*The valences (S) were calculated from the distances (R) by means of the expression $S = (R/R_0)^{-N}$ (7) where $R_0 = 2.843$, $N = 7$ for Rb—I(8) and $R_0 = 2.362$, $N = 7.5$ for Ag—I.

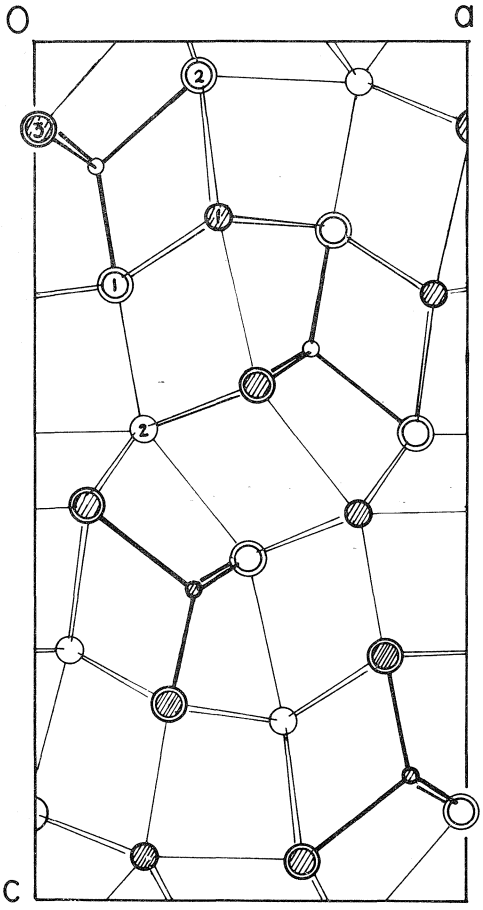

FIG. 1. Rb_2AgI_3 projected down the b axis. The double circles are I, large circles Rb, small circles Ag. Atoms at $y = 3/4$ are shaded; those at $y = 1/4$ are unshaded.

Raman Procedure

Single crystals of Rb_2AgI_3 approximately 3 mm on an edge were polished on the faces perpendicular to the crystallographic axes and mounted on an X-ray goniometer. All spectra were measured at room temperature. An argon ion laser provided plane polarised radiation of 100 mW at 5145 Å. The laser beam was focused onto the crystal which had been mounted with one of the crystallographic axes parallel to the incoming beam. A Babinet compensator before the sample and a polariser in the scattered beam permitted the selection of various components of the Raman tensor. The spectrum of the scattered light was analysed with a SPEX 1400 double monochromator, the total instrumental width (laser and spectrometer) being 1.5 cm^{-1} for a slit width of 200 μm.

Discussion of Raman Spectrum

The scattering geometry can be described by the symbol $x(uv)y$ where x is the crystal axis parallel to the direction of the incident beam, y that parallel to the scattered beam, and u and v are the crystallographic axes parallel to the direction of polarisation of the incident and scattered beam respectively.

The spectra are shown in Fig. 2. The scattering geometry $a(bb)c$ (Fig. 2a) should give the $12A_g$ modes. The spectrum shows 12 or 13 lines some of which may be overtone modes. The geometry $a(ba)b$ (Fig. 2b) should show the $6B_{1g}$ modes and six lines can be seen. Similarly $a(ca)c$ (Fig. 2c) shows the expected 12 lines of the B_{2g} spectrum and $a(cb)c$ (Fig. 2d) shows the expected 6 lines of the B_{3g} spectrum.

Two features of the spectra are noteworthy; namely, the absence of any lines at frequencies above 112 cm^{-1} (none of the spectra show any features between 112 cm^{-1} and 1800 cm^{-1}), and the broadening of the higher frequency peaks.

The absence of high frequency modes is expected for a crystal with weak bonds. Table 5 lists a series of stretching force constants determined spectroscopically for a number of bonds

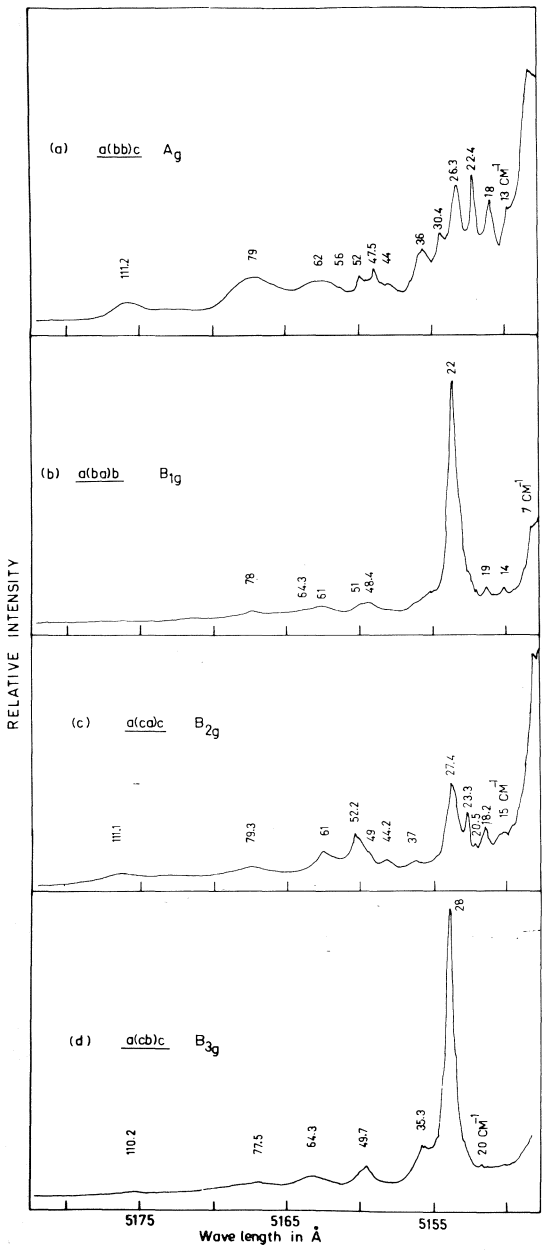

FIG. 2. Polarized Raman spectrum of Rb_2AgI_3. The scattering geometry and the corresponding symmetry species are indicated in the figure. The observed line positions are also marked in wave numbers, cm^{-1}.

with relatively small bond valence. There is a correlation between bond valence and force constant which allows one to estimate stretching force constants of around 0.30 mdyn $Å^{-1}$ (30 N m^{-1}) for Ag—I and 0.12 mdyn $Å^{-1}$ (12 N m^{-1}) for Rb—I. For such force constants the Ag—I stretching vibration would be around 93 cm^{-1} and the Rb—I stretching vibration around 63 cm^{-1}. Since the stretching vibrations generally have the highest frequency we do not expect to find lines much above 100 cm^{-1}. The Ag—I(terminal) stretching vibration will lie entirely in the mirror plane and, therefore, will appear in A_g or B_{2g}. The band at 111 cm^{-1} appears in both and probably represents factor group splitting of the Ag—I symmetric stretching vibration. Because there are many possibilities for two phonon and overtone bands, it is not possible to definitely assign such bands with any certainty.

JACKY KRESS et LUCIEN GUIBÉ. Can. J. Chem. **55**, 1515 (1977).

Des signaux de résonance quadripolaire nucléaire du brome (isotopes 79 et 81) ont été observés, à 77 K, dans quelques composés organomagnésiens cristallisés du type $RMgBr{\cdot}nR'_2O$, et dans $MgBr_2{\cdot}nEt_2O$. Les fréquences correspondantes, relativement basses (de l'ordre de 33 MHz pour le ^{81}Br, à comparer avec 220 MHz pour une liaison $\diagdown C—Br$) montrent le caractère fortement ionique de la liaison —Mg—Br, tandis que leur regroupement dans un intervalle restreint (30–42 MHz) suggère que la liaison Mg—Br est peu affectée par les changements des radicaux R ou R′ dans la série étudiée. Cependant l'évolution de la fréquence de résonance dans cet intervalle peut s'interpréter en fonction de la nature des groupes R et R′.

JACKY KRESS and LUCIEN GUIBÉ. Can. J. Chem. **55**, 1515 (1977).

Bromine nuclear quadrupole resonance signals corresponding to both isotopes ^{79}Br and ^{81}Br have been observed, at 77 K, in some crystallized organomagnesium bromides of formula $RMgBr{\cdot}nR'_2O$, and in $MgBr_2{\cdot}nEt_2O$. The low value of the resonance frequencies, of about 33 MHz to be compared to 220 MHz for a typical $\diagdown C—Br$ bond, shows the ionic character of the Mg—Br bond. The fact that the resonance frequencies are found within a restricted frequency range, between 30 and 42 MHz, shows that the Mg—Br bond is only slightly affected by the nature of the radicals R and R′ through the series studied. However the variation of the bromine resonance frequency in this series may be interpreted in terms of the nature of R and R′.

Introduction

Le grand nombre d'études physicochimiques déjà consacrées aux composés organomagnésiens s'explique par l'importance de ces composés en synthèse organique et par la complexité des problèmes que soulève leur constitution; la connaissance de cette dernière est évidemment d'un intérêt fondamental pour l'étude des réactions chimiques. Ces études physicochimiques ont porté non seulement sur les solutions organomagnésiennes, mais aussi sur les cristaux isolables à partir de ces solutions et elles ont fait appel à des techniques les plus diverses. La diffraction des rayons X, en particulier, a permis d'établir la structure des composés définis solides, obtenus à partir des solutions dans les éthers, et de montrer que ce sont des complexes moléculaires contenant une ou plusieurs molécules de solvant coordonnées au magnésium; c'est notamment le cas du diéthérate de bromure d'éthylmagnésium, $EtMgBr{\cdot}2Et_2O$ (1). Les spectrométries infra-rouge et Raman ont récemment permis de montrer que ces mêmes complexes constituent généralement l'espèce dominante dans les solutions et que les résultats obtenus sur les organomagnésiens cristallisés (1) peuvent souvent être étendus aux composés en solution (2).

Il nous a semblé souhaitable de compléter l'étude de ces complexes en faisant appel à une autre technique d'étude de l'état cristallisé, la résonance quadripolaire nucléaire (rqn), qui constitue une méthode de recherche particulièrement adaptée à l'étude des liaisons chimiques et des distributions de charges électriques autour des noyaux résonnants. Elle ne semble pas encore

avoir été utilisée pour l'étude de dérivés magnésiens, bien que les noyaux d'halogènes présents dans les halogénures de magnésium et les organomagnésiens mixtes possèdent un moment quadripolaire favorable et aient été largement étudiés dans des nombreux composés organiques et minéraux.

Nous présentons ici les premiers résultats obtenus sur des complexes bromés afin de tenter (*i*) de les caractériser et d'analyser leur structure, (*ii*) de préciser l'ionicité de la liaison magnésium–halogène et d'apporter ainsi un support expérimental aux conclusions des calculs de chimie quantique (3), (*iii*) d'examiner l'influence de la nature du ligand organique et du solvant sur la répartition des électrons dans ces complexes.

Aspects expérimentaux

A. Préparation des composés

Les composés étudiés étant très sensibles à l'oxygène et à l'humidité de l'air, toutes les manipulations ont été effectuées sous atmosphère inerte. Les solvants et les halogénures organiques de départ ont été distillés sous azote juste avant leur utilisation.

Les solutions des organomagnésiens mixtes MeMgBr, EtMgBr, *tert*-BuMgBr, PhMgBr, MeMgI et EtMgI dans l'éther éthylique, PhMgBr dans le tétrahydrofuranne et EtMgBr dans l'éther isopropylique ont été obtenues par la méthode classique (4) d'addition des halogénures MeBr, EtBr, *tert*-BuBr, PhBr, MeI et EtI sur le magnésium dans le solvant approprié; les solutions de $MgBr_2$ et de MgI_2 dans l'éther éthylique l'ont été par addition de dibromoéthane et d'iode, respectivement (5).

Les composés définis $MeMgBr{\cdot}2Et_2O$ (6), $EtMgBr{\cdot}2Et_2O$ (1), $MeMgI{\cdot}2Et_2O$ (6), $EtMgI{\cdot}2Et_2O$ (2), $PhMgBr{\cdot}2Et_2O$ (7), PhMgBr·2THF (8), $[EtMgBr{\cdot}(iso\text{-}Pr)_2O]_2$ (9), $MgBr_2$ (10) et $MgI_2{\cdot}2Et_2O$ (5) ont été isolés à l'état cristallisé à partir de ces solutions selon les procédés décrits dans les références citées. Les cinq premiers sont liquides à la température ambiante (2, 6, 7). Les complexes $MgBr_2{\cdot}Me_2O$ et $MgBr_2{\cdot}2Me_2O$ ont été obtenus par piégeage d'éther méthylique sur le bromure de magnésium non solvaté (10).

A partir des solutions de bromure de magnésium dans l'éther éthylique on peut obtenir, selon les conditions expérimentales, trois complexes de stoechiométrie 1–1, 1–2 et 1–3 (11). Notre étude a porté sur trois échantillons différents: les cristaux obtenus par refroidissement d'une solution concentrée et maintenus au contact du solvant (I), ceux obtenus par une évaporation limitée de l'éther à la rampe à vide et conservés en atmosphère d'éther (II) et ceux obtenus par un pompage plus poussé de l'éther à température ambiante (III) pour lesquels la microanalyse a montré qu'il s'agit du monoéthérate $MgBr_2{\cdot}Et_2O$.

Dans le cas du bromure de tertiobutylmagnésium, le magnésien n'a jamais été isolé de sa solution dans l'éther éthylique. Nous avons d'une part étudié les cristaux obtenus par refroidissement d'une solution concentrée et maintenus au contact du solvant (I) et, d'autre part, le solide obtenu par évaporation poussée de l'éther à la rampe à vide à 25°C (II).

B. Obtention des spectres de rqn

Les signaux de résonance ont été recherchés à l'aide d'un spectromètre à superréaction de type classique avec stabilisation du niveau de bruit, modulation Zeeman antisymétrique, amplification sélective, détection de phase et enregistrement. Tous les composés préparés, contenus dans des ampoules de verre Pyrex scellées, ont été étudiés à 77 K.

Les échantillons liquides à la température ambiante ont été refroidis avec précaution pour éviter la formation d'un verre; en particulier, pour les échantillons $MgBr_2{\cdot}nEt_2O$(I) et *tert*-$BuMgBr{\cdot}nEt_2O$(I), les raies non trouvées au cours d'une première recherche, n'ont pu être observées qu'à la suite d'une recristallisation par réchauffage modéré (début de fusion) et refroidissement lent de ces échantillons.

Les premiers essais, effectués sur $MgBr_2$ et $MgBr_2{\cdot}nEt_2O$(II), ont couvert une gamme de fréquence étendue, car l'ordre de grandeur des fréquences de résonance du brome dans ce type de composé était difficile à évaluer à priori. Les autres échantillons ont été étudiés entre 30 et 50 MHz environ.

Les fréquences des signaux ont été mesurées à l'aide d'un générateur haute fréquence relié à un fréquencemètre compteur à quartz. Malgré la grande précision de cet instrument, la précision des déterminations de fréquences de résonance n'excède pas ± 30 kHz, en raison de la largeur des raies, de leur faible rapport signal/bruit compris le plus souvent entre 4 et 10 et de la difficulté de repérer la position exacte de la composante centrale dans le spectre de superréaction. L'exactitude des pointés a pu être contrôlée par l'observation independante des signaux des deux isotopes ^{79}Br et ^{81}Br du brome dont les fréquences de résonance sont dans le rapport, 1.197, des moments quadripolaires.

Résultats et discussion

Des signaux ont été observés dans 9 échantillons parmi les 16 préparés et étudiés; les raies dues aux deux isotopes ^{79}Br et ^{81}Br ont été observées dans la majorité des cas. Les tableaux 1 et 2 donnent les fréquences de tous les signaux observés; cependant, seules celles de l'isotope ^{81}Br seront considérées au cours de la discussion. Les composés dans lesquels aucune résonance n'a été détectée sont les suivants: $MgBr_2$ (4.7–55), $MgBr_2{\cdot}2Me_2O$ (20–50), $MgBr_2{\cdot}Me_2O$ (25.8–59.6), $MeMgBr{\cdot}2Et_2O$ (24.3–59.4), $MgI_2{\cdot}2Et_2O$ (13.6–47.8), $MeMgI{\cdot}2Et_2O$ (30.6–50.1), $EtMgI{\cdot}2Et_2O$ (31.9–42); les nombres entre parenthèses indiquent les limites, en MHz, de la gamme de fréquence explorée pour chaque composé.

A. Remarques générales

(*1*) L'observation d'un signal unique, pour chacun des isotopes du brome, dans les quatre premiers composés du tableau 1 qui ont fait par ailleurs l'objet d'études radiocristallographiques est compatible avec les structures cristallines déterminées (1, 7–9) et montre que tous les

†Pour $MgBr \cdot nEt_2O$ seule une valeur moyenne de la fréquence de résonance de chaque isotope est donnée ici. Les valeurs de chacune des résonances observées sont données dans le tableau 2.
‡Signal très faible, la raie de ^{79}Br n'a pas été recherchée.

atomes de brome sont équivalents dans chacun de ces complexes.

Par contre, l'observation de deux résonances distantes d'environ 8 MHz dans le complexe $MgBr_2{\cdot}2Et_2O$ (*cf. B-3*, plus loin) indique l'existence de deux liaisons Mg—Br différentes et semble en contradiction avec l'étude radiocristallographique (12) qui montre quatre distances Mg–Br nettement différentes dans la maille cristalline.

(*2*) La fréquence moyenne de résonance dans les différents composés est d'environ 33 MHz et peut être comparée aux fréquences du brome dans des composés organiques à liaison essentiellement covalente, de l'ordre de 200 à 300 MHz (13), dans des complexes d'un autre métal tel que l'aluminium, 83.5 MHz pour $AlBr_3{\cdot}Et_2O$ (14), et dans des sels ioniques comme $BaBr_2{\cdot}nH_2O$ ($n = 0, 1, 2$): $3.8 < f < 22$ MHz (15).

Cette comparaison permet d'apprécier le caractère ionique de la liaison Mg—Br dans les composés organomagnésiens étudiés. Les fréquences de rqn du brome y sont particulièrement basses, apportant la preuve expérimentale directe d'une ionicité importante. Cette observation est en accord avec la faible électronégativité du magnésium et avec les résultats des études théoriques effectuées sur des molécules modèles linéaires (3).

Il est possible d'obtenir une valeur de l'ionicité par application de la théorie de Townes et Dailey (16, 17) prise sous sa forme simplifiée

$$e^2Qq = (1 - s^2)(1 - I)e^2Qq_{at}$$

s^2 mesurant le taux d'hybridation "*s*" de la liaison Mg—Br sur le brome, est pris égal à 0.25 par analogie avec le cas du chlore (17); e^2Qq_{at} est le couplage atomique du $^{81}Br \simeq -643$ MHz (16) et e^2Qq est le couplage du composé étudié valant deux fois la fréquence de résonance mesurée quand on néglige l'asymétrie η du couplage quadripolaire, soit $\simeq 66$ MHz. Il vient alors $I = 0.86$. Cette valeur doit être considérée avec précaution étant donné les nombreuses approximations faites dans le calcul. Elle est toutefois très voisine de celle obtenue à partir de la différence d'électronégativité suivant la relation (16) $I = (x_A - x_B)/2 = 0.80$ avec $x_{Br} = 2.8$ et $x_{Mg} = 1.2$, bien que cette dernière néglige en particulier l'effet des molécules d'éther coordonnées au magnésium.

(*3*) Les fréquences des différentes raies se situent toutes entre 30 et 42 MHz (*cf.* tableau 1) et restent ainsi bien groupées, suggérant que, malgré la faible valeur du gradient de champ électrique à l'emplacement des noyaux de brome, ce sont les électrons de la liaison Mg—Br qui y apportent la principale contribution bien plus que le champ cristallin. La liaison Mg—Br présente ainsi, dans la série étudiée, une structure bien définie, caractérisée par la fréquence de résonance quadripolaire du ^{81}Br voisine de 35 MHz et peu modifiée quand les radicaux R et R′ sont changés.

B. Etude particulière des différents composés

(*1*) Les trois composés $EtMgBr{\cdot}2Et_2O$, $PhMgBr{\cdot}2Et_2O$ et PhMgBr·2THF possèdent une structure moléculaire analogue comportant des motifs monomères dans lesquels les quatre ligands forment un arrangement tétraédrique autour du magnésium (1, 7, 8). Les fréquences de résonance du brome doivent donc refléter essentiellement les effets inductifs dus aux trois autres ligands portés par le magnésium et doivent permettre d'analyser directement l'influence de la nature du groupe organique et du solvant sur la distribution des électrons dans les complexes.

Effectivement, les variations de fréquence observées à la suite de la substitution de l'un des ligands s'interprètent bien en termes d'effets inductifs. D'une part le remplacement d'un groupe éthyle par un groupe phényle, plus électronégatif, entraîne une élévation de fréquence de 3 MHz (tableau 1) résultant d'un déplacement des électrons du brome vers le magnésium et le groupe phényle. Un effet analogue est observé pour la fréquence de résonance du chlore lors du passage de $EtCH_2Cl$ (32.968 MHz) à $PhCH_2Cl$ (33.627 MHz) ou de EtCl (32.704 MHz) à PhCl (34.622 MHz) (13).

D'autre part, le remplacement des molécules d'éther éthylique par celles de tétrahydrofuranne, meilleur donneur d'électrons, entraîne un abaissement de fréquence de 2.3 MHz (tableau 1) indiquant que les électrons se déplacent, cette fois, vers le brome. Une telle variation est compatible avec la différence observée entre les fréquences moyennes des bromes terminaux du dimère Al_2Br_6 (95.740 MHz) (13) et celles du complexe $AlBr_3 \cdot Et_2O$ (83.5 MHz) (14); l'abaissement de la fréquence est dans ce cas dû au déplacement d'électrons vers le brome à la suite de la fixation d'une molécule d'éther éthylique sur l'aluminium.

Ces observations sont en bon accord avec les conclusions du paragraphe *A-3* ci-dessus. Elles montrent en effet que ce sont bien les électrons de liaison qui sont principalement responsables du gradient de champ électrique vu par le noyau de brome; elles indiquent en outre que le magnésium transmet jusqu'au brome les effets des déplacements de charge induits par le remplacement du groupement organique R ou des molécules de solvant liées au magnésium et ceci malgré le caractère peu covalent des liaisons dans ces composés organomagnésiens.

(*2*) Le composé $[EtMgBr \cdot (iso\text{-}Pr)_2O]_2$ est constitué de dimères formés par l'intermédiaire de deux ponts brome entre deux atomes de magnésium. Chaque magnésium est tétracoordonné et lié à un groupe éthyle, une molécule d'éther isopropylique, et deux atomes de brome (9). La fréquence de résonance des atomes de brome en pont entre deux autres atomes étant, en principe, inférieure à celle des bromes terminaux (17), comme cela a été observé pour le dimère Al_2Br_6 dont les bromes en pont résonnent à 81.815 MHz et les bromes terminaux à 96.426 et 95.055 MHz (13, 17), la fréquence du brome de l'organomagnésien est de ce point de vue attendue à une valeur inférieure à celle du complexe $EtMgBr \cdot 2Et_2O$. Par contre, le remplacement dans la sphère de coordination du magnésium des deux molécules d'éther éthylique par un atome de brome et une molécule d'éther isopropylique, tous les deux plus faibles donneurs d'électrons que l'éther éthylique, laisse prévoir par effet inductif une fréquence de résonance supérieure à celle de $EtMgBr \cdot 2Et_2O$. La fréquence obtenue, 30.23 MHz, est en fait voisine de celle du composé $EtMgBr \cdot 2Et_2O$, ce qui est compatible avec l'existence des deux effets précédents qui semblent se compenser.

(*3*) Les trois échantillons I, II et III de complexes $MgBr_2 \cdot nEt_2O$ donnent lieu à des spectres différents, bien que les fréquences de certains signaux semblent très voisines. Ainsi, les signaux à 33.71 et 41.94 MHz dans I sont très voisins des signaux à 33.72 et 42.13 MHz dans II; de même les signaux à 31.79 et 32.66 MHz dans II sont voisins des signaux à 31.84 et 32.67 MHz dans III ($MgBr_2 \cdot Et_2O$). Ces ressemblances entre les spectres apparaissent de manière plus nette sur le diagramme de la fig. 1, où les différents groupes de raies ont été repérés par les lettres minuscules *a*, *b*, *c* et *d*; elles sont vraisemblablement dues à la présence de mélanges des trois complexes (11) déjà signalés à propos de la préparation des composés et les petits écarts de fréquence constatés sont dans les limites de précision de la détermination des fréquences, rendue difficile par la largeur ($\simeq 20$ kHz) des raies enregistrées. Compte tenu des conditions de préparation des trois échantillons, l'échantillon I contiendrait les composés les plus solvatés $MgBr_2 \cdot 2Et_2O$ et $MgBr_2 \cdot 3Et_2O$, ce dernier donnant lieu à la raie à 38.12 MHz, et l'échantillon II les composés $MgBr_2 \cdot Et_2O$ et $MgBr_2 \cdot 2Et_2O$, tandis que l'échantillon III est du monoéthérate. Les raies *a* étant dues au monoéthérate, les raies *b* correspondent donc au diéthérate et les raies *c* au triéthérate; les raies *d*, apparues dans l'échantillon I après que celui-ci ait été recristallisé (I′), sont de fréquences proches de celles des raies *a* du monoéthérate, mais néanmoins suffisamment éloignées, par rapport à la marge d'erreur dans la détermination des fré-

TABLEAU 2. Fréquences (MHz) des rqn de ^{79}Br et ^{81}Br dans les composés $MgBr_2 \cdot nEt_2O$ à 77 K

Composés	^{81}Br	^{79}Br	Fréquence*
$MgBr_2 \cdot nEt_2O$ (I)	33.71	40.35	*b*
	38.12	45.67	*c*
	41.94	50.35	*b*
(I′)	32.37	38.75	*d*
	32.87	39.35	*d*

	38.23	45.73	*c*
	42.13	50.43	*b*
(II)	31.79	38.06	*a*
	32.66	39.01	*a*
	33.74	40.37	*b*
	42.13	50.52	*b*
(III)	31.84	38.08	*a*
	32.67	39.14	*a*

*Les fréquences *a*, *b* et *c* correspondent respectivement au mono-, di- et triéthérate de $MgBr_2$. Les fréquences *d* seraient dues à une variété cristalline du monoéthérate.

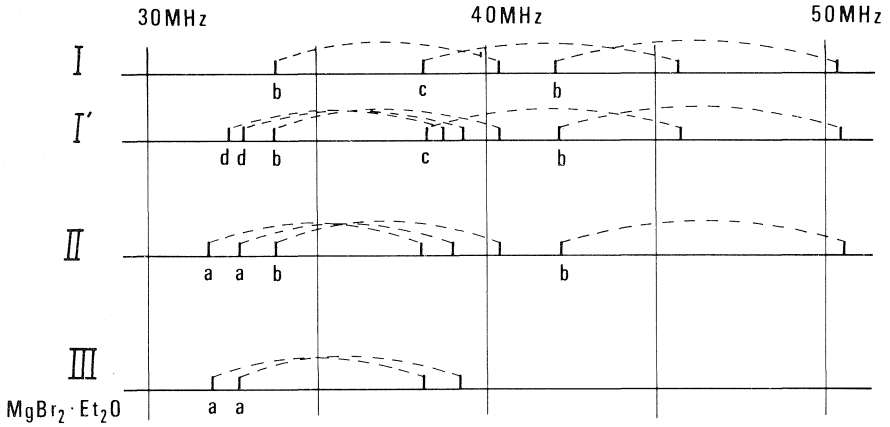

FIG. 1. Comparaison des spectres des différents échantillons I, I′, II et III de $MgBr_2 \cdot n Et_2O$ étudiés. Les raies correspondant aux deux isotopes ^{79}Br et ^{81}Br sont reliées par une ligne pointillée. La raie en pointillé dans le spectre I′ n'a pas été observée par suite de la présence, à cet endroit, d'une raie parasite intense.

quences, pour que les deux groupes de raies ne puissent être confondus. Elles correspondent, très vraisemblablement à une autre variété cristalline du monoéthérate.

La fréquence moyenne des résonances dans ces complexes de $MgBr_2$, environ 35 MHz, est supérieure à celle des composés précédents comme le laisse prévoir l'électronégativité du brome supérieure à celle des groupes éthyle et phényle. Des différences analogues ont été observées par ailleurs pour la fréquence de ^{79}Br dans Me_2InBr (68.75 MHz) et dans $MeInBr_2$ (102.92 MHz) (18), ainsi que pour la fréquence de ^{35}Cl dans $EtCH_2Cl$ (32.968 MHz) et $BrCH_2Cl$ (36.14 MHz) (13).

(*4*) Les deux échantillons de *tert*-BuMgBr·$n Et_2O$ donnent aussi lieu à des signaux de fréquences différentes, indiquant une composition ou une structure différente. Remarquons que leurs fréquences sont supérieures à celles des complexes EtMgBr·$2Et_2O$ et $[EtMgBr \cdot (iso\text{-}Pr)_2O]_2$. Or, un groupe tertiobutyle étant considéré comme moins électronégatif qu'un groupe éthyle, le remplacement du second par le premier devrait entraîner un abaissement de fréquence comme celui observé pour le chlore dans *tert*-BuCl (31.065 MHz) comparé à EtCl (32.704 MHz) (13). Les fréquences des deux échantillons de *tert*-BuMgBr·$n Et_2O$ ne semblent donc pas compatibles avec l'existence ni d'un diéthérate monomère *tert*-BuMgBr·$2Et_2O$ semblable à EtMgBr·$2Et_2O$, ni d'un monoéthérate dimère $[tert\text{-}BuMgBr \cdot Et_2O]_2$ semblable à $[EtMgBr \cdot (iso\text{-}Pr)_2O]_2$; d'autant plus que dans ce dernier cas, le remplacement des molécules $(iso\text{-}Pr)_2O$ par des molécules Et_2O, meilleurs donneurs d'électrons, serait un facteur supplémentaire d'abaissement de la fréquence de résonance du brome.

Par contre les fréquences de 33.72 MHz pour l'échantillon I, de 31.75 et 32.66 MHz pour l'échantillon II, sont très voisines des fréquences des signaux correspondants à $MgBr_2 \cdot 2Et_2O$ et $MgBr_2 \cdot Et_2O$ respectivement. Cette double coïncidence n'est certainement pas fortuite mais suggère que le magnésien mixte s'est dismuté en bromure de magnésium et ditertiobutylmagnésium selon un processus analogue à celui observé pour les halogénures de méthylmagnésium (6). Le bromure de magnésium ainsi obtenu serait disolvaté dans l'échantillon I et monosolvaté dans l'échantillon II pour lequel l'éther éthylique en excès a été évacué par pompage sur la rampe à vide. Cette description nous paraît très vraisemblable quoique tous les signaux de rqn des deux complexes de $MgBr_2$ (à une et deux molécules d'éther) n'aient pas été observés (le rapport signal sur bruit des signaux cités dans le tableau est faible), et elle semble confirmée par une étude parallèle (non publiée) des spectres Raman.

Conclusion

Cette première étude d'organomagnésien par rqn met en évidence les possibilités de cette technique pour l'étude de leur structure électronique et moléculaire, ainsi que pour l'identification des complexes présents dans un échantillon solide comme dans le cas des complexes de

$MgBr_2$ avec l'éther éthylique. A la suite de cette première étude, la poursuite de recherches sur ces composés apparaît souhaitable pour que la discussion des résultats obtenus repose sur une base expérimentale élargie.

Coefficients *B* de viscosité dans les systèmes ternaires aqueux. I. NaCl – alcool *tert*-butylique – eau et Bu_4NBr – alcool *tert*-butylique – eau à 25°C

MARC PALMA ET JEAN-PIERRE MOREL

Laboratoire d'Etude des Interactions Solutés–Solvants, Groupe de Chimie Physique, Université de Clermont, Les Cézeaux, B.P. 45, 63170 Aubière, France

Reçu le 27 septembre 1976

MARC PALMA et JEAN-PIERRE MOREL. Can. J. Chem. **55**, 1521 (1977).

Nous avons mesuré le coefficient *B* de viscosité des électrolytes NaCl et Bu_4NBr dans les mélanges hydroorganiques contenant jusqu'à 40% en poids d'alcool *tert*-butylique (TBA), ainsi que celui du non-électrolyte TBA dans les solutions aqueuses salines de NaCl et de Bu_4NBr. Les variations de *B* sont comparées à celles des grandeurs thermodynamiques de transfert ΔH_t^0 et ΔS_t^0 des solutés étudiés dans ces différents milieux. La contribution du soluté à l'enthalpie libre d'activation de viscosité est également calculée.

MARC PALMA and JEAN-PIERRE MOREL. Can. J. Chem. **55**, 1521 (1977).

We have measured the viscosity coefficient *B* of the electrolytes NaCl and Bu_4NBr in aqueous-organic mixtures containing up to 40% by weight of *tert*-butyl alcohol (TBA), as well as that of the non-electrolyte TBA in aqueous solutions of the salts NaCl and Bu_4NBr. The variations of *B* were compared with those of the thermodynamic quantities ΔH_t^0 and ΔS_t^0 of the solutes studied in these different media. The contribution of the solute to the free enthalpy of activation of viscosity has also been calculated.

[Journal translation]

Introduction

Le coefficient *B* de viscosité des électrolytes en mélange hydroorganique n'a pas fait l'objet de nombreuses études systématiques. La plupart des auteurs qui ont abordé ce sujet sont cités dans la revue de Padova (1) qui traite de la solvatation en milieux non aqueux et mixtes. Le travail le plus complet dans le domaine a été publié récemment par Feakins *et al.* (2) qui ont étudié les chlorures alcalins en milieu eau–méthanol.

La grandeur *B* peut se définir comme la limite lorsque la concentration molaire *c* tend vers 0 de:

$$\frac{\eta/\eta_0 - 1 - A\sqrt{c}}{c}$$

où η et η_0 sont les viscosités de la solution et du solvant, *A* le coefficient de la loi limite de Falkenhagen (3) qui rend compte des interactions ioniques pour ce phénomène. (Pour les non électrolytes: $A = 0$.)

Ainsi, en solution diluée, la viscosité relative obéit-elle en général à la loi de Jones–Dole (4):

$$[1] \qquad \eta_r = \eta/\eta_0 = 1 + A\sqrt{c} + Bc$$

B, caractéristique des interactions soluté–solvant comme le montre son additivité, peut donner des informations précieuses sur la solvatation. En solution aqueuse, les déterminations de *B* concernant tant les électrolytes que les non-électrolytes sont d'ailleurs fort nombreuses (5–10).

Nous avons mis au point un dispositif automatique de mesure de la viscosité des solutions qui devrait nous permettre d'acquérir un assez grand nombre de données suffisamment précises dans le domaine des mélanges hydroorganiques. Nous abordons ce projet avec l'étude des électrolytes types NaCl et Bu_4NBr dans les mélanges aqueux contenant jusqu'à 40% en poids d'alcool *tert*-butylique (TBA). Les propriétés thermodynamiques de nombreux solutés, et en particulier des halogénures alcalins, dans ces solvants, ont fait l'objet de travaux au laboratoire (11, 12); il nous sera ainsi possible de confronter ces grandeurs à la propriété de transport *B*. Afin de pouvoir examiner ces systèmes sous l'angle des interactions soluté–cosolvant où les deux espèces jouent un rôle symétrique, nous avons également mesuré le coefficient *B* du TBA dans les solutions salines de NaCl et de Bu_4NBr; cette approche a également fait l'objet de récents travaux dans le domaine des propriétés thermodynamiques (13).

Partie expérimentale

Dispositif

Notre dispositif permet de mesurer simultanément la viscosité et la masse volumique d'un liquide à une température donnée. Sa description détaillée a déjà été faite

dans une précédente publication (14). Il est constitué essentiellement (*i*) d'un viscosimètre à capillaire type Ubbelohde (diamètre intérieur du capillaire: 0.5 mm), (*ii*) d'un densimètre digital Anton Paar, (*iii*) d'une burette à dilution.

Il suffit d'introduire une masse déterminée de solvant dans le réservoir du viscosimètre et de remplir la burette d'une solution de concentration connue. La suite de la manipulation (mesure des temps d'écoulement, de la période du densimètre, neuf répétitions, six dilutions et impressions) se fait de façon entièrement automatique selon un programme prédéterminé. Afin que la composition du mélange reste constante pendant la durée des mesures, des saturateurs contenant un solvant identique à celui étudié isolent l'intérieur du dispositif de l'air atmosphérique. Le circuit de régulation thermique du densimètre et du viscosimètre donne sur une longue période une stabilité de $\pm 2 \times 10^{-3}$ K.

Réactifs

L'alcool *tert*-butylique a été purifié au laboratoire selon la méthode habituelle (15). Le chlorure de sodium est un produit pur pour analyses 'Prolabo' et le bromure de tétrabutyl-ammonium a été recristallisé dans l'acétate d'éthyle. L'eau est tridistillée dans un appareil en quartz. Toutes les solutions ont été filtrées sur un verre fritté de porosité n° 4.

Viscosités

La viscosité relative η_r se détermine par

$$[2] \qquad \eta_r = \eta/\eta_0 = \rho t/\rho_0 t_0$$

masses volumiques et temps d'écoulement relatifs respectivement à la solution et au solvant. Le volume de la boule de mesure du viscosimètre étant faible, la correction d'énergie cinétique d'Hagenbach (16) est négligeable. Nous avons déjà exposé ailleurs (14) de façon détaillée notre méthode d'exploitation des données numériques et en particulier la façon de déterminer le coefficient B. Nous traçons systématiquement les graphes $(\eta_r - 1)/\sqrt{c} = f(\sqrt{c})$ et $(\eta_r - 1 - A\sqrt{c})/c = f(c)$. Les coefficients A de la loi de Jones–Dole pour les différents mélanges ont été calculés à l'aide de la formule de Falkenhagen (3) et des données de la littérature (17). Le tracé des graphes $(\eta_r - 1)/\sqrt{c} = f(\sqrt{c})$ nous a permis de constater un accord satisfaisant entre les valeurs expérimentales et calculées du coefficient A. Les coefficients B de TBA dans eau–NaCl et eau–Bu_4NBr ont été obtenus à l'aide d'une mesure effectuée sur le solvant pur et six mesures à des concentrations variant de 0.01 à 0.1 M environ. Les graphes $(\eta_r - 1 - A\sqrt{c})/c = B + Dc$ montrent un coefficient D (14) nul à la précision des mesures. Quant à Bu_4NBr dans eau–TBA, la détermination a été effectuée dans un domaine de concentration un peu plus élevé: 0.025 à 0.25 M environ. En effet, dans un intervalle de concentration compris en moyenne entre 0 et 0.06 M, la loi de Jones–Dole n'est pas vérifiée.

Ce phénomène a déjà été signalé par Kay (18) et Desnoyers (7). Enfin, NaCl dans eau–TBA montre un coefficient D non négligeable pour certains mélanges.

Les incertitudes relatives moyennes sur les mesures sont inférieures aux valeurs suivantes: (*i*) molarité c (de 0.01 à 0.25 M): $\pm 5 \times 10^{-3}$, (*ii*) temps d'écoulement (de 100 à 500 s): $\pm 5 \times 10^{-5}$, (*iii*) masses volumiques ρ (de l'ordre de 1 g cm^{-3}): $\pm 2 \times 10^{-5}$.

Volumes molaires

A partir des masses volumiques utilisées pour le calcul des viscosités, nous pouvons déterminer les volumes molaires apparents par la méthode classique (19). En ce qui concerne NaCl et Bu_4NBr dans eau–TBA, l'accord avec la littérature est satisfaisant (20); de même pour TBA dans les solutions salines (13).

Résultats et discussion

Pour les résultats voir les tableaux 1 et 2. Les variations du coefficient B des divers solutés avec la concentration en cosolvant, exprimée par sa molalité dans l'eau, sont représentées sur les figs 1 et 2. Pour les deux électrolytes, dans les mélanges eau–TBA, on observe des courbes décroissantes à point d'inflexion plus ou moins marqué vers $m_{TBA} = 2.5$ soit environ 16% en poids d'alcool dans le solvant; pour NaCl, B passe par un minimum vers $m_{TBA} = 4$ soit 23%. Pour TBA, le coefficient B décroît de façon sensiblement linéaire avec m_{NaCl}; avec m_{Bu_4NBr} les variations sont qualitativement et quantitativement comparables à celles de B (Bu_4NBr) dans eau–TBA.

Deux constatations s'imposent: (*i*) Bu_4NBr et TBA jouent des rôles symétriques et les variations de B, qui sont importantes, sont sans doute gouvernées par les interactions hydrophobes des chaînes hydrocarbonées des deux espèces; (*ii*) Pour NaCl et TBA, on observe que les variations de B ($^s\delta B$) sont analogues dans leurs formes à celles des enthalpies de transfert: $\Delta H^\theta_{t(w\rightarrow w+TBA)}$ de NaCl et $\Delta H^\theta_{t(w\rightarrow w+NaCl)}$ de TBA (13), ceci au signe près.

Si aucune théorie satisfaisante du coefficient B n'a été proposée, on peut dire, en résumé, que sa valeur est déterminée par deux contributions: celle due aux interactions soluté–solvant qui

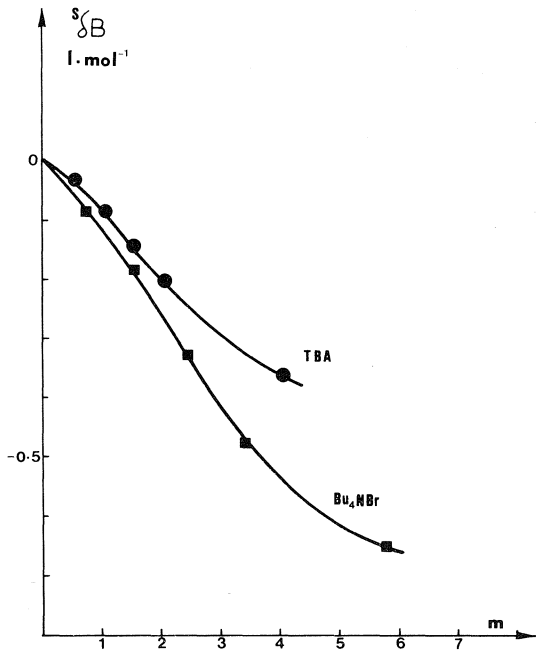

FIG. 2. Variations du coefficient B de Bu_4NBr et de TBA respectivement avec les molalités en TBA et Bu_4NBr dans l'eau.

modifient la structure du milieu et par suite sa viscosité; celle due au volume propre de l'espèce soluté dont le modèle macroscopique d'Einstein peut rendre compte. La première est prépondérante pour les petits ions minéraux; la deuxième, positive, prend de l'importance lorsque la molécule de soluté devient plus grosse que la molécule de solvant. Dans le premier cas, qui s'applique à NaCl, une corrélation intéressante a été proposée par Nightingale (21): dans l'eau, B varie linéairement avec l'entropie d'hydratation des ions. Quel que soit l'ion, ou l'électrolyte, on peut écrire:

$$[3] \qquad B = a + k\Delta S_h^{\theta}$$

On a observé que pour NaCl dans eau–TBA, $^{s}\delta B$ varie comme ΔH_t^{θ}, c'est-à-dire également comme ΔS_t^{θ} (12); aussi, comme nous le constatons sur la fig. 3, on observe une bonne corrélation linéaire en portant $^{s}\delta B$ en fonction de ΔS_t^{θ}. La relation de Nightingale peut fournir une explication, si elle reste valable dans les solvants concernés avec les mêmes valeurs de a et k; on aurait alors immédiatement:

$$[4] \qquad {}^{s}\delta B = k\Delta S_t^{\theta}$$

Malheureusement, la pente de la droite obtenue fig. 3 (5.3×10^{-3} ℓ J^{-1} K) n'est pas identique à celle de la corrélation de Nightingale (1.8×10^{-3} ℓ J^{-1} K). L'explication n'est donc pas aussi simple.

Avec pour modèle du processus de transport celui développé par Eyring (22), le coefficient B permet de calculer une grandeur d'activation: l'enthalpie libre d'activation de l'écoulement visqueux d'une solution de concentration donnée. Cette théorie a été appliquée par Nightingale et Benck (23) aux électrolytes dans l'eau et, récemment, par Feakins (2) aux solutions dans les mélanges eau–méthanol. Sans reprendre en détail un développement analogue à celui conduit par cet auteur, nous allons établir une expression qui conserve la forme logarithmique de $(1 + B)$ et reste satisfaisante lorsque B n'est pas petit devant 1.

La différence d'enthalpie libre d'activation entre 1 mol de solution de molarité c_i et 1 mol de solvant est:

$$[5] \qquad RT \ln (1 + Bc_i)\,\overline{V}/\overline{V}^0$$

où le volume molaire de la solution s'écrit en fonction de celui $\overline{V}^0$ du solvant:

$$[6] \qquad \overline{V} = \overline{V}^0 + x_i(\overline{V}_i - \overline{V}^0)$$

*m: molalité des sels respectifs dans l'eau.

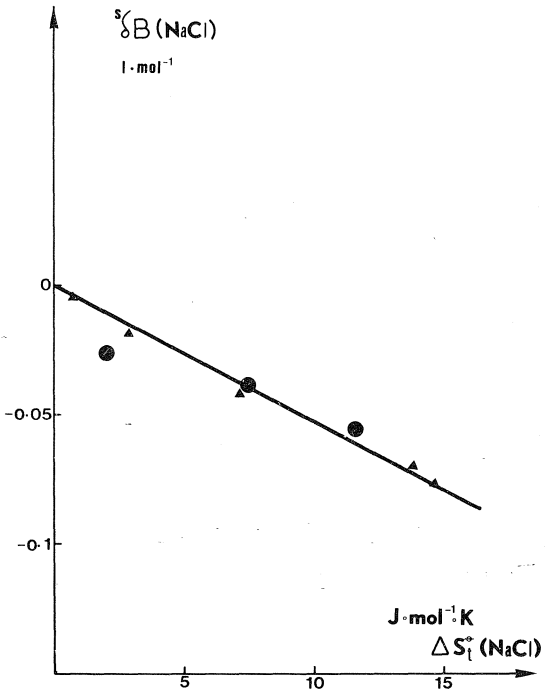

FIG. 3. Variations du coefficient B en fonction de l'entropie molaire de transfert pour NaCl dans les milieux eau–TBA: % en poids de TBA: ▲ 5, 10, 15, 20, 25; ● 30, 35, 40.

x_i est la fraction molaire en soluté de volume molaire partiel $\overline{V}_i$.

La différence ci-dessus est due au remplacement de x_i mole de solvant par x_i de soluté; elle est donc égale à $x_i(\Delta\mu_i^{\neq} - \Delta\mu_0^{\neq})$ où les $\Delta\mu^{\neq}$ représentent respectivement les contributions molaires du soluté et du solvant à l'enthalpie libre d'activation d'une solution. Dans la formule [5] n'intervient pas le terme $A\sqrt{c}$ puisque l'on s'intéresse uniquement aux interactions soluté–solvant, c'est-à-dire qu'on choisit comme état de référence la solution infiniment diluée; en complétant la définition de cet état de référence par la convention $c = 1$ on a alors:

$\overline{V}_i = \overline{V}_i^{\theta}$ volume molaire à dilution infinie

$x_i = c_i\overline{V}^0$ en solution diluée (avec $\overline{V}^0$ en ℓ mol^{-1})

$$[7]\quad \overline{V}/\overline{V}^0 = 1 + c_i(\overline{V}_i^{\theta} - \overline{V}^0) = 1 + c_i\Delta\overline{V}$$

et par suite:

$$[8]\quad \Delta\mu_i^{\neq} - \Delta\mu_0^{\neq} = \frac{RT}{\overline{V}^0}\ln(1 + B)(1 + \Delta\overline{V})$$

Cette expression donne donc la variation d'enthalpie libre d'activation quand on remplace 1 mol de solvant par 1 mol de soluté pour obtenir une solution idéale de molarité unité. En faisant les approximations $\ln(1 + \varepsilon) = \varepsilon$, on obtient l'expression proposée par Feakins:

$$[9]\quad \Delta\mu_i^{\neq} - \Delta\mu_0^{\neq} = \frac{RT}{\overline{V}^0}(B + \Delta\overline{V})$$

Dans cette expression, on peut considérer que le premier membre constitue la contribution à B d'interactions soluté–solvant; $\Delta\overline{V}$ est une contribution de volume telle que si $\Delta\overline{V} > 0$ (volume molaire partiel du soluté supérieur à celui du solvant) la valeur de B est diminuée d'autant. On voit donc que cette dernière contribution ne s'apparente en rien à l'effet de volume tel que le prévoit la relation d'Einstein dans laquelle B croît avec le volume du soluté.

Dans l'eau, (*i*) pour NaCl: $B = 79 \times 10^{-3}$ et $\Delta\overline{V} = -1.45 \times 10^{-3}$, (*ii*) pour Bu_4NBr: $B = 1200 \times 10^{-3}$ et $\Delta\overline{V} = 282 \times 10^{-3}$. Pour ce dernier sel, la contribution de volume n'est donc pas négligeable; de même pour le non-électrolyte TBA: $B = 387 \times 10^{-3}$ et $\Delta\overline{V} = 69 \times 10^{-3}$. L'importance relative des deux contributions a été analysée par Feakins (2).

Intéressons-nous maintenant à l'effet d'un changement de solvant. Comme l'a souligné l'auteur précédent, dans la mesure où l'on s'intéresse à l'interaction soluté–solvant, ce sont les variations de $\Delta\mu_i^{\neq}$ qui sont intéressantes. B varie d'un solvant à l'autre du fait des variations de $\Delta\mu_i^{\neq}$ mais aussi des caractéristiques propres du solvant: $\overline{V}^0$ et $\Delta\mu_0^{\neq}$; il dépend aussi des variations de $\Delta\overline{V}$. Par exemple, dans le mélange contenant 20% en poids de TBA on a:

$$\Delta\overline{V}(\text{NaCl}) = -1.86 \times 10^{-3}$$

$$B(\text{NaCl}) = 9 \times 10^{-3}$$

$$\Delta\overline{V}(Bu_4NBr) = 278 \times 10^{-3}$$

$$B(Bu_4NBr) = 720 \times 10^{-3}$$

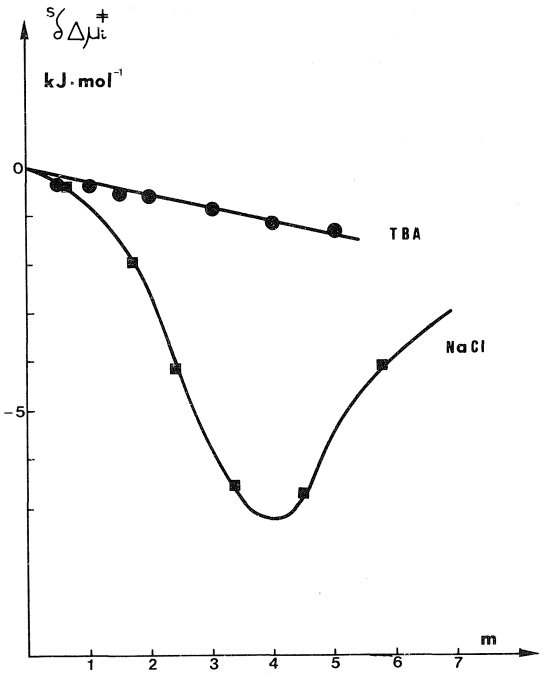

FIG. 4. Variations de la contribution molaire des solutés à l'enthalpie libre d'activation des solutions molaires de NaCl et TBA dans les mélanges de molalité m respectivement en TBA et NaCl.

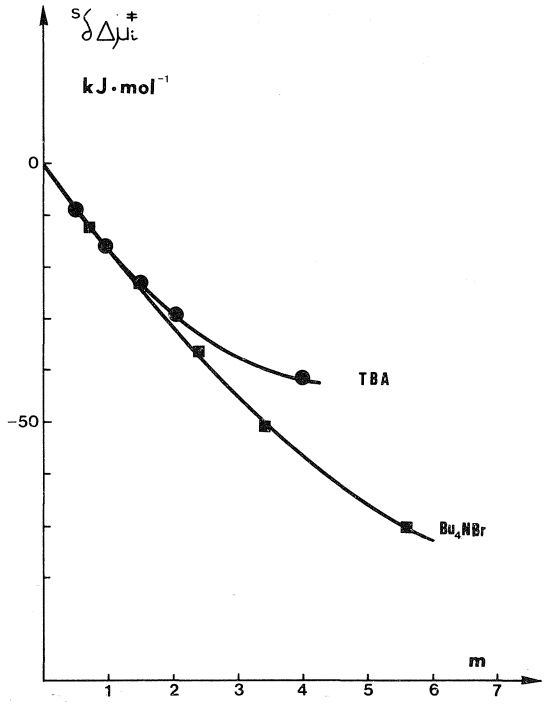

FIG. 5. Variations de la contribution molaire des solutés à l'enthalpie libre d'activation des solutions molaires de Bu_4NBr et TBA dans les mélanges de molalité m respectivement en TBA et Bu_4NBr.

En comparant avec les valeurs dans l'eau données ci-dessus, on voit que dans les deux cas les variations de $\Delta\overline{V}$ avec le solvant sont négligeables devant celles de B.

Sur les figs 4 et 5 nous avons tracé les variations des $\Delta\mu_i^{\neq}$($^{s}\delta\Delta\mu_i^{\neq}$) avec la composition du solvant; on voit que ces variations, quant à leurs formes et amplitudes relatives, sont très semblables à celles des coefficients B correspondants.

Dans le cas du système Bu_4NBr–TBA, on constate que, jusqu'à $m = 1.5$ les variations relatives à l'électrolyte en présence de non-électrolyte et, réciproquement, celle du nonélectrolyte en présence de l'électrolyte, coïncident; ceci contrairement aux variations $^{s}\delta B$ correspondantes. On peut rapprocher ce comportement de la grandeur d'activation $\Delta\mu_i^{\neq}$ de celui constaté pour les grandeurs thermodynamiques (13). Ainsi, sur la base du modèle d'Eyring, dans les solvants étudiés, les variations de B rendent essentiellement compte des variations de l'enthalpie libre molaire partielle d'activation du soluté. Donc, dans ces milieux, cette quantité varie proportionnellement à l'entropie du soluté dans l'état fondamental comme le montre la relation [4].

En conclusion, on voit que des relations intéressantes existent entre les propriétés thermodynamiques du soluté dans l'état fondamental et la propriété de transport B, ou la grandeur d'activation qui en découle à travers le modèle d'Eyring. Ces relations ne sont pas immédiatement prévisibles à partir des propriétés connues.

Des données expérimentales supplémentaires sont au moins nécessaires pour espérer une meilleure compréhension.

Coordination compounds of indium. Part XXXIII. X-Ray photoelectron spectroscopy of neutral and anionic indium halide species

BRIAN H. FREELAND,[1] JACOB J. HABEEB, AND DENNIS G. TUCK

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received October 14, 1976

BRIAN H. FREELAND, JACOB J. HABEEB, and DENNIS G. TUCK. Can. J. Chem. **55**, 1527 (1977).

The X-ray photoelectron spectra (metal and halogen energy levels) have been recorded for binary halides of indium in the +I, +II, and +III states, and for anionic halide complexes of indium(I) and (III). The results are internally consistent in terms of the relation between metal and ligand levels, but lattice effects prevent any detailed interpretation of indium levels in terms of oxidation state, ligand electronegativity, and/or coordination number.

BRIAN H. FREELAND, JACOB J. HABEEB et DENNIS G. TUCK. Can. J. Chem. **55**, 1527 (1977).

On a enregistré les spectres photoélectroniques de rayons-X (les niveaux d'énergie du métal et des halogènes) d'halogénures binaires d'indium dans les états +I, +II et +III et pour les halogénures complexes anioniques de l'indium(I) et (III). Les résultats sont en accord interne en termes de la relation entre les niveaux du métal et du ligand, mais des effets de réseaux empêchent toutes interprétations plus détaillées des niveaux de l'indium en termes d'états d'oxydation, d'électronégativité du ligand et/ou du nombre de coordination.

[Traduit par le journal]

Introduction

The literature now contains a number of papers on the use of X-ray photoelectron spectroscopy (ESCA) in studies of the structure and bonding in inorganic molecules. As part of a programme of studies of main group metallic elements, we have recently carried out a series of measurements of electron binding energies in compounds of indium with chlorine, bromine, and iodine. The species studied included the neutral halides of indium in the +III, +II, and +I states, and the anionic complexes of indium(I) and (III).

There has been little previous work on the electron spectroscopy of indium complexes. McGuire, Schweitzer, and Carlson (1) have measured the $3d_{5/2}$ and $3p_{3/2}$ levels in indium metal and a number of binary compounds, and have compared the results with those for the analogous compounds of other Group III metals. In general our results are in agreement with those reported by these authors.

Experimental

Preparative

The neutral indium(III) and indium(I) halides were prepared by methods reported previously (2, 3). Indium(II) halides were obtained from the reduction of InX_3 by indium metal in xylene (4). The preparation of the anionic halide complexes followed previously described procedures (5–7). The identity of the compounds was confirmed where necessary by elemental analysis.

Spectroscopy

Electron binding energies were measured on a McPherson ESCA-36 photoelectron spectrometer operated jointly by the Universities of Toronto, Western Ontario, and Windsor. Magnesium K_α X-radiation (1253.6 eV) was the exciting radiation.

Samples were inserted into a vacuum-locked target chamber as thin smears on platinum discs, and were in some cases covered with vacuum-deposited thin films of gold for calibration purposes. The preparation of these discs, and all other handling of samples, was carried out in a dry nitrogen atmosphere in order to prevent hydrolysis or oxidation of the indium compounds.

Electron energy measurements were recorded on tape, and were also obtained in graphical form after appropriate accumulation of results. In view of the accuracy of the binding energies (see below), it was not considered worthwhile to analyse the data by any computing procedure, and the results quoted below were obtained by measuring the peak height energy manually from the printed spectra. As a measure of the reliability of this procedure, five results for the $3d_{5/2}$ level in $InCl_3$ gave 446.1, 445.6, 446.1, 446.2, and 445.9 eV; the mean of these five values is $446.0 \pm 0.1_1$ (σ). For each spectrum we routinely measured the $3d_{5/2}$ and $3d_{3/2}$ levels of indium, the half-widths of each of these lines, the energies of Pt $4f_{7/2}$ or Au $4f_{7/2}$ as appropriate, and the most easily characterized line of the halide present (Cl $2p_{3/2}$; Br $3p_{3/2}$; I $3d_{5/2}$). The separation between $3d_{3/2}$ and $3d_{5/2}$ of indium was essentially constant in all the compounds studied, at 7.5 ± 0.2 eV. All experimental values quoted

[1]Present address: Department of Chemistry, University of Western Ontario, London, Ont., Canada.

are taken to be subject to a probable error of ± 0.1 eV unless otherwise noted. In view of the other uncertainties associated with the interpretation of these results, this is not an unduly large problem.

Results and Discussion

The original aim of the present work was to establish the effects of parameters such as oxidation state, coordination number, and ligand electronegativity upon the electron energy levels of indium in its complexes. As the results described show, this aim has not been realized, and some of the reasons for this are not hard to identify. One major problem of ESCA studies on solids is the appreciable line widths involved, with the resultant decrease in the accuracy of measurements of the binding energy, and this is certainly a significant factor in the present work (see below). Equally important is the nature of the energy relationships involved. The general treatment (8) shows that the incident energy $h\nu$ is distributed amongst electron binding (E_b), kinetic (E_k), and lattice or (Madelung) energy terms, *i.e.*

$$h\nu = E_k + (E_b + E_{lattice})$$

Clearly then in discussing atomic energy levels (E_b) derived from ESCA studies of solids, the effect of the Madelung terms cannot safely be ignored. A comparison of the results for (say) indium in different solids may therefore not be meaningful unless the lattices concerned are sufficiently similar for the assumption of a constant value for $E_{lattice}$ to be valid.

The results obtained are listed in Tables 1–4. The values for In $3d_{5/2}$ are in general similar to those reported by McGuire *et al.* (1), although there are some detailed differences which we note below. In order to examine the implications of these results in terms of indium–halogen bonding, we have plotted the indium $3d_{5/2}$ level *vs.* the appropriate halogen level for the neutral halides, and for those indium(I) and (III) complexes for which results are available. Figure 1 shows that within experimental error there is a monotonic increase in the levels of both metal and halogen, for each halogen, irrespective of oxidation state and/or coordination number of the indium. Comparison of the halogen levels with published results indicates that the bonding is strongly ionic. Thus for chlorine the range of 198.5–199.5 eV is substantially lower than in the neutral covalent silicon or germanium chlorides and organochlorides (9) (205–207 eV), but higher than in the alkali metal halides (8) (193–195 eV). The conclusion that the bonding in indium(I) and (III) halides is of the order of 50% ionic is in keeping with earlier discussions of the bonding based on force constant calculations (10) (and with nqr studies of tin(IV) species (11), in which the metal is formally isoelectronic with indium(III)).

TABLE 1. Indium and halogen energy levels (in eV) in neutral indium halides (relative to Pt $4f_{7/2} = 71.2$ eV)

Compound		In $3d_{5/2}$	In $3d_{3/2}$	Halogen[a]
1	InCl	445.2	452.8	198.5

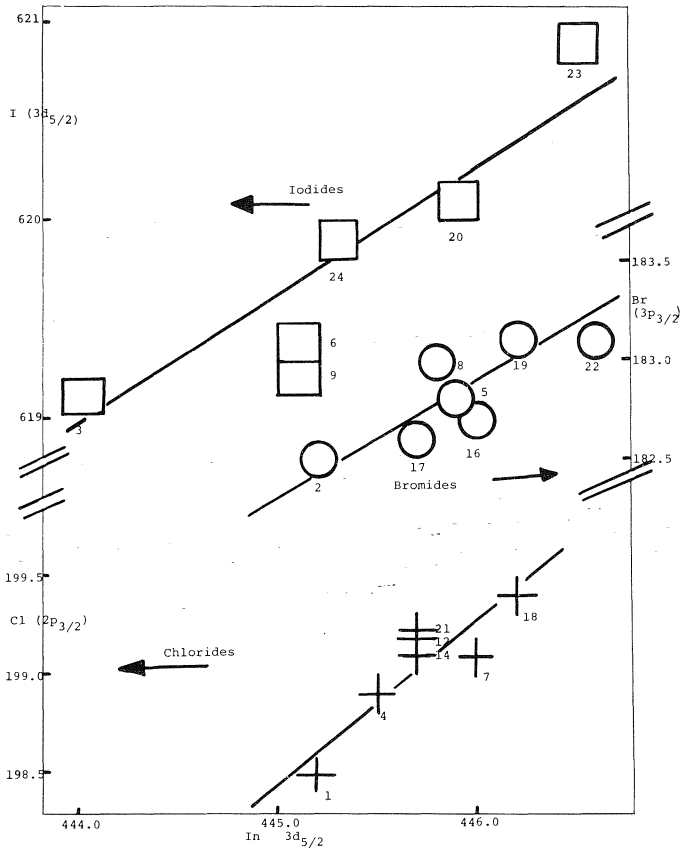

FIG. 1. Relationship between indium $3d_{5/2}$ and halogen energy levels (in eV) in indium halide compounds. Numbers identify compounds in Tables 1–4.

Given this model of bonding, it is not surprising that in each series of halogen compounds the monohalide involves the weakest interaction. There is no general ordering of the levels by oxidation state beyond the monohalides, no doubt because of perturbations imposed on any such order by lattice effects. As an example of such effects, we note that there are two sets of results for the $InCl_4^-$ anion, in salts with Et_4N^+ and n-Pr_4N^+ cations. These two sets of values are not identical (see Tables 2 and 3), but both lie reasonably on the plotted line in Fig. 1, establishing that both indium and chlorine levels are affected by the different $E_{lattice}$ terms for the two salts, but that the In–Cl interaction is the same in both cases. The emphasis which

this approach places on relationships between two atoms within a single molecule, rather than the levels for a given atom in a series of molecules, seems entirely appropriate in studying ionic solids. Some of the correlations of atomic levels claimed in the earlier literature may well flounder on the incorrect assumption that the lattice terms can be safely ignored.

Effect of Oxidation State, etc., on Indium Levels

One of the disappointing conclusions to be drawn from the above discussion is that one cannot use the energy levels measured in solid state ESCA experiments in order to determine the oxidation state of indium in a given compound. However, it is interesting to examine the overall effect of the oxidation state on these levels in a series of simple compounds, namely the binary halides. The results for these compounds are given in Table 1. Our value for InCl is close to that reported by McGuire *et al.* (1) (445.1 ± 0.3 eV), but their results for the trihalides are consistently higher than ours by approximately 1.1 eV. The reasons for this are not immediately apparent.

A number of authors have presented refined treatments of ESCA data (and more particularly of photoelectron spectra) whereby the levels are related to calculated atomic charges in molecules (8, 9, 12, 13). In view of the small range of experimental values and the relatively low accuracy achieved with crystalline samples, it does not seem worthwhile to pursue such arguments in the present case. Rather we have followed the simpler procedure of plotting E_b for indium against the sum of the atomic electronegatives of the ligand(s) concerned; the electronegativities are those quoted by Allred (14), namely Cl 3.16, Br 2.96, I 2.66. Figure 2 shows that five of the nine points lie on a straight line, which also extends to indium metal (E_b $3d_{5/2}$ 448.1 eV, from ref. 1).

Of those compounds studied, indium trichloride and tribromide involve six-coordination of indium by halide ions in a chromium trichloride structure (ref. 15, p. 235). Indium monochloride has a distorted sodium chloride structure while the monobromide and monoiodide have the thallium iodide structure, in which five halide nearest neighbours are at the vertices of an octahedron centred on the metal (ref. 15, p. 349). Indium triiodide exists as the iodide-bridged dimer In_2I_6 in the solid state (16),

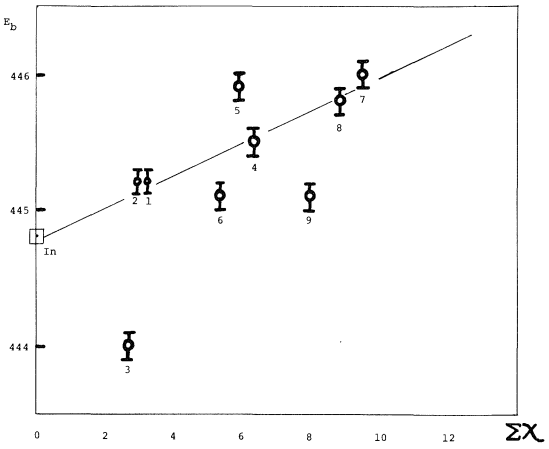

FIG. 2. Dependence of indium $3d_{5/2}$ energy levels (E_b, in eV) in indium halide compounds on ligand electronegativity ($\Sigma\chi$). Numbers identify compounds in Table 1.

with four-coordinate indium(III). Indium(II) bromide and iodide have been formulated as $In[InX_4]$ (X = Br, I) on the basis of the Raman spectra of the solids (3); indium dichloride has been assigned various structures, involving $[InCl_4]^-$, $[InCl_6]^{3-}$, or $[In_2Cl_9]^{3-}$ units with the appropriate number of indium(I) cations. Such ionic formulations are inevitably over-simplifications but for the present the more important point is that $InCl_2$ is structurally different from the related pair $InBr_2$ and InI_2.

The overall conclusion from an examination of Fig. 2 must be that indium $3d_{5/2}$ binding energies do indeed increase with the increasing (integrated) electronegativity of the environment, and hence with the presumed positive charge on the metal, within the limits discussed. There is no basis for predicting that a linear relationship would apply, but a monotonic dependence of energy level on ligand properties seems entirely reasonable. The compounds which lie on, or close to, the line drawn are those in which indium is in an ionic octahedral environment. The compounds $InBr_2$, InI_2, and InI_3 do not fit into this category, and here again lattice effects are presumably the source of the difficulties. The most serious remaining problem is then with InI, for which no explanation is forthcoming.

The results in Tables 3 and 4 show that with the two series n-$Pr_4N[InX_4]$ and $Et_4N[InX_2]$ the overall effect of increasing ligand electronegativity is to raise the indium energy level

TABLE 5. Widths at half-height (in eV) for indium levels in binary indium halides

Compound		$3d_{5/2}$	$3d_{3/2}$
1	InCl	1.7	1.6
2	InBr	1.5	1.5
3	InI	2.0	2.0
4	$InCl_2$	1.5	1.4
5	$InBr_2$	1.4	1.3
6	InI_2	1.4	1.3
7	$InCl_3$	1.4	1.3
8	$InBr_3$	1.2	1.2
9	InI_3	1.5	1.4

slightly. The salt $Et_4N[InCl_2]$ is a notable exception to this rule, even though the results for this compound apparently show a good correlation with other indium chloride species in Fig. 1. In view of the difficulties noted above for the neutral halides, we do not feel justified in extending the argument to a discussion of the results for the anionic halide complexes of indium(I) and (III). It is *a fortiori* impossible to discuss the effect of coordination number in such complexes, since changes in coordination number are necessarily accompanied by, and indeed are in part the result of, changes in cation and hence of lattice.

Such qualifications as expressed above clearly reduce, or remove completely, the value of ESCA studies of indium halides as a tool for structural investigation, due in the main to uncertainties as to the significance of lattice energy terms in any given situation.

Indium(II) Compounds

As noted earlier, the compounds InX_2 present an interesting structural problem, since they do not contain In^{2+} ions, being generally formulated as ionic dimers involving two indium species in the oxidation states I and III in the lattice. (See refs. 3 and 17 for a review of the evidence on this point.) We therefore examined the spectra of these compounds with particular interest in the hope of identifying two distinct binding energies. In fact, in none of the compounds $InCl_2$, $InBr_2$, or InI_2 did we detect more than a single indium level. The line shapes did not differ significantly from those for the other binary halides, and the half-widths were no larger than in other halides (Table 5). Given that the indium $3d_{5/2}$ levels in InCl and $InCl_3$ are 445.2 and 446.0 eV (Table 1), one could reasonably expect some indication of the presence of two oxidation states in $InCl_2$, and similar arguments can be advanced for $InBr_2$ and InI_2. The results clearly underline the statement made elsewhere (3, 17), that the ionic formulations noted earlier represent gross over-simplification of the structures involved, despite spectral evidence as to the nature of the indium(III) anionic complexes present.

We may note in the context of line-width measurements that the iodine results for indium(III) iodide, $I_2InI_2InI_2$, show no evidence for the existence of terminal and bridging iodide as required by the crystal structure (17). The line widths for $3d_{3/2}$ and $3d_{5/2}$ are 1.4 and 1.5 eV, with a separation of 11.5 eV; for the compound n-$Pr_4N.InI_4$ the comparable values are 1.5, 1.5, and 11.4 eV. Other iodine species show similar values. These results serve to emphasize the very considerable limits which must be conceded in X-ray photoelectron spectroscopy studies of crystalline solids.

Theoretical study of the vibrational structure of the $^1(n, \pi^*)$ transition in diimide: potential curves and Franck–Condon analysis

M. PERIĆ, R. J. BUENKER, AND S. D. PEYERIMHOFF

Lehrstuhl für Theoretische Chemie der Universität Bonn and Institut für Physikalische Chemie der Universität Bonn, Wegelerstr. 12, 5300 Bonn, Germany

Received November 11, 1976

M. PERIĆ, R. J. BUENKER, and S. D. PEYERIMHOFF. Can. J. Chem. **55**, 1533 (1977).

Ab initio CI potential curves are reported for the ground and $^1(n,\pi^*)$ excited states of diimide for each of the six possible internal coordinates. These results are then used to obtain vibrational wavefunctions and frequencies for both states, which in turn are combined with electronic transition moment data to allow a Franck–Condon analysis of the band structure of the (dipole-forbidden) n–π^* absorption system. This procedure allows one to reproduce the main features of the observed spectra of N_2H_2 and N_2D_2 and indicates that the majority of the vibrational transitions seen are vibronically induced via the antisymmetric NH stretching mode ν_5. The calculations are in essential agreement with the earlier experimental interpretation of the vibrational structure of this transition in terms of progressions in the symmetric bending (ν_2) and NN stretching (ν_3) frequencies, except that they indicate that the previous v_2' numbering should be altered by three units. According to this interpretation the isotope shift for the vibronic origin is 672 cm^{-1} compared with the corresponding calculated value of 666 cm^{-1}. It is argued that several other weaker transitions seen experimentally arise via a different inducement mechanism, namely the torsion (ν_4) mode, and as such are only observed in energy regions where ν_5-induced transitions cannot occur.

M. PERIĆ, R. J. BUENKER et S. D. PEYERIMHOFF. Can. J. Chem. **55**, 1533 (1977).

On rapporte des courbes de potentiel IC *ab initio* pour les états fondamentaux et excités $^1(n,\pi^*)$ de la diimide pour chacune des six coordonnées internes possibles. On utilise alors ces résultats pour obtenir des fonctions d'ondes vibrationnelles et des fréquences pour les deux états qui à leur tour sont combinées avec des données de moment de transition électronique pour permettre une analyse de Franck–Condon de la structure de bande du système d'absorption n–π^* (dipole-interdite). Ce procédé permet de reproduire les caractéristiques principales des spectres observés pour N_2H_2 et N_2D_2 et indique que la majorité des transitions vibrationnelles qui sont détectées sont induites par un processus vibronique par l'intermédiaire d'un mode de vibration antisymétrique de valence du NH (ν_5). Ces calculs sont en accord général avec l'interprétation expérimentale antérieure de la structure vibrationnelle de cette transition en termes de progression dans les fréquences de déformation angulaire symétrique (ν_2) et de vibration de valence (ν_3); toutefois ils indiquent que la numérotation antérieure v_2' devrait être modifieé par trois unités. D'après cette interprétation, le déplacement isotopique pour l'origine vibronique est 672 cm^{-1} comparé avec la valeur calculée correspondante de 666 cm^{-1}. On présente plusieurs arguments indiquant que plusieurs autres transitions faibles qui sont détectées expérimentalement dérivent d'un mécanisme d'induction différent soit le mode de torsion (ν_4) et que comme telles elles sont observées uniquement dans des régions d'énergie où des transitions induites ν_5 ne peuvent pas se produire.

Introduction

The absorption spectra of N_2H_2 and N_2D_2 (diimide) in the 3000–4300 Å region generally believed to correspond to the $^1(n,\pi^*)$ $^1B_g \leftarrow {}^1A_g$ transition have recently been reported by Back, Willis, and Ramsay (1). At roughly the same time *ab initio* SCF and CI calculations at the approximate (*trans*) ground state equilibrium geometry of this system were carried out by Vasudevan *et al.* (2) for a large number of electronic states for this molecule. In comparing these experimental and theoretical results for the $^1(n,\pi^*)$ transition it was noted, however, that the calculated vertical electronic energy difference for this species was some 0.6 eV *smaller* than the observed location of the absolute intensity maxima in the corresponding absorption systems (2). Because of the Franck–Condon Principle one normally expects the vertical electronic energy difference to very

nearly coincide with the energy of maximum transition probability and hence this result might be taken to indicate that the calculations were simply in error in this respect by roughly the entire 0.6 eV margin. On the other hand experience with this type of CI treatment for other systems such as formaldehyde (3), ethylene (4), and water (5), for example, indicates that the error limits for such calculated transition energy results should not exceed the 0.2–0.3 eV range. It was thereupon argued by Vasudevan *et al.* (2) that there is a strong likelihood that the *true* vertical electronic transition actually occurs well *below* the observed location of the absorption maximum in this case, especially since the $^1(n,\pi^*)$ system is electronically dipole-forbidden for the ground state equilibrium nuclear conformation (C_{2h} point group).

In order to investigate this hypothesis in more detail from the theoretical side it is necessary to calculate potential surfaces for both ground and $^1(n,\pi^*)$ excited states of N_2H_2 so as to allow for a vibrational analysis of this electronic transition. Clearly one of the key objectives in such a study is to determine the mechanism by which this formally dipole-forbidden transition gains sufficient intensity to be observed at all. In addition it is hoped that through this type of analysis a good correlation between calculated and experimental results for the band structure of the $^1(n,\pi^*)$ system will be obtained which allows for a definite assignment of the vibrational progressions observed in this spectral region (1). The present paper reports the results of such an *ab initio* CI treatment of the $^1(n,\pi^*)$ transition of diimide, in which all six possible vibrational modes are given explicit consideration.

Description of the Theoretical Treatment

Details of the AO basis (double-zeta plus Rydberg) and CI treatment employed in the present calculations have already been given in earlier work (2). One change has been made, however, namely in that approximate natural orbitals (NO's) are used (6, 7) for each of the CI states rather than simply the corresponding SCF MO's employed previously. This improvement in the CI treatment leads to an increase in the vertical transition energy of about 0.1 eV, but still not by a great enough amount to change any of the qualitative conclusions referred to in the Introduction. The sizes of the configuration spaces treated, for which secular equation eigenvalues have been obtained to an estimated accuracy of 0.01 eV (8), range from 15 000 to 25 000 in the present study.

The method employed for the vibrational analysis is similar to that used for ethylene and O_2 in previous work (9, 10) and is summarized below. In accordance with the Born–Oppenheimer (and Franck–Condon) Approximation the total wavefunction Ψ is first assumed to be separable into an electronic (ψ_e) and a vibrational (ψ_v) part. A further simplification is introduced by assuming that the six vibrational modes of diimide are independent of one another, that is

$$[1] \qquad \psi_v = \prod_{j=1}^{6} \psi_v^{(j)}(R_j)$$

where R_j is a (symmetrized) internal coordinate.[1] Under these conditions the transition moment for a given vibrational species can be written as:

$$[2] \quad \langle r \rangle = \int \cdots \int \prod_j \psi_{v'}^{(j)} \boldsymbol{R}_{e'e''} \psi_{v''}^{(j)} \, d\tau_v$$

where $\boldsymbol{R}_{e'e''} = \int \psi_{e'} \boldsymbol{r} \psi_{e''} \, d\tau_e$ is the electronic transition moment (with the usual primed notation being employed to distinguish between ground and excited species in each instance).

In principle the electronic transition moment should be a function of all six vibrational coordinates but in this work it is assumed that this quantity is independent of all such species except the inducing mode in each case, *i.e.* that vibrational excitation which makes the overall transition vibronically allowed under the dipole selection rules.[2] Whereupon one obtains the result:

$$[3] \quad \langle \boldsymbol{r} \rangle_{e'v'e''v''} = \prod_{j \neq I} S_{v'v''}^{(j)} \times \int \psi_{v'}^{(I)} \boldsymbol{R}_{e'e''}(R_I) \psi_{v''}^{(I)} \, dR_I$$

in which the subscript I denotes the inducing

[1]Note that the species used correspond to pure NN or NH stretch or analogous bending motions and therefore do not strictly satisfy the Eckart conditions, *i.e.* they are not completely orthogonal to the various translational and rotational modes.

[2]Note that the usual subsidiary assumption employed in deriving the Franck–Condon Principle for *allowed* transitions states that $\boldsymbol{R}_{e'e''}$ is independent of *all* vibrational species.

mode, and the quantities $S_{v'v''}^{(j)}$ are the vibrational overlaps for the various noninducing modes in a given vibrational transition. The corresponding f value or transition probability is then given in the usual way as

$$[4] \quad f_{e'v'e''v''} = \tfrac{2}{3}|\langle r\rangle_{e'v'e''v''}|^2 \cdot \Delta E_{e'v'e''v''}$$

where ΔE is the transition energy.

The necessary vibrational wavefunctions and energies are obtained (in the framework of the Born–Oppenheimer approximation) by solving the Schrödinger equation in which a given electronic energy curve serves as the potential for the nuclear motion. Since the present approach assumes that the various vibrational modes are independent of one another it is consistent to simply calculate appropriate sets of one-dimensional potential curves (with all other coordinates held fixed in a given case), and substitute these data in the corresponding Schrödinger equations for each type of nuclear motion. The requirement of choosing a set of fixed values for the (five) complementary coordinates in each case introduces a certain amount of ambiguity into the procedure since in practice there is some coupling observed between the various vibrational modes, but since the geometry changes encountered in going from ground to the $^1(n,\pi^*)$ excited states in diimide are relatively small this problem is not expected to be very critical in the present study.[3] Finally, to complete the vibrational analysis it is necessary to calculate the electronic transition moment $\boldsymbol{R}_{e'e''}$ as a function of each of the three antisymmetrical internal coordinates in *trans*-diimide.

Vibrational Frequencies and $R_{e'e''}$ Values

The CI potential curves calculated for the six vibrational coordinates in the ground and $^1(n,\pi^*)$ states of diimide are shown in Fig. 1 *a*, *b*; corresponding vibrational energy levels are also indicated in each case. The first three modes ν_1 to ν_3 are of a_g symmetry, corresponding respectively to (symmetric) NH stretch, HNN bending, and NN stretch. The torsional vibration ν_4 belongs to a_u while ν_5 (antisymmetric NH stretch) and ν_6 (antisymmetric HNN bending) are of b_u symmetry.

The calculated equilibrium values for each of the internal coordinates of ground and excited state are collected in Table 1. Significant distinctions are noted in the NN bond lengths and HNN angles of the two states as well as in the shapes of their respective torsional potential curves. The calculated increase in R_{NN} of 0.09 bohr ($\sim$0.05 Å) upon excitation[4] is in very good agreement with the experimental estimate for this quantity (0.05 Å) given by Back *et al.* (1), but the change in bond angle predicted by the calculations (13° toward a less bent geometry) is only about half that cited by the latter authors based on their assignment of the observed $^1(n,\pi^*)$ vibrational structure. The present result, however, is in very good agreement with the value of $\Delta\varphi = 12°$ obtained by Baird and Swenson (11) in an earlier theoretical treatment. Each state is calculated to possess equal NH bond lengths and HNN bond angles, with R_{NH} for the upper species being only 0.024 bohr smaller than the corresponding ground state value. Finally the CI energy of the ground state for its global potential minimum is found to be -110.166 hartree, which is 2.554 eV below the excited state minimum energy (all results based on curve fitting procedures).

The calculated vibrational frequencies for the various ground and excited state species are given in Table 2 and are compared with the corresponding observed values wherever possible (12,1); data for N_2D_2 have also been calculated and are likewise contained in the table. Two theoretical values are given in each case, one equal to the 0–1 frequency and the other obtained by doubling the calculated zero-point energy; the discrepancies between these results are a measure of the degree of anharmonicity present in the associated potential curves.

In general it appears that the calculations can reproduce the experimental frequencies to within

[3]In general (but not always) the values of the ground state equilibrium conformation are employed for these fixed parameters because of the emphasis which the Franck–Condon Principle places on the nuclear arrangement of the lower state.

[4]The absolute value calculated for R_{NN} in the N_2H_2 ground state is somewhat too large (2.366 bohr experimentally) because NN bond functions (or equivalent polarization functions) are not included in the AO basis set. Nevertheless this omission should have essentially the same effect on ground and excited state, and hence the calculations are expected to give a good estimate of the *change* in this geometrical coordinate which occurs during the $^1(n,\pi^*)$ transition.

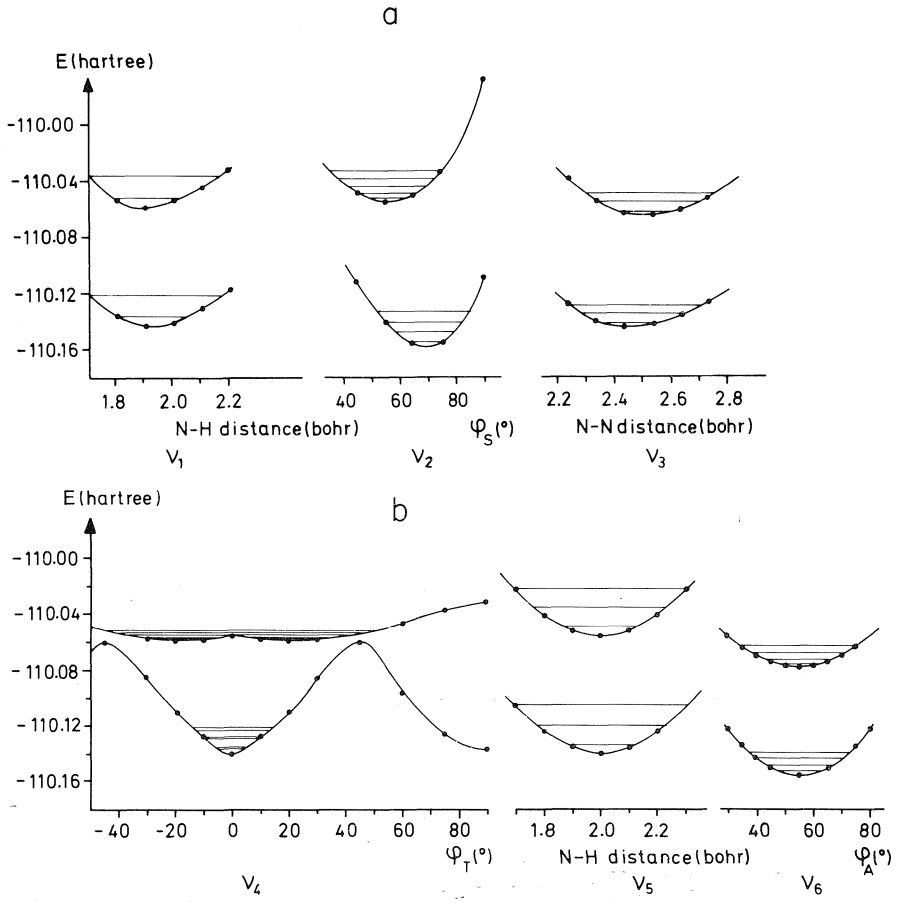

FIG. 1. CI potential curves calculated for the six vibrational coordinates in ground and $^1(n,\pi^*)$ excited state of diimide; vibrational energy levels are also indicated.

TABLE 1. Calculated equilibrium values for each of the internal coordinates of N_2H_2 obtained from a polynomial fit to the CI data displayed in Fig. 1

Parameter	Ground state	$^1(n,\pi^*)$ state
NH (bohr)[a]	1.932	1.908
Bending angle NNH	110°	123°
NN (bohr)	2.443	2.533
Torsional angle	0°	28°
Relationship between NH bond lengths	Equal	Equal
Relationship between HNN bond angles	Equal	Equal

[a]1 bohr = 0.52917 Å.

an error of 50–250 cm^{-1} in all cases; the largest discrepancies occur for ν_1 and ν_6. Considering the underlying assumptions in the theoretical procedure used, especially the failure to consider coupling between the various modes, such agreement between calculation and experiment for both ground and excited state frequencies appears to be quite reasonable; in particular, the results would seem to be of sufficient accuracy to allow for an unambiguous assignment of the band structure observed for this electronic transition (1).

Finally, the calculated $^1(n,\pi^*)$ transition moment results are given in Table 3 as a function of each of the three antisymmetric vibrational coordinates of diimide. For small excursions away from the symmetric (C_{2h}) nuclear conformation it is found that this quantity is largest in absolute value for the NH stretch species ν_5 and smallest for the corresponding antisymmetric bending mode ν_6. The transition moment ultimately becomes much larger upon torsion as the system approaches the *cis* limit ($\varphi_t = 90°$, C_{2v} symmetry), in which case the transition in question becomes dipole allowed ($^1B_1 \leftarrow {}^1A_1$).

TABLE 2. Calculated vibrational frequencies (in cm^{-1}) for the various modes in N_2H_2 and N_2D_2 and comparison with experiment

Vibrational modes	N_2H_2			N_2D_2		
	Calcd.[a]		Exptl.[b]	Calcd.[a]		Exptl.[b]

No experimental results for $\boldsymbol{R}_{e'e''}$ in diimide have yet been reported.

Vibrational Overlap and Transition Probability Integrals

In order to calculate an intensity distribution for the $^1(n,\pi^*)$ transition it is necessary to combine the vibrational wavefunctions obtained in the last section with the electronic transition moment data so as to evaluate the various integrals required on the right-hand side of eq. 3. The results of these computations are given in Table 4 for N_2H_2 and N_2D_2 respectively. The magnitudes of the dipole moment matrix elements in Table 4 are of special interest in the present study since these quantities ultimately determine the overall strength of transitions induced via a vibronic mechanism. The data for the NH stretching and bending antisymmetric modes ν_5 and ν_6 indicate quite strongly in each instance that only the $1 \leftarrow 0$ ($v' \leftarrow v''$) vibrational transitions are of sufficient magnitude to be of experimental significance. The fact that all other vibrational species ($n \leftarrow 0$) are much less probable is of course tied up with the result that for both modes the ground and excited state potential curves show minima at the same value of the internal coordinate (namely zero, *i.e.* for a symmetric equilibrium geometry). The finding that only the $1 \leftarrow 0$ ν_6 transition should be

TABLE 4. Vibrational overlaps and $\langle \psi_{v'} \boldsymbol{R}_{e'e''} \psi_{v''} \rangle$ values for the various vibrational modes of N_2H_2 and N_2D_2 (notation $0.n-a$ signifies $0.n \times 10^{-a}$)

observable in the entire $^1(n,\pi^*)$ manifold clearly puts to rest the speculation by Vasudevan *et al.* (2) to the effect that this species is actually responsible for the three long 1100 cm^{-1} progressions found by Back *et al.* (1) for this spectrum.

