2 - C_2H_4$ or $M^+ - C_2H_4 - N_2$). This fragmentation pattern was found in all of the ethylthio-1,2,3-thiadiazoles reported in this paper (see Experimental section). Furthermore, those 1,2,3-thiadiazoles which did not contain the ethylthio moiety did show the expected relatively intense $M^+ - 28$ peaks. The corresponding 1,3,4-thiadiazoles showed either a very weak $M^+ - 28$ absorption or this peak was absent entirely. For those cases where it was considered unsafe to rely on the intensity of the $M^+ - 28$ peak, the 1,3,4-thiadiazoles all lost a ring fragment (NCX) which identified the system without doubt (*e.g.* $M^+ - N{\equiv}C{-}Cl$ for **4***b* or $M^+ - N{\equiv}C{-}SC_2H_5$ for **4***e*).

both the 1,2,3- and the 1,3,4-thiadiazoles **3***b* and **4***b* were present. The structures of these compounds were proved by conversion into the known anilinothiadiazoles **3***f* (9) and **4***f* (13), respectively. Although the isolated yields of **3***b* and **4***b* varied considerably (see Table 1), for a given experiment the ratio in the crude product was nearly constant, as measured by nmr spectroscopy, and was invariant throughout the course of a reaction. For example, the ratio of **3***b*:**4***b* was about 2:3 for the reaction of thiophosgene with 4-chlorodiazoacetophenone, whereas it was 1:6 when the mercuric salt was used.

4-Methyldiazoacetophenone **1***c* and thiophosgene also furnished a mixture of the 1,2,3- and the 1,3,4-thiadiazoles, but the proportion of the 1,3,4-isomer was substantially greater (**3***c*:**4***c* = 1:6) than observed for 4-chlorodiazoacetophenone under the same conditions. In view of the fact that 1,3,4- as well as 1,2,3-thiadiazoles were formed from both of the *para*-substituted diazoacetophenones and thiophosgene, it is highly probable that the 1,3,4-thiadiazole **4***a* was also produced in the corresponding reaction with diazoacetophenone. This substance, without doubt, was selectively deacylated (9) to lower molecular weight compounds under the strongly basic conditions of the thiolate ion displacement reaction.[4]

The formation of 1,2,3-thiadiazoles from thiophosgene and diazoacetophenones, or salts thereof, under all the conditions examined in this study contrasts with the failure of Bacchetti *et al.* (9) to detect these substances.

A study of the reaction of thiophosgene with ethyl diazoacetate and the corresponding mercuric salt **7** showed that a 1:2 mixture of the 1,2,3- and the 1,3,4-thiadiazoles **8***a* and **9***a* was formed in every case. Ethyl-5-chloro-1,2,3-thiadiazole-4-carboxylate **8***a* was a known compound and the physical properties thereof corresponded to those reported (14) for it. The structure of this substance was confirmed by conversion into a mixture of the chloroamide **10** and the amino ester **8***b* with alcoholic ammonia. Ethyl-5-amino-1,2,3-thiadiazole-4-carboxylate **8***b* synthesized in this way was identical to the known compound prepared by the method of Goerdeler and Gnad (14). The identity of the

a X = Cl
b X = NH_2
c X = SC_2H_5

a X = Cl
b X = NH_2

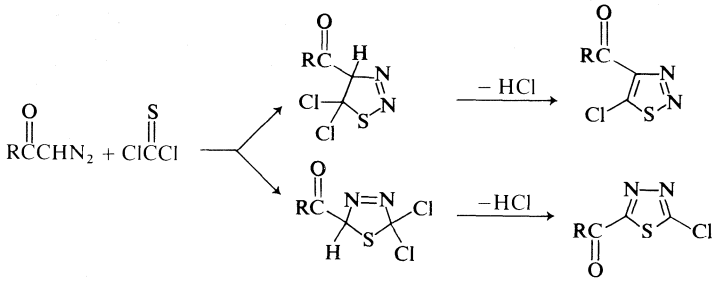
10 **11**

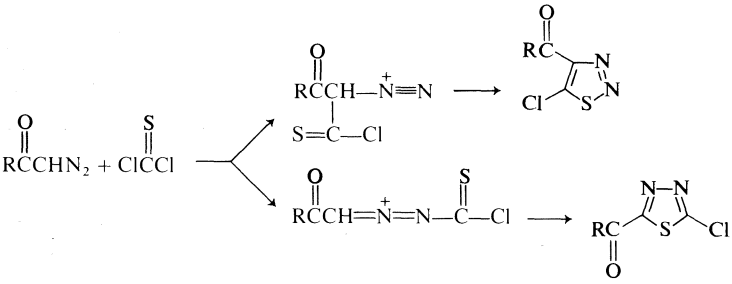
1,3,4-thiadiazole **9***a* was established as follows. The ester **9***a* was transformed exclusively into 2-chloro-1,3,4-thiadiazole-5-carboxamide **11** upon reaction with ethanolic ammonia. This substance was also prepared by the aminolysis of crude ethyl-2-chloro-1,3,4-thiadiazole-5-carboxylate **9***a* obtained by a Sandmeyer reaction on the known (15) amine **9***b*.

The data in Table 1 show that under all the conditions examined, α-diazocarbonyl compounds react with thiophosgene to give a mixture of 1,2,3- and 1,3,4-thiadiazoles with the latter predominating. The formation of these products can be interpreted in terms of the two possible modes (3) of dipolar cycloaddition of the diazo compound to the thiocarbonyl group of thiophosgene with subsequent loss of hydrogen chloride [1]. Alternatively, the thiadiazoles could stem from acylation of the dipolar system on carbon or nitrogen followed by either proton loss and cyclization, or cyclization and then proton loss [2]. It was considered that if acylation of the diazo compounds by the thioacyl halides played a significant role in the formation of the thiadiazoles, then utilization of an α-metalated diazo compound[5] might direct the acylation entirely to carbon. The exclusive formation of the 1,2,3-thiadiazoles **3***d*, **3***e*, and **8***c* from ethyl chlorodithioformate and the bis(α-diazoacyl)mercury compounds **2***a*, **2***b*, and **7** respectively, was consistent with this expectation. In contrast, the bis(α-diazoacyl)mercury reagents and thiophosgene gave mixtures in which the 1,3,4-thiadiazole always predominated, and for which the thiadiazole ratio was not greatly different from that observed for the free diazo compound. Indeed, the reaction of thiophosgene with ethyl diazoacetate or the corresponding mercury derivative, repeatedly gave mixtures of

[4]The reaction of **4***b* with ethanolic sodium ethyl mercaptide did not result in the formation of even traces of the ethylthio compound **4***e* (as shown by tlc), presumably for the same reason.

[5]Ethyl lithiodiazoacetate is acylated on carbon with benzoyl chloride (16). The acylation of bis(α-diazoacyl)-mercury compounds has not previously been reported.





8*a* and **9***a* which were identical in composition and yield.

It is also of considerable interest that, in the presence of an equivalent of triethylamine, the α-diazoketones **1***a* and **1***b* and ethyl chlorodithioformate produced only the 1,3,4-thiadiazoles **4***d* and **4***e*. This result apparently is restricted to the less reactive α-diazocarbonyl compounds since the reaction of diazomethane with this dithioacid chloride gave a 1:2.3 mixture of 5-ethylthio-1,2,3-thiadiazole and 2-ethylthio-1,3,4-thiadiazole in the presence or absence of triethylamine.

Finally, it is noteworthy that compositionally similar mixtures of the 1,2,3- and 1,3,4-thiadiazoles were obtained when thiophosgene was the acylating agent irrespective of whether triethylamine was present or absent.

The results described herein have several consequences of synthetic importance, and some of these will be described in due course.

Experimental

The melting points were determined in a Mel-Temp apparatus and are not corrected. The infrared spectra were measured with a Perkin-Elmer model 237 grating infrared spectrophotometer. The ultraviolet spectra were recorded with a Perkin-Elmer model 402 ultraviolet visible spectrophotometer. The nmr spectra were obtained with a Varian T-60 spectrometer. The chemical shifts are expressed as ppm (δ) from internal tetramethylsilane. The mass spectra were measured with an Atlas CH-4 spectrometer.

4-Benzoyl-5-ethylthio-1,2,3-thiadiazole 3d

(*A*) *Reaction of Ethanethiol with the Crude Reaction Product of Diazoacetophenone and Thiophosgene*

The reaction was carried out in the manner described by Ried and Beck (8) except that a 2:1 molar ratio of diazoacetophenone to thiophosgene was used. The crude product was used directly in the next step.

The crude material from above (1.213 g), dissolved in absolute alcohol (15 ml) was added dropwise to a stirred solution of ethanethiol (0.4 ml, 0.33 g, 5.33 mmol) in absolute alcohol containing sodium ethoxide (prepared from sodium metal (0.125 g, 5.43 mmol)). After 24 h at room temperature, the solvent was removed *in vacuo* and the residue was dissolved in chloroform. The chloroform solution was washed with water, dried over sodium sulfate and evaporated *in vacuo*. The residue was purified by tlc on silica gel using benzene as the developing solvent. The product with R_f 0.55 was taken and after crystallization from alcohol a solid (0.053 g, 8%), mp 93–95 °C, was obtained. After recrystallization from methanol it had mp 97–98 °C; uv (CH_3OH) 250 (12 300), 322 nm (13 500); ir ($CHCl_3$) 1639 cm^{-1}; nmr ($CDCl_3$) 1.52 (t, 3H, J = 7.4 Hz), 3.12 (q, 2H, J = 7.4 Hz), 7.64 (m, 3H), 8.39 (m, 2H); ms (relative intensity) 250(5), 222(2), 194(19), 105(100), 77(50). *Anal.* calcd. for $C_{11}H_{10}N_2OS_2$: C 52.80, H 4.03, N 11.20; found: C 52.86, H 4.10, N 11.37.

(*B*) *From Bis(α-diazophenacyl)mercury 2a and Ethyl Chlorodithioformate*

A suspension of bis(α-diazophenacyl)mercury (17) (0.980 g, 2 mmol) in dry acetonitrile (30 ml) containing ethyl chlorodithioformate (0.4 ml, 0.56 g, 4 mmol) was stirred at room temperature, with protection from light, for 60 h. The mixture was filtered, the filtrate was evaporated *in vacuo*, and the residue was purified by tlc on silica gel (benzene). The product (0.264 g, 26%) was crystallized from methanol to give a solid mp 95–96 °C, identical to the compound prepared via method *A*.

Phenyl(5-ethylthio-1,2,3-thiadiazol-4-yl)carbinol **5**

Sodium borohydride (0.250 g, 6.6 mmol) was added to a stirred solution of 4-benzoyl-5-ethylthio-1,2,3-thiadiazole (1.00 g, 4.0 mmol) in ethanol (50 ml). After 2 h at room temperature the solvent was removed *in vacuo* and water was added to the residue. The mixture was extracted with ethyl acetate and the extract was dried over sodium sulfate and evaporated *in vacuo*. The oily residue (0.867 g, 86%) crystallized spontaneously and after crystallization from aqueous methanol it had mp 63–65 °C; uv (CH_3OH) 307 nm (5250); ir ($CHCl_3$) 3585, 3410 cm^{-1}; nmr ($CDCl_3$) 1.50 (t, 3H, J = 7.4 Hz), 2.57 (s, 1H, W_H = 9 Hz, exchanged with D_2O), 6.15 (s, 1H), 7.28 (m, 5H); ms (relative intensity) 252(1), 224(3), 196(10), 163(46), 162(43), 134(22), 118(66), 107(88), 79(100), 77(74). *Anal.* calcd. for $C_{11}H_{12}N_2OS_2$: C 52.38, H 4.80, N 11.11; found: C 52.26, H 4.87, N 11.25.

2-Ethylthio-5-benzoyl-1,3,4-thiadiazole **4***d*

A mixture of diazoacetophenone (1.46 g, 10 mmol), ethyl chlorodithioformate (1.2 ml, 1.69 g, 12.0 mmol), and triethylamine (1.4 ml, 1.01 g, 10 mmol) in dry acetonitrile (30 ml), was stirred at room temperature for 24 h, at the end of which time additional ethyl chlorodithioformate (0.5 ml) and triethylamine (0.5 ml) were added. After a further 24 h the solvent was removed *in vacuo*, the residue was taken up in ethyl acetate, and this solution was washed with water and dried. Evaporation of the solvent *in vacuo* gave a red oil which was chromatographed on silica gel (300 g). A small amount of the starting material and other nonpolar materials were removed with hexane–dichloromethane (90:10). A nonaromatic product (1.14 g) of intermediate polarity (shown to be triethyldithiocarbamate by direct comparison with an authentic specimen) was eluted with hexane–dichloromethane (75:25) and the required thiadiazole (0.94 g, 38%) was removed from the column with dichloromethane. After evaporative distillation at 114 °C/0.005 torr and crystallization from hexane the product had mp 35–37 °C; uv (CH_3OH) 270 (8320), 326 nm (12 600); ir ($CHCl_3$) 1655 cm^{-1}; nmr ($CDCl_3$) 1.52 (t, 3H, J = 7.3 Hz), 3.42 (q, 2H, J = 7.3 Hz), 7.50 (m, 3H), 8.44 (m, 2H); ms (relative intensity) 250(42), 222(17), 163(6), 136(21), 105(100), 77(50). *Anal.* calcd. for $C_{11}H_{10}N_2OS_2$: C 52.80, H 4.03, N 11.20; found: C 52.73, H 3.95, N 11.23.

Phenyl-(5-ethylthio-1,3,4-thiadiazol-2-yl)carbinol **6***b*

(A) By the Sodium Borohydride Reduction of 2-Ethylthio-5-benzoyl-1,3,4-thiadiazole **4***d*

This reduction was effected in the same manner as described above for compound **3***d*, except that the reaction time was 20 h. The product (80% yield) had mp 67–68 °C after crystallization from benzene–hexane; uv (CH_3OH) 273 nm (6920); ir ($CHCl_3$) 3590, 3300 cm^{-1}; nmr ($CDCl_3$) 1.57 (t, 3H, J = 7.5 Hz), 3.22 (q, 2H, J = 7.5 Hz), 3.67 (s, 1H, exchanged with D_2O), 6.08 (s, 1H), 7.34 (m, 5H); ms (relative intensity) 252(100), 224(36), 219(17), 165(3), 138(24), 107(49), 79(51), 77(51). *Anal.* calcd. for $C_{11}H_{12}N_2OS_2$: C 52.38, H 4.80, N 11.11; found: C 52.37, H 4.90, N 11.12.

(B) By the Oxidation of 2-Ethylthio-5-benzyl-1,3,4-thiadiazole **6***a*

The ethylthio compound **6***a* was prepared from 5-benzyl-1,3,4-thiadiazole-2-thione (18) as follows. A solution of 85% potassium hydroxide (1.1 g, 16.7 mmol) in alcohol (10 ml) was added to the thione (3.4 g, 16.3 mmol) in alcohol (100 ml) containing ethyl iodide (3 ml). The solution was stirred at room temperature for 24 h, the solvent was removed *in vacuo*, and ethyl acetate was added to the residue. The resultant was washed with water, dried, and the solvent was removed *in vacuo*. Evaporative distillation of the residue at 110 °C/0.01 torr gave the product (3.1 g, 80%); uv (CH_3OH) 271 nm (7940); nmr ($CDCl_3$) 1.58 (t, 3H, J = 7.2 Hz), 3.25 (q, 2H, J = 7.2 Hz), 4.32 (s, 2H), 7.24 (s, 5H); ms (relative intensity) 236(50), 221(7), 208(23), 204(18), 149(50), 135(18), 122(12), 116(11), 91(100). *Anal.* calcd. for $C_{11}H_{12}N_2S_2$: C 55.93, H 5.12, N 11.86; found: C 55.69, H 5.16, N 12.06.

To a solution of lithium diisopropylamide (prepared from diisopropylamine (1.7 ml, 1.2 g, 12 mmol) and *n*-butyllithium in hexane (7.5 ml of a 1.6 *M* solution)) in anhydrous tetrahydrofuran (50 ml), maintained in a nitrogen atmosphere at 0 °C, was added a solution of **6***a* (1.9 g, 8.05 mmol) in dry tetrahydrofuran (10 ml). The solution became red in color and after 1 h at 0 °C, oxygen was bubbled through the solution for 20 h at room temperature. The solution was poured into water, and the resultant was extracted with ethyl acetate. The extract was washed with water, dried, and evaporated *in vacuo*. Thin-layer chromatography on silica gel (dichloromethane – ethyl acetate, 9:1) showed the presence of four products as well as starting material. The most polar material (R_f = 0.52), which was the desired product, was obtained pure (0.35 g, 17%) by preparative tlc using the above solvent system. After crystallization from benzene, it had mp 66–67 °C, undepressed on admixture with the compound prepared as described in *A*.

4-(4-Chlorobenzoyl)-5-chloro-1,2,3-thiadiazole **3***b and 2-Chloro-5-(4-chlorobenzoyl)-1,3,4-thiadiazole* **4***b*

(A) From 4-Chlorodiazoacetophenone and Thiophosgene

A solution of 4-chlorodiazoacetophenone (4.16 g, 23.1 mmol) in anhydrous benzene (30 ml) containing thiophosgene (0.88 ml, 1.32 g, 11.5 mmol) was stirred at room temperature, with protection from light, for 20 h. The solvent was removed *in vacuo*, toluene was added to the residue, and the resultant was once more evaporated *in vacuo*. This process was repeated once again with toluene and once with methanol at which point the residue partially crystallized. Hexane and a little methanol were added and the crystalline 1,3,4-thiadiazole **4***b* (0.93 g) was removed by filtration. The solvent was removed *in vacuo*, hexane was added to the residue, and the mixture was scratched until crystallization had occurred. The insoluble material (4-chlorophenacyl chloride and other more polar substances) was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was chromatographed on silica gel using hexane as the eluant. In this way, an additional quantity (0.28 g) of the 1,3,4-thiadiazole and a mixture of both thiadiazoles, contaminated with the phenacyl chloride (1.41 g), was obtained. Hexane and a little methanol were added to the mixture and more of the phenacyl chloride was removed by filtration. Evaporation of the filtrate gave an oil which was separated by tlc on silica gel (hexane – ethyl acetate, 95:5, two developments). In this way there was obtained a further quantity (0.19 g) of the less polar 1,3,4-thiadiazole as well as the more polar 1,2,3-thiadiazole **3***b*

(0.40 g, 13%). The combined yield of the 1,3,4-isomer was 47%. After crystallization from methanol it had mp 106–107 °C (lit. (10, 11) mp 114 °C); uv (CH_3OH) 286 nm (13 500); ir ($CHCl_3$) 1668, 1588 cm^{-1}; nmr ($CDCl_3$) 7.47 (d, 2H, J = 8.4 Hz), 8.44 (d, 2H, J = 8.4 Hz); ms (relative intensity) 260(10), 258(14), 232(2), 230(3), 199(19), 197(38), 172(27), 170(75), 141(33), 139(100), 113(22), 111(71), 75(47).

After crystallization from methanol, the 1,2,3-thiadiazole had mp 88–89 °C; uv (CH_3OH) 214 (15 850), 273 nm (13 200); ir ($CHCl_3$) 1670, 1590 cm^{-1}; nmr ($CDCl_3$) 7.48 (d, 2H, J = 8.6 Hz), 8.11 (d, 2H, J = 8.6 Hz); ms (relative intensity) 260(1), 258(3), 232(11), 230(15), 224(3), 222(2), 141(33), 139(100), 113(15), 111(46), 75(28). *Anal.* calcd. for $C_9H_4Cl_2N_2OS$: C 41.68, H 1.55, N 10.86; found: C 41.88, H 1.75, N 10.62.

(B) From 4-Chlorodiazoacetophenone and Thiophosgene in the Presence of Triethylamine

A solution of the diazoketone (0.45 g, 2.5 mmol) in dry benzene (50 ml) containing thiophosgene (0.19 ml, 2.5 mmol) and triethylamine (0.34 ml, 2.5 mmol) was left at room temperature for 24 h. The solvent was removed *in vacuo*, ethyl acetate was added to the residue, and the solution was washed with water, dried, and evaporated *in vacuo*. The residue was separated by tlc on silica gel (hexane – ethyl acetate, 95:5) to give the 1,3,4-thiadiazole (0.17 g, 25%) and the 1,2,3-thiadiazole (0.027 g, 4%).

(C) From Bis(4-chloro-α-diazophenacyl)mercury 2b[6] *and Thiophosgene*

Thiophosgene (2.3 ml, 30 mmol) was added to a suspension of the diazo mercury reagent (8.4 g, 29.5 mmol) in dry acetonitrile (200 ml) and the mixture was stirred at room temperature, with protection from light, for 48 h. The solvent was evaporated *in vacuo*, chloroform was added to the residue, and the mixture was filtered. The filtrate was evaporated *in vacuo* and the residue was separated by column chromatography on silica gel using hexane – ethyl acetate (98:2) as the eluant. The 1,3,4-thiadiazole (1.55 g, 20%) was eluted first, followed immediately by the 1,2,3-thiadiazole (0.39 g, 5%).

4-(4-Chlorobenzoyl)-5-ethylthio-1,2,3-thiadiazole 3e

The diazo mercury compound **2b** (0.33 g, 6 mmol) was suspended in anhydrous acetonitrile (50 ml) which contained ethyl chlorodithioformate (0.28 ml) and the mixture was stirred at room temperature, with protection from light, for 24 h. After the usual work-up and purification by tlc on silica gel (hexane – ethyl acetate, 95:5), there was obtained the 1,2,3-thiadiazole (0.087 g, 25%), which had mp 110–112 °C after crystallization from methanol; uv (CH_3OH) 270 (12 500), 324 nm (14 100); ir ($CHCl_3$) 1642, 1595 cm^{-1}; nmr ($CDCl_3$) 1.50 (t, 3H, J = 7.2 Hz), 3.25 (q, 2H, J = 7.2 Hz), 7.40 (d, 2H, J = 8.6 Hz), 8.28 (d, 2H, J = 8.6 Hz); ms (relative intensity) 286(0.5), 284(1), 258(0.5), 256(1), 230(5), 228(20), 141(34), 139(100), 113(16), 111(36), 75(17). *Anal.* calcd. for $C_{11}H_9ClN_2OS_2$: C 46.38, H 3.15, N 9.72; found: C 46.17, H 3.06, N 9.74.

2-Ethylthio-5-(4-chlorobenzoyl)-1,3,4-thiadiazole 4e

This compound was prepared from 4-chlorodiazoacetophenone and ethyl chlorodithioformate, in acetonitrile solution containing triethylamine, in the manner described for the synthesis of **4d**, except that the reaction time was 48 h. After the usual work-up, tlc (hexane – ethyl acetate, 95:5) did not show the presence of the 1,2,3-isomer **3e** (which had R_f 0.41) in the product mixture. The 1,3,4-isomer (R_f = 0.50) was purified by preparative tlc using the above solvent system. There was thus obtained, a solid (1.03 g, 36%) which, after crystallization from methanol, had mp 106–107 °C; uv (CH_3OH) 285 (19 300), 333 nm (13 800); ir ($CHCl_3$) 1643, 1580, 1510 cm^{-1}; nmr ($CDCl_3$) 1.51 (t, 3H, J = 7.4 Hz), 3.42 (q, 2H, J = 7.4 Hz), 7.39 (d, 2H, J = 8.6 Hz), 8.40 (d, 2H, J = 8.6 Hz); ms (relative intensity) 286(31), 284(66), 258(12), 256(28), 197(3), 172(7), 170(19), 141(35), 139 (100), 113(17), 111(37), 75(21). *Anal.* calcd. for $C_{11}H_9ClN_2OS_2$: C 46.38, H 3.15, N 9.72; found: C 46.19, H 3.16, N 9.78.

4-(4-Chlorobenzoyl)-5-anilino-1,2,3-thiadiazole 3f

This compound was prepared from **3b** (1 equiv.) and aniline (3 equiv.) in hot methanol according to the method described by Bacchetti *et al.* (9) for the isomeric 1,3,4-compound. The product **3f** obtained in 77% yield had mp 174 °C (lit. (13) mp 179 °C), undepressed on admixture with an authentic specimen prepared from phenylisothiocyanate and 4-chlorodiazoacetophenone.[4]

2-Anilino-5-(4-chlorobenzoyl)-1,3,4-thiadiazole 4f

This compound was prepared from **4b** and aniline as described by Bacchetti *et al.* (9). It had mp 278 °C (lit. (9) mp 278 °C).

4-(4-Methylphenyl)-5-chloro-1,2,3-thiadiazole 3c and 2-Chloro-5-(4-methylphenyl)-1,3,4-thiadiazole 4c

The diazoketone **1c** (1.60 g, 10 mmol) and thiophosgene (0.58 g, 5 mmol) in benzene (30 ml) was left at room temperature for 20 h. The reaction was worked-up in the manner described by Ried and Beck (8) and after crystallization of the crude product from methanol, the 1,3,4-thiadiazole **4c** (0.45 g), mp 93–94 °C (lit. (8) mp 97 °C) was obtained; uv (CH_3OH) 292 nm (12 300); ir ($CHCl_3$) 1653, 1608, 1571 cm^{-1}; nmr ($CDCl_3$) 2.43 (s, 3H), 7.25 (d, 2H, J = 8.3 Hz), 8.32 (d, 2H, J = 8.3 Hz); ms (relative intensity) 240(10), 238(25), 224(4), 210(6), 177(37), 150(82), 119(100), 91(87), 65(46). The mother liquors from the above crystallization were evaporated *in vacuo* and the residue was separated by tlc on silica gel (hexane – ethyl acetate, 96:4). There was obtained a further quantity (0.17 g, total yield 0.62 g or 52% yield) of the 1,3,4-thiadiazole, as well as 4-chlorophenacyl chloride (0.46 g) and a 1:1 mixture (0.24 g) of 4-chlorophenacyl chloride and the 1,2,3-thiadiazole **3c**. This mixture was separated by tlc on silica gel (hexane–acetone, 97:3) to give the 1,2,3-thiadiazole **3c** (0.088 g, *ca.* 90% pure) which, after crystallization from petroleum ether (bp 70–90 °C), had mp 56–58 °C; uv (CH_3OH) 214 (13 500), 273.5 nm (14 800); ir ($CHCl_3$) 1669, 1610 cm^{-1}; nmr ($CDCl_3$) 2.43 (s, 3H), 7.18 (d, 2H, J = 8.2 Hz), 7.88 (d, 2H, J = 8.2 Hz); ms (relative intensity) 240(1), 238(2), 212(6), 210(15), 119(100), 91(58), 65(27). *Anal.* calcd. for $C_{10}H_7ClN_2OS$: C 50.30, H 2.96, N 11.74; found: C 50.47, H 3.01, N 12.16.

Ethyl-5-chloro-1,2,3-thiadiazole-4-carboxylate 8a and Ethyl-2-chloro-1,3,4-thiadiazole-5-carboxylate 9a

(A) From Ethyl Diazoacetate and Thiophosgene

To a stirred solution of ethyl diazoacetate (18.5 ml,

[6]Prepared according to ref. 17 and used without purification.

19.9 g, 175 mmol) in acetonitrile (100 ml) at 0 °C was added thiophosgene (6.7 ml, 87.5 mmol). The reaction was then stirred at room temperature for 20 h and the solvent was removed *in vacuo*. The residue was separated by column chromatography on silica gel (500 g) using hexane – ethyl acetate (96:4) as the eluting solvent. The 1,2,3-thiadiazole **8***a* (3.33 g) was eluted first, then a mixture (2.21 g) of both thiadiazoles followed, and the 1,3,4-thiadiazole **8***a* (5.71 g) was eluted last. The above mixture was separated by tlc on silica gel (hexane – ethyl acetate, 95:5) and in this way additional amounts of the 1,2,3-thiadiazole (0.59 g; total yield 3.92 g or 23%) and the 1,3,4-thiadiazole (1.59 g; total yield 7.31 g or 44%) were obtained.

Ethyl-5-chloro-1,2,3-thiadiazole was further purified by evaporative distillation at 70 °C/0.05 torr. The oil solidified (mp 25 °C; lit. (14) mp 25 °C) on standing; uv (CH_3OH) 225 (5270), 257 nm (3630); ir ($CHCl_3$) 1735 cm^{-1}; ms (relative intensity) 194(1), 192(1), 166(7), 164(18), 149(9), 147(24), 136(6), 121(7), 119(18), 108(28), 105(22), 100(34), 92(100), 84(47). *Anal.* calcd. for $C_5H_5ClN_2O_2S$: C 31.17, H 2.61, N 14.54; found: C 30.91, H 2.65, N 14.86.

Evaporative distillation of ethyl-2-chloro-1,3,4-thiadiazole-5-carboxylate at 110 °C/0.02 torr gave an oil which solidified (mp 29 °C) on standing; uv (CH_3OH) 245 nm (6920); ir 1760, 1730 cm^{-1}; ms (relative intensity) 194(2), 192(5), 165(10), 150(24), 149(26), 148(65), 147(54), 122(39), 121(24), 120(100), 119(22), 93(17), 79(39), 59(82). *Anal.* calcd. for $C_5H_5ClN_2O_2S$: C 31.17, H 2.61, N 14.54; found: C 31.09, H 2.71, N 14.53.

(B) From Ethyl Diazoacetate and the Mercury Derivative **7** *of Ethyl Diazoacetate (19)*

To a suspension of the mercury derivative (3.49 g, 8.2 mmol) in dry acetonitrile (100 ml) was added thiophosgene (1.26 ml, 16.4 mmol) in a dropwise manner. The mixture was stirred at room temperature, with protection from light, for 3 h and the solvent was evaporated *in vacuo*. Chloroform was added to the residue, the mixture was filtered, the filtrate was evaporated *in vacuo*, and the residue was separated by tlc on silica gel (hexane – ethyl acetate, 95:5). Evaporative distillation of the 1,3,4-thiadiazole fraction at 110 °C/0.02 torr gave a liquid (1.26 g, 40%) which solidified mp 29 °C. Evaporative distillation of the 1,2,3-thiadiazole fraction at 70 °C/0.05 torr gave an oil (0.63 g, 20%) which crystallized (mp 25 °C) on standing.

(C) From Ethyl Diazoacetate and Thiophosgene in the Presence of Triethylamine

Thiophosgene (0.77 ml, 10 mmol) was added at 0 °C to a solution of ethyl diazoacetate (1.07 ml, 10 mmol) in acetonitrile (50 ml) containing triethylamine (1.4 ml, 10 mmol). The solution was stirred at room temperature for 22 h, the solvent was removed *in vacuo*, chloroform was added to the residue, and the mixture was filtered. Evaporation of the filtrate *in vacuo* gave a residue which was separated by column chromatography on silica gel in the manner described above. After distillation there was obtained the 1,2,3-thiadiazole (0.13 g, 7%) and the 1,3,4-thiadiazole (0.29 g, 15%).

Ethyl-5-ethylthio-1,2,3-thiadiazole-4-carboxylate **8***c*

(A) From the Mercury Derivative of Ethyl Diazoacetate and Ethyl Chlorodithioformate

Ethyl chlorodithioformate (0.46 ml, 4 mmol) was added to a stirred suspension of the mercury derivative (0.85 g, 2 mmol) in dry acetonitrile (50 ml). The mixture was stirred at room temperature, with protection from light, for 60 h and then the mixture was worked-up in the usual way. The product was purified by tlc on silica gel (hexane – ethyl acetate, 95:5). A solid (0.32 g, 37%) was obtained, which, after crystallization from hexane, had mp 52 °C; uv (CH_3OH) 233 (6310), 300 nm (9550); ir ($CHCl_3$) 1710 cm^{-1}; ms (relative intensity) 218(49), 190(22), 162(14), 144(10), 131(16), 118(66), 103(65), 90(100), 89(93), 73(51). *Anal.* calcd. for $C_7H_{10}N_2O_2S_2$: C 38.53, H 4.65, N 12.84; found: C 38.63, H 4.59, N 12.88.

(B) From Ethyl-5-chloro-1,2,3-thiadiazole-4-carboxylate and Ethanethiol

Ethyl mercaptan (0.22 ml, 3 mmol) was added to a solution of sodium ethoxide (from 0.072 g (3 mmol) of sodium hydride) in absolute ethanol (15 ml). The chlorothiadiazole (0.19 g, 1 mmol) was then added and after 10 min the solvent was removed *in vacuo*. Water was added to the residue and the product was extracted into chloroform. The extract was dried and evaporated *in vacuo* to give a solid (0.18 g, 81%) mp 51 °C, undepressed on admixture with a specimen prepared according to method *A*.

Ethyl-5-amino-1,2,3-thiadiazole-4-carboxylate **8***b and 5-Chloro-1,2,3,-thiadiazole-4-carboxamide* **10**

Ethyl-5-chloro-1,2,3-thiadiazole-4-carboxylate (0.19 g, 1 mmol) was dissolved in a solution of alcoholic ammonia (30 ml, 4.6 *N*) and left at room temperature for 8 h. The solvent was removed *in vacuo* and the residue was separated by tlc on silica gel (dichloromethane – ethyl acetate, 19:1) to give the amino ester **8***b* (0.020 mg, 11.5%) which after crystallization from benzene–hexane had mp 121 °C, (lit. (14) mp 126 °C) undepressed on admixture with an authentic specimen prepared according to Goerdeler and Gnad (14).

The major product (0.097 g, 60%) from this reaction was the carboxamide **10**. After crystallization from benzene it had mp 127–129 °C; uv (CH_3OH) 230 (6310), 242 nm (7240); ir (KBr) 3400, 3305, 1695, 1615 cm^{-1}; ms (relative intensity) 166(0.5), 165(0.3), 164(1), 163(1), 162(0.5), 137(12), 135(33), 109(19), 107(53), 94(36), 92(96), 57(57), 44(100). *Anal.* calcd. for $C_3H_2ClN_3O_2S$: C 22.04, H 1.23, N 25.69; found: C 22.11, H 1.19, N 25.85.

2-Chloro-1,3,4-thiadiazole-5-carboxamide **11**

(A) From Ethyl-2-chloro-1,3,4-thiadiazole-5-carboxylate **9***a and Ammonia*

The ester **8***a* (0.19 g, 1 mmol) was dissolved in an ethanolic ammonia solution (25 ml, 2.06 *N*) and left at room temperature for 16 h. The solvent was removed *in vacuo*, hexane was added to the residue, and a solid (0.16 g, 93%) which had mp 170–171 °C after crystallization from benzene, was obtained; uv (CH_3OH) 222 (5880), 259 nm (3240); ir (KBr) 3400, 3300, 3210, 1675 cm^{-1}; ms (relative intensity) 165(15), 163(40), 122(37), 120(100), 93(22), 79(17), 59(60), 44(97). *Anal.* calcd. for $C_3H_2ClN_3OS$: C 22.04, H 1.23, N 25.69; found: C 22.28, H 1.26, N 25.79.

(B) From the Chloro Compound **9***a obtained from Ethyl-2-amino-1,3,4-thiadiazole-5-carboxylate* **9***b (15)*

Concentrated sulfuric acid (2.02 ml, 6 mmol) was cooled to 0 °C in a nitrogen atmosphere and sodium nitrite (0.35 g, 5.1 mmol) was added portionwise. The reaction was left to react at room temperature and then

it was heated to 75 °C for 30 min. The resultant was cooled to 0 °C, the amine **9***b* (0.80 g, 4.6 mmol), suspended in acetic acid (5 ml), was added (reaction temperature < 5 °C), and after 10 min water (5 ml) was added below 5 °C. A solution of cupric chloride (0.83 g, 6.2 mmol) in water (5 ml) mixed with dichloromethane (5 ml) was then added at 0 °C. After 15 min the organic phase was separated and combined with a dichloromethane extract of the aqueous phase. The organic solution was washed with water, dried, and evaporated. The oil which remained was chromatographed on a column of silica gel (50 g). The column was first eluted with hexane – ethyl acetate (96:4) and then the ratio was changed to 92:8. The chloro compound **9***a* (0.20 g, 22%) had an ir spectrum identical to the material described above. It was converted into the carboxamide **11** in the manner described above. The material obtained in this way was identical to that obtained in the manner described previously.

1,4-Cycloheptadienes: preparation and comparison of their proton magnetic resonance spectra with those of the corresponding cycloheptatrienes

IVAN PIKULIK AND RONALD F. CHILDS[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 7, 1976

IVAN PIKULIK and RONALD F. CHILDS. Can. J. Chem. **55**, 251 (1977).

A general route to 3-substituted cyclohepta-1,4-dienes is described in this paper. 7-Substituted cycloheptatrienes were used as starting materials and these were reacted with 4-phenyl-1,2,4-triazoline-3,5-dione to give 4 + 2 cycloaddition products of the norcaradiene form of the cycloheptatrienes. Catalytic reduction of these adducts gave 9-substituted 4-phenyl-2,4,6-triazatetracyclo[5.3.2.$0^{2,6}$.$0^{8,10}$]dodeca-3,5-diones in good yield. Basic hydrolysis of the heterocyclic ring of these products followed by Cu^{2+} oxidation of the resulting hydrazo compounds gave the copper complexes of substituted 6,7-diazatricyclo[3.2.2.$0^{2,4}$]non-6-enes. The azo compounds, formed on decomplexation of the copper complexes, readily lost nitrogen to give 3-substituted cyclohepta-1,4-dienes. Care had to be taken during these last steps as the cycloheptadienes with carboxylate substituents very readily isomerized to the conjugated isomers. The pmr spectra of the cyclohepta-1,4-dienes and related cycloheptatrienes are compared and discussed in terms of the presence of an induced diamagnetic ring current in the latter systems.

IVAN PIKULIK et RONALD F. CHILDS. Can. J. Chem. **55**, 251 (1977).

On décrit une méthode générale de préparer des cycloheptadiènes-1,4 substitués en position 3. On a utilisé les cycloheptatriènes substitués en position 7 comme produits de départ; par réaction avec la phényl-4 triazoline-1,2,4 dione-3,5 ils donnent les produits de cycloaddition 4 + 2 correspondant à la forme norcaradiène des cycloheptatriènes. La réduction catalytique de ces adduits conduit avec des bons rendements aux phényl-4 triaza-2,4,6-tétracyclo[5.3.2.$0^{2,6}$.$0^{8,10}$]-dodécadiones-3,5 substitués en position 9. L'hydrolyse basique de l'hétérocycle de ces composés, suivie par une oxydation par le Cu^{2+} des composés hydrazo qui en découlent, conduit aux complexes du cuivre des diaza-6,7 tricyclo[3.2.2.$0^{2,4}$]nonènes-6 substitués. Les composés azo, formés par décomplexation des complexes de cuivre, perdent facilement de l'azote pour conduire aux cycloheptadiènes-1,4 substitués en position 3. On a pris beaucoup de soins au cours de ces dernières étapes car les cycloheptadiènes substitués par un groupement carboxylique s'isomérisent très facilement pour donner les isomères conjugués. On discute des spectres rmp des cycloheptadiènes-1,4 et des cycloheptatriènes qui leur ressemblent en terme de la présence d'un courant de cycle diamagnétique induit dans ces derniers systèmes.

[Traduit par le journal]

In the course of our studies of some 7-cycloheptatrienyl- and 7-norcaradienyl methyl zwitterions, it became necessary to determine the composition of some rapidly equilibrating mixtures of these tautomers (1). Such a measurement can be readily made by nmr spectroscopy, provided that the chemical shifts of appropriate nuclei in each individual tautomer are either known or can be reliably estimated. To this end it seemed that zwitterions formed from suitably substituted 1,4-cycloheptadienes would serve as good models for the cycloheptatriene form of these valence tautomeric mixtures. However, only a limited number of cyclohepta-1,4-dienes have been prepared (2) and as compounds with a carbonyl containing substituent at C_3 have not been reported, it was necessary to devise a synthesis of these materials. We describe here a general route to compounds of this type and discuss some of the fundamental differences in the pmr spectra of the 1,4-cycloheptadienes and cycloheptatrienes.

Results and Discussion

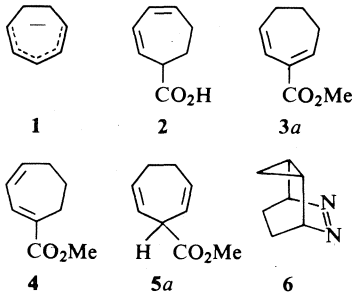
Synthesis of Cyclohepta-1,4-dienes

The cycloheptadienyl anion, **1**, has been reported to react with CO_2 to give a mixture of cyclohepta-1,3- and 1,4-diene and a carboxylic acid, tentatively identified as **2** (2). As the protonation of **1** is known to give cyclohepta-1,4-diene as one of the major products (3), this carbonation reaction was reexamined.

The acidic fraction resulting from the reaction of **1** with CO_2 was esterified by treatment with

[1]Author to whom correspondence should be addressed.

diazomethane and the crude product examined by pmr spectroscopy. One major component was present and this was shown to be **3***a* by comparison of its spectroscopic properties with those previously reported (4). This product was thermally unstable and on heating or attempted vpc purification, **3***a* was partially converted to a further ester which was tentatively identified as **4**. The spectroscopic properties of this ester are fully in accord with the assigned structure, however, the pmr spectrum differs somewhat from that previously reported for **4** (5). A comparable mixture of esters was obtained after esterification of the products obtained on the reduction of cycloheptatriene-7-carboxylic acid with lithium and liquid NH_3 (2, 5). No compound with a pmr spectrum consistent with **5***a* could be detected in either of these reactions.

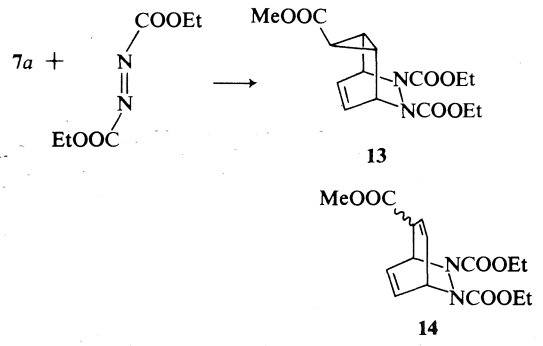


1 **2** **3***a* **4** **5***a* **6**

In view of the complexity of these reactions, a milder, more specific route to compounds such as **5***a* was sought. The azo compound **6** has been reported to decompose at 25 °C to give 1,4-cycloheptadiene and N_2 (6). Although the ease of this N_2 elimination has been shown to be very dependent on the relative configurations of the cyclopropyl ring and azo function (7), substituents on the methylene carbon of the cyclopropyl should not greatly affect this elimination reaction.

The cycloaddition of 4-phenyl-1,2,4-triazoline-3,5-dione to **7***a*, *b*, and *c* proceeded in high yield to give **8***a*, *b*, or *c*, respectively. The spectroscopic properties of these adducts were fully consistent with their assigned structures. The catalytic hydrogenation of the double bond of **8** was readily accomplished using a Pd catalyst. The *anti* relationship of the cyclopropyl ring and the nitrogen bridge of both **8** and **9** was indicated by the considerable downfield shift observed for the resonance of the cyclopropyl proton geminal to the substituent R in the pmr spectra of compounds **9** as compared to those of **8**. In **8** this proton is held in the shielding zone of the carbon–carbon double bond, an effect which is removed on saturation of the double bond (8*a*). Virtually no difference in the resonance positions of the cyclopropyl bridgehead hydrogens was detected in the pmr spectra of **8** and **9**.

It is interesting that no adducts could be detected which were formed from addition of the triazolinedione to the cycloheptatriene forms of **7**. In contrast, when diethyl diazodicarboxylate was reacted with **7***a*, both **13** and **14** were formed.[2] The ratio of **13** to **14** produced was found to be dependent on the temperature at which the cycloaddition was carried out. At +50 °C the ratio of **13** to **14** was 1.7:1 whereas at −5 °C this ratio was 5.7:1. In contrast to these results, no norcaradiene adducts were reported to be formed when cycloheptatriene itself was reacted with diethyl diazodicarboxylate (9). Thus the type of cycloaddition a cycloheptatriene undergoes appears not only to be a function of the dienophile but also the nature of any C_7 substituents on the cycloheptatriene ring.



Further structural modification of the cyclopropyl substituent of **9** was possible. For example, reaction of **9***c* with aqueous acid gave **9***e*, obviating the need to prepare **7***e*, a somewhat refractory material (10). Alternatively, treatment of **9***a* with methyllithium gave **9***d* in good yield.

The hydrolysis of **9** to give **10** was straightforward. In the case of **9***a* and *b*, concomitant hydrolysis of the ester also occurred to give **10***f*. The hydrazo compounds **10** were not isolated but were oxidized with cupric chloride to the corresponding azo compounds which subse-

[2]The pmr spectrum of **14** exhibited a temperature dependence arising from inversion of the ester groups about the nitrogen atoms.

TABLE 1. Proton chemical shifts of cyclohepta-1,4-dienes

Compound	Chemical shift*

quently formed copper complexes.[3] These complexes were stable and served as storable precursors to the dienes **5**.

The azo compounds **12** which were liberated on treatment of **11** with base, readily lost N_2 when warmed to 35 °C to give **5**. In order to prevent further isomerization of the dienes **5**, it was necessary to use limited quantities of a weak base to break up the copper complexes. The facile loss of N_2 from these azo compounds is in accord with the findings of Allred and Hinshaw (6*a*).

The structures of the 1,4-cycloheptadienes **5** were established from their spectroscopic properties (Table 1) and in the case of **5***c* and **5***d* by their elemental analyses. Compounds **5***a*, *f*, and *g* were unstable and isomerized to their respective conjugated isomers **3***a*, *f*, and *g*. The half-life for rearrangement of **5***a* to **3***a* at room temperature was about 12 h and this isomerization was much more rapid in the presence of base. The ease of isomerization of **5***a* makes it clear why compounds such as **5***a* or **5***g* were never detected as products of the carbonation of **1**. Dienes **5***c* and *d* were found to be relatively stable and could be heated to +60 °C without any detectable rearrangement.

It was not possible to prepare the aldehyde **5***e*. The only product that could be isolated either on the decomposition of **12***e* or the hydrolysis of the acetal **5***c*, was the conjugated aldehyde **3***e*. The structure of **3***e* was established on the basis of a comparison of its spectroscopic properties with those given before for **3***a*.

This route to substituted 1,4-cycloheptadienes should be capable of extension to include a wide range of substituents particularly as a large variety of 7-substituted cycloheptatrienes are

[3]It was not possible to prepare **11***c* by this route as hydrolysis of the acetal function occurred. Instead **10***c* was allowed to undergo aerial oxidation to give **12** directly and thence **5***c*.

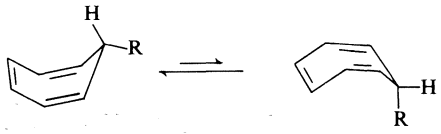
available (11). Overall, the yields are high and the route provides a viable entry to this type of molecule.

Comparison of the Proton Magnetic Resonance Spectra of 1,4-Cycloheptadienes and Cycloheptatrienes

As was stated earlier, our principal interest in these 1,4-cycloheptadienes was as model compounds for the corresponding 7-substituted cycloheptatrienes. As can be seen from the data in Table 2, the chemical shifts of the corresponding methine hydrogens of these two systems are by no means comparable. The resonances of the C_7 proton of the cycloheptatrienes all occur considerably further upfield than the corresponding C_3 proton resonances of the cycloheptadienes, the difference ranging from 0.6 ppm for the unsubstituted systems, to 1.75 ppm for the compounds with an ester substituent. The question arises as to what is the origin of this large difference in chemical shift and why does the absolute magnitude of this difference seem to depend on the nature of the substituent.

A consideration of the chemical shifts of these methine hydrogens shows that the 'normal' value is that found for the cycloheptadienes. Using the empirical relationship of Schoolery (12, 8*b*), the chemical shift of a proton attached to a tertiary carbon substituted with two vinyl groups and an ester function is expected to be about δ 4.4. This compares very favourably with the value δ 4.23 found for **5***a* and it would seem that it is the chemical shifts of the cycloheptatrienes which are anomalous.

It is known that the cycloheptatriene ring is not flat but exists in a boat conformation (13–15) with a substituent on C_7 preferentially adopting the pseudo-equatorial position (14, 16). As such it could be argued that the high field position of the C_7 proton resonance is caused by the magnetic anisotropy of the C_3,C_4 double bond. However, the long range shielding effect of a double bond may be estimated using the results of calculations by Tillieu (17) or Pople (18) and in either case the resulting shielding on an axial C_7 proton was found to be less than 0.2 ppm.



The possibility that the chemical shifts of these cycloheptatrienes are being influenced by the presence in each case of appreciable amounts of their norcaradiene valence tautomers can be discounted. Only in the case of **15***g* has the norcaradiene valence tautomer been directly observed to be in equilibrium with the cycloheptatriene form and even then less than 3% of the norcaradiene form was detected (19). One explanation for the anomalously high-field resonance positions of the C_7 hydrogens of these cycloheptatrienes is that cycloheptatriene ring can support an induced diamagnetic ring current when in a magnetic field.

The question of the aromaticity of cycloheptatriene has been under discussion ever since Doering *et al.* suggested that it could best be regarded as 'pseudo-aromatic' (20). In terms of more modern developments in the understanding of cyclic delocalization, cycloheptatriene is potentially a homoaromatic molecule and could be regarded as homobenzene (21). Homoaromaticity is a well defined and accepted phenomenon

with charged systems, both cationic and anionic, however, its importance in neutral molecules is by no means clearly defined (22).

Evidence for the importance of cyclic delocalization in cycloheptatriene has been claimed on the basis of its spectroscopic properties (23), its resonance energy of 7 kcal/mol (24), its diamagnetic susceptibility exaltation (25), the effect of it as a solvent on the chemical shifts of a solute molecule (26), and work with bridged bicyclic systems (27). However, despite this, there still seems to be a reluctance to accept cycloheptatriene as a bonafide homoaromatic species (28).

The high field chemical shifts of the C_7 protons of these cycloheptatrienes are completely in accord with cycloheptatriene sustaining an induced diamagnetic ring current when in a magnetic field. The presence of such a ring current would result in a shielding of the pseudo-axial and deshielding of the pseudo-equatorial C_7 hydrogens. Although these effects are in opposite directions, they will not be of the same magnitude and will depend very much upon the precise geometry of the molecule in question. Indeed,the low temperature pmr spectrum of cycloheptatriene, where the rate of interconversion of the two boat conformations is slow, exhibits two signals for the C_7 hydrogens, one at δ 1.43, attributed to the pseudo-axial hydrogen and another at δ 2.88 corresponding to the pseudo-equatorial proton (14). It is interesting that the equatorial hydrogen resonates at almost the same place as the corresponding C_3 hydrogens of cyclohepta-1,4-diene (29), suggesting that this hydrogen of cycloheptatriene is located in a nodal region of the magnetic field resulting from the induced ring current.

A substituent on C_7 of a cycloheptatriene preferentially adopts the pseudo-equatorial position. The remaining C_7 methine hydrogen is then largely in the pseudo-axial position and would be expected to be shifted upfield by almost the same amount as is observed for the axial hydrogen of cycloheptatriene itself. As can be seen from Table 2, this is true for **15***a* and **15***g*, however, the differences observed for **15***c* and **15***d* are somewhat smaller than might be expected. This could be the result of several factors, including for example a change in the degree of delocalization of the cycloheptatrienes as a function of the substituent, a change in the conformation of the ring (30), or a change in the axial/equatorial preference of the C_7 substituent.

In conclusion it would seem that the chemical shifts of the C_7 resonances of cycloheptatrienes can be most reasonably explained on the basis of a diamagnetic ring current being induced in these molecules and further more direct evidence for this is presented in the following paper (31). If the presence of such a ring current is a criterion of aromaticity (32), then on this basis these cycloheptatrienes must be regarded as homoaromatic molecules.

Experimental

Proton magnetic resonance spectra were recorded on a Varian HA-100 spectrometer and are referred to internal tetramethylsilane. A Hewlett-Packard 201C audiogenerator was employed for the double irradiation experiments. Infrared spectra were recorded on a Perkin-Elmer 521 spectrometer. Vapour phase chromatography was carried out on a Varian Aerograph A90-P3 instrument using column A (10 ft × ¼ in. column packed with 15% Carbowax on Chromosorb W) or column B (10 ft × ¼ in. column packed with 15% SE-30 on Chromosorb W). Melting points were obtained with a Thomas Hoover capillary melting point apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories in Knoxville, Tennessee.

Reaction of the Cycloheptadienyl Anion with Carbon Dioxide

Cycloheptatriene (10 g, 0.1 mol) was dissolved in liquid ammonia (150 ml) and lithium (1.4 g, 0.20 mol) was added in small pieces to the vigorously stirred solution. The reaction mixture was stirred for 2 h at −40 °C and then poured onto a large excess of crushed dry ice. The dry ice was allowed to evaporate and the volatile portion of the residue removed *in vacuo* at room temperature. This distillate (3.8 g) was separated by vpc (column B, 50 °C) into two fractions which were shown to be the 1,3- and 1,4-cycloheptadiene (in a ratio of 1:3.7) by comparison of their pmr spectra with those of the authentic materials (29). The involatile residue was dissolved in water (20 ml), acidified with HCl, and extracted with ether (3 × 10 ml). The combined ether extracts were washed with water (3 × 10 ml), dried over $MgSO_4$, and treated with diazomethane. The ether was removed and the residual product distilled under reduced pressure to give 2.7 g of an oil. This oil was separated by preparative vpc (column A, 160 °C) into seven fractions. The last two fractions, each 35% of the total, were further purified by vpc to give **3***a*, pmr (CCl_4) δ 1.97 (m, 2, H-6), 2.23 (m, 4, H-5,7), 3.70 (s, 3, OCH_3), 5.86 (m, 1, H-4), 6.39 (d, 1, H-3), 7.04 (t, 1, H-1); uv $\lambda_{max}(CH_3OH)$ 270 nm, ε 2880; ms *m/e* (M^+) calcd. for $C_9H_{12}O_2$: 152.0837; found: 152.0833; and **4**, pmr δ 1.97 (m, 2, H-6), 2.55 (m, 4, H-5,7), 3.70 (s, 3, OCH_3), 5.98 (m, 2, H-3,4), 6.93 (d, 1, H-2), uv $\lambda_{max}(CH_3OH)$ 278 nm; ε 8700. On heating **3***a* at 130 °C for 5 h an equilibrium was set up between **3***a* and **4** with a ratio of 7:3.

9-Methoxycarbonyl-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodec-11-en-3,5-dione ***8a***

A mixture of 4-phenyl-1,2,4-triazoline-3,5-dione (4.25 g, 24.7 mmol) and **7***a* (4.0 g, 24.4 mmol) in CH_2Cl_2 (120 ml)

was cooled in a dry ice – acetone bath at −60 °C. A solution of lead tetraacetate (14.5 g, 33.7 mmol) in methylene chloride (120 ml) was added at once to the rapidly stirred solution. The temperature of the mixture was allowed to rise to +20 °C and the stirring continued for an additional 4 h. The solvent was removed *in vacuo* and the residue was washed with 0.1 *N* HNO_3 (100 ml), 0.1 *N* NaOH (100 ml), and water (100 ml). The remaining brown material was dissolved in boiling methanol (400 ml), treated with charcoal, and the volume was reduced to 300 ml. On cooling this solution to room temperature 6.07 g of **8***a* crystallized and was filtered out. An additional 0.7 g of material was obtained as a second crop, bringing the total yield of **8***a* to 82%. The product was recrystallized from methanol to give pure **8***a*, mp 187 °C; pmr ($CDCl_3$) δ 1.41 (t, 1, J = 3.0 Hz, H-9), 2.19 (m, 2, H-8,10), 3.67 (s, 3, OMe), 5.23 (m, 2, bridgehead protons), 6.15 (t, 2, J = 3.7 Hz, olefinic protons), 7.40 (s, 5, Ph); ir (KBr) 1770, 1730, 1417, 1323, 1240 cm^{-1}. *Anal.* calcd. for $C_{17}H_{15}N_3O_4$: C 62.77, H 4.62; found: C 62.76, H 4.72.

9-Ethoxycarbonyl-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodec-11-en-3,5-dione **8***b*

7-Ethoxycarbonylcycloheptatriene was used as the starting material and the procedure used was the same as that described for the preparation of **8***a*. Yield 73%; mp 172.5 °C; pmr ($CDCl_3$) δ 1.26 (t, 3, Me), 1.45 (t, 1, H-9), 2.23 (d of d's, 2, H-8,10), 4.14 (q, 2, CH_2), 5.25 (m, 2, bridgehead H's), 6.18 (t, 2, olefinic H's), 7.42 (s, 5, Ph); ir (KBr) 1770, 1719, 1500, 1415, 1241 cm^{-1}. *Anal.* calcd. for $C_{18}H_{17}N_3O_4$: C 63.71, H 5.05; found: C 63.81, H 5.13.

9-Dimethoxymethyl-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodec-11-en-3,5-dione **8***c*

The compound **8***c* was prepared from dimethoxymethylcycloheptatriene using the same procedure as that described above for the preparation of **8***a*. Yield 73%; mp 158 °C; pmr ($CDCl_3$) δ 0.97 (d of t's, 1, H-9), 1.76 (m, 2, H-8,10), 3.33 (s, 6, OMe), 4.26 (d, 1, C-9 substituent), 5.22 (m, 2, H-1,7), 6.17 (t, 2, olefinic protons), 7.42 (s, 5, Ph); ir (KBr) 1773, 1755, 1605, 1500, 1398 cm^{-1}. *Anal.* calcd. for $C_{18}H_{19}N_3O_4$: C 63.33, H 5.63; found: C 63.12, H 5.70.

9-Methoxycarbonyl-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodeca-3,5-dione **9***a*

The olefin **8***a* (3 g) was partially dissolved in dioxane (100 ml) and a 5% palladium-on-carbon catalyst (185 mg) added. The mixture was vigorously stirred under H_2 (1 atm) at room temperature, and 1 equiv. of H_2 was absorbed in 10 min (all the solid material dissolved during this reaction). The catalyst was removed by filtration and the solvent removed *in vacuo*. The residue was recrystallized from MeOH to give **9***a* (2.6 g); mp 156 °C; pmr ($CDCl_3$) δ 1.55–2.22 (m, 7, cyclopropyl and methylene protons), 3.66 (s, 3, OMe), 4.7 (br s, 2, bridgehead protons), 7.47 (m, 5, Ph); ir (KBr) 1775, 1720, 1500, 1440, 1410, 1250 cm^{-1}. *Anal.* calcd. for $C_{17}H_{17}N_3O_4$: C 62.38, H 5.23; found: C 62.53, H 5.26.

9-Ethoxycarbonyl-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodeca-3,5-dione **9***b*

Starting with **8***b* the procedure used was the same as that described above for the preparation of **9***a*. Yield 95%; mp 156 °C; pmr ($CDCl_3$) δ 1.27 (t, 3, Me), 1.60–2.20 (m, 7, H-8–12), 4.15 (q, 2, CH_2), 4.73 (br s, 2, bridgehead H's), 7.32–7.62 (m, 5, Ph); ir (KBr) 1770, 1720, 1502, 1409, 1320, 1255 cm^{-1}. *Anal.* calcd. for $C_{18}H_{19}N_3O_4$: C 63.34, H 5.61; found: C 63.23, H 5.52.

9-Dimethoxymethyl-4-phenyl-2,4,5-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodeca-3,5-dione **9***c*

Olefin **8***c* was reduced in a directly comparable manner to that described above for reduction of **8***a*, to give 100% yield of **9***c*; mp 121 °C; pmr ($CDCl_3$) δ 1.41 (t, 1, H-9), 1.60–2.20 (m, 6, H-8,10,11,12), 3.34 (s, 6, OMe), 4.22 (br s, 2, bridgehead H's), 7.3–7.7 (m, 5, Ph); ir (KBr) 1750, 1696, 1500, 1430, 1410 cm^{-1}. *Anal.* calcd. for $C_{18}H_{21}N_3O_4$: C 62.93, H 6.18; found: C 62.85, H 6.18.

The Copper Complex of 6,7-Diazatricyclo[3.2.2.0^{2,4}]-nonane-3-carboxylic Acid **11***g*

A solution of **9***a* (2.85 g, 8.81 mmol) in methanol (15 ml) containing KOH (3 g, 65 mmol) was refluxed for 24 h in a nitrogen atmosphere. The reaction mixture was cooled and dissolved in water (500 ml). The solution was titrated with 10% HCl to p*H* 4 and $CuCl_2$ (3 g, 22.3 mmol) was dissolved in the mixture. After 30 min the green solution started turning red and during the following 15 h crystals of **11***g* accumulated on the bottom of the vessel. The complex was filtered off and thoroughly washed with acetone and ether to give **11***g*; yield 1.5 g (64%); mp 147 °C (dec.); ir (KBr) 1697,1470, 1340, 1280 cm^{-1}.

Cyclohepta-1,4-diene-3-carboxylic Acid **5***g and its Rearrangement to* **3***g*

The copper complex **11***g* (0.9 g, 3.22 mmol) was mixed with water (20 ml) containing K_2CO_3 (0.089 g, 6.44 mmol). The red solid immediately turned brown and a slow development of gas was observed. After 1 h of stirring, the precipitate was filtered off and the filtrate was heated to 35 °C until the production of nitrogen was complete (12 h). The solution was cooled to 2 °C, acidified with HCl to p*H* 3, extracted with ether (3 × 15 ml), and the ether extract dried with $MgSO_4$. The solvent was removed *in vacuo* to give **5***g* as a colorless oil; pmr Table 1; ir (film) 3500–2500, 1715, 1421, 1289 cm^{-1}.

Pure **5***g* was heated for 1 h at 45 °C to give **3***g* as a yellow oil; pmr ($CDCl_3$) δ 1.85 (m, 2, H-6), 2.38 (m, 4, H-5,7), 5.91 (d of t, 1, H-4), 6.35 (d of d, 1, H-3), 7.26 (t, 1, H-1), 11.2 (s, 1, OH). On irradiation of the resonance at δ 2.38 the signal at δ 7.26 collapsed to a singlet, that at δ 5.91 to a doublet, and the absorption at δ 1.85 collapsed to a broad singlet: $J_{1,7}$ = 5.3 Hz; $J_{3,4}$ = 11.5 Hz; $J_{4,5}$ = 4.5 Hz; $J_{3,5}$ = 1.0 Hz.

3-Methoxycarbonylcyclohepta-1,4-diene **5***a and its Rearrangement to* **3***a*

The ether solution of **5***g* obtained as above, was treated with a slight excess of diazomethane. The solvent was removed *in vacuo* and the residue distilled to give **5***a* (55%); bp 30 °C/0.1 torr; pmr Table 1; ir (film) 1725, 1465, 1415, and 1295 cm^{-1}.

Kept at room temperature **5***a* rearranged to give **3***a*, which exhibited an identical pmr spectrum to that quoted above.

3-Dimethoxymethylcyclohepta-1,4-diene **5***c*

A solution of acetal **9***c* (2.0 g, 5.8 mmol) in methanol (15 ml) containing KOH (1.5 g, 27 mmol) was refluxed under N_2 for 48 h. Degassed water (30 ml) was added and the mixture extracted with methylene chloride (3 × 15 ml). The combined extract was dried with $MgSO_4$ and the

solvent was removed *in vacuo*, to give an oil, pmr ($CDCl_3$) δ 1.05–2.02 (m, 7), 3.35 (s, 6), 4.20 (m, 4), 3.55 (s, 2), 6.9 (m, 5). This product was dissolved in CH_2Cl_2 and the solution was exposed to air for 8 h. Development of gas was observed during this time. The solvent was removed *in vacuo*, and the mixture of **5***c* and aniline so obtained was separated on a short column of basic alumina eluting with ether. Yield of **5***c* 0.47 g (48%); pmr (Table 1). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 72.26, H 9.70; found: C 71.97, H 9.77.

4-Phenyl-2,4,6-triazatetracyclo[5.3.2.0^{2,6}.0^{8,10}]dodeca-3,5-dione-9-carbaldehyde, **9***e*

Acetal **9***c* (0.8 g) was dissolved in acetone (30 ml), aqueous 37% HCl (0.5 ml) was added, and the solution was kept for 30 min at room temperature. At the end of this time $NaHCO_3$ (0.5 g) was slowly added and the solvent was removed *in vacuo*. The white residue was triturated with methanol, the inorganic salt removed by filtration, and the solvent evaporated *in vacuo* to yield crude **9***e* (0.65 g, 95%). Three recrystallizations from CCl_4–acetone mixtures gave pure **9***e*; mp 204 °C; pmr ($CDCl_3$) δ 1.50–2.30 (m, 7, H-8–12), 4.72 (br s, 2, H-1,7), 7.28–7.62 (m, 5, Ph), 9.72 (d, 1, H-8); ir (KBr) 1770, 1710, 1600, 1500, 1411, 1259 cm^{-1}. *Anal.* calcd. for $C_{16}H_{15}N_3O_3$: C 64.63, H 5.08; found: C 64.60, H 5.00.

Attempted Preparation of 3-Formylcyclohepta-1,4-diene

(*a*) The aldehyde **9***e* was hydrolyzed and treated with $CuCl_2$ as described above for the preparation of **11***g*, to give a copper complex, mp 120–122 °C (dec.); ir (KBr) 1695, 1619, 1401 cm^{-1}. This complex (0.2 g) was stirred with 5% K_2CO_3 solution (10 ml) at 4 °C for 3 h. The organic material was extracted into CH_2Cl_2, (3 × 5 ml), the combined extracts dried over $MgSO_4$, and then heated at 35 °C for 5 h. The solvent was removed *in vacuo* to yield 2-formylcyclohepta-1,3-diene **3***e*, pmr ($CDCl_3$) δ 1.65–2.20 (m, 2, H-6), 2.20–2.90 (m, 4, H-5,7), 6.05–6.60 (m, 2, H-3,4), 6.78 (t, 1, H-1), 9.37 (s, 1, —CHO).

(*b*) Reaction of the acetal **9***c*, using the same procedure as outlined for **9***e*, gave **3***e*, with the same pmr spectrum to that described above. Acetal **5***c* (20 mg) was dissolved in ether (4 ml) containing 3 drops of 37% HCl and stirred at −5 °C for 30 min. The ether solution was washed with 5% aqueous $NaHCO_3$ and water, dried over $MgSO_4$, and the solvent removed *in vacuo* (all operations were carried out at 0 °C). The pmr spectrum of the product was identical to that described above for **3***e*.

9-(2-Hydroxy-2-propyl)-4-phenyl-2,4,6-triazatetracyclo-[5.3.2.0^{2,6}.0^{8,10}]dodeca-3,5-dione, **9***d*

Methyllithium (4 ml, 1.3 *N* in hexane) was added to a vigorously stirred solution of **9***b* (1.4 g, 4.10 mmol) in dry 1,4-dioxane (100 ml). After 15 min, water (15 ml) was added and the volume of the solution was reduced to 30 ml *in vacuo*. Additional water (20 ml) was added and the mixture neutralized with 10% HCl and extracted with CH_2Cl_2 (3 × 20 ml). The organic layer was dried over $MgSO_4$ and reduced to 10 ml. Addition of CCl_4 (10 ml) caused precipitation of 0.2 g of white product. This material was recrystallized from CH_2Cl_2/CCl_4 mixtures to yield **9***d*, mp 147 °C; pmr ($CDCl_3$) δ 1.24 (s, 6, CH_3), 1.46–2.06 (m, 8), 4.66 (br s, 2, H-1,5), 7.30–7.62 (m, 5, ArH); ir (KBr) 3450, 1745, 1700, 1497, 1408, 1278, 1255 cm^{-1}. *Anal.* calcd. for $C_{18}H_{21}N_3O_3$: C 66.04, H 6.47; found: C 66.30, H 6.52.

3-(2-Hydroxy-2-propyl)-1,4-cycloheptadiene **5***d*

9*d* was hydrolyzed and treated with $CuCl_2$ in the same manner to that outlined above for **9***a* to give a copper complex, mp 107–110 °C. This complex was reacted with aqueous K_2CO_3 as described above for **11***g* to give, eventually, an oil which was purified by chromatography on alumina, eluting with ether. The final fraction was distilled (60 °C/0.5 torr) to yield **5***d* (30%); pmr Table 1; ir (film) 3400, 1170, 1450, 1370 cm^{-1}. *Anal.* calcd. for $C_{10}H_{16}O$: C 78.90, H 10.59; found: C 78.70, H 10.71.

Diamagnetic susceptibilities and susceptibility exaltations of some 7-substituted cycloheptatrienes

RONALD F. CHILDS AND IVAN PIKULIK

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 7, 1976

RONALD F. CHILDS and IVAN PIKULIK. Can. J. Chem. **55**, 259 (1977).

The diamagnetic susceptibilities of several 7-substituted cycloheptatrienes have been measured and used in conjunction with estimated values of their susceptibilities (Haberditzl increment system) to obtain the susceptibility exaltations of these compounds. These exaltations were found to be very large and to vary as a function of the size of the C_7 substituent. There was no apparent correlation of the exaltation of a compound with the electronic properties of its substituent. The effect of a substituent on the susceptibility exaltation is interpreted in terms of conformational changes in the seven-membered ring. The magnitude of the susceptibility exaltations of these cycloheptatrienes, for example 7-*tert*-butylcycloheptatriene ($\Lambda = 14.8$), in comparison to that of benzene ($\Lambda = 13.7$) would suggest that the presence of an induced diamagnetic ring current is not a good criterion of its aromaticity.

RONALD F. CHILDS et IVAN PIKULIK. Can. J. Chem. **55**, 259 (1977).

On a mesuré les susceptibilités diamagnétiques de plusieurs cycloheptatriènes substitués en position 7 et on a utilisé ces données, de concert avec les valeurs estimées pour leurs susceptibilités (système additif de Haberditzl), afin d'obtenir les augmentations de susceptibilités de ces composés. On a trouvé que ces exaltations sont très grandes et qu'elles varient en fonction de la grosseur du substituant en position C_7. Il n'y a apparamment aucune corrélation entre l'exaltation d'un composé et les propriétés électroniques de son substituant. On peut interprété l'effet d'un substituant sur l'exaltation de la susceptibilité en termes de changements conformationnels dans le cycle à sept membres. L'amplitude des exaltations des susceptibilités de ces cycloheptatriènes, par exemple pour la *tert*-butyl-7 cycloheptatriènes ($\Lambda = 14.8$) par opposition à celle du benzène ($\Lambda = 13.7$), pourrait suggérer que la présence d'un courant de cycle diamagnétique induit n'est pas un bon critère pour déterminer son aromaticité.

[Traduit par le journal]

The position of the equilibrium between cycloheptatriene and norcaradiene can be changed by the judicious introduction of substituents (1). Particularly dramatic shifts in the equilibrium position have been observed with substitution at C_7, the methylene carbon of these systems (2).

Several explanations have been advanced to account for the effect of a C_7-substituent on the position of this and other closely related equilibria, most of which tend to focus attention on the norcaradiene part of the system (3–6). At this present time the most widely accepted view seems to be that put forward by Hoffmann (4) and Günther (5) which considers the interaction of the molecular orbitals of a C_7 substituent with those of the cyclopropyl function of a norcaradiene. However, the problem is by no means fully resolved. For example, the recent report of Mukai and co-workers (6) on some 7,7-disubstituted systems or the earlier results of Hall and Roberts (7) do not seem to fit in with these proposals.

In the preceeding paper we showed that the large differences in the proton chemical shifts of some 7-substituted cycloheptatrienes and their corresponding cyclohepta-1,4-dienes were consistent with a diamagnetic ring current being induced in the cycloheptatrienes (8). The size of this effect seemed to be dependent on the nature of the substituent, possibly implying that the magnitude of the induced ring current was also determined by substitution at C_7. If this is indeed the case, then it is apparent that the properties of a cycloheptatriene are substituent dependent and this could conceivably have considerable bearing on the cycloheptatriene–norcaradiene equilibrium.

It is difficult on the basis of chemical shift arguments to establish the presence of a diamagnetic ring current in a molecule, particularly as the whole question of the origin of the typically low-field resonances of aromatic protons has been called into question (9). To circumvent this problem we have determined the magnetic susceptibilities and susceptibility exaltations of

a series of 7-substituted cycloheptatrienes and have found the magnitude of the exaltations to be very strongly dependent on the substituent used. The susceptibilities of a limited number of cycloheptatrienes have been reported previously by Dauben *et al.* (10–12), however, unlike the results reported here, no large dependence of the exaltation on substitution was found by these workers.

Results and Discussion

Measurement of Magnetic Susceptibility

The diamagnetic susceptibilities of some substituted cycloheptatrienes were measured using the method described by Douglas and Fratiello (13) and more recently utilized by Dauben *et al.* (10). A special nmr tube consisting of two concentric cylinders was used in conjunction with a high resolution nmr spectrometer. All measurements were carried out at a probe temperature of 36 °C, using toluene or nitromethane as the reference material and calibrating the system with a set of pure liquids of known volume magnetic susceptibilities. The cycloheptatrienes used in this study, compounds **1**–**7**, were chosen such that a variety of different types of substituents were present. In each case it is known that the corresponding norcaradiene valence tautomer is not present to any significant extent. The volume magnetic susceptibilities, κ, of cycloheptatrienes **1**–**7** and cycloheptadiene **8** are given in Table 1.

The densities of the various compounds were determined at 36 °C using a calibrated pycnometer. These were used in conjunction with the values of κ to obtain the magnetic susceptibilities per gram, χ ($\chi = \kappa/\rho$), and molar susceptibilities χ_M ($\chi_M = \chi M$; where M = mw).

The reliability of this method of obtaining χ_M was checked by repeating the measurement of the susceptibility and density of cycloheptatriene. As can be seen from the first two entries in Table 1, the value of χ_M obtained in this work differs from that reported by Wilson (10) by only 0.5×10^{-6} cm^3/g, which is within the error limits of this type of experiment (12). Similar cross checks with other compounds of known molar susceptibility proved to be equally as good.

Estimation of Magnetic Susceptibility

In order to determine whether the susceptibility of a compound includes a contribution from an induced diamagnetic ring current, it is necessary to estimate the expected susceptibility, χ_M', in the absence of any ring current. There are several methods available for the calculation of χ_M', the virtues and failures of which have been discussed extensively by Laity (12). The incremental system of Haberditzl (14) which has been shown to give fairly good results for a large number of hydrocarbons, ethers, and alcohols, was used in this work. The estimation of χ_M' for esters is somewhat less reliable,

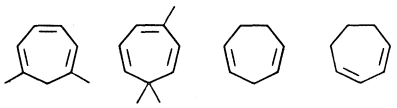
however the close agreement of χ_M' with the measured susceptibility χ_M of the cycloheptadiene ester **8** (Table 1), a molecule which cannot sustain an induced ring current, indicates that the Haberditzl system is not grossly in error with molecules of this type.

Some difficulty was encountered in the calculation of χ_M' for **5** as an increment for the C≡N bond has not been reported for the Haberditzl system. Using the known diamagnetic susceptibilities of several nitriles (15) it was possible to estimate a value for the C≡N bond increment by taking the average difference between the measured values of χ_M and the sum of all the other increments involved in these nitriles (Table 2). A value of -8.9×10^{-6} was used as the C≡N bond increment. With the limited number of model compounds used this value is tentative and no great significance should be attached to the absolute magnitude of the difference between χ_M and $\chi_{M'}$ for **5**.

The difference between the observed and calculated susceptibilities is defined as the susceptibility exaltation Λ ($\chi_M - \chi_{M'} = \Lambda$) (16, 11) and values of this parameter are listed in Table 3. This table also includes the susceptibility exaltations of some cycloheptatriene and dienes previously reported by Dauben *et al.* (11).



9 **10** **11** **12**

Discussion of Susceptibility Exaltations

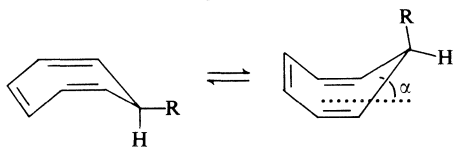
It is quite apparent on examination of the

data presented in Table 3 that all the cycloheptatrienes are diatropic, all exhibiting a substantial diamagnetic susceptibility exaltation (17, 18*a*).[1] These exaltations range from a low of 7.1 for the trimethyl compound **10** to a high of 14.8 for the *tert*-butylcycloheptatriene **7**.[2] The sort of discrepancies normally encountered between χ_M and χ_M' for atropic molecules are indicated by the exaltations of the various cycloheptadienes **8**, **11**, and **12** and as can be seen, these are very much smaller than those encountered for the cycloheptatrienes.

A second and most interesting feature of the exaltations of these cycloheptatrienes is that the magnitude of the exaltation is a function of the substituent on the ring. This is particularly noticeable with the change of substituents on C_7. Thus while **9**, with two methyl groups on C_1 and C_6, has almost the same susceptibility exaltation as cycloheptatriene itself, the 7-*tert*-butyl compound **7** has an exaltation which is close to 75% larger than that of **1**. This marked dependence of the exaltation of a cycloheptatriene on the C_7 substituent is different from the very small substituent effects usually encountered with diatropic molecules. For example, the susceptibility exaltation of benzene is not influenced to any significant degree by substitution (12). Clearly some change must be occurring with these cycloheptatrienes as the substituent on C_7 is varied.

Apart from the 7-cyano compound **5** for which there is some uncertainty in χ_M', there would appear to be a correlation between the steric size of a C_7 substituent and the susceptibility exaltations of these mono-substituted cycloheptatrienes. Based on the steric parameters deduced from cyclohexane equilibria, the substituent would be expected to increase in size in the order OMe < COOMe < CH_3 < $CH(OCH_3)_2$ < *tert*-Bu (20) and this is the exact order of increase of the exaltations of the similarly substituted cycloheptatrienes. There does not seem to be any correlation of the susceptibility exaltations with any electronic properties of the substituents. It is interesting that the introduction of a second substituent on C_7, *e.g.* **10** with two C_7 methyl groups, lowers the susceptibility exaltation back to a value slightly less than that of the unsubstituted system **1**.

These changes in the susceptibility exaltation of these cycloheptatrienes could result from conformational changes in the seven-membered ring. The seven-membered ring of cycloheptatriene is non planar and exists as a rapidly equilibrating mixture of two equivalent boat conformations (21). When a substituent is introduced onto the C_7 carbon of a cycloheptatriene, the two boat forms, while still rapidly equilibrating, are no longer of equal energy. The favoured conformation is the one in which the substituent is in the pseudo-equatorial position and this becomes increasingly the preferred conformation as the steric size of the substituent is increased (22).



Not only are the two conformations of a C_7 substituted cycloheptatriene no longer of equal energy but it has been suggested that the shape of the boat in each conformation is different (22). Thus with a pseudo-axial substituent, the boat tends to be somewhat flatter and the structural angle α reduced, while with an equatorial substituent the angle α tends to be greater than that found for cycloheptatriene itself. As the larger substituents enhance the population of the conformation in which the group is in the equatorial position, on average the angle α would be expected to increase as the substituent size is increased. One effect of an increase in the angle α is that the lobes of the *p* orbitals on C_1 and C_6 are tipped closer together, Fig. 1, and the possibility of cyclic delocalization enhanced. The magnitude of the magnetic susceptibility exaltations of these 7-substituted cycloheptatrienes parallel these conformational changes.

If such a change in the cyclic delocalization of the π-electrons of a cycloheptatriene is occurring as a function of C_7 substitution, then

[1]The term diatropic was originally defined in terms of the observed deshielding or shielding of the resonances of the peripheral protons in the pmr spectrum of a molecule sustaining an induced diamagnetic ring current (17, 18*a*). Rather than coin a new term, the definition has been extended here to include all molecules which exhibit an induced diamagnetic ring current, irrespective of how this ring current is measured. An alternative term which has been suggested is strobilic (19), however, this does not seem to have been generally accepted.

[2]For simplicity the units of the molar diamagnetic susceptibilities are omitted in the text of this paper. Throughout the units are $-\chi_M \times 10^{-6}$ cm^3 mol^{-1}.

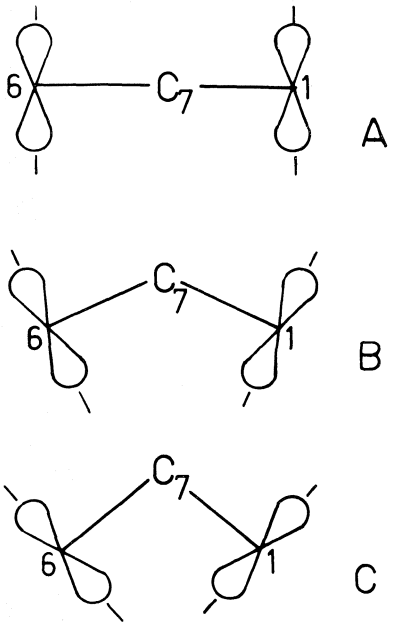


FIG. 1. Schematic representation of changes in the relative alignment of C_1 and C_6 of a cycloheptatriene as the structural angle α is changed; *A*, $\alpha = 0°$; *B*, $\alpha = 30°$; *C*, $\alpha = 55°$.

it should also be reflected in other electronic properties of these molecules. As can be seen from the data in Table 3, the position of the uv absorption maxima of these substituted cycloheptatrienes is increasingly blue shifted as the C_7 group becomes larger. These shifts in λ_{max} are not large but they are in the direction expected if cyclic delocalization were to become more important (23).

The susceptibility exaltation of 7-cyanocycloheptatriene, **5**, is higher and its uv absorption maximum more blue shifted than would be expected simply on the basis of the steric size of the nitrile group. It is interesting, however, that the cyano group of **5** also shows a larger preference for the pseudo-equatorial position than would have been anticipated on just steric grounds (24).

The conformation of the seven-membered ring of a cycloheptatriene with two C_7 substituents would appear to remain much the same as that of the unsubstituted system (25). As can be seen from the results in Table 3 the susceptibility exaltations of **10** and **1** are very similar.

It is instructive to compare the magnitudes of the exaltations of these cycloheptatrienes with their pmr spectra. In the previous paper it was shown that the C_7 proton resonances of 7-substituted cycloheptatrienes occurred substantially further upfield than the comparable resonances of similarly substituted cyclohepta-1,4-dienes (8). The difference in the chemical shifts of these two systems was seemingly inversely related to the size of the substituents, decreasing as the steric bulk of the substituent was increased. This is the exact reverse of the changes that have been found in the susceptibility exaltations of the systems that have been described in this paper. This points out how tenuous are any arguments based on chemical shifts for the presence of an induced ring current in a molecule.

Diatropic or Aromatic?

The question of whether cycloheptatrienes and related molecules are homoaromatic is a long standing, unresolved problem (10, 26–28). Part of this problem is tied up with the confusion which surrounds the term aromatic (29), the difficulty in the quantification of this much cherished term, and the question of the relationship of induced ring currents and pmr spectra (19).

If an aromatic molecule is defined as being "a diatropic molecule in which all the ring atoms are involved in a single conjugated system" (18*b*) and this definition extended to include homoaromaticity by the inclusion of diatropic homo-conjugated systems, then the cycloheptatrienes examined in this work must be considered to be homoaromatic. Indeed, a comparison of the susceptibility exaltations of benzene, 13.7, and the tropylium cation, 17, *vs.* 7-*tert*-butylcycloheptatriene, 14.8, and the homotropylium cation, 21, (11) would suggest that there is as much right to call this substituted cycloheptatriene a homobenzene as there is for the $C_8H_9^+$ cation to be called the homotropylium cation.[3]

This type of quantitative comparison of susceptibility exaltations must, however, be treated with a great deal of caution. Thus benzene, the archetype of all aromatic molecules, with a large resonance energy and showing no

[3]Susceptibility exaltations are related to the area of the ring system involved. In these comparisons, the change in area on going from benzene to cycloheptatriene is very comparable to that involved in going from the tropylium to homotropylium cation.

bond length alternation, would seem to be in an entirely different league to cycloheptatriene. The resonance energy of cycloheptatriene has been reported to be only 7 kcal/mol (27), which is not much greater than that expected for a regular conjugated triene. On the basis of equilibration studies Conrow (28) has suggested that the 1,6-overlap in cycloheptatriene only stabilizes the molecule by some 1–2 kcal/mol relative to systems bearing an exocyclic methylene group in which cyclic delocalization is not possible. Moreover, the several structural studies reported on cycloheptatriene and its derivatives (25) show that the C—C bonds of the seven-membered ring show the alternation in length expected of a linearly conjugated system.

Resonance energy has been advocated and used as a criterion of aromaticity (30). However, with these cycloheptatrienes there does not seem to be any correlation between the magnitude of their resonance energies and diamagnetic ring currents (31). This leads us to question whether the ability of a molecule to support an induced diamagnetic ring current is a useful, or even valid criterion of aromaticity. It would rather seem better, albeit somewhat less glamorous, if molecules exhibiting a diamagnetic ring current irrespective of how this is measured or detected, be termed diatropic.

Experimental

The cycloheptatrienes used in this study were prepared by standard procedures and their purity checked by pmr prior to use. Cycloheptatriene, commercial sample purified by preparative glpc (10 ft × ¼ in. column with 15% Carbowax on Chromosorb W); 7-methoxy and 7-methylcycloheptatrienes were prepared by the procedure of Dauben (32), 7-*tert*-butylcycloheptatriene by the procedure of Heyd (33); 7-cyano-cycloheptatriene by the addition of tropylium tetrafluoroborate to aqueous potassium cyanide according to the procedure of Dauben;[4] and 7-dimethoxymethylcycloheptatriene by the method reported by Cope (35).

Density Determinations

The densities of the cycloheptatrienes were determined at 36 °C using a Lipkin bicapillary pycnometer (0.25 ml, Ace Glass Company) which was calibrated with distilled water.

Diamagnetic Susceptibility Measurements

Volume diamagnetic susceptibilities were determined using the method of Douglass and Fratiello (13). A cell consisting of precision bore, thin wall, concentric, flat bottom tubes was used (Wilmad Glass Company). The reference material, toluene or nitromethane, was placed in the outer tube and the sample in the inner, central tube. With the sample not being spun, the pmr spectrum of each signal of the reference is distorted into a saddle shape; the separation of the two peaks being proportional to the susceptibility of the sample. A Varian HA100 spectrometer operated in the no-lock mode was used for these measurements. Since it was not possible to completely eliminate any drift of the magnetic field under these conditions, the error caused by the drift was reduced by scanning the signal 12 to 18 times alternately on the forward and backward directions and the average separation calculated. It was necessary to tune the spectrometer to a very high degree of field homogeneity.

The sample cell and spectrometer were calibrated with a series of compounds of known susceptibility. The compounds used for this calibration were: CH_2I_2, $CHBr_3$, CH_2Cl_2, H_2O, $C_6H_5CH_3$, CH_3CN, CH_3CH_2OH, and CH_3NO_2, all of which were purified by standard procedures (36) and distilled through a 20 in. glass column filled with glass helices under He. To check that no change in conditions occurred during the measurement of the susceptibilities of the samples, several standard samples were re-run at the end of the measurements. A plot of the separation of the methyl peak of the references (nitromethane and toluene) against the susceptibilities of the standards gave straight lines within each case a correlation coefficient of at least 0.999 and a standard deviation in κ of less than 0.004.

Milieux hyperbasiques: préparation de carbanions en α d'amides *N,N*-disubstitués. Synthèse de β- et γ-hydroxyamides et de γ-butyrolactones

PIERRE HULLOT, THÉRÈSE CUVIGNY, MARC LARCHEVÊQUE ET HENRI NORMANT

Laboratoire de Synthèse Organique – Laboratoire associé au C.N.R.S. n° 239, Université Pierre et Marie Curie, tour 44–45, 4, place Jussieu – 75230 Paris Cédex 05

Reçu le 6 juillet 1976

PIERRE HULLOT, THÉRÈSE CUVIGNY, MARC LARCHEVÊQUE et HENRI NORMANT. Can. J. Chem. **55**, 266 (1977).

Les carbanions en α d'amides *N,N*-disubstitués sont obtenus avec d'excellents rendements par action des "dialkylamidures activés" en solution dans le HMPT. Ils réagissent avec les aldéhydes et cétones pour conduire à des β-hydroxyamides; avec les époxydes on atteint les γ-hydroxyamides cyclisés in situ en γ-butyrolactones.

PIERRE HULLOT, THÉRÈSE CUVIGNY, MARC LARCHEVÊQUE, and HENRI NORMANT. Can. J. Chem. **55**, 266 (1977).

The α anions of *N,N*-disubstituted carboxamides can be conveniently prepared by treatment with "activated" lithium dialkylamides in HMPT. They react with aldehydes and ketones and lead to β-hydroxyamides; furthermore the ring opening of epoxides affords γ-hydroxyamides which may be cyclized *in situ* to γ-butyrolactones.

Nous avons envisagé dans un précédent mémoire la métallation en α des amides *N,N*-disubstitués à l'aide de bases très puissantes: les dialkylamidures de lithium "activés" préparés in situ par simple agitation du métal dans une solution benzène–amine–HMPT. Nous avons vu que les carbanions, aisément formés à basse température, pouvaient être alkylés dans d'excellentes conditions grâce à la présence du HMPT (1).

D'autre part, nous avons récemment montré que l'autoxydation de ces anions par un courant d'air menait aux α hydroxyamides avec des rendements très satisfaisants (2).

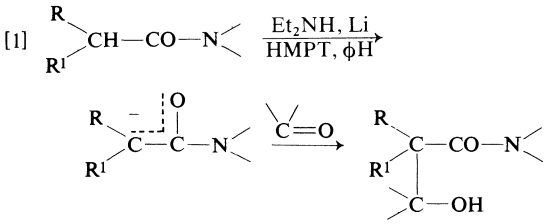
Nous aborderons maintenant la condensation de ces anions avec des dérivés carbonylés et des époxydes divers en vue d'obtenir des β- et γ-hydroxyamides.

I. Synthèse de β-hydroxyamides N,N-disubstitués (3)

Des β-hydroxyamides *N,N*-disubstitués ont déjà été obtenus par diverses méthodes. La condensation des amides avec les cétones aromatiques en présence de potasse donne des résultats satisfaisants (4) mais le procédé ne s'applique pas aux cétones énolisables. Les *N,N*-diméthyl acétamide et propionamide ont été métallés en α à l'aide du dérivé lithié du *s*-trithiane, cependant la réaction ultérieure avec des carbonylés énolisables ne se fait qu'avec des rendements médiocres (5).

L'emploi des amidures de lithium "usuels" (butyllithium + diisopropylamine) a permis la métallation de lactames dont le dérivé lithié ainsi formé a été condensé avec la benzophénone et la cyclohexanone (6) ou encore la méthylvinyl cétone (7) et a fourni les β-hydroxylactames correspondants. Cependant, nous n'avons pas relevé d'étude générale concernant la préparation de β-hydroxyamides *N,N*-disubstitués.

Nous avons réalisé la métallation des amides *N,N*-disubstitués selon le mode opératoire déjà décrit (1). Le carbanion se forme aisément sous l'action des amidures "activés" que l'amide soit linéaire, ramifié ou cyclique. Le dérivé carbonylé est introduit à basse température (−40 à −60 °C), le milieu, initialement violet foncé, se décolore vers la fin de l'addition [1].



Le tableau 1 résume quelques essais effectués avec les aldéhydes. Les rendements sont satisfaisants, quel que soit l'encombrement de l'amide.

Le *N*-méthyl *N*-phényl butyramide fournit l'hydroxyamide attendu (essai 6). Nous n'obser-

TABLEAU 1. Hydroxyalkylation de R R^1 $\bar{C}$—$CON(Me)_2$ par les aldéhydes

[a]En produits distillés.
[b]Polyoxyméthylène non dépolymérisé.
[c]Amide *N*-méthyl *N*-phényl.

vons pas de migration N → C du groupe phényle au cours de la métallation. Par contre, une telle migration est observée quand cet amide est traité par le dérivé lithié du *s*-trithiane (5). Le polyoxyméthylène non dépolymérisé est introduit à +20 °C dans la solution d'amide métallé et fournit ainsi des β-hydroxyamides à fonction alcool primaire avec d'excellents rendements (essais 3 et 6).

Le tableau 2 concerne les cétones. Dans les mêmes conditions que les aldéhydes elles se condensent bien dès −60 °C. Une cétone aussi énolisable que la cyclohexanone conduit au β-hydroxyamide attendu avec un très bon rendement (essai 8, 86%). La différence de comportement de cette cétone avec le dérivé lithié du *N*,*N*-diméthyl acétamide selon le procédé de métallation est frappante: le rendement tombe à 4% si l'on emploie le dérivé lithié du *s*-trithiane (5).

Malgré divers essais dans différentes conditions, nous n'avons pas réussi à condenser le dérivé lithié du *N*,*N*-diméthyl isobutyramide avec la benzophénone (essai 13). Nous pensons que l'encombrement de l'amide est responsable de cet échec (différence avec les essais 9, 10 et 11).

II. Synthèse de γ-hydroxyamides N,N-disubstitués: accès aux γ-butyrolactones

La condensation des époxydes sur les divers amides lithiés formés à l'aide des amidures activés constitue une préparation directe de γ-hydroxyamides *N*,*N*-disubstitués. Ces composés sont des précurseurs immédiats de γ-butyrolactones variées. De telles butyrolactones présentant en γ un ou deux groupes alkyle sont transformées par l'acide polyphosphorique en oxo-3 cyclopentènes dont on connaît l'importance dans la synthèse des prostaglandines (8). Quelques γ-hydroxyamides ont été également obtenus par action d'époxydes sur les *N*,*N*-diméthyl acétamide et propionamide préalablement métallés soit à l'aide des amidures usuels (9) soit avec l'amidure de sodium dans l'ammoniac liquide (10). Ces γ-hydroxyamides ont ensuite été cyclisés à l'aide d'une résine acide à reflux d'acétone (11) ou à reflux d'éthylène glycol en présence de bases fortes (9).

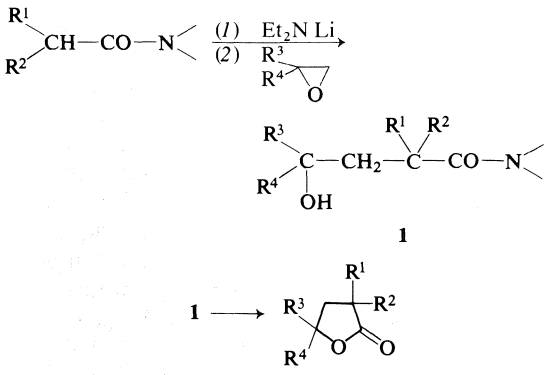
[b]Amide *N,N*-diéthyl.



Au cours de cette étude, nous avons utilisé une grande variété d'époxydes: oxydes d'éthylène, de propylène, de butylène, d'isobutylène, de styrène et de cyclohexène et nous les avons opposés aux dérivés lithiés d'amides linéaires: *N,N*-diméthyl acétamide et propionamide, d'amides ramifiés: *N,N*-diméthyl isobutyramide et isovaléramide ou encore cycliques: *N*-méthyl pyrrolidone.

La réaction a lieu dans des conditions douces, l'introduction de l'époxyde est effectuée entre −30 et +15 °C puis retour à température ambiante. Les produits isolés diffèrent selon l'hydrolyse, neutre ou acide.

(A) Hydrolyse neutre

Les résultats obtenus après hydrolyse neutre du mélange réactionnel sont consignés dans le tableau 3. On constate que les rendements en produits obtenus (*a* + *b*) sont généralement satisfaisants et ne sont pas affectés par l'encombrement de l'époxyde ou de l'amide mais, quelles que soient les conditions mises en œuvre, nous n'avons pu isoler les hydroxyamides purs. Ils sont toujours accompagnés d'une quantité plus ou moins importante de lactone.

Remarques—Quelques essais effectués avec les

34	Hydroxyamide 21				80–90
35	Hydroxyamide 23				80–90

[a]En produits distillés.

amidures "usuels" (Et_2NH + BuLi) ont conduit également à des mélanges (essais 17, 18, 19, 22). L'oxyde de styrène susceptible de réagir avec les anions en α et β a donné lieu à une attaque régio-sélective en β (contrôle rmn, essais 16 et 19).

(B) Hydrolyse acide

Les résultats sont résumés dans le tableau 4. On hydrolyse à 0 °C par HCl 4 *N* le mélange réactionnel et agite 24 h à température ambiante. On isole alors les lactones pures avec de bons rendements (essais 26, 27, 28 et 29). Les mélanges

γ-hydroxyamide + lactone isolés précédemment après hydrolyse neutre, conduisent, en milieu acide, aux lactones pures avec des rendements presque quantitatifs (essais 30 à 35).

Nous avons ainsi mis au point en une seule étape une préparation simple et directe de γ-butyrolactones variées à partir des amides *N,N*-disubstitués linéaires ou ramifiés et d'époxydes divers.

Partie expérimentale

La structure des divers hydroxyamides et lactones a été confirmée par ir et rmn. Les spectres infrarouges ont été effectués sur un spectrophotomètre Perkin-Elmer 457 sous forme de film pour les liquides ou dans le Nujol pour les cristaux. Les spectres rmn ont été enregistrés sur un appareil Perkin-Elmer R 12 à 60 MHz, en utilisant le CCl_4–TMS comme solvant.

La pureté des produits a été contrôlée par chromatographie en phase gazeuse (colonnes SE 30 de 3 m et UCON bas de 3 m) et les produits analysés ont donné des résultats satisfaisants à ±0.25%).

Préparation du diéthylamidure de lithium activé

Dans un tétracol de 250 ml on introduit sous argon 10 ml de HMPT, 10 ml de benzène et 4 g (0.055 mol) de diéthylamine. On ajoute alors 0.055 at-g de lithium martelé, le milieu devient rapidement rouge foncé; la température est maintenue à 20 °C à l'aide d'un bain d'eau. Le lithium disparaît en 2–3 h.

β-*Hydroxyamides*

Métallation et hydroxyalkylation du N,N-diméthylacétamide

Le diéthylamidure de lithium dilué de 10 ml d'éther ou de THF pour éviter la prise en masse est refroidi à −60 °C. On introduit 0.055 mol d'amide dilué d'un égal volume d'éther ou de THF. Le milieu devient rapidement violet, on laisse revenir la température à −50 °C pendant 30 min. Le composé carbonylé (0.055 mol) dilué dans 80 ml de THF est introduit à −60 °C. On observe une décoloration rapide de la solution qui devient jaune. On laisse revenir à température ambiante toute la nuit et hydrolyse. Après extraction à l'éther, la couche organique est séchée sur sulfate de magnésium, on chasse sous vide les solvants, puis on distille sous pression réduite le résidu.

Métallation et hydroxyalkylation des amides linéaires, ramifiés ou cycliques

On opère comme précédemment en introduisant l'amide à −20 °C puis la température est ramenée progressivement à +15 °C pendant 1½ h. On introduit alors le dérivé antagoniste. Les températures d'addition et la durée de la réaction seront données pour chaque cas.

Purification

La distillation ne permet pas toujours de séparer le HMPT de l'hydroxyamide. La chromatographie sur colonne d'alumine fournit un produit pur. L'élution se fait à l'aide de solutions hexane–éther (20:80 puis 50:50) et pour finir à l'éther pur. Le HMPT reste fixé sur la colonne.

Les amides de départ ont été obtenus par action du chlorure d'acide sur la diméthylamine, la diéthylamine ou la *N*-méthylaniline anhydres. Le *N*-triméthylsilyl caprolactame a été préparé par action de l'hydrure de sodium en milieu THF sur le caprolactame, suivie d'une alkylation par le triméthylchlorosilane.

Nous remercions vivement la Société Bayer Chemie qui nous a aimablement fourni les oxydes de butylène et d'isobutylène.

γ-Hydroxyamides

Condensation des époxydes sur le N,N-diméthylacétamide lithié

A l'époxyde à −30 °C (0.055 mol dans 80 ml de THF) on ajoute, goutte à goutte, le carbanion (0.050 mol refroidi à −50 °C). La solution jaune-orange revient à température ambiante en 1½ h et on agite toute la nuit, après hydrolyse on traite comme décrit précédemment.

Amides linéaires, ramifiés ou cycliques

L'amide lithié (0.050 mol à +15 °C) est introduit sur l'époxyde (0.055 mol dans 80 ml de THF) à −30 °C. Dans le cas de l'oxyde de cyclohexène, l'amide lithié est introduit à température ambiante.

Préparation de l'amidure usuel

Une solution de butyllithium dans l'éther (0.055 mol) est ajoutée goutte à goutte à −10 °C à une solution de diéthylamine (0.060 mol dans 30 ml de THF). On revient à température ambiante en 30 min.

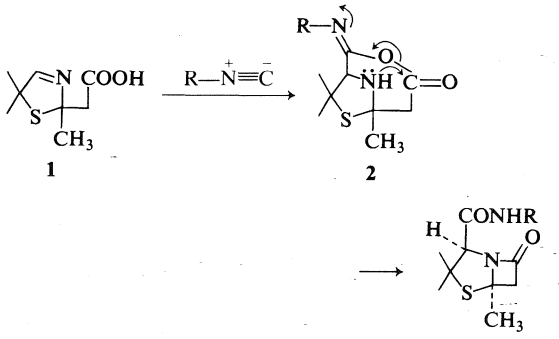
An attempted synthesis of an oxacepham derivative, using isonitriles as β-lactam forming agents, is described. The reasons for the failure of this approach are discussed.

G. JUST, B. Y. CHUNG et K. GRÖZINGER. Can. J. Chem. **55**, 274 (1977).

On décrit un essai de synthèse d'un dérivé oxacéphame où on utilise des isonitriles comme agents formateurs de β-lactames. On décrit les raisons pour l'échec de cette approche.

[Traduit par le journal]

In 1962, Ugi and Wischöffer reported (1) the synthesis of a penam derivative **3** using the reaction of thiazoline **1** with an isonitrile.



SCHEME 1

This approach to penicillins was not used any further (see, however ref. 2) because of the wrong stereochemistry of the carboxamide group introduced in **3**. We decided to use an analogous procedure to prepare oxacephams **5** and **6** (X = O) in which the stereochemical problem is resolved by the eventual introduction of a double bond.

The main features of the proposed procedure are outlined in Scheme 2.

From previous experience (3, 4) we knew that the hydrolysis of a methyl ester in **4***a* (R = CH_3) was difficult, leading to the decomposition of the ring system. It was therefore obvious that the ring system of type **4** (R = H) could only be built if R were a group removable by non-hydrolytic methods.

We focused our attention on the synthesis of **4** where R = *p*-methoxybenzyl, benzyl, and trichloroethyl, and where -N- was benzamido or phthaloyl. The latter amine-blocking group was chosen because of the crystallinity of many phthalimide containing compounds, and because benzamide esters gave azlactones with considerable ease under relatively mild conditions.

p-Methoxybenzyl 2-benzamido-3-hydroxy acrylate **9** was prepared by condensation of 4-hydroxymethylene-2-phenyl-5-oxazolone **7** (5) with *p*-methoxybenzyl alcohol, and converted to its sodium salt **9***a* with sodium ethoxide in ethanol.

Condensation of the thiazolidine mesylate **10** (6) with the sodium salt **9***a* in 2-butanone at 80 °C gave a 95% yield of the thiazolidine ester **11**. Hydrolysis of the aldehyde protecting group was carried out using mercuric chloride in aqueous tetrahydrofuran. Treatment of the

SCHEME 3

aldehyde ester **12** with ammonia in tetrahydrofuran gave imine ester **14**, which was purified by column chromatography using ether as eluent. The imine ester **14**, mp 114–117 °C, was eluted first followed by a second fraction, which was identified as the reaction product **15** of ethanol with the imine ester **14**. The pmr spectrum of **15** showed a triplet at δ 1.20 ppm coupled with a methylene group at δ 3.32 ppm (J = 7 Hz), indicating the presence of an ethyl group. An exchangeable triplet at 2.80 ppm, coupled with a methylene group at δ 3.67 ppm (J = 6 Hz) confirmed the presence of a hydroxymethylene group. Furthermore, there were 11 protons downfield, with one representing a CH=N group. The rest of the spectrum was similar to that of the required product, the imine ester **14**. The mass spectrum of **15** showed the

molecular ion peak at *m/e* 514. The base peak at *m/e* 499 represented the loss of a methyl group.

The origin of the ethanol was traced back to the solvent which was used for chromatography. That in fact the imine is very reactive toward alcohol was demonstrated by reacting **14** with 1 equiv. of methanol in tetrahydrofuran; an almost quantitative yield of **15***a* was isolated. The above results excluded all alcohols for the hydrogenolysis of the imine ester **14** and also demonstrated the sensitivity of this compound. Furthermore, stability tests on **14** in solvents such as dioxane, ethyl acetate, and chloroform indicated that the imine ester was not stable long enough to permit hydrogenolysis of the ester group.

In a parallel series, we prepared the analogous compound **14***b*. Phthaloylglycine benzyl ester **8** was formylated with benzyl formate and sodium benzyloxide in refluxing toluene to benzyl 2-phthalimido-3-hydroxy acrylate **9***d* (7) and its sodium salt **9***e* was prepared by treatment of **9***d* with sodium ethoxide. Condensation of the thiazolidine mesylate **10** with **9***e* gave **11***c* in 89% yield. Hydrolysis of the thiazolidine group and treatment of the resulting aldehyde **12***c* with ammonia in ether gave crystalline carbinolamine **13**, mp 108–110 °C, in 40% yield. Proton magnetic resonance studies in DMSO-d_6 of the carbinolamine **13** showed that immediately after dissolving and deuterium exchange, *CH*—OD absorbed at δ 4.28 ppm and ND—*CH*—O showed as a doublet at δ 5.43 ppm. After 20 h, the *CH*=N absorption appeared at δ 7.72 ppm, and H_b resonated downfield at δ 5.68 ppm as a double doublet, coupled with H_c ($J_{b,c}$ = 3 Hz), indicating that elimination of water took place to form the imine **14***b*. Mild hydrogenolysis of **14***b* with palladium on charcoal at atmospheric pressure in ethyl acetate at 20 °C gave the decarboxylated product **16**, mp 151–153 °C, in 50% yield.

The pmr spectrum was consistent with the proposed structure **16**. The two protons, H_a and H_c, which had appeared at δ 7.72 and 4.97 ppm respectively in the imine ester **14***b*, disappeared. Eight protons appeared as multiplets at δ 2.98–4.05 ppm and one exchangeable proton at 1.90 ppm. Also, a double doublet at δ 4.35 ppm was assigned to the N—*CH*—O proton.

The mass spectrum of the product showed a molecular ion ($M^+ + 1 = 333$) and a base peak at *m/e* 317, indicating cleavage of the methyl group of the acetonide, which is an important fragmentation process.

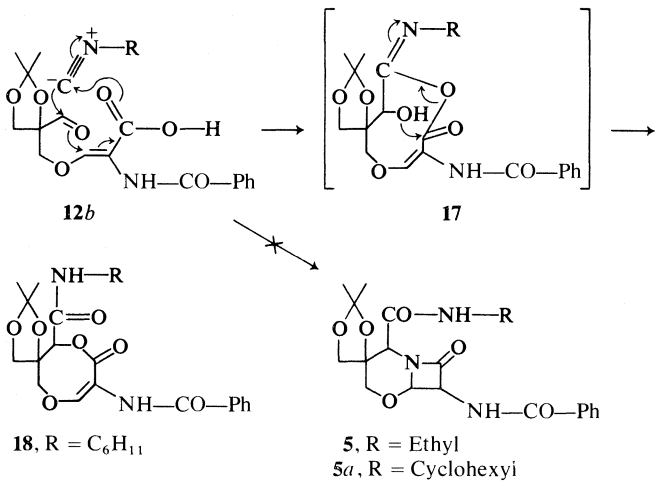
It is known that β-imino acids of type **14** are easily decarboxylated, and there is some experimental evidence (1; 5, p. 759) that similar imine acids lost carbon dioxide even on standing at room temperature. We concluded, on the basis of the spectral data of **16**, that the hydrogenolysis produced the desired imine acid, but that the C=N bond was reduced equally rapidly. Further studies using different catalysts gave essentially the same results, and it was not possible to hydrogenolyze the benzyl esters without reducing the C=N bond. Since we were unable to hydrogenolyze the imine esters **14** or **14***b* to the imine acid **4**, we turned to the use of the 2,2,2-trichloroethyl ester as the acid protecting group.

Treatment of 4-hydroxymethylene-5-oxazolone **7** (5) with 2,2,2-trichloroethanol gave **9***b*, mp 87–88 °C. The sodium salt **9***c* was prepared by treatment of **9***b* with sodium ethoxide in ethanol. Condensation of the thiazolidine mesylate **10** with the sodium salt of the benzamide acrylate **9***c* gave **11***a*, mp 126–128 °C, in 68% yield. Treatment of the thiazolidine ester **11***a* with zinc dust in 90% aqueous acetic acid afforded the thiazolidine acid **11***b*, mp 159–160 °C, in 53% yield. The aldehyde protecting group was removed by treatment of **11***b* with mercuric chloride in aqueous tetrahydrofuran, yielding **12***b* in 93% yield.

However, the aldehyde acid **12***b*, which was initially soluble in ether, decomposed on standing at room temperature within 30 min, and the resulting product was insoluble in ether. The pmr spectrum immediately after dissolving of the aldehyde acid showed the required protons. However, after some time, a broad pmr spectrum was obtained.

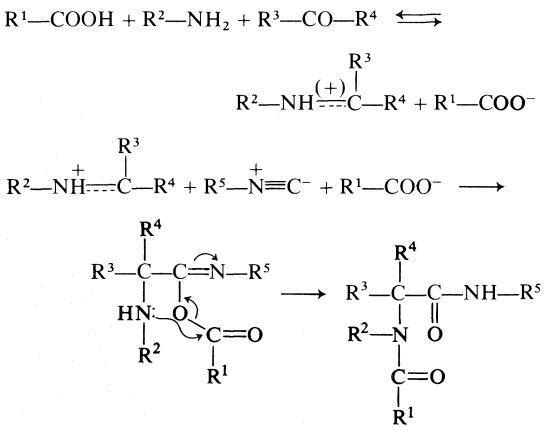
Since the above results showed that the aldehyde acid **12***b* was unstable, we attempted a four component condensation using the aldehyde acid **12***b* *in situ*. It is known (8) that ammonia, primary and secondary amines, as well as hydrazine derivatives can be used as the amine component in the Ugi reaction.

The combination of ammonia or primary amines and aldehydes or ketones reacts with carboxylic acids and isonitriles to form the intermediate α-adducts. These undergo O → N



SCHEME 4

acyl transfer by a cyclic mechanism yielding α-acylaminocarbonamides. The formation of the two carbonamide groups in the final product provides the reaction with a strong driving force (see arrows, Scheme 5). In our example, the aldehyde acid **12***b* functions simultaneously as the aldehyde and acid component. Furthermore the reaction with the isonitrile takes place in the aqueous phase (1, 8) and "under dilute conditions", otherwise the formation of resins predominates. Ammonium hydroxide (0.9 equiv.) and cyclohexyl isonitrile (0.9 equiv.) and phosphate buffer (p*H* 6) were added to freshly prepared aldehyde acid **12***b* in petroleum ether. The two-phase system was vigorously stirred for 24 h. After work-up, the mixture was purified by chromatography and the major fraction recrystallized from ether. The product

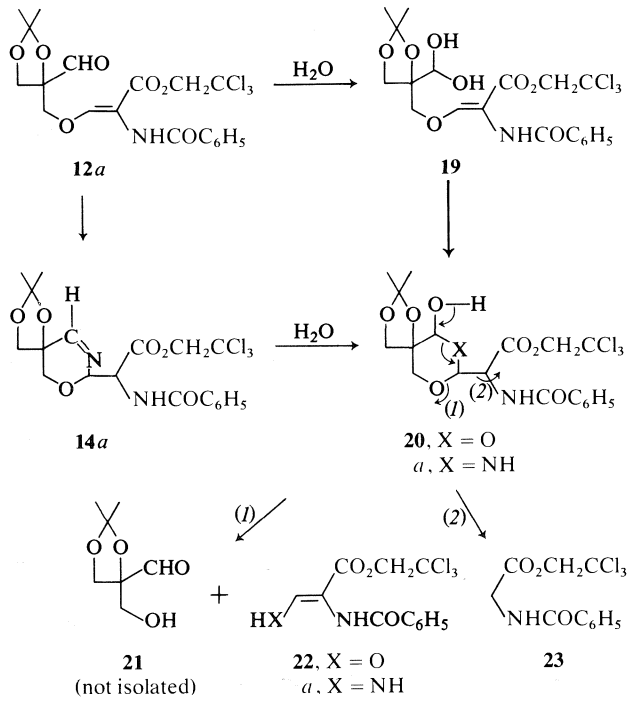


SCHEME 5

showed an absorption at 1730 cm^{-1}, and the mass spectrum showed an ($M^+ + 1$) at *m/e* 458, the cleavage of the methyl group at *m/e* 443, and the loss of acetone at *m/e* 400. The rest of the fragmentation was characteristic for the required product. Although the pmr spectrum was consistent with structure **5** ($C_{24}H_{31}N_3O_6$) microanalysis pointed to $C_{24}H_{30}N_2O_7$, indicating that the isonitrile reacted with the aldehyde in a Passerini-like reaction to give **18**. The ir absorption at 1730 cm^{-1} could now be explained as an α,β-unsaturated lactone and the peak at *m/e* 458 as the molecular ion peak. All other spectral data were consistent with the structure proposed.

Because of the instability of the imine acid **4**, and aldehyde acid **12***b*, we developed a mild method for cleaving the 2,2,2-trichloroethyl esters, involving stirring a tetrahydrofuran solution of the ester with zinc and a 1 *M* phosphate buffer solution for 10 min (9). Using this method the hydrolysis of the 2,2,2-trichloroethyl ester **11***a* could be accomplished smoothly and thiazolidine acid **11***b*, mp 159–160 °C, was obtained within 5 min. It was identical to the acid obtained with zinc – acetic acid.

We then prepared the imine trichloroethyl ester **14***a*. Hydrolysis of the thiazolidine trichloroethyl ester **11***a* with mercuric chloride in aqueous tetrahydrofuran for 5 min gave the aldehyde ester **12***a* in a partially hydrated form. Treatment of **12***a* with ammonia in ether gave the ester **14***a*, mp 157–159 °C, in 66% yield.



SCHEME 6

Thin layer chromatography of the mother liquors of crystallization indicated the presence of two by-products. These were separated by column chromatography and identified as the acrylate ester **22** and hippuric acid 2,2,2-trichloroethyl ester **23**. Their formation was explained in the following manner: the hydrated aldehyde **19** reacted via the dioxane **20** to give the two products as outlined in Scheme 6.

Since the imine acid **4** was expected to undergo decarboxylation readily, the hydrolysis step and the Ugi reaction were superimposed, without isolation of the intermediate **4**.

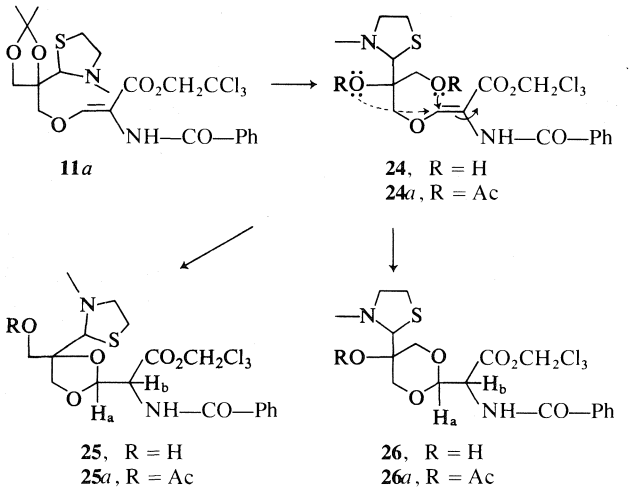
We used cyclohexylisonitrile and phosphate buffer solutions at p*H* 4.5, 6.0, or ammonium acetate at p*H* 7.0, which removed the 2,2,2-trichloroethyl ester group in all models studied (9) and subjected the reaction product to the action of isonitriles. Under these reaction conditions, we found no trace of the oxacephalosporin derivative **5** neither by mass spectroscopy (*m/e* 457), nor by infrared spectroscopy (ν 1750–1780 cm^{-1}).

Similar results were obtained when the hydrolysis of the ester group was carried out in the presence of isonitrile.

The failure of these approaches was attributed to the reactivity of the imine esters **14** with water. Stability tests showed that treatment of the imine ester **14***a* with aqueous tetrahydrofuran, using similar conditions to those which are used for the hydrolysis of the ester and subsequent Ugi reaction, resulted in the formation of 2,2,2-trichloroethyl hippurate and 2-benzamido-3-amino acrylate **22** (the latter identified by nmr only).

We believed a possible reason for the instability of the imine acid could be the presence of the spiro moiety. Consequently, our next approach consisted of the removal of the isopropylidene group by 80% trifluoroacetic acid, followed by acetylation with pyridine and acetic anhydride. A crystalline monoacetate, mp 121–122 °C was obtained.

The pmr of the obtained product was different from the expected one **24***a*. Although the isopropylidene group was no longer present, the spectrum showed only one acetyl group at δ 1.85 ppm. Furthermore, the olefinic proton at δ 7.66 ppm was not present. Two protons, H_a, doublet at δ 5.55 ppm ($J_{a,b}$ = 2.5 Hz) and H_b, dd at δ 5.16 ppm ($J_{a,b}$ = 2.5 Hz and $J_{b,NH}$ = 8 Hz) appeared, indicating that one of the hydroxyl groups reacted with the carbon double



SCHEME 7

bond to form a five- or six-membered ring structure, **25** or **26**. The spectral data did not permit differentiation between these structures. From this result, it is evident that the intermedial diol could have structures **24**, **25**, or **26**.

In summary, the failure of these approaches can be attributed to four factors, all of which became evident as a result of the above studies: (*1*) reaction of the imine esters **14** with water, (*2*) isomerisation of the imine acid **4**, followed by decarboxylation and (*3*) polymerization of the imine acid **4** with isonitrile during the Ugi reaction, (*4*) non-participation of ammonia in the Ugi reaction. Consequently, this scheme had to be abandoned in its present form.

Experimental

Melting points were determined on an Electrothermal block and are corrected.

Mass spectra were obtained on an AEI-MS-902 mass spectrometer at 70 eV using a direct insertion probe. Proton magnetic resonance spectra were recorded on a Varian T-60 spectrometer, using tetramethylsilane as an internal standard. Doublets, triplets, and quartets in the pmr spectral data were recorded as the center of the peaks and multiplets as their range of absorption. Infrared spectra were obtained on a Perkin-Elmer 267B infrared spectrophotometer.

Microanalyses were carried out by Micro-Tech. Laboratories Inc. and C. Daessle, Montreal.

p-Methoxybenzyl 2-Benzamido-3-hydroxy Acrylate ***9***

4-Hydroxymethylene-2-phenyl-5-oxazolone (5) **7** (18.9 g, 0.1 mol) was suspended in benzene (400 ml) and *p*-methoxybenzyl alcohol (15.2 g, 0.11 mol) was added. The mixture was refluxed for 16 h, evaporated, and the residue recrystallized from benzene – petroleum ether. Yield 24.2 g (74%); mp 101–102 °C; pmr ($CDCl_3$): δ 3.82 (s, 3H, OCH_3), 5.20 (s, 2H, O—CH_2), 7.15 (q, 4H, *p*-substituted phenyl), 7.4–8.0 (m, 6H, phenyl, CH=C), 8.50, (s, 1H, NHCO), 12.32 ppm (d, J = 12 Hz, 1H, OH); ir (KBr): 3335 (OH), 1688, 1650, 1600, 1540, 1510, 1388 cm^{-1}; ms (70 eV): *m/e* 327 (M^+), 310 (M^+ − OH). *Anal.* calcd. for $C_{18}H_{17}NO_5$ (327.3): C 66.05, H 5.24, N 4.28; found: C 66.10, H 5.33, N 4.25.

p-Methoxybenzyl 2-Benzamido-3-hydroxy Acrylate Sodium Salt ***9a***

p-Methoxybenzyl 2-benzamido-3-hydroxy acrylate **9** (23 g, 0.07 mol), was suspended in ethanol (200 ml) and an ethanolic solution of sodium ethoxide (1.55 g, 0.075 mol of sodium) was added with vigorous stirring. The suspension dissolved immediately and the sodium salt precipitated. Ethyl ether (200 ml) was added and the white salt collected by filtration, washed with ether, and dried *in vacuo*. Yield 22 g (90%); mp 225–226 °C; ir (KBr): 3400, 3200, 1635, 1600, 1555, 1515, 1485, 1460, 1400, 1358, 1310 cm^{-1}; ms (70 eV): *m/e* 349 (M^+), 300, 243, and 228 ($M^+ - CH_2 - p$-$OMeC_6H_4$). *Anal.* calcd. for $C_{18}H_{16}NO_5Na$ (349.33): C 61.88, H 4.61, N 4.00; found: C 61.46, H 4.54, N 4.11.

p-Methoxybenzyl 2-Benzamido-3-(((2′,2′-dimethyl-4′-(3′′-methylthiazolidine-2′′-yl)-1′,3′-dioxolan 4-yl)-methyl)oxy) Acrylate ***11***

The sodium salt **9a** (22 g, 0.063 mol) was suspended in a solution of the thiazolidine mesylate **10** (12 g, 0.0386 mol) in 2-butanone (300 ml) and the mixture refluxed for 16 h. The salt was filtered off and the filtrate evaporated *in vacuo*. The residue was chromatographed on a silica gel column, eluted with chloroform–methanol (98:2). Evaporation of the solvent gave a colorless oil. Yield 20 g (95%); pmr ($CDCl_3$): δ 1.35, 1.42 (each s, 6H acetonide), 2.28, 2.38 (each s, 3H, N—CH_3), 2.8–3.1 (m, 4H, N—CH_2—CH_2—S), 3.80 (s, 3H, OCH_3), 3.8–4.2 (m, 4H, 2CH_2—O), 4.39, 4.49 (each s, 1H, N—CH—S), 5.18 (2H, CH_2), 7.20 (q, 4H, *p*-methoxyphenyl), 7.29–7.92, ppm (m, 7H, phenyl, NH, C=CH); ir ($CHCl_3$): 3420 (NH), 2980 (CH), 1670 (ester), 1368, 1378 cm^{-1} (*gem*-dimethyl). *Anal.* calcd. for

$C_{28}H_{34}N_2O_7S\cdot\frac{1}{2}H_2O$: C 60.96, H 6.39, N 5.07, S 5.81, found: C 60.59, H 6.14, N 4.95, S 6.05.

p-Methoxybenzyl 2-Benzamido-3-((4′-formyl-2′,2′-dimethyl-1′,3′-dioxolan-4′-yl)methoxy) Acrylate **12**

The thiazolidine ester **11** (20 g, 0.037 mol) was dissolved in acetonitrile (240 ml) and water (60 ml). Mercuric chloride (12 g, 0.0445 mol) was added to this solution. The milky suspension that immediately formed was refluxed for 30 min. The fine precipitate was filtered and the filtrate evaporated. The residue was extracted twice with methylene chloride; the extracts were washed with dilute hydrochloric acid and water and dried. After evaporation of the solvent, the residue was passed through a silica gel column using ether as eluent. Yield 14.6 g (84%), oily residue; pmr ($CDCl_3$): δ 1.38, 1.40 (each s, 6H, acetonide), 3.80 (s, 3H, OCH_3), 3.95–4.30 (m, 2H), 4.10, 4.21 (each s, 2H), 5.15 (s, 2H, CH_2—O), 7.10 (q, 4H, *p*-OCH_3—phenyl), 7.3–7.9 (m, 7H, phenyl, C═CH, NH), 9.70 ppm (s, 1H, CHO); ir ($CHCl_3$): 3410 (NH), 2980 (CH_2), 1700 (ester), 1670 (CO), 1608 (phenyl), 1370 cm^{-1} (*gem*-dimethyl); ms (70 eV): *m/e* 469 (M^+). *Anal.* calcd. for $C_{25}H_{27}NO_8\cdot H_2O$: C 61.59, H 6.00, N 2.87; found: C 60.99, H 5.99, N 2.91.

α-Benzamido-2,2-dimethyl-1,3,7-trioxa-9-azaspiro[4.5]-dec-9-ene-8-acetic Acid p-Methoxybenzyl Ester **14** *and By-product* **15**

The aldehyde ester **12** (14 g, 0.03 mol) was dissolved in dry tetrahydrofuran (75 ml) and 1.1 equiv. of gaseous ammonia in tetrahydrofuran were added. The mixture was kept at room temperature overnight, and then evaporated *in vacuo*. The residue was chromatographed on a silica gel column using ether as eluent.

The first product eluted was crystallized from ether–petroleum ether and its spectral data indicated it to be the required product **14**. Yield 3.0 g (22%); mp 114–117 °C; pmr ($CDCl_3$): δ 1.40 (s, 6H, acetonide), 3.62, 3.75 (each s, 2H, CH_2O), 3.80 (s, 3H, OCH_3), 3.92–4.10 (m, 2H, OCH_2), 5.18 (s, 2H, CH_2—O), 5.3–5.5 (m, 2H), 6.95 (s, 1H, NH), 7.10 (q, 4H, *p*-methoxyphenyl), 7.4–7.9 ppm (m, 6H, phenyl, C═CH); ir (KBr): 3408 (NH), 2983, 2937, 2865 (CH), 1745 (ester), 1659 (amide), 1611 (phenyl), 1578, 1514, 1484, 1379, 1372 cm^{-1}; ms (70 eV) *m/e*: 468 (M^+), 453 ($M^+ - CH_3$), 410 ($M^+ - (CH_3)_2CO$), 347 ($M^+ - CH_2$ – *p*′-methoxyphenyl), 303 ($M^+ - COOCH_2$ – *p*-methoxyphenyl). *Anal.* calcd. for $C_{25}H_{28}N_2O_7\cdot\frac{1}{2}H_2O$: C 62.88, H 6.12, N 5.86; found: C 62.38, H 6.12, N 5.42. The second fraction eluted gave **15** as a colorless oil. Yield 2.3 g (15%); pmr ($CDCl_3$): δ 1.20 (t, J = 7 Hz, 3H, CH_3—CH_2), 1.28 (s, 6H, acetonide), 2.80 (t, J = 6 Hz, 1H, OH), 3.32 (q, J = 7 Hz, 2H, CH_2—CH_3), 3.67 (d, J = 6 Hz, 2H, CH_2—OH), 3.77 (s, 3H, OCH_3), 3.6–3.8 (m, 1H, CH—N═), 4.00 (d, 2H, CH_2O), 4.48 (d, J = 9 Hz, 1H, N—CH—CO), 5.12 (s, 2H, CH_2—phenyl), 6.7–8.0 ppm (m, 11H, phenyl, *p*-methoxyphenyl, NH, N═CH); ir ($CHCl_3$): 3390 (OH), 2970 (CH_2), 1650 (ester, amide) 1370/1380 cm^{-1} (*gem*-dimethyl); uv (EtOH): max 231, 279 nm; ms (70 eV): *m/e* 514 (M^+), 499 ($M^+ - CH_3$), 484 ($M^+ - CH_2$═O), 469 ($M^+ - OEt$), 468 ($M^+ - EtOH$). *Anal.* calcd. for $C_{27}H_{34}N_2O_8$: C 63.02, H 6.66, N 5.44; found: C 62.92, H 6.68, N 5.32.

Treatment of α-Benzamide-2,2-dimethyl-1,3,7-trioxa-9-azaspiro[4.5]dec-9-ene-8-acetic Acid p-Methoxybenzyl Ester with Methanol **15***a*

An excess of methanol (1 ml) was added to a solution of the imine-*p*-methoxybenzyl ester **14** (468 mg, 1 mmol), in 50 ml of tetrahydrofuran. The reaction mixture was stirred at room temperature for 3 h. Evaporation of the solvent and purification by chromatography on silicic acid using ether as eluent gave 422 mg (84%) of **15***a*; pmr ($CDCl_3$): δ 1.37 (s, 6H, acetonide), 2.42 (t, J = 6 Hz, 1H, OH), 3.42 (s, 3H, OCH_3) 3.70 (d, J = 6 Hz, 2H, CH_2O), 3.80 (s, 3H, OCH_3), 3.7–3.9 (m, 1H, C—CHNH), 4.00 (m, 2H, OCH_2), 4.35 (d, 1H, N—CH—NH), 5.14 (s, 2H, CH_2—*p*-methoxy), 6.8–8.0 ppm (m, 11H, phenyl, *p*-methoxyphenyl, NH); ir ($CHCl_3$): 3390 (OH), 2970 (CH_2), 1650 (ester, amide, C═N), 1370, 1380 cm^{-1} (*gem*-dimethyl); uv (EtOH): max 231, 279 nm; ms (70 eV): *m/e* 500 (M^+), 485 ($M^+ - CH_3$), 468 ($M^+ - CH_3OH$). *Anal.* calcd. for $C_{26}H_{32}N_2O_8\cdot\frac{1}{2}H_2O$: C 61.28, H 6.52, N 5.49; found: C 61.50, H 6.44, N 5.52.

Benzyl 2-Phthalimido-3-(((2′,2′-dimethyl-4′-(3′′-methylthiazolidine-2′′-yl)-1′,3′-dioxolan-4′-yl)methyl)oxy) Acrylate **11***c*

The sodium salt **9***e* (13 g, 0.038 mol) was suspended in a solution of the thiazolidine mesylate **10** (7.8 g, 0.025 mol) in 2-butanone (300 ml) and the mixture refluxed for 16 h. The salt was filtered off and the filtrate evaporated *in vacuo*. The residue was chromatographed on a silica gel column using chloroform–methanol (98:2) as eluent. Evaporation of the solvent gave white crystals. Yield 12.0 g (89%); mp 143–145 °C; pmr ($CDCl_3$): δ 1.28, 1.37 (each s, 6H, acetonide), 2.25, 2.35 (each s, 3H, N—CH_3), 2.8–3.12 (m, 4H, N—CH_2—CH_2—S), 3.6–4.37 (m, 5H, two OCH_2 and N—CH—S), 5.1 (s, 2H, CH_2), 7.23 (s, 5H, CH_2—C_6H_5), 7.52–8.0 ppm (m, 5H, phthalimido and C═CH); ir (KBr): 1785/1725 (phthalamido), 1700 (ester), 1658 (C═C), 1465, 1450, 1442, 1380, 1367 cm^{-1}; ms (70 eV): *m/e* 538 (M^+). *Anal.* calcd. for $C_{28}H_{30}N_2O_7S$: C 62.44, H 5.62, N 5.20, S 5.94; found: C 62.59, H 5.51, N 5.40, S 6.02.

Benzyl 2-Phthalimido-3-(((4′-formyl-2′,2′-dimethyl-1′,3′-dioxolan-4′-yl)methyl)oxy) Acrylate **12***c*

The thiazolidine ester **11***c* (8.6 g, 0.016 mol) was dissolved in tetrahydrofuran–water (4:1) (100 ml) and mercuric chloride (1.2 g) was added. The milky suspension that formed immediately was stirred at room temperature for 1 h. The fine suspension was filtered off and the filtrate evaporated. The residue was extracted three times with benzene and the combined extracts were washed with dilute hydrochloric acid and water, and dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. The crude product was passed through a silica gel column using methylene chloride–ether (9:1) as eluent. Evaporation of the solvent gave a white foamy solid. Yield, 6.7 g (90%); pmr ($CDCl_3$): δ 1.38 (s, 6H, acetonide), 3.9–4.0 (m, 2H, OCH_2), 4.20 (m, 2H, OCH_2), 5.10 (s, 2H, CH_2—C_6H_5), 7.34 (s, 5H, phenyl), 7.6–8.1 (m, 5H, phthalimido, C═CH), 9.73 ppm (s, 1H, CHO); ir (KBr): 3480, 3072–2900, 1800/1735 (phthalimido), 1735 (ester), 1720 (aldehyde), 1665 (amide and C═C), 1430, 1395, 1382, 1290, 1100 cm^{-1};

ms (70 eV): *m/e* 465 (M^+). *Anal.* calcd. for $C_{25}H_{23}NO_8$: C 64.51, H 4.98, N 3.01; found: C 64.34, H 5.01, N 3.25.

α-Phthalamido-2,2-dimethyl-10-hydroxy-1,3,7-trioxa-9-azaspiro[4.5]decane-8-acetic Acid Benzyl Ester ***13*** *and Imine* ***14b***

The aldehyde ester **12***c* (6.0 g, 0.013 mol) was dissolved in benzene (50 ml) and refluxed for 30 min using a Dean Stark trap. The solvent was concentrated and the residue dissolved in anhydrous ether (50 ml). Ammonia was passed through the clear solution for 5 min at room temperature. It was then kept overnight. White crystals **13** were collected by filtration. Yield 2.5 g (40%); mp 108–110 °C; pmr (DMSO-d_6): δ 1.34 (s, 6H, acetonide), 3.33–4.00 (m, 5H, two OCH_2, OH), 4.28 (br s, 1H, C*H*—NH), 4.95–5.40 (m, 2H, CH—CH), 5.17 (s, 2H, CH_2—phenyl), 5.95 (d, 1H, J = 4 Hz, NH), 7.28 (s, 5H, phenyl), 7.88 ppm (s, 4H, phthalimido); ir (KBr): 3450, 3330, 3270 (NH, OH), 1780, 1720 (phthalimido), 1740 (ester), 1470, 1450, 1380 cm^{-1}; ms (70 eV): *m/e* 464 ($M^+ - H_2O$), 449 (464 − CH_3), 421 (449 − CO), 406 (421 − CH_3/or 464 $(CH_3)_2CO$). *Anal.* calcd. for $C_{25}H_{26}N_2O_8$ (482.5): C 62.23, H 5.43, N 5.80; found: C 62.44, H 5.45, N 5.81.

The filtrate was chromatographed on a silica gel column using methylene chloride – ether (95:5) as eluent. Evaporation of the major product gave a colorless oil, identified as the imine **14***b*. Yield, 2.0 g (33%); pmr ($CDCl_3$): δ 1.40, (s, 6H, acetonide), 3.4–4.3 (m, 4H, two OCH_2), 4.97 (d, 1H, N—CH—COO), 5.21 (s, 2H, CH_2—phenyl), 5.70 (dd, 1H, N—CH—O), 7.30 (s, 5H, phenyl), 7.6–8.0 ppm (m, 5H, phthalimido and N=CH); ir (KBr): 3500, 2995–2880, 1800, 1730 (phthalimido), 1760 (ester), 1660 (amide and C=N); ms (70 eV): *m/e* 464 (M^+). *Anal.* calcd. for $C_{25}H_{24}N_2O_7$: C 64.65, H 5.21, N 6.03; found: C 64.43, H 5.31, N 6.18.

2,2-Dimethyl-8-phthalimidomethyl-1,3,7-trioxa-9-azaspiro[4.5]decane ***16***

The carbinolamine ester **13** (482 mg, 1 mmol) or **14***b* (464 mg, 1 mmol), was suspended in 25 ml of ethyl acetate and added to 240 mg of palladium on charcoal (10%) in 25 ml of ethyl acetate, previously prehydrogenated with hydrogen. The mixture was hydrogenated at atmospheric pressure, until 24 ml of hydrogen were consumed (6 h). The catalyst was filtered off and the filtrate evaporated to dryness. Addition of ether gave white crystals, recrystallized once from ethyl acetate – ether. Yield 191 mg (50%); mp 151–153 °C; pmr ($CDCl_3$): δ 1.37 (s, 5H, acetonide), 1.90 (br s, 1H, NH), 2.98 (s, 2H, CH_2), 3.45–3.90 (m, 4H, two CH_2), 4.05 (d, 2H, CH_2O), 4.35 (dd, 1H, N—CH—O), 7.6–8.0 ppm (m, 4H, phthalimido); ir (KBr): 3200 (NH), 2980–2860 (CH), 1770, 1705 (phthalimido, amide), 1610 (phenyl), 1460, 1430, 1400 cm^{-1}; ms (70 eV): *m/e* 333 ($M^+ + 1$), 317 ($M^+ - CH_3$). *Anal.* calcd. for $C_{17}H_{20}N_2O_5$: C 61.43, H 6.07, N 8.43; found: C 61.67, H 6.04, N 8.19.

2,2,2-Trichloroethyl 2-Benzamido-3-hydroxy Acrylate ***9b***

4-Hydroxymethylene-2-phenyl-5-oxazolone **7** (5) (69.3 g, 0.365 mol) was suspended in dry benzene (3.5 l) and 2,2,2-trichloroethanol (109 g, 0.73 mol) was added. The suspension was stirred under reflux for 6 h and the clear solution evaporated. The oily residue was triturated with petroleum ether (30–60 °C) and kept overnight in the refrigerator. The red solid was collected by filtration and recrystallized from petroleum ether (60–80 °C). Treatment with charcoal gave pink needles. Yield 95 g, (76.6%); mp 87–88 °C; pmr ($CDCl_3$): δ 4.98 (s, 2H, CH_2—CCl_3), 7.57–8.15 (m, 6H, phenyl and C=CH), 8.6 (br, 1H, NH), 12.7 ppm (br, 1H, OH); ir (KBr): 3380, 1725 (ester), 1665 (amide and C=C), 1615, 1554, 1505, 1463, 1390, 1357, 1325, 1312, 1280, 1268, 1240, 1162, 1115 cm^{-1}. *Anal.* calcd. for $C_{12}H_{10}NO_4Cl_3$: C 42.57, H 2.98, N 4.14, Cl 31.61; found: C 42.83, H 2.74, N 4.27, Cl 31.29.

2,2,2-Trichloroethyl 2-Benzamido-3-hydroxy Acrylate Sodium Salt ***9c***

2,2,2-Trichloroethyl 2-benzamido-3-hydroxy acrylate **9***b* (91 g, 0.27 mol) was added to an ethanolic solution of sodium ethoxide (4.6 g of sodium in 200 ml of ethanol). The mixture was shaken for 10 min and ether (1 litre) added. The precipitated sodium salt was collected by filtration, washed several times with ether, and dried *in vacuo*. Yield 70 g (72%); mp 200–202 °C (dec.); pmr (DMSO-d_6): δ 4.74 (s, 2H, CH_2—CCl_3), 7.3–8.1 (m, 5H, phenyl), 8.42 (s, 1H, NH), 9.12 ppm (s, 1H, C=CH); ir (KBr): 3300 (br, salt), 3070, 2960, 1675, 1640, 1592, 1540, 1500, 1373, 1287, 1160 cm^{-1}. *Anal.* calcd. for $C_{12}H_9NO_4Cl_3Na$: C 39.87, H 2.52, N 3.89, Cl 29.50; found: C 39.90, H 2.63, N 4.13, Cl 29.74.

2,2,2-Trichloroethyl 2-Benzamido-3-(((2′,2′-dimethyl-4′-(3′′-methylthiazolidine-2′′-yl)-1′,3′-dioxolan-4′-yl)-methyl)oxy) Acrylate ***11a***

The sodium salt **9***c* (70 g, 0.195 mol) was suspended in a solution of the thiazolidine mesylate **10** (6) (40 g, 0.130 mol) in dry 2-butanone (1 litre) and the mixture stirred at 80–85 °C (bath temperature) for 12 h. The salt was filtered off and the filtrate evaporated. The red residue was dissolved in ether (50 ml), treated with charcoal, filtered, and evaporated. The yellow oil was further purified by passing through a silica gel column using benzene – ethyl acetate (9:1) as eluent. Evaporation of the solvent gave colorless crystals. On recrystallization from ether, a pure sample was obtained. Yield 48.8 g, (68.5%); mp 126–128 °C; pmr ($CDCl_3$): δ 1.35, 1.46 (each s, 6H, acetonide), 2.37 (s, 3H, N—CH_3), 2.8–3.2 (m, 4H, NCH_2—CH_2—S), 3.93 (q, J = 10 Hz, 2H, OCH_2), 4.24 (s, 2H, OCH_2), 4.46 (s, 1H, NCH—S), 4.84 (s, 2H, CH_2—CCl_3), 7.33–8.0 ppm (m, 7H, phenyl, NH and C=CH); ir (CCl_4): 2990–2800, 1730 (ester), 1698 (amide), 1660 (C=C), 1503, 1480, 1381, 1369, 1210 cm^{-1}; ms (70 eV): *m/e* 554 (M^+). *Anal.* calcd. for $C_{22}H_{27}N_2O_6SCl_3$: C 47.71, H 4.91, N 5.06, S 5.79, Cl 19.20; found: C 47.99, H 5.10, N 5.26, S 5.50, Cl 19.41.

2-Benzamido-3-(((2′,2′-dimethyl-4′-(3′′-methylthiazolidine-2′′-yl)-1′,3′-dioxolan-4′-yl)methyl)oxy) Acrylic Acid ***11b***

Zinc dust (2 g) was added at room temperature to a stirred solution of thiazolidine ester **11***a* (1.0 g, 1.8 mmol) in tetrahydrofuran (10 ml) and a 1*M* potassium dihydro-

gen phosphate solution p*H* 4.2 (2 ml). The acid liberation was followed by tlc (benzene–EtOAc 9:1). After 10 min the mixture was filtered and the tetrahydrofuran was evaporated. The residue was diluted with water (100 ml) and extracted with ether. The organic solution was dried over sodium sulfate, and evaporated *in vacuo* to give 580 mg (74%) of pure thiazolidine acid **11***b*, mp 159–160 °C; pmr ($CDCl_3$): δ 1.40 (s, 6H, acetonide), 2.31, 2.40 (each s, 3H, N—CH_3), 2.90–3.10 (m, 4H, N—CH_2-CH_2—S), 3.65–4.48 (m, 5H, two OCH_2 and N—CH—S), 7.30–7.90 (m, 7H, phenyl, NH and C=CH), 10.23 ppm (s, 1H, COOH); ir (KBr): 3250 (br), 2980, 2940 (CH_2), 1650 (br, amide), 1575, 1510, 1380 cm^{-1}; ms (70 eV): *m/e* 422 (M^+). *Anal.* calcd. for $C_{20}H_{26}N_2O_6S$: C 56.86, H 6.20, N 6.63, S 7.58; found: C 56.75, H 6.42, N 6.45, S 7.79.

2-Benzamido-3-(((4′-formyl-2′,2-dimethyl-1′,3′-dioxolan-4′-yl)methyl)oxy) Acrylic Acid ***12b***

The thiazolidine acid **11***b* (844 mg, 2 mmol), was dissolved in tetrahydrofuran–water (9:1) (10 ml) and mercuric chloride was added. The precipitate that formed immediately was stirred for 30 min. The solid was filtered off and the filtrate was dried over sodium sulfate. Filtration and evaporation of the solvent gave a white solid. Yield 650 mg (93%); mp 55–58 °C (50% hydrated form); pmr ($CDCl_3$): δ 1.43 (s, 6H, acetonide), 3.6–4.2 (m, 4H, two CH_2—O), 5.05 ($\frac{1}{2}$H, 50% hydrated aldehyde), 6.95 (1H, COOH), 7.5–7.9 (m, 7H, phenyl, NH, C=CH), 9.80 ppm ($\frac{1}{2}$H, CH=O); ir ($CHCl_3$): 3410 (OH), 2970, 2870 (CH_2), 1670 (CO), 1600 (phenyl), 1372, 1380 (*gem*-dimethyl); ms (70 eV): 349 (M^+), 334 ($M^+ - CH_3$), 305 ($M^+ - CO_2$), 290 (305 − CH_3), 273 ($M^+ - C_6H_6$), 244 ($M^+ - C_6H_5CO$). Microanalysis was not performed because of instability.

2,2-Dimethyl-9-benzamido-1,3,7,11-tetraoxaspiro[4.7]-dodec-8-ene-10-one-12-carboxycyclohexylamide ***18***

The thiazolidine acid **12***b* (698 mg, 2 mmol), was dissolved in tetrahydrofuran–water (9:1) (10 ml) and mercuric chloride was added. The reaction mixture was stirred at room temperature for 30 min. The solid was filtered off and ammonium hydroxide (1.5 mmol) was added. The p*H* was adjusted to 6.5 by adding phosphate buffer (2 ml). Cyclohexyl isonitrile (655 mg, 6 mmol) was added and the two phases mixed with vigorous stirring for 20 h. The reaction mixture was diluted with water (100 ml) and the aqueous phase extracted with ether. The combined ether extracts were dried over anhydrous sodium sulfate and evaporated *in vacuo*. The residue was washed with petroleum ether to remove the unreacted isonitrile. The residue was purified by chromatography on silica gel using chloroform–methanol (9:1) as eluent, to give 316 mg (36%) of white crystals, mp 254–256 °C; pmr (DMSO-d_6): δ 1.32, 1.40 (each s, 6H, acetonide), 1.0–1.9 (br m, 10H, cyclohexane), 3.20 (s, 1H, CH—N), 4.1–4.4 (m, 4H, two CH_2O), 5.00 (s, 1H, CH—O), 7.45–8.00 ppm (m, 8H, phenyl, 2NH, CH=C); ir (KBr): 3330, 2280 (NH), 2925, 2850 (CH_2), 1732 (lactone), 1637 (amide), 1600 (phenyl), 1370, 1380 cm^{-1} (*gem*-dimethyl); ms (70 eV): 458 (M^+), 443 ($M^+ - CH_3$), 400 ($M^+ - (CH_3)_2CO$). 383 ($M^+ - (CH_3)_2C$  , H transfer), 360 ($M^+ - C_6H_6N$). *Anal.* calcd. for $C_{24}H_{30}N_2O_7$: C 62.87, H 6.60, N 6.11; found: C 62.21, H 6.84, N 5.94.

2,2,2-Trichloroethyl 2-Benzamido-3-(((4′-formyl-2′,2′-dimethyl-1′,3′-dioxolan-4′-yl)methyl)oxy) Acrylate ***12a***

Mercuric chloride (9.7 g, 35 mmol), was added to a solution of the thiazolidine ester **11***a* (19.8 g, 35 mmol), in tetrahydrofuran (200 ml) and water (20 ml); the resulting suspension was stirred for 5 min (tlc benzene – ethyl acetate showed absence of thiazolidine ester). The reaction mixture was filtered and the filtrate evaporated. The residue was chromatographed on silicic acid, first eluted with benzene–ether (9:1), to remove all the mercuric salts, then with benzene–ether (1:1). The main fraction containing the aldehyde ester was concentrated to give a yellowish foamy solid. Yield: 13.5 g, (77%); pmr ($CDCl_3$): δ 1.39, 1.45 (6H, each s, acetonide), 4.10, 4.25 (4H, each s, two CH_2O), 4.80 (2H, s, CH_2CCl_3), 7.2–7.9 (m, 7H, phenyl, NH, C=CH), 9.63 ppm (s, 1H, CHO); ir (KBr): 3340 (br, NH, hydrated form), 1730 (ester, aldehyde), 1650 (amide), 1600 (phenyl), 1380, 3170 cm^{-1} (*gem*-dimethyl); ms (70 eV): *m/e* 481 [M^+, (^{37}Cl)], 479 [M^+(^{35}Cl)], 466 (M^+(^{37}Cl) − CH_3], 464 [M^+ (^{35}Cl) − CH_3]. *Anal.* calcd. for $C_{19}H_{20}NO_7Cl_3$: C 47.47, H 4.19, N 2.90, Cl 22.12; found: C 47.20, H 4.26, N 3.15, Cl 21.98.

α-Benzamido-2,2-dimethyl-1,3,7-trioxa-9-azaspiro[4.5]-dec-9-ene-8-acetic Acid 2,2,2-Trichloroethyl Ester ***14a***

A solution of aldehyde ester **12***a* (15.2 g, 33 mmol) in ether (250 ml) was treated at room temperature with anhydrous ammonia for 1 min (p*H* ≈ 8). After standing for 30 min, the ether was evaporated and the residue chromatographed on silicic acid using ether–benzene (1:1) as eluent. The product first eluted was identified as the imine ester **14***a*. Yield 10.0 g, (66.2%); mp 157–159 °C; pmr ($CDCl_3$): δ 1.42 (s, 6H, acetonide), 3.80 (q, 2H, CH_2O), 4.06 (t, 2H, CH_2O), 4.82 (q, 2H, CH_2—CCl_3), 5.43–5.62 (m, 2H, CO—CH—NH, N—CH—O), 6.77 (d, J = 9 Hz, 1H, NH), 7.3–7.9 ppm (m, 6H, phenyl, CH=N); ir (KBr): 3280 (NH), 3060, 2960, 2870 (CH), 1760 (ester), 1650 (amide), 1600 (aromatic C—H), 1378 cm^{-1} (*gem*-dimethyl); ms (70 eV): *m/e* 478 [M^+ (^{35}Cl)], 480 (M^+ (^{37}Cl)], 464, 463 ($M^+ - CH_3$), 422, 420 (M^+ − acetone). *Anal.* calcd. for $C_{19}H_{21}N_2O_6Cl_3$: C 47.57, H 4.41, N 5.84, Cl 22.17; found: C 47.46, H 4.61, N 6.02, Cl 22.24.

2,2,2-Trichloroethyl α-Benzamido-5-acetoxy-5-(3′-methylthiazolidine-2′-yl)-1,3-dioxacyclohex-2-ylacetic Acid ***26a***

Thiazolidine ester **11***a* (2.2 g, 4 mmol) was added at room temperature to a solution of trifluoroacetic acid (8 ml) and water (2 ml) and the mixture subsequently evaporated to dryness. The residue was neutralized with 2 *N* sodium bicarbonate and extracted with chloroform and the extracts dried over sodium sulfate. Solvent removal left an oil which was treated with a mixture of acetic anhydride (5 ml) and pyridine (5 ml) overnight. Purification on a silica gel column, eluting with chloroform–methanol gave 1.3 g, (59%) of a colorless oil. The product was crystallized from ether, mp 117–119 °C; ir (KBr): 3392 (NH), 1770, 1740 (ester), 1655 (amide),

1522 cm^{-1}; pmr ($CDCl_3$): δ 1.85 (s, 3H, OCH_3), 2.40 (s, 3H, NCH_3), 3.00 (s, 4H, N—CH_2—CH_2—S), 4.00 (s, 2H, OCH_2), 4.20 (s, 1H, N—CH—S), 4.27 (s, 2H, CH_2O), 4.80 (d, 2H, CH_2CCl_3), 5.16 (dd, J = 2 Hz, J = 4 Hz, 1H, C—CH—N), 5.54 (d, J = 2 Hz, 1H, O—CH—O), 6.85 (d, J = 8 Hz, 1H, NH), 7.2–7.0 ppm (m, 5H, phenyl); ms (70 eV): *m/e* 556/554 ($^{37}Cl/^{35}Cl$), 541/539 ($M - CH_3$), 497/495 ($M^+ - OCOCH_3$), 407 ($M^+ - OCH_2CCl_3$), 379 ($M^+ - COOCH_2CCl_3$). *Anal.* calcd. for $C_{21}H_{25}Cl_3N_2O_7S$: C 45.37, H 4.53, Cl 19.13, N 5.03; found: C 45.38, H 4.49, Cl 19.32, N 5.01.

An alternative view of unimolecular reaction theory

HUW OWEN PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received June 7, 1976

HUW OWEN PRITCHARD. Can. J. Chem. **55**, 284 (1977).

A primitive form of unimolecular reaction theory is constructed, based on the master equation. Application of the theory depends upon the way in which eigenvalues of large stochastic matrices behave as certain of the matrix elements are varied. Some of the required eigenvalue properties have been deduced by numerical experiment, and others are available from earlier work on diatomic dissociation reactions. Comparison of the results from this primitive approach with those of existing theories of unimolecular reactions suggests some reinterpretation of parameters used in those theories: most interestingly, the number of effective oscillators occurring in Kassel theory (or its Slater-theory equivalent) appears to be the ratio, at infinite pressure, of the total rate to the rate of the only reaction channel which survives at the low-pressure limit.

HUW OWEN PRITCHARD. Can. J. Chem. **55**, 284 (1977).

On a construit une forme primitive de la théorie des réactions unimoléculaires qui est basée sur l'équation maîtresse. L'application de la théorie dépend de la façon de se comporter des valeurs de eigen de grandes matrices stochastiques lorsque l'on fait varier certains éléments de la matrice. Faisant appel à des expériences numériques, on a déduit quelques unes des propriétés des valeurs de eigen qui sont requises; d'autres sont disponibles à partir de travaux antérieurs sur des réactions de dissociation diatomique. Une comparaison des résultats obtenus grâce à cette approche primitive avec ceux prévus par les théories de réaction unimoléculaire existante suggère que l'on doit faire quelques réinterprétations des paramètres utilisés dans ces théories: la réinterprétation la plus intéressante a trait au nombre d'oscillateurs effectifs se produisant dans la théorie de Kassel (ou le nombre equivalent dans la théorie de Slater) qui semble être le rapport, à pression infinie, de la vitesse totale par rapport à la vitesse du seul chemin réactionnel qui survie à la limite de basse pression.

[Traduit par le journal]

Introduction

The formulation of the rate of a unimolecular reaction using the master equation is relatively commonplace (1–3). However, despite this general acceptance of its validity, the approach has yielded singularly little in the nature of a concrete predictive theory. The basic reason for this is that in the master-equation approach, there is one differential equation for every discrete state of the molecule, and since an interesting molecule from the point of view of unimolecular reaction theory may have many millions of energy levels, one is faced with a two-fold problem, that of finding solutions for enormously large sets of simultaneous differential equations, whose constant coefficients comprise an even larger number of unknown transition rates between the discrete states (4). The usual method of trying to overcome these difficulties is to partition the set of energy levels into blocks whose size is determined by the average amount of internal energy per collision transferred to the heat bath (2); this is really no more than simulating the real process using a model consisting of (at most) a few hundred levels, which is perfectly acceptable provided (4) that the partitioning is not too restrictive. We then encounter the main obstruction to the formulation of a useful theory of unimolecular reactions, since these sets of simultaneous differential equations, although transformed into matrix notation (2, 4), have to be solved numerically. Unfortunately, there appear to be no useful theorems in existence connecting the eigenvalues with the elements of these transition matrices (5, 6), even for the simplest conceivable changes in the elements. Modern developments in linear algebra, stimulated by complementary computational activity, will clearly lead to some new theorems in this area (7, 8), but it has to be remembered here that in our case, we are interested in the behaviour of the eigenvalue of smallest numerical magnitude, which is the rate constant, rather than in the dominant eigenvalue which is generally more amenable to study.

The aim of this investigation, therefore, was to

set out the simplest and most primitive master-equation formulation which exhibits unimolecular reaction characteristics. The behaviour of the eigenvalues was then examined numerically over a wide range of conditions using matrices of the order of about 30; a few calculations were carried out on much larger matrices, of the order of 300, to confirm that some of the properties of interest were not artefacts of the relatively small size of the transition-rate matrix. It is then conjectured that any 'theorems' so deduced will be valid for the almost infinitely large matrices required for a proper description of the unimolecular reaction problem. The supposition that progress can be made in this way is not entirely without foundation. Earlier work on diatomic dissociation reveals two things: first, that the eigenvalue representing the rate of the reaction is very insensitive to the transition probabilities assumed between the internal states of the molecule, even for systems consisting of quite moderately few energy levels (4, 9); and second, that once one considers the molecule to consist of more than 20 levels or so, the rigid one-to-one dependence (9–11) of certain eigenvalues (relating to the internal relaxation) on specific elements of the matrix disappears, and we enter a regime where network or connectivity effects seem to dominate, with the eigenvalues determined co-operatively by contributions from most of the elements of the matrix (9, 12, 13). Clearly, even in the simplest cases, any connection between eigenvalues and the elements in the matrix is extremely complicated (11) and equally clearly, one can hope to elucidate some of the rules without detailed knowledge of individual matrix elements, or transition probabilities.

Examination of Four Primitive Models

We will consider the simplest possible case, that of a molecule A, infinitely diluted in a heat bath of molecules M, decomposing to give products. The energy levels ε_i of the molecule are assumed to be slightly convergent as the energy increases, and the degeneracy g_i of each level is assumed, for the time being, to be unity. We have three choices for the possible description of the reaction process itself. (*a*) To assume a cut-off at some level which is assumed to be an absorbing barrier (1); this is unnecessarily restrictive, and precludes any discussion of the behaviour of states above the critical level, or of phenomena like chemical activation or the decomposition of ions. (*b*) Following Widom (14) we can restrict ourselves to an isomerisation and include all the internal states of the product molecule as well: this gives, in principle, a totally complete and exact description of the process. However, most unimolecular reactions are studied experimentally far away from equilibrium, *e.g.* methyl isocyanide, cyclopropane, and obviously we can (for now) dispense with the luxury of including all the product states, with a consequent reduction in both the size and complexity of the problem; when we need to include any reference to the product molecules, we can simply treat them as structureless entities. (*c*) We can treat the reaction processes as a series of predissociations from certain energetic states of the molecule: if these predissociating levels are embedded in the total manifold of energy levels, then it is clear that the description can encompass, if necessary, such concepts as chemical activation or decomposition to more than one set of products.

It becomes clear that the present treatment has many similarities to those examined by Valence and Schlag (15) and by Tardy and Rabinovitch (16) a decade ago, but whereas they were forced to circumvent the exact solution of the master-equation problem because of computational limitations, we will go directly for the exact solution. The strategy is that we may be able to discover the behaviour of interest for unimolecular reactions using the exact solutions for relatively small matrices and then make a 'mental extrapolation' to those larger matrices of real interest. It should also be noted that there are strong similarities to some aspects of the papers of Buff and Wilson (17) and of Gilbert and Ross (18).

Figure 1*a* depicts the simplest model of this kind which exhibits unimolecular reaction characteristics. In the actual numerical experiments, a series of $N = 30$ internal energy levels was used, spread over an energy range of 100 kcal/mol: they were slightly convergent, with a quadratic dependence on the index i which would cause the levels to converge at 1000 kcal/mol; in a sense then, the latter figure can be regarded as the heat of atomisation of the molecule, but because the temperature is low, we can truncate the series of levels at a much lower energy value than this. There is one predissociating state, with a decay rate constant k_r, arbitrarily assigned as 10^{13} s^{-1}: in this scheme, this is the 20th level, placed at

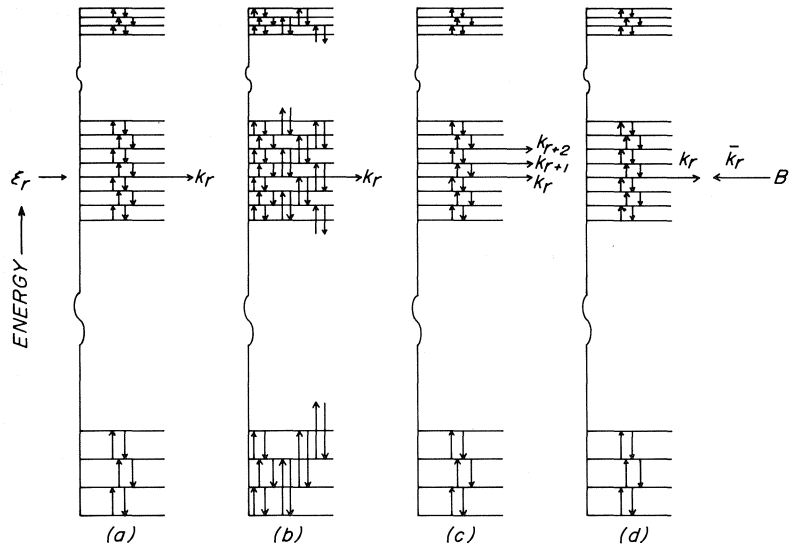

FIG. 1. Schematic representation of four unimolecular reaction models. All models have the same slightly convergent set of energy levels, and the same critical energy ε_r, but with the following variations: (*a*) nearest-neighbour-only transitions, dissipative, one predissociating level (model I); (*b*) one- and two-quantum transitions, dissipative, one predissociating level (model II); (*c*) nearest-neighbour-only transitions, dissipative, two or three predissociating levels (model III); (*d*) nearest-neighbour-only transitions, conservative, one predissociating level giving product molecule B; back-reaction rate constant $\bar{k}_r$ (model IV).

about $\varepsilon = 70$ kcal/mol above the ground state; (note that the subscript r will be reserved for the index i when the state is a predissociating one). Each downward transition was given a transition probability which increased very weakly as the energy gap decreased, and all downward transitions had probabilities of the order of 10^{-3} per collision; upward transition probabilities were generated by detailed balancing from the equilibrium populations $\tilde{n}_i$ for the temperature in question. The temperature T was chosen in the range 500–1000 K to match the practical region in which a reaction with a critical energy of 70 kcal/mol might be studied. The actual numerical details of the model are immaterial, and are only presented for the purposes of clarifying the nature of the model, and as a vehicle for appreciating some of the later discussion; moreover, the philosophy of the experiment is that the model only serves to elucidate some numerical 'theorems', which can then be transferred to more realistic matrices of much larger size.

Most of the numerical experiments were performed upon what may be termed a dissipative model: in these calculations, the product molecules are unspecified and no reverse reaction is included; such dissipative models are models I, II, and III, Figs. 1 *a*, *b*, and *c*. Representing the set of simultaneous differential equations in matrix form, the matrix elements for the dissipative cases are (13)

$$[1] \quad [A]_{ij} \equiv (1 - \delta_{ij})Q_{ji} - \delta_{ij}\left[k_i + \sum_{k=0}^{N-1}(1 - \delta_{ik})Q_{ki}\right]$$

where

$$Q_{ji} = [M]ZP_{ji}$$

$$\tilde{n}_i P_{ji} = \tilde{n}_j P_{ij}$$

and [M] is the concentration of inert molecules, Z is the collision number between M and A, and P_{ji} is the probability per collision of a change in the internal state of A from $i \rightarrow j$. The matrix A_{ij} has N eigenvalues, none of which is zero because the system does not conserve particles: $(N - 1)$ of the eigenvalues represent the internal relaxation times ($\tau_j = -\lambda_j^{-1}$) and the eigenvalue of smallest numerical magnitude λ_N is (minus) the rate constant (k_{uni}) for the loss of particles from the system. Figure 2 shows the behaviour of these N eigenvalues, for fixed P_{ij} and fixed k_r, as a function of the inert gas concentration [M]: such

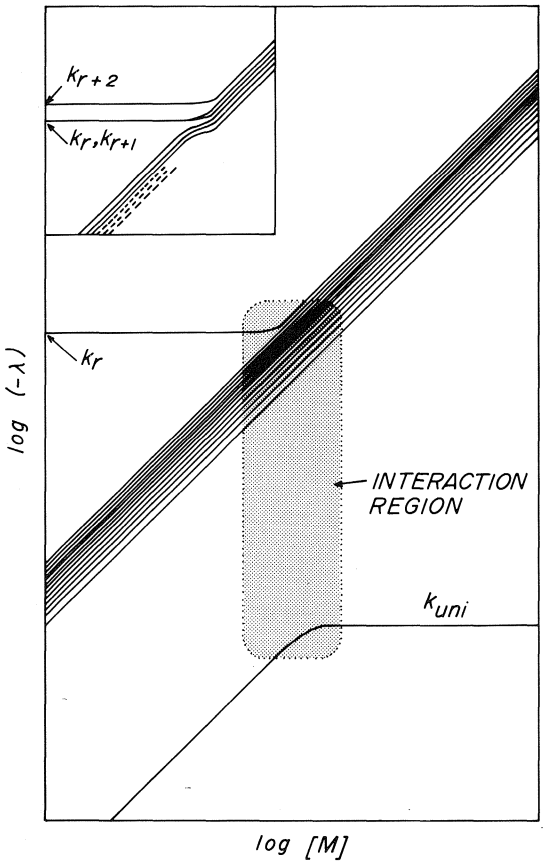

FIG. 2. Schematic representation of the behaviour of the eigenvalues of the reaction-rate matrices as a function of the concentration of M. The inset shows the behaviour of the six eigenvalues of largest numerical magnitude in the interaction region when there are three decay channels, two of them having the same decay constant *i.e.* $k_r = k_{r+1} \neq k_{r+2}$.

behaviour has been shown before for a two-state system (19), and this is the generalisation to an N-state system. The principal features are as follows: There is a bundle of $(N - 2)$ eigenvalues (very closely spaced because all the downward P_{ij} are very similar in numerical magnitude) which appear to be directly proportional to [M]; these are the rates of the internal relaxations of the molecule A in the presence of M. At very low [M], there is an eigenvalue $\lambda_0 = 10^{13}\ s^{-1}$, since this is much faster than any internal process under these conditions; however, as [M] increases and the rates of the internal processes become comparable with $10^{13}\ s^{-1}$, the largest eigenvalue is assimilated into the bundle. In the diagram, the bundle of internal eigenvalues is drawn as though they were all straight lines, but in fact, in the interaction zone (depicted by the shaded area) each member of the bundle exhibits a small displacement such that in the limit of high pressure, λ_j is the continuation of the low-pressure λ_{j-1} (see the inset in Fig. 2 for more details, remembering that the inset actually refers to another calculation of type III); also, for each successive eigenvalue, the centre of the displacement moves slightly to the right as λ decreases in numerical magnitude. Finally, the eigenvalue of smallest numerical magnitude ($\lambda_N = -k_{uni}$) is parallel to the main bundle of internal-relaxation eigenvalues until the interaction region is reached, whence it turns over and becomes independent of [M].

The properties of k_{uni} are as follows:

(a) High pressure

The infinite pressure rate constant is exactly

$$[2] \quad k_{uni,\infty} = \tilde{n}_r k_r; \quad \left(\text{normalisation } \sum_i n_i = 1\right)$$

i.e. the product of the equilibrium population and the predissociation rate constant; this equation also remains true if the state $i = r$ is assigned a degeneracy g_r other than unity.

(b) Low pressure

The identification of the rate constant is not so decisive, and it appears that the low-pressure limiting form is

$$[3] \quad k_{uni,0} \sim 0.26 \tilde{n}_r |\lambda_{N-1}|$$

Obviously, this equation could be written in other suggestive forms, *e.g.* in terms of $\tilde{n}_{r-1}$ which is the state supplying the predissociating one; other possible forms investigated involved the arithmetic or geometric means of the bundle of λ_j, but the relationships here were dependent on the number of levels considered, whereas in the form of [3], it was independent of both the number of levels and the index of the predissociating state, provided $r > \sim 5$, $N > 30$. Equally obviously, the rate of dissipation is simply $n_r k_r$ where n_r is the actual nonequilibrium population of the predissociating state, whence

$$[4] \quad \frac{n_r}{\tilde{n}_r} \sim 0.26 \frac{|\lambda_{N-1}|}{k_r}$$

The coefficient 0.26 is clearly only appropriate for the particular set of energy levels and transition probabilities used in this calculation.

(c) Intermediate pressures

The most interesting property of k_{uni} is that it is exactly a Lindemann fall-off curve: close to a hundred values of k_{uni} as functions of [M] have been obtained during the variety of numerical experiments carried out and in no case, given the high-pressure limit (eq. 2) and the numerical form of the low-pressure limit (eq. 3), did a value of k_{uni} for model I deviate by more than 1 part in 10^6 from Lindemann behaviour, *viz.*

$$k_{uni} = \frac{a[M]}{b + c[M]} \qquad [5]$$

It seems safe to presume therefore that eq. 5 can be regarded as a valid rule for λ_N for *large* matrices of the form [1] with only one dissipative element k_r, given that r is embedded well within the body of the values of the energy-ordering index i; eq. 2 identifies the ratio a/c unambiguously in terms of the properties of the matrix, and eq. 3 gives an approximate form for the ratio $a[M]/b$.

The next interesting question is whether this Lindemann behaviour is specific only to this primitive formulation, or whether it is more general: model I contains two exceedingly restrictive assumptions, that of nearest-neighbour-only transitions, and that of only one allowed predissociating state, and the Lindemann form for λ_N could be confined only to this special case.

The step-ladder or nearest-neighbour approximation (*viz.* $P_{ij} = 0, |i - j| \neq 1$) is a common one in theoretical chemical kinetics, and it is now well established (4, 10) that in diatomic dissociation, the activation flux is essentially step-ladder in form and that the principal result of making the step-ladder approximation is to effect a relatively small decrease in the overall reaction rate. Consequently we will examine this restriction first. This is done using model II, Fig. 1*b*, which includes both one- and two-quantum level transitions: the nearest-neighbour transition probabilities P_{ij} and the predissociating decay rate k_r were kept the same as for model I, and the values of $P_{i-1,i+1}$ were assumed to be quite large, of the order of $0.3P_{i-1,i}$. $P_{i,i+1}$, in order to exaggerate any effect of non-nearest-neighbour transitions. The behaviour of the eigenvalues did not change, of course, from the pattern shown in Fig. 2, except in minor numerical detail. Referring only to λ_N, the high-pressure limiting value remained the same as before *i.e.* eq. 2, as demanded by the physics of the situation, and the low-pressure limiting value was about 1% higher than before, eq. 3; the latter is reasonable since the predissociating level is now fed by two pathways from below, from levels $i = r - 1$ and $i = r - 2$, and the net result is a slightly higher non-equilibrium population n_r. However, in the intermediate-pressure region, the values of $-\lambda_N$ again conformed, to better than 1 part in 10^6, to the Lindemann form, eq. 5. Consequently, we can assume from now on that the step-ladder or nearest-neighbour assumption is only a matter of detail; it will affect the calculated rate somewhat, as it also did in the diatomic dissociation case, but it will not lead to qualitatively invalid results: this of course is a great advantage, because matrix [1] is then only a tridiagonal matrix, and once symmetrised, can be manipulated on a computer with great efficiency. An alternative (but not quite rigorous) rationalisation of this is to say that a full symmetric matrix can always be reduced to tridiagonal form: hence, a nearest-neighbour model, given suitable weighted transition rates, will always mimic the behaviour of the full transition matrix.

A brief digression: it is common in most unimolecular reaction theories to make the assumption, for want of something better, of unit deactivation efficiency, at least for the interesting states. Our model I has deactivation efficiencies which are monotonically increasing as the index i increases, but all of them are close to 10^{-3} per collision in magnitude. The calculation was repeated with all downward transitions $P_{i,i+1}$ having the value of unity, which does no more than shift Fig. 2 to the left by three log units. Alternatively if we make some deactivation probabilities unity, and leave others as 10^{-3}, the thickness of the bundle increases by about three log units, and with it, the width of the (shaded) interaction region. Hence, assumptions about the numerical magnitudes of the transition probabilities themselves also only affect the detail of the calculation, but not the overall picture.

Returning now to the question of more than one decay channel, *i.e.* model III. Calculations were performed using the same standard set of P_{ij}, with k_r having its usual value of 10^{13} s^{-1}, and with various values assigned to $k_{r+1}, k_{r+2}, \ldots$. The pattern of eigenvalue behaviour remains very much as is shown in Fig. 2, except that there is now one eigenvalue, horizontal in the top left-hand portion of the diagram, for each non-zero

value of k_i, and correspondingly one less in the diagonal bundle. At very low pressures, λ_0, λ_1, $\lambda_2, \ldots$ are exactly the values assigned to the k_i in descending order of magnitude. If all the k_i are the same, *e.g.* 10^{13} s^{-1}, then there is a set of degenerate λ_j at this value: this degeneracy begins to split as the interaction region is approached, and each one merges into the corresponding member of the bundle (see inset to Fig. 2). At the high-pressure limit, the obvious result was obtained for the rate constant, *viz.*

$$[6] \qquad -\lambda_N = k_{\text{uni}} = \sum_{i \geqslant r} \tilde{n}_i k_i$$

At the low-pressure limit, a rather startling, but in hindsight very obvious result was obtained, namely that k_{uni} was *exactly* the same as if there was only one decay channel, k_r! The physical explanation is very simple, and in fact is an implicit assumption of earlier master-equation theories (2, 15): level $i = r$ decays to products just as quickly as molecules can be supplied to it from level $i = r - 1$; consequently, in the limit, no molecules can ever find their way into levels $i = r + 1, r + 2, \ldots$, and these decay channels become inoperative at very low pressures.

Moreover, the form of k_{uni} in the intermediate-pressure region can no longer be fitted to the Lindemann form. This is an interesting asymmetry: models I and II have a common high-pressure limit, but different low-pressure limits (arising from additional off-diagonal elements in the matrix); models I and III have a common low-pressure limit, but different high-pressure limits (arising from additional diagonal elements in the matrix); models I and II are Lindemann, model III is not.

Another digression: in order to confirm the interpretation that at the low-pressure limit the steady-state population distribution contains no molecules in states $i > r$, it is necessary to generate the population distribution for a time t in the process for which $|\lambda_j^{-1}| < t < k_{\text{uni}}^{-1}$. This is most easily done using model IV, Fig. 1*d*, which conserves particles. Model IV is identical with model I except for the addition of one more equation representing the concentration of the (unstructured) product molecules B; the equations now conserve particles, and the generation of the population distribution, in principle at least, follows simply in the normal way (20). The equilibrium concentration of B was chosen to be large (as it is in many real isomerisation experiments *e.g.* methyl isocyanide, cyclopropane): this makes $\bar{k}_r$ very small, yielding the result that apart from the introduction of the conservative zero eigenvalue, the remaining N eigenvalues λ_j do not change. It turns out that the calculation of the steady-state population distribution is relatively straightforward in the intermediate pressure range, but is rather ill-conditioned at the pressure extremities, especially at low pressure. At relatively high pressures, where λ_{N-1} is within 0.1% the high-pressure limit, we recover the expected result that all levels below $i = r$ are in thermal equilibrium with each other, all levels above $i = r$ are also in equilibrium with each other, but there is a disparity of the order of 0.1% between the two sets of populations. At relatively low pressures, where $[M]^{-1}\lambda_{N-1}$ is (say) about 1% above the limiting value (it is difficult to get much nearer to the low-pressure limit because of severe cancellation problems) the predicted result is also recovered: levels below $i = r$ are in equilibrium, more or less, with each other, but with the degree of equilibration falling successively as i increases towards r, very much like plots given by Tardy and Rabinovitch some years ago (16); n_r is of course about 1% greater at this pressure than the value given by eq. 4, and all the levels above $i = r$ are very closely in equilibrium with each other, having populations of the order of 0.1% of their normal equilibrium values. Thus, the reason for the common low-pressure limit for models I and III is confirmed.

Now, if the behaviour of k_{uni} for model III does not conform to a Lindemann plot, does it have some other recognisable form? It was found that if two non-zero values of k_i were used *viz.* $k_r = k_{r+1} = 10^{13}$ s^{-1}, the fall-off behaviour of k_{uni} could be represented very well by a Kassel curve. The conformity to a Kassel curve was not exact, but nowhere was the deviation more than 0.1%, and the best value of s for this case was $s = 1.14$, using, of course, the high-pressure Arrhenius parameters appropriate to this model, *i.e.* eq. 6. The most interesting feature of this observation, however, is that at the temperature in question, the rate constant given by eq. 6 was just 1.14 times the value of $k_r\tilde{n}_r$, the single-channel value. Let us therefore introduce the conjecture that

$$[7] \qquad s \cong \sigma = \sum_{i \geqslant r} \tilde{n}_i k_i / \tilde{n}_r k_r \; ?$$

Two model calculations were then constructed

having the value of $\sigma = 2$. This can be done for example by keeping both k_r and k_{r+1} fixed at 10^{13} s^{-1} and increasing the degeneracy g_{r+1} to give the desired result, or by keeping the degeneracy fixed and increasing k_{r+1} correspondingly; either way, the best fit to a Kassel curve was obtained when s was within the range 1.98 to 2.02. The coincidence between s and σ is remarkable and suggestive: however, an attempt to extend eq. 7 to higher values of σ does not lead to a one-to-one correspondence between s and σ; for example, two calculations with $\sigma = 3$ (one with equal contributions to the rate from $i = r$, $r + 1$, and $r + 2$, and the other using only two channels $i = r$ and $r + 1$) both gave good fits to Kassel curves having $s \simeq 2.65$. Considering the density of states in the critical region and the relatively narrow width of the bundle of internal eigenvalues, the calculations for $\sigma = 3$ really are very strained and probably unrealistic, and it would seem therefore not unreasonable at the present juncture to leave conjecture [7] as it stands, to be verified for larger σ at a later stage using much larger matrices.

Relationship to Existing Theories

Rather than compare the present approach specifically and in turn with each of Hinshelwood–Lindemann theory (2), Slater theory (2, 21), and RRK or RRKM theory (2, 3), it seems more economical at this primitive state of development to make associations with the general body of ideas used in these theories, and highlight the shortcomings where they appear. We have constructed an incredibly primitive master-equation formulation of a unimolecular reaction. The fact that this is worth attempting stems from our experience with the master-equation treatment of diatomic dissociation, (*a*) that the step-ladder activation assumption will give results only quantitatively but not qualitatively different from a full network of activation steps, and (*b*) that once the network becomes sufficiently large, the reaction rate is rather insensitive to the internal transition rates. The molecule is represented only as a series of energy levels: they are not subdivided into classes or subgroups which could be regarded as oscillators in the normal sense, and yet fall-off behaviour is found which is often treated using the idea of a number s of coupled oscillators. In a sense, the present model corresponds to complete randomisation of energy and could easily be extended, in principle at least, to accommodate separate interleaving manifolds of energy levels with high transition rates within each manifold and relatively low transition rates between members of different manifolds to examine effects caused by non-randomisation of energy. The concept of oscillators in other theories is associated with both the *shape* of the fall-off curve and the *decline* of the Arrhenius temperature coefficient with pressure; in practice also, there is a correspondence between the complexity of the molecule and the *position* of the fall-off curve on the pressure scale. We have shown that the varying shape of the fall-off curve may have an alternative interpretation: if we use the Kassel s to describe approximately the shape of the fall-off curve, then s appears via the conjecture [7] to be the ratio at infinite pressure of the total rate to the contribution of that particular decay channel which persists at the low-pressure limit.

On the other hand, there is no direct correspondence between the value of σ (or s) and the position of the fall-off. As we showed, the position of the fall-off is adjustable trivially by changing the mean value of the deactivation probabilities in the system. The major determinant of the position of the fall-off curve on the log [M] axis is simply that the top left-hand portion of the interaction region (*cf.* Fig. 2) occurs when

$$[8] \qquad k_r = -\lambda_0' \sim [M]ZP_{ij}(\max)$$

where λ_0' is the eigenvalue of largest numerical magnitude for the unperturbed matrix (*i.e.* all $k_i = 0$), and $P_{ij}(\max)$ is the largest collisional deactivation probability in the system. Thereafter, each successive member of the bundle of eigenvalues exhibits its displacement at a successively higher pressure, and therefore k_{uni} bends over and becomes horizontal at a pressure value higher than that given in [8] by an amount determined in some topological fashion by the *thickness* of the bundle; thus, eq. 8 is the major determinant of the position of the fall-off, with the thickness of the bundle being a secondary factor. Clearly there is some scope for establishing a tenuous connection between σ and the thickness of the bundle of eigenvalues corresponding to the internal processes: this aspect has not been examined in detail, but it seems obvious that the main factor will be the dynamic range of deactivation probabilities for the dominant steps in the network, and this range will probably be greater

for more complex molecules than for simple ones. The necessary relationship which we cannot establish is the one between σ and the k_i required to define the position of the interaction region via eq. 8; this of course is where oscillator-based theories have some strength since, for a fixed deactivation probability, the predicted fall-off pressure decreases with increasing complexity of the molecule.

The present model yields distinctly different Arrhenius temperature coefficients at the high- and low-pressure limits. At the low-pressure limit, when the reaction flux is through only the $i = r$ channel (in the single-step excitation model) or only a few channels just above $i = r$ (in the general multi-step excitation model), the behaviour of the rate constant, to a first approximation, is $\sim \exp(-\varepsilon_r/kT)$. Another factor will be the way in which the depopulation of the predissociating levels and of those below them change with temperature, which will depend to a large extent on the temperature coefficients of the internal relaxation eigenvalues. Making the plausible assumption that any non-equilibrium effects become more severe at higher temperatures, the Arrhenius temperature coefficient would then be just slightly less than ε_r in numerical magnitude (4). At the high-pressure limit, where the rate constant behaves as $\sigma g_r \exp(-\varepsilon_r/kT)$ (from eq. 7), the Arrhenius temperature coefficient will depend on ε_r again, and on the way σ varies with temperature. If σ is small, there will be relatively little scope for deviation from ε_r, if σ is large, there may be considerable scope, so in a sense we recover a relationship between the change in Arrhenius temperature coefficient with pressure and σ (crudely the number of effective oscillators), but not a quantitative one as in other theories. We may distinguish two types of behaviour, one which we may regard as 'normal' and one 'abnormal'. (*a*) If reaction takes place from states immediately above the state $i = r$, and the products $k_i g_i$ for the dominant reactive channels are not very different from the product $k_r g_r$ for the critical level, then the 'activation energy' will be only a little in excess of ε_r, and the frequency factor A_∞ will be of the order $\overline{k_i g_i}$. (*b*) If, because of a peculiar distribution of predissociating rotational states of high J somewhat above the level $i = r$, with $\overline{k_i g_i} \gg k_r g_r$, one can have an Arrhenius temperature coefficient considerably greater than ε_r, and a 'high' frequency factor A_∞. The behaviour of these two cases as the pressure decreases will be different: case (*a*) will exhibit a small decline in 'activation energy' with a relatively constant frequency factor, whereas case (*b*) will exhibit a large decline in 'activation energy' and also a relatively severe change in frequency factor. Obviously σ plays some role in the change in both cases, but not a clearly defined one.

In discussing the results of a similar investigation about 10 years ago, Valance and Schlag (15) concluded that there were three necessary and sufficient conditions for RRK behaviour of the master-equation model: (*i*) the steady-state assumption; (*ii*) the strong-collision assumption; (*iii*) all levels below the critical energy are required to be in equilibrium. We have not established in a detailed sense that the present model gives exactly RRK behaviour, only that it is Kassel-like or Slater-like, but without *any* of these artificial restrictions, which it would seem arise from the partitioning procedure used by Valance and Schlag rather than the physics of the situation: essentially, this partitioning reduced the problem to a two- or three-state problem (admittedly with internal structure within the two or three states concerned) and the risks attendant upon making such drastic assumptions are by now reasonably well recognised (4).

Finally we note that, of course, one of the attractions of the master-equation approach is that it can encompass naturally different efficiencies of colliding molecules in restoring the fallen-off rate, which is not always easy in other approaches. It does not seem entirely unreasonable to envisage at this stage a hybrid theory in which the details of the internal relaxations are treated in the present fashion but the calculation of the lifetimes of the interesting states rests heavily on RRKM-like considerations.

The triple helical structure of lentinan, a linear β-(1→3)-D-glucan

TERRY L. BLUHM AND ANATOLE SARKO

Department of Chemistry, State University of New York College of Environmental Science and Forestry, Syracuse, NY 13210

Received June 28, 1976

TERRY L. BLUHM and ANATOLE SARKO. Can. J. Chem. **55**, 293 (1977).

Probable models for the crystalline structure of lentinan, the β-(1→3)-D-glucan of the fungus *Lentinus elodes*, were evaluated by X-ray fiber diffraction and theoretical conformational analysis of single and multiple helices. The X-ray diagram is consistent with a hexagonal unit cell with dimensions $a = b = 15.8$ Å and c (fiber repeat) = 6 Å. Conformational analysis predicts five probable models for this fiber repeat, of which one is a single helix, two are double helices, and two are triple helices. On the basis of packing of these helices into the unit cell and a comparison of their calculated Fourier transforms with the observed X-ray diffraction intensity distribution, all but the two triple helical models are eliminated from consideration. The two triple helices differ only in chirality and both left- and right-handed models are stabilized by interstrand O(2)---O(2) hydrogen bonds, such as are found in the triple helical structure of β-(1→3)-D-xylan. The right-handed triple helix may be the more probable structure of the two, by analogy with the known structure of the β-(1→3)-D-xylan. It is likely that the β-(1→3)-D-glucan of curdlan and those of *Armillaria mellea* and *Lilium longiflorum* also possess the same structure.

TERRY L. BLUHM et ANATOLE SARKO. Can. J. Chem. **55**, 293 (1977).

On a évalué, par diffraction de rayon-X de fibre et par une analyse conformationnelle théorique des hélices simples et multiples, les modèles probables pour la structure cristalline du lentinane, le β-(1→3)-D-glucanne du champignon *Lentinus elodes*. Le diagramme de rayon-X est en accord avec une maille hexagonale ayant des dimensions $a = b = 15.8$ Å et c(répétition de la fibre) = 6 Å. L'analyse conformationnelle prédit cinq modèles probables pour cette répétition de fibre: un correspond à une hélice simple, deux sont des doubles hélices et deux sont des triples hélices. Sur la base de l'entassement de ces hélices dans la maille et par comparaison de la transformation de Fourier calculée avec celle observée pour la distribution des intensités dans la diffraction des rayons-X, on peut éliminer tous les modèles excepté les deux triples hélices. Les deux triples hélices diffèrent uniquement par leur chiralité et les modèles gauches et droits sont aussi stabilisés par des ponts hydrogène O(2)---O(2) entre les chaines comme on en trouve dans la structure triple hélice du β-(1→3)-D-xylane. Il est possible que la triple hélice droite soit la plus probable des deux si l'on se base sur une analogie avec la structure connue du β-(1→3)-D-xylane. Il est probable que le β-(1→3)-D-glucanne du curdlane ainsi que ceux des *Armillaria mellea* et *Lilium longiflorum* possèdent la même structure.

Introduction

Although cellulose is the principal structural polysaccharide of the plant world, a number of other β-linked polysaccharides have been found in that capacity. For example, cellulose is replaced by β-(1→4)-mannan in the siphoneous green algae *Codiaceae* (ref. 1, p. 94) and *Dasycladaceae* (2), and by β-(1→3)-xylan in *Caulerpaceae* (3). The β-(1→3)-glucans have similarly been found as the main structural component in baker's yeast, *Saccharomyces cerevisiae* (4), and, along with cellulose, in the pollen tube of *Lilium longiflorum* (5). In the latter, the glucan is fibrillar and crystalline and this is the first known instance of finding this glucan in a structural capacity in higher plants. In addition, β-(1→3)-glucans occur widely in nature as storage polysaccharides, as for example, in brown seaweeds of the species *Laminaria* (6), in unicellular algae such as *Euglena gracilas* (7) and in filamentous green algae such as *Cladophora rupestris* (ref. 1, pp. 196, 197).

Other investigations of the crystalline structure of β-(1→3)-glucans have shown that this polysaccharide can be crystallized in oriented form and that the resulting diffraction diagrams are nearly identical with those obtained from the native crystalline form. For example, Scott and Rees (8) obtained fiber X-ray diffractograms of curdlan, the extra-cellular β-(1→3)-glucan from a mutant of *Alcaligenes faecalis*. Their diffraction data were insufficient for a detailed X-ray analysis of the structure; however, they were able to measure the fiber repeat as between 5.8 and

6.2 Å and the fiber density as 1.43 g/cc. Jelsma and Kreger (9) obtained identical diagrams and fiber repeat data from oriented fungal tissue of *Armillaria mellea* and Herth *et al.* (5) recorded a fiber diagram from the lily pollen tube that appears to be identical with both of the above. Marchessault *et al.* (10) showed that curdlan crystallizes well after annealing and that its diffraction diagrams vary with the degree of hydration of the sample. All diffraction diagrams, however, were similar to those obtained from other β-(1→3)-D-glucans.

On the strength of the similarities between the X-ray diagram of the glucan and that of the β-(1→3)-xylan, the structure of which was shown by Atkins and Parker (11) to be a triple helix, both Jelsma and Kreger (9) as well as Scott and Rees (8) have suggested that the glucan has a similar structure. In fact, Scott and Rees (8) performed a computer modeling analysis using hard-sphere techniques to show that a triple helix for the glucan was possible. In addition, Jelsma and Kreger concluded that a triple helix was in agreement with the observed unit cell (9). Similarly, the triple helix of the β-(1→3)-D-xylan was predicted from conformational calculations by Sathyanarayana and Rao (12).

In this article, we report the results of a conformational analysis of possible single and multiple helices for β-(1→3)-glucan, performed with Lennard–Jones potential energy functions augmented with a term for hydrogen bonds (13). The allowed models were evaluated with the help of X-ray data from a fiber diagram obtained from oriented gels of lentinan, a linear β-(1→3)-glucan isolated from the fungus *Lentinus elodes* (14).

Experimental

Sample

A sample of pure lentinan was obtained from Dr. J. Hamuro of Ajinomoto Co., Inc., Kawasaki, Japan. The polysaccharide was reported to be predominantly linear with some β-(1→6) branching linkages present in the molecule. The average molecular weight was approximately one million. The nmr spectrum of the sample (in DMSO) revealed no inconsistencies with the expected structure and the sample was used without further purification.

X-Ray Diffraction

Fibers of lentinan suitable for X-ray diffraction were prepared by drying of 2% aqueous gels. The material was first dissolved in 1 *N* NaOH overnight at room temperature and subsequently dialyzed 2 days against distilled water. A small amount of the resulting gel was placed between two glass beads held in a fiber stretching clamp, stretched about 50% and left to dry at room temperature. The density of the fibers was measured by flotation in a solution of *p*-xylene/carbon tetrachloride and was 1.547 g/cc (±0.002).

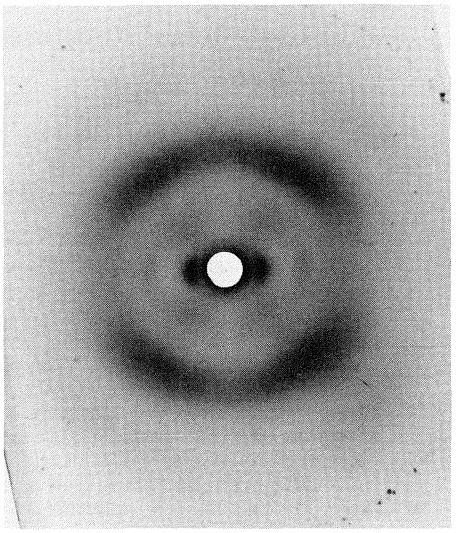

FIG. 1. X-Ray diffractogram of lentinan fiber taken in vacuum. Fiber axis is vertical.

X-Ray diffraction diagrams were obtained in a flat plate camera using CuK_α radiation and at relative humidities ranging from 50% to 100%. A typical fiber diagram of lentinan is shown in Fig. 1.

Conformational Calculations

The conformational analysis was performed for all possible single-strand helices obtainable by rotations of a specified, fixed monomer residue about the bonds linking it to glycosidic oxygens. (The rotational angle about the $C(1)—O_{glyc}$ bond is henceforth referred to as ϕ and the angle about the $C(3)—O_{glyc}$ bond as ψ.) The monomer residue was kept rigid in the *C1* conformation and its atomic coordinates were taken from the average residue of Arnott and Scott (15). The bond angle at the glycosidic oxygen was fixed at 118° and the O(6) hydroxymethyl group was left invariant in the *gg* rotational position.[1] The same conformational analysis was performed for double parallel-stranded, double antiparallel-stranded, and triple parallel-stranded helices in which the strands were translationally in phase, *i.e.* the glycosidic oxygens of each strand were on the same level along the helix axis.

The single-strand helical conformations were created in the usual fashion, by performing ϕ and ψ rotations at 10° intervals in the range −180° to +180° (or at 1° intervals in areas of particular interest). The multi-strand helices were obtained by symmetry operations on the first strand. For example, a double parallel-strand helix with

[1]Refer to ref. 16 for the description of *gt*, *gg*, and *tg* terminology.

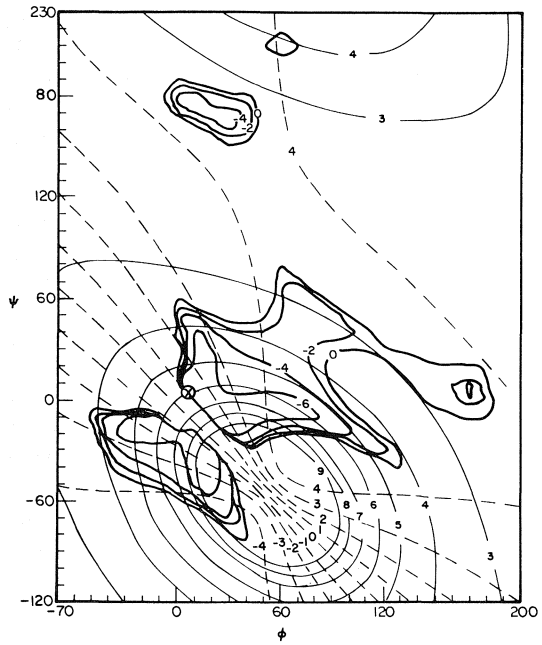

FIG. 2. Conformational energy map for single helical β-(1→3)-D-glucan as a function of rotations about the C(1)—O bond (ϕ) and the C(3′)—O bond (ψ). The (ϕ,ψ) = (0,0) position is with the atom sequence H(1)—C(1)—O—C(3′)—H(3′) in plane and the bonds H(1)—C(1)—O—C(3′) and C(1)—O—C(3′)—H(3′) *cis*. The energy contours are in kcal/mol; the thin solid lines denote constant n; the dashed lines denote constant h (negative h indicates left-handed helices). The conformation denoted by a cross is a minimum energy conformation in agreement with observed X-ray data.

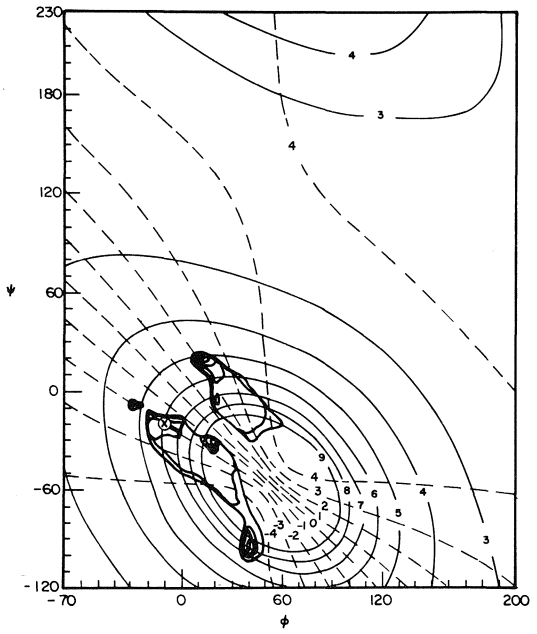

FIG. 3. Conformational energy map for double parallel stranded helical β-(1→3)-D-glucan. (For further explanation see the caption of Fig. 2.)

given ϕ,ψ angles was obtained by first creating the required single strand (by ϕ–ψ rotations), then creating the second strand by imposing a two-fold rotation about the helix axis on the first strand. Similarly, the double antiparallel-strand helix was created by symmetry operations involving two-fold rotation about the helix axis coupled with inversion about an axis at right angles to the helix axis. (The inversion axis was at $z = 0$.) The triple parallel-strand helix was created by a three-fold rotation about the helix axis. All strands of a multiple helix thus possessed the same ϕ,ψ angles.

The probability of the helices was evaluated by calculating their conformational nonbonded energy V_{NB}, using a Lennard–Jones potential energy function augmented with a third term for non-directional hydrogen bonds (13)

$$[1] \quad V_{NB} = \sum_{\substack{i=1 \\ j=1}} A r_{ij}^{-12} + B r_{ij}^{-6} + C r_{ij}^{-3}$$

where the summation is over all pairwise interactions between atoms i and j separated by a distance r_{ij}. In the evaluation of V_{NB} for a given multi-strand helix, the interactions between all atoms of a reference residue and those in the residues in one complete turn of the helix of each strand above and below the reference residue were included in the summation. The conformations with V_{NB} higher than 0 kcal/mol were judged to be improbable. The regions of probable conformations were described as isoenergy contour maps as a function of ϕ and ψ rotations. The resulting maps, with superimposed n (number of residues per turn) and h (axial rise per residue in Å) contours, are shown in Figs. 2–5.

All conformational calculations were done with a CDC 3200 computer.

Results and Discussion

The diffraction diagrams of lentinan showed only poor crystallinity, but they were similar in appearance to the diagrams obtained from native crystalline β-(1→3)-glucans of the pollen tube of *Lilium longiflorum* (5) and the fungus *Armillaria mellea* (9). The patterns were apparently not affected by the relative humidity of the surroundings, as all of them showed two well oriented equatorial reflections at ~14.5 and ~6.7 Å, and a spread of intensity on the first layer line centered at ~4.5 Å. The fiber repeat was ~6 Å. The equatorial reflections and the fiber repeat are in rough agreement with the hexagonal unit cell $a = b = 15.8$ Å and $c = 5.95$ Å proposed for *A. mellea* (9). This unit cell

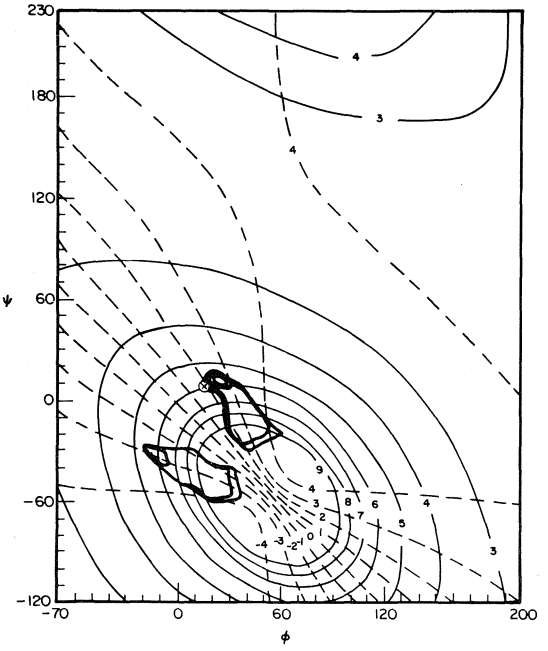

FIG. 4. Conformational energy map for double antiparallel stranded helical β-(1→3)-D-glucan. (For further explanation see the caption of Fig. 2.)

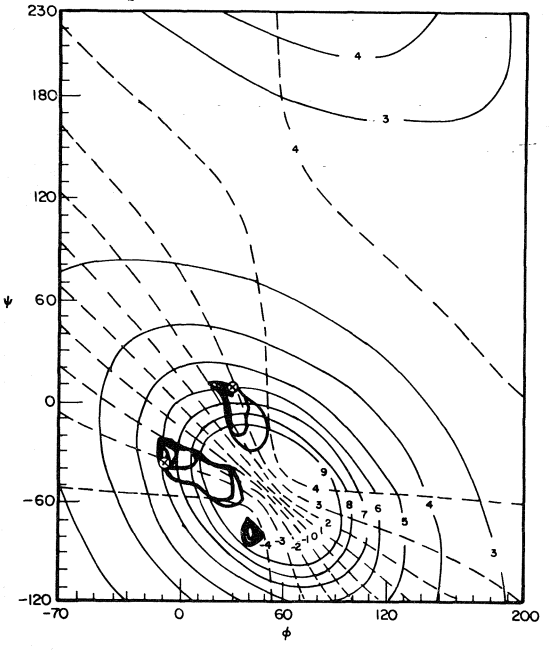

FIG. 5. Conformational energy map for triple all parallel stranded helical β-(1→3)-D-glucan. (For further explanation see the caption of Fig. 2.)

is also in agreement with those obtained on curdlan by Scott and Rees (8) and Marchessault *et al.* (10). It thus appears that regardless of source, all β-(1→3)-glucans that have been studied crystallize in nearly the same hexagonal unit cell. The volume of this cell and the observed density are in agreement with six glucose residues and approximately 12 water molecules per cell. However, as demonstrated by Marchessault *et al.* a lower hydrate can be obtained, with decreased hexagonal unit cell dimensions (10).

As is evident from the conformational energy maps (*cf.* Figs. 2–5), minimum energy conformations that are in agreement with the fiber repeat exist for the single helix as well as all multiple helices. A total of five such conformations were found: one single helix, one parallel-stranded double helix, one antiparallel-stranded double helix, and two triple helices. Their features are shown in Table 1. It must be remembered that the symmetry rules require that for the double parallel helix only layer lines with $l = 2n$ (where n is an integer) be present in the diffraction diagram and, similarly, for the triple helix only layer lines with $l = 3n$. The same is not true for the antiparallel-stranded double helix but the odd-order layer lines are likely to be so weak as to be unobservable. The repeats per turn shown in Table 1 are thus consistent with the observed $c \cong 6$ Å crystal repeat.

The types of hydrogen bonds possible in these conformations have been included in Table 1. The lengths of these bonds do not reflect the most probable values because they result from fixed conformations. When a promising conformation is refined as described below, the hydrogen bond lengths always undergo adjustments toward more reasonable values, provided the structure itself is stereochemically reasonable.

The probability of each of the five helices as a suitable model for the crystal structure of lentinan was tested in two ways: (*1*) by packing analysis, and (*2*) by Fourier transform calculations. In the packing analysis, each model was packed into the unit cell while minimizing the function (17)

$$[2] \quad Y = \sum_{i=1}^{l} \left(\frac{r_i - r_{0i}}{\mathrm{SD}_i^r} \right)^2 + \sum_{i=1}^{m} \left(\frac{\theta_i - \theta_{0i}}{\mathrm{SD}_i^\theta} \right)^2 + \sum_{i=1}^{n} \left(\frac{\phi_i - \phi_{0i}}{\mathrm{SD}_i^\phi} \right)^2 + \frac{1}{W^2} \sum_{\substack{i=1 \\ j=1}}^{N} w_{ij}(d_{ij} - d_{0ij})^2$$

TABLE 1. Helix characteristics of the most probable predicted conformations

Helix type	Handedness	n	h (Å)	Repeat/turn (Å)	ϕ, ψ (deg)	V_{NB} (kcal/mol)	Hydrogen bond type and approximate length (Å)
Single	Right	6	0.98	5.88	6, 5	−8	O(2)---O(2′) intrachain, 2.7
Double parallel	Left	6	2.0	12.0	−11, −20	−14	O(2)---O(2′) intrachain, 3.0

where r_i are bond lengths, θ_i bond angles, ϕ_i conformation angles and d_{ij} nonbonded distances. The corresponding standard values (r_{0i}, θ_{0i}, ϕ_{0i}) were obtained from known carbohydrate structures (15) and the standard d_{0ij} were previously determined by us from packing of carbohydrate crystal structures (18). In this fashion, both the chain conformation and packing were simultaneously optimized.

The results of this analysis are shown in Table 2. It has been found convenient to compare the packing of different models by comparing values of the last term of eq. 2, which has been termed a 'packing energy', PE. The latter can be subdivided into two parts, one for interchain and the other for intrachain contacts and both are shown in Table 2. The conformational energies described by the first three terms of eq. 2 usually change little and for that reason, are not shown. (Generally, only terms 2, 3, and 4 of eq. 2 were minimized during refinement. Bond lengths were usually left fixed because they varied very little.) It was previously found with other polysaccharides that when PE increases above 20, packing of chains becomes increasingly difficult. With this criterion in mind, it is clear that both the single helix and the two triple helices can pack into the unit cell of lentinan extremely well, but the double helical models are encountering difficulties. When the packing tests were repeated with smaller hexagonal cells, such as the one for the lower hydrate (10), neither the single nor the double helical models could pack, but both triple helices still packed with ease.

As a second test, the Fourier transform of each helix was calculated using the equation:

$$[3] \quad F(R,\psi,Z) = \sum_n \sum_j f_j J_n(2\pi R r_j) \times \exp\{i[n(\psi - \phi_j + \pi/2) - 2\pi Z z_j]\}$$

where $F(R,\psi,Z)$ is the numeric value of the transform at the point in reciprocal space with cylindrical coordinates R,ψ,Z, f_j is the atomic scattering factor and r_j, ϕ_j, z_j are the cylindrical polar coordinates of the jth atom. $J_n(X)$ is the Bessel function of order n and argument X. The transform was calculated for the rotational coordinate ψ ranging from 0° to 60° in 10° increments and for the Z coordinate of all required layer lines. Radial sections of the transforms at ψ identical with best packing position of each model are shown in Fig. 6. The relative magnitudes of the observed intensities are shown for comparison in each transform as vertical lines.

Even a casual comparison of the transforms shows that only the triple helices account in a satisfactory manner for the observed intensities.

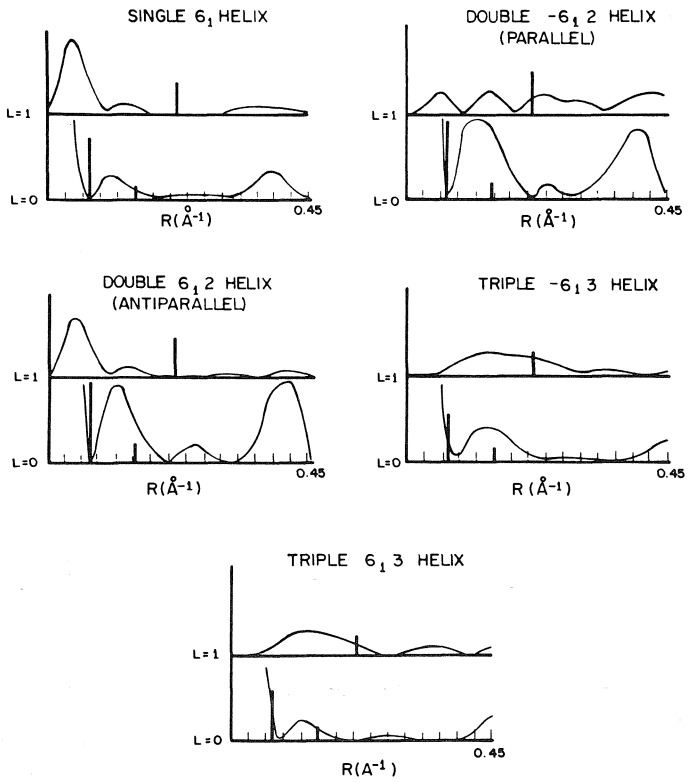

FIG. 6. Predicted intensity distribution on observed layers 0 and 1 for the five probable conformations of β-(1→3)-D-glucan, as calculated from eq. 3. The observed intensities are denoted by vertical lines of approximately correct height as an indication of magnitude.

TABLE 3. Structure amplitudes of equatorial reflections for the triple helical models

Reflection	*F*(calcd) Left-handed helix	*F*(obs)*	*F*(calcd) Right-handed helix
100	69	54	62
110	23	31	38
200	30	37	22

*It was assumed that the reflections (110) and (200) each contributed 50% of the uncorrected intensity occurring at 6.7 Å.

The single helix and the antiparallel double helix can be ruled out immediately because they predict no intensity on the first layer where substantial intensity is present in the X-ray diagram. Likewise, the double parallel helix can be ruled out because the observed high intensity equatorial reflection falls into a trough in the transform. On the other hand, both left- and right-handed triple helices yield transforms that are in good agreement with the observed intensity distribution. This agreement is particularly evident when a comparison is made of calculated and observed structure amplitudes for the equatorial reflections, as shown in Table 3. Furthermore, the triple helix transforms in best agreement with experimental intensity distributions were obtained when the rotational coordinate ψ was nearly identical with the rotational position of the best packing triple helix models. This was true for both left- and right-handed triple helices.

It is thus probable that the crystal structures of β-(1→3)-glucans of lentinan, curdlan, *A. mellea*, and *Lilium longiflorum* are based on a triple helix. The limited X-ray data available from lentinan do not allow determination of the helix chirality, but this should not be a problem with the data available from curdlan (10). In any case, the left- and right-handed triple helices are surprisingly alike, as shown in Fig. 7, both

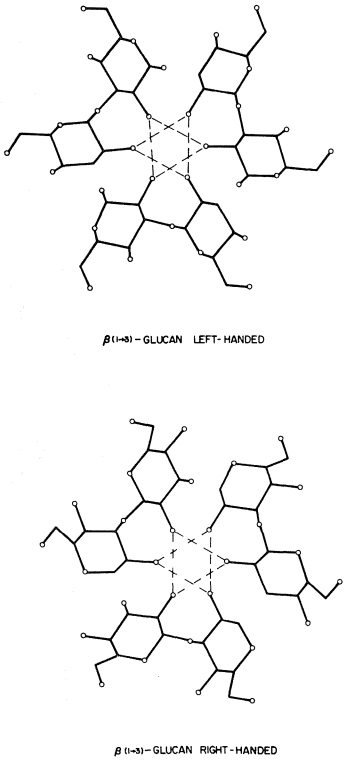

FIG. 7. Projection in the x–y plane of the first two residues of each strand of the left- and right-handed triple helical models.

structures being stabilized by an interstrand O(2)---O(2) hydrogen bond network, as was the case in the structure of β-(1→3)-xylan. Because the latter is right-handed, it is probable that the triple helix of the glucan may also be right-handed.

R. H. MARCHESSAULT, Y. DESLANDES, K. OGAWA, and P. R. SUNDARARAJAN. Can. J. Chem. **55**, 300 (1977).

The conformation of a bacterial β-(1→3)-D-glucan (curdlan) was studied by X-ray diffraction measurements on fiber diagrams. The glucan fiber, prepared by extruding a dimethyl sulfoxide solution of the glucan into methanol and washing in water (**A**) was of low crystallinity but with a characteristic diffraction and orientation 'as spun'. The same fiber annealed in water, under tension, at 140 °C, in a closed bomb, was of higher crystallinity and occurred as two reversible crystalline polymorphs: one at high relative humidity (**B**) and the other at relative humidities less than 20% (**C**). All three X-ray diagrams displayed the X-shaped patterns characteristic of helical conformations; equatorial diffraction corresponded to hexagonal packing. The fiber axis data for **B** and **C** coupled with a conformational study and density data leads to a proposed three-stranded helical structure with $P6_3$ symmetry.

Curdlan in water forms an irreversible gel when a 2–4% solution is heated above 55 °C. The same gel given the annealing treatment described above undergoes syneresis and the gel properties are lost.

R. H. MARCHESSAULT, Y. DESLANDES, K. OGAWA et P. R. SUNDARARAJAN. Can. J. Chem. **55**, 300 (1977).

La conformation d'un β-(1→3)-D-glucan d'origine bactérienne ("curdlan") a été étudié par diffraction de rayons-X (diagramme à fibre). Les fibres du glucan préparé par extrusion de ce dernier en solution dans le diméthylsulfoxide dans le méthanol et lavés à l'eau (**A**) étaient de faible cristallinité, mais montraient une orientation dès l'extrusion. Les mêmes fibres après avoir été recuites, dans l'eau sous tension, à 140 °C dans une bombe fermée, montraient une haute cristallinité, ainsi que la présence de deux polymorphes cristallins, réversibles: le premier à une humidité relative élevée (**B**) et le second à une humidité relative plus faible que 20% (**C**). Les 3 différents diagrammes montrent un cliché de diffraction caractéristique d'une conformation hélicoidale et correspondent à une maille hexagonale. Les dimensions selon l'axe de la fibre pour **B** et **C**, les valeurs des densités, ainsi qu'une étude conformationnelle nous amènent à proposer une triple-hélice pour la structure du "curdlan", ayant une symétrie $P6_3$.

Le "curdlan" forme dans l'eau un gel irréversible quand une solution de 2–4% est chauffée au dessus de 55 °C. Le même gel exposé au "recuit" décrit précédemment, subit une synérèse et les propriétés du gel sont perdues.

We wish to report X-ray fiber diffraction data which we have obtained from the extracellular bacterial polysaccharide curdlan produced by the Takeda Chemical Co., Osaka, Japan (1). This sample was dissolved in dimethyl sulfoxide (DMSO) and high resolution proton and ^{13}C resonance spectra were recorded and interpreted to show that the polysaccharide was >99% pure β-(1→3)-D-glucan (2). A proof of the chemical homogeneity of this polysaccharide based on chemical methods has also been given (3).

Oriented fibers were prepared by extruding a 10% solution of curdlan in DMSO into methanol at room temperature. The weakly crystalline and oriented fibers were further crystallized by washing in water and annealing in a thermostated, sealed bomb at 143 °C in the presence of H_2O. The fibers which were under a constant load elongated about 70% under these conditions but did not break. The observed X-ray diffraction patterns, after the annealing treatment, were of a quality significantly better than what has been reported so far, both as regards orientation, crystallinity, and number of polymorphs (1, 4, 5).

X-Ray fiber patterns were recorded in a flat film camera at controlled relative humidities (r.h.). Shown in Fig. 1 (and schematically in Fig. 2) are patterns corresponding to: **A**, the extruded fiber washed in water and exposed to X-rays at

[1]On leave from: Radiation Center of Osaka, Prefecture, Sakai, Osaka 593, Japan.

[2]Present address: Xerox of Canada, Mississauga, Ontario, Canada.

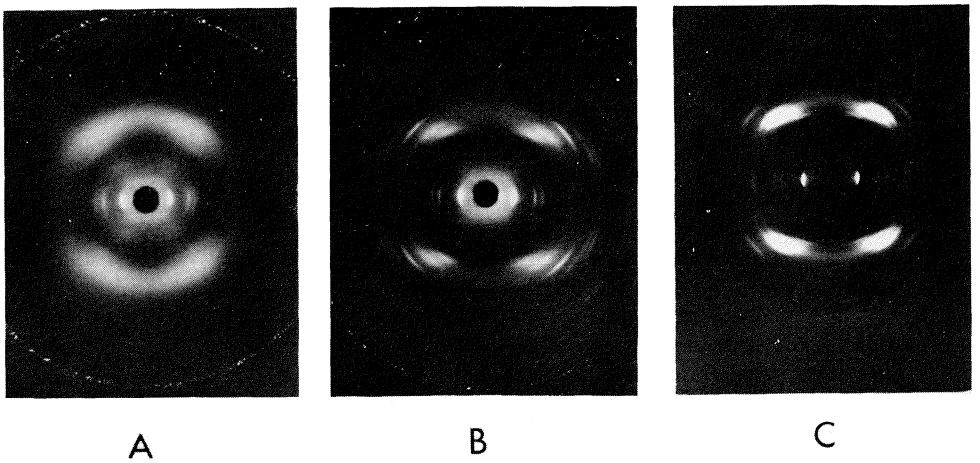

FIG. 1. X-Ray diffraction patterns of oriented curdlan fibers showing the three different polymorphs: **A** as spun, after washing and drying, at 75% r.h.; **B** after annealing in water at 143 °C, at 75% r.h.; **C** same as **B**, at 0% r.h. Data were recorded at same film to sample distance.

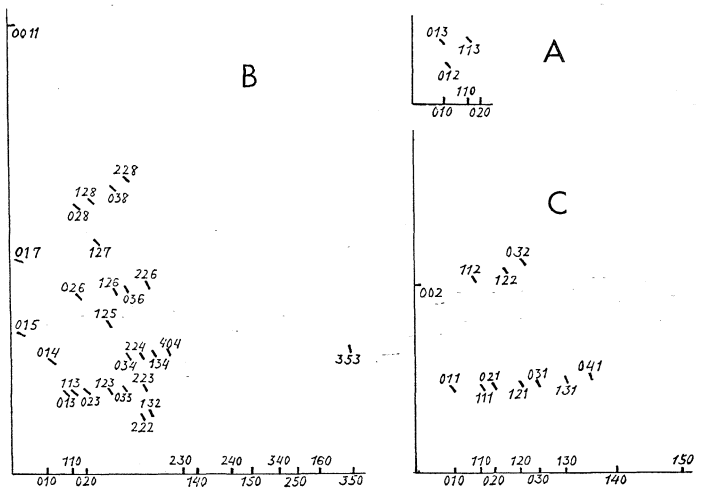

FIG. 2. Indexed schematic display of the X-ray patterns corresponding to those in Fig. 1.

75% r.h., a similar pattern was also observed at 0% r.h.; **B**, the annealed fiber exposed to X-rays at 75% r.h.; **C**, the same fiber as **B** at 0% r.h. It was possible to go reversibly from **B** to **C** simply by adjusting the relative humidity in the camera.

It seemed that 20% r.h. was the changeover point where elements of both patterns **B** and **C** were observed together and there was no obvious evidence of a gradual transition from one phase to the other.

The very extensive change in the patterns on going from **A** to **B** is not unexpected when one considers the annealing treatment. It seems likely that the 'melting' of curdlan crystals in the presence of H_2O occurs somewhere around 140 °C, hence a drastic recrystallization has occurred in going from **A** to **B**.

Although **C** is less rich in diffraction data than **B**, it is a pattern of equal quality as may be judged by the extensive equatorial diffraction and sharpness of the diffraction spots. Since this pattern was recorded at zero r.h., and did not change even after the sample was dried at 60 °C in vacuum, it is believed to be a dehydrated form of **B** which would then correspond to a crystalline hydrate.

TABLE 1. Parameters of curdlan fiber diffraction patterns interpreted as multiple helices

Pattern	Characteristic	Hexagonal base $a = b$ (Å)	Fiber axis c (Å)	Density† (g/cm^3)	Number of glucose units per unit cell	Number of water molecules per unit cell	Number of chains per unit cell
A	Before annealing	17	22	1.45	30	—	4–6
B	Hydrated form* (after annealing)	15.71 ± 0.05	18.82 ± 0.05	1.47	18	36	3
C	Dehydrated* (after annealing)	14.38 ± 0.05	5.79 ± 0.05	1.49	6	0	3

*Lattice parameters were obtained by a least-squares refinement program.
†As measured by flotation in a solution of *p*-xylene and chloroform.

Table 1 gives the unit cell, density, and other data corresponding to the crystal structures of the three samples. The fiber repeat changes drastically from **B** to sample **C**. The latter could correspond to a sixfold helix with a 0.96 Å advance per monomer but both conformational analysis and intensity calculations reject this possibility (4, 6). It is hard to explain the drastic change in the fiber repeat in the transformation **B** $\rightleftharpoons$ **C** unless there is a very close similarity between the helix parameters in the two cases since there is no visible macroscopic rearrangement in the sample. At this point, the data for **C** are best interpreted in terms of three intertwined 6_1 helices with an advance per monomer of 2.89 ± 0.05 Å, *i.e.* a triple helical structure similar to what has been proposed (7) for its crystalline homolog β-(1→3)-D-xylan. This leads to a c value which is 1/3 of the repeat of the individual helices and we propose that this same symmetry, which corresponds to the space group $P6_3$, is present in **C**. Conformational analysis by the virtual bond method (8) for a sixfold helix with a 5.79/2 Å advance per monomer leads to a stereochemically acceptable structure. Fourier transform calculations for triple helices of this kind (4) confirm the above interpretation.

In the case of the hydrated polymorph **B** the $P6_3$ symmetry is lost in the triple strand structure as evidenced by the 18.82 ± 0.05 Å repeat instead of 5.79 ± 0.05 Å repeat. A simple explanation is that addition of water of hydration takes place in a fashion so as to destroy the $P6_3$ symmetry and cause a slight increase in helix pitch which now becomes the fiber repeat. The observed intensification of the apparent 11th order meridional reflection (1.7 ± 0.1 Å) on tilted-fibre photographs characterizes the new molecular periodicity, the significance of which is yet to be established.

The base plane parameters for **B** are similar to those reported by Kreger and Jelsma (5) as well as Bluhm and Sarko (4), while **A** lattice is similar to that reported by Harada (1). The dry form **C** has not been reported to date. The fiber repeat of 18.82 ± 0.05 Å for **B** is reported for the first time thanks to the superior resolution of our patterns.

Evidence so far points to the fact that the β-(1→3)-D-glucan linkage encourages multiple helices (4, 5, 7). In fact at this point we have no definitive interpretation of the helical arrangement in **A** but it would appear that a somewhat irregular and disordered multiple helical structure would be in keeping with the poor quality of the observed data. In view of the importance of gaining a full understanding and definition of the triple helical structure in glucans it would appear that **C** is the pattern whose full interpretation will be most rewarding.

Gelation Phenomenon

Multiple helix interactions have been suggested as a gelling mechanism for polysaccharides (9) and one would expect that the aqueous curdlan system would fall into this category also. Indeed it is reported to form an irreversible gel on heating (1) but the quality of the gel is related to the different types of interactions between chains such as involved in the different crystal structures **A** and **B**. Our original sample is an amorphous, particulate material derived from a spray-drying process. On heating a 2–4% suspension in water, a slight clearing of the suspension occurs at 55 °C then gelation to a resilient gel which resists further change even at the boil. This gel on drying gives an X-ray pattern corresponding to **A** in Fig. 1. When the gel is placed in a sealed bomb with H_2O and heated to 160 °C for 1 h, there is considerable deswelling (syneresis) of the gel and

a pattern corresponding to **B** is obtained. The syneresis can be sufficiently severe to crumple the gel. Finally if the syneresed gel is dried over P_2O_5 it will yield a pattern corresponding to **C**.

Observations in the polarizing microscope show that under 100 °C, the gel was only slightly birefringent and was made of the swollen original particles which filled the container. The cohesion between these particles would seem to be due to a cocrystallization of 'surface solubilized' chains of touching particles. The syneresed gel is highly birefringent and clearly the high temperature has encouraged solution then extensive interaction between the intertwining helices so as to expel the intercrystalline water and form a far less swollen gel. Thus if the degree of crystallinity is too great in multiple stranded structures the 'pseudo-crosslink' effect of the crystallites, which leads to gelation, is lost. In other words, under the right conditions crystallization forces can 'squeeze' the gel dry.

The preparation of tetradecamethylcycloheptaphosphazene, by the methylation of the corresponding fluorophosphazene $(NPF_2)_7$ with methylmagnesium bromide, is reported. Crystals of tetradecamethylcycloheptaphosphazene are monoclinic, $a = 13.160(1)$, $b = 11.685(1)$, $c = 18.576(1)$ Å, $\beta = 108.333(5)°$, $Z = 4$, space group $C2/c$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.046 and R_w of 0.063 for 2568 reflections with $I \geq 3\sigma(I)$. The molecule has crystallographic C_2 symmetry with mean bond lengths (rms deviations from the mean in parentheses, bonds not involving hydrogen have been corrected for libration) P—N, 1.592(6), P—C, 1.804(11), and C—H, 0.94(7) Å, and mean angles in the 14-membered ring are 132.9° at N and 117.1° at P.

KEITH D. GALLICANO, RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 304 (1977).

On rapporte la préparation du tétradécaméthylcycloheptaphosphazène par méthylation du fluorophosphazène correspondant $(NPF_2)_7$ par le bromure de méthylmagnésium. Les cristaux de tétradécaméthylcycloheptaphosphazène sont monocliniques, $a = 13.160(1)$, $b = 11.685(1)$, $c = 18.576(1)$ Å, $\beta = 108.333(5)°$, $Z = 4$, groupe d'espace $C2/c$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.046$ et $R_w = 0.063$ pour 2568 réflexions avec $I \geq 3\sigma(I)$. La molécule a une symétrie cristallographique C_2 avec des longueurs de liaison moyennes (les déviations rms par rapport à la moyenne sont entre parenthèses et les liens n'impliquant pas d'hydrogène ont été corrigés pour les librations) P—N, 1.592(6), P—C, 1.804(11), et C—H, 0.94(7) Å; les angles moyens dans le cycle à 14 membres sont 132.9° au niveau de l'azote et de 117.1° au niveau du phosphore.

[Traduit par le journal]

Introduction

The methylphosphazenes $(NPMe_2)_{3,4}$ have been known for many years (1), but the preparation of the pentameric compound $(NPMe_2)_5$ has only recently been reported (2). In the present paper the preparation of the heptameric derivative $(NPMe_2)_7$ is described. The method, which employs the action of methylmagnesium bromide on the appropriate fluorophosphazene, is generally applicable to the preparation of methylphosphazenes $(NPMe_2)_n$ of large ring size ($n \geq 6$), and has been used to extend the series of known methylphosphazenes from the trimeric to the decameric derivatives.

Unlike dimethylsiloxanes (3–5), and many phosphazenes of large ring sizes, all the methylphosphazenes $(NPMe_2)_{3-10}$ are crystalline solids at room temperature and, as such, are potentially useful sources of structural information. The molecular structures of $[NP(OMe)_2]_{4,6,8}$ (6–8) and $[NP(NMe_2)_2]_{4,6,8}$ (9–11) all show interesting conformational effects, but their interpretation in terms of nonbonded interactions is complicated by the size and shape of the ligands. In the case of the methylphosphazenes however, the more nearly spherical nature of the methyl ligands and their smaller size greatly reduces the number of nonbonded interactions, and conformational trends are therefore more easily understood. Consequently, the crystal structure determinations of several methylphosphazenes of large ring size are currently being carried out; that of the heptamer $(NPMe_2)_7$ has recently been completed and is reported here.

A comprehensive analysis of the structural data is planned for the series $(NPMe_2)_{3-10}$ upon completion of the structural work.

Experimental

Preparation of $(NPMe_2)_7$

A solution of $(NPF_2)_7$[1] (3.28 g, 5.65 mmol) in 50 ml of diethylether was added, under an atmosphere of nitrogen, to a stirred solution of MeMgBr (from 2.54 g, 104 mmol of magnesium) in 250 ml of ether. No immediate reaction occurred, but, after an induction period of approximately 2 h, precipation of magnesium salts commenced. To ensure the completion of the reaction, the mixture was heated under reflux for a further 48 h. The solvent was then distilled from the reaction vessel, and the reaction mixture dissolved in 200 ml of water. A 1 *M* solution of sodium carbonate (200 ml) was then added to precipitate all the magnesium as its carbonate. The solution was filtered and the solvent evaporated from the filtrate to leave a white solid, which was repeatedly extracted with chloroform. The solvent was distilled from the combined chloroform extracts to leave a white crystalline solid (0.620 g). The original water-insoluble precipitate was recombined with the water-soluble residue and the mixture boiled in 200 ml of ~1 *M* NaOH for 1 h. This mixture was then refiltered, the solvent removed from the filtrate, and the residue extracted with hot chloroform, thereby affording a further 0.523 g of material soluble in chloroform. The two fractions of the product were combined and purified by sublimation *in vacuo* and recrystallization from hexane to give colourless blocks of $(NPMe_2)_7$ (1.14 g, 2.17 mmol, 40% yield); mp 128–130 °C. *Anal.* calcd. for $C_{14}H_{42}N_7P_7$: C 32.01, H 8.06, N 18.66; found: C 31.90, H 7.96, N 18.80.

The methylphosphazenes $(NPMe_2)_n$ (n = 6 and 8–10) have been prepared using a procedure analogous to that just described. The melting points and the ν_{as}(P=N) stretching frequencies of these compounds are given in Table 1.

X-Ray Crystallographic Analysis of $(NPMe_2)_7$

Colourless crystals of $(NPMe_2)_7$ are obtained by recrystallization from hexane. The crystal chosen for study was mounted with (110) perpendicular to the goniostat axis and had dimensions of *ca.* 0.28 × 0.30 × 0.50 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares treatment of $\sin^2\theta$ values for 36 reflections measured on a diffractometer with Cu K_α radiation. Crystal data are:
$C_{14}H_{42}N_7P_7$ f.w. = 525.4
Monoclinic, a = 13.160(1), b = 11.685(1), c = 18.576(1) Å, β = 108.333(5)°, V = 2711.6(4) Å^3, Z = 4, ρ_c = 1.2868(2) g cm^{-3}, $F(000)$ = 1120 (22 °C, Cu K_α, λ = 1.54178 Å, μ = 43.1 cm^{-1}). Absent reflections: hkl, $h + k \neq 2n$, $h0l$, $l \neq 2n$, and $0k0$, $k \neq 2n$. Space group $C2/c$ (C_{2h}^6, No. 15) from structure analysis.

[1] $(NPF_2)_{6-10}$ were prepared by fluorination, with KSO_2F, of a mixture of chlorophosphazenes $(NPCl_2)_n$ (n > 5), and separated by vpc (23).

TABLE 1. Melting points and (P=N) stretching frequencies for the methylphosphazenes $(NPMe_2)_n$ (n = 6–10)

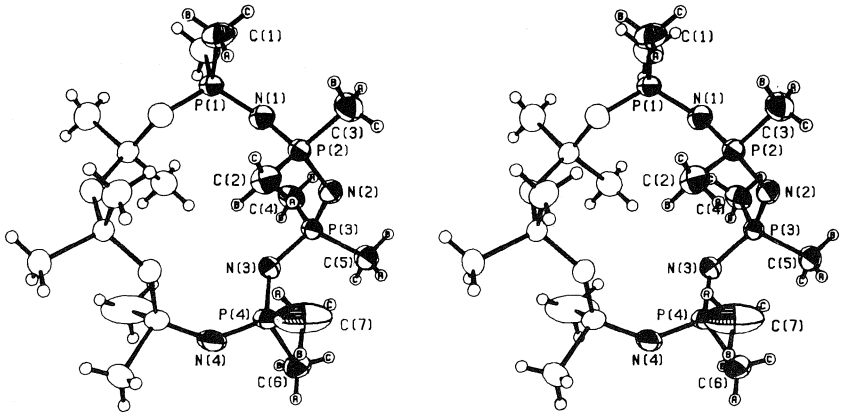

FIG. 1. A stereo view of the tetradecamethylcycloheptaphosphazene molecule; 50% ellipsoids are shown for the nonhydrogen atoms. Hydrogen atoms have been assigned artificially small temperature factors for the sake of clarity.

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, Cu K_α (nickel filter and pulse height analyser), and a θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ, with 10 s background counts being measured at each end of the scan. Data were measured to $2\theta = 160°$ (minimum interplanar spacing 0.78 Å). The intensity of the check reflection, measured every 50 reflections throughout the data collection, decreased slowly to a final value which was 0.97 times the initial value. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (12, 13). Transmission factors ranged from 0.262 to 0.447. Of the 2963 independent reflections measured, 2581 (87%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were used in the solution and refinement of the structure.

The systematic absences allow space groups *Cc* or *C2/c*. The centrosymmetric space group *C2/c* was strongly indicated by the *E*-statistics. The structure was solved by direct methods (14). Fourteen of the 15 nonhydrogen atoms were found among the 20 highest peaks on the *E*-map calculated from the set of signs having the highest consistency index (0.97). Two cycles of isotropic full-matrix least squares refinement of the 14 atoms gave $R = 0.162$. A difference map gave the position of the remaining nonhydrogen atom, C(7). Anisotropic refinement lowered R to 0.066 and a subsequent difference map gave positions for all 21 hydrogen atoms. The entire structure (hydrogen atoms having isotropic thermal parameters) was refined for 8 cycles giving a final R of 0.046 and R_w of 0.063 for 2568 reflections with $I \geq 3\sigma(I)$ (13 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $1.6(2) \times 10^{-7}$. The scattering factors of ref. 15 were used for the nonhydrogen atoms and those of ref. 16 for the hydrogen atoms. Anomalous scattering factors from ref. 17 were used for the nonhydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^0 \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

In the later stages of refinement it became apparent from the large thermal parameters that C(7) and N(4) were most likely disordered. Attempts to refine a split atom disordered model in *C2/c* and an ordered model in *Cc* were unsuccessful. On the final cycle of refinement the mean parameter shift was 0.11σ and the largest shift, 1.0σ, was associated with the x coordinate of H(7*c*). The mean error in an observation of unit weight was 1.625. The final positional and thermal parameters appear in Tables 2 and 3 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the nonhydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (18) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least squares analysis) is 0.0017 Å^2. Analysis of all nonhydrogen atoms except C(7) and N(4) with constraints of C_2 symmetry resulted in an rms ΔU_{ij} of 0.0054 Å^2, a

[2]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

value which indicates some independent motion but the rigid-body parameters resulting from this analysis are otherwise physically reasonable. Analysis of the P(4) tetrahedron without symmetry constraints gave an rms ΔU_{ij} of 0.0019 Å^2 and indicates that N(4) is probably twofold disordered about the C_2 axis as was inferred from the large thermal parameters of N(4) and C(7).

The appropriate bond distances have been corrected for libration (19, 20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Bond angles about P(4) and N(4) in Table 5 are corrected for libration. Corrected angles about other atoms differ by less than 0.5σ from the uncorrected values.

Results and Discussion

Figure 1 shows a view of the molecule with the crystallographic numbering scheme. The unique intraannular torsion angles in the 14-membered ring are listed in Table 6. The mean structural parameters for $(NPMe_2)_7$ are compared with those of the related molecule $(NPMe_2)_4$ (21) in Table 7.

The crystal structure consists of well separated molecules of tetradecamethylcycloheptaphosphazene. The shortest intermolecular nonbonded distance, H(4*c*)···H(7*b*) ($\frac{1}{2} + x$, $y - \frac{1}{2}$, z), 2.41(6) Å, corresponds to a normal van der Waals contact.

Idealized local conformations (22) at each P atom are defined in terms of the intraannular torsion angles about the two P—N bonds. The

TABLE 6. Intra-annular torsion angles (deg), 14-membered ring*

Bond	Value
P(1)—N(1)	−68.7(1)
N(1)—P(2)	156.4(1)
P(2)—N(2)	−46.3(1)
N(2)—P(3)	−57.4(1)
P(3)—N(3)	−72.7(1)
N(3)—P(4)	166.8(1)
P(4)—N(4)	−36.1(1)

*Symmetry related torsion angles have the same signs as those listed above.

TABLE 7. Mean* structural parameters for $(NPMe_2)_n$ ($n = 4$ and 7) (distances in Å and angles in deg)

	Value	
Parameter	$n = 4$	$n = 7$
P—N	1.596(5)	1.592(6)
C—P	1.804(3)	1.804(11)
N—P—N	119.8(2)	117.1(16)
P—N—P	132.0(2)	132.9(20)
C—P—C	104.1(2)	103.9(5)

*Weighted mean values with rms deviations from the mean in parentheses (where appropriate).

ideal *GG* conformation has both torsion angles 60° while the *GT* conformation has one torsion angle of 60° and one of 180°. In $(NPMe_2)_7$ phosphorus atoms P(1) and P(3) have *GG* local conformations and atoms P(2) and P(4) have *GT* local conformations. The adjacent phosphorus atoms, therefore, have alternately *GG* and *GT* local conformations around the 14-membered ring except for the symmetry related pair P(4) and P(4′)[3] which both have *GT* local conformations.

The mean structural parameters for the heptamer are compared with those of the tetramer in Table 7. The mean P—N and P—C bond lengths and the C—P—C and P—N—P angles are nearly the same for all three structures, while the N—P—N angles are seen to decrease with increasing ring size. There are statistically significant variations among the individual values averaged to give the means shown in Table 7 which probably arise from differences between the local conformations of the ring atoms.

[3]Here and elsewhere in this paper primed atoms are related to those in Table 2 by rotation about the twofold axis passing through P(1) and N(4).

Vibrational analysis and force field for some secondary iodides

G. CROWDER AND ZAHRA NAJAFI
Deparment of Chemistry, West Texas State University, Canyon, Texas 79016
Received August 11, 1976

G. CROWDER and ZAHRA NAJAFI. Can. J. Chem. **55**, 310 (1977).

Normal coordinate calculations were made for 2-iodopropane and the three conformers of 2-iodobutane. A forty-seven parameter modified valence force field was used that fit eighty-four frequencies of those four molecules in the 250–1500 cm^{-1} region with an average error of 4.8 cm^{-1}, or 0.6%. Infrared spectra were obtained for 2-iodopentane and 3-iodopentane, and zero-order normal coordinate calculations were made for three conformers of 2-iodopentane and for five conformers of 3-iodopentane. The S_{HH}, $S_{HH'}$, and S_{CH} conformers of 2-iodopentane are present, along with one or two unidentified ones, and 3-iodopentane exists as a mixture of the S_{HH}, $S_{HH'}$, S_{CH}, and $S_{CH'}$ conformers. The force constants that were determined for the four conformers of 2-iodopropane and 2-iodobutane were transferred to the two secondary iodopentanes with good success. The average difference between observed and calculated wavenumbers for 164 frequencies of seven conformations of these two compounds was 5.8 cm^{-1}.

G. CROWDER et ZAHRA NAJAFI. Can. J. Chem. **55**, 310 (1977).

On a fait des calculs de coordonnées normales pour l'iodo-2 propane et pour les trois conformères de l'iodo-2 butane. On a utilisé un champ de force de valence modifié à 47 paramètres qui permet d'ajuster 84 fréquences de ces quatre molécules dans la région de 250–1500 cm^{-1} avec une erreur moyenne de 4.8 cm^{-1} ou 0.6%. On a déterminé les spectres infrarouges de l'iodo-2 pentane et de l'iodo-3 pentane et on a effectué des calculs de coordonnées normales avec un ordre zéro pour les trois conformères de l'iodo-2 pentane et pour cinq conformères de l'iodo-3 pentane. Les conformères S_{HH}, $S_{HH'}$, et S_{CH} de l'iodo-2 pentane sont présents aux côtés d'une ou deux autres conformations non-identifiées et l'iodo-3 pentane existe sous forme de mélange des conformères S_{HH}, $S_{HH'}$, S_{CH} et $S_{CH'}$. Les constantes de force qui ont pu être déterminées pour les quatre conformères de l'iodo-2 propane et de l'iodo-2 butane ont pu être transferrées aux deux iodopentanes secondaires avec un bon succès. La différence moyenne entre les nombres d'onde observés et calculés pour 164 fréquences de sept conformations de ces deux composés est de 5.8 cm^{-1}.

Introduction

Infrared and Raman spectra for 2-iodopropane have been published by Klaboe (1), and he proposed a tentative vibrational assignment in terms of group vibrations. Benedetti and Cecchi (2) made normal coordinate calculations for 2-iodopropane and 2-iodobutane and obtained a force field that fit the frequencies of 2-iodopropane, the S_{HH} conformer of 2-iodobutane, and most of those of the $S_{HH'}$ and S_{CH} conformers of 2-iodobutane, all in the 250–1400 cm^{-1} region, with an average difference between observed and calculated values of 1.1% (fifty-two frequencies).

The calculations for 2-iodopropane and 2-iodobutane have now been repeated for the following reasons: (*1*) Benedetti and Cecchi did not list the calculated results for 2-iodopropane, of which the normal coordinate descriptions of the normal modes are of interest, (*2*) several force constants obtained in the previous work (2) cannot be compared with those of similar compounds, because the C—I stretching force constant was held fixed at the C—Br value that had been obtained for secondary bromides (3), a value obviously too high for the iodides, (*3*) the average error of 1.1% in the previous work seems rather high. A force field that would more accurately reproduce the observed frequencies of these molecular species could be used with more confidence as an aid in making vibrational assignments for other secondary alkyl iodides.

Infrared spectra have been reported for 2-iodopentane and 3-iodopentane only in the region 400–800 cm^{-1} (4). Carbon–iodine stretching bands were assigned to four conformers of 2-iodopentane and five conformers of 3-iodopentane. Gates, Mooney, and Willis (4) assigned the C—I stretch of the S_{CC} conformer of 3-iodopentane to a band at 460 cm^{-1}, contrary to

the normal assignment of the highest-frequency carbon–halogen stretch to a conformer with a carbon *trans* to the halogen.