The situation for the third antisymmetric variable (ν_4, torsion) is less clear, however; primarily because of the extremely flat potential curve which characterizes the $^1(n,\pi^*)$ upper state upon vibrating in this mode (see Fig. 1*a* and also the work of Baird and Swenson (11)). The main difficulty therein is that the vibrational overlap integrals for higher upper state quantum numbers are quite sensitive to the shape of the torsional potential curve at relatively large angles, particularly in the region of the energy maximum for the *cis* conformation.[5] Since the electronic transition moment increases by an order of magnitude as the angle of torsion varies from 10° to 90° (*cis*) the magnitude of the dipole matrix elements for large ν_4' is critically dependent on the manner in which these overlap integrals decrease over the same region. The present calculations do not rule out the possibility that the dipole integrals increase for the higher torsional levels (beyond $\nu_4' = 4$). On the other hand, if such behavior were observed experimentally progressions in $2\omega_4'$ (200–500 cm^{-1}, see Table 2) would be detected; since such activity does not appear in the experimental diimide absorption spectrum it therefore seems unlikely that such considerations play a decisive role in arriving at a satisfactory assignment of the band systems contained therein.

In any event it seems clear from the calculations that the most probable inducing mode for the $^1(n,\pi^*)$ transition in *trans*-diimide is the $(1 \leftarrow 0)$ NH antisymmetric stretching mode ν_5. The *f* value for this species (see eq. 4) is 1.0×10^{-4}, some three times larger than the corresponding result for the most probable $(1 \leftarrow 0)$ torsion-induced system and 40 times greater than the analogous ν_6 quantity (Table 5). Moreover, the calculated intensity for the ν_5-induced complex seems to be at least qualitatively consistent with the overall strength of the observed transition. The corresponding *f* value for the (dipole-allowed) $^1(n,\pi^*)$ transition in *cis*-diimide is 9×10^{-3} for example, only 90 times greater than the ν_5 vibronically-induced oscillator strength for the *trans* isomer. Given the well-known weakness of both quadrupole and mag-

[5]Note that the structural parameters of the *trans* conformer are employed exclusively in calculating this potential curve.

TABLE 5. Calculated oscillator strengths for key vibronic transitions in the N_2H_2 $^1(n,\pi^*)$ system (see eq. 4)[a]

Inducing mode ($v' \leftarrow v''$)	$f_{e'v'e''v''}$	Ratio
$1 \leftarrow 0$, ν_5	1.0×10^{-4}	1/1
$1 \leftarrow 0$, ν_4	0.3×10^{-5}	1/3
$3 \leftarrow 0$, ν_4	0.4×10^{-6}	1/23
$1 \leftarrow 0$, ν_6	0.2×10^{-6}	1/40

[a]The corresponding f value for the (allowed) $^1(n,\pi^*)$ transition in the *cis* conformer (torsion 90°) is 0.9×10^{-2}, *i.e.* 90 times stronger than the $1 \leftarrow 0$, ν_5 (reference) value for *trans*-diimide.

netic dipole-allowed transitions, and also the fact that diimide apparently exists almost exclusively in the *trans* form (13), it is thus the clear indication of the present calculations that at least the major features of the observed diimide spectrum in the 3000–4300 Å region are vibronically induced through the $(1 \leftarrow 0)$ NH antisymmetric stretching species.

The vibrational overlap integrals of Table 4 for the six possible N_2H_2 modes indicate further that the intensity distribution for the symmetric NH stretching species ν_1 should be localized in a single transition while the data for the ν_2 and ν_3 vibrational modes (of relatively high frequency, see Table 2) predict that in these instances the intensity of the corresponding transitions should be distributed over a fairly large wavelength region. Significantly large NN stretching (ν_3) overlap integrals are calculated from $v' = 0$ up to at least $v' = 2$ (Table 4), with similarly large values for the symmetric bending ν_2 mode occurring from $v' = 0$ up to as high as $v' = 7$ and 8 for N_2H_2 and N_2D_2 respectively.

Intensity Distribution for the $^1(n,\pi^*)$ ν_5-induced Portion of the Spectrum

The band structure observed for the 3000–4300 Å region of the diimide spectrum has been assigned (1) in terms of progressions in the upper state ν_2 (symmetric bending) and ν_3 (NN stretching) frequencies. The present calculations are seen to be in general agreement with this interpretation, complete with the finding that the short progression in the spectrum should be assigned to ν_3 and the long to ν_2 (see Table 4). They indicate further that the transitions are most likely vibronically induced via the NH stretching mode ν_5 $(1 \leftarrow 0)$. To obtain a more detailed correlation between calculation and experiment in this regard the results of Table 4 can be substituted into eqs. 3 and 4 in order to calculate an intensity distribution for this electronic transition in both N_2H_2 and N_2D_2. The most important feature of this analysis can then be given rather concisely in terms of a table

TABLE 6. Products of Franck–Condon overlap integrals $\langle\psi_{0''}|\psi_{v_2'}\rangle$ $\langle\psi_{0''}|\psi_{v_3'}\rangle$ for the $v' \leftarrow v'' = 0$ transitions for the symmetric bending (ν_2) and the NN stretching (ν_3) vibrational modes for the $^1(n,\pi^*)$ system in N_2H_2 (part *a*) and N_2D_2 (part *b*)

[a]Note that while the discrepancies between calculated and experimental (1) energy values in the present assignment are only roughly 1000 cm^{-1} for the (0,0) species in N_2H_2 and N_2D_2, they become progressively larger toward higher quantum numbers because the calculated vibrational frequencies are underestimated by 100–200 cm^{-1} (Table 2).

[b]This level corresponds to the strongest band observed experimentally (1) in a given progression.

of products of Franck–Condon overlaps for the two vibrational modes ν_2 and ν_3 which appear to be involved in the observed progressions (Table 6). The corresponding energies for the $(1 \leftarrow 0)$ ν_5-induced vibronic transitions (assuming that only the lowest transitions in the other three modes are observed[6]) are then listed in Table 7. For all practical purposes the oscillator strength for each $(v_2',v_3') \leftarrow (0,0)$ transition in this $(1 \leftarrow 0)$ ν_5-induced series (complex) can be obtained by multiplying the square of the corresponding product of Franck–Condon overlaps of Table 6 by the total calculated f value of 1×10^{-4} listed in Table 5.

The (0,0) transitions[7] in this complex are thus calculated to occur at 22 833 cm^{-1} and 22 167 cm^{-1} for N_2H_2 and N_2D_2 respectively. According to the interpretation of Back *et al.* (1) the corresponding (0,0) experimental lines are not

[6]The $2 \leftarrow 0$ ν_4 transition would have perhaps been a more logical choice (Table 4) but since the corresponding $0 \leftarrow 0$ species lies only 320 cm^{-1} lower in N_2H_2 and 225 cm^{-1} lower in N_2D_2 very little of quantitative significance would be changed in Table 7 as a result of this alteration.

[7]Hereafter the notation (v_2',v_3') is used to indicate the vibronically-induced transition from $v_2'' = 0$ to v_2' and from $v_3'' = 0$ to v_3'; for the ν_5-induced series a transition from $v_5'' = 0$ to $v_5' = 1$ is always assumed.

observed but can be expected at roughly 20 330 cm^{-1} and 20 530 cm^{-1} respectively based on extrapolations in the ν_2' frequencies of N_2H_2 (1170 cm^{-1}) and N_2D_2 (880 cm^{-1}).

In the experimental assignment (1) transitions from $v_3'' = 0$ to $v_3' = 0$ and 1 are found to be about equally strong while a third progression involving the upper $v_3' = 2$ state is said to be rather weak. The calculated results of Tables 4 and 6 are in reasonably good agreement with this assignment, except that the $v_3' = 1$ Franck–Condon factor is found to be smaller than that for $v_3' = 0$. The calculated ν_3' frequency fits in well with the experimental values in both N_2H_2 and N_2D_2 (Table 2).

The situation for the symmetric bending (long) progression is less obvious, however. In this case the interpretation of Back *et al.* (1) associates the most probable transition with the upper quantum number $v_2' = 6$ in N_2H_2 and $v_2' = 8$ in N_2D_2, thereby putting the energy difference between absorption maximum and 0–0 transition in this progression at roughly 7100 cm^{-1} in both systems. According to the Franck–Condon Principle this energy difference should correspond roughly to the relaxation energy of the $^1(n,\pi^*)$ state reached exclusively through the bending vibration following vertical excitation from the ground state equilibrium conformation. Since *ab initio* calculations at both the SCF and CI levels predict that the actual symmetric bending relaxation energy is less than half this amount, Vasudevan *et al.* (2) called into question this aspect of the experimental interpretation. In at least qualitative support of this argument the present vibrational treatment indicates that the most probable transition occurs for $v_2' = 2$ for N_2H_2 and $v_2' = 3$ for N_2D_2 (Table 4) rather than for quantum numbers 6 and 8.

Considering both the theoretical and experimental evidence available (including some doubts expressed about the exact numbering for the ν_2' species in ref. 1) it seems advisable to reassign the members of each observed long progression in the following manner. In the $(v_2',0)$ species the longest-wavelength transition reported to be *certain* for N_2H_2 (occurring at 23 840 cm^{-1}) is assigned in the notation of Back *et al.* as $v_2' = 3$; the situation is equivalent in N_2D_2. Since the calculations indicate that these progressions should be shorter by at least three v_2' levels it seems reasonable to assign these species instead as $v_2' = 0$ (in both isotopes). This procedure would result in an assignment of the most intense line observed in the $v_3' = 0$ progressions as $v_2' = 3$ and 5 for N_2H_2 and N_2D_2,[8] respectively, compared with the corresponding calculated results of $v_2' = 2$ and 3. Given the error limits in both the *ab initio* calculations and in the experimental intensity measurements such discrepancies seem well within reason. According to this assignment the measured isotope shift for the (0,0) transition in this system is thus indicated to be 672 cm^{-1} (Fig. 2), with the N_2H_2 species occurring at the higher frequency, which result in turn compares rather well with the corresponding calculated quantity of 666 cm^{-1} (Table 7) in both magnitude and sign.

According to this interpretation the absolute error in the calculated ν_5-induced (0,0) transition energies is 1007 cm^{-1} for N_2H_2 and 1001 cm^{-1} for N_2D_2, an underestimation of some 0.12 eV in both cases. This finding is consistent with the position taken earlier (2) in which error limits in the calculations are claimed to be considerably smaller than the roughly 0.6 eV value indicated by a direct comparison of the calculated vertical electronic energy difference with the location of the measured absorption maximum. A small portion of the decrease in this quantity (roughly 0.1 eV) comes about because of the use of natural orbitals in the present CI study in contrast to the earlier theoretical treatment, but the rest of the improvement is traced to more fundamental considerations. Although the energy of the *strictly vertical* ν_5 excitation agrees quite closely with that of the corresponding $0 \leftarrow 0$ transition, the *most probable observed* vibrational ν_5 species is $1 \leftarrow 0$, occurring at one ν_5' quantum (3120 cm^{-1} or 0.4 eV; Table 2, N_2H_2) *higher* in energy; thus it is clear that use of the vertical energy difference between the two states to predict the location of the absorption maximum for this formally forbidden band is not a good approximation in this instance. In summary then, although the present calculations quite definitely rule out the occurrence of a progression in the antisymmetric bending frequency ν_6, as speculated earlier (2), they do support the two basic conclusions of the earlier theoretical work

[8]Note also that in the $v_3' = 1$ progression of N_2D_2 the reported maximum occurs for one v_2' quantum lower than in the $v_3' = 0$ series, thus coming into even better agreement with the present calculations.

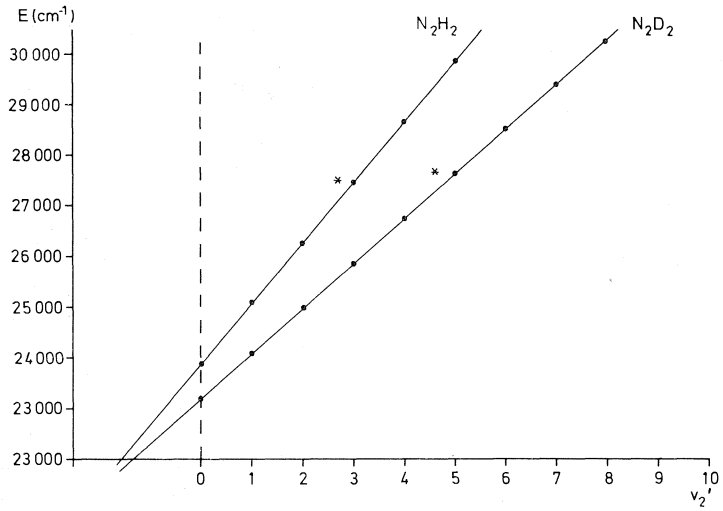

FIG. 2. Extrapolation of the first observed v_2' progression in N_2H_2 and N_2D_2 using the numbering of the present assignment. (The strongest bands are denoted by an asterisk.) The isotope shift for the respective 0–0 bands is 672 cm^{-1}.

[a]Values in square brackets are reported to be less certain (1).
[b]Given are the (v_2',v_3') assignments.
[c]According to the present assignment this transition differs from the corresponding species in the first column only in the mode of inducement (the lower-energy (E_a) transition is induced through ν_4, the higher (E_b) through ν_5).

(2) to the effect that: (*a*) error limits for the CI transition energy results seem to fall uniformally in the 0.2 eV range; and (*b*) the width of the v_2' symmetric bending progressions does not exceed 0.4 eV from the position of the absorption maximum to the corresponding 0–0 member.

Possible ν_4-induced Vibronic Transitions

The analysis of the preceding section alone is not capable of accounting for all the known vibrational transitions observed in the region of the diimide spectrum, in particular those which have been assigned by Back *et al.* (1) with $v_2' <$ 3; the wavenumbers of the band centers falling in this category are given in Table 8. If one accepts the premise that the ν_2' progressions are not as long as claimed earlier (1) it is necessary to find another explanation for the occurrence of these vibrational transitions. Since the band systems in question appear to fit in reasonably well with the same type of two-dimensional frequency analysis as has been discussed previously it seems fairly unlikely that the lower electronic state is different than in the other cases, that is, that the *cis* isomer could somehow be involved. Instead it seems considerably more

plausible that the levels in question simply arise through a different vibronic mechanism, whereupon the calculations suggest that the most likely candidate for such a secondary inducing mode is the $1 \leftarrow 0$ torsion (ν_4) species (see Table 5).

If this hypothesis is correct the intensity distribution for such torsional-induced transitions should resemble quite closely that of their counterparts with $v_5' = 1$ treated in the preceding section. Ideally one would expect that the corresponding transitions of the two types possessing the same (v_2',v_3') set of quantum numbers would differ in energy by an amount roughly equal to the difference in their inducing mode frequencies $(\nu_5' - \nu_4')$. In addition the intensity *ratio* for each such pair of transitions should always have essentially the same value, with the calculations indicating that the ν_4-induced species should generally be about three times weaker than the corresponding ν_5 species (see Table 5).

According to Table 2 the difference between ν_5' and ν_4' is $(3120 - 40) = 3080\ cm^{-1}$ for N_2H_2 and $(2212 - 9) = 2203\ cm^{-1}$ for N_2D_2.[9] If one adds the appropriate value of $(\nu_5' - \nu_4')$ to the frequencies of the transitions listed in Table 8 the new energy result does in fact in all but a single case (the very weak 22 794 cm^{-1} species) agree quite well with that of another observed transition within the ν_5-induced complex discussed earlier. Furthermore, the fact that *all* the observed transitions can be arranged in a single two-dimensional (v_2,v_3) frequency table points out the near equality between the quantity $(\nu_5' - \nu_4')$ and an integral combination of the key progression frequencies ν_2' and ν_3' in both N_2H_2 and N_2D_2, namely $\nu_5' - \nu_4' \cong 4\nu_2' - \nu_3'$ in each case.[10] In other words, each ν_5-induced transition with $v_3' > 0$ has a (weaker) ν_4-induced counterpart at nearly the same frequency with a v_2' value four units higher and v_3' one unit smaller.

There is in fact some doubling observed in the $v_3' = 2$ progression of N_2D_2 (1) but if this phenomenon were caused by such multiply-induced transitions, the 30 368 and 30 478 cm^{-1} pair, for example, would have to be assigned as the (5,2) ν_5-induced and (9,1) ν_4-induced species on this basis; the observation of the latter transition would be unexpected, however, since the corresponding (9,1) ν_5-induced line has not been seen experimentally ((12,1) in the notation of Back *et al.*). On the other hand the earlier suggestion (1) that such doubling arises in N_2D_2 because there $\nu_1' \approx \nu_2' + \nu_3'$ seems very unlikely on the basis of the present calculations since this hypothesis seemingly requires that transitions with $\nu_1' \neq 0$ be observed even though one estimates from Table 4*b* that the largest Franck–Condon factor of this type is roughly 300 times smaller than that for $\nu_1' = 0$. A third possibility which is probably more realistic than either of the foregoing is that a progression in the very small torsional frequency is involved (according to this view the respective transitions would be ν_5-induced). In any event it seems very difficult to explain such phenomena with any high degree of certainty based on the evidence presently available.

The hypothesis of nearly coincident transitions induced by two different asymmetric modes does appear to receive some additional support from the experiments in another context, however. In the earlier view (1) the lines reported at 25 973 and 26 985 cm^{-1} in the N_2H_2 spectrum (for $v_2' = 2$ and 3) should differ by a single v_2' quantum; the actual energy difference of 1012 cm^{-1} on the other hand does not agree very well with the other values in the same progression, particularly with the succeeding case in which $\nu_2' = 1208\ cm^{-1}$. By contrast in the present hypothesis there is a more complicated relationship between the above two transitions, since it is at this point that the ν_5-induced series (responsible for the 26 985 cm^{-1} line, with $v_3' = 2$) should end and the ν_4-induced progression of different v_3' quantum numbers should begin. Clearly such observations neither prove nor disprove either of the interpretations discussed, but it seems somewhat more than coincidence that the long progressions found by Back *et al.* should show their greatest deviation from

[9]In this computation the $1 \leftarrow 0$ frequencies of Table 2 are used since the energy difference sought actually involves ν_5 and ν_4 transitions between these levels; other values for this difference would emerge if one uses the so-called zero-point frequencies for this computation, a practice which does not fully conform to the physical situation under discussion.

[10]In N_2H_2 the actual measured energy differences for such pairs of transitions vary from 2900 cm^{-1} to 3200 cm^{-1} and similar consistency is noted in N_2D_2 (Table 8). Furthermore in each case the higher-energy transition in the correspondence turns out to be one of the most intense species found in the spectrum.

the harmonic condition precisely at the point where the calculations predict a break in the normal pattern to be most probable.[11]

The last point which still would seem to require discussion is the assignment of the feature observed at 22 794 cm^{-1} in the N_2H_2 spectrum; it is the shortest-wavelength line reported (1) and is said to be very weak. As such it might be best explained as a totally extraneous feature, but if one proceeds under the assumption that it is a *bona fide* diimide transition it is clear that it does not fit in well with either of the ν_5- and ν_4-induced series previously discussed; in the first case its assignment would require $v_2' = -1$, whereas in the torsion-induced series it would correspond to $v_3' = -1$. This result would seem to narrow the possibilities for a vibrationally-induced transition down to a single choice, namely via the $1 \leftarrow 0$ ν_6 mode. Using the same type of arguments as before such an assignment would require that the frequency of the band center in question to differ from that of an observed ν_5-induced species by an amount equal to roughly $\nu_6' - \nu_5'$ or 2235 cm^{-1} according to the present calculations (Table 2). Adding this amount to the value of 22 794 cm^{-1} yields a frequency which in fact differs by only 44 cm^{-1} from that of the band center of Back *et al.*'s (4,0) transition (the (1,0) ν_5-induced species according to the present interpretation). Again the occurrence of such a possible coincidence is seen to be tied up with the fact that the difference in the pertinent inducing frequencies is close to being an integral combination of the experimental progression frequencies, in this case approximately $2\nu_2'$. Since the calculations indicate that such ν_6-induced transitions should be much weaker (by a factor of about 40) than the corresponding ν_5-induced lines it is certainly plausible that they could be observed only under extremely favorable conditions, in particular in an area of the spectrum where no other strong transition is found. As with the discussion of the doubling phenomena in N_2D_2, however, it seems extremely difficult to devise an experimental test which could provide a definitive basis on which to determine whether such an assignment for the 22 794 cm^{-1} feature is actually justified.

[11]In the $v_3' = 1$ progression of N_2H_2 no such obvious break is observed, but in the $v_3' = 0$ series v_2' is reported to change from 1233 cm^{-1} to only 1046 cm^{-1} across the analogous border (1). In N_2D_2 a change from 976 cm^{-1} to 891 cm^{-1} is reported at an equivalent point in the $v_3' = 1$ progression.

Conclusion

In summary the present calculations indicate that the major portion of the 3000–4300 Å spectrum of diimide arises through vibronic inducement via the $1 \leftarrow 0$ transition in the NH antisymmetric stretching mode. Within this framework the individual vibrational transitions can be assigned in a very straightforward manner on the basis of progressions in v_2' and v_3', much as Back, Willis, and Ramsay have argued in their original paper; the only difference in the present interpretation is that its v_2' assignments are always three units lower than those given earlier (1). The calculations indicate further that $1 \leftarrow 0$ torsion (ν_4)-induced transitions overlap quite closely with ν_5-induced species in the $v_3' = 1$ and 2 progressions, and in fact occur as separate transitions in spectral regions lying outside the range in which such $v_5' = 1$ species can occur. According to this interpretation the calculated 0–0 vibrational transition energies obtained in the present CI treatment are found to lie about 1000 cm^{-1} below their measured values.

Acknowledgements

The authors wish to thank Professor D. A. Ramsay for some lively correspondence and discussions on the subject treated in this paper. One of us (M.P.) is grateful for the hospitality shown him at the University of Bonn and for the financial support given to him by the DAAD. The services and computer time made available by the University of Bonn Computer Center have been essential to this study and are gratefully acknowledged.

Received June 15, 1976[2]

FRANK C. ADAM and ALLEN JOHN ELLIOT. Can. J. Chem. **55**, 1546 (1977).

Simple alkyl sulfides and disulfides have been photolysed at 253.7 nm in dilute rigid glasses of 3-methylpentane, and the reactions which occur both at 77 K and in the glass at higher temperatures have been studied using epr and optical spectroscopy. The end products of photolysis have been determined using glc at room temperature. In sulfides, C—S bond cleavage leads to 'hot' radical pairs that react with each other giving rise to the main diamagnetic products observed, or react with nearby solvent molecules in the matrix by hydrogen abstraction yielding RSH and the solvent derived radicals (M·) which dominate the initial epr spectrum at 77 K. Thiyl radicals (RS·) are produced in significant amounts only after the sulfide glasses have been warmed slightly to allow the cage reaction,

$$RSH + M\cdot \rightarrow RS\cdot + MH$$

to occur. Pethiyl radicals ($RS_2\cdot$) are not ordinarily observed in sulfide photolyses. Photolysis of disulfide-containing glasses gives rise to S—S bond rupture and mainly diamagnetic products, or to C—S bond cleavage resulting in the formation of solvent radicals and $RS_2\cdot$. Very little RS· is generated on warming the matrices. As with ethyl mercaptan photolysis, radicals corresponding to α-hydrogen abstraction of the substrate are obtained for both ethyl sulfide and disulfide. The spectral characteristics and photolytic behaviour of the sulfur containing radical species have been investigated where possible.

FRANK C. ADAM et ALLEN JOHN ELLIOT. Can. J. Chem. **55**, 1546 (1977).

On a effectué la photolyse, à 253.7 nm, de sulfures et de disulfures simples d'alkyles; ces études ont été réalisées dans des verres rigides et dilués de méthyl-3 pentane et on a évalué les réactions qui se produisent à 77 K et dans le verre à des températures plus élevées par rpe et par spectroscopie optique. Les produits finaux des photolyses ont été déterminés en utilisant la chromatographie en phase gazeuse à température de la pièce. Dans le cas des sulfures, la coupure du lien C—S conduit à des paires de radicaux "chauds" qui réagissent les uns avec les autres pour conduire aux principaux produits diamagnétiques qui ont pu être observés ou qui réagissent avec des molécules environnantes de solvant dans la matrice par enlèvement de l'hydrogène avec formation de RSH et des radicaux dérivés du solvant (M·) qui dominent le spectre rpe initial à 77 K. Il n'y a formation de radicaux thiyles (RS·) en quantité appréciable qu'uniquement après que les verres de sulfure ont été légèrement réchauffés de façon à permettre la réaction en cage:

$$RSH + M\cdot \rightarrow RS\cdot + MH$$

On n'observe généralement pas la formation de radicaux perthiyles ($RS_2\cdot$) lors de la photolyse des sulfures. La photolyse de verres contenant des disulfures donne lieu à la rupture du lien S—S et conduit principalement à la formation de produits diamagnétiques ou à la rupture du lien C—S avec formation de radicaux de solvants et de $RS_2\cdot$. Lorsque l'on réchauffe les matrices, les radicaux RS· ne sont formés qu'en faible quantité. Comme dans le cas de la photolyse de l'éthylmercaptan, les radicaux correspondants à l'enlèvement d'un hydrogène en α du substrat peuvent être obtenus à partir des sulfures ainsi que des disulfures d'éthyle. Lorsque de telles possibilités existent, on a étudié les caractéristiques spectrales et les comportements photolytiques des espèces radicalaires contenant du soufre.

Introduction

The radical scavenging ability of thiols may play an important role in the protection and repair of living biological materials subjected to the effects of ionizing radiation (1). The thiyl radical produced during this scavenging process may also be involved in the degradation of the charged species resulting from such radiation. For instance the process

$$(RSSR)^- \rightarrow RS\cdot + RS^-$$

has been reported (2) to occur with amino acids

[1]Present address: Department of Chemistry, Queens University, Kingston, Ont., Canada.

[2]Revision received November 23, 1976.

such as cystine in the aqueous phase. In order to further the understanding of the formation and the reactions of the thiyl radical in a variety of surroundings, we have undertaken to study the photolysis of simple alkyl sulfides and disulfides in dilute rigid glasses. The solid state is chosen so that the transient species may be readily trapped and studied by conventional techniques. The matrices are dilute so as to minimize solute–solute interactions.

In an earlier publication (3), it was found that alkyl mercaptans undergo a number of interesting cage reactions when photolysed as solutes in dilute (0.01 mol dm^{-3}) glass solutions of 3-methylpentane (3MP) at 77 K. The thiyl radical produced by 253.7 nm radiation results from S—H cleavage; it is 'hot' in the sense that it is very reactive and immediately abstracts a hydrogen atom from a nearby solvent molecule, regenerating the thiol molecule.

The hydrogen atoms may also be kinetically hot, and abstract from the nearby solvent to produce a second solvent radical, or may be thermalized, diffusing away to eventually yield molecular hydrogen or to interact with a distant photodamaged centre in the matrix. Each photolysed mercaptan (RSH) is therefore associated with a solvent cage containing either one or two solvent radicals. As a result, the epr spectrum at 77 K is mainly due to solvent radicals (M·); thiyl radicals (RS·) result only when the matrix is relaxed by warming so as to allow the 'repair' reaction 1 to occur

$$\text{RSH} + \text{M}\cdot \rightarrow \text{RS}\cdot + \text{MH} \qquad [1]$$

within the still rigid solvent cage. When a second M· radical is present in the same cage, one gets recombination to the thioether RSM

$$\text{RS}\cdot + \text{M}\cdot \rightarrow \text{RSM} \qquad [2]$$

The thiyl radical itself is characterized by a yellow color (3, 4) with $\lambda_{max} \simeq 400$ nm; single crystal studies (5) have established that this radical has an axial g-tensor ($g_{\parallel} \simeq 2.2, g_{\perp} \simeq 2.0$) and an isotropic β-hydrogen coupling constant with $a_{max} \simeq 48$ G. The epr of rigid randomly oriented RS· is accordingly very broad and at low concentrations would be expected to give only a weak asymmetric resonance near $g \simeq 2.00$ due to those molecules situated with C—S bonds perpendicular to the magnetic field (*i.e.* $g_{obs} \simeq g_{\perp}$).

In more concentrated mercaptan glasses (0.1 mol dm^{-3}) a second species is also observed. It is thought to be the non-linear perthiyl radical $RS_2\cdot$ and is characterized by an anisotropic g-tensor with principal values near 2.06, 2.025, and 2.00, and for those radicals with an α-methylene group, a 6–10 G doublet proton hyperfine coupling. These parameters match those observed for photolysed (6) or γ-radiolysed cystine single crystals (7, 8) and were unambiguously assigned by Gordy and co-worker (9) to $CyS_2\cdot$ by virtue of their ^{33}S and proton hyperfine structures. A second resonance (α) was also assigned by Gordy to CyS·, but this may be in error since the characteristic g-values ($g_{\parallel} \simeq 2.06$, $g_{\perp} \simeq 2.00$) do not correspond to those given above and a comparison of the photolytic behaviour of this species in ref. 8 shows it to be different from that exhibited by CyS· in ref. 5 or from the thiyl radicals studied in the present research.

From liquid (10) or gas phase (11) studies it is known that sulfides undergo the primary photolytic process

$$\text{RSR} \xrightarrow{h\nu} \text{R}\cdot + \text{RS}\cdot \qquad [3]$$

while for disulfides

$$\text{RSSR} \xrightarrow{h\nu} 2\text{RS}\cdot \qquad [4]$$

with a minor contribution from C—S cleavage

$$\text{RSSR} \xrightarrow{h\nu} \text{R}\cdot + \text{RS}_2\cdot \qquad [5]$$

If such processes can be made to occur in dilute glassy matrices of RSR or RSSR in 3MP, then large concentrations of either thiyl and/or perthiyl radicals may be built up for further characterization and study. The object of the present investigation is to produce by photolytic action damage centres containing either a one-sulphur species (from a sulfide) or a two-sulfur atom intermediate (from a disulfide) isolated in a rigid solvent cage. In this way it was hoped to avoid the association effects observed for mercaptans in either the low temperature hydrocarbon–thiol glasses, or in the undiluted crystalline state where both monomer (one-sulfur) and dimer (two-sulfur) cages may be formed at the same time. Since neither sulfides nor disulfides are expected to dimerize in dilute solution, a satisfactory correlation with the concentration effects observed in the thiol studies of ref. 3 would reinforce the conclusions reached there.

Experimental

The procedures and apparatus used were essentially the same as those described in ref. 3. The symmetrical methyl,

ethyl, *i*-propyl, *n*-butyl, *i*-butyl, and *t*-butyl disulfides were distilled before use, as were the ethyl, *n*-propyl, *i*-propyl, and *i*-butyl sulfides studied. Both low temperature epr and optical spectra were obtained using samples prepared and sealed off from a high vacuum line. Ethyl and *i*-propyl sulfide and disulfide glasses (0.1 mol dm^{-3} in 3MP) were photolysed for 90 min at 77 K using the 253.7 nm mercury resonance line, and were subsequently melted, warmed to room temperature, unsealed, and analysed by glc, using 3% squalane or 3% SE30 on Chromosorb W for the heavy fractions (longer retention times than the solvent) and Poropak Q for the lighter hydrocarbon ends. Hydrogen gas analyses were carried out as in ref. 3.

An attempt has been made to keep photolytic conversion to a minimum. Even so, the quantum efficiency for the formation of trapped paramagnetic species is lower for both sulfides and disulfides than it was for thiols. This means that somewhat long photolysis times and higher concentrations (0.1 mol dm^{-3}) must be used to obtain satisfactory epr, optical, and product analyses.

Results

On the basis of eqs. 3–5 one would expect the initial epr spectrum of photolysed sulfides to contain the alkyl fragment R· and the thiyl radical RS·. In the case of disulfides RS_2· would be produced as well. In no case were the spectra of the combination of radicals predicted by these equations obtained simultaneously. Upon completion of the 253.7 nm photolysis, there were no intense optical absorptions near 400 nm, and the epr spectra of the isomeric propyl and butyl derivatives give hyperfine structure characteristic of the solvent radical M· rather than that of the alkyl radical R· expected. While most of the alkyl radicals have even-line spectra, and may be difficult to detect in the presence of the six line hyperfine pattern of M· (12), the isobutyl radical is known to have an odd line hyperfine spectrum in a rigid medium (13) and should therefore be readily detectable in this system. In fact the initial epr spectra of the propyl and butyl sulfides and the high field portion of the disulfide spectra are to all intents and purposes identical. The ethyl and methyl derivatives behave slightly differently and will be considered separately.

In no case were epr signals due to trapped hydrogen atoms obtained, nor half-field resonances due to trapped radical pairs ($\Delta M = \pm 2$) observed in normal operation of the spectrometer (14). None of the processes to be described is thermally reversible.

The experiments are divided up according to the following scheme:

Phase I: Photolysis of glass at 77 K with 253.7 nm light.

Phase II: Warming the glass to allow cage reactions ($\simeq$80 K) and diffusion of smaller species such as Et· etc.

Phase III: Warming toward softening point of glass (85–90 K). This allows the diffusion of larger species, and eventual annihilation of all paramagnetic compounds.

Phase IV: A (fresh) Phase II glass is recooled to 77 K and subjected to photobleaching experiments on the species produced in the first warming.

Phase V: A Phase IV glass is warmed slightly to allow the cage reactions of photobleached species ($\simeq$80 K). Further warming leads to annihilation as in Phase III.

A. Alkyl Sulfides

As noted above each of the higher alkyl sulfides in 3MP give (Phase I) epr spectra which are very similar; that of *n*-Pr_2S–3MP is given in Fig. 1, curve *a*. It is virtually identical to the six line proton hyperfine spectrum obtained by photolysis of any of the dilute (0.01 mol dm^{-3}) alkyl thiol–3MP or H_2S–3MP glasses studied in ref. 3, and is accordingly assigned to the solvent radical M·. In this particular instance *n*-Pr· would have been expected (13) to give rise to a 1:3:4:4:3:1 sextet, compared to the 1:9:19.5:19.7:11.5:1.75 sextet obtained here. The *g* values (2.002) and splittings ($\simeq$23 G) are similar for each. Apart from the fact that the main constituent of the epr spectrum appears to be M· and not R·, it is important to note there is the epr absorption at $g = 2.06$ and there is no gross asymmetry in the spectrum near $g = 2.00$. The same applies to the Et_2S–3MP glass which gives an absorption as in curve *a* of Fig. 2. Although Fig. 2*a* is still basically a six line hyperfine pattern, it has considerably more detail, most of which can be ascribed to the ethyl radical. The splittings (a(3H) = 28.8 G, a(2H) = 22.3 G) are similar to those obtained by γ-radiolysis of ethyl halides at 77 K (13). Generally speaking the Phase I epr spectra contain only hydrocarbon radicals such as M· or Et·. The optical spectra of Phase I sulfide glasses typically contain two weak absorptions, one at 400 nm, the other at 520 nm, and a representative spectrum is shown in Fig. 3, curve *a*. The 520 nm peak is ascribed to the n–π* transition of a thiocarbonyl, expected to absorb in this region (15, 16), while the 400 nm peak will be considered below.

Warming the photolysed glasses slightly (79–

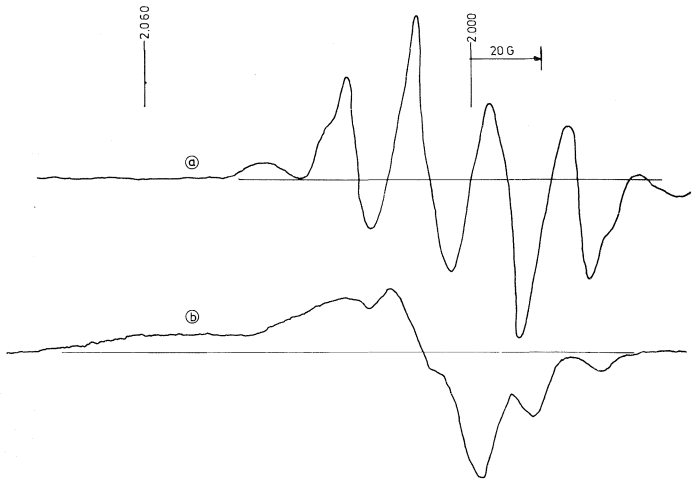

FIG. 1. (*a*) Initial (Phase I) epr spectrum of 0.1 mol dm^{-3} *n*-Pr_2S in 3MP photolysed at 253.7 nm for 180 min, showing solvent radical M·. (*b*) Phase II spectrum obtained by warming sample (*a*) slightly, showing spectrum of RS· and some residual M·.

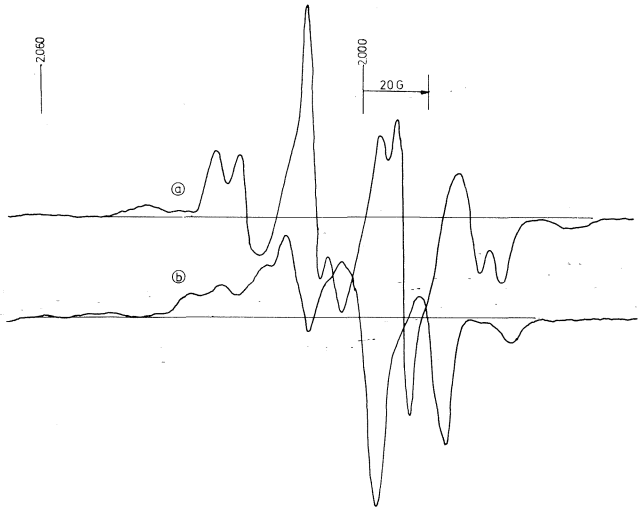

FIG. 2. (*a*) Initial (Phase I) epr spectrum of 0.1 mol dm^{-3} Et_2S in 3MP photolysed for 180 min at 77 K showing hyperfine structure of Et·. (*b*) Phase II spectrum of sample in (*a*) after slight warming, demonstrating five line hyperfine pattern of $CH_3\dot{C}HSX$ and asymmetry due to EtS·.

80 K) gives Phase II; the glasses become intensely yellow as typified in curve *b* of Fig. 3, and the hydrocarbon radicals M· or Et· initially present, decay, to be replaced by a broad asymmetric resonance depicted in Fig. 1*b*. This resonance is assigned to the RS· radicals formed by the reaction 1. In the case of Et_2S a similar spectrum to Fig. 1*b* results upon decay of the Et· radicals, presumably by an analogous process. When Et_2S has undergone a longer Phase I photolysis ($\simeq$1.5 h) an additional five line hyperfine spectrum as in Fig. 2*b* is observed. It is similar to radical C of ref. 3 ($g_{iso} \simeq 2.004$, $a(4H) = 19.7$ G, $\Delta H_{pp} = 6$ G) which was assigned to a species of the sort $CH_3\dot{C}HSX$, with X being H, R, or M. The basis of this assignment is that it is not observed with other alkyl sulfides and the hyperfine splittings are close to the weighted means of those observed for such components in the liquid phase ($a(1H) = 16.8$ G, $a(3H) = 19.8$ G) (17) or in γ-irradiated urea clathrates of Et_2S (18) with $a(1H)_{\parallel} = 24.6$ G, $a(1H)_{\perp} = 12.8$ G; $a(3H)_{\parallel} =$

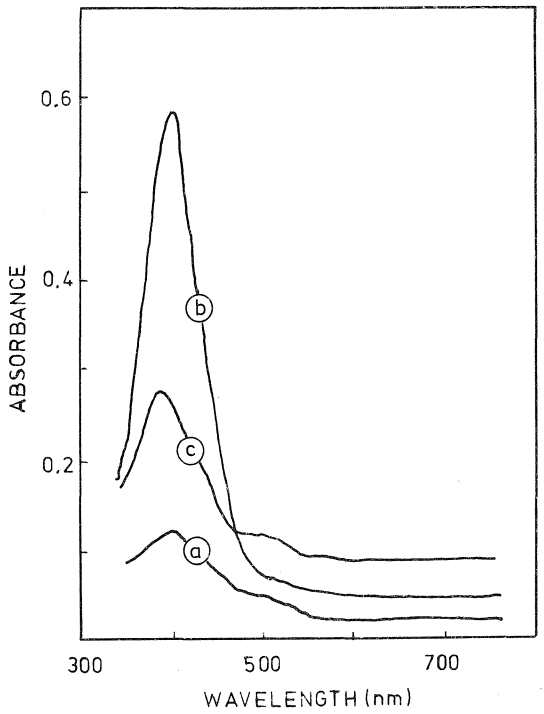

FIG. 3. (*a*) Initial (Phase I) optical spectrum of 0.1 mol dm^{-3} *i*-Pr_2S in 3MP photolysed for 60 min at 253.6 nm. Absorptions due to $(CH_3)_2C{=}S$ (520 nm) and *i*-$PrS_2\cdot$ (405 nm). (*b*) Phase II spectrum of sample in (*a*) warmed slightly. Absorption at 410 nm due to *i*-$PrS\cdot$. (*c*) Phase IV spectrum of sample in (*b*) obtained by recooling to 77 K and 30 min 253.7 nm photolysis. Absorption due to *i*-$PrS_2\cdot$ at 405 nm and $(CH_3)_2C{=}S$ at 520 nm.

21.8 G, $a(3H)_\perp$ = 19.4 G. The asymmetry of the five line spectrum in Fig. 2*b*, and the intense yellow of the glass can be ascribed to EtS· which is also present. As with all other sulfide–3MP glasses, there is little epr absorption near g = 2.06 for the Phase II glass of Fig. 2*b*.

Phase III is obtained by warming the glass toward the softening point of the matrix. It is characterized by the gradual loss in intensity of all of the absorptions represented by Figs. 1*b*, 2*b*, or 3*b* with little change in the line shapes. No new epr absorptions appear in the region near g = 2.06.

The photolytic behaviour of RS· can be studied by resort to Phase IV conditions. Such photolysis is distinct from either Phase I or II. The intensity of the yellow color is diminished and shifts to the blue to give a new absorption maximum, as seen in Fig. 3, curve *c*. This new maximum corresponds in wavelength to the weak absorption originally observed in curve *a* of Phase I. Meanwhile in epr samples, the resonance of Fig. 1*b* is replaced by a complex hyperfine pattern apparently characteristic of the solute (since it is quite different from that obtained in Phase I) and, in addition, signals appear to the low field end of the spectrum near g = 2.06. Apart from this last feature, the spectrum obtained from EtS· is similar to that in Fig. 2*a* and can again be assigned to the ethyl radical. This Phase IV photolysis is also quite different from that in Phase I, however. Besides generating the low field $EtS_2\cdot$ hyperfine doublet at g = 2.0596, a 5–10 min Phase IV photolysis will produce about the same amount of ethyl radical as was obtained in a 30 min Phase I photolysis. It is apparent from the visual bleaching that the EtS· species is being photolysed by 253.7 nm radiation during this step to yield Et· and ^3P sulfur atoms, as was suggested in ref. 3. It is thought that these sulfur atoms are able to diffuse in 3MP glasses at 77 K and react according to the scheme,

$$\mathrm{RS}\cdot \underset{\Delta}{\overset{h\nu}{\rightleftarrows}} \mathrm{R}\cdot + \mathrm{S}:$$

$$\mathrm{RS}\cdot + \mathrm{S}: \rightarrow \mathrm{RS_2}\cdot$$

$$n\mathrm{S}: \rightarrow \cdot\mathrm{S}_n\cdot$$

That the first of these reactions is thermally reversible is easily demonstrated by warming a Phase IV glass. This is Phase V and is typified by loss of all alkyl radical signal, slight intensification of the $RS_2\cdot$ absorption, and a partial recovery of the spectral characteristics attributed to RS·. The various systems can be recycled between Phases IV and V several times, the only apparent differences between successive spectra being that $RS_2\cdot$ signals continue to grow, while the overall intensities of the remaining absorptions diminish and the glasses assume a more distinct and permanent yellow colouration. The photolysis of RS· has been observed in analogous single crystal studies; CyS· was photolysed to give a carbon centred radical with an isotopic g value near g = 2.004 (5, 19) and CyS· was reformed on warming.

It is apparent from the optical spectra that both RS· and $RS_2\cdot$ absorb near 400 nm, although the actual maxima are slightly different for each alkyl function. For the various sulfides in 3MP, the RS· and $RS_2\cdot$ maxima are given, respectively, by Et_2S (405, 398 nm), *i*-Pr_2S (410, 405), *n*-Pr_2S (405, 395), and *i*-Bu_2S (415, 410 nm). The weak peak occurring near 400 nm in Fig. 3*a* must also

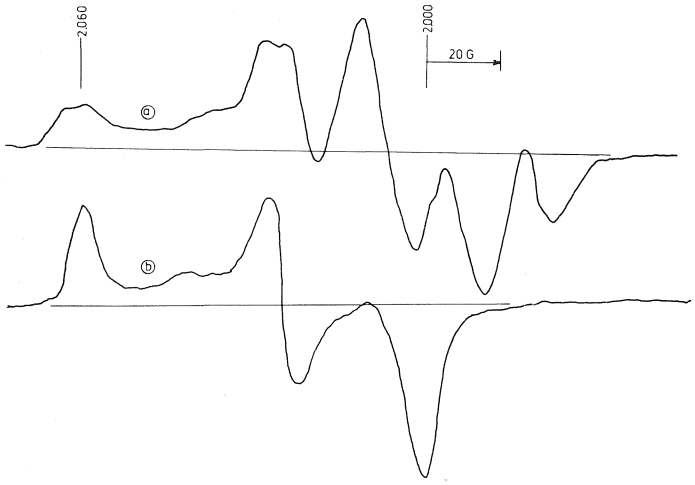

FIG. 4. (*a*) Initial (Phase I) epr spectrum of 0.1 mol dm^{-3} *n*-Bu_2S_2 in 3MP, 180 min 253.7 nm photolysis at 77 K showing absorptions due to *n*-$BuS_2\cdot$ and M· superimposed. (*b*) Phase II epr spectrum obtained from 0.1 mol dm^{-3} *t*-Bu_2S_2 in 3MP, 180 min 253.7 nm photolysis at 77 K and warmed slightly. The absorption is due to *t*-$BuS_2\cdot$.

be attributed to *n*-$PrS_2\cdot$ being formed during Phase I. This possibly results from photolysis of *n*-PrS· obtained from localized Phase II type warming in the large optical samples, a condition which is not replicated in the smaller epr samples which are in better thermal contact with the refrigerant.

The photobleaching of the $CH_3\dot{C}HSEt$ spectra found in Et_2S–3MP glasses has also been studied. Following a longer 3 h Phase I photolysis (to enhance the yield relative to the other photoproducts discussed above), it was found that photobleaching with 253.7 nm light in Phase IV reduced the intensity of the five line absorption. Ethyl radicals were still the major product of this photobleach. The five line spectrum is regenerated upon warming the matrix in Phase V, suggesting the following equilibrium

$$CH_3\dot{C}HSEt \underset{\Delta}{\overset{h\nu}{\rightleftarrows}} CH_3CH{=}S + Et\cdot$$

B. Alkyl Disulfides

When the higher dialkyl disulfides are photolysed in 3MP glasses at 77 K, the initial Phase I epr spectrum indicates that both $RS_2\cdot$ and M· are produced. These disulfides, including *i*-Bu_2S_2, all give similar spectra of which that for *n*-Bu_2S_2 is a representative example and is shown in Fig. 4*a*. It should be compared to the spectrum of a corresponding sulfide in Fig. 1*a*, especially near $g = 2.06$. The M· hyperfine spectrum is of much lower intensity compared to the photolysed sulfides. With Et_2S_2–3MP glasses, a strong hyperfine quintet is obtained, which has, within the experimental limits of these measurements, the same splitting and *g* value as observed in Fig. 2*b*. Because it arises from a substrate with two sulfur atoms, it is assigned to the species $CH_3\dot{C}HSSX$, the justification being that an analogous species observed in liquid solution has virtually the same splitting as does its $CH_3\dot{C}HSX$ counterpart (17). Me_2S_2 gives a hyperfine triplet with a similar splitting, and both demonstrate epr absorptions in the $g = 2.06$ region.

The optical spectra of all disulfides are similar to curve *a* of Fig. 3 in that two absorptions are obtained at 400 and 520 nm. In the case of *t*-Bu_2S_2, the latter is very weak; the former peak is probably stronger than in the case of the sulfides, but analysis is made difficult due to the onset of absorption by the substrate in this spectral region.

In contrast to the sulfide and thiol glasses, warming of disulfide glasses in Phase II produces neither the spectacular growth of yellow colouration, nor does the asymmetry in the epr spectrum at $g = 2.00$ increase. In the epr spectrum of *t*-Bu_2S_2 the solvent radicals decay to reveal the complete perthiyl spectrum of Fig. 4*b*. In this case the absorption at 380 nm is essentially unchanged during warmup as is the intensity of the $RS_2\cdot$ resonance in the epr spectrum. The $g = 2.06$ peak shows a 5–10 G doublet splitting for only those perthiyl radicals with an α-methylene

group. The epr signals fade as the matrix is warmed to its melting point in Phase III.

If a freshly photolysed Et_2S_2 glass is warmed slightly, recooled, and then subjected to a second Phase IV 253.7 nm photolysis, one can detect growth of weak hyperfine lines corresponding to Et· with little other change in the epr spectrum. This implies that EtS· is also formed in the disulfide photolysis, but that there is very little of it, correlating with the above observation in that there is no intensification of the yellow colour on warming, and that any asymmetry in the epr spectra that may be observed at $g = 2.00$ is due to RS_2· and not RS·. The five line hyperfine spectrum is unaffected by this second photolysis, a feature which is in contrast to that observed with the sulfides, and which supports the assignment made above.

C. Product Analysis

A somewhat greater variety of products were obtained by the glc than might have been expected from the simple photolytic process indicated in the Introduction, and the situation is clearly much more complex than had been hoped. The amounts of these products vary according to the substrate, concentration, photolysis time, and sample size, but the values in Table 1 are representative. The results for the 30 min photolysis of a 0.01 mol dm^{-3} *i*-PrSH glass have been included for comparison. The sulfide and disulfide results are for 0.1 mol dm^{-3} glasses and 90 min photolysis. All concentrations in Table 1 are in mmol dm^{-3}, referred to room temperature. Many other peaks are obtained in the glc chromatogram which had very much lower peak height than those reported. In some instances these peaks can be assigned to species such as CH_3SR, MSH, etc., but they individually form only a small part of the total. A mass balance is not possible since products (such as RSH) with similar retention times to the solvent could not be assayed. The fate of the thiocarbonyls formed is not known but is presumed to be high molecular weight polymers (16) or disulfides resulting from reaction with the alkyl mercaptans also produced in the photolysis. Authentic samples of RSM were not available so the total area of the three peaks was related to concentration using the corresponding RSSR conversion factors multiplied by the inverse ratio of the number of carbon atoms.

TABLE 1. Product yields for 90 min photolysis of 0.1 *M* sulfide and disulfide glasses, and for 30 min photolysis of a 0.01 *M* mercaptan glass at 77 K using 253.7 nm light

	Yield (mmol ℓ^{-1}) for substrate =			
Product	Et_2S	*i*-Pr_2S	*i*-Pr_2S_2	*i*-PrSH
H_2	0.3	0.5	0.5	1.1
CH_4	0.2	0.46	0.3	1.7
C_2H_4	0.9	0.09	0.03	0.15
C_2H_6	0.4	0.10	0.04	0.7
C_3H_6	<0.01	1.6	0.12	0.06
C_3H_8	<0.01	0.6	0.07	0.09
RSSR	0.22	0.08	—	0.3
RSM	(0.13)	(0.16)	(0.12)	(0.73)
C=S	0.7	0.7	1.5	<0.5

Thiocarbonyl concentrations were estimated using the known extinction coefficients of stable thioketones (15).

The amount of C—S bond rupture in *i*-Pr_2S can be estimated from the alkene (R′) and alkane (RH) yields. For the conditions given in Table 1 it is about 1–3% of the total sulfide. The amount of C—S bond rupture in disulfides is significantly less, being 0.1 to 0.2% of the total disulfide. From the hydrogen yield, the conversion of thiol to damage centres is 10–15%.

In the glc there is no material change in the substrate heights caused by photolysis of either *i*-Pr_2S or *i*-Pr_2S_2 glasses so that the overall conversion of these substances is within the experimental accuracy of the method (~10%).

Discussion

There are a number of points of difficulty which must be considered before proceeding to an analysis of the experimental results. These are as follows: (*a*) the radical pairs predicted from the liquid and gas phase work in eqs. 3–5 are not those radicals immobilized in the glassy matrix at 77 K following photolysis. (*b*) While the primary radicals are produced in pairs, not all decay by cage recombinations although in many instances the two radicals would be much too large to be able to diffuse out of their original cage and into the 3MP matrix at temperatures below 84 K. (*c*) There are products obtained in Table 1 which are unexpected on the basis of eqs. 3–5.

The observation that very little thiyl radical is present following photolysis is consistent with the suggestion made in ref. 3 which supposes that RS· can carry off a larger-than-normal share of the photon energy because of the availability of an energetically low lying electronic state. Since the photons have energies of 469 kJ mol^{-1} and

TABLE 2. Cage reactions of divalent sulfur compounds in a rigid hydrocarbon (MH) medium; *A*, thiols; *B*, sulfides; *C*, disulfide S—S cleavage; *D*, disulfide C—S cleavage. the C—S and S—S bonds have energies of only about 293 kJ mol^{-1} (1) then the excess energy available to the separated fragments far exceeds 4 kJ mol^{-1} required to effect H-atom abstraction from the geminal radical or from a neighbouring solvent molecule (20). Photolytic scission of the C—S bond may also produce a kinetically 'hot' alkyl radical in a fashion analogous to the photolysis of alkyl halides in 3MP (21) which give at 77 K solvent radicals M· as the trapped metastable species rather than the appropriate alkyl radical R·. In keeping with the idea that either one or both of the photolytic fragments may be born with energies in excess of thermal, Table 2 has been drawn up to give in general terms the cage reactions most likely to occur in a rigid medium following the photolytic rupture in Phase I,

$$XY \xrightarrow{h\nu} X\cdot^* + Y\cdot^*$$

Included are bond dissociations for S—H (*i.e.* mercaptans in row *A*), C—S (for sulfides, *B*, and disulfides, *D*) and for S—S rupture (disulfides in row *C*). Reactions 6 and 7 (columns 2 and 3) represent α-hydrogen abstractions for primary alkyl groups, and would not be expected to be important for the tertiary alkyl function. Reaction 8*B* is taken to mean that hot R· (Y*) attacks the solvent MH in the presence of thermalized RS· (X) and so on. The entries are chosen to correspond to the usual situation where relatively little R· or RS· is observed at the cessation of photolysis, while M· and RS_2· are detected experimentally. The occurrence of the appropriate thiocarbonyl, alkane RH, alkene R″, and thioether RSM are seen to result in an obvious way from cage processes.

This brings up the second difficulty. With the exception of cage type [9*A*], warming the matrix should result in loss of all paramagnetic species because the residual radicals are all large molecules, occur as proximal pairs in cages such as given by [10], and should decay by "composite first order" kinetics (22). The fact that epr signals and radical conversions are observed right up to the melting point of the matrix clearly contradicts this supposition, and some mechanism must be found which will allow for the formation of stable populations of isolated radicals at 77 K. The most plausible explanations involve secondary photolysis of the caged products. While we have not been able to produce paramagnetic species by the photolysis of a stable thioketone in 3MP at 77 K, products which are known to be photochemically active to 253.7 nm radiation are butyl radicals (23), M· (24), RS· (3), RSH (3), and probably RSSH. The solvent radicals have been reported to rupture giving CH_3· (24*a*) or C_2H_5· (24*b*) leaving an alkene trapped in the matrix.

$$CH_3CHCHC_2H_5 \xrightarrow{h\nu} CH_3CH{=}CH + C_2H_5\cdot$$

This rearrangement would effectively remove one radical from a cage such as reaction 10*B* with the result that annealing the residual cage would give

RS· rather than the RSM which would result from the unmodified cage. The liberated Et· could then produce a second thiyl radical by a diffusion encounter with RSH in an inactive cage during the annealing. Secondary photolysis of RSH is another possibility. It would create a type [9*A*] cage from one such as [9*B*], liberating a thermal hydrogen atom, which is mobile in 3MP at 77 K (25), and which could perform a function similar to the mobile ethyl radical mentioned above, but at a lower temperature. The mobile species could also react with other radicals, thiocarbonyls, or with distant solvent molecules (20).

With regard to the unexpectedly diverse variety of the products formed, there appear to be hydrocarbon fragments resulting from both the solute and solvent molecules. A great number of modes exist for their formation, for instance by decomposition of excited molecules produced as a result of radical recombinations (*e.g.* M*, RM*, or M_2* resulting from cage reactions in Table 2), or from photolysis of M·. The situation is clearly too complex to be sorted out on the basis of the present evidence. As will be seen below, we have tried to relate all these secondary products in isopropyl sulfide and disulfide photolyses back to those occurring in the primary photolysis of *i*-PrSH, not because this is felt to be the only operative mechanism but because many of the accompanying processes, such as photolysis of M·, would be expected to give very similar product distributions in these very diverse systems.

A. Sulfide Photolysis

The primary reactions cited in Table 2 can be justified by the results which appear in Table 1, except that it is necessary to sort out which of the products are due to the primary process and which are due to secondary photolytic processes. Columns 1 and 4 of Table 1 show relatively small amounts of propane and propene result from Et_2S and *i*-PrSH photolysis, or from solvent fragmentation. These are, however, the main products in the photolysis of *i*-Pr_2S (column 2) and justify the primary products of [6*B*] and [7*B*]. For reasons given in the previous section the remaining products are considered to be equivalent to mercaptan photolysis. A rough estimate of the magnitude of this effect can be obtained by scaling down the results in column 4 of Table 1 to correspond to the situation actually met in the sulfide photolysis. The total sulfide decomposition must exceed the amount of propane and propene recovered (2.2 mmol dm^{-3}) whereas the analysed sulfur amounts to 1.02 mmol dm^{-3}. If the remaining sulfur appears as *i*-PrSH as Table 2 would suggest, then the total *i*-PrSH yield must exceed 1.18 mmol dm^{-3}, or a mean mercaptan concentration of 0.6 mmol dm^{-3}. Thus a 90 min *i*-Pr_2S photolysis should produce sufficient mercaptan to be equivalent to a 30 min photolysis of 10 mmol dm^{-3} *i*-PrSH, scaled down by a factor somewhat greater than 0.18. Since in both systems, disulfide can result only from thiyl recombination, and this has been assumed to result only from mercaptan photolysis, a comparison of disulfide yields should give a more reliable scaling factor. One obtains 0.27 as the proportion of secondary process in sulfides to primary process in mercaptan. By multiplying column 4 of Table 1 by this factor and subtracting it from column 2, one obtains a relatively good agreement for all products except H_2 which is too low (by 0.2 mmol dm^{-3}) and RH which is also too low to explain the thione yield by process [7*B*]. If in addition a molecular reaction is included,

$$\text{RSR} \xrightarrow{h\nu} \text{R}'' + \text{R}'\text{CH}{=}\text{S} + \text{H}_2 \qquad [11]$$

then all yields are brought into correspondence. The analysis suggests that *i*-Pr_2S photolysis proceeds 60% by [6*B*], 22% by [7*B*], 8.5% by [11], 6% by [9*B*], and 3.5% by [10*B*] and represents reaction of 2.3% of the sulfide initially present. Of the total mercaptan produced by these processes, about 20% is subject to secondary photolysis. From the M· signal in the epr spectrum, an estimate of ~0.5 mmol dm^{-3} can be made for this paramagnetic transient (23*b*), in reasonable agreement with the amount required to produce the observed RSSR and RSM (0.38 mmol dm^{-3}). Viewed from another point, over 90% of the sulfide decomposition gives diamagnetic products directly, the remainder involving detectable paramagnetic intermediates. Of these, roughly a third undergo a repair reaction such as [1].

The five line hyperfine spectrum observed following decay of the Et· and M· radicals in the Et_2S photolysis can be attributed to radicals resulting from attack of the thioaldehyde present as a result of reactions 7*B* or 11. During the primary photolysis at 77 K,

$$\text{H}_{\text{th}}\cdot + \text{S}{=}\text{CHCH}_3 \rightarrow \text{HS}\dot{\text{C}}\text{HCH}_3$$

while during warmup,

$$Et\cdot + S{=}CHCH_3 \rightarrow EtS\dot{C}HCH_3$$

or

$$M\cdot + S{=}CHCH_3 \rightarrow MS\dot{C}HCH_3$$

The formation of the first will be obscured by the presence of M· or Et· but might be expected to give rise to a similar five line hyperfine spectrum as the other $CH_3\dot{C}HSX$ species, and since their appearance depends upon the buildup of a secondary species, their observation will be favoured by longer photolysis times. Radicals of this size remain immobilized in the matrix until it softens, and can subsequently be repaired by photolytically produced thiol at higher temperatures. As a result, the ethyl disulfide yield eventually obtained at room temperature is probably undiminished by the formation of this type of radical.

B. Alkyl Disulfides

The disulfide–3MP photolysis is somewhat more complicated since there is a greater number of primary processes possible, as can be seen from Table 2. While the diversity of products is at least as great with the sulfides and thiols, their yields are only slightly lower, and the production of RS· is substantially reduced in the case of the disulfides. Since there is a strong possibility that each of the primary products RSH and RSSH will undergo secondary photolysis, and hence act as a source of thermal hydrogen atoms, then an analysis similar to that of the last section can be carried out, at least as far as the fragmentation products are concerned. By using a scaling factor of 0.2 to relate column 4 to column 3 of Table 1, and assuming a molecular process similar to [11] namely:

$$[12] \qquad RSSR \xrightarrow{h\nu} RSSR^* \rightarrow 2R'CH{=}S + H_2$$

one finds a reasonable fit for the isopropyl disulfide data. Of the assayed products, about 25% of the primary S—S cleavage occurs by [12] and about 75% by [6*C*], [7*C*]. Of the decomposed disulfide assayed, 12% gives $RS_2\cdot$ and RSSH by C—S bond rupture. No estimates of the processes [10*C*] or [9*D*] can be made. This particular analysis suggests that the contribution from reaction [8*C*], [9*C*] is very small so that most of the thiol produced by S—S cleavage is present in a cage as a geminal thiol pair [10*C*] or is combined with a thiocarbonyl compound as in [6*C*], [7*C*]. On absorption of a second photon, these cages would appear to regenerate the parent disulfide or to give rise to a diffusible hydrogen atom and intermediates similar to those found in the photolysed thiol systems (3). For [10*C*]

$$2RSH \xrightarrow{h\nu} R\dot{S}S(H)R + H_{th}\cdot$$

$$R\dot{S}S(H)R \xrightarrow{h\nu?} RS_2\cdot + RH$$

$$\rightarrow RSSR + H_{th}\cdot$$

These reactions have already been considered in [3] and occur in concentrated thiol glasses which contain dimers of the mercaptan. For cages typefied by [6*C*] one obtains

$$RSH + S{=}CHR' \xrightarrow{h\nu} RSS\dot{C}HR' + H_{th}\cdot$$

This last reaction would give rise in the case of ethyl and methyl disulfide, a hyperfine quintet and triplet, respectively, as observed in the Phase I epr spectra of these compounds photolysed at 77 K.

Although $CH_3CH_2SS\dot{C}HCH_3$ gives an epr spectrum essentially identical to that of the molecules $CH_3\dot{C}HSH$ and $CH_3\dot{C}HSC_2H_5$ produced in the sulfide or mercaptan photolysis, it is generated under circumstances which would photolyse the latter compounds. Such radicals are neither expected nor found in *t*-Bu_2S_2 photolysis.

Conclusions and Summary

One of the reasons for which the present research was undertaken was to provide a positive identification and determine the reaction characteristics of the neutral intermediate species which may be involved in the γ-radiolysis of divalent compounds in the solid state. Both the thiyl and perthiyl radicals are implicated in the radiolysis of cysteine, for instance, which forms cystine even in the crystalline state (26) and which also gives stable perthiyl radicals at room temperature (5).

Although the divalent sulfur compounds undergo a very complex set of reactions when photolysed in dilute matrices, the following facts now appear verified:

(*a*) Thiyl radicals are preferentially formed from photolysed sulfides and monomeric thiols (3) which contain a single S atom in the reactive cage. As produced photolytically RS· is kinetic-

ally hot and may damage surrounding molecules by H-atom abstraction.

(*b*) In the glassy state thiyl radicals have a single broad unsymmetrical epr absorption near $g = 2.00$.

(*c*) Thiyl radicals may be photolysed by 253.7 nm radiation to give alkyl radicals and ^3P sulfur atoms. Wavelengths much longer than 350 nm are ineffectual, although these radicals also have strong absorption near 400 nm.

(*d*) ^3P sulfur atoms diffuse in 3MP matrices at 77 K.

(*e*) Perthiyl radicals will not be produced in dilute mercaptan (3) or sulfide systems unless ^3P sulfur atoms are liberated by photolysis of thiyl radicals.

(*f*) RS· has a tautomeric form R′ĊHSH which does not appear to be the preferred isomer in 3MP at 77 K. The reverse is true for the oxygen analogues, methoxyl (27), and ethoxyl (28) radicals.

(*g*) The α-abstraction product of Et_2S, $CH_3\dot{C}HSC_2H_5$ has been observed. It is photodecomposed by 253.7 nm radiation to give Et· and thiocarbonyl at 77 K, and reforms by a cage reaction on warming.

(*h*) The perthiyl radical is preferentially formed from photolysed disulfides or from mercaptan dimers where the sulfur atoms appear as 'pairs' in an otherwise dilute matrix.

(*i*) RS_2· is characterized in esr by an anisotropic *g*-tensor with principal values near 2.00, 2.025, and 2.06, and doublet hyperfine splitting of 5–10 G when the R-group contains an α-methylene group. In the optical spectrum, there appears to be reasonably strong absorption in the 375–400 nm region. RS_2· is not photolabile above 240 nm.

(*j*) The α-abstraction product of disulfides is photochemically stable to 253.7 nm, and has epr hyperfine spectra similar to the compound in (*g*). Neither has strong visible absorption.

(*k*) The above paramagnetic species constitute only a small fraction of the total sulfide or disulfide photo-decomposition, being $\simeq 10\%$ and less than 12% respectively. The remainder are diamagnetic products such as mercaptans, thiocarbonyl, mixed thioethers, and alkanes or alkenes corresponding to the R group of the original substrate.

(*l*) Mercaptan produced in Et_2S and Et_2S_2 may be subject to secondary photolysis, leading to EtS· in sulfides, and to $EtSS\dot{C}HCH_3$ or EtS_2· in the case of disulfides.

There are many points of agreement between the present work and other research where sulfides and disulfides have been photolysed under widely different experimental conditions. Included in these studies are the room temperature liquid phase photolysis carried out with or without dilution of the substrates by a hydrocarbon solvent. It must be recognized that under such conditions cage processes such as [8*B*] forming RSM will have reduced significance and that all reactions which occur in Phase I through Phase V in the glassy state will be proceeding simultaneously in fluid media. Thus while mercaptans are the major products obtained from room temperature photolytic cleavage of the S—S bonds in disulfides (1), this mercaptan will scavenge other mobile radical products such as M·, R′ĊHSSR, etc. giving rise to thermal RS·. RS· will itself be photolysed during the experiment and, by virtue of the atomic sulfur released, will eventually lead to the formation of the mono-, tri-, and tetrasulfide products observed (10). It is perhaps significant that the RSH concentration reaches a steady state maximum during disulfide photolysis (29). This was assumed due to secondary RSH photolysis much as has been suggested by the present results. Evidence of H_2 formation and unexpected hydrocarbon residues is also found in the room temperature photolysis of both sulfide and disulfides (30).

With regard to research carried out in the rigid matrices, it is now apparent that Rosengren, who used only optical and glc methods to study the photolysis of alkyl disulfides in hydrocarbon glasses at 77 K (16) did not have RS· but rather RS_2· as the species which absorbed near 400 nm. We are in agreement that the major photoreaction is that given by [6*C*], [7*C*].

There is also agreement between our work and that of Bolman *et al.* (31) and of Windle and coworker (32) who photolysed at 77 K a variety of mercaptans, sulfides, and disulfides as polycrystalline solids or adsorbed on Vicor plates. Their spectra of mercaptans and disulfides agree with earlier (3) and present work, respectively, in that RS_2· is produced in both concentrated RSH and in R_2S_2 matrices along with other species which exhibit proton hyperfine coupling. However, photolysis of *n*-decyl sulfide (32) produces

$RS_2\cdot$ along with an eight line hyperfine pattern due to an alkyl radical. This result would be anticipated if the stronger binding of the sulfide in the crystalline lattice led to formation of a higher proportion of thermalized alkyl thiyl radicals which are then subsequently photolysed to liberate free sulfur atoms much as in our Phase IV experiments.

Reference has already been made to the correspondence between our results and those for photolysed or γ-irradiated cysteine and cysteine single crystals.

Determination of motional asymmetry of methyl rotators from ^{13}C spin dynamics

LAWRENCE G. WERBELOW AND DAVID M. GRANT
Department of Chemistry, University of Utah, Salt Lake City, UT, U.S.A. 84112

Received December 11, 1976

LAWRENCE G. WERBELOW and DAVID M. GRANT. Can. J. Chem. **55**, 1558 (1977).

Recent advances in the theory of dipolar relaxation in multispin systems are applied to studies of methyl rotators in isotropic fluids. A simple methodology is outlined which is very attractive for the investigation of anisotropic methyl group reorientation. It is demonstrated that this approach does not suffer from many of the inherent limitations of conventional applications of dipolar relaxation to such studies. Analogous extensions of the propounded method become temptingly obvious.

LAWRENCE G. WERBELOW et DAVID M. GRANT. Can. J. Chem. **55**, 1558 (1977).

On a appliqué des connaissances acquises récemment dans le domaine de la théorie de la relaxation dipolaire de systèmes multispin pour étudier des rotors méthyles dans des fluides isotropes. On décrit une méthodologie simple qui est très attrayante pour l'étude de la réorientation anisotrope du groupe méthyle. On démontre que plusieurs des limitations inhérentes des applications conventionnelles de la relaxation dipolaire à de telles études ne se retrouvent pas dans cette approche. Des extensions analogues de la méthode proposée deviennent rapidement évidentes.

Introduction

The investigation of the dynamical features of methyl rotators in liquid media has provided the central theme for numerous recent experimental applications of transient effects in magnetic resonance studies (1). However, recent advances in the theory of dipolar relaxation in multispin systems (2, 3) have yet to be routinely applied in such seemingly inviting experimental investigations of related topics. It is the intent of this work to emphasize how differential recovery rates of individual components in a fully coupled $^{13}CH_3$ subspectrum can yield detailed information on the motional asymmetry of methyl rotators.

In proton decoupled $^{13}CH_3$ spin systems, the apparently exponential (4)[1] recovery rate of the inverted collapsed quartet is related to molecular parameters by the following expression

$$[1]\quad \ln\left(\frac{\langle I_z^{C}(t)\rangle}{\langle I_z^{C}(0)\rangle}\right) \simeq \ln(5\gamma_H/\gamma_C) - \ln(10+\zeta_C) - J_{CH}(10+\zeta_C)t$$

The dipolar spectral density, J_{CH}, can be written in the specialized form,

$$[2a]\quad \frac{J_{CH}}{\alpha\chi} = \frac{1}{16} + \left(\frac{1}{5+\xi}\right) + 2\left(\frac{1}{2+4\xi}\right)$$

Nondipolar contributions to the carbon relaxation rate are approximated as random field interactions. The contribution of such interactions to the longitudinal relaxation rate of spin 'i' is conveniently represented by the term $R_1^{0}(i)$. The unitless interaction ratio appearing in [1] can be related to this quantity by the expression

$$[2b]\quad \zeta_C = \frac{R_1^{0}(C)}{J_{CH}}$$

The parameters α, χ, and ξ appearing in [2a] are defined by the following relationships

$$[3]\quad \alpha = 32/27$$

$$\chi = \frac{3}{40D_0}\left(\frac{\gamma_H\gamma_C\hbar}{r_{CH}^{3}}\right)^2$$

$$\xi = \frac{D_{int}}{D_0} + 1$$

Internuclear distances and magnetogyric ratios are conventionally defined.

For simplicity, it is assumed that the methyl rotator is affixed to a framework completely described by the isotropic rotational diffusion constant D_0. Superimposed upon this three dimensional isotropic motion is a one dimensional internal diffusional rotation of the proton triad about the threefold symmetry axis. This secondary motion, quantified by the rotational diffusion constant D_{int}, is assumed not to couple

[1]The cautionary remarks expressed in ref. 4 relating to the general validity of [1] should be carefully noted.

with the overall motion.[2] It is also important to note that expressions 1 and 2 imply the assumption of a featureless power density in which all frequency dependence of the power density has been suppressed.

The measurable kinetic equation [1] contains three unknown parameters, ζ_C, χ, and ξ. The conventional transcription (1) of this problem normally deduces χ from the dipolar recovery rate of an independent C—H dipolar interaction which is reflective of only the motions of the molecular framework. Once χ has been determined, ζ_C and ξ in principle can be determined from the simple linear form expressed in [1].

Although this conventional approach is very convenient and straightforward, it does suffer from the limitation that there may be instances when such an approach will yield misleading information (4).[1] Furthermore, unless D_0 and D_{int} are of comparable order of magnitude, it is not feasible to quantitatively determine the motional asymmetry of the methyl rotator. Equation 2*a* clearly indicates that if $\xi \gg 1$, then J_{CH} is independent of this parameter. In such instances, dynamic information may be limited to motions perpendicular to the rotator's principal axis. These motions are characterized by the parameter χ. One possible alternative approach which does not suffer from this latter limitation is the analysis of the spin rotation contribution to the relaxation rate of the carbon nucleus (5). Unfortunately, the dynamical information associated with spin rotation interactions are not as well understood at the present time as those arising from the intramolecular dipolar interaction.

Theory

There is a wealth of motional and structural information encoded in the time evolution equations of methyl groups which is generally ignored in the transient magnetic resonance experiment. When the kinetic analysis is done correctly, it can be shown that the time evolution of the fully coupled carbon quartet is of the general form (6)

$$[4]\quad \ln\langle I_z^C\rangle = f(J_{CH}, J_{HH}, J_{HCH}, J_{HHH}, J_{CHH}, J_{CHHH}, R_1^0(C), R_1^0(H); t)$$

The various auto and cross correlated dipolar spectral densities are defined in the notation of refs. 2 and 6. Assuming, for convenience, a tetrahedral geometry ($r_{HH} = (\sqrt{8}/\sqrt{3})r_{CH}$) and $\gamma_H/\gamma_C = 4$, these spectral terms can be written in the following abbreviated forms

$$\frac{J_{HCH}}{\alpha\chi} = \frac{1}{16} - \frac{1}{2}\left(\frac{1}{5+\xi}\right) - \left(\frac{1}{2+4\xi}\right)$$

$$\frac{\alpha J_{HH}}{\chi} = \frac{1}{6} + 3\left(\frac{1}{2+4\xi}\right)$$

$$[5]\quad \frac{\alpha J_{HHH}}{\chi} = \frac{1}{6} - \frac{3}{2}\left(\frac{1}{2+4\xi}\right)$$

$$\frac{\sqrt{\alpha} J_{CHH}}{\chi} = \frac{1}{9} + \frac{4}{3}\left(\frac{1}{2+4\xi}\right)$$

$$\frac{\sqrt{\alpha} J_{CHHH}}{\chi} = \frac{1}{9} - \frac{8}{3}\left(\frac{1}{2+4\xi}\right)$$

Figure 1 plots the amplitude of the six unique spectral densities defined by the previous equations *vs.* the motional asymmetry parameter, ξ. It is interesting to comment that conventional applications of magnetic relaxation phenomena to the problem of methyl rotator dynamics employ either the HH or CH autocorrelation power densities (the uppermost two curves in Fig. 1). A comparison of these two approaches indicates that it is advantageous to exploit CH interactions rather than HH interactions because of a twofold enhancement in motional sensitivity of the locked *vs.* freely rotating methyl spectral densities. Furthermore, the J_{HH} curve becomes experimentally insensitive to differences in ξ for values of this parameter larger than a factor of five or ten. A realistic upper limit for the usefulness of CH interactions is two or three times this value, and thus, relative values of D_{int} to D_0 may be studied up to a ratio of 10 to 20.

Also note that cross correlation spectral densities need not be intrinsically positive. Theories of rotational diffusion yield spectral representations of lattice correlations which are described as a superposition of *positive* amplitude Lorentzians. For autocorrelation densities, all weighting factors are non-negative geometrical constants. However, for the interference or cross

[2]When comparing the dynamical features of rigid, symmetric top rotators and internal rotators affixed to an otherwise isotropically rotating framework, it proves convenient to make the conventional identifications, $D_0 \sim D_\perp$ and $D_{int} \sim D_\parallel - D_\perp$ (for example, see ref. 9). However, the notations (D_{int}, D_0) and ($D_\parallel$, $D_\perp$) *imply* different physical models and hence the redundancy in variables is justifiable. It should be noted that $D_\parallel/D_\perp = 1 + D_{int}/D_0$. The notation introduced by [3] is chosen to render the definition of ξ compatible with previous and relatively standardized notation (*e.g.*, see ref. 4).

correlation spectral densities, no such restriction is imposed on the various weighting coefficients. Although puzzling to the uninitiated, this fact presents no anomalies of definition or in associated physical meaning (2). The interlevel transition rates are positive constraining the systems response to an arbitrary perturbation as a superposition of damping rather than oscillatory factors.

Comparison of [1] and [4] clearly indicates that considerably more information may be harvested from the fully coupled experiment (eq. 4) in contrast to the conventional approach (eq. 1). Under the geometrical and motional constraints imposed by the various assumptions, one may not presume that all of the spectral densities are independent, *e.g.*,

$$\frac{2}{27\sqrt{\alpha}}(7J_{HH} + 2J_{HHH}) = J_{CHH}$$

and

$$\frac{28}{27\sqrt{\alpha}}\left(J_{HHH} - \frac{5}{14}J_{HH}\right) = J_{CHHH}$$

If the model assumed for the internal motion is one of time modulated 120° random jumps, there would be only two independent power densities. Regardless of this linear dependence, there is no corresponding reduction in the complexity of [4].

It has been shown (6) that these additional power densities cause differential recovery rates of symmetrically positioned components in the carbon manifold.[3] Such effects are easily incorporated into the evolution equations by introducing a 'multiplet asymmetry magnetization' defined by the expression,

$$[6a]\quad \langle I_z^{\Delta}\rangle \equiv 4\langle I_z^{C}I_z^{H}I_z^{H'} + I_z^{C}I_z^{H}I_z^{H''} + I_z^{C}I_z^{H'}I_z^{H''}\rangle$$

$$[6b]\quad \langle I_z^{\Delta}\rangle \equiv 2(3(P_{\frac{3}{2},\frac{3}{2},\frac{1}{2}} - P_{\frac{3}{2},\frac{3}{2},-\frac{1}{2}}) - (P_{\frac{3}{2},\frac{1}{2},\frac{1}{2}} - P_{\frac{3}{2},\frac{1}{2},-\frac{1}{2}}) - 2(P_{\frac{1}{2},\frac{1}{2},\frac{1}{2}} - P_{\frac{1}{2},\frac{1}{2},-\frac{1}{2}}))$$

where P_{I^H,I_z^H,I_z^C} is the population of the symmetrized eigenstate characterized by a coupled proton spin I^H, a projection of I_z^H, and a carbon projection, I_z^C. No kinetic distinction between the symmetric and antisymmetric proton doublet states is necessary. Equality 6*b* identifies I_z^{Δ} as three times the sum of the outer components minus the intensity of the central components in the carbon quartet. Note for $\langle I_z^{\Delta}\rangle$, the thermal equilibrium value vanishes identically.

As demonstrated in the following section, the experimental determination of the time evolution of the multiplet asymmetry provides an enticing means to probe the dynamical features of mobile spin groupings.

[3]These differential effects are in no way related to the effects discussed by Schaublin *et al.* (10).

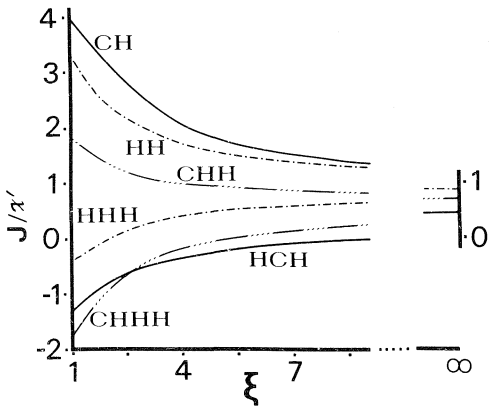

FIG. 1. Plot of the six unique dipolar spectral densities which characterize the spin kinetics of the $^{13}CH_3$ spin grouping *vs.* the motional asymmetry parameter, $\xi(\equiv 1 + D_{int}/D_0)$. The power densities are measured in units of $(\gamma_C\gamma_H\hbar/r_{CH}^3)^2(1/80D_0) \equiv \chi'$. In the limit as $\xi \to \infty$, it is explicitly noted that $J_{CH} = J_{HCH}$, $J_{HH} = J_{HHH}$, and $J_{CHH} = J_{CHHH}$. The various J's are defined in [2*a*] and [5] in the text.

Results and Discussion

Since the response of the multiplet asymmetry magnetization to an arbitrary homogenous perturbation is correctly described as a weighted sum of six exponential terms whose time constants may be determined by the solution of a sextic equation, it might be surmised that any approach utilizing this parameter does not warrant the increased numerical complications even though an expanded description is obtained. Figures 2, 3, and 4 illustrate that such pessimism is not justified. These figures are expanded versions of similar plots given in ref. 6 and depict the transient behaviour of the multiplet asymmetry magnetization subsequent to complete inversion of the proton spectral doublet for various anisotropy factors, ξ. Figure 2 assumes both the proton and carbon spins are relaxed solely by the intramolecular dipolar interaction. Conversely, Figs. 3 and 4 assume a fully correlated random field-type interaction (*e.g.* spin rotation, dilute paramagnetics, etc.) competes favourably with dipolar interactions in providing effective relaxation pathways for the carbon or hydrogen nuclei respectively. For clarity, the dynamics of I_z^{Δ} have been reproduced only from the point in time of maximum deviation onwards. The initial spin evolution can be deduced by noting that the

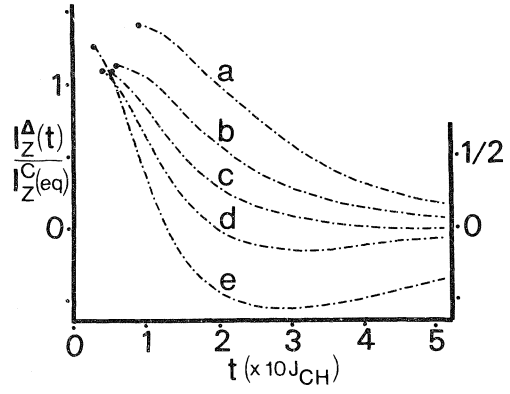

FIG. 2. Plot of the multiplet asymmetry magnetization as a function of time subsequent to complete inversion of the proton spectral doublet. Both the dependent and independent variables are measured in the natural units of the system which are $\langle I_z^{C}(eq)\rangle$ and $10J_{CH}^{-1}$, respectively. Curves *a*, *b*, *c*, *d*, and *e* correspond to a motional asymmetry (ξ) equal to 1, 4, 8, 16, and 100, respectively. Motional and geometrical assumptions are noted in the text. For clarity, the initial growth of I_z^{Δ} is not reproduced in the individual curves. Time dependent spin interactions other than the intramolecular dipolar coupling are assumed negligible.

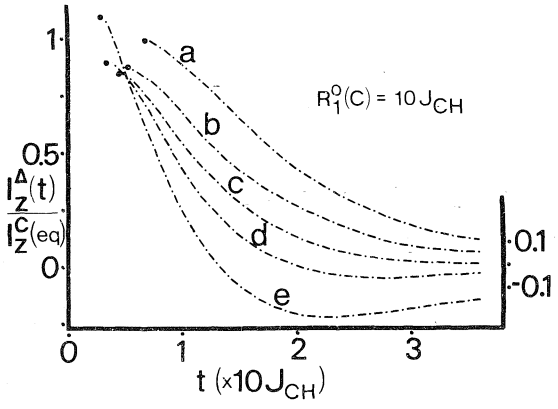

FIG. 3. Notation is identical to that described for Fig. 2. It is assumed that the carbon spin is relaxed by dipolar and random field interactions of equal magnitude. The protons are relaxed solely by intramolecular dipolar couplings.

initial values for the asymmetry magnetization must be zero whenever the perturbing influence is homogenous across each multiplet.

There are numerous reasons for preferring a spin preparation generated by a hard π-pulse on the proton spectral doublet. It can be shown (6) that I_z^{Δ} is coupled to I_z^{H} by the three spin power density, J_{CHH}. For the methyl rotator geometry, this spectral parameter is always characterized by an appreciable magnitude over the effective range of ξ. In contrast, Fig. 1 reveals that the

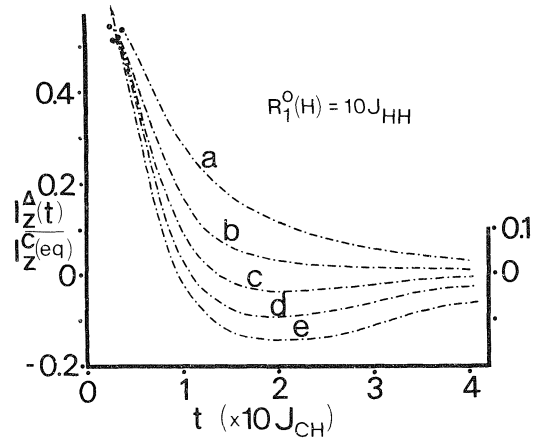

FIG. 4. Notation is identical to that described for Fig. 2. It is assumed that the protons are relaxed by dipolar and random field interactions of magnitudes $10(J_{HH} + \frac{1}{3}J_{CH})$ and $10J_{HH}$, respectively. The ^{13}C spin is relaxed exclusively by the dipolar mechanism.

other multispin power densities such as J_{CHH}, J_{HHH}, and J_{CHHH} become vanishingly small over certain motional ranges. For instance, I_z^{Δ} is directly coupled to I_z^{C} by the three spin power density, J_{HCH}. Hence, inversion of the carbon quartet results in a very weak transfer of magnetization into I_z^{Δ} over a considerable range of ξ. Indeed, for $\xi \cong 9$, this coupling vanishes, and stimulation of I_z^{C} only perturbs I_z^{Δ} inefficiently by second-order indirect couplings to other normal modes of magnetization.

Another benefit of inverting the proton magnetization is sensitivity. By stimulating the total proton magnetization a transient Overhauser enhancement is generated in the carbon and multiplet asymmetry magnetization reservoirs. For times much less that the intrinsic relaxation rates[4] (2) of the proton or carbon spins, the growth of I_z^{Δ} following a proton π-pulse is approximated as[5]

$$[7a] \quad (d/dt)\langle I_z^{\Delta}(t \to 0)\rangle \simeq -24J_{CHH}\langle I_z^{H}\rangle \simeq 24\left(\frac{\gamma_H}{\gamma_C}\right) J_{CHH}\langle I_z^{C}(eq)\rangle$$

[4]The intrinsic relaxation rate for the protons and carbon spins are $10J_{HH} + \frac{10}{3}J_{HCH} + R_1^{0}(H)$ and $10J_{HCH} + R_1^{0}(C)$ respectively. Continued usage of the implicative notation of T_{1H}^{-1} and T_{1C}^{-1} for these respective parameters is undoubtedly misleading and probably should be discouraged.

[5]Note the obvious but inconsequential omission of signs in eqs. 40–45 in ref. 6.

whereas following a homogenous carbon π-pulse

$$[7b] \quad (\mathrm{d}/\mathrm{d}t)\langle I_z^{\Delta}(t \to 0)\rangle \simeq \frac{10}{3} J_{\mathrm{HCH}} \langle I_z^{\mathrm{C}}(\mathrm{eq})\rangle$$

Noting that the absolute magnitude of J_{CHH} is always larger than J_{HCH}, it is rationalized that proton inversions are often orders of magnitude more stimulating than carbon inversions.

Figures 2, 3, and 4 demonstrate some very interesting and useful evolution characteristics of I_z^{Δ} subsequent to a hard π-pulse on the protons. It should be noted that if the parameter J_{HCH} is negative ($\xi \gtrsim 9$), then the normalized intensity of the outermost lines is invariably greater than the normalized intensity of the innermost lines. From the assumed spin preparation and previous discussion, it is apparent that the outer lines are always characterized by an initial transient rate which is greater in magnitude than the central components. However, if J_{HCH} is positive, then the normalized intensity of the central lines will invariably overcompensate for this initial inequity, and in fact, excede the normalized intensity of the outer lines. The existence of possible random field interactions does not significantly alter this generalization.

The effects of random field interactions are reflected in Figs. 3 and 4. Although not explicitly demonstrated by the various plots due to the suppression of the short time behaviour, the initial growth of $I_z^{\Delta}(t)$ is invariant with respect to random field interactions (*cf.* eq. 7*a*). Since the coupling coefficient between I_z^{H} and I_z^{Δ} is independent of both proton and random field interactions, it can be inferred to a good approximation that the amount of magnetization funneled into the multiplet asymmetry mode is limited by the intrinsic rate of the deviation decay of I_z^{H} and hence is reflective of various factors which determine this rate. This is clearly indicated by contrasting Figs. 2 and 4. Note that in the latter figure, the magnitude of magnetization transferred is about one-half of that transferred for the assumed intrinsic proton relaxation rate depicted in the former figure which is roughly one-half as efficient.

As a first approximation, a moderate random field contribution to the carbon spin dynamics does not influence significantly the amplitude of I_z^{Δ}. The primary effect of such interactions causes a contraction in the time domain since $R_1^0(\mathrm{C})$ contributes directly to the intrinsic relaxation rate of I_z^{Δ}. This behaviour is noted by contrasting Figs. 2 and 3.

If $R_1^0(\mathrm{H})$ dominates the spin kinetics, then I_z^{H} is relaxed so efficiently that very little magnetization is allowed to escape from this reservoir into I_z^{Δ} before the reestablishment of thermal equilibrium. On the other hand, if $R_1^0(\mathrm{C})$ dominates the spin kinetics, then I_z^{Δ} is relaxed so efficiently that very little magnetization is allowed to accumulate in this reservoir before being dissipated. In either of these instances utilization of the multiplet asymmetry magnetization will prove to be ineffective. Of course these generalizations presume a spin system prepared by a proton inversion. If one can tolerate the aforementioned limitations of carbon inversion, then it is also possible to observe useful cross correlation effects under different restrictions (4).

For large motional anisotropies, the thermal deviation of I_z^{H} decays at a rate which is roughly four times slower than for small anisotropies. Likewise, the coupling coefficient, $4J_{\mathrm{CHH}}$, is reduced by a factor of three. These counterbalancing effects result in a startling consistency in the observed maximum intensity of I_z^{Δ} for a given random field contribution.

Also note that there is much more variability in the relaxation kinetics for large ξ. This is a consequence of large magnetizations being generated in all six coupled normal mode reservoirs including the modes composed of degenerate proton transitions which are connected to I_z^{H} via J_{HHH} cross terms. Whereas autocorrelation spectral densities must decrease in amplitude with increasing internal degrees of freedom thus spreading a given area over a broader range of frequencies, cross correlation spectral densities are not bound to such limitations and may increase or decrease in magnitude depending upon the relative orientation of the internuclear vectors with respect to the principal axes of diffusion.

The true time behavior is somewhat misrepresented by these plots because the normalization factor, $10J_{\mathrm{CH}}$. In the limit where ξ becomes quite large, the abscissa is in reality contracted by a factor of 9 relative to the limit characterized by ξ equal to unity. This is simply a quantitative restatement of the fact that the longitudinal relaxation is sensitive to those molecular frequencies closest to the natural Larmor frequency of the system.

As mentioned earlier, the spectral density,

J_{CHH}, is always positive for any assumed ξ. Hence, it is rationalized that at times small compared to $(10J_{CH} + R_1^0(H))^{-1}$, the outer lines always grow relative to the central components due to a transient Overhauser effect. Likewise, the total carbon magnetization initially increases by the same reasoning. Comparison of the initial growth rates of the multiplet asymmetry magnetization and the total carbon magnetization would provide a useful experimental feature which can provide an initial estimate of the importance of cross correlation effects. The ratio of rates is given by the following equation

$$[8] \qquad \frac{-(d/dt)\langle I_z^A(t \to 0)\rangle}{-(d/dt)\langle I_z^C(t \to 0)\rangle} \cong \frac{12J_{CHH}}{5J_{CH}}$$

This valuable ratio is independent of χ and R_1^0(C, H) and yields ξ directly. Figure 5 plots this ratio as a function of ξ. It is noted that this experiment provides an excellent means to determine the magnitude of large motional anisotropies.

Using the simultaneous coupled differential equations presented in ref. 6, $(-d/dt)\nu(t) = \Gamma\nu(t)$, a solution may be obtained of the form $\nu(t) = \mathbf{B} \exp(-\mathbf{B}^{-1}\Gamma\mathbf{B})\mathbf{B}^{-1}\nu(0)$ where $\mathbf{B}$ is a unitary matrix composed of the eigenvectors of Γ and the matrix $\mathbf{B}^{-1}\Gamma\mathbf{B}$ is the diagonalized eigenvalue matrix of Γ. It becomes a straightforward task to generate comparative evolution plots of I_z^A from these solutions. With a suitable manifold of simulated evolution rates for I_z^A and some experience with the solutions, the experimentalist may deduce a fairly detailed view of the spin dynamics in the methyl rotator. Such simple comparative methods may provide sufficient information to the investigator and thereby obviate resorting to more exact but complex nonlinear least squares techniques (7). Applications of analogous graphical methods for more general dynamical investigations of three and four spin one-half systems are apparent even though the complexity of such treatments may be a serious deterrent.

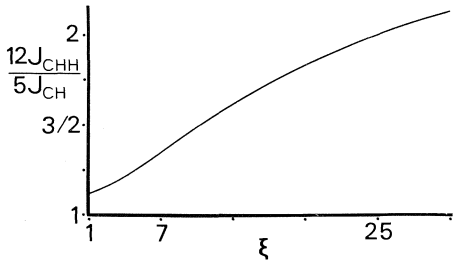

FIG. 5. The initial rate ratio

$$\frac{(-d/dt)I_z^A(t \to 0)}{(-d/dt)I_z^C(t \to 0)} = \frac{12J_{CHH}}{5J_{CH}}$$

following complete inversion of the proton spectral doublet is plotted as a function of the motional asymmetry parameter, ξ.

Conclusions

It is hoped that the suggested graphical approach and related discussion provide a meaningful approach to a study of rotationally anisotropic methyl groups and in general, by extrapolation, to the nature and practical consequences of multispin correlations in polyspin systems. An exhaustive discussion or exposition of the various ideas developed in the previous sections was neither attempted nor achieved; the primary motivation of this presentation was to merely introduce some basic lines of reasoning. The rather restrictive conditions hypothetically assumed for the methyl spin dynamics need not limit the approach as extensions to methyl groups attached to symmetric or asymmetric top rotators is straightforward (8) though less convenient in their application.

^{13}C nmr alkyl shifts of *N*-alkyl tetrazoles and azoles follow the pattern of proton shifts. The shielding of the *N*-alkyl group increases for the structural units

$$=N-N(R)-N= \; < \; =N-N(R)-\underset{|}{C}= \; < \; =\underset{|}{C}-N(R)-\underset{|}{C}=$$

The carbon spectra are more reliable for structural assignment. Synthesis of a number of mono- and dibenzyl derivatives of benzaldehyde tetrazol-5-ylhydrazone are reported.

R. N. BUTLER, T. M. MCEVOY, F. L. SCOTT et J. C. TOBIN. Can. J. Chem. **55**, 1564 (1977).

Les déplacements alkyles, en rmn du ^{13}C, des groupes des *N*-alkyltétrazoles et -azoles correspondent à ceux observés pour les déplacements du proton. Le blindage des groupes *N*-alkyles augmente pour les unités de structure

$$=N-N(R)-N= \; < \; =N-N(R)-\underset{|}{C}= \; < \; =\underset{|}{C}-N(R)-\underset{|}{C}=$$

Les spectres du carbone sont plus fiables pour l'attribution des structures. On rapporte la synthèse d'un certain nombre de dérivés mono- et dibenzylés de la tétrazolylhydrazone-5 de la benzaldéhyde.

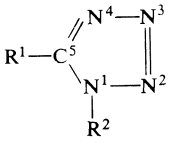
[Traduit par le journal]

Proton nmr alkyl shifts have proved useful for distinguishing between *N*-alkyl isomers in the azole series due to increased shielding of the alkyl group in the structural units (1)

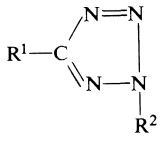
$$\underset{C}{=N-N(R)-N=} \; < \; \underset{B}{\overset{|}{=}C-N(R)-N=} \; < \; \overset{|}{=}C-N(R)-\underset{|}{C}=$$
$$A$$

However, these trends may break down when substituents containing special anisotropic effects are present. For example, in the tetrazole series, for 5-substituents such as —NH—N=CHAr and —NHCOMe, a 1-*N*-alkyl group (I) may be deshielded to the same region as the corresponding 2-*N*-alkyl isomer (II) and a distinction by proton nmr is not always possible (2, 3).

With a number of benzyl derivatives of benzaldehyde tetrazol-5-ylhydrazone (Table 1, compounds **9**–**12**) we have now found that the correlation previously noted (1) is reversed due to the anisotropic effects of the 5-hydrazono substituent at the 1-*N*-alkyl site. As far as we are



I



II

aware, these are the only reported examples where a 2-*N*-alkyl tetrazole isomer is more shielded than the corresponding 1-*N*-alkyl compound. ^{13}C nmr alkyl shifts have, however, proved more useful for structural assignments with these isomeric systems. The data in Table 1 clearly suggest that the same structural – chemical shift trends, which we noted (1) in proton spectra of *N*-alkyl azoles, also apply in the carbon spectra. There is consistently higher shielding of the C-1 atom of *N*-alkyl groups for the structural moieties A > B > C in diazoles,

triazoles, and tetrazoles. Furthermore, for tetrazoles with 5-substituents, which caused reversal of the shielding order for 1-*N*-alkyl protons (compounds **9–12**, Table 1), the deshielding anisotropic influence of the 5-substituent did not reach the 1-alkyl carbon atom and the normal shift pattern was retained. These results suggest that proton *N*-alkyl shifts need to be viewed with some caution for assigning isomeric *N*-alkyl tetrazoles, particularly when the 5-substituent contains >C=N or >C=O groups, and that ^{13}C nmr shifts are more reliable.

Benzylations

The new tetrazole benzyl isomers were obtained by direct benzylation reactions. Benzylation of the ambident anion of benzaldehyde tetrazol-5-ylhydrazone with benzyl chloride was endocyclic and occurred at the 1- and 2-tetrazole positions in the ratio of *ca.* 3:1, respectively, giving compounds **9** and **10** (Table 1). Benzylations of the anions of these 1- and 2-monobenzyl derivatives of the hydrazone were exclusively exocyclic, occurring at the 6-*N*-position giving compounds **11** and **12**, respectively. Benzylation of the anion of 6-monobenzyl derivative **13** was also endocyclic and occurred at both the 1- and 2-tetrazole positions in the ratio of *ca.* 2.5:1, respectively. The structures of the monobenzylated isomers, **9, 10,** and **13** were established by unequivocal preparations. The structures of the dibenzyl isomers **11** and **12** were proved from independent preparations by further benzylation of each of the possible monobenzyl precursors. The benzylation patterns observed were, in general, similar to those previously reported (3–6) for alkylations of other 5-aminotetrazole systems.

Experimental

Infrared spectra were measured for KBr discs or mulls with Perkin-Elmer 377 and 457 spectrophotometers. Nuclear magnetic resonance spectra were measured with JEOL JNM-MH-100 and FX 60 FT spectrometers. Benzaldehyde tetrazol-5-ylhydrazone (7) and the other tetrazoles **1–4** (8) were prepared by the literature procedure. The compound **13** (mp 239°C) was obtained by stirring 5-benzylnitrosoaminotetrazole (9) with zinc dust in glacial acetic acid followed by addition of benzaldehyde in ethanol. *Anal.* calcd. for $C_{15}H_{14}N_6$: C 64.75, H 5.05, N 30.2; found: C 64.85, H 5.1, N 30.1.

Benzylation Reactions

Benzylation of Benzaldehyde Tetrazol-5-ylhydrazone

A solution of the hydrazone (18.8 g) in a mixture of 10% sodium hydroxide (40 ml), absolute alcohol (80 ml), and water (40 ml) was treated with benzyl chloride (12 ml) and heated under reflux for 6 h after which the alcohol was distilled off. The remaining aqueous solution containing a white solid mass was cooled overnight and the solid was removed, washed with water, and stirred for 1 h in 10% sodium hydroxide (40 ml). The alkali insoluble material (solid A) was removed and after acidification of the alkaline filtrate, starting hydrazone (7.8 g, 42%, mp 238°C) separated. The solid A was washed with water and stirred in cold chloroform (100 ml) when compound **9** (6.65 g, mp 204–206°C) remained undissolved. The chloroform filtrate was evaporated under reduced pressure and the semi-solid residue treated with acetone and chilled to −40°C to initiate precipitation. After equilibrating for 1 h at ambient temperatures, a further crop (0.25 g) of compound **9** separated (total yield, 6.9 g, 25%) mp 208°C (from glacial acetic acid). *Anal.* calcd. for $C_{15}H_{14}N_6$: C 64.75, H 5.05, N 30.2; found: C 64.65, H 5.05, N 30.2.

Evaporation of the acetone filtrate gave a gum which, when treated with absolute alcohol (100 ml) followed by cooling to −40°C, yielded the dibenzyl derivative **11** (6.4 g, 17.5%, mp 127°C after repeated recrystallizations from absolute alcohol). *Anal.* calcd. for $C_{22}H_{20}N_6$: C 71.7, H 5.45, N 22.8; found: C 71.75, H 5.5, N 23.15. The alcoholic filtrate after evaporation yielded the 2-benzylhydrazone **10** (2.08 g, 7.5%) which was washed with ether and after recrystallization from alcohol had mp 145°C. *Anal.* calcd. for $C_{15}H_{14}N_6$: C 64.75, H 5.05, N 30.2; found: C 65.05, H 5.15, N 30.6.

Benzylation of Benzaldehyde 1- and 2-Benzyltetrazol-5-ylhydrazones

A suspension of the hydrazone **9** (1.4 g) in a mixture of 10% sodium hydroxide (2 ml), absolute alcohol (4 ml), and water (2 ml) was treated with benzyl chloride (0.6 ml), heated under reflux for 4 h, and poured into ice cold water (100 ml). Compound **11** (1.56 g, 85%) separated. The mp was raised to 130°C by repeated recrystallizations from absolute alcohol and the compound was identical (mixture mp and ir spectra) with that obtained from the benzylation of benzaldehyde tetrazol-5-ylhydrazone above. *Anal.* calcd. as above; found: C 71.75, H 5.45, N 22.85.

A similar treatment of the 2-benzylhydrazone **10** gave compound **12** (88%), mp 150–151°C (from absolute alcohol). *Anal.* calcd. for $C_{22}H_{20}N_6$: C 71.7, H 5.45, N 22.8; found: C 71.5, H 5.5, N 23.05.

Benzylation of the benzaldehyde 6-benzyltetrazol-5-ylhydrazone, **13**, in the manner described gave compound **12** (16%) and compound **11**, (41%) along with a 30% recovery of compound **13**.

All of the compounds **9–13** showed two >C=N ir stretch bands at 1600 and 1640 cm^{-1}. The compounds **9** and **10** showed N—H stretch bands at 3260–3280 cm^{-1} which were absent in compounds **11** and **12**. The following ^1H and ^{13}C nmr signals (in $CDCl_2$) were also observed: **9**, 1.93τ, 145.4 ppm (CH=N); **10**, 2.04τ, 143.5 ppm (CH=N) and 165.8 ppm (tetrazole 5-C); **11**, 2.53τ, 140.0 ppm (CH=N) and 156.1 ppm (tetrazole 5-C); **12**, 2.30τ, 138.3 ppm (CH=N) and 168.6 ppm (tetrazole 5-C). Compounds **9**, **10**, and **13** were also prepared by unequivocal routes which we have developed previously (3, 9) for methyl isomers.

Ab initio calculations on 4-substituted benzoic acids; a further theoretical investigation into the nature of substituent effects in aromatic derivatives

PAUL G. MEZEY AND WILLIAM F. REYNOLDS

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 19, 1976

PAUL G. MEZEY and WILLIAM F. REYNOLDS. Can. J. Chem. **55**, 1567 (1977).

Ab initio (STO-3G) molecular orbital calculations for 4-substituted benzoic acids and XCH_3–HCO_2H pairs are used to derive a theoretical field, T_F, and resonance, $T_{R(BA)}$, substituent scale. Comparison with previous calculations for 4-substituted styrenes shows that a common field scale can be used for different systems but that different resonance scales are necessary, depending upon the electronic nature of the probe group. The field effect primarily reflects the direct electrostatic interaction between the substituent and the carboxylic acid. However, there are also significant contributions due to field-induced polarization of the intervening phenyl π electron system. By contrast, the π polarization effect seems to be the dominant field effect in the case of non-interacting probes (such as carbon atomic charges or chemical shifts). A very close parallel is noted between substituent effects upon atomic charges and acid dissociation energies.

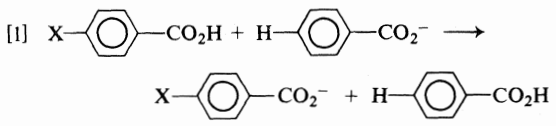
PAUL G. MEZEY et WILLIAM F. REYNOLDS. Can. J. Chem. **55**, 1567 (1977).

Des calculs *ab initio* d'orbitales moléculaires (STO-3G) sur des acides benzoïques substitués en position 4 et sur des paires XCH_3–HCO_2H sont utilisés pour établir une échelle théorique pour les substituants impliquants deux paramètres soit T_F et $T_{R(BA)}$. Une comparaison avec des calculs antérieurs, sur des styrènes substitués en position 4, montre qu'une échelle de champ commune peut être utilisée pour différents systèmes mais que différentes échelles de résonance sont nécessaires suivant la nature électronique du groupe examiné. L'effet de champ est premièrement un reflet de l'interaction électrostatique directe entre le substituant et l'acide carboxylique. Toutefois il y a aussi des contributions importantes qui sont dues à la polarisation induite par le champ du système d'électrons π du groupement phényle impliqué. Par opposition, l'effet de polarisation π semble être l'effet de champ le plus important dans le cas de groupements qui n'interagissent pas (telles que les charges atomiques du carbone ou les déplacements chimiques). On note un parallélisme très important entre les effets des substituants sur les charges atomiques et les énergies de dissociation des acides.

[Traduit par le journal]

Introduction

In a previous paper (1), we have shown that *ab initio* (STO-3G minimal basis set) calculations of atomic charges in 4-substituted styrenes can be used to derive a theoretical dual (field and resonance) substituent parameter scale, T_F and T_R^0, which closely parallels the σ_I,σ_R^0 scale of Taft and co-workers (2) and the *F*,*R* scale of Swain and Lupton (3). While both *F* and σ_I are claimed to be applicable to all aromatic derivatives, there is a significant difference between the two resonance scales. While the *R* parameter scale is claimed to also be applicable to all aromatic systems (3), Taft has concluded that different resonance scales are necessary, depending upon the electronic nature of the probe group (2). In addition, the relationship between substituent effects upon atomic charges and upon energy effects is not entirely clear. Both the original Hammett σ scale (4) and the *F*,*R* scale (3) were based upon energy changes. While the σ_I,σ_R^0 scale is based partially on ^{19}F chemical shifts (2) and while numerous correlations of ^1H, ^{13}C, and ^{19}F chemical shifts (5–7) and atomic charges (7) with substituent parameters have been reported, there is not always a direct parallel between energy changes and changes in atomic charges (8). Consequently, it was decided to carry out a theoretical investigation of substituent effects on energy changes in aromatic compounds, both to check the universality of field and resonance substituent scales and to check the relationship between substituent effects upon energies and upon atomic charges. In addition, it was hoped that the calculations would provide further insight into the mechanisms of transmission of polar substituent effects. The system chosen was a series of 4-substituted benzoic acids. Energy changes were calculated for the isodesmic (9) reaction [1]. Defined in this



manner, the energy change, $\Delta E_{BA}{}^0$, for [1] measures the effect of the substituent upon the acid dissociation energy. This system was chosen because it is the original system chosen to define the Hammett equation (4) and because experimental energies are available for [1] in the gas phase (10), allowing a check of the accuracy of the calculations.

Results and Discussion

Energy changes associated with [1] are tabulated in Table 1. Calculations were performed for planar and pyramidal NH_2 groups, OH, CHO, CH_3, F, CF_3, CN, and NO_2. These correspond to the minimal substituent set of Taft (2) with planar NH_2, OH, and CHO substituting for $N(CH_3)_2$, OCH_3, and $COCH_3$ for reasons of computational economy. Calculated energies for several substituents are compared with experimental energies for [1] in the gas phase (1) in Table 1. There is a close parallel between experimental (10) and calculated energies for [1]. Although the two sets of energies are not strictly comparable (since the calculations correspond to the hypothetical vibrationless state at 0 K), the close parallel lends confidence to the accuracy of the calculations.

By contrast with styrene (1), there is no obvious way to separate and isolate field and resonance effects upon the ionization energies of benzoic acid derivatives. Experimentally, field effects on acid dissociation constants have been estimated for 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids (3, 11, 12). While these compounds could also be investigated theoretically, basically the same information can be obtained at much lower computational cost by carrying out calculations for ionization energies of CH_3X–HCO_2H pairs with the C—X bond and the CO_2H group in the same relative orientation as in benzoic acid (Fig. 1). These calculations should estimate the through-space field effect of the substituent while eliminating resonance effects and other through-bond effects.

TABLE 1. Comparison of experimental and calculated energies, ΔE_{BA} for [1] (in kcal/mol)

Substituent	Calculated energy	Experimental energy[a]
NH_2(pl)[d]	+5.14[b]	—
NH_2(py)[e]	+3.10	+2.3
OH	+0.60	+0.75[c]
CH_3	+1.10	+1.05
F	−1.51	−2.9
CHO	−4.53	—
CF_3	−5.26	—
CN	−9.87	−10.3
NO_2	−13.55	−11.1

[a]From ref. 10.
[b]Positive sign indicates weaker acidity.
[c]Experimental value for OCH_3 derivative (10). In OH derivatives the proton transfer [1] involves phenolic hydrogen.
[d]Planar NH_2 group.
[e]Pyramidal NH_2 group.

The calculated energies, $\Delta E_{IM}{}^0$ (where IM refers to isolated molecules, *i.e.* CH_3X–HCO_2H pairs) are summarized in Table 2. These calculated energies are directly proportional to the theoretical field substituent parameter scale, $T_F(q)$ derived from the differences in β hydrogen atomic charges in 4-substituted styrenes (1):

$$[2] \quad T_F(q) = -0.139\Delta E_{IM}{}^0 \quad (r = 0.9979)$$

The slope from [2] can be used to convert $\Delta E_{IM}{}^0$ to a field substituent parameter scale based upon energies, $T_F(E)$ (see Table 2).

It is seen that there is nearly perfect agreement between the theoretical field effect parameters, T_F, estimated from the ionization energies for CH_3X–HCO_2H pairs and from atomic charges from 4-substituted styrenes. There is also good agreement with σ_I although field effects are overestimated for CN and NO_2 (possible reasons for these deviations have been discussed previously (1)).[1] Two important conclusions follow from these observations. Firstly, the data for these two systems indicate that field substituent parameters are essentially identical for different systems, in agreement with the assumptions of both Taft and co-workers (2) and Swain and Lupton (3). Secondly, the results indicate that, at least in these systems, the same field substituent parameter can be used to investigate substituent effects upon charge densities and upon dissociation energies.

Unfortunately, the field contributions to ionization energies of CH_3X–HCO_2H pairs cannot be directly subtracted from the ionization energies for the corresponding benzoic acids to obtain resonance contributions to the latter

[1]Taft and co-workers have calculated proton affinities for β-substituted ethylamines (13). The proton affinities correlate reasonably well with σ_I but the effect of CN and particularly NO_2 also appear overestimated in this system.

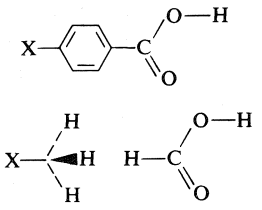


FIG. 1. Geometries for 4-substituted benzoic acids and XCH_3–HCO_2H pairs.

TABLE 2. Substituent effect upon acid dissociation energy for XCH_3–HCO_2H pairs, ΔE_{IM}, and theoretical parameters based upon ΔE_{IM}, and atomic charges for 4-substituted styrenes

[a] T_F values derived by multiplying $\Delta E_{IM}{}^0$ by −0.139, the slope from the correlation of $T_F(q)$ with $\Delta E_{IM}{}^0$ (see [2]).
[b] T_F values based on atomic charges (1). Values derived by scaling β hydrogen atomic charge difference for 4-hydroxystyrene to 0.27, the experimental σ_I value for OH (2). Values differ slightly from those in ref. 1 due to C—O bond length optimization for the OH derivative (see Experimental).
[c] From ref. 2.

ionization energies. The reason that this cannot be done is the dependence of the magnitude of the field effect upon the effective dielectric constant of the intervening medium (14, 15). Previous theoretical investigations for similar molecules in the gas phase suggest that the field effect should be enhanced due to transmission through the phenyl group (1, 15, 16).

Since it is difficult to predict the magnitude of the field enhancement factor, an alternative approach to separating field and resonance contributions was attempted. Since there is a direct relationship between T_F values based upon atomic charges and acid dissociation energies, it was felt that a similar relationship might exist for resonance effects. It has previously been shown that there is a good linear relationship between $\sigma_R{}^0$ and $\sum q_c\pi$ (the substituent induced change in carbon π electron density) for substituted benzenes (7, 17) and styrenes (1, 18). In the case of benzoic acid derivatives, there is a different substituent-induced change in π electron density for the neutral compound, $\sum q_\pi n$, and the benzoate anion, $\sum q_\pi{}^-$ (see Table 3). Previous experimental data for benzoic acid dissociation constants in solution indicate that the resonance effect of a substituent upon acidity is mainly determined by resonance interactions in the neutral molecule (19). Consequently, it was anticipated that $\sum q_\pi n$ would provide the appropriate measure of the resonance effect on the ionization energy. However, to check this point, dual substituent parameter correlations were performed for $\Delta E_{BA}{}^0$ *vs.* $\Delta E_{IM}{}^0$ plus $\sum q_\pi n$ and $\Delta E_{BA}{}^0$ *vs.* $\Delta E_{IM}{}^0 + \sum q_\pi{}^-$, to see which parameter gave the better fit (this is the technique recommended by Taft and co-workers to determine which σ_R scale is best suited to a particular experimental system (2)).

The correlations were:

$$[3]\quad \Delta E_{BA} = 1.714\Delta E_{IM} - 37.36\sum q_\pi n \qquad (r = 0.9998)\quad \text{s.d.} = 0.12 \text{ kcal/mol}$$

$$[4]\quad \Delta E_{BA} = 1.68\Delta E_{IM} - 39.4\sum q_\pi{}^- \qquad (r = 0.9974)\quad \text{s.d.} = 0.66 \text{ kcal/mol}$$

While both correlations are very good, there is a clear discrimination in favour of the correlation with $\sum q_\pi n$, as anticipated (the discrimination is particularly apparent in the standard deviations).

Several conclusions can be drawn from these correlations. First, the existence of a precise correlation such as [3] provides strong support for the basic concept of separating substituent effects into field and resonance components. Second, [3] indicates that there is a very substantial enhancement of the polar effect of the substituent (71%) in benzoic acid, relative to the CH_3X–HCO_2H pairs. The significance of this large enhancement factor is discussed below. Equation 3 also indicates a very close relationship between resonance effects upon acid dissociation energies and upon atomic charges (since a resonance parameter based upon π electron density changes quantitatively predicts acid dissociation energies). Assuming that the very minor deviations in the correlation arise because this relationship is not perfect, this equation can be recast to estimate resonance contributions to acid dissociation energies, $\Delta E_{res}{}^0$:

$$[5]\quad \Delta E_{res}{}^0 = \Delta E_{BA}{}^0 - \Delta E_{field}{}^0 = \Delta E_{BA}{}^0 - 1.714\Delta E_{IM}{}^0$$

These values are also given in Table 3.

In the case of 4-substituted styrenes, $\sum q_\pi$ was used to derive a theoretical resonance parameter,

[d]$T_{R(BA)}q$ scale based upon $\Sigma q_\pi n$ with $T_{R(BA)}$ for OH taken as −0.61 (see text).
[e]$T_{R(BA)}E$ scale based upon $\Delta E_{res}{}^0$ with $T_{R(BA)}$ for OH taken as −0.61 (see text).
[f]From ref. 2.
[g]Substituent-induced change in total π electron density for styrene (×10⁴) (1). First three entries are different than those in ref. 1 due to C—X bond length optimization (see Experimental).
[h]$T_R{}^0$ scale based upon $\Sigma q_\pi c$ with $\Sigma q_\pi c$ for the OH derivative scaled to −0.45, the $\sigma_R{}^0$ value for OCH_3 (2). Values differ slightly from ref. 1 due to change in $\Sigma q_\pi c$ for OH derivative (see footnote *g*).

$T_R{}^0$, which is analogous to the experimental $\sigma_R{}^0$ scale for aromatic molecules containing neutral probe groups (2). This was done by scaling Σq_π for OH (-922×10^4)[2] to $\sigma_R{}^0$ for OCH_3 (−0.45). A similar theoretical resonance scale, $T_{R(BA)}$, for benzoic acid can be derived by scaling either $\Sigma q_\pi n$ or $\Delta E_{res}{}^0$ for the OH group to −0.61, the experimental $\sigma_{R(BA)}$ value for OCH_3 (2). These $T_{R(BA)}$ scales can then be compared with $\sigma_{R(BA)}$ (2).

These comparisons are presented in Table 3, along with $\sigma_R{}^0$ and $T_R{}^0$ scales. A comparison of $T_{R(BA)}$ and $T_R{}^0$ scales indicates that the former scale predicts enhanced effects of π donor groups (*e.g.* NH_2), relative to π acceptor groups, in agreement with $\sigma_{R(BA)}$ relative to $\sigma_R{}^0$ (2). Thus our results indicate that resonance parameters depend upon the nature of the probe groups while field parameters do not. This supports the fundamental model of dual substituent parameters proposed by Taft and co-workers (2) but is contradictory to the assumption of Swain and Lupton that there is a universal resonance parameter (3). In general there is a close parallel between $\sigma_R{}^0$ and $T_R{}^0$ and between $\sigma_{R(BA)}$ and $T_{R(BA)}$. The major deviation is for pyramidal NH_2 in the $T_{R(BA)}$ scale. This deviation may be in part due to the use of fixed substituent geometries. Other calculations indicate that the amino group becomes more nearly planar when electron-withdrawing groups are substituted in the *para* position of aniline (20); this would increase the magnitude of $T_{R(BA)}$ for this group to a value closer to that for planar NH_2.

The most striking feature of the results in both Tables 2 and 3 is the very close parallel between substituent parameters based upon energies and upon atomic charges. This provides further justification for the use of chemical shifts in substituent parameter correlations (in cases where substituent-induced chemical shift changes parallel changes in ground state atomic charges),[3] even though σ constants were originally defined from energy changes (4). However, one cautionary note is necessary. Although [3] indicates a quite precise relationship between energy changes and π electron density changes, preliminary results of calculations to estimate the relative ability of substituents to stabilize benzoic acid and benzoate anions suggest that the origins of this apparently simple relationship may be quite complex.[4]

The calculations also provide further insights into the nature of transmission of polar substituent effects. The $\sigma_{R(BA)}$ scale is defined so that

[2]The value of Σq_π for OH is different than that previously reported (1), due to optimization of the C—O bond length in the styrene derivative (see Experimental). This results in a change in the $T_R{}^0$ scale from that previously reported (1).

[3]For a detailed discussion of the origins and limitations of chemical shift – charge density correlations in aromatic derivatives, see ref. 21. We have previously suggested that substituent-induced ^{13}C and ^1H chemical shifts can be used to monitor changes in ground state atomic charges in aromatic derivatives provided that a large number of substituents are included and provided that the substituent is at least three bonds removed from the probe nucleus (22–24).

[4]W. F. Reynolds and P. G. Mezey, work in progress.

polar and resonance contributions to acid dissociation energies are equal for benzoic acid derivatives in H_2O (2):

$$[6]\quad \Delta G_{BA}{}^0 = -1.36\sigma_I - 1.36\sigma_{R(BA)} \qquad (\rho_R/\rho_I = 1.00)$$

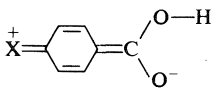
When [2] is redefined in terms of T_F and $T_{R(BA)}$ it is seen that while both field and resonance effects are enhanced in the gas phase relative to aqueous solutions, the enhancement is greater for field effects:

$$[7]\quad \Delta E_{BA}{}^0 = -12.3T_F - 5.9T_{R(BA)} \qquad (\rho_R/\rho_I = 0.48)$$

A similar result is obtained when gas phase ionization energies (10) are correlated with σ_I and $\sigma_{R(BA)}$.[5]

$$[8]\quad \Delta G_{BA}{}^0 = -14.1\sigma_I - 7.2\sigma_{R(BA)} \qquad (\rho_R/\rho_I = 0.51)$$

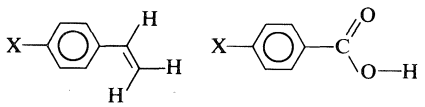
There are several previous reports of solvation decreasing substituent effects by up to a factor of ten (10, 25, 26). The relatively greater decrease for polar effects on going from the gas phase to solution may partly reflect specific solvation of the polar substituents. Solvation of the CO_2^- group should also decrease the field effect since this effect is mainly due to electrostatic interactions of the substituent with CO_2^- (see below). However, another factor may be involved. The calculations of Hermann show that the field effect of a substituent is enhanced when transmitted through a dielectric sphere surrounded by a vacuum (15) (as confirmed by [2]). However, according to the Kirkwood–Westheimer model (14), the field effect is decreased when the surrounding medium is of higher dielectric constant than the sphere. The gas phase measurements and measurements in H_2O should respectively correspond to the former and latter cases. Thus there should be a less effective transmission of field effects in solution than in the gas phase. Finally, the smaller decrease in resonance effects may partly



1

be due to solvent enhancement of donor–acceptor interactions as in **1**. This type of interaction should be favoured in polar solvents since it involves an increase in dipole moment. It has previously been suggested that this is an important interaction in solution (19, 27) but probably not in the gas phase (10).

It is also instructive to consider the relative importance of field effects on benzoic acid derivatives and upon charge densities in aromatic derivatives. There are structural similarities between benzoic acid and styrene derivatives:



The correlation of $q_{C(\beta)}\pi$, the β carbon charge density of styrene (1) with T_F and $T_R{}^0$ reveals

$$[9]\quad q_{C(\beta)}\pi = +0.023T_F + 0.035T_R{}^0 \qquad (\rho_R/\rho_I = 1.53)$$

A similar result is obtained if the ^{13}C chemical shifts for C(β) of styrene derivatives (measured in an inert solvent (18)) are correlated with σ_I and $\sigma_R{}^0$:

$$[10]\quad \delta_C(\beta) = 5.09\sigma_I + 8.33\sigma_R{}^0 \quad (\rho_R/\rho_I = 1.64)$$

It is seen that, in relative terms, there is a much greater field dependence on the dissociation energy for benzoic acid in the gas phase than on the C(β) π electron density (and chemical shift) for styrene (comparing [7] and [8] with [9] and [10]). This reflects a fundamental difference in the transmission of field effects in the two systems. In benzoic acid, the energy change is primarily a result of a direct electrostatic interaction between the polar substituent and a changing probe group (28). In styrene (and other aromatic systems) one is dealing with a non-interacting probe (carbon atomic charges or chemical shift). In these systems, the main mechanism of transmission of polar substituent effects is believed to be a charge redistribution of the π electron system (without π charge transfer to or from the substituent), *i.e.* a π inductive effect (29, 30).[6] A

[5]The experimental measurements are based upon equilibrium constants and therefore represent free energy changes while the calculations reflect internal energy changes. However, the gas phase results should be comparable since entropy changes are generally very small for gas phase proton transfer reactions (10). The solution values are also comparable if one makes the usual assumption of a linear free energy relationship (4). The negative signs in [6]–[8] result because the equations are expressed in energy changes rather than in terms of log *K*.

[6]Similar observations concerning the different mechanisms of transmission of polar effects in these two cases have been made by Fukunaga and Taft (31).

particularly important mechanism is polarization of the π electron system due to the electric field of the substituent (22, 24, 32–34). Until recently, this was regarded as a relatively unimportant mechanism of transmission of polar substituent effects in aromatic derivatives (29). The main reason was that most earlier investigations involved acid dissociation constants (where direct electrostatic interactions dominate (14, 15, 28)) or infrared measurements (where resonance effects dominate (35)). It was only with the advent of ^{13}C nmr spectroscopy, where (in appropriate cases) the chemical shifts can be used to monitor charge density changes at each carbon, that evidence for significant π polarization effects in aromatic derivatives was obtained (15).

Although direct electrostatic effects undoubtedly dominate, π inductive effects should also contribute to the field dependence of benzoic acid dissociation energies. The latter effect should contribute in the same way as resonance effects. In particular, π polarization of the intervening phenyl groups may account for part of the calculated enhanced field dependence for benzoic acid relative to XCH_3–HCO_2H. Since the direct field effect depends upon the distance of the ionizable proton from the substituent (28), the difference in dissociation energies ($\Delta\Delta E_{IM}^0$) for *syn* and *anti* conformations of formic acid (see Fig. 2) should also be directly proportional to the field effect. Similarly $\Delta\Delta E_{BA}^0$ for benzoic acid should also be directly proportional to the direct field effect in this system since through-bond effects should affect both conformations equally. (This is precisely analogous to the estimation of direct field effects in styrenes from the β vinyl proton charge density difference (1)). Values for $\Delta\Delta E_{IM}^0$ are given in Table 4. Correlation of $\Delta\Delta E_{IM}^0$ *vs.* ΔE_{IM}^0 for the *anti* conformation of the proton shows the expected parallel:

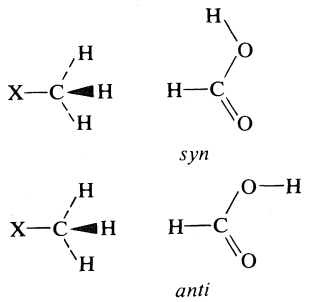


FIG. 2. The *syn* and *anti* conformations for formic acid.

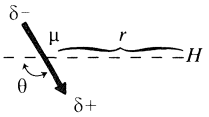
[11] $\Delta E_{IM}^0(anti) = 17.9\Delta\Delta E_{IM}^0 \quad (r = 0.998)$

In the case of benzoic acid, calculations were only performed for the highly polar CN and NO_2 derivatives due to cost limitations. Comparing $\Delta\Delta E_{BA}^0$ and $\Delta\Delta E_{IM}^0$ for these two derivatives indicates an average 47% enhancement of the direct field effect in the former system (a very similar direct field enhancement factor was estimated in the case of styrene (1)). Since the total enhancement is 71%, (see [3]), approximately one third of this enhancement must be due to polarization of the phenyl group, suggesting a small but significant π polarization effect on benzoic acid dissociation energies.

One surprising feature is the very small magnitude of $\Delta\Delta E_{IM}^0$. As first pointed out by Bjerrum (28)), the substituent effect upon an acid dissociation energy can be estimated from the energy required to remove the proton from the vicinity of a dipolar substituent:

[12] $$\Delta E^0 = \frac{e\mu \cos\theta}{r^2}$$

where the parameters are as shown below:



2

(The Kirkwood–Westheimer modification of [11] includes a term on the bottom for the effective dielectric constant, D_E, of the cavity (14). However, this term should be unnecessary for CH_3X–HCO_2H pairs.

This equation predicts larger ΔE_{IM}^0 values for the *syn* conformation than for the *anti* conformation of the OH bond, due to the closer proximity of the *syn* hydrogen. However, the values for $\Delta\Delta E_{IM}$ from [11] are much larger than those from the STO-3G calculations while the individual values are smaller. (Table 5 shows typical values for the cyano derivative.) It appears that these discrepancies occur because the Bjerrum model is a gross oversimplification. The protonation of the acid function induces considerable charge redistribution within this group. In fact, far better agreement is obtained with the results of the STO-3G calculations if one calculates the energy of interaction of the CN dipole with the entire atomic charge distribution for neutral formic acid and for the formate anion (Table 5).

TABLE 4. Comparison of substituent-induced changes in acid dissociation energies for *syn* and *anti* OH conformations in XCH_3–HCO_2H pairs and for two derivatives of benzoic acid

Substituent	$\Delta E_{IM}^0(syn)$	$\Delta E_{IM}^0(anti)$	$\Delta\Delta E_{IM}^{0\,b}$	$\Delta\Delta E_{BA}^{0\,b}$	$\Delta\Delta E_{BA}^0/\Delta\Delta E_{IM}^0$

[a]In kcal/mol. Positive sign indicates weaker acid.
[b]$\Delta\Delta E^0 = \Delta E^0(syn) - \Delta E^0(anti)$.

TABLE 5. Comparison of substituent-induced changes in acid dissociation energies for *syn* and *anti* OH conformations of CH_3CN–HCO_2H pairs as estimated by STO-3G calculations and from the Bjerrum equation (26)

Calculation	$\Delta E_{IM}(syn)$	$\Delta E_{IM}(anti)$	$\Delta\Delta E_{IM}^b$
STO-3G	−5.66[a]	−5.36	−0.30
[12][c]	−4.42	−3.29	−1.15
[12] using complete formic acid charge distribution[d]	−5.06	−4.88	−0.18

[a]In kcal/mol (negative sign indicates stronger acid).
[b]$\Delta\Delta E_{IM}^0 = \Delta E_{IM}^0(syn) - \Delta E_{IM}^0(anti)$.
[c]Energy required to remove a unit positive charge from the vicinity of the C≡N dipole (μ = 3.09 D (1)). The dipole was considered to be located at the mid-point of the C≡N bond while the unit positive charge was located respectively at the position of the syn and anti protons.
[d]Energy of interaction of C≡N dipole with atomic charge distribution for formate anion minus energy of interaction with atomic charge distribution of formic acid. Atomic charge distributions taken from STO-3G calculations for CH_3CN–HCO_2H pairs.

The calculations also suggest that the major interaction of the substituent dipole is with the anion; the CN group stabilizes the anion (−4.50 kcal/mol) while slightly destabilizing neutral formic acid (respectively, +0.38 kcal/mol and +0.56 kcal/mol for *anti* and *syn* conformations).

The dipolar field effect of the substituent also alters the electron distribution within the probe group (1). However, it appears that this makes a negligible contribution to the acid dissociation energy of CH_3X–HCO_2H pairs. For example, if one performs the same calculation as in line 3 of Table 5 but uses the atomic charges calculated for isolated HCO_2H and HCO_2^- rather than those obtained from CH_3CN–HCO_2H and CH_3CN–HCO_2^-, the calculated acid dissociation energies are changed by only 0.03 kcal/mol. Thus, although there is a very close parallel between field effects upon atomic charges and upon acid dissociation energies (Table 2), this does not appear to be a cause–effect relationship. Rather the parallel changes in the two parameters occur because field effects upon both atomic charges (36, 37) and acid dissociation energies (28) both depend directly upon the substituent dipole moment. Davis and Shirley have recently concluded that substituent-induced changes in atomic charges play an important role in determining the proton affinities of methanol derivatives (38). However, the latter involve close range interactions where inductive effects may dominate over field effects (1). Thus their conclusions and ours are probably not contradictory.

In summary, calculated acid dissociation energies for 4-substituted benzoic acids and for XCH_3–HCO_2H pairs have been used to derive a theoretical dual substituent parameter scale which is in good agreement with the σ_I,$\sigma_{R(BA)}$ scale of Taft. The results of this and a previous investigation show that the same field substituent parameter scale can be used for different systems, but different resonance parameters are necessary for different systems, in agreement with the proposals of Taft (2). The results also confirm that identical substituent parameter scales can be used for acid dissociation energies and atomic charges (or chemical shifts where these parallel atomic charges). The field effect of a substituent upon the acid dissociation energy of an aromatic acid primarily reflects electrostatic interactions between the substituent and the CO_2^- group, but field induced polarization of the intervening π electron system also contributes. Finally, the results support the basic concept of the separability of field and resonance substituent effects in aromatic derivatives.

Details of Calculations

Throughout this study an STO-3G basis set as contracted to a minimal basis (39) was used in

calculations. All *ab initio* SCF MO calculations were carried out on an IBM370/165 computer using a version of the Gaussian 70 program (40).

Standard bond lengths were assumed for benzoic acid and the benzoate anion (41) with all bond angles of 120°. Fixed substituent geometries were assumed for most substituents (42). In the case of strongly conjugating groups (planar and pyramidal NH_2 and OH), energy minimization calculations were performed for 4-substituted styrene derivatives, optimizing the C—X bond length only. Optimum bond lengths were 1.406 Å for planar NH_2, 1.428 Å for pyramidal NH_2, and 1.389 Å for OH, compared to values of 1.40 Å, 1.43 Å, and 1.36 Å used previously (1). Energy optimization calculations for the OH derivative of benzoic acid gave a C—O bond length change of less than 0.003 Å from the corresponding styrene derivatives. Consequently the optimized styrene substituent bond lengths were used for the benzoic acid calculations.

Chemical constituents of the physodes of brown algae. Characterization by ^{1}H and ^{13}C nuclear magnetic resonance spectroscopy of oligomers of phloroglucinol from *Fucus vesiculosus* (L.)[1]

JAMES S. CRAIGIE, A. GAVIN MCINNES, MARK A. RAGAN,[2] AND JOHN A. WALTER

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, N.S., Canada B3H 3Z1

Received December 22, 1976

JAMES S. CRAIGIE, A. GAVIN MCINNES, MARK A. RAGAN, and JOHN A. WALTER. Can. J. Chem. **55**, 1575 (1977).

Alcoholic extracts of *Fucus vesiculosus* contain small quantities of low molecular weight polyphenols derived from phloroglucinol and 2,2′,4,4′,6,6′-hexahydroxybiphenyl. ^{1}H and ^{13}C nmr were used to identify two of these as 4-(2″,4″,6″-trihydroxyphenoxy)-2,2′,4′,6,6′-pentahydroxybiphenyl and 4-(2″-(2‴,4‴,6‴-trihydroxyphenoxy)-4″,6″-dihydroxyphenoxy)-2,2′,4′,6,6′-pentahydroxybiphenyl.

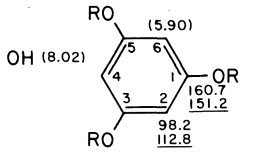
JAMES S. CRAIGIE, A. GAVIN MCINNES, MARK A. RAGAN et JOHN A. WALTER. Can. J. Chem. **55**, 1575 (1977).

Les produits obtenus par extractions alcooliques du *Fucus vesiculosus* contiennent des petites quantités de polyphénols de bas poids moléculaires dérivés du phloroglucinol et de l'hexahydroxy-2,2′,4,4′,6,6′ biphényle. On a utilisé la rmn ^{1}H et ^{13}C pour en identifier deux qui sont le (trihydroxy-2″,4″,6″ phénoxy)-4 pentahydroxy-2,2′,4′,6,6′ biphényle et le [(trihydroxy-2‴,4‴,6‴ phénoxy)-2″ dihydroxy-4″,6″ phénoxy]-4 pentahydroxy-2,2′,4′,6,6′ biphényle.

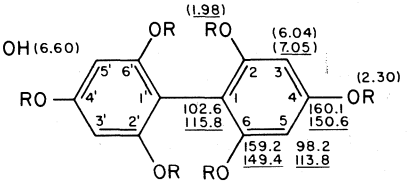
[Traduit par le journal]

Introduction

In 1892 it was demonstrated (1) that brown algal subcellular bodies, called physodes, gave a fiery red colour with the Lindt reagent (vanillin–HCl). This distinctive reaction led to the generally accepted belief that brown algae contained phloroglucinol **1***a* or related compounds (2).[3] Chemical evidence that brown algal cells produce **1***a*, however, was lacking until quite recently when it was demonstrated in hydrolysates of the tannins of *Sargassum ringgoldianum* (3), exudates of *Fucus vesiculosus* (4), and in the direct extracts of seventeen algal species (5). In a previous communication (6) we showed that extracts of Nova Scotian *F. vesiculosus* contained **1***a* and 2,2′,4,4′,6,6′-hexahydroxybiphenyl **2***a* ('dimer'), other oligomers, and high molecular weight polymers composed of **1***a* and **2***a*. Glombitza *et al.* (7) have independently identified the peracetylated derivatives of **1***a* and **2***a* in acetylated



1a R = H[a]
1b R = $COCH_3$ [a,b]



2a R = H[a]
2b R = $COCH_3$ [a,b]

extracts of *F. vesiculosus*, and also claimed the presence of a terphenyl and two quaterphenyls presumably derived from residues of **1***a*. However, on the basis of their published data it is

[3]In the structures illustrated the superscripts *a–f* refer to the following: *a*, numbers in parentheses are δ (TMS) (ppm); numbers not in parentheses are δ_c (TMS or TSP) (ppm); underlined numbers refer to R = CH_3CO; numbers not underlined to R = H; *b*, resonances for ^{13}C nuclei in CH_3CO— groups have not been individually assigned; *c*, data from ref. 13; *d*, data from ref. 8; *e*, data from ref. 19; ^{13}C resonances were reassigned by comparison with **5***b*, using the substituent effect of a CH_3CO_2 group at C-4′ (from **9** and **10**, see text); *f*, data from ref. 17.

difficult to assess the validity of the latter structures. Structure **3***b* has also been proposed (8) and ether linked derivatives of **1***a* have been identified in the extracts of the brown seaweeds *Bifurcaria bifurcata* (9, 10) and *Halidrys siliquosa* (11). We now report ^1H and ^{13}C nuclear magnetic resonance (nmr) evidence for the structures of two compounds, isolated from the extracts of *F. vesiculosus*, containing **1***a* and **2***a* linked through oxygen in the ratio of 1:1 (**3***a*) and 2:1 (**4***a*).

Experimental

^1H nmr spectra were recorded at 100 MHz with a Varian HA-100 continuous-wave spectrometer, and ^{13}C nmr spectra with a Varian XL-100/15 pulse Fourier-transform instrument (25.16 MHz, spectral width 5120 Hz, acquisition time 0.8 to 1.6 s, flip angle 40°, ^1H-decoupling field strength $\gamma H_2/2\pi = 3800$ Hz, internal ^2H pulse lock). Broadband ^1H-decoupling from ^{13}C was accomplished by phase modulation of the decoupling field from 0 to 180° at 150 Hz (12). High-resolution (h.r.) ^{13}C spectra were recorded with retained nuclear Overhauser enhancement by applying the decoupling field for 1.6 s between data acquisition periods (13).

Mass spectra were obtained from a Consolidated Electrodynamics Corporation 21-110B spectrometer, and precise masses were measured by the peak matching method using an ion in the spectrum of perfluorokerosene as a standard.

Fucus vesiculosus (L.) was collected near Morris Point, Halifax Co., Nova Scotia and its alcoholic extracts were fractionated on Avicel columns as described in our earlier report (6). Compounds in the acetone eluate were purified by repeated preparative chromatography on layers of SilicAR TLC-7GF (Mallinckrodt) until chromatographically homogenous on silica gel or polyamide tlc plates (6). Bands were detected by ultraviolet absorption (254 nm) or by spraying guide strips with vanillin–HCl. Final purification was accomplished on columns (1.5 × 15 cm) of Woelm polyamide developed with methanol–water (3:1 v/v). Typically 70 mg of **3***a* and 40 mg of **4***a* could be recovered in this manner from 8 kg of fresh alga. Acetates were prepared routinely (6), and the trimethylsilyl ethers used for mass spectrometry were formed using Tri-Sil (Pierce Chemical Co.). Compounds **2***a*, **2***b* (6), and **5***b* (14) were synthesized.

Proton chemical shifts, δ (ppm) referenced to tetramethylsilane (TMS) contained in a concentric tube in the case of the hydroxy compounds (solvent H_2O), or to internal TMS (acetylated derivatives in acetone-d_6), are enclosed in parentheses. ^{13}C chemical shifts (δ_c) of the hydroxy compounds were referenced to internal sodium 3-trimethylsilylpropionate 2,2,3,3-d_4 (TSP) (solvent H_2O containing a small amount of HOD); the shifts of the acetylated compounds (solvent acetone-d_6) to internal TMS.

Results and Discussion[3]

Precise mass measurements of the molecular ions observed as intense peaks in the mass spectra of the trimethylsilyl derivatives (**3***c*, **4***c*) of the unknowns **3***a* and **4***a* established the molecular formula $C_{42}H_{78}O_9Si_8$ (*m/e* 950.3788 ± 0.0029; calcd.: 950.37996) for **3***c* and $C_{54}H_{98}O_{12}Si_{10}$ (*m/e* 1218.471 ± 0.004; calcd.: 1218.475) for **4***c*. Thus **3***a* possesses eight hydroxy groups and the molecular formula $C_{18}H_{14}O_9$, while **4***a* contains ten hydroxy groups and has a molecular formula of $C_{24}H_{18}O_{12}$ (15). The molecular ions in the mass spectra of **3***a*, **3***b*, **4***a*, and **4***b* were of low intensity.

^1H and ^{13}C chemical shift data from our experiments and other sources as indicated are shown on the structural diagrams, with the data for acetylated derivatives being underlined. Spin–spin coupling constants $J_{^{13}C^1H}$ measured from high-resolution ^{13}C spectra are listed in Table 1.

A comparison of the ^1H nmr spectra data for **3***b* with those for the model compounds **2***b*, **5***b*, and **7***b* showed that three resonances (δ 2.03–2.06, 6H, CH_3CO_2; δ 2.25–2.27, 3H, CH_3CO_2; δ 7.02–7.04, 2H, aromatic H), were common to the spectra of **3***b*, **5***b*, and **7***b*. The signals originated from hydrogens associated with a 2,4,6-triacetoxyphenoxy residue in the case of both **5***b* and **7***b*, thus the presence of this structural unit may be inferred for **3***b*. The five resonances remaining for **3***b* were consistent with the presence of a biphenyl ring system substituted as in **2***b*, but possessing a 2,4,6-triacetoxyphenoxy substituent at C-4. Three of the signals (δ 1.93, 6H, CH_3CO_2 at C-2′,C-6′; δ 2.28, 3H, CH_3CO_2 at C-4′; δ 7.07, 2H, H-3′,H-5′) were essentially identical to those obtained for **2***b* (δ 1.98, δ 2.30, and δ 7.05), thus confirming the presence, and substitution pattern, of one of the biphenyl rings. The shift of the signal for the remaining two chemically equivalent aromatic hydrogens of **3***b* (δ 6.76) closely resembled that for H-2′,H-6′ of **7***b* (δ 6.72), which would be almost unaffected if the acetoxy group attached to C-4′ was replaced

	R_1	R_2	R_3	R_4
4 d		R	R	4 e		R		R
4 f			R	R
4 g		R	R	
4 h	R	R	R	R

by a phenyl substituent (16). Each of the **3***b* hydrogens (H-3, H-5) would, therefore, lie between a phenoxy and an acetoxy (δ 2.13, 3H) substituent, like H-2′ and H-6′ of **7***b*. The presence of only two signals with chemical shifts $\delta \geqq 2.20$ from acetoxy methyl groups in **3***b* excluded the possibility of a 3,4,5-triacetoxyphenoxy substituent as in **7***b*, the spectrum of which contains three such signals. In both **5***b* and **7***b*, a phenoxy substituent shields the protons of adjacent acetoxy groups. This eliminates **6***a* and **6***b* as possible structures. The combined ^{1}H nmr results favour structure **3***a* for the unknown and **3***b* for its acetate derivative.

The structures of **3***a* and **3***b* were finally established by comparing their ^{13}C spectra with those for the model compounds **1***a*, **1***b*, **2***a*, **2***b*, **5***a*, and **5***b*. All of the model compounds possessed symmetry elements which resulted in a reduction in the number of signals observed for the aromatic carbons. Thus the ^{13}C spectra of **1***a* and **1***b* contained only two resonances for such carbons, the one arising from those bearing hydrogen being easily recognized because it was split by one-bond ^{13}C–H spin–spin coupling

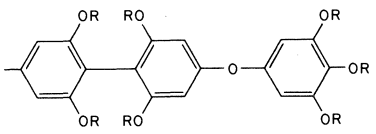
*For the carbons of acetate groups, spin–spin coupling constants (Hz) were: $^{13}CH_3$, $^{1}J_{CH}$ 130.4q; $^{13}C{=}O$, ^{2}J 6.9q. ma: characteristic multiplet (doublet of doublets) due to coupling to one *ortho* and one *para* proton in h.r. spectra of hydroxy compounds; mb: similar multiplet for acetylated compounds; m: multiplet; d: doublet; t: triplet; q:quartet; $w_{1/2}$ line width at half height.
†Poor S/N due to insufficient material for h.r. spectrum.

($^1J_{CH}$) in the h.r. spectra, and occurred at higher field than the signal due to the ring carbons bonded to oxygen, in accord with known ^{13}C substituent effects (17). Similarly, four resonances were observed for the biphenyl ring carbons of **2***a* and **2***b*, the two at highest field arising from quaternary carbons (C-1, C-1′) and carbons carrying hydrogens (C-3, C-3′, C-5, C-5′; $^1J_{CH}$). The remaining resonances due to the two types of carbon bonded to oxygen occurred at low field as expected, and could be assigned because the signal for C-2, C-2′, C-6, and C-6′ was about twice the intensity of the one arising from C-4 and C-4′, the relative intensities of the two sets of resonances being independent of the conditions used to record the spectra.

Compound **5***b* was synthesized in 5% yield following Glombitza *et al.* (14). Its ^{13}C spectrum contained three signals arising from aromatic carbons bearing hydrogen. Two which appeared as doublets ($^1J_{CH}$) of triplets ($^3J_{CH}$ to two hydrogens) could be assigned to C-4′ (δ_c 110.5) and C-2′,C-6′ (δ_c 107.6), the relative intensity of the former resonance being approximately half that of the latter, a result independent of experimental conditions. The signal for C-3,C-5 was a doublet ($^1J_{CH}$) of doublets ($^3J_{CH}$ to one hydrogen) as expected. Resonances at δ_c 167.9 to δ_c 168.5 were readily ascribed to the acetoxyl carbonyl carbons, and one at δ_c 158.1 clearly belonged to C-1′ (the corresponding carbon in diphenyl ether resonates at δ_c 157.9 (17)). A low-intensity signal at δ_c 136.5 could be ascribed to the poorly-relaxed carbon C-1, which is shielded by a *para* and two *ortho* acetoxy substituents. The resonance at δ_c 151.6 could be assigned to C-3′, C-5′ as their chemical shift should not differ significantly from that of C-1,C-3,C-5 (δ_c 151.2) in **1***b*, the *meta* substituent effects of acetoxy and phenoxy groups being small (17). The remaining

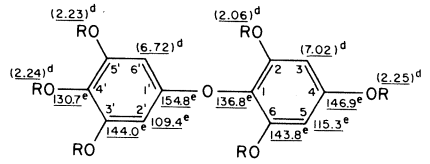


6a R = H
6b R = $COCH_3$

two resonances at δ_c 146.8 and δ_c 143.7 were assigned to C-4 and C-2,C-6, respectively. the relative intensity of the former signal being approximately half that of the latter under a variety of experimental conditions. Additional support for this assignment is provided by the spectrum of diphenyl ether (17), where C-2,C-6 (δ_c 119.3) is shielded to a greater extent than C-4 (δ_c 123.6). It is reasonable to assume that the corresponding carbons in **5***b* would show comparable differences in chemical shift. A similar analysis assigned the resonances in the ^{13}C spectrum of **5***a*, although there was insufficient sample for a h.r. spectrum of the carbons not bonded to hydrogen.

The 18 carbons of **3***a* gave rise to 12 resonances in the aromatic region of the ^1H broadband-decoupled ^{13}C spectrum. This is consistent with the ^1H nmr results discussed above which showed that **3***a* was symmetrical, and indirectly but unequivocally established the presence of at least six pairs of chemically equivalent aromatic carbons. Twelve resonances for the aromatic carbons were also observed in the high resolution ^{13}C spectrum of **3***b*, but the ^1H broadband-decoupled ^{13}C spectrum contained only ten resonances due to superposition of signals (C-1 hidden by C-3′,C-5′ and C-1′ by C-3″,C-5″).

It was apparent from the ^{13}C chemical shift and spin–spin coupling data (Table 1) that **3***a* (**3***b*) possessed three sets of aromatic carbons. Each set contained two chemically non-equivalent, plus two pairs of chemically equivalent, carbons and gave rise to four resonances. The ^{13}C data for one set of carbons (**3***a*, **3***b*; C-1′ through C-6′) was virtually identical to that for **2***a* (**2***b*), and that of another set (**3***a*, **3***b*; C-1 through C-6) differed only slightly, and predictably (see comments on chemical shift calculations below). Similarly the ^{13}C data for the carbons in the remaining set (**3***a*, **3***b*; C-1″ through C-6″) were almost indistinguishable from those obtained for C-1 through C-6 of **5***a* (**5***b*).



7a R = H[a]
7b R = $COCH_3$[a,b,d,e]

The ^{13}C chemical shifts expected for C-1 through C-6 of **3***a* and **3***b* were calculated from the known chemical shifts for **1***a*, **1***b*, **2***a*, **2***b*, **5***a*, and **5***b* as follows. Comparison of **1***a*,**1***b* and **5***a*,**5***b* yields the changes in chemical shift at all

the carbons of **1***a*,**1***b* due to replacement of one hydroxy (or acetoxy) substituent by a 2,4,6-trihydroxy (or triacetoxy) phenoxy group: at the directly bonded carbon +2.2(+6.9) ppm; *ortho* −1.0(−5.2) ppm; *meta* 0.0(+0.4) ppm; *para* +1.6(−2.3) ppm. These chemical shift changes applied to **2***a*,**2***b* for the same change of substitution at C-4 predict the following chemical shifts for C-1 through C-6 of **3***a*,**3***b*. The close correspondence of measured and predicted (in parentheses) shifts provides further support for the ^{13}C resonance assignments and the structures: **3***a* C-1 104.2 (104.2), C-2,C-6 159.4 (159.2), C-3,C-5 97.4 (97.2), C-4 162.5 (162.3); **3***b* C-1 113.9 (113.5), C-2,C-6 150.0 (149.8), C-3,C-5 108.8 (108.6), C-4 157.7 (157.5).

In addition, hydrogen to deuterium exchange in D_2O eliminated ^{13}C–^{1}H spin–spin coupling from all resonances except those assigned to C-1 through C-6 of **3***a*, which partially retained coupling. This confirms that the latter carbons belonged to the same ring. The centre ring of **3***a* would be expected to exchange hydrogen less rapidly, as it provides less opportunity for keto–enol tautomerism. The combined evidence therefore establishes that **3***a* is 4-(2″,4″,6″-trihydroxyphenoxy)-2,2′,4′,6,6′,-pentahydroxybiphenyl.

The ^{1}H nmr spectrum for **4***a* (solvent acetone-d_6) contained three singlet resonances at δ 6.01, 6.03, and 6.14 due to three pairs of chemically equivalent aromatic hydrogens. Two of these (δ 6.01, 6.03) corresponded closely to the signals for hydrogens at C-3, C-3′, C-5, C-5′ of **2***a* and C-3, C-3′, C-5, C-5′, C-3″, C-5″ of **3***a*, while the third (δ 6.14) was similar apart from a small downfield shift. The spectrum also contained an AB multiplet for two *meta*-coupled aromatic hydrogens (centroid δ 6.01, Δν 32.7 Hz, $^{3}J_{HH}$ 2.8 Hz) and a broad OH signal (δ 6.88) integrating for 10 protons.

The ^{13}C spectrum of **4***a* contained 18 resonances, 12 of which corresponded almost exactly in chemical shift, relative intensity (recorded under widely varying conditions), and ^{13}C–H coupling (Table 1) with the resonances for **3***a*. This information combined with the known molecular formula established that **4***a* contained 2,2′,4′,6,6′-pentahydroxybiphenoxy and 2,4,6-trihydroxyphenoxy residues, which were asymmetrically substituted on another aromatic ring containing $C_6H_4O_3$. Similarly the ^{13}C spectrum of **4***b* supported these conclusions.

The presence of two *meta*-coupled hydrogens limits the choice of structure of the acetylated material to five possibilities, **4***b*, and **4***d* to **4***g*. The choice of **4***b* as the correct structure was based on a comparison of the measured ^{13}C chemical shifts for the carbons of the asymmetrically substituted aromatic ring (C-1″ to C-6″) with predicted shifts derived from measurements of acetylated model compounds, as follows. Firstly, three independent predictions were made of the ^{13}C shifts for **4***h*.

(*a*) The average effect of replacement of an acetoxy substituent on a ring by a 2,4,6-triacetoxyphenoxy group was estimated by comparing the measured δ_c values for **1***b*, **5***b*; **2***b*, **3***b*; **1***b*, **8** (18); **5***b*, **8** (18): at substituent +6.9 ± 0.2 ppm; *ortho* −5.4 ± 0.4 ppm; *meta* +0.4 ± 0.2 ppm; *para* −2.6 ± 0.7 ppm. This information was then used to predict the ^{13}C chemical shifts for **4***h* by applying the substituent effects above, in reverse, to allow for substitution of an acetoxy group at C-1′ of **7***b*.

(*b*) The measured shifts of **5***b* and **7***b* were compared to estimate the substituent effects of acetoxy-substitution at C-4′ of **5***b* and these were applied to predict the result of substitution of an acetoxy group at C-2 of **1***b*.

(*c*) **1***b* and **9** were compared to obtain the effects of acetoxy substitution at C-5 of **9**, and these were used to predict the effect of acetoxy substitution at C-5 of **10**. The averages of these predictions (*a*,*b*,*c*) of the δ_c values for **4***h* were: C-1″ 132.2 ± 0.9; C-2″,6″ 143.3 ± 0.6; C-3″,5″ 114.4 ± 0.5; C-4″ 147.5 ± 0.6 ppm. When these values were compared with the measured δ_c values for C-1″ to C-6″ of **3***b*, the effect of replacing an acetoxy substituent by a (2,2′,4′,6,6′)-pentaacetoxy biphenoxy group was obtainable: at substituent +4.4(±0.9); *ortho* +0.5(±0.6); *meta* +0.8(±0.5); *para* −0.6(±0.6) ppm. The predicted δ_c for **4***h* and the substituent effects above were used to predict the chemical shifts for the five alternative structures **4***b*, **4***d* to **4***g*. For example, δ_c for C-1″ of **4***b* is given by δ_c for C-1″ of **4***h* (132.2 ppm), plus the effect of replacing the acetoxy substituent at C-1″ with a 2,2′,4′,6,6′-pentaacetoxy biphenoxy group (+4.4 ppm) and the effect of replacing the *ortho*-acetoxy at C-2″ by a 2,4,6-triacetoxyphenoxy substituent (−5.4 ppm). The total, 131.2 ppm, is the predicted δ_c. The nearest experimental δ_c values for this ring are compared with predictions in Table 2, which also shows the sum of

TABLE 2. Comparison of experimental δ_c (ppm) for C-1″ through C-6″ of **4***b*, **4***d–g* with nearest predicted values

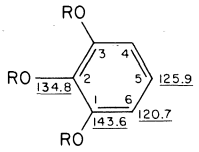
9 R = $COCH_3$ a,b



10 R = $COCH_3$ a,b

the absolute magnitudes of the differences between predicted and experimental values. Thus, structure **4***b* is clearly favoured. The predicted shifts for **4***b* (or **4***a*) may also be calculated from the experimental shifts for **3***b* (**3***a*) and the substituent effects under (*a*) above (or the corresponding substituent effect for replacement of OH by a 2,4,6-trihydroxyphenoxy substituent, estimated from experimental data for **1***a*,**5***a*; **2***a*,**3***a*), again giving close agreement (Table 3) with the other predicted shifts (Table 2, structure **4***b*) and with the experimentally measured values.

F. vesiculosus from Nova Scotia has been shown to contain 4-(2″,4″,6″-trihydroxyphenoxy)-2,2′,4′,6,6′-pentahydroxybiphenyl **3***a* and 4-(2″-(2‴,4‴,6‴-trihydroxyphenoxy)-4″,6″-dihydroxyphenoxy)-2,2′,4′,6,6′-pentahydroxybiphenyl **4***a* in addition to compounds **1***a* and **2***a* (6). If a terphenyl or quaterphenyls (7) were present in our extracts, their trimethylsilyl ethers should appear at *m/e* 1022 and 1362, respectively. In fact, only a trace of an otherwise unidentified compound appeared at *m/e* 1022, and no *m/e* 1362 ion was observed following gc/ms (Ragan and Craigie, unpublished) and high resolution ms with photoplate ion beam integration. Similarly, the ether linked C_{12} and C_{18} polyphloroglucinols reported from *Bifurcaria bifurcata* (9, 10), *Cystoseira tamariscifolia* (14), *Halidrys siliquosa* (11), and *Laminaria ochroleuca* (18) must occur only in minute quantities, if at all, in our *F. vesiculosus*.

Synthesis and structure of dichlorobis(thiosemicarbazide)mercury(II)

CHUNG CHIEH

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received December 29, 1976

CHUNG CHIEH. Can. J. Chem. **55**, 1583 (1977).

The reaction between mercury(II) chloride and thiosemicarbazide (1:2 molar ratio) in ethanol–water (1:1 by volume) gave, almost quantitatively, dichlorobis(thiosemicarbazide)-mercury(II), $HgCl_2(tsc)_2$. There was a trace of unidentified black material as a side product. The crystals of $HgCl_2(tsc)_2$ are orthorhombic with $a = 8.675(7)$, $b = 8.123(6)$, $c = 15.786(11)$ Å, $Z = 4$, and space group *Pbcn*. The $HgCl_2(tsc)_2$ molecule in the crystal has a twofold axis and the mercury atom is bonded to two chlorine atoms at 2.841(3) Å, and two sulfur atoms at 2.417(3) Å, in a highly distorted tetrahedron. The bond angles are: S—Hg—S = 160.7(1)°; Cl—Hg—Cl = 96.6(1)°; S—Hg—Cl = 89.5(1)° (twice) and 103.4(1)° (twice). However, if the close contacts, Hg···Cl = 3.250(3) Å, were counted, the coordination around the Hg atom would be an approximate octahedron.

CHUNG CHIEH. Can. J. Chem. **55**, 1583 (1977).

La réaction du chlorure mercurique(II) avec la thiosemicarbazide (rapport molaire 1:2) dans un mélange éthanol–eau (1:1 par volume) donne, presque quantitativement, le dichloro bis(thiosemicarbazide) mercurique(II), $HgCl_2(tsc)_2$. On a retrouvé comme sous-produit une trace d'un composé noir non-identifié. Les cristaux de $HgCl_2(tsc)_2$ sont orthorhombiques avec $a = 8.675(7)$, $b = 8.123(6)$, $c = 15.786(11)$ Å, $Z = 4$ et groupe d'espace *Pbcn*. La molécule de $HgCl_2(tsc)_2$ dans le cristal possède un axe binaire et l'atome de mercure est lié aux deux atomes de chlore distant de 2.841(3) Å, et à deux atomes de soufre qui se trouvent à 2.417(3) Å à l'intérieur d'un tétraèdre fortement déformé. Les angles de liaison sont: S—Hg—S = 160.7(1)°; Cl—Hg—Cl = 96.6(1)°; S—Hg—Cl = 89.5(1)° (deux fois) et 103.4(1)° (deux fois). Toutefois si les contacts immédiats Hg···Cl = 3.250(3) Å sont comptés, la coordination autour de l'atome de Hg serait approximativement octaédrique.

Introduction

Like thiourea (tu), thiosemicarbazide (tsc) contains a $\diagdown C{=}S \diagup$ group which can coordinate to mercury. Thiourea forms a series of compounds with formula $HgX_2(tu)_n$ where $n = 1, 2, 3,$ or 4; and X = Cl, Br, or I. The mercury atom is coordinated in an unusual, approximately trigonal planar, arrangement by two equivalent thiourea sulfur atoms and one chlorine atom in $HgCl_2(tu)_2$ (1). However, in $HgI_2(tu)_2$, the mercury atom is coordinated to two sulfur and two iodine atoms in a distorted tetrahedron (2). In $HgCl_2(tu)_3$ (3) and $HgCl_2(tu)_4$ (4), the mercury atom is coordinated to three and four sulfur atoms respectively. These structural studies revealed the complexity of the interaction between the $\diagdown C{=}S \diagup$ group and the mercury(II) ions.

Thiosemicarbazide is different from thiourea in that it can also be a bidentate ligand which forms a five-membered chelating ring in many nickel complexes (5, 6). Although the *cis*- and *trans*-dithiosemicarbazidenickel(II) dinitrate exist in different crystal forms (7), both *cis*- and *trans*-dithiosemicarbazidenickel(II) sulfate are present in one crystal (5). When tsc is a chelating agent, the configuration is different from that of the free molecule (8). However, in the structure of thiosemicarbazidesilver(I) chloride, the ligand is monodentate with only Ag—S bond (9). The configuration of tsc is the same as that of the free molecule. The energy difference between the two configurations has been estimated to be small (9). Our previous study indicated that there is a tendency for organo-mercury to bond to the amino-group of penicillamine (10). It is interesting to see how the NH_2 groups in tsc interact with the mercury(II) ion. Recently, nickel was found to form a 4-coordinated complex with *N*,*N*-diethylphenylazothioformamide, a derivative of thiosemicarbazide. The ligand was bidentate with S and N bonded to the nickel

ion despite the presence of a bulky phenyl group on the nitrogen (11). The configuration of tsc in a complex is therefore very delicately determined by the energy of bonding between the metal and the nitrogen atoms. It is in search of an understanding of the chemical interaction between mercury and tsc that these studies are carried out. Whether compounds of formula $HgX_2(tsc)_n$ with $n = 1$, 2, 3, and 4 can be synthesized is still to be established. This paper reports the synthesis and crystal structure of $HgCl_2(tsc)_2$.

Experimental

Preparation of $HgCl_2(tsc)_2$

Commercial thiosemicarbazide (Fluka) and mercury(II) chloride (Baker) of reagent grade were used and the mixed solvents were made up from equal volumes of absolute ethanol and deionized water. The mixed solvent was chosen because a similiar system was used in the preparation of *N,N'*-diethylthiourea (dietu) complexes of the type $MX_2(dietu)_2$ (M = Zn, Cd, Hg; X = Cl, Br, I) (12). The solubility of tsc in ethanol is small but tsc is very soluble in the mixed solvent. Ethanol is a good carrying solvent for $HgCl_2$ in other types of reactions (13). To 40 ml solution containing 0.3646 g (4 m*M*) of tsc, 0.5431 g (2 m*M*) $HgCl_2$ crystal was added. No stirring was applied to this natural heterogenous mixture. The reaction was left to proceed slowly at room temperature, 25 ± 3°. Some long, fine needles, observed under a 40 × microscope, formed very quickly around the crystals of $HgCl_2$. The reaction vessel was then covered. On the next day, crystals of $HgCl_2$ had disappeared and the long needles were no longer there. In their place were colorless prismatic crystals. There was also a trace of black particles possibly resulted from the formation of HgS or mercury metal. These prisms were separated by filtration, but the bulk sample so obtained was tinged with a brown color because of the presence of the black material. The filtrate was allowed to evaporate in a partially-covered beaker at room temperature and more colorless prismatic crystals were obtained. When the filtrate evaporated totally, there was a trace of tsc crystal left in the beaker, together with some prisms.

Crystallographic Measurement

Rotation, Weissenberg and precession photographs were used to determined the cell constants and space group which was unique, from the systematic absences. Photographic data also confirmed that crystals obtained in the first batch are the same as those obtained from the filtrate. Crystals are usually prisms with (±100) and (00 ±1) planes developed. The {111} type planes are developed on the ends of slightly elongated crystals. The cell constants were refined by least-squares methods from the 2θ values of 17 reflections measured on the diffractometer. Crystal data are as follows:

$C_2H_{10}Cl_2HgN_6S_2$ fw = 453.8

Orthorhombic, $a = 8.675(7)$, $b = 8.123(6)$, $c = 15.786(11)$ Å. $V = 1112.4$ Å^3, $D_o = 2.70$ (by flotation), $Z = 4$, $D_c = 2.709$ g cm^{-3}. Systematic absences: $0kl$: $k = 2n + 1$; $h0l$: $l = 2n + 1$; $hk0$: $h + k = 2n + 1$; space group *Pbcn*. $\mu(MoK\alpha) = 149.3$ cm^{-1}; $\lambda(MoK\alpha) = 0.7107$ Å.

The crystal used for intensity measurements had dimensions of 0.10 × 0.15 × 0.12 mm along *a*, *b*, and *c* directions. It was mounted with *b*-axis along the the φ-axis of the G.E. XRD-6 automatic diffractometer, which was equipped with a pulse height analyser, a scintillation counter, and a Hewlett Packard Scaler Timer (Model 5201L). A total of 975 reflections with $2\theta(MoK\alpha) \leq 50°$ were measured using θ–2θ scan technique at a constant speed of 2° per min. The scan range was ±(0.95 ± 0.43 tan θ) with respect to the calculated 2θ. Backgrounds were counted for 20 s on each side of the scanning range. During data collection, four standard reflections (400, 021, $\bar{1}10$, and $02\bar{7}$) were measured repeatedly between each 100 reflections. The negative indices used for the standard reflections gave four values evenly spread on the φ circle. The variation of intensities for the standard reflections was less than 3%. There were 720 reflections (74%) with integrated intensities (I = count − background) greater than $2\sigma(I)$, and they were considered as observed reflections. The standard deviations $\sigma(I)$ were calculated from counting statistics. No absorption correction was made ($\mu R = 1.05$). Lorentz and polarization factors were applied to derive the structure amplitudes.

From the Patterson synthesis, the mercury atom was found to be located at the special positions, 4*c*, of space group *Pbcn*. It was very difficult to differentiate the corresponding Hg—S from Hg—Cl vector peaks in the Patterson map and two Cl atoms were put in both positions to begin with. The Fourier map revealed all the non-hydrogen atoms. With isotropic temperature factors for all the atoms, the R factor ($= \Sigma||F_o| - |F_c||/\Sigma|F_o|$) was reduced to 0.10. When anisotropic thermal parameters were introduced, the R factor became 0.048. A difference Fourier map calculated at this stage gave two peaks of electron density 2.0 e/Å^3, one at (0.0 0.39 0.25) and another one in the vicinity of the Hg atom. It was not possible to have a water molecule at the point (0.0 0.39 0.25) because this position is only 2.1 Å from two neighboring N(1) and 2.3 Å from two N(2) atoms. In fact, this point would be the position for Hg had the alternative origin been chosen. All other peaks were less than 0.8 e/Å^3 and only two of them were located clearly at possible positions for hydrogen atoms, which were included in the full-matrix least-squares refinements. The revised program written by Doedens and Ibers was used. The atomic scattering factors from Cromer and Waber (14) were used with anomalous dispersion coefficients for Hg from Cromer (15). At the final stage, a weighting function $w^{-1} = (70.0 - |F_o| + 0.01F_o^2)$ was introduced and the final R and R_w ($= [\Sigma w^2(|F_o| - |F_c|)^2/\Sigma w^2F_o^2]^{1/2}$) were 0.046 and 0.057 respectively. The weighting scheme gave uniform errors, $\Sigma w(|F_o| - |F_c|)^2/(m - n)$, in all ranges of F_o and the final atomic coordinates are given in Table 1. The table of structure factors and anisotropic temperature factors is available from the Depository of Unpublished Data.[1]

Results and Discussion

The long fine needles observed at the beginning when mercury(II) chloride was added to the solution of tsc were probably a compound of composition $HgCl_2(tsc)$. Presently, we are using other mole ratios for the synthesis of other compounds $HgCl_2(tsc)_n$, $n = 1$, 3, and 4, in the hope of obtaining a series similiar to that observed in reactions between $HgCl_2$ and thiourea. Spectroscopic evidence has shown that the needles are not the same as the prisms.

The crystals are composed of individual molecules of $HgCl_2(tsc)_2$. The bond lengths and angles are given in Fig. 1, which also shows the thermal anisotropy of the atoms. The molecule is located at a special position, 4*c*, of the space group *Pbcn* (No. 60, International Tables for X-ray Crystallography (16)), and therefore has a twofold rotation axis. The mercury is bonded to two sulfur, Hg—S = 2.417(3), and two chlorine, Hg—Cl = 2.821(3) Å, atoms in a very distorted tetrahedron. The bond angles are: S—Hg—S = 160.7(1)°, Cl—Hg—Cl = 96.6(1)°, S—Hg—Cl = 89.5(1)° (twice) and 103.4(1)° (twice). However, the chlorine is also very close to the mercury atom of a neighboring molecule with Hg· · ·Cl = 3.250(3) Å. This relation can be seen from the stereo-packing diagram, Fig. 2. If these weak interactions are counted, the coordination of the mercury can be described as very distorted octahedral.

The free tsc molecule is planar with a maximum deviation from the least-squares plane of 0.03 Å. The bonded tsc in $HgCl_2(tsc)_2$ is also planar with a displacement of only 0.01 Å. The mercury atom is 1.5 Å from the plane of the tsc. The bond lengths in the ligand are similiar to those of tsc; but C=S is lengthened because of coordination. The bond lengths are 1.74(1) and 1.701(5) Å for the bonded and free tsc respectively. The dihedral angles are 1.1° for NNCN and 2.1° for NNCS.

TABLE 1. Final fractional coordinates ($\times 10^4$) $\pm(xyz, \frac{1}{2}-x\ \frac{1}{2}-y\ \frac{1}{2}+z, \frac{1}{2}+x\ \frac{1}{2}-y\ \bar{z}, \bar{x}\ y\ \frac{1}{2}-z)$

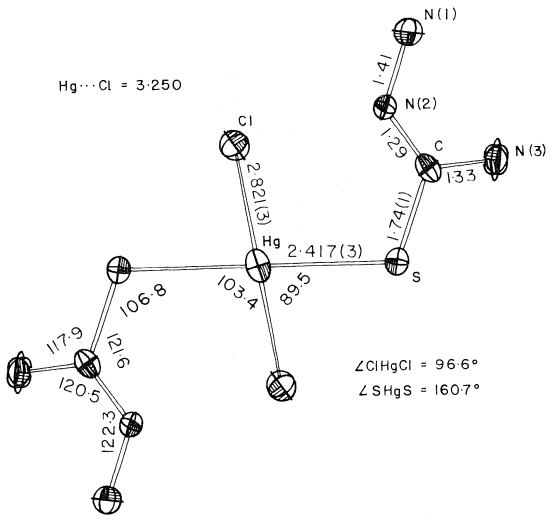

FIG. 1. Bond distances and angles for $HgCl_2(tsc)_2$ with anisotropic thermal ellipsoids. The important standard deviations are given in parentheses and the remainder are: σ(C—N, N—N) = 0.02 Å; σ(angles around Hg) = 0.02°; σ(HgSC) = 0.3°; σ(other angles) = 0.5°.

The comparison of Hg—S and Hg—Cl distances of tsc and thiourea complexes are set out in Table 2. In general, the Hg—S distance increases with coordination number (CN). When there are three or more Hg—S bonds around the Hg atom, the Hg—S distances vary. A similarity was observed in a series of compounds that contain $Hg(SCN)_n^{(n-2)-}$ as part of the molecule (18–20). The four Hg—S distances for $(Ph_4P)_2 \cdot Hg(SCN)_4$ are included in Table 2. A notable similarity in the Hg—S distances between $Hg(SCN)_4^{2-}$ (2.531(40) Å) and $Hg(tu)_4^{2+}$ (2.549(48) Å) exists regardless of the difference in charge for the two species. The values in parentheses are the standard deviations of the mean, $\bar{s}$, calculated by $\bar{s} = ((\sum x^2 - (\sum x)^2/3)/3)^{1/2}$, where the x's represent the bond lengths used to calculate the mean. The angles Hg—S—C for the two series of compounds are different.

The Hg—Cl distance for $HgCl_2(tsc)_2$ is the largest among the compounds listed in Table 2. This may due to the fact that the chlorine atom is unsymmetrically bridged to two mercury(II) ions.

Strong intramolecular hydrogen bonds

†Values calculated from the coordinates of ref. 3.

may exist between the terminal nitrogens, N(1)···N(3) = 2.72(2) Å, H(3)—N(3) = 0.89 Å, and N(1)···H(3) = 2.3(2) Å. A similar N(1)···N(3) distance of 2.69(12) is found in the free tsc molecule (8). Despite the unfavorable angle, N(2)—N(3)···N(1) = 31° and N(3)—H(3)···N(1) = 105°, the hydrogen bond exists because it forms a six-membered ring. The hydrogen H(2) is bonded to N(2), N(2)—H(2) = 0.83 Å.

The structure consists of layers of $HgCl_2(tsc)_2$ molecules. Each layer, which is perpendicular to the *c*-axis, is composed of three sublayers in the form of a sandwich. The centre layers are two-dimensional Hg—Cl···Hg— linkage networks which hold the tsc layers through strong Hg—S bonds. Intermolecular hydrogen bonds are very weak. The shortest intermolecular distances are: N(1)···N(3) (x, $1-y$, $1-z$) = 3.14(2) Å, and N(1)···Cl ($-0.5+x$, $0.5+y$, $0.5-z$) = 3.37 Å. A packing diagram viewed from the *b*-axis or the twofold axis of the

molecule is given in Fig. 2. Both N(1) and N(3) are oriented toward the S atoms in the structure. This is the same as the packing of the free tsc, in which the hydrogen atoms are pointing toward the S atoms due to electrostatic attraction (8).

Entropy production in bulk isothermal relaxation

ANDREW W. YAU AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received November 4, 1976

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. **55**, 1588 (1977).

Four theorems relating to complete monotonicity of entropy production in isothermal bulk relaxation have been proved, and in another two cases, it is shown by numerical experiment that the entropy production is probably monotonic also. The total entropy and the total energy do not in general relax with the same rate constant, and under many conditions the time constant for entropy relaxation approaches twice the time constant for energy relaxation. We speculate that the maximum entropy principle used in the information-theoretic approach to bulk relaxation may be synonymous with the principle of complete monotonicity of entropy production.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. **55**, 1588 (1977).

On a prouvé quatre théorèmes reliant la monotonicité complète de la production d'entropie lors de la relaxation globale isotherme et, dans deux autres cas, on montre par des expériences numériques que la production d'entropie est aussi probablement monotone. L'entropie totale et l'énergie totale ne se détentent pas d'une façon générale avec la même constante de vitesse et dans plusieurs conditions la constante de temps pour la détente de l'entropie approche une valeur à peu près deux fois plus grande que la constante de temps pour la relaxation de l'énergie. On croit que le principe d'entropie maximum utilisé dans une approche information-théorique à la détente globale peut être synonyme du principe de monotonicité complète de la production d'entropie.

[Traduit par le journal]

Introduction

Following from a conjecture by McKean in 1966 (1) we have investigated the time-dependence of the total entropy in a number of model relaxations (2, 3) and found that often they seem to be in conformity with McKean's supposition, *i.e.*

$$[1] \quad (-1)^n \mathrm{d}^n S/\mathrm{d}t^n \leq 0 \qquad n = 1, 2, 3, \ldots$$

where S is the total entropy and t is the time; an extensive list of references to other work of a similar nature, particularly by Harris and by Simons, can be found in ref. 2. However, eq. 1 is by no means a universal rule, and there are frequent exceptions. For example, the exception of (isothermal) autocatalytic processes (and consequently also of oscillatory processes) is readily demonstrated; also, Lissi (4) has recently noted another class of exceptions, that of highly exothermic processes taking place adiabatically, a point we also confirmed by numerical integration for the explosive thermal decomposition of methyl isocyanide (5).

A process conforming to [1] is said to be "completely monotonic". In this paper, we present a summary of cases of complete monotonicity proved for an assembly of molecules undergoing bulk rotational and/or vibrational relaxation under isothermal conditions: the cases are presented under two headings, those which can be proved algebraically in the normal fashion, and those which we have only been able to demonstrate as plausibly correct (3) by numerical experiment; the details of these proofs will be made available in thesis form subsequently (6).

Following our existing notation[1] (7), the evolution of population distribution in an isothermal relaxation is given by

$$[2] \quad n_i(t) = \tilde{n}_i^{1/2} \sum_j S_{ij} \, \mathrm{e}^{\lambda_j t} \sum_k S_{kj} \tilde{n}_k^{-1/2} n_k(0)$$

We then write, following Bernstein and Levine (8), an expression for the total entropy as

$$[3] \qquad S(t) = -\boldsymbol{k} \sum_i n_i(t) \ln [n_i(t)/\tilde{n}_i]$$

whence

$$[4] \quad S^{(l+1)} = \frac{\mathrm{d}^{l+1} S}{\mathrm{d}t^{l+1}} = -\boldsymbol{k} \sum_i \sum_{m=0}^{l} \binom{l}{m} \frac{\mathrm{d}^m}{\mathrm{d}t^m} \ln \left(\frac{n_i(t)}{\tilde{n}_i} \right) \times \frac{\mathrm{d}^{l-m+1}}{\mathrm{d}t^{l-m+1}} n_i(t)$$

[1] Briefly, $n_i(t)$ is the population at time t, $\tilde{n}_i$ is the equilibrium population, and λ_j and S_{ij} are respectively the eigenvalues and eigenvectors of the relaxation matrix.

A. Cases Proved Analytically

A1. Canonically Invariant Relaxation

The properties of a canonically invariant relaxing system have been established by Andersen, Oppenheim, Shuler, and Weiss (9). For such a system, the mean energy $\langle E(t)\rangle$ relaxes as $\exp(-\mu t)$ where

$$[5] \qquad \mu = Z[M]\,P_{0\leftarrow 1}[1 - a\mathrm{e}^{-\tilde{\beta}\varepsilon_1}]$$

(a being related to state degeneracy factors) and the population evolution is characterised by the time-dependent inverse temperature $\beta(t) = [\boldsymbol{k}T(t)]^{-1}$, *viz.*,

$$[6] \qquad n_i(t) = [Q(t)]^{-1} g_i \exp[-\beta(t)\varepsilon_i]$$

where $Q(t)$ is the partition function. Hence

$$[7] \quad S^{(1)} = \boldsymbol{k}\beta^{(1)}(t)[\tilde{\beta} - \beta(t)] \times [\langle E^2(t)\rangle - \langle E(t)\rangle^2]$$

where $\langle E^2(t)\rangle$ is the mean square energy at time t. Since

$$[8] \qquad \frac{\mathrm{d}\langle E(t)\rangle}{\mathrm{d}t} = \frac{\mathrm{d}\langle E(t)\rangle}{\mathrm{d}\beta}\frac{\mathrm{d}\beta}{\mathrm{d}t}$$

and

$$[8a] \quad \frac{\mathrm{d}\langle E(t)\rangle}{\mathrm{d}\beta} = [\langle E(t)\rangle^2 - \langle E^2(t)\rangle] < 0$$

eq. 7 becomes

$$[7a] \quad S^{(1)} = -\boldsymbol{k}[\tilde{\beta} - \beta(t)]\frac{\mathrm{d}\langle E(t)\rangle}{\mathrm{d}t} \geq 0$$

Differentiating further

$$[9] \quad S^{(l)} = -\boldsymbol{k}\sum_{m=0}^{l-1}\binom{l-1}{m}\frac{\mathrm{d}^{l-m}}{\mathrm{d}t^{l-m}}\langle E(t)\rangle \cdot \frac{\mathrm{d}^m}{\mathrm{d}t^m}[\tilde{\beta} - \beta(t)]$$

and since the inverse temperature $\beta(t)$ has already been derived by Andersen *et al.* (9) and is monotonic, then [9] itself can be shown (6) to be *completely monotonic*.