In an effort to learn more about the conformational behavior of these two compounds, to make vibrational assignments, and to check the transferability of the force constants obtained from 2-iodopropane and 2-iodobutane, infrared spectra have been obtained and zero-order normal coordinate calculations have been made for three conformers of 2-iodopentane and for five conformers of 3-iodopentane.

Experimental

Infrared spectra were obtained with a Beckman IR12 spectrophotometer. The compounds were obtained from Pfaltz & Bauer and were used without further purification.

Normal Coordinate Calculations

Normal coordinate calculations were made with a PDP-10 computer and utilized programs written by Schachtschneider and co-worker (5, 6) for calculation of the **G**-matrix (gmat), solution of the vibrational secular equation (vsec), and for the least-squares refinement of designated force constants to fit the calculated to the observed frequencies (fpert). These references should be consulted for details of the calculations, treatment of the redundancy problem, etc. The molecular parameters used were C—C = 1.54 Å, C—H = 1.09 Å, C—I = 2.135 Å, and all angles were assumed to be tetrahedral.

A forty-seven parameter modified valence force field was used, with initial values being taken from secondary bromides (3), secondary chlorides (7), and primary iodides (8). Calculations were first made for 2-iodopropane, to which thirty-five of the force constants were applicable. Symmetry coordinates were constructed in order to factor the secular equation into two symmetry blocks. The transferred force constant values resulted in an average difference of 14 cm^{-1} between observed and calculated frequencies. Several changes in the force constants were made manually, using the potential energy distributions and **JZ** matrices as guides. Thirteen force constants were then refined by the least-squares program, resulting in an average difference of 1.6 cm^{-1}, or 0.2%, for the twenty frequencies below 1500 cm^{-1}. These force constant values will not be given here, but are available from the author, along with a normal coordinate description of the normal modes obtained with the use of these constants.

The force constants obtained for 2-iodopropane and additional ones transferred from a hydrocarbon force field (9) were used in a zero-order calculation of the frequencies of the S_{HH} conformer of 2-iodobutane. The average difference between calculated and observed wavenumbers was 12.9 cm^{-1}. Several computer runs were then made with the least-squares program adjusting different sets of force constants. In the final run, seventeen constants were refined to fit

forty-five frequencies (excluding C—H stretch) of 2-iodopropane and the S_{HH} conformer of 2-iodobutane. The average error was 5.0 cm^{-1}.

The next step was to use the force constant values obtained from 2-iodopropane and S_{HH} 2-iodobutane in a zero-order calculation of the frequencies of the $S_{HH'}$ and S_{CH} conformers of 2-iodobutane. The average error for forty-one frequencies between 200 and 1500 cm^{-1} was 8.1 cm^{-1}. The two calculated C—I stretching frequencies were in error by 35 cm^{-1} each, and exclusion of these two values leaves an average error of 6.7 cm^{-1}.

Finally, force constants were refined in several attempts to simultaneously fit twenty frequencies of 2-iodopropane, twenty-three frequencies of S_{HH} 2-iodobutane, twenty-three frequencies of $S_{HH'}$ 2-iodobutane, and eighteen frequencies of S_{CH} 2-iodobutane. In the final run, nineteen force constants were refined to fit these eighty-four

frequencies with an average difference between observed and calculated values of 4.8 cm^{-1}, or 0.6%. The observed and calculated wavenumbers are listed in Tables 1 and 2, along with normal coordinate descriptions of the normal modes in terms of the symmetry coordinates whose definitions are given in Table 3. The force constants, their definitions, and their values are listed in Table 4.

Results and Discussion

The normal coordinate descriptions of the normal modes of 2-iodopropane listed in Table 1 support the assignments made by Klaboe (1) except for the two bands observed by him at 250 and 269 cm^{-1}. He assigned these two bands to a'' and a' skeletal bends, respectively, but the reverse assignment was made in the present work, based on the calculations. Both bands are very strong in the Raman spectrum, and Klaboe reported both bands as polarized (1). However, one of these bands must be due to an a'' bend and should be depolarized. Decomposition of the sample may have caused a problem with the polarization data.

It should be noted that calculation of the two methyl torsional frequencies of 2-iodopropane (192 and 217 cm^{-1}) required introduction of F_τ, the interaction constant between the two torsional internal coordinates. The value of F_τ required is approximately 9% of the value of H_τ. Without F_τ, the a' and a'' torsional frequencies were calculated to differ by only 2 cm^{-1}.

There are several differences in the potential energy distributions of the three conformers of 2-iodobutane listed by Benedetti and Cecchi (2) and the distributions listed in Table 2. For example, they found the band to which the transverse CH bend makes its largest contribution to be 1346, 1340, and 1349 cm^{-1}, respectively, in the S_{HH}, $S_{HH'}$, and S_{CH} conformers. The present assignment is 1289, 1311, and 1311 cm^{-1}, in the same order. The calculated values for 2-iodopropane were not given by Benedetti and Cecchi, but with our force field, the two CH bends of 2-iodopropane were calculated at 1202 (a') and 1324 (a'') cm^{-1}, in good agreement with Snyder's (3) values of 1221 and 1322 cm^{-1} for 2-bromopropane.

Another difference between the present work and that of Benedetti and Cecchi that should be pointed out lies in the C—I stretching coordinates. They calculated a larger percentage of C—I stretch to the bands at 487, 454, and 579 cm^{-1} in the three conformers of 2-iodobutane than shown in Table 2. However, this difference was due mainly to their use of a larger value for the C—I stretch force constant (2.312 mdyn/Å) than used in the present work (1.716 mdyn/Å). The effect of using the larger value is to increase the C—I stretching contribution to the higher frequency band and decrease this contribution to the lower-frequency bands to which it contributes. Their value is the C—Br value transferred from a secondary bromides force field, and so cannot give the correct potential energy distributions to the low-frequency bands.

2-Iodopentane

Gates *et al.* (4) show the liquid and solid-state spectra of this compound in the region 400–700 cm^{-1}, and they list the bands observed between 400 and 800 cm^{-1}. They have assigned bands to four separate conformers, namely the S_{HH} (all carbons coplanar), $S_{HH'}$ (fourth carbon oriented on same side of plane as iodine), S_{CH} (fourth carbon *trans* to iodine), and a fourth conformer they call *cis* X—H. We obtained

[a]Stretching constants are in units of mdyn/Å; stretch–bend constants are in units of mdyn/rad; bending constants are in units of mdyn Å/(rad)².
[b]These constants were constrained to the 2-iodopropane value.
[c]These constants were refined.

spectra for this compound and made normal coordinate calculations in order to make vibrational assignments and to check the transferability of the force field determined previously. Calculations were made only for three conformers, namely S_{HH}, $S_{HH'}$, and S_{CH}. The $S_{HH'}$ and S_{CH} conformers are formed from the S_{HH} by rotation about the C_2—C_3 bond. Calculations were not made for the '*cis* X—H' conformer because previous calculations were not made for such a configuration, and interaction force constants were not available.

The observed and calculated wavenumbers are listed in Table 5. There are four observed bands assigned solely to the S_{HH} conformer, and there is little doubt about this form being present. There are five bands assignable to both $S_{HH'}$ and S_{CH} conformers, so one or both of these must also be present. There are two bands assigned solely to the S_{CH} and one solely to $S_{HH'}$, and it seems likely that both of these conformers are present. All other observed bands are due to overlapping bands from more than one conformer.

Gates *et al.* (4) assigned a weak band observed at 559 cm^{-1} to the C—I stretch of the $S_{HH'}$ conformer and the shoulder observed around 480 cm^{-1} to the '*cis* X—H' conformer. The present calculations indicate assignment of the shoulder around 480 cm^{-1} to the S_{HH} conformer, and this assignment seems more logical than the previous assignment. The weak band at 559 cm^{-1} can be explained as a summation band.

Assignment of 71 calculated wavenumbers for all three conformers between 400 and 1500 cm^{-1} to observed bands resulted in an average difference between observed and calculated values of 5.6 cm^{-1}.

There are three bands observed at 768, 795, and 810 cm^{-1} that have not been assigned to the three conformers for which calculations were made. This indicates the presence of one or more additional conformers. Two likely conformers are the ones with the methyl group that is located on the end away from the iodine oriented on either side of the plane of the other four carbons.

3-Iodopentane

Infrared spectra were obtained for this compound in the liquid and solid states, and normal coordinate calculations were made to aid in assigning the observed bands to the different conformers. Calculations were made for the S_{HH}, $S_{HH'}$, S_{CH}, $S_{CH'}$, and S_{CC} conformers.

The liquid-state infrared spectrum in the region 425–700 cm^{-1} is shown by Gates *et al.* (4). The spectrum observed in this region in the present investigation differs in relative intensities for the 461 and 590 cm^{-1} bands, the latter being observed as a shoulder on the 574 cm^{-1} band. Their spectrum shows the 461 cm^{-1} band to be only a little less intense than the one at 485 cm^{-1}, whereas the ratio of the areas of the 485 to 461 cm^{-1} bands in the present work is four to one. The shoulder on the 574 cm^{-1} band is also less intense here than in the spectrum of Gates *et al.*

The solid-state spectrum was obtained for a film which was formed by cooling a liquid film held between salt plates. The sample was solidified several times with no simplification of the spectrum resulting. The solid was annealed with no success in getting it to crystallize. The solid-state spectrum shown by Gates *et al.* also shows their solid to be amorphous.

Gates *et al.* assigned the band they observed

at 461 cm^{-1} to the C—I stretch of the S_{CC} conformer. It seems unlikely from steric considerations that this conformer would be present in an appreciable concentration at room temperature. Moore and Krimm (10) found no evidence for the presence of S_{CC} 3-chloropentane. The band assigned by Gates *et al.* to the C—Cl stretch of the S_{CC} conformer of 3-chloropentane, 534 cm^{-1}, was shown by Moore and Krimm to be due to both $S_{HH'}$ and $S_{CH'}$ conformers. We have found almost the same assignment for 3-iodopentane, except that we have assigned the 461 cm^{-1} band to the $S_{HH'}$ and S_{CH} conformers. The present calculations for the S_{CC} conformer indicate a band at *ca.* 658 cm^{-1}, due to a mixture of C—I stretch, C—C—C bend, and C—C—I bend. There is no observed band in this region of the spectrum.

The observed and calculated wavenumbers for the S_{HH}, $S_{HH'}$, S_{CH}, and $S_{CH'}$ conformers are listed in Table 6. In order to conserve space, the potential energy distributions are not given here, but are available from the author. The transferred force constants resulted in good agreement between observed and calculated wavenumbers, with the average difference being 6.0 cm^{-1} for the 93 values of the four conformers that had observed values assigned to calculated values.

The state assignments corresponding to the second and third ionization potentials of oxirane have been the subject of some uncertainty due to the great sensitivity of Koopmans' theorem predictions to the type of calculation performed for this molecule. In this study, the assignments made by Basch *et al.* for oxirane are confirmed through measurement of the photoelectron spectra of methyl-, 1,1-dimethyl-, 1,2-dimethyl, ethyl-, vinyl-, phenyl-, chloromethyl-, and fluoromethyloxirane. The second and third ionizations of thiirane are confirmed to be of the opposite order from those in oxirane by correlations of these values with those reported here for methyl-, vinyl, and methoxymethylthiirane.

In these compounds, mono-substitution by alkyl groups causes a decrease in ionization potential not obviously related in a simple way to the type of orbital involved. Thus, assignments cannot be made straightforwardly by observing ionization potential changes caused by hyperconjugating or inductive substituents. Alkyl group substitution in both oxirane and thiirane lowers IP's in the same order: $a_2 > b_2 > a_1 > b_1$. The effects of alkyl and heteroalkyl groups on the four lowest IP's of oxirane are linearly related to the electronegativities of the groups, and to the influence of alkyl and heteroalkyl substituents on the π IP of ethylene.

Comparisons of the IP's of ethylheteranes and dimethylheteranes are quite useful in determining the site of localization of orbital density in the various orbitals.

Conjugating substituents, which for symmetry reasons, selectively interact with only a few orbitals make definite assignments possible. Comparisons of experimental ionization potential changes and those predicted by Koopmans' theorem using *ab initio* STO-3G calculations are in good agreement.

E. J. McAlduff et K. N. Houk. Can. J. Chem. **55**, 318 (1977).

Les attributions d'état correspondant aux potentiels d'ionisation second et tierce de l'oxiranne ont fait l'objet de beaucoup d'incertitudes dues à la grande sensibilité des prédictions du théorème de Koopman au type de calcul effectué sur cette molécule. Dans cette étude, les attributions faites par Basch et coll. pour l'oxiranne sont confirmées par des mesures de spectres photoélectroniques du méthyles, du diméthyl-1,1, du diméthyl-1,2, de l'éthyl-, du vinyl-, du phényl-, du chlorométhyl- et du fluorométhyloxiranne. On confirme que les ionisations seconde et tierce du thiirane sont d'un ordre opposé à celles de l'oxiranne par corrélation de ces valeurs avec celles rapportées ici pour le méthyl-, le vinyl et le méthoxyméthylthiirane.

Dans ces composés, la mono-substitution par des groupes alkyles cause une diminution du potentiel d'ionisation qui n'est pas reliée d'une façon apparente ou directe avec le type d'orbitales impliquées. Donc les attributions ne peuvent pas être faites d'une façon directe par les changements des potentiels d'ionisation observés et causés par des substituants qui provoquent de l'hyperconjugaison ou de l'induction. La substitution de groupes alkyles soit dans l'oxiranne ou le thiirane diminue les potentiels d'ionisation dans le même ordre $a_2 > b_2 > a_1 > b_1$. Il y a une relation linéaire entre les effets des groupes alkyles et hétéroalkyles sur les quatre potentiels d'ionisation les plus bas de l'oxiranne et sur les électronégativités des groupes et les influences des substituants alkyles et hétéroalkyles sur les potentiels d'ionisation π de l'éthylène.

Une comparaison des potentiels d'ionisation des éthylhétérannes et diméthylhétérannes est très utile pour déterminer le site de la localisation de la densité orbitale dans les diverses orbitales. Les substituants, provoquant de la conjugaison et qui pour des raisons de symétries interagissent d'une façon sélective avec seulement quelques orbitales, permettent d'obtenir des attributions définitives. Il existe un bon accord entre les changements des potentiels d'ionisation expérimentaux et ceux prédits par le théorème de Koopman utilisant des calculs *ab initio* STO-3G.

Introduction

Photoelectron spectra are often assigned using Koopmans' theorem (1):

$$\mathrm{IP}(i) = -\varepsilon_{\mathrm{SCF}}(i)$$

This useful approximation relates ionization potentials to the negatives of SCF orbital energies. (For discussion of the limitations of Koopmans' theorem, see ref. 2.) Koopmans' theorem ionization potentials differ from experimental vertical ionization potentials by the sum of the amount by which the radical cation is stabilized by reorganization of the MO's upon ejection of one electron and the amount by which the correlation energies of the ground and radical cation states differ. The electron reorganization effect will cause the predicted IP to be too high, while the correlation effect will cause the predicted IP to be too low. Only if the sum of these two effects is a constant, or a linear function of IP, will linear correlations between $-\varepsilon_{\mathrm{SCF}}$ and IP be found.

In spite of this limitation, the assignments of states using Koopmans' theorem are often valid as long as only π states are involved (3). Incorrect assignments may result if π and σ ionizations are similar in energy. In such cases, Koopmans' theorem errors are apparently significantly different for different types of orbitals. An excellent case in point is provided by oxirane, where three different types of *ab initio* SCF calculations give three different orders for the lowest three ionization potentials (4). Our previous work attempted to confirm the order of radical cation states in oxirane by correlations with ionization potentials of dimethyl ether and oxetane. Whereas this procedure proved effective in making assignments for analogous amines and sulfides, it proved less than definitive in the oxygen cases. The study reported here was carried out in order to confirm assignments for oxirane by comparing substituent effects in oxiranes and thiiranes. This goal has been accomplished, and general observations about the effects of substituents on ionization potentials involving σ orbitals and upon the difficulties in applying Koopmans' theorem to systems lacking symmetry were made in the course of this work.

Molecular Orbitals and Radical Cation States of Oxiranes and Thiiranes

The familiar degenerate Walsh orbitals of cyclopropane (of e' symmetry in D_{3h}) give rise to a Jahn–Teller split ionization centered at 10.9 eV in the photoelectron spectrum (5, 6). The degenerate e'' orbitals are combinations of the methylene π_{CH_2} orbitals and give rise to $^2E''$ states centered at 13.2 eV (5). As shown in Fig. 1, the degeneracies of these orbitals (and of the radical ion states arising from them) are removed by inclusion of a heteroatom in the ring as a consequence of the lowered (C_{2v}) symmetry of the resulting molecules. Figure 1 shows the orbital energies calculated for cyclopropane, oxirane, and thiirane by an *ab initio* LCAO-MO-SCF method using the STO-3G basis set (4). The various atomic orbital coefficients are reflected approximately by the shapes and sizes of the lobes drawn in Fig. 1. The experimental vertical ionization potentials are shown in parentheses.

The e'' orbitals of cyclopropane evolve into the b_1 lone pair orbital, and a lower-lying a_2 combination of π_{CH_2} orbitals, while the e' orbitals of cyclopropane evolve into the a_1 and b_2 orbitals of the heterocyclopropanes. The fine-structured ionizations at 10.57 and 9.05 eV in the photoelectron spectra of oxirane (5, 6) and thiirane (6, 7), respectively, represent transitions to the $^2B_1$ radical cation states of these compounds, while the 14.2 and 13.59 eV ionizations arise from transitions to $^2A_2$ states in these molecules (4–7). The assignment of the 11.7 and 13.7 eV ionizations of oxirane and the 11.3 and 11.7 eV ionizations of thiirane are more difficult to make, since various calculations disagree upon the relative energies of the b_2 and a_1 orbitals. Schweig and Thiel have used intensity changes in He(II) spectra to conclude that the order shown in Fig. 1 is, indeed, correct (6).

An assignment of the 11.71 eV transition to the $^2A_1$ state and the 13.7 eV to the $^2B_2$ state of oxirane was made by Basch *et al.* (5) but this order of energy levels has not always been predicted by calculations. Basch *et al.* found that double zeta *ab initio* SCF calculations predicted the b_1 and a_1 orbitals to be accidentally degenerate, with b_2 lower in energy. Direct calculations on the relative energies of the radical cations gave the order $^2B_1 < {}^2A_1 < {}^2B_2 < {}^2A_2$, and this order was also predicted when correlation corrections were taken into account.

Pople and co-workers (8) performed *ab initio* calculation on oxirane using an extended basis set. The orbital energy order $a_1 > b_1 > a_2 > b_2$ was found, in variance with the results of Basch

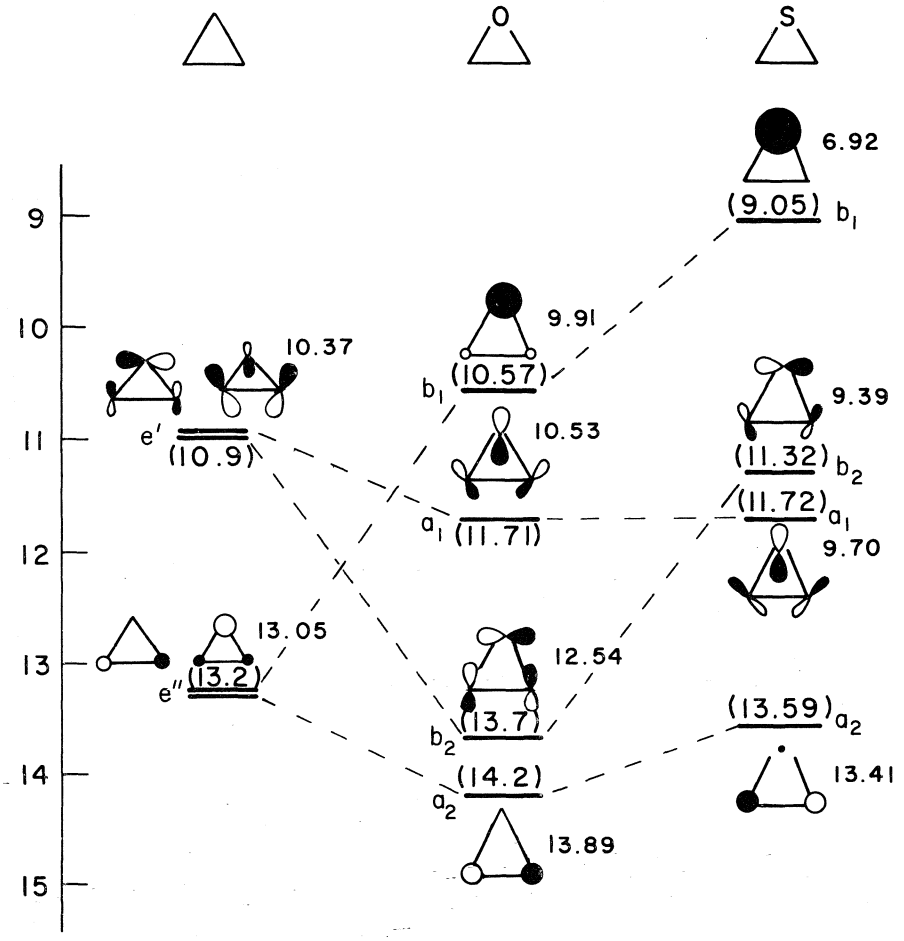

FIG. 1. Molecular orbitals (STO-3G) of cyclopropane, oxirane, and thiirane (negatives of orbital energies are shown next to each orbital, and experimental IP's are given in parentheses).

et al. and with the orbital energies obtained using the STO-3G basis or a minimal Slater basis (4).

For thiirane, less extensive calculations are available, but both semi-empirical (7) and *ab initio* (4) calculations agree on the order $^2B_1 > {}^2B_2 > {}^2A_1 > {}^2A_2$ for the radical cation states. The order of the $^2B_2$ and $^2A_1$ states is curiously different from that in oxirane.

Substitution of heterocyclopropanes with various substituents can clarify these assignments if the substituents cause significant differences in the changes in various ionization potentials. Furthermore, these molecules provide an opportunity to study the effect of substitution on σ orbitals. In particular, most compounds have σ levels that are either at high ionization potential or else lie close together so that their location and assignment proves difficult. However, for oxirane and thiirane the a_1 and b_2 σ levels are resolved from adjacent bands making the study of substituent effects possible.

Results

Alkyl and Halomethyloxiranes

Alkyl groups are generally considered to lower ionization potentials of appended moieties by a combination of inductive and hyperconjugative effects. For π systems, the extent of increase of a given orbital energy (and lowering of the corresponding ionization potential, using Koopmans' theorem) is normally assumed to be proportional

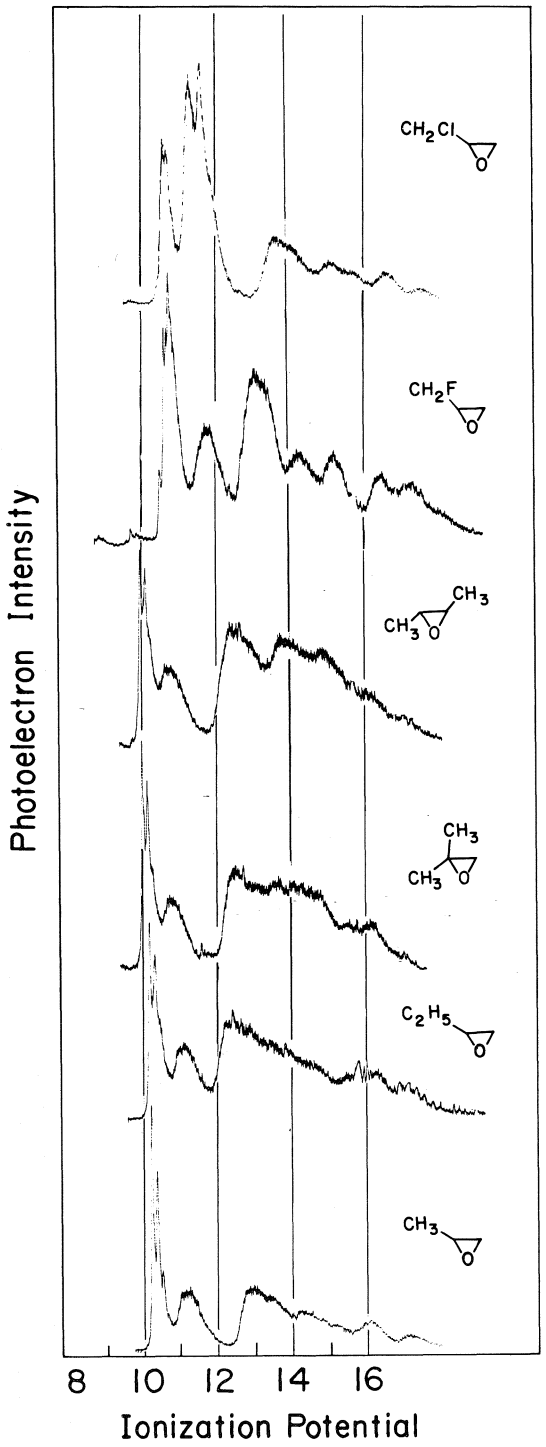

FIG. 2. Photoelectron spectra of alkyl and haloalkyl oxiranes.

to some function of the coefficient in the orbital at the site of substituent attachment (9). However, substitution which destroys the C_{2v} symmetry of the molecule also induces mixing of the formerly orthogonal orbitals, with a resulting further change in orbital energies (9). In the following discussion, we will retain the C_{2v} designations to describe the various orbitals, even though the molecules, and their orbitals, have no symmetry.

The effect of methyl and ethyl substituents on the photoelectron spectra of oxirane can be ascertained by considering the spectra of methyloxirane (propylene oxide) and ethyloxirane (Fig. 2). The assignments given in Fig. 3 are made by assuming that STO-3G and the Basch *et al.* assignment are correct, and that the orders of the first four IP's of oxirane and the two alkyloxiranes are the same. This is supported by calculations discussed below. The first four IP's are lowered by alkyl substitution, but there is no obvious correspondence between the alkyl substituent effect and the shape of the corresponding orbital assuming the shapes in Fig. 1, other than that the b_1 orbital is affected least by alkyl substitution. The ethyl substituent effect is 30% greater than the methyl effect for the first two IP's, and 70% greater on the third and fourth IP's. By comcomparison, the ethyl group lowers the IP of ethylene only 14% more than the methyl group lowers this IP (0.92 *vs.* 0.81 eV) (10).[3]

Methyl substitution cause the b_2 and a_2 ionization potentials to decrease by 0.82 and 0.87 eV, respectively, whereas the b_1 and a_1 are decreased by 0.31 and 0.48 eV. In the case of ethyloxirane the peaks after b_2 are broad and difficult to assign. Assuming that the shoulder on the b_2 peak at 12.7 eV corresponds to ionization from the a_2-like orbital, then ethyl substitution causes a decrease of 1.44 and 1.5 eV in b_2 and a_2 ionization potentials, respectively, whereas the b_1 and a_1 ionization potentials decrease by 0.42 and 0.63 eV, respectively.

Some insight into the mechanism of IP lowering by the substituent may be gained by comparing the first four IP's of oxirane and its alkyl and haloalkyl derivatives.

The photoelectron spectra of the halomethyl-

[3]Ionization potentials reported in ref. 10 are adiabatic; 0.16 eV has been added to all except ethylene to convert them to vertical ionization potentials.

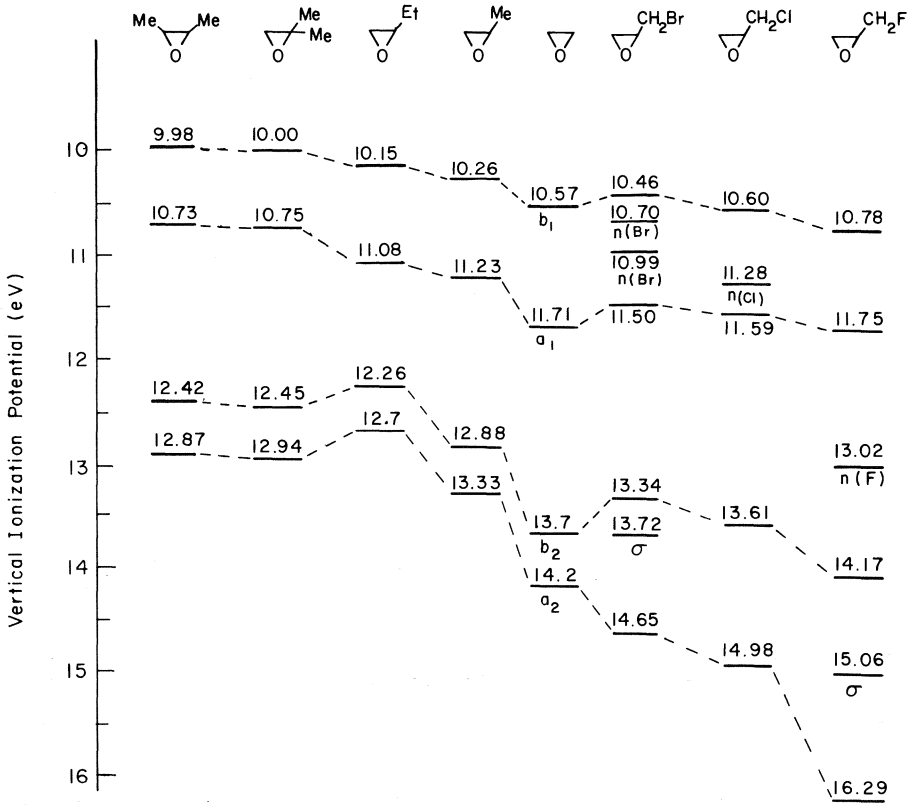

FIG. 3. Correlations between ionization potentials of oxirane and substituted oxiranes.

oxiranes have been reported previously by Baker *et al.* (11). Since these authors did not report the experimental spectra and gave no assignments, we have measured the photoelectron spectra of fluoromethyloxirane and chloromethyloxirane. By comparison of the spectra of halomethyloxiranes with methyloxirane it is possible to assign the first few ionization potentials for fluoromethyloxirane and chloromethyloxirane. We can also assign the bromomethyloxirane spectrum of Baker *et al.* (11). The photoelectron spectra of fluoromethyl- and chloromethyloxirane are shown in Fig. 2 and the correlation diagram with oxirane and methyloxirane in Fig. 3.

Substitution of halogen for hydrogen in methyloxirane stabilizes all levels and increases all ionization potentials. As with alkyl substitution, the third and fourth orbitals, analogous to b_2 and a_2 in oxirane, are lowered to a greater extent than the first two levels which are analogous to b_1 and a_1 in oxirane.

The spectrum of fluoromethyloxirane is in good agreement with that reported by Baker *et al.* (11) except for the peak at 13.17 eV which is found at 13.02 eV in this work. This peak has been assigned to the fluorine lone pair. This is in reasonable agreement with its location in methyl and vinyl fluoride (12). In methyl fluoride, a level due to a methylene-π, fluorine-lone-pair combination orbital occurs as a broad band between 12.5 and 14.5 eV, whereas in vinyl fluoride, the fluorine lone pair is assigned to the band in the region of 13.7 eV.

In fluoromethyloxirane, the band at 14.17 eV is assigned to the level analogous to the b_2 level in oxirane. This represents an increase in IP of 1.29 eV with respect to methyloxirane or 0.56 eV with respect to the same level in chloromethyloxirane.

There is some ambiguity about which of the next two levels at 15.06 and 16.29 eV is to be assigned to the a_2-like orbital. In view of the fact that this orbital has been the one most affected by substitution it has been assigned to the band at

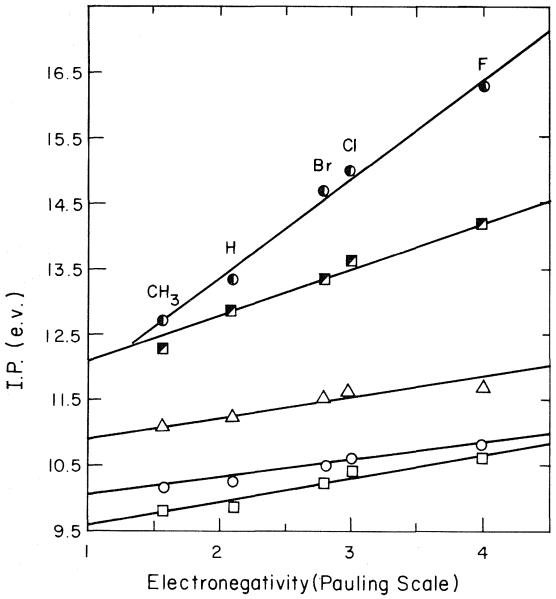

FIG. 4. Plot of IP's of substituted methyl oxiranes and propenes *vs.* substituent electronegativity (Pauling). □, propenes; ○, IP_1; △, IP_2; ◩, IP_3; ◑, IP_4 of methyloxiranes.

16.29 eV. This would represent an increase in ionization potential of 1.31 eV from chloromethyloxirane whereas the alternative assignment would result in an increase of only 0.08 eV.

The spectrum of chloromethyloxirane also agrees well with the peak positions reported by Baker *et al.* (11) except for the band at 13.61 eV which is indicated to be at 13.78 eV by them. The peak at 11.28 eV is assigned to the chlorine lone pair orbital since this peak is absent in the spectrum of fluoromethyloxirane.

The ionization potentials of all four oxirane-like orbitals of the halomethyloxiranes and methyloxirane correlate with electronegativity of the substituent as shown in Fig. 4. The ionization potentials of the π level in propylene and the allyl halides (13) are also plotted as a function of electronegativity for comparison purposes. In order to include the ionization potentials of ethyloxirane in the discussion of $—CH_2X$ substituted oxiranes, an effective electronegativiy of the methyl group is required. This was obtained by assuming that the ionization potential for 1-butene correlates with the plot of propylene and allyl halides *vs.* electronegativity. The π ionization potential of 1-butene (9.79 eV) (10) corresponds to an effective electronegativity of 1.57 for the methyl group. Using this value for the electronegativity of the methyl group, the ionization potentials of ethyloxirane are also included in Fig. 4. It can be seen that the points for ethyloxirane are in reasonable agreement with the lines drawn for the ionization potentials of methyloxirane and the halomethyloxiranes. The value of electronegativity of methyl determined in this way deviates somewhat from literature values (14), which indicate that methyl is nearly the same as, or more electronegative than, nitrogen.

Alternatively, one may think of Fig. 4 as a demonstration of the linear correlation between the first IP of substituted propenes and the first four IP's of the corresponding substituted methyloxiranes.

In Fig. 4, the slopes are 0.27 and 0.28 for the b_1 and a_1-like orbitals and 0.67 and 1.58 for the b_2 and a_2-like orbitals. The slope for the propenes is 0.34, indicating that substituents affect the b_1 and a_1 orbitals of methyloxirane to about the same extent as the π level of propene. The changes in b_2 and a_2 ionization potentials of oxirane brought about by the substituent are considerably larger.

The conclusion drawn from the linear relationship in Fig. 4 is that the combination of inductive and hyperconjugative effects that cause the changes in π ionization potentials from propene to the allyl halides must also be operating in the alkyloxiranes and halomethyloxiranes to produce changes in each of the four oxirane-like orbitals. Further comments are made in the Discussion section.

The STO-3G(15)[4] calculations on oxirane and methyloxirane support the assignments proposed from the experimental data. The calculated (STO-3G) and experiment ionization potentials for oxirane and methyloxirane are listed in Fig. 6. The STO-3G calculations tend to underestimate the ionization potentials with the result that the calculated values are in the range 0.87 to 0.97 of the experimental ones. Despite the disagreement between calculated and experimental values of

[4]The STO-3G calculations were done using the Program Gaussian 70 by Newton *et al.* (15) and R. Ditchfield, Quantum Chemistry Program Exchange, Indiana University, Bloomington, Indiana. The total energies (au) obtained in these calculations are: oxirane, −150.92698; methyloxirane, −189.51265; vinyloxirane, −226.86334; thiirane, −470.27285; methylthiirane, −508.85587; vinylthiirane, −546.20917.

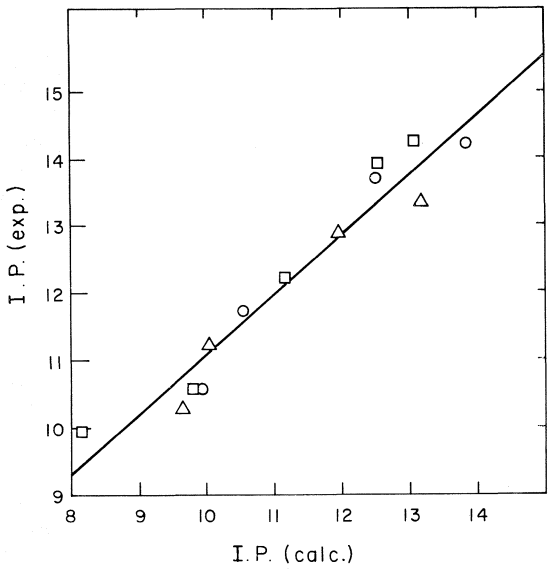

FIG. 5. Correlations between experimental IP's of oxirane, ○; methyloxirane, △; and vinyloxirane, □; and STO-3G orbital energies.

the ionization potentials, a good linear correlation between experimental and calculated ionization potentials is obtained as shown in Fig. 5. This correlation follows the least-squares relationship:

$$\text{IP(exp)} = 0.892\text{IP(calcd)} + 2.15$$

Figure 6 shows the shapes of the first four orbitals of oxirane and methyloxirane and the first five orbitals of vinyloxirane taken from STO-3G calculations. The size of the orbitals of various nuclei is approximately proportional to the square of the coefficient at that nucleus. One can see that the order of energy levels for oxirane agrees with that assigned by Basch *et al.* (5) ($b_1 > a_1 > b_2 > a_2$). From Fig. 6 it is also possible to conclude that even though the C_{2v} symmetry has been lost by addition of the methyl group to oxirane, the order of energy levels remains unchanged; *i.e.* the first one is b_1-like, the second a_1-like, etc.

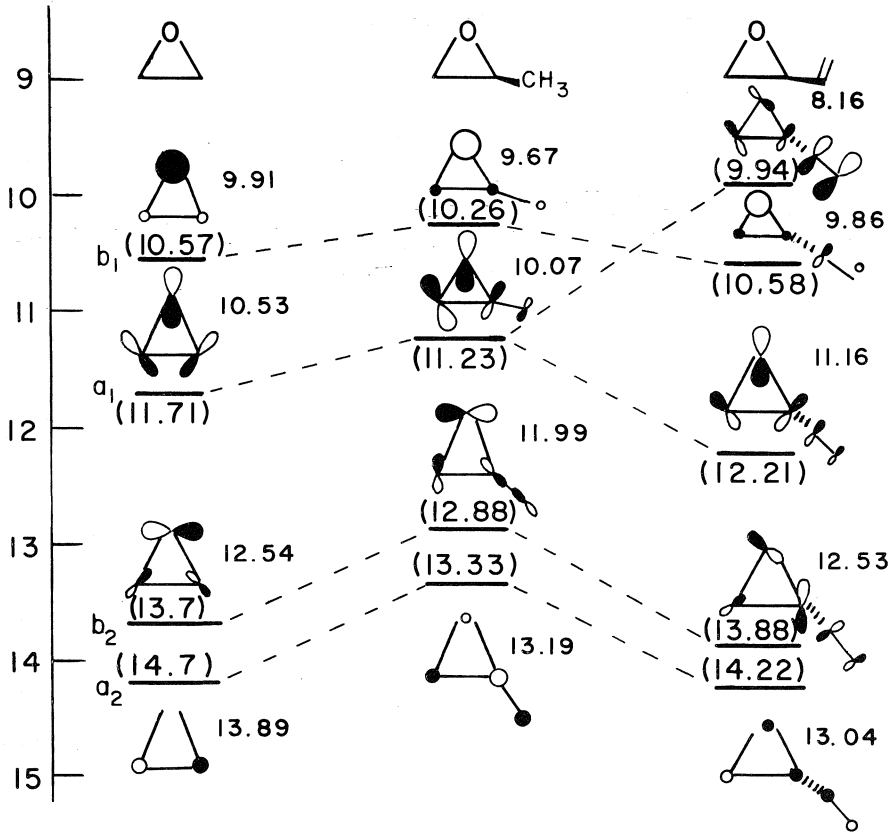

FIG. 6. STO-3G molecular orbitals of oxirane, methyloxirane, and vinyloxirane (negatives of orbital energies are shown next to each orbital, and experimental IP's are given in parentheses).

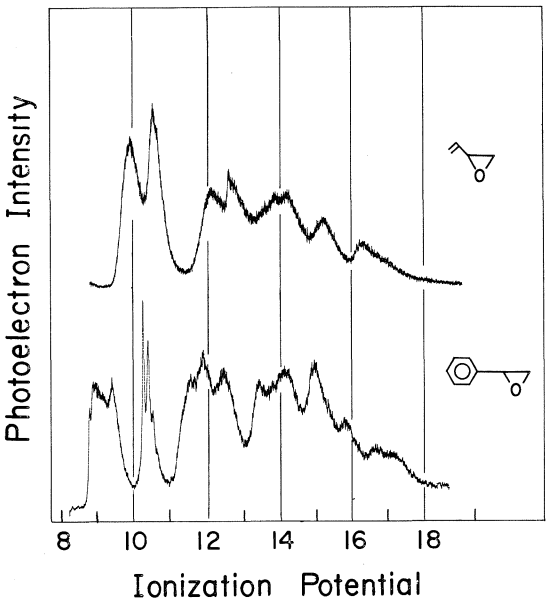

FIG. 7. Photoelectron spectra of vinyloxirane and phenyloxirane.

Disubstituted Oxiranes

The photoelectron spectra of 1,1-dimethyloxirane and *trans*-1,2-dimethyloxirane are shown in Fig. 2. The ionization potentials are correlated with those of oxirane and methyloxirane, and assignments are listed in Fig. 3. From the correlation diagram it can be seen that all four ionization potentials of the disubstituted oxiranes have been decreased relative to methyloxirane. However, the effect of a second methyl substituent on the b_2 and a_2 IP's is less than that of the first methyl. The ionization potentials of 1,1-dimethyloxirane and 1,2-dimethyloxirane are identical within experimental error, and the same order of energy levels is observed for disubstituted oxiranes as was observed for methyloxirane and oxirane (5). The effect of mono-methyl and di-methyl substitution observed here is analogous to that observed in substituted alkenes where the π ionization potential of ethylene decreases 0.62 eV (10) or 0.78 eV (9) upon methylation, but substitution of a second methyl groups has less of an effect. Conversion of propene to 2-methylpropene decreases the IP by 0.50 eV (10) or 0.64 eV (9), and conversion of propene to *trans*-2-butene decreases the IP by 0.62 eV (10) or 0.69 eV (9).

Vinyl and Phenyl Oxiranes

The spectra of these molecules are shown in Fig. 7 and correlations with oxirane and substituent moieties are shown in Fig. 8. Both phenyl and vinyl substituents possess several molecular orbitals whose ionization potentials lie below 15 eV. Vinyloxirane has three ionization potentials virtually unchanged from oxirane. These are located at 10.58 (b_1), 13.88 (b_2), and 14.22 (a_2). Interaction of the ethylenic π orbital at 10.52 eV (12) with a_1 orbitals of oxirane results in two new orbitals, one whose IP is increased by 0.50 eV from that of the a_1 level in oxirane to a value of 12.21 eV. The other ionization in this region corresponds to ionization from the σ levels of the vinyl moiety at 12.71 eV which compares favorably with the corresponding band in ethylene at 12.38 eV (12).

Assignments made in this way correlate exactly with those predicted by the STO-3G calculations (Fig. 6). The only disagreement between the STO-3G calculations and the experimental ionization potentials occurs for the a_2-like orbitals of vinyloxirane where the calculation predicts a decrease in ionization potential of 0.85 eV from oxirane and the observed change is an increase of 0.02 eV. Using the relationship discussed previously between calculated and experimental ionization potentials (IP(exp) = 0.892 IP(calcd) + 2.15) it is possible to predict a value of the a_2-like orbital from the calculated value. A predicted value of 13.78 eV is obtained in this way. From the spectrum of vinyloxirane in Fig. 7, it can be seen that the peak at 13.88 eV is broad and could contain the a_2-like orbital. Thus, there is some uncertainty in the exact position of the a_2-like orbital of vinyloxirane. However, as in the case of oxirane and methyloxirane, the calculations for vinyloxirane support the assignment arrived at from the photoelectron spectra.

In phenyloxirane, the ionization potentials at 10.30, 11.55, 13.42, and 14.08 eV can be assigned to the oxirane moiety. All of these ionization potentials are less than the corresponding ones in oxirane, indicating the superior inductive and/or hyperconjugative donor ability of the phenyl group as compared to the vinyl group. The b_1 and b_2 levels are destabilized by 0.27 and 0.28 eV, respectively, which is somewhat larger than for the a_1 and a_2 whose ionization potentials have decreased by 0.16 and 0.12 eV from those in oxirane.

The first two ionization potentials in phenyloxirane (9.07, 9.47 eV) can be correlated with the

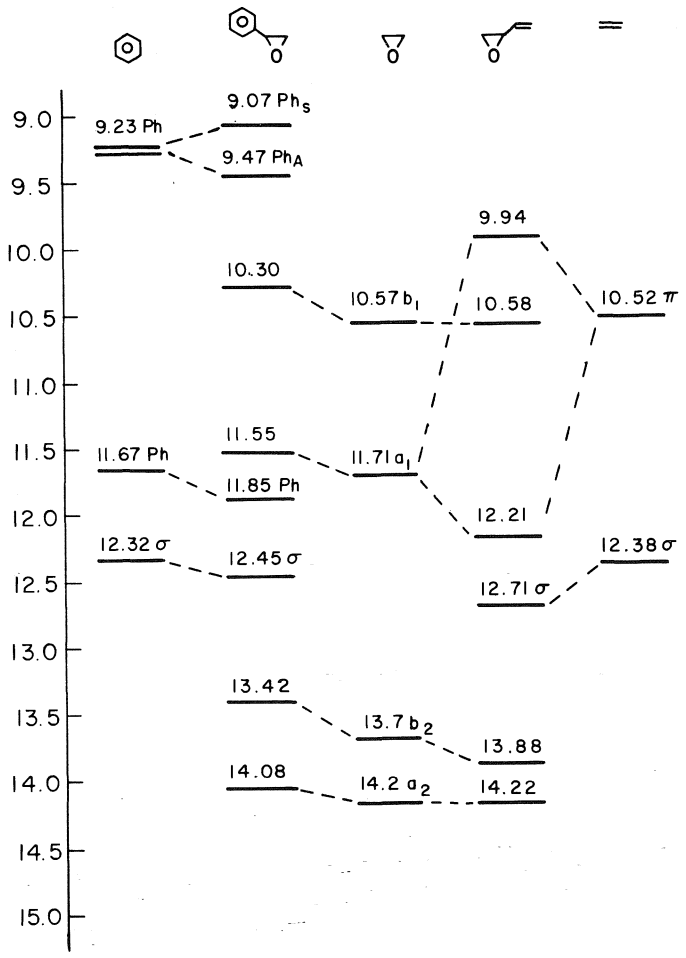

FIG. 8. Correlations between ionization potentials of vinyloxiranes, phenyloxirane, and substituents.

doubly degenerate highest occupied orbitals of benzene at 9.25 eV (12), which split under the influence of a substituent. The symmetric or Ph_S orbital of symmetry b_1 is characterized by being delocalized over the entire phenyl ring and substituent, with the region of highest electron density being at the position of substitution and *para* to it. In phenyloxirane this orbital is that giving rise to the IP at 9.07 eV. The antisymmetric or Ph_A orbital (symmetry a_2) is characterized by a node passing through the position of substitution and *para* to it and high electron density in the *ortho* and *meta* position. The band with IP at 9.47 eV in phenyloxirane is assigned to this orbital.

The ionization potential at 11.85 eV is also due to a phenyl orbital and is analogous to the one at 11.67 eV in benzene. The IP at 12.45 eV in phenyloxirane is assigned to σ ionization and is to be compared to the one at 12.32 eV in benzene (12).

Heilbronner and co-workers (16) have reported the photoelectron spectra of *cis*- and *trans*-diethynyloxirane and *cis*- and *trans*-diethynylthiirane. They assigned the same order to the oxirane and thiirane moiety ionization potentials as reported here. Since the a_1 level of oxirane is of the correct symmetry to interact with the ethynyl groups, the largest changes were observed for this orbital when comparing the photoelectron spectra of oxirane and diethynyloxirane. This is analogous to what has been found here for vinyloxirane.

Thiirane and Alkyl Thiiranes

TABLE 1. Effects of methylation on ionization potentials

Parent	Orbital	IP (eV)	IP on methylation (eV)			
			P → Me[a]	Me → Et[b]	Me → 1,1-Me_2[c]	Me → 1,2-Me_2[d]
Ethylene (10)	π	10.52	0.62	0.11	0.50	0.62
Oxirane (5)	b_1	10.57	0.31	0.11	0.26	0.28
	a_1	11.71	0.48	0.15	0.48	0.50
	b_2	13.7	0.82	0.62	0.43	0.46
	a_2	14.2	0.87	0.63	0.39	0.46
Thiirane (7)	b_1	9.05	0.17			
	b_2	11.32	0.56			
	a_1	11.72	0.28			
	a_2	13.59	0.70			

[a]Change in IP upon monomethylation of the parent.
[b]Change in IP upon conversion of a methyl substituent to an ethyl substituent.
[c]Change in IP upon introduction of a second methyl α- to the first.
[d]Change in IP upon introduction of a second methyl β- to the first.

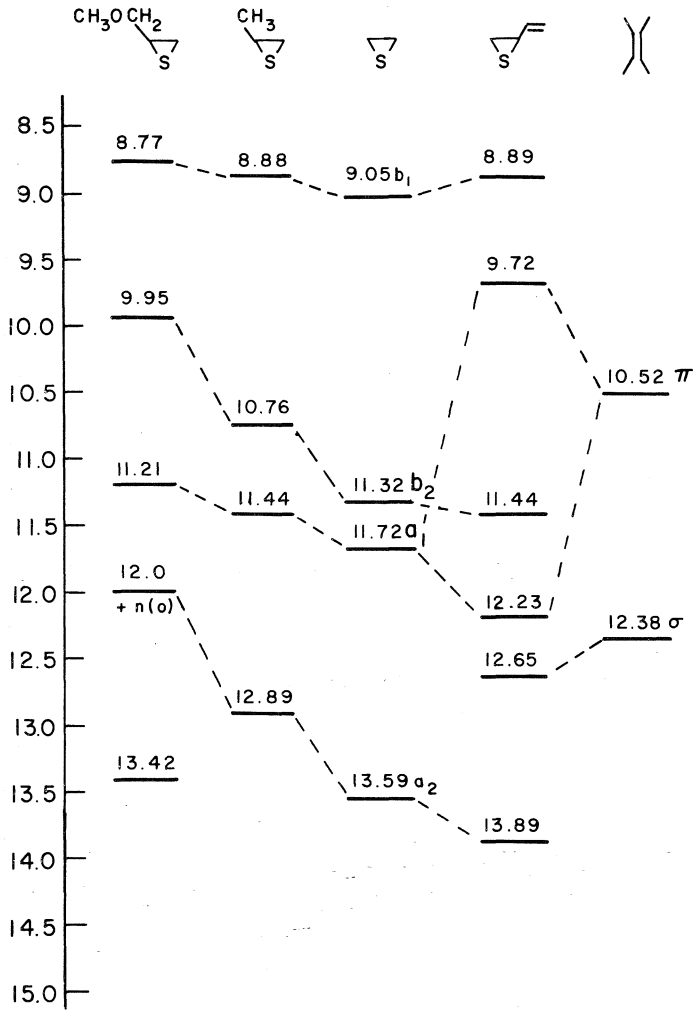

FIG. 10. Correlations between thiirane ionization potentials.

spectra of thiirane have been reported (6, 7). They agree except for the a_1 band which is reported at 11.86 eV by Schweig and Thiel (6) and 11.72 eV by Frost *et al.* (7). We have chosen to compare the latter with our spectra of substituted thiiranes which are shown in Fig. 9. Ionization potentials and assignments are listed in Table 1. Thiirane differs from oxirane in the order of its energy levels. The b_2 level whose ionization potential is 13.7 eV in oxirane has its ionization potential lowered to 11.32 eV in thiirane. This places it at a lower ionization potential than a_1 which is located at 11.72 eV. As with oxirane the first IP at 9.05 eV is associated with the heteroatom lone pair orbital and the fourth ionization potential at 13.59 eV is assigned to an a_2 orbital.

As shown in Fig. 10, methyl substitution on thiirane produces an effect similar to that observed for the alkyl substituted oxiranes, that is, a decrease in all four lowest IP's. The decrease in b_1 and a_1 occurs to a lesser extent than b_2 and a_2 (0.12 and 0.42 eV *vs.* 0.74 and 0.61 eV). As in the oxirane case, the b_2 and a_2 levels undergo greater destabilization upon alkyl substitution.

With methoxymethylthiirane the same phenomena are observed. The ionization potentials at 8.77 and 11.21 eV are analogous to the b_1 and a_1 of thiirane and have decreased less than the ionization potentials at 9.95 and 12.0 eV which

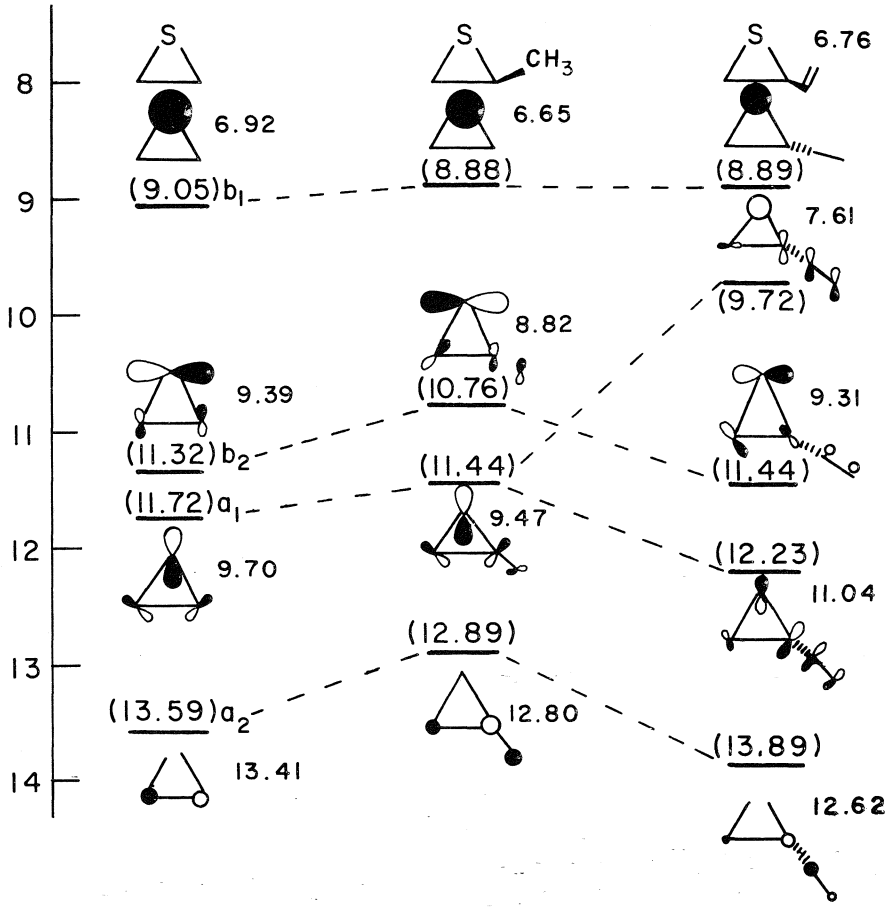

FIG. 11. STO-3G orbitals of thiirane, methylthiirane, and vinylthiirane.

are correlated with the b_2 and a_2 levels of thiirane (Fig. 10). The band at 12.0 eV in methoxymethylthiirane is broad and probably contains two unresolved bands. One of these could correspond to the oxygen lone pair on the methoxy group and the other to the a_2-like orbital.

STO-3G calculations have been performed on thiirane and methylthiirane. Figure 11 represents the shape of the first four orbitals of thiirane and methylthiirane from the STO-3G calculations. The size of the orbital at each nucleus is proportional to the square of the coefficient at that nucleus. As in the case of the oxiranes the calculated order of ionization potentials agrees with the experimental assignments for thiirane (6, 7). The same order is observed both experimentally and in the calculations for methylthiirane as well ($b_1 > b_2 > a_1 > a_2$). Figure 12 shows the correlation between experimental ionization potentials and STO-3G orbital energies for thiirane, methylthiirane, and vinylthiirane. As in the case of the oxiranes, even though the calculated orbital energies do not reproduce the experimental ionization potentials a linear correlation is obtained between them. The following least-squares correlation exists between the calculated and experimental quantities:

$$\text{IP(exp)} = 0.720\text{IP(calcd)} + 4.32$$

Thus, for thiirane and the alkyl-substituted thiiranes there is agreement between the assignments arrived at from the photoelectron spectra and those from the STO-3G calculations.

Vinylthiirane

Vinylthiirane is analogous to vinyloxirane in that the π orbital interacts with the orbital of a_1

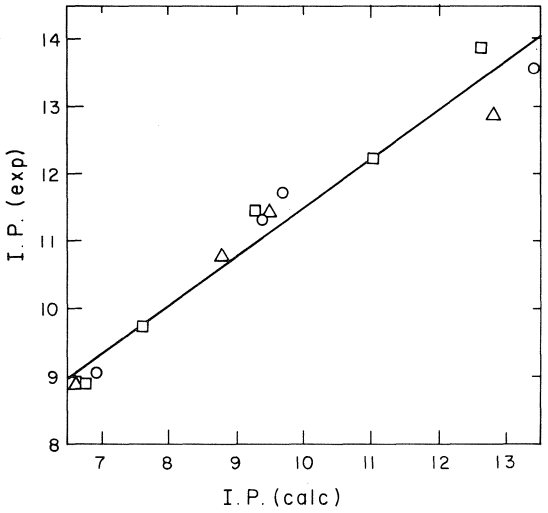

FIG. 12. Correlation between experimental IP's of thiirane, ○; methylthiirane, △; and vinylthiirane, □; and STO-3G orbital energies.

symmetry on the thiirane moiety producing an antibonding and a bonding combination of levels. The antibonding combination which is principally alkene-like is found at 9.72 eV (9.94 eV in vinyloxirane). The bonding combination of the a_1 on thiirane with the vinyl π is found at 12.23 eV which represents an increase of 0.51 eV from the unperturbed a_1 level in thiirane. The other ionization potentials in vinylthiirane are the lone pair on sulfur (b_1-like) at 8.89 eV and the b_2-like ionization potential at 11.44 eV as well as a σ level at 12.65 eV (12.71 eV in vinyloxirane) and the a_2-like level at 13.89 eV. The order $b_2 < a_1$ is obtained in vinylthiirane as it was in thiirane and the alkylthiiranes. As noted previously this is the reverse of the order of these levels in oxirane and the substituted oxiranes.

STO-3G calculations have also been performed on vinylthiirane. The calculated orbital energies are plotted in Fig. 11 and correlated with the experimental ionization potentials in Fig. 12. The shapes of the first five STO-3G orbitals of vinylthiirane are also included in Fig. 11. As can be seen in Fig. 11, the calculated and experimental values agree as to the order of energy levels for vinylthiirane. Thus the first ionization is from the b_1-like level corresponding to the sulfur lone pair and the second is the antibonding combination of the vinyl π and the a_1 orbital of the thiirane moiety. This order is the reverse of that obtained in vinyloxirane.

The third level is the b_2-like and is not changed significantly from thiirane. The fourth level undergoes an increase in ionization potential from thiirane to vinylthiirane and corresponds to the bonding combination of the a_1 and vinyl π orbitals. This increase is predicted in the calculation and realized in the spectrum.

As in the oxirane case, the most serious disagreement between calculated and experimental ionization potentials occurs for the a_2-like level of vinylthiirane where the calculation predicts a 0.79 eV decrease in ionization potential and experimentally an increase of 0.30 eV is observed. Using the least-squares relationship with the STO-3G calculations, the a_2-like ionization potential of vinylthiirane is predicted to occur at 13.41 eV. The band with maximum at 13.89 eV in the photoelectron spectrum of vinylthiirane is a broad one and could possibly result from the overlapping of several bands. Thus the uncertainty in the location of the a_2-like band in vinyloxirane seems to present itself in the case of vinylthiirane as well.

The overall result is that the photoelectron spectra and STO-3G calculation on methylthiirane and vinylthiirane have confirmed the earlier assignment of the order of energy levels in thiirane (6, 7).

Discussion

The first goal of this investigation was to confirm the assignments of IP's of oxirane and thiirane. The spectra of vinyloxirane and vinylthiirane proved to be most useful in this regard. That is, the vinyl moiety leaves three IP's unchanged in both molecules, and has a large influence upon only the second IP of oxirane, and the third of thiirane. These are the IP's which calculations most often assign to ionizations from the a_1 orbitals of the heterocycles. In the parent heterocycles, the a_1 orbitals have identical IP's (11.71 eV in oxirane and 11.72 eV in thiirane) and the densities of these orbitals at carbon are identical in the STO-3G calculations, and provide ideal local symmetry for overlap with a vinyl substituent in a 'bisected' conformation.

In vinyl cyclopropane (17) the first and third IP's at 9.15 and 11.7 eV correspond to the antibonding and bonding interactions of the vinyl π with one of the cyclopropane e' orbitals (b_2 in C_{2v}) centered at 10.9 eV. The other cyclopropane orbital of e' symmetry (a_1 in C_{2v}) is destabilized to

10.65 eV in vinylcyclopropane by the inductive effect of the vinyl substituent. Thus, the influence of the cyclopropyl groups on the vinyl IP (1.37 eV lowering of the vinyl IP; 0.8 eV raising of the cyclopropyl IP) is considerably larger than the effect of thiirane (0.8 eV lowering of vinyl; 0.51 eV raising of the a_1 IP), which, in turn, is larger than the effect of oxirane (0.58 eV lowering of the vinyl IP; 0.50 eV raising of the a_1 IP). These results are comparable quantitative measures of the conjugative power of these three small rings.

The small changes in the remaining three low-energy IP's of oxirane and thiirane upon vinyl substitution indicate that the vinyl moiety exerts a similar inductive effect to that of hydrogen, and that a *C*–vinyl bond hyperconjugates to about the same extent as a C—H bond.

All of the results found in this work are compatible with the assignments made by Basch *et al.* (5) and in our previous work for oxirane (4) ($b_1 > a_1 > b_2 > a_2$), and by all calculations for thiirane ($b_1 > b_2 > a_1 > a_2$) (4).

The influence of alkyl substituents upon the IP's of these molecules is less obviously related to the shapes of the orbitals of the parent molecules. However, the order of decreasing methyl (or other alkyl) influence for oxirane ($a_2(0.9) > b_2(0.8) > a_1(0.5) > b_1(0.3)$) is the same as that for thiirane ($a_2(0.7) > b_2(0.6) > a_1(0.3) > b_1(0.2)$). Furthermore, the effect of the methyl substituent upon the oxirane IP's is 1.3–1.7 times that of the effect on the thiirane IP's. Other alkyl or heteroalkylsubstituents follow the same pattern for oxirane.

The fact that a_2 orbitals are affected most by substitution is reasonable, since this orbital is a symmetry adapted CH bonding orbital in the parent molecules, and becomes largely C—C bonding in the substituted molecules. Thus, the correlation of the a_2 orbital energy with the electronegativities given in Fig. 4 indicates that the largely C—C bonding (but delocalized) orbital has an IP linearly related to the electronegativity of the substituent on this bond.

As indicated by the calculations shown in Figs. 6 and 11, the top three orbitals are polarized, but are less affected by alkyl substitution than is the a_2 orbital. The b_1 (lone pair) orbitals are affected to a very minor extent, but the changes in IP's are reproduced rather well by the calculations. This indicates that a breakdown in Koopmans' theorem (orbital relaxation) cannot

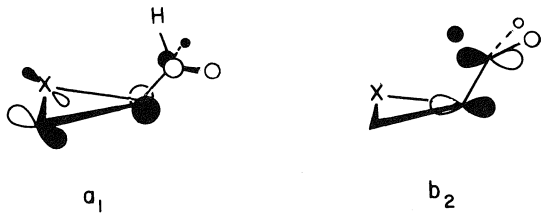

FIG. 13. The a_1 and b_2 orbitals of methyl heteranes, showing the π interaction in the former and $\pi + \sigma$ interactions in the latter.

be the source of the IP change, but instead, the alkyl groups influence the heterocycle lone pair IP's by a combination of a minor increase in hyperconjugative destabilization of the lone pair orbital, and a small inductive effect, reflected in the small increase in charge at the heteroatoms in the calculations on methylheteranes as compared to the parent heteranes: q_O(oxirane) = -0.213; q_O(methyloxirane) = -0.222; q_S(thiirane) = $+0.108$; q_S(methylthiirane) = $+0.078$.

The b_2 orbitals are influenced by alkyl substitution more than the a_1 orbitals in both oxirane and thiirane. This is contrary to the naive expectation that the a_1 should be affected more due to its larger coefficient at carbon (0.25–0.26) than for the b_2 orbital (0.16–0.19). On reflection the experimentally observed trends can be rationalized in the following way: the a_1 orbital can interact only inductively and in a π-hyperconjugative fashion with the alkyl substituent, while the b_2 can interact not only inductively and π-hyperconjugatively, but also in a σ fashion. That is, superimposed on the hyperconjugative interaction between methyl π_{CH_3} orbitals and the heterane b_2 orbitals, there is a change in the b_2 orbital resulting from the substitution of C—C bond for a C—H bond, as shown in Fig. 13.

Finally, we turn to disubstitution on the oxirane ring. Table 1 compares the effects upon IP's arising from monomethylation of ethylene, oxirane and thiirane, as well as upon ethylation, α,α-dimethylation, and *trans*-α,β-dimethylation of ethylene and oxirane. Alkylation of the a_2 and b_2 orbitals of oxirane and thiirane has an effect equal to, or larger than, that upon the π orbital of ethylene. This arises from the fact that substitution causes the a_2 and b_2 orbitals to take on C—C bonding character. This is shown particularly dramatically by the comparison of conversion of methyloxirane to ethyloxirane or either of the dimethyloxiranes. Substitution on the methyl group (Me → Et) causes a much

larger change in b_2 and a_2 IP's than methylation at the ring, compatible with the concept that these orbitals have significant ring-methyl C—C character. By contrast, ring methylation has a much greater influence on the b_1 and a_1 IP's than methylation of the methyl group. The similarity of the ethylene IP changes, and the a_1 changes are quite striking, and fully compatible with the model proposed by Hoffmann *et al.* (18) and Rohmer and Roos (19) in which the a_1 orbital of heteranes is formally constructed by the union of an ethylene π orbital with a vacant a_1 orbital of the heteroatom. The influences of alkyl substituents upon the b_1 IP are smallest, compatible with the weak inductive and hyperconjugative influence discussed earlier. As with the ethylene IP, β-methylation has a larger effect than α-methylation, compatible with the polarization of orbitals away from the site of alkyl substitution.

There is an apparent qualitative agreement between the Hoffmann (18) – Rohmer–Roos (19) model for bonding in oxirane and thiirane and the changes in IP's upon alkyl substitution. These authors described the b_2 orbital of three-membered ring heterocycles as arising from the interaction of a b_2 donor orbital of the heteroatom and the π^* orbital of the ethylene fragment. Because the b_2 orbital of S is higher than that of O, the former should mix in more π^* (carbon) character than the latter. While this shows up in the calculations to a small extent, the IP changes are larger for oxirane than for thiirane, opposite to the expectation based on site of localization of electron density. However, the fact that the b_2 orbital of oxirane is at considerably lower energy than that of thiirane allows great hyperconjugative interaction with the lower lying methyl orbital.

The a_1 orbitals of these molecules formally arise from the union of an a_1 heteroatom acceptor orbital and the π orbital of ethylene. The a_1 acceptor is lower for S than for O, so the thiirane a_1 orbital should have less C—C character than oxirane. This effect is manifested to a small extent in the calculated coefficients, but it is apparent in IP changes upon methylation. The a_1 IP's of oxirane and thiirane are of equal energy, but the change of oxirane a_1 IP upon methylation is 1.7 times that for thiirane.

Experimental

All samples except vinylthiirane were commercially available and were used without further purification. Vinylthiirane was prepared by a standard procedure (20). Photoelectron spectra were recorded on a Perkin-Elmer Ltd., PS-18 Photoelectron Spectrometer using argon and xenon as internal calibrants. Resolution as determined from the argon peak at 15.76 eV was 25–30 meV and the recorded peak positions represent an average of five determinations.

Acknowledgements

Financial support of this research was generously provided by the National Science Foundation and the National Institutes of Health. We are grateful to Andrew Caruso for the preparation of vinylthiirane, and to Ruth W. Gandour for carrying out the STO-3G calculations.

Studies of the rhenium–oxygen bond. III. The crystal and molecular structure of 1-oxo-6-ethoxo-2,4-dichloro-3,5-dipyridinerhenium(V)

COLIN JAMES LYNE LOCK[1] AND GRAHAM TURNER

Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 16, 1976

COLIN JAMES LYNE LOCK and GRAHAM TURNER. Can. J. Chem. **55**, 333 (1977).

The crystal and molecular structure of the title compound has been examined by single crystal X-ray diffraction. The crystals are monoclinic with $a = 28.045(10)$, $b = 8.766(3)$, $c = 12.376(5)$ Å, $\beta = 91.14(3)°$. The space group is $C2/c$ and there are eight molecules per unit cell. A total of 5053 independent reflections, of which 2860 were observed, were examined on a Syntex $P\bar{1}$ diffractometer. The structure was refined by full matrix least squares to an R_2 value of 0.0449. The ligands form a very rough octahedron around the rhenium atom with Re—Cl(1), 2.441(3); Re—Cl(2), 2.366(3), Re—O(1), 1.684(7); Re—O(2), 1.896(6); Re—N(1), 2.144(7); Re—N(2), 2.132(7) Å. The pyridine rings are a dominant factor in determining the details of the molecular structure.

COLIN JAMES LYNE LOCK et GRAHAM TURNER. Can. J. Chem. **55**, 333 (1977).

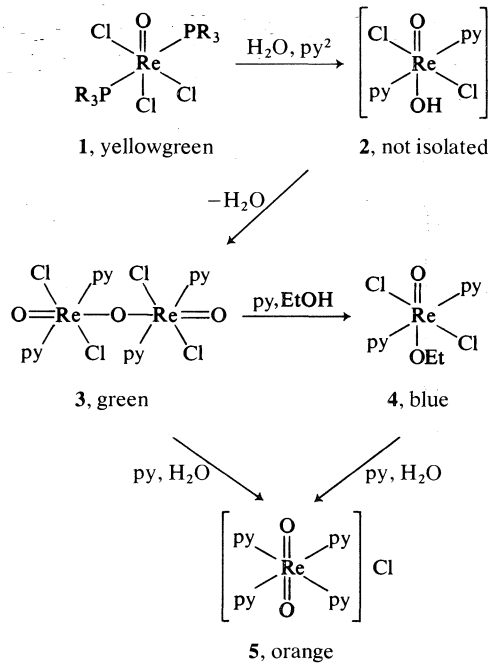
On a examiné les structures cristallines et moléculaires du composé mentionné dans le titre par diffraction de rayon-X sur un cristal unique. Les cristaux sont monocliniques avec $a = 28.045(10)$, $b = 8.766(3)$, $c = 12.376(5)$ Å, $\beta = 91.14(3)°$. Le groupe d'espace est $C2/c$ et il y a huit molécules par maille. Utilisant un diffractomètre Syntex $P\bar{1}$, on a examiné un total de 5053 réflexions indépendantes desquelles 2860 ont pu être observées. La structure a été affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R_2 = 0.0449$. Les ligands forment approximativement un octaèdre autour de l'atome de rhénium et Re—Cl(1), 2.441(3); Re—Cl(2), 2.366(3), Re—O(1), 1.684(7); Re—O(2), 1.896(6); Re—N(1), 2.144(7); Re—N(2), 2.132(7) Å. Les cycles de pyridine sont un facteur déterminant dans les déterminations des détails de la structure moléculaire.

[Traduit par le journal]

Introduction

The reaction of wet pyridine with oxotrichlorobis(triphenylphosphine)rhenium(V) is postulated to go through the following steps (1).

Chatt and Rowe (2) claimed the structure of **1** was as shown for R = C_6H_5 on the basis that $Z = 4$ for a $C2/c$ monoclinic cell which has an eightfold general position. The molecule thus had a twofold axis of symmetry. There is a possible ambiguity, however, since a simple space group determination will not differentiate $C2/c$ and Cc, with a fourfold general position. There is no indication given by Chatt and Rowe (2) that this ambiguity was resolved by an attempt at crystal structure determination and therefore the structure of **1** must still be considered unknown. We have examined the structure of **5** and shown it is correct (3). More recently we have examined the structure of **3**, and shown that the structure given is incorrect:



[1]To whom correspondence should be addressed.

[2]py is pyridine, C_5H_5N; Et is the ethyl radical, $C_2H_5\cdot$; en is ethylenediamine, $NH_2\cdot CH_2\cdot CH_2\cdot NH_2$.

the halves of the dimer actually contain *cis* chloro and pyridine groups (4). As a consequence, if the production of **4** is as shown, it seemed possible that the structure postulated was incorrect. We have examined the structure of **4** by single crystal X-ray diffraction and report our results here.

Experiments

Preparation of 1-Oxo-6-ethoxo-2,4-dichloro-3,5-di(pyridine)rhenium(V), $ReCl_2 \cdot O \cdot OC_2H_5(C_5H_5N)_2$

The title compound was prepared by the method of Johnson *et al.* (1). The compound was recrystallized from a 9:1 mixture of 1,1,2,2-tetrachloroethane and absolute ethanol, in a dry atmosphere at 5 °C. The final crystals were blue plates.

Collection of the Diffraction Data

A crystal of the title compound, selected after examination under a polarizing microscope, was mounted with its longest dimension approximately parallel to the goniometer axis. The crystal was bounded by {100}, {010}, and {001}, which were 0.007, 0.018, and 0.022 cm apart, respectively. Precession photographs, using MoKα radiation, of the 0*kl* and *h*0*l* projections showed monoclinic symmetry with C centering. Weissenberg photographs, using CuKα radiation, confirmed the C centering, and revealed an unusually long ***a*** axis. Further precession photographs of 1*kl*, 2*kl*, *h*1*l*, and *h*2*l*, showed the systematic absences, *hkl*, $h + k = 2n + 1$, *h*0*l*, $l = 2n + 1$ ($h = 2n + 1$), and 0*k*0 ($k = 2n + 1$). These absences correspond to the space groups $C2/c$ (#15) or Cc (#9).

The crystal was transferred to a Syntex P$\bar{1}$ diffractometer and unit cell parameters were obtained by least squares refinement of 15 reflections in the range $20° < 2\theta < 30°$. The density of a few single crystals was measured by flotation in a degassed aqueous solution of zinc bromide. Crystal data were:

$C_{12}H_{15}Cl_2N_2O_2Re$ f.w. = 476.2

Monoclinic, $a = 28.045(10)$, $b = 8.766(3)$, $c = 12.376(5)$ Å, $\beta = 91.14(3)°$, $V = 3042(2)$ Å^3, $C2/c(C_{2h}^6$, #15), $\rho_o = 2.10(2)$, $Z = 8$, $\rho_c = 2.08$ (22 °C, $\lambda = 0.70926$ Å), $\mu = 87.98$ cm^{-1}.

Intensities were recorded on the Syntex P$\bar{1}$ diffractometer using graphite monochromatized MoKα radiation for the quadrant defined by *h*, *k*, ±1 up to $2\theta = 55°$. Data were collected using a coupled θ(crystal)–2θ(counter) scan, 1° on either side of the peak. Scan rates were selected by the program supplied with the instrument and varied from 4 to 24°/min. The stability of the system was monitored by measuring a standard reflection, 0,2,2, after every 49 reflections. The counting esd of the standard was 1.3%, and the fluctuation was random (Gaussian). The intensity, *I*, and its esd, σ_I, were calculated as outlined previously (5). A total of 5053 reflections were measured, including 2860 observed, 1567 unobserved, and 626 rejected ($I < \sigma_I$). The intensities were corrected for absorption.[3] After correction for Lorentz and polarization effects, unscaled structure factor amplitudes, *F*, and their standard deviations, σ_F, were calculated as outlined previously (5).

Solution of the Structure

The Patterson map was solved uniquely for one independent rhenium atom at the approximate coordinates $x = 0.11$, $y = 0.25$, $z = 0.02$. This indicated the space group $C2/c$, with an eightfold general position; one cycle of refinement, varying only the scale factor gave $R_1 = 0.30$.[4] A three-dimensional electron density difference map revealed the positions of all the remaining non-hydrogen atoms, except C(2). A further cycle of refinement, using unit weights, followed by a difference map revealed C(2). In further refinement it was necessary to keep the *y* coordinate of the rhenium atom fixed at 0.25. Allowing this parameter to vary by even 0.001 caused the temperature factors of other atoms to blow up or become non-positive definite. This is because in reflections with *k* odd, the rhenium atoms do not contribute to the intensity if *y* is precisely ¼, but this is not so if the rhenium atom moves out of this position. The high scattering power of the rhenium atom tends to swamp other contributions.

In all further refinement the pyridine rings were constrained to the geometry given by Bak *et al.* (6) and refinement was done using the program GROUPLS. In addition, the temperature factors of the rhenium and chlorine atoms were made anisotropic. A weighting scheme of the type $W = [104.4 - 1.016|F_o| + 0.00293|F_o|^2]^{-1}$ was used for further refinement which was stopped at $R_1 = 0.0789$, $R_2 = 0.0453$. At this point a correction was made for secondary extinction by the method of Larsen (7) ($g = 2.93 \times 10^{-8}$), and all reflections, including those previously considered unobserved, were used in further refinement. The weighting scheme was modified to $W = [104.4 - 1.016|F_o| + 0.00293|F_o|^2 + 1390|\sigma/|F_o||^2]^{-1}$ for reasons outlined previously (4). Further refinement was terminated at $R_1 = 0.0713$ and $R_2 = 0.0449$. The maximum shift/error was 0.04 and the average shift/error was 0.007. A final difference map showed no peak higher than 1.02 e/Å^3 at 0.11, 0.20, 0.02 near the rhenium atom and no valley lower than −1.06 e/Å^3 at 0.11, 0.30, 0.02, also near the rhenium atom. The final atom parameters are given in Table 1 and the moduli of F_o and F_c are given in Table 2.[5]

An alternative refinement using anisotropic temperature factors for the oxygen atoms was terminated at

[3]All calculations were carried out on a CDC 6400 computer. The programs DATCO3, ABSORB, DATRDN and ORTEP were taken from the X-RAY 71 package. The full matrix least squares programs, CUDLS and GROUPLS (J. S. Stephens), Fourier program, SYMFOU (J. S. Rutherford), and least squares planes program, PALS (P. G. Ashmore) were written locally.

[4]$R_1 = \dfrac{\sum ||F_o| - |F_c||}{\sum |F_o|}$;

$R_2 = \left[\dfrac{\sum \omega(|F_o| - |F_c|)^2}{\sum \omega F_o^2}\right]^{1/2}$.

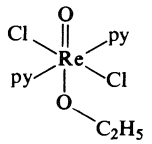
*Anisotropic temperature factors (Å $\times$ 10^3). Anisotropic temperature factors U_{ij} were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through exp $[-(\beta_{11}h^2 + \ldots 2\beta_{12}hk + \ldots)]$ in the structure factor expression and b_j are the reciprocal lattice vectors. Estimated standard deviations are given in parentheses.

$R_1 = 0.0712$ and $R_2 = 0.0448$. This is not significantly better than the above refinement using Hamilton's test (8). A final refinement was tried moving the rhenium atom y parameter to 0.249 or 0.251. In both cases the light atom temperature factors misbehaved, as observed previously. Throughout the refinements the scattering curves used were those from the *International Tables for X-ray Crystallography* (ref. 9, Table 2.2A, p. 72*ff.*) and anomalous dispersion corrections from the same source (ref. 9, Table 2.3.1, pp. 149–150) were applied to the curves for Re and Cl.

Discussion

The molecule is shown in Fig. 1 and selected interatomic distances and angles are given in Table 3. The six bonded ligand atoms form a very rough octahedron about the rhenium atom; that is, although the bond lengths vary markedly, all *cis* angles, except two, are close to 90°. The angles which differ markedly from 90° are O(1)—Re—Cl(2), 97.4(3)° and O(2)—Re—Cl(1), 84.9(3)°. This is apparently caused by non-bonded interactions. The Cl(2)—O(1) distance is normal (13), whereas the other Cl—O distances, particularly Cl(1)—O(1) and Cl(1)—O(2), are more characteristic of systems whereas steric strain is present (10). Re—N(1), 2.144(7), and Re—N(2), 2.132(7), do not differ significantly and the distances agree well with previously determined values (3, 4, 11). Re—Cl(1), 2.441(3) Å, and Re—Cl(2), 2.366(3) Å, do differ significantly, Re—Cl(2) having a distance considered 'normal' by Ibers and co-workers (12). Thus, Re—Cl(1) is long and we shall show below this is caused by steric repulsion. The two Re—O distances differ as would be expected for a structure written formally as



The actual values, however, cast serious doubts on this formulation. Re—O(1), 1.684(7), lies well within the range of distances (1.60(5)–1.73(6) Å) considered to be representative of Re—O triple bonds (13 and references therein),

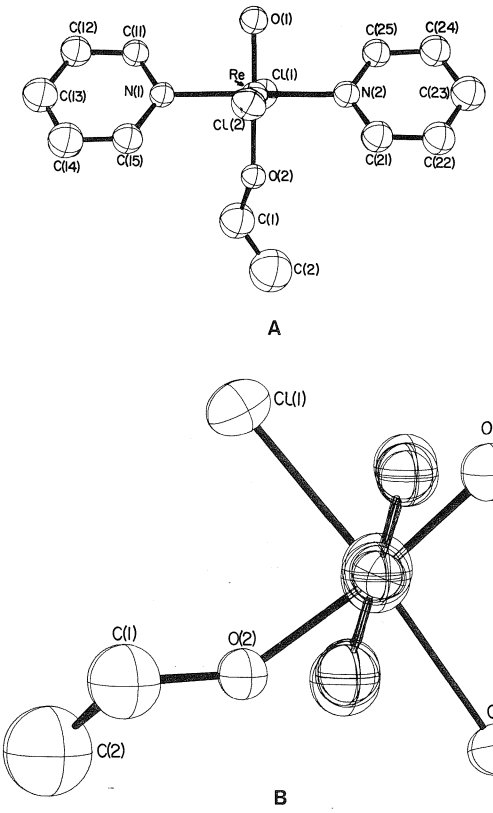


FIG. 1. (*A*) The molecule, $ReOCl(OEt)(C_5H_5N)_2$, oriented such that the plane O(1)N(1)O(2)N(2) lies in the plane of the paper. The numbering of the atoms is as in Table 1. (*B*) The same molecule viewed down the N(1)N(2) vector, and not retouched in the neighbourhood of the pyridine rings, to show the almost complete coplanarity.

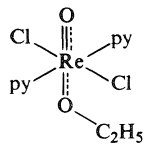
and Re—O(2), 1.896(6), is substantially less than 2.04 Å, considered by Cotton and Lippard (14) to be representative of an Re(V)—O single bond. The Re—O(2) distance is closer to the Re—O double bond distance, 1.76–1.78 Å, (3, 15–19) and the Re—O(bridging) distance observed in Re—O—Re systems (19–21) where multiple bonding has been postulated (20). If one uses the above single bond value, the value of 1.765 Å (obtained from accurate redeterminations of the structures of $[ReO_2(en)_2]Cl$ and $[ReO_2(py)_4]Cl{\cdot}2H_2O$, (22)) as the double bond value, and the Pauling bond order – bond length relationship (23), then the Re—O(2) bond has an order of 1.44 and Re—O(1), 2.45. Thus a more realistic picture would be



The partial multiple bonding in Re—O(2) is consistent with the very large Re—O(2)—C(1) angle, 144.3(9)°, although this cannot be the only cause since, with an Re—O double bond we would expect Re—O(2)—C(1) to be close to 120°. Again, we shall suggest this is caused by steric repulsion. We note that the Re—O distances observed herein are quite close to those observed by us for the $[ORe(NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2)_2{\cdot}OH]^{2+}$ ion (11), and thus the multiple bonding postulated here appears to be a general effect for O≡Re—OR systems. This is in complete contrast to the normal behaviour of formally single-bonded groups *trans* to an oxo-ligand in six-coordinate rhenium(V) compounds (13, 14) and is in direct contravention of the model of Porai-Koshits and Shustorovich (24). Normally the *trans* ligands are at distances from the metal even greater than normal metal–ligand single bond distances. We do not consider the effect anomalous; four orbitals are used in bonding along the O—Re—O axis in *trans*-$ReO_2L_4^{n+}$ complexes. In this complex we have gone part way to an O≡Re—X system, but the total bond order still remains close to 4.

The O(2)—C(1) distance (1.41(2) Å) is normal, but the C(1)—C(2) distance (1.40(2) Å) appears to be short (25). We considered the possibility of some inexplicable hydrogen loss to give a vinyl group rather than an ethyl group but proton nmr studies show unambiguously that an ethyl group is present (δ $H(CH_3)$, 1.00; δ $H(CH_2)$, 3.76 ppm downfield relative to TMS, J_{HH} = 7.42 Hz; δ $H(C_5H_5N)$, complex, centered at roughly 7.6 ppm downfield). The shortening of the bond length may be artificial, since both C(1) and C(2), especially C(2), have large temperature factors.

The steric requirements of pyridine, noted previously (3, 4), are again manifest. The pyridine rings are essentially coplanar, as shown in Fig. 1*B*, and are oriented such that the pyridine planes make an angle of 34° with the best plane through O(1)(2)ReN(1)N(2) and 55°

TABLE 3. Selected interatomic distances and angles for $ReOCl_2(OC_2H_5)(C_5H_5N)_2$

O(1)–N(1)	2.73(1)	O(1)–N(2)	2.74(1)
O(1)–C(11)	2.98(1)	O(1)–C(25)	3.00(1)
O(2)–N(1)	2.81(1)	O(2)–N(2)	2.87(1)
O(2)–C(15)	3.04(1)	O(2)–C(21)	3.12(1)

with the best plane through N(1)N(2)ReCl(1)-Cl(2). Because of the orientation of the pyridine rings, atom C(1) is constrained, and must lie in the general direction of Cl(1). We noted above the large Re—O(2)—C(1) angle. If this angle was 120°, as would be expected for a double bond – single bond system at an oxygen atom, the C(1)—Cl(1) distance would be 2.65–2.84 Å, depending on the exact features of the model, which is unacceptably short. The Cl(1)—C(1) distance has been increased to a more acceptable 3.34(1) Å, by lengthening the Re—Cl(1) bond, opening up the Re—O(1)—C(1) angle to 144.3(9)° and twisting C(1) out of the Cl(1)-ReO(2) plane. The dihedral angle between the planes ReO(2)C(1) and Cl(1)O(1)ReCl(2)-O(2) is 33°. This final displacement is restricted because C(1) is now only 3.44(1) Å from C(15). The displacement of C(1) out of the Cl(1)Re(2) plane brings one of the hydrogen atoms on C(1) closer to Cl(1) (2.74 Å) than if C(1) had been in the plane (3.09 Å).[6] Presumably a short Cl–H non-bonded distance is preferable to a short Cl–C non-bonded distance.

The packing, shown in Fig. 2, is complex. In the ***a*** direction contact in the plane at $x = \frac{1}{4}$ is primarily between the ethyl groups and pyridine rings on adjacent molecules. In the $x = \frac{1}{2}$ plane, down the $y = \frac{1}{2}$ line contact is between oxygen and chlorine atoms on adjacent molecules. In the same plane and down the $y = 0$ line, however, we have contact between parallel pairs of pyridine rings. A similar contact is observed dominating packing in the ***b*** direction. In the ***c*** direction, contact is between a pyridine ring on one molecule

[6]Calculations are based on an H—C—H angle of 109.8°, a CH distance of 1.000 Å, and C_{2v} symmetry of the bonds about C(1).

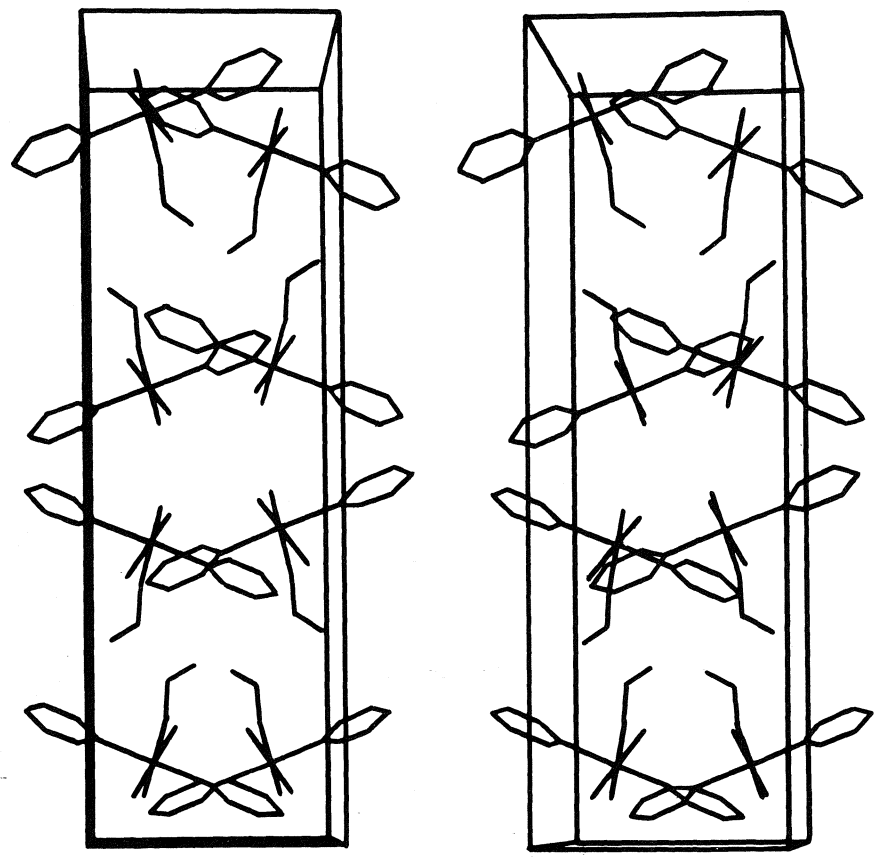

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of $ReOCl_2(OC_2H_5)(C_5H_5N)_2$. The contents of one unit cell are shown. ***a*** and ***b*** are parallel to the side and top of the page respectively and the view is down ***c****.

and chlorine and pyridine groups on another, or a pyridine ring on one molecule and pyridine, chlorine, and ethoxo groups on the other. All contacts mentioned above are equal to or greater than Van der Waals contact distances. There appear to be no features of the packing which would have any dominant effect on the intramolecular structural features.

Finally, we note that the pyridine rings are *trans*, as was correctly postulated by Johnson *et al.* (1). This raises the problem of why the *trans* isomer was obtained from **3**, in which the pyridine rings were arranged *cis*. We have shown that the *cis* arrangement in the dimer is a steric requirement of the structure. It may be that in the monomer species the *trans* arrangement of the pyridine groups is more stable. Octahedral or pseudo-octahedral complexes having two pyridine groups attached to the central metal show both *cis* and *trans* arrangements (26–42). It is notable, however, that *cis* arrangements of the pyridine groups only occur where the remaining coordinated groups are not very large or sterically demanding (26–30). In compounds containing ligands such as halogens the pyridine ligands are *trans* (31–42). It appears therefore, that steric requirements will generally cause pseudo-octahedral complexes which contain two pyridine groups to have a *trans* arrangement of the pydrine groups.

Electrical conductivity studies on $Cd_3O_2Cl_2$ and Cd_3OF_4

MAHADEVA NATARAJAN AND ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received July 19, 1976

MAHADEVA NATARAJAN and ETALO A. SECCO. Can. J. Chem. **55**, 340 (1977).

Electrical conductivity data on compressed discs of $Cd_3O_2Cl_2$ and Cd_3OF_4 show contrasting electrical behavior. The relative high room temperature conductivity and its quasi-independence of temperature suggest Cd_3OF_4 to be a novel semiconductor compound.

MAHADEVA NATARAJAN et ETALO A. SECCO. Can. J. Chem. **55**, 340 (1977).

Des données de conductivité électrique sur des disques compressés de $Cd_3O_2Cl_2$ et de Cd_3OF_4 montrent des comportements électriques qui sont en opposition. La conductivité relativement élevée à température de la pièce et son indépendance presque totale de la température suggèrent que le Cd_3OF_4 est un nouveau composé semi-conducteur.

[Traduit par le journal]

The cadmium oxyhalides, $Cd_3O_2Cl_2$ and Cd_3OF_4, have been isolated and identified in this laboratory (1, 2). These compounds were expected to possess contrasting electrical conductivity behavior from elementary crystal structure and charge neutrality considerations.

$Cd_3O_2Cl_2$ crystallizes in the monoclinic system (3) in common with $Hg_3O_2Cl_2$ (4) which suggests the structural formula $Cd(OCdCl)_2$. On the other hand, Cd_3OF_4 crystallizes in the cubic system in common with its reactants CdO and CdF_2. With the ionic radii of O^{2-} and F^- given as 1.40 and 1.36 Å, respectively, (5), the oxyfluoride is visualized as a substitution compound with normal F sites in the fluoride lattice replaced by O units. This substitution can be accommodated by singly charged O^- species, F^- vacancies, or Cd^{2+} interstitials.

The inherent defects speculated for oxyfluoride are expected to display characteristic electrical conductivity properties in contrast to the non-defective $Cd_3O_2Cl_2$ and this report includes such a conductivity study.

Experimental

The compounds were prepared according to procedures already described (1, 2) and confirmed by their characteristic DTA and X-ray diffraction patterns. Conductivity measurements were made on compressed polycrystalline discs (13 mm diameter and 2–3 mm thick) held between Pt plates by a spring loaded support (6). Measurements were also made with silver dag painted on the disc contact faces, instead of Pt plates, with no difference in conductivity discernible. The cell was heated at the rate of 20 °C h^{-1} and the temperature was monitored by chromel–alumel thermocouple. The frequency of 1 kHz, unless otherwise specified, employing GR-1608 A Impedance bridge was used in all measurements.

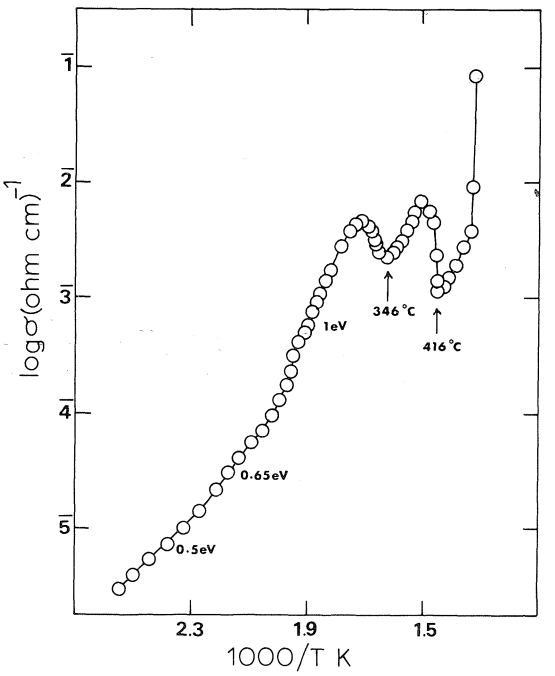

FIG. 1. Logarithm of specific conductivity, σ, *vs.* $10^3/T$ K in vacuum for $Cd_3O_2Cl_2$ preannealed at 220 °C in N_2 for 1 h.

Results and Discussion

The logarithm of conductivity σ *vs.* $1000/T$ K for $Cd_3O_2Cl_2$ is given in Fig. 1. The disc of freshly prepared compound yields $\sigma \approx 10^{-9}$

[1]To whom correspondence should be addressed.

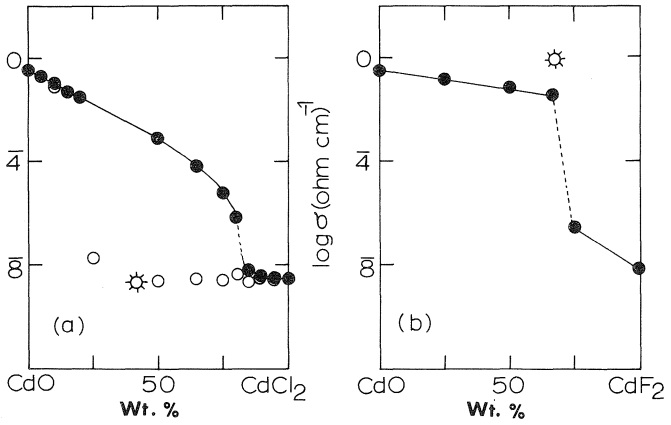

FIG. 2. Logarithm of specific conductivity, σ, *vs.* composition (wt. %) of mixtures, (*a*) $CdO–CdCl_2$, filled circles for unannealed samples, open circles for samples annealed at 500 °C in air for 6 h; (*b*) $CdO–CdF_2$, filled circles for unannealed samples; the spiked circle in each diagram represents the respective compound.

$(ohm\ cm)^{-1}$ at room temperature whereas σ increases to 10^{-6} $(ohm\ cm)^{-1}$ after preannealing at 220 °C for 1 h. The low temperature slope corresponds to an activation energy of 0.5 eV with regional slopes increasing to 0.65 and 1.0 eV at higher temperatures. A pronounced anomaly exists at 346 °C followed by a second effect at 416 °C prior to the sharp rise in conductivity above 460 °C; these latter two effects were observed both in preannealed and unannealed discs. Above 495 °C the compound undergoes trace decomposition with $CdCl_2$ depositing on the cell walls. The characteristic X-ray pattern for $Cd_3O_2Cl_2$ remained unaffected in the temperature region 320–430 °C, thus precluding any phase transition.

Room temperature conductivity measurements were made on $CdO–CdCl_2$ mixtures over the entire composition range; the data are plotted in Fig. 2*a*. The conductivity for annealed and unannealed mixtures remains constant, $\sim 10^{-9}$ $(ohm\ cm)^{-1}$, from $CdCl_2$ to 85% $CdCl_2$. This result supports the earlier suggestion (1) that a solid solution of limited solubility is formed prior to compound formation. The conductivity of the compound (spiked circle) is comparable to $CdCl_2$ and 10^6 lower than the corresponding unannealed composition. Excess CdO in the compound effects a rise in conductivity attaining the unannealed value at ~85% CdO.

Plots of log σ *vs.* $1000/T$ for Cd_3OF_4 under different measurements and preannealed conditions are presented in Fig. 3. Cd_3OF_4 was

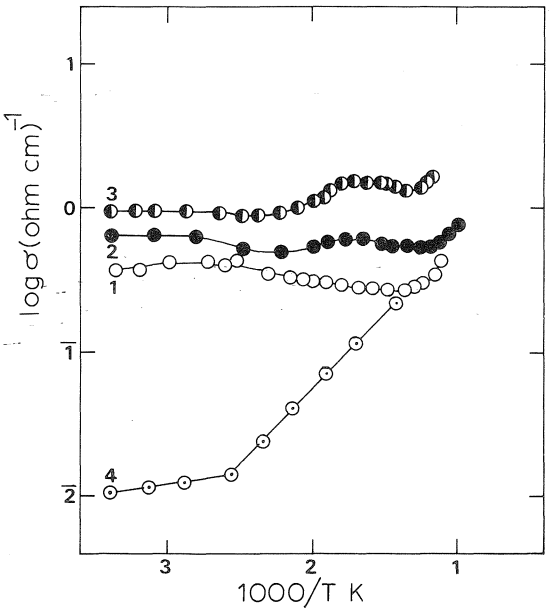

FIG. 3. Logarithm of specific conductivity, σ, *vs.* $10^3/T$ K for Cd_3OF_4 under different conditions of pretreatment and measurement; (*1*) fresh sample in vacuum, (*2*) same sample in N_2 after annealing 1 h at 600 °C, (*3*) same sample in vacuum after annealing in N_2 at 600 °C for ~5 h, (*4*) fused product (prior to compound formation) in N_2.

prepared by prefusing the stoichiometric mixture of CdO and CdF_2 and annealing the fused product at 500 °C for 2 h (2). Curve *1* refers to data obtained in vacuum ($\sim 10^{-4}$ torr) on the freshly prepared compound. Curve *2* represents

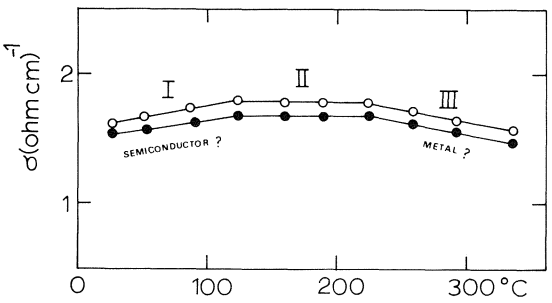

FIG. 4. Specific conductivity, σ, as a function of temperature (°C) at 50 Hz (open circle) and 10 kHz (filled circle).

data obtained in 1 atm N_2 on the same disc from curve *1* after further annealing in N_2 at 600 °C for 1 h and cooled to room temperature. Curve *3* refers to measurements in vacuum on the same disc after prolonged annealing, ~5 h at 600 °C in N_2. The high temperature conductivity is extrapolated to $\sigma_0 \simeq 10 \pm 4$ $(\text{ohm cm})^{-1}$ at $1/T = 0$. The X-ray diffraction pattern of the specimen after curve *3* measurements remained unaltered from its original pattern. Curve *4* represents the conductivity behavior of the fused product, that is, prior to compound formation. The curve shows an initial slope of 0.028 eV with a break at ~100 °C and a second slope of 0.28 eV up to 500 °C. At 500 °C the fused product is completely transformed into the compound.

Figure 2*b* exhibits room temperature conductivities in N_2 for CdO–CdF_2 unannealed mixtures. The conductivity value of Cd_3OF_4, spiked circle, is higher than the CdO value.

Figure 4 shows Cd_3OF_4 conductivity data obtained in vacuum at two frequencies, *viz.* 50 Hz and 10 kHz in the temperature range 25–325 °C. Three σ–*T* regions are identified: region *I*, 25–125 °C, resembles semiconductor behavior; region *II*, 125–225 °C, the conductivity is independent of temperature; and region *III*, 225–325 °C, the gently decreasing conductivity parallels metallic behavior. These data along with curves *1–3* in Fig. 3 suggest a novel semiconductor with an interesting semiconductor–metal transition.

The compound Cd_3OF_4 is visualized as an anion substitution compound incorporating lattice defects. The fused product of 1:2 mole ratio of CdO and CdF_2, however, represents a physical state with a random distribution of defects. At low temperatures, <100 °C, these defects in the fused product behave as so-called shallow impurities where their energies are slightly displaced from the edge of an intrinsic band; similar to shallow donors or acceptors in II–VI compounds (Group III or Group VII substitutional impurities) which exhibit ionization energies of 0.028 eV order of magnitude (7). Above 100 °C the defects become more mobile establishing order in the Cd_3OF_4 lattice with an energy of 0.28 eV. Complete ordering of the lattice is achieved at ~500 °C and the conductivity reaches its maximum value remaining essentially constant on subsequent heat–cool modes, curves *1–3*.

The relatively high room temperature and quasi-constant conductivity presents an interesting case for interpretation. The conductivity behavior of Cd_3OF_4 may be interpreted from the viewpoint of a very heavily doped compound and the discussion implies the presence of electronic defects originating from lattice defects or impurities hitherto unspecified. As the concentration of impurities increases in a semiconductor the quantitative theory of the effect of these impurities on the energy bands becomes a formidable problem. A qualitative appreciation may be had, however, from a simple progression from low to high impurity concentrations. As the impurity concentrations become sufficiently high, appreciable overlap of the wave functions of the carriers at neighboring impurity sites begins to occur, interaction effects give rise to impurity bands in much the same way that the LCAO approach gives energy bands for interacting atoms. We could expect the impurity band to be very wide in Cd_3OF_4 and in fact, overlap the adjacent intrinsic band. When the impurity band overlaps the intrinsic band the impurity activation energy disappears and no freezeout of carriers onto impurity levels at low temperatures should occur; hence, a quasi-independent temperature effect on conductivity.

An alternate mechanism responsible for the unusual conductivity properties of Cd_3OF_4 may reside in the nature of a very fast ionic conductor (8). The three principal features of a fast ionic conductor, *viz.* (*i*) unusually high ionic conductivity value, (*ii*) small temperature dependence of conductivity, and (*iii*) very small value of σ_0, appear consistent with Cd_3OF_4. Assuming the conductivity to be ionic then Cd_3OF_4 exhibits one of the highest values of ionic con-

ductivity $\sigma \approx 1.0$ (ohm cm)$^{-1}$ at 25 °C. With the reasonable assumption of ionic transport, the diffusion coefficient of the mobile species at 25 °C can be estimated as $D \approx 10^{-5}$ cm^2 s^{-1}.

It is hoped that this communication will stimulate further experimental, *e.g.* Hall effect measurements and theoretical studies to elucidate the nature of the electrical species and transport mechanism in Cd_3OF_4.

N,N'-Bis(phenylaminomethyl)parabanic acid as a complexing agent. Complexes of some bivalent first row transition metals

ANTONIO COSTANTINO FABRETTI, GIAN CARLO FRANCHINI, CARLO PRETI,[1] AND GIUSEPPE TOSI

Istituto di Chimica Generale ed Inorganica, University of Modena, 41100 Modena, Italy

Received June 24, 1976

ANTONIO COSTANTINO FABRETTI, GIAN CARLO FRANCHINI, CARLO PRETI, and GIUSEPPE TOSI. Can. J. Chem. **55**, 344 (1977).

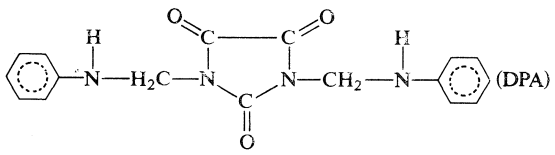
The preparation of some complexes of *N,N'*-bis(phenylaminomethyl)parabanic acid with halides of cobalt(II), nickel(II), and copper(II) is reported. The complexes of the type MLX_2 seem to have pseudo-tetrahedral and pseudo-octahedral symmetry. The complexes have been studied by means of magnetic susceptibility measurements, infrared and far infrared spectra, electronic and nmr spectra, and conductivity measurements. The ligand behaves as bidentate N-bonded. The various ligand field parameters, *Dq*, *B'*, and β have been evaluated. The *B'* values suggest a strong covalency in the metal–ligand σ bond and *Dq* values show a medium strong ligand field. The presence of metal–nitrogen bonds is suggested. The possible stereochemistries of the complexes are discussed in the light of the experimental results.

ANTONIO COSTANTINO FABRETTI, GIAN CARLO FRANCHINI, CARLO PRETI et GIUSEPPE TOSI. Can. J. Chem. **55**, 344 (1977).

On rapporte la préparation de quelques complexes de l'acide *N,N'*-bis(phénylaminométhyl) parabanique avec les halogénures du cobalt (II), du nickel (II) et du cuivre (II). Il semble que les complexes du type MLX_2 possèdent des symétries pseudo-tétraédriques et pseudo-octaédriques. On a étudié les complexes au moyen de mesures de susceptibilité magnétique, de leurs spectres infrarouges et infrarouges lointains, de leurs spectres électroniques et rmn et de mesures de conductivités. Les ligands se conduisent comme des entités bidentates liées par l'azote. On a évalué les divers paramètres de champ de ligand *Dq*, *B'* et β. Les valeurs de *B'* suggèrent une forte covalence du lien σ métal–ligand et les valeurs de *Dq* montrent un champ de ligand moyennement fort. On peut présumer de la présence de lien métal–azote. A la lumière des résultats expérimentaux, on discute des stéréochimies possibles pour les complexes.

[Traduit par le journal]

N,N'-Bis(phenylaminomethyl)parabanic acid has three carbonyl oxygens, two nitrogen atoms in the ring and two nitrogen atoms exocyclic as potential donors. It is obvious from the structure of the molecule that all the donor atoms cannot coordinate simultaneously to the same metal ion. The complexation may be achieved by coordination with the ligand acting as monodentate or by formation of a chelate structure involving both oxygen and nitrogen atoms. Polymeric structures involving a bridging ligand are also possible, therefore it is of interest to investigate the nature of the complexes formed from this ligand. The parabanic acid, from which this ligand has been obtained, is quite similar to the hydantoin and to the barbituric acid, widely employed as hypnotics and sedatives. We have undertaken a study of the stereochemistries and of the chemical reactivity of the coordination compounds of the derivatives of parabanic acid in order to further our present knowledge in the determination of the relationship existing between chemical structure and biological activity of these drugs. It is well known that the metal complexes of ligands having biological activity are more active than the free ligands (1, 2).



(DPA)

This paper reports the coordinating behaviour of DPA with bivalent cations, Co(II), Ni(II), and Cu(II). The infrared, uv, visible, and nmr spectra, and the magnetic moments of these complexes have been examined. Based on these studies the structures of the complexes have been proposed.

Results and Discussion

Experimental section we have obtained complexes of the type $[M(DPA)X_2]$ (M = Co, Ni, X = Cl, Br, I) and $[Cu(DPA)X_2]$ (X = Cl, Br). In Table 1 the coordination compounds obtained are reported together with analytical results, colours, melting points, and magnetic values. The most important ir data are shown in Table 2. The principal features of the visible absorption spectra of this series of complexes are given in Tables 3 and 4. The complexes are microcrystalline, soluble in *N,N'*-dimethylformamide, nitromethane, dimethylsulfoxide. These derivatives are nonelectrolytes, Λ lying in the range 12.7–51.3 ohm^{-1} cm^2 mol^{-1} in nitromethane; the Λ values, even for 1:1 electrolytes, are 75–95 ohm^{-1} cm^2 mol^{-1} in this solvent (3).

It is interesting to point out that all the bands typical of the ligand appear in the ir spectra of the complexes and the ligand can be recovered by chemical decomposition of the compounds.

A formulation of the type $[ML_2][MX_4]$ must be ruled out for these complexes having only one coordinated ligand because these compounds behave as nonelectrolytes and because the typical vibrations for the tetrahalo group $[MX_4]^{2-}$ (X = Cl, Br, I) have not been found in the ir spectra, see below.

Infrared Spectral Studies

The spectra of the ligand in the solid state and in chloroform solution show a difference in the position of the ν(NH) stretching frequency, clearly indicating intermolecular or intramolecular hydrogen bonding between the hydrogen of the NH groups and the oxygen of the keto groups. The ν(NH) in the complexes is shifted towards lower wave numbers by about 80 cm^{-1}. The ν(C=O) vibrational modes are present in the solid state free ligand spectrum as medium bands at 1760 and 1645 cm^{-1}, A_1, while the very strong absorption of the type B_1 is present at 1715 cm^{-1} (4). In the spectrum of the free ligand in chloroform solution only two bands at 1780 and 1745 cm^{-1} are present. On going from the spectra of the free ligand to those of the complexes, these bands are present at the same wave numbers or show very small red shifts. From these facts we can suppose that the coordination centres are the nitrogen atoms of the amino groups of the ligand, but we prefer to use

*Calculated values.
†B is taken to be 967 and 1 041 cm^{-1} for Co^{2+} and Ni^{2+} free ions respectively.

electronic spectra to confirm this hypothesis and to delay the question of the assignment of ν(M—L) until after the discussion of the electronic spectra and nmr measurements.

Medium absorption bands are present in all the complexes in the ranges expected for ν(OH) and δ(HOH), clearly confirming the presence of water of crystallization. We can exclude the presence of coordinated water because from a detailed analysis of the infrared spectra the other vibrational modes such as wagging, twisting, and rocking activated by coordination to the metal have not been found in the expected ranges (5). Furthermore this water is lost near 95–100 °C, while coordinated water is lost near 150–160 °C (5).

As for the metal–halogen stretching modes, Table 2, the bands at 324 and 300 cm^{-1}, 238 and 216 cm^{-1}, and 205 cm^{-1} in the cobalt chloro-, bromo-, and iodo-derivative, respectively, are in accord with the literature data for pseudo-tetrahedral complexes with terminal halides (6–12). In the complexes $[Ni(DPA)Cl_2]$ and $[Ni(DPA)Br_2]$ the values found at 190 and 169 cm^{-1}, and at 158 and 148 cm^{-1} are typical for halide bridged nickel(II) complexes; no bands have been observed for terminal halides. In the iodo-derivative of nickel(II) the vibrational modes at 200 cm^{-1} and 153 cm^{-1} are due to terminal iodide atoms (6, 13–16). In the copper derivatives the bands present at 300 and 242 cm^{-1}, and at 250 cm^{-1} for the chloro- and bromo-derivative respectively are typical for ν(Cu—X) in halide bridged structures. This assignment is supported by the fact that the value of the ratio ν(Cu—Br)/ν(Cu—Cl) equals to 0.83 (6, 17).

We have never observed the wave numbers of the ν(M—X) bands similar to the values reported in the spectra of the halogenometallates of the type $[MX_4]^{2-}$ (M = Co, Ni, Cu; X = Cl, Br, I) (18–22).

These ir results agree very well with the conductivity values.

Electronic Spectral and Magnetic Studies

The spectral data and the values chosen for the energies ν_2 and ν_3 from which the values of

the parameters Dq, B', and β have been derived, are reported in Tables 3 and 4 respectively. With the cobalt halides, complexes of pseudo-tetrahedral geometry are formed, the chloro- and bromo-derivative of nickel have an octahedral polymeric structure while the nickel iodo-complex seems to be tetrahedral. For the copper derivatives, octahedral, polymeric halide-bridged structures seem likely.

The Dq values of the complexes, Table 4, suggest the order Cl > Br > I for the halides in the spectrochemical series and this fact is consistent with the generally accepted sequence. In order to determine the position of the ligand in the spectrochemical series, the Dq values of the complexes were compared with the Dq values of known tetrahedral halide complexes of cobalt(II) and we can suggest the following order for the ligands (7, 15, 16, 23–28):

benzothiazole > benzoxazole-2-thione > 2-methylbenzimidazole > 3-methyl-5-phenylisoxazole > 2-aminobenzimidazole > thiomorpholin-3-thione > thiazolidine-2-thione > 3,5-dimethylisoxazole > DPA > thiazolidine-2-selenone

Table 4 shows that the B' values for the cobalt derivatives are of the order of 60–68% of the free ion value (967 cm^{-1}), which suggests that there is a considerable orbital overlap in the metal–ligand σ bond. The ligands can be placed in the nephelauxetic series in the order:

thiazolidine-2-selenone > thiazolidine-2-thione > thiomorpholin-3-thione > DPA > 2-aminobenzimidazole > 3,5-dimethylisoxazole > benzothiazole > benzoxazole-2-thione > 3-methylbenzimidazole > 3-methyl-5-phenylisoxazole

Our ligand is at the end of the spectrochemica series and almost at the beginning of the nephelauxetic series. This fact can be explained as the former is a measure of the electrical field produced by the ligand while the latter is a measure of the covalency of the metal–ligand bond.

In the cobalt derivatives the bands at 15 565–14 355 cm^{-1} may be assigned as the $^4A_2(F) \rightarrow {}^4T_1(P)$ transition, the second at 7510–7300 cm^{-1} as the $^4A_2(F) \rightarrow {}^4T_1(F)$ transition. These bands passing from the chloro- to the iodo-derivative are shifted towards lower energies. The ν_3 transition is split because of the distorted tetrahedral structure of the complexes; we have calculated the ligand field parameters using only the ν_2 transition and the visually estimated frequency of the centre of gravity of the split bands corresponding to ν_3 using the equations proposed by Underhill and Billing (29). The assignment of ν_1 is made difficult by the presence of vibrational modes in the range where this transition should be expected. The calculated ν_1 wave numbers are reported in Table 4.

From the analysis of the electronic spectra we could determine the mode of bonding of the ligand by comparison of Dq values reported for CoL_4^{2+} and CoX_4^{2-} ions (30, 31). Table 4 shows that Dq values are in good agreement, using the 'law of the average environment', with the literature data for derivatives containing cobalt–nitrogen bonds.

The magnetic susceptibility values, 4.6–4.9 B.M., lie in the range normally accepted for the metal tetrahedrally coordinated in high-spin complexes (32).

The reflectance spectra of $[Ni(DPA)X_2]$ (X = Cl, Br) complexes show two major bands at some 23 000 cm^{-1} and at 13 950–13 460 cm^{-1} and all these are very weak in intensity. This is characteristic of octahedral nickel(II) complexes. These bands may be assigned to the transitions $^3A_{2g}(F) \rightarrow {}^3T_{1g}$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ ν_2. A pseudo-tetrahedral stereochemistry has been assigned to the nickel iodo-derivative on the basis of its electronic spectrum, Table 4 (29). The medium strong band at 9390 cm^{-1} can be attributed to the $^3T_1 \rightarrow {}^3A_2$ transition (ν_2), while the band present at 17 790 cm^{-1} accompanied by a shoulder at 11 495 cm^{-1} may be assigned to the ν_3 transition $^3T_1 \rightarrow {}^3T_1(P)$. The Dq values for these nickel derivatives have been calculated using only ν_2 and ν_3 values, the assignment of ν_1 being very often ambiguous because of the presence of vibrations due to the ligand itself in the region where this band usually lies.

The magnetic moments at room temperature of chloro- and bromo-nickel(II) derivatives lie within the range usually observed for octahedral nickel(II) compounds. The magnetic moment of the iodo-complex is near the lower limit of the range normally accepted for nickel(II) in a pseudo-tetrahedral stereochemistry (32). Comparison of the electronic spectra of our complexes with those of derivatives involving Ni—O bonds and Ni—N bonds confirms that these derivatives are N-bonded as the band energies are at higher values than in O-bonded derivatives (30).

On the basis of the solid state electronic spectra, Table 3, we can assign an octahedral distorted symmetry to the copper(II) derivatives (30); the band at 16 950 and 16 420 cm^{-1}, in the chloro- and bromo-derivative, respectively, accompanied by a shoulder at some 13 000 cm^{-1} and a second band around 23 250 cm^{-1} are in accord with this stereochemistry. The anomalously low effective magnetic moments observed for the copper complexes at room temperature indicate that there is a strong spin–spin interaction between two cupric ions. It is very difficult to decide without complete X-ray analyses whether spin–spin interaction takes place because of σ or δ bond formation or by a superexchange mechanism.