A2. Canonically Invariant Relaxation

In our previous numerical examination of bulk relaxation (10), it was found (11) that there often did not appear to be any simple connection between the relaxation rates for entropy and energy. Consequently, we examined this relationship and can show (6), using eq. 7*a*, that whereas in a canonically invariant process the total energy decays as $\exp(-\mu t)$, *the total entropy decays as* $\exp(-2\mu t)$ *in the limit as* $t \to \infty$. This suggests that it may be possible to introduce the concept of a relaxation time for the total entropy: certainly, almost pure exponential behaviour of the total entropy at long time has been observed previously (2), but any simple relationship of the rate with the rate of energy relaxation escaped notice.

A3. $(N-1)$-fold Degenerate System

In our previous paper (7), we showed that if the relaxation matrix had $(N-1)$ degenerate eigenvalues of magnitude μ, eq. 2 becomes

$$[10] \qquad n_i(t) = \tilde{n}_i + (n_i(0) - \tilde{n}_i)\mathrm{e}^{-\mu t}$$

Writing

$$\gamma_i = n_i(t)/\tilde{n}_i$$

and

$$\Delta_i = (n_i(0) - \tilde{n}_i)/\tilde{n}_i$$

we can put

$$[11] \qquad S^{(1)} = \boldsymbol{k}\sum_i \tilde{n}_i S_i^{(1)}$$

where[2]

$$[12] \quad S_i^{(1)} = -\ln\gamma_i\frac{\mathrm{d}\gamma_i}{\mathrm{d}t} = \mu\Delta_i\,\mathrm{e}^{-\mu t}\ln(1 + \Delta_i\mathrm{e}^{-\mu t})$$

It is a simple matter to show that successive derivatives of [12] alternate in sign and therefore that S itself is *completely monotonic*; the monotonicity of the individual S_i-terms probably stems from the absence of overshoot or fluctuation in the degenerate system. Notice, as in *A2*, the long-time behaviour of the entropy is $\exp(-2\mu t)$.

A4. General Relaxing System at Long Time

As $t \to \infty$, the population vector [2] can be written as

$$[13] \qquad n_i(t) = \tilde{n}_i(1 + \phi_i(t))$$

If $\phi_i(t)$ is sufficiently small that we can assume

$$[14] \qquad \ln n_i(t) = \ln\tilde{n}_i + \phi_i(t)$$

then

$$[15] \quad \lim_{t\to\infty} S = -\tfrac{1}{2}\boldsymbol{k}\sum_{j=0}^{N-2}\mathrm{e}^{2\lambda_j t} \times \left[\sum_\alpha S_{\alpha j}\tilde{n}_\alpha^{-1/2}n_\alpha(0)\right]^2$$

Since [15] is in normal-mode form, *viz.*

$$[16] \qquad S = -\boldsymbol{k}\sum_i a_i\mathrm{e}^{-b_i t}$$

[2]Note that the subscript i here denotes an index for each level in the system (not the internal entropy).

and all the a_i are positive, then by Descartes' rule of sign for a sequence of exponentials [15] is *completely monotonic*. Notice again, as in *A2*, the appearance of $2\lambda_j$ in the expression for the relaxation time for the total entropy.

B. Cases Established Numerically

The four cases noted above represent the limit of the new theorems of entropy production which we have been able to establish by conventional means: unfortunately, three of them (*A1*, *A2*, and *A3*) refer to rather idealised systems, but the correspondence between *A2* and *A4* is suggestive enough that we should examine numerically some more realistic cases. Following our previous approach (3), we constructed analytical formulae for the first *six* derivatives of the total entropy and examined their behaviour for a series of practical relaxations: in this way, the following 'rules' were established.

B1. Transition Probabilities Obeying the Sum Rule

We examined both vibrational and rotational relaxations, using a wide variety of starting distributions including delta-distributions and bimodal delta-distributions. In many cases, populations of levels overshot, often in succession, but of course the energy does not overshoot since the sum rule guarantees exponential decay of the energy. *In all cases eq. 1 held up to* $n = 6$.

B2. Transition Probabilities of Linear Surprisal Form with Minimum Eigenvalue Spread

As discussed previously (7), this form of the transition-probability matrix often yields energy relaxation which is close to exponential: only rotational relaxation was examined.

(*a*) In simple heating or cooling processes *eq. 1 holds up to* $n = 6$; inspection of the population vectors during the relaxation shows that the systems are *not canonically invariant*, although there are no overshoots in either population or energy.

(*b*) In relaxations from delta- or bimodal delta-distributions, *eq. 1 fails randomly at some value of* $3 \leq n \leq 6$: the greater the number of levels overshooting or the greater the magnitude of the energy overshoot, the lower the value of n at which [1] appears to fail; nevertheless, the failure is only temporary, and the system soon gets back on a monotonic path.

B3. Mixed Rotation–Vibration Relaxation with our Standard Set (10) of Transition Probabilities

The results are essentially as in *B2*(*a*) and *B2*(*b*) although, because of the much greater range of eigenvalues (7), the decay departs more seriously from a pure exponential and the overshoots are more frequent and/or severe.

B4. The Time Scale for Entropy Relaxation

Theorems *A2*, *A3*, and *A4* above suggest that the total entropy relaxes exponentially in the limit, and with a characteristic time which is *half* of that for the energy relaxation. Numerical examination shows that this factor of two relating the relaxation times for the total energy and the total entropy is a persistent feature. Figure 1 compares the energy relaxation and the entropy relaxation for two sum-rule cases: (*a*) a simple temperature change in which the total-entropy relaxation (open circles) is almost indistinguishable from a pure exponential having twice the time constant of that associated with the energy relaxation; (*b*) one in which the initial distribution is a delta function, where it is seen that

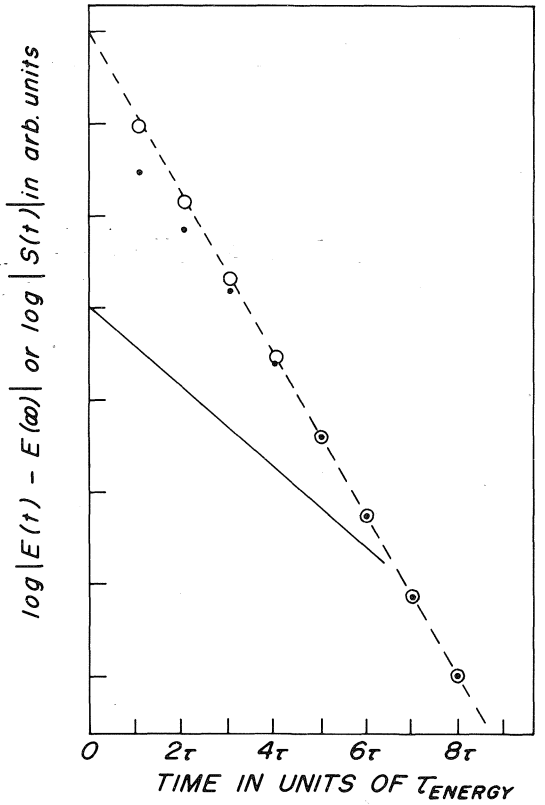

FIG. 1. Comparison of energy and entropy production rates in rotational relaxation, with transition probabilities obeying the sum rule. —, total energy; ---, line having exactly twice the slope of the solid line; ○, total entropy for a simple temperature change; ●, total entropy for a delta-function as the initial population distribution.

beyond $t \approx 3\tau_{energy}$ the total entropy (dots) approaches very closely to that in case (*a*). Other cases of simple temperature relaxation, either assuming canonical invariance, assuming $(N-1)$-fold degeneracy, or assuming probabilities with a small eigenvalue range, would be indistinguishable from curve (*a*) and are not reproduced here. However, using our standard set of transition probabilities (10) having a very wide range of eigenvalues (7), the limiting behaviour shown in Fig. 1 is not reached before all numerical accuracy is lost, and all we can see in these cases is that the *internal* entropy, in the limit, relaxes with the same time constant as does the total energy (which can also be shown analytically as a step in establishing *A4*, *cf.* also *A2*).

Speculation

Clearly the monotonicity principle does not hold for all isothermal relaxing systems, but it does appear to hold for many systems for most of the time. In the cases we examined, it seems that such departures as exist are only 'weak' in the sense that they are temporary, and they appear to be self-correcting. One is reminded here of other examples of relaxations which seem to get on to the same track in their approach to equilibrium, regardless of the starting distribution (12).

Furthermore, the results depicted in Fig. 1 suggest that there does appear to be such a concept of a maximum rate of entropy production, having a limiting value of the time constant exactly twice that of the time constant for the decay of the energy. In no case that we examined did the time constant for the relaxation of the entropy exceed twice that for the relaxation of the energy. Noting that under the conditions when the entropy relaxation rate most nearly approaches the limit of twice the energy relaxation rate the monotonicity principle appears to be most strongly obeyed, we suppose that maximum entropy production and monotonicity are intimately related. Moreover, because of the non-negativeness of the a_i in [15] and [16], there would be no 'negative' contributions to the entropy production rate, and we would fulfill, at least intuitively, the requirement for a maximum rate of production. Again, one is reminded of the information-theoretic description of bulk relaxation in which the entropy is maximised against some assumed dynamical constraints, such as the pure-exponential relaxation of the energy (13). Since in fact these dynamical constraints are all embodied in the master equation and in the way in which it operates on the initial distribution, perhaps the monotonicity of entropy production is synonymous with that maximum entropy principle, but without any explicit reference to the constraints. Moreover, it is relevant to note in further consideration of the results of Fig. 1 that, as conjectured by Andersen *et al.* (9) and proved by Cukier and Deutch (14), a canonical distribution minimises $S^{(1)}$ at a fixed value of $S(t)$ against all other distributions $n_i(t)$.

The perturbation by anesthetics of hydrogen bonds involving water

A. NAGYRÉVI AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received February 17, 1977

A. NAGYRÉVI and C. SANDORFY. Can. J. Chem. **55**, 1593 (1977).

It is shown through the measurement of infrared spectra at low temperatures, on the examples of two fluorocarbon anesthetics and a protein denaturing agent, that such compounds shift the association equilibrium in hydrogen bonds involving water in favor of free or less hydrogen bonded species.

A. NAGYRÉVI et C. SANDORFY. Can. J. Chem. **55**, 1593 (1977).

On montre par des spectres infrarouges mesurés en solution à basse température que des anesthésiques comme le chloroforme ou l'halothane aussi bien que la tétraméthylurée déplacent vers les espèces libre ou plus faiblement associées l'équilibre d'association dans des liaisons hydrogène que forment les molécules d'eau.

In previous publications from this laboratory attention has been drawn to the fact that halofluorocarbon anesthetics "break" hydrogen bonds (HB) of the N—H---N, O—H---O or N—H---O=C type in solution (1, 2). In other words these halofluorocarbons shift the equilibrium of association in favor of the "free" or less associated species. It has been suggested that this observation could be relevant for the elucidation of the mechanism of inhalation anesthesia. It is then natural to inquire whether similar observations can be made on hydrogen bonds involving water.

The means of doing this has been, as before, measuring infrared spectra and using low temperature measurements in order to magnify the effects. For this we needed a solvent in which polar molecules dissolve more easily than in the solvents which we used previously. Thus we were led to use 2-methyltetrahydrofuran (MTF) which can be cooled down to liquid nitrogen temperature where it is a glass. Even after thorough dehydration MTF contains a small amount of water, estimated to be 0.004 *M*. In our experiments some more water has been added to have a H_2O concentration about ten times higher. The HB breakers were chloroform, halothane (CF_3—CHClBr), and tetramethylurea. The two former are well known anesthetics. Urea is known as a protein denaturing agent; we had to use its tetramethylderivative which is soluble in MTF.

Figure 1 shows the infrared spectrum of 0.04 *M* water in MTF at 22°C and at −190°C. At 22°C the main peaks are at about 3575 and 3490 cm^{-1}. The band at higher frequency is probably due to the weak HB in which the oxygen in the MTF molecule is the proton acceptor while the band at lower frequency is likely to involve water–water bonding as well. Upon lowering the temperature more highly associated species become preponderant as shown by the spectacular changes in the spectrum.

The changes that occur upon addition of 0.5–1 *M* chloroform or halothane, or tetramethylurea at room temperature are slight. Upon lowering the temperature, however, con-

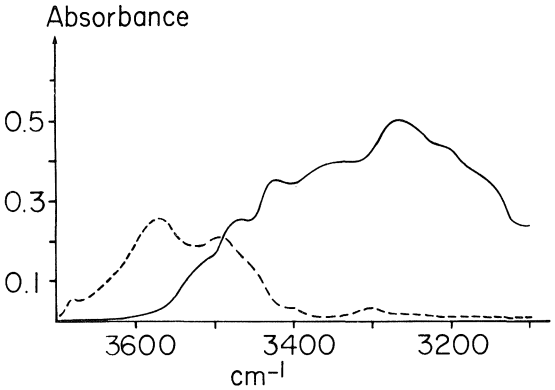

FIG. 1. The infrared spectrum of a 0.04 *M* solution of water in 2-methyltetrahydrofuran: --- at 22°C; — at −190°C.

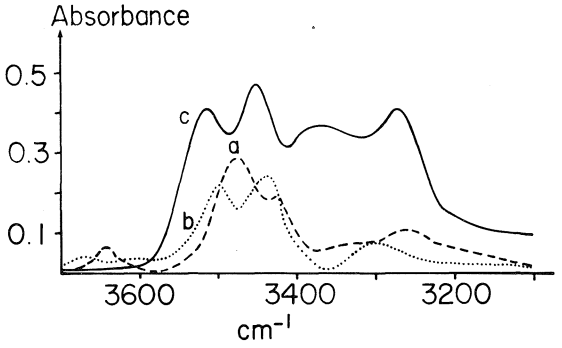

FIG. 2. The infrared spectrum of (*a*) 0.03 *M* water + 1.02 *M* chloroform in 2-methyltetrahydrofuran at −190°C. (*b*) 0.04 *M* water + 0.87 *M* halothane in 2-methyltetrahydrofuran at −190°C. (*c*) 0.04 *M* water + 0.60 *M* tetramethylurea in 2-methyltetrahydrofuran at −190°C.

spicuous changes occur (Fig. 2). They are different with the three hydrogen bond breakers but the change invariably favors the less associated species. (Compare the spectra in Fig. 2 with the low temperature spectrum in Fig. 1.)

We are making no attempt to assign the numerous bands present in these spectra. The only point we wish to make is that HB's involving water are just as sensitive to perturbation by halogenated anesthetics and other "HB breakers" as the other types of hydrogen bonds mentioned above. The changes occur gradually with decreasing temperature. They only become spectacular at very low temperatures; it is our belief, however, that the lesser changes occurring at normal temperature might be sufficient for biological action. The reason why HB's are broken might be the formation of other HB's or other types of aggregates but discussion on this will also be reserved for a later publication.

Experimental

2-Methyltetrahydrofuran was purchased from the Eastman-Kodak Company and was purified according to a prescription given by Fieser and Fieser (3). Its purity was checked by taking the boiling point (78°C) and by its known infrared spectrum (4). The samples were prepared and stored under dry nitrogen atmosphere and were kept on P_2O_5. Chloroform was washed with water, dried and distilled. Halothane and tetramethylurea were high purity commercial products and were not purified further. The spectra were measured on a Perkin-Elmer model 621 infrared spectrometer. The low temperature techniques have been described before (5).

The unimolecular isomerisation of monofluorocyclopropane: a reaction with multiple fall-off characteristics?

MOHAMMAD H. BAGHAL-VAYJOOEE, ANDREW W. YAU, AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received November 15, 1976

MOHAMMAD H. BAGHAL-VAYJOOEE, ANDREW W. YAU, and HUW O. PRITCHARD. Can. J. Chem. **55**, 1595 (1977).

Monofluorocyclopropane isomerises at 475°C to give four products, *cis*-1-fluoropropene, *trans*-1-fluoropropene, 2-fluoropropene, and 3-fluoropropene; the ratios of product formation are not independent of pressure and it is shown that, using the Kassel representation, the individual fall-off curves correspond to values of the parameter $s = 9$, 6, 4, and 4 respectively. It is shown that although conventional RRKM theory can account satisfactorily for the difference in fall-off behaviour between the *cis*- and *trans*-1-propene yields, it cannot account for the pressure dependence of the formation of 2- and 3-fluoropropene; the latter behaviour is, however, easily understood in terms of the master-equation approach.

MOHAMMAD H. BAGHAL-VAYJOOEE, ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. **55**, 1595 (1977).

Le fluorocyclopropane s'isomérise à 475°C pour conduire à quatre produits: le fluoro-1 propène *cis*, le fluoro-1 propène *trans*, le fluoro-2 propène et le fluoro-3 propène; les rapports des produits formés ne sont pas indépendants de la pression et on montre qu'à l'aide d'une représentation de Kassel les courbes individuelles de décroissance correspondent respectivement aux valeurs des paramètres $s = 9$, 6, 4 et 4. Quoique la théorie RRKM conventionnelle peut tenir compte d'une façon satisfaisante des différences dans les comportements de décroissance entre les rendements des propènes-1 *cis* et *trans*, on peut montrer qu'elle ne peut tenir compte de la dépendance qui existe entre la pression et la formation des fluoro-2 (et -3) propènes. Toutefois ce dernier comportement peut être facilement compris en termes d'une approche d'une équation maîtresse.

[Traduit par le journal]

Many unimolecular reactions yield more than one product (1, 2), but despite the intrinsic interest in studying comparative fall-off behaviour for the decomposition of a single molecule to several products (3), there exists very little information of this kind. A question of interest is whether the same molecule could exhibit *markedly* different fall-off behaviour in respect of its alternative reaction paths?

The thermal isomerisation of monofluorocyclopropane to four distinct isomeric products was studied at 475°C by Casas, Kerr, and Trotman-Dickenson (4) over a pressure range from 464 to 0.167 Torr, and the individual rates of production of the four products are shown in Fig. 1. The solid lines drawn through these points are the best Kassel curves (5) which will fit the data, having values of $s = 9$, 6, 4, and 4 for *cis*-1-, *trans*-1-, 2-, and 3-fluoropropene respectively. In presenting their experimental results, Casas, Kerr, and Trotman-Dickenson *presumed* that the much sharper fall-off behaviour of the 2- and 3-fluoropropene production rates was due to some loss (by polymerisation) of these two products at low pressures, although apparently there was no firm evidence to indicate

TABLE 1. Unimolecular behaviour in the thermal isomerisation of monofluorocyclopropane

Reaction designation	Product	Kassel s	$P_{1/2}$ (Torr)	Reaction order at 0.2 Torr
[1c]	*cis*-1-Fluoropropene	9	0.4	1.3
[1t]	*trans*-1-Fluoropropene	6	1.2	1.6
[2]	2-Fluoropropene	4	~16	~1.8
[3]	3-Fluoropropene	4	~16	~1.8

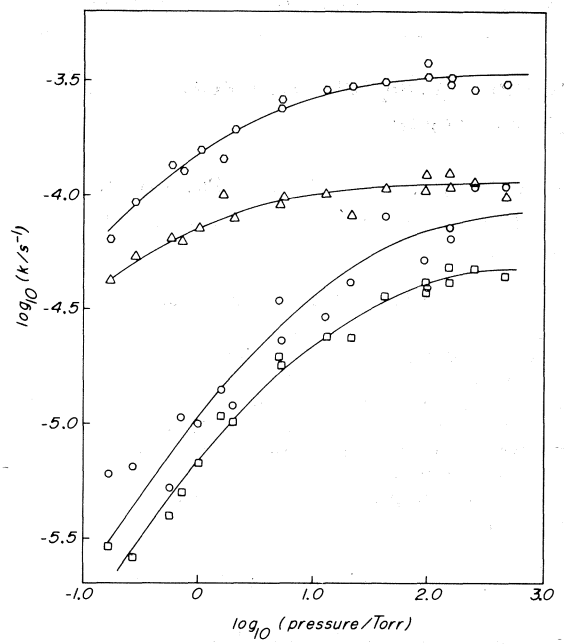

FIG. 1. Experimental rates, taken from the work of Casas, Kerr, and Trotman-Dickenson, for the formation of *cis*-1-fluoropropene (△), *trans*-1-fluoropropene (○), 2-fluoropropene (□), and 3-fluoropropene (○) from monofluorocyclopropane as a function of total pressure, at 475°C. The solid lines are Kassel curves having s = 9, 6, 4, and 4 respectively (a slight shift in the pressure axis being apparent between the latter two cases).

that these two molecules were lost preferentially by polymerisation. We will argue that an equally plausible assumption is that Fig. 1 represents a case of a molecule showing distinctly different fall-off behaviour for different reaction channels, and in support of this hypothesis, we present a set of consistency tests, summarised in Table 1. The four products certainly exhibit the normal expected patterns in respect of the number of effective oscillators and the half-pressure ($P_{1/2}$), or the reaction order at some fixed pressure in the fall-off region and, despite the difficulties inherent in this particular experiment, Table 1 presents at least a *prima facie* case for considering that each channel exhibits genuinely different fall-off behaviour.

A further consistency test can be applied to reactions [1c] and [1t]. If we assume that the rate constant for the ith unimolecular reaction channel obeys strict Arrhenius form

$$[4] \qquad k_{\infty,i} = A_i \exp(-E_{a,i}/RT)$$

then the specific rate constant is given by (6, 7)

$$[5] \qquad k_i(E) = \frac{A_i N(E - E_{a,i})}{N(E)}$$

where $N(E - E_{a,i})$ is the density of states of the molecule at $(E - E_{a,i})$. We will show later (8) using the master-equation formulation (9) that it is possible to relate the half-pressure $P_{1/2}$ to the function $k_i(E)$, whence if we assume that reactions [1c] and [1t] have the same critical energy E_a

$$[6] \qquad \frac{P_{1/2}[1t]}{P_{1/2}[1c]} \sim \frac{k_{1t}(E)}{k_{1c}(E)} \equiv \frac{A[1t]}{A[1c]} = \frac{k_\infty[1t]}{k_\infty[1c]} \simeq \frac{k_{464\,\mathrm{Torr}}[1t]}{k_{464\,\mathrm{Torr}}[1c]} = \frac{54.8}{17.6} = 3.1$$

The ratio of the half-pressures shown in Table 1 and Fig. 1 is 3: thus, the discrimination in the fall-off behaviour between the products *cis*- and *trans*-1-fluoropropene (which Casas, Kerr, and Trotman-Dickenson (4) state is a kinetic effect, and not due to any subsequent *cis–trans* isomerisation after the initial formation) is clearly consistent with current ideas of unimolecular reaction behaviour.

The question then is: can RRKM theory account for the much more severe fall-off in the formation of 2- and 3-fluoropropene? The simple answer, using *conventional* RRKM theory (1) is no, as is shown by the following set of calculations. The forms of the normal modes of vibration for a cyclopropyl halide molecule are

known (10) and normal-mode vibrational analyses have been made for cyclopropyl chloride, bromide, and iodide (11) and of course for cyclopropane itself (12). From this information, we have estimated by conventional comparative techniques (13) the frequencies of the 21 normal vibrational modes for monofluorocyclopropane, and carried out a series of RRKM calculations. Modern efficient methods for calculating the sum of states (14, 15) are about two orders of magnitude faster than the conventional method, as programmed by Robinson and Holbrook (1) for 21 oscillators, and it is not necessary to perform any grouping of the frequencies as is normally the case with such complicated molecules.

Figure 2 shows the theoretical fall-off curves for the four products, compared with the experimental curves (now plotted in conventional k/k_∞ form), calculated using the "ring breathing" frequency (16) of 1200 cm^{-1} as the one removed to define the activated complex. It can be seen that this calculation represents the fall-off behaviour for the *cis*- and *trans*-1-fluoropropene channels excellently, as would of course be expected because of the earlier agreement in eq. 6. However, the fall-off curves for the other two channels are much too shallow, shallower in fact that the 1-fluoropropene curves when in fact they should be much steeper. Isolation of either of two other frequencies, the "C—F deformation" near 300 cm^{-1} or the "asymmetric C—F stretch" near 3000 cm^{-1} leads to calculated fall-off curves for the formation of 2- and 3-fluoropropene very similar to those shown in Fig. 2. Such gross insensitivity of the calculated fall-off has already been noted in less extreme form by others (16–18) and in this particular reaction, in order to reproduce the fall-off behaviour for the production rates of 2- and 3-fluoropropene given the values of k_∞, one would have to choose critical energies in the region of 75 kcal/mol for both channels; this is clearly at variance with the experimental observations (4) which place the critical energies at *about* 4 kcal and 1 kcal respectively above the 1-fluoropropene threshold.

The difficulty here, as is well recognised in chemical activation studies (19), is that one cannot apply conventional RRKM theory to a second reaction channel placed above the first because the decay via the first channel distorts the population distribution below the second threshold, and the normal RRKM assumptions become invalid for this second channel. King,

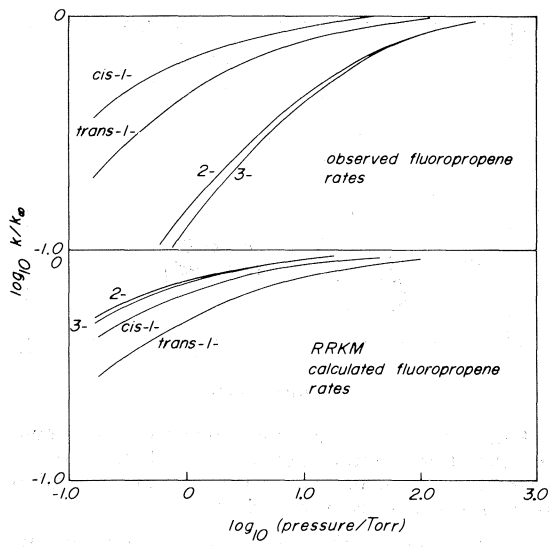

FIG. 2. Comparison of experimental data from Fig. 1 with the results of RRKM calculations. In these calculations the following parameters were used: collision efficiency $\lambda = 0.2$; critical energy (all reactions) = 61 kcal/mol; log (A_∞/s^{-1}) = 13.85, 14.37, 13.54, and 13.64 for *cis*-1-, *trans*-1-, 2-, and 3-fluoropropene respectively; vibration frequencies (cm^{-1}); $\nu_1 = 3100$; $\nu_2 = 3020$; $\nu_3 = 2980$; $\nu_4 = 1450$; $\nu_5 = 1305$; $\nu_6 = 1200$; $\nu_7 = 1090$; $\nu_8 = 1025$; $\nu_9 = 885$; $\nu_{10} = 770$; $\nu_{11} = 865$; $\nu_{12} = 325$; $\nu_{13} = 3095$; $\nu_{14} = 3065$; $\nu_{15} = 1415$; $\nu_{16} = 1275$; $\nu_{17} = 1165$; $\nu_{18} = 1045$; $\nu_{19} = 935$; $\nu_{20} = 810$; $\nu_{21} = 355$; (the numbering of the modes is as in ref. 10). Frequency isolated in this calculation, ν_6; frequencies isolated in other calculations were ν_3 and ν_{12}.

Golden, Spokes, and Benson (20) have discussed a generalisation of the Kassel formulation in the competitive pyrolysis of the two propyl iodides, and an analogous generalisation of the RRKM formulation would be straightforward. However, neither generalisation could take into account properly the mutual perturbation of one channel by the other, whereas it is automatically included in our master-equation formulation (9). Using a very simple extension (8) of the pentadiagonal master-equation model (*i.e.* non-nearest-neighbour transitions included) depicted in Fig. 1*b* of ref. 9, the results of a numerical simulation are as shown in Fig. 3. The curve labelled "channel I" shows the fall-off behaviour for a single decay channel placed at $E = 60$ kcal/mol (with channel II closed): the curve marked "channel II" shows the fall-off behaviour for a single channel placed at $E = 62$ kcal/mol *with channel I closed*; the properties of the probability matrices were chosen so that these fall-off curves would be disposed with respect

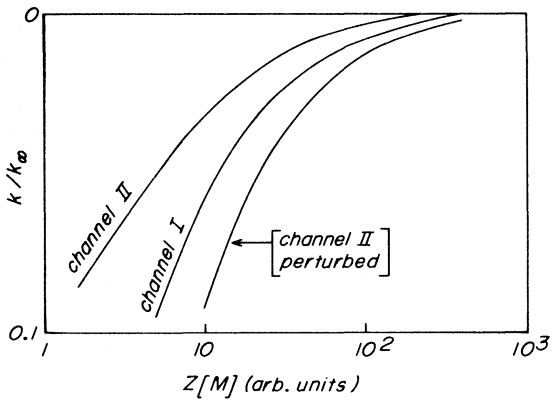

FIG. 3. Results of a master-equation calculation showing the strong perturbation of the fall-off curve for channel II depending upon whether channel I, slightly below it in energy, is open or closed.

to each other rather like those calculated by RRKM theory in Fig. 2, say for 1- and 2-fluoropropene respectively. When the calculation is repeated with both channels open, the fall-off behaviour of channel I remains virtually unchanged, but that of channel II moves markedly to the position denoted by "channel II perturbed", which is in fact in a position very like that observed for 2- and 3-fluoropropene in its relationship to the 1-fluoropropene channel(s). We conclude, therefore, that a plausible interpretation of the thermal isomerisation data for monofluorocyclopropane is that of the four channels available two, leading to *cis*- and *trans*-1-fluoropropene, have the same critical energy and their fall-off behaviour is well represented by RRKM methods; the two other channels, leading to 2- and 3-fluoropropene, have slightly higher critical energies, and their fall-off curves are severely perturbed by the existence of the lower channel(s), giving them a much sharper curvature than would be normal in a molecule of this complexity, for the given values of the critical energy.

ROGER A. CRAIG and HUW O. PRITCHARD. Can. J. Chem. **55**, 1599 (1977).

Modifications are reported to a conventional gas-kinetics computer program which allow for the continuous addition of chemical species to the flowing gas. This is necessary in modelling the gas flows in a jet engine where air is continuously entrained with the burnt or burning gases, and it also facilitates the investigation of introducing chemical additives into a flowing reaction mixture.

The program is used to compare, under the same *one-dimensional* modelling approximations, the nitric-oxide emissions from a conventional jet engine and from a proposed lean-burning modification, and it is concluded that the lean-burning model has potential for reducing nitric-oxide emission by more than two orders of magnitude.

ROGER A. CRAIG et HUW O. PRITCHARD. Can. J. Chem. **55**, 1599 (1977).

On rapporte des modifications à un programme conventionnel d'ordinateur pour la cinétique en phase gazeus qui permettent de tenir compte de l'addition continue d'espèces chimiques à un gaz en mouvement; ces modifications sont nécessaires si l'on veut développer un modèle pour des gaz qui se déplacent dans un réacteur où l'air est entraîné d'une façon continue aux côtés des gaz qui ont déjà brûlé et de ceux qui sont en train de brûlés; cette modification facilite aussi l'étude de l'effet produit par l'introduction d'additifs chimiques dans un mélange réactionnel en déplacement.

On utilise ce programme pour comparer, dans les mêmes approximations d'un modèle unidimentionnel, les émissions d'oxyde nitrique provenant d'un réacteur conventionnel avec celles d'un système de combustion à mélange pauvre qui est proposé; on en conclut que le système de combustion à mélange pauvre pourrait permettre de réduire les émissions d'oxyde nitrique par au moins deux ordres de grandeur.

[Traduit par le journal]

Introduction

The importance of minimising nitric-oxide emissions from both aircraft and automobile engines needs no amplification (1, 2). The basic problem is that whilst most engine pollutants are the result of incomplete combustion, and can (in principle) be suppressed by improving combustion efficiency, nitric oxide is synthesised from air itself when it is exposed to the high temperatures normally accompanying the combustion. It is well known (3, 4), again in principle, that the formation of nitric oxide can be lessened by carrying out the combustion at much lower temperatures, which would mean using much leaner combustion mixtures than are normally feasible (5). If we now confine our attention to the (axially symmetric) turbine aircraft engine, which is a considerably less difficult modelling problem than is the reciprocating automobile engine, there are two difficulties associated with using much leaner combustion mixtures. First, and most important, the flame becomes unstable, and may blow out; second, the combustion becomes slower, and it may be difficult to achieve complete combustion either within the length of a normal combustion chamber, or even at all (6, 7).

There have been at least three different proposals for achieving complete and stable combustion at low equivalence ratios (ϕ = molar ratio of fuel to air, with the stoichiometric ratio being $\phi = 1$). Roffe and Ferri (6) have experimented with a preheat system in which the air used in the combustion is heated to a higher temperature than is typical in a normal jet engine (1100–1200 K as opposed to, say, 700 K). Oppenheim and co-workers (8) have examined the feasibility of stabilising the combustion by heat recirculation from the later stages of the combustion. A third suggestion is that stabilisa-

tion can be achieved by using a small pilot flame burning under conditions that produce large numbers of free radicals which will support a lean combustion when it would otherwise die (9). This paper presents a brief summary of this proposal, together with the modification of the usual gas-dynamic equations which are necessary for such a study. We emphasise that this analysis uses a highly simplified description of the flow processes in a turbine engine (as discussed more fully below) but the calculated reduction in the nitric-oxide formation is so dramatic that we believe it could persist even when proper account is taken of the neglected complexities.

It should be noted that combustion at low equivalence ratio is not the only possible attack on the problem of reducing nitric-oxide emissions. Staged combustion, in which a slightly fuel-rich mixture is burnt first and the remaining air required to complete the reaction added later, is known to reduce nitric-oxide formation by a factor of 2 or so and has been used in steam-generating plants (10): similar proposals have been made for aircraft-borne power plants (11). Water injection, which has the general effect of lowering the gas temperatures, has been shown to reduce nitric-oxide emissions from turbine combustors (12–14). However, large amounts of water are required and so this approach is unattractive for continuous use with power plants in aircraft. On the other hand, water injection has been used on take-off in some aircraft, causing unacceptable smoke problems. Another idea is the swirl-can combustor (1) which attempts to achieve a very rapid combustion followed by a very rapid quenching, and there have also been proposals which try to blend together the concepts of staged and swirling combustions (15, 16). Entrainment of suitable additives intended to catalyse the reformation of oxygen and nitrogen from nitric oxide is also a common idea. Metallic or ammonium formates or oxalates have been claimed to be effective (17), but one can see many operational difficulties to be overcome before such additives could be used in aircraft engines. We ourselves have examined several plausible additives (*e.g.* O_3), but so far have found none which would appear to be effective (9). Finally one need not, in principle, have to modify the combustion process since (18) the flow patterns of the exhaust gases around the turbine blades are such that a suitable catalytic coating on the blades could destroy all the nitric oxide present, but again there are many technical details to be solved.

The Computer Program

The combustor is modelled conventionally as consisting of two major zones, illustrated in Fig. 1: a primary zone in which combustion is achieved, and a secondary zone in which air is entrained to cool the combustion products. Fuel and air are pre-mixed at the inlet conditions and then flow through the combustor, with the combustion defined by kinetic chemical reactions. The conservation equations used to describe this process are:

Mass

$$[1] \qquad \frac{1}{\rho VA}\frac{\mathrm{D}}{\mathrm{D}t}(\rho VA) = \frac{\mu}{\rho}$$

Species

$$[2] \qquad \frac{\mathrm{D}}{\mathrm{D}t}\frac{C_i}{\rho} = \frac{1}{\rho}\left(r_i + \frac{\mu_i}{M_i} - \frac{C_i\mu}{\rho}\right) \qquad i = 1, \ldots N$$

Momentum

$$[3] \qquad \rho\frac{\mathrm{D}V}{\mathrm{D}t} + \frac{1}{V}\frac{\mathrm{D}p}{\mathrm{D}t} = \mu(V_\mathrm{p} - V)$$

Energy

$$[4] \qquad \rho\frac{\mathrm{D}}{\mathrm{D}t}\left(h + \frac{V^2}{2}\right) = \mu[h_\mathrm{p} - h + \tfrac{1}{2}(V_\mathrm{p}^2 - V^2)]$$

and gas ideality is assumed

$$[5] \qquad P = \rho\frac{RT}{M_\mathrm{w}}$$

In eqs. 1–5, P is the pressure, ρ is the density, R is the gas constant, V is the axial velocity, A is the local area, M_i are the species molecular weights, and M_w is the mean molecular weight, all in g, cm, and s units; h is the enthalpy per g, and quantities labelled with a subscript p refer to combustor inlet conditions. The C_i are the individual species concentrations in mol cm^{-3}, the r_i are the rates of production in mol $cm^{-3}\,s^{-1}$, the μ_i represent the local rates of introduction of mass of each individual species due to entrainment in g cm^{-3} s^{-1}, and μ is the sum over all species of the μ_i. Equations 1–5 describe a chemically reacting one-dimensional flow which is assumed to be inviscid and adiabatic, and transport is by convection only. In the secondary zone, the entraining air is injected uniformly around the wall of the combustor and instantaneous radial mixing with the bulk of the flow is

assumed; the composition of the entraining gas is specified by the μ_i terms in eq. 2, enabling chemical additives introduced along with the cooling air to be treated very simply. A fuller account of the derivation and solution of these equations is available in thesis form (9).

The computer program used in this work was the NASA-Lewis General Chemical Kinetics Program (19), modified as outlined in eqs. 2 and 3 above to allow for the entrainment of air or the inclusion of additives in the flow, and extensively tested for consistency (9). Since the main aim of this work was to compare overall nitric-oxide formation rates in two very different model combustions, rather than to examine the combustion processes themselves, a number of fairly drastic approximations were made. Probably the most drastic assumption (from an engineering point of view) was the complete neglect of turbulence, which has been included in some other modelling studies (20, 21), and which is known to correlate to some extent with nitric-oxide formation rates (3). This sensitivity to turbulence can be rationalised qualitatively by regarding the macroscopic turbulent process as a series of microscopic staged combustions. The neglect of turbulence, which is a very important part of any practical combustion process, was justified *a posteriori* by the fact that the calculated difference between the two models was much greater than any expected variation in nitric-oxide formation rates arising from turbulent effects (22). For similar reasons, we chose to model the much simpler combustion of hydrogen in air, rather than jet fuel in air, simulating the practical process by adding a portion of argon as a diluent so as to match simultaneously both the equivalence ratio and the flame temperature of the real combustion; in fact, it is known not only that jet engines which ordinarily operate on kerosene will perform reasonably well on gaseous hydrogen (23) but that similar amounts of nitric oxide are emitted using either hydrogen or jet fuel (24).

For the modelling calculations, we chose to use the specific flow rates of fuel and air characteristic of a typical commercial gas turbine at a fairly high power setting (20), as shown in Table 1,[1] and the first task was to establish the conditions under which the model would mimic the practical combustion. The rate constants chosen for the hydrogen–oxygen combustion processes (25) are shown in Table 2. Some of these rate constants may be somewhat imprecise, but as is now well established, the overall rates of complex chemical reaction schemes are often rather insensitive to the rates of many of the detailed processes, and as long as the dominant processes are reasonably correct, an acceptable computed rate will emerge (26). Finally, the calculation includes one adjustable parameter, the amount of recirculation in the primary zone, depicted by the two vortex arrows in Fig. 1. A mixture of air and hydrogen will not sustain combustion unless some of the heat of combustion is transferred back (as it is in a real flame by a variety of complex processes) so as to raise the initial temperature of the reaction mixture. Thus, a fraction (15–18% depending on ϕ) of the combusted gas was assumed to be recirculated so as to bring the inlet temperature of the gases up to

TABLE 1. The JT8D combustion chamber

(*a*) Approximate dimensions

Parameter	Value
Diameter	19 cm
Cross-sectional area	297 cm²
Overall length	38 cm
Primary zone length	8 cm
Secondary zone length	30 cm

(*b*) Inlet conditions

Parameter	Value
Overall air flow	7700 g/s
	267 mol/s
Temperature	700 K
Pressure	15 atm

(*c*) Computed flow parameters (typical)

Parameter		Value
Induction times	$\phi = 1$	0.7 ms
	$\phi = 0.8, 1.2$	1.1 ms
Primary zone residence time		4–5 ms
Secondary zone		
Residence time		10–12 ms
Initial temperature	$\phi = 0.8$	2390 K
	$\phi = 1.0$	2600 K
	$\phi = 1.2$	2590 K
Initial velocity	$\phi = 0.8$	2800 cm/s
	$\phi = 1.0$	3200 cm/s
	$\phi = 1.2$	3300 cm/s

[1]The JT8D engine is used in such aircraft as the Boeing 727, Douglas DC9, and Sud Caravelle 10, and a complete engine consists of nine combustor cans (such as depicted in Table 1), arranged symmetrically about the engine axis.

TABLE 2. Combustion reactions*

	Reaction	Rate parameters		
		A	n	E (kcal/mol)

[*xv*]	$H_2 + O_2 \rightleftarrows OH + OH$	1.0×10^{14}	0	47.6
[*xvi*]	$H_2 + O_2 \rightleftarrows H + HO_2$	2×10^{14}	0	67
[*xvii*]	$OH + H_2O_2 \rightleftarrows H_2O + HO_2$	1×10^{13}	0	1.8
[*xviii*]	$O + H_2O_2 \rightleftarrows OH + HO_2$	8×10^{13}	0	1
[*xix*]	$H + H_2O_2 \rightleftarrows H_2O + OH$	3×10^{14}	0	9

*Rate constants (in units of mol, cm^3, and s) are for the forward direction and are given by $k = AT^n \exp(-E/RT)$. All third body efficiencies are 1.0 except for reaction *iv* in which the efficiency of H_2 is taken as 3.3 and of H_2O as 21.

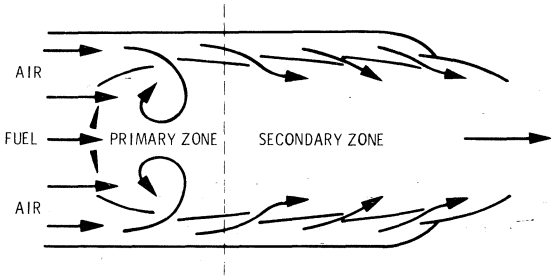

FIG. 1. Schematic representation of a jet-engine combustor can.

the design inlet temperature of 1000 K (14). This gives a self-sustaining stable combustion with an acceptable induction time and flame-front thickness; more extensive discussion of this recirculation procedure can be found in ref. 7 where our program has been used to model the methanol–air combustion in an engine, and in ref. 9. Moreover, not only are the induction times acceptable, but so are their relationships with equivalence ratio and inlet pressure when compared with observed data (9). Hence, it would seem that extension of this model to include nitric-oxide forming reactions is warranted, particularly so since the temperature history of the nitrogen–oxygen mixture is the principal determinant of the final nitric-oxide mass flow.

The reaction rates involved in the formation of nitric oxide (25, 27, 28) are shown in Table 3. Again, some of these rates are still rather uncertain at the present time, but with the exception of reaction *xxii* (which is discussed further below), are thought to be accurate within a factor of two (29). Only 9 chemical reactions are included in Table 3, other reactions (such as $NO_2 + O \rightleftarrows NO + O_2$, $M + NO_2 \rightleftarrows M + NO + O$) were discarded as making no significant contribution to the nitric-oxide mass flow (9). This gives a total of 28 chemical reaction-rate equations to be integrated, coupled with the eqs. 1–5 describing the flow and the air entrainment, using our modification of the NASA–Lewis General Chemical Kinetics Program (9, 19). With appropriate integration step lengths, determined by the error criteria in the usual way, a typical computer run would take about 200 s on a CDC 7600 machine.

Results

First we present very briefly the results obtained for a conventional combustor design: many details of the combustion itself will not be discussed here, only those pertaining to the formation of nitric oxide. Smooth combustion is achieved (as noted above) by recirculating 15–

TABLE 3. Nitric-oxide formation reactions*

	Reaction	Rate parameters		
		A	n	E (kcal/mol)
[xx]	$N + NO \rightleftarrows N_2 + O$	3.1×10^{13}	0	0.33
[xxi]	$N + O_2 \rightleftarrows NO + O$	6.43×10^{9}	1	6.2
[xxii]	$N + OH \rightleftarrows NO + H$	4×10^{13}	0	0
[xxiii]	$H + N_2O \rightleftarrows N_2 + OH$	3×10^{13}	0	10.8
[xxiv]	$O + N_2O \rightleftarrows N_2 + O_2$	3.6×10^{13}	0	24
[xxv]	$O + N_2O \rightleftarrows NO + NO$	5×10^{13}	0	24
[xxvi]	$M + N + O \rightleftarrows NO + M$	6.4×10^{16}	$-\frac{1}{2}$	0
[xxvii]	$M + N_2O \rightleftarrows N_2 + O + M$	2×10^{15}	0	57.6
[xxviii]	$M + N + N \rightleftarrows N_2 + M$	7×10^{14}	0	0

*Rate constants (in units of mol, cm³, and s) are for the forward directions and are given by $k = AT^n \exp(-E/RT)$.

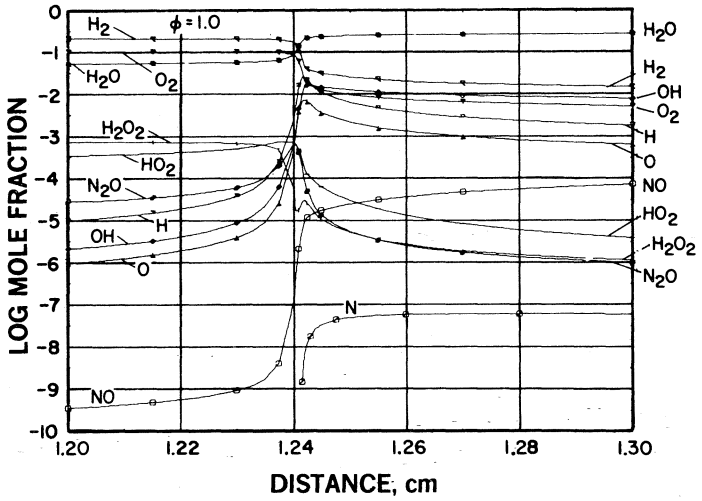

FIG. 2. Calculated species mole fractions in the combustion region of the primary zone for the case $\phi = 1.0$; note that the primary zone is approximately 8 cm long.

18% of the gas in the primary zone (7, 9) giving an effective inlet temperature in the steady state of 1000 K. Under these conditions, there is a short induction period, clearly shown in Figs. 2, 3, and 5: *cf.* also Table 1. During this time, the concentrations of various free radicals (O, OH, H, HO_2) increase, and when their concentrations become high enough, combustion occurs quite abruptly, after which most species relax to their equilibrium levels: a typical plot of the individual species concentrations through the flame front for an equivalence ratio $\phi = 1.0$ is shown in Fig. 2. Nitric oxide, however, does not equilibrate as quickly as the other species, and its concentration climbs slowly from a low value at the flame zone towards its equilibrium level. The net rates of the various nitric-oxide producing reactions are shown in Fig. 3 for the primary zone and in Fig. 4 for the secondary zone, using in each case three trial values of overall equivalence ratio (lean, $\phi = 0.8$; stoichiometric, $\phi = 1.0$; rich, $\phi = 1.2$). There is negligible production before the combustion zone, and thereafter, three reactions are responsible for the formation of nitric oxide, which are, in decreasing order of importance

[6] $O + N_2 \rightarrow NO + N$ (*xx*, reverse)

[7] $N + OH \rightarrow NO + H$ (*xxii*)

[8] $N + O_2 \rightarrow NO + O$ (*xxi*)

with the latter one only being significant under fuel-lean conditions (Fig. 3). The importance of reaction 7 has not been recognised until recently,

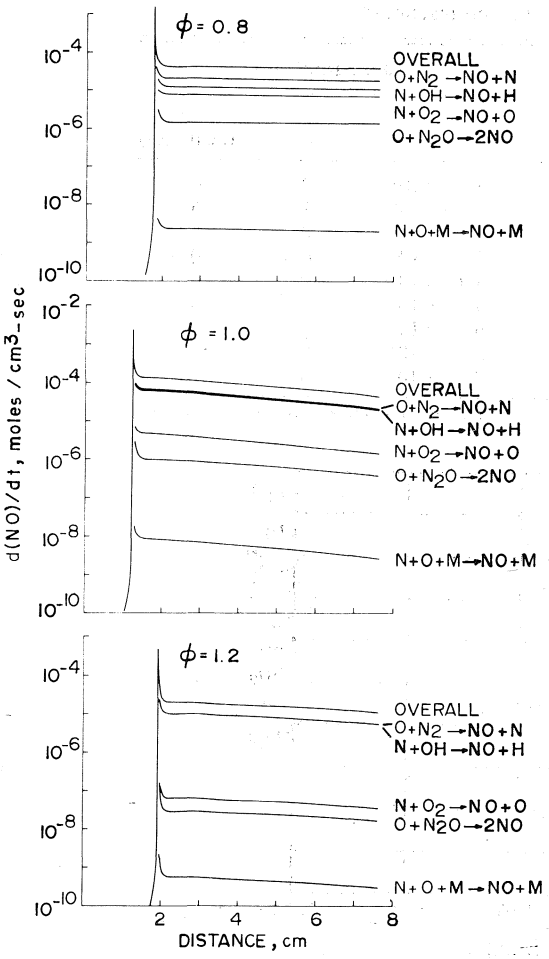

FIG. 3. Calculated overall and individual nitric-oxide production rates in the primary zone.

although its inclusion in model reaction schemes is now commonplace (7, 8, 30, 31), and the reaction scheme [6]–[8] is now often termed the extended Zeldovich mechanism (32). Moreover, we have assumed for reaction 7 the room-temperature rate constant with no activation energy, so its importance could well be underestimated in these calculations.[2] We may rationalise the results shown in Fig. 4 in the following way. In the fuel-lean case ($\phi = 0.8$), combustion is already complete at the 8 cm mark and the nitric-oxide formation rates continue to decline. On the other hand, the addition of more air to the fuel-rich case ($\phi = 1.2$) causes the combustion to proceed further, and along with it, all rates of nitric-oxide forming processes increase to maxima before falling off; the behaviour of the stoichiometric case ($\phi = 1.0$) is intermediate between the other two. Figure 5 shows an enlarged segment of Fig. 3 for the $\phi = 1.0$ case; similar plots for the other cases are available in thesis form (9).

Figure 6 presents a summary of the results in the form of nitric-oxide mass flows and temperature profiles for the conventional combustor. As we have seen in Figs. 2–5, the production of nitric oxide commences in the primary combustion zone, and the production rate is greatest in the stoichiometric case; in both this and the fuel-lean case, most of the production of nitric oxide occurs in the primary zone. However, in the fuel-rich case, there is a rather low rate of nitric-oxide production in the primary zone, since the concentrations of O_2 and O are low in this region, but a large amount is generated when the excess fuel is burned in the initial entraining air; in this burning zone, there is an excess of free radicals and a large amount of new O_2 to enhance the nitric-oxide production rate. Figure 6 also shows that in all three cases, nitric-oxide production ceases when the gas is cooled below about 2200 K in the secondary zone, and no significant amounts of nitric oxide are formed or destroyed after the 2200 K freezing mark is passed (9, 35). This effect becomes rather obvious when the results are presented as mass flow of nitric oxide rather than, as is usually done, the relative concentration of nitric oxide where the dilution effect of the entraining air obscures the real freezing points.

Before proceeding to examine the alternative model combustion, it is necessary to know that this, albeit, very simple model of the conventional combustor does not predict nitric-oxide flow rates which are wildly in error. In fact, they agree quite well with those found in practice, being very similar (9) to measurements made on an experimental combustor using hydrogen as a fuel (36), and about a factor of 2–4 greater than the observed values[3] for the JT8D combustor

[2]Nonetheless, since this work was completed, measurements of the reverse reaction have been made at high temperatures (2400–4200 K) by Flower (33) and the rate for reaction 7 used in our calculations is consistent with these measurements: Flower's results correspond to a value of k_7 of 3.5, 4.4, and 5.0×10^{13} mol^{-1} cm^3 s^{-1} at 1500, 2000, and 2500 K respectively, compared with the constant value of 4.0×10^{13} mol^{-1} cm^3 s^{-1} shown in [*xxii*] of Table 2.

[3]Recently, it has been suggested (38) that these measured nitric-oxide flow rates could be too low by a factor of between 2 and 5.

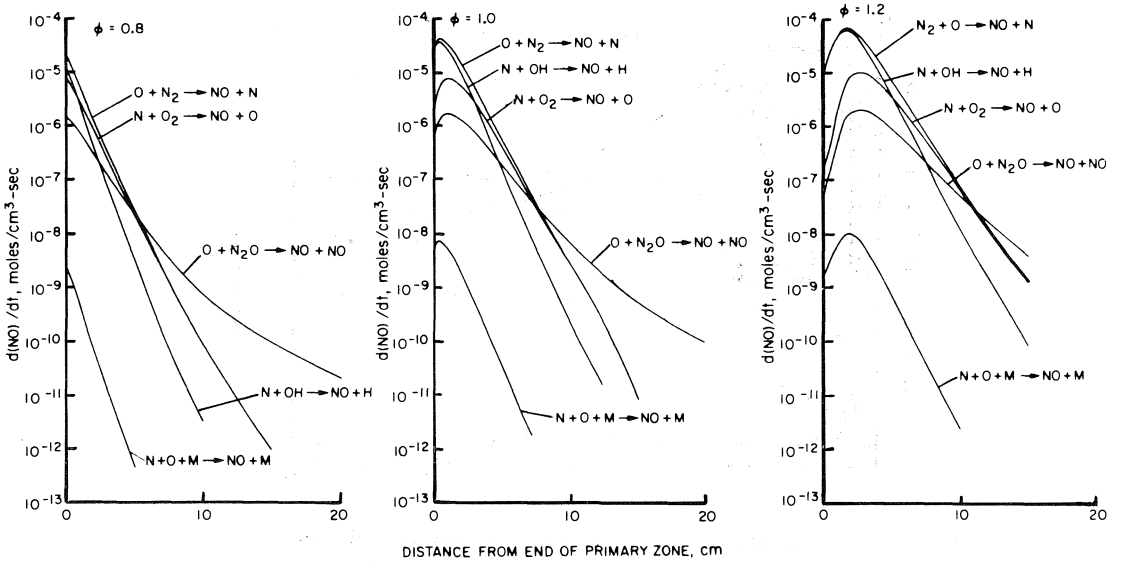

FIG. 4. Calculated nitric-oxide production rates in the secondary zone.

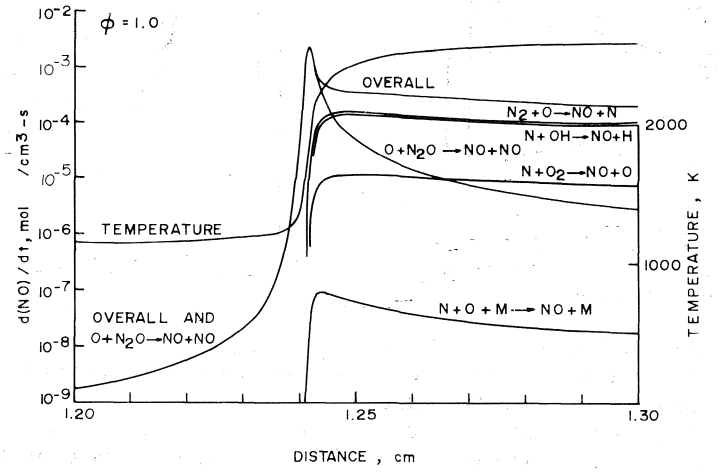

FIG. 5. Calculated temperature and nitric-oxide production rates in the combustion region of the primary zone for the case $\phi = 1.0$. Note that the oxidation of nitrous oxide appears to be an important early source of nitric oxide in all three calculations ($\phi = 0.8$, 1.0, and 1.2), but it is not clear whether this is a significant conclusion. It is marginally consistent with the observation that nitrous oxide is an important source of nitric oxide in fuel-lean systems at low temperatures (31), but at variance with the observation that "prompt NO" does not occur in hydrogen nor carbon-monoxide flames (34); the rate constant used for reaction *xxv* agrees with that most recently recommended (29), but no "sensitivity tests" were carried out on this reaction.

itself using jet fuel at the same inlet temperature (37). It would appear, therefore, that on these criteria, as well as other tests of the model (7, 9), the present reaction scheme and flow model should be adequate to test the likely success of the proposal for reducing nitric-oxide emissions using a pilot flame, rich in free radicals, to support a lean combustion (9).

There are many possible practical configurations for the support of a lean combustion by a pilot flame, but we are restricted in our computer program to those having axial symmetry. Hence, we examined the idealised model depicted in Fig. 7, having the length, exit diameter, and the fuel and air flows exactly the same as for the conventional combustor just described. Com-

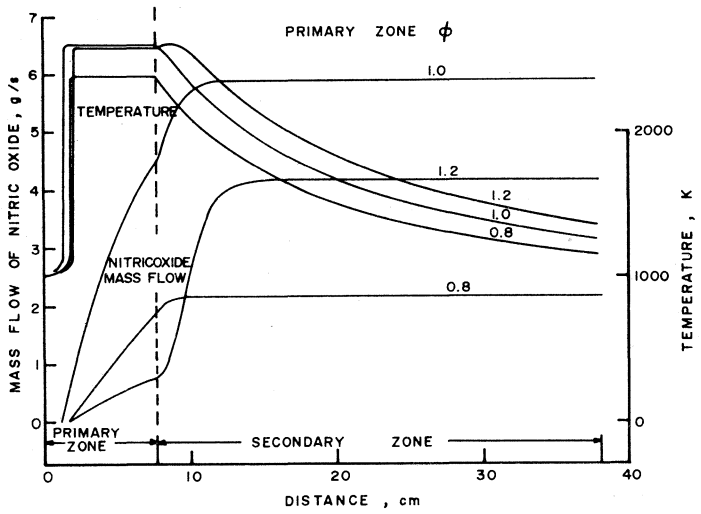

FIG. 6. Calculated temperature and nitric-oxide mass flow along the entire combustor.

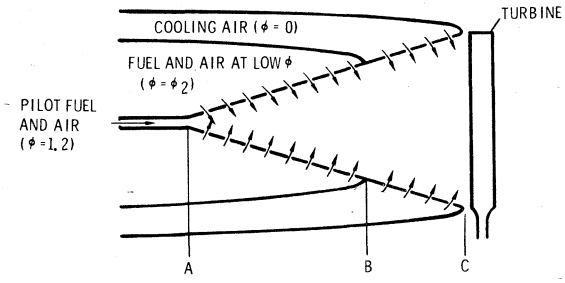

FIG. 7. Schematic representation of the novel combustor for low nitric-oxide emissions.

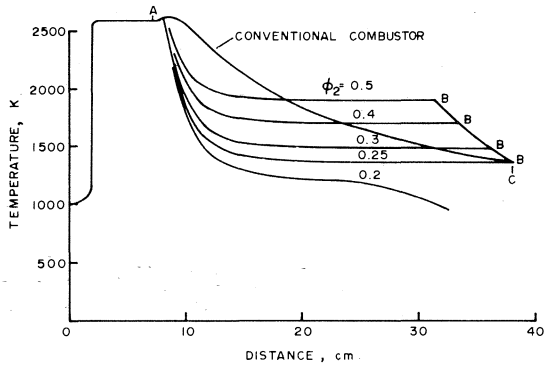

FIG. 8. Calculated temperature profiles along the conventional and the novel combustors.

bustion is established by burning a small portion of the fuel and air in a primary, or pilot stage. This pilot stage is assumed to have the same axial properties as the primary stage of the conventional combustor, but the diameter is reduced from 19 cm to 1 cm. The equivalence ratio in the pilot stage is 1.2, and the specific fuel and air flows are the same as in the conventional combustor. The remainder of the fuel is then burned in the conical section extending from A to B. The fuel is premixed with air at low equivalence ratios ϕ_2 and at normal air-entrainment conditions, and is introduced into the flow uniformly along the section A to B; the smaller ϕ_2, the greater is the distance between A and B. After all the fuel has been entrained, the remaining air is introduced between B and C in the normal manner. Figure 8 shows the calculated axial variation of temperature for this novel combustor, compared with the conventional combustor. The pilot stage temperature is just the temperature for the conventional combustor primary zone. The parameter ϕ_2 is varied from 0.5 to 0.2, but in each case the same total amount of fuel and air flows through the combustor. Thus, if all the fuel is burnt, the exit conditions (pressure, temperature, mass flow, thrust, etc.) will be the same as in the conventional combustor. The pilot gas is hot and rich in the free radicals required for combustion, so the fuel and air mixture introduced between A and B burns very rapidly although at a lower temperature. As ϕ_2 is reduced more and more below 0.5, combustion proceeds at successively lower temperatures, but nevertheless it proceeds! However, at $\phi_2 = 0.2$, the cooling effect of the entraining air overwhelms the heat liberated in the combustion

reactions and the combustion freezes near the 20 cm mark, leading to a very low exit temperature, large concentrations of unburnt gas, and of course low efficiency. The combustion does not extinguish itself in this way at $\phi_2 = 0.25$ or above.

Figure 9 shows the calculated nitric-oxide mass flow along this novel combustor, confirming that there is a much lower production of nitric oxide by as much as perhaps a factor of 100. However, the production of nitric oxide does not freeze at 2200 K as it does in the conventional combustor. This is because of the protracted combustion which, although the temperature is somewhat lower, still contains high concentrations of radicals; examination of the radical profiles shows that OH and HO_2 radicals have much higher concentrations in these lean flames than they do in the conventional ones. Thus, in the early stages of this novel combustor nitric oxide continues to be formed by reactions 6, 7, and 8 giving rise to the steep increase in the mass-flow curves just after point A. However, these reactions then become quenched and the curves bend over fairly sharply, leaving only reaction *xxv*, the oxidation of nitrous oxide as the important formation reaction. This reaction, it will be recalled, was the one apparently responsible for the peak nitric-oxide production in the flame zone of the conventional combustor, *cf.* Fig. 5.

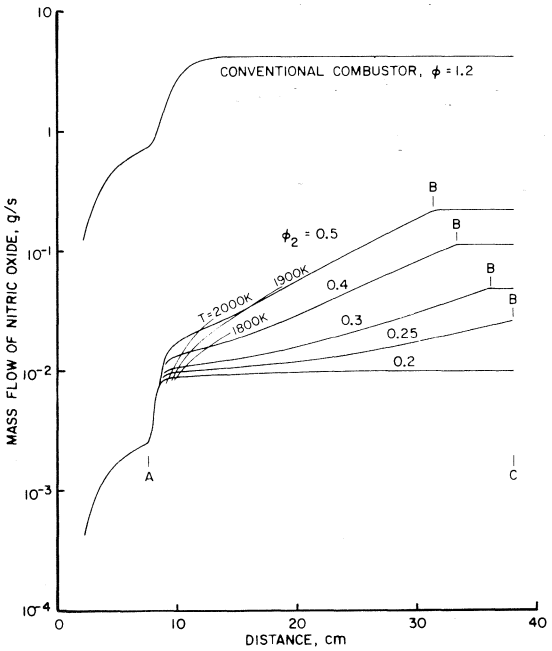

FIG. 9. Calculated nitric-oxide mass flow rates along the conventional and the novel combustors; (conventional combustor data taken from Fig. 6).

As was noted above, there appears to be a limit of about $\phi_2 = 0.25$ below which the flame dies and combustion is incomplete, but all the same, the system should be very resistant to a complete flame-out, since any downstream disturbance of this kind should encounter more and more difficulty propagating backwards and extinguishing the pilot flame. Also, one might expect that, although our calculations show that combustion is virtually complete at the exit for the $\phi_2 = 0.25$ case, a somewhat higher ϕ_2 might be needed to achieve a satisfactorily complete combustion in a real engine.

Conclusion

All the numerical tests we have undertaken show that our modifications of the NASA-Lewis General Chemical Kinetics Program to allow for the entrainment of air or the inclusion of additives into the flow are correct. The program was used to examine in a comparative way, making the same approximations in each case, a conventional and a proposed lean-burning combustion, and it would appear that using the lean-burning process, reductions of nitric-oxide emission of over a factor of 100 might be possible. In this design the combustion is protracted to low temperatures, and the (often neglected) details of the combustion may not be ignored. The super-equilibrium concentrations of free radicals during this combustion are important, and the nitric oxide produced from such a combustor cannot be estimated from equilibrium or from steady-state assumptions, but requires an analysis including the kinetics of the combustion reactions (*cf.* also ref. 39). Thus, in practical application, the extent of the improvement in nitric-oxide emissions using piloted flame techniques will be somewhat dependent on the nature of the fuel, but a significant improvement appears guaranteed by the fact that the overall temperature profile of the combustion is lower.

Solvent effects on thermodynamics and mechanism of dissociation of the monocomplex of nickel(II) with thiocyanate

PRAPHULLA KUMAR CHATTOPADHYAY AND BYRON KRATOCHVIL

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 24, 1976

PRAPHULLA KUMAR CHATTOPADHYAY and BYRON KRATOCHVIL. Can. J. Chem. **55**, 1609 (1977).

Rate constants and associated activation parameters for dissociation of $(NiSCN)^+$ were measured kinetically in methanol and dimethylsulfoxide by stopped-flow spectrophotometry using copper(II) as the decomposing ion. The data along with previous results by others on dissociation of $(NiSCN)^+$ in water, acetonitrile, and *N*,*N*-dimethylformamide are discussed mechanistically by considering the effect of solvent donor properties on the activation enthalpy for the dissociation process. Rate constants for dissociation at a single temperature are not systematically related to the Gutmann donor number of the solvent, but the enthalpy of activation for the dissociation process shows a linear inverse relation to the donor number. Pathways for dissociation of $(NiSCN)^+$ in these solvents are accommodated within an I_d-type mechanism.

PRAPHULLA KUMAR CHATTOPADHYAY et BYRON KRATOCHVIL. Can. J. Chem. **55**, 1609 (1977).

Opérant dans le méthanol et le diméthylsulfoxyde, faisant appel à la spectrométrie de flux stoppé et au cuivre(II) comme ion de décomposition, on a mesuré la cinétique, les constantes de vitesse et les paramètres d'activation qui sont associés avec la dissociation de $(NiSCN)^+$. Les données obtenues, de concert avec des résultats obtenus antérieurement par d'autres sur la dissociation de $(NiSCN)^+$ dans l'eau, dans l'acétonitrile et dans le *N*,*N*-diméthylformamide, peuvent être discutées du point de vue mécanistique en considérant l'effet des propriétés donneurs du solvant sur l'enthalpie d'activation pour le processus de dissociation. Les constantes de vitesse pour la dissociation à une température donnée ne sont pas reliées d'une facon systématique avec le nombre donneur de Gutmann du solvant mais l'enthalpie d'activation pour le processus de dissociation présente une relation linéaire inverse avec le nombre donneur. On peut accommoder les chemins de dissociation de $(NiSCN)^+$ dans ces solvants à l'intérieur d'un mécanisme du type I_d.

[Traduit par le journal]

Introduction

It was shown (1) recently that the pathways for dissociation of the $(S_5NiIsoquinoline)^{2+}$ ion in water, methanol, acetonitrile, propylene carbonate, dimethylsulfoxide, and *N*,*N*-dimethylformamide can be accommodated within an I_d-type mechanism represented by

$$[1] \quad L{-}NiS_5 + S \rightleftarrows \underset{\substack{\text{Outer}\\\text{sphere}\\\text{complex}}}{S,S_5Ni{-}L} \rightleftarrows S{-}NiS_5,L$$

where S is a solvent molecule, L is isoquinoline, and charges have been omitted. It was also pointed out that for this system dissociation rate constants at any single temperature do not show a systematic trend with the donicities of the solvents, as has been observed for the $(S_5NiSCN)^+$ ion (2), but enthalpies of activation ($\Delta H_d^{\ddagger}$) for dissociation of $(S_5NiIsoquinoline)^{2+}$ do bear a linear relation with Gutmann donor numbers (3) of the solvents. From this relation the best values for the donor numbers of methanol and water were suggested to be 9 and 18. To test whether results for the $(S_5NiIsoquinoline)^{2+}$ ion can be applied to other simple monocomplexes of nickel(II), similar investigations with different ligands are needed.

Although considerable data have been collected on rate constants and activation parameters for the formation of various labile complexes of nickel(II), only a few isolated studies of dissociation of these species have been reported, and systematic data on solvent effects are limited. Particularly needed are data on dissociation in systems where the ligand is an inorganic anion.

Recently Coetzee and Hsu (4) reported a stopped-flow spectrophotometric investigation of rates of formation and dissociation of $NiSCN^+$ in dimethylsulfoxide. They repeated some earlier studies (2, 5), and proposed that the reaction of nickel(II) with thiocyanate ion proceeds by an I_d-type mechanism. Although the formation rate

constant (k_f) of the reaction at 20°C reported by them agrees with the results of Dickert, Hoffmann, and Janjic (2) within 11%, the enthalpies of activation ($\Delta H_f^{\ddagger}$) for the reaction do not (7.8 ± 0.6 *vs.* 13.1 kcal). Coetzee and Hsu (4) also reported dissociation rate constants (k_b) and associated activation parameters ($\Delta H_b^{\ddagger}$ and $\Delta S_b^{\ddagger}$) for dissociation of S_5NiSCN^+ ion in dimethylsulfoxide as solvent. These values were obtained indirectly by calculation from stopped-flow spectrophotometrically measured formation rate constants (k_f) and spectrophotometrically measured overall equilibrium constants (K_{eq}) for the reaction. The uncertainty in $\Delta H_b^{\ddagger}$, 16.6 ± 2 kcal, is relatively high, owing to uncertainties in the measurement of k_f and K_{eq} as well as in the value used for a, the distance of closest approach between ions in the Fuoss-Eigen equation (6). Dickert, Hoffmann, and Janjic also reported values of $\Delta H_b^{\ddagger}$ and $\Delta S_b^{\ddagger}$ for dissociation of $NiSCN^+$ in water, acetonitrile, methanol, and *N*,*N*-dimethylformamide, and k_b at 20°C for this reaction in dimethylsulfoxide (2). These data were obtained by pressure-jump measurements, and estimates of uncertainties in the values were not given.

As shown before (1), a plot of $\Delta H_b^{\ddagger}$ for $(S_5NiIsoquinoline)^{2+}$ in various solvents against the Gutmann donor numbers of the solvents is linear, with methanol and dimethylsulfoxide lying near the ends of the donicity scale of the solvents considered. Because an improved understanding of the fine structure of the mechanism of dissociation of labile nickel(II) complexes may accrue from consideration of the donor properties of the solvents coordinated to the nickel(II) ion, accurate values of the dissociation rate constants and associated enthalpies of activation are needed, especially for solvents located at the ends of the donicity scale. An uncertainty in $\Delta H_b^{\ddagger}$ values of no more than ±1 kcal seems desirable. For these reasons, and because of the discrepancy of 5.3 kcal in $\Delta H_f^{\ddagger}$ values pointed out earlier, we decided to determine directly rate constants and associated activation parameters for dissociation of the $(S_5NiSCN)^+$ ion in methanol and dimethylsulfoxide. This was done by stopped-flow spectrophotometry, a high concentration of copper(II) ion being used as the decomposing species. Our results, in conjunction with earlier results in water, acetonitrile, and *N*,*N*-dimethylformamide (2), are discussed from a mechanistic point of view by considering the effect of solvent donor properties on the enthalpy of activation for the dissociation process.

Experimental Section

Solvents

Methanol (Fisher, ACS grade) was distilled fractionally over N_2. The middle fraction boiling at 64.3°C was decanted onto dry CaO after being dried over 3 Å molecular sieves (Linde) for 1 day, and was distilled fractionally from CaO over N_2. The middle fraction from this distillation, boiling point 64.5°C, was finally distilled from Mg metal over N_2 and the middle fraction was collected for the kinetic studies. Dimethylsulfoxide was purified as before (1).

Reagents

In methanol as solvent nickel(II) was introduced as nickel(II) perchlorate monohydrate, which was obtained from recrystallized hexahydrate (G. F. Smith) by heating at 90 ± 5°C under vacuum. In dimethylsulfoxide as solvent $Ni(ClO_4)_2 \cdot 6DMSO$ was prepared (7) and used. The concentration of each nickel(II) solution was determined by EDTA titration as before (1). Hexakis(acetonitrile)copper(II) perchlorate (8) was used in both methanol and dimethylsulfoxide as solvents. Potassium thiocyanate (J. T. Baker, Baker Analyzed Reagent, assay 100%) was dried at 60°C under vacuum for 2 days. Sodium perchlorate (Fisher) was recrystallized from distilled demineralized water and dried under vacuum at 65°C for 3 days.

Instrumentation and Experimental Procedure

All solvents were used within 3 days of purification. All nonaqueous solutions were prepared and dispensed in a dry box (Kewaunee Scientific) under dry N_2, using glassware that had been oven-dried at 110°C for several days. All other standard procedures for handling nonaqueous solutions were followed. Pseudo-first-order rate constants for formation of $CuSCN^+$ ion were obtained by measuring the rate of change of transmittance of the solution with time upon mixing of a copper(II) solution with a solution of the monocomplex of nickel(II) with thiocyanate ion at 394 nm in methanol and 375 nm in dimethylsulfoxide (where the absorbance is primarily due to $CuSCN^+$). Kinetic measurements were made with a stopped-flow spectrophotometer (Durrum Instrument Co., Model D-110). A description of the instrument and methods of recording the change in transmittance with time has been reported (9*a*), along with modifications for improved temperature control (9*b*). In methanol as solvent, concentrations of nickel(II) and thiocyanate ion were held constant at 2.5×10^{-3} *M* and 2.0×10^{-4} *M* respectively; copper(II) concentrations were varied from 2.5×10^{-2} *M* to 1.28×10^{-1} *M*. Ionic strengths of the solutions were varied from 0.082 *M* to 0.384 *M*; sodium perchlorate was added to adjust ionic strength levels. In dimethylsulfoxide as solvent, concentrations of nickel(II) and thiocyanate ion were held constant at 2.0×10^{-3} *M* and 1×10^{-3} *M* respectively, and the copper(II) concentrations were varied in five steps from 5×10^{-3} *M* to 20×10^{-3} *M*. All concentrations refer to final values after mixing in the stopped-flow cell. Each experiment was repeated with different batches of solvent and

Results and Discussion

Under the experimental conditions selected only monocomplexes of nickel(II) and copper(II) are expected to form (2, 4). Table 1 lists the observed pseudo-first-order rate constants (k_{obs}) for dissociation of $NiSCN^+$ ion in methanol by use of copper(II) as the decomposing ion at various temperatures, ionic strengths, and concentrations of copper(II). In all experiments, the concentrations of nickel(II) and thiocyanate ion were held constant. Figure 1 shows the variation in k_{obs} with ionic strength of the medium at a fixed concentration of copper(II) at 25°C and 15°C in methanol. Table 2 contains the values of observed pseudo-first-order rate constants at different temperatures in dimethylsulfoxide. The major features of the results in Table 1 and Table 2 are:

(*1*). Observed pseudo-first-order rate constants in methanol vary linearly with the first power of the ionic strength of the medium but are independent of the concentration of copper(II) ion as long as it is sufficiently high compared to the concentration of nickel(II); this is shown in the results of the experiments in Sets A, B, and C in Table 1. Contrary to observations in methanol, in dimethylsulfoxide observed pseudo-first-order rate constants are independent of the ionic strength of the medium and the concentrations of both copper(II) and nickel(II) (Table 2), as long as the copper(II) concentrations are much higher than the concentration of nickel(II).

(*2*). In methanol, observed pseudo-first-order rate constants at zero ionic strength and 25°C are the same whether the ionic strength is varied by addition of $Cu(ClO_4)_2$, (Set A, Table 1) or by addition of $NaClO_4$ (Set C, Table 1), assuming $NaClO_4$ and $Cu(ClO_4)_2$ are completely dissociated. The results of Sets A and C in Table 1 indicate that 0.128 M $Cu(ClO_4)_2$ and 0.164 M $NaClO_4$ are completely dissociated in methanol at 25°C.

(*3*). From the results of Sets C and D in Table 1, a plot of k_{obs} against the first power of the ionic strength of the medium (I) at 15°C shows curvature at higher concentrations (Fig. 1), while k_{obs} varies linearly with ionic strength at 25, 35, and 45°C.

The dependence of k_{obs} on ionic strength in methanol as solvent can be explained by assuming ion-pair association between $(S_5NiSCN)^+$ and ClO_4^- in methanol, the extent of association increasing with increasing ClO_4^- concentration. It is not possible on the basis of this work to state whether the association is 'contact' or

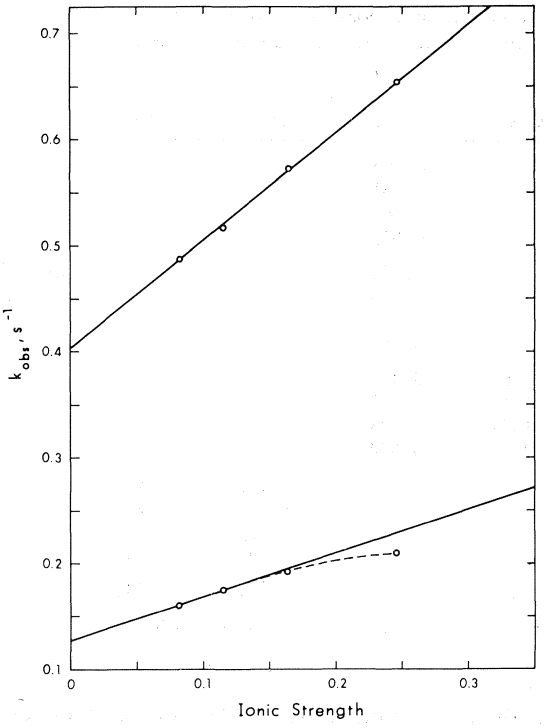

FIG. 1. Variation in observed pseudo-first-order rate constants (k_{obs}) for dissociation of $(S_5NiSCN)^+$ in methanol as function of ionic strength at 15°C (lower line) and 25°C (upper line). Concentrations of copper(II), nickel(II), and SCN^- held constant at 0.0274 *M*, 2.5×10^{-3} *M*, and 2.0×10^{-4} *M*.

[a]Concentrations of nickel(II) and thiocyanate ion held constant at 2×10^{-3} *M* and 1×10^{-3} *M* respectively.
[b]Value of k_b at $I = 0$ and 20°C is 73.4 s^{-1} (from plot of log k_b *vs.* $1/T$, *T* in K).

'solvent-separated' in nature, but it can be assumed that the effect of increasing concentrations of ClO_4^- on the extent of either type of association will be of the same type. Interaction between nickel(II) and SCN^- in the $(S_5NiSCN)^+$ ion in solution may be partly covalent and partly electrostatic in nature. The electrostatic interaction would be expected to be greater in methanol than in dimethylsulfoxide because of the lower dielectric constant of methanol. Because electrostatic interaction depends in part on the charge density of the interacting ions in a medium, association of ClO_4^- with nickel(II) in $(S_5NiSCN)^+$ may decrease the extent of electrostatic interaction between nickel(II) and SCN^-. The intensity of chemical interaction depends mainly on the intrinsic Lewis-acid character of the central coordinating atom relative to the intrinsic Lewis-base character of the donor atom in the ligand rather than on the overall magnitude of the charges on the reacting ions. In addition, the 'electrostatic' interaction would be expected to be weaker than the 'chemical' interaction, and so it can be predicted that the 'softer' electrostatic interaction will be most affected by association of ClO_4^- with nickel(II) in $(S_5NiSCN)^+$. The conclusion that electrostatic considerations are the important factor in ionic strength effects on observed rates is supported by the absence of ionic strength effects on k_{obs} for the dissociation of the monocomplexes of isoquinoline and 4-phenylpyridine with nickel(II) in methanol (1, 10).

It has been established that substitution reactions in acetonitrile (11) and methanol (11*a*, 12) for formation of labile complexes of nickel(II) with many ligands, including 2,2′,2″-terpyridine and thiocyanate ion, proceed by a dissociative (I_d) type of interchange mechanism (13), as was initially proposed and verified for similar reactions in aqueous solution by Eigen and Wilkins (14). From the observed effect of anions like Cl^-, Br^-, I^-, SCN^-, NO_3^-, CH_3COO^-, and $C_6H_5COO^-$ in the inner sphere of nickel(II) on ternary complex formation of nickel(II) in acetonitrile and methanol, it can be concluded that the effect of the presence of these anions in the inner sphere of nickel(II) on solvent-exchange rates in acetonitrile (15) is some 10 to 50 times higher than the corresponding effect in methanol (16). The effect observed with ClO_4^- in the inner sphere of nickel(II) is very small in acetonitrile (17). From this we conclude that in methanol the effect of ClO_4^- in the inner sphere of nickel(II), either as a contact or solvent-separated ion pair, has a negligibly small effect on the solvent exchange rate of methanol on nickel(II). This explains the absence of an ionic strength effect on the rate of formation of

nickel(II) with terpyridine in methanol (11). The absence of an ionic strength effect on the solvent exchange rate of nickel(II) in methanol was also observed in an investigation of the formation of labile complexes of nickel(II) with various ligands, including SCN^-, in methanol by Pearson and Ellegen (12*a*). From these pieces of evidence we conclude that in anhydrous methanol an ion pair exists between ClO_4^- and nickel(II) in $(S_5NiSCN)^+$ which, by decreasing the intensity of the electrostatic interaction between nickel(II) and SCN^- (without noticeably affecting the 'chemical' interaction involved in $(S_5NiSCN)^+$), increases the observed pseudo-first-order rate constant for dissociation of $(S_5NiSCN)^+$. Since the extent of ion-pair formation increases proportionally with increasing concentration of ClO_4^- in the medium, values of k_{obs} for dissociation of $(S_5NiSCN)^+$ in methanol vary directly with the ionic strength of the medium as adjusted by addition of $NaClO_4$.

In dimethylsulfoxide the electrostatic interaction involved in $(S_5NiSCN)^+$ will be smaller than in methanol because of the higher dielectric constant. Dimethylsulfoxide is also a better donor toward nickel(II) than is methanol. It is therefore expected that in dimethylsulfoxide ion-pair formation between nickel(II) in $(S_5NiSCN)^+$ and ClO_4^- will be less, and those ion pairs that do form likely will be mainly solvent separated. The combination of high dielectric constant and bulky size of DMSO would be expected to result in little or no ion-pair interaction between ClO_4^- and nickel(II) in that solvent, and consequently, ion-pairing effects on the weak electrostatic interaction involved in $(S_5NiSCN)^+$ should be negligibly small. This could explain why, contrary to what is observed in methanol, high concentrations of ClO_4^- in dimethylsulfoxide have no effect on the dissociation of $(S_5NiSCN)^+$ in that solvent. In methanol plots of ionic strength against observed pseudo-first-order rate constants for dissociation of $(S_5NiSCN)^+$ were linear at ionic concentrations up to 0.38 *M* at 25, 35, and 45°C, and up to 0.164 *M* at 15°C. Above 0.16 *M* at 15°C a deviation from linearity was observed that can be explained by assuming incomplete dissociation of $NaClO_4$. From the extent of deviation the association constant of $NaClO_4$ in methanol was calculated to be 3 at 15°C and 0 at 25°C. These values are reasonable relative to related systems (18).

The copper(II)-induced dissociation of $(S_5NiSCN)^+$ in methanol and dimethylsulfoxide can be represented by

$$[2] \qquad NiSCN^+ \underset{k_f}{\overset{k_b}{\rightleftharpoons}} Ni^{2+} + SCN^-$$

$$[3] \qquad Cu^{2+} + SCN^- \overset{k_1}{\rightleftharpoons} CuSCN^+$$

Solvent molecules associated with Ni^{2+} and Cu^{2+} are omitted for convenience. This scheme is the same as observed for copper(II)-induced dissociation of the monocomplex of nickel(II) with isoquinoline in propylene carbonate and acetonitrile (1), and for dissociation of the monocomplex of manganese(II) with bipyridine, terpyridine, and phenanthroline using H^+ and Hg^{2+} as electrophiles in anhydrous methanol (19).

From reactions 2 and 3 it can be shown that when $[Cu^{2+}] \gg [SCN^-]$, as used in this work, k_{obs} is given by

$$[4] \quad k_{obs} = k_b k_1 [Cu^{2+}]/(k_f[Ni^{2+}] + k_1[Cu^{2+}])$$

where k_{obs} is an experimentally determined pseudo-first-order rate constant. If, at high concentrations of copper(II), $k_f[Ni^{2+}] \ll k_1[Cu^{2+}]$, then k_{obs} is equal to k_b and is independent of $[Cu^{2+}]$, $[Ni^{2+}]$, and $[SCN^-]$. If the ionic strength of the medium does not influence the dissociation process by changing k_b in the rate-determining step, then k_{obs} is directly equal to the true k_b. This is the case in dimethylsulfoxide. On the other hand, if the rate-determining step is influenced by the ionic strength of the medium, as in methanol, k_{obs} will be affected. In such a case true values of k_b should be obtained by extrapolating values of k_{obs} to zero ionic strength of the medium. Under our experimental conditions k_{obs} was independent of $[Cu^{2+}]$, $[SCN^-]$, and $[Ni^{2+}]$. Also, if the influence of ionic strength on the magnitude of k_{obs} in methanol is assumed to stem from the effect of ion pairing between ClO_4^- and nickel(II) on the electrostatic interaction involved in $(S_5NiSCN)^+$, a plot of k_{obs} against ionic strength is expected to be a straight line. This is indeed observed (Fig. 1).

Rate constants for dissociation of $(S_5NiSCN)^+$ in dimethylsulfoxide and methanol at different temperatures and zero ionic strength are summarized at the bottom of Tables 1 and 2. Table 3 lists dissociation rate constants at

TABLE 3. Comparison of activation parameters for dissociation of $(S_5NiSCN)^+$ and $(S_5NiIsoquinoline)^{2+}$ in different solvents[a]

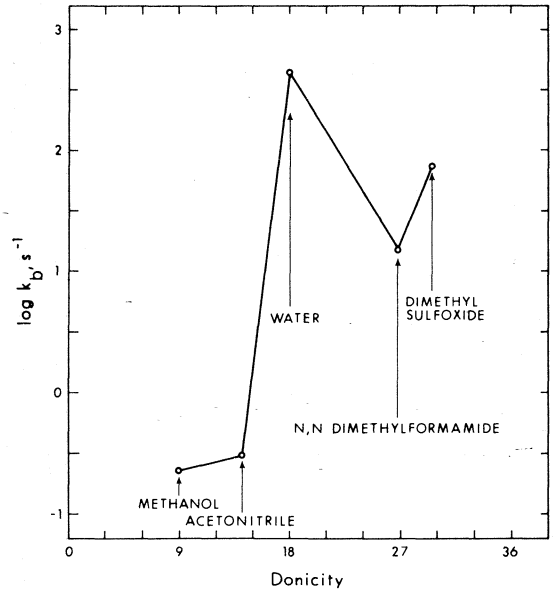

FIG. 2. Relation between log rate constants for dissociation of $(S_5NiSCN)^+$ in various donor solvents and the donicity of the solvent.

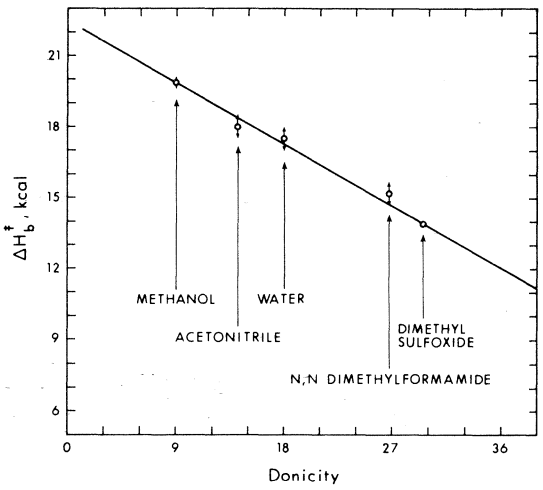

FIG. 3. Relation between enthalpy of activation ($\Delta H_b^{\ddagger}$) for dissociation of $(S_5NiSCN)^+$ in various donor solvents and the donicity of the solvent. (For acetonitrile, water, and dimethylformamide, arrows indicate ±0.5 kcal.)