Nuclear Magnetic Resonance Measurements

The ligand has been studied by means of nmr techniques. This spectrum shows a hyperfine structure in hexadeuterodimethylsulfoxide (DMSO-d_6); the chemical shift values of C_6H_5- and CH_2-proton resonances appear in the range 7.09–6.60 ppm and at 4.90 ppm respectively. The NH-proton resonance is at 5.39 ppm.

On going from the spectrum of the free ligand to those of the complexes in freshly-prepared DMSO-d_6 solutions we observe the disappearance of the hyperfine structure of the resonances as a consequence of line broadening because of the presence of a paramagnetic centre. A detailed analysis of the individual bands is, therefore, impossible; it is clear, however, that in all the derivatives studied here the NH-proton resonance is shifted towards lower field of about 2.30 ppm. This chemical shift towards lower fields is ascribed to the electron withdrawing of the metals from the nitrogen atoms and the noticeable deshielding effect supports the hypothesis that the studied complexes are N-bonded.

Conclusions

According to the above reported results, the halogen independent bands in the far ir region in the range 250–244 cm^{-1} for the cobalt(II) and nickel(II) derivatives and at 354 and 362 cm^{-1} for the copper chloro- and bromo-derivative, respectively, can be attributed to the ν(M—N) vibrations, Table 2, according to literature data (15, 19, 33, 34).

The cobalt(II) derivatives contain the metal ion tetrahedrally coordinated in high-spin complexes. The vibrational modes typical of ν(Co—X) for terminal halides only suggest for these complexes either a monomeric structure with DPA acting as a chelating ligand or a dimeric structure involving bridging ligands.

The nickel derivatives show different properties as the size of the halogen increases. The chloro- and bromo-derivatives are bright yellow and yellow, respectively, as opposed to the dark green iodo-derivative, and are less soluble than the iodo-derivative. It is known from literature data that the nickel(II) compounds possess a different stereochemistry on passing from chlorine to iodine; the dark green or dark brown iodo-derivatives have a pseudo-tetrahedral symmetry, whereas the yellow chloro- and bromo-derivatives have a pseudo-octahedral environment with bridging halides. The electronic spectra of our chloro- and bromo-derivatives are typical of the nickel(II) in a pseudo-octahedral symmetry, furthermore in the far ir region only the vibrational modes for ν(Ni—X) for bridging halides are present. It is likely for the nickel to attain a pseudo-octahedral geometry in a polymeric structure involving bridging ligands and bridging halides. Octahedral structures involving bridging ligands and terminal halides having coordinated water must be ruled out because from a detailed analysis of the infrared spectra the water was always uncoordinated lattice water. The iodo-derivative has a pseudo-tetrahedral stereochemistry containing terminal iodine atoms. We can therefore assign to this last complex a tetrahedral dimeric structure involving bridging ligands and terminal halide atoms.

Unfortunately it has not been possible to do vapor phase osmometric molecular weight determinations since the solubility of the complexes is too low for these measurements. Furthermore these experiments require a time longer than that of conductivity and nmr measurements and it is clear that dissociative and solvolytic problems, which could seriously interfere, can not be discounted. Therefore we can propose stereochemistries based upon the reported data only.

Experimental

Preparation of the Ligand

The ligand *N,N'*-bis(phenylaminomethyl)parabanic acid (DPA) was prepared starting with a mixture of 3.50 g (0.0375 mol) of aniline and the same amount of 50% ethanol which was added, drop by drop, to a solution of

2.75 g (0.0158 mol) of *N,N'*-bis(hydroxymethyl)parabanic acid in 75 ml of 50% ethanol, according to the method described by Tanimoto and co-workers (35). The solution turned yellow and a yellow crystalline product separated out. The precipitate was recrystallized from ethanol; mp 72–74 °C, lit. 71–74 °C (35). Anal. calcd. for $C_{17}H_{16}N_4O_3$: C 63.0, H 5.0, N 17.3; found: C 62.6, H 5.0, N 17.2.

Preparation of the Complexes

The complexes were all prepared by reaction of the appropriate metal salt with a small excess of the molten ligand, preliminary studies having shown that in each case only a single product was formed, regardless of the presence of excess ligand. The compounds were purified by means of repeated washing with ethanol. We have obtained complexes only in the metal:ligand ratio reported in Table 1.

Infrared Spectra

The ir spectra have been recorded in the range 4000–100 cm^{-1} with Perkin-Elmer 521 and 225 and Hitachi Perkin-Elmer FIS3 spectrophotometers as KBr discs and Nujol mulls between polyethylene sheets. Atmospheric water was removed from the spectrophotometer housing by flushing dry nitrogen.

Visible and Ultraviolet Spectra

Solid state electronic spectra have been recorded with a Shimadzu MPS-50L spectrophotometer.

Magnetic Susceptibility Measurements

These were carried out by Gouy's method. Molecular susceptibilities were corrected for diamagnetism of the component atoms by use of the Pascal's constants.

Conductivity Measurements

These measurements were carried out with a WTW LBR type conductivity bridge at 25 °C for 10^{-3} *M* solutions in nitromethane.

Nuclear Magnetic Resonance Measurements

The nmr spectra of the ligand and its metal complexes were measured in hexadeuterodimethylsulfoxide (DMSO-d_6) solutions with a Jeol JNM-C 60 HL instrument at 60 MHz; TMS was used as internal standard.

The electronic structures, geometries, and relative energies of some N_2H_2 and $N_2H_2^+$ systems[1]

N. COLIN BAIRD AND DAVID A. WERNETTE[2]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 13, 1976

N. COLIN BAIRD and DAVID A. WERNETTE. Can. J. Chem. **55**, 350 (1977).

Ab initio calculations using the 4-31G basis set and extensive configuration interaction are reported for the ^1A_g state of *trans*-diimide (**1**), the $^3A''$ and $^1A_1$ states of 1,1-dihydrodiazine (**2**), and the ground states of the positive ions of these systems and of *cis*-diimide. In all cases the geometries have been optimized. The relative stabilities of these systems are discussed, with particular reference to the heat of formation of *trans*-**1** and to the ionization potentials of **1** and **2**.

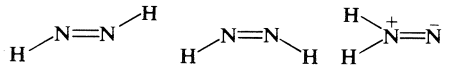
N. COLIN BAIRD et DAVID A. WERNETTE. Can. J. Chem. **55**, 350 (1977).

On rapporte des calculs *ab initio* utilisant une base 4-31G et des interactions de configuration étendues pour l'état ^1A_g de la diimide-*trans* (**1**) et les états $^3A''$ et $^1A_1$ de la dihydrodiazine-1,1 (**2**) et pour les états fondamentaux des ions positifs de ces systèmes et de la diimide-*cis*. Dans tous les cas, on a optimisé les géométries. On discute des stabilités relatives de ces systèmes en particulier par rapport à la chaleur de formation de **1**-*trans* et aux potentiels d'ionisation de **1** et de **2**.

[Traduit par le journal]

Introduction

The chemical and physical properties of the dihydrodiazines, N_2H_2, have been the subject of much theoretical interest (1–18), since their size admits to sophisticated *ab initio* treatments whereas experimental results are few and often inconclusive. As a continuation of our own theoretical efforts in this area (10, 11), we wish to report here the results of *ab initio* calculations which include extensive configuration interaction and which were undertaken to determine the structures and relative energies of 1,2-dihydrodiazine ('diimide'), **1**, and its tautomer 1,1-dihydrodiazine ('aminonitrene'), **2**, and the positive ions of these systems.



trans-**1** *cis*-**1** **2**

Method of Calculation

The extended 4-31G basis set of Ditchfield, Hehre, and Pople with standard molecular scale factors (19) was employed to expand the molecular orbitals. The single-determinant SCF wavefunctions were constructed using Roothaan's procedures for closed-shell (20) and open-shell (21) systems. To obtain a set of determinants in the configuration interaction (CI) calculations which would provide a reasonably consistent representation for all states and systems considered but which would still be tractable, the following procedure was employed. The set of molecular orbitals (MOs) employed was restricted to the twelve most stable SCF orbitals (*i.e.*, the number of orbitals in a minimal basis set), and the four MOs of lowest energy were kept doubly-occupied.

Determinants corresponding to all configurations (of appropriate spin eigenfunction) which are single or double electron excitations from the other four occupied orbitals of the SCF determinant were included in the CI wavefunction. However, determinants with six unpaired electrons were excluded.

In order to provide as accurate as possible an estimation of the heat of formation of *trans*-diimide, the geometry optimization, and energy calculation for this system and for $N_2 + H_2$ was repeated with only the lowest *two* MOs (essentially 1*s* orbitals on the nitrogens) held doubly-occupied in the CI determinants.

With the methods described above, nitrogen–nitrogen and nitrogen–hydrogen distances, and the bond angles were optimized for the following states:

[1]Research supported by the National Research Council of Canada.

[2]Present address: Department of Chemistry, Ohio State University, Columbus, Ohio 43210.

System	Symmetry assumed	State	Configurations used
N_2H_2 systems			
trans-Diimide ('*trans*-**1**')	C_{2h}	^1A_g	49
1,1-Dihydrodiazine ('triplet nitrene **2**')	C_s	$^3A''$	133
1,1-Dihydrodiazine ('singlet nitrene **2**')	C_{2v}	$^1A_1$	48
$N_2H_2^+$ systems			
trans-Diimide cation	C_{2h}	^2A_g	75
cis-Diimide cation	C_{2v}	$^2B_2$	82
1,1-Dihydrodiazine cation ('nitrene cation **2**$^+$')	C_{2v}	$^2B_2$	75

(Note that 102 configurations resulted when only the lowest two MOs of *trans*-diimide were kept doubly-occupied.)

For all systems, the SCF determinant strongly predominated in the CI wavefunction for the ground state; determinants involving double excitations into the π* orbital were next in importance.

Results and Discussion

The Neutral Molecules

Of particular interest for the neutral species are their geometries, their relative stabilities, their stabilities relative to N_2 and H_2, and the nature of the ground state for the nitrene form.

The optimum geometries calculated in the 4-31G + CI calculations are listed in Table 1. The predicted structure for *trans*-diimide agrees well with the experimental determination (22) with respect to HNN angle (106.5° experimental *vs.* 108° calculated) and nitrogen–hydrogen distance (1.028 Å *vs.* 1.02 Å); however the nitrogen–nitrogen separation of 1.252 Å is overestimated by 0.04 Å and 0.05 Å respectively by the CI calculations with 4 and 2 orbitals always doubly-occupied. A similar overestimation (of 0.027 Å) is obtained for N_2 itself.

The heat of formation ΔH_f of *trans*-diimide is of some interest, since it is a direct measure of the energetic stability of the molecule relative to its decomposition products N_2 and H_2. Table 2 lists all the experimental and theoretical values for ΔH_f (*trans*-**1**) known to the authors. Curiously, the more modern experimental values tend to be considerably lower than the older values, whereas the opposite trend is obtained[3] for the theoretical estimate, the more sophisticated the bases set and use of CI, the higher the calculated energy difference between N_2H_2 and $N_2 + H_2$. (Note that the theoretical results have *not* been corrected for differences in zero-point energies or PV work and thus the experimental and calculated results are not exactly comparable.) Our present value of 66 kcal mol^{-1} is a little larger than those derived from the calculations reported recently by Ahlrichs and Staemmler (1) and which not only included an extensive *sp* basis set and CI but also polarization functions. The best experimental estimate of 36 kcal mol^{-1} indicates that *trans*-diimide is actually 14–30 kcal mol^{-1} more stable than predicted.

The geometries calculated for the singlet and triplet states of the aminonitrene **2** are rather different from each other (see Table 1) but agree quite well with our previous estimates in which a minimal basis set and very little CI were employed. The nitrogen–nitrogen distance of 1.26 Å in the $^1A_1$ state is shorter than that computed for the double bond in diimide itself. In the SCF wavefunction, the population of the p_π orbitals of the nitrene nitrogen totals 0.39e.

Both the rather long nitrogen–nitrogen bond length of 1.39 Å, and the preference for a pyramidal geometry about the amino nitrogen, indicate little stabilization for the three-electron

[3]Plots of ΔH_f against year yield respectable straight lines for both experimental and calculated values. The lines cross in 1973 at a ΔH_f value of 38 kcal mol^{-1}. Curiously this value is identical to that obtained from thermochemical group additivity schemes, see ref. 26 for details.

TABLE 1. Calculated geometries using 4-31G + CI method

System	Geometric parameter	Calculated value for: Neutral molecule	Cation
trans-Diimide (*trans*-**1**)	R_{NN}	1.29 Å (1.30 Å)[a]	1.19 Å
	R_{NH}	1.02 Å	1.02 Å
	∠HNN	108° (108°)[a]	128°
cis-Diimide (cis-**1**)	R_{NN}		1.17 Å
	R_{NH}		1.02 Å
	∠HNN		138°
1,1-Dihydrodiazine (**2**)	R_{NN}	1.26 Å ($^1A_1$) 1.39 Å ($^3A''$)	1.24 Å
	R_{NH}	1.02 Å ($^1A_1$) 1.00 Å ($^3A''$)	1.02 Å
	∠HNN	124° ($^1A_1$) 115° ($^3A''$)	121°
	∠HNH	112° ($^1A_1$) 115° ($^3A''$)	118°
Dinitrogen	R_{NN}	$(1.12_5$ Å)[a]	
Dihydrogen	R_{HH}	0.73_6 Å	

[a]Values in parentheses computed using only two lowest MOs doubly-occupied in all configurations.

[b]Computed using $D_e(H_2) = 109.5$ kcal mol^{-1}.

π bond in the $^3A''$ state of 1,1-dihydrodiazine. Indeed the unpaired electrons are 90% and 98% localized in the $2p_\pi$ and the $2p_\sigma$ atomic orbitals of the nitrene nitrogen according to the single determinant results.

In Table 3 are listed the energetic separations between the $^3A''$ and $^1A_1$ states of 1,1-dihydrodiazine as calculated by previous workers and by ourselves. All previous work gave the triplet as the more stable state, although the most extensive calculation (that by Ahlrichs and Staemmler (1)) has a T_1–S_0 splitting of only 2.6 kcal mol^{-1}. Our CI results place the singlet *lower* in energy than the triplet, though by only 1.6 kcal mol^{-1}. In our opinion, the closeness in the calculated energies for the singlet and triplet states of the aminonitrene leaves open the question of which is the real ground state; in any event, the lowest excited state should be thermally accessible.

Finally it is worth noting that the CI calculations predict that the neutral *trans*-diimide

TABLE 3. Singlet–triplet energy gap in 1,1-dihydrodiazine

Method of calculation	Reference	Gap[a] (kcal mol^{-1})
STO-3G basis, minimal CI	10	26.3
4-31G unrestricted SCF (using optimum STO-3G geometries)	18	11.7
Extended basis + polarization functions,	1	2.6
4-31G basis, extensive CI	This work	−1.6

[a]A positive gap indicates the triplet is predicted to be more stable than is the singlet state.

molecule is 20.3 kcal mol^{-1} more stable than is the lowest singlet state of 1,1-dihydrodiazine, in fairly good agreement with the 24–26 kcal mol^{-1} values of Ahlrichs and Staemmler (1).

The N_2H_2 Cations

On the basis of qualitative reasoning, one expects the ionization potential for the aminonitrene to be significantly less than for the diimides. In particular, the least tightly-held electron in 1,1-dihydrodiazine occupies a molecular orbital which is almost exclusively $2p$ (nitrene N) in character. (For the triplet state the orbital involved is the $2p_\pi$, whereas for the singlet the electron ionized is one of the in-plane lone pair in $2p_\sigma$.) In contrast, the electron ionized from either isomer of diimide originates from an MO formed by the lone pairs, and to which there is a substantial contribution from the rather stable $2s$ orbitals on the nitrogens.

In agreement with these qualitative arguments, our *ab initio* calculations predict *vertical* ionization potentials for *trans*-diimide and for the singlet state of 1,1-dihydrodiazine to be 9.07 and 7.28 eV respectively. Note that even though Koopman's theorem has not been used, and optimal eigenvectors for the positive ions have been employed, the agreement between the calculated value and the photoelectron spectroscopic value of 10.02 eV for diimide (27) is not very good.

Using restricted open-shell MO theory with CI, the optimum geometries of the cations of both *trans*- and *cis*-diimide, and of the aminonitrene system, were calculated and are listed in Table 1.

The optimum HNN bond angles calculated for the cation of *trans*-diimide is 20° larger than that calculated for the neutral species. A substantial increase in the angles, giving a species closer to the linear geometry, is expected from Walsh's Rules for HAAH systems when a $3a_g$ orbital electron is removed. For the same reason the HNN angles in the *cis*-diimide cation are also large (Table 1). Although the HNN angle calculated for the *trans*-diimide cation agrees well with the 127° value deduced from the photoelectron spectra of diimide, the calculated bond length for the ion is 0.03 Å shorter than is the experimental. In fact the net contraction in the nitrogen–nitrogen separation due to ionization of a strongly-antibonding n_+ electron appears to be exaggerated in the *ab initio* results, the calculated value being 0.10 Å as contrasted with the experimental 0.03 Å.

The structural changes which are calculated to occur upon ionization in the aminonitrene system are much less dramatic than for diimide, since a nonbonding rather than an antibonding electron is removed. The nitrogen–nitrogen bond length decreases slightly (compared to the singlet neutral system) and the HNH angle opens somewhat. In our optimization calculations for H_2NN^+ the ion was assumed to be planar; a few computations with the final NN and NH bond lengths but with a flapped geometry at the amino nitrogen confirmed the assumed preference for a planar structure.

Given that only minor geometry changes occur in the 1,1-dihydrodizaine singlet upon ionization, it is not surprising that the calculated adiabatic ionization potential of 7.23 eV is only 0.05 eV smaller than is the vertical. For *trans*-diimide, the difference between the adiabatic and the vertical is much larger (0.81 eV calculated, 0.43 eV experimental), the former value for *trans*-**1** being 8.26 eV calculated (9.59 eV experimental (27)).

As a consequence of the 23.8 kcal mol^{-1} calculated advantage in adiabatic ionization potential, the 20.3 kcal mol^{-1} advantage held by *trans*-diimide over 1,1-dihydrodiazine in the

neutral molecules is just overcome, and our CI calculations predict the nitrene cation $\mathbf{2}^+$ to be more stable than the *trans*-diimide cation by about 3.5 kcal mol^{-1}. (Given the size of this energy difference, a reversal in stability order in more sophisticated calculations cannot be ruled out, however.) The *trans* isomer of the diimide ion is predicted to be 6.9 kcal mol^{-1} more stable than is the *cis*; this value is close to those obtained in most recent calculations for the energy difference between the *neutral* molecules.

After this work had been completed, Wiberg and co-workers (28) reported the discovery of a second isomer of N_2H_2. From the appearance potentials for N_2H^+, they concluded that the new species is 13 ± 2 kcal mol^{-1} less stable than is *trans*-**1**, a value which is midway between our calculated relative energy (of 20 kcal mol^{-1}) for the aminonitrene isomer **2** and that of 6–9 kcal mol^{-1} usually found (1, 15, 18) for the relative energy of the *cis*-**1** species. While the ionization potential of 9.52 eV found for the new species seems too high to be that for **2** and is close to that expected for *cis*-**1**, the lack of a 380 nm band in the spectrum of the new isomer seems to preclude *cis*-**1** as a candidate. Obviously more experimental and theoretical work is required to characterize the new isomer.

Dicyclohexanecarbonylsulphate: a precursor of cyclohexyloxocarbenium ions

E. MONTONERI, L. GIUFFRÉ,[1] M. CASSAGO, E. TEMPESTI, AND M. FORNAROLI

Istituto di Chimica Industriale del Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano, Italy

Received July 16, 1976

E. MONTONERI, L. GIUFFRÉ, M. CASSAGO, E. TEMPESTI, and M. FORNAROLI. Can. J. Chem. **55**, 355 (1977).

Dicyclohexanecarbonylsulphate (**1**) is the prevailing species in the equimolar solution of cyclohexanecarboxylic anhydride and sulphur trioxide in liquid sulphur dioxide. The ionization of **1** to cyclohexyloxocarbenium ions occurs only in the presence of excess sulphur trioxide. Both **1** and $C_6H_{11}CO^+$ are stable only in solution and at low temperature.

E. MONTONERI, L. GIUFFRÉ, M. CASSAGO, E. TEMPESTI et M. FORNAROLI. Can. J. Chem. **55**, 355 (1977).

Dans une solution équimolaire d'anhydride de l'acide cyclohexanecarboxylique et d'anhydride sulfurique dans l'anhydride sulfureux à l'état liquide, l'espèce principale est le sulfate du dicyclohexanecarbonyl (**1**). L'ionisation de **1** en ion cyclohexyloxocarbénium ne se produit qu'en présence d'un excès d'anhydride sulfurique. Les espèces **1** et $C_6H_{11}CO^+$ ne sont stables qu'en solution et à basse température.

[Traduit par le journal]

Introduction

From the few spectroscopic studies (1–3), which have been made on the interaction of carboxylic anhydrides with strong acids (Lewis and protonic acids), it appears that the employed acid determines the type of carbonyl intermediates formed and their behaviour.

In the presence of metal halides (1, 2), for instance, carboxylic anhydrides form donor–acceptor complexes via the C=O groups mainly (and also via the ethereal oxygen atoms) and no ionization is observed.

Olah *et al.* (3) have shown that, in the presence of HSO_3F—SbF_5, initial protonation of the anhydride is followed, in a large excess of 'magic acid', by ionization to acylium ions.

Other workers (4), however, investigated the behaviour of acetic anhydride toward some typical protonic acids and found that mixed anhydrides form. Of these species only $AcOSO_2CF_3$ was found to ioniz to Ac^+ in the presence of excess CF_3SO_3H. $AcOSO_3H$ (5, 6), however, can ionize as above, if in the presence of excess SO_3.

Although it may be concluded from the above studies that the strength of the excess protonic acid determines the ionization of mixed species, it is not clear if the formation of these last species may take place only after initial protonation of the carboxylic anhydride, and if their ionization may also be obtained in the presence of other aprotic acids.

In relation to these facts, we wish to report the behaviour of cyclohexanecarboxylic anhydride toward sulphur trioxide.

Results and Discussion

Cyclohexanecarboxylic anhydride and sulphur trioxide were mixed over a wide range of $SO_3/(C_6H_{11}CO)_2O$ mole ratios ($0.0 \leq n_S/n_A \leq 5.0$) in liquid SO_2 at -60 °C. The carboxylic anhydride molality always was 2.5. Of the spectroscopic techniques which were tried for studying the system, Raman spectroscopy could not be employed because of the high fluorescence exhibited by the carboxylic anhydride – SO_3 mixtures. Good quality ir and nmr spectra were obtained, however. The spectra recording temperature was -60 °C (ir) and between -78 and -20 °C (nmr). No substantial changes beyond band broadening were observed in the latter spectra on decreasing the temperature within the range reported above.

At ≤ -20 °C the system behaviour was found dependent only on the mole ratio and well consistent with reactions 1 and 2.

$$[1] \qquad (RCO)_2O + SO_3 \rightleftarrows (RCO_2)_2SO_2$$

$$[2] \qquad (RCO_2)_2SO_2 + SO_3 \rightleftarrows 2RCO^+ + S_2O_7^{2-}$$

However, above -20 °C significant changes occurred in the spectra, mainly because of sulphonation of the organic substrate. These

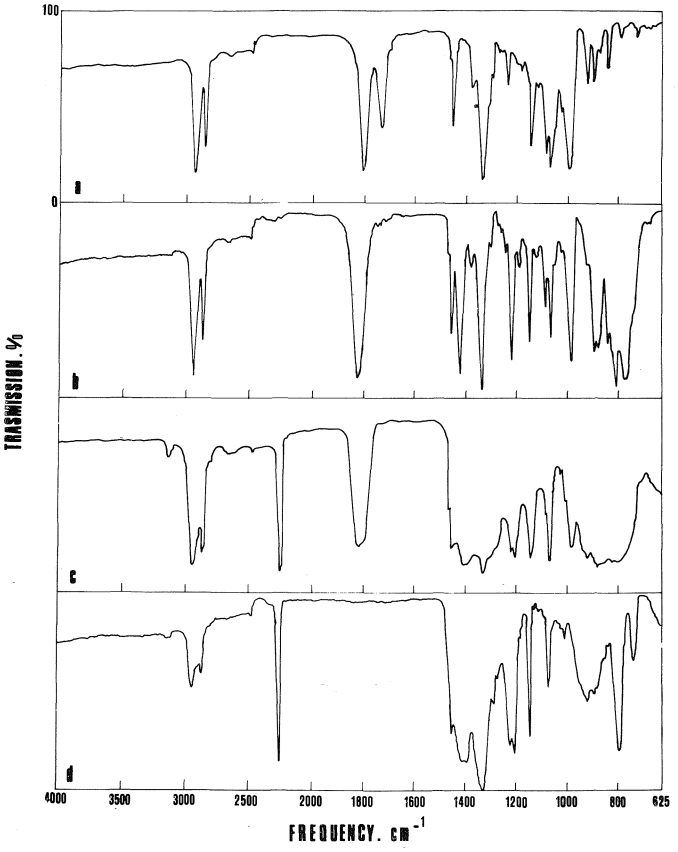

FIG. 1. Infrared spectra of cyclohexanecarboxylic anhydride – sulphur trioxide mixtures in liquid sulphur dioxide at −60 °C and at n_S/n_A = 0.0 (*a*), 1.0 (*b*), 3.0 (*c*), 5.0 (*d*).

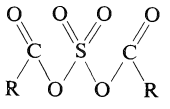
changes occurred also if SO_2 was evaporated under vacuum at lower temperature (−50 °C).

Formation and Characterization of Dicyclohexanecarbonylsulphate (1)

The ir spectrum of the cyclohexanecarboxylic anhydride and sulphur trioxide equimolar solution in liquid sulphur dioxide (Fig. 1*b*)



1

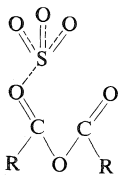
exhibits specific new bands compared to those of the carboxylic anhydride (Fig. 1*a*) and of free SO_3 (1390 and 1075 cm^{-1})[2] (*7*) in SO_2. Also in Fig. 1*b* the typical C=O stretching vibration bands of $(C_6H_{11}CO)_2O$ and S=O bands[3] of free SO_3 are absent; this implies that the equimolar addition of SO_3 to $(C_6H_{11}CO)_2O$ is rather quantitative and that at least one new species, which has characteristic absorption frequencies at 1826, 1422, 1220, 895, 882, 808, and 768 cm^{-1}, is prevalently formed.[4]

If this species is assumed to be a donor–acceptor complex, then on the basis of previous work (1, 2), a quite different spectrum from that reported in Fig. 1*b* should be expected. In fact for a donor–acceptor complex such as **2**, for instance, a couple of C=O bands should appear in the region 1700–1500 cm^{-1}. Assuming the ethereal oxygen as the favoured site for SO_3 addition, although not consistent with the reported studies, leads to an alternative structure

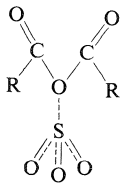
[2]The 1075 cm^{-1} band, although forbidden, is also observed by infrared spectroscopy (8).

[3]The 1060–1085 cm^{-1} bands in Fig. 1*b* are most likely due to C—O vibrations, as it is shown later.

[4]The other bands between 995 and 1455 cm^{-1} are common to both $(C_6H_{11}CO)_2O$ and the new species which is formed in the equimolar solution.



2



3

such as **3**. This complex may indeed absorb at $>1800\ cm^{-1}$ frequencies but, even in this case, two carbonyl bands should be observed. As to coordinated SO_3, both the S=O bands in each of the exemplified complexes **2** and **3** should fall at frequencies lower than 1390 and $1075\ cm^{-1}$ respectively. An attempt to identify these frequencies in Fig. 1*b* leads to a rather ambiguous interpretation of the spectrum.

Thus compound **1**, dicyclohexanecarbonylsulphate, whose formation may be visualized as in reaction 1, seems more convincing. The new bands, which appear in Fig. 1*b* ($\nu_{C=O}$ 1826; ν_{C-O} 995, 1060–1085; $\nu_{S=O}$ 1422, 1220; ν_{S-O} 895–768 cm^{-1}), have been assumed as the most characteristic ir absorption frequencies of **1**.

The carbonyl groups in the CO—OSO_2—OCO arrangement very likely are not planar, since no coupling of the C=O vibrations is observed (9). The frequency of the resulting single band is higher than the mean absorption frequency of the two C=O bands in pure $(C_6H_{11}CO)_2O$ as expected on the basis of the introduction of the electron-withdrawing SO_3 group in the CO—O—CO bridge (10). Furthermore the $1826\ cm^{-1}$ value is very close to the values reported for other carboxylic–sulphuric mixed anhydrides (4, 11).

Although C—O vibration bands are not generally as diagnostic as C=O bands, some consideration may be allowed in this case. The former bands of cyclohexanecarboxylic anhydride could be tentatively identified in the strong absorption[5] at 995 and 1060–1085 cm^{-1} (Fig. 1*a*). In Fig. 1*b* these bands are still present, but the $995\ cm^{-1}$ band relative to the 1060–1085 cm^{-1} doublet appears more intense than in Fig. 1*a*. This former band is also typical of other cyclic mixed carboxylic–sulphuric species (11*b*) and may be associated with the C—O vibration in the C—O—S bridge. From comparing Fig. 1 *a* and *b* it may therefore be concluded that the C—O bands of both $(C_6H_{11}CO)_2O$ and $(C_6H_{11}CO_2)_2SO_2$ have the same absorption frequencies, although slightly different relative intensities. This conclusion is further substantiated from the discussion of Fig. 1 *c* and *d* below.

The assignment of the 1422 and $1220\ cm^{-1}$ values respectively to the S=O asymmetric and symmetric stretching vibrations of **1** appears justified in view of the linear correlation between these vibration frequencies which has been found valid in a large number of sulphuryl compounds (12). Also the higher mean S=O frequency of **1** ($1321\ cm^{-1}$) compared to dimethylsulphate ($1290\ cm^{-1}$) (13) and dicyclohexylsulphone ($1221\ cm^{-1}$) (14) values reflects well the general dependence of S=O frequencies upon the electronegativity of substituents in $XYSO_2$ compounds (12). The S=O force constant (k = 10.96 dyn/cm), which may be obtained (13) from the 1422 and $1220\ cm^{-1}$ values in Fig. 1*b*, is more consistent with **1** than with **2** and **3**, where SO_3 bonds should lengthen (15) and the obtained k should be <9.50 dyn/cm (16).

Consistent with **1** and with the corresponding frequencies in covalent sulphates, the group

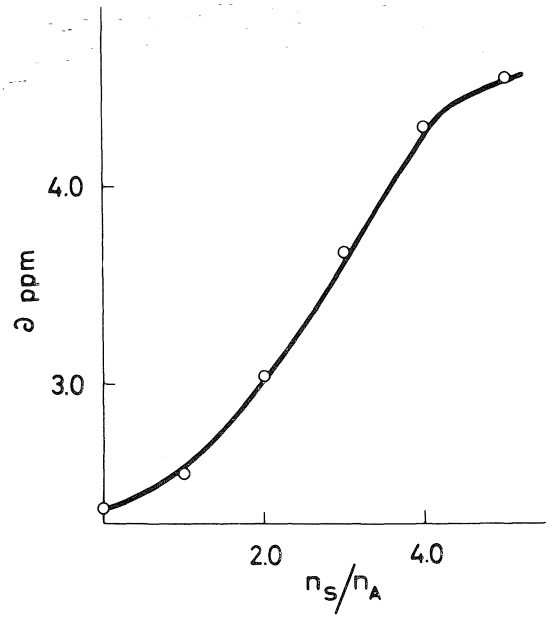


FIG. 2. The α-proton chemical shift (∂) *vs.* n_S/n_A at −20 °C for cyclohexanecarboxylic anhydride – sulphur trioxide mixtures in liquid sulphur dioxide.

[5]A similar spectra feature, although quite less intense, is in fact found for cyclohexanecarboxylic acid, but not for other carbonyl compounds such as cyclohexylamide, cyclohexanone, caprolactam, and dicyclohexylketone.

of bands at 895, 882, 808, and 768 cm^{-1} in Fig. 1*b* is to be clearly related to the S—O stretching vibrations, even considering probable interferences from CH vibrations (10).

In agreement with the infrared data the nmr spectrum of the equimolar solution may well represent that of pure dicyclohexanecarbonylsulphate in liquid SO_2. It was found that the proton chemical shifts in the system are strongly dependent on the mole ratio; in Fig. 2 the α-proton resonance chemical shift is 2.55 ppm (0.18 ppm higher than that of cyclohexanecarboxylic anhydride). The chemical shift is well in the range of values reported for other mixed carboxylic–sulphonic species (17) such as $C_6H_{11}CO_2SO_2X$ (with $X = CH_3$, C_6H_5, $CH_3C_6H_4$, $C_6H_{10}CO_2H$) and almost coincident with the last compound chemical shift (2.52 ppm). Furthermore the 0.18 ppm downfield shift displacement, which is observed in the formation of **1** from $(C_6H_{11}CO)_2O$ as in reaction 1, appears quite consistent with this type of interaction; a downfield chemical shift displacement of the same order of magnitude (0.13 ppm) is in fact reported in the formation of dimethyldisulphate from SO_3 and the corresponding monosulphate (18).

Ionization of Dicyclohexanecarbonylsulphate

The appearance of the known band of the cyclohexyloxocarbenium ion (2260 cm^{-1}) (19) at mole ratios >1.0 (Fig. 1 *c* and *d*) shows that, only in the presence of excess SO_3, **1** ionizes as in reaction 2. At 3.0 mole ratio both **1** and $C_6H_{11}CO^+$ bands are present (Fig. 1*c*), while at 5.0 mole ratio (Fig. 1*d*) only the latter band[6] is observed. This indicates that the ionization of **1** increases on increasing the SO_3 mole ratio and that, at *ca.* 5.0 mole ratio, reaction 2 may be assumed to lie well to the right. In analogy with the ionization of other carboxylic–sulphuric mixed species (6), the 1826 cm^{-1} band broadening which is observed at 3.0 mole ratio seems to imply participation of higher polysulphate mixed species (*e.g.* dicylohexanecarbonyldisulphate) in the formation of cyclohexyloxocarbenium ions. This participation, however, should not be relevant because, if so, a significant frequency shift (*ca.* 20 cm^{-1}) should be observed.

It may also be observed that the bands in the 995–1085 cm^{-1} range, which had been assigned in Fig. 1*a* to the C—O vibrations in the C—O—S bridge of **1**, undergo significant changes as the mole ratio increases above 1.0. These changes are also consistent with the displacement of reaction 2 to the right, which requires breaking of the C—O—S bridge. At 3.0 mole ratio (Fig. 1*c*), in fact, in place of the 1060–1085 cm^{-1} doublet, one band at 1070 cm^{-1} is observed. The intensity of this band is also slightly higher than that of the 995 cm^{-1} band. This may be due to the presence of free SO_3 (8) or to the SO_2 symmetric stretch of the $S_2O_7^{2-}$ ion in reaction 2. At 5.0 mole ratio (in concomitance with the absence of the C=O band of **1**) no absorption at 995 cm^{-1}, but only at 1070 cm^{-1}, is present.[7]

Specifically the other expected (21) absorption bands of $S_2O_7^{2-}$ ($\nu_{S=O\ asym}$ 1230 cm^{-1}; $\nu_{S-O\ asym}$ 795 cm^{-1}; $\nu_{S-O\ sym}$ 738 cm^{-1}) may be recognized in Fig. 1*c* and more evidently in Fig. 1*d*, since there is no interference from the SO frequencies of **1**. These assignments, however, cannot definitely justify the changes observed at >1.0 mole ratios within the regions 1450–1200 and 900–700 cm^{-1}, where the absorption frequencies of free SO_3, $S_3O_{10}^{2-}$, and higher polysulphuric species are also known to occur. Most of these species, as one of the referees pointed out, have rather similar vibrational spectra and further speculation at this point seems unjustified.

In agreement with the above conclusions the interpretation of nmr spectra in the mole ratio range >1.0 may be attempted. There is a strict parallelism between the appearance and intensity increase of the $C_6H_{11}CO^+$ ir band (Fig. 1 *c* and *d*) and the α-proton resonance chemical shift displacement to low fields with increasing SO_3 mole ratio (Fig. 2). The mole ratio dependent chemical shift at $n_S/n_A > 1.0$ is consistent with fast exchange[8] between the species involved in reaction 2. The shape of the curve in Fig. 2 is analogous to that reported

[6]Considering the nonideality of the system, no attempt was made to obtain molar absorptivities.

[7]The weak band at 1005 cm^{-1} may result from a CH vibration of $C_6H_{11}CO^+$; the same band, although more intense, occurs in the spectra of Ac^+ and has been identified as a rocking vibration band (20).

[8]An attempt to freeze out this equilibrium at lower temperatures proved unsuccessful, even at −78 °C. If, in fact, in the mole ratio range $1.0 < n_S/n_A < 5.0$, the exchange rate could have been slowed down sufficiently to observe the α-proton of $C_6H_{11}CO^+$ separately, then the ratio of this band area to the higher field proton bands areas sum should have been < 1/10.

for the formation and ionization of other carboxylic–sulphuric mixed species (5, 6). The slope increase at >1.0 mole ratio is largely accounted for by the formation of the highly deshielded species $C_6H_{11}CO^+$, as in reaction 2. It may also be inferred that this slope increase seems to exclude (as previously observed from ir spectra) a relevant participation of un-ionized organic polysulphuric mixed species in the ionization of **1**. On the basis of the nmr data relative to the formation of dimethylpolysulphate with varying dimethylsulphate/SO_3 mole ratios (18), it may be assumed that the α-proton in a hypothetical species such as dicyclohexanecarbonyldisulphate should not be greatly deshielded (≤ 0.18 ppm) relatively to the α-proton in **1**. Therefore the presence of significant concentrations of this last species should fairly flatten out the plot.

In correspondence with the curve maximum the nmr spectrum is virtually coincident with the spectra of other cyclohexyloxocarbenium salts (*e.g.* $C_6H_{11}CO^+SbF_6^-$) (19) and is a further confirmation that reaction 2 at 5.0 mole ratio lies well to the right.

Experimental

Cyclohexanecarboxylic anhydride (Snia Viscosa) was distilled twice immediately before use. Infrared and nmr spectra were recorded on Perkin-Elmer 157G and Varian NV 14 60 Mz spectrometers respectively. The nmr external reference solution (6% benzene in CS_2) and the sample were placed respectively in 513A-PP outer and sealed 516-1 inner tubes (Wilmad), which were equipped with a Teflon O-ring.

Two sets of runs were made respectively with and without tetramethylsilane (TMS) in the inner tube. TMS was found suitable for internal reference use up to 1.0 $SO_3/(C_6H_{11}CO)_2O$ mole ratio, although two small bands, at 0.47 and 3.28 ppm downfield from TMS, indicated some reaction of the internal standard with SO_3 in the 1.0 mole ratio solution. The TMS band was at 7.87 ppm upfield from the external reference. This value was used to obtain the reported chemical shifts (Fig. 2) from the internal standard even in the remaining mole ratio range, where TMS reacted completely and could not be observed in the spectra. This approximation should however suffice within the limits of our discussion as already evident in a previous work (6).

All other experimental details have been described previously (6).

σ-Aryl complexes of iridium: diphenyliodonium salts as phenylating agents in transition metal chemistry

NICHOLAS FARRELL AND DEREK SUTTON

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received June 10, 1976

NICHOLAS FARRELL and DEREK SUTTON. Can. J. Chem. **55**, 360 (1977).

Diphenyliodonium salts readily react with $[IrX(CO)(PR_3)_2]$ (X = Cl, Br; PR_3 = PPh_3 or $PMePh_2$) to yield iridium(III) σ-phenyl complexes of general composition $[IrXY(C_6H_5)(CO)(PR_3)_2]$ (Y = Cl, BF_4). The possible structures of these compounds, and their occurrence in the decomposition of iridium aryldiazenato complexes, are discussed.

NICHOLAS FARRELL et DEREK SUTTON. Can. J. Chem. **55**, 360 (1977).

Les sels de diphényliodonium réagissent facilement avec $[IrX(CO)(PR_3)_2]$ (X = Cl, Br; PR_3 = PPh_3 ou $PMePh_2$) pour conduire à des complexes σ-phényle d'iridium(III) ayant des compositions générales $[IrXY(C_6H_5)(CO)(PR_3)_2]$ (Y = Cl, BF_4). On discute des structures possibles pour ces composés et de leur présence dans la décomposition des complexes aryldiazénato d'iridium.

[Traduit par le journal]

Introduction

Extrusion of dinitrogen from aryldiazenato (aryldiazo) complexes of transition metals to form σ-aryl derivatives has frequently been reported. Thus, both $[PtCl(N_2C_6H_4p\text{-}F)(PEt_3)_2]$ (1) and $[Pt(N_2C_6H_4p\text{-}$ or $m\text{-}F)(PEt_3)_3]$ (2) have been shown to eliminate dinitrogen and the corresponding aryl complexes have been isolated. Similarly, Robinson and co-workers (3) have cited dinitrogen extrusion as a mode of decomposition for the rhodium(III) species $[RhCl_2(N_2Ar)(PPh_3)_2]$ and in numerous instances aryldiazonium salts have been used by Nesmeyanov's group as precursors for the preparation of metal–aryl complexes (4), two recent examples being the syntheses of $[Fe(\sigma\text{-}C_6H_5)(\eta\text{-}C_5H_5)(CO)_2]$ and $[W(\sigma\text{-}C_6H_5)(\eta\text{-}C_5H_5)(CO)_3]$ (5, 6).

During our investigation of aryldiazenato complexes of iridium(III) (7) several attempts to prepare $[IrCl_2(N_2Ar)(CO)(PPh_3)_2]$ and $[IrCl(N_2Ar)(CO)(PPh_3)_2]BF_4$ (8) gave products with significantly low nitrogen content, which we believed were mixtures of the desired complexes and the σ-aryl analogues resulting from dinitrogen extrusion. In view of this, we considered various ways in which these σ-aryl complexes might be synthesized directly, for comparison.

A literature survey revealed that a few examples of the desired complexes $[IrCl_2(Ar)(CO)(PR_3)_2]$ had been synthesized previously, also by extrusion reactions. Collman and Roper (9) and subsequent investigators (10–12) employed thermal desulfonation of aryl sulfinato complexes to obtain iridium(III) aryl complexes. Deeming and Shaw (13) employed thermal decarbonylation of the related benzoyl complex. We were interested to see whether iridium(III) σ-aryl complexes might be synthesized by direct methods. One possibility is oxidation of an iridium(I) σ-aryl complex. The iridium(I)–aryl complexes $[IrAr(CO)(PPh_3)_2]$ are usually prepared by metathesis of $[IrCl(CO)(PPh_3)_2]$ and the aryl–lithium, silver or Grignard reagent. Thus complexes for Ar = C_6H_5, C_6Cl_5, C_6F_5 have been reported by Rausch and Moser (14), Ar = C_6H_5, C_6Cl_5, C_6F_5, $p\text{-}C_6H_4NMe_2$, *p*-tolyl, and mesityl by Dahlenburg and Nast (15), Ar = C_6F_5 by Bruce and co-workers (16), and Ar = C_6H_5 by Wilkinson and co-workers (17). These complexes are generally much less reactive towards oxidative-addition than the parent Vaska's complex and products from HX and X_2 (X = halogen) addition have been reported for only the perhalophenyl complexes (14, 16).

We considered the possibility of oxidative-addition of phenyl ions to iridium(I) complexes such as $[IrX(CO)(PR_3)_2]$ in preference to attempted oxidation of the above iridium(I)–phenyl complexes. The oxidative-addition of alkyl halides to Vaska's complex and its analogues with $PMePh_2$ and PMe_2Ph is now well documented (18, 19) but aryl halides are much less reactive and no products from simple addition of ArX appear to have been found. However,

TABLE 1. Analytical and spectral data for σ-phenyl complexes of iridium(III)

	Complex	Melting point (°C)	ν(CO) (cm^{-1})	ν(Ir—Cl) (cm^{-1})	Analysis C Found	C Calcd	H Found	H Calcd

in view of the widespread use of diphenyliodonium salts as phenylating agents in organic chemistry (20) these appeared to offer considerable potential as phenylating agents for transition metal complexes.

Results and Discussion

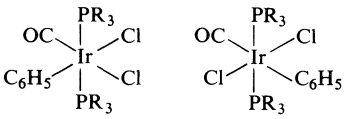
The diphenyliodonium salts used were $Ph_2I^+Cl^-$ and $Ph_2I^+BF_4^-$. Both are air-stable white solids, soluble in methanol and reasonably soluble in acetone. Their reactions with $[IrX(CO)(PR_3)_2]$ (X = Cl, Br, PR_3 = PPh_3, $PMePh_2$) proved to be a fast, clean, and convenient route to the required Ir(III)–phenyl complexes. The compounds prepared are listed in Table 1 with spectroscopic and analytical data. All complexes are air-stable, white solids. Those with PPh_3 are only very sparingly soluble in organic solvents, while those with $PMePh_2$ are soluble in chloroform, methanol, and acetone but insoluble in ether and hexane. Compound **2** is also soluble in benzene. The stability contrasts with that of $[Ir(\sigma\text{-}C_6H_5)(CO)(PPh_3)_2]$ which can only be handled in air for short periods (14, 15).

The properties reported here for $[IrCl_2(Ph)(CO)(PPh_3)_2]$ and for $[IrCl_2(Ph)(CO)(PMePh_2)_2]$ may be compared with those reported for the former compound (10) (but synthesised by carbon monoxide displacement of SO_2 from $[IrCl_2(Ph)(SO_2)(PPh_3)_2]$) and the properties of $[IrCl_2(Ph)(CO)(PMe_2Ph)_2]$ synthesised by decarbonylation of the benzoyl complex (13). Kubota and Loeffler (10) assigned structure **B** to $[IrCl_2(Ph)(CO)(PPh_3)_2]$ since only a single ν(Ir—Cl) band was observed, at 319 cm^{-1}, assigned as indicating Cl—Ir—Cl. By contrast $[IrCl_2(Ph)(CO)(PMe_2Ph)_2]$ was assigned structure **A**, since in addition to a band at 315 cm^{-1} (assigned as Cl—Ir—CO) others at 271, 251 cm^{-1} could be assigned as Cl—Ir—Ph. The situation is confused when the compounds $[IrCl_2(C_6F_5)(CO)(PPh_3)_2]$ and $[IrCl_2(C_6F_5)(CO)(PMePh_2)_2]$ are examined. The former has ν(Ir—Cl) at 320 and 290 cm^{-1} and was assigned structure **A**, whilst the latter has only ν(Ir—Cl) at 328 cm^{-1} and was assigned structure **B** (16).

For $[IrCl_2(Ph)(CO)(PPh_3)_2]$ (**1**) we observe ν(Ir—Cl) at 320 cm^{-1} in agreement with Kubota and Loeffler (10), and also a band at 255 cm^{-1}. A value of 320 cm^{-1} is borderline between typical Cl—Ir—Cl and Cl—Ir—CO values (21), but the 255 cm^{-1} band may readily be assigned to Cl—Ir—Ph in view of the *trans*-influencing nature of σ-bonded aryls. Thus we feel our compound to have structure **A**, but cannot neglect the possibility that it is contaminated with isomer **B** (assuming, as is probable, that the phosphines are mutually *trans*). Our value of ν(CO) is some 10 cm^{-1} higher than Kubota and Loeffler's and the band is not symmetric. It is known that the addition of MeX (X = Br, I) to $[IrCl(CO)(PMe_2Ph)_2]$ is solvent dependent and a mixture of isomers is obtained when methanol replaces benzene as solvent (13). The ν(Ir—Cl) values for $[IrCl_2(Ph)(CO)(PMePh_2)_2]$ show a reasonable correspondence with those reported for $[IrCl_2(Ph)(CO)(PMe_2Ph)_2]$ by Deeming and Shaw (13) and we assign our bands as 330 cm^{-1} (Cl—Ir—CO) and 274, 255 cm^{-1} (Cl—Ir—Ph) likewise in favour of structure **A**. Here again, however the high value of the upper band allows its assignment also to Cl—Ir—Cl in structure **B**, and we suspect that both isomers may again indeed be present. The *trans* disposition of the phosphine ligands in **2** is supported by the apparent 1:2:1 triplet ($|^2J_{PH} + {}^4J_{PH}| = 13$ Hz) for the methyl resonance in the ^1H nmr spectrum.

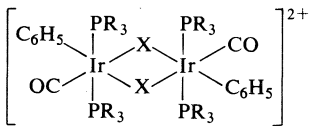
The ir spectra of compounds **3** to **5** exhibit typical broad ν(BF_4) absorptions at *ca.* 1100 cm^{-1}. Compounds **3** and **4** exhibit multiple

ν(Ir—Cl) absorptions in the 250–350 cm^{-1} region (absent in the bromo complex **5**) which are remarkably similar to those of **1** and **2**. This argues against a discrete monomeric pentacoordinate cation being present, and the spectra may be indicative of a chlorine-bridged cation such as structure **C**, not unlike the structure of $[IrCl_2(Me)(CO)_2]_2$ (22). We have not been able to obtain supportive evidence for this structure due to the limited solubility of these tetrafluoroborates and the likelihood of disruption of any halogen bridge bonds in more highly donor solvents



A

B



C

The formation of σ-aryl complexes as a source of impurity in the reactions of $[IrCl(CO)(PPh_3)_2]$ with benzenediazonium salts (7) was confirmed by deliberately conducting these reactions under reflux conditions so as to promote dinitrogen extrusion from the initially formed phenyldiazenato complexes. For example, $PhN_2^+BF_4^-$ reacted to give an initial orange solution of the phenyldiazenato complex $\{[IrCl(PhN_2)(CO)(PPh_3)_2]BF_4\}_n$ (7) which gradually lost its colour and precipitated the σ-phenyl complex as a white solid, identified by comparison of its composition, infrared spectrum and melting point with those of **3**.

Experimental

All solvents were dried by usual methods and distilled under nitrogen. The iridium starting materials were prepared by standard literature methods (23, 24). Diphenyliodonium chloride was purchased from Aldrich Chemical Company Inc. and used without further purification. Diphenyliodonium tetrafluoroborate was prepared by metathesis with $AgBF_4$ and recrystallised from methanol–ether. Infrared spectra were recorded on Perkin–Elmer 457 and Beckman IR-12 instruments for samples pressed in KBr discs or as Nujol mulls between polythene windows. Proton nmr spectra were recorded using Varian A60 and HA100 instruments. All τ values are relative to internal TMS. Melting points were recorded on a Fisher-Johns apparatus and are uncorrected. Elemental analyses were carried out by Mr. M. K. Yang of the Simon Fraser University microanalytical laboratory.

Preparation of Iridium(III)–Phenyl Complexes

In a typical synthesis a 10% excess of the salt in methanol was added to a refluxing solution of the iridium(I) complex in benzene under nitrogen. The reaction was considered complete at the disappearance of the yellow colour of $[IrX(CO)(PR_3)_2]$. As expected the more basic diphenylmethylphosphine complexes reacted faster than the triphenylphosphine ones.

Thus, to prepare $[IrCl(Ph)(CO)(PPh_3)_2]BF_4$, a solution of $Ph_2I^+BF_4^-$ (0.06 g) in MeOH (5 ml) was added to a refluxing solution of $[IrCl(CO)(PPh_3)_2]$ (0.1 g) in benzene (10 ml). Reflux was continued for 2.5 h during which time a white solid precipitated from the reaction mixture. The mixture was then evaporated to half-volume, cooled to 8° and the product filtered off, washed with benzene and ether, and dried *in vacuo*. Analytical data are given in Table 1. Complexes **1** and **5** were prepared in a similar manner, in 55–60% yield. Complexes **2** and **4** were precipitated by addition of ether to a cooled solution of the reaction mixture after 1.5 h (by which time only a very pale yellow solution was observed) and then recrystallized from acetone–hexane. ^1H nmr for **2** (τ): 2.25 m 5H (C_6H_5); 2.75 m 20H ($P—C_6H_5$); 7.86 t 6H ($P—CH_3$).

Reaction of [IrCl(CO)(PPh$_3$)$_2$] with Benzenediazonium Tetrafluoroborate

To a refluxing solution of $[IrCl(CO)(PPh_3)_2]$ (0.1 g) in benzene (10 ml) was added $PhN_2^+BF_4^-$ (0.025 g) in acetone (5 ml). Immediately a bright orange solution was obtained which, upon continued reflux, steadily became paler in colour. After 2.5 h the pale yellow solution was evaporated to half-volume and ether added. Upon cooling at 8° a white solid precipitated. This was filtered off and was shown to be $[IrCl(Ph)(CO)(PPh_3)_2]BF_4$ by comparison of mp, ir spectrum, and analysis with that of an authentic sample. Found: C 54.1, H 3.62; calcd. C 54.7, H 3.74.

The stereochemistry of addition of cyclopropanes to tetrachloro(diethylene)platinum(II)

N. DOMINELLI AND A. C. OEHLSCHLAGER

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received July 2, 1976

N. DOMINELLI and A. C. OEHLSCHLAGER. Can. J. Chem. **55**, 364 (1977).

The synthesis of *trans*-1-*n*-hexyl-*cis*-2,3-dideuterio cyclopropane and *cis*-1-*n*-hexyl-*cis*-2,3-dideuterio cyclopropane are reported. These specifically deuterated cyclopropanes were reacted with tetrachloro(diethylene)diplatinum to yield the product (dichloro(2-*n*-hexylpropane-1,3-diyl)platinum) of addition of Pt^{II} across the cyclopropyl C_2C_3 bond. It was shown by nmr spectroscopic analysis of the deuterated cyclopropanes and the bispyridine derivatives of the adducts that the Pt^{II}–cyclopropane reaction was stereospecific and involved retention of configuration at both reacting carbons. This outcome is interpreted in terms of a concerted cycloaddition mechanism.

N. DOMINELLI et A. C. OEHLSCHLAGER. Can. J. Chem. **55**, 364 (1977).

On rapporte la synthèse du *n*-hexyl-1 *trans* dideutério-2,3 *cis* cyclopropane et du *n*-hexyl-1 *cis* dideutério-2,3 *cis* cyclopropane. On a fait réagir ces molécules de cyclopropanes deutérés d'une façon spécifique avec le tétrachloro(diéthylène)diplatine et l'on obtient le produit (dichloro(*n*-hexyl-2 propanediyl-1,3)platine) provenant de l'addition de Pt^{II} à travers le lien C_2C_3 du cyclopropane. On montre, par des données spectroscopiques rmn des cyclopropanes deutérés et des dérivés bispyridine des adduits, que la réaction du platine avec le cyclopropane est stéréospécifique et implique une rétention de configuration aux niveaux des deux atomes de carbone qui réagissent. On interprète le résultat en terme d'un mécanisme concerté de cycloaddition.

[Traduit par le journal]

Introduction

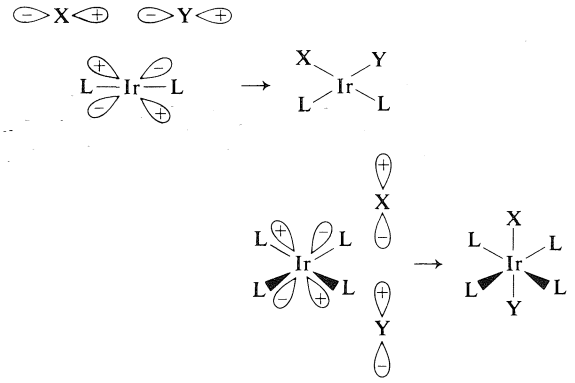
Many coordinatively unsaturated transition metal complexes with d^7, d^8, or d^{10} electron configurations undergo oxidative addition reactions by insertion of the metal into an X—Y substrate single bond. Owing to the stability of many square planar d^8 complexes of Ir^I, Rh^I, and Pt^{II}, a considerable amount of research has been directed at these complexes (1–4).

The mechanism for oxidative addition reactions is currently under dispute, undoubtedly due to the broad classification of such reactions. Pearson and Muir (5) have proposed a one step concerted mechanism, based on orbital symmetry arguments for the reaction of Ir(CO)-ZL_2 (Z = Cl, I, SCN; L = PPh_3, PPh_2Me) in dichloroethane with CH_3I which explains the occurrence of both *cis* and *trans* addition products.

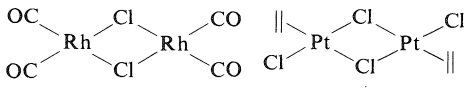
Evidence for operation of an S_N2 mechanism during oxidative additions of d^8 complexes to alkyl halides has been reported for Rh^I (6), Ir^I (7), and Pd^0 (8, 9) complexes.

Reactions involving insertion of two dimeric d^8 complexes of Rh^I (**1**) and Pt^{II} (**2**) into C—C single bonds have received extensive attention.

A variety of strained hydrocarbons including



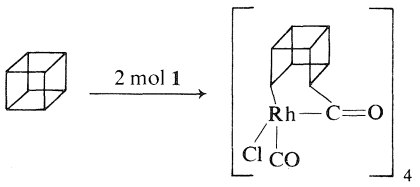
cyclopropanes (10–12), quadracyclane (13), and cubane (14) have been found to react with **1** to



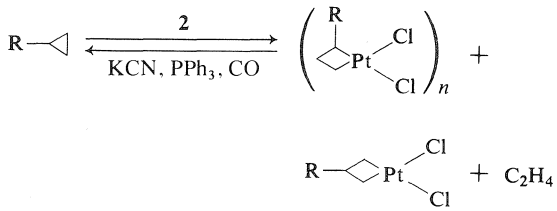
1 **2**

give products in which a rhodium acyl moiety is inserted into a strained C—C bond.

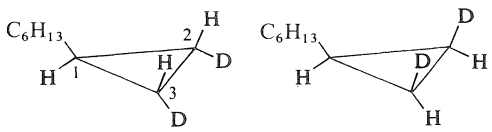
Insertion of the Pt^{II} complex **2** into substituted cyclopropanes has been investigated by several groups (15–23). In this case the reaction led to the formation of polymeric (16) cyclobutyl platinum adducts which reverted to the parent



cyclopropanes upon treatment with KCN, triphenylphospine, or carbon monoxide (21–23).



The present investigation was undertaken to determine the stereochemistry of the addition of **2** to the strained C—C bonds of substituted cyclopropanes. Knowledge of the stereochemistry of this addition process is crucial to the understanding of the mechanism of this and related oxidative addition reactions. Our choice of substrates for study was guided by the reports of McQuillin and co-workers (21–23) that **2** reacted with monoalkyl substituted cyclopropanes primarily at the least substituted C—C bond. This observation coupled with their reports (23) of differential shielding of hydrogens *cis* and *trans* to the alkyl substituent both in the parent cyclopropanes and derived metallocyclobutane adducts led us to investigate the reaction of **3** and **4** with **2**.



3 **4**

A priori, there are three stereochemical courses which could be observed during addition of Pt^{II} complex, **2**, to the C_2—C_3 bond of a cyclopropane. These are (Fig. 1): (*a*) retention of configuration (R,R) at both carbon centres (C_2 and C_3), (*b*) inversion of configuration (I,I) at both carbon centres (C_2 and C_3), and (*c*) retention of configuration at one carbon centre, and inversion at the other (R,I).

It was anticipated that the distinction between these three possibilities would be evident upon examination of the chemical shifts (23) and vicinal coupling (24, 25) of H_2 and H_3 in **3** and **4** and their Pt^{II} adducts.

Results and Discussion

Our initial efforts were directed at stereospecific syntheses of **3** and **4** and their protio analog *n*-hexylcyclopropane (**5**). Synthesis of **5** was carried out according to the procedure of Simmons and Smith (26). The synthesis of **3** (Fig. 2) proceeded from reaction of a mixture of *cis*- and *trans*-1-chloro-oct-1-enes (27, 28) with dichlorocarbene in the presence of a phase transfer agent (cetyltrimethylammonium bromide (29)). The mixture of hexyltrichlorocyclopropanes thus generated was reduced to the dichloro stage by reaction with tri-*n*-butyltin hydride (30, 31). Deuterium was placed in the molecule stereospecifically *trans* to the hexyl substituent by reduction of the dichlorocyclopropane isomers generated above with sodium in methanol-OD. This reduction is known to yield products in which deuterium is placed in the least hindered position at each chlorine containing carbon (32). In the present case analysis of the hexyldideuteriocyclopropane (**3**) by mass spectroscopy revealed 92% D_2 and 8% D_1. Analysis by nmr revealed the dideuterio species **3** was contaminated with **4** or the isomer in which the deuteriums were *trans* to one another to the extent of 9%. That is, the total contamination due to C_2, C_3 diprotio, and D_2 containing isomers with proton substitution *trans* to the hexyl group was 17% by nmr analysis.

The synthesis of **4** (Fig. 3) proceeded from 1-deuterio-1-chloro-oct-1-ene. This olefin was prepared by reaction of disiamylborane with 1-chlorooct-1-yne (33) followed by hydrolysis of the vinyl borane in acetic acid-OD (34). The deuterated chlorooctene thus produced was reacted with dichlorocarbene as above and the hexyltrichloro cyclopropanes produced were reduced to the dichloro stage by reaction with tri-*n*-butyltin deuteride (30, 31). This sequence placed one deuterium at each of the chlorinated carbons (C_2 and C_3). Reduction of the dichlorodideuterio cyclopropanes with sodium in methanol (32) gave predominantly **4**. Mass spectroscopic analysis revealed that **4** produced by this sequence was 73% D_2 and 27% D_1. Since nuclear magnetic resonance analysis revealed 28% contamination of **4** by isomers containing

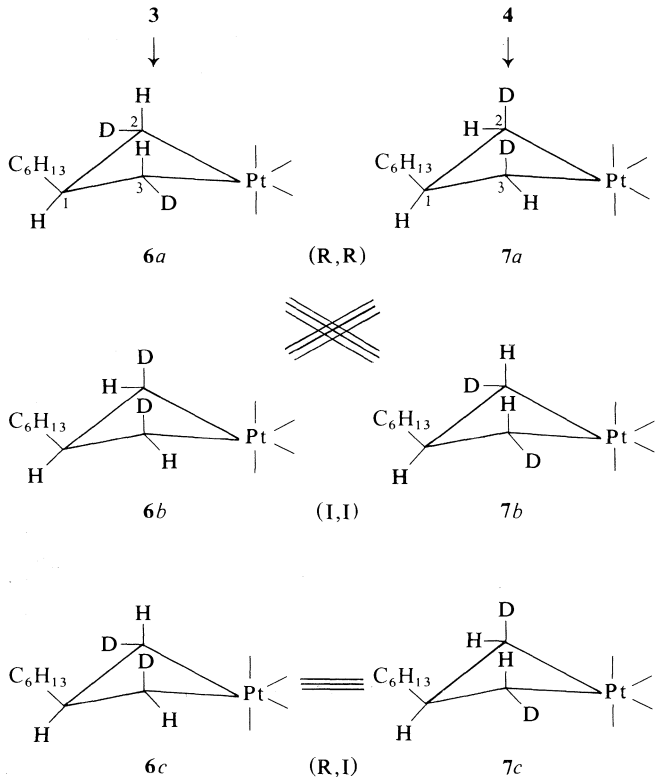


FIG. 1. Possible stereochemical courses of reaction of Pt^{II} complex **2** with deuterated cyclopropanes **3** and **4**.

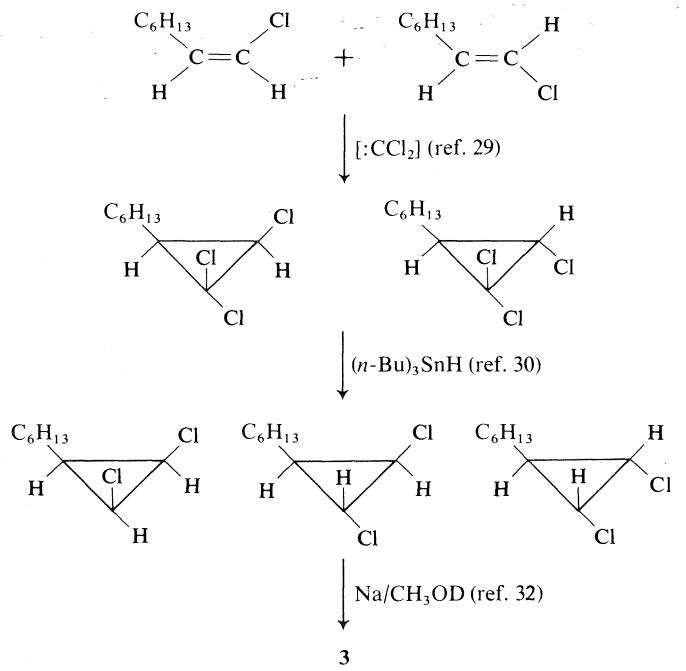

FIG. 2. Synthesis of *trans-n*-hexyl-*cis*-2,3-dideuteriocyclopropane (**3**).

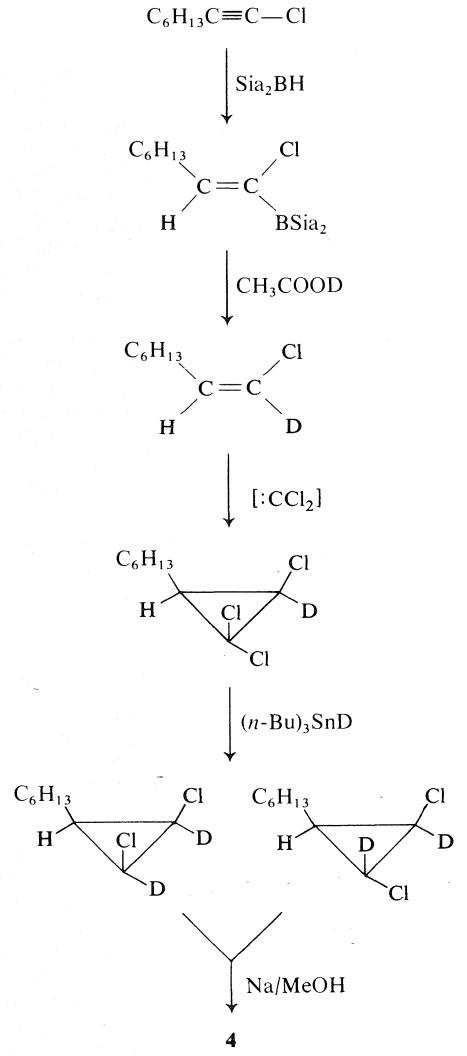

FIG. 3. Synthesis of *cis*-*n*-hexyl-*cis*-2,3-dideuteriocyclopropane **4**.

proton at C_2 and C_3 *cis* to the hexyl group one may deduce that within experimental limits of detection **4** was contaminated only with the monodeuterio species.

Each of **3**, **4**, and **5** were reacted with the Pt^{II} complex, **2**, under the conditions used by Powell and McQuillin (23). The insoluble yellow adducts thus formed were reacted with pyridine to give the corresponding bispyridine adducts (23). These adducts were then analyzed by 220 MHz nmr to determine the stereochemistry of the insertion reaction.

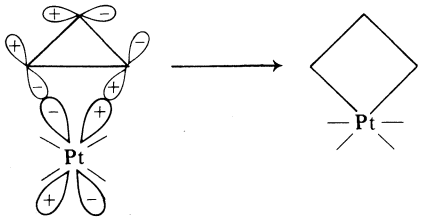
The ^1H nmr spectra of **3**, **4**, and **5** (220 MHz, C_6D_6, internal TMS) revealed the presence of broad multiplets at δ 1.20 assigned to the *n*-hexyl methylene hydrogens, a quartet at δ 1.08 (J = 7 Hz) assigned to the CH_2 group α to the ring, a methyl group appearing as a triplet at δ 0.83 (J = 6.7 Hz), and a one hydrogen multiplet at δ 0.50 attributable to H_1. The ^1H nmr spectrum of **5** revealed the C_2 and C_3 hydrogens *cis* to the hexyl group as a multiplet centered at 0.1 and the hydrogens *trans* to the hexyl group as a multiplet centered at δ 0.27. In the spectrum of **3** the signal due to the *cis*-2,3-hydrogens appears as a doublet ($J_{1,2(3)}$ = 5 Hz) and that due to the *trans*-2,3-hydrogens as a reduced size multiplet (17% of *cis*). The nmr spectrum of **4** revealed the signal of the *cis*-2,3-hydrogens to be 28% that of the *trans*-2,3-hydrogens which gave a doublet signal ($J_{1,2(3)}$ = 8 Hz).

The $PtCl_2(Py)_2$ adducts of **3**–**5** (220 MHz, C_6D_6 external TMS) revealed common ^1H nmr signals due to co-ordinated pyridine (δ 6.5–8.9) and the *n*-hexyl groups (CH_3, δ 0.80; $(CH_2)_4$, δ 1.25; CH_2-ring, δ 1.75). The nmr spectrum of **8**, the adduct of **5**, exhibited a multiplet signal at δ 3.39 assigned to H_1. The ring methylene hydrogen signals appear as quartets at δ 2.95 (*cis*-2,3-H) and δ 3.22 (*trans*-2,3-H) with ^{195}Pt quartet satellites. The couplings of the *cis*-2,3-hydrogens with H_1 was observed to be 9.0 Hz and coupling with ^{195}Pt 86 Hz. Coupling of the *trans*-2,3-hydrogens with H_1 was 7.5 Hz and with ^{195}Pt it was 82 Hz. The above assignments are consistent with the shielding and couplings observed in other three (24) and four (25) membered rings and previously reported for **8** (23).

Examination of the nmr spectrum of the $PtCl_2(Py)_2$ adduct **6** derived from **3** revealed the signals due to the *cis*-2,3-hydrogens as a doublet ($J_{1,2(3)}$ = 9.0 Hz) at δ 2.94 with ^{195}Pt satellites. A signal (δ 3.2) due to *trans*-2,3-hydrogens was unchanged from intensity compared to **3**. This observation unequivocally defines the structure of the adduct of **3** as **6***a*. Similarly the nmr spectrum of the adduct **7** derived from **4** revealed a doublet ($J_{1,2(3)}$ = 7.5 Hz) signal at δ 3.2 with ^{195}Pt satellites due to the *trans*-2,3-hydrogens. Contamination by isomers containing *cis*-2,3-hydrogens was unchanged (28%) from that noted in **4**. These observations define the structure of the adduct of **4** as **7***a*.

Within the limits of detection of our nmr method the addition of Pt^{II} complex **2** adds to cyclopropanes **3** and **4** stereospecifically with retention of configuration at both carbons.

The relatively high degree of stereospecificity noted in the reaction studied coupled with the nonpolar conditions of reaction lead us to the conclusion that the reaction involves a concerted cycloaddition as suggested by Pearson and Muir (5) for oxidative additions of Ir^I to alkyl halides. In the present case the process may be rationalized as involving interaction of the lowest Walsh (35, 36) orbital of the cyclopropane with a vacant orbital on platinum (37). Such a view is consistent with the increase in reactivity of cyclopropanes with **2** upon substitution of the former with electron donating groups (23).



Experimental

Mass spectra were obtained on a Hitachi – Perkin-Elmer RMU-6E double focusing mass spectrometer using an ionization voltage of 80 eV. Nuclear magnetic resonance spectra were obtained on Varian A56/60 and XL100 spectrometers using $CDCl_3$ as solvent and TMS as internal standard (δ 0) unless otherwise stated. Melting point determinations were carried out using a Fisher-Johns melting point apparatus and are uncorrected. Gas–liquid chromatographic analyses were done using a 6 ft × $\frac{1}{8}$ in. stainless steel column packed with 20% SE-30 on Chromosorb G (100/120 mesh) unless otherwise specified.

Synthesis of trans-1-n-Hexyl-cis-2,3-dideuteriocyclopropane, 3

Preparation of cis- and trans-1-Chlorooct-1-ene (28)

A solution of 34.7 g (100 mmol) of (chloromethyl)triphenylphosphonium chloride (27) in 50 ml of dry glyme was prepared and cooled in a dry ice – acetone bath while 60 ml of 2 *M* butyllithium in hexane was added dropwise with stirring over a period of 1 h. The reaction mixture became red and copious quantities of white precipitate formed. While maintaining the reaction mixture at −50 °C, heptanal, (14.9 g, 0.12 *M*), was added. The mixture was allowed to warm to room temperature, then was refluxed for 16 h. The reaction mixture was filtered, the solvent removed *in vacuo*, and the residue distilled under reduced pressure to yield 30–35% of *cis,trans*-1-chlorooct-1-ene: bp 43–67 °C (2.5 mm Hg); glpc analysis showed two major components, nmr (of mixture) δ ($CDCl_3$) 0.9 (3H, t, CH_3, J = 5 Hz), 1.3 (8H, b, $(CH_2)_4$—), 2.1 (2H, m, CH_2—C=C), and 5.9 (2H, m, ); ms (calcd. for $C_8H_{15}Cl$, M^+ 146): 146 (M^+, 18%), 148 (M^+ + 2, 5.7%), M^+/M^+ + 2 = 100/32), 43 (M^+ − $(CH_2)_3CH$=CHCl, 100%).

Preparation of 1,1,2-Trichloro-3-n-hexylcyclopropane (29)

A solution of 1-chlorooct-1-ene (7.5 g) and cetyltrimethylammonium bromide (0.2 g) in 18 g of chloroform was prepared, then heated under an N_2 blanket to 50 °C. A solution of 17 g of NaOH in 17 ml H_2O was added dropwise over a period of 15 min. The reaction progress was monitored by removing samples from the organic layer and analysis by glpc (170 °C). The reaction was allowed to proceed until no further decrease in 1-chlorooct-1-ene was observed after addition of base.

The reaction mixture was diluted with 100 ml H_2O, acidified with 10% H_2SO_4, and extracted with ethyl ether (3 × 100 ml). The solution was dried over anhydrous $MgSO_4$, and solvent removed *in vacuo*, and the residue distilled under reduced pressure to give a 67% yield of 1,1,2-trichloro-3-*n*-hexylcyclopropane; bp 95–96 °C (0.5 mm Hg); nmr δ ($CDCl_3$) 0.9 (3H, t, J = 4.5 Hz, CH_3, 1.5 (11H, b, —(CH_2)—$_n$), 3.1 (0.5H, b, *cis*-), 3.6 (0.5 H, d, J = 8.5 Hz, *trans*-); ms (15 eV, calcd. for $C_9H_{15}Cl_3$, M^+, 228): 193 (M^+ − Cl, 10%), 157 (M^+ − 2Cl, 68%), 122 (100%).

Preparation of 1,2-Dichloro-3-n-hexylcyclopropane

Reduction 1,1,2-trichloro-3-*n*-hexylcyclopropane was accomplished by the use of tri-*n*-butyltin hydride (30, 38) according to the method of Seyferth *et al.* (31). To 1,1,2-trichloro-3-*n*-hexylcyclopropane (4.0 g, 0.02 mol) neat was added tri-*n*-butyltin hydride (5.82 g, 0.02 mol). The reaction was maintained at 115 °C and monitored by glpc (180 °C) by following the disappearance of the starting compound. Gas–liquid phase chromatographic analysis after reaction for 0.5 h revealed the appearance of three new peaks of shorter retention times than the starting trichlorocyclopropane which were attributed to the three possible products of a single reductive process. The reaction was allowed to proceed until the starting material was exhausted (*ca.* 3.5 h). The mixture was distilled at 0.1 mm Hg, collecting fractions of boiling ranges from 65–80 °C. The overall yield of distillate was 80%; nmr δ ($CDCl_3$) 1.0 (3H, t, J = 4.5 Hz, CH_3), 1.4 (11H, broad, d, J = 8 Hz, CH_2) 2.9, 3.2 (2H, m, *cis,trans*,1,2-*H*).

Reduction of 1,2-Dichloro-3-n-hexylcyclopropane to give trans-1-n-Hexyl-cis-2,3-dideuteriocyclopropane

The reaction was carried out according to Willcott and Cargle (32) with minor modification. In a typical reaction, 1,2-dichloro-3-*n*-hexylcyclopropane (2.5 g) in 15 ml of methanol-OD and deuterium oxide (1%) were mixed under nitrogen. Clean pieces (~100 mg each) of sodium were added to the mixture and allowed to react under a positive N_2 atmosphere. The progress of the reaction was followed by glpc (180 °C) and allowed to proceed until the starting material was exhausted or no further consumption of starting material was observed upon further addition of sodium.

The mixture was diluted with water, extracted with hexane, dried over anhydrous $MgSO_4$, and distilled at

atmospheric pressure. Fractions distilling in the range 120–150 °C were collected and pooled giving an overall yield of *trans*-1-*n*-hexyl-*cis*-2,3-dideuteriocyclopropane (**3**) of 30%. Gas–liquid phase chromatographic analysis of the fraction with bp 145–150 °C showed one component with the same retention time as *n*-hexylcyclopropane: ms calcd. for $C_8H_{16}D_2$, M^+, 128; found: M^+, 128; D_0, 0%; D_1, 8%; D_2, 92%.

*Synthesis of cis-1-n-Hexyl-(cis-2,3-dideuteriocyclopropane), **4***

Preparation of cis-1-Chloro-1-deuteriooct-1-ene

The method of preparation of chlorodeuteriooctene was adopted from Brown and Zweifel (34). A solution, under argon, containing sodium borohydride (1.9 g) in 25 ml of dry diglyme and 2-methyl-but-2-ene (9.5 g) was cooled to 0 °C, flushed with argon, and freshly distilled boron trifluoride-etherate (9.2 g) in 10 ml of diglyme was added dropwise while maintaining a temperature below 10 °C. Stirring (0–5 °C) was continued for 2 h. After this time 1-chlorooct-1-yne (33) (7.25 g) was added (at 5–10 °C) and the reaction mixture was stirred for 0.5 h at 0–5 °C, then for 2.5 h at room temperature.

Acetic acid-d_1 (12 ml) was added at 0–5 °C and the reaction mixture stirred for an additional 2.5 h. Dilution with water (150 ml) and extraction with ether yielded an ether extract which was washed with dilute NaOH and subsequently several times with water. Removal of the ether *in vacuo* and distillation of the residue at reduced pressure gave a clear liquid (80%) bp 55–57 °C (8 mm Hg). Gas–liquid phase chromatographic analysis revealed this fraction contained a major component (*ca.* 90%) and a minor amount of starting material; nmr δ ($CDCl_3$) 0.9 (3H, t, J = 4 Hz, $—CH_3$), 1.3 (8H, b, $—CH_2—$), 2.2 (2H, d, J = 7 Hz, $—CH_2—C{=}C_1—$), 5.8 (1H, m, $C_{2\text{-}H}$); ms (calcd. for $C_8H_{14}DCl$, M^+, 147), 147 (M^+, 16%; D_0 21%, D_1 79%, D_2 0%), 43 ($M^+ - (CH_2)_3CH{=}CDCl$), 100%).

Preparation of 1,1,2-Trichloro-2-deuterio-3-n-hexylcyclopropane

A solution containing *cis*-1-chloro-1-deuterio-1-octene (7.5 g) and cetyl trimethylammonium bromide (CTAB) (29), in 20 ml of chloroform was heated to 50–55 °C. A solution of 20 g NaOH in 20 ml of water was added dropwise. The progress of the reaction was monitored by glc (170 °C) and allowed to proceed until no further decrease in concentration of starting material was noted upon further addition of base. The reaction mixture was cooled to room temperature, diluted with water (100 ml), acidified with 10% H_2SO_4, and extracted into ether. Solvent removal and distillation under reduced pressure afforded 1,1,2-trichloro-2-deuterio-3-*n*-hexylcyclopropane as a clear liquid; bp 70–75 °C (0.1 mm Hg). Gas–liquid chromatography at 170 °C showed the product to consist mainly of one component with minor impurities; ms (at 15 eV) (calcd. for $C_9H_{14}DCl_3$, M^+, 229) 194 ($M^+ -$ Cl, 20%), 123 (100%).

Reduction of 1,1,2-Trichloro-2-deuterio-3-n-hexylcyclopropane

The reaction was carried out under nitrogen and using tri-*n*-butyltin deuteride (30, 38). The progress of the reaction was followed by glpc using a 6 ft × $\frac{1}{8}$ in. 5% Carbowax 20M on Chrom G column at 180 °C. Work-up as previously described and distillation gave a main fraction bp 65–80 °C (0.1 mm Hg) consisting of two products (80%) and some unreacted starting material. The distillate was subjected to sodium and alcohol reduction without further purification.

Reduction of 1,2-Dichloro-1,2-dideuterio-3-n-hexylcyclopropane

The crude reduction product (3 g) was added to 25 ml of methanol containing 1% water. While keeping the reaction under N_2, clean pieces of sodium were added to the mixture and allowed to react at room temperature with constant stirring. The progress of the reaction was followed by glpc and terminated when no further reaction of the starting material was observed.

The mixture was diluted with water (100 ml), extracted with ether, the organic layer dried over anhydrous $MgSO_4$ and distilled at atmospheric pressure to give 40% of *cis*-1-*n*-hexyl-*cis*-2,3-dideuteriocyclopropane **4** (95%) pure by glpc; bp 145–150 °C; ms (at 15 eV) (calcd. for $C_9H_{16}D_2$, 128), 128 (M^+; D_0 0%, D_1 27%, D_2 73%).

*Preparation of Tetrachloro(diethylene)diplatinum **2***

The dimeric complex, **2**, was prepared from $K_2(PtCl_4)$ by the method of Chatt and Searle (39). Recrystallization from hot toluene gave a microcrystalline yellow-orange product; mp (darkens) 190 °C, (dec.) 205–210 °C (lit. (39) (dec.) 210 °C); ir ν_{max} (KBr) 1412 (C=C), 1250, 1019, 225, 485, and 335 (PtCl) cm^{-1}.

*Reaction of Complex **2** with Cyclopropanes*

Dichloro(2-n-hexylpropane-1,3-diyl)platinums

In a typical reaction, **2** (200 mg, 0.34 mmol) and an *n*-hexylcyclopropane (**3**, **4**, or **5**) (200 mg, 1.55 mmol) in 5–10 ml of ether was stirred under reflux for 8 h. During the course of the reaction, the orange colored complex, **2**, was replaced by a pale-yellow precipitate. The precipitate was filtered, washed with ether, and dried to give 80–90% yield of a pale-yellow powder; mp 120–125 °C (dec.), (lit. (23) (dec.) 120 °C).

Preparation of trans-Dichlorobispyridine(2-n-hexylpropane-1,3-diyl)platinum

Dichloro(2-*n*-hexylpropane-1,3-diyl)platinums **6**–**8** (100 mg) were individually cooled in an ice–water bath followed by the addition of ice-cold pyridine sufficient for dissolution. The solution was allowed to warm to room temperature then added dropwise and with constant stirring to 100 ml of cold H_2O. The resulting milky suspension was centrifuged, the water decanted, and the yellow precipitate dissolved in $CHCl_3$. Removal of the $CHCl_3$ *in vacuo* gave a pale-yellow solid (70–80%). Recrystallization from benzene – petroleum ether gave a pale-yellow crystalline solid which exhibited one spot on thin layer chromatography (Silcia Gel HF254, $CHCl_3$), mp 124–126 °C (lit. (23) (darkens) 125 °C, (dec.) 220 °C.

The cyclic carbamate unit of maytansine[1]

OLIVER E. EDWARDS AND PAK-TSUN HO

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 23, 1976

OLIVER E. EDWARDS and PAK-TSUN HO. Can. J. Chem. **55**, 371 (1977).

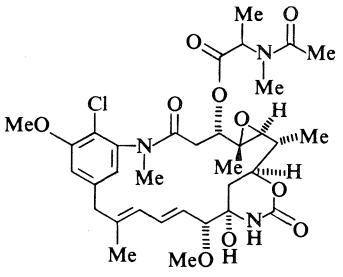
An eleven step sequence with control of the relative stereochemistry of four asymmetric centers has converted 3,4-epoxycyclohexene into a highly functionalized model for synthesis of the cyclic carbamate unit of maytansine.

OLIVER E. EDWARDS et PAK-TSUN HO. Can. J. Chem. **55**, 371 (1977).

Une série de onze réactions, impliquant un contrôle de la stéréochimie relative au niveau de quatre centres asymétriques, permet de transformer l'époxy-3,4 cyclohexène en un modèle hautement fonctionnalisé permettant d'effectuer la synthèse de l'unité carbamate cyclique de la maytansine.

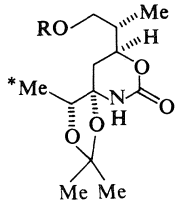
[Traduit par le journal]

Maytansine I is an ansa macrolide which has been found to show significant antitumor activity. Following extensive toxicity studies in animals it has recently been found suitable for clinical trials (1). Model studies for the synthesis of the cyclic carbamate unit in maytansine had been reported. However, these approaches provided either no steric control or partial control of the relative stereochemistry (2–5). We now wish to report a relatively efficient new approach to the cyclic carbamate **1** which involved the successful introduction of the required four asymmetric centers with complete stereospecificity.

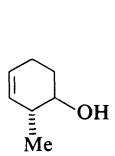


I

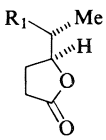
The readily available 3,4-epoxycyclohexene was converted to the alcohol **2** by reaction with methyllithium in ether (6).[2] Oxidation of compound **2** by a modified Lemieux periodate–permanganate method (7) followed by heating with acetic acid for 1 h led to the formation of the oily γ-lactone **3** in 71% yield[3]; ν_{max} 1770 (lactone), 1710 cm^{-1} (carboxylic acid); ^1H nmr δ 4.73 (q, 1H, —COOCH—), 1.41 ppm (d, 3H, CH_3CH—). Direct transformation of the carboxylic function of **3** to the corresponding alcohol **4** was accomplished (8) by reaction of **3** with ethyl chloroformate and triethylamine in anhydrous THF at −10 °C followed by reduction of the resulting anhydride with $NaBH_4$ in aqueous THF to yield the hydroxy lactone **4** as



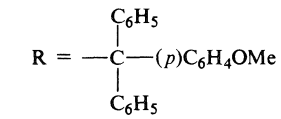
1



2



3 R_1 = COOH
4 R_1 = CH_2OH
5 R_1 = CH_2OR



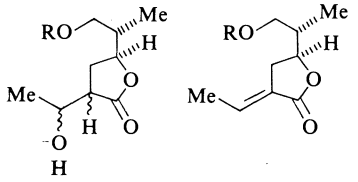
[1]Issued as NRCC No. 15702.

[2]The yield under our conditions (with 2.5 equiv. of methyllithium under argon at −10 °C for 1 h and at room temperature for 2 h, followed by acidic work-up) was improved to 68% after distillation.

[3]Satisfactory physical and spectral data were obtained for all new compounds.

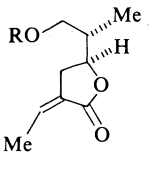
an oil in an isolated yield of 82%. Treatment of compound **4** with *p*-anisyldiphenylmethyl chloride (1.2 equiv.) in anhydrous benzene containing pyridine at room temperature afforded **5** in an almost quantitative yield.

Further elaboration of the lactone **5** was accomplished in the following way. Condensation of acetaldehyde with the lithium enolate from the lactone **5**, generated using lithium diisopropylamide (3 equiv.) in anhydrous tetrahydrofuran under argon at −70 °C, produced a mixture of isomeric alcohols **6** (80% yield). This mixture was dehydrated by conversion to the mesylates followed by elimination using 1,5-diazabicyclo[4.3.0]non-5-ene in anhydrous tetrahydrofuran at 0 °C. The resulting mixture of olefins could easily be separated by chromatography on silica gel to give the α,β-unsaturated lactones **7** and **8** (ratio 4:1) in 86% yield. The desired isomer **7** had ν_{max} 1750 and 1618 cm^{-1} and gave ^1H nmr signals at δ 7.46 (14H, m), 6.79

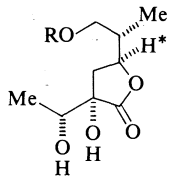


6

7



8

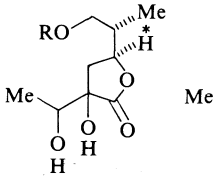


9

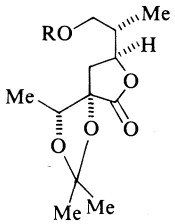
(1H, m, C=C*H*CH_3), 4.68 (1H, q, COOC*H*), 3.20 (2H, d, COCH_2), 2.67 (2H, m, C=C—CH_2), 1.87 (3H, br d, C=CHCH_3), and 1.04 (3H, d, CH—CH_3). Its mass spectrum had strong peaks at 442 (M^+), 364, 273, and 169. It had λ_{max} (EtOH) 226 nm (ε 11 600). The minor isomer **8** had ν_{max} 1750 and 1618 cm^{-1}, λ_{max} (EtOH) 228 nm (ε 8000) and gave ^1H nmr signals at δ 7.46 (14H, m), 6.23 (1H, m, C=C*H*CH_3), 4.64 (1H, q, COOC*H*), 3.16 (2H, d, COCH_2), 2.70 (2H, m, C=C—CH_2), 2.17 (3H, br d, C=CHCH_3), 1.03 (3H, d, CHCH_3). Its mass spectrum was essentially identical to that of **7**. The relative stereochemistry of these isomers was clear from the fact that the vinyl hydrogen in **7** and the vinyl methyl in **8** were deshielded by their proximity to the carbonyl oxygen (9).

Since osmium tetroxide is bulky it was anticipated that it would selectively approach the double bond of **7** from the side opposite to the space-filling side chain. This proved to be correct. Osmylation in the presence of pyridine in tetrahydrofuran, followed by reductive work-up using aqueous sodium hydrogen sulfite, converted **7** in 90% yield to a mixture containing 95% of the desired diol **9** accompanied by the isomer **10**.

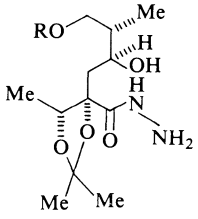
Compound **9** gave ^1H nmr signals at δ 4.61 (1H, q, COOC*H*), 3.20 (2H, d, COCH_2), 1.20 (3H, d, CHCH_3), and 1.08 (3H, d, CHCH_3) and gave M^+ 476. Isomer **10** gave δ 4.37 (1H, q, COOC*H*), 3.20 (2H, d, COCH_2), 1.32 (3H, d, CHCH_3), and 1.18 (3H, d, CHCH_3) and M^+ 476. The downshield shift of the hydrogen marked by an asterisk in **9** relative to that in **10** is clearly due to its closer proximity to the one hydroxyl group, and hence the relative stereochemistry can be assigned to each.



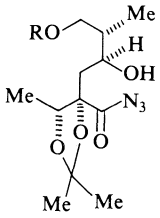
10



11



12



13

The diol **9** was converted into the acetonide **11** by reaction with 2,2-dimethoxypropane catalyzed by *p*-toluenesulfonic acid at room temperature (1 h, 82% yield). Treatment of **11** with excess 100% hydrazine hydrate in absolute ethanol at room temperature for 3 h produced the unstable hydroxy hydrazide **12**. This was immediately treated with a methylene chloride solution of N_2O_4 (4 equiv.) in the presence of a

large excess of sodium acetate.[4] After 5 min at −70 °C the sensitive hydroxy azide **13** was produced. This had ν_{max} 3500, 2140, and 1705 cm^{-1}. Finally, Curtius rearrangement of compound **13** in refluxing xylene gave 75% conversion to the cyclic carbamate **1** with 25% recovery of the lactone **11**. The desired model **1** could be recrystallized from hexane–ether to give a 78% yield (based on unrecovered **11**) with mp 85 °C. It had ν_{max} 3400 and 1710 cm^{-1}, and gave ^1H nmr signals at δ 7.71 (1H, exchanged with D_2O), 4.71 (1H, q, NHCOOC*H*—), 4.01 (1H, q, CH_3CHOC), 3.19 (2H, d, $CHCH_2OC$), 1.48 (3H, s, CH_3C), 1.34 (3H, s, CH_3C), 1.24 (3H, d, CH_3CH—), 1.13 (3H, d, CH_3CH). *Anal.* calcd. for $C_{32}H_{37}O_6N$: C 72.29, H 7.01, N 2.63; found: C 72.25, H 7.19, N 2.56.

It seems probable that the scheme can be modified to place a function on the starred carbon of **1**, thus giving a valuable synthon for construction of maytansine. Further work directed at the synthesis of this interesting molecule is in progress.

[4]Attempts to diazotize **12** either under neutral conditions (pyridine) or by the use of nitrosyl chloride led to quantitative conversion to the lactone **11**. These conditions were successful with a simple model in experiments by Dr. W. Rank, whom we cordially thank.

Reçu le 23 août, 1976

CHERUBALA P. VIJAYAN et DOMINIQUE-LOUIS PIRON. Can. J. Chem. **55**, 375 (1977).

Les résultats de ce travail ont permis de déterminer le mécanisme de la réaction de dégagement d'hydrogène sur le niobium immergé dans des solutions alcalines aqueuses à 24 °C. On a mesuré une pente de Tafel de 120 mV/décade (déviation standard de 8 mV/déc.) et un ordre réactionnel de zéro par rapport à la concentration des ions H^+. Ces résultats ont permis d'établir un mécanisme de Heyrovsky. La présence des anions sulfates ou chlorures n'a pas montré d'effets sur les résultats obtenus.

CHERUBALA P. VIJAYAN and DOMINIQUE-LOUIS PIRON. Can. J. Chem. **55**, 375 (1977).

The mechanism of the hydrogen evolution reaction on niobium is evaluated in alkaline media at 24 °C. The reaction order of zero, along with the observed Tafel slopes of 120 mV/decade (standard deviation 8 mV/dec.), indicate the Heyrovsky reaction mechanism to be applicable for the hydrogen evolution reaction. The presence of anions such as sulfate and chloride does not influence the mechanism.

Introduction

L'étude de la cinétique du dégagement d'hydrogène sur le niobium pur (99.85%) en milieu alcalin a été l'objet de la présente investigation. Ce travail constitue donc une étape vers une meilleure compréhension des propriétés électrochimiques de ce métal dont le minerai de pyrochlore est une des richesses du Canada (1).

La résistance à la corrosion du niobium a déjà fait l'objet de certains travaux. Fontana (2) rapporte une vitesse de corrosion de 1.1 mpy à 24 °C dans une solution aqueuse à 5% NaOH.

Tingley et Rogers (3) ont observé dans des solutions d'hydroxyde de sodium à 10% en poids une vitesse de corrosion inférieure à 2 mpy. Dans les limites de leur travail, ces auteurs ont observé que le niobium présente aussi une bonne résistance à la fragilisation. Ce dernier résultat est en contraste avec des observations précédemment rapportées par Taylor (4) dans des solutions de NaOH diluées.

Van Muylder, de Zoubov et Pourbaix (5) ont montré que le niobium est un métal peu noble qui se recouvre d'une couche d'oxyde dans tout le domaine de stabilité de l'eau. Le film ainsi formé peut protéger le niobium en solution aqueuse à n'importe quel p*H*. Il en résulte une résistance à la corrosion qui dépend toutefois de la stabilité et de l'étanchéité de la couche protectrice. Les propriétés électrochimiques sont donc généralement observées sur un revêtement naturel d'oxyde de niobium.

Leavenworth *et al.* (6) considèrent que la corrosion de ce métal en solution d'hydroxyde de sodium se produit par la nucléation et la formation de $Na_8Nb_6O_{19}\cdot 13H_2O$. Leur étude concerne plutôt le comportement anodique.

Le comportement cathodique a été abordé par

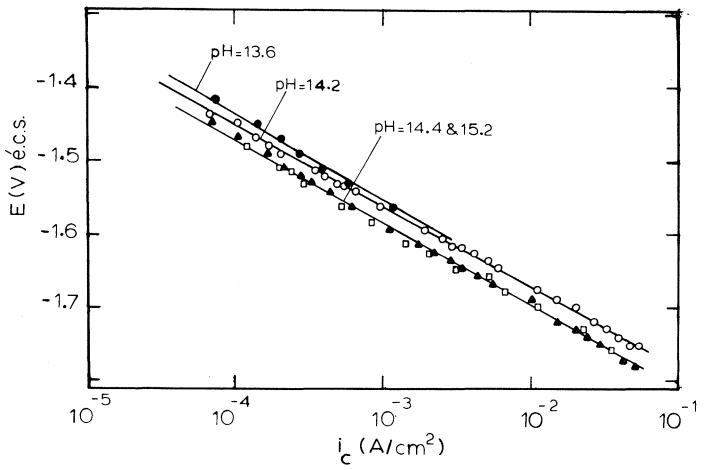

FIG. 1. Polarisation galvanostatique cathodique sur le niobium à 24 °C (bain NaOH).

Piron et Nobe (7) qui ont mesuré une pente de Tafel de 116 mV/décade en solution 1 *N* NaOH à 24 °C, et par Rotinyan et Kozhevnikova (8), qui ont obtenu 120 mV/déc. Lokshtanov et Rotinyan (9) ont obtenu une pente de 135 mV/déc. Piron et Vijayan (10) ont observé une pente de 122 ± 11 mV/déc. L'ordre réactionnel de dégagement d'hydrogène sur le niobium n'a toutefois pas encore été mesuré. Ce résultat a donc été recherché ici afin de pouvoir déterminer le mécanisme de ce procédé d'électrode, en employant la méthode décrite (11) et utilisée par Vetter (12) pour cette même réaction sur d'autres métaux.

Une telle étude est importante pour la compréhension des propriétés électrochimiques du niobium, et en particulier sa résistance à la corrosion. A côté de cet aspect assez fondamental, le présent travail est également un point de départ dans l'évaluation du niobium comme cathode dans de nouveaux électrolyseurs d'eau en relation avec l'économie de l'hydrogène.

Partie expérimentale

Le montage expérimental est analogue à celui décrit précédemment (10). Les solutions sont préparées à partir des produits chimiques NaOH, H_2SO_4, HCl, Na_2SO_4 et NaCl de qualité A.C.S., et de l'eau distillée. Des essais de polarisation galvanostatique sont effectués dans des solutions de p*H* 11.3 à 13.6 contenant des ions SO_4^{2-} ou Cl^-, et dans des solutions 1 *N* à 7 *N* NaOH, p*H* calculé variant entre 13.8 et 15.2, suivant la méthode de Littauer et Tsai (13).

Résultats

Les courbes de polarisation cathodique obtenues à 24 °C en milieu NaOH de normalité variant entre 1 et 7 sont représentées sur la fig. 1. On observe des pentes de Tafel de 114 mV/déc. avec une déviation standard de 9 mV dans un domaine de densité de courant variant entre 10^{-4} et 10^{-2} A/cm^2.

Les résultats de ces mesures montrent un changement non-ordonné par rapport au p*H* dans la position des droites de Tafel. Ceci correspond à une dispersion de 40 mV.

Une pente de Tafel de 120 mV/déc. a aussi été mesurée par Rotinyan et Kozhevnikova (8) dans le même domaine de densité de courant. Toutefois, dans une deuxième série d'essais, Lokshtanov et Rotinyan (9) ont obtenu des pentes de Tafel de 135 mV/déc. en solution 1 *N* NaOH à 20 °C.

Les résultats de polarisations cathodiques du niobium à 24 °C en bain NaOH de p*H* 11.3 à 13.6 contenant des ions sulfates (concentration: 1 équiv./litre) sont représentés sur la fig. 2. La solution de p*H* 13.6 est la solution normale en NaOH à laquelle on a ajouté une concentration normale de Na_2SO_4. La courbe de polarisation cathodique du Nb dans cette solution est identique à la courbe de polarisation du niobium obtenue dans la solution 1 *N* NaOH de la fig. 1 qui ne contient pas de sulfate.

Dans la fig. 2 on observe des pentes de Tafel de 125 mV/déc. avec une déviation standard de 11 mV dans un domaine de densité de courant qui varie entre 10^{-4} et 10^{-2} A/cm^2.

On observe une vibration de la position des droites de Tafel qui change avec le p*H* de

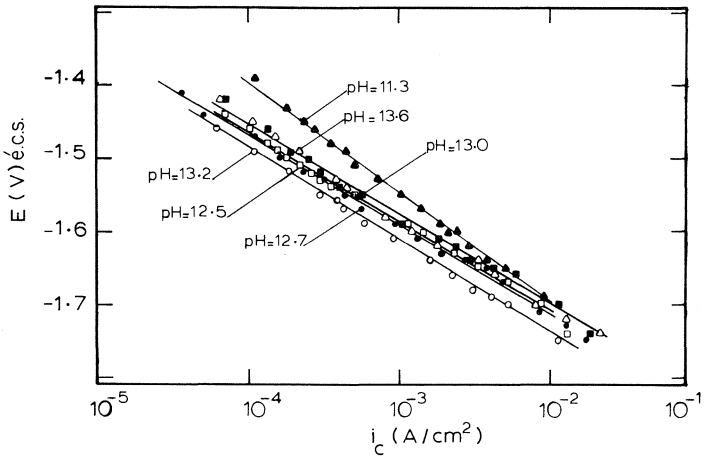

FIG. 2. Polarisation galvanostatique cathodique sur le niobium à 24 °C (bain alcalin contenant des sulfates).

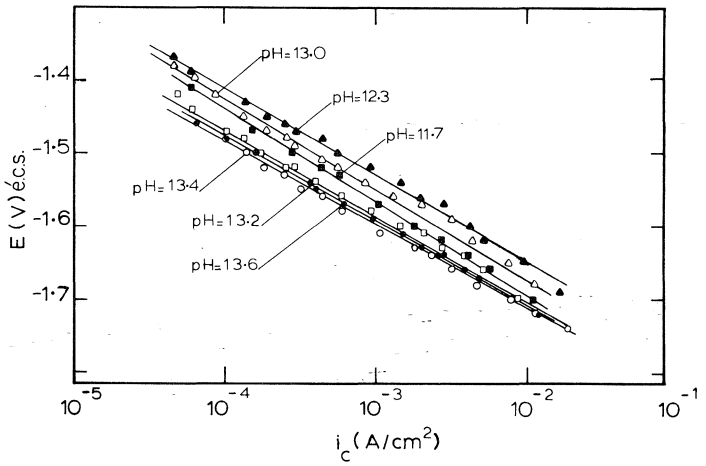

FIG. 3. Polarisation galvanostatique cathodique sur le niobium à 24 °C (bain alcalin contenant des chlorures).

manière désordonnée. Cette dispersion est de 70 mV.

La fig. 3 donne les résultats obtenus à 24 °C lors de la polarisation cathodique en solution de NaOH de p*H* variant entre 11.7 et 13.6 contenant 1 équiv. d'ions chlorures par litre.

Une pente de Tafel de 117 mV/déc., ayant une déviation standard de 6 mV, est observée entre 10^{-4} et 10^{-2} A/cm^2 de densité de courant.

Le changement de la position des pentes de Tafel, désordonnée par rapport au p*H*, se présente encore ici avec une dispersion de 80 mV. Cette dispersion dans la position des droites de Tafel pourrait s'expliquer par une différence de la microrugosité superficielle des électrodes. Ce point de vue semble être renforcé par une dispersion des valeurs de la capacité différentielle. La mesure de ces dernières varie entre 151 et 206 μF/cm^2 pour des électrodes de Nb au repos, après 3 h d'immersion dans une solution normale de NaOH à 25 °C.

L'identité des courbes de polarisation obtenues sur le Nb immergé dans une solution 1 *N* de NaOH ne contenant pas de chlorure (fig. 1) et une solution de même concentration de cette base à laquelle on a ajouté 1 équiv. par litre de NaCl (fig. 3) montre que dans ces conditions l'addition de chlorure n'a pas eu d'effet sur la polarisation.

Les résultats expérimentaux présentés dans les

trois premières figures peuvent être utilisés pour déterminer l'ordre de la réaction de dégagement d'hydrogène. La fig. 4 montre l'ordre réactionnel de zéro par rapport à l'ion H^+ dans un domaine de pH variant entre 11.3 et 15.2. Cette détermination sur le Nb n'ayant pas été publiée précédemment, il convient de la comparer avec les résultats de dégagement d'hydrogène obtenus sur d'autres métaux en milieu alcalin.

Vetter, utilisant les résultats expérimentaux de Lukowzew *et al.* (14) sur le nickel et de Bockris et Watson (15) sur le mercure, a établi également un ordre réactionnel de zéro pour l'ion H^+ dans la réaction de dégagement de l'hydrogène en milieu alcalin.

D'autre part, Bicelli *et al.* (16), travaillant sur le cobalt, ont, eux-aussi, obtenu en milieu alcalin un ordre réactionnel de zéro pour l'ion H^+.

Discussion

Vetter (12) et Bicelli (17) montrent les mécanismes possibles de dégagement d'hydrogène en milieu alcalin. Le mécanisme est en effet en grande partie déterminé par le fait que la fraction θ de la surface couverte par l'hydrogène adsorbé, tend vers zéro, vers l'unité, ou vers des valeurs intermédiaires.

Les résultats obtenus ici (pente de Tafel de 120 mV/déc. et l'ordre réactionnel de zéro) peuvent être expliqués par des mécanismes basés sur des valeurs de θ tendant vers 1 ou zéro, et sur l'hypothèse de Langmuir.

Les calculs de Vijh et Bélanger (18), utilisant la méthode de Stevenson (19) et les résultats d'Ehrlich (20), montrent que l'enthalpie libérée lors de l'adsorption d'hydrogène sur les métaux de transition est très élevée (~80 kcal/mol sur le niobium). Mueller *et al.* (21) aussi arrivent à la même conclusion. Une enthalpie aussi élevée rend l'adsorption de l'hydrogène fort probable sur une fraction importante de la surface du niobium. D'autre part, les résultats expérimentaux de Beeck (22) ont révelé que l'adsorption de l'hydrogène sur les métaux de transition se faisait si facilement qu'elle était instantanée.

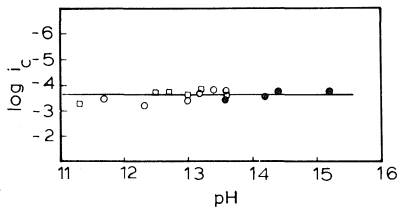

FIG. 4. Ordre réactionnel en milieu alcalin contenant des sulfates □, des chlorures ○, et ni sulfate ni chlorure ●, $E = -1.5$ V (é.c.s.).

La thermodynamique et l'expérience portent donc à penser que des valeurs de θ tendant vers zéro sont fort peu probables ici. De plus, les résultats de la présente investigation ne pouvant s'accorder à des valeurs de θ intermédiaires, il convient donc de conclure à des valeurs de θ tendant vers l'unité. Une conclusion similaire a été utilisée comme point de départ dans le travail de Lokshtanov (9) sur le niobium et aussi par Bicelli *et al.* (16) sur le cobalt.

En considérant les trois mécanismes simples possibles (12), et en les comparant avec les résultats obtenus dans ce travail, il est apparent que le mécanisme de Heyrovsky serait applicable pour le dégagement d'hydrogène sur le niobium.

[1] $$H_2O + e \rightarrow H_{ads} + OH^-$$
(réaction de Volmer, étape rapide)

[2] $$H_{ads} + H_2O + e \rightarrow H_2 + OH^-$$
(réaction de Heyrovsky, étape lente)

Pour ce mécanisme, on écrit la relation suivante, en prenant θ tendant vers l'unité:

$$[3] \quad i_c = -kC_{H_2O} \exp\left(-\frac{(1-\alpha)FE}{RT}\right)$$

où i_c densité de courant cathodique, k une constante, C_{H_2O} concentration de l'eau, α coefficient de transfert, F Faraday, E potentiel de l'électrode, R constante de gaz, T température absolue.

De ceci il résulte que la pente de Tafel est

$$-\frac{2.3RT}{(1-\alpha)F}$$

et l'ordre réactionnel est

$$\left(\frac{\partial \log i_c}{\partial\, pH}\right)_{E,T} = 0$$

On a mesuré une pente moyenne en milieu alcalin de 120 mV/déc. (déviation standard de 8 mV) à 24 ± 1 °C, qui amène une valeur de $\alpha = 0.5$.

Les résultats expérimentaux n'étant pas influencés par la présence d'ions chlorures et sulfates, le mécanisme de dégagement d'hydrogène est, lui-aussi, indépendant de la présence de ces ions.

De plus, il convient de noter que le mécanisme présenté ici permet d'expliquer les résultats expérimentaux sans faire appel à la présence de la

couche d'oxyde superficielle et d'un modèle à doubles barrières plus complexe (23, 24).

Conclusion

En conclusion, la présente étude montre que l'ordre pour la réaction de dégagement d'hydrogène sur le niobium en milieu alcalin est égal à zéro. Le dégagement peut être expliqué par un mécanisme de Heyrovsky. Ce dernier n'est pas influencé par la présence d'ions chlorures et sulfates.

Remerciements

Les auteurs tiennent à remercier la société Noranda pour l'aide financière apportée à ce travail. Ils ont tout particulièrement apprécié les discussions fructueuses qu'ils ont eues avec le Dr. P. Claessens du Centre de Recherche Noranda.

Trajectory study of dissociation reactions. Br_2 in Ar at 3500 K[1]

D. T. CHANG[2] AND GEORGE BURNS

Lash Miller Chemical Laboratory, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 8, 1976

D. T. CHANG and GEORGE BURNS. Can. J. Chem. **55**, 380 (1977).

Dissociation of Br_2 in Ar was studied at 3500 K using classical 3-D trajectory technique, and compared with earlier trajectory calculations. Some of the assumptions used previously were eliminated, while others were studied in some detail. The one-way flux, equilibrium rate coefficient, obtained from over 8400 trajectories, was found to be over an order of magnitude larger than the experimental rate constant. This was taken as an indication that at high temperatures the nonequilibrium effects are important in dissociation reactions. In order to understand these effects better, additional calculations using an improved set of assumptions were performed. The calculated dissociation rate constant for $Br_2 + Ar \rightarrow 2Br + Ar$ reaction, which accounted for nonequilibrium effects, agrees reasonably well with experimental results.

D. T. CHANG et GEORGE BURNS. Can. J. Chem. **55**, 380 (1977).

On a étudié la dissociation de Br_2 dans Ar à 3500 K en faisant appel à la technique classique de trajectoire 3-D et on a comparé ces résultats avec des calculs antérieurs des trajectoires. On a éliminé quelques-unes des hypothèses utilisées auparavant alors que d'autres ont été étudiées en détail. On a trouvé que le flux à sens unique, coefficient de vitesse d'équilibre, obtenu à partir de 8400 trajectoires est au moins dix fois plus grand que la constante de vitesse expérimentale. On en déduit qu'à haute température les effets de non-équilibration sont importants dans les réactions de dissociation. Afin de comprendre mieux ces effets, on a effectué des calculs additionnels en faisant appel à un meilleur ensemble d'hypothèse. Les constantes de vitesse de dissociation, calculées pour la réaction $Br_2 + Ar \rightarrow 2Br + Ar$, qui tiennent compte des effets de non-équilibration sont en bon accord avec les valeurs expérimentales.

[Traduit par le journal]

Dissociation of iodine and bromine molecules was studied earlier (1, 2), using 3-D classical trajectory calculations and Monte Carlo method of sampling. Calculated rate constants agreed reasonably well (1, 2) with experimental data. However, previous calculations incorporated some simplifying assumptions which made results less reliable than they could have been. In the present work, some of these assumptions are removed, and some others studied in greater detail.

The first step in 3-D trajectory computations of dissociation rate is the calculation (1, 2) of k_d^{eq}, the equilibrium one-way flux rate coefficient which is not an observable quantity because it does not include nonequilibrium effects (3). In the past (2), in order to obtain k_d^{eq}, typically several hundred to a few thousand trajectories were run. In the present calculations, it was possible to run 8430 trajectories for the particular case of Br_2 in Ar at 3500 K.

In the earlier studies (1, 2) it was assumed that $\tau(u) = \langle\tau\rangle_i$ for the internal energy range $u_{i-1} < u < u_i$, where $\tau(u)$ is a measure of the vibrational period of the diatomic molecule. Furthermore, earlier (1, 2) it was also assumed that $r = r_{min}(q)$, where r is the initial internuclear separation of the molecule and $r_{min}(q)$ is the position of the minimum of its effective potential at a given value of quadratic angular momentum, q. Both of these assumptions were eliminated in the present work.

In other respects, the present calculations were similar to those performed (2) previously. Specifically, stratified and importance sampling was employed and six energy strata, each one kT wide, around the dissociation limit were used. Within each energy stratum, three annular strata with three different ranges of the impact parameter b ($0 \rightarrow 3$ Å; $3 \rightarrow 5$ Å; $5 \rightarrow 6.5$ Å) were employed. Of the total 8430 trajectories, 279 led to a reaction, and in all but one case, the product was three separated atoms, 2Br + Ar. Only one collision of 8430 led to the formation of BrAr + Br. The most important reaction path involved collisions of Br_2 molecules within

$\pm 1\,kT$ of the dissociation limit and impact parameters less than 5 Å. The resultant k_d^{eq} was found to be 3.7×10^9 l mol^{-1} s^{-1}, which is larger than 2.3×10^9 l mol^{-1} s^{-1} reported (2) earlier. We attribute this discrepancy predominately to removal of the two assumptions mentioned above and, to some extent, to an improved trajectory size.

Earlier results (1, 2) yield k_r^{eq}, the equilibrium one-way flux recombination rate coefficient obtained from K, the equilibrium constant, via $k_r^{eq} = Kk_d^{eq}$, several times larger than the experimental recombination rate constant, k_r. In addition, k_r^{eq} displays (1, 2) a positive temperature dependence, while a negative temperature dependence of k_r is normally (1, 2) reported. This suggests that both the absolute magnitude and temperature coefficient of k_r is influenced to a significant extent, by the nonequilibrium effects (3). The fact that k_d^{eq}, presently obtained at 3500 K, is also larger than the experimental rate constant (2) also indicates that nonequilibrium effects are important. Presently, no exact method for calculation of nonequilibrium effects in a real system appears to exist. For these reasons further study of nonequilibrium effects for Br_2 + Ar system at 3500 K was undertaken. Again, the purpose of this study was to remove some of the assumptions used (2) and to study other assumptions in some detail.

The nonequilibrium correction factor is related (2) to the observable, steady state dissociation rate constant, k_d, and k_d^{eq} by:

$$f = \frac{k_d}{k_d^{eq}} = \left(\frac{\int_D \phi^{ss}(u)\,du}{\int_D \phi^{eq}(u)\,du}\right)\left(\frac{\langle S^{ss}\rangle}{\langle S^{eq}\rangle}\right)$$

where $\int_D \phi(u)du$ are integrals of the distribution functions in the reactive (dissociative) zone and $\langle S\rangle$ are average cross-sections, at steady state and at equilibrium.

In the present work, the f factors were calculated using the method of successive collisions (3), at first using assumptions employed (2) previously, except that the present calculation did not involve the assumption that $\tau(u) = \langle\tau\rangle_i$ and $r = r_{min}(q)$. For this purpose, an equilibrium ensemble of 800 bromine molecules at 3500 K was generated in the reactive zone, which ranges within $\pm 2kT$ around the dissociative limit and a reflecting barrier (2) at $-3kT$ was assumed. No stratified and importance sampling was attempted, and the whole ensemble was subjected to 31 successive collisions with argon. The average internal energy in the reactive zone reached a reasonably well defined steady state within about 27 collisions, which agrees well with earlier (2) calculations. As previously, fluctuations in $\langle S\rangle$ values, when plotted *vs.* number of collisions, were pronounced, and this alone produced the largest single uncertainty in the f factor. This calculation produced $f = 0.1$ and $k_r = 1.4 \times 10^7$ l^2 mol^{-2} s^{-1} compared to $f = 0.23$ and $k_r = 2.0 \times 10^7$ l^2 mol^{-2} s^{-1}, obtained (2) previously. In view of the uncertainty in $\langle S\rangle_{ss}$, these results are in reasonable agreement.

In order to improve the above calculations of the f factor, we have studied further assumptions previously (2) used. Thus, earlier calculations (2) do not take into account of all collisions which involve unenergized molecules and yield excited molecules in the reactive zone. It merely assumes (2) that the $J_{d\to nd}$ and $J_{nd\to d}$ fluxes, representing de-excitation and excitation of molecules from and into the reactive energy range, are equal. However, one should expect that for Br_2 in Ar at 3500 K, the excitation flux $J_{nd\to d}$ is considerably larger than $J_{d\to nd}$. This assumption may be improved upon by complete elimination of the barrier at $-3kT$. However, such an elimination would make trajectory calculations too expensive and too time consuming. In order to improve calculations, presently another stratum, between $-3kT$ and $-2kT$, is introduced. Although this energy region rarely yields a reactive collision, it contributes significantly to the $J_{nd\to d}$ flux.

It was also realized that upon a sufficient number of collisions, even the *l*owest *e*nergy *s*tratum, $-3kT$ to $-2kT$, (LES) considered, should become depopulated, if it is not allowed to be repopulated from even lower energy strata. In order to deal with this problem in the present work, we assumed that LES remains at equilibrium with all strata which have less energy than $-3kT$. This assumption is arbitrary, but seems reasonable because the LES ($-3kT - 2kT$) stratum is relatively far away from the dissociation limit and is almost in between it and the bottom of the Br_2 potential, where one should expect that molecular distribution functions are well described by the translational temperature of the gas. In order to maintain LES invariant with respect to the number of

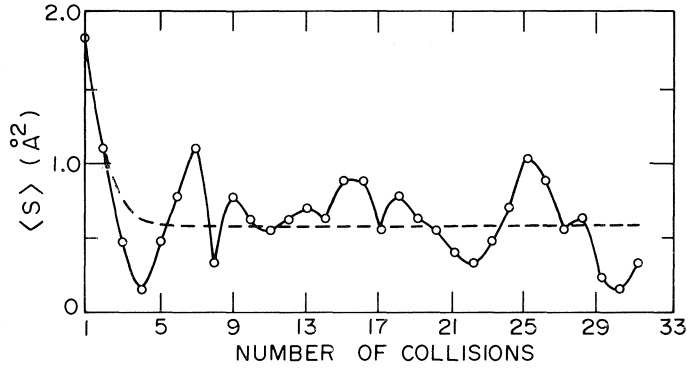

FIG. 1. Reaction cross-section in the dissociative zone ($-3kT$ to $+2kT$) for Br_2 in Ar at 3500 K *vs.* the number of collisions.

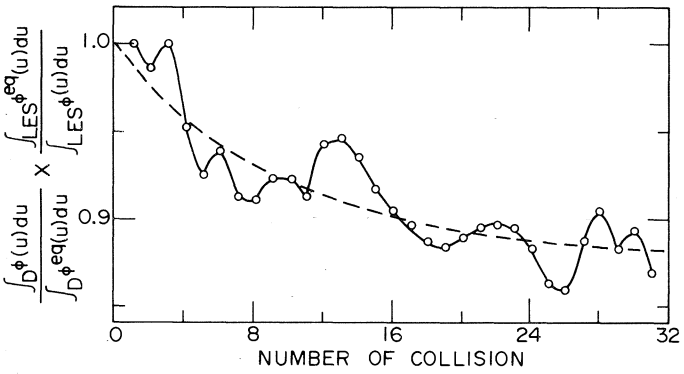

FIG. 2. Corrected normalized distribution function ratio for Br_2 in Ar at 3500 K *vs.* the number of collisions.

collisions, the ratio of the distribution function integrals was multiplied by a correction factor $\int_{LES}\phi^{eq}(u)du/\int_{LES}\phi^{ss}(u)du$, which thus increased the f factor.

In actual calculations, we again generated an equilibrium ensemble of 800 molecules at 3500 K within the dissociative zone, which was now defined by the internal energy of Br_2 from $-3kT$ to $+2kT$. The equilibrium ensemble was then subjected to 31 successive collisions with Ar. The resultant $\langle S\rangle$ and $\{\int_D\phi(u)du/\int_D\phi^{eq}(u)du\}$ $\{\int_{LES}\phi^{eq}(u)du/\int_{LES}\phi(u)du\}$ were plotted *vs.* number of collisions (Figs. 1 and 2). Both curves exhibit appreciable fluctuations, but the $\langle S^{ss}\rangle/\langle S^{eq}\rangle$ ratio, which after 31 collisions is 0.2 ± 0.1, provides the largest uncertainty. The ratios of the integrals of distribution functions (Fig. 2) are of the order of 0.9 at the steady state (30 collisions), and for this reason, fluctuations in Fig. 2 do not affect significantly the calculated values of k_d and k_r. The correction factor $\int_{LES}\phi^{eq}(u)du/\int_{LES}\phi(u)du$ increases the value of the f factor, k_r and k_d by 1.3. The resultant k_r is 3×10^7 l^2 mol^{-2} s^{-1} and is about three times larger than k_r obtained in experiments (2), a fair agreement, considering the precision of the present calculations as well as of the experimental results. Further work on reducing fluctuations in $\langle S\rangle$ is in progress. It should be added that present results do not indicate that the discrepancy between experimental and calculated results is due to nonequilibrium effects only.

NIGEL J. BUNCE. Can. J. Chem. **55**, 383 (1977).

Photolysis of aromatic azoxy compounds in non-basic solvents in the presence of 2-naphthol leads quite generally to azonaphthols in addition to the normal photorearrangement product. Free diazonium ions are implicated as the precursors of the azonaphthols, both the latter and the usual photorearrangement product being derived from the same excited state of the azoxy compound. Variation of the solvent, light intensity, substrate concentration, and percent reaction all cause changes in the product distribution. Such changes can be accommodated by postulating an intermediate which can either afford the normal rearrangement product by loss of a proton to a weak base, or expel a diazonium ion when no base is present.

NIGEL J. BUNCE. Can. J. Chem. **55**, 383 (1977).

La photolyse de composés azoxyaromatiques dans des solvants non-basiques en présence de naphthol-2 conduit généralement à la formation d'azonaphtols aux côtés du produit normal de photoréarrangement. Des ions diazonium libres sont impliqués comme précurseurs des azonaphtols; ces derniers ou de même que les produits habituels de réarrangement se formeraient à partir du même état excité du composé azoxy. Des variations dans le solvant, dans l'intensité de la lumière, dans la concentration du substrat et dans le pourcentage de la réaction causent toujours des changements dans la distribution des produits. On peut accommoder de tels changements en faisant l'hypothèse qu'un intermédiaire peut soit fournir le produit normal par perte d'un proton vers la base faible soit expulsé un ion diazonium quand il n'y a pas de base présente.

[Traduit par le journal]

Apart from *cis–trans* photoisomerization (1), the normal photoreaction of aromatic azoxy compounds is intramolecular rearrangement to an *o*-hydroxyazo compound (2) [1]. 2,2′-Azoxytoluene is known to be unusual in that it gives photo products additional to those predicted by [1] (3), and similar anomalous behaviour has also been observed recently for other *o*-substituted azoxybenzenes (4). The extra products are suppressed when 2,2′-azoxytoluene is photolyzed in the presence of 2-naphthol, and it has been suggested (5) that some intermediate such as **2**, originally proposed by Badger and Buttery (6), has the ability to fragment into a diazonium ion. This may couple with 2-naphthol, giving 1-*o*-tolylazo-2-naphthol **3** as an observed product.

[1]

2 **3**

The bulk of the substituent R might be expected to ease the departure of the diazonium ion from **2**. However, in benzene solution, photolysis of even azoxybenzene, which is sterically unencumbered, gave (5) three times as much (60%) of the azonaphthol as of the normal rearrangement product (22%). To the extent that formation of azonaphthol can be considered diagnostic of a diazonium ion precursor, it follows that at least in this solvent, most azoxybenzene molecules photolyze by cleavage to a trappable diazonium ion. Before this assertion can be justified, it must be determined (*i*) whether diazonium ions are *necessarily* the precursors of the azonaphthols and (*ii*) whether both the azonaphthol and the

[1]Presented in part at the 166th National Meeting of the American Chemical Society, Chicago, Illinois, August 1973.

rearrangement product are formed from the same excited state of azoxybenzene. If so, it would be possible that even in the absence of 2-naphthol, the normal product might arise, at least in part, by recombination of a geminate pair of diazonium cation and phenoxide anion.[2] That possibility, that diazonium ions may be intermediates in the azoxybenzene photorearrangement, is the subject of this paper.

Results and Discussion

Although no direct observation of the proposed diazonium ions has been made, it is consistent with their involvement in the photorearrangement that photolysis of *p*-substituted azoxybenzenes in benzene–2-naphthol gave a greater proportion of azonaphthol in the order *p*-Cl < *p*-H < *p*-CH_3, progressively stabilizing the diazonium ion. These results, and comparable ones for *o*-substituents of similar size, are given as product ratios in Table 1. The actual rates of reaction of the different derivatives seem to be subject to a substituent effect, which is currently being investigated.

At this point, it was possible that the naphthol, rather than trapping a free cation, attacks some intermediate such as **2** and abstracts the diazonium moiety with expulsion of the phenol or phenoxide. That this was not the case was shown by varying the concentration of 2-naphthol. The distribution was unchanged over a tenfold range of 2-naphthol concentration; neither was the rate of reaction affected by the naphthol concentration, except when the latter was so high that much of the light was filtered from absorption by azoxybenzene.

Previous sensitization studies of the azoxybenzene photorearrangement have shown that high energy ketone sensitizers retard the photorearrangement (9, 10). In the presence of 2-naphthol, the ratio of photorearrangement product and the azonaphthol was constant with added benzophenone, although their yields drop and photoreduction[3] increases with increasing benzophenone concentration. Potential triplet quenchers such as oxygen and pyrene likewise caused no change in product distribution,[4] so that it was concluded that both products are formed from the same, presumably singlet, excited state. This result meant that 2-naphthol could now be used as a mechanistic probe for the reaction, studying the effects of variation of reaction parameters upon the product distribution, in order to gain information about the intermediate immediately preceding the divergence of the mechanism to the two products.

TABLE 1. Substituent effect upon product ratio in the azoxybenzene photorearrangement[a]

Substituents	Product ratio
4,4′-Cl_2	1.1
None	3.8
4,4′-$(CH_3)_2$	5.3
2,2′-$(CF_3)_2$	0.9
2,2′-$(CH_3)_2$	8.3
2,2′-$(OCH_3)_2$	11.9[b]

[a]In benzene solution; product ratio is azonaphthol:photorearrangement.
[b]Data of ref. 4*b*.

It was suggested above that the size of the group R in intermediate **2** may ease the departure of the diazonium ion. Accordingly, azoxybenzenes substituted in the 2,2′-positions with groups of increasing bulk yield more of the azonaphthol upon photolysis in alcoholic solvents (Table 2). The same kind of steric effect is observed in benzene solution (see first entry to Table 3).

Because the azonaphthol predominates in benzene solution, the rate of azonaphthol formation approximates the overall rate of product formation in this solvent. An experiment was carried out in which azonaphthol production was monitored in the simultaneous photolysis of compounds differing in the bulk of the 2,2′-R_2 groups, and it was found that the quantum efficiencies vary by less than a factor of two, despite the enormous difference in steric hindrance. Thus steric hindrance seems to affect not so much the overall efficiency with which the azoxy compound is transformed to products, as the relative rates of partition of some inter-

[2]Solvent separated diazonium and phenoxide ions are presumably not formed, else *p*-hydroxyazobenzene would be a major product, since azo couplings on phenols invariably involve an available *para* position (7). No more than traces of *p*-hydroxyazobenzene result from photolysis of azoxybenzene (8).

[3]Photoreduction apparently involves not the triplet state of azoxybenzene (*cf.* ref. 9) but rather "chemical sensitization" by benzophenone (10).

[4]High concentrations of piperylene (in benzene) or lithium bromide or 1-bromopropane (in ethanol) cause changes in the product ratio. As shown below, however, the ratio is very sensitive towards solvent changes.

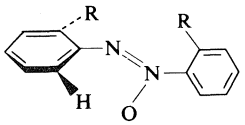
TABLE 2. Effect of *ortho* substitution on the photorearrangement of azoxybenzenes

R	Azonaphthol/hydroxyazo compound: In ethanol	Azonaphthol/hydroxyazo compound: In 2-propanol	Relative rate of azonaphthol formation[a]
H	<0.01	<0.01	1
2,2′-CH_3	0.2	0.7	0.7
2,2′-C_2H_5	0.2	1.1	0.7
2,2′-C_3H_7	1.2	1.4	0.6
2,2′,5,5′-CH_3	1.3	—	0.9

[a]Deviation from run to run was less than 5% over five runs. Solvent was benzene, see text.

mediate between the photorearrangement product and the azonaphthol.

ortho-Substituted azoxybenzenes are known from their electronic spectra (11) to be non-planar in their ground states, and facile deformation about the C—N bonds is compatible with the rather great length of these bonds determined crystallographically (12). Although we have no direct information about the geometry of the excited state, HMO calculations on azoxybenzene do not indicate a large increase in the C—N π-bond orders upon excitation. Thus the excited state is also likely to twist easily, and this is compatible with the aromatic substitution mechanism for photorearrangement (4, 6), in which attack by oxygen on the *ortho* carbon must involve a non-planar transition state such as **4**. This would minimize steric hindrance and explain why bulky substituents have only a small effect on the efficiency of the reaction.



4

This lack of steric interference parallels Tanikaga's (1) observation that 3,3′-disubstituted azoxybenzenes afford equal amounts of both possible photorearrangement products [2], *i.e.*, the 3-substituent offers no hindrance to substitution into the 2-position. Comparable amounts of both products are also obtained in the 3,3′-dimethoxy system (11), and even more strikingly, we now find that even 3,3′-di-*tert*-butylazoxybenzene yields equal amounts of both photorearrangement products.

The effect of solvent upon the product ratio

[2] 
R = CH_3, Br, OCH_3, $C(CH_3)_3$

was now investigated. Since expulsion of the diazonium ion involves separation of charge, it was expected that a higher proportion of diazonium ions, and hence azonaphthol, would be formed in more polar solvents. This was not the case, as Table 3 shows, with the highest proportion of azonaphthol being produced in benzene, while almost none was obtained in ethanol.

Subsequently, it was found that the product spread depends on whether the solvent has basic properties (Table 4). Addition of water to acetonitrile, or of various substances having non-bonded electrons to benzene, results in greatly reduced azonaphthol formation. The conclusion to be drawn is that there is some intermediate that can fulfil a dual role: in the presence of base it is converted to the normal hydroxyazo compound, but when base is absent, a diazonium ion may be expelled, and trapped by 2-naphthol if available. Although there is the possibility that a basic and hence nucleophilic solvent 'Nu' might trap the diazonium ions as ArN=N—Nu and make them unavailable for azonaphthol formation, this seems to be ruled out by the high

TABLE 3. Effect of solvent on the product ratio upon photolysis of azoxybenzene and 2,2′-azoxytoluene with 2-naphthol

chemical yields of products that can be obtained. Thus photolysis of azoxybenzene in benzene affords **1** and **3** in yields of 22% and 60%; in ethanol, **3** is almost suppressed but the yield of **1** is usually 60–70%.

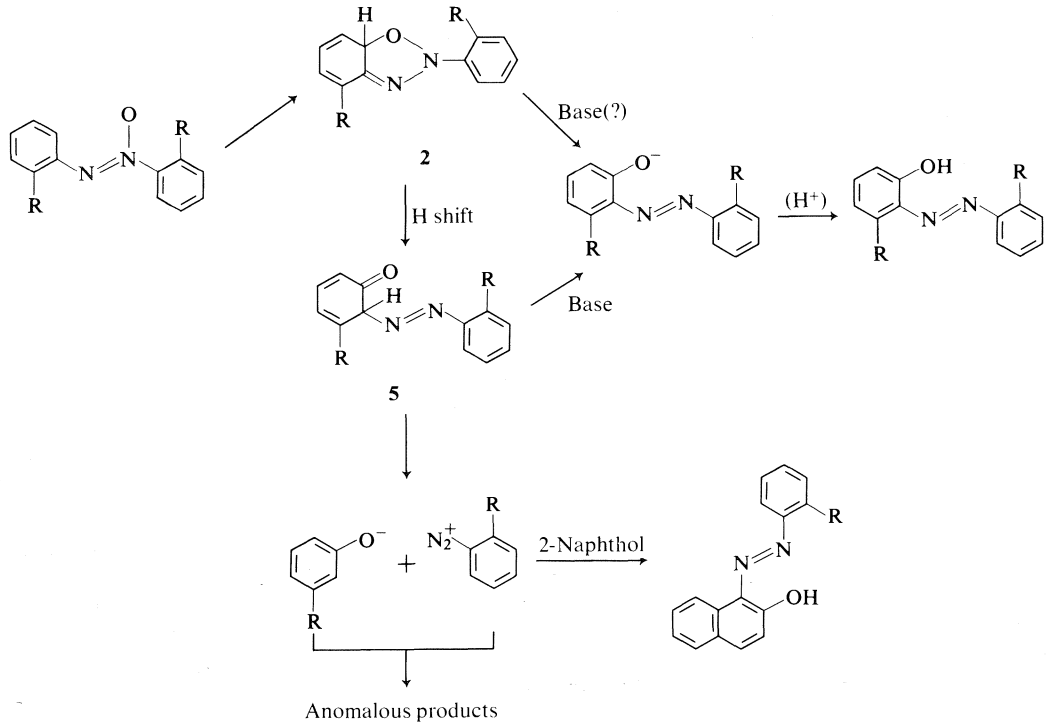
The complexity of the system increased with the finding that other reaction parameters affect the product distribution. In benzene solution, relatively more photorearrangement occurred as the percent conversion increased, although the rate of reaction declines with conversion due to competing light absorption by the products. This effect, which is most noticeable at small conversions, may be rationalized by noting that the azophenol products which accumulate in the (benzene) solution are the strongest bases present, more so than 2-naphthol (see Table 5). The situation may therefore be similar to that described above under solvent effects. This idea was tested by photolyzing azoxybenzene and 2-naphthol in the presence of *p*-hydroxyazobenzene; increasing the amount of *p*-hydroxy compound decreased the azonaphthol yield.

Especially at low azoxybenzene concentrations, the initial azoxybenzene concentration seems to influence the product spread, with more azonaphthol being formed at low substrate concentrations. Again, this may be an effect of conversion, but it is worth noting that in benzene solutions of azoxybenzene and 2-naphthol, ground state azoxybenzene is the strongest base present (14).

Light intensity was also found to affect the product composition, the amount of azonaphthol being greatest at low light intensities. Although the first excited state of azoxybenzene is a much stronger base than the ground state (17), it is unlikely that it survives long enough in solution to participate in bimolecular acid–base reactions in the absence of molecular association (for which there is no evidence). Likewise, postulation of a biphotonic process leading to photorearrangement but not to azonaphthol seems unlikely in view of the relatively high quantum efficiency of the normal photorearrangement. The effect of light intensity is thus unexplained at present.

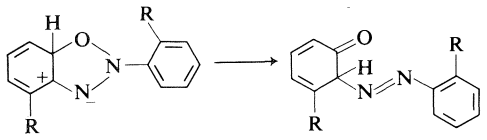
These experiments clearly require at least one intermediate to be formed between the disappearance of the excited singlet state of azoxybenzene and the production of the photorearranged isomer. Attempts to trap any intermediates by Diels–Alder reactions have been entirely unsuccessful, neither has it been possible to observe any intermediates by nmr following photolysis at low temperatures. Recently however, it has been disclosed that one, and under some conditions two, intermediates may be observed upon flash photolysis of azoxybenzene (18), though they are as yet unidentified.

Scheme 1 shows a possible pathway for the reaction that is compatible with our observations. Although it is possible that the Badger and Buttery intermediate **2** is the species with the dual reactivity, the intermediate **5** is chosen as that substance on the following grounds. (*i*) The proposed intermediate is the one that would be obtained by electrophilic attack of a diazonium ion at the *ortho* position of the phenol. Azo couplings are known to involve a reversible



SCHEME 1

addition step (19), the arylazo cation being a relatively good leaving group (20). (*ii*) Considering the resonance structure **6** of intermediate **2**, it might be expected that hydride migration to give **5** would be very facile. It is consistent with



6 **5**

this hypothesis that when 2,2′-azoxytoluene is photolyzed in ethanol-*O*-*d*, the recovered *m*-cresol contains no deuterium, *i.e.*, the hydrogen at C(2) does not come from the solvent. Perhaps related is the observation that 2,2′,4,4′,6,6′-hexamethylazoxybenzene affords no products on photolysis, even those emanating from diazonium ions, although the intermediate corresponding to **2** ought to be able to form, at least in principle, if steric effects are unimportant.

Conclusions

It has been shown that the azonaphthols that had previously been observed upon photolysis of *o*-substituted azoxybenzenes in the presence of 2-naphthol are formed quite generally when aromatic azoxy compounds are illuminated in non-basic solvents, particularly benzene. Free diazonium ions seem to be implicated, and the existence of at least one common intermediate is suggested in that both kinds of product derive from the same excited state of azoxybenzene. The presence in solution of weak bases can provide a self consistent (though probably not a unique) rationalization of the variations in product ratio that result from changes in solvent, substrate concentration, and extent of reaction. (With so many variables to be controlled, it is relatively difficult to obtain reproducible product ratios.) Thus, there exists a central intermediate, possibly **5**, that is capable of losing a proton to a very weak base to afford the *o*-hydroxyazo compound. In the absence of such a base, separation of a diazonium ion occurs and coupling with any available phenol gives the eventual products.

Returning to the original question, of whether diazonium ions are normally intermediates in the azoxybenzene photorearrangement, the answer seems to be no, at least in ethanol, the usual

solvent for the reaction, because ethanol is in this context a relatively strong base. In benzene solution however, diazonium ions are produced; some of these become free and lead by azo couplings to the anomalous products sometimes observed. Thus synthetically, side product formation can be minimized by effecting the photorearrangement in a solvent such as ethanol; in cases where the substrate contains *ortho* substituents, the side products can be suppressed still further by adding a base such as potassium hydroxide to the solvent.

Experimental

Photolytic procedures and methods for the separation and identification of photolysis products have been described in detail previously (4). In this work, photolyses were carried out without deoxygenation and with the light of a Hanovia 450 W medium pressure mercury arc filtered through Pyrex glass, except as noted otherwise. In preparative work, irradiations employed immersion well equipment with capacities of about 325 ml; photolyses on a smaller scale were run in ampoules or test tubes that were illuminated equally where appropriate using a merry-go-round. In either case, product mixtures were resolved by preparative tlc on silica gel (E. Merck #7747); for preparative scale irradiations carried out in the presence of 2-naphthol, the excess 2-naphthol was removed by washing with the stoichiometric amount of ~0.05 *M* aqueous NaOH. This procedure was shown not to affect the azophenols present. After separation, the bands were scraped off and eluted, either into chloroform (Soxhlet extractor) or by packing the sorbent in a short glass column and eluting with methanol, prior to evaporation and purification. In experiments conducted solely to obtain product ratios, the evaporated extracts were dissolved in ethanol, made up volumetrically, and analyzed spectrophotometrically. Absorption bands that were used for this purpose are recorded in Table 6.

Synthesis of Azoxy Compounds

Syntheses of azoxybenzene and 2,2′-azoxytoluene were described previously (4). Several compounds were prepared by reduction of the nitro compound with thallium–ethanol (21). These included 2,2′-diethylazoxybenzene, 2,2′-diisopropylazoxybenzene mp 27–28 °C (lit. (4) oil), 2,2′5,5′-tetramethylazoxybenzene mp 111–112 °C (lit. (22) mp 111 °C), 4,4′-dichloroazoxybenzene mp 155–156 °C (lit. (23) mp 156 °C), 4,4′-dimethylazoxybenzene mp 68.5–70 °C (lit. (24) mp 70 °C), and 3,3′-di-*tert*-butylazoxybenzene mp 49–50 °C, M^+ 310. *Anal.* calcd. for $C_{20}H_{26}N_2O$: C 77.38, H 8.44, N 9.02; found: C 77.65, H 8.47, N 9.17. The *m-tert*-butylnitrobenzene required for the latter preparation was obtained by conventional reactions from acetanilide. A published (24) modification of the Friedel–Crafts reaction gave *p-tert*-butylacetanilide, mp 167–169 °C (lit. (25) mp 169 °C), which was nitrated, deacetylated, diazotized, and deaminated (H_3PO_2).

2,2′-Bistrifluoromethylazoxybenzene was prepared by oxidation of *o*-trifluoromethylaniline with H_2O_2–CH_3CO_2H at room temperature. After purification by column chromatography (alumina) and recrystallization from ethanol, the yield of pale yellow needles, mp 87–88 °C, was 55%. Anal. calcd. for $C_{14}H_8F_6N_2O$: C 50.31, H 2.41; found: C 50.10, H 2.22. M^+ 334.

2,2′,4,4′,6,6′-Hexamethylazoxybenzene was prepared by the general method of Buncel and Cox (11). From oxidation of the azo compound with either H_2O_2–CH_3CO_2H or with *m*-$ClC_6H_4CO_3H$, the compound was obtained as yellow needles from ethanol, mp 89–90.5 °C (lit. (11) mp 63 °C). Elemental analysis and spectroscopic properties (uv, nmr, mass spectrum) agreed with those previously reported. A sample of the material of mp 63 °C was supplied by Dr. E. Buncel, and found to have mixture mp 87–89 °C in several proportions with the present substance. The discrepancy in mp is attributed to a difference in crystal form, the form of mp 63 °C being irregular granules.

1-Arylazo-2-naphthols

Photolysis products were compared with reference materials obtained by coupling the appropriate diazotized aniline with alkaline 2-naphthol. The following unreported reference compounds were prepared.

1-(o-Ethylphenylazo)-2-naphthol, red needles from ethanol, mp 122–123 °C; uv (EtOH) λ_{max} 482 nm (ε 19 600), 420 (11 000), 310 (7200); nmr ($CDCl_3$) δ 1.35 (t, J = 7 Hz, 3H, CH_3), 2.95 (q, J = 7 Hz, CH_2), 6.7–8.7 (m, 10 ArH), 16.5 (s, OH); ms m^+/e 276(M^+, 55%), 262(19), 261(100), 233(10), 143(57), 130(10), 128(10), 120(13), 119(43), 118(13), 115(68), 114(10), 105(20), 103(13). *Anal.* calcd. for $C_{18}H_{16}N_2O$: C 78.24, H 5.84, N 10.14; found: C 78.52, H 5.75, N 9.98.

1-(o-Isopropylphenylazo)-2-naphthol, dark red crystals with green glance from ethanol, mp 133–134 °C; uv (EtOH) λ_{max} 482 nm (ε 19 400), 419 (11 000), 311 (7300); nmr ($CDCl_3$) δ 1.35 (d, J = 6 Hz, 6H, CH_3), 2.50 (septet, J = 6 Hz, CH), 6.7–8.7 (m, 10 ArH), 16.6 (s, OH); ms m^+/e 290(M^+, 16%), 276(36), 158(13), 143(17), 134(12), 133(100), 132(16), 130(15), 118(13), 115(38). *Anal.* calcd. for $C_{19}H_{18}N_2O$: C 78.59, H 6.25, N 9.65; found: C 78.69, H 6.15, N 9.58.

1-(o-Trifluoromethylphenylazo)-2-naphthol, dark red needles from ethanol, mp 157–158 °C, also obtained as bronze platelets, mp 155–156 °C; uv (EtOH) λ_{max} 465 nm (ε 6200), M^+ 316. *Anal.* calcd. for $C_{17}H_{11}F_3N_2O$: C 64.56, H 3.51; found: C 64.12, H 3.42.

Substituted o-Hydroxyazobenzenes

Some of these were available from previous studies (4). All were obtained by photolysis of appropriate azoxy compounds and characterized by nmr (low field OH) and mass spectral fragmentation pattern. The following compounds had not been described previously.

2-Hydroxy-6,2′-diethylazobenzene, red needles from ethanol, mp 62.5–63.5 °C; uv (EtOH) λ_{max} 343 nm (ε 19 000), 240 (7400); ms m^+/e 254(M^+, 60%) 240(20), 239(100), 225(14), 121(71), 120(17), 119(41), 118(15), 106(31), 105(41), 103(36). *Anal.* calcd. for $C_{16}H_{18}N_2O$: C 75.56, H 7.13, N 11.01; found: C 75.32, H 7.13, N 11.04.

2-Hydroxy-2′,3,5′,6-tetramethylazobenzene, red needles from ethanol, mp 148–149 °C; uv (EtOH) 354 nm (ε 19 500); ms m^+/e 254(M^+, 92%), 253(33), 211(16), 149(19), 122(12), 121(100), 120(14), 106(14), 105(86), 103(13). *Anal.* calcd. for $C_{16}H_{18}N_2O$: C 75.56, H 7.13, N 11.01; found: C 75.36, H 7.02, N 11.05. Also obtained from the irradiation of 2,2′,5,5′-tetramethylazoxybenzene was a small yield of 2,2′,5,5′-tetramethylazobenzene, mp 118–119 °C (lit. (26) mp 119 °C), identified by mass spectrometry (M^+ 238) and by comparison with an authentic sample. The authentic sample was obtained by AgO oxidation (27) of 2,5-dimethylaniline; apart from the azocompound (15%) the oxidation also afforded a 5% yield of the previously unreported *1,4,5,8-tetramethylphenazine*, pale yellow needles from ethanol, mp 217–219 °C; uv (EtOH) λ_{max} 363 nm (ε 11 000), 274 (125 000); nmr (C_6D_6) δ 2.35 (s), 6.65 (s), ratio 4:1; ms m^+/e 236(M^+, 100%), 235(26), 221(18), 209(8), 118(M^{++}?, 6). *Anal.* calcd. for $C_{16}H_{16}N_2$: C 81.32, H 6.82, N 11.85; found: C 81.20, H 6.75, N 11.72.

2-Hydroxy-3,3′-di-tert-butylazobenzene and 2-hydroxy-5,3′-di-tert-butylazobenzene: the assignments of these compounds are not certain. More polar isomer: red needles from ethanol, mp 111–113 °C; nmr (CCl_4) δ 1.40, 1.43 (2s, *tert*-butyl), 6.8–8.2 (m, ArH), 12.5 (s, OH); M^+ 310. *Anal.* calcd. for $C_{20}H_{26}N_2O$: C 77.38, H 8.44, N 9.02; found: C 77.24, H 8.63, N 9.13. Less polar isomer: orange crystals from ethanol, mp 91–93 °C; nmr (CCl_4) δ 1.40, 1.42 (2s, *tert*-butyl), 6.8–7.9 (m, ArH), 13.7 (s, OH); M^+ 310. *Anal.* found: C 77.19, H 8.55, N 9.01.

2-Hydroxy-6,2′-bistrifluoromethylazobenzene, orange needles from ethanol, mp 128–130 °C; nmr (CCl_4) δ 7.0–8.1 (m, ArH), 12.6 (s, OH); M^+ 334. *Anal.* calcd. for $C_{14}H_8F_6N_2O$: C 50.31, H 2.41; found: C 50.28, H 2.47. Also obtained in this irradiation was the corresponding azo compound, *2,2′-bistrifluoromethylazobenzene*, mp 126–127 °C, as orange needles from ethanol, M^+ 318. *Anal.* calcd. for $C_{14}H_8F_6N_2$: C 52.84, H 2.53; found: C 53.12, H 2.77.

Electronic Effects on Azonaphthol Formation

The azoxy compound (2 mmol) and 2-naphthol (5 mmol) were irradiated in corked Pyrex test tubes for 28 h in benzene solution (40 ml). The mixtures were worked up by dilute base extraction and preparative tlc to give the results recorded in Table 7.

HMO Calculations on Azoxybenzene

The parameters used were $\alpha_N = \alpha + \beta_0$; $\alpha_{N(O)} = \alpha + 2\beta_0$; $\alpha_O = \alpha + 1.5\beta_0$; $\beta_{C-N} = 0.7\beta_0$; $\beta_{N-N(O)} = \beta_0$; $\beta_{N-O} = 0.8\beta_0$; $\beta_{N(O)-C} = 0.7\beta_0$. π-Bond orders follow, C—N then N(O)—C: ground state, 0.42, 0.31; first n,π* state, 0.38, 0.29; first π,π* state, 0.46, 0.36.

Effect of Varying the 2-Naphthol Concentration

Eight photolysis solutions were prepared by dissolving 2-naphthol (20–208 mg) in 3 ml aliquots of a solution of azoxybenzene (503 mg) in dry benzene (50ml). The solutions were irradiated for 2 h in corked Pyrex ampoules with the 450 W mercury arc, equal illumination being maintained through a merry-go-round which encircled the immersion well. After the usual work-up by preparative tlc, the average ratio of azonaphthol to 2-hydroxyazobenzene was 4.5 ± 0.06. No trend in the ratio was discerned over this concentration range.

Having established the constancy of the product ratio, the rates of reaction were monitored by following the production of the azonaphthol spectrophotometrically. Six aliquots (4 ml) of a solution of azoxybenzene (113 mg) in dry benzene were irradiated in the presence of 2-naphthol (11–158 mg) under similar conditions. After 2 h, the formation of azonaphthol was $3.42 \pm 0.09 \times 10^{-4}$ M. Values lower by more than two standard deviations were obtained when higher concentrations of 2-naphthol were used, probably because of competing light absorption.

Sensitization and Quenching

(i) In the Presence of Benzophenone

In order that light absorption by benzophenone should compete with the azoxy compound, the reactions were carried out in quartz ampoules using the unfiltered light of the 450 W mercury arc. Two millilitre aliquots of a solution of 2,2′-azoxytoluene (301 mg) and 2-naphthol (628 mg) in 25 ml of 2-propanol were irradiated for 1.5 h in sealed degassed quartz ampoules equipped with quartz to Pyrex graded seals. After the usual work-up, the following results were obtained.

	Ph_2CO (mg)			
Products	0	24	51	93
2,2′-Azotoluene	1.15	1.89	2.52	2.94
o-Hydroxyazotoluene	4.49	4.20	3.67	2.89
o-Tolylazonaphthol	7.23	6.38	5.88	4.61

In a similar experiment in which 2 ml aliquots of a solution of azoxybenzene (257 mg) and 2-naphthol (625 mg) dissolved in 25 ml of ethyl acetate were irradiated for 2 h in the presence of benzophenone (0–101 mg), the ratio of azonaphthol to hydroxyazo compound was 0.51 ± 0.04 (six samples).

TABLE 7. Products of irradiation of substituted azoxybenzenes with 2-naphthol

Substituents	Product (mg)			
	Azo compound	*o*-Hydroxyazo compound	Recovered azoxy compound	Azonaphthol

(ii) In the Presence of Quenchers

These experiments were done on a similar scale to those above. Some substances which had no effect on the product ratio were oxygen or anthracene (substrate 2,2′-azoxytoluene, solvent 2-propanol, quartz or Pyrex ampoules), *trans*-stilbene (substrate azoxybenzene, ethyl acetate solution), pyrene (substrate azoxybenzene, benzene solution). The relative proportion of azonaphthol was reduced in the presence of 2-methyl-1-butene or piperylene (substrate azoxybenzene, benzene solution), or heavy atom solvents (1-bromopropane or iodoethane in ethylacetate, substrate azoxybenzene; 1-bromopropane in ethanol or 2-propanol, substrate 2,2′-azoxytoluene) but increased when LiBr was added in large quantities (to 3 *M*) to solutions of 2,2′-azoxytoluene and 2-naphthol in ethanol.

Steric Effects

Ratios of *o*-hydroxyazobenzene derivatives to azonaphthols were obtained from experiments in which the azoxy compound (0.01 g/ml) was irradiated preparatively, in the appropriate solvent in the presence of 2-naphthol (0.05 g/ml). The reactions were worked-up by evaporation, extraction of a chloroform solution of the residue with ~0.05 *M* NaOH to remove excess 2-naphthol, and resolution by preparative tlc. Ratios of products are reported in Table 8.

Relative rates of azonaphthol formation were obtained by irradiating benzene solutions (100 ml) of the azoxy compound (0.50 mmol) and 2-naphthol (2.0 g). At 300–320 nm each azoxy compound had an absorbance > 20. Aliquots (3.5 ml) of each of the five solutions were irradiated simultaneously in a Rayonet photochemical reactor equipped with RUL 3000 lamps having maximal output at 300 nm. A 'merry-go-round' apparatus was used to ensure uniform illumination of the samples. Chamber temperature was 40 °C within about 3 min of striking lamps. The illuminated samples were examined by uv in the range 450–550 nm for azonaphthol formation. Table 2 records the average of five such determinations employing different irradiation times.

TABLE 8. Products of irradiation of 2,2′-disubstituted azoxy compounds with 2-naphthol in ethanol[a]

Substituents	Products (mmol)	
	o-Hydroxyazo compound	Azonaphthol
H	0.20	< 0.01
2,2′-$(CH_3)_2$	0.19	0.03
2,2′-$(C_2H_5)_2$	0.17	0.03
2,2′-$(C_3H_7)_2$	0.08	0.10
2,2′5,5′-$(CH_3)_4$	0.07	0.09

[a]The azoxy compound (1 mmol) and 2-naphthol (1.0 g) were irradiated in ethanol (20 ml) for 18 h.

The irradiation of 3,3′-di-*tert*-butylazoxybenzene (0.40 g) was done in ethanol solvent (325 ml) that was 0.25 *M* in KOH. After irradiation for 2 h, the solvent was evaporated and the residue acidified and extracted with chloroform. Preparative tlc yielded the two compounds described above (0.045 g each) and unreacted azoxy compound (0.28 g).

Solvent Effects

The concentrations used were azoxy compound: 10 mg/ml and 2-naphthol: 50 mg/ml. Results of these irradiations are given in Tables 3 and 4.

Variation of Initial Azoxybenzene Concentration

Aliquots (3 ml) of a solution of 2-naphthol (2.5535 g) in benzene (100 ml) were irradiated simultaneously in Pyrex ampoules for 3 h with different quantities of azoxybenzene. The usual work-up procedure afforded the results in Table 9.

Variation in Percent Reaction

In a typical reaction, 2 ml aliquots of a solution of azoxybenzene (253 mg) and 2-naphthol (834 mg) in ethyl acetate (25 ml) were irradiated on a merry-go-round for times varying from 2–100 h. The usual work-up gave the results in Table 10.

TABLE 9. Effect of variation of azoxybenzene concentration

[Azoxybenzene] (mg/ml)	Hydroxyazobenzene (mg)	Azonaphthol (mg)	Ratio
	Run 1		
3	0.49	3.32	5.5
7	0.53	4.15	6.2
12	0.66	4.77	5.8

1	21	0.60	0.19	0.26
2	20	1.04	0.42	0.33
3	24	1.42	0.77	0.44
4	22	1.15	0.61	0.53

Variation in Light Intensity

The reactant solution contained azoxybenzene (255 mg) and 2-naphthol (626 mg) in 25 ml ethyl acetate. Aliquots (2 ml) were placed in corked Pyrex ampoules which were clamped at a known distance from the lamp and irradiated by trial and error to comparable conversion. Work-up by the usual method gave the results in Table 11.

Effect of Added p-Hydroxyazobenzene

A solution of azoxybenzene (202 mg) and 2-naphthol (486 mg) was prepared with 25 ml benzene. Aliquots of this solution (3 ml) were irradiated with *p*-hydroxyazobenzene for 3 h. The usual analytical procedure gave the results in Table 12.

Attempts to Trap Intermediates

Solutions of azoxybenzene (1 g) in 20 ml of benzene were irradiated in the presence of substances such as maleic anhydride, dimethyl acetylenedicarboxylate, cyclopentadiene, and 1,3-cyclohexadiene. No products additional to those obtained in the absence of these substances were obtained.

Search for Intermediates by Nuclear Magnetic Resonance

This experiment was carried out in the laboratory of Dr. R. F. Childs. Solutions of azoxybenzene in perdeuterated toluene and in perdeuterated acetonitrile were irradiated at −50 °C for periods up to 3 h, then immediately examined by nmr, with the spectrometer probe already cooled to −70 °C. No new resonances were observed.

Irradiation of 2,2′-Azoxytoluene in Ethanol-O-d

Two solutions were prepared, each containing 2,2′-azoxytoluene (0.65 g), 2-naphthol (2.0 g), and ethanol-*O-d* (30 ml). Irradiation in Pyrex test tubes for 46 h gave ~50% conversion of the azoxy compound by tlc. The solvent was evaporated, ethanol (30 ml) added and

TABLE 12. Effect of added *p*-hydroxyazobenzene

p-Hydroxyazobenzene (mg)	Hydroxyazo compound I (mg)	Azonaphthol II (mg)	Ratio II/I
0	0.8	5.0	5.0
27	0.6	1.2	1.6
55	0.6	0.7	1.0
94	0.8	0.6	0.7

evaporated again, and the residue worked up by preparative glc (6 ft × ¼ in., 10% SE30 on Chromosorb W, 60/80, 150 °C). Only the peak corresponding to *m*-cresol was collected. Mass spectral analysis on the ratio of m^+/e 109 to m^+/e 108 gave the following results (average of five determinations): authentic *m*-cresol: 0.130 ± 0.002; reaction product *A*: 0.136 + 0.003; reaction product *B*: 0.132 ± 0.004.

Irradiation of 2,2′,4,4′,6,6′-Hexamethylazoxybenzene

The azoxy compound (5 mg/ml) and 2-naphthol (15 mg/ml) were irradiated together for 16 h. Periodic examination of the progress of the reaction by tlc showed only unchanged reactants and some tarry residue.

Acknowledgements

I wish to thank Mr. Jean-Pierre Schoch for assistance with the preparations of tetramethylazoxybenzene, *m-tert*-butylnitrobenzene and hexamethylazoxybenzene, Dr. E. Buncel for supplying a sample of the latter substance for comparison with our material, and Dr. R. F. Childs in whose laboratory the low temperature photolyses were carried out. I also thank the Ethyl Corporation for donating generous samples of *o*-ethylaniline and *o*-isopropylaniline and the National Research Council of Canada for financial support.

Electronic excited states of small ring compounds. IV. Bicyclo[2.1.0]pentanes by the photocycloaddition of cyclopropenes to olefins[1]

D. R. ARNOLD AND R. M. MORCHAT

The Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 10, 1976

D. R. ARNOLD and R. M. MORCHAT. Can. J. Chem. **55**, 393 (1977).

Direct irradiation of the charge-transfer complex between the cyclopropenes 3,3-dimethyl-1,2-diphenylcyclopropene (**3**) and 1,2,3-triphenylcyclopropene (**7**), and the electron deficient olefins dimethyl fumarate (**5**) and maleic anhydride (**11**) resulted in formation of the cycloadducts **6**, **12–15** which are the bicyclo[2.1.0]pentane derivatives. These products were also formed when the reaction was photosensitized by triplet–triplet transfer. The structure of the adducts rests largely upon the interpretation of ^{13}C and ^{1}H nmr spectra. Nuclear Overhauser effect studies were used to assign stereochemistry. The thermal stability of these new bicyclo[2.1.0]-pentane derivatives has been examined, particularly with regard to the ring-flipping process and the rearrangement to the corresponding cyclopentene derivatives.

D. R. ARNOLD et R. M. MORCHAT. Can. J. Chem. **55**, 393 (1977).

L'irradiation directe du complexe de transfert de charge entre les cyclopropènes diméthyl-3,3 diphényl-1,2 cyclopropène (**3**) et triphényl-1,2,3 cyclopropène (**7**), et des oléfines déficientes en électron comme le fumarate de méthyle (**5**) et l'anhydride maléique (**11**) conduit à la formation de cycloadduits **6**, **12–15** qui sont des dérivés bicyclo[2.1.0]pentanes. Ces produits se forment aussi lorsque la réaction est photosensibilisée par le transfert triplet–triplet. La structure des adduits a été déterminée principalement par l'interprétation des spectres rmn du ^{13}C et du ^{1}H. On a utilisé des études d'effet nucléaire Overhauser pour attribuer la stéréochimie. On a examiné la stabilité thermique de ces nouveaux dérivés bicyclo[2.1.0]pentanes particulièrement en ce qui a trait au processus d'inversion de cycle et de réarrangement en dérivés cyclopenténiques correspondants.

[Traduit par le journal]

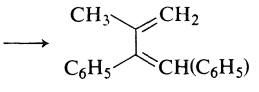
Introduction

When the vinyl diazo compound **1** was irradiated at long wavelengths ($340 < \lambda < 410$ nm), the cyclopropene **3** formed in nearly quantitative yield, (reaction 1) (1). Less than 1% of the dienes **4***a*, *b* were formed. This reaction is believed to involve the vinylmethylene or vinylcarbene **2** intermediate. In fact, the vinylmethylene (triplet) is produced upon irradiation of **1** at low temperature (4–30 K) and is stable under these conditions (2). On the other hand,

[1] 
1 **2** **3**

direct irradiation of the cyclopropene **3** produces the dienes **4***a*, *b* in nearly quantitative yield (reaction 2) and with a quantum yield of 0.045 (1). If the same intermediate was involved in reactions 1 and 2, the quantum yield of reaction 2 would require that *at least* 4% of the dienes **4***a*, *b* form during reaction 1.[2] This dichotomy has led us to propose that different pathways are involved in these two reactions.

[2] 
3 **2′**



4

(*a*) *cis*

(*b*) *trans*

[1]Contribution No. 159 from the Photochemistry Unit.

[2]That 4% be a lower limit is required since the quantum yield of formation of **2** from **3** may be less than unity.

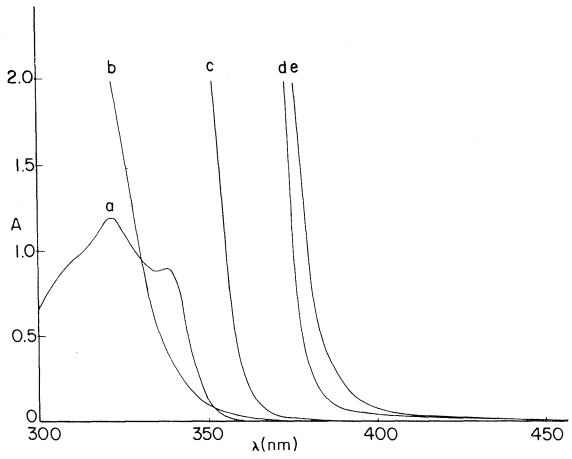


FIG. 1. Absorption curves for (*a*) **3** (2.75×10^{-4} *M*), (*b*) **5** (0.3 *M*), (*c*) filter solution *A* (see Experimental), (*d*) **3** (0.3 *M*), (*e*) **3** (0.3 *M*) and **5** (0.3 *M*). Curves (*a*) 0.1 cm cuvettes, (*b–e*) 1.0 cm cuvettes. Curves *a*, *b*, *d*, and *e* were obtained using benzene solutions.

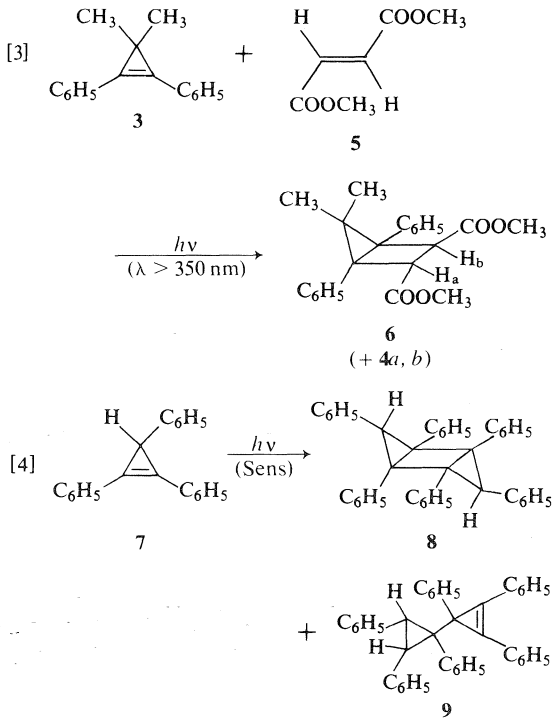
If two different intermediates are involved during reactions 1 and 2 there are several ways in which they might differ. For example, they might be structural isomers, they might be the singlet (carbene) and triplet (methylene) species, or they might have differing initial energy content. If the difference is due to spin multiplicity, conceivably these species could have different reactivity toward olefins. This criterion has traditionally been applied to distinguish other methylenes and carbenes[3] (3) and in fact there are reported examples of cycloaddition reactions of related vinylmethylenes or vinylcarbenes to olefins (4). We therefore attempted to trap an intermediate by carrying out both reactions 1 and 2 in the presence of dimethyl fumarate **5** (0.3 *M*, the limit of solubility in benzene) which is known to be a good dipolarophile.

In neither case were we able to detect an adduct resulting from trapping an intermediate. Furthermore, the quantum yield for the disappearance of cyclopropene **3** upon irradiation at 340 nm (near the maximum of the absorption of this cyclopropene, Fig. 1) remained 0.04 in the presence of dimethyl fumarate **5** (0.3 *M*).[4] We therefore conclude that if intermediates are involved in reactions 1 or 2, in neither case is the rate of reaction of the intermediate with dimethyl fumarate **5** (0.3 *M*) rapid enough to afford a detectable amount of adduct in competition with the formation of **3** and **4***a*, *b*.

While we were carrying out these experiments with reaction 2, we did, under some conditions, obtain a one-to-one adduct. This adduct has been shown to have the bicyclo[2.1.0]pentane structure **6** (reaction 3). This reaction represents



the first example of the photocycloaddition of a cyclopropene to an olefin. Previous work has shown that some cyclopropenes can dimerize to give tricyclo[3.1.0.$0^{2,4}$]hexanes upon irradiation; however, attempts to obtain cross-adducts have hitherto been unsuccessful (5). It has been suggested that the rate of reaction of the excited cyclopropene (triplet) with cyclopropene (ground state) is so rapid that observable cross-adduct formation is precluded (5*a*). The rate constant for the reaction of the triplet state of **7** with **7** (reaction 4) was found to be 1.1×10^8 l mol^{-1} s^{-1} (5*a*). Nevertheless, we have found conditions under which bicyclo-[2.1.0]pentane adducts can be formed from **7** in good yield.

These substituted bicyclo[2.1.0]pentanes are of interest in their own right, particularly with regard to the definition of the factors which

[3]The classic example of the application of this criterion is for the case of methylene *vs.* carbene.

influence the nature and strength of the central [0] bond in this class of compounds.

We report here: (*1*) the preparation and spectroscopic characterization of the adducts **6**, **12–15**; (*2*) the results of experiments which give an indication of the thermal stability of the central [0] bond in these compounds; and, (*3*) some preliminary results regarding the mechanism of the photocycloaddition reaction. A more thorough study of the scope and mechanism of the photocycloaddition reaction is now in progress and will be described later.

Results

Preparation of Adducts

A benzene solution of 3,3-dimethyl-1,2-diphenylcyclopropene **3** (0.3 *M*) and dimethyl fumarate **5** (0.3 *M*) has absorption at long wavelengths not present in the spectrum of the individual components at this concentration (Fig. 1). We attribute this long wavelength absorption to a charge-transfer complex transition. This solution was irradiated through chemical filter solution *A* which absorbs light of wavelengths shorter than 350 nm, Fig. 1 (reaction 3). The products were the known dienes **4***a*, *b* and the adduct to which we have assigned structure **6**.

When the irradiation was carried out without the filter solution (through Pyrex) so that a wavelength region including the cyclopropene absorption maximum was irradiated, the only products detected were the dienes **4***a*, *b*.

Presumably, if the charge-transfer complex could be irradiated without also exciting the cyclopropene, the ratio of adduct to dienes would increase. Unfortunately, the absorption due to the charge-transfer complex is not sufficiently separated from that of the cyclopropene to allow exclusive excitation at a convenient rate. Using chemical solution filter *B*, with a longer wavelength cut-off (<357 nm, Fig. 2) than that of *A*, some adduct **6** was formed after prolonged (122 h) irradiation; however, the extent of conversion was too small to allow a meaningful ratio of adduct to dienes to be determined. This filter solution was usually used in the sensitizer studies to be discussed below.

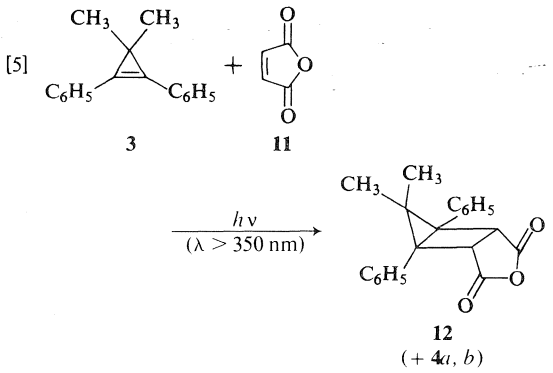
There was no evidence for charge-transfer complex formation between the cyclopropene **3** and dimethyl maleate **10**. A benzene solution of **3** (0.3 *M*) and **10** (0.3 *M*) had a long wavelength absorption curve which was superimposable upon that of a benzene solution of **3** (0.3 *M*) alone. When this solution was irradiated (filter *A*), the dienes **4***a*, *b* were the major products. The isomeric adduct(s) with the methyl ester groups *cis* was (were) not detected.

The photocycloaddition reaction can be sensitized by triplet–triplet transfer. For example, a benzene solution of **3** (0.3 *M*), **5** (0.3 *M*), and thioxanthen-9-one (0.01 *M*, $E_T = 65$ kcal mol^{-1} (6)) was irradiated through filter *A*. After 1 h, ^{1}H nmr analysis indicated the reaction was proceeding rapidly with formation of adduct **6** (14%) and *no* dienes (**4***a*, *b*). During this time,

10 (37%) was also formed by sensitized (triplet–triplet) isomerization of **5** (E_T *ca.* 61 kcal mol^{-1} (6)). Further irradiation increased the percentage of **10** to the reported (6) photosensitized stationary state (97% **10**) leaving a small amount of **5**. The photocycloaddition reaction became much less efficient; however, after 45 h all the cyclopropene **3** had been consumed leaving adduct **6** (74%) and dienes **4***a*, *b* (25%). No other adduct was detected.

The photosensitized (triplet–triplet transfer) isomerization of **5** is known to require sensitizers with triplet energy greater than 59 kcal mol^{-1} (6). When benzil (E_T = 54 kcal mol^{-1} (6)) or fluorenone (E_T = 53 kcal mol^{-1} (6)) were used as sensitizers for reaction 3, instead of thioxanthen-9-one, the photocycloaddition (filter *B*) went relatively rapidly (17 h) and completely to adduct **6** (*ca.* 100%) without complications due to sensitized isomerization of **5**.

The long wavelength region in the absorption spectrum of a benzene solution of the cyclopropene **3** (0.3 *M*) and maleic anhydride **11** (0.3 *M*), extends out to 420 nm (Fig. 2) which indicates charge-transfer complex formation occurs. Irradiation (700 h) of this solution through filter solution *A* gives an adduct to which we have assigned structure **12** (80%) along with the dienes **4***a*, *b* (20%) (reaction 5).



When this irradiation was carried out without the filter (through Pyrex) so that a wavelength region including the cyclopropene absorption maximum was irradiated, the only products detected were the dienes **4***a*, *b*.

The behaviour of cyclopropene **3**, upon both direct and triplet–triplet photosensitized irradiation (in the absence of added olefin), is very different from that of cyclopropene **7**. In contrast to **3**, which gives the dienes **4***a*, *b* upon

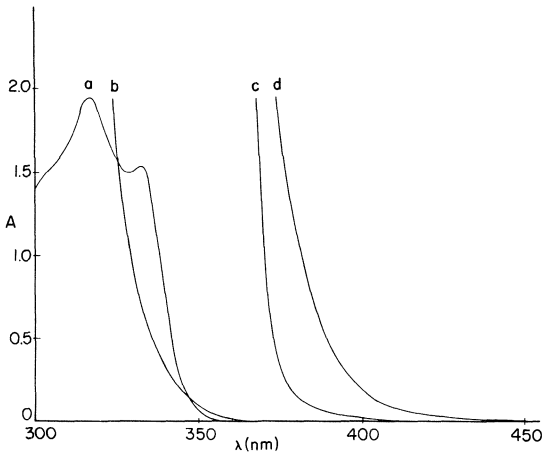


FIG. 3. Absorption curves for (*a*) **7** (6.70×10^{-4} *M*, the absorption maximum (λ = 312 nm) follows Beer's Law over the concentration range 10^{-4}–10^{-7} *M*), (*b*) **5** (0.3 *M*), (*c*) **7** (0.3 *M*), (*d*) **7** (0.3 *M*) and **5** (0.3 *M*). Curves (*a*) 0.1 cm cuvettes, (*b–d*) 1.0 cm cuvettes. The solvent was benzene.

direct irradiation (reaction 2), **7** is known to be stable under these conditions (5*a*). On the other hand, the triplet of **7** gives the dimers **8** and **9** (reaction 4) while no dimers are formed from the triplet of **3**. We therefore turned our attention to the study of the behaviour of **7** upon irradiation, direct and triplet–triplet sensitized, in the presence of **5**, **10**, and **11**.

A benzene solution of the cyclopropene **7** (0.3 *M*) and **5** (0.3 *M*) has long wavelength absorption not present in the spectra of the components (Fig. 3), indicative of charge-transfer complex formation. Irradiation (250 h) of this solution in the long wavelength region, through filter *A*, leads to formation of the one-to-one adduct as the major product (82%) to which we assign structure **13**; small amounts of the dimers **8** (9%) and **9** (9%) are also formed (reaction 6).[5]

These reactions can be sensitized (triplet–triplet transfer) using fluorenone; however, the ratio of adduct **13** to dimer **8** decreases under these conditions. Irradiation of a benzene solution of **7** (0.3 *M*), **5** (0.3 *M*), and fluorenone (0.1 *M*), through filter *B* until 83% of **7** was

[5]We have found that the ratio of the dimers **8**:**9** is not invariant. For example, the ratio of **8**:**9** obtained from reaction 4 depends upon the concentration of **7**; dilute solutions increase this ratio. This leads us to suggest that reaction 4 is more complex than was originally proposed (5*a*).

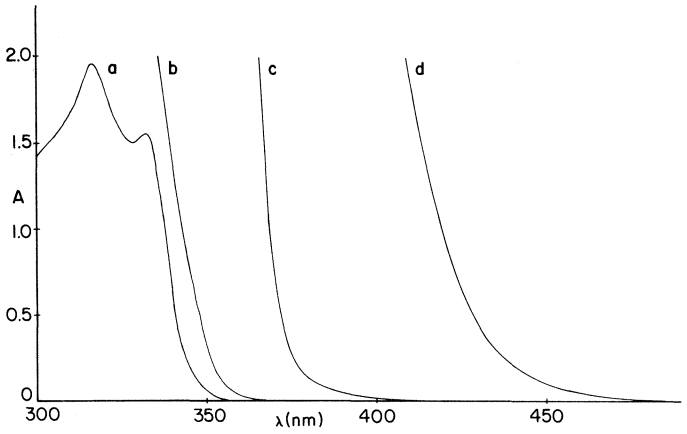

FIG. 4. Absorption curves for (*a*) **7** (6.70×10^{-4} *M*), (*b*) **11** (0.3 *M*), (*c*) **7** (0.3 *M*), (*d*) **7** (0.3 *M*) and **11** (0.3 *M*). Curves (*a*) 0.1 cm cuvettes, (*b–d*) 1.0 cm cuvettes. The solvent was benzene.

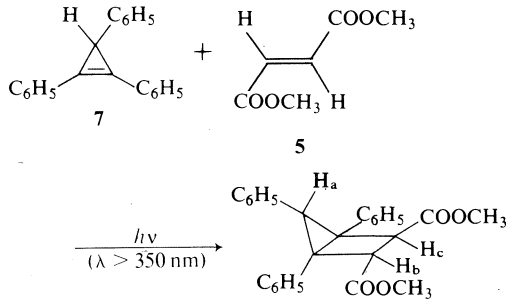
[6]



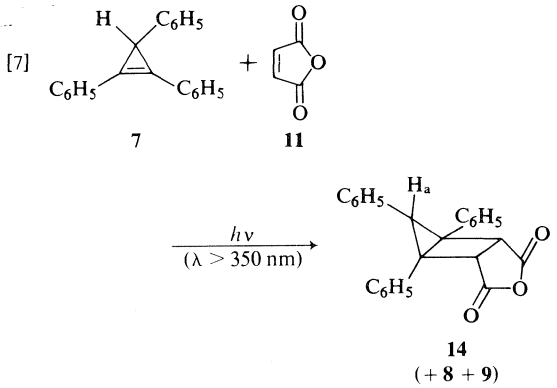
consumed, gave the products **13** (57%), **8** (14%), and **9** (12%). The ratio of **13** to dimer **8** was found to remain essentially constant (**13**/**8** = 3.5 ± 0.5) under sensitized (fluorenone) conditions, when the concentration of equimolar **7** and **5** was varied between 0.3–0.003 *M*.

A benzene solution of **7** (0.3 *M*) and **10** (0.3 *M*) showed only a very small increase in the long wavelength region of the absorption spectrum in comparison to that of the spectra of a benzene solution of **7** (0.3 *M*) alone. When this solution was irradiated (filter *A*) the dimers **8** and **9** were the major products. Some **5** and adduct **13** were also formed; however, no isomeric adduct(s) with the methyl ester groups *cis* was (were) detected.

A benzene solution of **7** (0.3 *M*) and **11** (0.3 *M*) was visibly coloured as a result of the charge-transfer complex absorption. The long wavelength absorption of this solution is shown in Fig. 4. Irradiation (188 h) of this solution through filter *B* gave a good yield (77%) of the adduct to which we have assigned structure **14**, along with some of the dimers, **8** (20%) and **9** (3%) (reaction 7).

This reaction was also sensitized by triplet–triplet transfer when fluorenone was added. The ratio of adduct **14** to dimer **8** again decreased under sensitized irradiation conditions. Irradiation (6 h) of a benzene solution of **7** (0.3 *M*) and **11** (0.3 *M*) and fluorenone (0.1 *M*), through filter *B* until the cyclopropene was consumed gave the following yield of products; **14** (60%), **8** (27%), and **9** (13%).

[7]

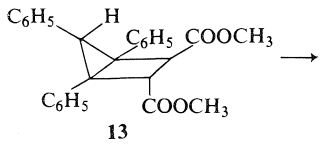


Thermal Stability of the Adducts

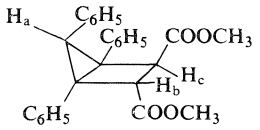
The adducts **6** and **12** are surprisingly stable thermally; little or no reaction was observed when solutions (*ortho*-dichlorobenzene) of these adducts were heated for several hours (5–15) at *ca.* 170 °C. In marked contrast, adduct **13** (reaction 6) is quite unstable thermally and rearranges quantitatively, even at room tem-

perature, to an isomer to which we have assigned structure **15**, (reaction 8). The progress of this

[8]



13



15

reaction was conveniently followed by ^{1}H nmr and the rate of isomerization as a function of temperature was determined. These data are given in Table 1. The kinetic parameters,

TABLE 1. The rate constants for the isomerization **13** to **15** in *ortho*-dichlorobenzene solution, as a function of temperature

T (°C)[a]	10^5k (s^{-1})[b]
71.18	7.53±0.30
72.38	8.19±0.17
77.47	15.22±0.37
81.00	21.57±0.57
84.02	30.45±0.50

[a]Measured with a copper–iron thermocouple (±0.02 °C).
[b]The rate, first order over 2–3 half-lives, was determined from a least-squares plot of at least six concentration measurements. The error limits are the calculated standard deviations.

$E_a = 26.9 \pm 0.6$ kcal mol^{-1} and $\log A = 14.7 \pm 0.4$, were determined from an Arrhenius plot (Fig. 5) of the data in Table 1. Prolonged heating of adduct **15** did cause further reaction ($t_{1/2}$ at 162 °C *ca.* 9 h). The structures of the products (reaction 9) have not been firmly established; however, the ^{1}H nmr, ultraviolet, and mass spectra are consistent with the cyclopentene derivatives **16** and **17**.

Adduct **14** is more thermally stable than **13**. The half-life of **14** at 76 °C is nearly 80 h. The products from **14** have not been fully characterized; however, from the ^{1}H nmr spectrum it is clear that an isomeric bicyclo-[2.1.0]pentane is not among them. We believe the products are isomeric cyclopentene derivatives analogous to **16** and **17** in reaction 9.

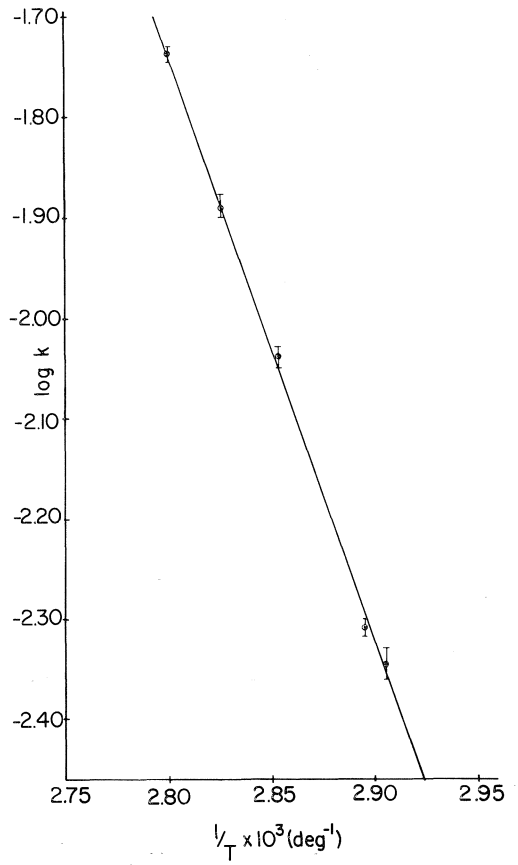


FIG. 5. Arrhenius plot for the isomerization **13** to **15**.

17

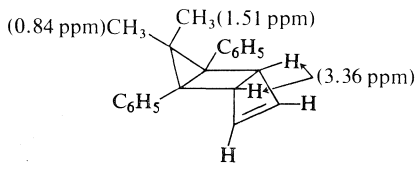
Proof of Structure of the Adducts

When adduct **6** was first obtained we initially suspected it to be the substituted cyclopentene derived from the cycloaddition of the vinylcarbene **2** (as a 1,3-dipole) to dimethyl fumarate. The ^{1}H nmr and infrared spectra were superficially in accord with such a structure. This structure was, however, easily ruled out because the ultraviolet spectrum of **6** gave no

indication of extended (*i.e.* styrene like) conjugation. The maximum at 221 nm (ε = 10 100) was typical of the phenyl chromophore. That the adduct was a one-to-one adduct was consistent with the elemental analysis, mass spectrum (*m/e* parent peak), and the molecular weight determined by the isopiestic method.

Convincing evidence for the bicyclo[2.1.0]-pentane structure for **6** came from analysis of the ^{13}C nmr spectrum. The assignments show clearly that only 14 (12 aromatic and 2 carbonyl) carbons are in the region expected for sp^2 hybridized carbon. The remaining nine carbons, (four methyl, three quaternary, and two methine (determined by off-resonance decoupling)) are sp^3 hybridized. The ^1H nmr spectrum is consistent with this assignment. The *trans*-ester stereochemistry is not only required, from the obvious lack of C_s symmetry which would be present in the *cis* isomer, but is consistent with the coupling of protons H_a and H_b (J_{ab} = 4 Hz) expected of the *trans* orientation. Double irradiation technique confirmed coupling between H_a and H_b. The signals due to the ester methyls and the methyls on the methylene bridge were assigned on the basis of chemical shift. The assignment of the *lower* field singlet to the *endo* methyl and the higher field doublet to H_a, also in the *endo*-position, was made by observing an increase in the intensity (18%) of the doublet (3.44 ppm) upon irradiation of the singlet (1.40 ppm). The intensity of the other doublet (4.02 ppm) was not affected by this double irradiation. Furthermore, double irradiation of the high field singlet (0.84 ppm) had no effect on the intensity of either doublet.

The magnitude of the observed increase in signal intensity, (nuclear Overhauser effect, nOe) is similar to that reported for the related structure **18** (7). The *exo* methyl group in **18** also occurs at higher field (0.88 ppm). An



18

nOe experiment revealed a 7% intensity enhancement in the allylic hydrogen absorption (3.36 ppm) upon saturation of the *endo* methyl singlet (1.44 ppm).

The structures of the other adducts were assigned in a similar fashion, and the ^{13}C and ^1H nmr spectral assignments are summarized in the Experimental section.

The stereochemistry of adduct **12** with the anhydride *exo* was established by observing a 8.4% nOe intensity enhancement of the singlet (3.47 ppm) assigned to the two equivalent hydrogens on the ethylene bridge, upon irradiation of the lower field methyl signal (1.50 ppm). No intensity enhancement was observed when the higher field methyl singlet (0.83 ppm) was double irradiated. This requires the anhydride to be in the *exo* position.

The assignment of configuration of adduct **13** having the *exo* phenyl on the methylene bridge was made by observing nOe enhancement (6.5%) of the singlet assigned to hydrogen H_a (3.15 ppm) upon double irradiation of the *higher* field doublet assigned to the *endo* hydrogen H_b (3.49 ppm). Conversely, double irradiation of the doublet (3.49 ppm) led to a 8.5% intensity enhancement of the signal due to H_a. Furthermore, double irradiation of the doublet due to H_c (4.17 ppm) had no effect on the intensity of the signal due to H_a.

The nmr (^{13}C and ^1H) spectra of **15** are similar to those of **13**. The isomeric nature of these compounds was apparent from the mass spectra (70 eV) which appeared to be identical. Isopiestic molecular weight determination confirmed the monomeric structure of **15**. Unlike **13**, however, double irradiation (nOe) of the signal assigned to hydrogen H_a (doublet, J = 0.7 Hz, 3.38 ppm) had no noticeable effect on the intensity of either of the signals assigned to hydrogens H_b (3.56 ppm) or H_c (4.40 ppm). The signal assigned to H_c is a doublet of doublets (J = 4.5 and 0.7 Hz). Double irradiation of this signal causes both the doublet assigned to H_a (J = 0.7 Hz) and the doublet for H_b (J = 4.5 Hz) to collapse to singlets. The configuration of **15** is such that H_a would be expected to be coupled to H_c. From this evidence we conclude that the more stable isomer has the phenyl on the methylene bridge oriented *endo* (**15**). This may be the result of the three phenyls in **13** being in close proximity, the relief of this steric interaction leads to **15** being more stable.

This observation causes us to open to question the structure of the tricyclohexane **8** obtained from reaction 4. The gross structure proposed (5*a*) for this compound is consistent with the

^{13}C nmr spectrum; however, no evidence has been provided which allows assignment of the configuration of the phenyl groups on the methylene bridges. In view of the relative stabilities of **13** and **15**, the phenyl groups on the methylene bridges of **8** may in fact be in the *endo*-position.

The assignment of configuration of adduct **14** having the *exo* phenyl on the methylene bridge and with the anhydride *exo* was established by observing a 11.8% nOe intensity enhancement of the singlet (3.59 ppm) assigned to the two equivalent hydrogens on the ethylene bridge upon irradiation of hydrogen H_a (3.06 ppm); furthermore, double irradiation of the singlet (3.59 ppm) led to a 20% intensity enhancement of the signal due to H_a. No coupling between the hydrogens on the ethylene bridge and H_a was observed; in contrast to **15**, in **14** the configuration is such that H_a would not be expected to be coupled.

Discussion

The long wavelength absorption spectra (Figs. 1–4), give an indication that charge-transfer complex formation occurs between the cyclopropenes **3** and **7** and dimethyl fumarate **5** and maleic anhydride **11**. There is no evidence from the absorption spectrum that a charge-transfer complex forms between **3** and dimethyl maleate **10** and, only a small increase in long wavelength absorption with a mixture of **7** and **10**. These observations are consistent with previous reports that dimethyl maleate is less prone to form charge-transfer complexes with olefins than are either dimethyl fumarate or maleic anhydride (8). The fact that **5** and **11** are reactive in the photocycloaddition reaction, while **10** is not, could be taken as an indication that the excited charge-transfer complex is a necessary intermediate leading to adduct formation. However, several observations negate this conclusion.

The small increase in long wavelength absorption may indicate some charge-transfer complexing occurs between **7** and **10**, yet adduct formation does not occur; however, dimers **8** and **9** are formed. The formation of the dimers **8** and **9**, in this reaction and in reactions 6 and 7, are typical of the triplet of **7** which suggests that irradiation of the charge-transfer complex between **7** and **5**, **10**, and **11** produces the triplet of **7**.

It is known that direct irradiation of **7** does not produce appreciable triplets (5*a*). Obviously, intersystem crossing is not able to compete with other processes which deactivate the excited singlet of **7**. In this connection we have observed intense fluorescence from **3** and **7** in rigid media at low temperature. Furthermore, the cyclopropene ring opening (reaction 2) is a singlet reaction. It may be that carbon–carbon bond breaking (or stretching) is a rapid non-radiative deactivation pathway of the singlet and some thermal activation is required for diene formation. A study of the effect of temperature on the quantum yield of diene formation (reaction 3) might answer this question. In any event, it seems likely that excitation of the charge-transfer complex serves to populate the cyclopropene triplet. There are several examples where irradiation of a charge-transfer complex leads ultimately to the triplet state of one of the components (9). This process has recently been reviewed (9*a*).

The singlet of cyclopropene **3** does not give the adduct with **5** or **11**; in fact, since the quantum yield of the disappearance of **3** upon direct irradiation near the cyclopropene maximum is not affected by **5** (0.3 *M*), the reaction ultimately yielding the dienes **4***a*, *b* is not significantly quenched by this concentration of olefin.

The triplet–triplet transfer sensitization experiments are consistent with adduct formation involving the cyclopropene triplet. The ratio of adduct **13** to dimer **8** does not vary when the concentration of equimolar **7** and **5** changes between 0.3 and 0.003 *M*. If adduct formation involved triplet–triplet transfer excitation of the charge-transfer complex, the amount of adduct formed should have decreased markedly upon dilution. On the other hand, if the cyclopropene triplet were involved the ratio of adduct to dimer should remain constant.

It is significant that the ratio of adduct **13** to dimer **8** is somewhat larger when the charge-transfer complex is excited than when the triplet of the cyclopropene **7** is obtained by triplet–triplet transfer. This observation is consistent with the rate of adduct formation, between the cyclopropene triplet and dimethyl fumarate, being competitive with diffusion, since the cyclopropene triplet formed from the excited charge-transfer complex must initially be next to dimethyl fumarate. Consistent with this view, the reported (5*a*) rate constant of triplet **7** with ground state **7** is close to the

diffusion limit; thus the binding energy between triplet **7** and dimethyl fumarate cannot be significantly larger than the barrier to diffusion.

The observation that dimethyl fumarate **5** leads to the *trans*-adducts **6** and **13** does not require the cycloaddition to be concerted (stereospecific). It may be that the second bond from a diradical intermediate is formed faster than bond rotation which would be required for formation of the *cis*-adducts; or, it may be that the *trans*-isomers are favoured as a result of thermodynamic, not kinetic factors. Knowledge of the extent of concertedness (stereospecificity) of these cycloadditions must await a case where both configurations of olefin undergo reaction.

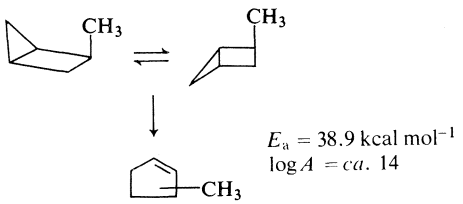
Dimethyl maleate **10** is known to be less reactive in other cycloaddition reactions than are dimethyl fumarate and maleic anhydride and this can account for the lack of adducts with **10** (10). A qualitative indication of the relative reactivities of dimethyl fumarate **5**, cyclopropene **7**, dimethyl maleate **10**, and maleic anhydride **11** with the triplet of **7**, can be obtained from the observed ratio of adduct to dimer **8** in the triplet–triplet transfer sensitized reactions. These product ratios indicate the relative rate constant of the cycloaddition reaction increases **10** < **7** (6×10^7 l mol^{-1} s^{-1} (*5a*)) < (*ca.* 4 times) **5** < (*ca.* 2 times) **11**. This conclusion, of course, assumes that the rate determining step is not reversible.

The stereochemistry of **13** from reaction 6 and **14** from reaction 7 indicates the photocycloaddition is sensitive to steric factors. The reactants approach minimizing steric hindrance so that the initial product is the less thermodynamically stable isomer.

In the photosensitized dimerization of **7** (reaction 4), two products are formed; the cycloaddition product **8** and the product of a photoene reaction **9** (*5a*).[5] We have not detected the photoene type product incorporating **5** or **11**.

The question regarding the nature and strength of the central bond in substituted bicyclo[2.1.0]-pentane compounds has been of interest for several years (11). We expect that the study of derivatives, readily available by the photocycloaddition reaction reported here, will help answer this question. However, the results of our study of the thermal stability of the adducts **6**, **12**–**15** are not easily explained.

The first reported study of the kinetics of *cis–trans*-isomerization, or ring-flipping process,

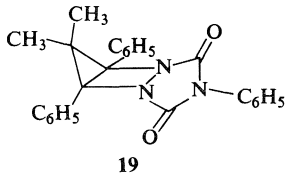


of a bicyclo[2.1.0]pentane was by Chesick who studied the 2-methyl derivative (11*a*). The barrier to isomerization was found to be 38.9 kcal mol^{-1}, significantly greater than the calculated value (19 kcal mol^{-1}) which assumed formation of a strain free cyclic diradical without bonding across the former central bond. The conclusion drawn from this result was that the transition state for the isomerization still maintained considerable strain energy as a result of incomplete rupture of the central bond.

If the radical stabilizing influence of the bridgehead phenyl groups is felt at the transition state for the ring-flipping process, the activation energy should be considerably lower. The thermal stability of the adduct **6** and **13** speak against a large decrease in the strength of the central bond.

The ring-flipping process in the case of **6** is a degenerate process and is therefore amenable to study by variable temperature ^{1}H nmr. Two techniques have been tried: (*1*) the signals due to the methyl groups on the methylene bridge are separated by 34 Hz, rapid exchange would be indicated by line shape analysis; (*2*) double irradiation of either signal would lead to decreased intensity of the other if exchange were occurring at a rate competitive with nuclear spin relaxation (nuclear magnetization transfer (13)). Both of these procedures have been applied in an attempt to detect the ring-flipping process of **6**; in neither case was there any indication of rapid flipping even at 190 °C.[6]

We have used these ^{1}H nmr techniques previously to study the ring-flipping process in the related 2,3-diazabicyclo[2.1.0]pentane system (*e.g.* **19**). We concluded that the diphenyl



19

[6]The ring-flipping process would have to be very rapid in order to be detected by these techniques (*i.e.* equilibration rate > *ca.* 0.5 s^{-1}).

derivative **19**, analogous to **6**, was isomerizing rapidly even at $-60\,^{\circ}C$ (13). The lack of rapid ring-flipping in the case of **6** now suggests that the urazole moiety plays a major role in decreasing the barrier to the flipping process in **19**.

The isomerization of **13** to **15** (reaction 8) provides the most dramatic indication that the ring-flipping process does occur in these derivatives. The activation energy for this process is 12 kcal mol^{-1} less than that reported for the flipping of 2-methylbicyclo[2.1.0]pentane. Once formed **15** has considerable stability toward further thermal rearrangement (reaction 9). This is consistent with the observation that the isomerization of bicyclo[2.1.0]pentane to cyclopentene has an activation energy 7.7 kcal mol^{-1} greater than the ring-flipping process with the 2-methyl derivative.

Throughout this discussion we have assumed the ring-flipping process involves change of configuration at the central bond; breaking the external cyclopropane bond should also be considered. There are some observations which support isomerization about the central bond. Reaction 9 certainly involves cleavage of the central bond and it seems reasonable to view reaction 8 as involving the same bond.[7] If the external cyclopropane bond were cleaving in reaction 8 there is no apparent reason why adduct **14** would not also rearrange at a low temperature to the *endo*-phenyl isomer analogous to adduct **15**. If, on the other hand, isomerization about the central bond is involved, the rearranged adduct would be less stable as a result of the proximate anhydride function. While adduct **14** is not particularly stable thermally, no isomeric bicyclo[2.1.0]pentane adduct was detected among the products.

Experimental Section

General

The melting points were determined on a Thermolyne hot-stage microscope and were not corrected. The combustion analyses were performed by Chemalytics, Inc., Tempe, Arizona.

Dimethyl fumarate was purchased from Aldrich Chemical Co. and recrystallized once from methanol.

Dimethyl maleate was purified by vapour phase chromatography.

Maleic anhydride was purchased from BDH and purified by recrystallization from chloroform followed by vacuum sublimation.

[7]To our knowledge no cyclobutene or methylene cyclobutane has ever been observed upon thermolysis of any bicyclo[2.1.0]pentane.

1,2,3-Triphenylcyclopropene was prepared from diphenylacetylene in 60–70% yield, via the *syn*-triphenylcyclopropenyl bromide which was reduced with lithium aluminum hydride, by the reported procedure (14).

Preparative thick layer chromatography was carried out on 2 mm layer plates of silica gel GF-254 (E. Merck) and developed with benzene. Bands were detected by viewing under uv light.

Molecular weight determinations by the isopiestic method were performed in benzene solutions using a Mecrolab Model 301A osmometer operating at 37 °C.

Mass spectra were recorded on a Varian M-66 or Mat 311A mass spectrometer and are reported as *m/e* (relative intensity). Unless diagnostically significant only the parent peak and base peak are reported.

The infrared spectra were run in carbon tetrachloride solution using 0.1 cm sodium chloride cells or in KBr disks on either a Beckman IR-5A or 20A spectrometer. The spectra were calibrated using the 1601 cm^{-1} absorption band of polystyrene.

The pmr spectra were determined on dilute solution of deuteriochloroform using tetramethylsilane as an internal reference. The spectra were obtained on a Varian HA-100 spectrometer. The chemical shifts are taken as the center of multiplets and the coupling constants are the result of first-order analysis.

The ultraviolet absorption spectra recorded as absorption against wavelength were run on a Cary 118 spectrometer in methanol using 1.0 cm quartz cuvettes unless otherwise noted.

The ^{13}C spectra were determined on solutions in deuteriochloroform (2–15% w/v) in 5 mm tubes using a Varian XL-100-15 system operating at 25.2 MHz in the Fourier transform mode. With 2000 Hz 'sweep widths' and the available memory core, the peak positions were determined to ± 1 Hz and measured relative to internal tetramethylsilane. Off-resonance decoupling was employed to confirm assignments for methyl, methylene, methine, and quaternary carbons.

Preparative irradiations were performed using a General Electric Co. 1 kW medium pressure mercury vapour arc lamp with a quartz cooling jacket which was immersed in a constant temperature bath maintained at 10 °C. All solutions were placed in Pyrex irradiation tubes, flushed with nitrogen, and sealed with a rubber septum.

Filter Solution A

$BiCl_3$ (200 mg) was dissolved in 10% HCl (150 ml) and this solution was placed in a container such that there was at least 1 cm of filter solution shielding the irradiation vessel. The long wavelength cut-off is shown in Fig. 1. The filter solution was photolabile and was replaced after 24 h irradiation.

Filter Solution B

Same as filter solution A except that a more concentrated solution of $BiCl_3$ was employed (800 mg $BiCl_3$ in 150 ml 10% HCl). The long wavelength cut-off is shown in Fig. 2.

Kinetic Measurements

Isomerizations were carried out in sealed thick-walled nmr tubes. The adduct was dissolved in 0.5 ml *ortho*-dichlorobenzene and placed in the tube which went through two freeze–pump–thaw cycles and was sealed.

The tubes were then placed in an oil-bath maintained

to ±0.02 °C by a Fisher Proportional Controller. The tubes were withdrawn at appropriate intervals and the extent of isomerization determined by analysis of the ^{1}H nmr spectra. At least six values were taken at each temperature. Activation parameters were calculated by standard methods.

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Dimethyl Fumarate

A solution containing 1.1 g (4.9 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene and 0.7 g (4.9 mmol) dimethyl fumarate in 17 ml benzene was irradiated through filter solution *A*. Progress of the reaction was monitored by periodic analysis of the ^{1}H nmr spectra. After 355 h irradiation almost all of the cyclopropene had been consumed (>97%) with the subsequent formation of the dienes **4***a*, *b* (11 and 31% respectively) and the photocycloadduct **6** (55%).

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Dimethyl Fumarate with 0.1 M Fluorenone Present as Sensitizer

A solution containing 330 mg (1.5 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene, 216 mg (1.5 mmol) dimethyl fumarate, and 90 mg (0.5 mmol) fluorenone in 5 ml benzene was irradiated through filter solution *A*. After 80 h irradiation a ^{1}H nmr spectrum of the reaction mixture revealed that all of the cyclopropene had been consumed. Remaining was the 1:1 adduct **6** (81%) and the dienes **4***a*, *b* (8 and 11% respectively).

By consecutive preparative thick layer chromatographic separations the adduct was isolated pure as a clear viscous liquid, **6**: ir (CCl_4) 2933, 1724, 1595, 1212, 1116, 904, and 698 cm^{-1}; uv λ_{max}(MeOH) 221 nm (ε 10 200); ^{1}H nmr δ_{TMS}($CDCl_3$) 0.84 (s, 3H), 1.40 (s, 3H), 3.38 (s, 3H), 3.44 (d, 1H, J = 4.4 Hz), 3.62 (s, 3H), 4.02 (d, 1H, J = 4.4 Hz), 7.0–7.7 ppm (m, 10H); ^{13}C nmr chemical shifts: bridgehead carbons, 41.6 and 44.7; methine carbons, 45.6 and 46.0; apex carbon, 30.7; *endo* methyl, 16.6; *exo* methyl, 23.1; ester methyls, 51.7 and 51.8; carbonyl carbons, 173.3; aryl carbons attached directly to bicyclopentane nucleus, 135.9 and 137.9; *ortho*, *meta*, and *para* carbons, 124.5–130.8 ppm; ms (70 eV), 364(2, M$^+$), 304(100). *Anal.* calcd. for $C_{23}H_{24}O_4$: C 75.80, H 6.64; found: C 75.99, H 6.68. *Mol. Wt.* calcd. for $C_{23}H_{24}O_4$: 364.42; found (isopiestic): 365.67.

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Dimethyl Maleate

A solution containing 410 mg (1.9 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene and 270 mg (1.9 mmol) dimethyl maleate in 6 ml benzene was irradiated through filter solution *A*. Progress of the reaction was monitored by periodic analysis of the ^{1}H nmr spectra. After 285 h irradiation 85% of the cyclopropene had been consumed with the subsequent formation of the dienes **4***a*, *b* (28 and 48% respectively). Also present was the adduct **6** (9%) which comes about from the photocycloaddition of the cyclopropene with dimethyl fumarate (produced via thermal isomerization of dimethyl maleate). No adduct with the esters *cis* was detected.

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Dimethyl Fumarate in the Presence of 0.01 M Thioxanthen-9-one as Sensitizer

A solution containing 33 mg (0.15 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene, 22 mg (0.15 mmol) dimethyl fumarate, and 1 mg (0.005 mmol) thioxanthen-9-one in 0.5 ml benzene was irradiated through filter solution *A*. The progress of the reaction was monitored by analysis of the ^{1}H nmr spectra.

Initially the reaction occurred rapidly with formation of adduct **6** (14%) and no dienes **4***a*, *b* being formed, but with 37% of the unconsumed dimethyl fumarate having been isomerized to dimethyl maleate. As the reaction proceeded more dimethyl maleate was formed leaving less dimethyl fumarate available to give the cycloadduct.

After 46 h irradiation all of the cyclopropene had been consumed. Present were the adduct **6** (74%) and the dienes **4***a*, *b* (9 and 17% respectively) with most (>95%) of the unconsumed dimethyl fumarate having been converted to dimethyl maleate.

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Dimethyl Fumarate with 0.1 M Benzil as Sensitizer

A solution containing 33 mg (0.15 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene, 21 mg (0.15 mmol) dimethyl fumarate, 10 mg (0.05 mmol) benzil, and 0.5 ml benzene was irradiated through filter solution *B*. After 18 h irradiation a ^{1}H nmr spectrum was taken which indicated that all the cyclopropene had been consumed with *ca.* 100% formation of the 1:1 adduct **6**. There was no appreciable formation of the dienes **4***a*, *b*.

Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene and 0.3 M Maleic Anhydride

A solution containing 500 mg (2.3 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene and 220 mg (2.2 mmol) maleic anhydride dissolved in 7.5 ml benzene was irradiated through filter solution *A* for 700 h. After irradiation the solvent was removed on a rotatory evaporator and the reaction mixture analyzed by ^{1}H nmr spectroscopy. The reaction mixture contained some unreacted cyclopropene (5%), the dienes **4***a*, *b* (17%) and the cycloadduct **12** (77%).

The reaction mixture was placed on a column packed with 60–120 mesh silica gel (BDH). Elution with benzene separated the adduct. Recrystallization from $CHCl_3$–hexane afforded pure **12**: mp 182–183 °C; ir (KBr) 2990, 1866, 1790, 1512, 1466, 1257, 1116, 912, 713, and 671 cm^{-1}; uv λ_{max}(MeOH) 220 nm; ^{1}H nmr δ_{TMS}($CDCl_3$) 0.83 (s, 3H), 1.50 (s, 3H), 3.47 (s, 2H), 6.90–7.40 ppm (m, 10H); ^{13}C nmr chemical shifts: bridgehead carbons, 46.2; methine carbons, 47.3; apex carbon, 33.6; *endo* methyl 14.9; *exo* methyl, 22.3; carbonyl carbons, 169.9; aryl carbons attached directly to bicyclohexane nucleus, 133.0; *ortho*, *meta*, and *para* carbons, 127.9–129.8 ppm; ms (70 eV), 318(1, M$^+$), 246(100). *Anal.* calcd. for $C_{21}H_{18}O_3$: C 79.22, H 5.70; found: C 78.90, H 5.73

Direct Irradiation of 0.3 M 3,3-Dimethyl-1,2-diphenylcyclopropene in the Presence of 0.3 M Maleic Anhydride

A solution containing 66 mg (0.3 mmol) 3,3-dimethyl-1,2-diphenylcyclopropene and 30 mg (0.3 mmol) maleic anhydride dissolved in 1 ml chloroform was irradiated for 1 h. Analysis of the ^{1}H nmr spectrum revealed 65% consumption of the cyclopropene and formation of the dienes **4***a*, *b* (23 and 43% respectively) with no formation of a cycloadduct.

Irradiation of 0.3 M 1,2,3-Triphenylcyclopropene with Equimolar and 0.16 M Dimethyl Fumarate in the Presence of 0.1 M Fluorenone as Sensitizer

Two solutions were prepared: (*a*) consisting of 40.1 mg (0.15 mmol) 1,2,3-triphenylcyclopropene, 22.3 mg (0.15 mmol) dimethyl fumarate, 9.9 mg (0.05 mmol) fluorenone in 0.5 ml benzene; and, (*b*) containing 40.7 mg (0.15 mmol) 1,2,3-triphenylcyclopropene, 11.5 mg (0.08 mmol) dimethyl fumarate, 9.9 mg (0.05 mmol) fluorenone in 0.5 ml benzene. Both solutions were irradiated through filter solution *B*. After 1 h irradiation the solvent was removed on a rotatory evaporator and the residues dissolved in $CDCl_3$. The extent of the reaction was determined by analysis of the ^1H nmr spectra.

The spectra revealed that in both solutions *ca.* 73% of the cyclopropene had been consumed. The amount of the adduct **13** decreased from 48% in solution (*a*) to 38% in solution (*b*). There was a corresponding increase in the amount of cyclopropene dimers **8** and **9** from 25% (13% and 12% respectively) in solution (*a*) to 35% (16% and 19% respectively) in solution (*b*).

Concentration Dependence on the Dimerization of 1,2,3-Triphenylcyclopropene in the Presence of Fluorenone as Sensitizer

Three solutions were prepared each containing 40 mg (0.15 mmol) 1,2,3-triphenylcyclopropene and 10 mg (0.05 mmol) fluorenone dissolved in 0.5, 5, and 50 ml benzene. These solutions were irradiated through filter solution *B*. After 5.5 h irradiation all the cyclopropene had been consumed. The solvent was removed on a rotatory evaporator and the residues dissolved in $CDCl_3$. The components of the reaction mixtures were determined by analysis of the ^1H nmr spectra. The concentration of the tricyclohexane dimer **8** increased, in the solutions containing the lower concentrations of cyclopropene, from 65% to 92% to 98% respectively. There was a corresponding decrease in the concentration of the cyclopropylcyclopropene dimer **9** from 35% to 8% to *ca.* 2%.

^{13}C nmr chemical shifts for **8**: bridgehead carbons, 51.5; apex carbons, 48.33; aryl carbons attached directly to tricyclohexane nucleus, 135.2 and 137.2; *ortho*, *meta*, and *para* carbons, 125.7–131.0 ppm.

Concentration Dependence on the Dimerization and Adduct Formation of 1,2,3-Triphenylcyclopropene in the Presence of Dimethyl Fumarate with Fluorenone as Sensitizer

Three solutions were prepared each containing 40 mg (0.15 mmol) 1,2,3-triphenylcyclopropene, 22 mg (0.15 mmol) dimethyl fumarate, and 10 mg (0.05 mmol) fluorenone dissolved in 0.5, 5, and 50 ml benzene. The solutions were irradiated through filter solution *B*. After 5 h the irradiations were stopped, the solvent removed on a rotatory evaporator, and the residues dissolved in $CDCl_3$. The extent of the reaction was determined by analysis of the ^1H nmr spectra.

The spectra revealed that *ca.* 83% of the cyclopropene had been consumed with formation of 57% of the adduct **13** and 26% of the cyclopropene dimers **8** and **9**. The concentration of the tricyclohexane dimer **8** increased in the solutions containing the lower concentration of cyclopropene from 14% to 23% and the concentration of the cyclopropylcyclopropene dimer **9** decreased from 12% to 3%.

Irradiation of 0.3 M 1,2,3-Triphenylcyclopropene and 0.3 M Dimethyl Fumarate

A solution containing 212 mg (0.8 mmol) 1,2,3-triphenylcyclopropene and 130 mg (0.9 mmol) dimethyl fumarate in 3 ml benzene was irradiated through filter solution *A*. Progress of the reaction was monitored by periodic analysis of the ^1H nmr spectrum. After 250 h irradiation all of the cyclopropene had been consumed. Formed were the cycloadduct **13** (82%) and the dimers **8** (9%) and **9** (9%).

By consecutive preparative thick layer chromatographic separations the adduct was isolated pure, **13**: mp 103–104 °C; ir (CCl_4) 3005, 2967, 1728, 1595, 1490, 1431, 1199, 1025, and 690 cm^{-1}; uv λ_{max}(MeOH) 219 nm (ε 21 500); ^1H nmr $\delta_{TMS}(CDCl_3)$ 3.15 (s, 1H), 3.38 (s, 3H), 3.49 (d, 1H, J = 4.2 Hz), 3.68 (s, 3H), 4.17 (d, 1H, J = 4.2 Hz), 6.39–7.43 ppm (m, 15 H); ^{13}C nmr chemical shifts: bridgehead carbons, 43.2 and 44.4; methine carbons, 47.7 and 49.9; apex carbon, 39.9; ester methyls, 51.8 and 51.9; carbonyl carbons, 171.9; aryl carbons attached directly to bicyclopentane nucleus, 136.0, 134.9, and 133.2; *ortho*, *meta*, and *para* carbons, 125.6–131.5 ppm; ms (70 eV), 412(1, M^+), 352(100). *Anal.* calcd. for $C_{27}H_{24}O_4$: C 78.62, H 5.86; found: C 78.55, H 5.55.

Irradiation of 0.3 M 1,2,3-Triphenylcyclopropene and 0.3 M Maleic Anhydride

A solution containing 82 mg (0.3 mmol) 1,2,3-triphenylcyclopropene, 29 mg (0.3 mmol) maleic anhydride in 1 ml benzene was irradiated through filter solution *B*. The solution was irradiated for 188 h, after which analysis of the ^1H nmr spectrum revealed that all the cyclopropene had been consumed with the subsequent formation of the photocycloadduct **14** (77%) and the cyclopropene dimers **8** (20%) and **9** (3%).

The solvent was removed on a rotatory evaporator and the resulting oil dissolved in minimal hot cyclohexane. Cooling of this solution resulted in precipitation of 108 mg slightly yellow crystals. Successive recrystallizations from cyclohexane afforded pure adduct **14**: mp 147–150 °C; ir (CCl_4) 2828, 2717, 1836, 1769, 1504, 1459, 1253, 1118, 1012, 956, and 694 cm^{-1}; uv λ_{max}(MeOH) 218 nm (ε 13 900); ^1H nmr $\delta_{TMS}(CDCl_3)$ 3.06 (s, 1H), 3.59 (s, 2H), 6.34–7.54 ppm (m, 15H); ^{13}C nmr chemical shifts: bridgehead carbons, 46.1; methine carbons, 50.6; apex carbon, 45.0; carbonyl carbons 169.0; aryl carbons attached directly to bicyclopentane nucleus, 134.3 and 132.8; *ortho*, *meta*, and *para* carbons, 124.8–131.1 ppm; ms (70 eV), 366(20, M^+), 294(100).

Exact mass calcd. for $C_{25}H_{18}O_3$: 366.1256; found (ms): 366.1264.

Irradiation of 0.3 M 1,2,3-Triphenylcyclopropene and 0.3 M Maleic Anhydride with 0.1 M Fluorenone Present as Sensitizer

A solution containing 82 mg (0.3 mmol) 1,2,3-triphenylcyclopropene, 30 mg (0.3 mmol) maleic anhydride, 18 mg (0.1 mmol) fluorenone in 1 ml benzene was irradiated through filter solution *B*. The progress of the reaction mixture was followed by analysis of the ^1H nmr spectrum at various time intervals. After 6 h irradiation, ^1H nmr analysis revealed that all of the cyclopropene had been consumed. Products formed were the photocycloadduct **14** (60%) and the two cyclopropene dimers **8** (28%) and **9** (13%).

Thermolysis of ***6***

A solution containing 30 mg (0.08 mmol) **6** dissolved in 0.5 ml *ortho*-dichlorobenzene was placed in a thick-walled nmr tube which was evacuated and sealed. The tube was placed in an oil bath maintained at 170 °C. Periodic checks of the solution by analysis of the ^{1}H nmr spectra revealed that even after 8 h heating no apparent change was observed.

Thermolysis of ***12***

A solution containing 5 mg (0.02 mmol) **12** dissolved in 0.5 ml *ortho*-dichlorobenzene was placed in a thick walled ^{1}H nmr tube which was evacuated and sealed. The nmr tube was placed in an oil bath maintained at 173 °C. Periodic checks of the solution by analysis of the ^{1}H nmr spectra revealed that even after 13 h heating no apparent change was observed.

Isomerization of ***13***

A solution of 31 mg (0.08 *M*) of **13** in 1 ml of *ortho*-dichlorobenzene in a thick walled ^{1}H nmr tube was sealed after three freeze–pump–thaw cycles. The tube was placed in a constant temperature oil bath which was maintained to ±0.02 °C by a Fisher Proportional Temperature Control Unit. The ^{1}H nmr spectra were evaluated periodically. The individual rate constants at each of the five temperatures are listed in Table 1. The rate constants were used in an Arrhenius plot to determine the activation parameters (Fig. 5).

Consecutive preparative thick layer chromatographic separations afforded pure rearranged adduct as a clear viscous oil, **15**: ir (CCl_4) 3040, 2960, 1735, 1600, 1433, 1202, 1006, and 693 cm^{-1}; ^{1}H nmr $\delta_{TMS}(CDCl_3)$ 3.27 (s, 3H), 3.38 (d, 1H, J = 0.7 Hz), 3.45 (s, 3H), 3.56 (d, 1H, J = 4.5 Hz), 4.40 (d of d, 1H, J = 4.5 and 0.7 Hz), 7.26–7.78 ppm (m, 15H); ^{13}C nmr chemical shifts: bridgehead carbons, 41.2; methine carbons, 42.3 and 44.8; apex carbon, 41.9; ester methyls, 51.1 and 51.9; aryl carbons attached directly to bicyclopentane nucleus, 133.6; *ortho*, *meta*, and *para* carbons, 127.4–130.9 ppm; ms (70 eV), 412(1, M$^+$), 352(100). *Anal.* calcd. for $C_{27}H_{24}O_4$: C 78.62, H 5.86; found: C 78.43, H 5.61. *Mol. Wt.* calcd. (isopiestic) of $C_{27}H_{24}O_4$: 412.46; found: 412.80.

Isomerization of ***15***

Heating of the solution used for the isomerization of **13** was continued, at <90 °C, till complete conversion to **15** occurred. This solution was then placed in a constant temperature oil. bath, maintained at 162.2 °C, and the progress of the thermolysis was followed by ^{1}H nmr spectroscopy. The isomerization ($t_{1/2}$ = 8.7 h) resulted in the formation of two products, **16** and **17**, (40 and 60%, respectively). After 69 h heating the tube was opened, the solvent removed on a rotatory evaporator, and the residue chromatographed on preparative tlc silica gel plates. Isolation afforded the two products **16** and **17** pure.

Evidence that these are the 1,2-diphenylcyclopentene isomers was obtained when both products generated a red colour when degassed methylcyclohexane–isopentane (4:1) solutions were irradiated at 5 °C with a 1 kW medium pressure mercury arc lamp, (indicative of dihydrophenanthrene formation).

The physical data are inconclusive in assigning the stereochemistry of the isomers.

Product 1: mp 109–110 °C; ir (CCl_4) 3043, 2945, 1737, 1436, 1204, 1170, 1100, 1033, and 698 cm^{-1}; uv λ_{max}(MeOH) 218 (ε 24 100), 260 (ε 12 900), 324 nm (ε 855); ^{1}H nmr $\delta_{TMS}(CDCl_3)$ 3.26 (s, 3H), 3.46 (s, 3H), 4.14 (d of d, 1H, J = 9.7 and 8.7 Hz), 4.81 (d of d, 1H, J = 9.7 and 0.9 Hz), 4.86 (d of d, 1H, J = 8.7 and 0.9 Hz), 6.94–7.40 ppm (m, 15H), ms (70 eV): 412(7, M$^+$); 352(100). *Exact mass* calcd. for $C_{27}H_{24}O_4$: 412.1674; found (ms): 412.1664.

Product 2: mp 136–137 °C; ir (CCl_4) 2996, 2934, 1726, 1422, 1183, 1158, 1088, 1021, and 687 cm^{-1}; uv λ_{max}(MeOH) 222 (ε 14 600), 251 nm (ε 10 000); ^{1}H nmr $\delta_{TMS}(CDCl_3)$ 3.58 (s, 3H), 3.62 (t, 1H, J = 6.4 Hz), 3.72 (s, 3H), 4.38 (d of d, 1H, J = 6.4 and 1.8 Hz), 4.62 (d of d, 1H, J = 6.4 and 1.8 Hz), 6.89 (m, 5H), 7.26 ppm (m, 10H); ms (70 eV): 412(7, M$^+$), 352(100). *Exact mass* calcd. for $C_{27}H_{24}O_4$: 412.1674; found (ms): 412.1670.

The sulfohaloform reaction. The stepwise conversion of dialkyl sulfides into alkanesulfonyl chlorides

J. STUART GROSSERT AND RICHARD F. LANGLER

Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 10, 1975[1]

J. STUART GROSSERT and RICHARD F. LANGLER. Can. J. Chem. **55**, 407 (1977).

A thorough examination of the aqueous oxidative chlorination of 1,3,5-trithiane is described. The results are utilized to explore and delineate the scope of a general, stepwise, oxidative cleavage reaction of dialkyl sulfides in which they are successively halogenated and oxidized to α-polychlorosulfoxides; subsequently, these cleave to form sulfinyl chlorides, which hydrolyze and become further oxidized to yield alkanesulfonyl chlorides. The overall stepwise process is named the 'Sulfohaloform reaction' and the structural requirements of the substrates at each step are explored in detail. A practical, general synthesis of sulfonyl chlorides is presented.

J. STUART GROSSERT et RICHARD F. LANGLER. Can. J. Chem. **55**, 407 (1977).

On a examiné la chloruration oxydative du trithiane-1,3,5 effectuée en phase aqueuse. On utilise les résultats obtenus pour explorer et délimiter l'étendue d'une réaction de clivage oxydative générale qui s'opère par étape et au cours de laquelle des sulfures de dialkyles sont successivement halogénés, oxydés en sulfoxyde d'α-polychlorés et par la suite clivés de façon à fournir des chlorures de sulfinyles qui par hydrolyse et oxydation subséquentes peuvent être transformés en chlorures d'alkanesulfonyles. On a appelé ce processus global par étape 'réaction sulfohaloformique' et on a déterminé en détail les conditions de structures du substrat qui sont nécessaires à chaque étape. On présente une synthèse générale et pratique des chlorures de sulfonyle.

[Traduit par le journal]

Introduction

Some time ago, we outlined (1) the preliminary results from a study of the pathway by which 1,3,5-trithiane, **1**, is converted upon treatment with molecular chlorine in aqueous media, into chloromethanesulfonyl chloride, $ClCH_2 \cdot SO_2 \cdot Cl$, **2**. We now wish to report the results in detail.

In 1940, Lee and Dougherty (2) reexamined the chlorination of 1,3,5-trithiane **1** in aqueous medium, which had originally been reported on by Kostsova (3) in 1935. Lee and Dougherty concluded that 1,4-dichloro-2,3-dithiabutane might be an intermediate and showed that no sulfone could be intervening. In a subsequent study, Douglass *et al.* (4) concluded that chloromethanesulfenyl chloride might be a short-lived intermediate.

Results and Discussion

The Aqueous Chlorination of 1,3,5-Trithiane

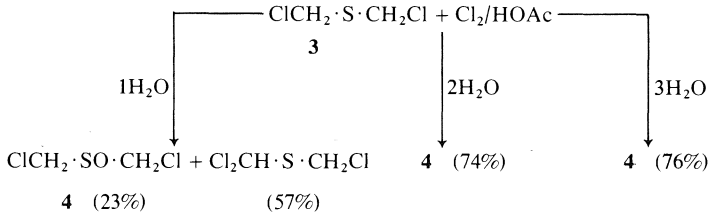
When we attempted to prepare **2** using the Lee and Dougherty procedure, it became obvious that **2** was grossly contaminated by other products and the mixture could not be separated conveniently. The nature of these other products was revealed by carrying out a partial chlorination of **1**, from which it was ascertained that no **2** had been formed but rather a number of intermediate products as detailed in Table 1. The results suggested the intermediacy of 1,3-dichloro-2-thiapropane, **3**, and this was confirmed by exhaustive chlorination of **3** in aqueous acetic acid from which **2** was isolated in 70% yield. Since Lee and Dougherty had already shown that oxidative chlorination of sulfides into sulfonyl chlorides did not proceed via sulfones, it became apparent that a study of the pathway of this conversion could be fruitful. In particular, the question as to whether C—S bond cleavage and S—Cl bond formation occurred at the sulfenyl or sulfinyl oxidation level was intriguing. Answers to these questions were obtained from a detailed examination of what emerged as a stepwise pathway by which the dichlorosulfide **3** is converted into the sulfonyl chloride **2** upon chlorination in aqueous medium. The study began with chlorination of the dichlorosulfide **3** in glacial acetic acid with varying water–sulfide ratios. This reaction provided the results shown in Scheme 1.

[1]Revision received September 20, 1976.

TABLE 1. Products from partial chlorination of 1,3,5-trithiane (1 mol) in glacial acetic acid containing water (5 mol)

Product*	Yield (g)	Number of moles isolated	Yield (%)
CH_2O	0.52	0.14	14
CO_2	0.57	0.11	11
$ClCH_2OAc$ (41, 42)	2.29	0.18	18
$ClCH_2{\cdot}O{\cdot}CH_2Cl$ (43, 44)	1.49	0.11	22
$ClCH_2{\cdot}S{\cdot}CH_2Cl$ **3** (40)	8.00	0.53	53
$ClCH_2{\cdot}SS{\cdot}CH_2Cl$	†	0.06	6
Unreacted $(CH_2S)_3$ **1**	1.00	0.06	6

*No CCl_4, $CHCl_3$, CH_2Cl_2, HCO_2H, $ClCH_2{\cdot}SO_2{\cdot}Cl$, or $ClCH_2{\cdot}S{\cdot}Cl$ was detected.
†Yield determined on a separate run.

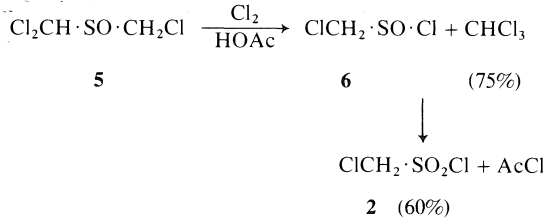


SCHEME 1

These experiments conclusively established 1,3-dichloro-2-thiapropane-2-oxide, **4**, as the next intermediate in the sequence. In a similar manner, chlorination of the dichlorosulfoxide **4** established the intermediacy of 1,1,3-trichloro-2-thiapropane-2-oxide ($Cl_2CH{\cdot}SO{\cdot}CH_2Cl$, **5**) as the subsequent intermediate.

When the trichlorosulfoxide **5** was chlorinated in aqueous acetic acid, only chloromethanesulfonyl chloride, **2**, could be obtained. Although Lee and Dougherty (2) had demonstrated that some sulfones were inert to chlorine–water oxidation, we prepared 1,1,3-trichloro-2-thiapropane-2,2-dioxide and subjected it to chlorination in aqueous acetic acid, from which it was recovered unchanged. Hence it was clear that the intermediate sulfoxide(s) must have reacted with chlorine and cleaved to furnish chloromethanesulfinyl chloride, **6**. Since sulfinyl chlorides are readily hydrolyzed to sulfinic acids (5), it would have been futile to attempt the isolation of **6** from aqueous medium. When the trichlorosulfoxide **5** was chlorinated in dry acetic acid, chloromethanesulfinyl chloride, **6**, could be observed in the nmr of the crude reaction mixture. This was demonstrated by adding authentic **6** to a sample of the crude and following the change in intensity of the chloromethyl signal.

Attempts to isolate the sulfinyl chloride **6** from acetic acid solution were unsuccessful. However, further chlorination led to a good conversion of **6** to the sulfonyl chloride **2** which could be isolated without difficulty.

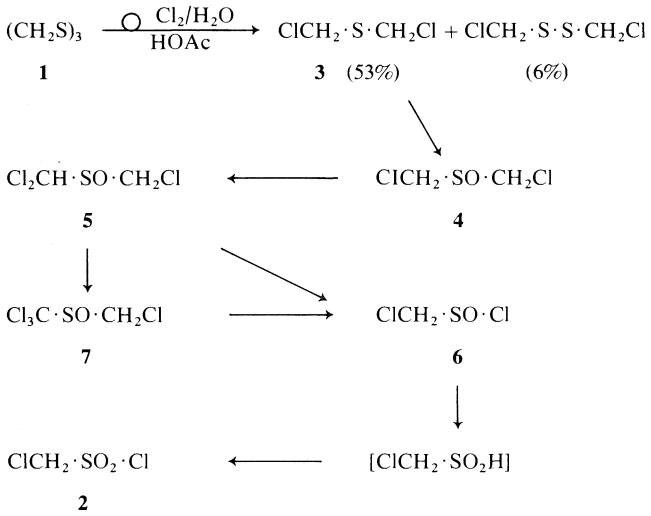


In order to obviate the difficulties experienced in isolating **6** from acetic acid, the trichlorosulfoxide **5** was chlorinated in methylene chloride which permitted the isolation of **6** without complication.

A summary of the pathway for the conversion of 1,3,5-trithiane, **1**, appears in Scheme 2. The grounds for including 1,1,1,3-tetrachloro-2-thiapropane-2-oxide, **7**, in Scheme 2 are presented later.

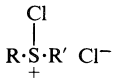
Mechanisms of Sulfide and Sulfoxide Chlorinations

Mechanisms for the various steps outlined in Scheme 2 are available from previous work. The pathway by which 1,3-dichloro-2-thiapro-

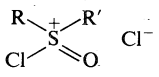


SCHEME 2

pane, **3**, is converted to the corresponding sulfoxide involves chlorosulfonium chloride salt **8** formation prior to nucleophilic attack by water on the sulfur atom of the sulfonium salt. This reaction has ample precedent (6–10). The intermediacy of a species with a sulfur–chlorine bond is supported in a more direct fashion by later work in which chlorination of selected sulfides has been shown to furnish sulfenyl chlorides (11–18).



8



9

The mechanism for the Pummerer rearrangement of chlorosulfonium chlorides has been carefully examined by Wilson *et al.* (13, 14). The mechanism basically involves an E2 type elimination of HCl from the intermediate chlorosulfonium chloride salt with attack by chloride ion on the resultant carbonium-sulfonium ion.

The chlorination of sulfoxides has received a great deal of attention (19–30) since 1968 and this now includes stereochemical studies (24, 27) also. These have led Montanari's group to postulate that the intermediate oxochlorosulfonium chloride **9** undergoes simultaneous proton abstraction and chlorine atom migration to furnish the α-chlorosulfoxide.

Our own observations that α-trichlorosulfoxides, such as **5**, furnish sulfinyl chlorides and chlorocarbons upon chlorination in methylene chloride are the most direct evidence available that the chlorination of sulfoxides proceeds through an intermediate species having a sulfur–chlorine bond.

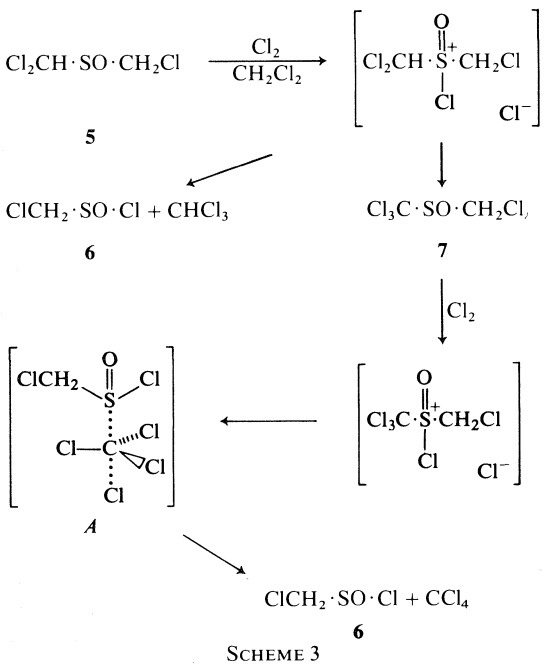
The Chlorine-induced C—S Cleavage Reaction of α-Polychlorosulfoxides

Although the reactions of sulfides and sulfoxides with chlorine to furnish α-chloro compounds via Pummerer rearrangements and/or to hydrolyze to give sulfoxides or sulfones had been observed previously, the cleavage reaction of the α-polychlorosulfoxide **5** had not been previously reported. We therefore examined it in some detail, by comparison of products formed in three solvents of different polarities.

Chlorination of **5** in methylene chloride furnished chloromethanesulfinyl chloride, **6** (72%), chloroform (53%), and carbon tetrachloride (11%). Direct cleavage of the oxochlorosulfonium chloride salt derived from **5** gives **6** and chloroform. However, the presence of carbon tetrachloride as a product implicated the intermediacy of the tetrachlorosulfoxide **7** (see Scheme 3).[2]

Chlorination of the trichlorosulfoxide **5** in glacial acetic acid furnished chloromethanesulfinyl chloride (isolated as the sulfonyl chloride) and chloroform. No carbon tetrachloride was formed indicating that direct

[2]An alternative formulation in which trichloromethyl carbanion ($:\bar{C}Cl_3$) is displaced by attack of Cl^- at sulfur in **7** is untenable in view of the product distribution when **10** or **11** are chlorinated (*vide infra*).



SCHEME 3

cleavage rather than Pummerer-type rearrangement is more favored in acetic acid than in the less polar methylene chloride.

By contrast, the results in [1] showed that chlorination of **5** in water permitted solvolysis to compete with cleavage by chloride ion.

[1] $Cl_2CH\cdot SO\cdot CH_2Cl \xrightarrow[H_2O]{Cl_2}$ (**5**)

$ClCH_2\cdot SO_2Cl + CHCl_3 + CCl_4 + CO_2$

2 (65%) (6%) (10%) (67%)

see footnote 3

The isolation of carbon dioxide indicated that much of the cleavage occurred by nucleophilic attack of water on the most electrophilic carbon atom of the intermediate oxochlorosulfonium chloride salt. The nucleophilic competition observed when the chlorinations were carried out in aqueous media is the basis for treating the cleavage step as an ionic rather than free-radical reaction.

Chlorination of the tetrachlorosulfoxide **7** in water afforded chloromethanesulfonyl chloride **2** (68%), carbon tetrachloride (20%), and carbon dioxide (60%). Simple calculations permit the formulation of a detailed pathway for the chlorination of **5** in water (see Scheme 4).

The reactions which involve sulfinyl chloride intermediates in aqueous medium are assumed to proceed through the sulfinic acids. However, in dry acetic acid, sulfinic acids cannot intervene. Amongst the mechanistic possibilities is the elimination of HCl from the intermediate oxodichlorosulfonium chloride salt **9** to furnish an intermediate analogous to sulfene (31). Should this have been the case, then chlorination of a sulfinyl chloride in acetic acid-d_1 would have furnished monodeuterated sulfonyl chloride. In fact, chlorination of methanesulfinyl chloride in acetic acid-d_1 furnished undeuterated methanesulfonyl chloride, thereby requiring acetolysis of the intermediate oxodichlorosulfonium chloride or, alternatively, the formation of a sulfinate–acetate mixed anhydride before reaction with molecular chlorine.

Hence, the complete pathway for the conversion of 1,3-dichloro-2-thiapropane, **3**, into chloromethanesulfonyl chloride, **2**, has been established and the cleavage step shown to occur on 1,1,3-trichloro-2-thiapropane-2-oxide, **5**. It seemed appropriate at this point to examine the structural requirements of the chlorosulfoxide substrates in general in terms of the cleavage step. It will be shown in the ensuing sections how both α-chlorosulfides and -sulfoxides, or just simply dialkylsulfides, may be subjected to stepwise chlorination, oxidation, and cleavage steps, leading ultimately to sulfonyl chlorides, by a process which we propose is aptly named the 'sulfohaloform reaction'.

Chlorination of Methyl Sulfoxides

In order to complement the work described above on α,α′-polychlorosulfoxides, 1,1-dichloro-2-thiapropane-2-oxide, **10**, was chlorinated in methylene chloride and the results in [2] were obtained.

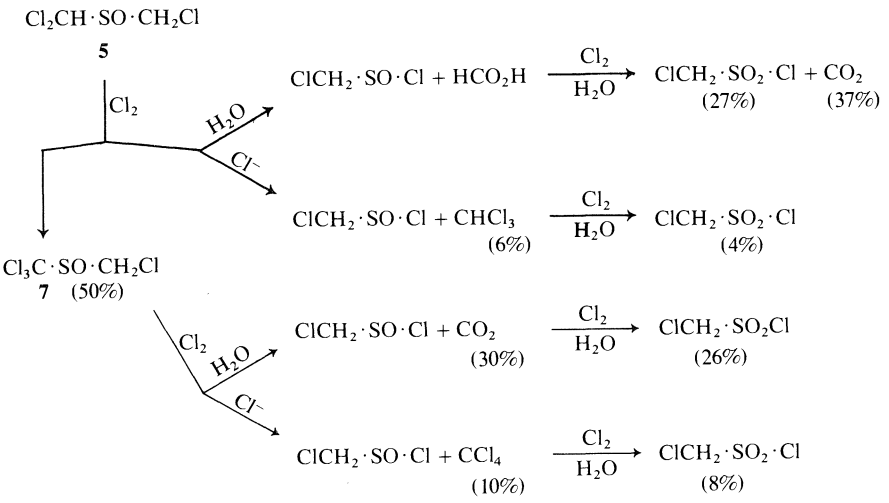
[2] $Cl_2CH\cdot SO\cdot CH_3 \xrightarrow[CH_2Cl_2]{Cl_2}$ (**10**)

$CH_3\cdot SO\cdot Cl + CCl_4 + CHCl_3$

(76%) (55%) (12%)

Since carbon tetrachloride was formed it is obvious that most of the cleavage reaction was occurring on the more highly chlorinated sulfoxide **11**. Similar results were observed when either **10** or **11** were chlorinated in glacial

[3]Formic acid is readily oxidized to carbon dioxide under the reaction conditions.



SCHEME 4

acetic acid:

	$CH_3 \cdot SO_2 \cdot Cl$	CCl_4	AcCl
$Cl_2CH \cdot SO \cdot CH_3$ (**10**) Cl_2/HOAc →	75%	76%	67%
$Cl_3C \cdot SO \cdot CH_3$ (**11**) →	86%	70%	70%

Hence, when cleavage occurs via nucleophilic attack by chloride ion, it is necessary for the sulfoxide substrate to have at least three α-chlorine atoms, regardless of the substitution pattern. It is interesting to note that the third chlorine atom is approximately equally effective in promoting smooth chlorinolysis of the sulfoxide (in methylene chloride or acetic acid) either when it is deployed to increase the electrophilicity of the carbon atom undergoing nucleophilic attack (*e.g.* **11**) or when it is located in a position which enhances the electronegativity of the leaving group (*e.g.* **5**).