20°C and associated activation parameters in different donor solvents. The value for k_b in dimethylsulfoxide at 25°C agrees with earlier work (4) within experimental error. The dissociation rate constants do not show a systematic relation with donicity of solvent (Fig. 2), but the enthalpy of activation for dissociation does show a linear correlation (Fig. 3). From Fig. 3 the donor numbers of methanol and water are best represented by values of 9 and 18. These results agree with those found earlier in the study of solvent effects on dissociation of the monocomplex of nickel(II) with isoquinoline (1). Recently Tanaka (20) predicted a value in the neighbourhood of 10 for the donor number of methanol from plots of (*a*) ΔH_{SbCl_5} against ΔH_{PhOH}, (*b*) ΔH_{SbCl_5} against ΔH_{I_2}, and (*c*) ΔH_{SbCl_5} against $C_B E_B$ for a variety of organic solvents. Values for ΔH_{PhOH}, ΔH_{I_2}, C_B, and C_E were those of Drago and co-workers (21). Values close to 9 and 18 for the donor numbers of methanol and water can also be predicted from recent measurements of downfield nmr chemical shifts of $CsClO_4$ in different solvents (22), though these results do not agree with values of 26 for methanol and 33 for water predicted from sodium-23 nmr chemical shifts for $NaClO_4$

in several donor solvents (23). The reasons for the differences in these nmr data are unclear, but the lower charge density of the cesium ion might give more meaningful results in comparisons of the donor properties of structured hydroxylic solvents such as water and methanol. Hinton also has predicted a value near 20 for the donor number of water on the basis of measurements of the infinite dilution resonance frequency of thallium-205 ion in several solvents (25).

Table 3 also summarizes the activation parameters for dissociation of monocomplexes of nickel(II) with thiocyanate ion and isoquinoline. Comparison of the enthalpies of activation suggests that the pathways for dissociation of $(S_5NiSCN)^+$ in the solvents considered can be accommodated within the I_d-type mechanism represented by eq. 1, as was observed for $(S_5NiIsoquinoline)^{2+}$. It was pointed out earlier (1) that for an I_d mechanism represented by eq. 1 the activation enthalpy for dissociation will depend upon both the Lewis-acid character of $(S_5Ni)^{2+}$ (24) and the Lewis-base character of the ligand relative to the free solvent molecule. If S is a solvent molecule coordinated to nickel(II) in the inner sphere, and it has little or no interaction with bulk solvent structure, the Lewis-acid character of $(NiS_5)^{2+}$ will be inversely related to the donicity of S, and $\Delta H_b^{\neq}$ for dissociation of $(S_5NiSCN)^+$ will increase with decreasing donicity of the solvent. The value of $\Delta H_b^{\neq}$ for dissociation of a nickel(II) monocomplex in a solvent S would be expected to increase with an increase in donicity of the donor atom in the ligand. Nitrogen is a better donor towards nickel(II) than sulfur. Thus $\Delta H_b^{\neq}$ for dissociation of $(S_5NiIsoquinoline)^{2+}$, in which N is the donor atom, is expected to be higher than the corresponding quantity for dissociation of $(S_5NiSCN)^+$, in which sulfur is the donor atom, in any solvent if only the Lewis-base property or donicity of the ligand coordinating site is considered. From Table 3 $\Delta H_b^{\neq}$ for $(S_5NiSCN)^+$ is greater than for $(S_5NiIsoquinoline)^{2+}$ in all the solvents considered. This trend in $\Delta H_b^{\neq}$ values is the opposite of that expected from consideration of the donicity of the ligands only, and suggests that in $(S_5NiSCN)^+$ an electrostatic effect is indeed involved. The electrostatic force between nickel(II) and thiocyanate ion causes $\Delta H_b^{\neq}$ for dissociation of $(S_5NiSCN)^+$ to be larger than for dissociation of $(S_5NiIsoquinoline)^{2+}$ in all solvents (Table 3). The same conclusion is supported by the results for dissociation of $(S_5Ni4\text{-phenylpyridine})^{2+}$ in different solvents (10).

Information on the position of other solvents on this scale would be useful. In tetrahydrofuran the copper salts used in this work were not adequately soluble, however, and in propylene carbonate a fine yellow-orange suspension, barely visible to the eye, appeared in solutions of $(S_5NiSCN)^+$ after 2 to 3 h. Benzonitrile absorbs strongly in the wavelength region where the isoquinoline and thiocyanate complexes absorb, and so spectral data on these systems in this solvent also could not be obtained.

In summary, we conclude that the pathway for dissociation of $(S_5NiSCN)^+$ in the solvents studied is best represented by an I_d-type mechanism, as observed previously for dissociation of $(S_5NiIsoquinoline)^{2+}$. Rate constants for dissociation at any particular temperature are not systematically related to the donicity of the solvent, but the enthalpy of activation for dissociation of $(S_5NiSCN)^+$ is inversely related to the Gutmann donor number of the solvent. Additional evidence is given in support of a value of 9 for the donor number of methanol, and of 18 for water. The meaning of such low donor numbers for these solvents is not clear at this time. Additional data on other systems in these solvents, as well as measurements in related hydroxylic solvents, are needed to provide further insight into the question.

Matrix effect on the structure of $\dot{G}e(CH_3)_3$

LYDIA BONAZZOLA, NICOLE LERAY, AND JACQUES RONCIN

Laboratoire de Résonance Electronique et Ionique, Associé au CNRS, Université de Paris-Sud, Bâtiment 350, Orsay, France 91405

Received November 2, 1976

LYDIA BONAZZOLA, NICOLE LERAY, and JACQUES RONCIN. Can. J. Chem. **55**, 1617 (1977).

An important matrix effect which can be correlated with the polarisability of radicals is observed for the ^{73}Ge coupling constant of $\dot{G}e(CH_3)_3$ radical.

LYDIA BONAZZOLA, NICOLE LERAY et JACQUES RONCIN. Can. J. Chem. **55**, 1617 (1977).

Un important effet de matrice est observé pour le couplage RPE du ^{73}Ge dans le radical $(CH_3)_3\dot{G}e$. Il peut être relié à la polarisabilité du radical.

It has been shown some years ago (1) that the unpaired spin density at the Si nucleus of $Cl_n\dot{S}i(CH_3)_{3-n}$ radicals and probably the geometry of the radical site were strongly dependent on the trapping matrix: the esr hyperfine coupling of ^{29}Si nucleus in $^{29}\dot{S}i(CH_3)_3$ varies from 172.5 G in a nonpolar $Si(CH_3)_4$ matrix to 129 G in a $ClSi(CH_3)_3$ matrix ($\mu = 2$ Debye).

Another example of the trapping matrix influence on the hyperfine coupling of an atom of group IV of the Periodic Table, bearing the unpaired electron is the $^{119}\dot{S}n(CH_3)_3$ radical: Lloyd and Rogers (2) find 1983 G for the ^{119}Sn coupling when the radical is trapped in an adamantane matrix. For the same radical in a $ClSn(CH_3)_3$ matrix ($\mu = 3.5$ Debye) ^{119}Sn coupling is found to be 1611 G (3).

We have looked for a possible extension of these results to other atoms of group IV and we have investigated the influence of the trapping matrix on the couplings of ^{73}Ge when $^{73}\dot{G}e(CH_3)_3$ radicals are trapped in a $Ge(CH_3)_4$ nonpolar matrix and a $ClGe(CH_3)_3$ polar matrix. The experimental conditions[1] are the same as those used for silicon compounds (1). The esr spectra are shown on Fig. 1 and the couplings tabulated in Table 1. These data show that ^{73}Ge coupling decreases when the dipole moment of the matrix increases.

The matrix effect observed in $\dot{S}i(CH_3)_3$ (1), $\dot{S}n(CH_3)_3$ (2), and $\dot{G}e(CH_3)_3$ (this work) is quite important: around 20% variation of the coupling from one matrix to the other. In contrast, such matrix effects have never been ob-

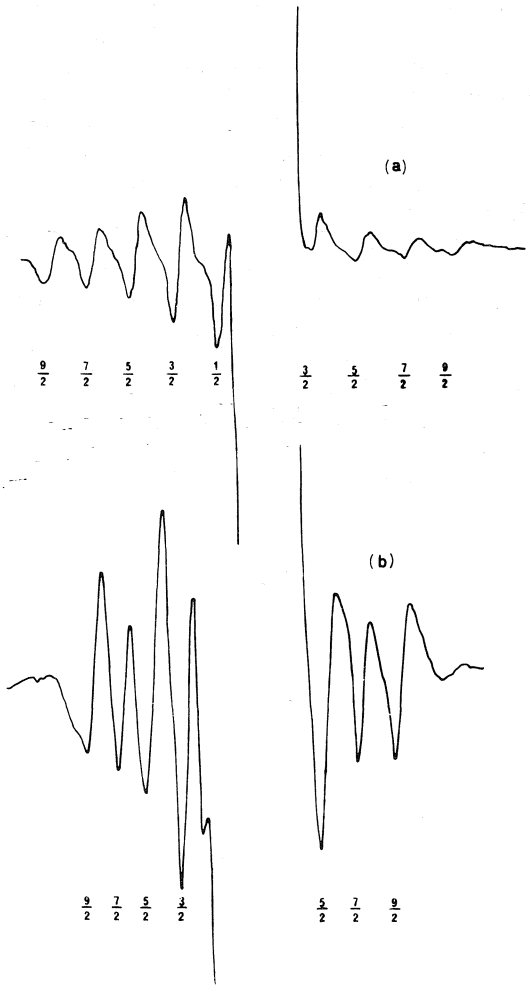

FIG. 1. Electron spin resonance spectra of $^{73}\dot{G}e(CH_3)_3$ radicals in $Ge(CH_3)_4$ (*a*) and $ClGe(CH_3)_3$ (*b*).

[1] $\dot{G}eCl(CH_3)_3$ was kindly provided by Professor Satge of Université Paul Sabatier, Toulouse, France.

TABLE 1. a_X couplings for $\dot{X}(CH_3)_3$ radicals (X = Si, Ge, Sn) in different matrices

served on uncharged hydrocarbon radicals except in the case of radicals adsorbed on solid surfaces, such as porous glass (4, 5).

In a previous paper, we have suggested that these couplings and structure variations might be related to the field due to the dipoles of the molecules of the matrix. If so, the different behaviour of hydrocarbon radicals may arise from the low polarisability of carbon compared to other elements in group IV of the Periodic Table.

Similar effects are to be expected whenever the polarisability of the atom bearing the unpaired electron is of the same order of magnitude or larger than that of group IV elements. Unfortunately esr data relative to the coupling of a radical in different matrices are scarce. The only data we have found concern $\dot{P}\varphi_2$ and $\dot{P}\varphi_3^+$ radicals and they confirm the above statement: ^{31}P coupling of $\dot{P}\varphi_2$ radical is 93 G when the trapping matrix is $PO\varphi_3$ (6) and 103 G when the matrix is $\varphi_2P(S)H$ (6). Similarly ^{31}P coupling of the radical ion $\dot{P}\varphi_3^+$ changes from 396 G (7) in a φ_3PBCl_3 matrix to 342 G (8) in φ_3PBF_3 matrix.

Structure and conformation of hydroxylubimin, a sesquiterpenoid phytoalexin[1]

GEORGE I. BIRNBAUM

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 2, 1976

GEORGE I. BIRNBAUM. Can. J. Chem. **55**, 1619 (1977).

In order to determine the orientation of the isopropenyl group and confirm the stereochemistry at other chiral centers in lubimin (**1**) and hydroxylubimin (**2**), two antifungal sesquiterpenes, an X-ray structure analysis of **2** was carried out. Crystals of **2** are orthorhombic, space group $P2_12_12_1$, $a = 6.190$, $b = 7.210$, $c = 63.082$ Å, $Z = 8$. The structure was solved by direct methods and refined to $R = 0.045$. In both independent molecules the six-membered ring is chair-shaped with all four substituents equatorially oriented. The five-membered ring, attached by a spiro junction, is a half-chair with the isopropenyl substituent in an equatorial position. This side-chain is *trans* to the methyl-bearing carbon in the six-membered ring.

GEORGE I. BIRNBAUM. Can. J. Chem. **55**, 1619 (1977).

Afin de déterminer l'orientation du groupe isopropényle et pour confirmer la stéréochimie au niveau d'autres centres chiraux de la lubimine (**1**) et de l'hydroxylubimine (**2**), deux sesquiterpènes fungicides, on a effectué une analyse de structure de rayon-X de **2**. Les cristaux de **2** sont orthorhombiques, groupe spatial $P2_12_12_1$, $a = 6.190$, $b = 7.210$, $c = 63.082$ Å, $Z = 8$. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à une valeur de $R = 0.045$. Dans les deux molécules indépendantes, le cycle à six chaînons est dans une forme chaise avec les quatre substituants orientés en position équatoriale. Le cycle à cinq chaînons, attaché par une junction spiro, est en forme de demi-chaise avec le groupe isopropényle en position équatoriale. Cette chaîne latérale est *trans* par rapport au carbone portant le méthyle dans le cycle à six chaînons.

[Traduit par le journal]

Phytoalexins are stress compounds produced by a plant as a result of fungal infection. They inhibit fungal growth, thereby preventing the full development of the disease (1). Lubimin (**1**) and hydroxylubimin (**2**) are two sesquiterpenoid phytoalexins which have been isolated from several species of the *Solanaceae* family, such as potatoes (*Solanum tuberosum*), egg plants (*Solanum melongena*), and thorn apples (*Datura stramonium*) (2–4). Stoessl *et al.* (3), and subsequently Masamune and his collaborators (4), proposed the correct skeleton structure of **1**. The latter authors also concluded that **2** was the 3-hydroxy derivative of **1**. The stereochemistry at most chiral centers of **1** and **2** was published later (5), but the orientation of the isopropenyl group could not be determined from spectroscopic data. In order to establish this feature, and to confirm the earlier stereochemical assignment, we undertook an X-ray analysis of **2**. A preliminary report of our investigation was recently published (6); it showed the relative and absolute configurations of **1** and **2**. The absolute configuration was assumed by analogy with related sesquiterpenoids.[2] It was recently verified by an application of the benzoate rule in the interpretation of a CD spectrum (7).

Experimental

3-Hydroxylubimin, $C_{15}H_{24}O_3$, was crystallized from ether/petroleum ether to give colorless prisms, mp 96.5–99.5°C. Precession photographs showed the following systematic absences: $h00$ for odd h, $0k0$ for odd k, and $00l$ for odd l. The space group was thus uniquely determined to be $P2_12_12_1$. A crystal fragment measuring 0.15 × 0.25 × 0.45 mm was mounted along the c axis on a card-controlled Picker four-circle diffractometer and the following crystal data were obtained.

$C_{15}H_{24}O_3$ fw = 252.3
Orthorhombic, $a = 6.190(1)$, $b = 7.210(1)$, $c = 63.082(2)$ Å, $V = 2815.3$ Å^3, $D_m = 1.18$ g cm^{-3}, $Z = 8$, $D_x = 1.19$ g cm^{-3} (22°C; CuKα_1, $\lambda = 1.54051$ Å, CuKα_2, $\lambda = 1.54433$ Å), $F(000) = 1104$, μ(CuKα) = 6.6 cm^{-1}.

The moving-crystal – moving-counter method (θ–2θ scan) was used to measure the intensity data. Monochromatization was achieved by the use of a nickel filter and a pulse-height analyzer. The 130 reflection was monitored at regular intervals; its intensity decreased by 5% during the data collection. A net count of 60 or 10% of the background, whichever was higher, was determined as threshold intensity below which reflections were considered unobserved. There were 2868 unique reflections accessible to the diffractometer ($2\theta \leq 130°$) of which 2301 had intensities above threshold values. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary in view of the low value of μ.

[a]The thermal vibration parameters are expressed as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

The structure was determined by direct methods with a multisolution procedure similar to that described by Kennard *et al.* (8). With $\alpha_{min} = 2.21$ and $t_{min} = 0.3$ one of the 64 permutations yielded $R_E = 0.18$ for 323 reflections with $E \geq 1.50$ after a tangent refinement was carried out in three stages. The E map revealed the positions of all 36 nonhydrogen atoms in the two crystallographically independent molecules. Atomic parameters were refined by block-diagonal least squares. All scattering factors were taken from the International Tables for X-Ray Crystallography (9) and the oxygen curve was corrected for anomalous dispersion. All hydrogen atoms were located on difference Fourier maps and their parameters were refined isotropically. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and the following weighting scheme was used during the final stages: $w = w_1w_2$, where $w_1 = 1$ for $|F_o| \leq 11.5$, $w_1 = 11.5/|F_o|$ for $|F_o| > 11.5$; $w_2 = \sin^2\theta/0.35$ for $\sin^2\theta < 0.35$, $w_2 = 1$ for $\sin^2\theta \geq 0.35$. Six strong reflections suffered severely from extinction effects and they were given zero weights. After the final cycle the average parameter shift equalled 0.08σ and the largest one 0.65σ. The conventional residual index R ($\Sigma|\Delta F|/\Sigma|F_o|$) is 0.045 and the weighted index R' ($\Sigma w\Delta F^2/\Sigma wF_o^2$) is 0.057 for 2330 reflections, including 35 unobserved ones for which $|F_o| < |F_c|$. A final difference Fourier map was featureless.

The final coordinates and temperature parameters, as well as their estimated standard deviations, are listed in Table 1. Table 2 lists the observed and calculated structure factors.[3] Bond lengths and endocyclic torsional angles are shown in Fig. 1 while bond angles are given in Fig. 2.

Discussion

A stereoscopic view of one of the molecules (A) is shown in Fig. 3. In each of the two inde-

pendent molecules the six-membered ring is chair-shaped and all four substituents are equatorially oriented. All torsion angles are within a few degrees of 55.9°, the value observed in cyclohexane, indicating that there is very little strain. The conformation of the five-membered rings can be expressed by their phase angles of pseudorotation (10). In molecule A $\Delta = 74.0°$ which is almost identical with the value (72°) corresponding to a perfect half-chair. C(7) and C(8) are displaced by 0.324 and 0.359 Å, respectively, to the opposite sides of the plane defined by C(5), C(6), and C(9). In molecule B the displacements of C(7) and C(8) amount to 0.269 and 0.392 Å, respectively, while $\Delta = 79.5°$ indicates a slightly distorted half-chair. The Newman

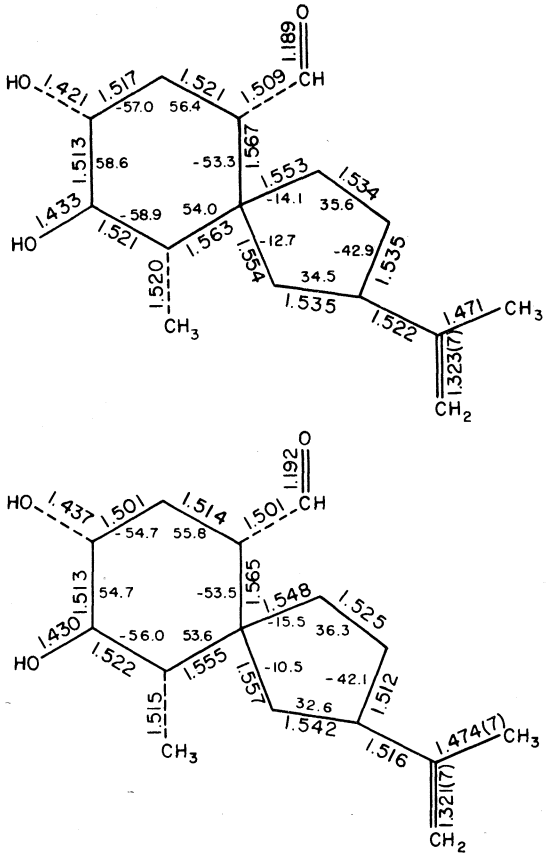

FIG. 1. Bond lengths and torsional angles in molecules A (top) and B (bottom). Unless otherwise indicated, the e.s.d.'s are 0.004–0.006 Å and 0.2–0.3°, respectively.

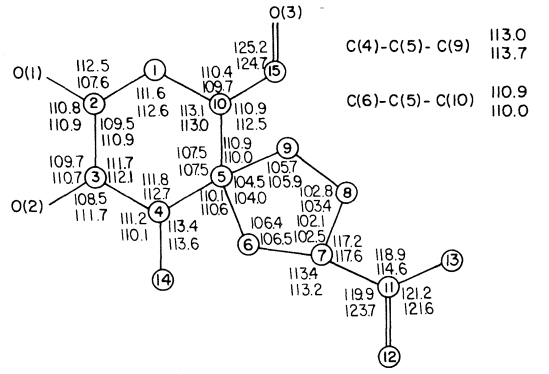

FIG. 2. Bond angles in molecules A (top) and B (bottom). The e.s.d.'s are 0.2–0.4°.

projections in Fig. 4 show the conformations of the aldehyde and isopropenyl groups attached to the two rings in each molecule. In the case of the aldehyde group the two projections look very similar, indicating a preferred conformation. This preference can be explained in terms of non-bonded intramolecular contacts. A clockwise rotation of the C=O group about the C(15)—C(10) bond would decrease the distances between O(3) and H(9,2) and between H(10,1) and H(15,1), 2.9 and 2.2 Å, respectively. On the other hand, a counterclockwise rotation would result in decreasing the distances between O(3) and H(1,1) (2.6 Å) and between H(15,1) and H(6,2) (2.2 Å). Of these four distances, the latter three are very close to van der Waals contacts. Consequently, the range of allowable conformation is very narrow. The conformation of the isopropenyl group is substantially different in the two molecules: there are no short contacts in molecule A, while in molecule B the H(8,2)···H(12,1) distance is 2.13 Å.

Equivalent bonds have the same lengths, within experimental error, in both molecules, except for the C(7)—C(8) bond which is significantly longer in molecule A than in molecule B. The reason is not quite clear, but it may be related to the difference in the conformation of the isopropenyl groups. None of the bond lengths are unusual. As expected, the longest ones are at the spiro junction, reflecting the high degree of substitution. The short C(11)—C(13) bond can be ascribed to the strong thermal vibration of the latter atom; in capsidiol, a closely related sesquiterpenoid phytoalexin isolated from sweet peppers, this bond was even shorter, 1.438 Å (11).

Two bond angles involving oxygen atoms, C(1)—C(2)—O(1) and C(4)—C(3)—O(2), are significantly different in the two molecules. This may be attributable to the different hydrogen bonds in which each molecule participates (see below). The large C(7)—C(11)—C(12) angle and the small C(7)—C(11)—C(13) angle in molecule B are presumably due to the fact that C(8) and C(12) are almost eclipsed. It is somewhat surprising that this interaction is not relieved by a rotation about the C(7)—C(11) bond.

The geometry of the hydrogen bonds in the crystal structure is given in Table 3. Both hydroxyl groups in each molecule act as proton donors and acceptors. However, only in molecule B does the aldehyde oxygen accept a proton from a hydroxyl group. This proton is shared by two acceptors and consequently the H···O distances are somewhat long. A bifurcated hydrogen bond with a similar geometry was encountered in the *trans–syn* photodimer of methyl orotate (12). Each molecule has a polar 'head' and a nonpolar 'tail' and the molecules are

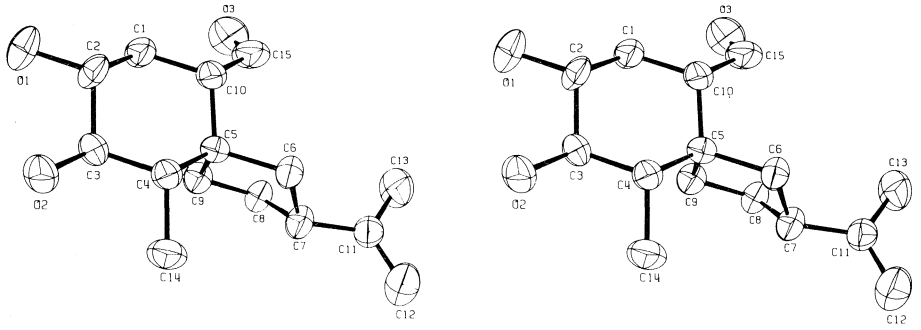

FIG. 3. Stereoscopic view of molecule A; the ellipsoids include 50% probability.

TABLE 3. Geometry of hydrogen bonds

Bonds	Length (Å)		Angle (deg)	
	$D\cdots A$	$H\cdots A$	D—$H\cdots A$	H—$D\cdots A$
O(A,1)—H···O(B,1)$(1-x,\frac{1}{2}+y,\frac{1}{2}-z)$	2.734	1.99	171	7
O(A,2)—H···O(B,2)$(2-x,\frac{1}{2}+y,\frac{1}{2}-z)$	3.008	2.36	144	28
O(A,2)—H···O(B,3)$(1-x,-\frac{1}{2}+y,\frac{1}{2}-z)$	2.950	2.44	126	42
O(B,1)—H···O(A,2)$(2-x,-\frac{1}{2}+y,\frac{1}{2}-z)$	2.862	2.03	175	4
O(B,2)—H···O(A,1)$(2-x,-\frac{1}{2}+y,\frac{1}{2}-z)$	2.962	2.09	165	10

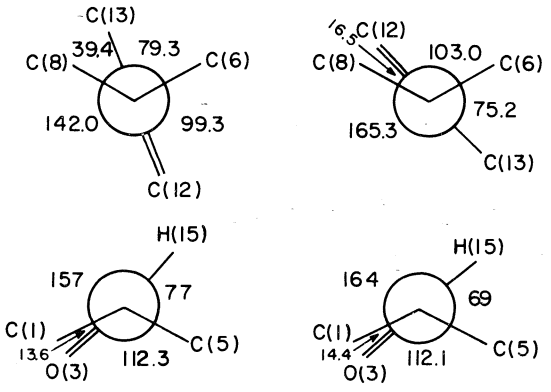

FIG. 4. Newman projections along C(7)—C(11) (top) and C(10)—C(15) (bottom) in molecules A (left) and B (right).

packed 'head' to 'head' and 'tail' to 'tail' along z in the sequence —A—B—B—A—. The isopropenyl groups, representing the non-polar 'tails', are close to the screw axes parallel to y. The hydrogen bonds join the polar 'heads' of molecules A and B to each other, thus forming chains of hydrogen-bonded molecules —A—B—A—B— parallel to x. Apart from these hydrogen bonds there are no intermolecular contacts which are shorter than normal van der Waals distances.

Acknowledgments

I am grateful to Dr. A. Stoessl, Agriculture Canada, for suggesting this investigation and for supplying me with crystals of hydroxylubimin. Figure 3 was drawn with the help of the ORTEP program by C. K. Johnson. All other crystallographic computations were performed with programs written by F. R. Ahmed, S. R. Hall, M. E. Pippy, and C. P. Huber.

C.-J. CHEN, M. H. BACK, and R. A. BACK. Can. J. Chem. **55**, 1624 (1977).

The thermal methyl-radical exchange reaction, $CH_4 + CD_4 \rightarrow CH_3D + CD_3H$, has been studied in a static system at temperatures from 880 to 1103 K, with equimolar mixtures at a pressure of 440 Torr. The exchange occurs by a methyl-radical chain mechanism, propagated by the reactions $CH_3 + CD_4 \rightarrow CH_3D + CD_3$ and $CD_3 + CH_4 \rightarrow CD_3H + CH_3$. Values of an average rate constant for these reactions have been estimated; $k_X = 1.42 \times 10^6$ ℓ mol^{-1} s^{-1} at 995 K. Comparison with shock tube data and photochemical measurements, at higher and lower temperatures respectively, indicates pronounced non-Arrhenius behaviour.

C.-J. CHEN, M. H. BACK et R. A. BACK. Can. J. Chem. **55**, 1624 (1977).

Utilisant des mélanges équimoléculaires à une pression de 440 Torr, on a étudié, dans un système statique et à des températures allant de 880 à 1103 K, la réaction d'échange thermique du radical méthyle $CH_4 + CD_4 \rightarrow CH_3D + CD_3H$. La réaction se produit par un mécanisme en chaîne du radical méthyle propagé par les réactions $CH_3 + CD_4 \rightarrow CH_3D + CD_3$ et $CD_3 + CH_4 \rightarrow CD_3H + CH_3$. On a évalué que les valeurs moyennes des constantes de vitesse de ces réactions sont $k_X = 1.42 \times 10^6$ ℓ mol^{-1} s^{-1} à 995 K. Une comparaison avec des données de tube de choc et des mesures photochimiques respectivement à des températures plus élevées et plus basses, indique que le comportement diffère considérablement de celui prédit par la théorie d'Arrhénius.

[Traduit par le journal]

Introduction

Non-Arrhenius behaviour in the rate constants for hydrogen abstraction has been observed in several recent studies where the measurements have been made at high temperatures (>1000 K) (1–7). Clark and Dove (8) have offered the most quantitative explanation of this effect, using the BEBO method to show that tunnelling corrections and quantum effects can account reasonably well for the observed curvature. The effect is of great interest in the understanding of the activated complex in chemical reactions, and more data for this type of reaction in the high-temperature region are needed.

The methyl radical exchange reaction in mixtures of CH_4 and CD_4 was studied some years ago by Burcat and Lifshitz (9) using a shock tube in the temperature range 1340–1745 K. They concluded that the exchange proceeded through a methyl-radical chain mechanism propagated by the reactions

[A] $CH_3 + CD_4 \rightarrow CH_3D + CD_3$

[B] $CD_3 + CH_4 \rightarrow CD_3H + CH_3$

and their measurement of an average rate constant for these reactions was considerably higher than an extrapolated value from measurements in a lower temperature region (500–800 K) (10). In a recent study in these laboratories of the thermal decomposition of methane (11), mixtures of CH_4 and CD_4 were used in some experiments to determine whether molecular hydrogen was formed in the primary dissociation. In the course of these experiments it was noted that an efficient H–D exchange was occurring, much faster than the decomposition itself, which closely followed the simple stoichiometry

$$CH_4 + CD_4 \rightarrow CH_3D + CD_3H$$

The present paper describes kinetic measurements of this exchange reaction in the static pyrolysis system at temperatures from 880 to 1103 K. The results are in substantial agreement

[1]NRCC No. 15865.

with the earlier results of Burcat and Lifshitz (9) and confirm their observation of non-Arrhenius behaviour in this reaction.

Experimental

Apparatus, techniques, and product analysis have already been described (11). Experiments were performed over the temperature range 880–1103 K with equimolar mixtures of CH_4 and CD_4 at a pressure of 440 Torr. Samples of methane were analyzed for isotopic composition by mass spectrometry.[2] Hydrogen was analyzed for H_2, HD, and D_2 by gas chromatography (11).

Results

Analysis of methane after the reaction showed that CH_3D and CD_3H were the only isotopic methanes produced in significant yields; CH_2D_2 was negligible when the extent of the exchange was $<20\%$. Figures 1 and 2 show typical first-order plots for the disappearance of CH_4 and CD_4 and the formation of the mixed methanes. Within experimental error, $-d[CH_4]/dt = -d[CD_4]/dt = d[CH_3D]/dt = d[CD_3H]/dt$ as required for the simple exchange mechanism suggested. There seems little doubt that the radical chain mechanism is operative in the present system.

In the thermal decomposition of CH_4, we have shown (7, 11) that the methyl radical concentration in the early stages is determined by the following reactions:

[1] $$CH_4 \rightarrow CH_3 + H$$

[2] $$H + CH_4 \rightarrow H_2 + CH_3$$

[3] $$2CH_3 \rightleftharpoons C_2H_6$$

[4] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[5] $$C_2H_5 \rightarrow C_2H_4 + H$$

Reaction 1 is slow and rate controlling, and is always followed by reactions 2 and 3, so that the steady-state methyl radical concentration is given by

[6] $$[CH_3] = \{(k_1[CH_4] + k_{-3}[C_2H_6])/k_3\}^{1/2}$$

Initially, $[CH_3]$ is determined by reactions 1 and 3 alone, but as ethane accumulates reaction -3 becomes important. Ethane is formed by reaction 3 at a rate equal to that of reaction 1, and begins to disappear by reaction 4 as its concentration rises. The ethane concentration will be given by the differential equation

[7] $$d[C_2H_6]/dt = k_1[CH_4] - k_4[CH_3][C_2H_6]$$

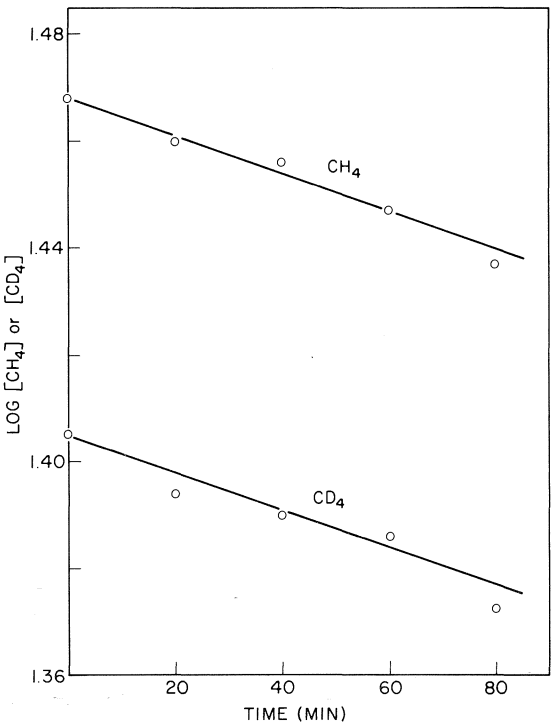

FIG. 1. First order plots for disappearance of CH_4 and CD_4 at 957 K. Initial pressure 440 Torr.

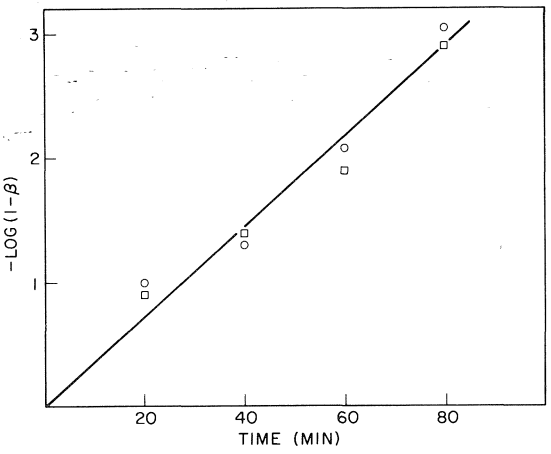

FIG. 2. First order plots for formation of CD_3H (○) and CH_3D (□), at 957 K where $\beta = 1 - [CD_3H]/[CD_4]$ or $1 - [CH_3D]/[CH_4]$ respectively. Initial pressure 440 Torr.

Calculation of the Rate Constant for Exchange

Equation 6 can be applied to the CH_4–CD_4

[2]We are grateful to Mr. Roger Pilon for assistance in the mass spectrometry.

system, after appropriate modifications to take into account kinetic isotopic effects in reactions 1 and 3, to calculate the total radical concentration, $[CH_3] + [CD_3]$. It is more difficult to determine the concentration of each radical. Because reactions A and B are much faster than reaction 1, the chain length of the exchange reaction is large, and the relative concentrations of CH_3 and CD_3 will adjust themselves to maintain the relation $k_A[CH_3][CD_4] = k_B[CD_3][CH_4]$. Values of k_A and k_B could in principle be obtained from the system in two ways. Measurements of the yields of C_2H_6 and C_2D_6 could be used to evaluate $[CH_3]$ and $[CD_3]$, making suitable assumptions about the relative combination rates. Alternatively, experiments could be done with $[CH_4] \gg [CD_4]$ so that $[CH_3] \gg [CD_3]$, and $[CH_3]$ could then be obtained simply from eq. 6, and k_A evaluated from the exchange rate; analogous experiments with $[CD_4] \gg [CH_4]$ could be used to determine k_B. Both these methods are thwarted by experimental difficulties inherent in the methane pyrolysis. In the first case, accurate isotopic analysis of the very small yields of ethane was impossible in the presence of the large excess of methane, while in the second method the exchange reaction became too slow compared to the thermal decomposition. The separate evaluation of k_A and k_B was therefore abandoned and the data treated instead in terms of an average rate constant for exchange, k_X, defined by the usual relation

$$[8] \quad \frac{d[CD_3H]}{dt} + \frac{d[CH_3D]}{dt} = \frac{2k_X[CD_4][CH_4]}{[CD_4] + [CH_4]}([CH_3] + [CD_3])$$

To evaluate k_X from eq. 8, the total methyl radical concentration must be estimated from eq. 6, taking account of all the isotopic species involved. While values of k_1, k_3, and k_{-3} are known with some confidence for the CH_4 system (7, 11) the corresponding values of k_1 for CD_4, k_3 for $CH_3 + CD_3$ and $CD_3 + CD_3$, and k_{-3} for CH_3CD_3, are not. The deuterium isotope effect in k_1 is undoubtedly in the normal direction, as will be seen from the isotopic composition of the hydrogen formed (below). A small inverse secondary deuterium isotope effect has recently been reported in k_{-3} for C_2H_6 and C_2D_6 (12); the isotope effect in k_3 is probably very small. The kinetic isotope effects in reactions 1 and -3 are thus in opposite directions, and the terms in eq. 6 involving k_1 and k_{-3} are of comparable importance at the ethane concentrations attained in the present experiments. It was therefore concluded that no large error would be introduced by simply ignoring all kinetic isotope effects in k_1, k_3, and k_{-3}, and calculating the total radical concentrations using equation 6 and the known rate constants used previously (7) for the CH_4 pyrolysis system. Details of the calculation of radical concentration and values of k_X obtained from eq. 8 are shown in Table 1. Radical concentrations used were simple averages of the initial value and the value corresponding to the steady-state in ethane, as the rate of the exchange reaction was measured between $t = 0$ and the attainment of the steady state. The first-order rate plots were linear, within experimental scatter (Figs. 1 and 2), although some upward curvature, as expected from the increasing radical concentration (Table 1) was perhaps evident in some of the experiments. Average rates and average radical concentrations were used to obtain k_X, and the absolute errors arising from the approximations involved, including the neglect of isotope effects, are probably less than $\pm 20\%$.

Isotope Effects in Reactions 1 and 2

The initial yields of H_2, HD, and D_2 from the pyrolysis of equimolar CH_4–CD_4 mixtures are shown in Table 2. Kinetic isotope effects in both reactions 1 and 2 combine to determine the isotopic composition of the hydrogen. The pertinent reactions are

$$[1A] \quad CH_4 \rightarrow CH_3 + H$$

$$[1B] \quad CD_4 \rightarrow CD_3 + D$$

$$[2A] \quad H + CH_4 \rightarrow H_2 + CH_3$$

$$[2B] \quad H + CD_4 \rightarrow HD + CD_3$$

$$[2C] \quad D + CH_4 \rightarrow HD + CH_3$$

$$[2D] \quad D + CD_4 \rightarrow D_2 + CD_3$$

To separate the isotope effects of the two reactions, some simplification must be made. If it is assumed that $k_{2A}/k_{2B} = k_{2C}/k_{2D} = Y$, and putting $k_{1A}/k_{1B} = X$, it can be shown that for equimolar CH_4–CD_4 mixtures,

$$[9] \quad XY = [H_2]/[D_2]$$

$$[10] \quad [D_2]X^2 - [HD]X + [H_2] = 0$$

$$[11] \quad [D_2]Y^2 - [HD]Y + [H_2] = 0$$

Equations 10 and 11 are identical in X and Y and can be solved when $[HD]^2 > 4[H_2][D_2]$, as was

	1.01	91.3	123	36.5	4.6
	1.51	154	204	65.2	4.2

found experimentally, to yield 2 roots. The initial rates, estimated from the data in Table 2, gave average values of $[H_2]/[D_2]$ of 3.6 ± 0.4 and of $[HD]^2/[H_2][D_2]$ of 5.2 ± 0.5, and from eqs. 9 and 11 values of X and Y of 1.2 and 3.0 were obtained. This implies that the overall isotope effect of 3.6 is unequally shared between reactions 1 and 2, but there is nothing to indicate which value belongs to which reaction. It should also be noted that the conclusion that X and Y are unequal depends on the value of $[HD]^2/[H_2][D_2]$ being significantly greater than 4, which considering the scatter in the data may be seriously questioned. A perhaps more accurate estimate of the kinetic isotope effect in reaction 1 can be obtained from the yields of ethane; it has been shown that the initial yield of ethane is an accurate measure of reaction 1 in the pyrolysis of methane (11), and the measurements of total initial ethane from equimolar CH_4–CD_4 mixtures showed this to be about 20% less than that expected from pure CH_4 at both 1068 and 1103 K. This corresponds to an isotope effect in reaction 1 of about 1.7 which combined with eq. 9 would suggest an isotope effect in reaction 2 of 2.2. There are considerable uncertainties in both these estimates of isotope effects, particularly in the measurement of the small quantities of deuterium in the initial stages of the reaction. It may be concluded only that the kinetic isotope effects in both reactions are normal in direction and magnitude, and that for reaction 2 is probably greater than that for reaction 1.

Discussion

In Fig. 3 our values of k_X are compared with data obtained at both lower and higher temperatures. The low-temperature data (425–800 K) were obtained by photolysis methods and have been recently reviewed by Kerr and Parsonage

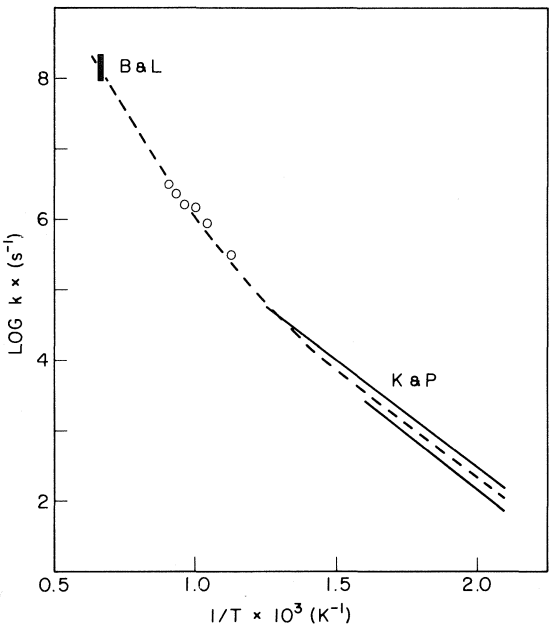

FIG. 3. Comparison of present experiments (○) with shock-tube data of Burcat and Lifshitz (B & L) (9) and the photochemical data compiled by Kerr and Parsonage (K & P) (10).

(10). The two lines shown in Fig. 3 are their recommended values for the rate constants for the reactions, CH_3 (or CD_3) + CH_4, and CH_3 (or CD_3) + CD_4 (secondary isotope effects were considered negligible in their assessment). The average rate constant, k_X, as defined in the present experiments, should fall about midway between the two lines.

The high-temperature value shown is based on an average of two experiments (No. 2 and 3) at 1500 K with equimolar CH_4–CD_4 mixtures reported by Burcat and Lifshitz (9) which appear to be representative of their measurements. These authors did not report values of k_X directly, but values are implicit in their comparison with low-temperature data. In this comparison they assumed reaction -3 to be unimportant, and their steady-state equation (VIII) is in error by a factor of 2; the neglect of reaction -3, and the error in their equation VII tend to cancel one another, and their estimate of methyl radical concentration is not greatly in error. Reaction -3 is far from negligible in their experiments, and in fact the second term in the numerator of the r.h.s. of eq. 6 becomes dominant at an early stage of the reaction, so that $[CH_3]$ approaches a value corresponding to the equilibrium $C_2H_6 \rightleftharpoons 2CH_3$. To estimate $[CH_3]$ accurately via eq. 6, it would be necessary to calculate an average value of $[C_2H_6]$ by integration of eq. 7. Because k_4 is not accurately known at this temperature, we have instead calculated lower and upper limits for $[CH_3]$, assuming in the first case that reaction -3 is negligible (which underestimates $[CH_3]$), and in the second that reaction 4 is negligible (which overestimates $[CH_3]$). The vertical bar in Fig. 3 corresponds to the range of k_X obtained between these two limiting values of $[CH_3]$. In the calculation, a value of $k_1 = 3.16 \times 10^9\ s^{-1}$ at 1500 K was taken, based on measurements in this laboratory (11), extrapolated by RRKM calculations, assuming argon to be 1/3 as efficient as CH_4 as a collision partner, which gives values in good agreement with experiment. Values of $k_3 = 4 \times 10^{10}\ M^{-1}\ s^{-1}$ and $k_3/k_{-3} = 7.7 \times 10^9\ M^{-1}$ (7) were also employed. The true value of k_X measured by Burcat and Lifshitz should lie well between the calculated limits, probably rather closer to the lower one.

The data in Fig. 3 appear to constitute strong evidence for non-Arrhenius behaviour in the reaction of methyl radicals with methane. While there is considerable uncertainty in all the rate constants shown, the curvature seems well beyond any reasonable estimate of the experimental error. There now appears to be good evidence for such behaviour in a number of simple hydrogen abstraction reactions (1–7).

Intramolecular alkylation of a ketone by 1,2-epoxide groups of differing stereochemistry

E. W. WARNHOFF AND V. SRINIVASAN

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 13, 1976

E. W. WARNHOFF and V. SRINIVASAN. Can. J. Chem. **55**, 1629 (1977).

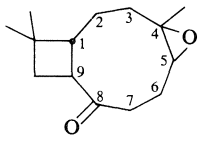
The intramolecular alkylation of a ketone by three epoxide stereoisomers of **1** has been studied. Although a variety of products are possible *a priori*, in *tert*-BuOH–H_2O–KOH each reaction yields a preponderant product. The course of these reactions can be rationalized by considering the accessibility of both faces of the three possible enolates to the backside of each carbon of the epoxide group for the S_N2 reaction.

E. W. WARNHOFF et V. SRINIVASAN. Can. J. Chem. **55**, 1629 (1977).

On a étudié l'alkylation intramoléculaire d'une cétone par trois époxydes stéréoisomères de **1**. Quoiqu'un grand nombre de produits soit possibles *à priori*, dans le milieu réactionnel *tert*-BuOH–H_2O–KOH, chaque réaction conduit à un produit principal. On peut rationaliser le cours de ces réactions en considérant l'accessibilité de chaque face des trois énolates possibles vis-à-vis une attaque par l'arrière de chaque atome de carbone du groupe époxyde pour la réaction du type S_N2.

[Traduit par le journal]

During the recently reported study (1) of base-catalyzed intramolecular opening of the epoxide ring of some derivatives of the sesquiterpene caryophyllene, the opportunity was provided to examine the base-catalyzed intramolecular alkylation of a ketone by the epoxide group. This reaction has been useful on occasion (2–7), and it seemed worthwhile to explore its stereodependence with the available stereoisomers of the keto oxide **1**.

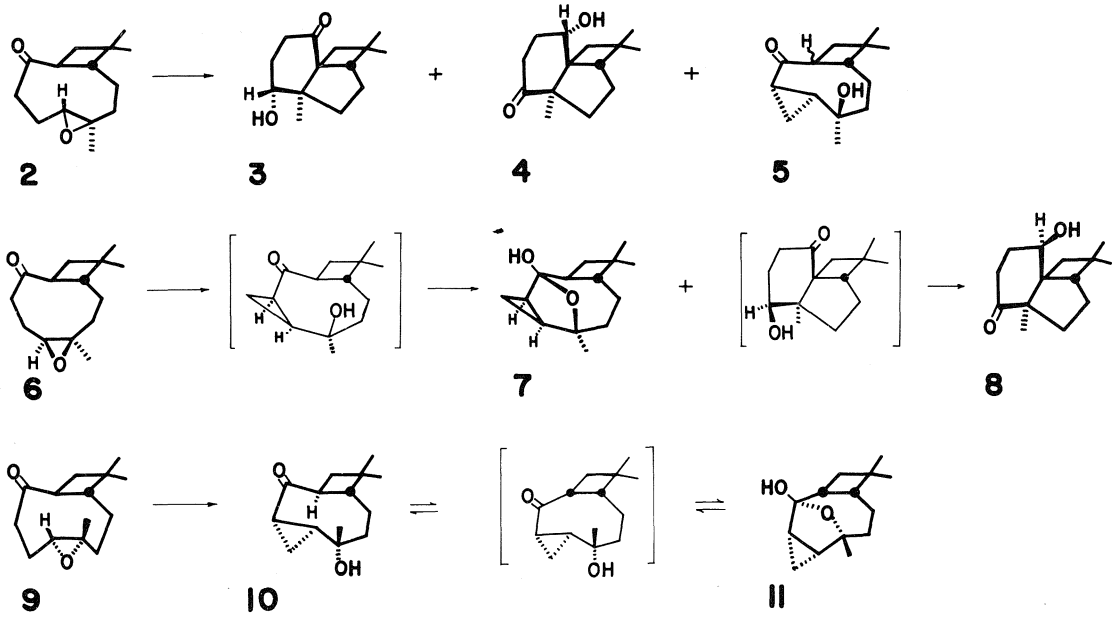


1

For each of the three isomers **2**, **6**, and **9** there was the possibility of reaction at either α-carbon of the ketone and at either carbon of the epoxide to yield a 3-, 4-, 5-, or 6-membered ring. Although either enolate could in principle be alkylated from either side, in fact there was one preponderant product formed in each reaction, as already noted for epoxide **2** by Barton and Lindsey (2). Structural assignments to products (Scheme 1) were readily made with ir (OH, C=O, and cyclopropyl CH), uv (C=O conjugated with cyclopropyl), and ^{1}Hmr spectra (C*H*OH, cyclopropyl H, see Table 1) in conjunction with acetylation and oxidation experiments. For two of the stereoisomers, the product distribution depended on the base–solvent system used. Thus with epoxide **2** in methanolic KOH the major product was **3** as found by Barton and Lindsey in the course of the structure determination of caryophyllene (2). However, there was also ~5% each of two other isomers formed, mp 119°C and 146°C, and in the *tert*-butyl alcohol–water–KOH system, the amount of one of the minor products (mp 119°C) was increased to 27%. The product of mp 146°C was a tertiary hydroxy cyclopropyl ketone and is assigned the stereostructure **5** on the assumptions of inversion during oxide ring opening and formation of the most stable configurations at the two enolizable α-positions of the ketone.

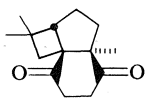
The third ketol isomer of mp 119°C was found to be the artifact **4** derived from the major product **3** by base-catalyzed intramolecular hydride transfer (9, 10).[1] Its structure follows from oxidation to the same dione **12** obtained by oxidation of **3**, and from photochemical cleavage (Scheme 2) which produced lactone **13** via intramolecular hydrogen abstraction in the diradical and cyclization of the resulting ketene. The ^{1}Hmr spectrum of this lactone contained a methyl

[1]Some of the facts (and consequently their interpretation) regarding the ketols of mp 119 and 130°C given in this paper and in refs. 9 and 10 differ from those given in ref. 8; the facts presented here and in ref. 10 are correct.



SCHEME 1

doublet at δ 0.91 (J = 6 Hz) in addition to the *gem*-dimethyl group. Irradiation of ketol **3** (Scheme 2) also produced a lactone **14** which, however, exhibited three methyl singlets in its ^{1}Hmr spectrum.



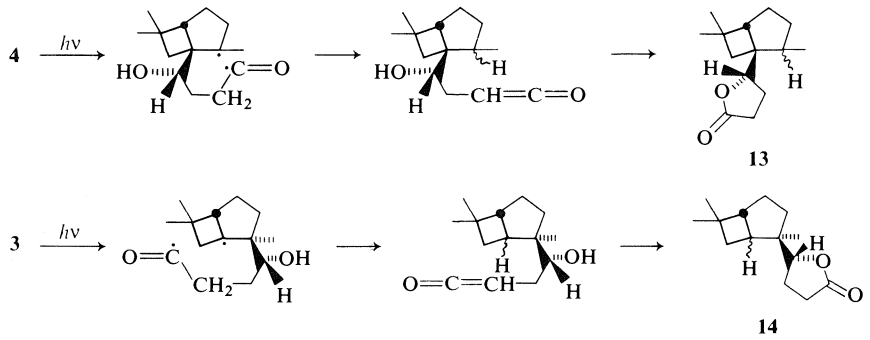
12

In the methanolic potassium hydroxide system, *cis*-keto oxide-a **6** gave a complex mixture of at least nine products, but in *tert*-butyl alcohol – water – potassium hydroxide only two products were formed. The major one (~60%), which had no carbonyl infrared absorption, was assigned the cyclopropyl hemiketal structure **7**. A monoacetate was formed at reflux in acetic anhydride – pyridine. Although the configuration at the cyclobutane ring fusion is epimerizable, it should be *trans* as shown because the *cis*-configuration would have more unfavorable non-bonded interactions on the α-face of the molecule.

The second product of the reaction formed in only 4% yield was **8**, mp 130°C, whose origin is discussed in the following paper (10).

The *cis*-keto oxide-b **9** gave a single alkylation product in both the methanolic potassium hydroxide and the *tert*-butyl alcohol – water – potassium hydroxide media. This product was a cyclopropyl ketone which was partially isomerized by base to a hemiketal. The isomerization was shown to be a true equilibration by obtaining the same 2:1 mixture of **10** and **11** starting with each pure compound. The geometry (Dreiding models) is much better for hemiketalization if the cyclobutane ring is *cis*-fused. The slow rate of hemiketalization is best explained if the cyclopropyl ketone **10** has a *trans*-fused cyclobutane ring and the hemiketal has a *cis*-fused cyclobutane ring so that an epimerization is required before hemiketalization can occur.

These alkylations are true S_N2 displacements of an enolate on the oxide group, and not solvolytic openings of the oxide with concomitant reaction of the enol(ate), because the oxide groups of caryophyllene monoxide (**2**, with $=CH_2$ in place of $=O$) and isocaryophyllene monoxides (**6** and **9** with $=CH_2$ in place of $=O$) are stable to these reaction conditions. The products found accord with expectations from examination of Dreiding models. The simplest case is that of *cis*-keto oxide-b **9** for which the C-9-enolate can not get within bonding distance of the back of either C-4 or C-5 of the oxide group, and hence only alkylation by the C-7-enolate can occur. Although in principle alkylation could occur with the enolate in the *cis*- or



SCHEME 2

TABLE 1. ^{1}Hmr data[a,b]

Compound	Methyl groups[c]	Other	
Cyclopropyl ketol **5**	0.97, 0.97, 1.03	3.13 (1H, m, ketone α-H)	0.7–0.95 (m, cyclopropyl H)
Cyclopropyl ketol **7**	0.92, 1.17, 1.21	—	0.4–0.8 (m, cyclopropyl H)
Cyclopropyl ketol **7** acetate	0.91, 1.13, 1.26	1.99 (CH_3C=O)	0.4–0.8 (m, cyclopropyl H)
Cyclopropyl ketol **10**	0.96, 1.05, 1.26	3.16 (1H, m, ketone α-H)	0.6–0.95 (m, cyclopropyl H)
Cyclopropyl hemiketal **11**	1.07, 1.15, 1.25	—	0.3–0.7 (m, cyclopropyl H)
Cyclopropyl hemiketal **11** acetate	1.06, 1.13, 1.31	2.00 (CH_3=O)	0.35–0.75 (m, cyclopropyl H)
Diketone **12**	0.91, 1.03, 1.08	—	—
γ-Lactone **13**	0.91, 1.18, 0.91 (d, J = 6)	4.64 (1H, q, CHOC=O)	
γ-Lactone **14**	0.86, 0.86, 1.16	4.25 (1H, t, CHOC=O)	

[a]Chemical shifts are given in ppm from tetramethylsilane (δ), and coupling constants are given in Hz for $CDCl_3$ solutions; d = doublet t = triplet, q = quartet, m = multiplet.
[b]For data on ketols **3**, **4**, and **8** see the following paper; for data on keto oxides **2**, **6**, and **9** see ref. 13.
[c]All peaks were singlets except as noted.

trans-configuration and with the cyclobutane fusion either *cis* or *trans*, only the transition state involving the *cis*-enolate and the *trans*-cyclobutane fusion (→**10**) has the proper orientation of the enolate α-carbon at the backside of C-5 without unfavorable transannular hydrogen interactions. The cyclopropyl ketol **10** with the *trans*-cyclobutane fusion might have been expected to form a hemiketal, but Dreiding models clearly show this hemiketal to be more strained than **11** with the *cis*-fused cyclobutane.

For the *cis*-keto oxide-a **6**, it is apparently not possible to get the α-face of the C-9-enolate properly positioned behind C-5 for S_N2 displacement, nor is it possible to get the β-face properly oriented behind either C-4 or C-5. However, the α-face of the C-9-enolate can approach the back of the tertiary C-4 correctly, and this path eventually produces the minor product **8** (10). With the C-7-enolate of **6**, when the cyclobutane fusion is *trans*, the *cis*-enolate is well situated for displacement at the backside of C-5 leading to **7** as the major product. Cyclopropane formation may predominate in this case because the transition state for the formation of the other product **8** has an unfavorable interaction of α-C-4-methyl with the α-hydrogen of the cyclobutane methylene group.

In contrast, the α-face of the C-9-enolate of the *trans*-keto oxide **2** has no unfavorable interactions for alkylation at tertiary C-4, and this path leads to the major product **3** observed. Attack of the C-9-enolate at secondary C-5 is apparently prohibited because strain prevents C-9 from getting properly oriented at the back of C-5. The alkylation of the β-face of the *cis*-C-7-enolate by C-5 to give cyclopropane **5** competes only to a minor extent with the formation of **3**.[2]

[2]Of the three products with the same structure, **5**, **10**, and the ketol precursor of **7**, only **5** gives no evidence of hemiketal formation. The probable reason for this situation is that, if the cyclobutane fusion in **5** is *trans*, hemiketal ring closure would increase the unfavorable nonbonded interactions (6αH ↔ 2αH ↔ 9αH) already present on the α-face of the molecule. On the other hand if the cyclobutane fusion is *cis*, hemiketal formation would jam the 6αH into the 2αH, while the uncyclized ketol structure can assume a conformation which minimizes these α-repulsions.

Experimental

General

Procedures and apparatus are the same as for ref. 1. Woelm neutral alumina was used for column chromatography and its activity is specified in parentheses. The colors specified for tlc spots are for incompletely charred plates. The following abbreviations were used: Py for pyridine, PE for petroleum ether, THF for tetrahydrofuran, EtOAc for ethyl acetate, Ac_2O for acetic anhydride, MeOH for methanol, and *tert*-BuOH for *tert*-butyl alcohol.

Isomerization of Caryophyllene Keto Epoxide **2**

Keto oxide **2** was prepared by the procedure of Treibs (2, 11).

(a) tert-BuOH–Water–KOH

A solution of 8.62 g (38 mmol) of **2**, mp 62.5–63°C, in 100 ml of *tert*-BuOH containing 7 ml of water and 18 g of KOH was refluxed for 64 h. Dilution with water and extraction with ether yielded 8.30 g (96%) of a light yellow solid whose tlc examination (EtOAc:PE, 65:35) revealed three intense spots: R_f 0.75 (brown), 0.55 (dark green), and 0.35 (light brown).

Recrystallization of the crude product from PE gave a first crop of 4.15 g (50%) of **3**, mp 144–146°C, R_f 0.55 (single spot). A second recrystallization raised the mp to 147–148.5°C, $[\alpha]_D$ −32.8° (*c* 3.12, $CHCl_3$) (lit. (2) mp 148–149°C, $[\alpha]_D^{22}$ −32° (*c* 4.68, $CHCl_3$)); $\nu_{max}(CHCl_3)$ 3600 and 3460 (OH), and 1700 cm^{-1} (6-ring C=O).

The mother liquor left from the first crop was concentrated and chromatographed on 100 g of alumina (IV). Elution with PE–benzene (50:50) afforded 2.30 g (27%) of **4**, R_f 0.75 (single spot). Two recrystallizations from PE furnished 1.60 g of small plates of **4**, mp 118–119°C, $[\alpha]_D^{17}$ +17.8° (*c* 3.11, $CHCl_3$); λ_{max}(EtOH) 292 nm (ε 34); $\nu_{max}(CS_2)$ 3600 and 3500 (OH), and 1705 cm^{-1} (6-ring C=O). *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.53, H 9.90.

Further elution of the column with benzene gave 1.15 g of a mixture of **3** and **4** (ratio of 95:5). Elution with MeOH washed off 400 mg (4.8%) of a yellow oil, R_f 0.35, trituration of which with ether followed by three recrystallizations from PE gave small colorless crystals of **5**, mp 145–146°C (crystal change at 123–125°C), $[\alpha]_D^{18}$ +73° (*c* 3.04, $CHCl_3$); λ_{max}(EtOH) 280 nm (ε 158); $\nu_{max}(CHCl_3)$ 3580 and 3420 (OH), 3000 (cyclopropane CH_2), and 1695 cm^{-1} (8-ring C=O conjugated with Δ). *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.21, H 10.13.

The cyclopropyl ketone **5** was recovered unchanged in 88% yield when a solution of 47 mg of **5** in 5 ml of MeOH containing 1 g of KOH was refluxed for 12 h. Examination of the recovered material by ir, tlc, and ^{1}Hmr gave no indication of any other compound.

(b) MeOH–KOH (Procedure of Barton and Lindsey (2))

A solution of 225 mg of **2** in 5 ml of MeOH containing 1 g of KOH was refluxed for 6 h, after which time the reaction mixture was worked-up (2) to give 200 mg (90%) of white solid. Thin layer chromatographic examination of the crude product revealed the presence of three spots with the same R_f and charring behaviour as the spots from the reaction in *tert*-BuOH, but since signals from **4** and **5** could not be clearly distinguished in the ^{1}Hmr spectrum of the total product, the amounts of **4** and **5** are estimated to be less than ~5% each.

Diketone **12**

A solution of 201 mg of **4** in 2 ml of Py was added to the orange mixture of 180 mg of CrO_3 in 2 ml of Py at room temperature. After 27 h the reaction mixture was diluted with CH_2Cl_2 and passed through alumina (IV). Evaporation of the solvent left 190 mg of an oil which was chromatographed on 15 g of neutral alumina (IV). PE eluted 190 mg (95%) of an oil (single tlc spot). Two recrystallizations from PE gave long colorless needles of *diketone* **12**, mp 51.5–52°C, $[\alpha]_D^{17}$ −161° (*c* 3.65, $CHCl_3$); $\nu_{max}(CS_2)$ 1700 cm^{-1} (6-ring C=O), identical (mmp, ir, tlc, ^{1}Hmr) with a specimen prepared by oxidation of **3**. *Anal.* calcd. for $C_{14}H_{20}O_2$ (220.3): C 76.33, H 9.15; found: C 76.80, H 9.25.

Photochemical Cleavage of Ketol **3**

A solution of 530 mg of pure **3** in 18 ml of thiophene-free benzene under a N_2 atmosphere in a quartz cell was irradiated with an 85 W Hanovia C-H-3 ultraviolet lamp for 17 h (30 cm from lamp to cell). Evaporation of the yellow solution left 530 mg of colorless solid which tlc examination (EtOAc:PE, 65:35) revealed to consist of one product, R_f 0.55, and starting material **3**, R_f 0.35. Partition between ether and H_2O–MeOH–KOH gave 300 mg of pure recovered **3**. Acidification (aqueous HCl) of the basic solution and extraction with ether yielded 170 mg of colorless solid (single tlc spot R_f 0.55). Two recrystallizations from PE gave 100 mg of lactone **14**, mp 93–94.5°C, $[\alpha]_D^{21}$ −62° (*c* 3.08, $CHCl_3$); $\nu_{max}(CS_2)$ 1770 cm^{-1} (γ-lactone C=O); ord (*c* 0.80, MeOH) $[\phi]_{450}$ −86°, $[\phi]_{350}$ −162°, and $[\phi]_{250}$ −287°. *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.22, H 10.18.

Photochemical Cleavage of Ketol **4**

A solution of 300 mg of pure **4** in 12 ml of thiophene-free benzene under a N_2 atmosphere was irradiated in the same cell and with the same lamp (same distance from lamp to cell) as in the previous experiment with **4** except that the irradiation time was 23 h. Evaporation of the solution left 300 mg of a liquid whose tlc examination gave a single spot different from that of starting material. Partition of 150 mg of the liquid between ether and base (as above) gave 100 mg of lactone recovered by acidification of the basic layer and 20 mg of neutral material (two spots, neither was **4**) from the ether layer. The lactone **13** was evaporatively distilled at 90–95°C/0.4 torr and gave a single tlc spot, R_f 0.65, $[\alpha]_D^{18}$ +5.8° (*c* 3.11, $CHCl_3$); $\nu_{max}(CS_2)$ 1775 cm^{-1} (γ-lactone); ord (*c* 1.99, MeOH) $[\phi]_{450}$ +10°, $[\phi]_{350}$ +12°, and $[\phi]_{250}$ −110°. *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.76, H 10.01.

Isomerization of Isocaryophyllene Keto Epoxide-a **6**

Liquid keto epoxide **6** was prepared by the $KMnO_4$ oxidation of pure crystalline isocaryophyllene oxide-a (12).

(a) tert-BuOH–Water–KOH

A solution of 1.21 g of **6** in 18 ml of *tert*-BuOH containing 1 ml of water and 3.5 g of KOH was refluxed for 70 h. Dilution with water and extraction with ether yielded 1.17 g (98%) of oily product whose tlc examination ($CHCl_3$:MeOH, 90:10) revealed four spots, R_f 0.90 (mauve, **6**), 0.80 (**8**), 0.70 (**7**) and a faint more polar spot. Chromatography on 30 g of alumina (IV) gave 135 mg (12%) of recovered **6** in the PE eluate. Further elution with PE:benzene (25:75) gave 790 mg (68%) of an oil.

Crystallization from PE gave 45 mg (4%) of colorless **8**, mp 129–130°C, unchanged on further recrystallization, $[\alpha]_D^{17}$ −44° (*c* 2.29, $CHCl_3$); $\nu_{max}(CS_2)$ 3600 and 3480 (OH), and 1708 cm^{-1} (6-ring C=O). *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 76.08, H 10.19.

The mother liquors from the crystallization were concentrated to obtain 350 mg (32%) of colorless prisms of hemi-ketal **7**, mp 115–116°C. Two recrystallizations from PE raised the mp to 116–117°C, $[\alpha]_D^{17}$ −8.7° (*c* 2.87, $CHCl_3$); $\nu_{max}(CS_2)$ 3580 and 3400 (OH), 3060 and 3030 cm^{-1} (cyclopropane CH_2), no C=O absorption. *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 76.09, H 10.36.

The mother liquor left from crystallizing **7** was found (tlc and infrared) to be mostly **7** with a minor amount of **8**.

(b) MeOH–KOH

A solution of 200 mg of **6** in 5 ml of MeOH containing 1 g of KOH was refluxed for 5.5 h. Dilution with water and ether extraction gave 180 mg of an oil. Thin layer chromatographic examination (EtOAc:PE 65:35) revealed at least nine spots, and the ^{1}Hmr spectrum of the oil contained methoxyl signals. The reaction was not investigated further.

*Hemiketal Acetate **7** (OAc for OH)*

Compound **7** was not acetylated when 80 mg in 1 ml of Py and 1 ml of Ac_2O was allowed to stand at room temperature for 24 h. However, when 175 mg of **7** in 5 ml of Py and 1 ml of Ac_2O was refluxed for 48 h, reaction occurred to give 208 mg (100%) of crude liquid after work-up. Thin layer chromatographic examination (EtOAc:PE, 65:35) revealed two spots, R_f 0.70 (major) and R_f 0.55 (trace of starting material **7**). Chromatography on 5 g of alumina (II) gave 125 mg of crystals in the PE eluate. Recrystallization from PE gave colorless needles of the monoacetate, mp 100–100.5°C, $[\alpha]_D^{17}$ −93° (*c* 2.00, $CHCl_3$); $\nu_{max}(CS_2)$ 3015 and 3000 (cyclopropane CH_2), and 1735 cm^{-1} (ester C=O). *Anal.* calcd. for $C_{16}H_{24}O_3$ (264.4): C 72.69, H 9.15; found: C 73.14, H 9.53.

*Oxidation of Hydroxy Ketone **8***

A solution of 11 mg of **8** in 0.5 ml of Py was added to the complex prepared from 25 mg of CrO_3 and 1 ml of Py. After 24 h at room temperature the reaction mixture was diluted with CH_2Cl_2 and passed through alumina (IV). Evaporation of the eluate left 7 mg of solid. One recrystallization from PE gave colorless crystals of **12**, mp 50–52°C, undepressed on admixture with the authentic specimen prepared from **3**.

*Isomerization of Isocaryophyllene Keto Epoxide-b **9***

Keto epoxide **9** was prepared by the $KMnO_4$ oxidation of isocaryophyllene oxide-b (12). The crude product was chromatographed on alumina (IV), and the PE eluate was recrystallized thrice from PE to give pure keto epoxide **9**, mp 77–78°C (lit. (12) mp 78–79°C).

(a) MeOH–KOH

A solution of 715 mg of pure **9** in 30 ml of MeOH containing 6 g of KOH was refluxed for 24 h. Dilution with water and extraction with ether yielded 720 mg of a colorless oil whose tlc examination (EtOAc:PE, 35:65) revealed only two spots, R_f 0.45 and 0.35, both different from starting material **9**, R_f 0.40. Chromatography on 20 g of alumina (III) gave 500 mg (69%) of colorless liquid hemiketal **11** (single tlc spot) in the PE eluate. A sample was evaporatively distilled at 60–65°C/0.1 torr for analysis, $[\alpha]_D^{18}$ −35° (*c* 3.72, $CHCl_3$); $\nu_{max}(CS_2)$ 3580 and 3440 (OH), and 3040 and 3070 cm^{-1} (cyclopropane CH_2). *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.22, H 10.14.

Further elution of the chromatogram with benzene gave 185 mg (25%) of the hydroxy cyclopropyl ketone **10** (single tlc spot). Two recrystallizations from PE gave colorless clusters of small needles of **10**, mp 131–132°C, $[\alpha]_D^{20}$ +71° (*c* 2.13, $CHCl_3$), λ_{max}(EtOH) 280 nm (ε 147), ε_{200} 4100, ε_{210} 2300; $\nu_{max}(CHCl_3)$ 3580 and 3440 (OH), and 1685 cm^{-1} (cyclopropyl conjugated C=O). *Anal.* calcd. for $C_{14}H_{22}O_2$ (222.3): C 75.63, H 9.97; found: C 75.40, H 9.88.

The hydroxy cyclopropyl ketone **10** was not acetylated when 112 mg in 1 ml of Py and 1 ml of Ac_2O was allowed to stand at room temperature for 24 h.

(b) tert-BuOH–KOH

A solution of 111 mg of **9** in 5 ml of *tert*-BuOH containing 0.5 ml of water and 1 g of KOH was refluxed for 14 h. Dilution with water and extraction with ether yielded 110 mg of oily product whose tlc examination revealed only two spots identical in R_f with the two products from the reaction in MeOH–KOH. Chromatography on alumina (III) gave 65 mg of **11** and 28 mg of **10**, mp 130–132°C, undepressed by the sample from the reaction in MeOH–KOH.

*Hemiketal Acetate **11** (OAc for OH)*

The hemiketal **11** was not acetylated when 57 mg in 1 ml of Py and 1 ml of Ac_2O was allowed to stand at room temperature for 24 h. However, when 200 mg of **11** in 5 ml of Py and 1 ml of Ac_2O was refluxed for 48 h, reaction occurred to give 200 mg (84%) of liquid product which solidified on cooling. Thin layer chromatographic examination (EtOAc:PE, 35:65) revealed an intense spot, R_f 0.75, and a faint spot, R_f 0.55, corresponding to **11**. Two recrystallizations from PE (bp 30–60°C) gave colorless needles of the monoacetate, mp 66–66.5°C, $[\alpha]_D^{18}$ −23° (*c* 1.27 $CHCl_3$); $\nu_{max}(CS_2)$ 3000 and 3030 (CH_2 of cyclopropane, and 1730 cm^{-1} (ester C=O). *Mol. Ion* calcd. for $C_{16}H_{24}O_3$: 264.1726; found: 264.1725.

*Equilibration of **10** and **11***

(a) A solution of 111 mg of hydroxy ketone **10** in 7 ml of MeOH containing 1.3 g of KOH was refluxed for 43 h. Dilution with water and extraction with ether yielded 105 mg of a mixture of **10** and **11** only (tlc). Chromatography on 7 g of alumina (III) gave 70 mg (66%) of liquid hemiketal **11** in the PE eluate and 28 mg (27%) of recovered hydroxy ketone **10**, mp 129–131°C, in the benzene–ether eluate.

(b) A solution of 78 mg of pure liquid **11** in 5 ml of MeOH containing 1 g of KOH was refluxed for 45 h. Dilution with water and extraction with ether gave 73 mg of a mixture of **10** and **11** only (tlc). Chromatography on 5 g of alumina (III) gave 48 mg (66%) of recovered hemiketal **11** in the PE eluate, and 21 mg (29%) of hydroxy ketone **10**, mp 128–130°C, in the benzene–ether eluate.

Intramolecular hydride shifts in 4-hydroxycyclohexanones

E. W. WARNHOFF

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 13, 1976

E. W. WARNHOFF. Can. J. Chem. **55**, 1635 (1977).

The two reversible base-catalyzed ketol rearrangements **1** ⇌ **2** and **3** ⇌ **4** have been proved to occur by intramolecular hydrogen (probably hydride) transfer. A combination of evidence including reduction studies, ^{1}Hmr data, and determination of absolute configuration has shown that both ketol pairs have the stereochemistry required for suprafacial hydride migration. In the course of this work, the anomalous sodium–1-propanol reduction of dione **9** has been reinvestigated.

E. W. WARNHOFF. Can. J. Chem. **55**, 1635 (1977).

On a prouvé que les deux réarrangements de cétols catalysés par les bases, **1** ⇌ **2** et **3** ⇌ **4**, se produisent par transfert intramoléculaire d'hydrogène (probablement un hydrure). Une combinaison de données incluant des études de réduction, les données de rm^{1}H et de détermination de configuration absolue a permis de montrer que les deux paires de cétols ont la stéréochimie requise pour une migration d'hydrure suprafaciale. Dans le cadre de ce travail, on a réexaminé la réduction anormale par le sodium et le propanol-1, de la dione **9**.

[Traduit par le journal]

There are a number of examples of base-catalyzed intramolecular hydride transfers of the Meerwein-Ponndorf–Oppenauer type which occur readily when C*H*OH and ketone groups are proximately disposed as pictured below in Fig. 1. These include geometrically favorable 1,4- and 1,5-hydride shifts across single and fused rings.[1] Recently, we reported an unambiguous case (**1** ⇌ **2**, Scheme 1) of such an intramolecular 1,4-hydride shift within a cyclohexanone ring (8) in several basic media. In this paper is presented detailed evidence that the transfer **1** ⇌ **2** is indeed intramolecular with the required suprafacial stereochemistry and, moreover, that **3** and **4**, the hydroxyl epimers of **1** and **2**, constitute another pair of ketols undergoing this type of hydride transfer.

The functional group positions in the interconvertible ketols **1** and **2** were verified by photochemical cleavage to the two lactones **5** and **6** (8, 9), but independent proof of hydroxyl stereochemistry in each was necessary to demonstrate the suprafaciality of the hydride shift required by an intramolecular process. The hydroxyl configuration of Barton's ketol **1** was already firmly established by Horeau's method (10) and by its mode of genesis which does not disturb the known configuration at this carbon atom in the keto oxide precursor (11). This α-configuration has the more stable equatorial conformation since we find that ketol **1** is the major product (~90%) from reduction of the 8,8-ethylene ketal **11** by sodium–1-propanol followed by hydrolysis. The application of Horeau's method to the 121° ketol from isomerization of **1** gave an excess of (−) enantiomer in the recovered α-phenylbutyric acid as expected for the *S* configuration at C-8 depicted in **2**. However, additional confirmatory evidence for the hydroxyl configuration in **2** was less directly obtained because the 5-carbonyl group in this compound is hindered. Initially we had hoped to carry out reductive experiments on the 5,5-ethylene ketal **12** to be prepared in turn from **2**, but it was found that the hydroxy ketal obtained from **2** was a product

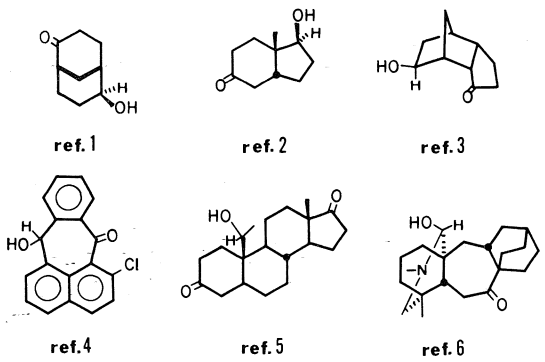

FIG. 1. Compounds in which base-catalyzed intramolecular hydride transfer occurs.

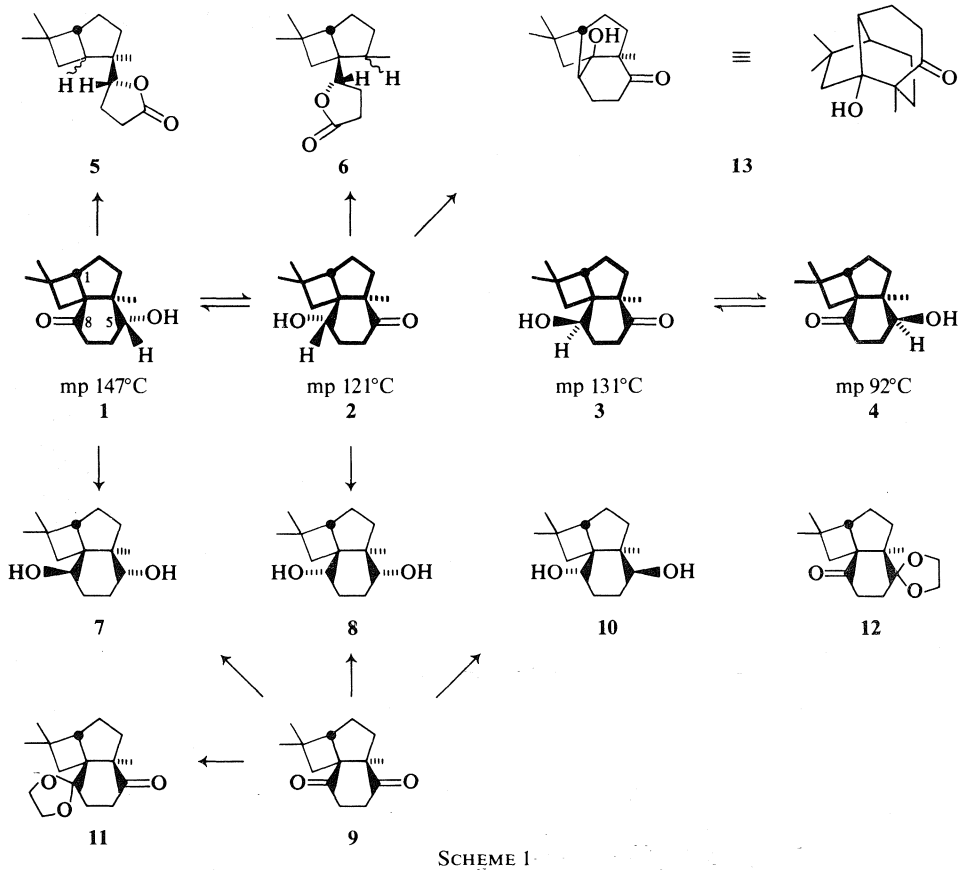
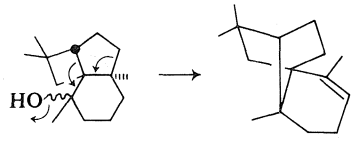
[1]There is even a postulated case of 1,3-hydride transfer during the saponification of a limonoid pointed out to us by Professor D. A. H. Taylor (7). However, the evidence is not conclusive.



SCHEME 1

of rearrangement since hydrolysis furnished a ketol in which the hydroxyl group was now tertiary (no C*H*OH in ^{1}Hmr, no oxidation by Cr(VI)).[2] The structure **13** is assigned to this product in analogy with the rearrangement of **14**



to **15** (12). For rearrangement to be initiated by the loss of a *secondary* hydroxyl group under such mild conditions is evidence for the α-hydroxyl stereochemistry (*anti* to the migrating alkyl carbon atom) as in **2**. Still milder conditions sufficient to ketalize **1** gave only recovered starting material with **2**. Direct evidence that the 5-keto group is more hindered than the 8-keto group was provided by ketalization of the dione **9** which produced only the 8,8-monoketal **11**.

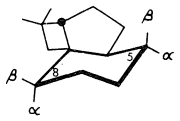
Reductive experiments with the two ketols and their acetates further strengthened the hydroxyl assignment in **2**. On the premise that borohydride reduction of **1** and **2** should add hydride mainly from the less hindered carbonyl side, inspection of Dreiding models revealed that reduction of **2** should give **8** with the same C-5-stereochemistry as in **1**, but reduction of **1** should give **7** with the opposite configuration at C-8 from that in **2**. In agreement, two different diols were obtained. The hydroxyl groups already present in **1** and **2** were not involved in any orienting effect during reduction because hydride reduction of the ketol acetates **1** (*OAc for OH*) and **2** (*OAc for OH*) followed by saponification produced, in each case, the same diol as obtained from the corresponding ketol. Proof that it was the hydroxyl configuration at C-8 alone that was responsible for the difference between the two diols came from two experi-

[2]At the time of our earlier submission (8) it was not known that rearrangement had occurred.

ments. Borohydride reduction of the 8,8-monoketal **11** afforded 82% of ketol **1** after hydrolysis and recrystallization, and oxidation of the diol from ketol **1** with 1 equiv. of Cr(VI) gave a mixture of four compounds: dione, recovered diol, ketol **1**, and a second ketol which was not **2**.

A further check on the configuration at C-8 was provided by reduction of the acetate of ketol **1** with sodium amalgam in acetic acid, a reaction that should produce the more stable equatorial hydroxyl configuration.[3] The product was the 5-monoacetate of the 162° diol **7** obtained from the borohydride reduction of **1**. This result is in agreement with that of Barton *et al.*, who obtained the same diol by reduction of **1** with sodium and 1-propanol (13).[3]

All of this interlocking evidence allows the confident assignment of the β-equatorial hydroxyl configuration in the flattened chair cyclohexane conformation shown in **16** to the



16

reduced C-8 carbonyl group, and therefore the 8α-axial hydroxyl configuration in ketol **2**. The half height band widths of the α-oxygenated carbinyl protons in the ^{1}Hmr spectra of these various derivatives (Fig. 2 and Table 1) are all in agreement with the chair conformation **16** deduced from the chemical data.

The fact that reduction of the 8-carbonyl group gave the opposite stereochemistry from that in **2** allowed preparation of a third ketol in this series by the sequence of reactions in Scheme 2. Surprisingly, this third ketol **3**, mp 131°C, proved to be identical with a minor product of base treatment of the keto oxide from *cis*-caryophyllene oxide-a (9). Therefore, during that alkylation reaction, the initial product **4** must have undergone hydride shift to **3** contrary to what was thought earlier (8). The reason for the mistaken conclusion became clear when **3** was isomerized in KOH – isopropyl alcohol. The equilibrium ratio of products **3**:**4** was 54:46 from ^{1}Hmr spectra, but both ketols had almost identical tlc R_f values. Pure 131° ketol **3** could be

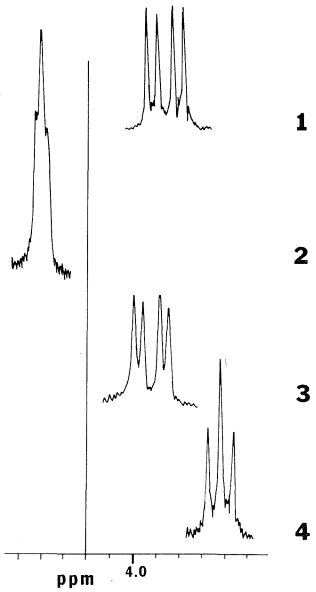


FIG. 2. The patterns of the C*H*OH signal in the four ketols **1**–**4** at 100 MHz.

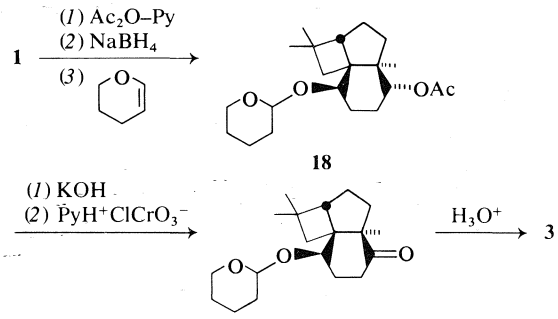

SCHEME 2

crystallized from the product mixture,[4] but the lower-melting ketol **4** could not be isolated in pure form from the mother liquors by crystallization or chromatography. However, pure ketol **4**, mp 92°C, was separated from the 90:10 mixture of **1**:**4** formed by borohydride reduction of ketal **11** followed by hydrolysis. The structure and stereochemistry of **4** follow from the fact that it is oxidized to the dione **9**, and with this carbon–oxygen skeleton there is no longer any alternative left.

The formal possibility of accounting for these isomerizations by homoenolization via **17** has

[3]The acetate was used instead of the ketol to avoid any ambiguity due to possible intramolecular protonation by the C-5 hydroxyl group during reduction.

[4]It was this behaviour together with the single, only slightly ellipsoidal tlc spot for the ketol mixture which caused us to think earlier (8) that the ketol pair **3** and **4** did not undergo hydride shift.

TABLE 1. 100 MHz ^{1}Hmr data[a]

Compound	Methyl groups[b]	C_5-H	C_8-H	$CH_3C{=}O$
Ketol **1**	0.85, 0.91, 1.02	3.87 ($J_{AX} + J_{BX} = 16$, $w_{1/2} = 18$, axH)	—	—
Ketol **2**	0.90, 1.17, 1.19	—	4.40 (nm, $w_{1/2} = 6$, eqH)	—
Ketol **3**	0.92, 1.02, 1.21	—	3.92 ($J_{AX} + J_{BX} = 16$, $w_{1/2} = 18$, axH)	—
Ketol **4**	0.90, 0.91, 1.02	3.63 ($J_{AX} + J_{BX} = 11$, $w_{1/2} = 12$, eqH)	—	—
Ketol **13**	1.02, 1.04, 1.20	—	—	—
1 (OAc for OH)	0.89, 0.89, 1.00	5.09 ($J_{AX} + J_{BX} = 16$, $w_{1/2} = 18$, axH)	—	2.07
2 (OAc for OH)	0.88, 1.14, 1.21	—	5.58 (nm, $w_{1/2} = 7$, eqH)	2.10
Diol **7**	0.82, 0.92, 1.20	3.32 (m, $w_{1/2} = 18$, axH)	3.45 (m, $w_{1/2} = 18$, axH)	—
Diol **8**	0.88, 0.94, 1.16	3.40 (m, $w_{1/2} = 17$, axH)	4.19 (nm, $w_{1/2} = 6$, eqH)	—
Diol **10**	0.90, 0.91, 1.20	3.60 (nm, $w_{1/2} = 12$ (or 9), eqH)	3.60 (nm, $w_{1/2} = 9$ (or 12), eqH)	—
7 (5-OAc for 5-OH)	0.89, 0.90, 1.20	4.60 (m, $w_{1/2} = 17$, axH)	3.44 (m, $w_{1/2} = 17$, axH)	2.03
8 (8-OAc for 8-OH)	0.87, 0.93, 1.19	3.42 (m, $w_{1/2} = 17$, axH)	5.40 (nm, $w_{1/2} = 5$, eqH)	2.03

[a]Chemical shifts are given in ppm from tetramethylsilane (δ), and coupling constants and half widths ($w_{1/2}$) are given in Hz for $CDCl_3$ solutions; m = multiplet, nm = narrow multiplet.
[b]All methyl peaks were singlets.

17

been excluded by failure to exchange the C*H*OH proton of **1** in KOD–*tert*-BuOD–D_2O (8), and therefore, by exclusion, these isomerizations must be hydride transfers. Both intra- and intermolecular transfers have been found to occur, but the much greater rate of the intramolecular process is evident from several observations. First, over periods of several hours in the hot basic isomerization media, the only products detectable by tlc and ^{1}Hmr are the respective ketol pair having the required suprafacial relationship. For **1** ⇌ **2** (or **3** ⇌ **4**) there are no traces of other (known) products expected from intermolecular hydride transfer reactions: dione **9**, diols such as **7** and **8**, or the ketols **3** and **4** (or **1** and **2**). Second, during this 'clean' period, **1** and **2** do not accept hydride from isopropyl alcohol solvent, nor do they donate hydride to added carbonyl compounds (2,2-dimethylcyclohexanone and fluorenone (14)). Third, if the isomerization **1** ⇌ **2** is continued for longer periods with higher KOH concentrations, either under nitrogen or not, then other intermolecular reaction products do build up. The first extra product is the 162° diol **7** which has the proper stereochemistry to have been formed by hydride donation from 2-propanol to the carbonyl group of **1** which was shown above to be less hindered than the carbonyl group of **2**. Then, more slowly the 155° diol **8**, probably from 2-propanol reduction of ketol **2**, begins to appear together with several other less polar products apparently resulting from aldol condensation of the newly formed acetone with **1** and/or **2** (see Experimental).

Although the *cis* fusion of the ketol ring to the cyclopentane ring would facilitate attainment of a boat-like transition state necessary for easy intramolecular hydride transfer in either pair of ketols, how important this factor is remains to be seen. Perhaps such 1,4-hydride shifts in 4-hydroxycyclohexanones are general.

Finally, some evidence is offered that our concern over complications during the reductive experiments was not excessive. In Barton's earlier work (13) it was found that sodium–1-propanol reduction of ketol **1** and dione **9** gave

different diols, and this result was apparently responsible for the incorrect assignment of stereochemistry to the ketol at that time (13, 15). In the expectation that this reduction method should have given the more stable equatorial hydroxyl configuration and therefore the same diol from **1** and **9**, the actual experimental result is puzzling. Our sodium amalgam reduction of the acetate of **1** was consistent with the earlier sodium reduction of **1**, and therefore we have re-examined the sodium–1-propanol reduction of dione **9**. The product was found to be a mixture of comparable amounts of four compounds, two of which corresponded in tlc behavior to diols **7** and **8**. When the crude product was recrystallized from chloroform as done previously (13), a third, higher-melting diol (probably **10**) corresponding to that reported (13) crystallized cleanly from the mixture even though it constituted a minor amount of the total product. Why such a mélange of products is formed in this reduction is not immediately obvious, but certainly no stereochemical conclusions can be drawn from the reaction.

Experimental

Melting points were taken on a Reichert Kofler microscope hot-stage and are corrected. Infrared spectra were obtained on a Beckman Acculab 4 spectrometer; ^{1}Hmr spectra were obtained by Mrs. Heather Schroder on a Varian HA-100 instrument; mass spectra were obtained by Mr. Doug Hairsine on a MAT 311A instrument; optical rotations taken with a 1-dm tube on a Rudolph Model 80 polarimeter by P.R.W. All thin and thick layer chromatograms were run on Merck GF_{254} silica gel developed in EtOAc:PE (67:33). Woelm neutral alumina was used and the grade is specified in parentheses. Pyridinium chlorochromate was obtained from the Aldrich Chemical Company. Organic solutions were washed to neutrality and dried by shaking with saturated NaCl solution and standing over anhydrous $MgSO_4$. For most of the new compounds, precise mass determinations for the molecular ion of a pure sample were obtained instead of combustion analyses. Purity was determined from constancy of mp together with ^{1}Hmr, ir, and tlc data. The following abbreviations were used: PE = petroleum ether of bp 60–80°C, p.e. = petroleum ether of bp 36–45°C, Py = pyridine, MeOH = methanol, *tert*-BuOH = *tert*-butyl alcohol, *i*-PrOH = 2-propanol, Ac_2O = acetic anhydride, EtOAc = ethyl acetate, and *p*-TsOH = *p*-toluene sulfonic acid.

Isomerization of Ketol ***1***

(a) tert-BuOH–H_2O–KOH

A solution of 140 mg of pure **1** in 7 ml of *tert*-BuOH containing 0.2 ml of water and 6 KOH pellets was refluxed for 47 h. Dilution with water and extraction with ether yielded 140 mg of solid whose tlc showed only two spots corresponding to **1** and **2**. Separation on a thick plate yielded 95 mg (68%) of recovered **1** and 46 mg (32%) of isomer **2**, mp 119–121°C after recrystallization from ether–PE. The 100 MHz ^{1}Hmr spectrum of the latter was identical with that of the product from the reaction of caryophyllene keto oxide with hydroxide (9), and the mixture mp was not depressed.

(b) tert-BuOD–D_2O–KOD

To a solution of 217 mg of K metal dissolved in 8 ml of *tert*-BuOD was added 1 ml of D_2O and 200 mg of pure **1**. The mixture was refluxed for 40 h with one evaporation and replacement of *tert*-BuOD–D_2O. The cooled reaction mixture was poured into a H_2O–HOAc–NaOAc buffer and extracted with ether to give 105 mg of deuterated product. Separation on a thick plate as in (*a*) followed by recrystallization from ether–PE gave 28 mg of pure **2** (42% d_4, 40% d_3, 15% d_2, 3% d_1) and 23 mg of pure **1** (40% d_4, 35% d_3, 19% d_2, 4.6% d_1). The 100 MHz ^{1}Hmr spectrum of the **2**-d_4 sample contained ~18H by integration. The C*H*OH proton of **2**-d_4 at δ 4.39 was a slightly broadened singlet of 1H intensity by integration (comparison with CH_3 signal). The 100 MHz ^{1}Hmr spectrum of the **1**-d_4 sample contained ~19H by integration. The C*H*OH proton of **1**-d_4 at δ 3.85 was a slightly broadened singlet (broadened base) of 1H intensity by integration (comparison with CH_3 signal).

(c) Fluorenone–tert-BuOH–H_2O–KOH (14)

A solution of 50 mg of **1**, 168 mg of fluorenone, and 6 KOH pellets in 7 ml of *tert*-BuOH and 0.2 ml of water was refluxed for 30 h. Dilution of the reaction mixture with water and extraction with ether yielded 176 mg of golden solid whose tlc showed spots corresponding to **1** and **2** but not to dione **9** or to any of its diol reduction products which are more polar than **3**. Thick layer chromatography in the same solvent system gave 47 mg of recovered **1** + **2**.

(d) 2,2-Dimethylcyclohexanone–tert-BuOH–H_2O–KOH

A solution of 50 mg of **1**, 0.5 ml of 2,2-dimethylcyclohexanone, and 6 KOH pellets in 7 ml of *tert*-BuOH and 0.2 ml of water was refluxed for 50 h. Dilution of the reaction mixture with water and extraction with ether yielded, after evaporation of most of the 2,2-dimethylcyclohexanone, 62 mg of oily solid whose tlc showed spots corresponding to **1** and **2**, but not to dione **9** or to any of its diol reduction products, or to 2,2-dimethylcyclohexanol.

Isomerization of Ketol ***2***

(a) tert-BuOH–H_2O–KOH

When 40 mg of **2** was refluxed with a mixture of 6 KOH pellets, 0.2 ml of H_2O and 7 ml of *tert*-BuOH for 50 h and worked-up as for the isomerization of **1**, 38 mg of a 63:37 ratio (^{1}Hmr integration of CHOH signals) of **1**:**2** was obtained.

(b) i-PrOH–KOH

When 35 mg of **2** was refluxed with a solution of 8 KOH pellets in 7 ml of *i*-PrOH for 14 h, it was transformed into 34 mg of the equilibrated mixture of **1**:**2** (69:31 from integration of the 100 MHz ^{1}Hmr spectrum).

(c) MeOH–KOH

When 18 mg of **2** was refluxed with a solution of 7 KOH pellets in 7 ml of MeOH for 102 h, it was partially isomerized into **1** but not to the extent of reaching equilibrium.

More Vigorous Isomerization of ***1***

A solution of 1.800 g of ketol **1** and 20 KOH pellets in 20 ml of *i*-PrOH was evacuated and put under a nitrogen atmosphere before being refluxed for 16.5 h. After cooling, tlc examination revealed the beginning of formation of diol **7** and the least polar acetone condensation product. Another 20 KOH pellets were added, and the reaction mixture was refluxed under nitrogen for another 23 h. Dilution with water and extraction with ether gave 1.925 g after removal of solvent. Thin layer chromatography R_f values: 0.73, 0.66, 0.59 (**2**), 0.53, 0.46 (**1**), 0.40 (**7** + **8**). Crystallization from ether–PE removed a total of 1.128 g of a mixture of ketols **1** + **7** + **8** which after further recrystallization from $CHCl_3$–PE and from ether gave 307 mg of diol **7** as thin blades, mp 162.5–163°C, 100 MHz ^{1}Hmr spectrum identical with that of **7** prepared by borohydride reduction of **1**.

A 202 mg sample of the material from the mother liquors of the original recrystallization was chromatographed on a thick plate. The most polar band contained 18 mg of **1**, **7**, and **8** (tlc and 100 MHz ^{1}Hmr). The least polar band contained 52 mg of liquid with R_f 0.73, $\nu_{max}(CS_2)$ 3640–3300 (OH) and 1703 cm^{-1} (C=O). *Mol. Ion* calcd. for $C_{17}H_{26}O_2$: 262.1932; found: 262.1933 (**1** or **2** + C_3H_6O − H_2O).

The next two bands of increasing polarity yielded mixtures with components having *m/e* 264.2094 ($C_{17}H_{28}O_2$ = **1** or **2** + C_3H_6O − H_2O + H_2), and 304.2407 ($C_{20}H_{32}O_2$ = **1** or **2** + $2C_3H_6O$ − $2H_2O$ + H_2).

The same order of appearance of the same spots was observed when another reaction of 50 mg of **1** and 3 KOH pellets in 3 ml of *i*-PrOH was refluxed and monitored by tlc over a 4 day period except that no products of condensation of acetone with **1** were observed (air oxidation of acetone enolate?).

Partial Resolution of α-Phenylbutyric Acid by Ketol ***2***

To a solution of 115 mg (0.37 mmol) of (±) α-phenylbutyric anhydride in 1 ml of dry Py was added 40 mg (0.18 mmol) of ketol **2**. After 20 h at room temperature in the dark, 0.1 ml of water was added to the colorless solution, and the excess anhydride was allowed to hydrolyze for 45 min. One millilitre of benzene was added and the reaction mixture was titrated to the phenolphthalein endpoint with 0.0815 *N* NaOH solution (9.10 ml required). The basic solution was extracted with three portions of benzene, acidified with 10% aqueous H_2SO_4, and extracted again with benzene (2 × 10 ml). The latter benzene extracts were washed thrice with water and evaporated to dryness. The residual α-phenylbutyric acid was dissolved in benzene and made up to 2 ml in a volumetric flask, $\alpha_{obs}^{22} = -0.185° \pm 0.022°$ corresponding to 21% levorotatory acid (based on recovered ketol **2**; see below). The blank for the rotation was a hydrolyzed 52 mg sample of the anhydride in benzene.

The benzene washes of the basic solution above were washed with aqueous H_2SO_4, aqueous $NaHCO_3$, and water and dried. Evaporation left 51 mg which tlc and 100 MHz ^{1}Hmr showed to consist of 60% of the α-phenylbutyrate of **2** and 40% of the unesterified ketol **2**.

Ketalization of Ketol ***2***

A solution of 232 mg (1.04 mmol) of ketol **2** and 0.1 g of *p*-TsOH·H_2O in 25 ml of toluene and 5 ml of ethylene glycol was slowly distilled. Fresh toluene was added at intervals to maintain the original volume. After collection of ~100 ml of distillate, the reaction mixture was cooled and partitioned between ether and aqueous $NaHCO_3$ to yield 280 mg (100%) of crude hydroxy ketal which crystallized, $\nu_{max}(CS_2)$ 3560 cm^{-1} (intramolecularly H-bonded OH), no ir C=O absorption. Thin layer chromatography gave a major spot with a trace of a more polar contaminant. Hydrolysis of the crude product in 2 ml of acetone with 0.5 ml of 2% aqueous H_2SO_4 at room temperature afforded 143 mg (98%) of crude product after dilution with water and extraction with ether. Recrystallization from ether–p.e. gave 92 mg of colorless blades of rearranged ketol, presumed to be **13**, mp 127–128°C, $[\alpha]_D^{20}$ −18.7° (*c* 1.05, $CHCl_3$), $\nu_{max}(CS_2)$ 3600–3200 (OH) and 1703 cm^{-1} (C=O). *Mol. Ion* calcd. for $C_{14}H_{22}O_2$: 222.1619; found: 222.1619.

The hydroxy ketal in this experiment was not oxidized by pyridinium chlorochromate in CH_2Cl_2 or by the CrO_3–Py reagent. The 100 MHz ^{1}Hmr spectrum did not contain a C*H*(OH) proton.

Ketol **2** was recovered from attempted ketalization with (*a*) ethylene glycol and γ-collidine·HCl in distilling CH_2Cl_2, and (*b*) ethylene glycol and pyridine·HCl in distilling benzene. This second set of conditions was sufficient to convert **1** into its ketal.

Ketalization of Dione ***9***

A mixture of 209 mg (0.95 mmol) of **9**, 5 ml of ethylene glycol, 100 mg of *p*-TsOH·H_2O, and 60 ml of toluene was slowly distilled. After 50 ml of distillate had been collected, a fresh 50 ml of toluene was added to the reaction mixture, and the distillation was continued until another 50 ml had been collected. The cooled residue was basified with aqueous NaOH and extracted with ether. The ether solution was washed with aqueous $NaHCO_3$, dried, and evaporated to leave 259 mg (98%) of almost pure liquid *monoketal* **11**, single tlc spot, $\nu_{max}(CS_2)$ 1705 cm^{-1} (C=O).

A solution of 250 mg of the monoketal in 10 ml of absolute ethanol was stirred for 1 h with 250 mg of $NaBH_4$. After addition of dilute H_2SO_4 the reaction mixture was allowed to stand for 2 h. Extraction with ether yielded 188 mg (89%) of partly crystalline material consisting mostly of ketol **1** and some (17 mg) recovered dione **9**. A combination of recrystallization (ether–PE) and chromatography gave 123 mg of pure ketol **1**, mp 144–146°C, single tlc spot.

Transformations of Ketol ***1***

Acetylation

A solution of 220 mg of ketol **1** in 2 ml of dry Py and 2 ml of Ac_2O was allowed to stand at room temperature for 47 h. Dilution with ether and extraction with aqueous $NaHCO_3$ and dilute H_2SO_4 gave 257 mg (98%) of pure liquid monoacetate of **1**, single tlc spot. A small sample was finally persuaded to crystallize from p.e., mp 57–59°C, $\nu_{max}(CS_2)$ 1740 (ester C=O) and 1702 cm^{-1} (ketone C=O). *Mol. Ion* calcd. for $C_{16}H_{24}O_3$: 264.1725; found: 264.1730.

Borohydride Reduction

A solution of 50 mg of ketol **1** in 7 ml of 95% ethanol was stirred (magnetic bar) at room temperature with 150 mg of $NaBH_4$ for 45 min. Addition of dilute H_2SO_4 and extraction with ether afforded 49 mg (98%) of white solid whose tlc showed only one spot. The 100 MHz ^{1}Hmr

spectrum also indicated only one diol. After recrystallization from ether,[5] fine white matted needles of *diol* **7** were obtained, mp 162–162.5°C, $[\alpha]_D^{22}$ −78° ± 1° (*c* 0.98, $CHCl_3$) (lit. (13) mp 159.5°C, $[\alpha]_D$ −69°), $\nu_{max}(CHCl_3)$ 3600 cm^{-1} (OH). *Mol. Ion* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1774.

Borohydride Reduction of Acetate of 1

A solution of 70 mg of the acetate of **1** in 4 ml of absolute ethanol was stirred at room temperature (magnetic bar) with 100 mg of $NaBH_4$ for 40 min. Addition of dilute H_2SO_4 and extraction with ether gave 71 mg (100%)of a colorless solid, $\nu_{max}(CS_2)$ 3640–3400 (OH) and 1735 cm^{-1} (ester C=O), whose tlc showed a single spot. The 100 MHz ^{1}Hmr spectrum also gave evidence of at least 95% of one compound. Recrystallization of a 46 mg aliquot from ether–PE gave 30 mg of colorless blades of the *5-monoacetate of* **7**, mp 100–101°C. *Mol. Ion* calcd. for $C_{16}H_{26}O_3$: 266.1881; found: 266.1876.

A 17 mg portion of this monoacetate dissolved in 1 ml of methanol containing two drops of water and half a KOH pellet was heated at 60°C for 1 h. Extraction with ether gave 16 mg of white solid identical with the *diol* **7** prepared by $NaBH_4$ reduction of **1**. Recrystallization from ether[5] gave fine white matted needles, mp 162–162.5°C.

Sodium Amalgam Reduction of the Acetate of 1

A vigorously stirred (magnetic bar) solution of 133 mg of the acetate of ketol **1** in 15 ml of ether and 5 ml of HOAc was treated with pieces of sodium amalgam. When the mixture became gelatinous from precipitated NaOAc, more ether (10 ml) and HOAc (7 ml) were added, and addition of sodium amalgam was continued. After the equivalent of ~2 g of Na had been added, the mixture was partitioned between ether and water, and the ether layer was washed with aqueous NaOH and water. Evaporation of the dried solution left 135 mg (100%) of a colorless glass whose tlc showed two spots corresponding to starting material (major) and the *5-monoacetate of* **7** (minor). The 100 MHz ^{1}Hmr spectrum showed the latter to be the only detectable reduction product.

Transformations of Ketol 2

Acetylation

A solution of 400 mg of ketol **2** in 2 ml of dry Py and 2 ml of Ac_2O was allowed to stand at room temperature for 27 h. Dilution with ether and extraction with aqueous $NaHCO_3$ gave after evaporation 460 mg of crude acetate. Chromatography on 15 g of grade IV alumina afforded in the PE eluate 370 mg (77%) of pure acetate of **2**, ν_{max}-$(CHCl_3)$ 1736 (ester C=O) and 1708 cm^{-1} (ketone C=O), single tlc spot. Recrystallization from p.e. gave colorless prisms of the acetate **5** (*OAc for OH*), mp 58–58.5°C, $[\alpha]_D^{17}$ +15.8° (*c* 3.46, $CHCl_3$). *Anal.* calcd. for $C_{16}H_{24}O_3$ (264.1): C 72.69, H 9.15; found: C 72.88, H 9.30.

The mixture mp with the acetate of ketol **1** (mp 57–59°C) was depressed to 28–53°C.

Borohydride Reduction

A solution of 45 mg of ketol **2** in 5 ml of absolute ethanol was stirred (magnetic bar) with 105 mg of $NaBH_4$ for 1 h. Addition of dilute H_2SO_4 and extraction with ether afforded 45 mg of white solid whose tlc contained one major spot and two minor less polar spots (one corresponding to **2**). Two recrystallizations from ether–PE gave colorless thin prisms of pure *diol* **8** (major product), mp 154–155°C, $[\alpha]_D^{20}$ −28° (*c* 0.79, $CHCl_3$), $\nu_{max}(CS_2)$ 3640–3560 cm^{-1} (OH). *Mol. Ion* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1777.

Borohydride Reduction of Acetate of 2

A solution of 100 mg of the acetate of **2** in 4 ml of absolute ethanol was stirred at room temperature for 50 min with 100 mg of $NaBH_4$. Addition of dilute H_2SO_4 and extraction with ether gave 100 mg (100%) of a colorless glass which tlc and ^{1}Hmr showed to be composed of a major product (>90%) R_f 0.53 and a minor product (<10%) R_f 0.66. Thick layer separation of a 75 mg aliquot yielded 58 mg of pure major product which was saponified in 2 ml of methanol containing two KOH pellets at 55–60°C for 3.5 h. Dilution with water and extraction with ether afforded 54 mg of pure *diol* **8**, mp 154.5–155°C after recrystallization from ether–PE, identical with the diol from borohydride reduction of **2**. On the same tlc plate with alternating spots, diol **7** had R_f 0.49 and diol **8** had R_f 0.46.

Partial Oxidation of Diol 7

To a solution of 16 mg (0.16 mmol) of CrO_3 in 3 drops of water and 0.5 ml of HOAc was added a solution of 50 mg (0.22 mmol) of **7** in 1.5 ml of HOAc. After 2 h at room temperature, the bluish green solution was diluted with water and extracted with ether to yield 44 mg (88%) of partially crystalline product. Thin layer chromatography revealed four spots: R_f 0.67 dione **9**, 0.54 ketol **3**, 0.46 ketol **1** (major component ~40%), and 0.40 recovered diol **7**. Three recrystallizations from ether–p.e. isolated pure *ketol* **1**, mp 144–147°C, undepressed on admixture with an authentic specimen.

Synthesis of Ketol 3

A solution of 444 mg (2.00 mmol) of ketol **1** in 3 ml of dry Py and 3 ml of Ac_2O was allowed to stand at room temperature for 48 h. Dilution with ether and extraction with aqueous $NaHCO_3$ and 10% aqueous H_2SO_4 afforded 525 mg (99%) of pure (tlc) colorless acetate of **1**.

The entire sample of acetate was dissolved in 20 ml of 95% ethanol and stirred for 45 min with 530 mg of $NaBH_4$. Addition of dilute H_2SO_4 and extraction with ether yielded 537 mg (100%) of the *5-monoacetate of* **7** as a colorless oil that crystallized, $\nu_{max}(CS_2)$ 3640–3400 (OH) and 1735 cm^{-1} (ester C=O).

A solution of 532 mg of this diol monoacetate in 15 ml of benzene was allowed to react for 8 h at room temperature with 4 ml of freshly distilled dihydropyran and 40 mg of *p*-TsOH·H_2O. Quenching with aqueous NaOH and extraction with ether gave 1.558 g of *tetrahydropyranyl ether* **18** plus impurities from dihydropyran, $\nu_{max}(CS_2)$ 1735 cm^{-1} (ester C=O).

The crude tetrahydropyranyl ether **19** plus impurities (1.488 g) was refluxed for 100 min with 15 KOH pellets in 20 ml of methanol. Dilution with water and extraction with ether furnished 1.347 g of yellow liquid *hydroxy tetrahydropyranyl ether*, $\nu_{max}(CS_2)$ 3640–3400 cm^{-1} (OH), no ir C=O absorption.

The total product was dissolved in 5 ml of CH_2Cl_2 and added to a stirred (magnetic bar) suspension of 1.50 g

[5]It was difficult to persuade this diol to crystallize, apparently because it could not decide whether to reappear as fine matted needles or thin blades.

(6.97 mmol) of pyridinium chlorochromate and 320 mg of anhydrous NaOAc in 10 ml of CH_2Cl_2. After 3 h ether was added and the organic solution was filtered and evaporated to leave 1.339 g of yellow oily *keto tetrahydropyranyl ether* **19** plus impurities. The ether group was removed by dissolving the oil in 15 ml of methanol containing 0.4 ml of concentrated hydrochloric acid. Dilution with water and extraction with ether afforded 744 mg of yellow oily partially crystalline material.

After standing for a week, the impurities in the crude ketol had changed into more polar contaminants which were easily removed by thick layer chromatography followed by recrystallization from ether–PE to yield 254 mg (57% overall from **1**) of ketol **3**, mp 130–131°C with previous sintering, $[\alpha]_D^{21}$ −35° (*c* 0.96, $CHCl_3$), $\nu_{max}(CS_2)$ 3640–3400 (OH) and 1710 cm^{-1} (C=O). *Mol. Ion* calcd. for $C_{14}H_{22}O_2$: 222.1619; found: 222.1621. The crystals require drying at reduced pressure and elevated temperature to remove occluded solvent. The mixture mp with the minor product of base treatment of isocaryophyllene keto oxide-a (mp 129–130°C (9)) was not depressed.

Isomerization of Ketol ***3***

A solution of 115 mg of ketol **3** and 12 KOH pellets in 15 ml of *i*-PrOH was refluxed for 10 h. Dilution with water and extraction with ether gave 121 mg of a glass which crystallized. Its tlc contained one elongated spot. Integration of the 100 MHz ^{1}Hmr spectrum gave the ratio of **3**:**4** as 54:46. Recrystallization of the crude product from ether–PE afforded 61 mg (50%) of thin blades of almost pure **3** (tlc). Thin layer chromatographic examination of the mother liquors now clearly showed two overlapping spots with the more polar predominant. Attempted separation of the components of the mother liquors on a thick layer gave in the most polar band a 26 mg fraction containing about 90% of ketol **4** (^{1}Hmr spectrum), but the 10% of **3** could not be separated by recrystallization.

Keto Ketal ***11***

A solution of 424 mg (1.91 mmol) of pure ketol **1** and 20 mg of *p*-TsOH·H_2O in 50 ml of toluene and 5 ml of ethylene glycol was slowly distilled. Fresh toluene was added at intervals to maintain the original volume. After collection of ~120 ml of distillate, the reaction mixture was cooled, and the residue was basified with aqueous NaOH and extracted with ether. Evaporation of the washed and dried ether layer left 535 mg (105%) of viscous oily *ethylene ketal of* **1** which had only a trace of carbonyl ir absorption. Crystallization of a sample from p.e. gave colorless crystals, mp 85–91°C, $\nu_{max}(CS_2)$ 3620–3200 cm^{-1} (OH).

The crude ketal dissolved in 6 ml of CH_2Cl_2 was added to a stirred (magnetic bar) suspension of 803 mg of Py chlorochromate and 300 mg of anhydrous NaOAc in 3 ml of CH_2Cl_2. After 3 h ether was added and the decanted solution was filtered through a 3-cm column of neutral alumina (IV). Evaporation of solvent left 488 mg (96%) of crystalline ketal. Recrystallization from p.e. gave 298 mg of long needles of *keto ketal* **11**, mp 65–67°C, $\nu_{max}(CHCl_3)$ 1702 cm^{-1} (C=O), no OH ir absorption. *Anal.* calcd. for $C_{16}H_{24}O_3$ (264.4): C 72.69, H 9.15; found: C 72.63, H 8.92.

Sodium–1-Propanol Reduction of Keto Ketal ***11***

A solution of 190 mg of **11** in 6 ml of 1-propanol was heated to boiling, and small pieces of Na metal were added until sodium alkoxide began to crystallize from the hot solution. The cooled reaction mixture was diluted with water and extracted with ether to yield 175 mg (92%) of colorless glass which slowly crystallized, $\nu_{max}(CS_2)$ 3640–3200 cm^{-1} (OH), no ir C=O absorption. A 169 mg portion of the product was hydrolyzed at room temperature for 12 h in a solution of 6 ml of 5% aqueous HCl and 10 ml of 95% ethanol. Dilution with water and extraction with ether gave 135 mg (96%) of solid which tlc showed to be mostly ketol **1**, contaminated by 5–10% of ketol **4**. Thick layer chromatography and recrystallization from $CHCl_3$–PE gave **1** (single tlc spot) whose 100 MHz ^{1}Hmr spectrum was identical with that of authentic **1** except for a trace of contamination by **10** which has the same tlc R_f.[6]

Borohydride Reduction of Keto Ketal ***11***

A solution of 298 mg (1.12 mmol) of pure crystalline **11** in 20 ml of 95% ethanol was stirred (magnetic bar) with 295 mg of $NaBH_4$ for 1 h. Excess $NaBH_4$ was destroyed with acetone, and the reaction mixture was partitioned between water and ether. The crude hydroxy ketal obtained (297 mg) was dissolved in 10 ml of 95% ethanol containing 0.5 ml of 7% aqueous HCl for 12 h at room temperature. Dilution with water and extraction with ether afforded 240 mg (95%) of crude ketol mixture whose tlc showed only two spots corresponding to **1** and **4**. The ratio of **1**:**4** from integration of the 100 MHz ^{1}Hmr spectrum was ~90:10. One recrystallization from $CHCl_3$–PE gave 180 mg of long thin colorless prisms of pure **1**, mp 145.5–146°C.

Isolation of Ketol ***4***

The mother liquors from the recrystallization in the previous experiment (57 mg) were chromatographed on a 10 × 20 cm thick plate bearing 10 g of silica gel. The material from the uppermost band (21 mg of approximately equal amounts of **1** and **4**) was re-chromatographed on a 20 × 20 cm thin plate. The uppermost band from this plate yielded 7 mg of pure **4**. Two recrystallizations from ether–p.e. gave 4 mg of colorless small flat prisms of **4**, mp 91–92°C, $[\alpha]_D^{22}$ −51° (*c* 0.36, $CHCl_3$), $\nu_{max}(CS_2)$ 3640–3300 (OH) and 1700 cm^{-1} (C=O). *Mol. Ion* calcd. for $C_{14}H_{22}O_2$: 222.1619; found: 222.1619.

On a single tlc plate with repeating sequences of spots, the four ketols had the following R_f values: **2** 0.58, **3** 0.53, **4** 0.49, and **1** 0.42.

Oxidation of Ketols

(*a*) To a stirred (magnetic bar) suspension of 91 mg (0.42 mmol) of Py chlorochromate in 1 ml of CH_2Cl_2 was added a solution of 30 mg (0.13 mmol) of ketol **3** in 1 ml of CH_2Cl_2. After 1.5 h the reaction mixture was diluted with ether, and the organic solution was filtered through 2 cm of neutral alumina (IV). Evaporation of solvent left 26 mg (86%) of colorless oily dione **9** which solidified on scratching. Recrystallization from p.e. gave white crystals, mp 51–53°C (lit. (16) mp 51–52°C), undepressed on admixture with authentic dione from oxidation of ketol **1**.

(*b*) A similar oxidation of 14 mg of *ketol* **4** with 50 mg of Py chlorochromate in 1.5 ml of CH_2Cl_2 for 2 h gave

[6]The contaminating diol **10** was presumably formed by reduction of dione **9** present as an impurity in the ketal **11**.

13 mg (93%) of almost colorless oily *dione* **9** (single tlc spot) whose complex 100 MHz ^{1}Hmr spectrum was identical with that of dione from *ketol* **1**.

Sodium–1-Propanol Reduction of Dione **9**

A solution of 108 mg of dione **9** in 6 ml of 1-propanol was heated to boiling, and small pieces of Na metal were added until sodium alkoxide began to crystallize from the hot medium. The cooled solution was diluted with water and extracted with ether to yield 121 mg of partially crystalline product, $\nu_{max}(CS_2)$ 3640–3200 cm^{-1} (OH), no ir C=O absorption. Thin layer chromatography revealed four spots in comparable amounts: R_f 0.52, 0.46, 0.39 (corresponds to **7**), and 0.34 (corresponds to **8**). One recrystallization from $CHCl_3$ gave 30 mg (27%) of almost pure R_f 0.46 material, mp 167–178°C. Three more recrystallizations from the same solvent gave felted needles of *diol* **10**, mp 182–183°C, $[\alpha]_D^{20} - 39° \pm 5°$ (*c* 0.45, $CHCl_3$) (lit. (13) mp 181–182°C, $[\alpha]\alpha - 43°$). *Mol. Ion* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1783. The assignment of hydroxyl stereochemistry rests on the half widths (9 and 12 Hz) of the ^{1}Hmr absorptions of the protons on the HO-bearing carbon atoms when these signals were shifted apart by the addition of $Eu(FOD)_3$.

The initial reaction of cupric dialkyldithiophosphates and dialkyldithiocarbamates with *tert*-butyl hydroperoxide and α-cumyl hydroperoxide is a free radical chain process. Initiation is achieved by a redox reaction between the complex and the hydroperoxide to give alkoxy and alkylperoxy radicals. The alkoxy radicals then abstract a hydrogen from excess hydroperoxide to give alkylperoxy radicals. The cupric complexes are converted to copper sulphate by reaction with peroxy radicals while the hydroperoxide is reduced to alcohol. About 5 mol of hydroperoxide are decomposed by each mole of complex. The decomposition of *tert*-butyl hydroperoxide then stops whereas complete destruction of α-cumene hydroperoxide occurs by a heterogeneous ionic reaction.

The kinetics of the initial reaction are second-order for both complexes. The dithiophosphate reaction is first-order in each reactant while the dithiocarbamate reaction is zero-order in the complex concentration and second-order in the hydroperoxide concentration. Simple kinetics, however, only hold for the initial rates of complex disappearance. Total dithiophosphate decomposition exhibits three stages, an initial fast reaction followed by an induction period and a rapid third stage. The concentration–time profile for dithiocarbamate decomposition is quite different and the overall rate of reaction in some instances increases as the complex concentration decreases.

JOSEPH HECTOR BERNARD CHENIER, JAMES ANTHONY HOWARD et JOHN CHARLES TAIT. Can. J. Chem. **55**, 1644 (1977).

La réaction initiale des dialkyldithiophosphates et dialkyldithiocarbamates cupriques avec l'hydroperoxyde de *tert*-butyl et l'hydroperoxyde d'α-cumène est un processus de radicaux libres en chaîne. L'initiation est obtenue par une réaction rédox entre le complexe et l'hydroperoxyde pour conduire aux radicaux alkoxy et alkylperoxy. Les radicaux alkoxy enlèvent alors un hydrogène de l'hydroperoxyde en excès pour conduire aux radicaux alkylperoxy. Il y a transformation des complexes cupriques en sulphate de cuivre par réaction des radicaux peroxy alors que l'hydroperoxyde est réduit en alcool. Il y a décomposition d'environ 5 mol d'hydroperoxyde par chaque mole de complexe. La décomposition de l'hydroperoxyde de *tert*-butyle s'arrête alors tandis que la destruction complète de l'hydroperoxyde d'α-cumène se produit par une réaction ionique hétérogène.

La cinétique de la réaction initiale est du second ordre pour les deux complexes. La réaction du dithiophosphate est du premier ordre par rapport à chaque réactif alors que la réaction du dithiocarbamate est d'ordre zéro par rapport à la concentration du complexe et du deuxième ordre par rapport à la concentration de l'hydroperoxyde. Des cinétiques simples ne s'appliquent toutefois que pour les vitesses initiales de disparition du complexe. La décomposition totale du dithiophosphate présente trois étapes: une étape initiale rapide suivit par une période d'induction en une troisième étape rapide. La profil de concentration en fonction du temps pour la décomposition du dithiocarbamate est très différente et la vitesse globale de réaction dans quelques cas augmente à mesure que la concentration de complexe diminue.

[Traduit par le journal]

Introduction

The previous paper in this series (1) described a kinetic and product study of the destruction of nickel dialkyldithiocarbamates and dialkyldithiophosphates by alkyl hydroperoxides which revealed that the overall reaction is principally a free radical chain process with at least five elementary reactions. It was suggested that the initial reaction involves electron transfer between the complex (A) and the hydroperoxide (ROOH) to generate alkoxy (RO•) and alkylperoxy (ROO•) radicals ([1] and [2]). In the

[1]NRCC No. 15859.

presence of excess hydroperoxide the alkoxy radicals abstract the hydroperoxidic hydrogen to give alcohol and peroxy radicals [3]. The peroxy radicals are then scavenged by reactions with the complex, reactions that are the major mode of complex destruction. Two peroxy radical-complex reactions were envisaged; a termination reaction [4] and an oxygen atom transfer reaction, [5], the latter being necessary to explain the fairly long chain lengths for induced hydroperoxide decomposition. The elementary reactions involved in the overall process are presented in Scheme 1.

$$\text{[1]} \quad A + ROOH \xrightarrow{k_1} A^{\cdot+} + RO^{\cdot} + {}^{-}OH$$

$$\text{[2]} \quad A^{\cdot+} + ROOH \rightarrow A + H^{+} + ROO^{\cdot}$$

$$\text{[3]} \quad RO^{\cdot} + ROOH \rightarrow ROH + ROO^{\cdot}$$

$$\text{[4]} \quad ROO^{\cdot} + A \rightarrow \text{Non-radical products}$$

$$\text{[5]} \quad ROO^{\cdot} + A \rightarrow Y^{\cdot}$$

SCHEME 1

where $Y^{\cdot}$ is the alkoxy radical $RO^{\cdot}$ or a radical derived from the ligand capable of abstracting the hydroperoxidic hydrogen from ROOH.

The analogous cupric complexes have received less attention than the nickel complexes. It is, however, known that they react rapidly with alkyl hydroperoxides and that at high ratios of hydroperoxide to complex, products characteristic of heterolytic hydroperoxide decomposition are formed (2, 3). Quantitative kinetic data and reaction products at different reactant ratios are, however, not available.

We have extended our work on metal complex – hydroperoxide reactions to include cupric dithiocarbamates and dithiophosphates and the results of a detailed study of these systems are reported here.

Experimental

Materials

Cupric dialkyldithiocarbamates and dialkyldithiophosphates were prepared by reaction of the sodium salt with copper sulphate. Crude complexes were recrystallized to give products with sharp melting points and satisfactory elemental analyses. The hydroperoxides and solvents were prepared and purified as described previously (1).

Kinetic Procedure

Cupric complex concentrations were monitored continuously using a Varian E-4 epr spectrometer equipped with a variable temperature accessory. In a typical experiment 30 μl of 10^{-2} *M* *tert*-butyl hydroperoxide in chlorobenzene were added to 270 μl of 10^{-4} *M* $Cu(Et_2NCS_2)_2$ in chlorobenzene agitated by a fine stream of argon. The variation in the complex concentration as a function of time was obtained either by scanning the esr spectrum at known intervals of time or by setting the field to coincide with the maximum absorption of the copper $M_I = -\frac{3}{2}$ or $-\frac{1}{2}$ transition with the field sweep switched off. The accumulation of cupric complex products was followed by identical procedures. *tert*-Butyl hydroperoxide concentrations were determined by iodometric titration on aliquots that had been pumped from the copper complex into a trap maintained at the temperature of liquid nitrogen. Control experiments showed that this hydroperoxide could be recovered in 100% yield by this procedure. Rates of hydroperoxide disappearance were also estimated by kinetic infrared spectroscopy $\nu = 3530$ cm^{-1}.

Products

Volatile organic products were identified by gas–liquid chromatography and yields were determined relative to standard authentic samples. Thin layer and liquid chromatography were used to investigate the formation of involatile organic products such as dialkylthiuram disulphides and *O*,*O*′-dialkyldithiophosphoryl disulphides. Copper sulphate was identified by X-ray analysis.

Results and Discussion

I. Cupric Dialkyldithiophosphates

Kinetics

Cupric diisopropyldithiophosphate, $Cu[(i\text{-}PrO)_2PS_2]_2$, is rapidly destroyed by excess *tert*-butyl hydroperoxide in argon saturated chlorobenzene at 30°C. Variations in the concentration of $Cu[(i\text{-}PrO)_2PS_2]_2$ as a function of time in the presence of 0.001 *M* and 0.01 *M* hydroperoxide are shown in Figs. 1*a* and 1*b*. It is apparent from these curves that $-d[Cu[(i\text{-}PrO)_2PS_2]_2]/dt$ is not a simple function of time but proceeds through three stages. There is an initial fast stage which decelerates to a slow second stage which is followed by a third fast stage.

Under these circumstances it is extremely difficult to obtain precise kinetic orders especially as the system has to be thoroughly mixed before measurements can be taken. Plots of ln $[Cu[(i\text{-}PrO)_2PS_2]_2]$ as a function of time during the first stage were, however, linear. Furthermore, initial rates of complex disappearance were approximately first-order with respect to each reactant (Table 1). The following rate law was, therefore, initially obeyed

$$\left(\frac{-d[Cu[(i\text{-}PrO)_2PS_2]_2]}{dt}\right) = k[Cu[(i\text{-}PrO)_2PS_2]_2][(CH_3)_3COOH]$$

with a 'best' value of $k \sim 2.4\ M^{-1}\ s^{-1}$.

Measurements of k over a temperature range

(253–300 K) gave the Arrhenius equation $\log (k/(M^{-1}\ s^{-1})) = 6.7 - 8.5/\theta$, where $\theta = 2.303RT$ kcal mol^{-1}.

The initial rate of disappearance of $Cu[(i\text{-}PrO)_2PS_2]_2$ was not influenced by oxygen ($\sim 10^{-3}$ M), *tert*-butyl alcohol, or the nature of the hydroperoxide (α-cumyl, α-tetralyl). It was, however, retarded by diisopropyldithiophosphoric acid, $(i\text{-}PrO)_2P(S)SH$, and completely inhibited by *O,O'*-diisopropyldithiophosphoryl disulphide $[(i\text{-}PrO)_2PS_2]_2$. Typical radical scavenging antioxidants such as 2,6-di-*tert*-butyl-4-methylphenol also retarded the initial rate of reaction. There was a very marked influence of solvent on $(-d[Cu[(i\text{-}PrO)_2PS_2]_2]/dt)_0$, the initial rate being a factor of ~25 times slower in benzene and toluene than in chlorobenzene.

The second stage or induction period, τ_{Cu}, began when 70–90% of the complex (depending on the initial ratio of complex to ROOH) had been destroyed. The length of the induction period was very approximately linearly dependent on the complex concentration and inversely proportional to the concentration of ROOH. Addition of *tert*-butyl alcohol to the initial reaction mixture had a marked influence on τ_{Cu} (Table 2).

It is impossible to obtain precise kinetic data for the disappearance of the hydroperoxide in this reaction. It did, however, appear to disappear faster than the complex when stoichiometric reactant concentrations were used.

Destruction of $(CH_3)_3COOH$ ceased when approximately ten times the initial complex concentration had been destroyed. For instance, $Cu[(i\text{-}PrO)_2PS_2]_2$ (10^{-3} M) was destroyed in ~4 h by $(CH_3)_3COOH$ (0.05 M), while the hydroperoxide concentration fell to 0.04 M and remained

TABLE 2. Influence of *tert*-butyl alcohol on the second stage of the destruction of cupric diisopropyldithiophosphate by *tert*-butyl hydroperoxide; $[Cu[i\text{-}PrO)_2PS_2]_2]_0 = 5 \times 10^{-5}$ *M*; $[ROOH]_0 = 10^{-2}$ *M*

unchanged for 20 days. The stoichiometric factor, $\Delta[ROOH]/\Delta[complex]$, is, therefore, approximately 10.

The *overall* behavior of cumene hydroperoxide was different in that a trace of $Cu[(RO)_2PS_2]_2$ (0.003 *M*) destroyed a large excess of hydroperoxide (0.05 *M*). In this case the disappearance of hydroperoxide followed a three stage reaction pattern analogous to the disappearance of $Cu[(RO)_2PS_2]_2$ but over a considerably longer period of time, *i.e.*, there was an initial fast reaction, a very slow second stage, and a fast third stage. Decomposition of cumene hydroperoxide by $Cu[(i\text{-}PrO)_2PS_2]_2$, therefore, gives a concentration–time profile similar to those observed by Burn *et al.* (4) for $Zn[(RO)_2PS_2]_2$–$C_6H_5C(CH_3)_2OOH$ systems.

Products

tert-Butyl hydroperoxide was quantitatively reduced by $Cu[(i\text{-}PrO)_2PS_2]_2$ to *tert*-butyl alcohol while the cupric ion was precipitated as copper sulphate. Oxygen was not formed in this reaction.

The major reaction products formed from decomposition of cumene hydroperoxide at different initial reactant ratios are summarized in Table 3. The only volatile organic products detected at low ratios of hydroperoxide to complex (runs 1 and 2) were α-cumyl alcohol, acetophenone, and α-methylstyrene with an alcohol to α-methylstyrene ratio of ~5.5 and an acetophenone to alcohol plus α-methylstyrene ratio of 0.1 to 0.2. α-Methylstyrene must arise by dehydration of α-cumyl alcohol and acetophenone by β-scission of cumyloxy radicals. We have shown that cumylperoxy radicals are reduced by $Cu[(RO)_2PS_2]_2$ to these three products.[4] Their formation in the present system is indicative of the intermediacy of cumyloxy and cumylperoxy radicals. It would, however, appear that only about 50% of the hydroperoxide decomposed could be accounted for as volatile organic products implying that the balance of the hydroperoxide derived products were somehow associated with the metal ion.

At higher ratios of hydroperoxide to complex (runs 3, 4, and 5) significant concentrations of phenol and acetone were formed by heterolysis of the hydroperoxide.[5] Heterolysis should give equal concentrations of these two compounds, a situation that was only realized in run 4. α-Methylstyrene, acetophenone, and α-cumyl alcohol were also formed at these reactant ratios. The ratio of α-cumyl alcohol to α-methylstyrene was quite low in these runs presumably because of enhanced dehydration of the alcohol by the Lewis acid responsible for hydroperoxide heterolysis.

The end of the first reaction stage was characterized by the precipitation of an insoluble fraction which was 50% $CuSO_4$ and a so far unidentified brown oil. A cumene hydroperoxide solution from which this precipitate had been removed by filtration was considerably more stable than the original reaction mixture. This precipitate did not decompose *tert*-butyl hydroperoxide whereas it did heterolytically decompose a fresh solution of cumene hydroperoxide.

Conclusions

The initial reaction between $Cu[(RO)_2PS_2]_2$ and ROOH is a free-radical chain process which obeys the rate laws,

$$-\frac{d[A]}{dt} = -\frac{1}{n}\left(\frac{d[ROOH]}{dt}\right) = k[A][ROOH]$$

with *n ca.* 5. The kinetics for this reaction are, therefore, identical with those for the analogous nickel complexes (1) with the value of *k* about an order of magnitude larger.

The reaction mechanism given in Scheme 1 explains most of the salient features of this reac-

[4]J. A. Howard and J. C. Tait, unpublished results.

[5]We have previously stated (1) that traces of nickel dialkyldithiophosphates and dialkyldithiocarbamates do not decompose cumene hydroperoxide to phenol and acetone. This is not strictly true as complete destruction of the hydroperoxide eventually takes place by a heterogeneous ionic process. We were, however, primarily concerned with the *initial* destruction of the complex by excess hydroperoxide which is a homolytic and not a heterolytic process.

tion. The reaction of ROO· with A is, however, better described by reactions 6 to 10 since n *ca.* 5

[6] $ROO\cdot + A \rightarrow RO\cdot + A_1$

[7] $ROO\cdot + A_1 \rightarrow RO\cdot + A_2$

[8] $ROO\cdot + A_2 \rightarrow RO\cdot + A_3$

[9] $ROO\cdot + A_3 \rightarrow RO\cdot + A_4$

[10] $ROO\cdot + A_4 \rightarrow$ Non-radical products

where A_1, A_2, A_3, and A_4 are oxidized forms of A. Under steady state conditions reactions 1 to 10 give the rate expressions presented above with $n = 5.5$ and $k = 2k_1$.

The nickel complexes did, however, appear to disappear completely by a pseudo first-order process in the presence of excess hydroperoxide (1) whereas $Cu[(RO)_2PS_2]_2$ did not disappear *completely* under these conditions. Instead, reaction ceased after a fraction of the complex had disappeared and commenced again after an induction period, τ_{Cu}. The dependence of τ_{Cu} on the reactant concentrations suggests the accumulation of radical scavengers in the system which prevents homolytic destruction of the chelate or to the regeneration of the complex at a rate equal to its rate of destruction.

The decomposition of $(CH_3)_3COOH$ by $Cu[(RO)_2PS_2]_2$ stops completely when the chelate has been destroyed and there is no evidence for heterolytic decomposition. The cumene hydroperoxide reaction initially follows a similar concentration–time profile; excess hydroperoxide is, however, eventually destroyed by a heterolytic process. The end of the homolytic reaction is marked by precipitation of an insoluble copper salt. In the case of *tert*-butyl hydroperoxide all the copper ions could be accounted for as copper sulphate while the precipitate produced by cumene hydroperoxide was more complex and contained organic ligands in addition to sulphate ions. This latter precipitate is the active catalyst for heterolytic decomposition of cumene hydroperoxide although it is not active enough to decompose *tert*-butyl hydroperoxide. This may be because cumene hydroperoxide undergoes O—O heterolysis while *tert*-butyl hydroperoxide undergoes C—O heterolysis (5).

Copper sulphate suspended in chlorobenzene does not decompose cumene hydroperoxide. It does, however, react with a mixture of diisopropyldithiophosphoric acid and *O,O'*-diisopropyldithiophosphoryl disulphide to give cupric diisopropyldithiophosphate although $CuSO_4$ does not react with these compounds individually. Yordanov and co-workers (6) have recently reported that production of $Cu[(RO)_2PS_2]_2$ from cupric salts and $[(RO)_2PS_2]_2$ requires the presence of a reductant. A reaction of this nature could be the reason for τ_{Cu}.

II. Cupric Dialkyldithiocarbamates

Kinetics

Cupric diethyldithiocarbamate was rapidly destroyed by excess *tert*-butyl hydroperoxide (see, *e.g.*, Fig. 2). Plots of ln $[Cu(Et_2NCS_2)_2]_t$ and $[Cu(Et_2NCS_2)_2]_t^{0.5}$ against time exhibited very pronounced downward curvatures indicative of a reaction that is neither first nor half-order in the complex concentration; in fact rates were close to zero-order. However, in many runs the rate increased as the complex was consumed. Changes in the hydroperoxide concentration had a pronounced effect on $(-d[Cu(Et_2NCS_2)_2]/dt)_0$ and the reaction was second-order in this reactant. Typical kinetic data for this system are presented in Table 4 and appear to support a rate expression of the form

$$-\frac{d[Cu(Et_2NCS_2)_2]}{dt} = k[ROOH]^2$$

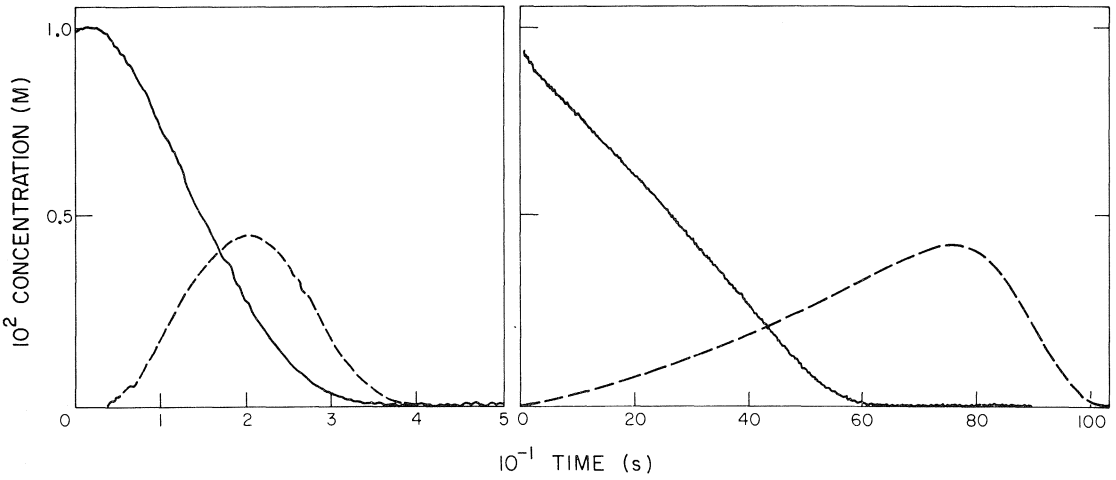

FIG. 2. The change in the concentration of $Cu[Et_2NCS_2]_2$ with respect to time after the addition of 0.11 *M* (*a*) and 0.011 *M* (*b*) $(CH_3)_3COOH$ at 30°C. The broken line illustrates the accumulation of the major transient Cu(II)product.

*Argon saturated chlorobenzene at 30°C.
†Air saturated chlorobenzene.
‡Containing 2,6-di-*tert*-butyl-4-methylphenol (0.2 *M*).

Oxygen, the nature of the non-coordinating solvent (toluene, chlorobenzene, and CCl_4), the nature of the alkyl groups in the dialkyldithiocarbamate ligands (Me, Et, *i*-Pr, and *n*-Bu), and the nature of the hydroperoxide (*tert*-butyl, α-cumyl, and α-tetralyl) had very little influence on $(-d[Cu(R_2NCS_2)_2]/dt)_0$.

The rate of disappearance of $Cu(i\text{-}Pr_2NCS_2)_2$ in the presence of excess *tert*-butyl hydroperoxide was inhibited by 2,6-di-*tert*-butyl-4-methylphenol. The initial inhibited rate was zero-order with respect to $Cu(i\text{-}Pr_2NCS_2)_2$ and second-order with respect to ROOH (Table 5). Inhibition by a radical scavenger is consistent with a reaction mechanism in which the principal mode of complex destruction is by alkylperoxy radical attack.

The initial rate of hydroperoxide disappearance was about 10 times faster than the initial rate of complex disappearance implying an induced decomposition with a stoichiometric factor of ~10.

The kinetics for the initial reaction of $Cu(R_2NCS_2)_2$ with alkyl hydroperoxides, zero-order in dithiocarbamate and second-order in ROOH, are anomalous when compared with the kinetics for destruction of $Ni(R_2NCS_2)_2$, $Ni[(RO)_2PS_2]_2$, and $Cu[(RO)_2PS_2]_2$. They imply that free-radical initiation is independent of the complex and occurs by decomposition of a hydroperoxide dimer. The copper complex then functions solely as a radical scavenger. Such an explanation is, however, unacceptable and we prefer to conclude at the present time that the apparent kinetics for this system are influenced by factors that are not immediately obvious. We should note that copper complex – hydroperoxide adducts have been invoked in these and related systems (7). We could, however, find no

esr evidence for the formation of such adducts since the isotropic and anisotropic spectra of $Cu(R_2NCS_2)_2$ were identical in the presence and absence of a large excess of ROOH.[6]

Products

tert-Butyl hydroperoxide was reduced quantitatively to *tert*-butyl alcohol by $Cu(Et_2NCS_2)_2$ while the dithiocarbamate was converted to $CuSO_4$ by excess hydroperoxide; no oxygen was evolved. The disappearance of the dithiocarbamate was accompanied by the appearance of a transient cupric complex, I (see Fig. 2). This complex had the isotropic esr parameters $g = 2.0651$ and $a_{Cu} = 77.1$ G, both parameters being different from those for $Cu(Et_2NCS_2)_2$ ($g = 2.0445$ and $a_{Cu} = 78.64$ G). The rate of appearance of this transient was equal to $(-d[Cu(Et_2NCS_2)_2]/dt)_0$ implying that it is the initial oxidation product. Its concentration reached a maximum when the dithiocarbamate had almost disappeared and it was then destroyed by excess ROOH. Vinogradova and Maizus (8, 9) have also observed the production of a transient cupric complex ($g = 2.066$, $a_{Cu} = 80.2$ G) during reaction of α-phenylethyl hydroperoxide with cupric hexamethyleniminedithiocarbamate and during the $Cu(Et_2NCS_2)_2$ inhibited autoxidation of ethylbenzene and have attributed it to the alkylperoxo dialkyldithiocarbamato copper, $PhCH(Me)OOCuS_2CNEt_2$, formed by displacement of $Et_2NCS_2^{\bullet}$ from the complex by $PhCH(Me)OO^{\bullet}$.

The concentration–time profiles for $Cu(Et_2NCS_2)_2$ and I for reaction of $Cu(Et_2NCS_2)_2$ (0.01 M) with less than a stoichiometric amount of *tert*-butyl hydroperoxide (0.056 M) are shown in Fig. 3. The carbamate was destroyed in approximately 700 s and at this time I had reached a maximum concentration and was then rapidly destroyed. There was then a period when two additional cupric complexes, with g-factors higher than I appeared in the esr spectrum of the reaction mixture, the total concentration of soluble Cu(II) species was, however, quite low during this period. The transient species I was then regenerated, reached a maximum concentration, and finally disappeared completely from the system. $Cu(Et_2NCS_2)_2$ was also regenerated and reached a steady-state concentration when about 75% of the initial concentration had been formed. A possible mechanism for regeneration of $Cu(Et_2NCS_2)_2$ in this system is reaction of diethyldithiuram disulphide, $(Et_2NCS_2)_2$, with cupric ions. Vinogradova and Maizus (9) have reported that this disulphide is formed during inhibition of ethylbenzene autoxidation by $Cu(Et_2NCS_2)_2$. However, their work suggests that it is not stable in the reaction mixture and follows a concentration–time profile that coin-

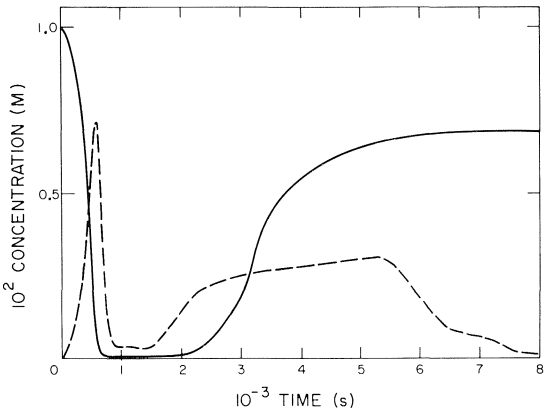

FIG. 3. The changes in the concentrations of $Cu(Et_2NCS_2)_2$ and the major transient Cu(II) product (broken line) during reaction of $Cu(Et_2NCS_2)_2$ (0.01 M) with $(CH_3)_3COOH$ (0.056 M) in argon saturated chlorobenzene at 30°C.

[6]NOTE ADDED IN PROOF—The ^{65}Cu hyperfine was studied on a 10^{-4} M $Cu[Et_2NCS_2]_2$ solution in toluene and 10 and 30% *tert*-butyl hydroperoxide – toluene from 263–233 K. The variation of the hyperfine with temperature was linear and identical for both solutions, the slope of $d|a_0|/dt > 0$ being characteristic for a non-coordinating solvent (F. G. Herring and R. L. Tapping, Can. J. Chem., **52**, 4016 (1974)). Line widths in both solutions were virtually identical.

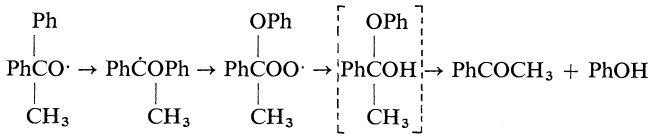
cides with the one for I. We were unable to positively identify $(Et_2NCS_2)_2$ at any stage of the reaction and are, therefore, reluctant to associate regeneration of $Cu(Et_2NCS_2)_2$ with this product.

α-Cumyl alcohol, α-methylstyrene, and acetophenone were the principal volatile organic products from decomposition of α-cumene hydroperoxide at ratios of hydroperoxide to complex less than 10. If, however, this ratio was greater than 10, phenol and acetone were formed and at ratios greater than 50 they were the major final reaction products[5] (Table 6). The accumulation of phenol and α-methylstyrene was followed during the decomposition of $C_6H_5C(CH_3)_2OOH$ (0.01 M) by $Cu(Et_2NCS_2)_2$ (0.0002 M). The concentration–time profiles are shown in Fig. 4 along with the disappearance of the complex. It is quite clear from these curves that α-methylstyrene is formed in the initial reaction whereas phenol is only formed after the complex has disappeared. An insoluble precipitate was deposited after the complex had been destroyed and if this precipitate was filtered from the solution the hydroperoxide was very much more stable. Heterolytic hydroperoxide decomposition is therefore, a heterogeneous process as was suggested by Burn *et al.* (4) for the $Zn[(RO)_2PS_2]_2$–cumene hydroperoxide system. The precipitate does not have the ability to decompose *tert*-butyl hydroperoxide but it does heterolytically decompose a fresh cumene hydroperoxide solution.

Decomposition of cumene hydroperoxide to α-cumyl alcohol, α-methylstyrene, and acetophenone is consistent with reactions 1–10 since reaction 3 gives the alcohol while [6]–[10] give alcohol, α-methylstyrene, and acetophenone[4].

Decomposition of 1,1-diphenylethyl hydroperoxide (0.02 M) by $Cu(i\text{-}Pr_2NCS_2)_2$ (0.01 M) gave 1,1-diphenylethanol (0.0085 M) 1,1-diphenylethylene (0.01 M), acetophenone (0.0026 M), and phenol (0.0023 M). The high yield of alcohol and its dehydration product in this system could be rationalized on the basis of a non-radical deoxygenation of the hydroperoxide analogous to that found with organosulphur compounds such as dialkyl sulphides (5). It is, however, much more likely that this alcohol arises from reaction of 1,1-diphenylethylperoxy radicals with the complex and reaction of 1,1-diphenylethoxy with the hydroperoxide.

The small yields of acetophenone and phenol could be the result of contribution from heterolysis of the hydroperoxide. 1,1-Diphenylethoxy radicals do, however, have a strong tendency to



undergo a 1,2-phenyl shift to give 1-phenoxy-1-phenylethyl (10). This radical could combine with oxygen to give the peroxy radical which would be deoxygenated and reduced to the alcohol by the complex. This alcohol would dissociate in solution to acetophenone and phenol.

We favor a homolytic mechanism for the production of acetophenone and phenol in this system because of the absence of a heterolytic process with cumene hydroperoxide at low ratios of hydroperoxide to complex.

Summary

Cupric dialkyldithiophosphates and dialkyldithiocarbamates are converted to copper sulphate by excess *tert*-butyl hydroperoxide while the hydroperoxide is reduced to *tert*-butyl alcohol. The principal reaction mechanism is homolytic with an induced decomposition of the hydroperoxide and destruction of the chelate by alkylperoxy radicals. The most plausible mode of initiation is a redox reaction between the hydroperoxide and complex. The overall behavior of an aralkyl hydroperoxide, such as cumene hydroperoxide, is affected by the formation of a heterogeneous product which is capable of catalyzing the ionic decomposition of cumene hydroperoxide but not *tert*-butyl hydroperoxide.

Simple reaction kinetics only hold for initial rates of complex disappearance. This is because secondary reactions influence the rate of reaction. In the case of the dithiophosphate the rate decelerates, stops completely, and increases rapidly to complete complex destruction. The rate of disappearance of the dithiocarbamate on the other hand appears to increase smoothly as the complex is consumed. The dithiocarbamate is converted to copper sulphate through at least three transient cupric complexes. These complexes are formed by reaction with alkylperoxy radicals and their structure and mechanism for their production will be discussed in a forthcoming publication.

Hydroxymethylbenzimidazole carboxylic acid models of the Asp-His-Ser charge relay system of serine proteases

J. Bryan Jones and Keith E. Taylor

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 1, 1976

J. Bryan Jones and Keith E. Taylor. Can. J. Chem. **55**, 1653 (1977).

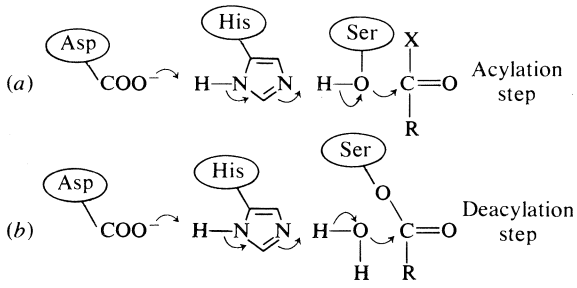
2-Hydroxymethyl- and 2-acetoxymethylbenzimidazole, and their *C*-4(7)-carboxy derivatives, have been synthesized and characterized for evaluation as chemical models of the Asp-His-Ser triad present at the active sites of several serine proteases. Preliminary studies of the 2-acetoxy compounds, which are analogues of the acyl enzymes, show that the rate of hydrolysis is augmented only 2.5 fold by the carboxylate group of the model charge relay system.

J. Bryan Jones et Keith E. Taylor. Can. J. Chem. **55**, 1653 (1977).

On a synthétisé et caractérisé, pour leur évaluation comme modèle chimique de la triade Asp-His-Ser présente au niveau des sites actifs de plusieurs protéases sérines, les hydroxy-2 méthyl- et acétoxy-2 méthylbenzimidazoles et leurs dérivés *C*-4(7) carboxy. Des études préliminaires sur des composés acétoxy-2, qui sont des analogues des enzymes acyles, montrent que la vitesse d'hydrolyse n'est augmenté que par 2.5 fois par le groupe carboxylate du modèle de système de relais de charge.

[Traduit par le journal]

The serine proteases are hydrolytic enzymes which possess a uniquely reactive serine hydroxyl group at the active site. Although the individual amino acid sequences can be quite dissimilar, the active sites of the enzymes for which X-ray structures are available, *viz.* α-chymotrypsin (1), trypsin (2), elastase (3), and subtilisin (4*a*), each possess an Asp-His-Ser triad in more or less the same geometrical arrangement. This triad has become known as the charge relay system of the serine proteases. Based largely on the chymotrypsin data (1, 5), the operation of the catalytic triad has been interpreted in the manner represented in Scheme 1.[1]



SCHEME 1

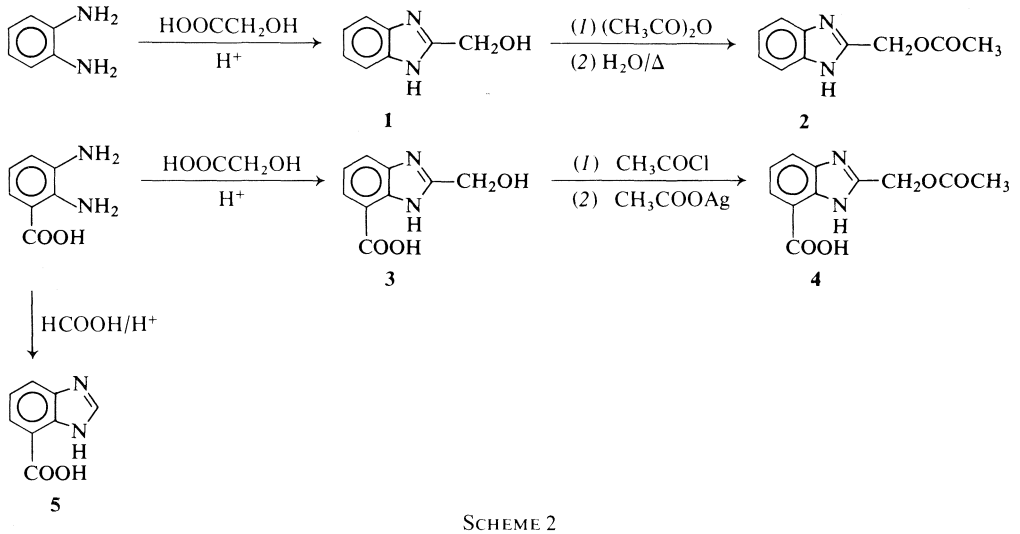
The degree to which the carboxylate function is capable of acting as a general base in the Scheme 1 manner is a question which is receiving increasing attention and several model studies have been reported recently (8–11). We felt that benzimidazole derivatives such as **1**–**4**, would serve as good chemical models for the Scheme 1 systems. This paper reports mainly on their synthesis and properties. Some very preliminary data on the rates of deacylation of **2** and **4** have also been obtained.

Results

The benzimidazole derivatives required were prepared in 60–90% yields as outlined in Scheme 2. The dissociation constants of their functional groups were then determined; the pK_a values obtained are summarized in Table 1. The abnormally low pK_{a_1} of **4** was obtained under conditions where $-\log [\mathbf{4}] > pK_a$ and thus may be somewhat insecure (13). However the pK_{a_2} value for **4** is considered reliable.

The rate constants for hydrolysis of the 2-acetoxybenzimidazole derivatives **2** and **4** were determined under pseudo first-order conditions for several half-lives. Data following 15–50% of reaction were used to calculate the rate constants; the same values were obtained when the hydrolyses were allowed to progress up to 80% completion. The results are summarized in Table 2. The fact that hydrolyses of **2** and **4** under the Table 2 conditions were proceeding as expected was confirmed by the isolation of **1** and **3** respectively in >80% yields.

[1]The exact nature of the mechanism of the charge relay system continues to be the topic of considerable debate, particularly with respect to assigning the role played by the asparatate carboxyl(ate) group (1*a*,*b*, 6, 7).



SCHEME 2

TABLE 1. Dissociation constants of benzimidazole derivatives*

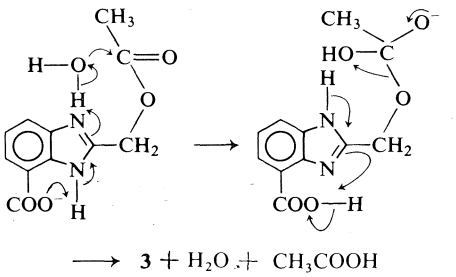
Compound	pK_{a_1}	pK_{a_2}
Benzimidazole	5.54±0.02 (5.55 (12))	
1	5.41±0.01 (5.40 (13))	
2	4.54±0.02†	
3·HCl	3.51±0.06†	5.61±0.01†
4	2.23±0.27†	4.85±0.12†
5·HCl	3.21±0.03†	5.52±0.03†

*Dissociation constants were determined at 25°C in aqueous solution.
†Solution 1% v/v in DMSO.

Discussion

Each of the benzimidazoles **1**–**5** was readily prepared. The heterocyclization steps, effected under Phillips-type conditions (14–16), all proceeded in high yield. Selective hydrolysis of the *N*,*O*-diacetyl precursors of **2** and **4** was also achieved without difficulty.

The selection of carboxybenzimidazole structures as suitable models for the Asp-His-Ser triad of serine proteases was influenced by several considerations, including the well-documented evidence for the abilities of imidazoyl and carboxyl groups to participate in hydrolysis reactions (17–20). Furthermore, benzimidazole derivatives have been employed previously in hydrolysis studies (21–24). Analysis of Dreiding models of **4** indicated that the carboxyl-oxygen to N-1 and hydroxymethyl-oxygen to N-3 distances were close to those reported for the His-57-$N^{\delta 1}$ to $O^{\delta 2}$ of Asp-102 (2.8 Å) and His-57-$N^{\varepsilon 2}$ to Ser-195-O^{δ} (3.0 Å) separations in chymotrypsin (1*c*). Charge relays of the Scheme 1 type are thus possible; one possible analogue of the first step of deacylation is depicted in Scheme 3.



SCHEME 3

Benzimidazole-4(7)-carboxylic acids of this kind have a natural inclination towards intramolecular alignments of the type required for a Scheme 3 orientation as a result of zwitterion formation (25). Analyses of the dissociation constants of Table 1 provide further support for this view. The overall pK_a values are consistent with a Scheme 4 ionization pathway, with the strongly electron-withdrawing protonated imidazolium moiety of **6** perturbing the normal dissociation constant of the carboxyl group. In contrast, the carboxylate group of zwitterions such as **7**[2] has little effect on the imidazolium

[2]The alternative ionization pathway, with the imidazolium group dissociating first merely as a consequence of the presence of a C-4(7) carboxyl group, is extremely improbable. For example, as strong an electron-withdrawing group as nitro is needed at the C-4(7) position in order to induce a lowering of the benzimidazolium pK_a by 2–2.5 units (12).

TABLE 2. Rates of hydrolysis of **2** and **4***

Substrate	p*H*	k ($s^{-1} \times 10^5$)	k_{H_2O} ($s^{-1} \times 10^5$)	k_{-OH} (M^{-1} s^{-1})	k_{H_2O} (**4**:**2**)	k_{-OH} (**4**:**2**)
2	8.0	0.75±0.02	0.62	1.3

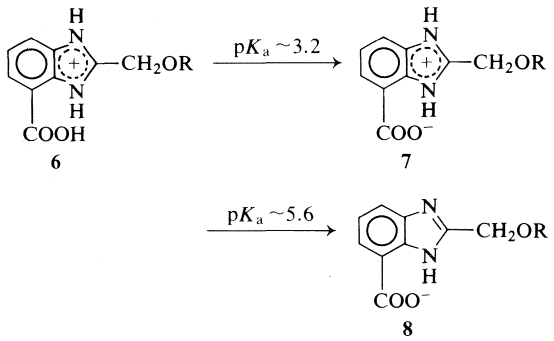
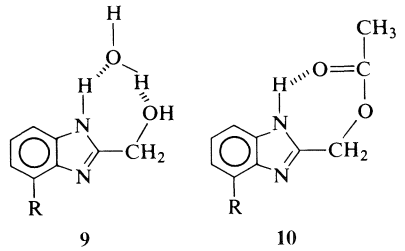


SCHEME 4

ionization. The Table 1 data are consistent with stabilization due to intramolecular hydrogen bonding of zwitterionic forms such as **7** over the corresponding anions **8**.

The Table 1 data also suggest that the CH_2OH and CH_2OCOCH_3 groups of the model compounds maintain themselves in Scheme 3 type orientations. Acetylation of the CH_2OH groups of **1** and **3** results in a lowering of the benzimidazole pK_a by ~0.8 units.[3] This degree of pK_a reduction suggests differential hydrogen bonding as in **9** and **10**. Solvent bridging as in **9** has been invoked previously to account for the low pK_a values of furan- (27) and pyrrole-2-carboxylic acids (24, 28).



Comparison of the rates of hydrolysis of **2** and **4** shows attack by water of the acyl enzyme model **4** to be only 2.5-fold faster than for **2**, which lacks the *C*-4(7)-carboxyl(ate) function.[4] The true degree of intramolecular acceleration attributable to carboxylate participation may in fact be even smaller than 2.5-fold since no attempt was made to correct for nitrogen basicity differences between **2** and **4** nor to exclude possible effects of elimination pathways (10*b*). Carboxylate participation is evidently not significant under the current assay conditions.[5]

Experimental

All starting chemicals were purchased from Fisher or Aldrich. Nuclear magnetic resonance spectra were obtained on Varian A-60 or T-60 instruments, ir spectra on a Perkin-Elmer 237 spectrophotometer, and mass spectra using an AEI MS-9 spectrometer. Elemental analyses were by A. B. Gygli, Toronto.

2-Hydroxymethylbenzimidazole (1)

O-Phenylenediamine (6 g, 56 mmol) and glycolic acid (6.33 g, 84 mmol) were reacted according to the procedure of Copeland and Day (31) to give a 63% yield of **1**, mp 174–175°C (lit.(31) mp 171–172°C); ir (KBr) 3280, 1062, and 1047 cm^{-1}; nmr (CF_3COOH) δ 5.42 (s, 2H) and 7.70 (m, 4H); (DMSO-$^2H_6$) δ 4.74 (s, 2H) and 7.35 (m, 4H) ppm; ms *m/e* 149.

2-Acetoxymethylbenzimidazole (2)

The procedure used was based on that of Porai-Koshits (32). A solution of 2-hydroxymethylbenzimidazole (**1**; 4.83 g, 32.6 mmol), acetic anhydride (6.5 ml, 69 mmol) and acetic acid (7 ml) was heated for 35 min on a steam bath and then chilled, diluted with water, and filtered. The *N*-1-acetyl-2-acetoxymethylbenzimidazole (5.9 g, 78%) obtained had mp 99–100°C (lit. (32) mp 97–98°C); ir ($CHCl_3$) 1722–1750 cm^{-1} (broad); nmr (C^2HCl_3) δ 2.20 (s, 3H), 2.79 (s, 3H), 5.54 (s, 2H), and 7.52 (m,

[3]A similar acid-strengthening effect has been reported when Ser-195 of chymotrypsin is acetylated (26).

[4]This degree of intramolecular acceleration is of the same magnitude as that observed for the structurally similar (2′-hydroxyphenyl)imidazole models (10*a*). Much larger accelerating effects have been attributed to carboxylate participation in intermolecular model systems (8, 9, 11) but questions have been raised (9*b*, 10*a*) with respect to the relevance of these results to the charge relay hypothesis. Estimates of the maximum rate enhancements to be expected from Asp-COO^- participation in a charge relay triad range from 10 (29) to 5000 (30)

[5]Larger effects should be observed in hydrophobic media.

4H) ppm. This diacetyl compound (5.70 g, 22.6 mmol) and water (20 ml) were refluxed for 10 min and the mixture chilled in ice and scratched to furnish 2-acetoxymethylbenzimidazole (**2**; 3.47 g, 79%), mp 165–166°C (lit. (32) mp 164–165°C); ir ($CHCl_3$) 3442 and 1730 cm^{-1}; nmr (C^2HCl_3) δ 2.05 (s, 3H), 5.40 (s, 2H), and 7.45 (m, 4H) ppm.

2,3-Diaminobenzoic Acid

2-Methyl-6-nitroaniline was acetylated by the procedure of James *et al.* (33) to give a 91% yield of 2-acetamino-3-nitrotoluene, mp 160–161°C (lit. (33) mp 157–158°C); ir ($CHCl_3$) 3445, 1700, 1514, 1480, and 1350 cm^{-1}; nmr (C^2HCl_3) δ 2.18 (s, 3H), 2.30 (s, 3H), and 7.50 (m, 3H) ppm. This was then oxidized with $KMnO_4/MgSO_4$ (31) to give 2-acetamino-3-nitrobenzoic acid (90% yield) which was recrystallized from EtOH and had mp 254–255°C (lit. (33) mp 245°C); ir (Nujol) 3315–2500, 1691, 1513, and 1350 cm^{-1}; nmr (DMSO-$^2H_6$) δ 2.09 (s, 3H), 2.53 (m, 1H), 7.35 (t, J = 7 Hz, 1H), and 8.24 (d, J = 7 Hz, 1H) ppm. The above acetamino compound (32.1 g, 143 mmol) in 5% (v/v) aqueous hydrochloric acid (200 ml) was refluxed for 1 h and then concentrated and cooled. The 2-amino-3-nitrobenzoic acid (94% yield) was recrystallized from water; it had mp 208.5–209°C (lit. (33) mp 205°C); ir ($CHCl_3$) 3470, 3357, 1688, 1559, and 1351 cm^{-1}; uv (MeOH) 234 (ε 13 870), 262 (ε 4940), and 412 nm (ε 6590); nmr (DMSO-$^2H_6$) δ 5.50 (br), 6.76 (t, J = 7 Hz, 1H), and 8.2–8.4 (m, 2H) ppm. 2-Amino-3-nitrobenzoic acid (4.0 g, 22 mmol), $SnCl_2 \cdot 2H_2O$ (15.2 g, 68 mmol), and concentrated hydrochloric acid (25 ml) were heated to 50°C on a steam bath and then placed in an ice bath to maintain the exothermic reaction at 100°C. The solution was then heated for 15 min on the steam bath, cooled, and poured into a solution of NaOH (18.5 g) in water (60 ml). The mixture obtained (pH 7) was filtered and the filtrate brought to pH 1 with concentrated hydrochloric acid. The precipitate of 2,3-diaminobenzoic acid hydrochloride (2.5 g, 75%) was filtered and sublimed (0.5 torr, 100°C) to give material mp 196–198°C (lit. (34, 35) mp 190–191°C (dec.), 201°C (dec.)); ir (Nujol) 3410, 3320, and 1670 cm^{-1}; nmr (DMSO-$^2H_6$) δ 5.73 (broad s, ^2H_2O exchangeable), 6.67 (t, J = 7.7 Hz, 1H), 7.39 (d of d, J = 1.8, 7.7 Hz, 1H), and 7.70 (d of d, J = 1.8, 7.7 Hz, 1H) ppm.

*2-Hydroxymethylbenzimidazole-4(7)-carboxylic Acid (**3**)*

A solution of freshly-sublimed 2,3-diaminobenzoic acid (2.11 g, 13.9 mmol), glycolic acid (3.2 g, 42 mmol), and 4 M aqueous hydrochloric acid (40 ml) was refluxed for 2 h under N_2 and then cooled in ice. The precipitated solid (2.97 g, 94%) was recrystallized twice from 0.5 M aqueous hydrochloric acid, and then thrice from methanol–acetone (1:3) to give **3**·HCl mp > 280°C; ir (KBr) 1695 cm^{-1}; nmr (DMSO-$^2H_6$) δ 5.13 (s, 2H), 7.67 (d of d, J = 2, 6 Hz, 1H), 8.04 (br s, 1H), and 8.15 (d, J = 1.5 Hz, 1H) ppm; ms m/e 193. *Anal.* calcd. for $C_9H_9N_2O_3Cl$: C 47.28, H 3.97, N 12.25, Cl 15.51; found: C 47.29, H 4.04, N 12.14, Cl 15.45.

The methyl ester was prepared by treatment of **3** with diazomethane. After recrystallization from methanol it had mp 166–167°C; ir (KBr) 1690 cm^{-1}; nmr (DMSO-$^2H_6$) δ 3.87 (s), 4.77 (s), and 7.82 (m) ppm; ms m/e 205. *Anal.* calcd. for $C_{10}H_{10}N_2O_3$: C 58.24, H 4.89, N 13.59; found: C 58.46, H 5.06, N 13.41.

*2-Acetoxymethylbenzimidazole-4(7)-carboxylic Acid (**4**)*

2-Hydroxymethylbenzimidazole-4(7)-carboxylic acid hydrochloride (**3**·HCl; 1.21 g, 5.3 mmol) and acetyl chloride (45 ml) were heated for 18 h at 50°C and then concentrated to ~2 ml. The solid which separated was collected (1.49 g); a portion (1 g) was then redissolved in acetic acid and silver acetate was added until no further precipitate formed. The mixture was filtered and the filtrate concentrated to give **4** (515 mg, 61%) mp > 290°C; ir (KBr) 2940–3220, 1729, 1718, and 1686 cm^{-1}; nmr (DMSO-$^2H_6$) δ 2.22 (s, 3H), 5.33 (s, 2H), 7.32 (m, 1H), 7.82 (m, 1H), and 7.95 (m, 1H) ppm; ms m/e 234.0656 (calcd. 234.0641). *Anal.* calcd. for $C_{11}H_{10}N_2O_4$: C 56.41, H 4.30, N 11.96; found: C 56.26, H 4.40, N 11.92.

*Benzimidazole-4(7)-carboxylic Acid (**5**)*

Freshly-sublimed 2,3-diaminobenzoic acid (1.51 g, 9.9 mmol), formic acid (1.20 ml, 29.7 mmol), and 4 M aqueous hydrochloric acid (24 ml) were refluxed for 1 h under N_2 (24, 25). The cooled mixture was then filtered and the precipitate (1.45 g, 73%) was recrystallized from 0.5 M aqueous hydrochloric acid to give **5**·HCl, mp > 300°C (lit. (34) mp > 360°C); ir (KBr) 2865–3570 and 1710 cm^{-1}; nmr (DMSO-$^2H_6$) δ 7.74 (t, J = 8 Hz, 1H), 8.22 (m, 2H), 9.78 (s, 1H), and 12.73 (br, 1H) ppm.

The methyl ester was obtained by reaction of **5**·HCl with diazomethane, mp 214–215°C; ir ($CHCl_3$) 3460, 1730, and 1697 cm^{-1}; nmr (DMSO-$^2H_6$), δ 3.98 (s, 3H), 7.36 and 7.95 (m, 3H), and 8.36 (s, 1H) ppm; ms m/e 176. *Anal.* calcd. for $C_9H_8N_2O_2$: C 61.35, H 4.58, N 15.90; found: C 60.53, H 4.42, N 16.21.

Determination of Dissociation Constants

The dissociation constants of benzimidazole and compounds **1**–**5** were determined by the method of Albert and Serjeant (13). Titration curves for 2–10 mM solutions of substrates, which were also 0.1 M in KCl, against 0.1–0.25 M aqueous NaOH were obtained under N_2 at 25°C using a Radiometer pH-stat. The solutions of **2**–**5** also contained 1% (v/v) DMSO to aid solubility.

*Rates of Hydrolysis of **3** and **4***

The rates of hydrolysis of **3** and **4** were determined, at least in duplicate, at 25°C under N_2 on 0.7–1.5 mM substrate solutions maintained at the selected pH (8 or 10) by automatic addition of 0.05 M aqueous NaOH with a Radiometer pH-stat. The reaction solutions were made up by injecting 100 μl of a DMSO stock solution of **3** or **4** into 10 ml of CO_2-free water. The data were analyzed by linear regression analysis, pseudo first-order plots with correlation coefficients > 0.996 being obtained. The pH 10 results were corrected for base uptake by the glass electrode (36–38). The observed and derived (from $k_{obs} = k_{H_2O} + k_{-OH}[^-OH]$) rate constants are summarized in Table 2. The hydrolysis products, **1** and **2** respectively, of **3** and **4** under the Table 2 conditions were isolated in > 80% yields from representative kinetic runs.

The adsorption, desorption, and exchange reactions of oxygen, hydrogen, and water on platinum surfaces. III. Water adsorption and exchange with oxygen and hydrogen

Y. K. PENG AND P. T. DAWSON

Chemistry Department and Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 30, 1976

Y. K. PENG and P. T. DAWSON. Can. J. Chem. **55**, 1658 (1977).

Ultra-high vacuum thermal desorption experiments have been carried out on the adsorption of water, and the D_2O/H and $D_2{}^{16}O/{}^{18}O$ exchange reactions on platinum previously characterized by oxygen and hydrogen adsorption studies. Water is weakly adsorbed and only at $T <$ 150 K, an observation confirmed by using H_2 adsorption as a chemical probe for the presence of adsorbed water. The thickness of the adsorbed D_2O layers was determined by a novel method involving monitoring the power output of the temperature programmer. Exchange occurs between adsorbed H and a D_2O overlayer and the extent of exchange increases with the thickness of the overlayer. Isotope distribution studies show that the surface is heterogeneous and the exchange reaction does not occur at uniform rate. Exchange occurs between adsorbed ^{18}O and a $D_2{}^{16}O$ overlayer. The extent of exchange is constant up to $T \sim 300$ K showing that D_2O is more strongly bound on O-covered Pt presumably as a result of H bonding. Heterogeneity also is apparent in the O-exchange reaction. The apparent activation energies for exchange are 1.8 and 2.9 kcal mol^{-1} for the half- and fully-covered surfaces, respectively.

Y. K. PENG et P. T. DAWSON. Can. J. Chem. **55**, 1658 (1977).

On a effectué des expériences de désorption thermique sous de très hauts vides au sujet de l'absorption de l'eau et des réactions d'échange D_2O/H et $D_2{}^{16}O/{}^{18}O$ sur du platine qui avait été caractérisé antérieurement par des études d'adsorption d'oxygène et d'hydrogène. L'eau n'est que faiblement adsorbée et uniquement à des températures < 150 K; cette observation est confirmée en faisant appel à l'adsorption de H_2 comme sonde chimique pour la présence d'eau adsorbée. On a déterminé l'épaisseur des couches de D_2O absorbé par une nouvelle méthode impliquant la mesure de la puissance fournit par le programmeur de température. Il se produit des échanges entre de l'hydrogène adsorbé et une couche superposée de D_2O et la quantité d'échange augmente avec l'épaisseur de la couche superposée. Des études de distribution isotopique montrent que la surface est hétérogène et que la réaction d'échange ne se produit pas à une vitesse uniforme. Les réactions d'échange se produisent entre du ^{18}O adsorbé et une couche superposée de $D_2{}^{16}O$. La quantité d'échange est constante jusqu'à environ 300 K ce qui démontre que le D_2O est adsorbé d'une façon plus forte sur du platine couvert d'oxygène et que ce fait résulte probablement d'un lien hydrogène. L'hétérogénéité est aussi apparente dans la réaction d'échange d'oxygène. Les énergies d'activation apparentes pour les échanges sont respectivement de 1.8 et de 2.9 kcal mol^{-1} pour les surfaces à moitié et complètement couvertes.

Introduction

Platinum dispersed on oxide supports is an extremely important practical catalyst. The activity of such catalysts will be determined, in part, by the degree of dispersion of the platinum on the support, *i.e.* the number of exposed platinum atoms per unit area. This important parameter is frequently determined by titration of preadsorbed O_2 with H_2 (1–3). However, many details concerning the correct application of this method remain controversial. In particular, there is considerable disagreement concerning the correct stoichiometry to use for hydrogen chemisorption, oxygen chemisorption, and titration experiments and the relative merits of these methods for determining the dispersion (1–10). Whether or not all the oxygen adsorbed on platinum can be reduced and whether water remains strongly bound to unreacted oxygen or the support or both remain unanswered questions. An enhancement in the uptake of hydrogen by oxygen pretreatment has been inferred from infrared studies on supported catalysts (11–13) and attributed to adsorption of water on the support (11), or re-arrangement of the platinum atoms (12). However, some observations (11) have subsequently been attributed to complications caused by CO impurities (12, 13).

Infrared studies have also been interpreted by the suggestion that the reaction of oxygen with preadsorbed hydrogen produces adsorbed Pt—OH but OH is not formed by either the reverse reaction or the adsorption of water on untreated platinum (14).

In this paper, ultra-high vacuum thermal desorption mass spectrometry experiments on the adsorption of water and the exchange reactions of oxygen and hydrogen with water are described for a pure platinum sample without an oxide support. The sample used has been previously characterized by oxygen and hydrogen adsorption (15, 16). Among the conclusions drawn from this work are that water is very weakly adsorbed on pure platinum but more strongly adsorbed on oxygen-covered platinum.

Experimental Methods

Apparatus

The ultra-high vacuum system used in this work is similar to that described previously (17). The reaction cell, shown schematically in Fig. 1, can be completely immersed in liquid nitrogen. The sample filament, a 12 cm length of 0.01 in. diameter platinum wire (Johnson, Matthey, and Mallory, Grade I), equipped with 0.003 in. diameter platinum sensing leads for temperature measurement and control, was spot welded to heavy tungsten leads. This sample was from the same spool and processed in the same way as that described in papers I and II of this series (15, 16).

Gas Purification

Hydrogen was purified by diffusion through palladium. Oxygen, $^{18}O_2$, with a specified isotopic purity of 99%, was supplied in a Pyrex flask with a break–seal by Stohler Isotope Chemicals and was used without further purification.

Heavy water, D_2O, used exclusively in this work, was supplied by Thompson-Packard Inc. with an isotopic purity of 99.8%. It was pre-purified by vacuum distillation in a bakeable vacuum line and stored in a small Pyrex flask with a break–seal. After this flask had been attached to the system and the system baked out up to the break–seal, further purification was carried out by repeated freezing of the D_2O and pumping. Mass spectrometric analysis showed that D_2O purified in this manner was accompanied by considerable amounts of CO and CO_2 when admitted into the system. The CO and CO_2 may have been present in the purified D_2O or generated within the system when the D_2O came into contact with the stainless steel and glass walls of the system.

In an attempt to further purify the water it was distilled three times over potassium permanganate before carrying out the vacuum distillations described above. However, there was no improvement in the CO and CO_2 contamination level in the system.

The CO and CO_2 contamination is a complication which restricts the type of experiment which can be performed. Thus, on opening valves A and B of Fig. 1 to introduce D_2O into the system, one observes an increase in first the CO and then the CO_2 partial pressures preceding the appearance of D_2O. In such experiments the sample surface would have been contaminated with CO and CO_2 before D_2O adsorption could occur. This problem was minimized in the following way. First a small amount of D_2O was trapped at 77 K in cold finger C and any permanent gases were pumped out. Then the liquid nitrogen coolant was removed for a time period just long enough for the evaporation of CO and CO_2. This was controlled by monitoring the CO and CO_2 partial pressures in the system with the mass spectrometer. Just prior to D_2O evaporation the cold finger was again immersed in liquid nitrogen. This procedure was repeated many times until most of the CO and CO_2 had been removed. It was found that this procedure was more effective the thinner the ice layer. Prior to the introduction of D_2O into the system for dosing, the liquid nitrogen surrounding C was replaced by a Dry Ice/acetone bath. D_2O was dosed onto the platinum sample filament by evaporation from the walls of the reaction cell and thus the total dose was determined by the amount of D_2O introduced into the cell. In this work three different procedures were used to control the size of the dose; in order of increasing magnitude these were as follows:

(*I*) With C immersed in Dry Ice/acetone, valve B was opened for 5 min to allow the D_2O pressure in the cell to come to the equilibrium value corresponding to 195 K, *i.e.* $\sim 10^{-4}$ Torr. Finally, the Dry Ice/acetone bath was replaced by liquid nitrogen and the D_2O trapped for 30 min before closing valve B.

(*II*) This procedure was identical to (*I*) except for the omission of the final trapping step. Consequently the D_2O pressure in the cell was $\sim 10^{-4}$ Torr.

(*III*) The final method used was to remove the Dry Ice/acetone bath from C with valve B open for a desired period of time; this time period determined the size of the subsequent D_2O dose on the sample.