Chlorination of **10**, **11**, and **7** in water furnished markedly different results, as follows:

Cl_2/H_2O	$CH_3 \cdot SO_2 \cdot Cl$	**2**	CCl_4	CO_2
$Cl_2CH \cdot SO \cdot CH_3$ (**10**) →	70%	40%	22%	68%
$Cl_3C \cdot SO \cdot CH_3$ (**11**) →	50%	24%	20%	56%
$Cl_3C \cdot SO \cdot CH_2Cl$ (**7**) →	0%	68%	20%	60%

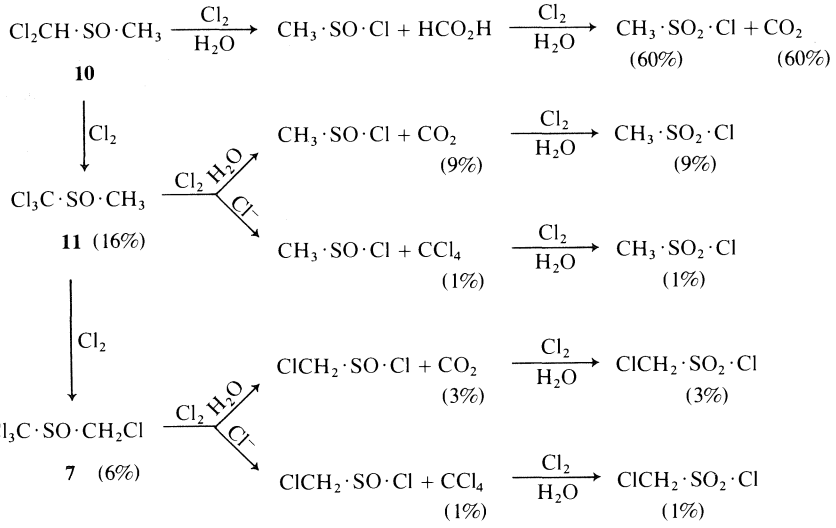
The intermediacy of **11** in the chlorination of **10** and of **7** in the chlorination of **11** was established by isolating **11** and **7** from the chlorination. A straightforward analysis permits the formulation of a detailed pathway for the reaction of **10** with chlorine in water (see Scheme 5). It is now evident that, unlike the haloform reaction which requires α-trichloro substrates (ketones) for cleavage to occur in aqueous medium, the sulfohaloform reaction can take place with α-dichloro substrates (sulfoxides) in aqueous medium.

Chlorination of α-Chlorosulfides to Form Sulfonyl Chlorides

Since the isolation of the intermediate sulfoxides in the sulfohaloform reaction was experimentally rather difficult we undertook an examination of the chlorination of α-chlorosulfides in aqueous medium in order to find evidence for the intermediacy of the α-chlorosulfoxides. The chlorination of 1,3-dichloro-2-thiapropane, **3**, in water furnished the corresponding sulfone (4%) and chloromethanesulfonyl chloride **2** (70%).

We have already established that chlorination of **3** proceeds primarily through the corresponding sulfoxide even in dilute aqueous medium. Thus the observation of low yields of the corresponding sulfone in this type of reaction can be taken to implicate the intermediacy of the sulfoxide since the sulfone must, of necessity, have been formed via the sulfoxide. Application of this criterion to 1-chloro-2-thiapropane, **12**, was successful in implicating the intermediacy of the corresponding sulfoxide also, since the sulfone was isolated in 1% yield.

These results along with those from 2-chloro-



SCHEME 5

3-thiapentane and 4-chloro-5-thianonane are tabulated in Table 2. The process is obviously a potentially useful sulfonyl chloride synthesis.

The overall results from the chlorination of chloromethyl phenyl sulfide in aqueous medium also showed the same behaviour, *i.e.* the formation of chloromethyl phenyl sulfone (2.5%) (along with benzenesulfonyl chloride (68%)) implicated the intermediacy of the chloromethyl sulfoxide. In contrast to the previous cases, the chlorination of chloromethyl phenyl sulfide took a long time to reach completion. Furthermore, analysis of the partially chlorinated reaction mixture indicated that large amounts of trichloromethyl phenyl sulfoxide were present before any significant amount of benzenesulfonyl chloride was formed. This result indicated that the phenyl ring virtually nullifies the electron-withdrawing effect of one chlorine atom. Such an observation can be readily rationalized via resonance forms in which the phenyl ring shares its π electrons with the sulfinyl group of the intermediate oxochlorosulfonium chloride.

TABLE 2. Yields of sulfonyl chlorides prepared by chlorination of α-chlorosulfides in water

Sulfide	Sulfonyl chloride	Yield (%)
$ClCH_2·S·CH_2Cl$	$ClCH_2·SO_2·Cl$	70
$CH_3·S·CH_2Cl$	$CH_3·SO_2·Cl$	75
$Ph·S·CH_2Cl$	$Ph·SO_2·Cl$	67
$CH_3CH_2·S·CHClCH_3$	$CH_3CH_2·SO_2·Cl$	90
n-$C_4H_9·S·CHCl·n·C_3H_7$	n-$C_4H_9·SO_2·Cl$	94

Thus far we had observed that α-polychlorinated sulfoxides could be converted to sulfonyl chlorides without the formation of any sulfones. Chlorination of α-dichloro and simple α-chlorosulfoxides gave rise to minor amounts of sulfones. It appeared, however, that a potential barrier to extending this reaction to unchlorinated sulfides and sulfoxides might be the formation of substantial amounts of unchlorinated sulfones. This problem was solved as follows.

Chlorination of Sulfides to Form Sulfonyl Chlorides

We began this portion of the work by exploring reactions of some conveniently available sulfoxides in order both to maximize sulfone formation and to see if we could find reaction conditions which would suppress it. Such chlorinations of DMSO were illuminating, giving the results in [3] and [4]. Similar results

[3] $CH_3·SO·CH_3 + Cl_2 \xrightarrow{H_2O\text{–}HOAc(1:1)}$

$CH_3·SO_2·Cl + CH_3·SO_2·CH_3 + ClCH_2·SO_2·CH_3$
(48%) (15%) (3%)

[4] $CH_3·SO·CH_3 + Cl_2 \xrightarrow{H_2O}$

$CH_3·SO_2·Cl + CH_3·SO_2·CH_3$
(26%) (70%)

were obtained from the chlorination of di-*n*-propyl sulfoxide in water. Hence, sulfone formation was indeed a major potential complication to the useful formation of sulfonyl chlorides from unchlorinated sulfides and sulfoxides. This was not surprising since the results are consistent with those of Durst and Tin (32) and of Cinquini and co-workers (33), both of whom have observed sulfone formation via nucleophilic attack on oxochlorosulfonium cations.

However, after experimentation, it was found that *chlorination of sulfides in dilute aqueous acetic acid was successful in converting the sulfides into sulfonyl chlorides, in high yield,* without the interference of sulfone formation (see Table 3). By contrast, chlorination of the corresponding sulfoxides under the same conditions furnished significantly larger quantities of sulfones, implying that the reaction pathway from the sulfides does *not* proceed through the corresponding sulfoxides but rather through the corresponding α-chlorosulfides, and hence through the α-chlorosulfoxides, etc.

Since the conditions had been established, which permitted direct chlorination of sulfides to sulfonyl chlorides by controlling the amount of water present in the solvent, one final mechanistic problem remained. In water, the cleavage step is primarily achieved with water functioning as the nucleophile. In dry acetic acid, chloride ion is the exclusive nucleophile. It was not obvious just how competitive chloride ions would be *vis-à-vis* water in dilute aqueous acetic acid, and in order to monitor this, we have chlorinated thiacyclopentane and isolated the ω-chlorinated butanesulfonyl chlorides, as in [5].

The formation of **13** was not unexpected, since chlorination of thiacyclopentane in glacial acetic acid permits its isolation in 28.6% yield as reported by Runge *et al.* (34). Since chloro-

TABLE 3. Yields of sulfonyl chlorides prepared from sulfides and sulfoxides by chlorination in dilute aqueous acetic acid

Sulfides/sulfoxide	Sulfonyl chloride	Yield (%)

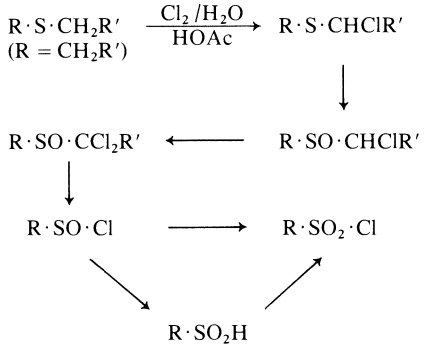
13 (8.9%) **14** (4.5%)

sulfonium chloride salts are inert to acetolysis (35), the origin of this monochlorosulfonyl chloride, under either conditions, is undoubtedly through direct chlorinolysis of thiacyclopentane to give 4-chlorobutane sulfenyl chloride. The driving force for this reaction is the release of ring strain and is parallel to the reactions of thiacyclobutane with chlorine in chloroform, or with sulfuryl chloride in pentane (36), which furnish 3-chloropropanesulfenyl chloride. Therefore the formation of **13** is not relevant to a consideration of the normal cleavage step in the sulfohaloform reaction.

However, Runge *et al.* (34) did not report the formation of 4,4-dichlorobutanesulfonyl chloride, **14**, upon chlorinating thiacyclopentane in glacial acetic acid. The sensitivity of α-chloro-chlorosulfonium chloride salts to hydrolysis, implicates the intermediacy of the α-chlorosulfoxide in the formation of **14**. The absence of larger amounts of the ω-dichlorosulfonyl chloride, as well as the failure of any ω-trichlorobutanesulfonyl chloride to form, indicate quite clearly that cleavage by chloride ions in dilute aqueous acetic acid is not an important or competitive process and therefore cleavage by the nucleophilic attack of water remains the major process in the cleavage step in dilute aqueous acetic acid.

The major pathways in the generalized sulfohaloform reaction have therefore been defined, and the overall reaction is outlined in Scheme 6.



SCHEME 6. The sulfohaloform reaction

Experimental

General

Most experimental details have been described previously (37). Mass spectral samples were directly introduced using an all-glass probe and the spectra run at 70 eV with a source temperature of 150 °C. Elemental analyses were by Dr. F. Pascher (Bonn) or Galbraith Laboratories (Knoxville, Tenn.). Gas–liquid chromatographic analyses were carried out with an N_2 flow rate of 50 ml/min and the column temperature was 40 to 50 °C. Unless otherwise indicated, "washing an organic layer with NaOH" means that a 2.5% w/v solution of NaOH was used to wash the organic layer, usually 100 ml aliquots, until the aqueous layer remained basic. "Standard work-up" of hydrophobic solvents implies that they were dried ($MgSO_4$), filtered, and then rotary evaporated.

Chlorinations

Chlorine flow rates were standardized by the use of a calibrated rotameter. All chlorinations were maintained at 25–30 °C by an ice–water bath. Unless otherwise stated, rates and reaction times are given in the form "232/50". This means a flow rate of 232 ml/min and a reaction time of 50 min. All times are given in minutes.

Yields

It was often necessary to analyze reaction mixtures quantitatively before work-up in order to avoid obtaining yields which reflected losses during work-up. None of the sulfur-containing compounds were detectable on glc. All sulfur compounds were observable in the nmr and integration of the nmr spectrum furnished satisfactory molar ratios. Carbon tetrachloride was detectable on glc and could be interrelated with the sulfur compounds by the addition of methylene chloride which appeared both in the glc trace and the nmr spectrum. The molar ratios, the total sample weight, and the following equation permit the calculation of the weight of each component in any mixture.

$$w_i = x_i a_i T\left(\sum_{c=1}^{n} x_c a_c\right)^{-1}$$

where x_i = mole fraction of 'i'th component, a_i = molecular weight of 'i'th component, w_i = weight (in grams) of the 'i'th component, T = total sample weight (in grams).

CO_2 Determinations

Full details are provided elsewhere (37).

Chlorination of 1,3,5-Trithiane

1,3,5-trithiane (17.11 g) was suspended in glacial acetic acid (38 ml) and distilled water (8 ml) was added. The reaction became non-exothermic by the end of the chlorination (232/40). The reaction mixture was diluted with ice water (25 ml), the organic phase separated, and the aqueous phase set aside.

The organic phase was diluted with $CHCl_3$[4] (150 ml), dried ($MgSO_4$), filtered, and the $CHCl_3$ distilled off.

The residue was fractionated giving the results outlined in Table 4.

[4]An additional run was carried out using ether as the solvent in order to check for the presence of chlorocarbons.

The aqueous phase was diluted to a volume of 150 ml with 95% ethanol, from 100 ml of which authenticated 2,4-dinitrophenylhydrazone of formaldehyde (2.03 g) was isolated (39). The results obtained after isolation and identification of the major products are given in Table 1. Full details of identification methods are provided elsewhere (37).

Preparation of 1,3-Dichloro-2-thiapropane, 3

1,3-Dichloro-2-thiapropane **3** was prepared from 1,3,5-trithiane as described by Truce *et al.* (40). The distilled material from this reaction contains a persistent impurity which showed an ir band at 1523 cm^{-1}. The contaminant was completely removed when the dichlorosulfide was chromatographed on silica gel with CCl_4 using sulfide–silica gel ratios as low as 1:3. In a typical run 1,3,5-trithiane (300 g) furnished crude 1,3-dichloro-2-thiapropane (170 g). After column chromatography and redistillation, high purity dichlorosulfide **3** (121 g, 42.5%) was obtained.

Chlorination of 3 in H_2O/HOAc

1,3-Dichloro-2-thiapropane **3** was dissolved in glacial acetic acid (50 ml) and distilled water added. Following chlorination (232 ml/min), ice water (75 ml) was added and the resultant mixture extracted with $CHCl_3$ (4 × 100 ml). The combined $CHCl_3$ layers were washed first with NaOH then with distilled water. Standard work-up afforded products which were isolated by fractional distillation. 1,3-Dichloro-2-thiapropane-2-oxide, **4**, had mp 36.5–37.5 °C; tlc (37) R_F 0.48 (ether), after recrystallization from CCl_4; ir ($CHCl_3$) 1070 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 4.57 (q, J = 11.0 Hz); ms ions at m/e 146 ($M^{\ddagger}$), 111 and 49. The dichlorosulfoxide **4** was identical with authentic material (45) by nmr, ir, mp, and mixture mp. See Table 5 for details of products obtained.

Chlorination of 1,3-Dichloro-2-thiapropane-2-oxide, 4

1,3-Dichloro-2-thiapropane-2-oxide **4** was chlorinated as described in the previous experiment.

The products were isolated by fractional distillation: 1,1,3-trichloro-2-thiapropane-2-oxide, **5**, had bp 94 °C/0.25 torr; R_F 0.55 on tlc (4:1 $CHCl_3$–ether); ir ($CHCl_3$) 1080 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 4.70 (s, 2H) and 6.60 (s, 1H); ms ions at m/e 180 ($M^{\ddagger}$) 83, 49. Oxidation of **5** (40) furnished material identical to authentic trichlorosulfone by ir, nmr, and bp. Details of the products obtained are found in Table 6.

Preparation of $Cl_2CH{\cdot}S{\cdot}CH_2Cl$

Details are provided elsewhere (37). The product was identical to known material (40).

Preparation of 1,1,3-Trichloro-2-thiapropane-2-oxide, 5

1,1,3-Trichloro-2-thiapropane (24.56 g) was dissolved in glacial acetic acid (100 ml), distilled water (4.4 ml) was added, and the mixture was chlorinated (232/50). The reaction mixture was fractionated, furnishing 1,1,3-trichloro-2-thiapropane-2-oxide (19.6 g, 72.5%).

Chlorination of 5 in H_2O–HOAc

1,1,3-Trichloro-2-thiapropane-2-oxide **5** (16.17 g) was dissolved in glacial acetic acid (50 ml) and distilled water (4.4 ml) was added. Following chlorination (232/39), ice water (75 ml) was added and the organic phase was separated. The aqueous phase was washed with $CHCl_3$ (100 ml) which was combined with the organic phase.

TABLE 4. Fractionation of the products from the chlorination of 1,3,5-trithiane

Fraction	Boiling point (°C/torr)	Components	Weight (g)
1	74–86/760	$CHCl_3$, $ClCH_2OAc$ $ClCH_2{\cdot}O{\cdot}CH_2Cl$*	1.84
2	20–40/25	$ClCH_2OAc$ $ClCH_2{\cdot}O{\cdot}CH_2Cl$	0.71
3	40–68/20	$ClCH_2{\cdot}S{\cdot}CH_2Cl$	5.31
4	70–80/20	$ClCH_2{\cdot}S{\cdot}CH_2Cl$ $ClCH_2{\cdot}S{\cdot}S{\cdot}CH_2Cl$ Unidentified products	3.87

**CAUTION*: bischloromethyl ether is a potent carcinogen (38).

TABLE 5. Products of the chlorination of **3** in H_2O/HOAc

Weight (g)	Chlorination time (min)	Volume H_2O (ml)	Products	Yield (g)*
15.67	22	2.2	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **4**	4.03 (22.7)
			$Cl_2CH{\cdot}S{\cdot}CH_2Cl$	11.29 (56.6)
16.21	20	4.4	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **4**	13.47 (74.2)
17.01	30	6.6	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **4**	14.52 (76.1)

*Percentage yield in parentheses.

Standard work-up gave a concentrate which was fractionated (glass-bead column, 67 torr), to give chloromethanesulfonyl chloride **2** (8.48 g, 64.0%) and a distillation residue of unreacted **5** (1.80 g, 11.2%).

*Chlorination of **5** in HOAc*

1,1,3-Trichloro-2-thiapropane-2-oxide **5** (15.85 g) was chlorinated (232/30) in glacial acetic acid (50 ml). An nmr spectrum of the reaction mixture showed a molar ratio of 100:73:27, $CHCl_3/ClCH_2{\cdot}SO{\cdot}Cl/ClCH_2{\cdot}SO_2{\cdot}Cl$ respectively. The reaction was chlorinated further with progress being monitored hourly. After 3.5 h the sulfinyl chloride – sulfonyl chloride ratio was 3:7.

Ice water (75 ml) was added to the reaction mixture and the organic phase was removed. The aqueous phase was extracted with ether (100 ml) and the ether layer combined with the organic layer. The combined organic portion was diluted with ether to 200 ml and then divided into equal portions, *A* and *B*.

A. Portion *A* was dried ($MgSO_4$) and concentrated. The bulk of the acetic acid was distilled off at 75 torr. The residue was dissolved in $CHCl_3$ (50 ml) and continuously extracted with water for 1 h. The aqueous phase was discarded and the extraction resumed with fresh water for 1 h. Standard work-up of the $CHCl_3$ gave a residue which was fractionated at reduced pressure to yield chloromethanesulfonyl chloride **2** (3.90 g).

B. Quantitative glc and nmr integration established the yield of $CHCl_3$ to be equal to 75%. The ether solution was extracted with NaOH, washed with distilled water, dried ($MgSO_4$), and fractionated, to furnish pure $CHCl_3$ identical with authentic material by bp, glc, and nmr.

*Chlorination of **5** in CH_2Cl_2*

1,1,3-Trichloro-2-thiapropane-2-oxide **5** (15.34 g) was chlorinated (232/30) in CH_2Cl_2 (50 ml). Methylene chloride (10 ml) was distilled off and the presence of both $CHCl_3$ (53.2%) and CCl_4 (10.7%) was demonstrated (glc). The bulk of the chlorocarbons were distilled off and the residue rectified at reduced pressure affording chloromethanesulfinyl chloride **6** (8.14 g, 71.7%), bp 163.5 °C/760 torr; ir ($CHCl_3$) 1150 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 4.83 (5); ms *m/e* 62, 49. Hydrolysis in distilled water, followed by chlorination in CH_2Cl_2, furnished chloromethanesulfonyl chloride **2** as expected.

*Chlorination of **5** in H_2O*

1,1,3-Trichloro-2-thiapropane-2-oxide **5** (11.32 g) was

TABLE 6. Products of the chlorination of 1,3-dichloro-2-thiapropane-2-oxide, **4**

Weight (g)	Chlorination time (min)	Volume H_2O (ml)	Products	Yield (g)*
16.25	25	2.2	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **4**	3.27 (19.8)
			$Cl_2CH{\cdot}SO{\cdot}CH_2Cl$ **5**	10.3 (51.3)
15.40	30	4.4	$Cl_2CH{\cdot}SO{\cdot}CH_2Cl$ **5**	14.20 (74.2)
16.07	30	6.6	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **4**	3.25 (20.2)
			$Cl_2CH{\cdot}SO{\cdot}CH_2Cl$ **5**	10.85 (55)

*Percentage yield in parentheses.

chlorinated (232/105) in distilled water (50 ml). The organic phase was pipetted off and dried ($CaCl_2$). Gas–liquid chromatography established the presence of $CHCl_3$ (6.3%) and CCl_4 (10%). The organic phase was distilled at reduced pressure furnishing chloromethanesulfonyl chloride **2** (6.05 g, 64.5%).

In a separate experiment on **5** (1.155 g), the CO_2 was isolated as $BaCO_3$ (0.802 g, 66.6%). Chlorination time was 50 min (116 ml/min).

*Preparation of 1-Chloro-2-thiapropane, **12***

Details of this preparation are given elsewhere (36, 37).

Preparation of $Cl_3C{\cdot}S{\cdot}CH_2Cl$

1-Chloro-2-thiapropane **12** (100 g) was chlorinated (448/330) in CCl_4 (250 ml). The reaction mixture was rectified furnishing 1,1,3-tetrachloro-2-thiapropane (181.9 g, 87.4%); bp 188 °C/760 torr; nmr δ 5.00 (s) ($CDCl_3$).

Preparation of 1,1,1,3-Tetrachloro-2-thiapropane-2-oxide, 7

Distilled water (12 ml) was added to 1,1,1,3-tetrachloro-2-thiapropane (31.19 g) in acetic acid (100 ml). After chlorination (232/50), the reaction mixture was fractionated to give **7** (16.8 g, 50%), bp 78 °C/0.5 torr; R_F 0.65 ($CHCl_3$) which could be crystallized from 95% ethanol at 0 °C but melted upon returning to ambient temperature; ir ($CHCl_3$) 1135 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 4.57 (q, J = 11.0 Hz); ms *m/e* 117, 82, 62, and 49. *Anal.* calcd. for $C_2H_2Cl_4SO$: C 11.13, H 0.93, O 7.41; found: C 11.35, H 0.98, O 7.38. Oxidation of **7** (40) yielded material identical to authentic tetrachlorosulfone by nmr, ir, and mixture mp.

Chlorination of 7 in H_2O

1,1,1,3-Tetrachloro-2-thiapropane-2-oxide **7** (16.56 g) was chlorinated (448/240) in distilled water (50 ml). The organic phase was pipetted off and dried ($CaCl_2$). Gas–liquid chromatography showed that CCl_4 (20%) had been formed. The residue was distilled furnishing chloromethanesulfonyl chloride **2** (7.80 g, 67.5%).

In a separate experiment (Cl_2: 232/50) on **7** (1.030 g) CO_2 was isolated as $BaCO_3$ (0.500 g, 60%).

*Preparation of 1,1-Dichloro-2-thiapropane-2-oxide, **10**[5]*

DMSO (16.21 g) was chlorinated (232/43) in glacial acetic acid (50 ml) and distilled water (6.6 ml). The reaction was repeated on a second portion of DMSO (16.01 g). The combined reaction mixtures were diluted with water (150 ml) and extracted ($CHCl_3$, 6 × 100 ml). The $CHCl_3$ was washed with NaOH then with distilled water (100 ml), dried ($MgSO_4$), and evaporated. The residue was distilled at reduced pressure to yield 1,1-dichloro-2-thiapropane-2-oxide **10**[5] (17.53 g, 28.8%). Recrystallization (CCl_4) of the distilled material afforded pure **10** as bundles of crystals (mp 32–33 °C); R_F 0.49 (ether); ir ($CHCl_3$) 1080 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 3.75 (3H, s) and 6.42 (1H, s); ms *m/e* 146 ($M^{\ddagger}$), 83 and 63. Oxidation of **10** (40) yielded material identical to authentic dichlorosulfone by nmr, ir, and mixture mp.

*Chlorination of **10** in CH_2Cl_2*

1,1-Dichloro-2-thiapropane-2-oxide **10** (16.22 g) was chlorinated (232/25) in CH_2Cl (50 ml). A fraction was distilled at atmospheric pressure (44–75 °C). The residue was rectified at reduced pressure with a −75 °C cold trap in the vacuum line. The fraction from the atmospheric distillation plus the trap material contained $CHCl_3$ (1.5 g, 11.8%) and CCl_4 (8.8 g, 51.8%). The vacuum distillation furnished methanesulfinyl chloride (8.24 g, 76.3%); bp 136.5 °C/760 torr; ir ($CHCl_3$) 1140 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 3.37 (s); ms *m/e* 98 ($M^{\ddagger}$), 82, 63, and 48. Hydrolysis in distilled water, followed by chlorination in CH_2Cl_2 furnished methanesulfonyl chloride.

*Chlorination of **10** in HOAc*

1,1-Dichloro-2-thiapropane-2-oxide **10** (15.81 g) was chlorinated (232/30) in glacial acetic acid (50 ml). Acetyl

[5]*CAUTION:* this sulfoxide ($Cl_2CH{\cdot}SO{\cdot}CH_3$) is very unstable at room temperature and if stored in a tightly stoppered container may generate sufficient gas pressure to explode the container within 4 h. Proper storage for periods of 2 weeks (maximum) requires that the sample be stored in the dark using an explosion-proof container, at or below −32 °C.

chloride was established as being present in a 1:1 ratio with CCl_4 by nmr and glc. The reaction mixture was added to CH_2Cl_2 (100 ml) and ice water (100 ml). The organic phase was separated, dried ($MgSO_4$), filtered, and the CH_2Cl_2 distilled off. A fraction (bp 44–75 °C) was collected at atmospheric pressure and the residue was distilled at 50 torr with a cold trap in the vacuum line. The atmospheric pressure fraction plus the trap material contained CCl_4 (11.10 g, 66.6%). The vacuum distillation afforded methanesulfonyl chloride (9.2 g, 75%).

*Chlorination of **10** in H_2O*

(a) Partial Chlorination

1,1-Dichloro-2-thiapropane-2-oxide **10** (4.30 g) was chlorinated (232/28) in distilled water (25 ml). The reaction mixture was extracted with $CHCl_3$ (100 ml) which was washed with NaOH (50 ml aliquots), then with distilled water (50 ml), followed by a standard work-up. The residue was the trichlorosulfoxide **11** (0.54 g, 10.3%), as established by nmr, ir, and tlc.

(b) Exhaustive Chlorination

1,1-Dichloro-2-thiapropane-2-oxide **10** (16.18 g) was chlorinated (232/85) in distilled water (50 ml). The organic phase was pipetted off and dried over $CaCl_2$. Gas–liquid chromatography established the presence of CCl_4 (2.4%), a sample of which was obtained by distillation at atmospheric pressure and was shown to be identical with authentic material by glc, ms, and bp.

Distillation of the residue at reduced pressure yielded methanesulfonyl chloride (8.84 g, 70.0%).

In a separate experiment on **10**, (1.130 g; Cl_2: 232/50), CO_2 was isolated as $BaCO_3$ (1.067 g, 67.5%).

Preparation of 1,1,1-Trichloro-2-thiapropane

1-Chloro-2-thiapropane (16.01 g) was chlorinated (232/35) in CH_2Cl_2 (50 ml). The reaction mixture was distilled, furnishing 1,1,1-trichloro-2-thiapropane (16.88 g, 61%); bp 148–149 °C; nmr ($CDCl_3$), singlet at δ 2.75.

*Preparation of 1,1,1-Trichloro-2-thiapropane-2-oxide (**11**)*

1,1,1-Trichloro-2-thiapropane (16.36 g) was chlorinated (232/27) in glacial acetic acid (50 ml) and distilled water (6.6 ml). Water (75 ml) was added and the solution was extracted with $CHCl_3$ (4 × 100 ml), which was washed with NaOH, followed by distilled water. After standard work-up, the residue was distilled furnishing **11** (11.00 g, 61.7%) bp 86–88 °C/1.6 torr; crystals (from methanol) had mp 63–65 °C; R_F 0.62 (4:1 chloroform–ether); ir ($CHCl_3$) 1100 cm^{-1} (ν_{SO}); nmr ($CDCl_3$) δ 2.92 (s); ms *m/e* 180 ($M^{\ddagger}$), 117, 82, 63, and 47. *Anal.* calcd. for $C_2H_3Cl_3SO$: C 13.24, H 1.67, O 8.82, S 17.67; found: C 13.26, H 1.56, O 8.74, S 17.27. Oxidation of **11** (40), yielded material identical to authentic trichlorosulfone by nmr, ir, and mixture mp.

*Chlorination of **11** in HOAc*

1,1,1-Trichloro-2-thiapropane-2-oxide **11** (16.83 g) was chlorinated (232/30) in glacial acetic acid (50 ml). Acetyl chloride was established as being present in a 1:1 ratio with CCl_4 by glc on the crude mixture. A small amount of acetyl chloride was distilled off and identified by ir, nmr, and glc. Work-up identical to that described under "Chlorination of **10** in HOAc" afforded CCl_4 (9.95 g, 69.9%) and methanesulfonyl chloride (9.20 g, 86.1%).

*Chlorination of **11** in H_2O*

(a) Partial Chlorination

1,1,1-Trichloro-2-thiapropane-2-oxide **11** (5.01 g) was chlorinated (232/30) in distilled water (25 ml). The organic phase was pipetted off and added to $CHCl_3$ (100 ml), which was washed with NaOH (50 ml aliquots) and then with water. After standard work-up, the residue was a mixture of unreacted **11** (0.75 g) and 1,1,1,3-tetrachloro-2-thiapropane-2-oxide **7** (1.06 g, 18.5%). The sulfoxide mixture was chromatographed on a column of silica gel (180 g). Elution with $CHCl_3$ (1100 ml) furnished **7** and an additional litre of $CHCl_3$ furnished **11**. The tetrachlorosulfoxide **7** was distilled and shown to be identical with authentic material by bp, nmr, ir, and tlc.

(b) Exhaustive Chlorination

1,1,1-Trichloro-2-thiapropane-2-oxide **11** (16.04 g) was chlorinated (448/185) in distilled water (50 ml). The organic phase was pipetted off and dried over $CaCl_2$. Gas–liquid chromatography established that CCl_4 had formed in 20% yield. The aqueous phase was extracted with $CHCl_3$ (2 × 100 ml) which was combined with the original organic phase. Standard work-up gave a residue which was fractionated at reduced pressure to furnish a mixture of methanesulfonyl chloride (5.08 g, 50%) and chloromethanesulfonyl chloride (3.16 g, 23.8%). Further distillation at atmospheric pressure gave four fractions, each of which was still a mixture. Fraction *1* (bp 161–163 °C) contained *ca.* 15% chloromethanesulfonyl chloride and 85% methanesulfonyl chloride.

A portion of fraction *1* (212 mg) was added dropwise to a cooled (5 °C) solution of vanillin (211 mg) in pyridine (0.5 ml). The ice water bath was removed and the solution was stirred at room temperature for 1 h. The reaction mixture was diluted with $CHCl_3$ (50 ml) which was extracted with 2.5% NaOH (50 ml), 2.5% HCl (50 ml), and distilled water (50 ml). Standard work-up gave a pale yellow oil (287 mg) which was dissolved in 95% ethanol (3 ml) and stored in the refrigerator overnight. Colorless crystals were filtered off and dried affording vanillin methanesulfonate (186 mg). After recrystallization, the sulfonate ester was shown to be identical to authentic material by tlc, ir, and mixture mp.

The concentrated mother liquor from the first crystallization was chromatographed on a preparative-layer plate (ether–$CHCl_3$, 1:19). Methanol extraction of the upper band (R_F 0.55, detected by 250 nm uv light) furnished a colorless oil (30.2 mg), which was identical to vanillin chloromethanesulfonate by tlc, nmr, and ir.

In a separate experiment on **11** (1.030 g) carbon dioxide was isolated as $BaCO_3$ (0.928 g, 55.5%). Chlorination time was 45 min.

*Chlorination of **3** in H_2O*

1,3-Dichloro-2-thiapropane **3** (16.41 g) was chlorinated (448/200) in distilled water (50 ml). Ice water (75 ml) was added and the reaction mixture extracted with $CHCl_3$ (2 × 100 ml). The residue from standard work-up of the $CHCl_3$ was distilled at reduced pressure yielding

chloromethanesulfonyl chloride (13.07 g, 70.4%). The distillation residue was covered with sufficient 10% NaOH to establish a pH > 7. The solution was acidified (concentrated HCl) and poured into $CHCl_3$ (200 ml). Standard work-up gave 1,3-dichloro-2,2-dioxide (790 mg, 3.8%); after recrystallization (95% ethanol), this was shown to be identical with authentic dichlorosulfone by nmr, ir, mp, and mixture mp.

Chlorination of ***12*** *in* H_2O

1-Chloro-2-thiapropane **12** (15.76 g) was chlorinated (448/98) in distilled water (50 ml) similarly to the chlorination of **3**. Products were methanesulfonyl chloride (14.10 g, 75.4%) and 1-chloro-2-thiapropane-2,2-dioxide (193 mg, 1.2%). Details are provided elsewhere (37).

Chlorination of $Ph{\cdot}S{\cdot}CH_2Cl$ *in* H_2O

Chloromethyl phenyl sulfide (16.01 g) was chlorinated (448/130) in distilled water (50 ml). By the end of this time all of the organic material had crystallized from solution and all reaction had ceased. The reaction mixture was extracted with $CHCl_3$ (2 × 100 ml), followed by standard work-up. Analytical tlc ($CHCl_3$ eluant) showed a spot at R_F 0.49 (assumed to be $Cl_2CH{\cdot}SO{\cdot}Ph$), a spot at R_F 0.70 (identical to $Cl_3C{\cdot}SO{\cdot}Ph$), and a spot at R_F 0.81 (identical to $Ph{\cdot}SO_2{\cdot}Cl$). The bulk of the material was $Cl_3C{\cdot}SO{\cdot}Ph$ and an ir of the crude showed the expected band at 1100 cm^{-1} (ν_{SO}). The crude product was dissolved in acetic acid – H_2O, 1:1, (50 ml) and chlorination (448/130) was repeated. Repetition of the work-up outlined above furnished crude product which showed about a 1:1 mixture of $Cl_3C{\cdot}SO{\cdot}Ph$ to $Ph{\cdot}SO_2{\cdot}Cl$ on tlc and the complete absence of the product previously observed at R_F 0.49. This new crude product was further chlorinated (448/130) in glacial acetic acid (15 ml) and distilled water (25 ml). The reaction mixture was extracted with $CHCl_3$ (4 × 100 ml) which was dried ($MgSO_4$) and rotary evaporated. Analytical tlc (37) showed the absence of $Cl_3C{\cdot}SO{\cdot}Ph$. The residue was fractionated at reduced pressure providing benzenesulfonyl chloride (12.04 g, 67.3%), identical to authentic material by tlc, nmr, ir, and bp. The distillation residue contained $Ph{\cdot}SO_2{\cdot}CH_2{\cdot}Cl$ (500 mg, 2.5%). Two preparative-layer plates were spotted with residue (100 mg/plate) and eluted with $CHCl_3$. Methanol extraction of the bands at R_F 0.70 furnished chloromethyl phenyl sulfone identical with authentic material by nmr, ir, and tlc.

Preparation of $Ph{\cdot}SO{\cdot}CCl_3$

Trichloromethyl phenyl sulfide (16.20 g) was chlorinated (232/27) in glacial acetic acid (50 ml) and distilled water (6.6 ml). The reaction was rerun on more $Ph{\cdot}SO{\cdot}CCl_3$ (15.96 g). The combined reaction mixtures were diluted with water (100 ml) and extracted with $CHCl_3$ (4 × 100 ml) which was washed with 5% NaOH and then with distilled water. Standard work-up gave a residue which contained unreacted sulfide (10.44 g) and $Ph{\cdot}SO{\cdot}CCl_3$ (20.19 g, 58.9%).

Some crude material (26.33 g) was chromatographed on silica gel (1560 g). Elution with CCl_4 (6 l) furnished trichloromethyl phenyl sulfide (8.86 g). Further elution with diethyl ether (5.2 l) yielded trichloromethyl phenyl sulfoxide (17.35 g). Recrystallization (95% ethanol) to give colorless needles; mp 77–78 °C; R_F 0.61 ($CHCl_3$); ir ($CHCl_3$) 1100 cm^{-1} (ν_{SO}); nmr δ 7.75 (m); ms m/e 242 ($M^{\ddagger}$), 125, 117, 109, 77, and 51. *Anal.* calcd. for $C_7H_5Cl_3OS$: C 34.52, H 2.07, Cl 43.7; found: C 34.79, H 2.28, Cl 42.9. Oxidation of the sulfoxide (40) gave sulfone identical to that obtained by oxidation of the sulfide by tlc, nmr, ir, and mixture mp.

Chlorination of $CH_3CH_2{\cdot}S{\cdot}CHClCH_3$ *in* H_2O

2-Chloro-3-thiapentane (16.77 g) was chlorinated (448/104) in distilled water (50 ml). The reaction mixture was partitioned between ice water (75 ml) and CH_2Cl_2 (10 ml). The aqueous phase was extracted with CH_2Cl_2 (100 ml). Standard work-up of the combined CH_2Cl_2 layers gave a residue which was rectified at reduced pressure giving ethanesulfonyl chloride (15.54 g, 89.6%) bp 90–92 °C/55 torr.

Chlorination of $n\text{-}C_4H_9{\cdot}S{\cdot}CHCl{\cdot}CH_2CH_2CH_3$ *in* H_2O

4-Chloro-5-thianonane (15.95 g) was chlorinated (448/100) in distilled water (50 ml). The reaction mixture was extracted with $CHCl_3$ (2 × 100 ml) which was dried ($MgSO_4$), and evaporated. The residue was fractionated at reduced pressure furnishing 1-butanesulfonyl chloride (13.0 g, 94.3%).

Chlorination of DMSO in 1:1 H_2O–*HOAc*

DMSO (15.91 g) was chlorinated (448/110) in glacial acetic acid (25 ml) and distilled water (25 ml). Products were methanesulfonyl chloride (11.30 g, 48%), dimethyl sulfone (2.78 g, 14.7%), and 1-chloro-2-thiapropane-2,2-dioxide (0.75 g, 2.9%). Details are provided elsewhere (37).

Chlorination of DMSO in H_2O

DMSO (16.11 g) was chlorinated (448/97) in distilled water. Total dimethyl sulfone isolated was 13.64 g (70.3%) and total methanesulfonyl chloride isolated was 6.23 g (26.2%). Details are provided elsewhere (37).

Chlorination of $(n\text{-}C_3H_7)_2SO$ *in* H_2O

Di-*n*-propyl sulfoxide (15.79 g) was chlorinated (448/105) in distilled water (50 ml). Ice water (75 ml) was added and the mixture was extracted with $CHCl_3$ (2 × 100 ml). Standard work-up gave a residue which was fractionated at reduced pressure to yield 1-propanesulfonyl chloride (6.71 g, 39.8%); bp 104–106 °C/65 torr, and di-*n*-propyl sulfone (5.65 g, 31.3%); bp 88 °C/0.1 torr.

Preparation of Sulfonyl Chlorides from the Corresponding Symmetric Sulfide or Sulfoxide

The substrate was dissolved in glacial acetic acid (50 ml) and the appropriate quantity of distilled water was added. Chlorine (448 ml/min) was bubbled through the solution. Chlorination was interrupted as necessary to maintain the reaction at room temperature. Ice water (75 ml) was added to the reaction mixture which was then extracted with $CHCl_3$ (4 × 100 ml). The $CHCl_3$ layers were washed with 2.5% w/v NaOH (3 × 100 ml) and subjected to standard work-up.

Diethyl sulfide (16.01 g, 7.5 ml H_2O_2 108 min chlorination) gave a residue which was fractionated at reduced pressure to yield ethanesulfonyl chloride (22.12 g, 96.6%).

Di-*n*-propyl sulfoxide (16.00 g, 6.6 ml H_2O, 90 min chlorination) gave a residue which was fractionated at reduced pressure to yield di-*n*-propyl sulfone (1.50 g,

8.4%) and 1-propanesulfonyl chloride (12.94 g, 75.6%).

Di-*n*-butyl sulfide (16.00 g, 6.6 ml H_2O, 126 min chlorination) gave a residue which was rectified at reduced pressure to furnish 1-butanesulfonyl chloride (14.74 g, 86.2%).

Dibenzyl sulfide (16.01 g, 6.6 ml H_2O, 75 min chlorination) gave a residue which was crystallized from benzene – low-boiling petroleum ether to yield phenylmethanesulfonyl chloride (8.82 g). The mother liquor furnished another 1.71 g to give a total yield of 73.3%.

Chlorination of Thiacyclopentane in HOAc–H_2O

Thiacyclopentane (15.97 g) was chlorinated (448/106) in glacial acetic acid (50 ml) and distilled water (7.5 ml). Ice water (75 ml) was added and the mixture was extracted with $CHCl_3$ (4 × 100 ml). The $CHCl_3$ was washed with 2.5% w/v NaOH (3 × 100 ml) and distilled water (100 ml), dried ($MgSO_4$), and rotary evaporated. The residue was fractionated at reduced pressure to yield a mixture of sulfonyl chlorides. The mixture contained $Cl(CH_2)_4SO_2Cl$ **13** (3.10 g, 8.9%) and $Cl_2CH(CH_2)_3SO_2Cl$ **14** (1.83 g, 4.5%). A sample (2.01 g) of the distillate was chromatographed on a silica gel column (200 g). Elution with $CHCl_3$ (650 ml) furnished a clean mixture of **13** and **14** (2:1). A second column run on 1.99 g of distillate furnished additional 2:1 mixture. The total chromatographed mixture from chromatography weighed 1.78 g. Strong bands at 1350 and 1162 cm^{-1} were virtually the only bands present in the ir of the 2:1 mixture.

A portion of the chromatographed mixture (1.01 g) was added drop-wise to a cold solution of phenol (419 mg) in pyridine (3 ml) and the reaction mixture was stirred at room temperature for 1 h. Chloroform (100 ml) was added and the solution washed with 2.5% NaOH (50 ml), 2.5% HCl (50 ml), and distilled water (50 ml). The $CHCl_3$ was dried ($MgSO_4$), and rotary evaporated to yield a crude phenate mixture (938 mg), crystallization of which (95% ethanol) afforded three crops. Crops *1* and *2* (150 mg) were mixtures of phenates. Crop *3* (130 mg) was pure $Cl_2CH(CH_2)_3SO_2OPh$. The mother liquor from the third crystallization afforded residual phenate mixture (560 mg).

The mixture (560 mg) was chromatographed on five preparative tlc plates with benzene elution (2×). Each plate had five bands visible under uv light, *i.e.*, R_F 0.97, 0.91, 0.83, 0.77, 0.68.

The band at R_F 0.77 gave $Cl(CH_2)_4SO_2OPh$ (251 mg) as a colorless oil.

The band at R_F 0.83 gave $Cl_2CH(CH_2)_3SO_2OPh$ (138 mg) as fine needles from 95% ethanol, mp 60–61.5 °C; ($CHCl_3$) 1375 and 1140 cm^{-1} (ν_{SO_2}); nmr δ 2.25 (4H, t), 3.34 (2H, t), 5.83 (1H, t), and 7.34 (5H, s); ms *m/e* 125, 94, 65 and 53. *Anal.* calcd. for $C_{10}H_{12}Cl_2O_3S$: C 42.42, H 4.27, Cl 25.04, O 16.95, S 11.32; found: C 42.80, H 3.94, Cl 24.84, O 17.04, S 11.19.

The remaining three bands gave minor quantities and were discarded.

Intermediate stages of the sulfohaloform reaction. Preparation of α-halosulfoxides and sulfinyl chlorides. Oxygen-transfer reactions

J. STUART GROSSERT, WILLIAM R. HARDSTAFF, AND RICHARD F. LANGLER
Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 10, 1975[1]

J. STUART GROSSERT, WILLIAM R. HARDSTAFF, and RICHARD F. LANGLER. Can. J. Chem. **55**, 421 (1977).

Details are provided of synthetic routes from dialkyl sulfides to both α-halosulfoxides and sulfinyl chlorides. In the case of the former, oxidation of α-halosulfides to the sulfoxide stage is achieved by chlorine in acetic acid containing controlled amounts of water. Sulfinyl chlorides are prepared by chlorination of α-polyhalosulfoxides in methylene chloride. During investigations into the details of the sulfohaloform reaction, a number of novel redox reactions involving oxygen transfer between sulfur species have been observed and these are presented. They include a reduction of a sulfoxide with thionyl chloride.

J. STUART GROSSERT, WILLIAM R. HARDSTAFF et RICHARD F. LANGLER. Can. J. Chem. **55**, 421 (1977).

On fournit des détails permettant de synthétiser à la fois les α-halosulfoxydes et les chlorures de sulfinyles à partir des sulfures de dialkyles. Dans le premier cas, l'oxydation des sulfures α-halogénés en sulfoxyde est effectuée par du chlore dans de l'acide acétique contenant des quantités contrôlées d'eau. On prépare les chlorures de sulfinyles par chloruration de sulfoxydes α-polyhalogénés dans le chlorure de méthylène. Au cours des études effectuées afin d'élucider les détails de la réaction sulfohaloformique, on a observé un certain nombre de nouvelles réactions d'oxydo réduction impliquant un transfert d'oxygène entre des espèces contenant du soufre; on présente ces nouvelles réactions. Elles comprennent une réduction d'un sulfoxyde par le chlorure de thionyle.

Synthesis of α-Polychlorosulfoxides

Sulfoxides are usually synthesized by the controlled oxidation of sulfides (1, 2). Such a reaction always has the potential of giving higher oxidation products, for example, sulfones, and there is ample literature documentation of reactions designed to avoid such complications (2, 3). Initial investigations of the use of halogens in aqueous media to oxidize sulfides demonstrated that molecular bromine afforded much smoother and more readily controlled reactions than did molecular chlorine (ref. 1, p. 216). Since the work of Fries and Vogt in 1911 (4), no further attempts appear to have been made to use chlorine for the oxidation of sulfides to sulfoxides.

The excessive reactivity of chlorine becomes an advantage, however, when the oxidation of heavily chlorinated sulfides is attempted since the

$$R_1R_2R_3C{\cdot}SO{\cdot}CH_2R_4$$

1 $R_1 = Cl; R_2 = R_3 = R_4 = H$

2 $R_1 = R_2 = Cl; R_3 = R_4 = H$

3 $R_1 = R_4 = Cl; R_2 = R_3 = H$

4 $R_1 = R_2 = R_4 = Cl; R_3 = H$

5 $R_1 = R_2 = R_3 = R_4 = Cl$

6 $R_1 = R_2 = R_3 = Cl; R_4 = H$

low nucleophilicity of such sulfides introduces a rate retardation, in comparison to that of unchlorinated sulfides, which makes the reaction easy to control. The complication involved in chlorinating more nucleophilic sulfides and sulfoxides is that the product is often nearly as reactive as the starting material. For example, chlorination of DMSO in aqueous acetic acid, at room temperature, leads to the formation of 1-chloro-2-thiapropane-2-oxide, **1**, which is seriously contaminated with 1,1-dichloro-2-thiapropane-2-oxide, **2**. The desired control for the oxidation of sulfides with chlorine in aqueous media does not obtain until the starting sulfide has at least two α-chlorine atoms. Thus controlled chlorination of 1,3-dichloro-2-thiapropane furnished the corresponding sulfoxide **3** without difficulty (5).

In a typical experiment, the polychlorosulfide

[1]Revision received September 20, 1976.

TABLE 1. Preparation of α-polychlorosulfoxides from α-polychlorosulfides by chlorination (232 ml/min) in glacial HOAc containing 3 equiv. of water

Starting sulfide	Sulfoxide product	Yield (%)	Chlorination time (min)
$ClCH_2{\cdot}S{\cdot}CH_2Cl$	$ClCH_2{\cdot}SO{\cdot}CH_2Cl$ **3**	77	20
$Cl_2CH{\cdot}S{\cdot}CH_2Cl$	$Cl_2CH{\cdot}SO{\cdot}CH_2Cl$ **4**	65	20
$Cl_3C{\cdot}S{\cdot}CH_2Cl$	$Cl_3C{\cdot}SO{\cdot}CH_2Cl$ **5**	50	50
$Cl_3C{\cdot}S{\cdot}CH_3$	$Cl_3C{\cdot}SO{\cdot}CH_3$ **6**	62	27
$Cl_3C{\cdot}S{\cdot}Ph$	$Cl_3C{\cdot}SO{\cdot}Ph$ **7**	63	27

(*ca.* 16 gm) was dissolved in acetic acid (50 ml) and 3 equiv. of water were added. Chlorine was bubbled into the solution and the temperature maintained at 25 to 30 °C. The results obtained on the systems utilized in this study are given in Table 1.

Many reagents available for the conversion of sulfides to sulfoxides give rise to some sulfone as well (2, 6). Although the preparation of α-polychlorosulfoxides utilizing chlorine and aqueous acetic acid is not complicated by sulfone formation, it is normally complicated by sulfonyl chloride formation. However, sulfonyl chloride formation occurs as a minor side reaction and the sulfonyl chloride can be readily removed by washing the sulfoxide with aqueous base. By contrast, sulfones are often difficult to remove from the corresponding sulfoxide, particularly when purification is attempted by recrystallization (6).

A useful modification of this synthetic method involves the conversion of a sulfide to the corresponding α-chlorosulfoxide in one step. Since chlorosulfonium chloride salts are inert to acetolysis (7), the starting sulfide can be chlorinated in glacial acetic acid to furnish the homologous α-chlorosulfide. After the addition of water further chlorination affords the corresponding sulfoxide. In this way, 1,3-dichloro-2-thiapropane has been converted routinely into 1,1,3-trichloro-2-thiapropane-2-oxide, **4**, in 50% yield.

Synthesis of Sulfinyl Chlorides

The development of synthetic methods for the preparation of sulfinyl chlorides has received relatively little attention. Most sulfinyl chlorides have been made by variations of the same reaction developed by Douglass, namely the controlled solvolysis of alkyldichlorosulfonium chloride salts (8, 9). The chief difficulties with this method center around finding a suitable solvent in which to carry out the solvolysis. For example, when acetic acid is employed as the solvent, excess chlorine initiates a slow but smooth transformation of the sulfinyl chloride into the corresponding sulfonyl chloride. However, this problem seems to have been overcome by employing acetic anhydride for the solvent. Using a different synthetic method, some aromatic sulfinyl chlorides have been prepared by reaction between the sulfinic acid and thionyl chloride (10).

Our studies on the cleavage of α-polychlorosulfoxides with chlorine (5) led to the selection of methylene chloride as the solvent in order to prevent solvolysis reactions. The results of the initial examination of this reaction indicated that α-trichlorosulfoxides would undergo facile cleavage when treated with chlorine in methylene chloride, whereas α-dichlorosulfoxides would not undergo cleavage in useful yields.

A summary of the sulfoxide substrates examined is presented in Table 2.

It is noteworthy that the yield of sulfinyl chloride from chlorination of phenyl trichloromethyl sulfoxide was poor and that the compound could not be separated intact from the reaction mixture. This observed poor yield and the long chlorination time are precisely what would have been expected from an alkyl α,α-dichloroalkyl sulfoxide. It appears, therefore, that the phenyl ring acts to suppress the electron-withdrawing effect of approximately one chlorine atom, which may be rationalized by postulating the delocalization in the intermediate oxochlorosulfonium chloride of positive charge on sulfur around the aromatic ring.

In its generalized form, this method of alkanesulfinyl chloride preparation requires that trichloromethyl alkyl sulfoxides be available. Since the chlorination of alkyl methyl sulfides normally

TABLE 2. Preparation of alkanesulfinyl chlorides from α-polychlorosulfoxides by chlorination (232 ml/min) in CH_2Cl_2

Starting sulfoxide	Sulfinyl chloride product	Yield (%)	Chlorination time (min)
$ClCH_2{\cdot}SO{\cdot}CHCl_2$ **4**	$ClCH_2{\cdot}SO{\cdot}Cl$	72	30
$ClCH_2{\cdot}SO{\cdot}CCl_3$ **5**	$ClCH_2{\cdot}SO{\cdot}Cl$	80	50
$CH_3{\cdot}SO{\cdot}CHCl_2$ **2**	$CH_3{\cdot}SO{\cdot}Cl$	76	25
$CH_3{\cdot}SO{\cdot}CCl_3$ **6**	$CH_3{\cdot}SO{\cdot}Cl$	77	25

goes preferentially into the alkyl group (11), it might appear that this method is not generalizable on account of the lack of availability of the intermediate trichloromethyl sulfides. However, this is not so, since both chloromethyl and dichloromethyl alkyl sulfides are available through established methods. Böhme (12, 13) has developed the preparation of chloromethyl alkyl sulfides from alkyl thiols, paraformaldehyde, and HCl. More recently a method for the preparation of dichloromethyl alkyl sulfides from the thiolformates and phosphorus pentachloride has been published by Holsboer and van der Veek (14). These authors have also reported the preparation of a number of trichloromethyl alkyl sulfides from the dichloromethyl alkyl sulfides.

It should be noted that the preferred method for the preparation of methanesulfinyl chloride utilizes 1,1-dichloro-2-thiapropane-2-oxide, **2**, as starting material. Although the chlorination of 1,1,1-trichloro-2-thiapropane-2-oxide, **6**, has been examined and proceeds quite satisfactorily, **6** is considerably less convenient to prepare than is **2**.

Oxygen-transfer Reactions

Most of the reactions which we encountered during our studies on the sulfohaloform reaction (5, 7) involved sulfur behaving as a nucleophile towards electrophilic chlorine. However, we also observed a number of reaction pathways in which sulfoxides acted as nucleophiles at oxygen. This type of reaction by sulfoxides is of course well documented (15, 16), but the reactions described below are novel and warrant a brief discussion.

Although chlorination of 1,3-dichloro-2-thiapropane-2-oxide, **3**, in dilute aqueous acetic acid was a relatively straightforward reaction yielding primarily **4** (5), the use of glacial acetic acid as solvent permitted the observation of a chlorinated sulfoxide behaving as an oxygen nucleophile in a more complex reaction. The products shown in [1] were obtained. The previous report

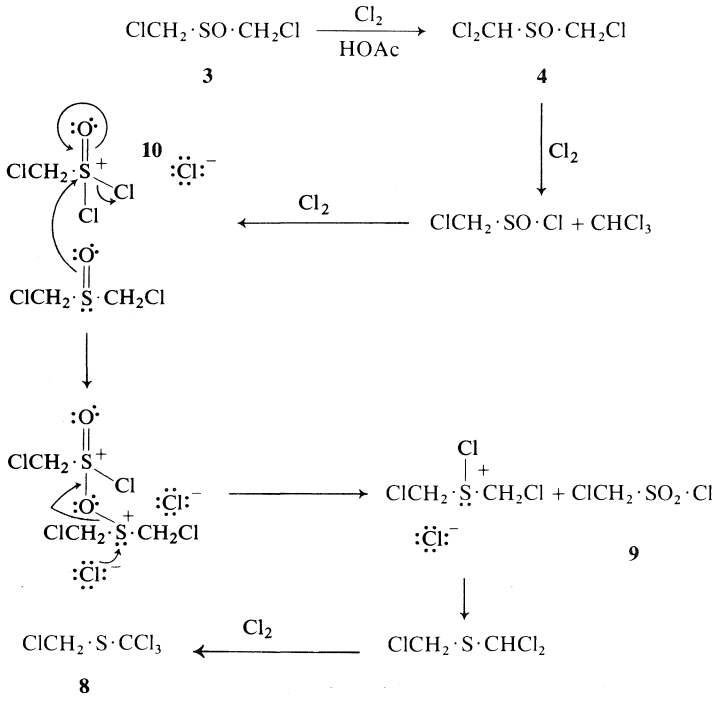
$$[1]\quad 3 \xrightarrow[HOAc]{Cl_2} 4\ (19\%) + \underset{\mathbf{9}}{ClCH_2{\cdot}SO_2{\cdot}Cl}\ (26\%) + \underset{\mathbf{8}}{Cl_3C{\cdot}S{\cdot}CH_2Cl}\ (26\%) + CHCl_3\ (26\%)$$

(5) established that the chloromethanesulfonyl chloride, **9**, is produced from the corresponding sulfinyl chloride which in turn is produced from the trichlorosulfoxide, **4**. It is also clear that the sulfinyl chloride acquires an oxygen atom from a sulfoxide which is converted to the corresponding α-chlorosulfide. The simplest assumption, since the isolated sulfide is in fact the tetrachlorosulfide **8**, is that oxygen is transferred from the trichlorosulfoxide **4**. Chlorination of the trichlorosulfoxide **4** in glacial HOAc furnishes no tetrachlorosulfide **8** as we have shown previously (5). It therefore follows that the oxygen transfer must have occurred from the dichlorosulfoxide **3**. This reasoning was supported by chlorination of a 1:1 mixture in glacial acetic acid of chloromethanesulfinyl chloride and the dichlorosulfoxide **3** which did indeed furnish the expected mixture of chloromethanesulfonyl chloride **9** and tetrachlorosulfide **8** in a 1:1 ratio. The pathway for the chlorination of the dichlorosulfide **3** in glacial acetic acid is depicted in Scheme 1.

It is interesting to compare the reactions of **3** (*cf.* reaction 1) and **2** (reaction 2) (5) with chlorine in glacial acetic acid. No oxygen-

$$[2]\quad 2 \xrightarrow[HOAc]{Cl_2} CH_3{\cdot}SO_2{\cdot}Cl\ (72\%) + CCl_4\ (72\%) + AcCl\ (72\%)$$

transfer products were observed in [2]. The differences between **2** and **3** may be explained by a number of factors. These include the fact that **2** undergoes rapid further chlorination to the less-nucleophilic trichlorosulfoxide **6** and the fact that in [1], the oxygen transfer arises from the



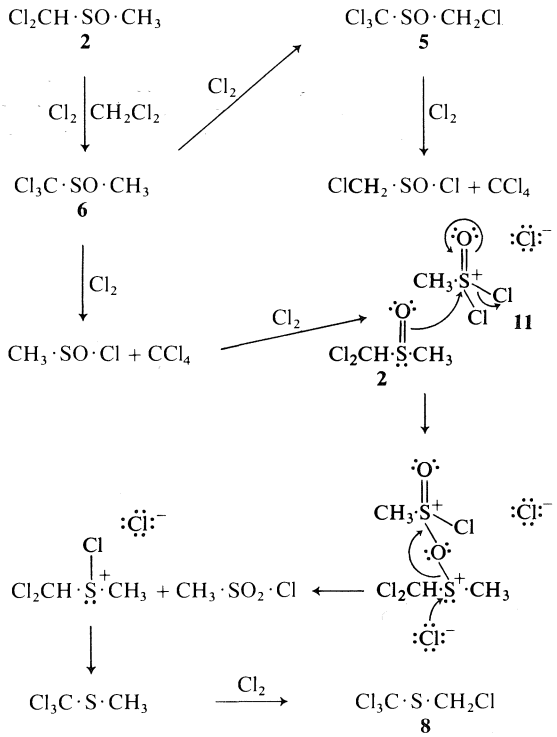
SCHEME 1

more nucleophilic sulfoxide **3** attacking the more electrophilic oxodichlorosulfonium salt **10**. This compares with [2] in which for a comparable process to occur, the predominant sulfoxide would be **6** and the comparable electrophilic species to **10** would be **11** (*cf.* Schemes 1 and 2).

That an oxygen-transfer reaction could occur in the case of dichlorosulfoxide, **2**, was found by a careful examination of its chlorination in methylene chloride solvent. The reaction is depicted in [3].

[3] $2 \xrightarrow[CH_2Cl_2]{Cl_2} CH_3{\cdot}SO{\cdot}Cl\ (75\%) + CH_3{\cdot}SO_2{\cdot}Cl\ (1\%) + \mathbf{8}\ (1\%) + ClCH_2{\cdot}SO{\cdot}Cl\ (3\%)$

The chloromethanesulfinyl chloride must originate from the tetrachlorosulfoxide **5** since methanesulfinyl chloride did not give rise to any chloromethanesulfinyl chloride when chlorinated in methylene chloride. The selective oxidation of methanesulfinyl chloride to the sulfonyl chloride in the presence of chloromethanesulfinyl chloride can be rationalized on the grounds that the concentration of methanesulfinyl chloride is much greater during the reaction and that the methanesulfinyl chloride reacts at a faster rate with

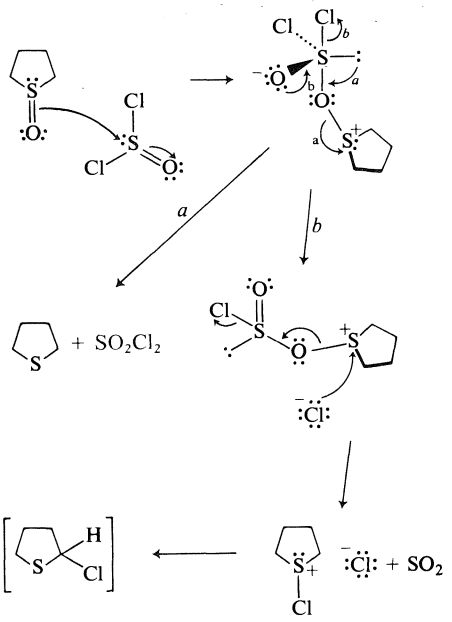


SCHEME 2

chlorine to form the oxodichlorosulfonium chloride salt **11**. A reasonable reaction pathway is outlined in Scheme 2.

It might have been expected that methanesulfinyl chloride would best be prepared by simple chlorination of DMSO, especially in light of the literature report that sulfoxides may be cleanly chlorinated in methylene chloride (17). However, in our hands, DMSO produced a plethora of products with chlorine in either methylene chloride or glacial acetic acid. This is undoubtedly due to oxygen-transfer reactions. We did find that these processes could be suppressed to give a useful reaction by use of a controlled amount of water in the acetic acid (5).

We have also observed a novel oxygen transfer reaction which did not involve molecular chlorine. In 1955, Bordwell and Pitt (18) examined the reaction of sulfoxides with thionyl chloride. Upon subjecting thiacyclopentane-1-oxide to the appropriate conditions, they reported the formation of "a dark colored material with a wide boiling range". A reinvestigation of this reaction furnished the unexpected result that the major isolable product was thiacyclopentane (25% yield). As initially isolated, it was contaminated with a small amount of material that may have been the expected 2-chlorothiacyclopentane (nmr). Redistillation gave thiacyclopentane of satisfactory purity. This apparently unprecedented reduction of a sulfoxide by thionyl chloride (ref. 10, p. 341) can be rationalized as depicted in Scheme 3.



SCHEME 3

Experimental

General

Details have been provided previously (5).

Preparation of $Cl_2CH{\cdot}SO{\cdot}CH_2Cl$, 4

1,3-Dichloro-2-thiapropane (16.00 g) in glacial acetic acid (50 ml) was chlorinated (232 ml/min) for 20 min. Water (6.6 ml) was added and Cl_2 (232 ml/min) was bubbled through the reaction mixture for an additional 35 min. Water (75 ml) was added and the solution was extracted with chloroform (4 × 100 ml). The combined chloroform layers were washed with 2.5% NaOH until the p*H* of the aqueous layer remained basic, and then given a standard work-up. The residue was fractionated at reduced pressure to furnish **4** (11.08 g, 50%).

Chlorination of $Cl_3C{\cdot}SO{\cdot}CH_2Cl$, 5

5 (15.25 g) was dissolved in methylene chloride (50 ml) and chlorine (232 ml/min) was bubbled through the reaction mixture for 50 min. The solvent was distilled off at atmospheric pressure and the residue was rectified at reduced pressure affording chloromethanesulfinyl chloride **9** (7.62 g, 80.3%) bp 94 °C/80 torr.

Chlorination of $Cl_3C{\cdot}SO{\cdot}C_6H_5$, 7

7 (9.64 g) was dissolved in methylene chloride (50 ml) and chlorine (232 ml/min) was bubbled through the reaction mixture for 90 min. The methylene chloride was rotary evaporated to yield an orangish residue (10.02 g). Methanol (50 ml) was added to the residue and the solution stirred at ambient temperature for 60 min. The methanol was rotary evaporated affording a residue containing Ph·SO·OMe (1.90 g, 39%), unreacted $Ph{\cdot}SO{\cdot}CCl_3$ (2.25 g, 23%), as well as at least two other compounds. Some of this residue was chromatographed on two preparative-layer plates (150 mg/plate) which were eluted with carbon tetrachloride. The lowest band (R_F 0.12 detected by uv light) was removed, and chloroform extraction gave a partially crystalline residue (142.7 mg) which was about equal parts $Cl_3C{\cdot}SO{\cdot}Ph$ and Ph·SO·OMe. This residue was rechromatographed (plc, chloroform eluant), the lower band (R_F 0.62) from which furnished methyl benzenesulfinate (66 mg), which was identical with authentic material by tlc, nmr, and ir, and the upper band (R_F 0.83) from which furnished $Ph{\cdot}SO{\cdot}CCl_3$ **7** (67 mg), identical with the starting material by tlc, nmr, and ir.

Chlorination of $ClCH_2{\cdot}SO{\cdot}CH_2Cl$, 3

3 (15.01 g) (5) was dissolved in glacial acetic acid (50 ml) and chlorinated (232 ml/min) for 30 min. The nmr of the crude showed that $Cl_3{\cdot}C{\cdot}S{\cdot}CH_2Cl$ **8** and $ClCH_2{\cdot}SO_2{\cdot}Cl$ **9** were present in a 1:1 ratio. Ice water (75 ml) was added and the solution extracted with chloroform (2 × 100 ml). The chloroform layer was extracted with 2.5% NaOH (100 ml aliquots) until the p*H* of the aqueous layer remained basic. Standard work-up gave a residue which was fractionated at reduced pressure affording $Cl_3C{\cdot}S{\cdot}CH_2Cl$ **8** (5.47 g, 26.4%) and $Cl_2CH{\cdot}SO{\cdot}CH_2Cl$ **4** (3.72 g, 19.6%). Both compounds were identical with authentic samples by nmr, ir, and bp.

The reaction was repeated. After addition of water and chloroform extraction, a portion of the chloroform solution (50 ml) was continuously extracted with water[2] for 24 h. The chloroform was dried ($MgSO_4$), filtered, and concentrated and a portion of the residue (500 mg) was added drop-wise to a chilled solution of vanillin (218 mg) in dry pyridine (1 ml). After the reaction mixture was stirred at ambient temperature for 1 h, work-up in the usual way gave a residue which was chromatographed on five preparative-layer plates using ether–chloroform, 5:95. Extraction of the band visible under uv light furnished vanillin chloromesylate (152 mg) which was identical with authentic material by tlc, ir, and nmr.

Chlorination of $Cl_2CH{\cdot}SO{\cdot}CH_3$, 2

2 (16.81 g) in methylene chloride was chlorinated (232 ml/min) for 25 min. The methylene chloride was distilled off at atmospheric pressure and the residue was fractionated at 34 torr. Methanesulfinyl chloride (bp 52–54 °C/34 torr) was removed and a residue (1.00 g) was obtained. Nuclear magnetic resonance spectra indicated the presence of $Cl_3C{\cdot}S{\cdot}CH_2Cl$ **8** (264 mg, 1.2%), $ClCH_2{\cdot}SO{\cdot}Cl$ (437 mg, 2.9%), $CH_3{\cdot}SO_2{\cdot}Cl$ (163 mg, 1.2%), and $CH_3{\cdot}SO{\cdot}Cl$ (139 mg, 1.2%). The crude residue was treated with vanillin (1.002 g) in pyridine (2.5 ml) as outlined previously, the product of which was evacuated (0.45 torr) and immersed in an oil bath (which had been preheated to 100 °C), for 2 min. Condensation of the distillate in a cold trap (−50 °C) furnished **8** (153 mg) identical to authentic material by nmr, ir, and bp. The residue from the bulb-to-bulb distillation weighed 498 mg. A portion of the residue (200 mg) was chromatographed on two preparative tlc plates (silica gel HF-254) which were developed with 5% ether in chloroform. Vanillin mesylate (32.3 mg, R_F 0.50) was isolated and shown to be identical to authentic material by ir, nmr, and tlc.

The chlorination was rerun and a portion of the distillation residue (250 mg) was chlorinated (232 ml/min) in distilled water (1.7 ml) for 5 min. The reaction mixture was diluted to 10 ml with distilled water and extracted with chloroform (3 × 10 ml). Standard work-up gave a residue which was treated with vanillin (200 mg) in pyridine (1.0 ml) as described previously. Vanillin chloromesylate (48.2 mg, R_F 0.55) was isolated by preparative-layer chromatography, as outlined above and was shown to be identical to authentic material by nmr, ir, and tlc.

Reaction of Thiacyclopentane-1-oxide and $SOCl_2$

Thiacyclopentane-1-oxide (28.85 g) was dissolved in methylene chloride (40 ml) and was added drop-wise over a period of 1¾ h to a gently refluxing solution of thionyl chloride (34.89 g) in methylene chloride (40 ml). Upon completion of the addition the reaction mixture was fractionated and the material (7.32 g) which had bp 90–120 °C was collected. Redistillation furnished clean thiacyclopentane (bp 116–120 °C, 3.65 g) which was identical with authentic material by bp, nmr, and ir.

[2]The water was distilled from 5% NaOH to prevent recycling of the acetic acid.

C-Nucleosides and related compounds. XII. The synthesis of the carbocyclic analogues of D,L-6-azapseudouridine, 2-thio-6-azapseudouridine, and pyrazofurin A. On the cyclization of semicarbazones of α-keto esters

GEORGE JUST AND SUNGGAK KIM[1]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3C 3G1

Received August 12, 1976

GEORGE JUST and SUNGGAK KIM. Can. J. Chem. **55**, 427 (1977).

The preparation of the title compounds is described. The cyclization of the *syn*- and *anti*-isomers of semicarbazones, thiosemicarbazones, and carbomethoxymethyl hydrazones to azauracils, thioazauracils, and pyrazoles is described. The photochemical isomerization of the hydrazones has been carried out. Whereas both *syn*- and *anti*-isomers of the thiosemicarbazones and carbomethoxymethyl hydrazones cyclize, only the *syn*-isomer of the semicarbazones can be converted to the corresponding azauracil.

GEORGE JUST et SUNGGAK KIM. Can. J. Chem. **55**, 427 (1977).

On décrit la préparation des composés mentionnés dans le titre. On décrit la cyclisation des isomères *syn* et *anti* des semicarbazones, des thiosemicarbazones et des carbométhoxyméthyles hydrazones en azauracils, thioazauracils et pyrazoles. On a effectué les isomérisations photochimiques des hydrazones. Alors que les isomères *syn* ainsi que *anti* des thiosemicarbazones et carbométhoxyméthyles hydrazones peuvent se cycliser, il n'y a que l'isomère *syn* des semicarbazones qui peut être transformé en azauracil correspondant.

[Traduit par le journal]

In the course of the synthesis of the carbocyclic analogue of D,L-pyrazofurin A **17** (1), it was noted that the cyclization of the corresponding hydrazone **10** proceeded in low yield, and that the hydrazone consisted of a mixture of the *syn*- and *anti*-isomers. It occurred to us that perhaps only one isomer underwent cyclization.

The cyclization behaviour of semicarbazones is also a somewhat capricious reaction. It has been reported that semicarbazones of α-keto acids and α-keto esters are cyclized under the influence of aqueous sodium hydroxide directly to the corresponding azauracil in variable yield (2). The reaction is normally carried out at 100 °C. Higher yields are obtained by working at room temperature, but the reaction then often takes several months. The cyclization proceeds best with semicarbazones with a higher alkyl or even better an aryl or aralkyl group in the α-position (3). Furthermore, with the semicarbazones of lower α-keto acids the reaction proceeds with some difficulty or, in case of pyruvic acid, not at all (4).[2]

Bougault observed that the thiosemicarbazone of pyruvic acid underwent a high yield cyclization resulting in the formation of **6**. Replacement of the sulfur atom with an oxygen atom then allowed him to prepare 6-azathymine **4** (5). In contrast with the cyclization of semicarbazones of α-keto acids, the cyclization of thiosemicarbazones proceeds consistently in good yield. The cyclization of the thiosemicarbazones has therefore served as the basis for the synthesis of 6-azauracils.

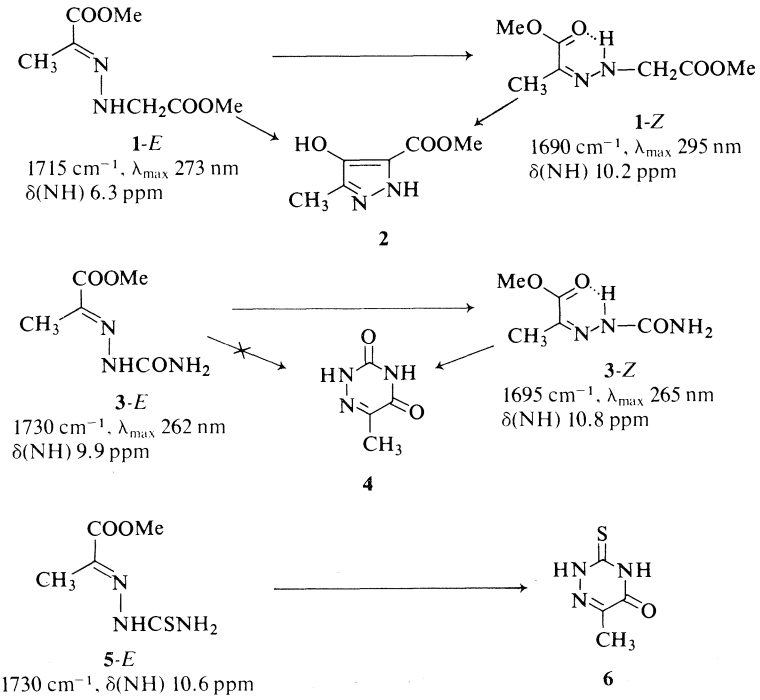
Since we were interested in the synthesis of 6-azauracils, 4-thio-6-azauracils, and pyrazoles, we decided to investigate the cyclization reactions.

Methyl pyruvate was transformed into its hydrazone **1**, semicarbazone **3**, and thiosemicarbazone **5**. Spectral data indicated them to consist only of one isomer, assigned the *anti* geometry based on data to be discussed later. All cyclization reactions were carried out in a standard manner, involving sodium methoxide in boiling methanol for 2 h, unless specified differently. Thiosemicarbazone **5**-*E* cyclized in 70% yield to thioazauracil **6**, presumably after isomerization to the *syn*-isomer. Pyrazole **2** was obtained in only 30% yield from hydrazone **1**-*E* and the *anti*-semicarbazone **3**-*E* did not react at all.

Irradiation of methanolic solution of the *anti*-

[1]Holder of a McConnell Fellowship, 1974–1976.

[2]Note: Chang (4*c*) prepared **4** from the semicarbazone of pyruvic acid by treatment with sodium ethoxide in ethylene glycol at reflux for 15 h in 51% yield.



SCHEME 1

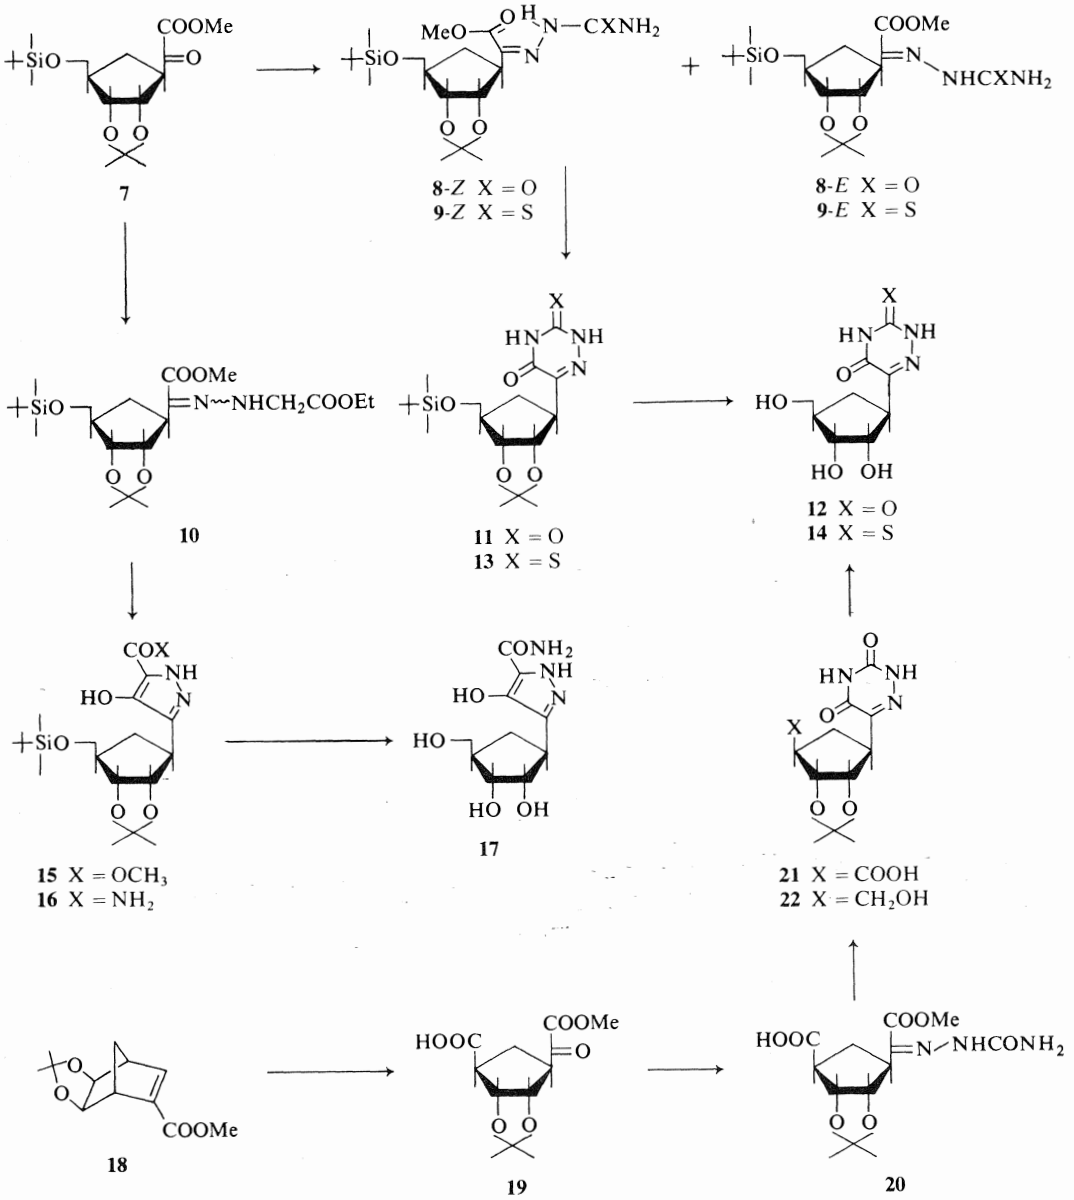
semicarbazone **3**-*E*, λ_{max} 262 nm, with 254 nm light for 2 days, shifted the absorption maximum to 265 nm. Purification by tlc gave in 80% yield the crystalline *syn*-isomer **3**-*Z*. Treatment of the *syn*-isomer with sodium methoxide in methanol at room temperature for 30 min gave, after acidification, a crystalline 6-azathymine in 75% yield. During the course of reaction, a precipitate formed. The precipitate turned out to be the sodium salt of **4**. The assignment of the geometry of the semicarbazones is based on the sharply contrasting cyclization behaviour of the two isomers. It is corroborated by the following spectral data. In the *syn*-isomer **3**-*Z*, the NH proton appeared at 10.8 ppm and the carbomethoxy group absorbed at 1695 cm^{-1} due to hydrogen bonding. For the *anti*-isomer, the corresponding bands appeared at 9.9 ppm and 1730 cm^{-1}. It should be noted that the *syn*-isomer absorbed in the ultraviolet at higher wavelength than the *anti*-isomer. Similar spectral data were observed for the hydrazones **1** and **10**, and the semicarbazone **8**. The spectral data are summarized in Scheme 1.

In order to make sure that the poor cyclization yield of hydrazone **1**-*E* was not due to slow conversion of the *anti*-isomer **1**-*E* to the *syn*-isomer **1**-*Z*, a methanolic solution of the *anti*-isomer, λ_{max} 273 nm, was irradiated with 254 nm light for 2 days. Purification by tlc gave the *syn*-isomer in 70% yield as an oil. Treatment of **1**-*Z* with sodium methoxide in methanol gave pyrazole **2** in 35% yield, indicating that *syn–anti* isomerization had occurred during the reaction and that the low yield obtained from the *anti*-isomer was not related to its lack of convertibility to the *syn*-isomer. In the case of the thiosemicarbazones it was obvious that the *anti*-isomer was easily converted to the *syn*-isomer under the reaction conditions, and no further work was done on that system.

These findings were applied to the synthesis of *C*-nucleoside analogues **13**, **14**, and **17**, which fully corroborated the observations made.

The keto ester **7** (1) was converted to its thiosemicarbazone **9**. Spectral data indicated it to consist of the *syn*- and *anti*-isomers in a ratio of approximately 1:1. Treatment of **9** with sodium methoxide in methanol gave **13** in 76% yield. Hydrolysis of protecting groups with 50% aqueous trifluoroacetic acid at room temperature for 30 min gave the crystalline 4-thio-6-azapseudouridine **14** in good yield.

For the preparation of a carbocyclic analogue



of 6-azapseudouridine, the keto ester **7** was converted to its semicarbazone **8**. Spectral data indicated it to consist of the *syn*- and *anti*-isomers in a ratio of 2:3. Cyclization with sodium methoxide in methanol gave the cyclized product **11** in 30% yield. Pure *anti*-isomer **8**-*E* was recovered in 50% yield. Irradiation of the *anti*-isomer, λ_{max} 263 nm, with 254 nm light for 2 days gave the *syn*-isomer, λ_{max} 272 nm, in quantitative yield. Cyclization of this product resulted in the formation of **11** in 80% yield. Hydrolysis of the protecting groups with 50% aqueous trifluoroacetic acid gave crystalline **12** in 75% yield. The same compound was obtained in the following manner. Olefinic ester **18** (6) was oxidized with potassium permanganate and sodium periodate (7). The resulting keto ester **19** was converted in 78% yield to its crystalline semicarbazone **20**, which consisted of the *syn*-isomer only according to its nmr and uv spectra. It could be cyclized readily using the standard procedure. The resulting cyclized product **21** was

reduced with diborane to give **22**. Treatment of **22** with 90% aqueous trifluoroacetic acid gave **12**, identical in all respects with the product described above.

The carbocyclic analogue of pyrazofurin A was synthesized in the following manner. The keto ester **7** was converted to its hydrazone **10**, which consisted of the *syn*- and *anti*-isomers in a ratio of 6:5, as established by high-pressure liquid chromatography. Cyclization of the mixture gave the crystalline pyrazole **15** in 40% yield. Treatment of **15** with ammonia for 7 days at room temperature gave the amide in 85% yield as a foam. Hydrolysis of the protecting groups gave the crystalline product **17**.

In conclusion, it may be stated that the variability in cyclization behaviours of the semicarbazones of α-keto esters reflects the *syn–anti* isomer ratio of the semicarbazones, which in turn depends to a large extent on the steric bulk of the alkyl or aryl substituent in the keto ester (8). In case of **20**, hydrogen bonding by the carboxyl group of the semicarbazone group seems to stabilize the *syn*-isomer considerably.

Experimental

Melting points were determined on a Gallenkamp block and are uncorrected. Mass spectra were obtained on an AEI-MS-902 mass spectrometer at 70 eV using a direct-insertion probe. Nuclear magnetic resonance spectra were recorded on a Varian Associates T-60 spectrometer. Infrared spectra were obtained on an Unicam SP 1000 and a Perkin–Elmer 257 ir spectrophotometer. Ultraviolet spectra were determined with an Unicam SP 800 spectrophotometer. The photolyses were carried out in Vycor tubes using a Rayonet photochemical reactor equipped with lamps with maximum output at 2537 Å. An Altex Model 300 liquid chromatograph was used for high pressure liquid chromatography. Microanalyses were carried out by Dr. C. Daessle, Montreal and Heterocyclic Chemical Corp., Harrisonville, Mo., U.S.A.

Preparation of Methyl Pyruvate Hydrazone ***1-E***

Methyl pyruvate (1.02 g), methyl hydrazinoacetate hydrochloride (1.68 g, 1.2 equiv.), and sodium acetate (990 mg, 1.2 equiv.) were dissolved in 15 ml of methanol and 5 ml of water. The solution was stirred at room temperature for 6 h. The solution was evaporated under reduced pressure. The residue was taken up in 20 ml of chloroform. The chloroform solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. Yield 1.62 g (86%); mp 70–72 °C; nmr ($CDCl_3$) δ 2.03 (s, 3H, $CH_3C{=}N$), 3.73 (s, 3H, COOMe), 3.80 (s, 3H, COOMe), 4.2 (bs, 2H, $NHCH_2COOMe$), 6.3 (bs, 1H, $NNHCH_2$); ir ($CHCl_3$) 3300 (NH), 1745/1715 (C=O), 1605 cm^{-1} (C=N); uv (MeOH) 273 nm (log ε 4.11).

3(5)-Carbomethoxy-4-hydroxy-5(3)-methylpyrazole ***2***

To a solution of hydrazone **1**-*E* (420 mg) in 5 ml of methanol was added 0.63 *M* sodium methoxide (6.8 ml, 2.5 equiv.). The solution was refluxed for 4 h and evaporated under reduced pressure. The residue was taken up in 10 ml of water, acidified in 0.5 *M* hydrochloric acid and then extracted three times with ethyl acetate. The ethyl acetate solution was dried over sodium sulfate and evaporated to dryness *in vacuo*. The crude product was chromatographed on silica gel plates using chloroform as an eluant (R_f = 0.6). Yield 102 mg (30%); mp 140–142 °C; nmr ($CDCl_3$) δ 2.2 (s, 3H, CH_3), 3.8 (s, 3H, COOMe), 8.4 (b, 2H, NH and OH); ir ($CHCl_3$) 3200–2500, 1720/1690 (C=O), 1640 cm^{-1}; uv λ_{max} 225 (log ε 3.75) and 275 nm (log ε 3.65) in 0.1 *N* HCl; λ_{max} 237 (log ε 3.78) and 317 nm (log ε 3.74) in 0.1 *N* NaOH.

Conversion of the anti-Isomer ***1-E*** *into the syn-Isomer* ***1-Z***

The hydrazone **1**-*E* (320 mg) was dissolved in 20 ml of methanol. The solution was irradiated for 2 days at 254 nm. The solvent was evaporated under reduced pressure and the crude product was chromatographed on silica gel plates using chloroform as an eluant for the separation. The *syn*-isomer was an oil (R_f = 0.7). Yield 225 mg (70%); nmr ($CDCl_3$) δ 2.00 (s, 3H, $CH_3C{=}N$), 3.67 (s, 3H, COOMe), 3.70 (s, 3H, COOMe), 4.13 (d, J = 6 Hz, 2H, $NHCH_2COOMe$), 10.2 (b, 1H, $NNHCH_2$); ir ($CHCl_3$) 330 (NH), 1750/1690 (C=O), 1570 cm^{-1} (C=N); uv (MeOH) 295 nm (log ε 3.97).

Preparation of Pyrazole ***2*** *from the syn-Hydrazone* ***1-Z***

The *syn*-hydrazone **1**-*Z* was treated with sodium methoxide at reflux for 4 h. After usual work-up and separation on silica gel plates, the pyrazole **2** was obtained in 35% yield. Spectral data (nmr, ir, and uv) were identical with those of **2** which was obtained from the *anti*-hydrazone **1**-*E*.

Preparation of the Semicarbazone of Methyl Pyruvate ***3-E***

To a solution of methyl pyruvate (1.02 g) in 20 ml of methanol was slowly added a solution of semicarbazide hydrochloride (1.22 g, 1.1 equiv.) and sodium acetate (900 mg, 1.1 equiv.) in 10 ml of water. The solution was stirred at room temperature for 1 h and the white precipitate was filtered off and washed several times with methanol. Yield 1.40 g (88%); mp 198–200 °C; nmr ($CDCl_3$) δ 2.08 (s, 3H, CH_3—C), 3.77 (s, 3H, COOMe), 6.4 (bs, 2H, $CONH_2$), 9.9 (bs, 1H, NNHCO); ir (KBr) 3540, 3400, 3300–3000, 1730 (COOMe), 1690 ($CONH_2$), 1595 (C=N), 1450 cm^{-1}; uv (MeOH) 262 nm (log ε 4.39).

Conversion of the anti-Semicarbazone ***3-E*** *into the syn-Semicarbazone* ***3-Z***

The *anti*-semicarbazone **3**-*E* (210 mg) was dissolved in 20 ml of methanol. The solution was irradiated at 254 nm for 2 days and separated by chromatography on silica gel plates using ethyl acetate as an eluant (R_f = 0.85). Yield 160 mg (80%); mp 128–130 °C; nmr ($CDCl_3$) δ 2.07 (s, 3H), 3.77 (s, 3H), 6.6 (bs, 2H, $CONH_2$), 10.8 (bs, 1H, NNH); ir (KBr) 3440, 3300, 1695 (C=O), 1600, 1450 cm^{-1}; uv (MeOH) 265 nm (log ε 4.37).

6-Methyl-3,5-dioxo-2,3,4,5-tetrahydro-1,2,4-triazine (6-Azathymine) ***4***

The *syn*-semicarbazone **3**-*Z* (140 mg) was added to 3.0 ml of 0.63 *M* (2.1 equiv.) methanolic sodium meth-

oxide. The solution was stirred at room temperature for 30 min. The formation of a white precipitate was observed after stirring a few minutes. Without filtration of the white precipitate, the reaction mixture was neutralized with Dowex 50W-X8 (H). The resin was filtered and the solvent was evaporated to dryness *in vacuo*. The crude product was crystallized from ethyl ether. Yield 85 mg (75%); mp 209–211 °C (lit. (4*c*) 210–212 °C); nmr (DMSO-d_6, external TMS) δ 2.03 (s, 3H, CH_3), 9.0–11.0 (b, 2H, NHCONH); ir (KBr) 3280, 3200, 1730/1680 (C=O), 1620 (C=N), 1480 cm^{-1}; uv λ_{max} 261 nm (log ε 3.73) in 0.1 *N* HCl; λ_{max} 246 nm (log ε 3.67) in 0.1 *N* NaOH.

Preparation of the Sodium Salt

The *syn*-semicarbazone **3**-*Z* (100 mg) was added to 1.2 ml of 0.6 *M* sodium methoxide (1.2 equiv.). The solution was stirred at room temperature for 10 min and the white precipitate was filtered off and washed with 1 ml of methanol. Drying *in vacuo* gave the sodium salt (45 mg) in 48% yield. Its uv spectrum was identical with that of **4** and the nmr spectrum in D_2O showed a singlet at 2.10 ppm for the methyl group.

Preparation of Thiosemicarbazone **5**-*E of Methyl Pyruvate*

Methyl pyruvate (2.06 g) and thiosemicarbazide (1.83 g, 1 equiv.) were dissolved in 30 ml of 80% aqueous methanol. The solution was stirred at room temperature for 30 min. The precipitate was filtered and washed several times with methanol. Yield 3.50 g (78%); mp 137–138 °C; nmr (DMSO, external TMS) δ 2.0 (s, 3H, CH_3—C), 3.7 (s, 3H, COOMe), 7.6 (bs, 1H), 8.5 (bs, 1H), 10.6 (b, 1H); ir (Nujol) 3540, 3250, 3180, 1730 (C=O), 1640 (C=N) cm^{-1}.

6-Methyl-3-thioxo-5-oxo-2,3,4,5-tetrahydro-1,2,4-triazine ***6***

A solution of the thiosemicarbazone **5**-*E* (285 mg) in 6.6 ml of 0.63 *M* sodium methoxide (2 equiv.) was refluxed for 3 h, cooled, and acidified with concentrated hydrochloric acid. The precipitate was filtered. Yield 155 mg (70%); mp 219–220 °C. (lit. (5*a*) mp 220 °C); uv λ_{max} 272 nm (log ε 4.27) in 0.1 *N* HCl; λ_{max} 265 nm (log ε 4.22) in 0.1 *N* NaOH.

*Methyl-2-(2′α,3′α-dihydroxy-di-O-isopropylidene-4*β*-tert-butyldimethylsiloxymethylcyclopent-1*β*-yl)glyoxylate Semicarbazone* ***8***

The keto ester **7** (290 mg), semicarbazide hydrochloride (135 mg, 1.5 equiv.), and sodium acetate (100 mg, 1.5 equiv.) were dissolved in 10 ml of methanol and 5 ml of water. The solution was stirred at room temperature overnight and then evaporated under reduced pressure to remove most of methanol. The reaction mixture was diluted with 5 ml of water and extracted with methylene chloride. The methylene chloride solution was washed with water, dried over sodium sulfate, and then evaporated to dryness *in vacuo*. Purification on silica gel plates using ethyl acetate as an eluant gave an oily semicarbazone **8** (300 mg) in 90% yield; nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.90 (s, 9H), 1.33 (s, 3H), 1.4–2.5 (m, 6H), 3.0–3.4 (m, 1H), 3.5–3.9 (m, 5H, COOMe, SiO—CH_2), 4.3–4.9 (m, 2H), 6.0 (b, 2H, $CONH_2$), 9.6 (bs, 0.4H, NNHCO), 11.3 (bs, 0.6H, NNHCO); ir ($CHCl_3$) 3540/3430/3400 (NH), 1720 (C=O), 1580 (C=N), 1470, 1395, 1385 cm^{-1}; uv (EtOH) 265 nm (log ε 4.00). *Anal.* calcd. for $C_{19}H_{35}O_6N_3Si$: C 53.15, H 8.16, N 9.79; found: C 52.97, H 8.04, N 9.49.

A mixture of geometrical isomers was separated using high pressure liquid chromatography on a silica gel column using 0.5% methanol in methylene chloride as an eluant at 920 psi. The first fraction, the *syn*-isomer **8**-*Z*: yield 40%; nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.90 (s, 9H), 1.33 (s, 3H), 1.53 (s, 3H), 1.7–2.5 (m, 3H), 3.1–3.5 (m, 1H), 3.67 (bd, J = 4 Hz, SiO—CH_2), 3.86 (s, 3H, COOMe), 4.3–4.8 (m, 2H), 5.8 (b, 2H, $CONH_2$), 11.3 (bs, 1H, NNHCO); ir ($CHCl_3$) 3540/3420/3300 (NH), 1700 (C=O), 1570 (C=N) cm^{-1}; uv (MeOH) 272 nm (log ε 4.01). The second fraction, the *anti*-isomer **8**-*E*: yield 60%; nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.90 (s, 9H), 1.30 (s, 3H), 1.58 (s, 3H), 1.7–2.4 (m, 3H), 3.0–3.4 (m, 1H), 3.73 (bd, J = 4 Hz, 2H), 3.83 (s, 3H, COOMe), 4.3–4.9 (m, 2H), 6.0 (b, 2H, $CONH_2$), 9.6 (bs, NNHCO); ir ($CHCl_3$) 3540/3440/3360 (NH), 1720 (C=O), 1570 cm^{-1}; uv (MeOH) 263 nm (log ε 4.06).

*6-(2′α,3′α-Dihydroxy-di-O-isopropylidene-4′*β*-tert-butyldimethylsiloxymethylcyclopent-1′*β*-yl)-3,5-dioxo-2,3,4,5-tetrahydro-1,2,4-triazine* ***11***

To a solution of a mixture of geometrical isomers of semicarbazone **8** (430 mg) in 10 ml of methanol was added 0.63 *M* sodium methoxide (3.2 ml, 2 equiv.). The solution was refluxed for 2 h and evaporated under reduced pressure. The residue was taken up in 10 ml of water, acidified with 0.5 *M* hydrochloric acid, and immediately extracted three times with ethyl acetate. The ethyl acetate solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The crude product was separated by chromatography on silica gel plates using ethyl ether and chloroform (5:1) as an eluant. Major product (R_f = 0.5): 215 mg (50%); spectral data (nmr, ir, uv) were identical with those of **8**-*E* which was separated using high pressure liquid chromatography. Minor product **11** (R_f = 0.7): 120 mg (30%); nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.90 (s, 9H), 1.33 (s, 3H), 1.53 (s, 3H), 1.7–2.7 (m, 3H), 3.10–3.85 (m, 3H), 4.2–4.6 (m, 1H), 4.6–5.1 (m, 1H), 10.0–11.0 (b and bs, 2H, NHCONH); ir ($CHCl_3$) 3420, 3380, 3100–3300, 1730/1710 (C=O), 1600 (C=N), 1470, 1460, 1395, 1385 cm^{-1}; uv λ_{max} 265 nm (log ε 3.78) in 0.1 *N* HCl; λ_{max} 255 nm (log ε 3.70) in 0.1 *N* NaOH; ms (150 °C) *m/e* 397 (M^+), 382 ($M^+ - CH_3$), 340 ($M^+ - C(CH_3)_3$), 282 (M^+ – *tert*-butyldimethylsilyl), 140 (B + 28), 139 (B + 27). *Anal.* calcd. for $C_{18}H_{31}O_5N_3Si$: C 54.37, H 7.87, N 10.57; found: C 54.18, H 8.01, N 10.61.

Conversion of **8**-*E into* **8**-*Z*

The *anti*-semicarbazone **8**-*E* (120 mg) was dissolved in 20 ml of methanol. The solution was irradiated at 254 nm for 2 days and evaporated to dryness *in vacuo* to afford the *syn*-semicarbazone **8**-*Z* in essentially quantitative yield. Spectral data (nmr, ir, and uv) were identical with those of **8**-*Z* which was separated using high pressure liquid chromatography.

*Preparation of (***11***) from the syn-Semicarbazone* **8**-*Z*

To a solution of the *syn*-isomer **8**-*Z* (110 mg) obtained from the above reaction in 5 ml of methanol was added 0.8 ml of 0.63 *M* sodium methoxide (2 equiv.). The solution was refluxed for 2 h and evaporated under reduced pressure. The residue was taken up in 10 ml of water.

The resulting solution was acidified with 0.5 *M* hydrochloric acid and extracted three times with ethyl acetate. The ethyl acetate solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo* to give **11** (81 mg) in 80% yield. Spectral data (nmr, ir, and uv) were identical with those of **11** which obtained from **8**.

6-(2′α,3′α-Dihydroxy-4′β-hydroxymethylcyclopent-1′β-yl)-3,5-dioxo-2,3,4,5-tetrahydro-1,2,4-triazine ***12***

To a solution of **11** (180 mg) in 5 ml of methanol was added 5 ml of 50% aqueous trifluoroacetic acid. The solution was stirred at room temperature for 20 min and evaporated to dryness *in vacuo*. The crude product was crystallized from methanol and ethyl ether. Yield 85 mg (75%); mp 184–186 °C; ir (KBr) 3480/3250/3150 (OH, NH), 1735/1690 (C=O), 1620, 1470 cm^{-1}; uv: λ_{max} 265 nm (log ε 3.80) in 0.1 *N* HCl; λ_{max} 254 nm (log ε 3.74) in 0.1 *N* NaOH; ms (200 °C) *m/e* 244 ($M^+ + 1$), 243 (M^+), 225 ($M^+ - H_2O$), 207 ($M^+ - 2H_2O$), 196, 194, 178, 140 ($B + 28$), 139 ($B + 27$). *Anal.* calcd. for $C_9H_{13}O_5N_3$: C 44.44, H 5.39, N 17.28; found: C 44.38, H 5.19, N 17.02.

Methyl-2-(2α,3α-dihydroxy-di-O-isopropylidene-4β-tert-butyldimethylsiloxymethylcyclopent-1β-yl)glyoxylate Thiosemicarbazone ***9***

To a solution of the keto ester **7** (530 mg) in 20 ml of methanol was added thiosemicarbazide (150 mg, 1.1 equiv.). The reaction mixture was refluxed overnight and evaporated to near dryness under reduced pressure. The residue was taken up in 20 ml of chloroform. The solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The crude product was purified on silica gel plates using ethyl ether as an eluant. Yield 545 mg (86%); nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.9 (two s, 9H), 1.2–2.8 (m, 10H), 3.4–3.8 (m, 5H), 4.2–4.6 (b, 2H), 4.9–5.1 (b, 1H), 7.0–7.2 (b, 1H), 9.2 (bs, 0.5H), 12.1 (bs, 0.5H); ir ($CHCl_3$) 3540, 3400, 3300, 1730/1710 (C=O), 1580 (C=N), 1480, 1395, 1385 cm^{-1}; uv (MeOH) 273 nm (log ε 3.78) and 315 (log ε 3.68); ms (195 °C) *m/e* 445 (M^+), 430 ($M^+ - CH_3$), 388 ($M^+ - C(CH_3)_3$), 386, 356, 330, 298.

6-(2′α,3′α-Dihydroxy-di-O-isopropylidene-4′β-tert-butyldimethylsiloxycyclopent-1′β-yl)-3-thioxo-5-oxo-2,3,4,5-tetrahydro-1,2,4-triazine ***13***

To a solution of the thiosemicarbazone **9** (200 mg) in 5 ml of methanol was added 0.8 ml of 0.63 *M* sodium methoxide (1.1 equiv.). The solution was refluxed for 3 h and evaporated under reduced pressure. After adding 10 ml of water, the solution was acidified with 0.5 *N* hydrochloric acid and then extracted three times with ethyl acetate. The ethyl acetate solution was dried over sodium sulfate and evaporated to dryness *in vacuo*. Purification of the crude product on silica gel plates using chloroform and ethyl ether (1:2) as an eluant gave the desired product **13** (146 mg) as an oil in 76% yield; nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.93 (s, 9H), 1.43 (s, 3H), 1.67 (s, 3H), 1.8–2.7 (b, 3H), 3.3–3.9 (m, 3H), 4.4–4.7 (m, 1H), 4.9–5.2 (m, 1H), 10.7–12.2 (b, 2H); ir ($CHCl_3$) 3420, 3380, 3200–3300, 1710, 1610, 1530 cm^{-1}; uv λ_{max} 215 (log ε 3.91) and 269 nm (log ε 4.18) in 0.1 *N* HCl; λ_{max} 224 (log ε 4.11), 258 (log ε 4.07) and 310 nm (log ε 3.60) in 0.1 *N* NaOH; ms (185 °C) *m/e* 389 ($M^+ - CH_3$), 356 ($M^+ - C(CH_3)_3$), 298 (M^+-*tert*-butyldimethylsilyl), 280, 206.

6-(2′α,3′α-dihydroxy-4′β-hydroxymethyl-1′β-yl)-3-thioxo-5-oxo-2,3,4,5-tetrahydro-1,2,4-triazine ***14***

To a solution of **13** (110 mg) in 2 ml of tetrahydrofuran was added 5 ml of 50% aqueous trifluoroacetic acid. The solution was stirred at room temperature for 30 min and evaporated to dryness *in vacuo*. The crude product was crystallized from methanol and ethyl ether. Yield 50 mg (72%); mp 163–165 °C; ir (KBr) 3480, 3280, 3100, 1705, 1610, 1560 cm^{-1}; uv λ_{max} 215 (log ε 3.96) and 269 nm (log ε 4.20) in 0.1 *N* HCl; λ_{max} 224 (log ε 4.11), 258 (log ε 4.08), and 310 nm (log ε 3.52) in 0.1 *N* NaOH; ms (190 °C) *m/e* 259 (M^+), 241 ($M^+ - H_2O$), 223 ($M^+ - 2H_2O$), 212, 210, 156 ($B + 28$), 155 ($B + 27$).

Preparation of its Hydrazone ***10*** *from* ***7***

The keto ester **7** (720 mg), ethyl hydrazinoacetate hydrochloride (450 mg, 1.5 equiv.), and sodium acetate (240 mg, 1.5 equiv.) were added in 15 ml of methanol and 5 ml of water. The solution was stirred at room temperature overnight. The solution was evaporated under reduced pressure to remove most of the methanol and 20 ml of chloroform was added to the reaction mixture. The chloroform solution was washed with water, dried over sodium sulfate, and then evaporated to dryness *in vacuo*. The crude product was purified by chromatography on silica gel plates using ethyl ether as an eluant. Yield 850 mg (89%); nmr ($CDCl_3$) δ 0.05 (s, 6H), 0.90 (s, 9H), 1.1–1.7 (m, 9H, O—CH_2CH_3, acetonide), 1.8–2.4 (m, 3H), 3.0–3.3 (m, 1H), 3.5–3.9 (m, 5H, COOMe, SiO—CH_2), 4.0–4.9 (m, 6H), 6.90 (t, $J = 5$ Hz, 0.6H, NH), 10.2 (t, $J = 5$ Hz, 0.4H, NH); ir ($CHCl_3$) 3300 (NH), 1750/1700 (C=O), 1580 (C=N) cm^{-1}; uv (MeOH) 287 nm (log ε 3.93); ms (160 °C) *m/e* 472 (M^+), 457 ($M^+ - CH_3$), 441 ($M^+ - OCH_3$), 415 ($M^+ - C(CH_3)_3$), 357 (M^+ – *tert*-butyldimethylsilyl group) 257, 169. *Anal.* calcd. for $C_{22}H_{40}O_7N_2Si$: C 55.93, H 8.33, N 5.93; found: C 55.98, H 8.68, N 6.06.

Unusual formation of *N*-(1-isoquinolinyl)benzamide from 1-*o*- and 1-*m*-chlorobenzoylisoquinolines

D. Prasad Aysola and Martin S. Gibson

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received July 6, 1976

D. Prasad Aysola and Martin S. Gibson. Can. J. Chem. **55**, 435 (1977).

Syntheses of 1-*o*- and 1-*m*-chlorobenzoylisoquinolines are described, (*a*) from 2-benzoyl-1,2-dihydroisoquinoline-1-carbonitrile and the appropriate chlorobenzaldehyde, and (*b*) from 2-*o*- and 2-*m*-chlorobenzoyl-1,2-dihydroisoquinoline-1-carbonitrile. Treatment of either ketone with potassamide – potassium *tert*-butoxide in ammonia gives *N*-(1-isoquinolinyl)benzamide. The mechanism of this reaction is discussed.

D. Prasad Aysola et Martin S. Gibson. Can. J. Chem. **55**, 435 (1977).

On décrit des synthèses des *o*- et *m*-chlorobenzoyl-1 isoquinoléines à partir: (*a*) du benzoyl-2 dihydro-1,2 isoquinoléine carbonitrile-1 et du chlorobenzaldéhyde approprié et (*b*) des *o*- et *m*-chlorobenzoyl-2 dihydro-1,2 isoquinoléine carbonitriles-1. Le traitement de l'une ou l'autre des deux cétones par de l'amidure ou du *tert*-butylate de potassium dans l'ammoniac conduit au *N*-(isoquinolynyl-1) benzamide. On discute du mécanisme de cette réaction.

[Traduit par le journal]

Bunnett and Hrutfiord have noted that potassamide in ammonia cleaves *o*-chlorobenzophenone to give a mixture of aniline, benzamide, and benzoic acid, but converts *m*-chlorobenzophenone to a mixture of *o*- and *m*-aminobenzophenones (1). Our main interest in these reactions lies in the area of cleavage suppression and heterocyclic synthesis (2), but we have a supplementary interest in problems connected with synthesis of aporphine alkaloids (3), including those of the 7-oxoaporphine sub-group typified by liriodenine (4). To this end we have investigated the behaviour of 1-*o*- and 1-*m*-chlorobenzoylisoquinolines in this type of reaction.

These ketones were prepared from the Reissert compound, 2-benzoyl-1,2-dihydroisoquinoline-1-carbonitrile (5). Treatment with sodium hydride, followed by the appropriate chlorobenzaldehyde, gave the corresponding chlorophenyl-1-isoquinolinylmethyl benzoate. Hydrolysis of the ester to the secondary alcohol, followed by oxidation, gave in each case the desired ketone. We note parenthetically that we have encountered difficulties similar to those reported previously (6) for reactions of the anion of 2-benzoyl-1,2-dihydro-6,7-dimethoxyisoquinoline-1-carbonitrile. However, we find the latter Reissert compound to be stable in refluxing benzene (though not at its melting point) and the earlier reference to its thermal instability would seem to be associated rather with solvolysis in ethanol or ethanolic picric acid.

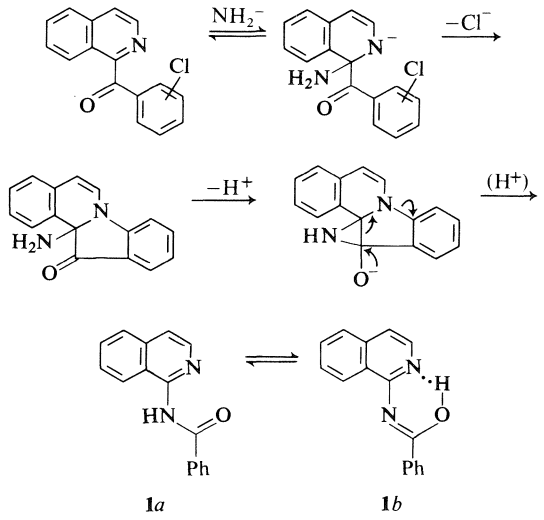
An alternative synthesis for each of the two ketones was also considered. Reaction of isoquinoline with the corresponding chlorobenzoyl chloride and potassium cyanide in dichloromethane–water (5) gave the corresponding Reissert compound. Treatment of the latter with sodium hydride in dimethylformamide (DMF) (7) gave the desired ketone by expulsion of cyanide ion, but in each case the yield was poor.

A somewhat dirty mixture resulted from reaction of 1-*o*-chlorobenzoylisoquinoline with potassamide – potassium *tert*-butoxide in ammonia, from which a compound, $C_{16}H_{12}N_2O$, was isolated in 17% yield. A similar reaction, conducted in presence of dibenzo-18-crown-6 ether (8), was much cleaner and gave the same product in 77% yield. The same compound was obtained from 1-*m*-chlorobenzoylisoquinoline. This product was isomeric with, but not identical to 1-*o*-aminobenzoylisoquinoline (9) (mixture mp and mass spectrum). The mass spectrum showed peaks at *m/e* 248 (M^+), 171 ($C_9H_7N_2CO$), 143 ($C_9H_7N_2$), 105 (C_6H_5CO), and 77 (C_6H_5). These data suggested that the compound was *N*-(1-isoquinolinyl)benzamide (**1***a*), and identification was subsequently confirmed by direct comparison with an authentic sample (10). Tamura *et al.* (10) have suggested that compound (**1***a*) exists in the enolic form (**1***b*) as the ir spectrum exhibited no CO absorption band in the expected region. We concur in this, noting further that the ir spectrum (KBr) exhibits a broad peak at 2480 cm^{-1}, indicative of a strong O—H· · ·N hydrogen bond (11). The nmr spec-

trum ($CDCl_3$) shows the signal due to the proton involved at unusually high field (δ 15.4 ppm).

We view the formation of **1** in these reactions in terms of a mechanism of the following type (Scheme 1). Amide ion adds reversibly at position 1 in competition with amide ion addition to the carbonyl group. This increases the nucleophilicity of the ring N-atom which bonds to the *ortho*-position of the chlorobenzoyl group; chloride ion is lost by substitution or aryne mechanisms as appropriate. Intramolecular acylation of the angular amino-group (or its conjugate base) is accompanied by regeneration of the isoquinoline system and formation of a carbanion which is protonated to form the phenyl group in the product. Another possibility follows an earlier suggestion (1) that amide ion adds to the carbonyl group and that after deprotonation the amide derived nitrogen then bonds as above to the *ortho*-position of the chlorobenzoyl group. Reformation of the carbonyl group with migration of the 1-isoquinolinyl group to nitrogen and ring cleavage would then produce the same carbanion as that in the above mechanism. This latter mechanism would suggest that benzanilide should be found amongst the products from the reactions of *o*- and *m*-chlorobenzophenones with potassamide, though its presence was not observed (1).

Lastly, we have noted that treatment of either 1-*o*- or 1-*m*-chlorobenzoylisoquinoline with potassium *tert*-butoxide – water in 1,2-dimethoxyethane (12) for 3 h at 20 °C resulted in almost quantitative recovery of the ketone.[1] It seems that neither ketone is very susceptible to cleavage.



SCHEME 1

Experimental

Mass spectra were determined with an AEI-MS30 double beam mass spectrometer; data are quoted as *m/e* values for the lowest isotopic species. Proton magnetic resonance spectra were recorded on a Bruker WP-60 spectrometer at 60 MHz using tetramethylsilane as internal reference.

Preparation of Reissert Compounds

o-Chlorobenzoyl chloride (14 g, prepared from *o*-chlorobenzoic acid and $SOCl_2$) was added during 1 h under nitrogen to the stirred two-phase system composed of 6,7-dimethoxyisoquinoline (6) (3.5 g) dissolved in CH_2Cl_2 (120 ml) and KCN (12 g) in water (60 ml). More KCN (7 g) in water (30 ml) was added and stirring was continued for 6–8 h. The phases were separated and the aqueous layer was washed with CH_2Cl_2. The CH_2Cl_2 solutions were combined, washed in turn with water, 5% HCl, water, 5% NaOH, and water, dried ($MgSO_4$) and evaporated *in vacuo* to give a brown solid. Crystallization from benzene gave *2-o-chlorobenzoyl-1,2-dihydro-6,7-dimethoxyisoquinoline-1-carbonitrile* as cubes (4.0 g, 61%), mp 174–176 °C; ms *m/e* 354 (M^+, 25%) and 139 (ClC_6H_4CO, 100%). *Anal.* calcd. for $C_{19}H_{15}ClN_2O_3$: C 64.00, H 4.20, N 7.90; found: C 64.09, H 4.21, N 7.76.

Similarly prepared were: 2-benzoyl-1,2-dihydroisoquinoline-1-carbonitrile (65%) (5); 2-*o*-chlorobenzoyl-1,2-dihydroisoquinoline-1-carbonitrile (28%) (13); 2-*m*-chlorobenzoyl-1,2-dihydroisoquinoline-1-carbonitrile (30%) (5); and 2-benzoyl-1,2-dihydro-6,7-dimethoxyisoquinoline-1-carbonitrile (54%) (6).

o-Chlorophenyl-1-isoquinolinylmethyl Benzoate

To a solution of 2-benzoyl-1,2-dihydroisoquinoline-1-carbonitrile (1.3 g) in dry benzene (25 ml) heated under reflux was added 50% sodium hydride dispersion in mineral oil (0.54 g). After 3 min, *o*-chlorobenzaldehyde (0.6 ml) was added. Heating under reflux was continued for 2 h and then the mixture was filtered, washed with water (25 ml), 0.5 *M* HCl (25 ml), and water (25 ml). The benzene solution was dried and evaporated. Trituration of the residue gave *o-chlorophenyl-1-isoquinolinylmethyl benzoate*, which crystallized from ethanol as needles (0.93 g, 50%), mp 104–105 °C; ms *m/e* 373 (M^+, 8%) and 105 (C_6H_5CO, 100%). *Anal.* calcd. for $C_{23}H_{16}ClNO_2$: C 73.90, H 4.28, N 3.75; found: C 73.90, H 4.42, N 3.75.

Similarly prepared was *m-chlorophenyl-1-isoquinolinylmethyl benzoate*, which crystallized from benzene – light petroleum (bp 30–60 °C) as needles (1.27 g, 67%), mp 156–158 °C; ms *m/e* 373 (M^+, 6%) and 105 (C_6H_5CO, 96%). *Anal.* found: C 74.05, H 4.22, N 3.72.

o-Chlorophenyl-1-isoquinolinylmethanol

A solution of *o*-chlorophenyl-1-isoquinolinylmethyl

[1]In a parallel study, Deborah T. Allen has noted that refluxing ethanolic potassium hydroxide slowly reduces 1-benzoylisoquinoline to the corresponding alcohol, with little cleavage; under similar conditions, 2-methyl-1-benzoylisoquinolinium iodide is partially cleaved, the products including 2-methyl-1-isoquinolone and benzoate ion.

benzoate (0.5 g), KOH (3.0 g), ethanol (50 ml), and water (25 ml) was boiled under reflux for 24 h. The mixture was concentrated *in vacuo* and then diluted with water. Extraction with ether gave an oil which solidified on trituration with cold ether. Crystallization from cyclohexane gave *o-chlorophenyl-1-isoquinolinylmethanol* as needles (0.34 g, 95%), mp 115–117 °C; ms *m/e* 269 (M^+, 11%) and 234 ($C_{16}H_{12}NO$, 100%). *Anal.* calcd. for $C_{16}H_{12}ClNO$: C 71.13, H 4.50, N 5.20; found: C 71.20, H 4.44, N 5.27.

m-Chlorophenyl-1-isoquinolinylmethanol was similarly prepared and obtained as an oil (0.3 g, 83%); ms *m/e* 269 (M^+, 31%) and 129 (C_9H_7N, 100%).

1-o-Chlorobenzoylisoquinoline

(a) By Oxidation

A solution of sodium dichromate (0.66 g) in glacial acetic acid (5 ml) was added to *o*-chlorophenyl-1-isoquinolinylmethanol (0.54 g) dissolved in acetic acid (10 ml). The mixture was heated on a steam bath for a few minutes and then diluted with water and basified (NH_4OH). The solid was filtered off and dried. Crystallization from cyclohexane gave *1-o-chlorobenzoylisoquinoline* as needles (0.48 g, 90%), mp 100–103 °C; ms *m/e* 267 (M^+, 4%) and 232 ($C_{16}H_{10}NO$, 100%). *Anal.* calcd. for $C_{16}H_{10}ClNO$: C 72.00, H 3.70, N 5.20; found: C 71.50, H 3.80, N 5.28.

1-m-Chlorobenzoylisoquinoline, similarly prepared, crystallized from cyclohexane as needles (0.48 g, 90%), mp 104–105 °C; ms *m/e* 267 (M^+, 67%) and 266 ($C_{16}H_9ClNO$, 100%). *Anal.* found: C 71.71, H 3.64, N 5.24.

(b) By Rearrangement

Sodium hydride (48 mg, weighed as 50% dispersion in mineral oil and washed free of oil with light petroleum) was suspended in dry DMF (10 ml) and stirred at 18 °C under dry nitrogen. A solution of 2-*o*-chlorobenzoyl-1,2-dihydroisoquinoline-1-carbonitrile (0.97 g) in DMF (15 ml) was added during 10 min and the mixture was then stirred at ambient temperature for 2 h. Ethanol (1 ml) was added and solvents were evaporated *in vacuo* leaving a solid residue. Crystallization from cyclohexane gave 1-*o*-chlorobenzoylisoquinoline (0.1 g, 16%), identical (mp and mixture mp, nmr and mass spectra) with the previous sample.

1-*m*-Chlorobenzoylisoquinoline (52 mg, 13%) was similarly prepared and identified by comparison with the previous sample.

N-(1-Isoquinolinyl)benzamide

(*a*) A solution of 1-*o*-chlorobenzoylisoquinoline (1.0 g) in dry tetrahydrofuran (10 ml) was added dropwise to a stirred solution of potassamide, prepared from potassium (10 g), and potassium *tert*-butoxide (1 g) in redistilled liquid ammonia (150 ml). The resulting brown mixture was stirred for 5 h and then NH_4Cl (28 g) was added in small portions and the ammonia was allowed to evaporate overnight under nitrogen. Water (60 ml) was added and the mixture was extracted with CH_2Cl_2. The extract was washed with water, dried (K_2CO_3), and evaporated. Chromatography on silica gel and elution with benzene–acetone (4:1) gave a buff solid which crystallized from cyclohexane to give colourless crystals of *N*-(1-isoquinolinyl)benzamide (160 mg, 17%), mp 105–106 °C (lit. (10) mp 105.5–106.5 °C). Identity was established by mixture mp, tlc, and spectroscopic correlations with an authentic sample. Spectroscopic data were: ms *m/e* 248 (M^+, 50%), 247(38%), 232(7%), 220(21%), 219(63%), 171(62%), 143(5%), 128(7%), 105(100%), and 77(16%); nmr ($CDCl_3$) δ 15.4 (br s, 1H, exchangeable with D_2O), and 10–8 ppm (10H, aromatic protons). *Anal.* calcd. for $C_{16}H_{12}N_2O$: C 77.45, H 4.69, N 11.43; found: C 77.42, H 4.84, N 11.29.