The D_2O was trapped as a thin layer on the reaction

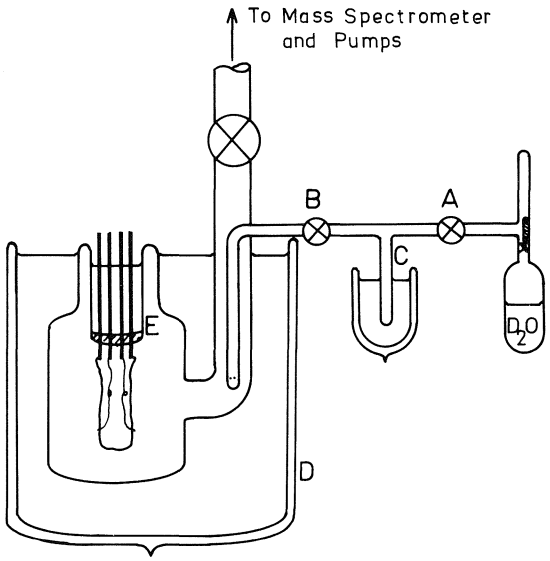

FIG. 1. Schematic diagram of the reaction cell and dosing system.

cell walls by completely surrounding the cell with liquid nitrogen in Dewar D and the procedure described above for removing CO and CO_2 was again repeated several times. Then, with the reaction cell completely immersed in liquid nitrogen, the sample filament was finally flashed clean. The sample surface was dosed with D_2O by removing the liquid nitrogen Dewar D, but leaving Dewar E filled, to keep the filament at low temperature. Consequently, more of the D_2O evaporating from the wall condensed on the larger area of the cold glass surface than on the platinum filament. Monitoring masses 28 and 44 during desorption showed that this dosing procedure successfully reduced the CO and CO_2 contamination to an acceptable level.

Results and Discussion

D_2O Adsorption on Platinum

Mass 20, D_2O, desorption spectra obtained after D_2O adsorption at several platinum filament temperatures in the range 100 to 300 K are shown in Fig. 2. These spectra were all obtained with the reaction cell walls at room temperature, but Dewar E was filled with liquid nitrogen. Consequently, desorbed water was pumped by this cold glass surface. Nevertheless some desorbed D_2O does reach the mass spectrometer as can be seen in spectra (*a*) and (*e*) for adsorption at 100 K. Spectra (*a*)–(*d*) were obtained after a relatively light dose of D_2O using procedure (*II*), *i.e.* the total amount of D_2O in the cell corresponded to a pressure of $\sim 10^{-4}$ Torr, whereas spectrum (*e*) was for a much heavier D_2O dose using procedure (*III*) with the Dry Ice/acetone bath removed for 10 min. It should be noted that a D_2O desorption peak only appears in spectra (*a*) and (*e*) for adsorption at 100 K, and that desorption occurs in the range 150–270 K. The high D_2O partial pressure during desorption caused a reduction in the mass spectrometer emission current which is partly responsible for the rapid decrease in the D_2O peak in spectrum (*e*). Mass 4 has also been monitored during these experiments and no D_2 desorption was observed. These results show that water is adsorbed weakly and nondissociatively on platinum and only at temperatures below 150 K. This is in agreement with recent field emission (18) and photoelectron spectroscopic observations (19). There is no evidence to support a strong adsorption of water at 300 K which has been deduced from contact potential measurements (20), calorimetry (1), and thermal desorption experiments (21) or assumed without verification (7).

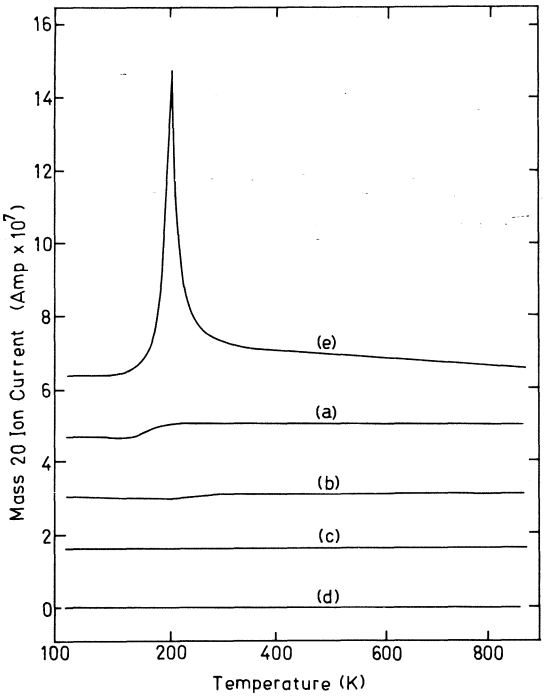

FIG. 2. I_{20}^+ desorption spectra following D_2O adsorption. Spectra (*a*) to (*d*) were for a light dose using procedure (*II*) at 100, 150, 200, and 300 K and spectrum (*e*) followed a heavy dose at 100 K using procedure (*III*) for 10 min. Heating rate 14 deg s^{-1}, curves offset.

H_2 Adsorption on Preadsorbed D_2O

In these experiments, H_2 adsorption was used as a chemical probe for the presence of D_2O on the platinum surface. The D_2O dose was carried out following procedure (*II*) in an identical manner to that used for spectra (*a*) to (*d*) of Fig. 2, but with the sample filament at $\sim$90 K in each case. The reaction cell was next surrounded by liquid nitrogen and then H_2 admitted up to a pressure of 10^{-5} Torr. The sample filament was flashed to 100, 150, 200, or 300 K for 10 s and then allowed to cool to 100 K for 4 min. After pumping out the H_2 from the cell, thermal desorption spectra were obtained with the cell walls at 77 K, monitoring masses 2, 3, and 4 simultaneously. These spectra, shown in Fig. 3, confirm the observation that water is only weakly adsorbed on a platinum surface and only at temperatures below 150 K. It can be seen that H_2 adsorption only occurs to a significant extent at 150 K and higher temperatures and thus does not take place on the D_2O-covered platinum surface. The small de-

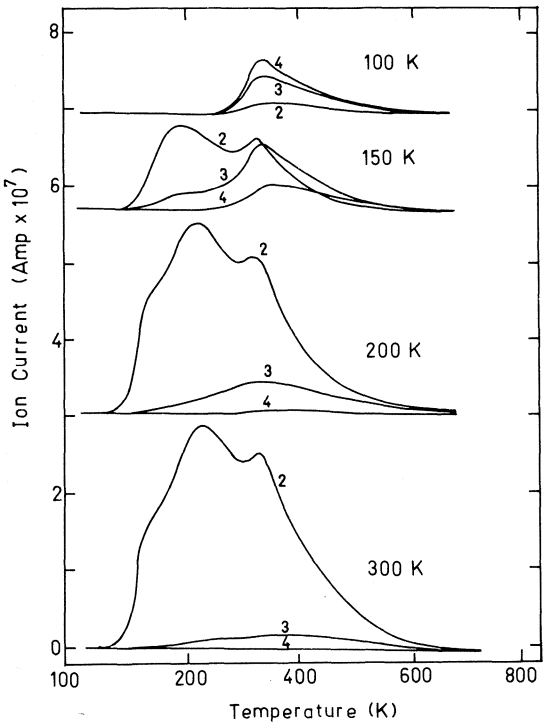

FIG. 3. I_2^+, I_3^+, and I_4^+ desorption spectra following interaction of H_2 with preadsorbed D_2O after heating to the temperatures indicated with the cell wall at 77 K. Heating rate 14 deg s^{-1}, curves offset.

sorption peaks observed after interaction at 100 K are caused by adsorption of background hydrogen gas into the β_3- and β_4-states (16) during the cooling period. This was confirmed by performing a thermal desorption experiment immediately after the filament had cooled to 100 K and without dosing either D_2O or H_2. Also note that the amount of hydrogen observed after adsorption at 150 K is much less than that at 200 K. Desorption of D_2O may be incomplete at 150 K, but the reduced H_2 adsorption is mainly caused by the nonuniform temperature of the filament. When the central portion of the filament is at 150 K the ends will be at temperatures lower than 150 K and therefore partly D_2O-covered. However, at 200 K most of the filament will be at temperatures higher than 150 K. The spectra obtained after heating to 200 K, or higher, are identical to those observed for hydrogen adsorption on clean platinum in paper II of this series (16).

The Thickness of the D_2O Adlayers

The mass 20 desorption spectra of Fig. 2 show qualitatively that D_2O adsorbs on platinum at 100 K and desorbs at temperatures above 150 K, but it would be impossible to analyse these spectra quantitatively to determine the total amount of D_2O desorbing; nor does the dosing method permit the size of the dose to be determined. Fortunately there is an alternative method which can be used to estimate the thickness of the D_2O layers by monitoring the power output of the Kelvin double bridge during desorption. The bridge is programmed to increase the resistance, and hence the temperature, of the central section of the Pt filament linearly with time. The potential drop across the central section, *viz.* IR where R is its resistance and I the current through the filament, is shown as a function of time (temperature) in Fig. 4. Curve

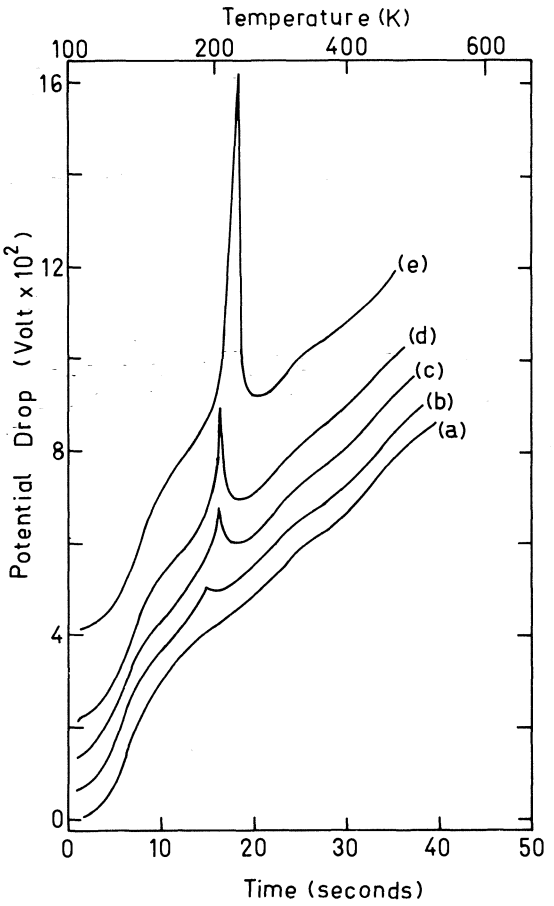

FIG. 4. Potential drop across the central portion of the filament as a function of time (temperature) during the heating of (*a*) a clean surface and also after adsorbing D_2O at 100 K using procedure (*III*) for (*b*) 1, (*c*) 2, (*d*) 3, and (*e*) 10 min. Curves are offset.

(*a*) is for the clean Pt filament. The energy required to desorb an adlayer would place an additional power requirement on the bridge but for monolayer amounts this would be below the detection limit. Curves (*b*)–(*e*) show the corresponding *IR vs.* time curves for steadily increasing D_2O doses, using procedure (*III*) with the Dry Ice/acetone bath removed from cold finger C for 1, 2, 3, and 10 min for spectra (*b*) to (*e*) of Fig. 4 respectively. Clearly there is an increased power requirement over the temperature range where D_2O desorbs, 150–270 K (Fig. 2), and thus the D_2O layer must be quite thick in these experiments. From the measured *IR vs. t* and the known *R vs. t* temperature programme the increased power (I^2R) required to desorb the D_2O layer can be determined. Then from the heat capacity of ice it is an easy matter to calculate the amount of D_2O desorbed and hence estimate the thickness of the ice layer. For the experiments shown in Fig. 4, this thickness varies from $\sim$100 layers for curve (*b*) to $\sim 10^4$ layers for curve (*e*). It is not possible to estimate the magnitude of the lighter doses obtained using procedures (*I*) and (*II*).

The H_2–D_2O Exchange Reaction

A major objective of this study was to obtain information which would improve our understanding of the H_2–D_2O exchange reaction. Conventional approaches in which the rate of production of some species in the gas phase is measured when D_2O interacts with preadsorbed H_2 are complicated by the CO and CO_2 contamination problem. To minimize this problem the sample surface was flash cleaned with the whole reaction vessel immersed in liquid nitrogen and then saturated with H_2 by allowing the filament to cool in an H_2 ambient. Then the D_2O dose was allowed to evaporate from the reaction vessel walls in the manner already described. Blank experiments confirmed that CO does not replace preadsorbed H_2. The extent of the H_2–D_2O exchange was followed by determining the surface isotope composition by thermal desorption.

(a) H_2–D_2O Exchange at 100 K

Following interaction of D_2O with the preadsorbed H adlayer at 100 K, the reaction cell was again cooled in liquid nitrogen. Just prior to commencing the thermal desorption Dewar D was again removed, and during desorption mass 2, 3, or 4 was monitored. It was necessary to obtain the mass 2, 3, and 4 spectra in separate experiments because the spectra contained sharp peaks.

For the spectra shown in Fig. 5, the saturated H adlayer was obtained by adsorbing H_2 at a pressure of 10^{-5} Torr for 4 min with the Pt filament at 100 K. The light D_2O dose was produced using procedure (*II*), *i.e.* the same magnitude as used for spectra (*a*)–(*d*) of Fig. 2. In Fig. 5, the H_2, HD, and D_2 desorption spectra obtained from the H adlayer with a D_2O overlayer can be compared with the H_2 spectrum obtained when H_2 alone was adsorbed on the filament which is shown as a dashed curve. For the D_2O overlayer situation the hydrogen desorption spectra, especially mass 2, have a remarkably sharp peak which coincides with the temperature range over which D_2O evaporates (Figs. 2 and 4) and has a peak maximum temperature at $\sim$188 K. Quite clearly what has happened is that the D_2O overlayer acts as an ice-cap which prevents most of the low temperature H_2 desorption. Once the ice-cap is removed, all the weakly adsorbed hydrogen

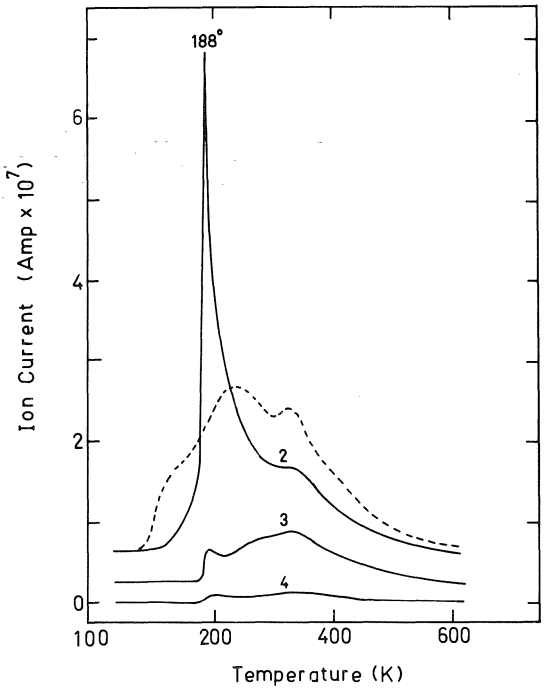

FIG. 5. H/D_2O exchange reaction. Hydrogen was adsorbed at 10^{-5} Torr for 4 min at 100 K followed by a light D_2O dose using procedure (*II*). The H_2, HD, and D_2 desorption spectra were obtained in separate experiments using a heating rate of 14 deg s^{-1}. Curves are offset.

will desorb extremely rapidly and produce the spike observed. It is stressed that since the reaction cell is immersed in liquid nitrogen for these experiments, no D_2O reaches the mass spectrometer and so no drop in electron emission current complicates the interpretation of these results (*cf.* Fig. 2).

The HD and D_2, mass 3 and 4, desorption spectra show that an exchange reaction between the preadsorbed H adlayer and the D_2O overlayer has taken place. In this experiment the extent of the exchange was 27.2%. The D_2O overlayer was relatively thin for the experiments of Fig. 5. As can be seen from the curves of Fig. 4, the thicker the D_2O overlayer the longer is the time required for desorption of the D_2O. Thus it seemed feasible to study the extent of exchange as a function of D_2O overlayer thickness. For thicker overlayers, the contact time between the H adlayer and D_2O overlayer would be increased and extended to higher temperatures and thus might increase the extent of exchange.

In Fig. 6, curve (*a*) is a mass 2 spectrum produced when procedure (*I*) was used to produce the D_2O overlayer. This procedure gives an even lighter dose than procedure (*II*) used for the experiments of Fig. 5 and thus, as expected, the peak maximum is at a lower temperature. For curves (*b*) and (*c*) of Fig. 6, procedure (*III*) was used to produce thicker D_2O overlayers and this produces a steadily increasing peak maximum temperature; peaks (*a*) and (*c*) are 50 K apart. In addition to the peak maximum shift, the thicker D_2O overlayers result in a steadily decreasing amount of preadsorbed H_2 desorbing as H_2, *viz.* the extent of exchange increases. This is confirmed by monitoring the HD and D_2 desorption spectra in addition to that of H_2 as shown in Fig. 7 for the same D_2O overlayer thickness as that for spectrum 6(*c*). For these conditions, the extent of exchange has increased to slightly more than 50%. Thus for thicker D_2O overlayers, the preadsorbed H is forced to stay longer on the surface. This not only increases the time interval during which exchange can take place, but also allows the reaction to proceed at higher temperatures.

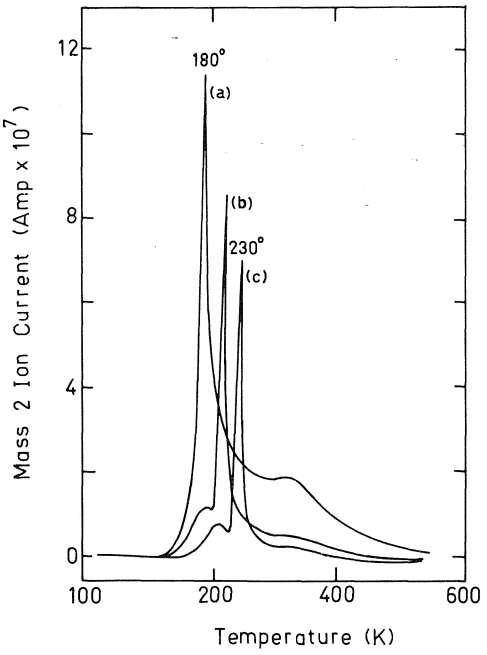

FIG. 6. I_2^+ desorption spectra for H adlayers with D_2O overlayers of varying thickness at 100 K, *cf.* Fig. 5. Curve (*a*) is for a lighter dose using procedure (*I*) whereas curves (*b*) and (*c*) were for procedure (*III*) for 1.5 and 8 min respectively. Heating rate was 14 deg s^{-1}.

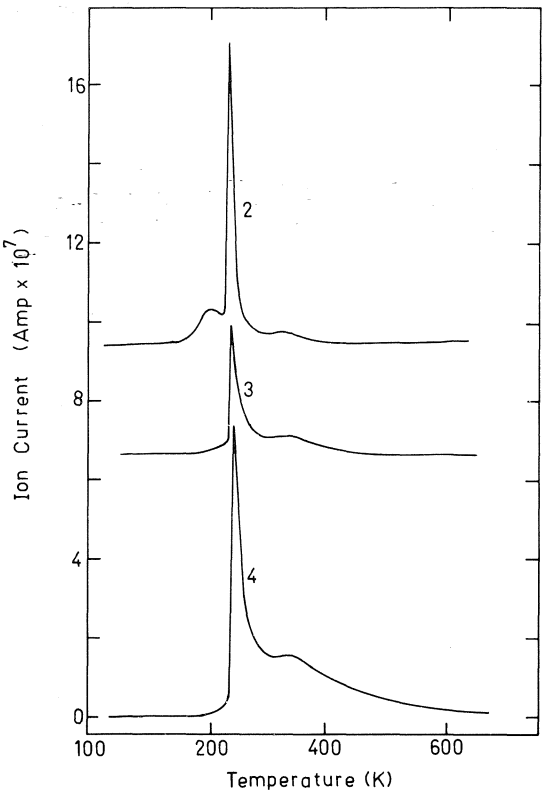

FIG. 7. The mass 2, 3, and 4 desorption spectra for the same experiment as Fig. 6(*c*). Curves are offset.

The mass 2, 3, and 4 spectra of Fig. 7 do not have identical shapes. Furthermore, the amounts of H_2, HD, and D_2 desorbing do not always correspond to the equilibrium statistical distribution of isotopes. For the hydrogens desorbing in the spike, it appears as though the exchange has proceeded beyond statistical in that the HD component is less than one-half of both the H_2 and D_2 components. Undoubtedly this is the result of surface heterogeneity and can be accounted for by a similar explanation to that proposed for the H_2/D_2 exchange reaction reported in paper II of this series (16). On some planes the exchange reaction

$$H_2 + D_2O \rightarrow D_2 + H_2O$$

may be rapid and, in view of the excess D_2O in the system, proceed close to completion. On other planes, exchange may be very slow and the H_2 will desorb substantially unexchanged. The reaction

$$H_2 + D_2O \rightarrow HD + HDO$$

represents an intermediate case. It has already been documented (16) that at the spike temperature the H_2/D_2 exchange reaction is incomplete, and thus the distribution of isotopes observed in Fig. 7 can be understood. Note also that exchange of the hydrogen desorbing at temperatures above that of the spike is more complete and closer to a statistical distribution. This can be also understood in terms of greater H_2–D_2O exchange rates and greater mobility for the adsorbed hydrogen at the higher temperatures (16).

(b) H_2–D_2O Exchange at 150 K

In these experiments the platinum surface was saturated with H_2 at 150 K and then allowed to interact with D_2O desorbing from the reaction vessel walls, in the same manner as for the 100 K exchange experiments. Of course at 150 K the D_2O will not remain on the surface. Figure 8 shows the mass 2, 3, and 4 spectra, monitored simultaneously, for a D_2O dose obtained using procedure (*II*), *i.e.* the same as for Fig. 2 (*a*)–(*d*) and Fig. 5. Also shown in Fig. 8, as a dashed curve, is the desorption spectrum obtained from a pure H adlayer at 150 K.

In this experiment the H + D_2O exchange reaction can take place only during the dosing, and therefore at 150 K. The total amount of exchange is 16.3% and is comparable, apart from the low temperature H_2 desorption which occurs in the mass 2 spike, with that observed in Fig. 5 at 100 K for the same total D_2O dose.

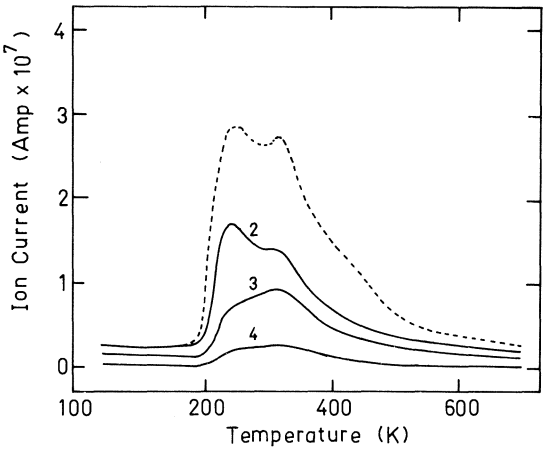

FIG. 8. Mass 2, 3, and 4 desorption spectra following the interaction of D_2O with a saturated H adlayer at 150 K. The D_2O dose was produced using procedure (*II*). The dashed curve shows the desorption spectrum obtained from a pure H adlayer at 150 K. Heating rate 14 deg s^{-1}. Curves are offset.

The ^{18}O–$D_2{}^{16}O$ Exchange Reaction

In these experiments oxygen, $^{18}O_2$, was preadsorbed on the platinum surface and then $D_2{}^{16}O$ was allowed to interact with the preadsorbed ^{18}O by evaporation from the reaction cell walls in the manner already described. This interaction was investigated at different filament temperatures in the range 150–500 K and for two different initial ^{18}O coverages, $N_{18}{}^0 = 3.4 \times 10^{14}$ and $N_{18}{}^0 = 1.6 \times 10^{14}$ atoms cm^{-2} which represent saturated and about half-saturated adlayers respectively (15). An identical $D_2{}^{16}O$ dose was used for each experiment, using procedure (*III*), removing the Dry Ice/acetone bath for 3 min. Oxygen desorption spectra were obtained by monitoring masses 32, 34, and 36 simultaneously. A typical example is shown in Fig. 9 for the interaction of $D_2{}^{16}O$ with a saturated ^{18}O adlayer at 400 K. In this example, the amount of ^{16}O exchanged is 27.3% and the isotopes desorb in a ratio which approximates a statistical distribution. The extent of exchange at different temperatures for the two initial ^{18}O coverages is shown in Fig. 10.

These results have several interesting features.

(*1*) The exchange reaction

$$^{18}O(a) + D_2{}^{16}O(g) \rightarrow {}^{16}O(a) + D_2{}^{18}O$$

does take place.

(*2*) Up to 300 K, the amount of oxygen being exchanged is independent of temperature, but above 300 K the extent of exchange increases considerably with temperature.

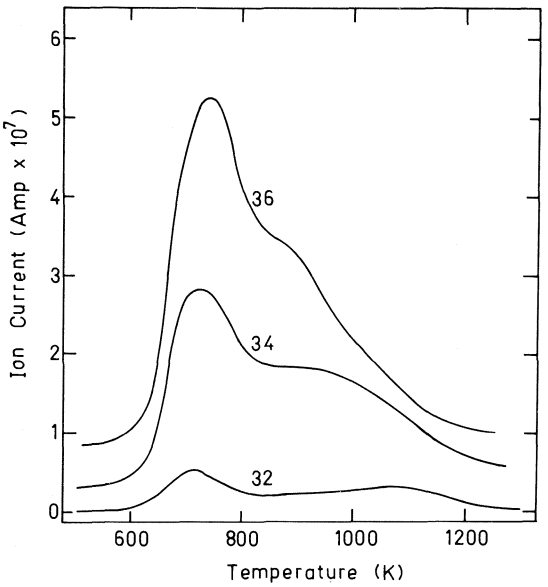

FIG. 9. $^{18}O/D_2{}^{16}O$ exchange reaction. A $D_2{}^{16}O$ dose interacted with a saturated ^{18}O adlayer using procedure (*III*) for 3 min at 400 K. The mass 32, 34, and 36 desorption spectra were obtained simultaneously with a heating rate of 14 deg s^{-1}. Curves are offset.

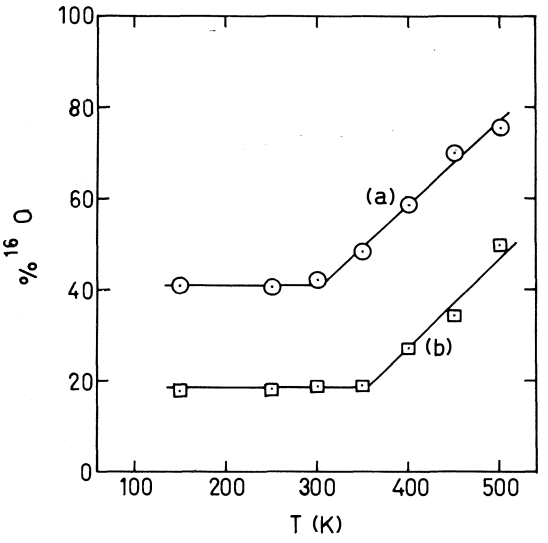

FIG. 10. Percentage ^{16}O in desorption spectra following $^{18}O/D_2{}^{16}O$ exchange experiments typified by Fig. 9 for temperatures in the range 150–500 K and for (*a*) half- and (*b*) fully-saturated ^{18}O adlayers.

(*3*) The % ^{16}O in the desorbing gas for the saturated ^{18}O adlayer is close to one-half that for the half-coverage ^{18}O adlayer. Thus, the actual amount of ^{18}O being exchanged is the same for both ^{18}O coverages. This could imply, most simply, that it is the more tightly bound oxygen which exchanges most rapidly.

The temperature independence of the amount of oxygen being exchanged in the range 150 to 300 K is surprising. If the D_2O does not remain on the surface above 150 K, as already documented for the clean or H-covered surfaces, then it is difficult to understand why the extent of exchange does not increase with temperature in this range. The constant amount of exchange must mean that D_2O is stable on the oxygen-covered surface at least up to 300 K and that the exchange reaction takes place during thermal desorption, prior to desorption of the D_2O at ~300 K. Above 300 K, most of the exchange reaction takes place during dosing, *i.e.* D_2O is not adsorbed, since the extent of exchange does increase with temperature.

In view of the hydrogen bonding possibilities between D_2O and strongly adsorbed oxygen atoms, it is not surprising that preadsorbed oxygen stabilizes the D_2O adlayer.

It is possible to estimate the activation energy for ^{18}O–$D_2{}^{16}O$ exchange from the temperature dependence of the exchange rate for $T > 300$ K. Thus the rate at which ^{16}O is incorporated into the oxygen adlayer can be expressed as

$$\frac{dN_{16}}{dt} = kP_{D_2O}N_{18} = kP_{D_2O}(N_{18}{}^0 - N_{16})$$

where N_{16} and N_{18} are the numbers of ^{16}O and ^{18}O atoms cm^{-2} and $N_{18}{}^0$ is the initial ^{18}O coverage. This rate expression can be integrated to give

$$\ln\left(1 - \frac{N_{16}}{N_{18}{}^0}\right)^{-1} = k\int_0^t P_{D_2O}\,dt = kX$$

where X represents the integrated $D_2{}^{16}O$ dose which is constant for all experiments. If the apparent rate constant, k, is expressed in the usual Arrhenius form, the apparent activation energy for the exchange reaction, $E^{\ddagger}$, can be obtained from the slope of a plot of ln $\{\ln [1 - (N_{16}/N_{18}{}^0)]^{-1}\}$ *vs.* $1/T$. This plot is shown in Fig. 11. The apparent activation energies are 1.8 kcal mol^{-1} for the half-saturated and 2.9 kcal mol^{-1} for the saturated ^{18}O adlayers. A lower activation energy for the half-saturated ^{18}O adlayer suggests that a configuration in which the adsorbed water molecule can interact with both platinum and adsorbed oxygen is more favourable for exchange.

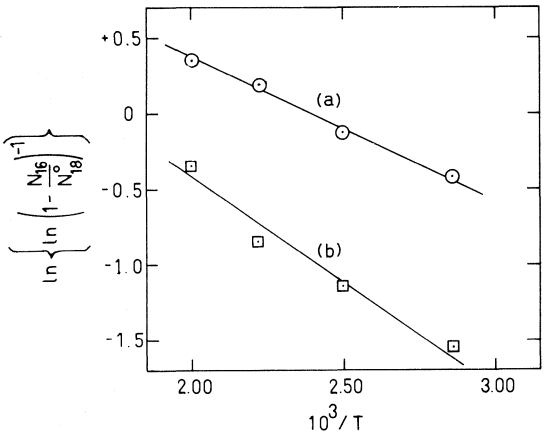

FIG. 11. Arrhenius plot for the data of Fig. 10. The apparent activation energies for $^{18}O/D_2{}^{16}O$ exchange are 1.8 and 2.9 kcal mol^{-1} for the half- and fully-oxygen covered surfaces, (*a*) and (*b*) respectively.

Conclusions

(*1*) Water adsorbs only weakly on clean unsupported platinum and desorbs at temperatures above ~150 K. Hydrogen does not adsorb on the water-covered surface.

(*2*) When D_2O is adsorbed into overlayers of varying thickness onto preadsorbed H, an H/D exchange reaction does take place. The thicker the overlayer, the longer the time and the higher the temperature at which exchange can take place, resulting in an increase in the extent of exchange. The isotope distributions show that the surface is heterogeneous and that exchange takes place at different rates on different areas.

(*3*) $D_2{}^{16}O$ adsorbed into an overlayer on preadsorbed ^{18}O also results in an $^{16}O/^{18}O$ exchange reaction. The constant extent of exchange up to ~300 K shows that water is more strongly adsorbed onto oxygen-covered compared with clean platinum surfaces. The measured activation energies for exchange are 1.8 for half- and 2.9 kcal mol^{-1} for fully-O-covered surfaces. The number of ^{18}O atoms exchanged under given conditions is the same for half and fully saturated ^{18}O adlayers and thus heterogeneity also plays a role in $^{18}O/D_2{}^{16}O$ exchange.

Synthesis, ion-exchange properties, and analytical applications of thermally stable tin(IV) vanadate

MOHSIN QURESHI, SYED ASHFAQ NABI, AND NIGHAT ZEHRA

Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

Received April 2, 1976[1]

MOHSIN QURESHI, SYED ASHFAQ NABI, and NIGHAT ZEHRA. Can. J. Chem. **55**, 1667 (1977).

Samples of stannic vanadate have been synthesized by varying the mixing ratio of the reagents and p*H* of the mixture. The most stable sample has been synthesized by mixing 0.25 *M* solutions of stannic chloride and sodium metavanadate in the ratio of 2:3 at p*H* 2.5. The material behaves as a weak cation exchanger. This sample has been critically studied for its ion-exchange, chemical, and thermal behaviour. The analytical utility of the material has been demonstrated by achieving some binary separations of metal ions on its column. Arsenate has also been quantitatively removed from a mixture of tungstate, phosphate, and antimonate.

MOHSIN QURESHI, SYED ASHFAQ NABI et NIGHAT ZEHRA. Can. J. Chem. **55**, 1667 (1977).

On a synthétisé des échantillons de vanadate stannique faisant varier le rapport des réactifs mélangés et le p*H* du mélange. L'échantillon le plus stable a été synthétisé en mélangeant des solutions 0.25 *M* de chlorure stannique et métavanadate de sodium dans un rapport de 2:3 à un p*H* 2.5. Le composé se comporte comme un échangeur faible de cations. Cet échantillon a été étudié d'une façon critique pour son comportement comme échangeur d'ions et ses comportements chimique et thermique. On démontre l'utilité analytique de ce composé en effectuant quelques séparations binaires d'ions métalliques sur cette colonne. On a aussi pu enlever d'une façon quantitative l'arsénate à partir d'un mélange de tungstate, de phosphate et d'antimonate.

[Traduit par le journal]

Introduction

Synthetic inorganic ion-exchangers are receiving increasing attention owing to their thermal stability and resistance to radiations. The recent work in this field has been well summarized in the various reviews and monographs (1–3). The selectivity and ion-exchange properties of a material depend considerably on its chemical composition. It is, therefore, always interesting to synthesize new materials and to study their ion-exchange behaviour. Moreover, numerous attempts have been made to study the cation adsorption behaviour of insoluble solids, but very few studies have been made on their anion adsorption properties. In the case of our systematic studies on inorganic ion-exchangers, we found that stannic vanadate selectivity adsorbs the arsenate. Vanadates have not been studied in detail as ion-exchangers. The few studies on the vanadates as ion-exchangers have been summarized recently in the communication on titanium vanadate (4) from this laboratory. As no work on stannic vanadate has been reported so far, hence the present study was taken up.

[1]Revision received January 14, 1977.

Experimental

Reagents

Tin(IV) chloride pentahydrate (Poland) and sodium metavanadate (BDH, England) were used for the synthesis of samples. All other reagents were of AnalaR grade.

Synthesis

Tin(IV) vanadate samples were synthesized by adding 0.25 *M* sodium metavanadate solution in portions to 0.25 *M* solution of tin(IV) chloride with continuous stirring at room temperature (23 ± 3°C). Turbidity appeared in the beginning. The precipitation seemed to increase on subsequent additions of sodium metavanadate solution; when the addition of sodium metavanadate was completed, the p*H* of the mixture was adjusted to the required values by adding either sodium hydroxide or hydrochloric acid solution. The precipitate was allowed to stand for 24 h in the mother liquor. The exact conditions for the synthesis of various samples are given in Table 1. The precipitate was then washed by decantation with demineralized water and finally filtered under suction. The products so obtained were dried at the desired temperatures as indicated in Tables 1 and 2. The dried product on immersing in water gave fine granules which may contain a mixture of Na^+ and H^+ as counter ions. To get the exchanger completely into the H^+ form, the granules were treated with 2 *M* nitric acid in the usual manner (5).

Apparatus

Spectrophotometric, p*H*-metric, and ir studies were performed on the Bausch and Lomb Spectronic-20

200	Yellowish-green	0.80
400	Green	0.36
700	Dark green	0.10

colorimeter, the Elico p*H* meter model LI-10, and the Perkin Elmer model 137 spectrophotometer respectively. Thermogravimetric analysis was performed on the Stanton thermobalance type H_4. For shaking an electric temperature-controlled Sico Shaker was used.

Analytical Procedure

The Sn(IV) vanadate samples were converted into the H^+ form and then analysed for tin and vanadium. For this purpose 200 mg of the sample was dissolved in concentrated hydrochloric acid. Tin was determined gravimetrically as stannic oxide (ref. 6, p. 1077) and vanadium titrimetrically using potassium permanganate as the titrant (ref. 6, p. 1211). The chemical dissolution was determined by treating a 500 mg sample with 50 ml of the desired solvent. The mixture was then shaken for 6 h in a shaker incubator at room temperature. The amounts of tin and vanadium released in the solution were determined spectrophotometrically using phenyl fluorone (ref. 7, p. 862) and hydrogen peroxide (ref. 7, p. 930) respectively.

Thermal Treatment

Tin(IV) vanadate (sample 4) was dried at different temperatures (Muffle furnace was used for drying at higher temperature) to observe the effect of the drying temperature on the composition and ion-exchange capacity of the sample. Figure 1 shows thermograms of stannic vanadate in the H^+ and K^+ form at the heating rate of 4°C/min.

Infrared Spectra

Infrared absorption spectra were obtained by the KBr disc technique.

pH Titrations

p*H* titrations of the samples in the H^+ form were performed with KCl–KOH and LiCl–LiOH systems by the usual method (8).

Ion-Exchange Capacity

Ion-exchange capacity of various samples of stannic vanadate was determined by the standard column technique (9) at p*H* = 6. The effect of the drying temperature of the product on exchange capacity was also studied. The results are summarized in Tables 1–3.

Sorption Studies

For distribution studies 500 mg of the exchanger in the H^+ form was equilibrated with 50 ml of the required solvent containing the ion under study in an Erlenmeyer flask. The temperature of the shaker was maintained as desired. The amount of metal ions before and after equilibrium was determined by titration with 0.002 *M*

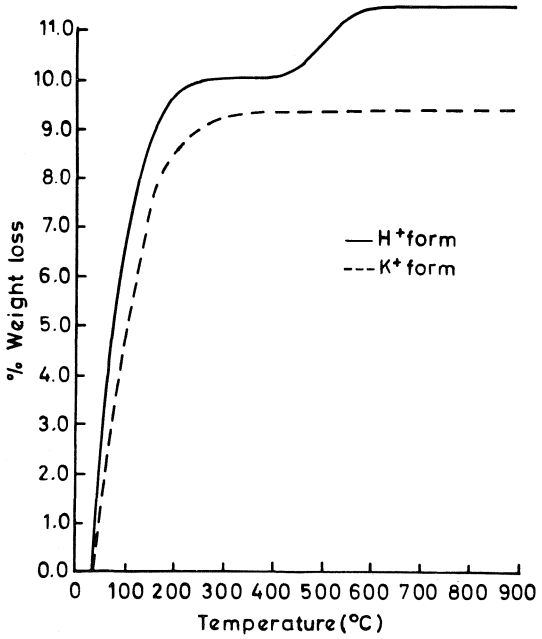

FIG. 1. Thermograms of stannic vanadate (sample 4). (—) H^+ form, (---) K^+ form.

TABLE 3. Ion-exchange capacity of stannic vanadate (sample 4) at pH = 6 for some univalent and bivalent cations

Ion	Hydrated radii (Å)	Ion-exchange capacity (mequiv/g)
Li^+	3.0	0.70
Na^+	2.0	0.78
K^+	1.5	0.85
Mg^{2+}	4.0	0.57
Ca^{2+}	3.0	0.60
Sr^{2+}	2.5	0.75
Ba^{2+}	2.5	0.73

solution of the disodium salt of EDTA. The determinations of arsenate (ref. 7, p. 286), phosphate (ref. 6, p. 819), antimonate (ref. 7, p. 258), and tungstate (ref. 7, p. 886) were done spectrophotometrically. The distribution coefficients were calculated according to the usual formula (4). To study the effect of temperature on the ion-exchange selectivity, the exchange reaction was also carried out in 10^{-3} M HNO_3 at temperatures 25, 40, 60, and 80°C.

Separations

For separation studies, a glass column (id 3.9 mm) filled with 1.5–2.0 g of stannic vanadate in H^+ form on glass wool support was used. The rate of flow of the effluent in all the separations studied was 0.5–0.8 ml/min.

Metal Ion Separations

Binary, separations of Pb^{2+} (400–1360 μg) from Zn^{2+} (1000–2000 μg), Mn^{2+} (800–2000 μg), and Ca^{2+} (500–2000 μg) were achieved quantitatively. The metal ions mixture was poured into the column. It was then allowed to pass through the exchanger with a very slow rate. Then the metal ions absorbed in the exchanger phase were eluted with appropriate eluting reagent Ca^{2+} (500–2000 μg) was also separated from Mg^{2+} (400–1500 μg) in the same manner. The elution curves and the eluting reagents are given in Fig. 3.

Anion Separations

Different amounts of arsenate (100–1000 μg) were quantitatively separated from phosphate, antimonate, and tungstate (200–2000 μg) on a 1 g exchanger column. The procedure was the same as described above. The anions other than arsenate were eluted with demineralized water. Arsenate was also quantitatively removed from a synthetic mixture of phosphate, tungstate, and antimonate.

Results and Discussion

Figure 1 shows the thermograms of stannic vanadate in the H^+ and K^+ forms. It is apparent from the curve for the exchanger in the H^+ form that the exchanger suffers continuous loss in weight, when it is heated to 210°C. The weight becomes constant in the temperature range 210–400°C. The loss in weight is again observed when the temperature is raised further. This continues up to 570°C. No further weight loss is observed beyond this temperature. Therefore the thermogram of stannic vanadate clearly suggests that the loss in weight up to 210°C is due to the removal of external water molecules. The stability of the exchanger is quite significant in the temperature range 210–400°C. When the temperature exceeds 400°C, condensation of OH groups begins resulting in the removal of water molecules. This removal is complete at 570°C. Above this temperature weight remains constant due to the conversion of the material into the oxides. These facts are also well supported by the data on ion-exchange capacity of the exchanger dried at different temperatures (Table 2). It is clear from these observations that there is no change in the capacity when the exchanger is dried at 200°C. The removal of external water molecules has no effect on the exchange capacity. However, when the drying temperature is increased above 400°C, the gradual loss in ion-exchange capacity is observed, as the condensation of OH groups starts. The exchange capacity sharply falls to a negligible value (0.10 mequiv/g) when the drying temperature of the product is 700°C. The thermogram of stannic vanadate in the K^+ form suffers less weight loss than in the H^+ form and shows only one break. After the removal of external

water molecules the weight becomes almost constant. The weight loss due to the removal of internal water molecules is not observed as the condensation is not possible in this case. Therefore the hydroxyl group attached to vanadium is most probably responsible for the cation exchange behaviour of stannic vanadate. This is also supported by the chemical composition data (Table 1). The exchange capacity increased with increase in their vanadium content of the product.

It may be easily inferred from Table 1 that in the preparation of stannic vanadate, variation in the mixing ratio of stannic chloride and sodium vanadate does not have any significant effect on the chemical composition and the ion-exchange capacity of the product, if the p*H* of the mixture is kept constant. However, if the preparation is done in the neutral or basic medium the tin content in the final product is increased. This is probably due to the formation of some stannic hydroxide at higher p*H* values, causing a considerable decrease in the capacity of the sample.

Stannic vanadate is apparently fairly stable in various solvents such as dilute mineral acids, acetic acid, formic acid, dilute alkalies, acetone, alcohols. It is apparent from the chemical dissolution studies of this material with water, dilute nitric acid, and formic acid (Table 1) that stannic vanadate is much more chemically stable than titanium vanadate (4).

A comparison of the effect of drying temperatures on the ion-exchange capacity for some inorganic ion exchangers reveals that stannic vanadate is superior to other ion exchangers as it retains almost 100% exchange capacity up to 200°C. However, the capacity starts decreasing when the drying temperature is further increased. But in fact it shows sufficient ion-exchange capacity even when the drying temperature is raised to 400°C (0.36 mequiv/g). On the other hand, stannic tungstate (10), stannic molybdate (5), titanium selenite (11), titanium arsenate (12), and titanium tungstate (13) lose their capacity sharply as the drying temperature increases and the exchange capacity becomes negligible when the temperature reaches 200°C.

p*H* titration curves apparently show only one inflexion point. Initially when KCl is added in the absence of KOH there is a sharp decrease in p*H* due to the release of hydrogen ions. On the addition of the base, the p*H* increases rapidly, and above p*H* 9 the exchanger begins to hydrolyse. It is also evident from Fig. 2 that in the acidic medium the uptake of the K^+ ion is greater than that of the Li^+ ion. However, the situation is reversed in the p*H* range 7–10.5. The capacity of stannic vanadate increases with increase in p*H* as expected. This is because as the hydrogen ion concentration is increased the exchange reaction tends to proceed in the reverse direction and therefore the adsorption of the metal ions on the exchanger is decreased.

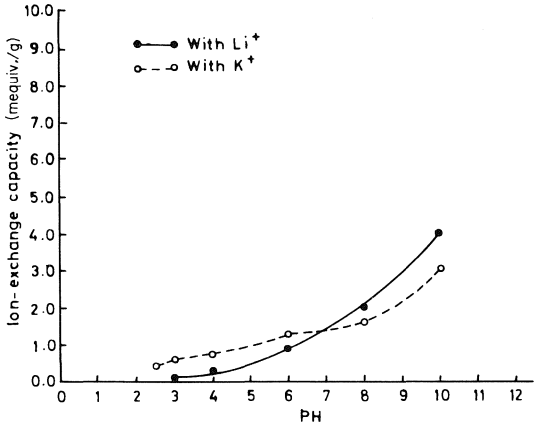

FIG. 2. Ion-exchange capacity as a function of p*H*.

From the ion exchange capacity data (Table 3) it can be concluded that the affinity sequence for monovalent ions is $K^+ > Na^+ > Li^+$ and for bivalent ions is $Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$. This sequence is in accordance with the hydrated radii. Ion-exchange capacity decreases with increase in the hydrated radii. The ions with smaller hydrated radii easily enter the pores of the exchanger, resulting in higher adsorption (14).

The sorption studies on stannic vanadate reveal the possibility of many analytically difficult separations of metal ions and anions. The order of the ion-exchange selectivity in various solvents is as follows:

Demineralized water

$$K^+ > Pb^{2+} > Na^+ > Cd^{2+} \simeq Ca^{2+} > Zn^{2+} > Mn^{2+} > Sr^{2+} > Ba^{2+} > Mg^{2+}$$

0.001 *M* HNO_3

$$K^+ > Pb^{2+} > Na^+ > Zn^{2+} > Ba^{2+} > Cd^{2+} > Ca^{2+} \simeq Mn^{2+} > Sr^{2+} > Mg^{2+}$$

0.005 *M* HNO_3

$$K^+ > Pb^{2+} \simeq Na^+ > Zn^{2+} > Ba^{2+} > Cd^{2+} > Mn^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$$

0.01 *M* HNO_3

$$K^+ > Cd^{2+} > Pb^{2+} > Na^+ > Zn^{2+} > Ba^{2+} > Mn^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$$

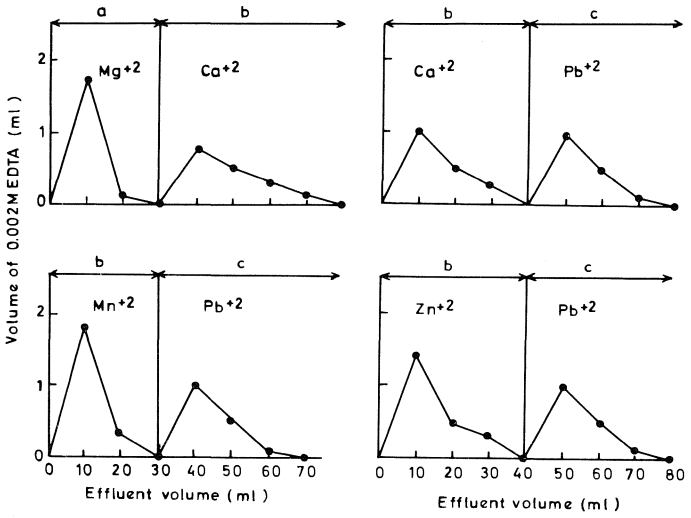

FIG. 3. Separations of metal ions on stannic vanadate columns. a = demineralized water, c = 0.1 M NH_4NO_3 in 0.1 M HNO_3, b = 0.001 M HNO_3.

0.1 M HNO_3

$$Pb^{2+} > K^+ \simeq Na^+ > Mn^{2+} > Cd^{2+} > Zn^{2+} > Sr^{2+} > Ba^{2+} \simeq Ca^{2+} > Mg^{2+}$$

The exchanger has very high affinity for Na^+, K^+, Pb^{2+}, Cd^{2+}, Zn^{2+}, and Ca^{2+} even in the nitric acid medium. Therefore separations of these metal ions are possible from the rest of the ions. The adsorption of Mg^{2+} is very small as compared to other ions and hence it can be easily separated from alkaline earths and other metal ions. Titanium vanadate was found to show the highest affinity for Sr^{2+} ion amongst alkaline earths, but stannic vanadate adsorbs the Ca^{2+} ion more strongly in most solvents. It is also observed that adsorption of ions decreases with increase in nitric acid concentration and can be explained as above. The effect of temperature on the adsorption of metal ions shows that the uptake gradually increases as the equilibrating temperature is increased as usually observed in other ion-exchangers. The following selectivity sequence is observed.

At 25°C

$$Pb^{2+} > Zn^{2+} > Ba^{2+} > Cd^{2+} > Mn^{2+} \simeq Ca^{2+} > Sr^{2+} > Mg^{2+}$$

at 40°C

$$Pb^{2+} > Sr^{2+} > Ba^{2+} > Zn^{2+} > Ca^{2+} > Mn^{2+} > Cd^{2+} > Mg^{2+}$$

at 60°C

$$Pb^{2+} > Sr^{2+} > Zn^{2+} > Ca^{2+} > Cd^{2+} \simeq Mn^{2+} > Ba^{2+} > Mg^{2+}$$

at 80°C

$$Pb^{2+} > Mn^{2+} > Sr^{2+} > Ba^{2+} > Zn^{2+} > Ca^{2+} > Cd^{2+} > Mg^{2+}$$

To demonstrate the practical utility of the exchanger, quantitative separations of Pb^{2+} from Zn^{2+}, Mn^{2+} and Ca^{2+} and of Mg^{2+} from Ca^{2+} have been efficiently achieved on small columns of stannic vanadate.

The anion adsorption studies on stannic vanadate show the specificity for arsenate ion. The reaction is sufficiently fast to be of practical importance. The arsenate which is irreversibly adsorbed has been quantitatively separated from phosphate, antimonate, and tungstate on a 1 g stannic vanadate column. The eluent volumes required to elute phosphate, antimonate, and tungstate are 40, 30, and 30 ml respectively. The arsenate strongly interacts with stannic vanadate and could not be eluted. To understand the mechanism of the reaction the vanadate released was determined and it was found that no excess of vanadate is released and therefore it is probably a case of irreversible adsorption to form either a heteropoly acid salt, *i.e.* stannic vanado-arsenate or to give a mixture of the two insoluble salts, *i.e.* stannic vanadate and stannic arsenate.

Infrared spectrum of stannic vanadate resembles that of titanium vanadate (4). The strong peak between 3000–3600 cm^{-1} with a maximum at 3400 cm^{-1} is due to stretching vibration of interstitial water molecules and OH groups [r_1 (H_2O or OH)] (15). The band between 1600–1700 cm^{-1} with a maximum absorption at 1650 cm^{-1} is due to deformation vibration of M—OH[$\delta_2(H_2O)$]. The peak at 1400 cm^{-1} is due to deformation vibration of

interstitial water [$\delta_1(H_2O)$]. The fourth broad peak with a maximum at 700 cm^{-1} represents the stretching vibration of M—O bond [r_2(Sn—O, V—O)].

Crystal structure of vanadium(III) tris(metaphosphate)

NORA MIDDLEMISS, FRANK HAWTHORNE, AND CRISPIN CALVO

Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received October 12, 1976

NORA MIDDLEMISS, FRANK HAWTHORNE, and CRISPIN CALVO. Can. J. Chem. **55**, 1673 (1977).

Vanadium(III) tris(metaphosphate), $V(PO_3)_3$, crystallizes in the monoclinic space group *Ic* with lattice parameters $a = 10.615(2)$, $b = 19.095(4)$, $c = 9.432(1)$ Å, $\beta = 97.94(1)°$ with $Z = 12$. The equivalent parameters in the standard space group *Cc* are $a = 13.189(1)$, $b = 19.095(4)$, $c = 9.432(1)$ Å, and $\beta = 127.15(1)°$. The structure was refined by full-matrix least-squares to an $R = 0.091$ ($R_\omega = 0.065$) utilizing 2467 reflections with the atomic positions and their isotropic vibration amplitudes as parameters. The structure consists of infinite chains of PO_4 tetrahedra sharing corners with each other and bridged by VO_6 octahedra. All oxygen atoms are shared between just two cations. The average P—O⟨—P⟩ bond is 1.581 Å while the average of those shared with vanadium is 1.483 Å. The VO_6 group is moderately distorted, with differences of less than 0.06 Å between the longest and shortest V—O bond lengths in any of the three distinct VO_6 groups. The average V—O bond lengths for the three VO_6 groups are 1.995, 1.991, and 1.987 Å. A marked superlattice effect based on a cell with $b/3$ is noted.

NORA MIDDLEMISS, FRANK HAWTHORNE et CRISPIN CALVO. Can. J. Chem. **55**, 1673 (1977).

Le tris(métaphosphate) de vanadium(III), $V(PO_3)_3$, cristallise dans le groupe d'espace monoclinique *Ic* avec des paramètres de maille $a = 10.615(2)$, $b = 19.095(4)$, $c = 9.432(1)$ Å, $\beta = 97.94(1)°$ avec $Z = 12$. Les paramètres équivalents dans le groupe d'espace standard *Cc* sont $a = 13.189(1)$, $b = 19.095(4)$, $c = 9.432(1)$ Å et $\beta = 127.15(1)°$. On a affiné la structure par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R = 0.091$ ($R_\omega = 0.065$) utilisant 2467 réflexions et les positions atomiques et leurs amplitudes de vibration isotrope comme paramètres. La structure consiste de chaînes infinies de tétraèdres de PO_4 partageant des coins les uns avec les autres et reliées par un octaèdre de VO_6. Tous les atomes d'oxygène sont partagés uniquement entre deux cations. La longueur moyenne du lien P—O⟨—P⟩ est de 1.581 Å alors que la moyenne des longueurs partagées avec le vanadium est de 1.483 Å. Le groupe VO_6 est modérément déformé; il existe des différences de moins que 0.06 Å entre les longueurs des distances V—O les plus courtes et des plus longues dans chacun des trois groupes VO_6 distincts. Les longueurs moyennes des liens V—O pour les trois groupes VO_6 sont 1.995, 1.991 et 1.987 Å. On note un effet marqué de superstructure basé sur une maille avec $b/3$.

[Traduit par le journal]

Introduction

The systematic study of various solid vanadium oxides has shown that a wide variety can be prepared. In addition to the oxides with vanadium having integral valences, *i.e.* V_2O_3, VO_2, and V_2O_5, series with variable valency for the cation have been prepared. Two well characterized series correspond to V_nO_{2n-1} (1, 2) with $3 \leq n \leq 8$ and V_nO_{2n+1} (3, 4) with $n = 3, 4, 6$. Polymorphic transformations and a variety of changes in physical properties have been noted (2, 4). These structures are characterized by octahedral and/or five-fold coordinate V.

Adding P_2O_5, thus forcing some of the cations into tetrahedral coordination, has to date resulted in a substantially diminished number of phases and variety of solid state properties. This may be due to the instability of stable shear structures based upon tetrahedrally coordinated cations. Among the compositions which do occur are $V(PO_3)_3$, $VO(PO_3)_2$ (5, 6), and VPO_5 (7) with the oxidation state of vanadium progressively increasing in integral steps from 3 to 5. Polymorphs have been reported for only VPO_5 to date and the structures of these have been determined (8, 9). A second tetravalent vanadium compound, $(VO)_2P_2O_7$, whose structure is being studied in this series, has not been reported generally.[1] Surprisingly, only one mixed valency vanadium phosphate system is presently known. This system consists of glasses whose conductivities indicate that polaronic hopping involves an electron hopping from V^{4+} to V^{5+} (11). The structure of these glasses is based upon a

[1]P. Courtine and E. Bordes, private communication.

perturbed α-VPO_5 structure (12). Substitution of phosphorus into metavanadate chains and vanadium into trimetaphosphate rings has been reported (13). However, substitution of V for P in $VO(P_2SiO_8)$ (14, 15), where one might logically expect it, has not been substantiated nor has phosphorus been substituted for tetrahedral V^{5+} in $K_2V_3O_8$ (16). In each case the structure suggests that such substitution, leading to a mixed valency state vanadium in a vanadium phosphate system, should be possible.

The general conclusion available from the details of the preparation of these vanadium phosphorus compounds is that at fixed partial pressure of oxygen the fraction of vanadium reduced increases with temperature (17) as it does with an increased P/V ratio (5, 6, 18) at fixed temperature. The structural studies indicate that as the P/V ratio increases the degree of condensation of the phosphate increases. That is, VPO_5 has non-condensed phosphate groups, and infinite chains of corner sharing PO_4 groups were found (in this laboratory)[2] in $VO(PO_3)_2$ and $V(PO_3)_3$. $VPO_{4.5}$ has both condensed VO_6 groups and P_2O_7 groupings, according to our incomplete studies, while in the vanadium phosphate glasses, prepared from a mixture of $(1 + x)V_2O_5$ and $(1 - x)P_2O_5$, for $x \geq 0$ condensed vanadium polyhedra are proposed to account for the oxygen lost. Although many structures based upon condensed VO_6 groups are possible, in the vanadium phosphate system only a few have been realized. The dearth of mixed valency crystalline vanadium phosphates is worthy of note.

Trivalent metal ion trimetaphosphates have been reported for Al, Ti, Fe, Cr, Mo in addition to V (20–25). The structure of the cubic polymorph, as $Al_4(P_4O_{12})_3$, was reported by Pauling and Sherman (26). Six polymorphs have been reported for $Cr(PO_3)_3$ (25) thus presenting an interesting challenge in both preparing and determining these structures.

Experimental

Crystals of $V(PO_3)_3$ were prepared by reacting a V_2O_5–P_2O_5 mix in an evacuated sealed quartz tube at temperatures near 900°C. The product was found to contain small crystals of $VO(SiP_2O_8)$, $VO(P_2O_7)$, $V(PO_3)_3$ plus at least one additional phase. All the diffraction studies were performed on a crystal from this batch. Crystals with the same lattice parameters and symmetry as reported here were also prepared following the procedure of Lavrov *et al.* (5) and Tofield *et al.* (6).

A small equi-dimensional crystal with a radius of about 0.1 mm was used for the crystallographic study. Unit cell parameters were obtained by measuring both $\pm 2\theta$ values on a Suntex $P2_1$ automatic diffractometer using 2θ values in the range 20 to 30°. Graphite monochromatized MoKα radiation ($\lambda_{\alpha_1} = 0.70926$ Å) was used. The parameters were determined by least-squares refinement methods. Crystal data are as follows:

$V(PO_3)_3$ fw = 287.85
Monoclinic $a = 10.615(2)$, $b = 19.095(4)$, $c = 9.432(1)$ Å, $\beta = 97.94(1)°$, $Z = 12$, $D_m = 3.0 \pm 0.1$ g cm^{-3}, $D_{calcd} = 3.03$ g cm^{-3}. Space group: *Ic* or *I*2/*c*. Absences: $h+k+l$ odd in general and $h0l$ with l odd.

Data were collected with a scintillation counter up to $2\theta = 60°$ using a scan of 2° plus the α_1–α_2 separation. Backgrounds were measured on either side and one degree removed from each peak. The scan rate depended upon the peak intensity. A total of 2847 symmetry independent peaks were scanned and 2467 of these had intensity of positive measure after correcting the peak intensities for background. The latter set was used to determine the structure. All the data were corrected for Lorentz and polarization effects and for absorption based upon a spherical crystal with a radius of 0.1 mm.

At lower 2θ values the diffraction pattern showed reflections indexed with $k \neq 0$ (mod 3) to be substantially weaker than those with $k = 0$ (mod 3). Thus a Patterson function with these latter reflections was used to determine the average atomic positions assuming that the space group of this smaller cell was *I*2/*c*. The structure model at this point showed some P—O bond lengths that were unacceptable and an R value near 0.20. Tofield *et al.* (6) on the basis of a second-harmonic generation signal selected *Cc* as the space group for the standard cell. The final structure was derived in this space group by arbitrarily displacing the atoms sequentially from the average position in conjunction with a decreasing R value.[3] Although the model obtained seemed satisfactory the possibility of a false minimum exists. Therefore, the Patterson function, without the vanadium contribution and a β synthesis (27) based upon the vanadium and phosphorus positions of the model were examined for an alternative structure. None was found. Finally, the structure of $Al(PO_3)_3$ (28), reported recently, is isostructural.

The final atomic parameters, with isotropic thermal parameters, derived by full-matrix least-squares methods, are in Table 1. (The cell has been transformed to one with *Ic* symmetry.) The refinement used scattering curves for neutral atoms (29) and a weighting scheme, ω, so that $\omega(F_o - F_c)^2$ was substantially independent of F_o, *i.e.* $\omega = (46 - 0.53F + 0.0023F^2 + 1000\,(\sigma/F)^2)^{-1}$, where σ is the standard deviation based on counting statistics. (The final R and R_ω were 0.091 and 0.065 respectively considering all reflections and 0.134 and 0.094 considering the $k \neq 0$ (mod 3) reflections only.) Scattering curves were corrected for anomalous dispersion but this

effect was not large enough to distinguish the absolute configuration.

Description

The structure is an example of polyhedral packing with three tetrahedra for every octahedron and with each corner shared between two polyhedra. The general bonding motif can be discussed by considering the average structure, shown in projection in Fig. 1, since no new major features arise in the extended structure.

The VO_6 octahedra lie in pseudo-hexagonal arrays with $[10\bar{1}]$ as the normal. Adjacent layers are related by the glide plane. One of the three-fold axes of the octahedra nearly parallels the *b* axis and another nearly parallels the layer direction. Each VO_6 group is bridged to six neighbouring VO_6 groups by phosphate groups. These lie in one of the two adjacent layers and lead to the three dimensional bonding.

The $(PO_3)_n$ chains snake their way between these octahedra while running parallel to *c*. Three distinct PO_4 groups form links in this chain. Although all the PO_4 groups are oriented with a two-fold axis roughly parallel to *b*, the configuration of the central PO_4 group is inverted with respect to the end members of the link. This permits the central PO_4 group to share oxygen atoms with VO_6 groups at the same *y* level and one such bridging occurs between a given VO_6

TABLE 2. Average bond geometry in $V(PO_3)_3$*

*A complete table of bond lengths and bond angles is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

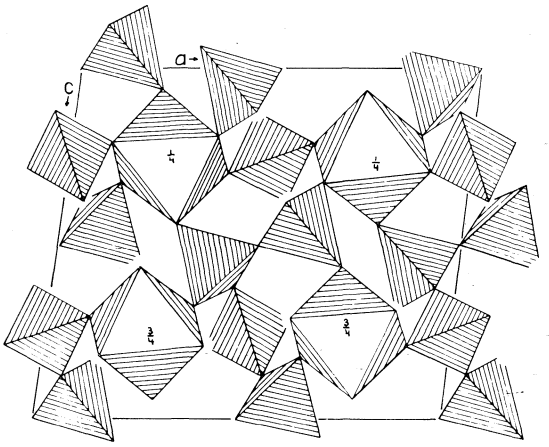

FIG. 1. The average structure of $V(PO_3)_3$ projected down the b axis. The vanadium ion lies within the octahedra and the phosphorus atom within the tetrahedra. The approximate y coordinates of the V^{3+} are shown. Oxygen atoms lie at the corners of the polyhedra.

group and each of its two VO_6 neighbours at the same y level. The remaining phosphate groups are shared between VO_6 groups whose y values differ by $\frac{1}{2}$ of the b axis of the average structure. Each VO_6 has four neighbouring metaphosphate chains. One oxygen is shared with each of the two chains connected to VO_6 at the central phosphate and two oxygens are shared with the other chains. The chains are rectangularly arranged about VO_6, with the rectangle defined by the vectors $\frac{1}{2}a$ and $\frac{1}{2}b$. Adjacent links in the chain have the configurations of the PO_4 groups inverted as required by the glide plane.

In the true structure all the tetrahedra are distorted with the P—O(—V) bond consistently shorter than the P—O(—P). The average values of these are 1.483 and 1.581 Å respectively (Table 2). Although the (V—)O—P—O(—V) bond angles are always the largest within a given tetrahedron, averaging 117.7 ± 0.8°, the deviation from ideality is not solely related to a displacement of the P from the center of the tetrahedron away from the P ions of the nearest neighbouring PO_4 groups. If the deviations, as measured by this angle, are to be considered random, the standard errors would have to increase by a factor of three. Even then, the deviations of the (P—)O—P—O(—P) angle would be significant since they range from 98.7 to 108.1°. Further, this angle is not always the smallest in the congruent PO_4 group. Thus the tetrahedra are not congruent and the deviations, perhaps examined with 3σ in mind, must be related to the angles of the polyhedra at the bridging oxygen. Since the distortions of the PO_4 are thus postulated to be related to the configuration of the four surrounding polyhedra the systematics of the effect is not apparent.

The angle subtended at the oxygen atom by the cations to which it is bonded ranges from 135 to 151° (9 values) when both cations are phosphorus and from 133 to 158° (18 values) otherwise. No strong correlation exists between these angles and the distortions of the polyhedra.

It is conceivable that V^{5+} could substitute for P^{5+} in the PO_4 groups, and this could be the source of some of the polyhedral distortions. The site populations of the tetrahedral cations were

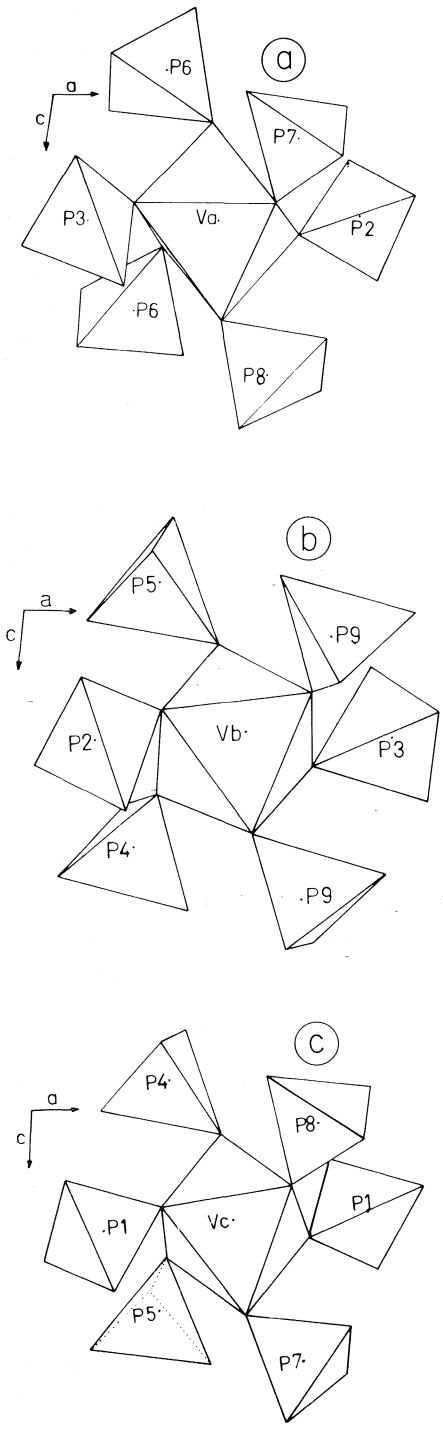

FIG. 2. The environments about the vanadium ions near $x,z = \frac{1}{4}, \frac{1}{4}$ for the three ranges (*a*) $0 \leq y \leq \frac{1}{3}$, (*b*) $\frac{1}{3} \leq y \leq \frac{2}{3}$, (*c*) $\frac{2}{3} \leq y \leq 1$. Oxygen atoms lie at the corners of the polyhedra.

varied. Changes at the 2σ level were found but not considered significant.

The displacement of the atoms from translational equivalence by $b/3$ was calculated. Two of the vanadium ions nearly superimpose, with the third displaced by about $\frac{1}{3}$ Å equatorial to *b*. A similar result applies to the P atoms in the set P(7), P(8), and P(9). The maximum displacement from superposition amongst the set P(4), P(5), and P(6) is $\frac{1}{4}$ Å whereas the set P(1), P(2), and P(3) has the largest set of displacements ranging from 0.16 to 0.51 Å. The major changes occur among the oxygen atoms. This results in a rotation of the polyhedra as shown in Fig. 2 *a*, *b*, *c*. Here the vanadium ions differing by about $\frac{1}{3}b$ and their nearest neighbour PO_4 environments are shown. In every case the phosphate groups sharing oxygen atoms with the upper faces of the VO_6 groups are inverted with respect to those sharing the oxygen atoms of the lower faces. Although the groups in Fig. 2*b* and Fig. 2*c* are substantially nearer to superposing with each other than with those in Fig. 2*a*, the displacements needed for superposition are large. In fact, the largest displacement from superposition of the oxygen atoms is over 1 Å with the average over 0.6 Å. Although it is possible to discuss the mutual angular displacements of each of the polyhedra it is not apparent that this will result in an understanding of the enlarged cell.

The intensities of five strong $k = 0 \pmod 3$ reflections and the 25 strongest $k \neq 0 \pmod 3$ reflections were measured at room temperature, 300°C, and 500°C. The higher temperature intensities were compared to the room temperature ones. The results shown in Fig. 3, indicate that, although the errors are large, the $k \neq 0 \pmod 3$ reflections become substantially weaker with increasing temperature while the $k = 0 \pmod 3$ reflections only weaken slightly. This suggests that the structure tends towards becoming the average structure at high temperatures. This average structure may be modified slightly, possibly through differential axis changes, from the room temperature one since there are some unacceptable bond lengths at room temperature. No evidence of a phase transition at higher temperatures was found by DTA in this laboratory confirming the results of Lavrov *et al.* (5).

Discussion

In light of the many distinct polymorphs of

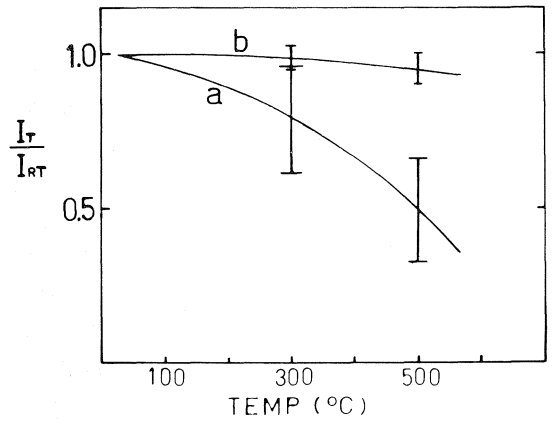

FIG. 3. The ratio of the intensity at various temperatures compared to room temperature for (*a*) 25 strongest reflections with $k \neq 0$ (mod 3) and (*b*) 5 strong reflections with $k = 0$ (mod 3).

$Cr(PO_3)_3$ (25) it is surprising that $V(PO_3)_3$ crystallizes as only one of these. The present structure is one common to one of the polymorphs of Al, Cr, Ti, and Mo trimetaphosphate. The structure of the cubic modification, found for Cr, Al, and Fe as cations, is based upon rings of four tetrahedra and thus bears no direct relationship to the present structure.

Unit cell dimensions of a hexagonal form are known for $Cr(PO_3)_3$ (25) and $Fe(PO_3)_3$. Although the present structure has some features of hexagonal packing, the structure is not easily transformed to a hexagonal or trigonal one. The direction of the chain should lie in a plane perpendicular or parallel to the unique axis of the hexagonal cell. In the present structure these chains are arrayed at the corners of a rectangle normal to the *c* axis and thus a substantial change will be needed to bond the VO_6 with two phosphate groups in each of three chains, as would be required for the hexagonal phase.

Deviations in the bond lengths of the two types of P—O bonds are expected based upon Baur's (30) correlation between bond length and bond strength. Thus the P—O(—P) bond with a bond strength at the oxygen atom of 2.5 will show a longer bond than the P—O(—V) where the bond strength is 1.75. The predicted bond length difference of 0.08 Å is comparable to 0.10 Å as found here.

The V^{3+}—O bond lengths and VO_6 geometry are as found in V_2O_3 (31) and other V_nO_{2n-1} structures (19, 31, 32), as well as for Al^{3+} in $Al(PO_3)_3$ (28). The higher valent vanadium systems are characterized by the short vanadyl bond and as a result, for these systems, the vanadium analogue of structures with the same stoichiometry can often differ. A case in point is MP_2O_7 where for M = Hf, Zr, Sn, Ti, and Si (10) the structures are isostructural and based upon a binary condensation of PO_4 groups. In the vanadium system the structure is written as $VO(PO_3)_2$ to emphasize the vanadyl bond and the infinite chain of corner sharing PO_4 groups.

$V(PO_3)_3$ is one of many structures and structure-types having each oxygen atom shared between only two cations. These structures involve cations with large charges in order to maintain reasonable bond orders on the oxygen atoms. Another structure where the ratio of the numbers of octahedra to tetrahedra is the same as in the present case is $VO(P_2SiO_8)$. This latter structure consists of chains of VO_6 groups containing tetravalent V and bridged by vanadyl groups (14, 15). The PO_4 groups form four membered rings bridged in the chain direction by SiO_4 groups. If P^{5+} were to fully substitute for Si^{4+}, the vanadium would be reduced yielding the same stoichiometry as in the present crystal. This form is unstable presumably because of the instability of the vanadyl bond for trivalent vanadium. Without these bonds the oxygen atom bridging the octahedra would be too underbonded.

Effective fixed charge densities of cobalt and nickel sulphide (parchment supported) membranes in contact with various 1:1 electrolyte solutions have been evaluated from membrane potential measurements. The methods used for the estimation of charge densities were: (*a*) the Teorell–Meyer–Sievers method (TMS) and (*b*) the methods developed recently by Kobatake and co-workers. The two limiting forms of Kobatake's equation for dilute and concentrated solutions gave identical values of charge densities. The theoretical predictions for membrane potential were borne out quite satisfactorily by experimental results obtained with both the membranes. Apparent transference numbers of coions and permselectivities of the membranes for electrolytes have also been calculated. A method based on permselectivity values for the determination of charge density was also used. It was interesting to note that the charge densities evaluated from different methods of Kobatake and co-workers gave identical values and that the results were comparable to those derived from the TMS method.

M. Nasim Beg, Fasih A. Siddiqi et Radhey Shyam. Can. J. Chem. **55**, 1680 (1977).

On a évalué, à partir de mesures de potentiel de membranes, les densités effectives de charges fixes pour des membranes de sulfures de cobalt et de nickel (supportés sur du parchemin) en contact avec diverses solutions d'électrolytes 1:1. Les méthodes utilisées pour évaluer les densités de charges sont: (*a*) la méthode de Teorell–Meyer–Sievers et (*b*) les méthodes développées récemment par Kobatake et ses collaborateurs. Les deux formes limites de l'équation de Kobatake pour des solutions diluées et concentrées conduisent à des valeurs identiques pour les densités de charge. Les prédictions théoriques pour les potentiels des membranes concordent bien avec les résultats expérimentaux obtenus avec les deux membranes. On a aussi calculé les nombres apparents de transferts des coions et les permsélectivités des membranes pour les électrolytes. On a aussi utilisé une méthode basée sur des valeurs de permsélectivité pour la détermination de la densité de charge. Il est intéressant de noter que les densités de charges évaluées par diverses méthodes de Kobatake et ses collaborateurs conduisent toutes à des valeurs identiques et que les résultats sont comparables à ceux que l'on peut obtenir à partir de la méthode TMS.

[Traduit par le journal]

In a series of communications (1–10) on parchment supported membranes, Siddiqi, Beg, and co-workers (1–6) have, on the basis of the Eisenman–Sherry model of membrane selectivity (11, 12) and by the application of the theory of rate processes to diffusion (13), demonstrated the small density of fixed charge on the membrane matrix. In order to substantiate these findings, membrane potential measurements have been carried out for the evaluation of effective fixed charge density which is an important characteristic of a membrane by various methods (14–16) including those developed recently by Kobatake and co-workers (17–23).

Experimental

Parchment supported cobalt and nickel sulphide membranes were prepared by the method of interaction suggested by Siddiqi, Beg, and co-workers (1–6). To precipitate these substances in the interstices of the parchment paper, a 0.2 *M* solution of sodium sulphide was placed inside a glass tube, to one end of which was tied parchment paper. The tube was suspended for 72 h in a 0.2 *M* solution of either cobalt(II) or nickel(II) chloride. The two solutions were interchanged later and kept for another 72 h. The membranes were washed with deionized water to remove free electrolyte.

were used for measuring membrane potentials. The reference electrodes used were reversible Ag–AgCl standing in chloride solutions. The total potential difference between Ag–AgCl electrodes placed on either side of the membrane is the algebraic sum of the electrode potential, *i.e.* concentration potential and the membrane potential E_m (2, 24). A tenfold difference in concentration of chloride solutions (*i.e.* $C_2/C_1 = 10$) was maintained and measurements were made using a Pye precision potentiometer (No. 7568). The solutions were replaced by fresh solutions and when there was no change in potential with the addition of fresh solutions, with constant vigorous stirring by a pair of magnetic stirrers, it was taken as the true total potential difference across the Ag–AgCl electrodes. In both the membranes it could be reproduced within a few tenths of a mV. The whole cell was immersed in a water thermostat maintained at 25 ± 0.1°C. The various salt solutions (chlorides of Li^+, Na^+, K^+, and NH_4^+) were prepared from B.D.H. A.R. grade chemicals and deionized water. The parchment paper was supplied by M/S Baird and Tatlock (London) Ltd.

Results and Discussion

The values of membrane potential measured across two sulphide membranes in contact with various 1:1 electrolytes are given in Table 1.

When two electrolytic solutions having different concentrations are separated by a membrane, the mobile species penetrate the membrane and various transport phenomena are induced into the system (23). The fixed charge concept of Teorell (14) and Meyer and Sievers (15) (the TMS theory) for charged membranes is a pertinent starting point for the investigation of the actual mechanisms of the ionic or molecular processes which occur in the membrane phase. These authors obtained the following mathematical expression eq. 1 for the emf across a charged membrane by integrating the equation for the emf due to diffusion of ions within a membrane and subsequently adding the two phase-boundary (Donnan) potentials to the intramembrane diffusion potential

$$[1]\quad E_m = 59.2\left[\log \frac{C_2\,(\sqrt{4C_1^2 + \bar{X}^2} + \bar{X})}{C_1\,(\sqrt{4C_2^2 + \bar{X}^2} + \bar{X})} + \bar{U}\log \frac{\sqrt{4C_2^2 + \bar{X}^2} + \bar{X}\bar{U}}{\sqrt{4C_1^2 + \bar{X}^2} + \bar{X}\bar{U}}\right]$$

Here, $\bar{U} = (\bar{u} - \bar{v})/(\bar{u} + \bar{v})$, $\bar{u}$ and $\bar{v}$ are the mobilities of cation and anion, respectively, in the membrane phase, and $\bar{X}$ is the charge on the membrane expressed in equiv./ℓ of imbibed solution. In order to evaluate this parameter for the simple case of a 1:1 electrolyte and a membrane carrying a net negative charge of unity ($\bar{X} = 1$), theoretical concentration potentials E_m existing across the membrane were calculated as a function of C_2, the ratio (C_2/C_1) being kept at a constant value of 10 for different mobility ratios $(\bar{u}/\bar{v})$ and plotted as shown in Fig. 1. The observed membrane potential values for different membranes and KCl electrolyte were plotted in the same graph. The experimental curve for any given membrane was shifted horizontally and ran parallel to one of the theoretical curves. The extent of this shift gave $\log \bar{X}$ and the parallel theoretical curve gave the value for $(\bar{u}/\bar{v})$. The values of $\bar{X}$ and $(\bar{u}/\bar{v})$ derived in this way for the different membranes and electrolytes are given in Table 2.

Recently Kobatake *et al.* (17) derived the following equation for the electrical potential E_m which arises when a negatively-charged membrane separates two solutions of a 1:1 electrolyte of concentrations C_1 and C_2 ($C_1 < C_2$):

$$[2]\quad E_m = -\frac{RT}{F}\left[\frac{1}{\beta}\ln \frac{C_2}{C_1} - \left(1 + \frac{1}{\beta} - 2\alpha\right)\ln\left(\frac{C_2 + \alpha\beta X}{C_1 + \alpha\beta X}\right)\right]\ldots$$

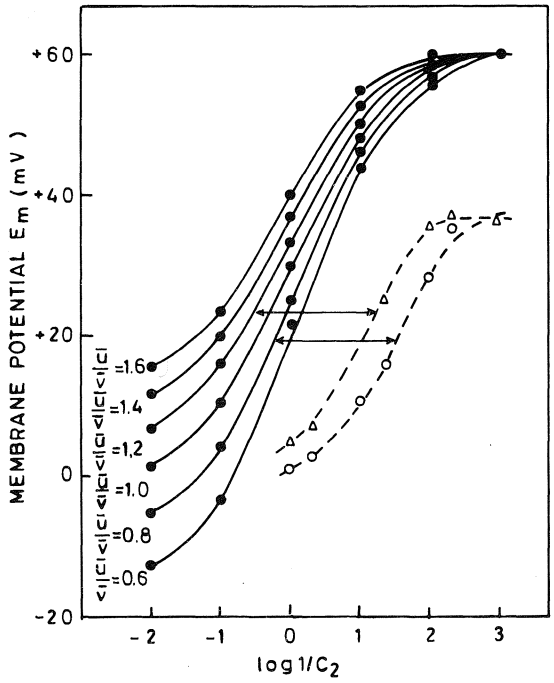

FIG. 1. Evaluation of membrane charge density $\bar{X}$ and the mobility ratio $\bar{u}/\bar{v}$ in the membrane phase. Smooth curves on the left are the theoretical concentration potentials for a cation – selective membrane ($\bar{X} = 1$) using 1:1 electrolytes at different mobility ratios $\bar{u}/\bar{v}$. The experimental values of E_m for (Δ) cobalt and (○) nickel sulphide membranes and KCl electrolyte solution are shown by the broken lines, see text.

TABLE 2. Derived values for membrane parameters ($\bar{X}$) and ($\bar{u}/\bar{v}$) using Teoreil–Meyer–Sievers theory

	Cobalt sulphide		Nickel sulphide

LiCl	2.5	1.0	2.2	0.8
NH_4Cl	2.2	0.8	1.5	1.0

where

$$\alpha = u/(u + v)$$

$$\beta = 1 + KFX/u$$

F and K represent, respectively, the Faraday constant and a constant dependent upon the viscosity of the solution and structural details of the polymer network of which the membrane is composed. To evaluate the membrane parameters, β and X, two limiting forms of the above equation were derived. When the external salt concentration C is sufficiently small,

$$[3] \quad |E_m^{\sigma}| = \frac{1}{\beta}\ln\gamma - \left(\frac{\gamma - 1}{\alpha\beta\gamma}\right) \times \left(1 + \frac{1}{\beta} - 2\alpha\right)\left(\frac{C_2}{X}\right) + \ldots$$

where

$$|E_m^{\sigma}| = FE_m/RT$$

and

$$\gamma = C_2/C_1$$

When the salt concentration C is high,

$$[4] \quad \frac{1}{t_-} = \frac{1}{1-\alpha} + \frac{(1 + \beta - 2\alpha\beta)(\gamma - 1)}{2(1-\alpha)^2 \ln\gamma}\left(\frac{X}{C_2}\right) + \ldots$$

where t_- is the apparent transference number of coions (anions) in a negatively-charged membrane defined by

$$[5] \quad |E_m^{\sigma}| = (1 - 2t_-)\ln\gamma$$

The values of t_- calculated from observed membrane potentials using [5] are given in Table 3. Equation 3 was used to give the value of β and a relation between α and X by evaluating the intercept and the initial slope of the plot of $|E_m^{\sigma}|$ against C_2 (Fig. 2), while [4] was used to evaluate α from the intercept of a plot of $1/t_-$ against $1/C_2$ (Fig. 3). The value of X (or X_d) was determined by inserting this value of α in the relation between α and X obtained earlier. Once α and β are known in the manner described above, X (or X_c) was also evaluated from the initial slope of $1/t_-$ against $1/C_2$. Kobatake and co-workers (17) have suggested that provided their equation for the membrane potential is correct then the two values of charge densities namely X_c and X_d obtained under opposite limiting conditions (concentrated and dilute) should be the same. In the present case, the two values thus obtained agree well with each other (Table 4), thereby confirming the applicability of the Kobatake and co-workers equation to parchment supported membranes.

Once the values of the parameters α, β, and X for a given membrane electrolyte system have been determined, one can get the theoretical E_m *vs.* C_2 curve using [2] for any given γ (= C_2/C_1) and compare it with the corresponding experimental data. For this comparison eq. 2 can be rewritten in the following form as suggested by Kobatake and co-workers (17)

TABLE 3. Transference number t_- of coions derived from observed membrane potential at various electrolyte concentrations

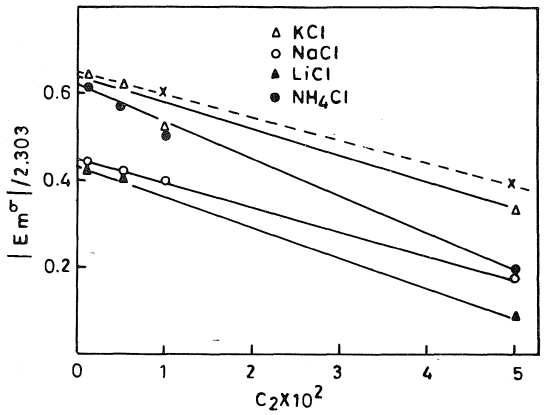

FIG. 2. Plots of $|E_m^\circ|/2.303$ *vs.* $C_2 \times 10^2$ for nickel sulphide membrane (—) in contact with various 1:1 electrolyte solutions and (---) for cobalt sulphide membrane with KCl solutions.

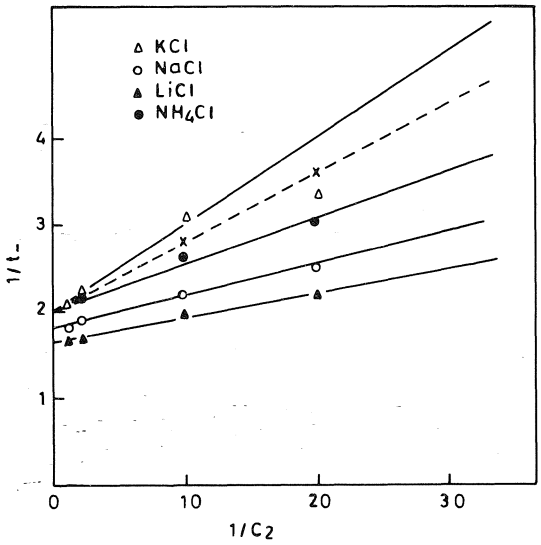

FIG. 3. Plots of $1/t_-$ *vs.* $1/C_2$ for nickel sulphide membrane (—) in contact with various 1:1 electrolyte solutions and cobalt sulphide membrane (---) with KCl solution.

$$[6] \qquad \frac{(\gamma - e^q)}{(e^q - 1)} = Z$$

with q and Z defined by

$$q = \frac{[|E_m^\circ| + (1 - 2\alpha) \ln \gamma]}{1/\beta + (1 - 2\alpha)}$$

and $Z = C_2/\alpha\beta X$. Thus if [6] is valid, the value of $(\gamma - e^q)/(e^q - 1)$ calculated from the measured E_m with predetermined α, β, and X and the given value of γ must fall on a straight line which has a unit slope and passes the co-ordinate origin when plotted against Z. This behaviour should be observed irrespective of the value of γ and the kind of membrane–electrolyte system used. Figure 4 demonstrates that the theoretical prediction of [6] (or eq. 2) is borne out quite satisfactorily by our experimental results on parchment supported membranes.