(*b*) The yield of *N*-(1-isoquinolinyl)benzamide was increased to 77% by increasing the quantity of potassium metal (18 g) and adding dibenzo-18-crown-6 ether (0.1 g) to the reaction mixture.

(*c*) Experiment *a* was repeated, substituting 1-*m*-chlorobenzoylisoquinoline (1.0 g) for the *o*-isomer, to give *N*-(1-isoquinolinyl)benzamide (200 mg, 21%), mp 105–106 °C. Identity was established as in the previous case.

Acknowledgments

We are indebted to Professors Y. Tamura (Osaka University, Japan) and J. L. Neumeyer (Northeastern University, Boston, Mass.) for samples of *N*-(1-isoquinolinyl)benzamide and 1-*o*-nitrobenzoylisoquinoline respectively, I. D. Brindle for helpful discussion, and the National Research Council of Canada for financial support.

Charge distribution in dioxygen complexes of cobalt(III). The crystal structure and absolute configuration of $(+)_{546}$-Δ-*cis*-β-[{2,13-dimethyl-6,9-diphenyl-2,6,9,13-tetraarsatetradecane}(dioxygen)cobalt(III)] perchlorate

DAVID B. CRUMP, ROBERT F. STEPANIAK, AND NICHOLAS C. PAYNE

Received May 21, 1976

DAVID B. CRUMP, ROBERT F. STEPANIAK, and NICHOLAS C. PAYNE. Can. J. Chem. **55**, 438 (1977).

The crystal structure and absolute configuration of an optically active dioxygen complex of cobalt(III) have been determined from three dimensional X-ray diffraction data collected by counter techniques. $(+)_{546}$-Δ-*cis*-β-[Co{*R*,*R*-$(CH_3)_2As(CH_2)_3As(C_6H_5)(CH_2)_2As(C_6H_5)(CH_2)_3As(CH_3)_2$}$O_2$]$ClO_4$ crystallizes in the orthorhombic space group $P2_12_12_1$, in a unit cell of dimensions $a = 12.595(7)$, $b = 20.937(10)$, and $c = 11.509(6)$ Å. There are four formula units per cell. The structure was refined on F by full matrix least-squares techniques, and converged with an agreement factor $R = 0.0474$ based on 2988 independent observations collected from two crystals. The absolute configuration of the cation was determined by the Bijvoet absorption edge technique to be Δ. The tetradentate ligand adopts the *cis*-β configuration around the cobalt atom. One six-membered ring has a chair conformation; the other is disordered, and occurs with equal probability in a chair and a distorted boat conformation. The five-membered chelate ring has a *gauche* conformation, of absolute configuration λ. The absolute configurations at the asymmetric arsenic atoms are both *R*. The O—O bond length is 1.424(10) Å. The assignment of formal oxidation states to the cobalt atom and the dioxygen ligand is discussed in light of the molecular geometry and the optical properties of the cation.

DAVID B. CRUMP, ROBERT F. STEPANIAK et NICHOLAS C. PAYNE. Can. J. Chem. **55**, 438 (1977).

On a déterminé la structure cristalline et la configuration absolue d'un complexe dioxygéné optiquement actif du cobalt(III); ces résultats ont été obtenus à partir de données de diffraction de rayon-X en trois dimensions recueillies par la technique des compteurs. Le $(+)_{546}$-Δ-*cis*-β-[Co{*R*,*R*-$(CH_3)_2As(CH_2)_3As(C_6H_5)(CH_2)_2As(C_6H_5)(CH_2)_3As(CH_3)_2$}$O_2$]$ClO_4$ cristallise sous forme orthorhombique avec un groupe d'espace $P2_12_12_1$ et une maille de dimension $a = 12.595(7)$, $b = 20.937(10)$ et $c = 11.509(6)$ Å. Il y a quatre unités de formule par maille. On a affiné la structure sur le fluor par la technique des moindres carrés (matrice complète) jusqu'à un facteur final de $R = 0.0474$ basé sur 2988 observations indépendantes recueillies à partir de deux cristaux. Faisant appel à la technique des absorptions limites de Bijvoet on a établi que la configuration absolue du cation est Δ. Le ligand tétradentate adopte une configuration *cis*-β autour de l'atome de cobalt. Un des cycles à six membres existe sous une conformation chaise; l'autre est désordonné et se produit avec une probabilité égale de conformation chaise et de bateau croisé. Le chélate de cycle à cinq membres a une conformation *gauche* de configuration absolue λ. Les configurations absolues au niveau des atomes d'arsenic asymétriques sont tous les deux *R*. La longueur du lien O—O est de 1.424(10) Å. On discute de l'attribution des états formels d'oxydation au niveau de l'atome de cobalt et du ligand dioxygéné en termes de géométrie moléculaire et de propriétés optiques du cation.

[Traduit par le journal]

Introduction

Dioxygen complexes of group VIII transition metals have been the subject of several recent reviews (1–4). Two different modes of attachment of the O_2 ligand to the metal atom have been demonstrated. Firstly, the diamagnetic 1:1 adducts in which the ligand is 'sideways' bonded with equivalent M—O distances. Secondly, there are complexes with a 'bent' geometry, and two unequal M—O distances. Examples of both geometries have been found for cobalt.

Monomeric complexes evincing the bent geometry are commonly regarded as superoxo compounds of Co(III). Thus, the 1:1 adducts with Co(II) Schiff base complexes have been described as containing the Co(III)—O_2^- group (5–7). The binuclear cobalt amine complexes are considered to be Co(III) complexes of either the superoxide or the peroxide, O_2^{2-}, ligands (8–10). Prior to this study we are aware of only one cobalt complex in which definitive evidence exists for a 'sideways' bonded dioxygen ligand.

Amma and co-workers (11) reported the X-ray structural characterization of the diamagnetic complex $[Co(O_2)\{(C_6H_5)_2PCHCHP(C_6H_5)_2\}_2]$-$BF_4(C_6H_6)_2$. The O_2 ligand is symmetrically bonded, with Co—O bond lengths of 1.871(7) and 1.902(7) Å. The metal coordination geometry was described as either that of a trigonal bipyramid, or a distorted octahedron, with two metal–oxygen bonds. The authors pointed out that conventional coordination numbers and integral oxidation states, *i.e.*, Co(III)—O_2^{2-} or Co(II)—O_2^- represent localised states in a continuum of bonding situations, in a manner analogous to that described for metal–acetylene complexes by Maitlis and co-workers (12), Chatt and Duncanson (13), and Dewar (14).

We present here the first crystal structure analysis of an optically active cobalt dioxygen complex in which the O_2 ligand is 'sideways' bonded to the metal atom. This study was undertaken to determine the geometry of the Co—O_2 bond, and the absolute configuration of the cation. In addition, the results have permitted some conclusions to be drawn as to the charge distribution over the Co—O_2 moiety (15).

Experimental Section

A crystalline sample of $[Co(O_2)(As_4C_{24}H_{38})]ClO_4$ was prepared by Jackson and co-workers (15). The salt forms deep red crystals elongated along [001]. A series of photographs of reciprocal lattice layers $hk(0,1)$, $h(0,1)l$, and $(0,1)kl$, taken with CuKα radiation, indicated the crystals to be orthorhombic, with Laue symmetry *mmm*. There are very few reflections with intensities significantly greater than background for which $\lambda^{-1}\sin\theta$ exceeded 0.40. Systematic absences of h odd, $h00$; k odd, $0k0$; and l odd, $00l$ demonstrated unambiguously the space group to be $P2_12_12_1$ (no. 19, D_2^4) (16). Preliminary cell constants were obtained from the films. The density of the crystals was measured by flotation in a mixture of carbon tetrachloride and ethyl iodide. The values so obtained indicated four formula units per cell. There can be no crystallographic symmetry conditions imposed upon the ions.

The analysis of the structure has taken several years. The collection of intensity data is complicated by the susceptibility of the crystals to X-ray damage. Initially data were collected using Nb filtered Mo radiation, but an examination of the intensities of several standard reflections recorded frequently during the experiment showed a decrease in intensity sometimes approaching 50%, and a deterioration in peak quality as shown by ω-scans (17). These data were sufficient to solve the structure. A second data set was then collected using Cu radiation and a small crystal to minimise absorption effects ($\mu \simeq 100\ cm^{-1}$). Again, radiation damage and the lack of reflections of significant intensity for which $2\theta > 75°$ resulted in unacceptably low precision. Data collected from several other small crystals provided better results, but too few observations to yield acceptable precision. Finally sufficient data were obtained only by using two large crystals, (each approximately 0.4 mm × 0.3 mm × 0.4 mm), which were carefully measured using a filar micrometer eyepiece to facilitate an absorption correction. Crystal data and details of experimental conditions for data collection are summarised in Table 1.

The observations were corrected for background, Lorentz and polarisation effects. A standard deviation σ was assigned to each observation

$$(\sigma(I))^2 = C + \tfrac{1}{4}(t_c/t_b)^2(b_1 + b_2) + (pI)^2$$

where $I = C - \frac{1}{2}(b_1 + b_2)(t_c/t_b)$, C is the total count measured in time t_c, and b_1 and b_2 are background counts, each measured in time t_b. An absorption correction was applied to the data from each crystal.[1] The value of p was chosen to be 0.02.

Structure Solution and Refinement

An initial solution was obtained using 957 observations recorded with MoKα radiation. The Co atom and one As atom were located from a three dimensional Patterson synthesis, and a series of full matrix least-squares refinements and difference Fourier syntheses yielded the positions of the remaining 34 non-hydrogen atoms. When the first set of data collected with Cu radiation became available, the structure was refined with isotropic thermal parameters assigned to the C atoms, and anisotropic parameters to the Co, As, Cl, and O atoms. The phenyl rings were treated as rigid groups. The absolute configuration of the cation was determined to be Δ by the Bijvoet technique (18). Conformational disorder between a chair and a distorted boat was observed in one chelate ring. Refinement converged with 1349 unique observations at $R = 0.067$. The O—O bond length of 1.45 Å had an estimated standard deviation of 0.03 Å, a value considered unacceptably large. The analysis remained at this stage until fresh data were collected using larger crystals.

The final refinement described hereafter was based upon 2654 observations with $F^2 > 0$ collected from crystal 1 within the range $0 < 2\theta \leqslant 90°$, and 1006 observations with $F^2 > 0$ collected from crystal 2 over the range $90 < 2\theta \leqslant 110°$. At greater 2θ values fewer than 1 in 20 observations were significantly different from zero, so no further data were collected. Although the $0kl$ data were collected over the range $0 < 2\theta \leqslant 60°$ for both crystals (60 observations) with a view to scaling the two sets of data, in the final calculations a scale factor was refined for each data set and no other attempt was made to convert the intensities to a common scale.

Refinement was by full matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where the weight w is defined as $4F_o^2/\sigma^2(F_o^2)$. The atomic scattering factors for Co, As, Cl, O, and C were taken from Cromer and Waber's tabulation (19); that of H

[1]Computing was carried out on the CDC Cyber 73-14 at the University of Western Ontario. Programs used include local modifications of: orientation matrix and cell refinement, PICK by Ibers; absorption correction, AGNOST, by Cahen and Ibers; Fourier syntheses, FORDAP, by Zalkin; least-squares refinements and structure factor calculations, WOCLS, a version of NUCLS by Ibers; function and error calculations, ORFFE by Busing, Martin, and Levy, and ORTEP, by Johnson.

from Stewart *et al.* (20). Values of F_c were corrected for the real and imaginary contributions to anomalous dispersion of the Co, As, and Cl atoms. Values of $\Delta f'$ and $\Delta f''$ were taken from Cromer and Liberman (21). The phenyl rings were treated as groups, with D_{6h} symmetry, and a C—C bond length of 1.392 Å (22). Isotropic thermal parameters were assigned to all atoms except the Co, As, Cl, and O atoms. One cycle of least-squares refinement converged at agreement factors

$$R_1 = \frac{\sum (||F_o| - |F_c||)}{\sum |F_o|} = 0.089$$

and

$$R_2 = \left(\frac{\sum w(|F_o| - |F_c|)^2}{\sum wF_o^2}\right)^{1/2} = 0.117$$

An examination of the molecular geometry showed several disturbing features. C(1), C(2), C(3), C(4), and C(5), which comprise one $(CH_3)_2AsCH_2CH_2CH_2$ fragment in the tetradentate ligand, all had abnormally high thermal parameters, and were related by unacceptable bond lengths. The existence of disorder, as observed before, whether static or dynamic, was therefore considered. A difference Fourier synthesis calculated from structure factors computed omitting C(4) showed two peaks so positioned as to indicate a chair/boat conformational disorder. The C atoms bonded to C(4), C(3), and C(5) were then omitted also, and a difference Fourier synthesis computed. Both C(3) and C(5) appeared as single peaks of electron density, though elongated in a direction perpendicular to the plane formed by As(1), As(2), C(3), and C(5). C(4) appeared as two peaks, of electron density 1.81(7) and 1.76(7) e $Å^{-3}$, separated by 1.64 Å. A disorder model was therefore considered in which two chelate rings with ideal boat and chair geometries were superimposed at As(1), As(2), C(3), and C(5). Various attempts were made to refine such disorder models employing rigid group contraints. However a model giving a suitable geometry could be obtained by simply including two atoms of 50% multiplicity for C(4): C(40) and C(41). These atoms were fixed in ideal positions in subsequent refinements, and allotted isotropic thermal parameters. C(3) and C(5) were refined in normal fashion. Two cycles of refinement, with all atoms other than C(40) and C(41) assigned anisotropic thermal parameters, the phenyl C atoms allotted individual isotropic thermal parameters, and using all data with $F^2 > 3\sigma(F^2)$ converged at $R_1 = 0.0654$ and $R_2 = 0.0913$ (2988 observations, 215 variables).

There are 38 H atoms in the cation. A difference Fourier synthesis showed evidence of many of these, though the 12 methyl H atoms were not well resolved. The contributions of the remaining 26 H atoms whose positions could be calculated from the known geometries of the CH_2 and C_6H_5 groups were included in subsequent calculations of F_c. Values of $R_1 = 0.0488$ and $R_2 = 0.0530$ were obtained, a significant improvement.

The absolute configuration of the cation was established by the Bijvoet method. Heretofore, the model chosen was Δ. Accordingly, the enantiomeric model Λ was refined under identical conditions. This model converged at agreement factors $R_1 = 0.0808$ and $R_2 = 0.0941$, confirming that our original choice of the Δ enantiomer was correct at the 0.005 significance level (23). This assignment is confirmed by an examination of Bijvoet pairs of reflections.

In the final model all non-group, non-hydrogen atoms except C(40) and C(41) were assigned anisotropic thermal parameters. Phenyl ring C atoms were given individual isotropic thermal parameters. All data with $F^2 > 0$ were used. H atom positions were calculated prior to the final cycles. Three cycles of least-squares refinement (3660 observations, 233 variables) converged at $R_1 = 0.0557$ and $R_2 = 0.0499$. The error on an observation of unit weight is 2.29 electrons.

A final difference Fourier synthesis on the Δ model contained no peaks greater than 0.77(19) e $Å^{-3}$. This peak, at (−0.12, 0.06, 0.00), was in the neighbourhood of As(4). A comparison of F_o and F_c showed secondary extinction could be neglected. A statistical analysis of the R_2 values of all reflections showed no unusual trends with $|F_o|$, indices, $\lambda^{-1} \sin\theta$ or the χ and ϕ diffractometer setting angles.

The final positional and thermal parameters of the non-group atoms are given in Table 2. The parameters varied for each of the two rigid groups, and the derived positional parameters of the 12 group C atoms are listed in Table 3. Structure amplitudes are tabulated in Table 4, as $10|F_o|$ *vs.* $10|F_c|$ in electrons.[2] Some selected Bijvoet pairs of reflections are given in Table 5, based upon the Δ model, where the difference exceeds 25%. Hydrogen atom parameters are listed in Table 6.[2]

Results and Discussion

The crystal structure is built up from discrete ions, for the closest approaches of anion and cation are 3.32 Å, between O(5) and 2C6, and 3.34 Å, between O(3) and C(8). The shortest non-bonding interaction is 2.4 Å, between O(5) and H2C(6).

The cation is shown in Fig. 1, and some bond distances and bond angles in the inner coordination sphere in Fig. 2. The C atoms are numbered sequentially around the arsine ligand commencing with C(1) and C(2) as the methyl substituents on As(1), and ending with C(11) and C(12) bonded to As(4). A selection of bond distances and bond angles is given in Table 7.

The geometry of the cation may be described either as distorted trigonal bipyramidal, in which case the O_2 ligand is considered to occupy one coordination site, or alternatively, if the ligand occupies two coordination sites, then the geometry is that of a severely distorted octahedron. The angles subtended at the Co atom by the As atoms and the centre of the O_2 moiety (*i.e.* a trigonal bipyramidal geometry) are, in degrees: axial/equatorial, ideal value 90, observed 85.5,

8	2	3	8.16	<	16.09

87.4(6), 99.34(8), 90.3, 85.61(7), and 93.36(8); equatorial/equatorial, expected 120, observed 129.0, 121.7, and 109.33(8); axial/axial, expected 180, observed 166.99(9)°. However, if each O atom is considered to occupy one coordination site (an octahedral geometry) the equatorial/equatorial angles, expected 90, are 44.9(3), 99.2(3), 106.6(3), and 109.33(8)°. Of these values, the most unacceptable, 44.9(3)°, arises from the small 'bite' of the dioxygen ligand. Other deviations from idealized values may be attributed to steric strain resulting from the coordination of the tetradentate arsine ligand. A further indication as to the geometry of the coordination sphere may be obtained from several weighted least-squares planes, Table 8. Thus, the atoms in the 'equatorial' plane, Co, As(2), As(4), O(1), and O(2) show deviations from the plane not exceeding 0.040(7) Å (whether it be the equatorial plane of a trigonal bipyramid, or of an octahedron). If an octahedral geometry is assumed,

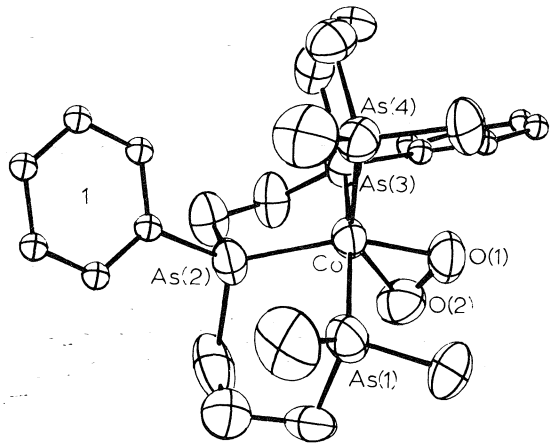

FIG. 1. An overall view of the cation. Atoms are drawn with 50% probability thermal ellipsoids.

and the two other planes expected for an octahedron are calculated, then significant deviations of the oxygen atoms result. Overall, the structural data may perhaps be adduced to support the assignment of a trigonal bipyramidal inner coordination sphere.

The arsine ligand adopts the *cis*-β configuration, with a mean Co—As bond length of 2.306(7) Å. The angles subtended at the Co atom by the two six-membered rings are 87.55(6) and 93.36(8)°, both being between axial and equatorial As atoms. The angle subtended by the five-membered ring is 85.61(7)°. The disordered six-membered ring is that which subtends the smaller angle. The disorder model assumed involves the inclusion of two C atoms, C(40) and

TABLE 8. Weighted least-squares planes

C(41). The four C—C bond lengths involving C(3), C(40), C(41), and C(5) have a mean value of 1.54(1) Å. The mean of the remaining C—C bond lengths is 1.490(8) Å. The average As—C(sp^2) bond length is 1.930(8) and the average As—C(sp^3) bond length is 1.958(10) Å. The five-membered chelate ring adopts the *gauche* conformation of absolute configuration λ (24). The six-membered rings have a chair, and a disordered chair/distorted boat conformation. The absolute configuration at each of the asymmetric As atoms is *R* (25).

The dioxygen ligand is 'π-bonded', with two equivalent Co—O bond lengths of 1.862(6) and 1.867(7), a mean value of 1.865(2) Å. The O—O bond length of 1.424(10) is equivalent to that found by Amma and co-workers (11), 1.420(10) Å, and intermediate between those of 1.28 and 1.49 Å for the superoxide and peroxide ions respectively. The perchlorate ion has the expected tetrahedral structure, with an average Cl—O bond length of 1.424(7) Å, and a mean O—Cl—O angle of 109.5(5)°. The anisotropic thermal parameters of the O atoms are indicative of considerable vibration of the anion, consistent with the absence of any short interionic contacts. However, there was no evidence in the final difference Fourier synthesis of a disordered anion.

It has been noted that conventional coordination numbers and integral oxidation states are inadequate for a discussion of the bonding in these types of compounds (11). We have seen that the inner coordination sphere geometry as deduced from the structural parameters may be viewed either as trigonal bipyramidal, or as

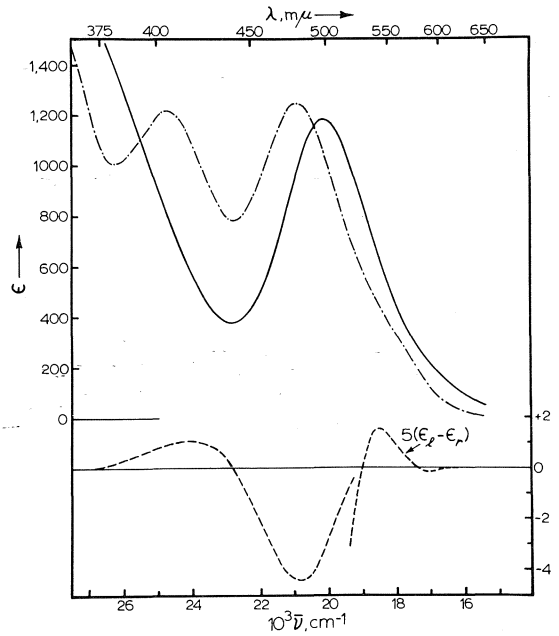

FIG. 3. Optical properties of the cation: —, absorption spectrum of the O_2 complex, in H_2O, 2% v/v CH_3CN. - - -, circular dichroism of the O_2 complex in H_2O, 2% v/v CH_3CN. -·-·-, absorption spectrum of *cis*-$[Co(OH_2)_2(diars)_2](ClO_4)_3$, in 0.5 *M* $HClO_4$.

severely distorted octahedral. However, independent evidence is available for this complex from the optical properties of the cation (15), which are presented in Fig. 3. There is a marked similarity in the electronic spectra between the O_2 complex, and *cis*-$[Co(OH_2)_2(diars)_2](ClO_4)_3$, (diars = *o*-phenylenebis(dimethylarsine)), in which the metal atom is certainly regarded as being in the +3 oxidation state. More convincing, per-

haps, is the circular dichroism spectrum of the O_2 complex, which shows three components under the lower energy band, which may be assigned to the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition of an 'octahedral' Co(III) complex. Therefore the optical properties are best interpreted in light of an octahedral geometry, and a peroxo ligand. A similar formulation has recently been reported by Gray and co-workers (26) for the bis(*cis*-1,2-bis(diphenylphosphine)ethylene)cobalt(III) dioxygen species (11) on the basis of the electronic structure of the complex.

Thus it appears that the charge distribution in this complex is such that, in order for the unipositive cation to contain a Co(III) chromophore, two electrons must have been transferred to the dioxygen ligand. Of the possible bonding schemes, that adopted is closest to the Co(III)—O_2^{2-} description. The chemical and optical properties are characteristic of an octahedral Co(III) chromophore, although the O(1)—Co—O(2) angle of 44.8(3) is far from 90°. The description of the dioxygen ligand as a peroxo species has been further supported by the reaction of resolved *cis*-β-[Co(*R*,*S*-($C_{24}H_{28}As_4$))-$(H_2O)_2]^{3+}$ with hydrogen peroxide in neutral water solution. A dioxygen complex identical with that studied was obtained, with retention of configuration at the Co atom (15).

The bicyclo[2.2.2]octan-2-one and -[3.2.1]octan-6-one skeletons are interconvertible under strongly basic conditions. Their α,α-dimethyl derivatives in *tert*-BuO^-/*tert*-BuOH at 185 °C undergo very slow interconversion by β-proton abstraction. Using ^2H nmr the stereoselectivity of deuterium incorporation at the β-methylene sites was established. The relative reactivities of β-methyl exchange in the [3.2.1] system were also determined. As models for this process, exchange in the α,α,α′,α′-tetramethyl derivatives of the monocyclic ketones, C_5–C_8, was also studied.

A. K. CHENG, J. B. STOTHERS et C. T. TAN. Can. J. Chem. **55**, 447 (1977).

Dans des conditions fortement basiques, on peut interconvertir les bicyclo[2.2.2]octanone-2 et bicyclo[3.2.1]octanone-6. Leurs dérivés α,α-diméthylés, mis en présence de *tert*-BuO^-/*tert*-BuOH à 185 °C, subissent une interconversion très lente par enlèvement d'un proton en β. Utilisant la rmn du ^2H, on a pu établir la stéréosélectivité de l'incorporation du deutérium au niveau méthylènes β. On a aussi déterminé les réactivités relatives des échanges des méthyles en β dans le système [3.2.1]. Afin d'obtenir des modèles pour ce processus, on a aussi étudié l'échange dans les dérivés α,α,α′,α′-tétraméthylés des cétones monocycliques C_5–C_8.

[Traduit par le journal]

Although it is well-established that enolates can be generated by β-proton abstraction from ketones in strong base, much of the available data has been obtained for systems in which the carbonyl group is in an elaborated norcamphor skeleton (1, 2). Since these β-enolates have synthetic utility (3, 4) it is of interest to define the scope of the process more precisely in terms of the constraints imposed by molecular geometry and to examine the stereochemical features of the process. To this end we have extended our studies to the bicyclooctanone skeleton using the α,α-dimethyl derivatives of bicyclo[2.2.2]octan-2-one (**1**) and bicyclo[3.2.1]octan-6-one (**2**) as substrates. These ketones were chosen since, in principle, these skeletons are interconvertible through a common intermediate, β-enolate **3**, and the methyl substituents preclude possible complications arising through competitive α-enolization. A preliminary report on this system has appeared (4) in which ^{13}C nmr was employed to assay deuterium incorporation from experiments conducted in *tert*-butyl alcohol-*O*-d_1. The several advantages of ^2H nmr as a monitor for hydrogen–deuterium exchange studies (2), however, have led us to a reexamination of this system primarily to obtain information on the stereochemistry of the exchange at the β-methylene sites and more precise data on the stereoselectivity of methyl exchange. As models for comparison of the latter process in a variety of bicyclic systems, we have examined the methyl exchange occurring in the α,α,α′,α′-tetramethyl derivatives of the monocyclic ketones having 5- to 8-membered rings. All of the experiments in this study were conducted under the same strongly basic conditions, *tert*-BuO^-/*tert*-BuOH-(D) at 185 °C, to permit direct comparisons with the results previously reported for a variety of closely related systems.

Experimental

Materials

The preparations of *tert*-butyl alcohol-*O*-d_1, 3,3-dimethylbicyclo[2.2.2]octan-2-one, and 7,7-dimethylbicyclo[3.2.1]octan-6-one have been described (2, 4, 5). The α,α,α′,α′-tetramethyl derivatives of cyclopentanone, cyclohexanone, cycloheptanone, and cyclooctanone were obtained by repeated alkylations with sodium amide and methyl iodide. For the first two ketones, three cycles furnished the tetramethyl derivative as the sole product, each exhibiting the appropriate ^1H, ^{13}C, and infrared spectra and the physical data agreed well with published

[1]For part XXX see ref. 12.

[2]Present address: Department of Pharmacology, University of Toronto, Toronto, Canada.

values (6, 7). After some initial difficulties, our standard methylation procedure was modified slightly to obtain the tetramethyl derivatives of cycloheptanone and cyclooctanone.

To a stirred suspension of 10.5 g (0.269 mol) of freshly powdered sodium amide in 800 ml of anhydrous ether under a nitrogen atmosphere was added, in one portion, a solution of 10 g (0.089 mol) of cycloheptanone in 25 ml of dry ether. The mixture was agitated vigorously for 4 h at room temperature after which 127 g (0.89 mol) of methyl iodide was added slowly. Stirring was continued for another 20 h. Excess sodium amide was hydrolyzed by the addition of water and the product isolated by ether extraction. The ether extracts were washed with water and saturated sodium chloride solution and then dried over anhydrous magnesium sulphate. After removal of the ether by distillation, the residue was recycled through the methylation procedure. A third cycle gave the pure product which was isolated by fractional distillation under reduced pressure.

2,2,7,7-Tetramethylcycloheptanone: ν_{max} ($CDCl_3$) 1695 cm^{-1}; δ_H ($CDCl_3$) 1.16 (s, methyl protons), 1.63 (br s, methylene absorption). *Anal.* calcd. for $C_{11}H_{20}O$: C 78.51, H 11.98; found: C 78.62, H 12.03.

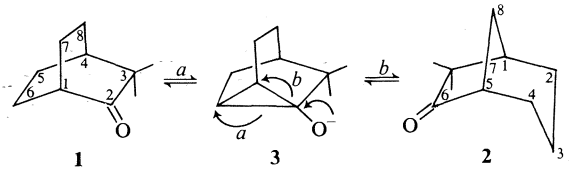
2,2,8,8-Tetramethylcyclooctanone: ν_{max} ($CDCl_3$) 1690 cm^{-1}; δ_H ($CDCl_3$) 1.17 (s, methyl protons), 1.17–1.22 (m, methylene pattern). *Anal.* calcd. for $C_{12}H_{22}O$: C 79.06, H 12.17; found: C 79.08, H 12.28.

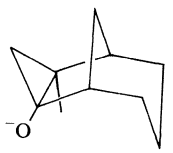
Rearrangement and Exchange Experiments

The general procedure has been described (2). To a solution of the base, prepared by dissolving potassium metal in dry *tert*-butyl alcohol under a nitrogen atmosphere, was added the ketone to give a solution containing ketone: *tert*-BuO^- : *tert*-BuOH in a molar ratio of 1:4:40. Aliquots were placed in glass tubes which were sealed after degassing and then heated at 185 ± 3 °C for various periods of time. For the exchange experiments, *tert*-butyl alcohol-*O*-d_1 (99% deuterated and <0.005 *M* in water) was used. After cooling, the tubes were opened and the products were isolated by pentane extraction; the yields for the bicyclic ketones were in the range 70–80%, while the monocyclic ketones were recovered in ~90% yields. Gas chromatography (gc) on a 20% SE-30 column was employed to determine the composition of the total product and preparative gc furnished samples of the major components for nmr and mass spectrometric analysis. Both ^{13}C and ^2H spectra, obtained as previously described (2), were employed to determine the individual sites and extents of deuterium incorporation. The total deuterium content was measured by mass spectrometry. A Varian XL-100-15 system operating in the Fourier transform mode at 25.2 and 15.4 MHz, respectively, was employed for the nmr measurements while a Varian M66 spectrometer furnished the mass spectral data. Shift reagent studies of the proton spectra of the bicyclic ketones, using a Varian HA-100 instrument, were carried out to confirm the assignments in the ^2H spectra.

Results

Analysis of the product obtained upon treatment of **1** under the strongly basic conditions revealed the presence of two ketones, the starting material and **2**, which were readily isolated by preparative gc. The rearrangement of **1** → **2** was found to be very slow, but the equilibrium ratio appears to be approximately 1:4. A large sample of **1** was repeatedly taken through the base treatment a total of nine cycles, each time heated for about 100 h yielding a final mixture containing 60% of **2**. From another series of experiments using various mixtures enriched in **2** it became apparent that the equilibrium concentration of **2** is ~80%. From a series of experiments carried out using *tert*-butyl alcohol-*O*-d_1, samples of **1** and **2** were isolated and their deuterium contents assayed to follow the exchange processes. Initially ^{13}C spectra were employed for these determinations and these results were reported in preliminary form (4). The several advantages of ^2H nmr for this purpose (2), however, led us to reexamine the samples using their ^2H spectra to improve the precision and to determine the stereoselectivity of exchange at the methylene sites. For this purpose, samples of **1**-d_x and **2**-d_x were examined in a solvent mixture of $CHCl_3$/C_6F_6 using $Pr(fod)_3$ as shift reagent to obtain suitable shift dispersion for precise integration. Proton spectra of **1** and **2** were also recorded in the same media to confirm individual assignments.





The ^2H spectra of samples of **1**-d_x recovered after treatment with *tert*-BuO^-/*tert*-BuOD consisted of two signals separated by 0.76 ppm with that at higher field presumably arising from the methyl deuterons. Upon addition of $Pr(fod)_3$, these signals moved to higher field with the less shielded absorption splitting into two signals whose separation increased with increasing $Pr(fod)_3$ concentration. Over the range of 0–0.2 equiv. of $Pr(fod)_3$ these signals shifted 0.94, 1.68, and 2.48 ppm with the methyl signal exhibiting the largest change. Proton spectra of **1** were

[b]Atoms ^{2}H, ±0.01.

recorded under analogous conditions and it was found that the readily identified methyl singlet exhibited the same change. With increasing [$Pr(fod)_3$], a broad 1-proton singlet showed a larger shift, 3.35 ppm, such that with 0.2 equiv. of $Pr(fod)_3$ it was 0.56 ppm above the methyl signal. Thus it was assigned to the α-bridgehead proton. To unravel the remaining absorptions at lower field, ^{1}H spectra of solutions containing up to 0.8 equiv. of $Pr(fod)_3$ were obtained and the shift dispersion permitted identification of the multiplets. One, an ill-defined 'triplet' with a 32 Hz half-width arising from 2 protons, exhibited the largest shift and its behavior coincided precisely with that of the central signal in the ^{2}H spectra. Because of its sensitivity to $Pr(fod)_3$ it was assigned to the *endo*-6 and -7 nuclei. A second multiplet, integrating for 3 protons with >0.1 equiv. of $Pr(fod)_3$, was discernible and, in the more highly shifted samples, was shown by spin-decoupling to be coupled to the 'triplet'. Since its sensitivity to $Pr(fod)_3$ was different from that of the remaining ^{2}H signal it was tentatively assigned to the 4-, *endo*-5, and -8 protons. The sensitivity of the third ^{2}H absorption, however, was the same as that of the complex multiplet which was least sensitive to added $Pr(fod)_3$ and spin decoupling revealed a strong interaction with the 'triplet' described above. Thus the three ^{2}H signals could be assigned, in order of increased shielding, to the *exo*-6,-7, *endo*-6,-7, and methyl deuterons. In the spectra of the **1**-d_x samples isolated after the longer reaction times, a small signal whose behavior with added $Pr(fod)_3$ paralleled that of the α-bridgehead proton was barely discernible but it could not be reliably integrated. It should be noted that the ^{13}C spectra of these **1**-d_x samples clearly showed that major deuterium incorporation occurred only at C-6, C-7, and the methyl sites; without this information, the foregoing analysis of the ^{2}H spectra would not be unequivocal since the absorption patterns are ill-defined multiplets. Integration by line-shape fitting of the ^{2}H spectra gave the deuterium content at each site and these results are collected in Table 1.

A second series of experiments using **2** as the starting material led to the data collected in Table 2. The individual ^{2}H spectra of these **2**-d_x samples contained four signals whose assignments followed from comparisons of the effect of added $Pr(fod)_3$ on the ^{1}H and ^{2}H spectra. In the absence of $Pr(fod)_3$ the methyl protons are equivalent and the skeletal protons give a complex pattern of essentially three multiplets integrating for 7, 1, and 2 protons in order of decreasing shielding. With addition of the shift reagent, the methyl absorption splits into two singlets and four 1-proton multiplets displaying different sensitivities to [$Pr(fod)_3$] were discernible. A 2-proton multiplet was also clear having the least sensitivity to added reagent. A variety of spin decoupling experiments were carried out to establish the identity of these multiplets and with 0.4–0.7 equiv. of $Pr(fod)_3$ the order of shieldings was found to be: H-5 > *endo*-H-3 ~ *endo*-CH_3 > *endo*-H-4 > *exo*-CH_3 > *syn*-H-8 > *exo*-H-4 ~ *anti*-H-8 > H-1 ~ *endo*-H-2 > *exo*-H-2 ~ *exo*-H-3. The four signals in the ^{2}H spectra could then be assigned to the following sites in order of decreasing shielding: 5 > *endo*-Me > *exo*-Me > *exo*-4. In the initial stages using ^{13}C spectra (4) deuterium incorporation was not detected at the 4-position. Our later refinements of the experimental procedure (2) presumably account for this difference. A spectrum of **2**-d_x isolated after 400 h treatment with *tert*-BuO^-/*tert*-BuOD is shown in Fig. 1. Samples of **2**-d_x formed from **1** after treatment for the

longer reaction times were isolated and then ^{2}H spectra recorded; an example is illustrated in Fig. 2. The additional low field signal can be assigned to the *exo*-3 nucleus having been incorporated at the *exo*-6 (7) site in **1** before rearrangement. To optimize the dispersion of the *exo*-3 and -4 signals, as illustrated, the signals for the *endo*-3 and *endo*-methyl sites become essentially equivalent but the relative ^{2}H content at the latter sites is not particularly informative. It can be emphasized, however, that none of the **2**-d_x samples examined contained detectable signals for an *endo*-4 deuterium. If present this signal would have appeared midway between the methyl signals and inspection of the figures reveals no absorption in this region. The results for two samples of **2**-d_x formed from **1** are included in Table 2.

The behavior of four α,α,α′,α′-tetramethyl monocyclic ketones (C_5–C_8) upon treatment with *tert*-BuO^-/*tert*-BuOD at 185 °C was also examined and the ^{2}H assays for these are listed in Table 3. Gas chromatographic analysis of the six-, seven-, and eight-membered ring ketones recovered from the reaction mixtures (~90% yields) revealed the presence of a new peak in the chromatograms of the products from the longer reaction times. In each case, these new component(s) constituted ~1% of the recovered ketone and no attempts were made to isolate these very minor products. Tetramethylcyclopentanone was recovered unchanged with no evidence of rearrangement. The ^{2}H spectra of the recovered tetramethylcyclanones showed that exchange occurred almost entirely at the methyl sites. Only in the cases of the six- and seven-membered rings was there any indication of methylene exchange and this only after >200 h at 185 °C with less than 0.02 atoms ^{2}H incorporation. Although it was not rigorously established, it can be assumed that this very minor process involves the β-methylene sites by analogy with the several results for six- and seven-membered rings incorporated into bicyclic systems (1–4). Since a shift reagent study of the behavior of 2,2,8,8-tetramethylcyclooctanone with added $Pr(fod)_3$ showed that the δ-methylene protons are nearly as sensitive as the methyl protons, indicating their proximity to the carbonyl group, exchange was anticipated to occur at C-5 but even after 375 h at 185 °C no ^{2}H was detected at this site. The presence of a small

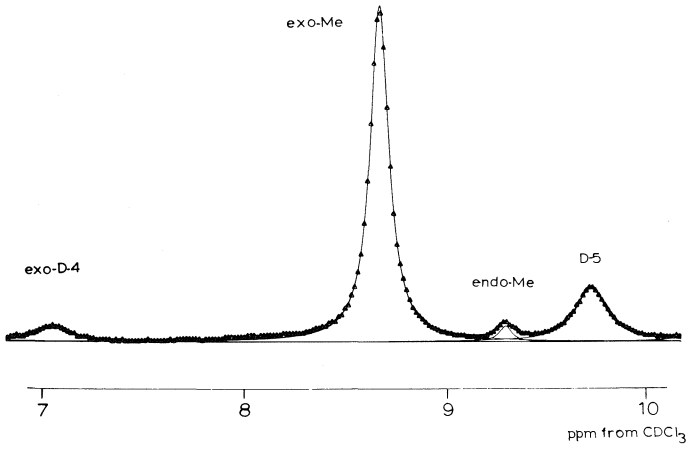

FIG. 1. Observed (△) and computer fitted (full line) ^2H spectra of **2**-d_x isolated after 400 h treatment with *tert*-BuO^-/*tert*-BuOD at 185 °C. The spectrum was obtained in $CHCl_3/C_6F_6$ (4:1) containing 0.3 equiv. of $Pr(fod)_3$.

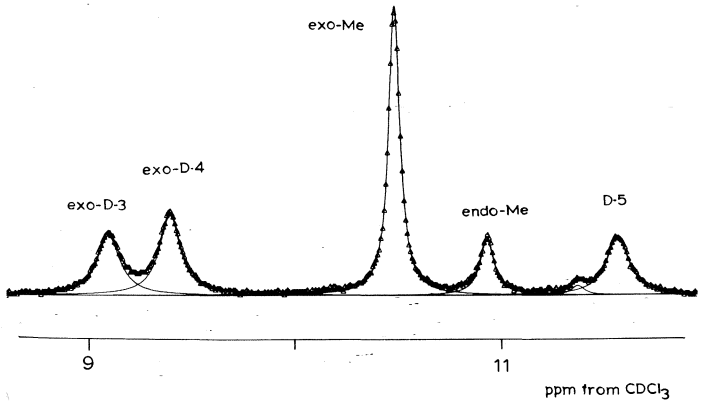

FIG. 2. Observed (△) and computer fitted (full line) ^2H spectra of **2**-d_x obtained after treatment of **1** for 400 h with *tert*-BuO^-/*tert*-BuOD at 185 °C. The spectrum was obtained in $CHCl_3/C_6F_6$ (1:4) containing 0.3 equiv. of $Pr(fod)_3$.

amount (~1%) of a new component could be taken as evidence of very slow isomerization which could conceivably involve a bicyclo[3.3.0]-octan-1-ol intermediate but the second component has not been investigated.

Discussion

From the results for the **1**-d_x samples (Table 1), estimated first-order rate constants for ^2H incorporation are 150×10^{-8}, 17×10^{-8}, and $5 \times 10^{-8}\ s^{-1}$ for the *exo*-6 (7), *endo*-6 (7), and methyl sites, respectively. Clearly *exo*-deuteration is favored over *endo*-deuteration by almost a factor of 10, a somewhat higher degree of stereoselectivity than that found for fenchone (2) but lower than that exhibited by adamantanone (8) both under comparable conditions. It is interesting that the reactivity of bicyclo[2.2.2]-octan-2-one is also intermediate between that of fenchone and adamantanone with the rates of *exo*-deuteration approximately in the order, 700:150:15 and for *endo*-deuteration at the β-methylene site the corresponding order is *ca.* $200:20:1 \times 10^{-8}\ s^{-1}$. Thus, the selectivities for *exo*:*endo* deuteration at this site are approximately 3.5, 7.5, and 15 for fenchone, **1**, and adamantanone, respectively. A similar comparison cannot be made for **2** since we were

unable to detect measurable amounts of deuterium at the *endo*-C-4 site. The rate constant for *exo*-deuteration, however, is 30×10^{-8} s^{-1} from the data in Table 2, indicating an even greater stereoselectivity for **2** than for the preceding systems. It should be noted that while these crude rate constants may be internally consistent for a given substrate, comparisons from one compound to another are less reliable since competitive experiments were not performed. Such measurements would present major separational difficulties. In any event, the differences seem sufficiently large that the qualitative order of reactivity: fenchone > **1** > **2** > adamantanone is correct and the stereoselectivities for β-methylene exchange in each substrate are certainly reliable. Thus, the most rapidly formed β-enolate exhibits the least selectivity for deuterium capture upon cleavage and in all cases the preferred course is inversion at the β-methylene site, *i.e. exo*-deuteration.

It is apparent from Table 2 that bridgehead exchange at C-5 is the fastest process in **2** in contrast to the almost complete absence of the corresponding process for **1**. This is consistent with earlier observations of bridgehead enolization in [3.2.1] bicyclic systems (9). The barely detectable traces of bridgehead deuterium in samples of **1**-d_x isolated from the longer reaction times presumably arose from small amounts of **2** reformed from **1** in the slow equilibration of the two ketones. The progressively decreasing ^{2}H content at the bridgehead with increasing reaction time (Table 2) reflects the dilution of the deuterium pool by the exchange processes.

The most striking difference between the data for **1** and **2** is the contrast in the relative rates of methyl exchange. In the [3.2.1] system, *exo*-methyl exchange is 100 times faster than *endo*-methyl exchange and the latter is comparable to methyl exchange in the [2.2.2] ketone. For comparison, the *exo*-methyl site in fenchone was also found to be the most reactive but only *ca.* 4 times more rapid than *endo*-methyl exchange. The stereoselectivity of methyl exchange in fenchone and **2**, however, implicates β-enolates such as **4** as intermediates since the inductive effect of the carbonyl group as an activating influence for proton abstraction should be comparable for each methyl site. Formation of **4** could be anticipated to lead to rearrangement of the skeleton to the ring expanded [3.3.1] system but no evidence for this isomerization was obtained. Since cyclopropanols cleave in base to form the product from the more stable carbanion (10), the favored **4** → **2** cleavage is not unexpected. Recently we have observed rearrangement through β-enolates involving methyl sites in acyclic systems which have severely splayed C—C—C bond angles at the carbonyl group (11).

Since it appears that this feature may be the major driving force for cleavage in the less favored direction, it is not surprising that ring expansion does not occur in the bicyclic systems because the skeletal constraints preclude appreciable increases in this bond angle. It is interesting that the rates of methyl exchange in the monocyclic ketones are similar for the six-, seven-, and eight-membered rings and comparable to the values for *endo*-methyl exchange in fenchone and **2**, as well as that for **1** in which the two methyl groups are equivalent, while methyl exchange is significantly faster (*ca.* 10-fold) for tetramethylcyclopentanone. Thus the relative rates for the methyl sites in the systems having five-membered rings are 300, 50, and $20 \times 10^{-8}\ s^{-1}$ for **2**, fenchone, and tetramethylcyclopentanone, respectively, and for the remaining cases the first-order rate constants are in the range $2\text{–}5 \times 10^{-8}\ s^{-1}$. Clearly ring size and stereochemistry govern the reactivity for methyl exchange but it is difficult to be more specific with regard to an interpretation of the observed rates. The 100-fold difference in methyl reactivity for the [3.2.1] system, however, may be useful for tracer studies of selectively deuterated derivatives.

Décharge triboélectrique dans les alcanes C_1–C_5 à basse pression

JAN A. HERMAN, GILLES MAYRAND ET HADI TARKI
Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Reçu le 19 juillet 1976

JAN A. HERMAN, GILLES MAYRAND et HADI TARKI. Can. J. Chem. **55**, 454 (1977).

On a soumis à la décharge triboélectrique les gaz suivants: CH_4, C_2H_6, C_3H_8, n-C_4H_{10}, iso-C_4H_{20} et n-C_5H_{12} et certains produits provenant de leur décomposition ont été mesuré. La proportion des produits insaturés mesurés compte pour environ 75%. Le taux de décomposition augmente avec le nombre d'atomes de carbone du squelette du composé paraffinique. La composition relative des produits provenant de la décomposition du méthane varie en fonction de la pression: la proportion des produits saturés croît avec l'augmentation de la pression. On propose certaines explications du comportement observé des gaz étudiés dans la décharge triboélectrique.

JAN A. HERMAN, GILLES MAYRAND, and HADI TARKI. Can. J. Chem. **55**, 454 (1977).

The following gases were submitted to a triboelectric discharge: CH_4, C_2H_6, C_3H_8, n-C_4H_{10}, iso-C_4H_{10}, and n-C_5H_{12} and their decomposition products were analyzed. The proportion of unsaturated in the products is around 75% of the total. The total yield of decomposition products increases with the number of carbon atoms in the compound submitted to the discharge. The proportion of saturated products formed from methane increases with pressure. Tentative explanations are offered to elucidate the observed behaviour of gases in the tribo-discharges.

Introduction

Selon Harper (1) le nom "triboélectrisation" (anglais: triboelectrification) englobe deux phénomènes distincts de formation d'électricité statique, l'un par séparation de deux phases dissemblables (électrisation de contact), l'autre par frottement de deux matériaux similaires ou non (électrisation par frottement). Dans des nombreux cas, il est difficile de distinguer clairement entre les deux phénomènes; il est alors préférable de parler de triboélectrisation (2). Beaucoup de détails du mécanisme fondamental de triboélectrisation ne sont pas encore élucidés (1, 3), mais le processus lui-même consiste de façon globale en une séparation de charges à l'interface de deux phases suivi d'une recombinaison subséquente des charges pouvant prendre la forme d'une décharge à travers le gaz. Dans le cas particulier du mouvement relatif des surfaces contigues du mercure et du verre la recombinaison est suffisamment énergétique pour produire des états excités jusqu'à 20 eV au-dessus de l'état fondamental des gaz rares, du mercure et aussi de la silice et du bore du verre (4). De la même façon le mouvement du mercure sur le verre recouvert avec des colorants scintillants produit l'émission du spectre caractéristique du colorant et les tensions d'électrisation de contact mesurées dans ces systèmes sont en excès de 20 V, valeur limite de l'électromètre employé dans ces expériences (5). On doit donc s'attendre à des effets chimiques résultant du processus triboélectrique et de telles transformations chimiques ont été récemment décrites (6–8).

Le rôle de certains paramètres (tels la nature des phases misent en contact, le prétraitement des surfaces, la pression, le champ électrique, etc.) a été étudié à plusieures reprises (9, 10), cependant les conséquences chimiques de ces paramètres sont beaucoup moins bien connues. L'étude de Alcock et coll. (8) sur le méthane soumis à la décharge triboélectrique est probablement la plus détaillée à ce sujet. Dans le présent travail nous examinons la décomposition de quelques hydrocarbures gazeux soumis à la décharge triboélectrique. Les gaz utilisés dans ces expériences sont le méthane, l'éthane, le propane, les n- et iso-butanes, le n-pentane. Les expériences sur le méthane sont faite entre 1 et 200 torr de manière à étendre les conclusions de Alcock et coll. (8) à un domaine de pression qui n'a pas été couvert par ces auteurs. La décomposition des autres hydrocarbures dans la décharge triboélectrique est intéressante par comparaison à celle du méthane.

Partie expérimentale

Les cellules de réactions (réacteurs) sont en Pyrex. Elles sont équipées d'un robinet à haut vide en teflon inséré de telle façon sur les réacteurs que le mercure n'entre jamais en contact avec le robinet. Ces réacteurs

de forme cylindrique d'environ 200 cm^3 (diam. int. 5.6 cm) sont soumis à un mouvement de rotation autour de l'axe longitudinale du récipient.

La triboélectrisation est très sensible à la qualité de la surface. Pour cette raison on a adopté une procédure rigoureuse de nettoyage des réacteurs. Ceux-ci sont nettoyés à l'acide sulfurique concentré bouillant, rincés à l'eau distillée et sechés à 450 °C. La cellule propre est ensuite remplie d'une quantité pesée de mercure frais, ou de billes d'acier propres, connectée à une rampe à vide et chauffée à nouveau pour enlever l'humidité et les gaz adsorbés sur le métal. Pendant environ 12 h on pompe sur le réacteur (limite du vide $\sim 10^{-5}$ torr) avant son remplissage par une quantité controllée de gaz.

Les hydrocarbures saturés proviennent de Matheson Co. On les purifie par distillation de piège à piège à -195 °C et par adsorption sur tamis moléculaire à basse température. De façon générale ils ne contiennent que des traces d'autres hydrocarbures. Dans le cas de l'éthane on a pris la précaution supplémentaire de la sécher sur un mirroir de sodium métallique, cependant son comportement dans la décharge triboélectrique n'est guère différent de l'éthane purifié par voie habituelle. Les gaz sont analysés par chromatographie en phase gazeuse. On utilise une colonne de squalane pour analyser les hydrocarbures.

Toutes les expériences sont faites à la température ambiante, soit 23 ± 2 °C.

Résultats

Deux genres de mouvements de réacteurs ont été essayé: (*1*) agitation sur un agitateur de laboratoire, et (*2*) rotation autour de l'axe longitudinal de la cellule de réaction. Des résultats qualitativement similaires ont été obtenus dans les deux cas, mais une comparaison quantitative n'est guère possible. En effet, l'agitation est difficilement reproductible d'une expérience à l'autre malgré les précautions prises dans l'ensemble des manipulations. Il est fréquent de trouver des résultats sur les mêmes réacteurs qui diffèrent de 100%. Cela est dû au moins en partie à la difficulté de positionner les réacteurs de manière rigoureusement reproductible, ce qui entraine des différences dans l'agitation du mercure. L'avantage de l'agitation par rapport à la rotation est une transformation plus grande du gaz soumis à la décharge triboélectrique. Ainsi après quelques heures d'agitation énergique on peut transformer jusqu'à 50% de la quantité initiale du gaz parent, à condition qu'il soit à basse pression.

Par contre, les résultats obtenus par rotation sont reproductibles à 20% près pour une même série d'expériences. L'avantage de cette méthode réside surtout dans la reproductibilité du mouvement du mercure, la connaissance de la vitesse du métal par rapport au verre et celle de la surface totale parcourue au cours de l'expérience. En choisissant une géométrie simple du réacteur on peut mésurer la longueur du contour de l'interface mercure/verre. Chacun de ces paramètres intervient dans le processus triboélectrique, donc influence le taux de décomposition du gaz enfermé dans le réacteur.

(a) Dimensions du réacteur

Le siège de la triboélectrisation est situé à l'endroit de la séparation des phases dissemblables, donc dans le cas présent sur le bord arrière du mercure en mouvement sur la surface isolante. Dans le cas de la rotation d'une cellule, ce contour "actif" de l'interface Hg/verre est facile à déterminer. On s'attend à ce que l'effet chimique soit proportionnel à la longueur de ce contour "actif", et dans le cas de la décomposition du N_2O cela est confirmé (11). D'autre part, pour une longueur constante du contour de l'interface, l'effet chimique est indépendant de la masse du mercure.

(b) Durée de la rotation

Celle-ci est présentée sur la fig. 1 pour l'éthane et le *n*-butane. On a porté sur le graphique le pourcentage de transformation (ordonnées) en fonction du temps de rotation (abcisses) à vitesse constante. Dans le cas du *n*-butane la transformation par unité de temps est plus importante que celle de l'éthane. On voit qu'on s'écarte de la linéarité après environ 3% de transformation du *n*-C_4H_{10}, tandis que dans les mêmes conditions de vitesse le C_2H_6 n'est décomposé que 1.5% après 8 h de rotation. Ces résultats suggèrent que dans les conditions de nos expériences, la linéarité du taux de décomposition des molécules parentes persiste jusqu'à environ 2%. Au-delà de cette limite on doit s'attendre à une diminution de la vitesse de décomposition, due selon toutes vraissemblance, à des dépots polymériques qui modifient les propriétés des surfaces en contact.

(c) Les hydrocarbures paraffiniques C_1 à C_5

La décomposition du CH_4 en fonction de la pression est présentée aux figs. 2 et 3. On constate que la quantité décomposée du méthane à vitesse et à surface parcourue constantes croît avec la pression. Cette constatation est en accord avec les données de Alcock et coll. (8) lesquels ont trouvé une augmentation du taux de conversion jusqu'à 200 torr suivi ensuite d'une brusque chute. La composition relative

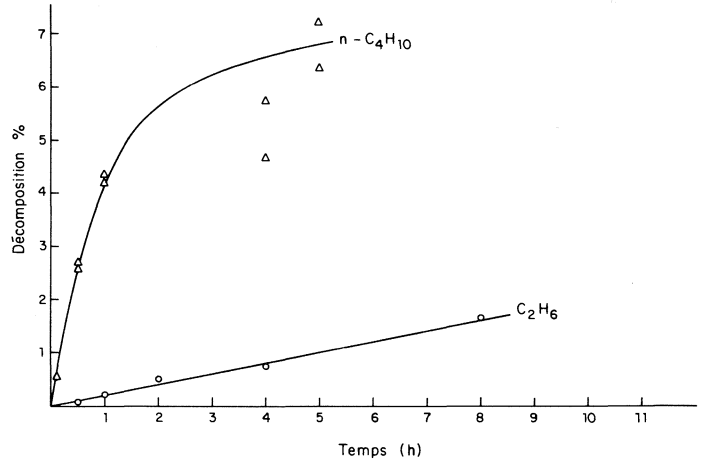

FIG. 1. Décomposition du C_2H_6 et du n-C_4H_{10} en fonction de la durée de rotation. Vitesse: ~21 cm s^{-1}.

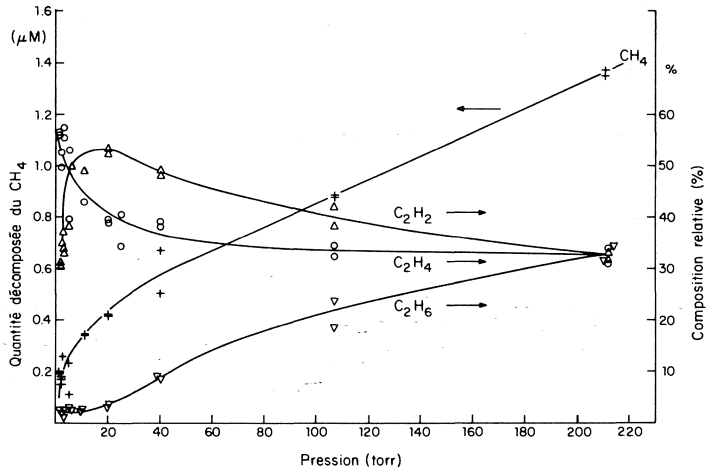

FIG. 2. Quantité (en μM) décomposée du méthane et composition relative des C_2H_2, C_2H_4 et C_2H_6 en fonction de la pression dans une décharge triboélectrique. Vitesse: ~21 cm s^{-1}, durée de rotation: 60 min.

des produits C_2H_2, C_2H_4, C_2H_6 et les C_3 formés dans la décharge triboélectrique change aussi avec la pression. Tandis que les insaturés C_2H_2, C_2H_4, C_3H_6 et C_3H_4 diminuent avec l'augmentation de la pression, les produits saturés: C_2H_6 et C_3H_8 augmentent dans les mêmes conditions.

L'influence du NO sur la décomposition du CH_4 à pression totale 2.6 torr est illustrée à la fig. 4. Des faibles quantités de l'oxyde nitrique baissent de moitié la formation de l'éthane, tandis que l'éthylène montre une faible hausse. L'acétylène diminue très légèrement et de manière progressive. Les résultats relatifs aux C_2H_2 et C_2H_4 sont dans les limites de l'incertitude expérimentale, néamoins la tendance semble réelle dans les deux cas.

La comparaison du comportement chimique dans le processus triboélectrique du CH_4, C_2H_6, C_3H_8, n-C_4H_{10}, iso-C_4H_{10} et n-C_5H_{12} à basse pression (2.5 torr) est présentée dans les tableaux 1 et 2. Dans le tableau 1 sont indiqués les pourcentages absolus et relatifs (entre parenthèses) pour une vitesse de rotation de ~21 cm s^{-1}. Dans l'avant-dernière colonne on trouve le pourcentage globale de transformation. La dernière colonne indique la fraction des produits saturés formés dans la décharge. Dans le tableau

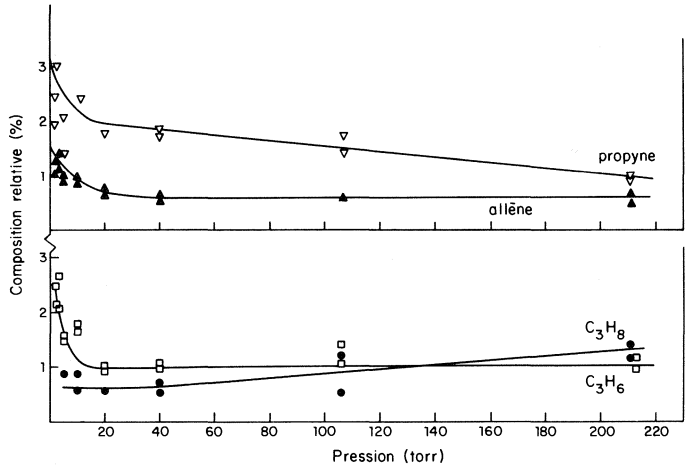

FIG. 3. Variation de la composition relative en fonction de la pression pour les produits mineurs formés dans la décharge triboélectrique dans le méthane. Vitesse: ~21 cm s^{-1}, durée de rotation: 60 min.

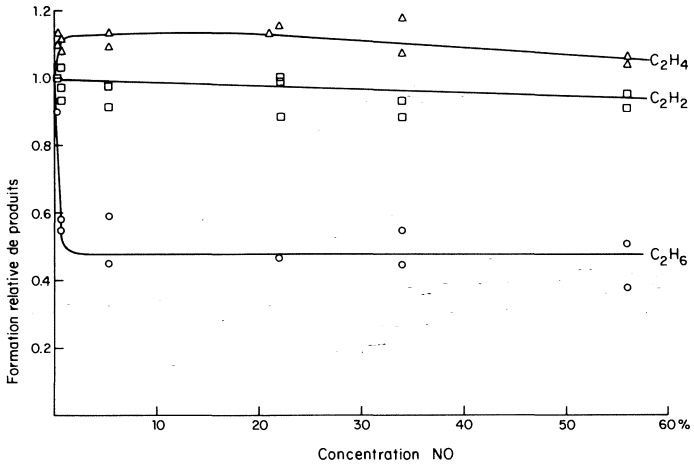

FIG. 4. Formation relative des produits C_2H_2, C_2H_4 et C_2H_6 en fonction de la concentration du NO dans une décharge triboélectrique du méthane. Pression totale: 2.6 torr, vitesse: ~21 cm s^{-1}, durée de rotation: 60 min.

2 sont présentées uniquement les valeurs relatives: (*a*) pour une vitesse de rotation trois fois moindre, soit 6.3 cm s^{-1}, pour les réacteurs Hg/verre, et (*b*) pour les expériences faites dans des réacteurs en verre contenant des billes d'acier. Dans le cas des réacteurs à interface billes d'acier/verre les transformations globales sont environ 30 fois plus faible pour un temps de rotation comparable à celui du tableau 1.

Les données du tableau 1 indiquent que dans la série: méthane–*n*-butane le taux global de transformation (avant-dernière colonne) augmente avec le nombre d'atomes de carbone. Le taux de décomposition du *n*-pentane est plus faible, mais l'analyse n'a pas été faite pour tous les produits en C_5 et supérieurs. La valeur rapportée est donc une valeur par défaut et peu facilement être supérieure à 3%. Dans le cas de l'isobutane, seul alcane ramifié, étudié, celui-ci masque sur le chromatogramme les C_4 insaturés, par conséquent le taux de décomposition de 2.0% n'est qu'un minimum.

Discussion

L'existence de la décharge électrique est prouvée par l'émission des ondes électromagné-

[b]b.a. = billes d'acier.

tiques dans la région des MHz accompagnant le mouvement du mercure (ou des billes métalliques) sur le verre. Cette émission d'ondes électromagnétiques est facilement captée par un récepteur radio dans le domaine des ondes courtes. L'effet lumineux qui en principe accompagne le processus triboélectrique est parfois difficilement perceptible, on ne peut donc se fier entièrement à sa présence comme élement caractéristique de ce processus et de plus il ne prouve pas en soit l'existance d'une décharge électrique.

La décharge triboélectrique

En se basant sur la caractéristique des phénomènes triboluminescents accompagnant la rotation d'un système Hg–pyrex Mandeville et coll. concluent qu'on est en présence d'une décharge de Townsend (4). La décharge de Townsend n'a lieu que si la tension de claquage ou de disruption, V_c, est atteinte, et pour une pression donnée elle sera atteinte à une distance critique de séparation métal/verre. Dans un champ uniforme la tension de claquage est donnée par la loi de Paschen: $V_c = f(P \cdot d)$, où P est la pression et d est la distance entre électrodes planes et parallèles. Toujours selon cette loi V_c passe par un minimum et pour la plupart des *n*-paraffines $V_{c,min} \approx 400$ V et correspond à des valeurs $(P \cdot d)$ comprises entre 0.6 et 1 torr · cm (12). La densité moyenne de charges accumulées sur la surface diélectrique par triboélectrisation dans un système métal/verre est de l'ordre de 2 u.e.s./cm^2 (8, 9), ainsi le champ électrique (supposé uniforme) qui en résulte est suffisant pour que V_c soit atteint sur des distances courtes (<1 mm) de séparation des phases en mouvement aux pressions de nos expériences. Pour les champs électriques non-uniformes la tension de claquage passe par un minimum en fonction de la pression, mais sa dépendance par rapport à la distance entre électrodes ne peut être établie, sauf dans le cas des électrodes de symétrie simple. Dans le cas présent le champ électrique est de forme inconnue.

Par ailleurs, Heylen et Lewis ont remarqué qu'une activité considérable en impulsions électriques nettement en dessous du V_c a lieu dans des nombreux hydrocarbures gazeux (12, 13). Cela peut être attribué à ce que le deuxième coefficient de Townsend, α, pour les hydrocarbures est environ 10^5 fois plus faible que pour les gaz atmosphériques (13, 14). Il est difficile à présent de déterminer quel genre de décharge se produit dans le réacteur Hg/verre en rotation, il se peut que les conditions locales favorisent soit l'un soit l'autre mécanisme de décharge et on peut aussi assister à un régime mixte.

La variation du rapport E/P (où E est le champ électrique) détermira l'importance des divers processus primaires de fragmentation des molécules des gaz enfermées dans le réacteur. Or, la complexité physique du système étudié ne permet pas de prédire comment varie le paramètre E/P avec la pression. On peut s'attendre qu'à valeur élevée de E/P (de 200 à 500 V cm^{-1} torr^{-1}) à basse pression (<15 torr) la fragmentation des molécules soit plus prononcée qu'à E/P modéré ($P > 50$ torr). D'autre part, la décharge triboélectrique semble être très localisée. Nous aurons donc une forte densité d'espèces excitées et radicalaires et les réactions qui en suivront favoriseront la recombinaison entre radicaux.

Le méthane

Nos résultats concordent raisonnablement bien avec ceux de Alcock et coll. à 200 torr et 60 min de rotation (8). Dans ces conditions nous trouvons les trois produits principaux: C_2H_2, C_2H_4 et C_2H_6 en proportion 1:1:1 (fig. 2), tandis qu'Alcock donne un rapport 1:1:3. En raison des vitesses de rotation différentes et des difficultés de reproductibilité de ces expériences on doit se contenter d'une telle précision.

La quantité totale du méthane décomposé croit avec la pression au moins jusqu'à 200 torr en raison du nombre croissant de collisions effectives entre électrons accélerés et molécules parentes sur le parcours de la décharge. Simultanément la composition relative des produits formés subit des changements importants comme témoignent les figs. 2 et 3. La présence des spectres des radicaux CH$^\cdot$ (dans l'état $^2\Delta$) et $CH_2^\cdot$ mais l'absence de celui du C_2 (observé dans la décharge à étincelle (15)) dans la décharge triboélectrique du CH_4 est rapporté par Alcock et coll. (8). Ainsi on peut postuler des processus primaires de décomposition suivants:

$$[1] \quad CH_4 + e \rightarrow (CH_4)^* \rightarrow CH^\cdot + H + H_2(2H)$$
$$\rightarrow CH_2^\cdot + H_2(2H)$$
$$\rightarrow CH_3^\cdot + H$$

Les voies subséquentes de réactions de ces intermédiaires dépendent des états d'excitation dans lesquels ils sont formés, états que nous ignorons. De manière générale on peut dire que

les radicaux $CH^{\cdot}$ dans les états $^2\pi$ (16) et $^2\Delta$, ainsi que $^1CH_2$ dans l'état $\tilde{a}_1\,^1A_1$ (17) vont réagir rapidement avec le méthane pour donner des expèces excitées lesquelles peuvent se décomposer ou être stabilisées par collision:

[2] $$CH^{\cdot} + CH_4 \rightarrow (C_2H_5)^* \rightarrow C_2H_4 + H$$
$$\rightarrow C_2H_3^{\cdot} + H_2$$
$$\rightarrow C_2H_2 + H + H_2$$

[3] $$^1CH_2 + CH_4 \rightarrow (C_2H_6)^* \rightarrow 2CH_3^{\cdot}$$
$$\xrightarrow{M} C_2H_6$$

La réactivité avec le méthane du radical $CH^{\cdot}$ dans des états d'excitation supérieurs $\tilde{b}^1B_1$ et $\tilde{c}^1A_1$ (18) n'est pas connue.

La conversion du radical $^1CH_2^{\cdot}$ à l'état triplet $^3B_1$ à la suite de collision avec le méthane (19) et les réactions subséquentes du $^3CH_2^{\cdot}$ avec les radicaux $^3CH_2^{\cdot}$ et $CH_3^{\cdot}$ pour donner de l'acétylène et de l'éthylène (19–21) ne semblent pas être important, même si les constantes de vitesses de ces réactions sont comparables en grandeur à celle de la recombinaison de radicaux méthyl en éthane:

[4] $$CH_3^{\cdot} + CH_3^{\cdot} \rightarrow C_2H_6$$
$$k_4 \approx 4.2 \times 10^{-11}\ \text{cm}^3\ \text{molécule}^{-1}\ \text{s}^{-1}\ (22, 23)$$

Cela est montré par l'effet inhibiteur peu significatif du NO dans la formation du C_2H_2 et du C_2H_4 dans la décharge triboélectrique à basse pression (fig. 4). Ce même capteur de radicaux indique qu'environ 50% de l'éthane est produit à partir d'intermédiaires qui ne sont pas impliqués dans la formation des C_2H_2 et C_2H_4. La même insensibilité à l'action inhibitrice de l'oxygène est rapporté par Alcock et coll. (8). Cela peut être une indication que l'acétylène et l'éthylène sont formés dans les processus [2] et [3] à partir d'intermédiaire peu sensible à l'action de l'oxygène ou de l'oxyde nitrique, confirmant ainsi le mécanisme proposé par Alcock et coll.

En fait il y a une certaine similitude entre les résultats obtenus à 100 torr dans la radiolyse éclair du CH_4 (24) et les résultats présents. Cependant, l'influence du SF_6 est différente dans les deux cas. Des expériences faites en présence du SF_6 (capteur d'électrons thermalisés) n'ont pas indiqué clairement de processus impliquant la neutralisation des charges ou la participation des ions négatifs dans la décharge triboélectrique, mais la présence d'un champ électrique fort peut très bien masquer le cours de ces processus (11).

Le mercure atomique gazeux joue le rôle d'intercepteur de radicaux méthyles

[5] $$Hg + 2CH_2^{\cdot} \rightarrow Hg(CH_3)_2$$

Ce composé identifié par Paoli et Strausz (7) est produit à 10 torr avec un rendement d'environ le double de celui de l'acétylène. C'est donc une espèce (de même que H_2) majeure dans le système.

La variation de la composition relative des hydrocarbures saturés par rapport aux insaturés en fonction de la pression (figs. 2 et 3) peut s'expliquer par l'influence de trois facteurs: (*a*) la diminution du rapport E/P avec l'augmentation de la pression se fera sentir sur le processus [1] en favorisant en proportion croissante les décompositions primaires de moins en moins énergétiques, (*b*) l'accroissement de la pression favorisera les processus de stabilisation par collision, (*c*) la proportion des atomes de mercure gazeux diminuant avec l'augmentation de la pression du CH_4, l'importance de la réaction [5] diminuera en faveur de la recombinaison [4]. L'importance de chacun de ces trois facteurs reste à déterminer, mais *à priori* on peut supposer qu'à basse pression (1–20 torr) le facteur (*b*) aura plus de poids que les deux autres, tandis qu'à pression élevée ce sera le contraire.

L'allure de la formation de l'acétylène qui passe par un maximum à $P \approx 10$ torr (fig. 2) est une indication des dimensions de la trajectoire de la décharge. A basse pression (< 10 torr) le nombre de collision inélastiques menant à des états d'excitation très élevés du CH_4 est faible sur la distance du parcours des électrons entre les deux phases verre–mercure en voie de séparation. Ce nombre de collision très énergétiques entre électrons et molécules parentes augmentera avec la pression, mais simultanément le processus de stabilisation des espèces excitées prend de l'ampleur. Ainsi l'allure de la formation de l'acétylène sera la résultante de ces deux effets opposés.

Les hydrocarbures C_2–C_5

La comparaison des données des tableaux 1 et 2 est intéressante à plusieurs points de vue:

(*a*) le taux absolu de décomposition croissant avec le nombre d'atomes de carbone du composé paraffinique peut être mis en corrélation soit avec le potentiel d'ionisation (25) ou avec le spectre d'excitation électronique du composé (26). L'énergie nécéssaire à ioniser et/ou à exciter étant plus faible à mesure que le nombre de

carbones croît dans le composé permet un accroissement du nombre de collisions effectives entre électrons et molécules parentes sur la distance du parcours des électrons dans la décharge.

(*b*) la fraction des produits saturés gazeux formés dans la tribodécharge à basse pression est d'environ 25% par rapport à celle des produits insaturés. Cependant dans les réacteurs Hg/verre on n'a pas analysé les composés alkylmercuriques, dont la présence a été démontré par De Paoli (7). Par conséquent, la fraction calculée des produits saturés doit être augmentée pour la présence de ces composés. Selon De Paoli pour le propane à $P = 10$ torr, la formation en (RH)Hg(R′H) est à peu de chose près égale à celle du C_2H_2, et en rapportant ce résultat à nos données la fraction de produits saturés devient ~34%. On peut supposer que pour les autres *n*-paraffines (à l'exception du CH_4) le pourcentage de produits saturés gazeux est du même ordre de grandeur. Ce n'est peut être qu'une coincidence, mais pour les systèmes à interface billes d'acier/verre la fraction des produits saturés est d'environ 35%. La diminution des quantités d'acétylène formé dans les réacteurs contenant des billes d'acier est due selon toute vraissemblance à une moindre densité de charges crée au point de contact entre les deux phases solides. La décharge qui en résulte est beaucoup moins énergétique et ne permet pas d'atteindre les niveaux d'excitation élevés des molécules parentes.

(*c*) la production relative de l'acétylène diminue pour le méthane et l'éthane soumis à la tribodécharge à vitesse 3 fois plus lente (tableau 2). Cet effet de vitesse peut s'expliquer en admettant que la densité de charge produite est moindre à faible vitesse de rotation en raison de possibilité accrue de neutralisation de charges par migration de surface. Le rapport E/P serait moindre dans ce cas, et il aura un effet plus marqué pour le hydrocarbures à potentiel d'ionisation plus élevé. On comprendrait ainsi pourquoi le C_3H_8 et les C_4H_{10} ne montrent pas d'effet de vitesse par opposition aux CH_4 et C_2H_6. L'effet de vitesse de rotation fera l'objet d'une étude séparée.

Il serait téméraire de proposer des schémas cinétiques détaillés pour la formation des produits pour chacun des hydrocarbures étudiés. La difficulté réside dans les concentrations élevées d'intermédiaires générés pendant la décomposition induite par une décharge. Les réactions secondaires qui en résulte sont difficile à interpreter. De façon générale, parmi les produits de décomposition d'un système organique soumis à une décharge il y a une importante proportion d'oléfines et d'acétylèniques, proportion qu'on ne retrouve pas pour d'autres modes de déposition d'énergie (27). Dans beaucoup de cas, cet excès de produits insaturés est dû à l'impossibilité de retirer les produits stables de la zone de réaction. Il en est pareillement pour la tribodécharge, surtout pour les réacteurs contenant du mercure. Néamoins, quelques mécanismes réactionnels peuvent être aperçus à travers les données des tableaux 1 et 2. Par exemple, l'élimination des radicaux $CH^{\cdot}$ et $CH_2^{\cdot}$ doit être un important processus primaire pour les paraffines étudiées. L'insertion subséquente de ces intermédiaires dans la molécule parente suivie d'une décomposition conduit au moins en partie aux C_2 insaturés qu'on retrouve régulièrement en quantité abondante parmi les produits. L'élimination d'alcanes à faibles poids moléculaire (CH_4, C_2H_6) à partir de la molécule parente hautement excitée est un autre processus dont on peut soupçonner la présence. Ce processus est observé en photolyse dans l'ultraviolet à vide pour les paraffines C_3–C_6 et il est d'autant plus important que l'énergie des photons incidents est plus élevée (28). Dans le cas de l'isobutane c'est surtout le groupement méthyl qui est impliqué dans ce processus si on en juge d'après la quantité importante du propène formé. En admettant qu'une importante proportion du C_2H_4 provient par élimination directe à partir du *n*-butane et du *n*-pentane, il faut conclure que la rupture de la liaison β(C—C) du squelette carboné serait la plus importante parmi les divers modes de décomposition.

Remarquons que dans la décharge tribo-électrique des C_2–C_5 certains produits mineurs, tels le cyclopropane, le butyne-1-ène-3, sont formés en proportion constante. Les processus qui mènent à leur formation sont probablement les mêmes pour tous les hydrocarbures étudiés et ils impliquent un ou des produits particuliers accumulés dans le système.

Remerciements

Nous remercions le Conseil national de recherches du Canada et le Ministère d'Education du Québec (octroi FCAC) pour l'aide financière qui a permis la poursuite de cette étude.

Received August 3, 1976

JANUSZ GAWŁOWSKI, JAN NIEDZIELSKI, and JAN A. HERMAN. Can. J. Chem. **55**, 463 (1977).

The yields of products formed in the recombination of free radicals in the radiolysis of gaseous ethane and propane have been determined. The yields of butane from ethane radiolysis, and of 2,3-dimethylbutane from propane radiolysis were found to be much lower than those reported in the literature.

The yields of these products increased markedly in the presence of the traces of water, either desorbed from the walls or introduced with insufficiently dried reagents. The details of experimental procedures warranting the total elimination of water are given.

JANUSZ GAWŁOWSKI, JAN NIEDZIELSKI et JAN A. HERMAN. Can. J. Chem. **55**, 463 (1977).

On a déterminé les rendements des produits formés par recombinaison de radicaux libres dans la radiolyse de l'éthane et du propane gazeux. Les rendements en butane et en 2,3-dimethylbutane dans la radiolyse respectivement de l'éthane et du propane sont beaucoup plus bas que ceux rapportés dans la litterature.

Les rendements de ces produits augmentent substanciellement en présence de trace de vapeur d'eau, soit désorbée des parois, soit introduit avec les réactifs qui non pas étaient suffisamment sechés. On donne les détails expérimentaux, guarantissant une élimination totale de l'eau.

Introduction

Gas-phase radiolysis of saturated hydrocarbons has been studied extensively (1–11). However, there are still many doubts concerning the mechanism of ion neutralization, the effects of scavengers on the yield of products, and so on. This paper presents our preliminary results related to the effects of impurities on the yields of some products, originating from the radiolysis of gaseous ethane and propane.

Experimental

(a) Materials

Phillips research grade ethane and propane were purified from the traces of higher and unsaturated hydrocarbons by passing them through a column filled with activated carbon (ethane at −76 °C, propane at 0 °C), then through a column filled with $Hg(ClO_4)_2$ on firebrick, and finally by the usual freeze–pump–thaw cycles. No impurities could be found in the ethane using gas-chromatography methods, propane contained less than 0.005% ethane (limit of detection $< 10^{-5}$%). Further purification procedures included drying over highly activated molecular sieve 3A, and immediately before use exposure to the action of highly dispersed metallic sodium (12). These drying procedures were not applied in some experiments.

Phillips research grade ethylene and propylene were purified by adsorption in activated carbon, distilled under vacuum, and dried as described above. Triply distilled water was thoroughly degassed by vacuum distillation from the potassium hydroxide solution.

(b) Sample Preparation and Irradiation

Glass ampoules of a volume of about 140 ml, 45 mm in diameter, provided with break-off tips, were used. Ampoules were baked in an oven before pumping, and then evacuated in vacuum. In some experiments the ampoules were heated under vacuum at 350–400 °C.

In a series of separate experiments the ampoules were provided with a small glass tip, into which 2–3 mg of sodium azide were inserted. After prolonged heating of the ampoules under vacuum, sodium azide has been thermally decomposed, and nitrogen formed in such a process has been pumped off. Thus, a sodium mirror has been obtained in the tip, of an area less than 3% of a total area of the ampoule.

Ethane samples were irradiated in a γ-source of the Institute of Radiation Techniques (Lodz) at a dose rate of approx. 0.4 Mrad h^{-1}.

Propane samples were irradiated at the Laval University irradiation facilities, with ^{60}Co rays in AECL Gammacell 220 at a dose rate of about 0.08 Mrad h^{-1}.

(c) Gas-chromatographic Analyses

Propane and butane, originating from the radiolysis of ethane, were analyzed on a 9 m (20% by weight) UCON LB 550X column, operated at room temperature.

Saturated C_5–C_6 hydrocarbons, originating from the radiolysis of propane, were analyzed on a 5 m (20% by weight) isoquinoline column (with 1% DC 550 added), operated at room temperature. An additional short

§The results of Bone *et al.* (9) computed using $W_{C_3H_8} = 23.4$ eV.

column filled with $Hg(ClO_4)_2 + HClO_4$ was placed after the isoquinoline column in order to lower the detection limit of analyses, otherwise too high due to the isoquinoline volatility. Further advantage of this column was that it absorbed all olefinic hydrocarbons. Isobutane and butane were resolved in a separate determination using additional 3 m dibutyl phthalate on Chromosorb P, placed after the isoquinoline column. The results for isobutane were not entirely satisfactory owing to a pronounced propane tail.

Results and Discussion

The radiation yields of some products originating from radical processes in ethane and propane are summarized in Tables 1 and 2, and are shown in Fig. 1.

The results of our preliminary experiments were much different than those obtained by many other authors (see Tables 2 and 3). Slight differences in experimental conditions could not explain such big discrepancies as slightly more than half the values for G(*n*-butane) from ethane, and G(2,3-dimethylbutane) from propane radiolysis, compared with the results of earlier investigators. Looking for the impurities which could affect the results we obviously turned our attention to water, known to be extremely difficult to remove from the ampoule walls.

The traces of water were reported to interfere with radiation processes. Hydrogen originating

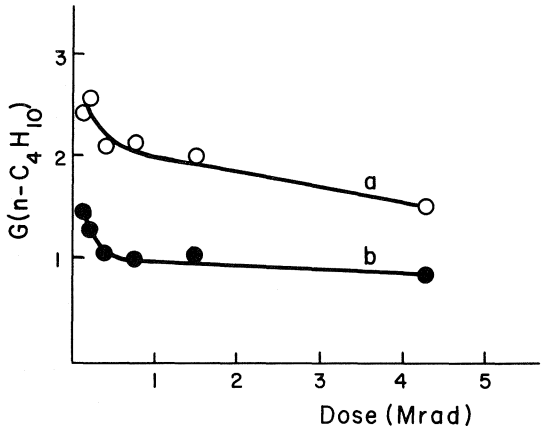

FIG. 1. $G(n\text{-}C_4H_{10})$ as a function of total dose. (*a*) Ampoules not heated in vacuum; (*b*) ampoules heated in vacuum.

from the radiolysis of pure perdeuterated hydrocarbons (propane, cyclohexane, *n*-heptane) contained substantial amounts of HD (7, 10, 13). Ion neutralization on vessel walls, covered with a layer of adsorbed water, as well as reactions of hydrocarbon ions with the traces of desorbed water, followed by neutralization of H_3O^+ ions, were supposed to account for such a surprising result.

In order to check whether these phenomena would occur in our system, we performed four series of experiments: (*1*) ethane and propane purified only using usual method: distillation under vacuum with only middle fraction of the gas retained, thorough degassing, heating of the ampoules in vacuum for many hours before use; (*2*) ethane and propane dried by passing them through a column with molecular sieve 3A at room temperature, and subsequently exposed to the action of metallic sodium deposited onto the walls of a glass bulb; radiolytic vessels were only degassed in a high-vacuum system, no heating of them was applied; (*3*) the ampoules were heated in vacuum, ethane and propane dried as described previously, and the water was purposely introduced into the ampoules; (*4*) all drying procedures previously described were used and additionally a small tip with sodium deposited onto its walls was attached to the ampoules. This should warrant the total elimination of the traces of water present in reactants as well as those desorbed from the walls.

The results of the first two series (*1* and *2*) were much higher than those obtained using highly purified ethane or propane (by the method described in part (*a*) of the Experimental section), and closely resembled those of other authors. Water introduced in series *3* increased the results up to those obtained in series *1* and *2*.

*Results of this work (see Fig. 1), extrapolated to zero dose, ampoules heated in vacuum.
†Results of this work (see Fig. 1), extrapolated to zero dose, ampoules not heated in vacuum.

The explanation of these results seems straightforward: the traces of water, either present as impurities or desorbed from the walls, have a pronounced effect on the yields of radiation products. In order to obtain the correct results, meticulous care should be taken when preparing the samples. Our experimental procedures seem to be adequate, since the presence of sodium in series *4* had no effect on the results.

The effect of dose on the yield of *n*-butane from the ampoules heated and unheated under vacuum are shown in Fig. 1. It is interesting to note that the curves are very similar despite the differences in yields in these two experiments.

We have further examined the effects of the presence of unsaturated hydrocarbons. Propylene was found to have no effect on the yield of 2,3-dimethylbutane from the propane radiolysis; this observation is different from that of Bone *et al.* who reported that the presence of propylene reduced the yield of this hydrocarbon to less than one-half. Propylene added to those samples from which the traces of water were not thoroughly removed decreased the yield of 2,3-dimethylbutane. It seems likely that this yield depends on the ratio of water and propylene concentrations.

Ethylene added to irradiated ethane increased the yield of *n*-butane. This result is unexpected and opposed to that described above for the radiolysis of propane. It is also in disagreement with the results of earlier investigations (18) where no influence of ethylene on the yield of *n*-butane could be found. In the presence of water

ethylene had no effect on the yield of *n*-butane within the limit of experimental error.

Unfortunately the explanation of our results is not unambiguous.

(a) Ethane

The main free radicals originating from the irradiated ethane are CH_3 and C_2H_5, the latter one may be formed either in primary processes or in reaction 1 (3, 4)

[1] $$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

Recombination and disproportionation of these radicals leads to a sequence of reactions:

[2] $$CH_3 + CH_3 \rightarrow C_2H_6$$

[3*a*] $$CH_3 + C_2H_5 \rightarrow C_3H_8$$

[3*b*] $$\rightarrow CH_4 + C_2H_4$$

[4*a*] $$C_2H_5 + C_2H_5 \rightarrow n\text{-}C_4H_{10}$$

[4*b*] $$\rightarrow C_2H_6 + C_2H_4$$

On the basis of this mechanism the increase in *n*-butane yield should be ascribed to the increase in the yield of ethyl radicals. The yields of methyl and ethyl radicals were calculated assuming $k_{3b}/k_{3a} = 0.04$ and $k_{4b}/k_{4a} = 0.14$ (14), and taking into account the yields of propane and *n*-butane formed in ionic processes (not scavenged by oxygen), equal to 0.22 and 0.21, respectively (see Table 1). The increase in the yield of ethyl radicals due to the presence of water is equal to 2.1–2.6. Such a marked increment is observed in the presence of the traces of water (either desorbed from the walls or introduced with the ethane insufficiently dried). Thus, water interference must involve a very slow ionic process.

Even though reaction of primary ethane ions $C_2H_6^+$ with water is known to be very fast:

[5] $$C_2H_6^+ + H_2O \rightarrow C_2H_5 + H_3O^+$$

$$k_5 = 1.2 \times 10^{-9} \text{ cc molecule}^{-1} \text{ s}^{-1} \text{ (15)}$$

it cannot compete effectively with condensation reaction 6 under our experimental conditions

[6] $$C_2H_6^+ + C_2H_6 \rightarrow (C_2H_6)_2^+$$

$$k_6 \approx 10^{-10} \text{ cc molecule}^{-1} \text{ s}^{-1} \text{ (16)}$$

Dimeric ion formed in reaction 6 is unreactive towards ethane (16), its structure and heat of formation are unknown, either a chemical bond is formed between the ion and the molecule or the link is due to attractive physical forces. If the latter case is true, the occurrence of reaction 7 may be assumed.

[7] $$(C_2H_6)_2^+ + H_2O \rightarrow C_2H_5 + C_2H_6 + H_3O^+$$

Such reaction may, at least partly, be responsible for the increase in $G_{C_2H_5}$.

Another possible source of ethyl radicals (strictly speaking, of atomic hydrogen, precursor of ethyl radicals in reaction 1) may be neutralization of H_3O^+ ions formed in reaction 7, and in other similar reactions. Reaction of hydrated ions of the type of $C_2H_4(H_2O)_n^+$ may also be involved. Similar mechanism has been advanced by Fujisaki and Gaumann to explain the formation of HD in the radiolysis of gaseous cyclo-C_6D_{12} and *n*-C_7D_{16} (13).

The phenomena described above are far from being well understood. Further studies are needed, especially those concerned with the dependence of G(*n*-butane) on dose, and with the increase in $G_{C_2H_5}$ in the presence of ethylene. The latter result may be tentatively explained by the H atom transfer from $C_2H_6^+$, $(C_2H_6)_2^+$ and other higher order ions. Reaction 8 is exothermic

[8] $$C_2H_6^+ + C_2H_4 \rightarrow C_2H_5^+ + C_2H_5$$

$$\Delta H_8 = -13.3 \text{ kcal mol}^{-1}$$

The enthalpy of analogous reaction involving dimeric $(C_2H_6)_2^+$ ions is unknown.

[9*a*] $$(C_2H_6)_2^+ + C_2H_4 \rightarrow C_2H_5 + C_2H_5^+ + C_2H_6$$

[9*b*] $$\rightarrow C_4H_{11}^+ + C_2H_5$$

Also the assumption that the yield of molecular propane and butane, persisting in the presence of oxygen (and therefore formed in reactions other than [3*a*] and [4*a*]) would be the same in the absence of oxygen is open to serious doubts. Wodetzki *et al.* have reported G(*n*-C_4H_{10}) equal to 0.4 in the presence of NO, but lowered down to 0.1 in the presence of propylene (4).

According to mass-spectrometric evidence ion–molecule reactions in ethane give $C_3H_9^+$ and $C_4H_{11}^+$ ions (16). Oxygenated compounds, formed as a result of radical scavenging by oxygen, may intercept these ions in proton transfer reactions, yielding propane and butane.

(b) Propane

The main free radicals in the radiolysis of gaseous propane are CH_3, C_2H_5, *i*-C_3H_7, and *n*-C_3H_7 (9). The yields of propyl radicals, calculated using the pertinent ratios of k_d/k_r, are in-

cluded in Table 2 (14). The presence of water traces increases the yield of i-C_3H_7 by $\Delta G_{i\text{-}C_3H_7} \approx 2.7$ to 3.1, affecting but slightly the yield of n-propyl radicals.

In this case, the increment in $G_{i\text{-}C_3H_7}$ may also be ascribed to the proton transfer from $(C_3H_8)_2^+$ dimer to the water molecule, ultimately followed by the neutralization of H_3O^+ ions:

[10] $$C_3H_8^+ + C_3H_8 \rightarrow (C_3H_8)_2^+$$

[11] $$(C_3H_8)_2^+ + H_2O \rightarrow i\text{-}C_3H_7 + C_3H_8 + H_3O^+$$

Proton transfer from propane $C_3H_8^+$ ions to the water has been observed in a mass spectrometer

[12] $$C_3H_8^+ + H_2O \rightarrow i\text{-}C_3H_7 + H_3O^+$$

$$k_{12} = 1.4 \times 10^{-9} \text{ cc molecule}^{-1}\text{ s}^{-1} \quad (15)$$

The effect of propylene on the yield of i-C_3H_7 may be explained by the interception of ions by this hydrocarbon, prior to their reaction with water. Higher order unsaturated ions are unlikely to produce atomic hydrogen upon neutralization, according to Bone *et al.* (9). This conclusion is supported by the results of ethylene radiolysis. The yield of atomic hydrogen formed in ethylene radiolysis by the neutralization of ions was assessed as equal to $G_H = 2.9$ (17); in the presence of 1–3% propylene the formation of H atoms by this mechanism was totally suppressed (18). Apparently, higher order ions with inserted propylene molecules do not yield atomic hydrogen upon neutralization, the effect of propylene is exactly similar to that of isobutylene (17).

Conclusions

(*1*) The traces of water, either present as an impurity in insufficiently dried reagents or desorbed from the walls, have a pronounced effect on the yields of some products, originating from the gas-phase radiolysis of ethane and propane.

The yields of products, formed as a result of free radical recombination in pure ethane and propane, are about half as large as those reported hitherto in the literature.

(*2*) Our experimental procedure, including drying of the reactants over molecular sieve, exposing to the action of subtly dispersed sodium, heating of the ampoules in high vacuum, is adequate for removing the traces of water.

The preparation by total synthesis of a saturated cephalosporin analog 7-β-phenoxyacetamido-3-ethoxy-*O*-2-isocepham-4-α-carboxylic acid **30**, is described. Compound **30** was prepared via cycloaddition of azidoacetyl chloride to the cinnamylidene Schiff base of ethyl 2-amino-3,3-diethoxypropionate **13***b* to give the *cis*-3-azido-4-styryl β-lactam **15***b*. Ozonolysis of **15***b* followed by sodium borohydride reduction gave the alcohol **18***b*. Boron trifluoride treatment of **18***b* gave ethyl 7-β-azido-3-β-ethoxy-*O*-2-isocephem-4-carboxylate **27**. Reduction of the azido group followed by coupling with phenoxyacetic acid and saponification of the ester gave **30**. The mechanism of the cycloaddition reaction and the stereochemical assignments are also discussed.

TERRENCE WILLIAM DOYLE, BERNARD BELLEAU, BING-YU LUH, CARRADO F. FERRARI et MICHAEL PATRICK CUNNINGHAM. Can. J. Chem. **55**, 468 (1977).

On décrit la préparation, par synthèse totale, d'un analogue d'une céphalosporine saturée soit l'acide β-phénoxyacétamido-7 éthoxy-3 *O*-isocépham-2 α-carboxylique-4 **30**. On a préparé le composé **30** en effectuant une cycloaddition du chlorure d'azidoacétyle sur la base de Schiff dérivée du cinnamaldéhyde et de l'amino-2 diéthoxy-3,3 propionate d'éthyle **13***b* qui conduit à l'azido-3 styryl-4 β-lactame-*cis* **15***b*. L'ozonolyse de **15***b*, suivie par une réduction au borohydrure de sodium, conduit à l'alcool **18***b*. Le traitement de **18***b* par le trifluorure de bore fournit la β-azido-7 β-éthoxy-3 *O*-isocéphème-2 carboxylate-4 d'éthyle **27**. La réduction du groupe azido, suivie par un couplage avec l'acide phénoxyacétique et une saponification de l'ester, conduit à **30**. On discute du mécanisme de la réaction de cycloaddition et des attributions stéréochimiques.

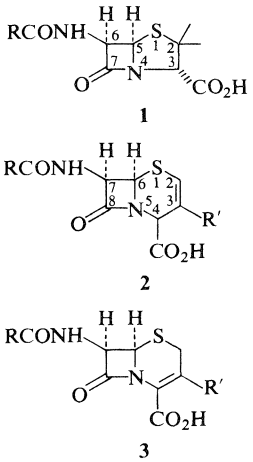
[Traduit par le journal]

Early work on the penicillin and cephalosporin groups of antibiotics (Fig. 1) soon established the following criteria for optimal biological activity (1).

(*1*) The presence of a β-lactam ring fused to a second ring in such a manner as to impart strain to the amide bond of the β-lactam is required. In the penicillins **1** the ring size alone is sufficient to do this. The lack of activity of the Δ^2-cephalosporins **2** relative to the Δ^3-cephalosporins **3** and penicillins leads to the second criterion.

(*2*) In 4–6 fused systems a double bond in conjugation with the β-lactam amide is a requirement either on steric or electronic grounds.

(*3*) An acylated amino function α to the carbonyl of the β-lactam is usually necessary.



1

2

3

FIGURE 1

(*4*) The protons attached to the bridgehead position and α to the amido side chain must be oriented *cis* to one another.

(*5*) A free carboxylic acid at position 3 in the

penicillins or position 4 in the cephalosporins seems to be necessary.

At the time we started our research, the role played by the sulfur atom at position 1 in both the penicillins and cephalosporins had not been empirically elucidated. Topp and Christensen (2) have stated, on the basis of molecular orbital calculations of the penicillins and cephalosporins, that it may play a role in transpeptidase enzyme deactivation by controlling the equilibrium conformation which governs binding to the enzyme and in reducing the barrier to reaction with the enzyme.

While a number of nuclear analogs of the penam and cepham systems have been synthesized, the majority of these have involved retention of the sulfur atom at position 1 (for leading references to work carried out prior to 1972 see refs. 1 and 3).[4] Only recently the syntheses of the 1-oxocephalosporin and the desthiacephalosporin systems have been reported (4*i*, *j*) (Fig. 2, **4** and **5**). These compounds exhibited biological activity comparable to that of the natural cephalosporins, thus demonstrating for the first time the non-essential role of the sulfur atom in β-lactam antibiotics (4*i*).

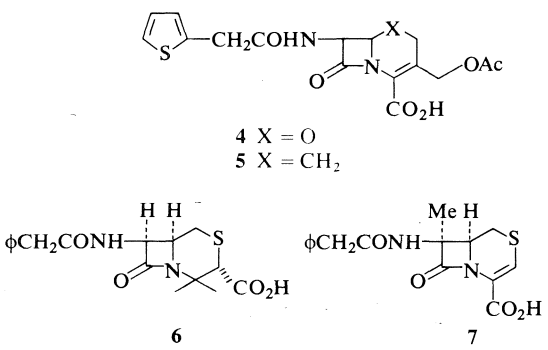

FIGURE 2

Recently, Lowe and co-workers have reported the syntheses of two cephalosporin analogs in which the heteroatom has been transposed from the 1 to the 2 position (4*h*) (Fig. 2, **6** and **7**). The failure of these analogs to exhibit activity is not surprising in view of the fact that they do not fulfill the necessary criteria alluded to earlier. Compound **7** (4*h*) comes closest to doing so but the substitution of the 7α position by a methyl group would be expected to impair the antibacterial activities of the system by analogy with the results in the natural series (5).

For the past several years, we have been engaged with the development of a general synthetic route to nuclear analogs of the cephalosporins of general structure **8** (Fig. 3). In this and the accompanying papers of this series, we would like to report our results in this area.[5]

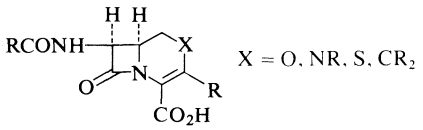

FIGURE 3

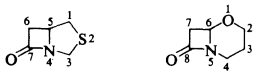
A priori one may envisage a number of ways by which the bicyclic systems represented by **8** might be formed (Fig. 4). Formation of the β-lactam amide bond in the latter stages of the synthesis is the classical approach used by Sheehan in his synthesis of penicillin and adapted by Heymes and Dolfini to the synthesis of cephalosporins.[6] Alternatively, the C_6—C_7 bond may be formed onto a preexisting six-membered ring either by ring contraction (4*e*), carbene insertion (4*f*–*h*), or condensation (7) reactions. A third approach is the formation of the C_6—C_7 and C_8—N bonds simultaneously via cycloaddition reactions. This has been used by Bose in his synthesis of epipenicillin, and several nuclear analogs of the penam and cepham systems (3, 4*a*, 4*d*). More recently, Ratcliffe and Christensen have utilized this approach in their total synthesis of cephalothin and cefoxitin (8). A somewhat similar approach has been used by Edwards *et al.* (9) to prepare desacetylcephalothin lactone via

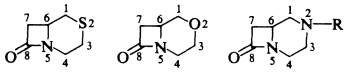
[4]For a list of references to nuclear analogs involving heteroatom substitutions and transpositions which have appeared in the literature recently, see ref. 4.

[5]In order to preserve the numbering system currently in use with the cephalosporins, we propose that the following trivial nomenclature be used for these systems by analogy with that used by Manhas and Bose (3*a*) for **i** and Sheehan and Dadic (6) for **ii**.



Isopenam **i** *O*-Cepham **ii**

thus:



2-Isocepham *O*-2-Isocepham *N*-2-Isocepham

[6]For a review of this work, see K. Heusler in ref. 1.

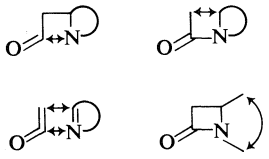


FIGURE 4

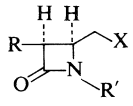
furo[3,4-*c*]cephams. The last approach is to build a six-membered ring onto a preformed β-lactam. This approach is perhaps the most versatile with regard to permitting the synthesis of a variety of nuclear types from a common intermediate as has been elegantly demonstrated by Woodward and co-workers in their total synthesis of cephalosporin C and a number of nuclear analogs[6] (10). More recently Kuhlein and Jensen (11) have utilized the approach to prepare a number of analogs of the cephalosporins.

In view of the potential versatility of the approach, the synthesis of a monocyclic β-lactam of general structure **9** became our first target (Fig. 5) wherein R would be either an amino or



9

FIGURE 5

amido function (or some function readily converted to these) and R′ would either be an easily removed protecting group or would incorporate the requisite functionality for conversion of **9** to **8**.

In principle, the synthesis of structures such as **9** might be approached in a variety of ways.[7] Recently, Hlubucek and Lowe (13) have reported the synthesis of **9** (R = ϕCH_2CONH, R′ = $CH_2\phi$, X = $SCH_2\phi$) as a mixture of *cis* and *trans* isomers. Since we wished to avoid as far as possible the problems associated with *cis–trans* mixtures an approach to compounds such as **9** utilizing the method originally discovered by Staudinger (14) and extended by Bose and co-workers (3, 4*a*, 4*d*, 15) was developed. The addition of ketenes (or substituted acetyl halides in the presence of suitable bases) to Schiff bases yields β-lactams. The stereochemistry of the resultant β-lactams may be controlled by the order of addition of the reagents and by the substitution pattern of both the acid chloride and Schiff base (15*b*, 15*l*). Inasmuch as we wished to avoid working with the highly labile β-substituted acetaldehydes and in view of the possibilities of elimination reactions occurring in competition with cycloaddition we decided to mask the desired substituent at C_4 in the 2-azetidinones as a styryl function.[8] The use of cinnamylidene Schiff bases in the acid chloride – imine formation of β-lactams has been reported only seldom in the literature (14, 16*a*). As early as 1907 Staudinger (14) claimed to have obtained β-lactams from the reactions of dimethyl and diphenyl ketenes with cinnamylidene anil. The work was repeated during the early work on penicillin (16*a*). In contrast to these results Pfleger and Jager (17) have reported that the reaction of phenylketene and ketene with cinnamylidene anil gave dihydropyridones. Similar results with dichloroketene have been reported (18). In a related reaction, Mohan has reported the formation of dihydropyridinone **12***d* from the reaction of an oxazolidinone with this same anil (19) (Fig. 6). While our work was in progress,

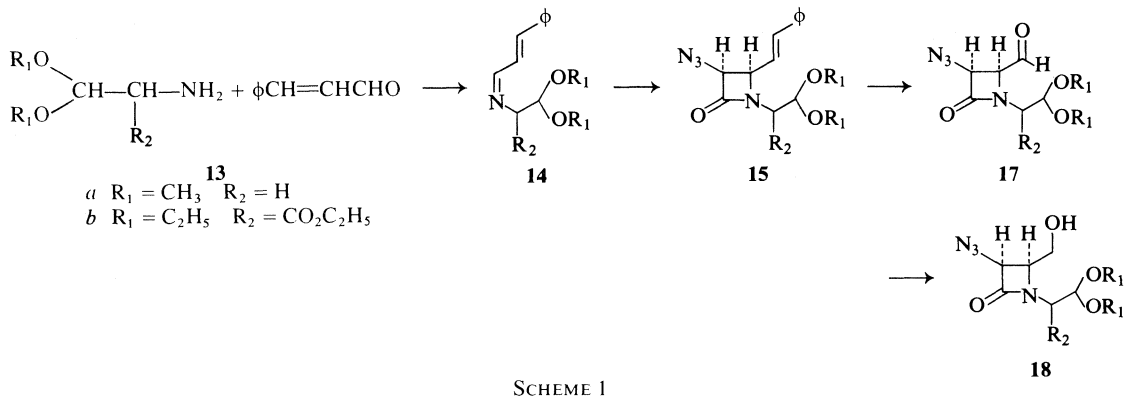
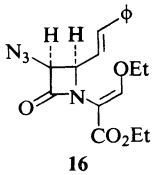
iii



SCHEME 1

Results and Discussion

As a model for future work, the synthesis of **15***a* was studied first (Scheme 1). Treatment of Schiff base **14***a* (derived from cinnamaldehyde and aminoacetaldehyde dimethyl acetal **13***a* in quantitative yield) and an equimolar amount of triethylamine in methylene chloride with an equivalent of azidoacetyl chloride gave *cis*-*N*-(β,β-dimethoxyethyl)-3-azido-4-styryl-2-azetidinone **15***a* in 52.5% yield. That the product was not a dihydropyridone was shown by the β-lactam carbonyl absorption at 1755 cm^{-1} and the nmr spectrum (Table 1). The 5 Hz coupling constant between the C_3—H and the C_4—H was indicative of the *cis* stereochemistry.[9] No trace of the *trans* isomer could be detected by nmr spectroscopy of the crude product. The magnetic non-equivalence of the two protons of the side chain adjacent to the nitrogen and of the two methoxy groups (to a lesser extent) was as expected from the earlier observations of Barrow and Spotswood (21*c*) on *N*-benzyl substituted 2-azetidinones.



16

Similarly, treatment of Schiff base **14***b* (derived from amine **13***b*[10] and cinnamaldehyde) and triethylamine with azidoacetyl chloride gave *cis*-*N*-(α-carboethoxy-β,β-diethoxyethyl)-3-azido-4-styryl-2-azetidinone **15***b* in high yield. Compound **15***b* was obtained as a mixture (~1:1) of diastereoisomers about the α-carboethoxy function as was indicated by the nmr spectrum of **15***b* (Table 1). Chromatography of the crude product gave a small amount (<5%) of a byproduct **16** which was identified by its nmr and ir spectra and by elemental analysis. Since we envisaged eventually removing the asymmetric center in the side chain of **15***b* no attempt was made to separate the diastereoisomers.

The mechanism of β-lactam formation via the acid chloride – imine route is by no means clear. *A priori*, one may envisage prior formation of an acid chloride – imine complex which undergoes dehydrohalogenation with triethylamine to give β-lactam (Fig. 7). Bose (15*b*, 15*m*) has proposed that with acid chlorides possessing an atom with a free pair of electrons at the α position these atoms are capable of stabilizing transition states such as *B* via the formation of donor–acceptor complexes. Proton abstraction from complex *B* in which the carbon atoms C_3 and C_4 are held in close proximity would lead to β-lactams. This proposal is especially attractive in systems capable of exhibiting extended conjugation such as ours. An examination of Dreiding models indicates that the conformation in which such a donor–acceptor complex would be maximized is as shown in Fig. 8. In such a conformation the C_3—H′ bond axis is aligned with the cationic *p*-orbital at C_4. Removal of C_3—H′ by base with concerted formation of the C_3—C_4 bond would lead to a β-lactam of *cis* stereochemistry. Alternatively, abstraction of C_3—H would give an anion stabilized by the carbonyl. Rotation

[9]The stereochemistry of monocyclic β-lactams may be determined from the coupling constants between C_3—H and C_4—H. *Trans* isomers show *J*'s of approximately 1–2 Hz while the corresponding *cis* isomers have *J* values of approximately 5 Hz (21).

[10]This amine was prepared via a modification of the method reported by Brown in ref. 16*b*.

[a]Recorded in $CDCl_3$ at 60 MHz using tetramethylsilane as internal standard unless otherwise noted. The chemical shifts are reported in δ values and *J* values are in Hz. [b]AB quartet for N—CH_2—CH(OMe)$_2$. [c]Two diastereoisomers. [d]A broad multiplet 4.35–4.8 for C_4-H, C*H*(CO_2R)C*H*(OR)$_2$ integrating for 3 protons. [e]Addition of benzene to the sample causes these two overlapping signal sets to resolve into a doublet for C_3-H, *J* = 5.5 Hz and a doublet of doublets for C_4-H, J_1 = 7.0, J_2 = 5.5 Hz. [f]An unresolved multiplet at ~3.80 integrating for 4*H*, assigned to CH_2OH and C_4-*H*. [g]An unresolved multiplet at ~3.80 integrating for 3H, assigned to CH_2OH and C_4-H. The protons N—CH_2—CH(OR)$_2$ appear as an unresolved multiplet at 3–3.6 δ. [h]A broad multiplet centered at 3.85 δ integrating for 5 protons assigned to C_4-H, CH_2—O*H*, and the lower arm of the AB quartet for N—CH_2CH(OR)$_2$. [i]Upfield arm of AB quartet for N—CH_2—CH(OR)$_2$. [j]A broad multiplet centered at ~3.90 δ integrating for 4 protons assigned to C_4-H and CH_2—OH. [k]Complex multiplet from 4.2–4.6 δ integrating for 3 protons assigned to C_3-H, C_4-H, C*H*(OR)$_2$. [l]Two diastereoisomers integrating ~1:1. [m]Assigned to C_4—H and C*H*(OEt)$_2$. [n]Assigned to CH_2—O*H* and N—C*H*(CO_2Et).

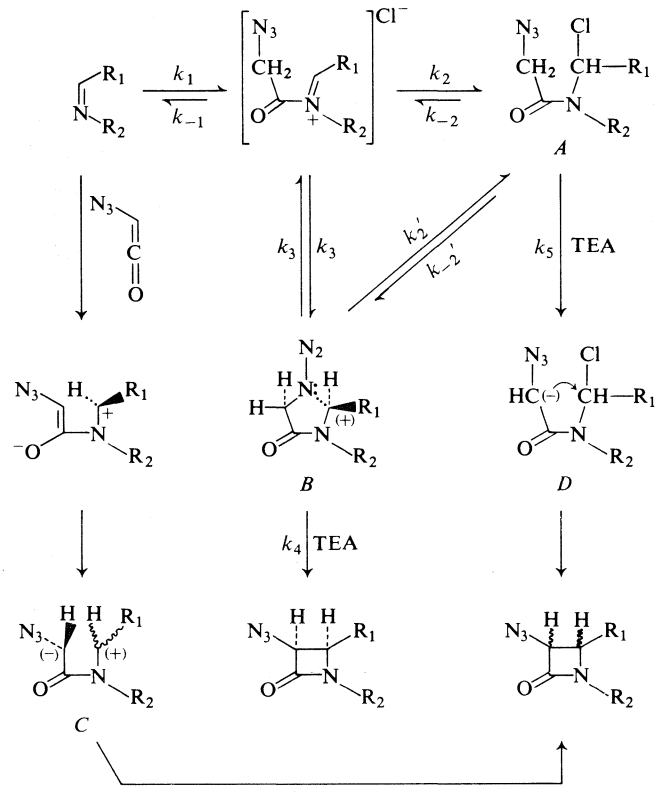

FIGURE 7

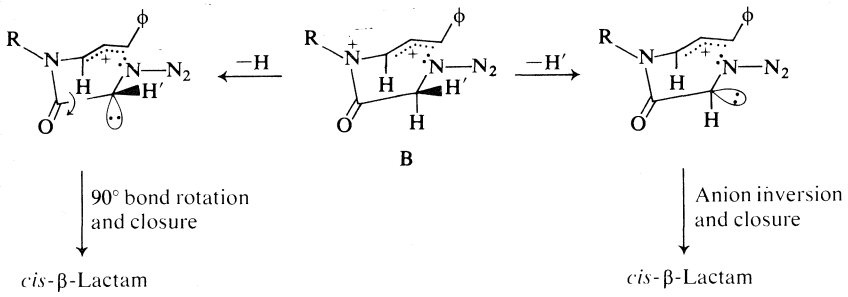

FIGURE 8

through 90° with concomitant C_3—C_4 bond formation would also give a β-lactam of *cis* stereochemistry.

That our β-lactams could arise via ketene addition is unlikely in view of the reports that the additions of aldoketenes generally proceed to give only *trans* adducts (22) with the stereochemistry of the adduct being determined by the energies of the respective transition states leading to intermediates *C*.

That such a degree of selectivity should be exhibited by the presumed azidoketene in the cycloaddition to our cinnamylidene Schiff bases is highly unlikely. Bose has shown (15*m*) that in the addition of acid chlorides to Schiff bases the *trans* stereochemistry generally predominates.

For example, in the addition of azidoacetyl chloride to benzal aniline followed by the addition of triethylamine the *cis–trans* ratio is 1:3 (15*l*). When the order of addition is reversed, the ratio becomes 3:1.[11]

An explanation which accommodates these results would be as follows. When an acid chloride is added to a Schiff base, rapid and reversible formation of an acylimonium ion occurs followed by a slower ($k_1 > k_2$) formation of chloro compound *A*. Where the acid chloride carries a group α to the carbonyl with a pair of free electrons capable of stabilizing the imonium ion one of the conformers of the originally formed acyl imonium ion becomes stabilized as in *B*. The rate with which this occurs would be greater than the formation of *A* depending on the substituents on the acid chloride and on the original Schiff base *e.g.* where R_1 was a simple alkyl function, the rate of formation of *A* would be enhanced whereas when R_1 is aromatic (as in benzalimines) the rate of formation of *A* would be repressed. It has been shown that in the absence of added base (triethylamine) the equilibrium concentrations of the chloride are high. Bose has demonstrated that it is the covalently-bonded form *A* which is produced in the reaction (15*m*). Proton abstraction from *A* would be expected to lead to *D* which would be expected to give both *cis* and *trans* β-lactams (depending on the energies of the transition states leading to the respective isomers) (Fig. 8). If, on the other hand, formation of the initial acylimonium ion were to occur *in the presence of triethylamine* proton abstraction from *B* would lead to exclusively *cis* β-lactam if the assumptions outlined earlier are correct. Where the rate of proton abstraction from *B* and concomitant ring closure to *cis*-β-lactam k_4 is greater than either k_2' or k_2 mixtures of β-lactams in which the *cis* isomer predominates would be obtained. Thus the isomer mixture which is obtained from the acid chloride–imine reaction to form β-lactam is dependant on a number of factors:

(*1*) The equilibrium concentrations of *A* and *B* in the reaction mixture. This would depend upon the degree to which the carbonium ion were to be stabilized by interactions with the lone pair on the amide nitrogen, by the electron pair of the donor atom in *B* and by R_1 itself.

(*2*) The rate with which the equilibrium between *A* and *B* were to be established relative to the rates of proton abstraction from *A* and *B*.

(*3*) The degree to which a conformationally restrained complex *B* could be formed would also affect the stereospecificity of the reaction. One would expect that for disubstituted acid chlorides or for ketoimines that the formation of such a complex would be sterically hindered to some degree. In such cases, the stereochemistry of the adducts might well be governed by steric interactions between the substituents.

In the case of the cinnamylidene Schiff bases the possibility of extended conjugation would tend to stabilize the acylimonium ion *B* thus the high stereospecificity of the reaction.

Ozonolysis of **15***a* in methanol at −78 °C followed by reduction with sodium borohydride gave a mixture of **18***a* and benzyl alcohol. Chromatography of the oil gave pure **18***a* in 77% yield. Treatment of **18***a* with 1 equiv. of boron trifluoride etherate in methylene chloride gave a mixture of the isomeric 3-methoxy-7-azido-*O*-2-isocephams **19** and **20** in 59% yield. On chromatography, there was obtained pure 3-β-methoxy-7-β-azido-*O*-2-isocepham **19** and pure 3-α-methoxy-7-β-azido-*O*-2-isocepham **20** in a ratio of 2:1. The assignment of configuration to each isomer was made on the basis of its nmr spectrum (Table 2). An examination of Dreiding models indicates that the *O*-2-isocepham system may exist in a chair form (C) either of two boat forms (B_1 and B_2) or a twist-boat form (TB) (Fig. 9). The boat forms B_1 and B_2 were eliminated from consideration due to prohibitive steric interactions in each. The chair form C and the twist-boat form were each capable of explaining the pattern of coupling constants observed for **19** and **20** respectively, but led to opposite configurational assignments.

The signals at 2.99 δ and 2.63 δ in compounds **19** and **20** respectively have been assigned to 4-α-protons since we would expect the 4-β-protons to be shifted to lower fields by the β-lactam carbonyls with which they are eclipsed in both conformers. An examination of the

[11]We have observed a similar result in the reaction of azidoacetyl chloride with cinnamylidene anil. Addition of the acid chloride to the Schiff base followed by the addition of triethylamine gave a 29% yield of 1-phenyl-3-azido-4-styryl-2-azetidinone with a *cis–trans* ratio of 3:5. Inverse addition gave an 85% yield of pure *cis* β-lactam (unpublished).

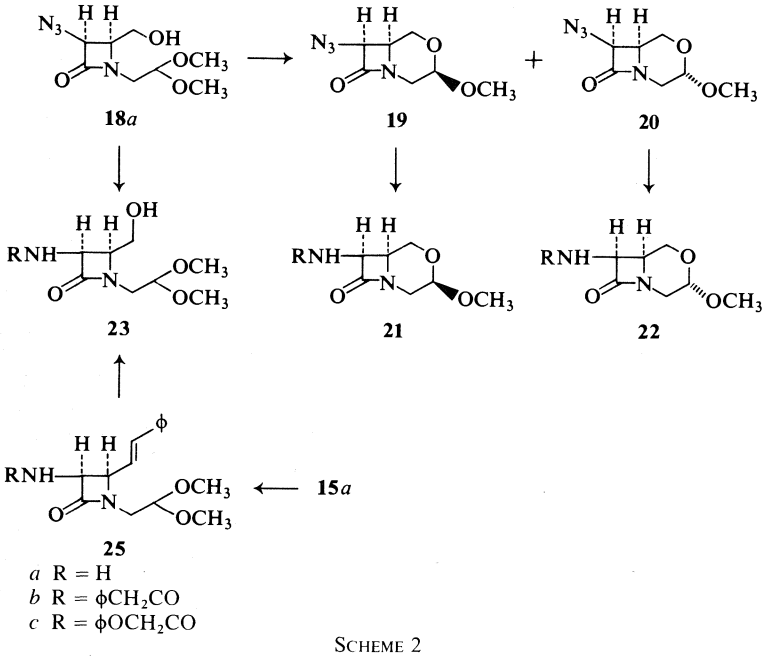
[a]Recorded in $CDCl_3$ at 60 MHz on a Varian A-60-A spectrometer using tetramethylsilane as internal standard unless otherwise noted. The chemical shifts are in δ (ppm) and *J*'s in Hz. [b]Assigned to C_4-Hα-upfield arm of AB quartet. [c]Assigned to C_6-H, C_1-H_2, and C_4-Hβ. [d]Resolution poor. [e]Obscured by ϕOCH_2 signal. [f]Assigned to C_6-H, C_1-H_2, OCH_2CH_3.



SCHEME 2

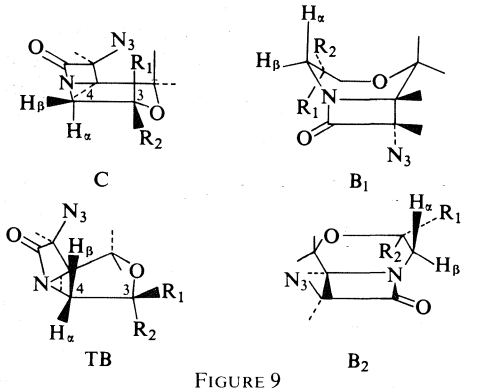


FIGURE 9

splitting patterns in **19** and **20** of the C_3 and $C_4\alpha$ protons indicates that **19** has an axial methoxyl group and **20** an equatorial group. This is further borne out by the relative positions of the C_3 protons in **19** and **20**. The C-3 proton of **20** is at higher field than in **19** which is in accord with the observation that axial protons are usually found at higher fields than equatorial ones in similar systems (23). The preponderance of axial isomer **19** over **20** in this system is in accord with what would be expected on the basis of the anomeric effect (24). To confirm that the isomer ratio produced in the cyclization of **18***a* to **19** and **20** reflects the thermodynamic equilibrium between **19** and **20** each of the isomers was equilibrated in deuteriochloroform with boron trifluoride etherate and the isomer ratios determined by nmr spectroscopy. Treatment of **20** with a catalytic amount of boron trifluoride etherate led to a rapid establishment (~1 h) of an equilibrium between **19** and **20** (66% **19** and 34% **20**). When **19** was treated similarly, the establishment of equilibrium was slower but yielded the same results.

We have assigned the 3-β-methoxy configuration to compound **19** and the 3-α-methoxy configuration to **20**. Although the splitting pattern of **19** could be accommodated by the 3-α-methoxy configuration with twist-boat conformation the observation that the C_4-α proton in **19** appears at lower field than the C_4-α proton in **20** by 20 Hz is better accommodated by the assignment of the 3-β-methoxy configuration in the chair conformation. In the twist-boat conformation, the dihedral angles between the C_4-Hα bond and the C_3-α-methoxy and C_3-β-methoxy C—O bonds are 45° and 75° respectively. In the chair conformation on the other hand the dihedral angle between the 3-β-methoxy C—O bond in **19** and the C_4-Hα bond is 165° and that between the 3-α-methoxy C—O bond in **20** and the C_4-Hα bond is 45°. One would expect that if compounds **19** and **20** were to adopt the twist-boat conformations, the

TABLE 3. $Eu(fod)_3$ shifts $\Delta\delta^{a,b}$

Compound	C_7-H	C_3-Hα	C_3-Hβ	C_4-Hα	β-OCH_3	α-OCH_3
19[c]	6.74 (1.0)	6.50 (0.97)	—	4.75 (0.70)	3.88 (0.58)	—
20[d]	6.23 (1.0)	—	5.20 (0.84)	4.60 (0.74)	—	1.96 (0.32)

[a]Recorded in $CDCl_3$ relative to internal TMS at 60 MHz.
[b]Values extrapolated to 1:1 *M* $Eu(fod)_3$; ratios in parentheses.
[c]Initial concentration 0.001 mol/0.4 ml $CDCl_3$.
[d]Initial concentration 0.00067 mol/0.3 ml $CDCl_3$.

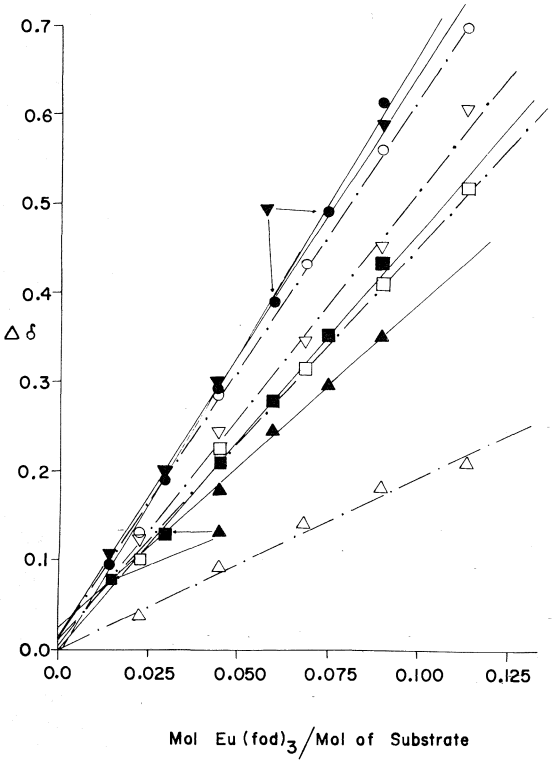

FIG. 10. Shifts in the nmr spectra of **19** and **20** due to the addition of Eu $(fod)_3$: compound **19** —, ● C_7-H, ▼ C_3-Hα, ■ C_4-Hα, ▲ C_3-βOCH_3; compound **20** ----- ○ C_7-H, ▽ C_3-Hβ, □ C_4-Hα, △ C_3-αOCH_3.

difference in chemical shift between the C_4-α protons would be small. On the other hand if **19** and **20** were to adopt the chair conformations, the C_4-α proton would not be expected to be shifted to higher field by the C—O bond whereas it would be expected to do so in **20**.

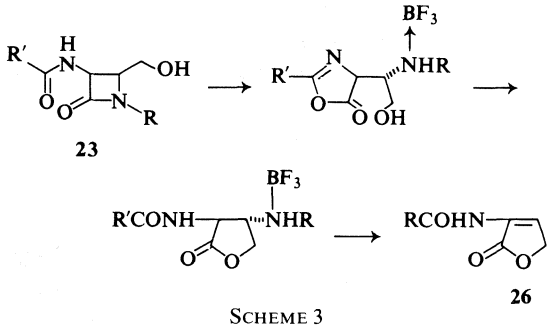
Incremental addition of $Eu(fod)_3$ caused downfield shifts in the nmr spectra of **19** and **20** (Fig. 10 and Table 3). From the data in Table 3 it is apparent that the primary site of coordination of the $Eu(fod)_3$ is the β-lactam carbonyl since in each isomer C_7-H shows the greatest lanthanide induced shift (LIS) (25*a*).[12] The greater LIS of the 3-β-methoxy in compound **19** over the 3-α-methoxy in compound **20** was as expected. The larger LIS of the 3-α-proton in **19** over the 3-β-proton in **20** may be explained if one assumes that **19** is capable of exhibiting bidentate complexation with the europium.

Reduction of the azido functions of compounds **19** and **20** with triethylamine – hydrogen sulfide[13] in methylene chloride solution gave the amino *O*-2-isocephams **21***a* and **22***a* respectively. These compounds were characterized spectroscopically (ir and nmr) and were coupled with phenoxyacetic acid using *N*-carboethoxy-2-ethoxy-1,2-dihydroquinoline (EEDQ) as the coupling agent (26) to give **21***b* and **22***b* in 77% and 96% yields respectively. The nmr spectra of compounds **21***a*, **21***b*, **22***a*, and **22***b* are recorded in Table 2. Compounds **21***b* and **22***b* exhibited β-lactam carbonyl bands in the ir at 1753 and 1765 cm^{-1} respectively.

Similarly **18***a* was reduced and coupled with phenylacetic acid to yield **23***b* in 38% yield. Compound **23***b* could also be prepared by the reduction of compound **15** followed by coupling of the amine **25***a* with phenylacetic acid to give **25***b* in 34% yield. Ozonolysis of **25***b* in methanol followed by sodium borohydride reduction *in situ* gave **23***b* in 74% yield identical in all respects with the sample prepared from **18***a*. Similarly the coupling of phenoxyacetic acid with **25***a* gave **25***c* in 77.5% yield. Ozonolysis of **25***c* in

[12]The preference for complexation with amides in the presence of acetals has been demonstrated by Wenkert and co-workers (25*b*).

[13]The use of ammonium sulfide in the reduction of azido groups has been demonstrated (9, 27). We have found the hydrogen sulfide – triethylamine procedure to be quite convenient since it permits the operation to be carried out in non-aqueous solution. The yields are generally high, 70–95%, and the method very selective for the azido function. The role of the triethylamine is catalytic although the reaction proceeds faster when at least an equivalent of triethylamine is used.



SCHEME 3

methanol followed by sodium borohydride reduction gave **23***c* in 65% yield.

Attempts to cyclize either **23***b* or **23***c* with boron trifluoride etherate led to decomposition and loss of the β-lactam. The decomposition of **23***b* was instantaneous while **23***c* required the addition of slightly greater than 1 equiv. of boron trifluoride etherate. Presumably these compounds undergo a penicilloyl type rearrangement. In the case of **23***c* 1 equiv. of the boron trifluoride is probably bound by the side chain (Scheme 3). In related experiments, low yields of **26** were isolated from the reaction and **26** was identified by spectroscopic methods as part of the product mixtures from the reactions of **23***c* with boron trifluoride etherate.

Treatment of alcohol **18***b* with boron trifluoride etherate gave 3-β-ethoxy-4-α-carboethoxy-7-β-azido-*O*-2-isocepham **27** in 77% yield after chromatography (Scheme 4). While the formation of four configurational isomers of **27** was possible only a single isomer was obtained which has been assigned to the 3-β-ethoxy-4-α-carboethoxy configuration on the basis of its nmr spectrum (Table 2). The axial configuration of the carboethoxy group is not surprising since in the equatorial position a severe interaction with the β-lactam carbonyl would be encountered. In addition in the axial position there is only one *syn–axial* interaction with the C_6 proton. The failure to observe any of the 4-β-carboethoxy isomer may be due to the failure of the side chain on the nitrogen of the β-lactam to adopt a conformation suitable for the cyclization of **18***b* to the 4-β-carboethoxy-3-ethoxy-*O*-2-isocephams due to the carboethoxy–β-lactam carbonyl interaction.

The failure to observe any of the 3-α-ethoxy-4-α-carboethoxy isomer may be due to destabilization of this isomer relative to the 3-β-ethoxy isomer by steric interaction of the ethoxy with the carboethoxy groups in the former case (Fig. 11). Attempts to epimerize **27** to its 4-β-carboethoxy isomer with base failed. Treatment of the anion of **27** with D_2O led to the exchange of the C_4-β proton with no epimerization as determined by nmr spectroscopy.

Reduction of the azido group of **27** with ammonium chloride and zinc in methanol gave 3-β-ethoxy-4-α-carboethoxy-7-β-amino-*O*-2-isocepham **28** in 50% yield. Acylation of the amino function with phenoxyacetic acid and EEDQ proceeded as before to give 7-β-(aminophenoxyacetoyl)-3-β-ethoxy-4-α-carboethoxy-*O*-2-isocepham **29** in 90% yield. Saponification of **29** with dilute alcoholic sodium hydroxide gave 7-β-(aminophenoxyacetoyl)-3-β-ethoxy-*O*-2-isocepham-4-α-carboxylic acid **30** in 55% yield. The ir spectrum of **30** exhibited a β-lactam carbonyl band at 1773 cm^{-1}.

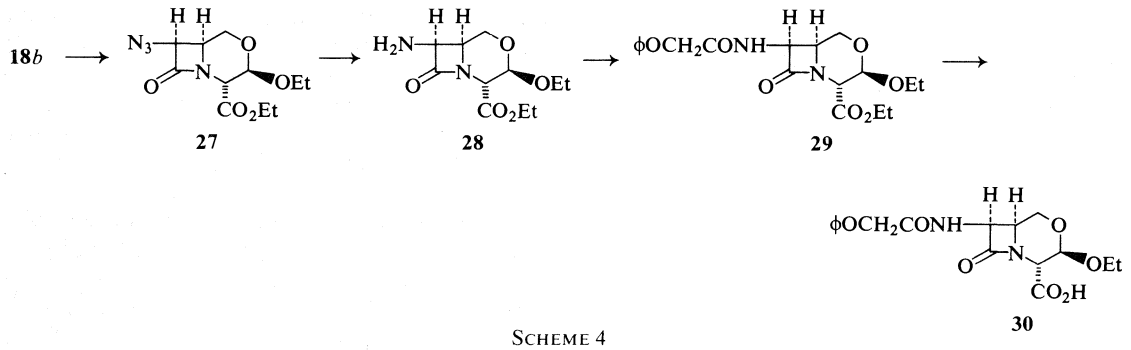
Compound **30** exhibited only weak antibacterial activity which will be discussed in a subsequent publication.

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

Ethyl α-Amino-β,β-diethoxypropionate ***13b***

To a suspension of 360 g (5 mol) sodium ethoxide in 2800 ml of benzene was added a solution of 393 g (3 mol) ethyl *N*-formylglycinate in 1300 ml of ethyl formate over a period of 2 h at 0–5 °C with vigorous stirring under nitrogen. Stirring was continued for 4 h at 0–5 °C and the suspension was allowed to stand 18 h at 4 °C. The supernatant liquid was carefully decanted from the solid. The residue was taken up in 1.5 l of ethanol and 4.0 l methylene chloride. The solution was cooled to 0–5 °C in an ice bath and a stream of dry hydrogen chloride passed through the solution for 6 h. Cooling was removed after 1 h. Following this, the solution was permitted to stand at ambient temperature (~23 °C) for 18 h then purged of excess hydrogen chloride by passage of a stream of dry nitrogen through the solution. To the solution was added a stream of ammonia until the p*H* of the solution was 9. The suspension was filtered and the filtrate was evaporated at reduced pressure. The oily residue was extracted into petroleum ether (30–60 °C) (6 × 700 ml). The extracts were dried over sodium sulfate and evaporated to give 464 g crude amine which yielded 256 g (42%) of **13***b* on distillation, bp 72–78 °C/0.05 torr (lit. (16*b*) bp 71 °C/1 torr); nmr ($CDCl_3$) δ 4.54 (1H, d, J = 5.0 Hz,, $CH(OR)_2$), 4.16 (2H, q, J = 7.0 Hz, $CO_2CH_2CH_3$)



SCHEME 4

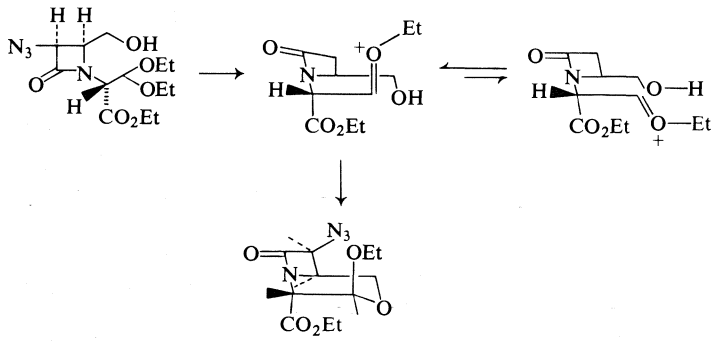


FIGURE 11

3.55 (5H, m, $(OCH_2CH_3)_2$; CH—NH_2), 1.65 (2H, s, NH_2), 1.30 (3H, t, J = 7.0 Hz, $CO_2CH_2CH_3$), 1.19 (6H, t, J = 7.0 Hz, CH_3).

Preparation of Schiff Bases

The Schiff bases **14***a* and **14***b* were prepared via the procedure given for the preparation of **14***a*.

N-Cinnamylidene-β,β-dimethoxy Ethyl Amine ***14a***

To a solution of 13.2 g (0.1 mol) *trans*-cinnamaldehyde in 200 ml dry methylene chloride was added 10.5 g (0.1 mol) aminoacetaldehyde dimethyl acetal. The solution was brought to reflux and the methylene chloride distilled slowly with the constant addition of additional dry methylene chloride so as to maintain the same volume of liquid in the reaction vessel. After the water of reaction ceased to azeotrope (~1 h) the solution was cooled and magnesium sulfate added to complete the reaction. After 1 h, the suspension was filtered and evaporated to yield 21.9 g of **14***a* as a pale yellow oil. The last traces of solvent were removed at low pressure; ir (film) 1640 cm^{-1} (C=N); nmr ($CDCl_3$) δ 8.00 (1H, t, J = 4.0 Hz, CH=N broadened), 7.38 (5H, m, aromatic), 6.94 (2H, d, CH=CH—ϕ), 4.63 (1H, t, J = 5.5 Hz, $CH(OR)_2$), 3.69 (2H, dd, J = 5.5 Hz, J_2 = 1.5 Hz, CH_2—N=), 3.41 (6 H, s, OCH_3).

Ethyl α-Amino-(N-cinnamylidene)-β,β-diethoxy Propionate ***14b***

The Schiff base **14***b* was similarly prepared from 92.5 g (0.46 mol) ethyl α-amino-β,β-diethoxy propionate and 60.8 g (0.46 mol) cinnamaldehyde to give 158 g (quantitative) of **14***b* as a pale yellow oil; ir ($CHCl_3$) 1640 cm^{-1}, 1740 cm^{-1}; nmr ($CDCl_3$) δ 8.08 (1H, dd, J_1 = 3.5 Hz, J_2 = 5.0 Hz, CH=N), 7.35 (5H, m, aromatic), 6.97 (2H, d, J = 5.0 Hz, CH=CH=ϕ), 4.93 (1H, d, J = 7.0 Hz, $CH(OR)_2$), 4.24 (2H, q, J = 7.0 Hz, $CO_2CH_2CH_3$), 3.98 (1H, d, J = 7.0 Hz, CH—N=), 3.62, 3.65 (4H, q, J = 7.0 Hz, OCH_2), 1.20 (9H, m, CH_3).

cis-N-(β,β-Dimethoxyethyl)-3-azido-4-styryl-2-azetidinone ***15a***

A solution of 21.9 g (0.1 mol) Schiff base **14***a* in 500 ml dry methylene chloride was cooled to −10 °C in an ice–methanol bath. To this was added 10.1 g (0.1 mol) triethylamine following which a solution of 12.0 g (0.1 mol) azidoacetylchloride in methylene chloride (100 ml) was added in a dropwise manner over 1 h. After the addition was complete, the solution was stirred an additional 15 min and washed with water (100 ml), 10% hydrochloric acid (100 ml), and brine (100 ml). The organic layer was dried over sodium sulfate, filtered, and evaporated to yield 33.8 g of the crude β-lactam **15***a*. The oil was purified by chromatography over silica gel (10% water w/w) to yield 15.9 g (52.5%) of *cis-N*-(β,β-dimethoxyethyl)-3-azido-4-styryl-2-azetidinone as an oil; ir ($CHCl_3$) 2100 (N_3), 1755 (β-lactam C=O) cm^{-1}. *Anal.* calcd. for $C_{15}H_{18}N_4O_3$: C 59.59, H 6.00, N 18.53; found: C 59.66, H 6.09, N 18.50.

cis-N-(α-Carboethoxy-β,β-diethoxyethyl)-3-azido-4-styryl-2-azetidinone ***15b***

A freshly prepared solution of Schiff base **14***b* (0.46 mol in 1.3 l methylene chloride) was cooled to 0–5 °C with an ice bath. To this 46.1 g (0.46 mol) triethylamine was

added. A solution of 56.0 g (0.46 mol) azidoacetyl chloride in 500 ml methylene chloride was added dropwise over 1 h. The solution was stirred an additional 30 min, washed with water and saturated NaCl solution, and dried over Na_2SO_4. Evaporation of the solution yielded 187.0 g (> 98% crude yield) of compound **15***b* as a reddish oil. Generally this oil was used as such in subsequent reactions. A small sample of the crude product was chromatographed on silica gel (10% water, w/w) using methylene chloride to give pure **15***b* as a mixture of diastereoisomers; ir ($CHCl_3$) 2100 (N_3), 1760 (β-lactam C=O), 1740 (ester C=O) cm^{-1}. *Anal.* calcd. for $C_{20}H_{26}N_4O_5 \cdot \frac{1}{10} CH_2Cl_2$: C 58.50, H 6.35, N 13.64; found: C 58.48, H 6.48, N 13.38.

Further elution of the column with ether gave compound **16**; ir (neat) 2100 (N_3), 1775 (β-lactam C=O), 1720 (ester C=O), 1650 (enol ether >=<) cm^{-1}. *Anal.* calcd. for $C_{18}H_{20}N_4O_4$: C 60.66, H 5.66, N 15.72; found: C 60.78, H 5.73, N 15.91.

cis-N-(β,β-Dimethoxyethyl)-3-azido-4-hydroxymethyl-2-azetidinone ***18a***

A solution of 4.60 g (15.2 mmol) of **15***a* in 200 ml methanol was ozonized at −78 °C (acetone – dry ice bath) until an excess of ozone had been delivered as determined by the development of a faint blue-green color in the solution. The excess ozone was purged by passing a stream of nitrogen through the solution. The solution was allowed to rise to −40 °C at which time was added 500 mg (13 mmol) of sodium borohydride. The temperature of the solution was permitted to rise to 25 °C over 30 min following which 3 ml of 10% hydrochloric acid were added. The solution was evaporated to dryness at reduced pressure and the residue partitioned between brine (100 ml) and a mixture of ether and methylene chloride (5:1) (3 × 100 ml). The combined extracts were dried over magnesium sulfate, filtered, and evaporated at reduced pressure to yield 4.7 g of an oil. The oil was chromatographed on 30 g of silica gel (10% water, w/w) eluted with 15% ether–benzene which was gradually increased to 25% ether–benzene. A total of 2.67 g (76.5%) of pure *cis-N*-(β,β-dimethoxyethyl)-3-azido-4-hydroxymethyl-2-azetidinone **18***a* was collected as an oil; ir ($CHCl_3$) 3450 (OH), 2100 (N_3), 1755 (β-lactam C=O) cm^{-1}. *Anal.* calcd. for $C_8H_{14}N_4O_4$: C 41.74, H 6.13, N 24.34; found: C 41.97, H 6.10, N 24.05.

cis-N-(α-Carboethoxy-β,β-diethoxyethyl)-3-azido-4-hydroxymethyl-2-azetidinone ***18b***

A solution of 43.0 g (0.107 mol) of compound **15***b* in 700 ml of dry methylene chloride was ozonized at −78 °C in an acetone – dry ice bath, until the solution turned bluish-green, at which time the ozone was replaced by a stream of dry nitrogen. When the excess ozone had been purged (as indicated by the disappearance of the blue color) 30 ml of dimethyl sulfide was added. The solution was allowed to come to room temperature (~25 °C) over 1 h. The solution was evaporated to dryness and the residue redissolved in 800 ml CH_2Cl_2. The solution was washed with water and brine and dried over $MgSO_4$. Evaporation of the solution gave an oily residue which was heated *in vacuo* for 18 h at 40–50 °C and 0.1 torr to remove benzaldehyde. This yielded 40.5 g of an oil. The nmr spectrum indicated 76% free aldehyde. The crude aldehyde was used in the next step without further purification.

A solution of 40.3 g of crude aldehyde in 250 ml ethanol – 12.5 ml H_2O was prepared and cooled to 0–5 °C in an ice bath. To this was added 1.56 g (0.041 mol) sodium borohydride and the solution was stirred for 30 min at 0–5 °C. To the solution was added 10% hydrochloric acid to p*H* 4. The reaction mixture was evaporated to dryness at reduced pressure below 35 °C. To the residue was added 200 ml of brine and the solution was extracted with chloroform (3 × 200 ml). The extracts were dried over Na_2SO_4, filtered, and evaporated to yield 37.0 g of crude alcohol. The crude alcohol was filtered through a column of activity III alumina (550 g) using chloroform as an eluent to yield 27.0 g of reasonably pure alcohol (> 90%). The ir and nmr spectra of the oil were compatible with the assigned structure.

The overall yield from compound **15***b* was 67%. A small sample of the alcohol was purified by column chromatography on alumina (activity III); ir ($CHCl_3$) 3300 (OH), 2090 (N_3), 1755 (β-lactam C=O), 1745 (ester C=O) cm^{-1}. *Anal.* calcd. for $C_{13}H_{22}N_4O_6$: C 47.27, H 6.71, N 16.96; found: C 47.26, H 6.85, N 17.15.

α- and β-3-Methoxy-7-β-azido-O-2-isocepham ***20*** *and* ***19***

To a solution of 4.40 g (19.1 mmol) of **18***a* in 40 ml of dry methylene chloride at 25 °C was added a solution of 2.4 ml (19.1 mmol) of boron trifloride etherate in 20 ml methylene chloride over 2 h under an atmosphere of nitrogen. The solution was stirred an additional 30 min then filtered through a pad of activity III alumina. The pad was washed with 300 ml of chloroform–methanol (95:5) and the combined filtrates were evaporated to dryness to yield 4.0 g of an oil. The oil was chromatographed on activity II silica gel (40 g) using benzene–ether (4:1) as eluent. The α-isomer eluted first from the column to give 710 mg of α-3-methoxy-7-β-azido-*O*-2-isocepham **20**. The β-isomer eluted second from the column to yield 1.5 g of an oil which crystallized on standing, mp 73–74 °C. The combined yield was 58.1%; ir of β-isomer ($CHCl_3$) 2100 (N_3), 1772 (β-lactam C=O) cm^{-1}; ir of α-isomer ($CHCl_3$) 2100 (N_3), 1770 (β-lactam C=O) cm^{-1}. *Anal.* calcd. for $C_7H_{10}N_4O_3$: C 42.42, H 5.09, N 28.27; found (for α-isomer): C 42.32, H 5.22, N 28.00; found (for β-isomer): C 42.68, H 5.13, N 28.26.

7-β-(Aminophenoxyacetoyl)-3-α-methoxy-O-2-isocepham ***22b***

To a solution of 400 mg (2 mmol) of **20** in 20 ml methylene chloride at 0 °C was added 0.28 ml triethylamine (2 mmol). A stream of hydrogen sulfide gas was bubbled in for 5 min and the solution allowed to stand for 1 h. Evolution of nitrogen was observed. The solution was evaporated to dryness. An additional 50 ml methylene chloride was added and the solution again evaporated. This procedure was repeated twice more. The resultant yellow oil was taken up in 30 ml methylene chloride and to this was added 310 mg (2 mmol) phenoxyacetic acid followed by 500 mg (2 mmol) EEDQ. The solution was let stand 1 h at room temperature after which it was washed successively with 5% hydrochloric acid (25 ml), water (25 ml), and brine (25 ml). The solution was dried over sodium sulfate, filtered, and evaporated to yield an oil which was purified by chromatography on silica gel (10% water, w/w) (20 g) to yield 587 mg (96%) of 7-β-(aminophenoxyacetoyl)-3-α-methoxy-*O*-2-isocepham **22***b* mp 156–157 °C on elution with benzene–ether (4:1); ir ($CHCl_3$) 3380 (NH), 1765 (β-lactam C=O), 1695

(*CO*NH) cm^{-1}. *Anal.* calcd. for $C_{15}H_{18}N_2O_5$: C 58.82, H 5.92, N 9.15; found: C 58.93, H 6.01, N 9.11.

7-β-(Aminophenoxyacetoyl)-3-β-methoxy-O-2-isocepham ***21b***

From 500 mg (2.5 mmol) of compound **19** was prepared 750 mg of crude **21***b* following the procedure for the preparation of **22***b*. The oil was chromatographed on activity II silica gel (20 g) using benzene–ether (4:1) as the eluting solvent to yield 578 mg (77%) of pure **21***b*, mp 105–106 °C (recrystallized from methanol–ether); ir ($CHCl_3$) 3490 (NH), 1753 (β-lactam C=O), 1680 (*CO*NH) cm^{-1}. *Anal.* calcd. for $C_{15}H_{18}N_2O_5$: C 58.82, H 5.92, N 9.15; found: C 58.80, H 5.91, N 9.08.

cis-N-(β,β-Dimethoxyethyl)-3-amino-4-styryl-2-azetidinone ***25a***

From 2.1 g (6.95 mmol) of **15***a* was prepared 1.34 g (73%) of **25***a* according to the procedure described for **22***b*. The oily amine formed a crystalline oxalate, mp 138–148 °C, recrystallized from methanol–ether; ir (free base) ($CHCl_3$) 3390 (NH_2), 1750 (C=O) cm^{-1}. *Anal.* calcd. for $C_{15}H_{20}N_2O_3 \cdot C_2H_2O_4$: C 55.73, H 6.05, N 7.65; found: C 55.70, H 5.92, N 7.62.

cis-N-(β,β-Dimethoxyethyl)-3-(aminophenylacetoyl)-4-styryl-2-azetidinone ***25b***

From 4.91 g (14.85 mmol) of **15***a* was prepared 4.8 g crude **25***b* according to the method given for the preparation of **22***b*. The oil was purified by column chromatography on silica gel to yield 2.1 g pure **25***b*, mp 121–123 °C (recrystallized from benzene); ir ($CHCl_3$) 3490 (NH), 1755 (C=O), 1680 (NH C=O) cm^{-1}. *Anal.* calcd. for $C_{23}H_{26}N_2O_4$: C 70.03, H 6.64, N 7.10; found: C 70.46, H 6.73, N 7.10.

cis-N-(β,β-Dimethoxyethyl)-3-(aminophenoxyacetoyl)-4-styryl-2-azetidinone ***25c***

To a mixture of 540 mg (1.96 mmol) of amine **25***a* and 304 mg (2.0 mmol) phenoxyacetic acid in 20 ml methylene chloride was added 500 mg (2.02 mmol) EEDQ. The solution was let stand 1.25 h at 25 °C. Upon work-up (see **22***b*) there was obtained 605 mg (77.5%) of pure **25***c* mp 105–106 °C, recrystallized from methylene chloride – ether; ir ($CHCl_3$) 3400 (NH), 1752 (β-lactam C=O), 1690 (amide C=O) cm^{-1}. *Anal.* calcd. for $C_{23}H_{26}N_2O_5$: C 67.30, H 6.38, N 6.83; found: C 67.37, H 6.35, N 6.72.

cis-N-(β,β-Dimethoxyethyl)-3-(aminophenylacetoyl)-4-hydroxymethyl-2-azetidinone ***23b***

From ***18a***

From 2.46 g (10.7 mmol) of **18***a* was prepared 3.5 g of crude **23***b* according to the procedure given for the preparation of **22***b*. The oil was chromatographed on 25 g activity II silica gel using methylene chloride – methanol (19:1) as eluent to yield 1.31 g (38%) pure **23***b*, mp 100–101 °C; ir ($CHCl_3$) 3470 (OH, NH), 1755 (C=O), 1680 (CONH) cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_5$: C 59.61, H 6.88, N 8.69; found: C 59.70, H 6.88, N 8.57.

From ***25b***

Into a solution of 394 mg (1 mmol) of **25***b* in 20 ml methanol was passed ozone at −78 °C (acetone – dry ice) until a pale blue color persisted. The excess ozone was purged by passing a stream of dry nitrogen through the solution for 10 min. To the solution was added 38 mg (10 mmol) of sodium borohydride and the solution was let warm to 25 °C over 1 h. On work-up (see **18***a*) there was obtained 250 mg (74%) of **23***b* identical in all respects with that prepared from **18***a*.

cis-N-(β,β-Dimethoxyethyl)-3-(aminophenoxyacetoyl)-4-hydroxymethyl-2-azetidinone ***23c***

The preparation of **23***c* was carried out in a similar manner to the preparation of **23***b* from **25***b*. From 410 mg (1 mmol) of **25***c* there was obtained 220 mg (65%) of **23***c*; mp 120–121.5 °C, recrystallized from ethyl acetate; ir ($CHCl_3$) 3390 (NH), 1760 (β-lactam C=O), 1690 (amide C=O) cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_6$: C 56.79, H 6.55, N 8.28; found: C 56.82, H 6.60, N 8.22.

3-β-Ethoxy-4-α-carboethoxy-7-β-azido-O-2-isocepham ***27***

To a solution of 6.20 g (18.8 mmol) of alcohol **18***b* in 100 ml of dry methylene chloride was slowly added a solution of 4.0 g (28.2 mmol, 3.54 ml) boron trifluoride etherate in 20 ml dry methylene chloride over 15 min at 0–5 °C. The cooling bath was removed and stirring was continued for 18 h. The reaction mixture was filtered through a column of activity III alumina (40 g). The column was washed with 300 ml chloroform. The eluted fractions were evaporated to dryness to yield 6.0 g of an oil. The oil was chromatographed on silica gel (10% water, w/w) to yield 4.10 g of **18** as an oil (77%); ir ($CHCl_3$) 2110, 1773, 1746 cm^{-1}. *Anal.* calcd. for $C_{11}H_{16}N_4O_5$: C 46.47, H 5.67, N 19.71; found: C 46.54, H 5.85, N 19.34.

3-β-Ethoxy-4-α-carboethoxy-7-β-amino-O-2-isocepham ***28***

A mixture of 760 mg (2.8 mmol) of compound **27**, 925 mg ammonium chloride (17.1 mmol), and 620 mg (17.1 mmol) zinc powder in 35 ml methanol was stirred at 25 °C for 3 h. The reaction mixture was filtered through Celite and the filtrate evaporated to dryness. The residue was taken up in chloroform and filtered through 30 g of alumina (activity III). Evaporation of the eluent yielded 578 mg of crude amine. The amine was redissolved in 15 ml chloroform and extracted into 10% HCl (2 × 3 ml). The aqueous layer was neutralized with sodium bicarbonate and extracted into chloroform. The extracts were dried over Na_2SO_4, filtered, and evaporated to yield 360 mg (50%) of an oil which crystallized on standing; mp 98.5–99 °C recrystallized from ether; ir ($CHCl_3$) 3420, 1770, 1745 cm^{-1}. *Anal.* calcd. for $C_{11}H_{18}N_2O_5$: C 51.15, H 7.03, N 10.85; found: C 51.16, H 7.01, N 11.03.

7-β-(Aminophenoxyacetoyl)-3-β-ethoxy-4-α-carboethoxy-O-2-isocepham ***29***

A solution of 400 mg (1.55 mmol) of compound **28**, 410 mg (1.64 mmol) EEDQ, and 250 mg (1.69 mmol) phenoxyacetic acid in 20 ml dry methylene chloride was stirred at 25 °C for a period of 1.5 h. The reaction mixture was filtered through a column of alumina (activity III, 8 g) and the eluent evaporated to dryness. The resultant solid was washed with ether and filtered to yield 554 mg (90%), mp 162–164 °C. Recrystallization from chloroform–ether gave analytically pure amide, mp 166.5–167.5 °C; ir ($CHCl_3$) 3550, 1770, 1740 (s), 1692, 1601, 1598 cm^{-1}. *Anal.* calcd. for $C_{19}H_{24}N_2O_7$: C 58.15, H 6.16, N 7.14; found: C 57.93, H 6.23, N 7.34.

7-β-(Aminophenoxyacetoyl)-3-β-ethoxy-O-2-isocepham-4-α-carboxylic Acid ***30***

A solution of 392 mg (1 mmol) compound **29** in 13 ml warm methanol was added to 12 ml, 1% NaOH at 25 °C with stirring over 10 min. After 1 h the methanol was

evaporated and the alkaline solution was extracted with chloroform (2 × 20 ml). The aqueous solution was acidified to p*H* ~4 with 10% HCl and extracted with chloroform (2 × 15 ml). The extracts were washed with water, dried over Na_2SO_4, filtered, and evaporated to give 200 mg (55%) of a white solid. Recrystallization from methanol–ether gave pure acid **30**; mp 150–155 °C; ir ($CHCl_3$) 1775 cm^{-1}. *Anal.* calcd. for $C_{17}H_{20}N_2O_7 \cdot \frac{1}{2}CH_3OH$: C 55.26, H 5.83, N 7.37; found: C 55.08, H 5.53, N 7.48.

Received July 8, 1976

TERRENCE W. DOYLE, BERNARD BELLEAU, BING-YU LUH, TERRY THOMAS CONWAY, MARCEL MENARD, JAMES L. DOUGLAS, DANIEL TIM-WU CHU, GARY LIM, LEESON R. MORRIS, PIERRE RIVEST, and MICHAEL CASEY. Can. J. Chem. **55**, 484 (1977).

The preparation by total synthesis of a new class of β-lactam antibiotics is reported. Conversion of alcohol **1***b* to its mesylate **9***b* followed by hydrolysis of the acetal to the enol **1***b* and base-catalyzed ring closure gave benzyl 7-β-azido-Δ^3-*O*-2-isocephem-4-carboxylate **8***b*. Similarly prepared were the 3-methyl, 3-benzyl, and 3-phenethyl analogs (**32***b–d*). Reduction of the azides followed by coupling of the resultant amines with phenoxyacetic acid and removal of the benzyl groups by hydrogenolysis gave the acids **35***a–e* which exhibited high antibacterial activity. The structural assignments to the *O*-2-isocephems which were made on the basis of their spectral characteristics (ir, uv, and nmr) are discussed.

TERRENCE W. DOYLE, BERNARD BELLEAU, BING-YU LUH, TERRY THOMAS CONWAY, MARCEL MENARD, JAMES L. DOUGLAS, DANIEL TIM-WU CHU, GARY LIM, LEESON R. MORRIS, PIERRE RIVEST et MICHAEL CASEY. Can. J. Chem. **55**, 484 (1977).

On rapporte la préparation, par synthèse totale, d'une nouvelle classe d'antibiotiques contenant une β-lactame. La conversion de l'alcool **1***b* en mésylate **9***b* suivie par une hydrolyse de l'acétal en énol **1***b* et par la fermeture de cycle catalysée par les bases, conduit à la β-azido-7 Δ^3-*O*-isocéphème-2 carboxylate-4 de benzyle **8***b*. On a préparé par la même procédure les analogues méthyl-3, benzyl-3 et phénéthyl-3 (**32***b–d*). La réduction des azotures, suivie par un couplage des amines qui en résultent avec l'acide phénoxyacétique et l'élimination des groupes benzyles par hydrogénolyse fournit les acides **35***a–e* qui montrent une grande activité antibactérielle. On discute des attributions de structures pour les *O*-isocéphèmes-2 qui ont été faites en se basant sur leurs caractéristiques spectrales (ir, uv et nmr).

[Traduit par le journal]

In the preceding paper the synthesis of **1***a*, its conversion to **2***a*, and the subsequent conversion of **2***a* to **2***e* was described. The low order of antibacterial activity exhibited by **2***e* was as had been anticipated.[5] It remained for us to effect the elimination of a mole of ethanol from **2***e* in order to complete our synthesis of the *O*-2-isocephem nuclear analog of cephalosporin.[6] In this paper we wish to report our efforts in this area and the synthesis of a number of *O*-2-isocephems which exhibit high antibacterial activity.

All efforts to effect direct elimination of ethanol from **2** (Scheme 1) failed as did attempted hydrolysis of **2** to its 3-hydroxy analogs. Treatment of **2***a* with zinc chloride in acetic anhydride gave **3***a* in 85% yield rather than the hoped for 3-acetoxy derivative. This result might have been anticipated from the stereochemistry of **2***a* (Fig. 1). In **2***a* the C_3—O_2 bond and the C_4—H_β bond are *trans* to one another thus facilitating cleavage of the C_3—O_2 bond with formation of the double bond in **3***a* which is formed as a single geometrical isomer. Alternatively, **3***a* could be

[1]For part I of this series see ref. 1.

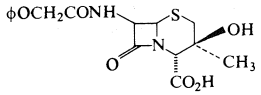
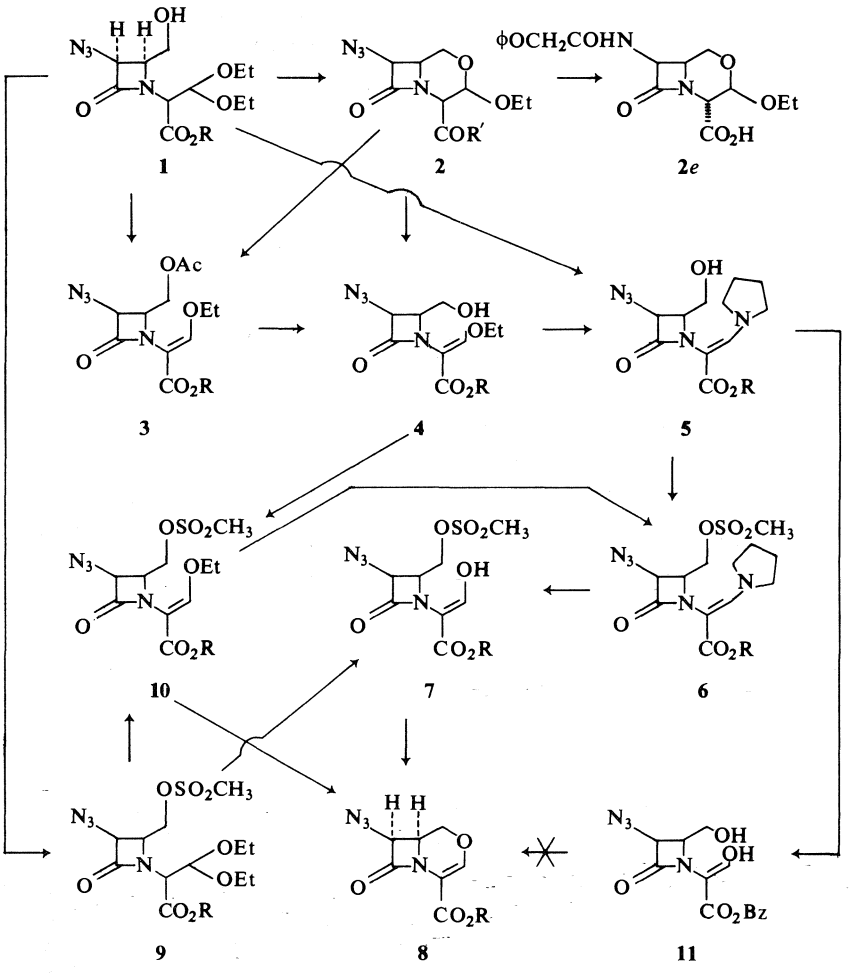
[5]Gutowski *et al.* have reported that compound **i** exhibits low antibacterial activity in comparison with its unsaturated counterpart (2).



i

[6]See ref. 1 for a review of the literature concerning nuclear analogs of the penicillins and cephalosporins and an explanation of the trivial nomenclature used in this and the accompanying papers.



Compounds **1**, **3–10** *a* R = C_2H_5; *b* R = $CH_2\phi$; *c* R = H

Compound **2** *a* R′ = OEt; *b* R′ = OH; *c* R′ = Cl; *d* R′ = $OCH_2\phi$

SCHEME 1

obtained directly from **1***a* in 75% yield. In this case, **3***a* was obtained as a mixture of isomers in which the isomer obtained in major amount (>90%) was identical with that from **2***a*.

Hydrolysis of **3***a* gave **4***a* in 94.5% yield. Compound **4***a* could also be obtained in low yield (26%) by treatment of **2***a* with titanium tetrachloride in methylene chloride.

The nmr and ir spectra (Tables 2 and 4 respectively) of these compounds were in accord with the assigned structures. In the nmr compounds **3***a* and **4***a* showed signals at 7.34 and 7.73 δ respectively for the olefinic proton. In the

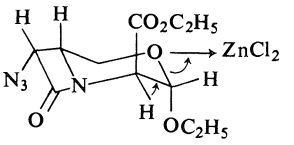


FIGURE 1

ir they exhibited $\diagdown C{=}C \diagup$ stretching frequencies at 1640 and 1645 cm^{-1} for enol ethers in addition to the expected carbonyl bands.

Treatment of compound **4***a* with pyrrolidine – acetic acid in refluxing benzene gave the vin-

ologous urethane **5***a* in 75% yield as a single isomer. The nmr spectrum of **5***a* showed considerable line broadening for all protons with the exception of the signals for the ethyl ester. We attribute this broadening-hindered rotation about the $N\rightarrow C(CO_2R)=CHNC_4H_8$ bond. Compound **5***a* was also prepared directly from **1***a* in 50% yield. Treatment of **5***a* with triethylamine and methane sulfonyl chloride in methylene chloride gave **6***a* in 73.5% yield. Alternatively **6***a* could be prepared by treatment of **4***a* with triethylamine – methane sulfonyl chloride to give **10***a* in 65% yield followed by treatment of **10***a* with pyrrolidine – acetic acid to give **6***a* in 63% yield. Hydrolysis of **6***a* with hydrochloric acid in aqueous acetone gave the enol mesylate **7***a* in 89% yield. The nmr spectrum of **7***a* suggested that it exists as a mixture of geometrical isomers of the enol as well as, to a small extent, the aldehydo form. The enolic hydroxyl appears as a singlet at 12 δ integrating for ~0.85 protons. The signals for the methyl group of the ester appears as a pair of triplets of approximately equal intensities. Compound **7***a* gave a strong ferric chloride test for an enol (deep purple). In the ir spectrum of **7***a* there are bands at 1680 and 1630 cm^{-1} which we assign to the aldehydo and enolic forms respectively.

Treatment of **7***a* with sodium hydride in dimethyl sulfoxide gave ethyl 7-β-azido-Δ^3-*O*-2-isocephem-4-carboxylate **8***a* in 91% yield. Alternatively **7***a* could be converted to **8***a* by refluxing **7***a* with 1 equiv. of triethylamine in chloroform in 47.5% yield. A third route to **8***a* consists of treating **10***a* with aqueous dilute sodium hydroxide in tetrahydrofuran, lyophilizing the resulting solution and taking up the residue in DMSO. The yield of **8***a* from **10***a* by this procedure was 33%. Compound **10***a* was also prepared by mesylation of **1***a* to give **9***a* in 86% yield. Treatment of **9***a* with zinc chloride – acetic anhydride or with triethyloxonium fluoroborate in methylene chloride gave **10***a* in 45% yield. Hydrolysis of the acetal function in **9***a* with trifluoroacetic acid at 50 °C effected the conversion of **9***a* to **7***a* in 58% yield. The overall yield of **8***a* from **1***a* proceeding via the best sequence **1***a* → **9***a* → **7***a* → **8***a* was 45%.

As we required an *O*-2-isocephem carrying an easily deblocked ester function the synthesis of benzyl 7-β-azido-Δ^3-*O*-2-isocephem-4-carboxylate **8***b* was attempted next.

Saponification of **2***a* with dilute sodium hydroxide solution gave **2***b* in 66% yield. The carboxylic acid was converted to its acid chloride **2***c* and subsequently to the benzyl ester **2***d* in 83.5% yield. Treatment of **2***d* with zinc chloride – acetic anhydride gave **3***b* in 94% yield. Alternatively **3***b* could be prepared directly from **1***b* in 41% yield.

The synthesis of **1***b* was accomplished by the following sequences (Scheme 2). Treatment of benzyl nitroacetate (3) **12** with triethylorthoformate in acetic anhydride at 80–90 °C gave a mixture of **13** and **14** in quantitative yield (4). The nmr spectrum of the mixture indicated that the ratio of **13** to **14** was 3:2 and that **13** was present as a mixture of geometric isomers one of which predominates. On distillation, the mixture decomposed extensively and yielded only the starting material **12**. Treatment of the mixture of **13** and **14** with ethanol in the presence of a catalytic amount of sodium ethoxide gave exclusively **14**. The yield of **14** from **12** was quantitative. Reduction of **14** to **15** with aluminum amalgam proceeded in 42.5% yield (not optimized) (5). The ir and nmr spectra of **15** were compatible with the assigned structure.[7] Compound **15** was converted to its cinnamylidene Schiff base **16** in quantitative yield as previously described (1) following which **16** was converted to the β-lactam **17** in 89% yield by treatment with triethylamine–azidoacetylchloride as before (1). The mixture of diastereoisomeric β-lactams could be separated chromatographically, although this was not done generally as the crude product was pure enough for use in the subsequent reactions. The nmr spectra of the isomers of **17** are recorded in Table 2. Compound **17** could also be prepared from the ethyl ester **19** (1). Saponification of **19** with sodium hydroxide gave the corresponding carboxylic acid **20** in 60% yield. Treatment of **20** with triethylamine and benzyl chloroformate gave the mixed anhydride which spontaneously decomposed to the ester **17** in 55% yield. Ozonolysis of **17** at −78 °C gave the aldehyde **18** in 95% yield. The nmr spectrum of crude **18** indicated at least 77% free aldehyde.[8] Reduction of **18** with sodium borohydride in ethanol gave **1***b* in 85% yield.

Hydrolysis of **3***b* gave **4***b* in 87% yield. Com-

[7]In some runs the reduction step stopped at the hydroxylamine stage in which case the hydroxylamine was recycled over fresh aluminum amalgam.

[8]A number of the aldehydes prepared in this manner were found to form hydrates which on reduction gave the desired 4-hydroxymethyl 2-azetidinones.

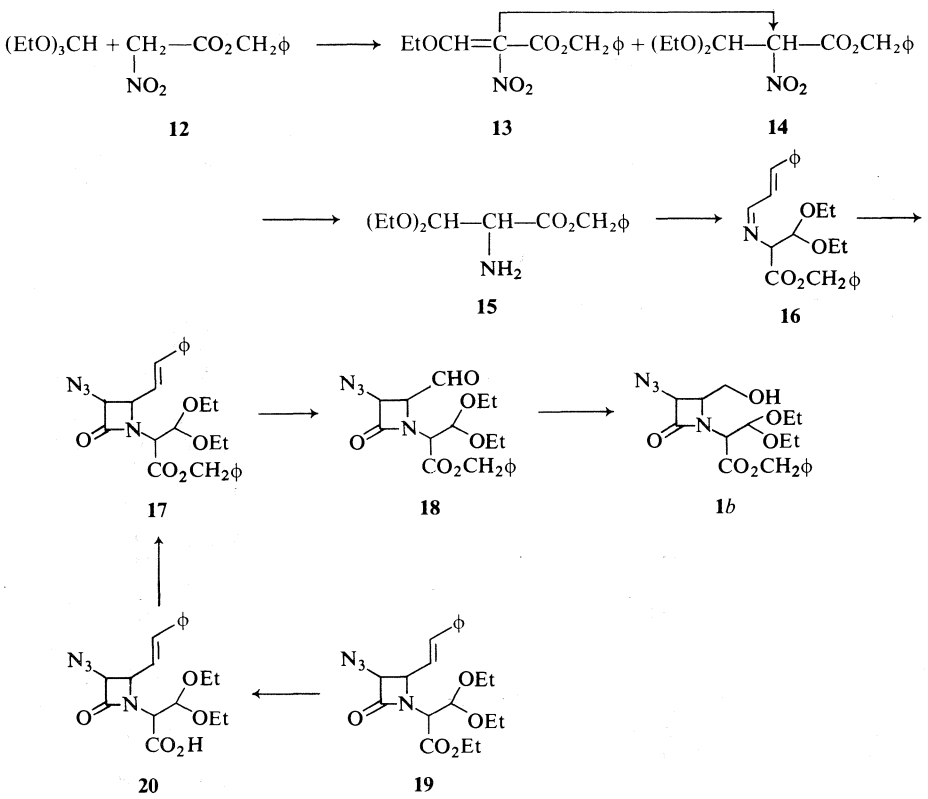
[a]All spectra were recorded at 60 MHz as $CDCl_3$ solutions using tetramethylsilane as internal reference unless otherwise noted. The chemical shifts are reported in δ units and the coupling constants in Hz. [b]Major isomer. [c]Minor isomer. [d]The proton signals for $CH(OR)_2$ and $CH—NO_2$ are obscured under the $CH(OCH_2—CH_3)$ signals. [e]Assigned to NH_2. [f]Assigned to $CH(OR)_2$. [g]Assigned to $CH—CO_2R$. [h]Assigned to $CH(OCH_2—CH_3)_2$. [i]Assigned to —N=CH—. [j]Assigned to =N—OH. [k]Assigned to $CO_2CH_2—CH_3$. [l]Assigned to $CH_2—CH_2—\phi$. [m]Taken in D_2O. [n]Assigned to $\phi CH_2—C\equiv$. [o]Assigned to $\phi CH=CH$.



SCHEME 2

pound **4***b* was converted to **5***b* in 71% yield following which it was converted to its mesylate **6***b* in 90% yield. Hydrolysis of **6***b* gave **7***b* (81%) which was converted to **8***b* by treatment with sodium hydride in DMSO in 42% yield. On refluxing **7***b* with 1 equiv. of triethylamine in methylene chloride **8***b* was obtained in 71.5% yield. As in the case of the ethyl ester series compound **4***b* was converted to **10***b* (70%) and thence to **8***b* (40%). The conversion of **1***b* to **9***b* (83.5%) and the hydrolysis of **9***b* to **7***b* (91%) followed by ring closure also gave **8***b* in 54.5% overall yield from **1***b*.

Compound **9***b* could also be obtained from **9***a* via saponification to **9***c* in 55% yield (in addition to **9***c* there was also produced **10***a* in this reaction). Treatment of **9***c* with triethylamine – benzyl chloroformate as before gave **9***b* in 84% yield. Hydrolysis of **5***b* to **11** was carried out in 75% yield. All attempts to prepare **8***b* via the elimination of 1 mol of water from **11** failed.

The structural assignments to **8***a* and **8***b* rest on their mode of synthesis, correct elemental analyses, and their ir, uv, and nmr spectral characteristics. The ir spectra of **8***a* and **8***b* show absorptions at 2110 cm^{-1} for the azide, 1790 cm^{-1} for the β-lactam carbonyl, 1715 cm^{-1} for the α,β-unsaturated ester carbonyl, and an absorption at ~1625 cm^{-1} for the double bond. In the uv spectra of **8***a* and **8***b* there are bands at 268 nm with extinction coefficients of 6800 and 6700 respectively. These values are in accord with those observed in the cephalosporins (6). The pronounced bathochromic shift observed in going from the non-cyclized chromophore in **3**, **4**, and **10** to the chromophores in **8***a* and **8***b* may be explained as being due to participation of the amide lone pair in the chromophore of the latter compounds (the uv spectra are recorded in Table 4). This is further borne out by comparison of the uv spectra of **3**, **4**, and **10** with that of genepin (7) and the simpler dihydropyran system (8) (see Fig. 2) both of which contain the $-O-\overset{R}{C}=\overset{R'}{C}-CO_2CH_2CH_3$ chromophore. The λ_{max} and extinction coefficients for **3**, **4**, and **10** are very similar to those for genepin and the dihydropyran system indicating little contribution of the β-lactam chromophore to the β-alk-

[a]Recorded in $CDCl_3$ at 60 MHz unless otherwise noted. The chemical shifts are recorded in δ units and coupling constants in Hz. [b]A mixture of diastereoisomers. [c]Assigned to $CH(OCH_2—CH_3)_2$, CH_2OH, and the C_4 proton. [d]Assigned to N_3CH and $CH(OR)_2$. [e]Assigned to methyl group of acetate. [f]Assigned to —CH—CH_2—OR. [g]Assigned to $CO_2CH_2—CH_3$ and =CH—O—$CH_2—CH_3$. [h]For single isomer. [i]Assigned to =CH—$OCH_2—CH_3$. [j]Quadrupole broadening of all proton signals was observed. [k]Assigned to $CO_2CH_2—CH_3$. [l]Assigned to pyrrolidine protons. [m]Assigned to mesylate methyl protons. [n]Two geometrical isomers observed in the nmr. [o]Assigned to $CH(OCH_2CH_3)_2$. [p]Assigned to $CH—CO_2R$ and $CH—CH_2—OSO_2CH_3$. [q]Isomer *A*. [r]Isomer *B*. [s]Assigned to $CH(OR)_2$. [t]Assigned to CH—CH=CH—ϕ. [u]Assigned to $\phi CH=CH—$. [v]Assigned to $\phi CH=CH—$. [w]Assigned to CH—CH=$CH\phi$, N_3CH, and $CH(OR)_2$. [x]Assigned to —CHO. [y]Assigned to $CH(OCH_2CH_3)_2$ and $CH—CO_2R$. [z]Assigned to CHCHO and $CH(OR)_2$. [aa]Assigned to $CHCO_2R$. [bb]Assigned to O—$CH_2—CH_2$—O. [cc]Assigned to N_3CH and CH—CH=CH—ϕ. [dd]Assigned to $CH_2CH_2\phi$. [ee]Assigned to N_3CH, CH—C=, and $CH—CO_2R$. [ff]Assigned to O—CH_2CH_2—O and $CH_2\phi$. [gg]Assigned to arms of AB quartet for CH_2—ϕ. [hh]Assigned to CH—CHO. [ii]Assigned to —O—$(CH_2)_2$—O, CH—CH_2—OH. [jj]Assigned to N_3CH, CH—CH_2—OR, $CHCO_2R$.

oxyacrylate chromophore in these systems. In contrast to these observations is the marked bathochromic shift (+23 mm) observed in **8***a* and **8***b* in comparison with **3**, **4**, and **10**.

While the nmr spectra of **8***a* and **8***b* in deuteriochloroform were not first order they provided confirmation of the structures. In **8***a* the C_7—H appears as a doublet J = 5.0 Hz confirming the *cis* stereochemistry of the protons on C_6 and C_7. In **8***b* the C_7—H was partially obscured by the signal of the benzylic protons. The $C_{1\alpha}$ protons in **8***a* and **8***b* appear at 4.63 and 4.58 δ respectively as complex multiplets (six lines). The protons at $C_{1\beta}$ and C_6 appear as sets of overlapping multiplets at ~3.9 and 3.8 δ respectively. In view of the complexity of the nmr spectrum of **8***a* in $CDCl_3$ the spectrum was recorded in $CDCl_3$–C_6D_6 (1:1) at 100 MHz which resulted in aromatic solvent induced shifts (ASIS) and enabled the assignment of each proton in the spectrum as well as an assignment of conformation to **8***a*.[9] The proton signals in the shifted spectrum were assigned on the basis of their coupling constants, spin decoupling experi-

[9]The use of ASIS for the configurational assignments to the isomeric penicillin and cephalosporin sulfoxides has been demonstrated (9).

[a]Recorded at 60 MHz in $CDCl_3$ with tetramethylsilane as internal reference. The chemical shifts are recorded in δ values and coupling constants in Hz. [b]Assigned to —CO_2-CH_2CH_3, and the protons at C_6 and C_1. [c]Assigned to $CO_2CH_2CH_3$. [d]Assigned to C_1-Hα proton, see text for discussion. [e]Assigned to C_1-Hβ proton and C_6-H, see text for discussion. [f]Obscured by aromatic signal. [g]Arms of AB quartet. [h]CON*H* appears obscured by aromatic resonance. [i]The benzylic protons, the protons at C_1 and the proton at C_6 appear as a complex multiplet. [j]The C_3-proton is obscured by the aromatic signals. [k]Recorded in DMSO-d_6. [l]Recorded in $CDCl_3$, $(CD_3)_2C{=}O$.

FIGURE 2

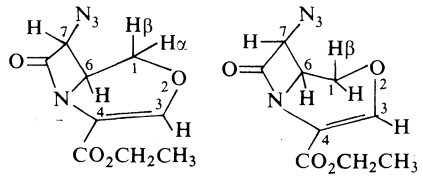

FIGURE 3

ments, and the relative magnitudes of the ASIS (Fig. 3 and Table 5). From the data in Table 3, it is seen that $J_{H6H1\alpha} = 3.75$ Hz and $J_{H6H1\beta} = 9.5$ Hz. Of the two possible conformations for **8** *A* and *B* (Fig. 3) only conformer *A* would be expected to exhibit this splitting pattern for H_6. One would predict for conformer *B* that $J_{6H1\alpha} \simeq 3.20$ Hz and $J_{H6H1\beta} \simeq 0$ Hz.

The assignment of the signals at ~4.6 to $H_{1\alpha}$ and ~3.9 to $H_{1\beta}$ is also in accord with the expectation that the axial proton $H_{1\beta}$ should appear at higher field than the equatorial proton $H_{1\alpha}$. These assignments are also supported by the relative magnitudes of the ASIS for $H_{1\alpha}$ and $H_{1\beta}$. One would expect that complexation of the solute with the C_6D_6 molecules would occur preferentially from the less hindered α face of the molecules and that the ASIS for protons on the α face would be greater than the ASIS for protons on the β-face. Our observations are fully in accord with this prediction, protons H_6 and H_7 show the greatest ASIS. The ASIS for $H_{1\alpha}$ is greater than the ASIS for $H_{1\beta}$ thus adding further evidence for the assignments.

With the experience gained in the synthesis of **8***a* and **8***b* the syntheses of the 3-methyl, 3-benzyl, and 3-phenethyl systems were attempted next.

The syntheses of the starting amines **25***a–d* for these systems were carried out as follows. Oximation of the β-keto esters **21***a–d* (Scheme 3) was achieved using the method of Adkins and Reeve (10) to yield the oximes **22***a–d* in good yields. Reduction of **23***a* with 10% Pd/C in ethanol in the presence of hydrochloric acid gave the amine hydrochloride **24** in 55% yield in accord with the results of Laver *et al.* (11). The amine hydrochloride **24** was readily converted to its ethylene ketal **25***a* in 70% yield. The presence of benzylic ester functions in **22***b–d* precluded the reduction of the oximes via Laver's method. Consequently, compounds **22***b–d* were converted to their ethylene ketals **23***a–c* in 94, 57, and 91% yields respectively. Reduction of **23***a–c* with aluminum amalgam in moist ether (12) gave compounds **25***b–d* in 71, 93, and 68% yields respectively.

Conversion of amines **25***a–d* to their Schiff bases **26***a–d* (Scheme 4) proceeded as before in quantitative yields. Treatment of the Schiff bases **26***a–d* with triethylamine and azidoacetyl chloride as before gave the *cis*-3-azido-4-styryl-*N*-substituted-2-azetidinones **27***a–d* in 98, 94, 100, and 100% crude yields[10] respectively. Saponification of **27***a* with sodium hydroxide in tetrahydrofuran gave the corresponding carboxylic acid **27***e* in 86% yield as a solid. Re-

[10]The crude materials were generally of sufficient purity (as determined by nmr spectroscopy) to be used as such without further purification.

crystallization of **27***e* gave one of the diastereoisomeric acids.[11] Conversion of **27***e* to **27***b* (in 99% yield) was carried out using the triethylamine–benzylchloroformate method used earlier. Ozonolysis of **27***b* (single isomer) in methylene chloride at −78 °C followed by decomposition of the ozonide with dimethyl sulfide gave **28***a* as a crystalline solid in 69% yield. The yield of **28***a* (as a mixture of diastereomers) from **27***b* (isomer mixture) was 71%. Similarly, ozonolysis

[11]Compounds **27***a–d* were produced as mixtures of diastereoisomers epimeric about the carbon directly attached to the nitrogen of the β-lactam and the ester function.

[a]Expressed as MIC's (μg/ml) and determined by a 2-fold serial dilution assay in Difco nutrient broth by the method of Pursiano *et al.* (20).

of **27***c* and **27***d* gave the aldehydes **28***b* (95% crude yield) and **28***c* (45% purified yield) respectively.

The aldehydes **28***a–c* were reduced to the corresponding alcohols **29***a–c* using sodium borohydride, following which **29***a–c* were converted to their mesylates **30***a–c*. The yields of **30***a–c* from the aldehydes **28***a–c* were 80, 84, and 42% respectively. In the reduction of **28***a* to **29***a* some epimerization of the product was observed in that a mixture of mesylates was obtained epimeric about the ester position in the side chain.

Hydrolysis of **30***a* with 95% trifluoroacetic acid at 25 °C gave the enol **31***a* in greater than 90% yield. Compound **31***a* was converted to benzyl 7-β-azido-3-methyl-Δ^3-*O*-2-isocephem-4-carboxylate **32***a* in 80% yield using triethylamine in refluxing methylene chloride. Similarly, compounds **30***b* and **30***c* were hydrolyzed to the enols **31***b* and **31***c*. In these cases it proved necessary to use higher temperatures (50–55 °C) to effect hydrolysis. The enols were converted to benzyl-7-β-azido-3-benzyl-Δ^3-*O*-2-isocephem-4-carboxylate **32***b* (33%) and benzyl 7-β-azido-3-phenethyl-Δ^3-*O*-2-isocephem-4-carboxylate **32***c* (33%) respectively. The structures of compounds **32***a–c* were confirmed by their elemental analyses, and ir, nmr, and uv spectral characteristics (Tables 3 and 4).

With the appropriately substituted *O*-2-isocephems **8***a–b*, **32***a–c* on hand the conversion of these to their 7-β-(phenoxyacetamido)-Δ^3-*O*-2-isocephem-4-carboxylic acids **35** was examined.

Reduction of **8***a* and **8***b* with hydrogen on 10% Pd/C gave the amines **33***a* and **33***b*. The amines were converted to the amides **34***a* and **34***b* using triethylamine – phenoxyacetyl chloride in 56 and 29% yields respectively. The ir, uv, and nmr spectra of **34***a* and **34***b* confirmed the structural assignments.

Reduction of **32***a* with hydrogen and PtO_2 in ethanol gave **33***c* which was coupled with phenoxyacetic acid using EEDQ (13) to give **34***c* in 65% yield. Compounds **32***b* and **32***c* were reduced to their amines **33***d* and **33***e* using triethylamine – hydrogen sulfide (1) and these were in turn converted to their amides **34***d* and **34***e* using phenoxyacetic acid – EEDQ.

Hydrogenolysis of the benzyl esters **34***b–e* (see Experimental) gave the desired acids **35***a*, **35***c–e* in 70, 84, 20, and 92% yields respectively. Compound **35***a* was also converted to its potassium salt **35***b* in 45% yield (14). The structures of **35***a–e* assigned on the basis of their elemental analyses, ir, uv, and nmr spectral characteristics.

Compounds **35***a*, **35***c*, **35***d*, and **35***e* all exhibited high antibacterial activity. The activities are listed in Table 6 along with those of **2***e*, **34***a*, and the phenoxyacetyl derivative of 7-aminodesacetyl cephalosporanic acid **36** (Fig. 4) for comparison purposes. The activities of these compounds are comparable with or better than those of the comparably substituted natural product (compare **35***c* and **36**).

It should also be noted that **35***a–e* are racemic materials whereas **36** is a single enantiomer. It has been shown (15) that all of the activity in the natural series resides in a single enantiomer, thus the MIC's reported for **35***a–e* are probably too high by a factor of two. A full discussion of structure–activity relationships in this series will be reserved to a later publication.

The obvious modifications of the syntheses reported herein to the syntheses of compounds of general formula **37** have been made and will be reported in subsequent papers of this series (Fig. 5).

FIGURE 5

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating ir spectrophotometer. The uv spectra were recorded on a Unicam SP-800 uv spectrophotometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. The 100 MHz spectra and spin-decoupling experiments were performed by Dr. Perlin of McGill University whose assistance we gratefully acknowledge. Melting points are uncorrected except where noted and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

7-β-Azido-3-β-ethoxy-O-2-isocepham-4-α-carboxylic Acid ***2b***

To a solution of 12.2 g (43 mmol) of compound **2***a* in 180 ml ethanol was added 175 ml 1% sodium hydroxide over a period of 10 min at < 25 °C. The solution was stirred an additional 20 min. The ethanol was evaporated at reduced pressure and the alkaline solution was extracted with ether (2 × 100 ml). The organic layer was discarded and the aqueous solution acidified to p*H* 3–4 with 10% hydrochloric acid. The solution was extracted with chloroform (2 × 100 ml) and the organic layer washed with water (50 ml), brine (50 ml), and dried over $MgSO_4$. Evaporation gave 7.25 g (66%) of acid. Trituration with ether and filtration gave pure acid, mp 114–115 °C.

Benzyl 7-β-Azido-3-β-ethoxy-O-2-isocepham-4-α-carboxylate ***2d***

To a solution of 6.25 g (25.6 mmol) of compound **2***b* in 100 ml of ether was added 5.35 g (25.6 mmol) phosphorous pentachloride. The suspension was refluxed for 15 min after which the clear solution was decanted and evaporated to dryness. The residual oil was taken up in 50 ml benzene and evaporated to dryness at reduced pressure. This procedure was repeated three times to remove phosphorous oxychloride. The residual oil was then pumped in high vacuum (0.05 torr) at 30 °C for 1 h.

The acid chloride was taken up in 20 ml dry methylene chloride and was added to a mixture of 2.7 g (26 mmol) benzyl alcohol and 3.2 g triethylamine in 50 ml dry methylene chloride at 25 °C over a period of 10 min. The solution was stirred for 1 h, washed with water (2 × 20 ml) and brine, and filtered through 20 g of Florisil. The eluent was treated with Norite, dried over $MgSO_4$, filtered, and evaporated to give 7.4 g (83.5%) of crude benzyl ester **2***d*. Trituration with benzene – petroleum ether caused crystallization. The solid was recrystallized from benzene – petroleum ether to yield pure **2***d*, mp 79–79.5 °C.

cis-N-(α-Carboethoxy-β-ethoxyvinyl)-3-azido-4-acetoxymethyl-2-azetidinone ***3a***

From ***1a***

A mixture of 4.8 g (14.5 mmol) compound **1***a*, 2.1 g (15.1 mmol) zinc chloride, and 15 ml acetic anhydride was stirred at 25 °C for 18 h. The solvent was removed at reduced pressure and the residue taken up in $CHCl_3$ (100 ml) – H_2O (20 ml), dried over Na_2SO_4, filtered, and the filtrate passed through 50 g Al_2O_3 (activity III) column. Elution with $CHCl_3$ gave 2.5 g pure acetate. The other fractions were rechromatographed to give an additional 1.1 g (75% total yield).

From ***2a***

Treatment of 1.0 g (3.5 mmol) of **2***a* with 1.1 g zinc chloride in 12 ml of acetic anhydride as above gave **3***a* in 85% yield. The compound was identical in all respects with that obtained from **1***a*.

cis-N-(α-Carbobenzoxy-β-ethoxyvinyl)-3-azido-4-acetoxymethyl-2-azetidinone ***3b***

From ***1b***

A mixture of 3.2 g (8.17 mmol) compound **1***b*, 11 ml acetic anhydride, and 1.12 g (8.2 mmol) zinc chloride was stirred 18 h at 25 °C. The reaction mixture was evaporated at reduced pressure and the residue taken up in 40 ml methylene chloride – 20 ml water. The organic phase was separated, washed with water and brine, dried over $MgSO_4$, filtered, and the filtrate evaporated to yield 3.0 g of an oil. The oil was chromatographed on 50 g silica gel (deactivated, 5% water) by dry column technique using chloroform as an eluent. Evaporation of the eluent gave 1.3 g (41%) of pure **3***b* as an oil.

From ***2d***

Treatment of 104 mg (0.3 mmol) of **2***d* with 82 mg zinc chloride in 3 ml acetic anhydride as in the preparation of **3***a* from **2***a* gave 110 mg pure **3***b* (94%).

cis-N-(α-Carboethoxy-β-ethoxyvinyl)-3-azido-4-hydroxymethyl-2-azetidinone ***4a***

From ***3a***

A solution of 12.18 g (34.8 mmol) of compound **3***a* in 40 ml MeOH and 40 ml 10% HCl was boiled at reflux for 1 h. The methanol was distilled at reduced pressure and the aqueous residue extracted with $CHCl_3$ (3 × 50 ml). The extracts were washed with water and brine, dried over $MgSO_4$, filtered, and the filtrate was evaporated to yield 9.33 g (94.5%) pure alcohol.

From ***2a***

To a solution of 90 mg (0.316 mmol) of **2***a* in 5 ml of methylene chloride was added 3 drops (~ 20 mg) titanium tetrachloride at 25 °C. The solution was let stand for 24 h at 25 °C and filtered through 1.5 g of alumina (activity III). There was obtained 23.7 mg of pure **4***a* (26%) identical in all respects with that obtained from **3***a*.

cis-N-(α-Carbobenzoxy-β-ethoxyvinyl)-3-azido-4-hydroxymethyl-2-azetidinone ***4b***

Hydrolysis of 5.95 g (15.35 mmol) of **3***b* according to the procedure described above for the conversion of **3***a* to **4***a* gave 4.6 g (87%) of **4***b* as an oil.

cis-N-(α-Carboethoxy-β-N-pyrrolidinovinyl)-3-azido-4-hydroxymethyl-2-azetidinone ***5a***

From ***4a***

A solution of 224 mg (0.785 mmol) of **4***a*, 141 mg (2 mmol) pyrrolidine, and 200 mg acetic acid in 15 ml dry benzene was boiled at reflux for 22 h. The solution was washed with 5 ml of saturated sodium bicarbonate solution, washed with water (25 ml), and dried over sodium sulfate. The solution was filtered and evaporated to dryness to give an oil which crystallized on standing. The oil was triturated with ether and filtered to yield 175 mg (72%) pure **5***a*, mp 147–148 °C after recrystallization from benzene.

From ***1a***

Treatment of 2.78 g (8.45 mmol) of **1***a* with 2.5 g pyrrolidine and 2.5 g acetic acid in 50 ml benzene as described above gave 137 g (50%) of pure **5***a* identical in all respects to the sample prepared from **4***a*.

cis-N-(α-Carbobenzoxy-β-N-pyrrolidinovinyl)-3-azido-4-hydroxymethyl-2-azetidinone ***5b***

From ***4b***

In a manner analogous to the preparation of **5***a* from **4***a*, compound **5***b* was prepared from **4***b* in 71% yield; mp 111.5–112.5 °C.

cis-N-(α-Carboethoxy-β-N-pyrrolidinovinyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***6a***

From ***5a***

To a solution of 618 mg (2 mmol) of **5***a* and 404 mg (4 mmol) triethylamine in 15 ml methylene chloride at 0 °C was added 456 mg (4 mmol) methane sulfonyl chloride in 5 ml methylene chloride over 15 min. The solution was allowed to come to 25 °C over 1 h and washed with water (10 ml) and brine (2 × 10 ml). The solution was dried over sodium sulfate and filtered through 4.0 g of alumina (activity III) to give 570 mg of pure **6***a*, mp 138–139 °C.

From ***10a***

Treatment of 181 mg (0.5 mmol) of **10***a* with pyrridineacetic acid according to the procedure given for the preparation of **5***a* gave 125 mg (63%) of **6***a* identical with the sample prepared from **5***a*.

cis-N-(α-Carbobenzoxy-β-N-pyrrolidinovinyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***6b***

A solution of 2.44 g (6.6 mmol) compound **5***b*, 3.9 g (33 mmol) methane sulfonyl chloride, and 3.3 g (33 mmol) triethylamine in 50 ml methylene chloride was stirred at ambient (25 °C) temperature for 74 h. The reaction mixture was washed with water (2 × 10 ml) and brine and dried over Na_2SO_4. The drying agent was filtered and the filtrate evaporated to dryness. The oil was filtered through a silica gel column (deactivated, 15% water) (16 g) with chloroform to give 2.6 g (90%) of crystalline mesylate, mp 116–117 °C.

cis-N-(α-Carboethoxy-β-hydroxyvinyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***7a***

From ***6a***

A solution of 1.27 g (33 mmol) of **6***a* in 20 ml acetone – 5 ml 10% hydrochloric acid was refluxed 20 min and diluted to 100 ml with water. The solution was extracted into methylene chloride (5 × 20 ml). The methylene chloride extracts were extracted with 10% sodium carbonate. The aqueous extracts were acidified with hydrochloric acid and the solution extracted into methylene chloride and dried over sodium sulfate, yielding 0.98 g of pure enol **7***a* as an oil on evaporation (89%).

From ***9a***

A solution of 207 mg (0.51 mmol) of **9***a* in 1 ml of 95% trifluoroacetic acid was warmed to 50 °C for 1 h. The trifluoroacetic acid was removed at reduced pressure and the residue partitioned between methylene chloride – water (50 ml:20 ml). The organic layer was extracted with sodium carbonate as above. Work-up yielded 95 mg (58%) of pure **7***a* identical with that obtained from **6***a*.

cis-N-(α-Carbobenzoxy-β-hydroxyvinyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***7b***

From ***6b***

A solution of 2.28 g (5.26 mmol) compound **6***b* in 25 ml of acetone and 25 ml 10% hydrochloric acid was refluxed 15 min. The acetone was evaporated at reduced pressure and the residue extracted with chloroform (3 × 30 ml). The chloroform layer was washed with water and evaporated to dryness. The residual oil was dissolved in ether (20 ml) and the solution extracted with saturated sodium bicarbonate solution (4 × 8 ml). The bicarbonate was acidified to p*H* 4 with 10% HCl and reextracted with chloroform (3 × 50 ml). The chloroform was washed with water and brine and dried over $MgSO_4$. The drying agent was filtered and the filtrate evaporated to give 1.62 g (81%) of compound **7***b*.

From ***9b***

A solution of 673 mg (1.43 mmol) of **9***b* in 4 ml 95% trifluoroacetic acid was warmed to 50 °C for 25 min. After the work-up (see **9***a* → **7***a*) there was obtained 513 mg (91%) of **7***b* identical with the sample prepared from **6***b*.

Ethyl 7-β-Azido-Δ^3*-O-2-isocephem-4-carboxylate* ***8a***

Method A

To a suspension of 0.0665 g sodium hydride (1.5 mmol) (55% mineral oil dispersion washed three times with petroleum ether) in 2 ml dimethyl sulfoxide (DMSO) was added 500 mg (1.5 mmol) of **7***a* in 4 ml DMSO. The solution was stirred 1 h at 25 °C and then diluted to 30 ml with brine containing 2 ml 10% hydrochloric acid. The aqueous solution was extracted with methylene chloride (5 × 25 ml). The extracts were washed with water (3 × 25 ml) and brine (1 × 25 ml) and dried over sodium sulfate. Evaporation of the extracts gave 327 mg (91.5%) of **8***a*, mp 137–138 °C after recrystallization from benzene.

Method B

A solution of 268 mg (0.8 mmol) of **7***a* and 105 mg triethylamine in 10 ml of chloroform was refluxed for 50 min. The solution was cooled and washed with water,

10% hydrochloric acid, water, and brine. The solution was dried over sodium sulfate, filtered, and evaporated to yield 90 mg (47.5%) of pure **8***a* after crystallization.

From ***10a***

To a solution of 1.83 g (5.00 mmol) of compound **10***a* in 20 ml of tetrahydrofuran was added 20.0 ml of 0.25 *M* sodium hydroxide solution dropwise over 10 min. The resulting solution was concentrated to 20 ml on the rotary evaporator at 30 °C. The concentrate was washed with chloroform (3 × 10 ml). The aqueous layer was evaporated to dryness under high vacuum. The resulting residue was stirred with 7.5 ml of dimethyl sulfoxide for 1 h. Water (30 ml) and saturated sodium chloride (40 ml) followed by a few drops of 10% hydrochloric acid were added to the dimethyl sulfoxide solution. The resulting mixture was extracted with chloroform (3 × 40 ml) and the combined chloroform layers were washed with water and evaporated to give the crude product. Pure compound **8***a* was obtained by recrystallization from benzene–cyclohexane, then chloroform, as colorless crystals, 0.39 g (33% yield).

Benzyl 7-β-Azido-Δ³-O-2-isocephem-4-carboxylate ***8b***

Method A

To a suspension of 198 mg (4.70 mmol) sodium hydride (55% mineral oil dispersion, washed 3× with petroleum ether) in 5 ml dry DMSO was added a solution of 1.62 g (4.27 mmol) compound **7***b* in 5 ml DMSO over 5 min with stirring at 25 °C. After 1 h, the reaction mixture was poured into 50 ml 1% HCl – ice water and was extracted with chloroform (4 × 30 ml). The organic layer was washed with water (3 × 10 ml) and brine and dried over $MgSO_4$. Filtration and evaporation of the filtrate gave 1.2 g of an oil. Trituration with ether caused crystallization; 545 mg (42%) of **8***b*; mp 110 °C.

Method B

A solution of 370 mg (0.935 mmol) of **7***b* and 100 mg triethylamine in 10 ml methylene chloride was refluxed for 4 h. Work-up as in method *B* for **8***a* gave 200 mg (71.5%) of pure **8***b*.

From ***10b***

To a solution of 260 mg (0.64 mmol) of compound in 2.5 ml of tetrahydrofuran was added 2.55 ml of 0.25 *M* sodium hydroxide solution dropwise over 10 min. The solution was concentrated to 2 ml on the rotary evaporator. The concentrate was washed with chloroform (2 × 2 ml), then evaporated to dryness under high vacuum. The residue was stirred with 1 ml of dimethyl sulfoxide for 1 h. Water (1 ml), saturated sodium chloride (1 ml), and one drop of 10% hydrochloric acid were added. The mixture was extracted with chloroform (3 × 2 ml) and the combined chloroform layers were washed with water and evaporated to give crude compound as a yellow solid, 103 mg (54% yield). The nmr spectrum indicated the product to be only 75% pure (*i.e.* a true yield of 40%).

cis-N-(α-Carboethoxy-β,β-diethoxyethyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***9a***

Treatment of 102.0 g (0.308 mol) of **1***a* with 34.3 g (0.34 mol) triethylamine and 39.4 g (0.34 mol) methane sulfonyl chloride according to procedure given for the preparation of **10***a* from **4***a* gave 108.4 g (86%) of **9***a* as an oil.

cis-N-(α-Carbobenzoxy-β,β-diethoxyethyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***9b***

From ***1b***

Treatment of 12.2 g (31.2 mmol) of **1***b* with 3.42 g (34 mmol) triethylamine and 2.90 g (34 mmol) methanesulfonyl chloride as in the above experiment yielded 12.3 g (83.5%) of **9***b* as an oil.

From ***9a***

To a solution of 1.065 g (2.61 mmol) of **9***a* in 25 ml tetrahydrofuran was added 10 ml of 0.25 *N* sodium hydroxide over 5 min. The solution was stirred 30 min at 25 °C following which 3 ml 10% hydrochloric acid was added and the solution diluted to 100 ml with brine. The solution was extracted into ether (4 × 50 ml). The ethereal extracts were extracted with sodium carbonate solution (10%). The ethereal layer was dried over sodium sulfate and evaporated to yield an oil which crystallized on trituration with ether (5 ml). Filtration gave 283 mg (26.6%) pure **10***a*. The alkaline extracts were acidified with 10% hydrochloric acid and extracted into methylene chloride (5 × 20 ml). The extracts were dried over sodium sulfate and evaporated to yield 542 mg (55%) of the desired acid **9***c*. Compound **9***c* was characterized spectroscopically and used without further purification in the next step. The yields of **10***a* from this reaction ranged from10–30% while the yields of **9***c* ranged from 45–70%.

To a solution of 2.64 (7 mmol) of **9***c* and 2.0 g (20 mmol) triethylamine in 30 ml methylene chloride at 0–5 °C was added 2.0 g (11.7 mmol) of benzyl chloroformate. As the solution was stirred gas evolution was observed. After 15 min at 0–5 °C, the solution was refluxed for 30 min. The solution was washed with water (50 ml), 10% hydrochloric acid (10 ml), and brine (50 ml), dried over sodium sulfate, and evaporated to yield 3.07 g of an oil which yielded 2.76 g (84%) of **9***b* on chromatography over silica gel (deactivated with 15% water) using chloroform as eluent.

cis-N-(α-Carboethoxy-β-ethoxyvinyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***10a***

From ***4a***

To a solution of 5.68 g (20 mmol) of **4***a* and 3.0 ml (21 mmol) triethylamine in 50 ml methylene chloride at 0–5 °C was added 2.28 g (20 mmol) methane sulfonyl chloride. The solution was stirred for 30 min at 25 °C after which it was washed with water (2 × 25 ml), 10% hydrochloric acid (2 × 10 ml), and brine (1 × 50 ml), dried over sodium sulfate, and concentrated to give an oil. The oil was triturated with 50 ml ether and the crystalline mesylate isolated by filtration, 4.37 g (60.2%). The mother liquors were chromatographed on a column of 50 g silica gel (deactivated with 15% water). An additional 380 mg (5%) of pure **10***a* was isolated from the latter fractions from ether elution; mp 101–102.5 °C (dec.).

From ***9a***

(A) A mixture of 4.9 g (12 mmol) of compound **9***a*, 10 ml of acetic anhydride, 10 ml of acetic acid, and 1.75 g (13 mmol) of zinc chloride was stirred at 25 °C for 17 h, then evaporated to a tar. A methylene chloride solution of the tar (50 ml) was washed with equal volumes of

water, 5% sodium bicarbonate, and dilute sodium chloride. The methylene chloride solution was filtered through 15 g of alumina (grade III) and evaporated to give an oil. Trituration of the oil with ether gave pure compound **10***a* as a colorless powder, 1.88 g (45% yield).

(B) Treatment of 1.90 g (4.65 mmol) of **9***a* with 2.0 g triethyloxonium fluoroborate in 20 ml methylene chloride for 18 h at 25 °C gave 0.75 g (46.5%) of **10***a*.

*cis-N-(α-Carbobenzoxy-β-ethoxyvinyl)-3-azido-4-mesyloxymethyl-2-azetidinone **10b***

Treatment of 15.2 g (43.8 mmol) of **4***b* with triethylamine and methanesulfonyl chloride as in the procedure for the preparation of **10***a* from **4***a* yielded upon work-up 13.0 g (70.4%) of pure **10***b*, as an oil.

*cis-N-(α-Carbobenzoxy-β-hydroxyvinyl)-3-azido-4-hydroxymethyl-2-azetidinone **11***

A solution of 3.71 g (10 mmol) compound **5***b* in 50 ml of acetone and 25 ml of 10% HCl was boiled at reflux for 30 min. The acetone was removed at reduced pressure and the oily aqueous residue extracted with ether (3 × 35 ml) and methylene chloride (3 × 25 ml). The organic layer was extracted with saturated aqueous $NaHCO_3$ (5 × 20 ml). The aqueous extracts were acidified with 10% HCl and saturated with NaCl. The aqueous layer was extracted thoroughly with ether (3 × 25 ml) then CH_2Cl_2 (3 × 25 ml). The extracts were dried over Na_2SO_4 and concentrated to yield 2.40 g of enol alcohol **11**, 75.5%, as an oil.

*Benzyl α-Amino-β,β-diethoxypropionate **15***

A solution of 62.0 g (0.325 mol) of benzyl nitroacetate **12**, 76.6 g (0.52 mol) triethylorthoformate and 65.0 g (0.64 mol) acetic anhydride was heated to 85–90 °C for 18 h. Following this the excess triethylorthoformate, acetic anhydride, and ethyl acetate were removed by evaporation of the solution at reduced pressure (50 °C/1 torr). There was obtained 85.2 g of an oil the nmr spectrum of which indicated that a mixture of the desired acetal **14** (40%) and the elimination product of **14** (**13**, 60% as *Z* and *E* isomers) had been obtained. To the oil was added 25 ml of ethanol followed by 1.0 g sodium ethoxide. A mildly exothermic reaction ensued. After 15 min the excess ethanol was removed by evaporation at reduced pressure (30 °C/1 torr). There was obtained 95.0 g (100%) of the desired acetal **14** which was used as such in the reduction step.

To 37.5 g aluminum amalgam (19) covered by 450 ml moist ether was added 95.0 g (0.325 mmol) of **14** in 250 ml ether. Initially 50% was added over 10 min. After 10–15 min a violent exothermic reaction ensued which was controlled by ice-bath cooling. When the reaction had subsided the remaining acetal was added over 30 min. After 1 h the reaction had subsided sufficiently that heating became necessary so as to maintain a gentle reflux. The solution was refluxed an additional 2 h then allowed to stand 24 h at 25 °C. The gelatinous aluminum hydroxide was removed by filtration. The filtrate was dried over sodium sulfate and evaporated to give 53.0 g of an oil. The oil was taken up in 1 litre of ether and extracted with 5% hydrochloric acid (5 × 150 ml). The extracts were neutralized with sodium carbonate and the resultant solution extracted with ether. The extracts were dried over sodium sulfate and evaporated to yield 35.0 g (42.5%) of benzyl α-amino-β,β-diethoxypropionate **15**. Compound **15** was characterized by nmr spectroscopy and used as such in the preparation of **17**.

*cis-N-(α-Carbobenzoxy-β,β-diethoxyethyl)-3-azido-4-styryl-2-azetidinone **17***

*From **15***

The cinnamylidene Schiff base **16** of **15** was prepared from 35.0 g (0.13 mol) of **15** and 17.3 g (0.13 mol) cinnamaldehyde by the previously described method (1) in quantitative yield. Treatment of 58.0 g (0.13 mol) of **17** with 13.3 g (0.13 mol) triethylamine followed by 15.7 g (0.13 mol) of azidoacetyl chloride (1) gave 54.14 g (89%) of the desired β-lactam **17** as an oil. A small sample (0.90 g) of the oil was chromatographed on 50 g of silica gel (deactivated with 15% water) using chloroform as eluent. The two isomers of **17** were isolated.

*From **19***

To a solution of 15.5 g (38.6 mmol) of **19** (1) in 300 ml ethanol was added 160 ml of 0.25 *N* sodium hydroxide over 20 min at 25 °C. The solution was stirred an additional 40 min. The solution was acidified to p*H* 3 with 10% hydrochloric acid and extracted into chloroform (3 × 50 ml). The extracts were evaporated to dryness and the resultant oil taken up into 50 ml ether. The ethereal solution was washed once with water and then extracted with saturated sodium bicarbonate (3 × 15 ml). The extracts were made acid with 10% hydrochloric acid and extracted with chloroform. The extracts were dried over sodium sulfate and concentrated to give 8.9 g (60%) of the acid **20**.

Treatment of 8.9 g (23.8 mmol) of **20** with 2.4 g (24 mmol) triethyl amine and 4.6 g (27 mmol) benzylchloroformate according to the procedure given for the conversion of **9***c* to **9***b* gave 6.16 g (55%) of the desired ester **17**.

*cis-N-(α-Carbobenzoxy-β,β-diethoxyethyl)-3-azido-4-hydroxymethyl-2-azetidinone **1b***

A solution of 4.8 g (10.04 mmol) compound **17** in 80 ml dry methylene chloride was prepared and cooled to −78 °C in an acetone – dry ice bath. To this was added ozone until a blue color persisted. The ozone addition was stopped and the excess ozone removed by bubbling dry nitrogen through the solution. To the solution was added 5 ml of dimethyl sulfide and the solution was allowed to come to room temperature over 1 h. The solution was then washed with water (20 ml), saturated $NaHCO_3$ (20 ml), water (10 ml), and brine and dried over $MgSO_4$. The solution was filtered and evaporated to give 5.0 g of an oil. The byproduct benzaldehyde was removed by distillation at 0.05 torr and a bath temperature of ~65 °C. The residual oil 4.0 g (95%) was analyzed by nmr which indicated 77% free aldehyde **18**.

To 3.5 g (9.0 mmol) of compound **18** in 30 ml 95% ethanol at 0–5 °C was added 255 mg (6.0 mmol) of sodium borohydride with stirring. After 30 min at 0–5 °C the solution was stirred an additional 30 min at 25 °C. The solution was acidified to p*H* ≃ 4 with 10% hydrochloric acid and diluted with 40 ml ice water. The aqueous layer was extracted with chloroform (3 × 30 ml). The combined extracts were washed with water (2 × 10 ml) and brine, dried over $MgSO_4$, filtered, and

evaporated to yield 3.4 g crude alcohol **1***b*. The oil was chromatographed on silica gel (5% water) with chloroform to yield 3.0 g pure alcohol **1***b* (85%).

Benzyl γ-Phenylacetoacetate ***21c***

A mixture of 166 g (0.76 mol) of ethyl γ-phenylacetoacetate (16) and 100 g (0.92 mol) benzyl alcohol was heated to 170 °C at atmospheric pressure and the ethanol produced removed by distillation. When the still head temperature began to rise, the pot was cooled and the residue distilled at reduced pressure. Following removal of a forerun (bp 65–80 °C/100 torr) pure **21***c* was obtained 171 g (85%), bp 155–157 °C/0.002 torr.

Benzyl γ-Benzylacetoacetate ***21d***

From 204 g (1.1 mol) phenethyl bromide, 24.30 g (1 mol) magnesium and a trace of iodine in 250 ml of ether was prepared 2-phenylethyl magnesium bromide (17). The pot temperature was maintained at 25–30 °C and 45.2 g (0.40 mol) of ethyl cyanoacetate was added. The solution was stirred 24 h at 20–25 °C following which the excess Grignard reagent was decomposed by addition of saturated ammonium chloride and 10% hydrochloric acid. The phases were separated and the organic phase stirred vigorously with 10% hydrochloric acid for 3 h. The organic phase was washed with brine, dried over sodium sulfate, and concentrated to give 83.5 g of an oil which yielded 12.67 g (21%) of ethyl γ-benzylacetoacetate on distillation, bp 114–122 °C/0.1 torr.

From 12.67 g (50 mmol) of the ethyl ester and 8.1 g (75 mmol) benzyl alcohol was obtained 6.15 g pure **21***d*, bp 160–163 °C/0.1 torr in the same manner as the preparation of **21***c*.

Benzyl Oximinoacetoacetate ***22b***

Treatment of 173 g (0.9 mol) benzylacetoacetate (18) with sodium nitrite – acetic acid according to the method of Adkins and Reeve (10) gave 186.5 g (93.2%) of benzyl oximinoacetoacetate **22***b*; mp 81–82 °C, (lit. (11) mp 79–79.5 °C).

Benzyl γ-Phenyloximinoacetoacetate ***22c***

From 85.5 g (0.32 mol) of benzyl γ-phenylacetoacetate was prepared 92.50 g of oily oxime by the method of Adkins and Reeve (10). Trituration with carbon tetrachloride gave 52.8 g (56%) of pure **22***c*, mp 69–70 °C.

Benzyl γ-Benzyloximinoacetoacetate ***22d***

From 37.0 g (0.13 mmol) of **21***d* was prepared 40.1 g (98%) of **22***d* as a yellow oil by the method of Adkins and Reeve (10). The oil was characterized by its nmr and ir spectra and was used as such in subsequent experiments.

Benzyl Oximinoacetoacetate Ethylene Ketal ***23b***

In a 2 l flask fitted with a Dean Stark water separator and a condenser were placed 186.5 g (0.85 mol) of benzyl oximinoacetoacetate **22***b*, 62 g (1 mol) of ethylene glycol, 800 ml of benzene (reagent grade), and 2 g (10.5 mmol) of *p*-toluenesulfonic acid monohydrate. The reaction mixture was boiled at reflux until 15 ml of water was removed (3 h). The benzene solution was washed once with saturated sodium bicarbonate solution and once with brine. After drying over anhydrous sodium sulfate, the benzene solution was evaporated, leaving 212 g (94%) of benzyl oximinoacetoacetate ethylene ketal **23***b* as a mixture of *syn* and *anti* isomers. Generally, the product was used as such in subsequent reactions but one of the isomers could be crystallized from toluene – petroleum ether (bp 30–60 °C), mp 52 °C.

Benzyl γ-Phenyloximinoacetoacetate Ethylene Ketal ***23c***

From 5.94 g (20 mmol) of **22***c* and 1.36 g (22 mmol) ethylene glycol there was obtained 6.70 g of an oil which crystallized on standing in 20 ml carbon tetrachloride. On filtration 4.0 g (57%) of pure **23***c*, mp 90–92 °C was obtained.

Benzyl γ-Benzyloximinoacetoacetate Ethylene Ketal ***23d***

From 8.48 g (27 mmol) of **22***d* and 1.85 g (30 mmol) of ethylene glycol was obtained 9.40 g crude **23***d* which was used as such in the subsequent reaction.

Ethyl α-Aminoacetoacetate Hydrochloride ***24***

Ethyl α-oximinoacetoacetate **22***a* (10) (80 g; 0.5 mol) was dissolved in a mixture of 200 ml of ethanol and 70 ml of ethanolic HCl (9.28 *N* HCl–EtOH; 1.25 equiv). 10% palladium-on-carbon (8 g) was added carefully and the mixture was hydrogenated in a Parr hydrogenation apparatus starting at 70 psig (11). After absorption of the theoretical amount of hydrogen (1–2 h) the catalyst was filtered off and washed with ethanol. The ethanol was removed *in vacuo* at 40–50 °C leaving a thick red-brown oil. The oil was diluted with 8 volumes of acetone with vigorous stirring. Yellow crystals of the amine hydrochloride **24** separated out on cooling, 49 g (55%), mp 122–123 °C (corr.) (lit. (11) mp 114–116 °C (uncorr.)). This material was used without further purification.

Ethyl α-Aminoacetoacetate Ethylene Ketal ***25a***

To a mixture of 1.75 kg (28.2 mol) of ethylene glycol and 210 g (1.95 mol) *p*-toluenesulfonic acid monohydrate which had been warmed to 90 °C, 460 g (2.54 mol) of amine hydrochloride **24** was added with vigorous mechanical stirring. The mixture was stirred for 40 min at 90 °C, then poured into a mixture of water (2 l), concentrated ammonium hydroxide (650 ml), and ice (1 litre), and extracted four times with 500 ml of methylene chloride. The combined organic extracts were washed with brine, dried (Na_2SO_4), and evaporated to give 491 g of a dark red oil. The oil was diluted to 1.8 l with Et_2O, cooled in an ice bath, and ethanol saturated with hydrogen chloride was added until the p*H* reached 2–3. The resulting solid was filtered off and washed with ether to give 398 g (70%) of a light yellowish solid (70%), mp 153–156 °C (corr.). An analytical sample of **25***a* was recrystallized from 2-propanol–ether to give white crystals, mp 158–160 °C (corr.).

The free base of **25***a* is conveniently prepared from its hydrochloride by neutralization with concentrated ammonium hydroxide and extraction with CH_2Cl_2.

Benzyl α-Aminoacetoacetate Ethylene Ketal ***25b***

Freshly prepared aluminum amalgam (19) (from 27 g of aluminum foil) was covered with 500 ml of diethyl ether. The flask was fitted with a mechanical stirrer, a condenser, and a dropping funnel. A solution of benzyl oximinoacetoacetate ethylene ketal **23***b* (132.5 g; 0.5 mol) in 300 ml of wet diethyl ether was added dropwise at such a rate as to maintain boiling at reflux. After stirring for 4 h, the reaction mixture was filtered through a Buchner funnel. The filtrate was evaporated leaving

110 g of yellowish oil. The oil was dissolved in 800 ml of dry diethyl ether and dry hydrogen chloride gas was bubbled into the solution until no further precipitation occurred. The white precipitate was filtered off and washed once with diethyl ether and then dried *in vacuo*. This provided 108 g of benzyl aminoacetoacetate ethylene ketal hydrochloride, mp 157–158 °C.

To obtain the free base, the hydrochloride salt was suspended in 500 ml of diethyl ether and concentrated ammonium hydroxide was added with shaking until the solid went into solution. The diethyl ether layer was separated and washed twice with brine. After drying over anhydrous sodium sulfate, the solvent was evaporated leaving 90 g (71%) of colorless oil.

Benzyl α-Amino-γ-phenylacetoacetate Ethylene Ketal ***25c***

To freshly prepared aluminum amalgam (19) (from 6.9 g aluminum foil) in 100 ml ether was added solution of 29.5 g (85 mmol) of **23***c* in 600 ml of moist ether over 1 h. There was a mildly exothermic reaction and after the addition was complete, it was refluxed for 2 h. It was cooled, filtered through Celite, and extracted with 4 × 100 ml 10% hydrochloric acid. White crystals separated from the aqueous phase, were filtered, washed with cold water, and dried to give 29.0 g (93%) solid, mp 181–183 °C, recrystallized from ethanol–ether; mp 182–184 °C. The free base was obtained by suspending the hydrochloride in water and neutralizing with cold concentrated ammonium hydroxide.

Benzyl α-Amino-γ-benzyl Acetoacetate Ethylene Ketal ***25d***

To freshly prepared aluminum amalgam (19) (prepared from 27 g aluminum foil) covered with 300 ml moist ether was added with stirring a solution of 43 g (0.2 mol) of **23***d* in 300 ml ether. There was an exothermic reaction and after it subsided, the system was refluxed for 4 h. The inorganic material was filtered on Celite and the filtrate shaken well with 10% hydrochloric acid (100 ml). White crystals separated, were collected by filtration, washed with ether, and dried in a dessicator to give 54.0 g solid; mp 186–188 °C. The free base was obtained by suspending the solid in water, carefully neutralizing with cold concentrated ammonium hydroxide, and extracting with methylene chloride. After evaporation of the solvent, 27.91 g (69%) of a yellow oil was obtained.

Preparation of Schiff Bases ***26a–d***

The Schiff bases **26***a–d* were prepared from cinnamaldehyde and the appropriate amine **25***a–d* in quantitative yields according to our previously published method (1). The nmr spectra of **26***a–d* are listed in Table 1.

cis-N-(α-Carboethoxy-β,β-ethyleneketalpropyl)-3-azido-4-styryl-2-azetidinone ***27a***

From 197.2 g (0.65 mol) of **26***a*, 72 g (0.715 mol) triethylamine and 85.19 g (0.715 mol) azidoacetylchloride was prepared 245 g (98%) of crude **27***a* as a red oil according to our previously published method. A small sample crystallized from methanol to give a white solid, mp 81.5–82.5 °C.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketalpropyl)-3-azido-4-styryl-2-azetidinone ***27b***

From ***27a***

To a solution of 64.31 g (0.168 mol) of **27***a* in 700 ml tetrahydrofuran was added 670 ml of 0.25 *N* sodium hydroxide solution (0.168 mol) at such a rate as to maintain the temperature at 25 °C. The addition took 1 h following which the solution was stirred an additional hour until thin layer chromatography indicated that no **27***a* remained in the mixture. The reaction mixture was carefully acidified to p*H* 3 with concentrated hydrochloric acid, saturated with salt, and extracted with methylene chloride (3 times). The methylene chloride extracts were washed with brine, dried over sodium sulfate, and evaporated at reduced pressure. The residue was dissolved in ether and extracted with 10% sodium bicarbonate solution until the extracts were colorless. The combined basic extracts were washed twice with ether, then carefully acidified to p*H* 3 with concentrated hydrochloric acid saturated with salt and extracted with methylene chloride. The extracts were washed with brine, dried over sodium sulfate, filtered, and evaporated to yield 51.86 g (86%) of the acid as a brown solid. Recrystallization from benzene gave pure **27***e*, mp 131–131.5 °C (dec.) (single isomer).

Treatment of **27***e* with triethylamine and benzyl chloroformate according to the procedure given for the conversion of **9***c* to **9***b* gave pure **27***b* in 99% yield, mp 65.5–66.5 °C after recrystallization from benzene – petroleum ether (30–60 °C) as a single isomer.

From ***25b***

Treatment of **26***b* with triethylamine and azidoacetyl chloride according to our previously published procedure (1) gave **27***b* in 94% yield as a mixture of diastereoisomers.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-phenylpropyl)-3-azido-4-styryl-2-azetidinone ***27c***

Treatment of **26***c* with triethyl amine and azidoacetyl chloride as in ref. 1 gave **27***c* as a mixture of diastereoisomers in quantitative yield. The crude oil was used as such in subsequent experiments.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-benzylpropyl)-3-azido-4-styryl-2-azetidinone ***27d***

Treatment of **26***d* with triethylamine and azidoacetyl chloride as in ref. 1 gave **27***d* as a red oil in quantitative yield and as a mixture of diastereoisomers. The crude oil was used as such in subsequent experiments.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketalpropyl)-3-azido-4-formyl-2-azetidinone ***28a***

A solution of 117.5 g (0.262 mol) of **27***b* in 1 litre of methylene chloride was cooled to −50 to −60 °C in a dry ice – acetone bath, and ozonized until a faint blue-green color appeared. The solution was then flushed with nitrogen until the color faded. Methyl sulfide (100 ml) was added to the solution at −50 °C which was then allowed to slowly reach 25 °C as the cooling bath gradually melted. It was kept overnight at room temperature under nitrogen and then it was washed twice with 1% sodium bicarbonate solution and twice with brine, dried over anhydrous sodium sulfate, and evaporated to dryness. The resulting oil was triturated four times with 100 ml portions of petroleum ether (bp 30–60 °C) to remove benzaldehyde. The oil was then triturated carefully with diethyl ether whereupon it solidified. The solid was filtered off and dried to provide 75 g (71.5%) of aldehyde as a mixture of isomers diasteriomeric at the carbon α to the carbonyl of the benzyl ester.

In another experiment, 36.36 g (81.24 mmol) of a single isomer of **27***b* was ozonized at −78 °C in 300 ml

of methylene chloride. After work-up as above, there was obtained 32.92 g of an oil which crystallized on standing. This material was slurried with ether and filtered to provide 18.84 g (69%) off-white solid, mp 97–100 °C (corr). The analytical sample was recrystallized from ether; white crystals, mp 101–102 °C (corr.).

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-phenylpropyl)-3-azido-4-formyl-2-azetidinone ***28b***

Ozonolysis of **27***c* according to the procedure described above for **28***a* gave **28***b* as an oil (95%). The nmr and ir spectra of **28***b* were compatible with the assigned structure and it was used as such in subsequent experiments.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-benzylpropyl)-3-azido-4-formyl-2-azetidinone ***28c***

Ozonolysis of **27***d* according to the procedure given for **28***a* to yield **28***c* as an oil. Chromatography of the oil (7.0 g) on silica gel (deactivated with 15% water) (250 g) using ether – petroleum ether (2:1) as eluent to remove the benzaldehyde followed by pure ether gave **28***c* in 45% yield. The oil was used as such in subsequent experiments.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketalpropyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***30a***

The aldehyde **28***a* (116.3 g; 0.31 mol) was dissolved in 600 ml of THF (reagent grade) and the solution was then cooled to −10 °C (ice–methanol bath). Sodium borohydride (5.88 g; 0.155 mol) was added and the reaction mixture was stirred 1 h. 10% aqueous hydrochloric acid was added until the mixture was slightly acidic, then 600 ml brine was added. The THF layer was separated and the aqueous phase was extracted twice with 250 ml portions of diethyl ether. The combined organic phases were washed twice with 400 ml portions of brine, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to yield 117.3 g of crude alcohol **29***a* as an orange oil. This oil was used as such in the next reaction.

A solution of methanesulfonyl chloride (37.8 g; 0.34 mol) in 100 ml of methylene chloride was added dropwise at 0 °C (ice–water bath) to a stirring solution of alcohol **29***a* (105.6 g; 0.28 mol), triethylamine (56.6 g; 0.34 mol), and 1 litre of methylene chloride. Afterwards, the reaction was stirred for 30 h at 25 °C. It was then washed twice with brine (500 ml portions), dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The resulting oil was dissolved in methylene chloride, treated with Norite, and then filtered over *ca.* 200 g of activity I silica gel. The silica gel was then washed with *ca.* 2 l of methylene chloride. The filtrate was evaporated to dryness and the resulting oil (116 g) was covered with diethyl ether. It crystallized on standing giving 87.2 g (80% from aldehyde **28***a*) of mesylate **30***a* as an off-white solid, mp 97–99 °C (corr.) after recrystallization from benzene–ether.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-phenylpropyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***30b***

Reduction of **28***b* with sodium borohydride as in **28***a* gave **29***b* in 89% yield. The alcohol was mesylated as in the above example to yield **30***b* as an oil in 95% yield. This oil was used as such in subsequent reactions.

cis-N-(α-Carbobenzoxy-β,β-ethyleneketal-γ-benzylpropyl)-3-azido-4-mesyloxymethyl-2-azetidinone ***30c***

Reduction of **28***c* with sodium borohydride as in **28***a* gave **29***c* in 92% yield. The alcohol was mesylated as in the conversion of **29***a* to **30***a* to give **30***c* in 46% yield after chromatography on silica gel (deactivated with 15% water) (4.0 g substrate to 250 g silica gel) using ether – petroleum ether (3:1) as eluent. The oil was used as such in subsequent reactions.

Benzyl 7-β-Azido-3-methyl-Δ³-O-2-isocephem-4-carboxylate ***32a***

A mixture of mesylate **30***a* (3.19 g; 6.43 mmol) and 30 ml of 95% trifluoroacetic acid was stirred at 25 °C for 2 h. The mixture was diluted with 300 ml of brine and extracted three times with methylene chloride (100 ml portions). The combined extracts were washed three times with water (50 ml portions, until neutral), dried (anhydrous sodium sulfate), and evaporated to dryness *in vacuo* leaving 3.17 g of a brown oil. The nmr spectrum of this oil indicates the presence of > 90% enol **31***a*.

A solution of 12.02 g (29.4 mmol) of **31***a* and 2.95 g (29.5 mmol) triethylamine in 100 ml of methylene chloride was refluxed for 2 h. The solution was washed with 10% hydrochloric acid and brine, and dried over sodium sulfate. Evaporation gave 8.56 g of an oil which was filtered through 100 g silica gel in methylene chloride. Evaporation of the filtrate gave 6.58 g (80.5%) of **32***a*, mp 87–88 °C after recrystallization from ether.

Benzyl 7-Azido-3-benzyl-Δ³-O-2-isocephem-4-carboxylate ***32b***

The ketal mesylate **30***b* (1.36 g; 2.5 mmol) was dissolved in 95% trifluoroacetic acid (15 ml) and stirred at 50–55 °C for 2 h on an oil bath. It was poured into brine and extracted with CH_2Cl_2. After washing the organic extracts with water and drying over Na_2SO_4, the solvent was removed on the aspirator and left 1.20 g red oil, **31***b*. No further purification was attempted.

A mixture of crude enol mesylate **31***b* (5.4 g) and triethylamine (2 ml) in dry CH_2Cl_2 (100 ml) was refluxed for 5 h. It was cooled, washed with 10% HCl and water, dried over Na_2SO_4 and evaporated on the aspirator to give 4.24 g oil. This was purified by chromatography on 200 g of silica gel (deactivated with 15% water) eluting with ether – petroleum ether (2:1) to give 1.3 g (33%) of **32***b*, mp 117–118 °C, recrystallized from methanol.

Benzyl 7-Azido-3-phenethyl-Δ³-O-2-isocephem-4-carboxylate ***32c***

Ketal mesylate **30***c* (2.05 g; 3.7 mmol) was dissolved in 95% trifluoroacetic acid (200 ml) and stirred at 50–55 °C for 2 h on an oil bath. It was then poured into a mixture of crushed ice and brine and extracted with CH_2Cl_2. After washing the organic extracts with water, and drying over Na_2SO_4, the solvent was removed on the aspirator and left 1.73 g oil. No further purification was attempted.

A mixture of crude 'enol mesylate' **31***c* (1.71 g; 3.4 mmol) and triethylamine (0.48 ml; 3.4 mmol) in CH_2Cl_2 (50 ml) was refluxed for 5 h. It was cooled, washed with 10% HCl and water, dried over Na_2SO_4, and evaporated on the aspirator to give 1.35 g oil. This was purified by chromatography on 75 g silica gel (deactivated with 15% water) eluting with ether – petroleum ether (2:1) to yield 0.45 g (33%) pure **32***c*, mp 97–98 °C after recrystallization from methanol.

Ethyl 7-β-(Aminophenoxyacetoyl)-Δ³-O-2-isocephem-4-carboxylate ***34a***

A suspension of 242.5 mg (1.02 mmol) of **8***a* and

260 mg 10% Pd/C in 15 ml ethyl acetate was stirred under hydrogen at atmospheric pressure for 30 min. The suspension was filtered through diatomaceous earth and evaporated to yield 220 mg of an oil. The nmr and ir spectra of which were compatible with the amine **33***a*.

The oil was taken up in 15 ml methylene chloride and 101 mg (1 mmol) triethylamine was added. The solution was cooled to 0–5 °C and a solution of 170.5 mg (1 mmol) phenoxyacetyl chloride in 5 ml methylene chloride was added over 5 min. The solution was stirred 30 min at 25 °C and washed with water, 10% hydrochloric acid, and saturated sodium bicarbonate solution. The solution was dried over sodium sulfate and concentrated to yield 316 mg of an oil. The oil was chromatographed on 25 g silica gel with benzene–acetone as eluent (initially 100% benzene gradually changed to 1:1 5% every 50 ml). There was obtained 194 mg (56%) of **34***a*, mp 148–148.5 °C, recrystallized from benzene–ether.

Benzyl 7-β-(Aminophenoxyacetoyl)-Δ^3-O-2-isocephem-4-carboxylate **34***b*

Compound **8***b*, 500 mg (1.66 mmol) was dissolved in 20 ml of dry ethyl acetate. To this was added 450 mg of 10% Pd/C and the solution was stirred under hydrogen at atmospheric pressure and room temperature for 30 min. The solution was filtered through Celite and the filter cake washed thoroughly with methylene chloride. Evaporation of the filtrate yielded 500 mg of crude amine. The nmr and ir spectra of the compound were compatible with the assigned structure.

Compound **33***b* (500 mg) was dissolved in 10 ml of dry methylene chloride and cooled to 0–5 °C in an ice bath. To this was added 280 mg (2.8 mmol) of triethylamine and 346 mg (2.0 mmol) of phenoxyacetyl chloride was added slowly. After stirring for 1 h at 0–5 °C, the solution was washed with water (2 × 10 ml) and dried over Na_2SO_4. After evaporation, the residual oil was taken up in 50 ml of ether and filtered. The filtrate was evaporated and triturated with ether – petroleum ether (1:1). The solid thus obtained was filtered to yield 570 mg crude amide. The amide was chromatographed on a silica gel column (not deactivated) (25 g) with benzene–acetone (initially in a ratio 50:1, gradually changed to 1:1, 2% more acetone every 25 ml). The desired amide was obtained pure, 195 mg (29%), as a gum.

Benzyl 7-β-(Aminophenoxyacetoyl)-3-methyl-Δ^3-O-2-isocephem-4-carboxylate **34***c*

A suspension of 210 mg (0.64 mmol) of **32***a* and 100 mg PtO_2 in 35 ml absolute ethanol was hydrogenated at atmospheric pressure for 7 min. Filtration and evaporation of the filtrate gave 190 mg (100%) of **33***c*, mp 91–92 °C. The nmr and ir spectra of **33***c* were compatible with the assigned structure.

To a solution of 190 mg (0.64 mmol) of **33***c* in 20 ml methylene chloride was added 97.4 mg (0.64 mmol) of phenoxyacetic acid followed by 158 mg (0.64 mmol) EEDQ. The solution was let stand 1 h. It was washed with 1% sodium bicarbonate solution (2 × 10 ml), 10% hydrochloric acid (2 × 10 ml), and brine (50 ml), and dried over sodium sulfate. Evaporation of the solvent gave 180 mg (65%) of **34***c* which crystallized on trituration with ether, mp 133–135 °C (dec.).

Benzyl 7-β-(Aminophenoxyacetoyl)-3-benzyl-Δ^3-O-2-isocephem-4-carboxylate **34***d*

A mixture of compound **32***b* (0.49 g; 1.25 mmol) and triethylamine (0.9 ml; 6.5 mmol) in CH_2Cl_2 (50 ml) was cooled in an ice bath and while being stirred, was saturated with H_2S. The cooling bath was removed and there was gas evolution which subsided in 10 min. At this point, tlc showed no starting material remained. Attempts to extract the amine from the solution as its hydrochloride failed as it is more soluble in CH_2Cl_2 than in water. The CH_2Cl_2 solution of the free base was dried over Na_2SO_4 and evaporated on the aspirator to leave 0.49 g (87%) of **33***d* as a semisolid. It was used as such with no further purification.

A solution of **33***d* (0.46 g; 1.25 mmol), phenoxyacetic acid (0.19 g; 1.25 mmol), and EEDQ (0.31 g; 1.25 mmol) in CH_2Cl_2 (100 ml) was stirred at room temperature for 16 h. It was washed with 1% $NaHCO_3$ solution, then with brine, dried over Na_2SO_4, and evaporated on the aspirator to leave 0.56 g (89%) of a slightly yellow gum. It was used as such with no further purification.

Benzyl 7-β-(Aminophenoxyacetoyl)-3-phenethyl-Δ^3-O-2-isocephem-4-carboxylate **34***e*

A mixture of **32***c* (0.81 g; 2 mmol) and triethylamine (0.56 ml; 4 mmol) in methylene chloride (50 ml) was cooled in an ice bath and while being stirred, was saturated with H_2S. The cooling bath was removed and there was gas evolution. After stirring at room temperature for 1 h, the solution was evaporated at room temperature and partitioned between ether and 10% HCl. White crystals separated and were collected by filtration, washed with ether, and dried to give 1.12 g white solid, mp 120–123 °C. The free base was obtained by suspending the solid in water, alkalizing with cold concentrated ammonium hydroxide and extracting with methylene chloride. This was washed with brine, dried over sodium sulfate, and evaporated on the aspirator. There was obtained 0.68 g (90%) of **33***d* as an oil.

A solution of **33***e* (0.40 g; 1.05 mmol), phenoxyacetic acid (0.16 g; 1.05 mmol), and EEDQ (0.26 g; 1.05 mmol) in CH_2Cl_2 (50 ml) was stirred at room temperature for 2 h. It was washed with 1% $NaHCO_3$ solution, then with brine, dried over Na_2SO_4, and evaporated on the aspirator to leave 0.49 g (91%) white solid, mp 146–148 °C. This was used as such in the subsequent step.

7-β-(Aminophenoxyacetoyl)-Δ^3-O-2-isocephem-4-carboxylic acid **35***a*

Compound **34***b* 210 mg (0.514 mmol) was dissolved in 40 ml ethyl acetate and 1 ml glacial acetic acid was added. Using 610 mg (~20%) palladium hydroxide on charcoal as catalyst, the solution was hydrogenated at 58 psi for 50 min.

The reaction mixture was filtered through Celite (twice) and the catalyst was washed thoroughly with chloroform (20 ml). The filtrate was evaporated to dryness. It was evaporated 3 times with benzene in order to strip off the acetic acid. A very viscous oil was obtained which was washed with 10 ml benzene. The residual oil was scratched with 10 ml ether. The solid material formed was filtered out. Yield: 115 mg (70.5%). Compound **35***a* did not show a sharp melting point but decomposed in the range of 215–250 °C. The ir and nmr spectra of **35***a* were compatible with the assigned structure.

Compound **35***a* was converted to its potassium salt **35***b*.

To a solution of 30 mg, compound **35***a* in 3 ml methylisobutylketone was added one or two drops of 50% solution of potassium 2-ethylhexanoate in butanol. A

white crystalline material separated almost immediately which was filtered out and washed with methyl isobutylketone and dried over P_2O_5 for 48 h under high vacuum. There was obtained 18 mg (53.5%) of **35***b*. This compound slowly decomposed on heating 230–260 °C.

7-β-(Aminophenoxyacetoyl)-3-methyl-Δ³-O-2-isocephem-4-carboxylic Acid 35c

Benzyl ester **34***c* (100 mg; 0.237 mmol) was dissolved in a mixture of absolute ethanol (10 ml) and tetrahydrofuran (7 ml). 10% Pd–C (100 mg) was carefully added and the mixture was hydrogenated at atmospheric pressure. Hydrogen uptake was complete after *ca.* 7 min. The catalyst was filtered off and washed once with EtOH. The EtOH was removed *in vacuo* leaving 90 mg of partly crystalline residue. The residue was crystallized from acetone–ether to give **35***c*, mp 171–172 °C (dec.), 65 mg (84%).

7-β-(Aminophenoxyacetoyl)-3-benzyl-Δ³-O-2-isocephem-4-carboxylic Acid 35d

Compound **34***d* (0.49; 1 mmol) was dissolved in ethyl acetate (100 ml) and glacial acetic acid (10 ml), 20% $Pd(OH)_2$-on-carbon (0.50 g) was added, and the mixture was agitated on a Paar apparatus at 60 psi of H_2 for 2 h. The solid was filtered off on Celite and the filtrate evaporated to dryness. The residue was extracted with saturated $NaHCO_3$, the aqueous phase was acidified with 10% HCl, and extracted with CH_2Cl_2. This was then washed with water, dried over Na_2SO_4 and evaporated to dryness. The resulting solid was recrystallized from benzene and gave white crystals, mp 123–125 °C. There was obtained 0.08 g (20%) of **35***d*.

7-β-(Aminophenoxyacetoyl)-3-phenethyl-Δ³-O-2-isocephem-4-carboxylic Acid 35e