Kobatake and Kamo (23) derived another equation (eq. 7) for membrane potential using a different set of assumptions, namely: (*a*) the contribution of mass movement is negligible (23), and (*b*) small ions do not behave ideally in a charged membrane (23).

$$[7] \quad E_m = \frac{RT}{F}\left[\ln \frac{C_2}{C_1} + (2\alpha - 1) \times \ln \frac{\sqrt{4C_2^2 + \phi^2 X^2} + (2\alpha - 1)\phi X}{\sqrt{4C_1^2 + \phi^2 X^2} + (2\alpha - 1)\phi X} - \ln \frac{\sqrt{4C_2^2 + \phi^2 X^2} + \phi X}{\sqrt{4C_1^2 + \phi^2 X^2} + \phi X}\right]$$

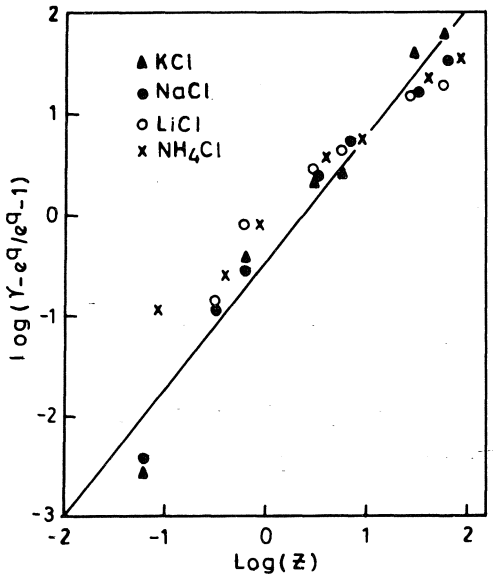

FIG. 4. Plot of log $(\gamma - e^q)/(e^q - 1)$ *vs.* log Z for nickel sulphide membrane in contact with various 1:1 electrolyte solutions.

where ϕ is a characteristic factor of the membrane–electrolyte pair, and represents a fraction of counterions not tightly bound to the membrane skeleton. The product ϕX is termed the thermodynamically effective fixed charge density of a membrane. Other terms have their usual significance. Equation 7 has the same functional form as that given by the TMS theory for the membrane potential E_m (*i.e.* eq. 1) except that the thermodynamically effective fixed charge density ϕX of the membrane is used in place of stoichiometric fixed charge density $\bar{X}$. Equation 7 reduced to the TMS membrane potential for $\phi = 1$. Since it is somewhat troublesome to evaluate ϕX at an arbitrary external electrolyte concentration from the observed membrane potential E_m using [7], Kobatake and Kamo (23) have proposed a simple method using the following approximate equation for the diffusive contribution to the emf of a cell with transport.

$$[8] \qquad E_m = -\frac{RT}{F}(1 - 2\tau_{app}) \ln C_2/C_1$$

where τ_{app} is the transference number of coions in the membrane phase. Comparison of [7] and [8] gives

$$[9] \qquad \tau_{app} = \frac{1-2\alpha}{2} \frac{\ln\left(\frac{\sqrt{4\xi_2^2+1}+2\alpha-1}{\sqrt{4\xi_1^2+1}+2\alpha-1}\right)}{\ln \gamma} + \frac{\ln\left(\frac{\sqrt{4\xi_2^2+1}+1}{\sqrt{4\xi_1^2+1}+1}\right)}{2 \ln \gamma}$$

where $\xi = C/\phi X$, when the concentration of the external salt solution is large as compared to the effective charge density ϕX, *i.e.* when $C_1/\phi X = \xi_1 \gg 1$, [9] is expanded to

$$[10] \qquad 1/\tau_{app} = \frac{1}{1-\alpha} + \frac{\gamma - 1}{\gamma \ln \gamma} \frac{\alpha}{1-\alpha}\left(\frac{\phi X}{C_1}\right) + O\left(\frac{1}{C_1}\right)^2$$

This equation indicates that the plot of $1/\tau_{app}$ *vs.* $1/C_1$ with a fixed γ (or C_2/C_1) should give a straight line, and the values of α and ϕX in the concentrated solution for a given combination of membrane and electrolyte can be determined

from the intercept and the slope of the line. The values of thermodynamically effective fixed charge densities thus derived using Fig. 5 for two sulphide membranes in contact with various 1:1 electrolytes are given in Table 4.

On the other hand (22, 23), the mass-fixed transference number of coions in a negatively-charged membrane immersed in an electrolyte solution of concentration C is defined by

$$[11] \qquad \tau_- = vC_-/(uC_+ + vC_-)$$

where C_+ and C_- are the concentrations of cation and anion respectively in the membrane phase. This equation is transformed to

$$[12] \quad \tau_- = 1 - \alpha\frac{\sqrt{4\xi^2 + 1} + 1}{\sqrt{4\xi^2 + 1} + (2\alpha - 1)}$$

using equations given by Kobatake and co-workers (22, 23) for the activity coefficients, mobilities of small ions in the membrane phase, and the equilibrium condition for electrical neutrality. The difference between τ_{app} calculated from [9] and τ_- from [12] for various reduced concentrations ξ is found to be less than 2%. Therefore τ_{app} and τ_- are considered practically the same. As a result, the apparent transference number τ_{app} evaluated from the membrane potential data permits the determination of the thermodynamically effective fixed charge density ϕX of the membrane at a given average salt concentration C (*i.e.* $(C_1 + C_2)/2$) using [12]. At the same time rearrangement of [12] leads to the definition of permselectivity P_s by the

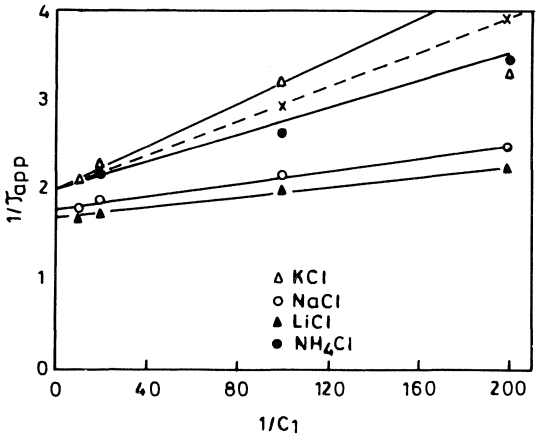

FIG. 5. Plots of $1/\tau_{app}$ *vs.* $1/C_1$ for nickel sulphide membrane (—) in contact with various 1:1 electrolyte solutions and cobalt sulphide membrane (---) with KCl solutions.

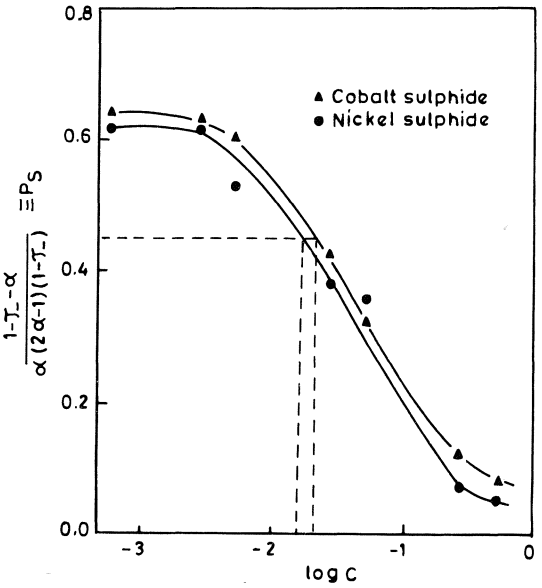

FIG. 6. Plots of P_s *vs.* log $(C_1 + C_2)/2$ for membranes using different concentrations of KCl solutions.

expression

$$[13] \quad \frac{1}{(4\xi^2 + 1)^{1/2}} = \frac{1 - \tau_- - \alpha}{\alpha - (2\alpha - 1)(1 - \tau_-)} \equiv P_s$$

This equation can be used to find the permselectivity P_s from the membrane potential measurements using [8]. If the transport number of coions (τ_- or τ_{app}) is zero, the membrane is perfectly selective and $P_s = 1$, while if the transport number of coions has the value in free solution, $P_s = 0$. The values of P_s obtained using the right-hand side of [13] were plotted against log C. The concentration at which P_s becomes $1/\sqrt{5}$ (*i.e.* $\xi = C/\phi X = 1$) gives the value of the thermodynamically effective fixed charge density ϕX as demanded by the left-hand side of [13]. Figure 6 represents a typical plot of P_s *vs.* log C for two parchment supported sulphide membranes in contact with the KCl electrolyte. The values of ϕX thus derived from both the membranes and 1:1 electrolyte combinations are given in Table 4. Further, it is noted from Tables 2 and 4 that the charge densities found by the three theories are of the same magnitude.

DONALD J. NORRIS and ROSS STEWART. Can. J. Chem. **55**, 1687 (1977).

Fourteen pyridinium salts, substituted at the 1- and 3-positions, have been prepared and their stabilities determined in aqueous acetate and tris(hydroxymethyl)aminomethane (Tris) buffers. The 1,4-dihydro derivatives of eleven of these have been prepared and characterized and their stabilities likewise determined. The pyridinium ions are stable in acidic solution but undergo either ring attack or amide or ester hydrolysis under basic conditions, whereas the dihydropyridines undergo covalent hydration in acid solution. For only four pairs of compounds and one buffer system (Tris) are there p*H*-ranges in which the pyridinium and dihydropyridine forms are simultaneously stable (less than 10% decomposition in 24 h). These compounds have a carbamoyl or acetyl group at the 3-position and either a methoxymethyl, acetonyl, or carbamoylmethyl group at the 1-position. The acetic acid catalyzed rates of hydration of the 1-alkyl-3-carbamoyl-1,4-dihydropyridines are correlated by σ^* values with a ρ^* of -2.00, consistent with protonation being the rate-controlling step.

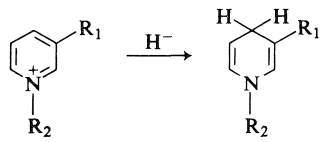
DONALD J. NORRIS et ROSS STEWART. Can. J. Chem. **55**, 1687 (1977).

On a préparé 14 sels de pyridinium substitués dans les positions 1 et 3 et on a déterminé leur stabilité dans des tampons d'acétate aqueux et de tris(hydroxyméthyl) aminométhane (Tris). On a préparé les dérivés dihydrogénés en 1,4 d'onze de ces composés et on les a aussi caractérisés et déterminé leur stabilité. Les ions pyridinium sont stables en solution acide mais subissent soit des attaques au niveau du cycle ou des hydrolyses de l'amide ou de l'ester dans des conditions basiques; par ailleurs, les dihydropyridines subissent une hydratation covalente en solution acide. Il n'y a que quatre paires de composés et un système de tampons (Tris) qui fournissent des écarts de p*H* dans lesquels les formes pyridinium et dihydropyridine sont stables d'une façon simultanée (une décomposition de moins de 10% en 24 h). Ces composés possèdent un groupe carbamoyle ou acétyle en position 3 et soit un groupe méthoxyméthyle, acétonyle ou carbamoylméthyle en position 1. Il y a une corrélation entre les vitesses catalysées par l'acide acétique pour l'hydratation des alkyl-1 carbamoyl-3 dihydro-1,4 pyridines et les valeurs σ^*; la valeur de ρ^* de -2.00 est en accord avec une protonation qui agirait comme étape déterminante de la réaction.

[Traduit par le journal]

Introduction

Nicotinamide coenzymes, such as NAD^+, nicotinamide adenine dinucleotide (**1**, $R_1 = CONH_2$, R_2 = adenine dinucleotide), are two-equivalent oxidants which occupy one of the termini of the so-called electron-transport chain in living systems, with oxygen, a one-equivalent oxidant, occupying the other (1). The pyridinium ring in such systems oxidizes alcoholic and other groups by a two-equivalent process which is essentially a hydride transfer, and is converted to a 1,4-dihydropyridine thereby.



1 **2**

We were interested in determining the effect of substituents in the pyridine ring on the relative free energy levels of the oxidant and reductant, and ultimately, to find NAD^+ model compounds whose equilibrium with flavin nucleotides (the next redox system in the chain) could be directly measured. Accordingly, we have prepared a number of pyridinium and dihydropyridine compounds, **1** and **2** which are models for NAD^+ and its reduction product NADH, and have examined their properties. The present article describes the synthesis of these compounds and a determination of their stabilities in aqueous buffers, the medium in which the redox studies have been made.

Experimental

Synthesis of Quaternary Pyridinium Salts

Quaternary pyridinium salts were prepared from the

corresponding pyridines and alkyl halides. Methyl chloroacetate was prepared from chloroacetic acid and methanol by the method of Clinton and Laskowski (2); isopropyl chloroacetate was similarly prepared by using 2-propanol in place of methanol. All of the other alkyl halides and the pyridines were obtained commercially and used without further purification.

The general method for preparing the pyridinium salts consisted of mixing 30 mmol of each of the pyridine and alkyl halide in 15 ml of solvent (usually acetone or acetone–dimethylformamide) and refluxing for 1–3 days until sufficient crystals had formed. The crystals were filtered, washed with acetone, and dried under aspirator vacuum. Individual variations on this scheme are noted in Table 1. Analytical data appear in Table 2.

Two of the pyridinium compounds, **1***a* and **1***n*, can undergo protonation or deprotonation in the aqueous p*H* range. The p*K* of the carboxylate group of **1***a* was determined to be 1.62 ± 0.12 by monitoring the spectral changes at 250 nm (8). In most aqueous solutions, therefore, **1***a* exists as the dipolar ion. The dissociation constant of the 3-hydroxy group in **1***n* was determined by titration with standard base. A p*K* of 4.69 ± 0.01 was found, close to that for the 3-hydroxypyridinium ion (9). In neutral and basic solutions, therefore, the compound exists predominantly in the dipolar ion form.

Synthesis of 1,4-Dihydropyridines

The 1,4-dihydropyridines were prepared by the classical method of reduction of the corresponding pyridinium salts with sodium dithionite (5, 11–13). The pyridinium salts were used directly as recovered from their preparative reaction mixtures (*vide ante*). Unless stated otherwise crude yields were approximately 50%, and the product crystals could not be stored in contact with air without appreciable decomposition occurring. Compounds **2***m* and **2***n* are expected to be highly unstable in aqueous solution and their attempted preparations were unsuccessful.

In all dihydropyridine syntheses, a solution of 10 mmol of the corresponding pyridinium salt in 15 ml of water was used. These solutions were flushed with nitrogen and then treated by one of the following methods.

Method I

$Na_2S_2O_4$ (2.6 g) was mixed with 20 mmol of sodium or potassium carbonate powder and this mixture was added portionwise to the stirred pyridinium ion solution. Stirring under nitrogen was continued for 15 to 20 min after the first signs of crystallization, after which the crystals were filtered, washed with water, and dried under aspirator vacuum.

*1-Carbamoylmethyl-3-carbamoyl-1,4-dihydropyridine (**2i**)*—The crude crystals were recrystallized from water (30 ml/g) giving an overall 66% yield of yellow, rod-like crystals, which are stable indefinitely in the presence of air at room temperature, mp 179–182°C (dec.). *Anal.* calcd. for $C_8H_{11}N_3O_2$: C 53.04, H 6.07, N 23.20; found: C 52.79, H 6.21, N 23.05.

*1-Carbomethoxymethyl-3-carbamoyl-1,4-dihydropyridine (**2f**)*—The crude product was recrystallized from benzene to give yellow needles, which were stable in air for a few months, mp 128–132°C (dec.). *Anal.* calcd. for $C_9H_{12}N_2O_3$: C 55.12, H 6.12, N 14.29; found: C 55.11, H 6.19, N 14.26.

*1-Cyanomethyl-3-carbamoyl-1,4-dihydropyridine (**2h**)*—The crude crystals were dissolved in refluxing methylene chloride and filtered. Petroleum ether was added until crystallization began. The solution was cooled under nitrogen to yield fluffy, pale yellow crystals, mp 127–130°C (dec.). *Anal.* calcd. for $C_8H_9N_3O$: C 58.89, H 5.52, N 25.77; found: C 58.72, H 5.68, N 25.75.

Method II

Reduction of the pyridinium ions was carried out as in method I, but since the resulting dihydropyridines would not precipitate from the reaction mixture an alternative recovery method was used. After the mixture had turned a bright yellow colour, it was extracted continuously overnight with methylene chloride which had been stored over KOH pellets. The methylene chloride extract was concentrated from about 200 ml to about 20 ml on a rotary evaporator. The remaining solvent was evaporated under aspirator vacuum in a flask fitted with a nitrogen bleed. The nitrogen bleed was necessary in order to recover a crystalline product; without it, evaporation of the remaining methylene chloride left only a yellow oil.

*1-Acetonyl-3-carbamoyl-1,4-dihydropyridine (**2e**)*—The crude product was recrystallized from ethyl acetate, mp 118–121°C (dec.). *Anal.* calcd. for $C_9H_{12}N_2O_2$: C 60.00, H 6.67, N 15.56; found: C 60.38, H 6.68, N 15.20.

*1-Carbamoylmethyl-3-acetyl-1,4-dihydropyridine (**2j**)*—The crude material (64% yield) was recrystallized from ethyl acetate (160 ml/g) under nitrogen to give fine yellow needles, which are stable for several days in air, mp 162–163°C (dec.). *Anal.* calcd. for $C_9H_{12}N_2O_2$: C 60.00, H 6.67, N 15.56; found: C 60.31, H 6.80, N 15.30.

*1-Carbo-i-propoxymethyl-3-carbamoyl-1,4-dihydropyridine (**2g**)*—The crude product was recrystallized from ethyl acetate (20 ml/g) under nitrogen. The crystals appear to require several days of exposure to air for noticeable decomposition, mp 112–114°C (dec.). *Anal.* calcd. for $C_{11}H_{16}N_2O_3$: C 51.06, H 5.80, N 10.83; found: C 50.89, H 5.69, N 10.88.

*1-Methoxymethyl-3-carbamoyl-1,4-dihydropyridine (**2d**)*—The crude crystals (70% yield) were recrystallized twice from ethyl acetate. The recrystallization flask must be scraped with a glass rod before sealing the solution under nitrogen or recrystallization will not occur. The pure crystals are stable for only a few days in the presence of air, mp 106–107°C (dec.). *Anal.* calcd. for $C_8H_{12}N_2O_2$: C 57.14, H 7.14, N 16.67; found: C 57.40, H 7.07, N 16.66.

*1-Carbamoylmethyl-3-cyano-1,4-dihydropyridine (**2k**)*—A small amount of product crystallized from the reaction mixture. These crystals were combined with the extraction product and recrystallized from benzene (100 ml/g). A yield of 70 mg (approximately 10%) of pure product was obtained, mp 139–139.5°C. *Anal.* calcd. for $C_8H_9N_3O$: C 58.89, H 5.52, N 25.77; found: C 59.18, H 5.72, N 25.45.

Method III

The dihydropyridines which are quite acid-labile decompose too rapidly in carbonate solutions for methods I and II to be practical. In these cases, potassium hydroxide was used instead of carbonate. The sodium dithionite and KOH were alternately added to the stirred

1-Carbamoylmethyl-3-acetylpyridinium chloride (**1***j*)	50.35	5.13	13.05	50.33	5.00	12.87
1-Carbamoylmethyl-3-cyanopyridinium chloride (**1***k*)	48.61	4.05	21.27	48.74	4.10	21.23
1-Carbamoylmethyl-3-fluoropyridinium chloride (**1***l*)	44.09	4.20	14.70	43.80	4.17	14.67
1-Carbamoylmethylpyridinium chloride (**1***m*)	48.70	5.22	16.23	48.82	5.08	15.96
1-Carbamoylmethyl-3-hydroxypyridinium chloride (**1***n*)[a]	44.56	4.78	14.85	44.73	4.68	14.80

[a]To confirm that alkylation had not occurred at the hydroxyl group the uv spectrum was compared to that of 1-methyl-3-hydroxypyridinium chloride in acidic and basic solutions. The latter compound has a maximum at 288 nm at p*H* 1 which shifts to 245 and 322 nm at p*H* 13 (10). **1***n* has a maximum at 289 nm at p*H* 1 which shifts to 238 and 313 nm at p*H* 13.

pyridinium ion solution so as to maintain the p*H* close to 10. The products with the exception of **2***l* were recovered as described in method II.

*1-(2′-Hydroxyethyl)-3-carbamoyl-1,4-dihydropyridine (**2***c*)—The product which crystallized from the methylene chloride was filtered, dried, and stored under nitrogen in a dry box. Less than a day's exposure to air is sufficient to cause noticeable discoloration of the crystals, mp 133–133.5°C (dec.); lit. (14) mp 119–121°C. *Anal.* calcd. for $C_8H_{12}N_2O_2$: C 57.14, H 7.14, N 16.67; found: C 56.97, H 6.96, N 16.53.

*1-Methyl-3-carbamoyl-1,4-dihydropyridine (**2***b*)—A yield of 0.4 g (35%) of bright yellow crystals was obtained, mp 73.5–78°C (dec.); lit. (5) mp 84°C, (15) mp 85.3–86.8°C; λ_{max} (ε) = 360 (7820); lit. (15). λ_{max} (ε) = 355 (6680). Attempts to recrystallize the crude product were unsuccessful. The lower extinction coefficient reported in the literature was recorded in water, where this compound decomposes even in the absence of buffer acid. The spectrum of this compound was recorded at p*H* 9.8 in this study to slow down the decomposition reaction, but even at this p*H* a decomposition of a few percent an hour is observable.

*1-Carbamoylmethyl-3-fluoro-1,4-dihydropyridine (**2***l*)—Crystals formed within a few minutes and were filtered immediately. If the crystals were stirred in solution for more than 10 min, they redissolved. Continuous extraction of the filtrate with methylene chloride yielded no product. Presumably the dihydropyridine is so susceptible to acid-catalyzed decomposition that the product must be recovered immediately, even at a p*H* as high as 10. The crude product was recrystallized from benzene (40 ml/g) giving a 10% yield of product, mp 116.5–118°C (dec.). *Anal.* calcd. for $C_7H_9N_2OF$: C 53.85, H 5.77, N 17.95; found: C 53.88, H 5.80, N 17.94.

*1-Carboxymethyl-3-carbamoyl-1,4-dihydropyridine (**2***a*)—This compound could be prepared by method III but it did not prove possible to purify it to analytical standards. When required it was prepared *in situ* by hydrolysis of **2***f* in p*H* 10 buffer for an hour.

Rate Measurements

Kinetic runs were followed by visible or uv absorption spectroscopy. Reactions which had half-lives greater than 5 min were followed on a Cary 16 spectrophotometer. Whenever the absorbance was not being read, the sample cell was removed from the path of the light beam. Reactions which had half-lives less than 5 min were followed on a Bausch and Lomb Spectronic 505 recording spectrophotometer.

Acid-catalyzed Decomposition of 1,4-Dihydropyridines

The rates of decomposition of 1,4-dihydropyridines in acid buffers (acetate or tris(hydroxymethyl)aminomethane, hereafter designated Tris) were measured by following the loss of dihydropyridine absorbance in the region between 300 and 390 nm.

The reaction mixtures were analyzed within a few hours after the decomposition was begun. The p*H* was measured on a Radiometer 26 p*H* meter standardized at p*H* 4 and 7 or 7 and 10. The concentration of acetic acid was determined by titration to a phenolphthalein end point with a standard sodium hydroxide solution. The concentration of protonated Tris was determined by titration to p*H* 10.5 with a standard sodium hydroxide solution.

Absorbance Spectra

Absorbance spectra were recorded on a Cary 16 spectrophotometer between 220 and 520 nm at 10 nm intervals. Spectral determinations were repeated until the extinction coefficients near λ_{max} were reproducible to within 3%. The values of λ_{max} and the corresponding extinction coefficients of most of the compounds used in this study are listed in Table 3. The spectra were recorded in water, except those of **2***a*, **2***b*, **2***c*, and **2***l*, which decompose rapidly in pure water and, therefore, were recorded in p*H* 10 buffer.

Results and Discussion

In view of the ubiquity of NAD^+ and NADH in living systems it is, perhaps, surprising that pyridinium and dihydropyridine rings are subject to ring attack in buffered aqueous systems. A considerable amount of work has been done on these reactions and the pyridinium ring lability been shown to result from nucleophilic

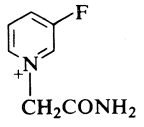
attack at the 2- or 4-positions, reaction 1 (1*b*, 16, 17). The dihydropyridine reaction appears to involve protonation at the 5-position, followed by attack by water or other nucleophile at the 6-position, reaction 2. A second, slower, reaction leads to further decomposition.

[1] 
[2] 
A further cause of instability in aqueous buffers of many of the compounds studied is the lability of the carboxamido and carbalkoxy groups toward hydrolysis (17, 18).

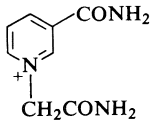
The three principal causes of instability in the model compounds, amide and ester hydrolysis, nucleophilic attack on the pyridinium ring, and acid-catalyzed hydration (or related reaction) of the dihydropyridine ring are discussed below. Since basic conditions favour the first two of these reactions and acidic conditions the third we have sought to define p*H* ranges in which both the oxidized and reduced forms have sufficient stability to enable measurements to be made of redox equilibria involving these compounds.

Amide and Ester Hydrolysis

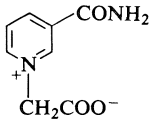
At p*H* 10.05, 1-carbamoylmethyl-3-fluoropyridinium ion (**1***l*) is slowly converted to a new compound whose polarographic half-wave potential is approximately 200 mV more negative. A similar difference in half-wave potentials is observed between 1-carbamoylmethyl-3-carbamoylpyridinium ion (**1***i*) and 1-carboxymethyl-3-carbamoylpyridinium ion (**1***a*).[1] Thus the



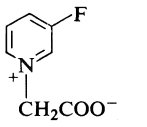
1*l*



1*i*



1*a*

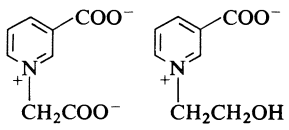


3

half-wave potentials are consistent with hydrolysis of the amide group on the 1-substituent to give 1-carboxymethyl-3-fluoropyridinium ion, **3**. In order to limit the amide hydrolysis rate of **1***l* to 10% or less over a period of 24 h, the cation should not be subjected to a p*H* greater than approximately 9.5.

[1]D. J. Norris and R. Stewart, to be published.

Similar behaviour was observed with solutions of 1-carboxymethyl-3-carbamoylpyridinium ion (**1***a*) and 1-(2′-hydroxyethyl)-3-carbamoylpyridinium ion (**1***c*) left for long periods at p*H*'s near 10. At p*H* 10 the polarographic wave of **1***a* at −1.07 V (*vs.* s.c.e.) disappears with a half-life of 5–6 days and is replaced by a wave at −1.33 V (*vs.* s.c.e.). The polarographic wave of **1***c* decays slightly more rapidly, having a half-life of approximately 3 days at p*H* 9.72 and 10 days at p*H* 10.26. The polarographic half-wave potentials of the products are in the regions one might expect for the dipolar 3-carboxypyridinium ions, **4** and **5**. Thus, the decomposition of **1***a* and **1***c*



4 **5**

is consistent with hydrolysis of the amide group at the 3-position. In order to limit this decomposition of **1***a* and **1***c* to no more than 10% over a period of 24 h, these ions should not be subjected to p*H*'s greater than 10.1 and 9.9, respectively.

Although no other pyridinium ions were tested for stability in the p*H* region above 10, it is likely that the hydrolysis observed with **1***a*, **1***c*, and **1***l* will occur with any pyridinium ion containing a 1-carbamoylmethyl or 3-carbamoyl group. Consequently, 3-carbamoylpyridinium ions should not be subjected for long periods to p*H*'s greater than 10.0 and 1-carbamoylmethylpyridinium ions to p*H*'s greater than 9.5. Two esters, 1-carbomethoxymethyl- and 1-carbo-*i*-propoxymethyl-3-carbamoylpyridinium ions (**1***f* and **1***g*) underwent rapid decomposition in alkaline solutions. At p*H* 9.2 the methyl ester decomposition had a half-life of approximately 3 min and the *i*-propyl ester reacted about one-sixth as fast. The products from both esters have polarographic half-wave potentials similar to that of 1-carboxymethyl-3-carbamoylpyridinium ion (**1***a*),[1] indicative of hydrolysis of the ester functions. Assuming the hydrolysis rate to be proportional to hydroxide ion concentration over this p*H* range, the decomposition of **1***f* and **1***g* will exceed 10% over a period of 24 h for p*H*'s greater than 5.7 and 6.5, respectively.

Reactions of the Pyridinium Ring

The instability in base of most of the compounds studied was due, in the first instance, to amide or ester hydrolysis. However, in the case of compounds **1***h*, **1***j*, and **1***k*, all of which contain strongly electron-withdrawing groups, the ring is the first site to be attacked as the p*H* is raised.

When **1***h* is mixed with Tris buffer at p*H* 8.2, the solution immediately turns yellow from an increase in absorbance in the region near 340 nm. In more basic solutions, the absorbance at 340 nm is higher still. Upon acidification, the absorbance spectrum reverts to that of **1***h*.

If **1***h* is left at p*H* 8.2 a second, slower reaction occurs with a half-life of approximately 80 min. This reaction is accompanied by further increases in absorbance at 340 nm and decreases in the pyridinium absorbance at 265 nm.

Reaction can also be observed polarographically under the same conditions. Concurrent with the increase in optical density at 340 nm, the polarographic half-wave potential shifts from −800 mV (*vs.* s.c.e.) to −900 mV[1] and the total limiting current of the polarographic wave decreases throughout the reaction to a final value of approximately two thirds of the initial limiting current. The rate of these changes increases with increasing p*H*, but the final value of the limiting current is independent of p*H*. On the other hand, the final value of the absorbance at 340 nm, like the initial value of this quantity, increases with increasing p*H*.

The very rapid, reversible reaction in alkaline solutions probably results from nucleophilic addition of hydroxide to the pyridinium ring (19, 20). (Glycine also appears to react by nucleophilic addition to the ring.) The nature of the subsequent reactions is, however, not clear. In order to avoid these reactions, these cations (**1***h*, **1***j*, **1***k*) should not be subjected to p*H*'s greater than 6.5, 9.5, and 6.5, respectively.

Reactions of the Dihydropyridine Ring

The decomposition of 1,4-dihydropyridines in the presence of acids has been studied by several groups in the past (1*b*, 21–26) and is known to involve several successive reactions (23–25). The primary acid decomposition reaction is a two-step process resulting in hydration of the 5,6-double bond, [2] (21, 26). The first step, which is believed to be rate-determining in aqueous media (21) is protonation at C-5, followed by nucleophilic attack at C-6. In aqueous solutions, the nucleophiles are primarily hydroxide ion and water, although adducts resulting from attack by other nucleophiles are also known (1*b*, 22).

We have measured the rates of the primary acid decomposition reaction for the 1,4-dihydropyridines **2***a–f*, **2***h–l* in acetate and tris(hydroxymethyl)aminomethane (Tris) buffers. The decomposition was followed spectrophotometrically at the λ_{max} of the 1,4-dihydropyridine, near 350 nm. The product generally has an absorbance of approximately 3% of that of the 1,4-dihydropyridine (25) which further decays as the product is consumed in a slower secondary decomposition reaction. Using an absorbance at infinite time, A_∞, of 3% of the initial absorbance, plots of log $(A - A_\infty)$ against time were linear over at least five half-lives as shown in Fig. 1.

The observed rate constants at different p*H*'s and buffer concentrations were analyzed to determine the acetic acid catalytic rate constants using [3] and the results given in Table 4.

$$[3]\quad k_{obs} = k_0 + k_{H^+}[H^+] + k_{AcOH}[AcOH]$$

The uncatalyzed rate, k_0, is a negligible fraction of the rate in acetate buffers, though it does account for a significant fraction of the decomposition in dilute Tris buffers, in which the dihydropyridines are much more stable. The contribution of the term $k_{H^+}[H^+]$ to the overall decomposition rate in 0.1 *M* acetate buffers is less in all cases than that made by the buffer acid term $k_{HOAc}[HOAc]$. 1-Carbamoyl-3-fluoro-1,4-dihydropyridine (**2***l*) decomposed too rapidly in acetate buffer for the reaction to be followed on a recording spectrophotometer. In fact, it underwent the acid decomposition reaction within minutes in unbuffered 1 *M* potassium perchlorate. The decomposition rate in Tris buffer was fast but measurable.

As a result of acid-catalyzed decomposition each 1,4-dihydropyridine will have a minimum allowed p*H* below which it decomposes rapidly enough to interfere with experiments. This value will be to some extent dependent on the choice of buffer. We have calculated a minimum effective p*H* for each dihydropyridine in two buffer systems: acetate ($pK_a = 4.8$), and Tris ($pK_a = 8.1$) (Table 5). (The need to retain buffer capacity places an effective lower limit on such values, one p*H* unit below the p*K* of the buffer acid.)

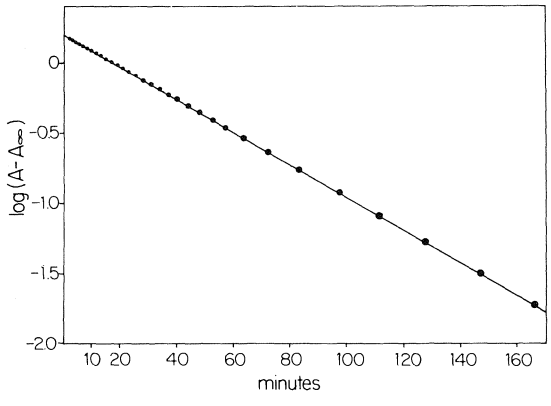


FIG. 1. First-order plots of the rate of hydration of 1-methyl-3-carbamoyl-1,4-dihydropyridine (**2***b*) in 1.0 *M* Tris buffer at p*H* 7.1; *A* is absorbance at 360 nm.

TABLE 4. Acetic acid catalytic coefficients for the hydration of substituted dihydropyridines

Compound	$10^2 k_{HOAc}$ $(M^{-1}\ s^{-1})$	Compound	$10^2 k_{HOAc}$ $(M^{-1}\ s^{-1})$
2*a*	3.3	**2***f*	0.48
2*b*	16	**2***g*	0.03
2*c*	6.2	**2***h*	0.53
2*d*	0.77	**2***i*	0.02
2*e*	0.77	**2***j*	0.02

The minimum allowed p*H* will, of course depend on the decomposition rate which is acceptable. Since some of the equilibration reactions we are concerned with are relatively slow we have arbitrarily chosen a decomposition rate of no more than 10% over 24 h as acceptable for experiments requiring as much as 5 to 6 h. However, for many of the dihydropyridines a decomposition rate this slow cannot be attained in some buffers, the extent of decomposition being as high as 10% in 45 min. Even for these compounds kinetic and other experiments requiring short reaction times can still be conducted with little interference from the decomposition reaction.

The minimum allowed p*H* will depend not only on the choice of buffer system, but also the buffer strength. The values in Table 5 have been calculated assuming a total buffer concentration of 0.1 *M*. Using a lower buffer concentration will generally allow the dihydropyridine to be used at a slightly lower p*H* without increasing the decomposition rate.

The 1,4-dihydropyridines **2***a* through **2***k* can be divided into three groups based on their acid lability. Compounds **2***a*, **2***b*, and **2***c* undergo a relatively rapid decomposition, thus preventing their use in buffers as acidic as acetate or phosphate. Even in Tris buffer, these dihydropyridines are not stable for 24 h (>10% decomposition), although **2***a* does meet the criterion of less than 10% decomposition in 6 h at p*H* 8.5 or higher.

Errata 2 - The captions for Table 4 & 5 should indicate the following: T = 25°C.

TABLE 5. Effective acidity limits for 1,3-substituted pyridinium ions and dihydropyridines[a] in aqueous buffers

				Minimum p*H* for dihydropyridine (**2***a–f, h–l*)	
	R_1	R_3	Maximum p*H* for pyridinium ion (**1***a–l*)	Acetate buffer (p*K* 4.8)	Tris buffer (p*K* 8.1)
a	$CH_2CO_2^-$	$CONH_2$	10	—[b]	—[c]
b	CH_3	$CONH_2$	10	—[b]	—[d]
c	CH_2CH_2OH	$CONH_2$	10	—[b]	—[d]
d	CH_2OCH_3	$CONH_2$	10	—[b]	8.3
e	CH_2COCH_3	$CONH_2$	10	—[b]	8.1
f	$CH_2CO_2CH_3$	$CONH_2$	5.7	—[b]	7.7
g	CH_2CO_2-*i*-Pr	$CONH_2$	6.5		
h	CH_2CN	$CONH_2$	6.5	—[e]	7.1[f]
i	CH_2CONH_2	$CONH_2$	9.5	—[b]	8.1
j	CH_2CONH_2	$COCH_3$	9.5	—[e]	7.1[f]
k	CH_2CONH_2	CN	6.5	—[e]	7.1[f]
l	CH_2CONH_2	F	9.5	—[g]	—[g]

[a]Less than 10% decomposition in 24 h in 0.1 *M* buffer.
[b]Greater than 10% decomposition in 45 min at all p*H* values less than 5.8 (p*K* + 1.0).
[c]10% decomposition in 6 h at p*H* 8.5.
[d]10% decomposition in 3 h at p*H* 8.8 (**2***b*) and p*H* 8.2 (**2***c*).
[e]10% decomposition in 6 h at p*H* 5.6.
[f]Stable over entire buffer range, *i.e.* p*K* ± 1.0.
[g]Extensive decomposition in 24 h at all acidities.

Dihydropyridines **2***h*, **2***j*, and **2***k*, on the other hand, are relatively stable. These compounds show little decomposition for long periods in buffers as basic as Tris, can be expected to show less than 10% decomposition over 24 h in phosphate buffers greater than p*H* 7.8, (based on the relative rates found by Johnston *et al.* for the 1-propyl compound (25)), and can even be used in acetate buffers of p*H* 5.5 for periods of up to 6 h. The remaining dihydropyridines, **2***d*, **2***e*, **2***f*, and **2***i* are too labile to be used in acetate buffers but meet the criterion of less than 10% decomposition over 24 h in Tris buffers.

The acetic acid-catalyzed rate constants for the hydration of the 1-*R*-3-carbamoyl-1,4-dihydropyridines (**2***b*–**2***i*) show a good correlation ($r = 0.991$) with the σ* values (27, 28) for the 1-substituent as shown in Fig. 2. A reaction constant ρ* of −2.00 is observed when the rate constant for 1-carboxymethyl-3-carbamoyl-1,4-dihydropyridine (**2***a*) is excluded. Its exclusion is not unreasonable considering (*a*) the possibility of interaction between the carboxylic acid and carboxylate groups of the mono-basic malonic acid used to define the $\sigma^I_{COO^-}$ value and (*b*) the possibility of non-inductive interactions between the negatively charged carboxylate ion and the dihydropyridine **2***a*.

Johnston *et al.* (25) have made an intensive investigation of the general-acid-catalyzed hydration of 1-propyl-3-carbamoyl-1,4-dihydropyridine in acetate and other buffers. Using −0.06 for the σ* value of the *n*-propyl group (27) and the plot in Fig. 2 a value of −0.84 can be calculated for log k_{AcOH} for this compound, in good agreement with the value of −0.82 measured by Johnston *et al.* (25).

The sign and magnitude of the reaction con-

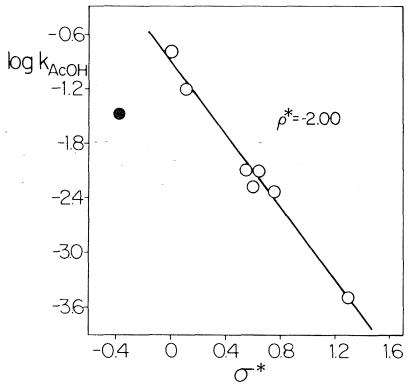

FIG. 2. Hammett plot for the acetic acid catalyzed hydration of 1-substituted 3-carbamoyl-1,4-dihydropyridines; correlation coefficient 0.991. The σ* values were calculated using Charton's σ^I values and the relation $\sigma^*_{(CH_2X)} = \sigma_x^I/0.45$ (27, 28). The point for carboxymethyl (filled circle) was not included in the calculation (see text).

stant ρ* is consistent with protonation at ring carbon being the rate-controlling step in the acid-catalyzed hydration process shown in [2], in agreement with the suggestions of Johnston *et al.* (25) and Kim and Chaykin (21).

Conclusions

The limitations on the p*H* range available for the study of 1,4-dihydropyridines are imposed mainly by the rate of the acid-catalyzed hydration of the 5,6-double bond and therefore represent a lower p*H* limit. The pyridinium ions on the other hand are stable at low p*H*, but undergo a variety of reactions in alkaline solutions. In experiments involving both pyridinium ions and 1,4-dihydropyridines, a narrow p*H*-range will be available for study in some cases. In others there is no p*H* at which the pyridinium ion and the corresponding 1,4-dihydropyridine are stable to the extent of less than 10% decomposition over 24 h. Overlap of the stable p*H*-regions does occur in Tris buffers for four pairs of compounds (*d*, *e*, *i*, and *j*), all of which have similar substituents. The 3-substituent is either carbamoyl or acetyl and the 1-substituent methoxymethyl, acetonyl, or carbamoylmethyl. The σ* values for these three 1-substituents vary only from 0.55 to 0.64 so one might expect rather similar behaviour from them. Dihydropyridines containing more electron-donating groups become very acid-labile while pyridinium ions containing more electron-withdrawing groups become very base-labile with a resulting loss of overlap between the stable p*H*-regions. It is interesting that the coenzyme NAD has the appropriate 1- and 3-substituents that place it among those compounds for which both the pyridinium and 1,4-dihydropyridine forms are relatively stable near neutral p*H*.

Primary isotope effects and mechanism of base initiated β-elimination reactions of di-(*p*-nitrophenyl)fluoroethanes

JAN KURZAWA[1] AND KENNETH T. LEFFEK

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 24, 1976

JAN KURZAWA and KENNETH T. LEFFEK. Can. J. Chem. **55**, 1696 (1977).

The second-order rate constants have been determined for the β-elimination reactions of 2,2-di-(*p*-nitrophenyl)-1,1,1-trifluoroethane, 2,2-di-(*p*-nitrophenyl)-1-fluoroethane, and their β-deuterated analogues with sodium methoxide in methanol. The primary isotope effects and activation parameters for these reactions are reported. It is suggested that the trifluoro-compound reacts via the pre-equilibrium carbanion mechanism $(E1cB)_R$ and that the mono-fluoro compound follows the E2 mechanism via a carbanion-like transition state.

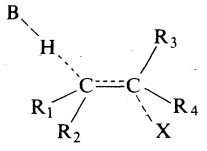
JAN KURZAWA et KENNETH T. LEFFEK. Can. J. Chem. **55**, 1696 (1977).

On a déterminé les constantes de vitesse du deuxième ordre pour les réactions d'élimination β, sous l'influence du méthylate de sodium dans le méthanol, du di-(*p*-nitrophényl)-2,2 tri-fluoro-1,1,1 éthane, du (*p*-nitrophényl)-2,2 fluoro-1 éthane et de leurs analogues deutérés en β. On rapporte les les effets isotopiques primaires et les paramètres d'activation pour ces réactions. On suggère que le composé trifluoré réagit par un mécanisme de carbanion pré-équilibré $(E1cB)_R$ alors que le composé monofluoré suit un mécanisme E2 par l'intermédiaire d'un état de transition ressemblant à un carbanion.

[Traduit par le journal]

Introduction

Considerable attention has been focused recently on the mechanism of β-elimination reactions. The original concerted E2 mechanism, with a transition state **1**, involving simultaneous



1

breaking of the βC—H bond and the C—X bond where X is the leaving group (1, 2), has been developed into a spectrum of transition states with different extents of C—H and C—X bond rupture, designated carbanion-like or E1cB-like when the βC—H bond breaking is more advanced than the αC—X bond breaking, or carbonium- or E1-like when the opposite situation pertains (3, 4).

Bordwell has proposed (5) that a great many more of these reactions actually proceed via a two step mechanism, [1] and [2], than many current text-books indicate. Bordwell has also suggested that the most common elimination mechanism is the pre-equilibrium anion (reversible anion), $(E1cB)_R$ mechanism which he assumed (5) would occur whenever the leaving group is a poorer leaving group than bromine. Saunders, on the other hand, concludes in a recent review (6) that no major revisions to the current mechanistic assignments are justified. In

$$[1] \qquad B^- + R_1R_2HC{-}CXR_3R_4 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R_1R_2C^-{-}CXR_3R_4 + BH$$

$$[2] \qquad R_1R_2C^-{-}CXR_3R_4 \xrightarrow{k_2} R_1R_2C{=}CR_3R_4 + X^-$$

the $(E1cB)_R$ mechanism, k_{-1} [BH] is very much greater than k_2. McLennan and Wong (7) have studied the dehydrochlorination of 2,2-di-(*p*-nitrophenyl)-1,1,1-trichloroethane by sodium methoxide in methanol and concluded that the reaction went through an irreversible carbanion mechanism, $(E1cB)_I$, in which $k_2 \gg k_{-1}$ [BH].

In the present work, we have studied the fluoro analogue of the above compound and also the monofluoro derivative in an attempt to observe either a stable carbanion mechanism $(E1)_{anion}$ or a preequilibrium carbanion mechanism, $(E1cB)_R$. The criteria for both these mechanisms (5) are a primary kinetic isotope effect of unity and a substantial leaving group effect on the rate constant. The two mechanisms are distinguished by the kinetics which are first-order for the stable carbanion mechanism $(E1)_{anion}$ and second-order for the $(E1cB)_R$ mechanism.

Results and Discussion

Pseudo first-rate constants were determined at five different temperatures by following the appearance of the olefin product at 325 nm for the trifluoro compounds and 380 nm for the monofluoro derivatives in the presence of a large excess of sodium methoxide in methanol. The observed first-order rate constants gave straight lines when plotted against the methoxide concentration, indicating second-order kinetics. The second-order rate constants for both the normal and deuterated compounds are shown in Tables 1 and 2, together with the isotopic rate ratios. The precision of the second-order rate constants is estimated to be $\pm 2\%$.

Since the reactions are second order and no absorption in the visible or uv which could be attributed to the carbanion was observed, neither of the substrates reacts via the stable carbanion mechanism under these conditions. However, the 2,2-di-(*p*-nitrophenyl)-1,1,1-trifluoroethane shows no primary isotope effect, characteristic of the preequilibrium carbanion $(E1cB)_R$ mechanism. An exchange experiment showed that this substrate, recovered after reacting for one half-life, had fallen from an original deuteration level of at least 98% to about 75%. Thus, the trifluoro compound clearly reacts via the $(E1cB)_R$ mechanism which is not inconsistent with McLennan's finding of the irreversible carbanion mechanism $(E1cB)_I$ for the trichloro compound, since chlorine is a better leaving group than fluorine.

The second-order rate constant for the trifluoro compound may be compared to those reported by McLennan and Wong (7) for the substrates 2,2-di-(*p*-R-phenyl)-1,1,1-trichloroethanes reacting with sodium methoxide in methanol at 30°C. These authors demonstrated that these compounds reacted via an irreversible E1cB mechanism by comparison of the Brønsted plot for carbanion formation from hydrocarbons in the same medium, with the dehydrochlorination reaction. McLennan and Wong calculated pK_a values for these substrates using several assumptions (7) which give rise to a large uncertainty in the pK_a. However, a valid comparison can be made between our results and

*Initial concentration of substrates = 2.5×10^{-4} M.

theirs by calculating pK_a values using the same assumptions. On this basis, the trifluoro compound has a pK_a of 11.3 and the monofluoro compound a pK_a of 19.6, and the results are compared in the plot of log k_2 *vs.* pK_a shown in Fig. 1. From this graph it is predicted that if the trifluoro compound were reacting by an irreversible E1cB, the second-order rate constant should be 9.1 $\ell\ mol^{-1}\ s^{-1}$, whereas the point lies well below the line with $k_2 = 0.61\ \ell\ mol^{-1}\ s^{-1}$. Thus, the observed rate of dehydrofluorination is less than the predicted rate of carbanion formation for this compound, consistent with the postulate of an $(E1cB)_R$ mechanism.

The mechanism of the monofluoro compound is clearly different, since it shows a primary isotope effect of $k_H/k_D = 2.8$ at 30°C and also reacts about eight times slower than the trifluoro compound. However, its rate constant of 0.073 $\ell\ mol^{-1}\ s^{-1}$ at 30°C is considerably higher than the value of 0.01 $\ell\ mol^{-1}\ s^{-1}$ predicted by the results of McLennan and Wong (Fig. 1) for the irreversible E1cB mechanism. Thus, the monofluoro compound is observed to react in the

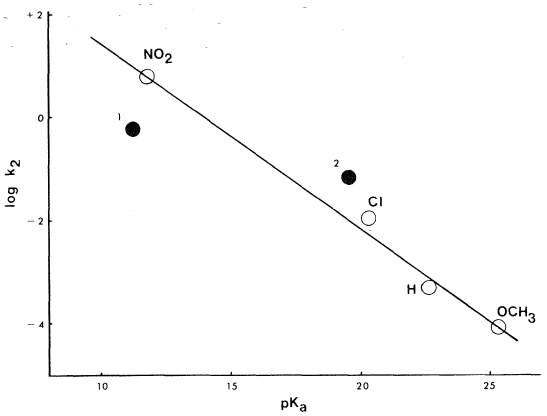

FIG. 1. Plot of log k_2 against pK_a for β-elimination reactions of substrates $(p\text{-}RC_6H_4)_2CHCCl_3$ (○) with sodium methoxide in methanol (●) (1) 2,2-di-(*p*-nitrophenyl)-1,1,1-trifluoroethane, (2) 2,2-di-(*p*-nitrophenyl)-1-fluoroethane.

dehydrofluorination about seven times faster than it is predicted to form carbanions. A mixed mechanism, $(E1cB)_I$ and E2, is excluded by the exact linearity of the activation parameter plots. Therefore, it is concluded that the monofluoro

compound reacts via an E2 mechanism. The small isotope effect of 2.8 shows that the transition state structure is unsymmetrical and there is no doubt, from the observation that di-(*p*-nitrophenyl)methane readily yields a carbanion on treatment with alkoxides in alcohol (8, 9), that the extent of C—H bond rupture must be considerably greater than that of C—F bond rupture. Thus, the mechanism is E2, with a carbanion-like transition state.

The activation parameters calculated from the data in Tables 1 and 2 are given in Table 3, with those for the trichloro compound (10) included for comparison. It can be seen that the dominant factors controlling the rate differences lie in the entropy term. The parameters for the trifluoro compound show a high enthalpy of activation which contains a component arising from the C—F bond rupture whereas the enthalpy of activation for the monofluoro compound is lower and the entropy of activation negative, quite similar to the activation parameters observed in proton transfer reactions from carbon acids (11). This is consistent with a carbanion-like E2 transition state for the monofluoro compound.

The isotope effects on the enthalpy of activation are the same for the monofluoro and trichloro derivatives, while the entropy isotope effects are both small but in the opposite direction. $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ for the monofluoro compound is $+1.1$ cal mol^{-1} deg^{-1}, while the corresponding quantity for the trichloro compounds is -1 cal mol^{-1} deg^{-1} (10). Positive values for this quantity are commonly observed and partially cancel the enthalpy difference giving a small isotope effect. Negative values, while unusual, have been reported on several occasions (8, 9, 12, 13) and enhance the rate ratio. However, the activation parameters quoted by McLennan and Wong (10) are based on rate constant measurements at only two different temperatures, so the uncertainties may be large.

TABLE 3. Activation parameters for the β-elimination reactions of 2,2-di-(*p*-nitrophenyl)fluoroethanes with sodium methoxide in methanol

Substrate	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1})

Experimental

Materials

Anhydrous methanol was prepared by drying commercial absolute methanol with Mg turnings and fractional distillation. The traces of basic material were removed by fractional distillation from anhydrous sulfanilic acid.

Sodium methoxide solutions were prepared by dissolving clean sodium metal in methanol in flasks protected from moisture and carbon dioxide. The concentration of methoxide was determined by titration with standard HCl solution using methyl red as indicator. 2,2-Di-(*p*-nitrophenyl)-1,1,1-trifluoroethane and 2,2-di-(*p*-nitrophenyl)-1-fluoroethane were prepared by methods described by Kaluszyner *et al.* (14) and Bergmann and Kalmus (15). Ethyl esters of trifluoroacetic acid and monofluoroacetic acid were converted to the diphenylcarbinols by treatment with phenylmagnesium bromide on a half mole scale. The reaction with the trifluoroester required refluxing for 1½ h, but the monofluoroester went readily at 0°C in 15 min. The carbinols were reduced with red phosphorous in a mixture of hydriodic and glacial acetic acids by refluxing for 10 days. The diphenylfluoroethanes were finally nitrated with a mixture of nitric and sulfuric acids. The oily products were crystallized several times from methanol. $C_{14}H_9F_3N_2O_4$: mp 120–122°C. *Anal.* calcd.: C 51.5, H 2.8, N 8.6; found: C 51.0, H 2.8, N 8.5; nmr ($CDCl_3$) δ 4.89 (1H, q, J = 8.5 Hz), AA′BB′ pattern 7.4–8.3 (4H). $C_{14}H_{11}FN_2O_4$: mp 82–84°C. *Anal.* calcd.: C 57.9, H 3.8, N 9.6$_5$; found: C 58.1, H 3.7, N 9.7$_5$; nmr ($(CD_3)_2SO$) δ 3.39 (2H, d, J = 8.0 Hz), 4.38 (1H, t, J = 8.0 Hz), AA′BB′ pattern 7.6–8.4 (4H).

The deuterium compounds were prepared from the diphenylcarbinols by reduction with red phosphorous and iodine in deuterated acetic acid. The products were nitrated and crystallized from methanol. The tertiary hydrogen nmr signals at δ 4.89 and 4.38 were completely absent in the deuterated compounds, indicating at least 98% deuteration.

Product Analysis

The reaction of the trifluoro compound was carried out on a 10–20 mg scale and the product was recovered by removal of the methanol, followed by repeated extraction with diethyl ether and then with chloroform. After removal of solvent, the nmr spectrum showed only aromatic hydrogen peaks. The mass spectrum gave a molecular ion at 306 au and the uv absorption a λ_{max} = 325 nm, ε = 15 000. Thus, there is no doubt that the product is the olefin formed by elimination of HF from the substrate molecule.

Kinetic Measurements

The reaction rates were measured using a Unicam SP800 spectrophotometer fitted with a temperature controlled cell block with a capacity of four cells. The absorbance of the olefin products was monitored at a fixed wavelength of 325 nm for the trifluoro and 380 nm

TABLE 4. Run 25.14; temperature 25.0°C; initial concentration $CH_2FCH(p\text{-}C_6H_4NO_2)_2 = 2.5 \times 10^{-4}$ *M*; initial concentration $CH_3\overset{+}{O}\overset{+}{N}a = 0.010$ *M*

Time (min)	x_1 (absorbance)	x_2 (absorbance)
0	0.17	0.84
5	0.33	0.86
10	0.44	0.88
15	0.53	0.90
20	0.60	0.91
25	0.66	0.92
30	0.71	0.93
35	0.75	0.94
40	0.78	0.95
45	0.81	0.96

Guggenheim analysis yields $k_1 = 5.53 \times 10^{-4}$ s^{-1}

for the monofluoro product, which are the maxima of their uv spectra. The absorbance values at definite times were read directly from the chart paper and the first-order rate constants were calculated by the Guggenheim method. Each run was carried out in triplicate with the aid of an automatic cell changer and the rate constants recorded in Tables 1 and 2 are the means of three runs. A sample run is given in Table 4.

Received December 10, 1976

T. Patrick Ahern, Handrick Fong, and Keith Vaughan. Can. J. Chem. **55**, 1701 (1977).

Treatment of the diazonium salts, $X{\cdot}C_6H_4N_2^+$, with aqueous methylamine affords good yields of the monomethyltriazenes, $X{\cdot}C_6H_4{\cdot}N{=}N{\cdot}NHMe$, when the substituent is a strongly electron-withdrawing group (X = *o*-, *m*-, and *p*-NO_2; *o*-, *m*-, and *p*-CO_2R; *p*-CN and *p*-$COCH_3$). Preparation of the triazene from the *p*-bromobenzene diazonium salt was accompanied by formation of a pentaazadiene. Monomethyltriazenes were not obtained when diazonium salts containing other substituents (X = H, *p*-CH_3, *o*-CF_3, *p*-Cl, *p*-F, *p*-NMe_2, *p*-OH, *p*-OCH_3, *p*-Ph, *p*-$NHCOCH_3$) were treated with methylamine. In these cases the products were either pentaazadiene, or 1,3-diaryltriazenes or unstable materials. The monomethyltriazenes vary considerably in stability and give rise to a number of different degradation products, which were either diaryltriazenes or 3-alkyl-1,3-diaryltriazenes or simply arylamines. 1(3)-(*p*-Nitrophenyl)-3(1)-methyltriazene was found to be a moderately effective methylating agent.

T. Patrick Ahern, Handrick Fong et Keith Vaughan. Can. J. Chem. **55**, 1701 (1977).

Le traitement de sels de diazonium $X{\cdot}C_6H_4N_2^+$ avec de la méthylamine en solution aqueuse conduit avec de bons rendements aux monométhyltriazènes, $X{\cdot}C_6H_4{\cdot}N{=}N{\cdot}NHMe$ quand le substituant est fortement électroaffinitaire (X = *o*-, *m*-, et *p*-NO_2; *o*-, *m*- et *p*-CO_2R; *p*-CN et *p*-$COCH_3$). La préparation du triazène à partir du sel de *p*-bromobenzène diazonium est accompagnée par la formation d'un pentaazadiène. On n'obtient pas de monométhyltriazènes quand on traite les sels de diazonium contenant d'autres substituants (X = H, *p*-CH_3, *o*-CF_3, *p*-Cl, *p*-F, *p*-NMe_2, *p*-OH, *p*-OCH_3, *p*-Ph, *p*-$NHCOCH_3$) par de la méthylamine. Dans ces cas, les produits sont soit un pentaazadiène ou des diaryl-1,3 triazènes ou des composés instables. La stabilité des monométhyltriazènes varie considérablement; leur dégradation conduit à un certain nombre de différents produits qui sont soit des diaryltriazènes ou des alkyl-3 diaryl-1,3 triazènes ou simplement des arylamines. On a trouvé que le *p*-nitrophényl-1(3) méthyl-3(1) triazène est un agent méthylant modérément actif.

[Traduit par le journal]

Introduction

1-Aryl-3-alkyltriazenes can be obtained by the reaction of aryl azides with aliphatic Grignard reagents (3, 4), or, in some instances, by reaction of diazonium salts with alkylamines (1, 5). Monomethyltriazenes have significant carcinogenic activity (6, 7), and have been implicated (8) as metabolites in the carcinogenesis of 1-aryl-3,3-dimethyltriazenes, which have shown considerable potential as antitumour agents (9). The activity of monomethyltriazenes is believed to derive from the facility with which they methylate biological substrates, such as the heterocyclic base units of nucleic acids (10). Chemically, methylation by monomethyltriazenes is also known, as for example in the esterification of carboxylic acids (11). Clearly, an understanding of the formation and properties of monomethyltriazenes is important from both chemical and pharmacological viewpoints.

In part I (1), the reaction of diazotized anthranilate esters with primary aliphatic amines was shown to give excellent yields of semi-stable 1-aryl-3-alkyltriazenes, which were formed without contamination by pentaazadiene. This result was surprising because it has been stated (12, 13) that the reaction of diazonium salts with primary alkylamines is complicated by the formation of pentaazadienes due to further coupling of the diazonium ion with the triazene. In a subsequent communication (2), it was shown that, in general, diazonium salts with strongly electron-withdrawing substituents in the aryl group give rise to pentaazadiene-free triazenes when treated

[1]For part I, see ref. 1.

[2]Preliminary communication, see ref. 2.

with methylamine. This report gives a full account of the reactions of a number of diazonium salts with methylamine and describes the characterization and degradation of the monomethyltriazenes formed in these reactions.

Experimental

Melting points were recorded on a hot-stage apparatus (Reichert) and are corrected. Infrared spectra were recorded with Nujol suspensions on a Perkin-Elmer model 467 grating spectrophotometer; nmr spectra were measured on a Varian A-60A spectrometer using tetramethylsilane as internal standard. Mass spectra were recorded with a Dupont/C.E.C. Model 21-491 spectrometer using direct insertion.

*1(3)-Aryl-3(1)-methyltriazenes (**2***a–h)*

General Procedure

A solution of the aromatic amine (0.006 mol) in 2 *M* hydrochloric acid (9.0 ml), diluted with water (20 ml), was diazotized at 0°C with sodium nitrite (0.45 g) in water and the resulting solution stirred for 1 h, or until clear. The diazonium salt solution was treated with 40% aqueous methylamine (2.8 ml), whereupon a precipitate of the triazene usually appeared immediately. Sometimes the precipitate was gummy in texture and required careful purification to obtain crystalline material without decomposition. In one case (**2***g*), the triazene was formed initially as a viscous, oily precipitate which was isolated by extraction into chloroform.

This procedure afforded the following triazenes.

*1(3)-(p-Nitrophenyl)-3(1)-methyltriazene (**2***a)*—(0.62–0.95 g, 57–88%), mp 111–113°C (benzene) (lit. (5) mp 114°C); ν_{max} 3180, 3140, 1605, 1600, 1515, 1340 cm^{-1}; δ ($CDCl_3$) 3.5 (br s, 3H, N-Me), 7.4 (br d, 2H, aromatic), 8.13 (d, J = 9 Hz, 2H, aromatic), and 9.2 ppm (br s, 1H, NH); M^+ 180(41%) ($C_7H_8N_4O_2$), *m/e* 165(1%) ($M - CH_3$), 150(77%) ($M - CH_3NH$), 138(97%) ($M - CH_2N_2$), 122(100%) ($C_6H_4NO_2$), 108(20%), 106(12%), and 92(74%).

*1(3)-(p-Cyanophenyl)-3(1)-methyltriazene (**2***b)*—(0.81 g, 83%) mp 135.5–136°C (dec.), (yellow prisms from benzene – petroleum ether); ν_{max} 3185, 3155, 2220, and 1605 cm^{-1}; δ ($CDCl_3$, +55°C) 3.40 (br s, 3H, N-Me), 7.3–7.8 (m, 4H, aromatic), and 8.6 (br s, 1H, NH); δ ($CDCl_3$, −30°C) 3.22 (d, J = 2 Hz, NHMe), 3.62 (s, =N—Me), 7.15–7.85 (m, aromatic), 8.4 (br s, NH), and 9.7 (br s, NH); M^+ 160(31%) ($C_8H_8N_4$), *m/e* 132(16%) ($M - N_2$), 130(34%) ($M - CH_3NH$), 120(1%) (C_7H_6NO), 118(78%) ($M - CH_2N_2$), 102(100%) ($NC{\cdot}C_6H_4$), and 92(17%).

*1(3)-(p-Acetylphenyl)-3-methyltriazene (**2***c)*—(0.77 g, 73%) as a yellow gummy solid which recrystallized from benzene – petroleum ether with mp 90–92°C; ν_{max} 3180, 3160, 1660, and 1600 cm^{-1}; δ ($CDCl_3$) 2.56 (s, 3H, acetyl Me), 3.43 (br s, 3H, N-Me), 7.33 (br d, J = 8 Hz, 2H, aromatic), 7.96 (d, J = 8 Hz, 2H, aromatic), and 8.8 (br s, 1H, NH); M^+ 177(50%) ($C_9H_{11}N_3O$), *m/e* 162 (0.4%) ($M - CH_3$), 149(16%) ($M - N_2$), 147(40%) ($M - CH_3NH$), 135(98%) ($M - CH_2N_2$), 134(53%) ($M - CH_3CO$), 120(100%) (C_7H_6NO), 106(27%), 92 (57%), and 77(37%).

*1(3)-(p-Methoxycarbonylphenyl)-3(1)-methyltriazene (**2***d)*—(0.98 g, 84%), mp 94–96°C (from benzene) (lit. (5) mp 97.5°C); ν_{max} 3180, 3160, 1705, and 1600 cm^{-1}; δ ($CDCl_3$) 3.40 (br s, 3H, N-Me), 3.88 (s, 3H, O-Me), 7.31 (br d, J = 8 Hz, 2H, aromatic), 8.0 (d, J = 8 Hz, 2H, aromatic); M^+ 193(53%) ($C_9H_{11}N_3O_2$), *m/e* 190(0.7%) ($M - H_3$), 165(9%) ($M - N_2$), 151(65%) ($M - CH_2N_2$), 133(13%), 134(17%) ($M - CO_2CH_3$), 120(100%) (C_7H_6NO), 106(3.5%), 103(5%), 92(27%).

*1(3)-(p-Ethoxycarbonylphenyl)-3(1)-methyltriazene (**2***e)*—(yield 64%) mp 83–85°C (benzene – petroleum ether); ν_{max} 3200, 3180, 1710, and 1610 cm^{-1}; δ ($CDCl_3$) 1.35 (t, J = 7 Hz, 3H, C-Me), 3.35 (br s, 3H, N-Me), 4.33 (q, J = 7 Hz, 2H, O-CH_2), 7.30 (br d, J = 8 Hz, 2H, aromatic), and 8.0 (d, J = 8 Hz, 2H, aromatic).

*1(3)-(m-Nitrophenyl)-3(1)-methyltriazene (**2***f)*—(0.65 g, 60%), mp 94–96°C (from ether – petroleum ether); ν_{max} 3380, 1580(W), 1535, and 1345 cm^{-1}; δ ($CDCl_3$) 3.32 (s, 3H, N-Me), 7.3–8.3 (m, 4H, aromatic), and 8.5 (br s, 1H, NH); M^+ 180(41%) ($C_7H_8N_4O_2$); *m/e* 165(0.3%) ($M - CH_3$), 164(0.6%) ($M - O$), 150(77%) ($M - CH_3NH$), 138(36%) ($M - CH_2N_2$), 122(100%) ($C_6H_4NO_2$), 108(4.6%), 106(12%), 92(68%).

*1(3)-(m-Methoxycarbonylphenyl)-3(1)-methyltriazene (**2***g)*—(1.19 g, 90%), mp 107–110°C (from benzene); ν_{max} 3240 and 1720 cm^{-1}; δ ($CDCl_3$) 3.26 (br s, 3H, N-Me), 3.86 (s, 3H, O-Me), 7.3–8.3 (m, 4H, aromatic), and 9.1 (br s, 1H, NH).

*1-Methyl-3-(o-nitrophenyl)triazene (**2***h)*—(0.81 g, 75%), mp 38–40°C; ν_{max} 3330, 1615, 1520, and 1340 cm^{-1}; δ ($CDCl_3$) 3.65 (s, 3H, N-Me), 6.8–8.3 (m, 4H, aromatic), and 11.5 (br s, 1H, NH). The *o*-nitrophenyltriazene decomposed completely within hours of preparation, even when stored in a vacuum desiccator. Some samples were found to contain *o*-nitroaniline after decomposition.

Attempted preparation of 1-(o-Cyanophenyl)-3-methyltriazene

Anthranilonitrile (0.75 g) was dissolved in hot 2.5 *M* hydrochloric acid (10 ml) diluted with water (20 ml), and diazotized at 0°C with sodium nitrite (0.45 g). Aqueous methylamine (2.8 ml of 40%) was added to the clear solution and a yellow colouration developed, followed by the formation of a brown, oily precipitate. The mixture was extracted with chloroform; the residue in the chloroform (yield 0.96 g) displayed triazene characteristics in the ir spectrum, ν_{max} 3400 (NH), 2210 (C≡N), and 1480 (N=N) cm^{-1}, but decomposed immediately.

Reaction of p-Bromobenzene Diazonium Chloride with Methylamine

p-Bromoaniline (1.03 g) was dissolved in 2 *M* hydrochloric acid (9 ml), diluted with water (20 ml), and diazotized at 0°C with sodium nitrite (0.45 g). The clear diazonium salt solution was treated with 40% aqueous methylamine (2.8 ml) in one portion. A yellow precipitate separated immediately, which was filtered to yield a solid mixture of 1(3)-(*p*–bromophenyl)-3(1)-methyltriazene (**2***l*) and 1,5-bis-(*p*–bromophenyl)-3-methylpentaazadiene (**7***b*) (approximate proportion 9:1) (1.02 g), mp 68–70°C; ν_{max} 3190, 3160, 1590, and 1540 cm^{-1}; δ ($CDCl_3$) 3.25 (s, triazene N-Me), 3.76 (s, pentaazadiene N-Me), and 7.1–7.6 (m, aromatic). Recrystallization of the solid mixture from ethanol – dimethyl sulfoxide

resulted in decomposition and formation of a different high melting solid, mp 180–183°C; ν_{max} 1570 (W) cm^{-1}, which could not be identified.

*1,3-Bis-(o-trifluoromethylphenyl)triazene (**4d**)*

o-Aminobenzotrifluoride (0.97 g) in 2 *M* hydrochloric acid (9.0 ml) was diazotized at 0°C with sodium nitrite (0.45 g). The diazonium salt precipitate was dissolved by dilution and 40% aqueous methylamine (2.8 ml) was added in one portion. The yellow solution was stirred for 0.5 h and filtered to afford an off-white solid. Recrystallization from ethanol gave 1,3-bis-(*o*-trifluoromethylphenyl)triazene (51 mg) mp 177–179°C (lit. (19) mp 170–171.5°C); ν_{max} 3355, 1610, and 1590 cm^{-1}; δ ($CDCl_3$) 7.1–7.9 (m, 8H, aromatic), 9.7 (br s, 1H, NH); M^+ 333(1%) ($C_{14}H_9N_3F_6$), *m/e* 314(1%) (*M* − F), 305(16%) (*M* − N_2), 216(1%), 173(48%) ($CF_3C_6H_4N_2$), 160(4%) ($NH{\cdot}C_6H_4CF_3$), 145(100%) ($C_6H_4CF_3$), 131(4%) ($C_7H_5N_3$), 115(4%), 104(4%).

*1,3-Bis-(p-nitrophenyl)-3-methyltriazene (**3a**)*

The *p*-nitrophenyltriazene **2***a* recrystallizes unchanged from benzene when the crystallization is done quickly. Prolonged heating in benzene solution or in alcohol, resulted in decomposition. The product of the decomposition was identified as 1,3-bis-(*p*-nitrophenyl)-3-methyltriazene (yield 31%) mp 228–230°C (from ethanol) (lit. (14) mp 219°C); ν_{max} 1600, 1590, 1500, and 1330 cm^{-1}; δ (DMSO-d_6) 3.35 (s, N-Me), 7.43 (d, *J* = 9 Hz, aromatic), and 7.91 (d, *J* = 9 Hz, aromatic); M^+ 301(2%) ($C_{13}H_{11}N_5O_4$); *m/e* 273(4%) (*M* − N_2), 180(2%) (*M* − $C_6H_3NO_2$), 166(1%) (*M* − $C_6H_3N_2O_2$), 150(76%) ($N_2C_6H_4NO_2$ *or* $CH_2N{\cdot}C_6H_4NO_2$), 122(100%) ($C_6H_4NO_2$), 105(14%), 92(26%).

*1,3-Bis-(o-nitrophenyl)-3-methyltriazene (**3b**)*

1-Methyl-3-(*o*-nitrophenyl)triazene was dissolved in 95% ethanol at room temperature. After standing, a yellow solid separated, which was identified as 1,3-bis-(*o*-nitrophenyl)-3-methyltriazene (yield 3%) mp 107–110°C (from ethanol), ν_{max} 1600, 1520, and 1355 cm^{-1}; M^+ 301(2.4%) ($C_{13}H_{11}N_5O_4$) *m/e* 273(2%) (*M* − N_2), 255(0.4%) (*M* − NO_2), 180(2%) (*M* − $C_6H_3NO_2$), 167(0.6%) (*M* − $C_6H_2N_2O_2$), 150(100%) ($N_2C_6H_4NO_2$ *or* $CH_2NC_6H_4NO_2$), 123(30%) ($C_6H_5NO_2$), 105(4.4%), 92(22%).

*1,3-Bis-(p-methoxycarbonylphenyl)triazene (**4c**)*

The *p*-methoxycarbonylphenyltriazene **2***d* recrystallizes unchanged from benzene when the crystallization is done quickly. However, recrystallization in ethanol, and also on occasion in benzene, when heating is prolonged, results in decomposition. The product of decomposition was identified as the bis-(*p*-methoxycarbonylphenyl)triazene **4***c* (yield 10%) mp 205–210°C (from benzene) (lit. (15) mp 218–219°C); ν_{max} 3230, 1720, 1710, 1690, and 1610 cm^{-1}; δ ($CDCl_3$) 3.93 (s, 6H, O-Me), 7.46 (d, *J* = 8 Hz, 4H, aromatic), and 8.06 (d, *J* = 8 Hz, 4H, aromatic); M^+ 313(0.6%) ($C_{16}H_{15}N_3O_4$), *m/e* 285(7%) (*M* − N_2), 254(8%) (*M* − CH_3CO_2), 194(0.6%) ($C_6H_4N_3C_6H_4$), 163(37%) ($CH_3O_2CC_6H_4N_2$), 135(100%) ($C_6H_4CO_2CH_3$), 120(25%) (C_7H_6NO), 103(25%), 92(7%).

Reaction of o-Nitrobenzenediazonium Salt with Ammonia

o-Nitroaniline (0.83 g) was dissolved in 2 *M* hydrochloric acid (9.0 ml), diluted with water (100 ml), and diazotized at 0°C with sodium nitrite (0.45 g) over a period of 1 h. The clear solution was treated with concentrated ammonia (2.18 ml) in one portion and, after stirring for 5 min, the precipitate was collected to yield an unidentified reddish-brown solid (77 mg), which rapidly decomposed. On standing, further precipitation in the mother liquor produced *o*-nitroaniline (19 mg) identical with a commercial sample.

Reaction of Benzenediazonium Chloride with Methylamine

*(a) 1,5-Diphenyl-3-methylpentaazadiene (**7a**)*

Aniline (0.635 g) was dissolved in 2 *M* hydrochloric acid (9.0 ml), diluted with water (20 ml), and diazotized at 0°C with sodium nitrite (0.45 g). After stirring for 0.75 h, the diazonium salt solution was treated quickly with 40% aqueous methylamine (2.8 ml). The yellow precipitate was filtered to afford the pentaazadiene (0.56 g), mp 109–110°C (lit. (16) mp 112–113°C) (yellow needles from benzene or ethanol); ν_{max} 1580 (W) cm^{-1}; δ ($CDCl_3$) 3.81 (s, 3H, N-Me) and 7.3–7.8 (m, 10H, aromatic).

*(b) 1,3-Diphenyltriazene (**4a**)*

The procedure in (*a*) was repeated with a smaller volume (1.0 ml) of 40% methylamine, added in three successive portions (0.5, 0.3, and 0.2 ml) immediately after the addition of sodium nitrite. A precipitate appeared from the yellow solution after 5 min, and the mixture was filtered to yield 1,3-diphenyltriazene (0.22 g, 27%), identical with a sample prepared below.

Reactions of Benzenediazonium Chloride

(a) With Acetamide

A solution of acetamide (1.5 g) in water was added to a solution of benzene diazonium chloride (0.006 mol) in one portion at 0°C and the solution remained clear. Sodium acetate (6 g) was added, whereupon the solution turned yellow and a precipitate slowly appeared. After stirring for 1 h, the solid was filtered and recrystallized from petroleum ether to give 1,3-diphenyltriazene (0.28 g, 47%), mp 95–97°C (lit. (17) mp 98–99°C), ν_{max} 3150 and 1590 cm^{-1}, identical with a sample prepared by diazotization of aniline alone.

(b) With Urea

Likewise, a solution of benzene diazonium chloride (0.006 mol) was treated with a solution of urea (1.36 g), followed by addition of sodium acetate, whereupon 1,3-diphenyltriazene (78 mg) precipitated.

(c) With Sodium Acetate

Treatment of a solution of benzene diazonium chloride (0.006 mol) with an excess of sodium acetate produced a yellow solution which, after standing for 1 h, afforded a yellow precipitate of 1,3-diphenyltriazene (0.11 g).

*1,3-Bis-(p-tolyl)triazene (**4b**)*

p-Toluidine (0.64 g) was dissolved in 2 *M* hydrochloric acid (9 ml), diluted with water (100 ml), and diazotized at 0°C with sodium nitrite (0.45 g). Aqueous methylamine (2.8 ml of 40%) was added in one portion, whereupon the solution went cloudy. After 5 min, the tan-coloured precipitate was filtered and triturated with methanol. The methanol solution was filtered and the filtrate diluted with water to afford, 1,3-bis-(*p*-tolyl)triazene, mp 116°C (lit. (18) mp 116.5°C), ν_{max} 3170 and 1605 cm^{-1}, identical

with a sample prepared by diazotization of *p*-toluidine alone.

3-Methyl-1,2,3-benzotriazin-4-one

Anthranilic acid (0.86 g), dissolved in 2 *M* hydrochloric acid (9.5 ml) and diluted with water (20 ml), was diazotized at 0°C with sodium nitrite (0.45 g) and treated with 40% aqueous methylamine (2.8 ml). The solution turned yellow, but no immediate precipitate was observed. After standing overnight a white precipitate had formed, which was filtered to yield 3-methyl-1,2,3-benzotriazin-4-one (0.175 g) mp 121–122°C, identical in all respects with an authentic sample (1).

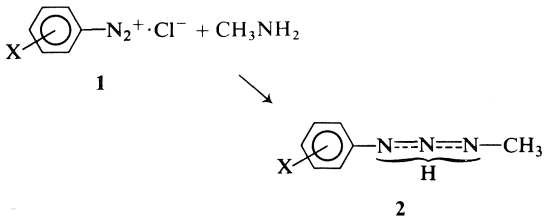
Chloroform extraction of the mother liquor afforded a second batch of the triazinone (0.135 g), mp 116–120°C.

Methylation of 3,5-Dinitrobenzoic Acid

The *p*-nitrophenyltriazene **2***a* (0.63 g, 3.5 mmol) was suspended in ether (10 ml) and stirred at room temperature while a solution of 3,5-dinitrobenzoic acid (0.75 g) in ether (20 ml) was added dropwise. The mixture was left for 17 h at room temperature, filtered, and partially evaporated. The crystalline precipitate was separated to give methyl 3,5-dinitrobenzoate (0.14 g). Evaporation of the ether filtrate gave a red, oily residue which solidified on standing. The solid was scrubbed with 2 *N* hydrochloric acid, filtered, washed with water, scrubbed with 5% aqueous sodium carbonate, filtered, washed with water, and dried to give a second batch of methyl 3,5-dinitrobenzoate (combined yield 0.72 g), which was identical with a sample obtained from reaction of 3,5-dinitrobenzoyl chloride with methanol.

Discussion

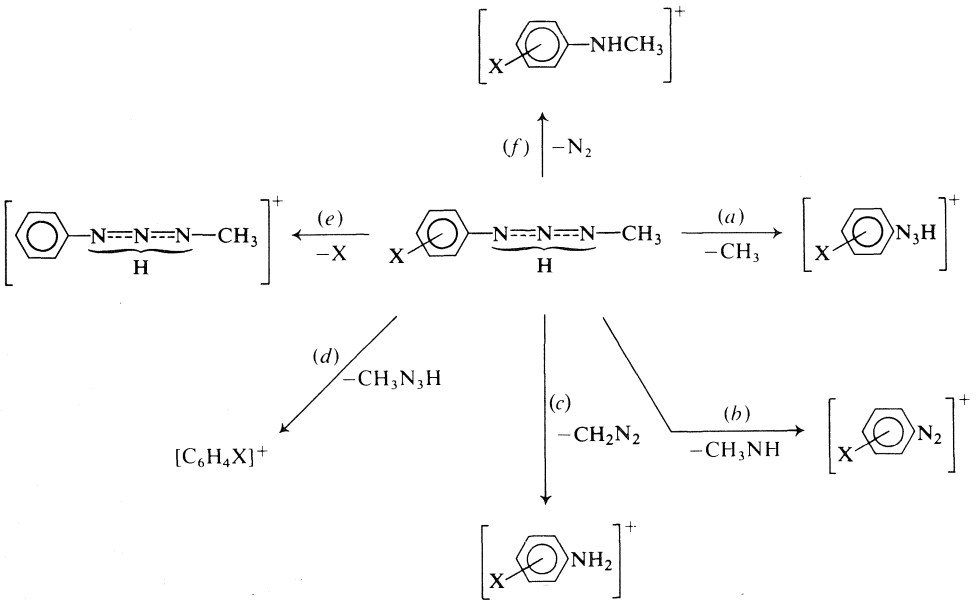
Treatment of the *para*-substituted benzene diazonium chlorides **1***a–e* with methylamine in aqueous solution gave good yields of the monomethyltriazenes **2***a–e*. The *meta*-substituted triazenes **2***f* and *g* were also obtained readily from the corresponding diazonium salts **1***f* and *g*. However the *o*-nitrophenyltriazene **2***h* was obtained only with considerable difficulty; treatment of *o*-nitrobenzene diazonium salt with methylamine frequently resulted in decomposition. The *meta*- and *para*-substituted triazenes **2***a–g* are moderately stable yellow solids, but usually decompose on standing, with the exception of the *p*-cyanophenyltriazene **2***b*, which appears to be completely stable. By contrast, the *o*-nitrophenyltriazene **2***h* decomposes very quickly in the solid state and in solution. As previously described (1, 20), the *o*-alkoxycarbonyl- and *o*-acetylphenyltriazenes **2***i* and **2***j* are also unstable and readily cyclize to benzotriazinones and methylenebenzotriazines, respectively. In the present work, the triazene obtained by coupling methylamine with diazotized anthranilic acid cyclized spontaneously to afford 3-methyl-1,2,3-benzotriazin-4-one. The product of the reaction of methylamine with *o*-cyanobenzene diazonium salt displayed ir characteristics of the *o*-cyanophenyltriazene **2** (X = *o*-CN), but decomposed very quickly preventing full characterization.



a X = *p*-NO_2	*g* X = *m*-CO_2Me
b X = *p*-CN	*h* X = *o*-NO_2
c X = *p*-$COCH_3$	*i* X = *o*-CO_2R
d X = *p*-CO_2Me	*j* X = *o*-$COCH_3$
e X = *p*-CO_2Et	*k* X = *p*-CH_3
f X = *m*-NO_2	*l* X = *p*-Br

As described more fully elsewhere (21), the spectral properties of the *para*-substituted phenyltriazenes **2***a–e* show that these triazenes exist as a mixture of tautomers in equilibrium (ArN=NNHMe ⇋ ArNHN=NMe). The *N*-methyl proton resonances in the nmr spectra of **2***a–e* are considerably broadened by the tautomeric equilibrium; the presence of both tautomers was confirmed in the case of the *p*-cyano-derivative **2***b* by low temperature nmr measurement. The infrared spectra of these triazenes also give evidence for two tautomers. Two bands appear in the regions 1415–1430 and 1480–1485 cm^{-1}, assigned to the azo-group (N=N) stretching vibration in the 1-aryl- and 3-aryltautomers, respectively. Furthermore, the *para*-substituted triazenes **2***a–e* show two NH absorption bands in the ir at 3140–3160 and 3180–3185 cm^{-1}, whereas the *ortho*-substituted triazenes **2***h* and **2***i* display only one NH band at 3300–3330 cm^{-1}. The low temperature nmr study showed conclusively that the *o*-ethoxycarbonylphenyltriazene **2***i* (R = Et) (and by analogy the *o*-nitrophenyltriazene **2***h*) exists solely as the 3-aryl tautomer.

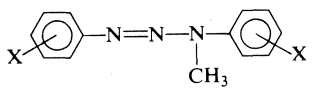
The structures of the monomethyltriazenes were confirmed, whenever possible, by mass spectral analysis; the observed fragmentation pathways are shown in Scheme 1. The *m*- and *p*-nitrophenyltriazenes have strikingly similar mass spectra showing fragments arising from pathways (*a*) *N*-methyl fragmentation, (*b*) fragmentation at N_2—N_3, (*c*) loss of the fragment diazomethane, CH_2N_2, and (*d*) *N*-aryl



SCHEME 1. Mass spectral fragmentation of 1(3)-Aryl-3(1)-methyltriazenes

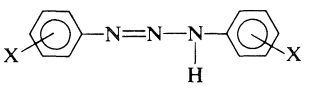
fragmentation. Surprisingly, the nitro-derivatives did not show fragmentation by direct loss of N_2 (path *f*), although this pathway was clearly evident in the fragmentation of other *para*-substituted triazenes **2***b*, *c*, and *d*. The *p*-acetyl derivative **2***c* and the ester **2***d* fragmented by loss of the substituent, X, unlike the nitro- and cyanophenyltriazenes. These results are significantly different from the mass spectra reported (22*a*) for the unsubstituted 3-alkyl-1-phenyltriazenes (*e.g.*, **2** X = H), which fragment by the analogous pathways *b*, *c*, and *d*, but did not show fragmentation by loss of N_2 (path *f*) or by breakage of the *N*-alkyl linkage (path *a*).

Several types of decomposition product have been obtained from the unstable triazenes **2**, but the course of the decomposition does not appear to be determined by the reaction medium. The *p*-nitrophenyltriazene **2***a* could be purified by rapid crystallization from benzene, but decomposed when boiled in ethanol to afford the alkyldiaryltriazene **3***a*. The structure of **3***a* was apparent from the ir spectrum, which did not show an NH band, from the nmr spectrum, which displayed *N*-methyl resonance and the expected aromatic pattern, and from the mass spectrum, which showed the molecular ion at M^+ 301. The principal fragments in the mass spectrum of **3***a* showed that fragmentation occurs by path *a* loss of N_2, path *b* fragmentation between N-2 and N-3, and path *c* *N*-aryl fragmentation (Scheme 2).



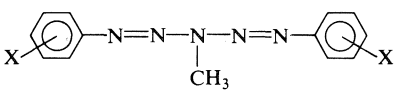
3

a X = *p*-NO_2
b X = *o*-NO_2



4

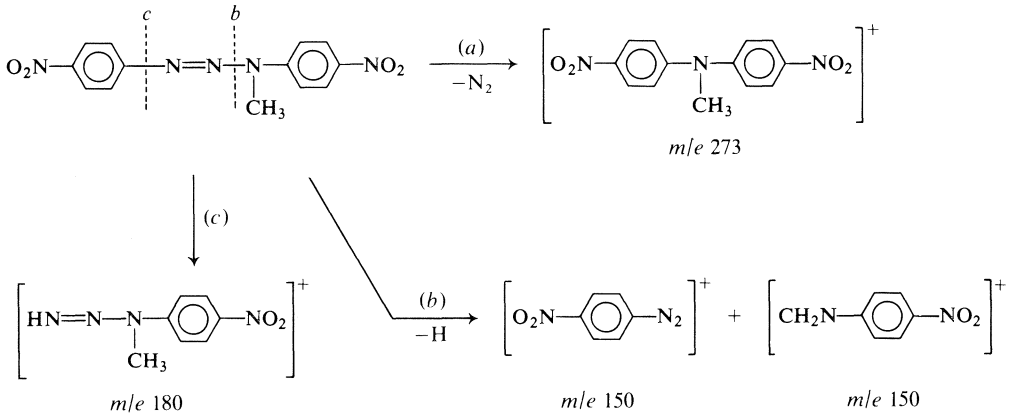
a X = H
b X = *p*-CH_3
c X = *p*-CO_2Me
d X = *o*-CF_3



7

a X = H
b X = *p*-Br

The alkyldiaryltriazene **3***b* was similarly obtained when the *o*-nitrophenyltriazene **2***h* was treated with ethanol. **3***b* has a mass spectrum almost identical (in both fragment mass numbers and relative intensities) to that of the *para*-isomer **3***a*. The formation of the alkyldiaryltriazenes **3***a* and *b* in protic media must involve

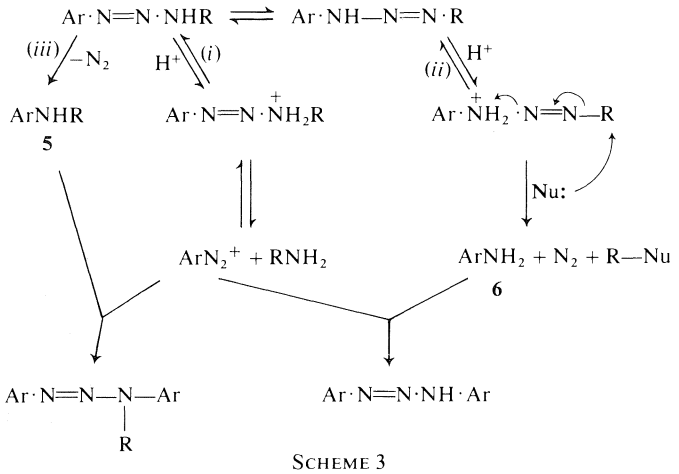


SCHEME 2. Mass spectral fragmentation of 1,3-bis-(*p*-nitrophenyl)-3-methyltriazene

two courses of cleavage (Scheme 3). Thermal loss of nitrogen gives the secondary amine **5** (reaction *ii*), whereas protonation at N-3, followed by retrocoupling (reaction *i*), liberates free aryl diazonium ion, which may then couple with the secondary amine to give the trisubstituted triazene.

Attempted purification of the *o*-nitrophenyltriazene **2***h* in benzene gave only *o*-nitroaniline, which was also the product of solid state decomposition of **2***h*. The facility with which this triazene reverts to the arylamine is possibly a consequence of the preference of **2***h* to exist as the 3-aryl-tautomer, Ar·NH—N=N—R. This preference has been attributed to intramolecular hydrogen bonding (21). *o*-Nitroaniline was also recovered in low yield directly from the reaction of *o*-nitrobenzene diazonium salt with ammonia; in this case the diazonium salt probably couples with NH_3 to give a monoaryltriazene, $Ar{\cdot}N{=}N{\cdot}NH_2$, which would rapidly lose N_2 to give the amine, as has been observed previously when the diazonium salt from *o*-aminoacetophenone was treated with ammonia (20).

A slightly different decomposition course was experienced in the case of the *p*-methoxycarbonylphenyltriazene **2***d*, which reacted in hot ethanol to give the diaryltriazene **4***c*. Analogous decomposition probably occurred when *o*-aminobenzotrifluoride was diazotized and treated with methylamine, in which case the diaryltriazene **4***d* was obtained in low yield, presumably by decomposition of an unstable monomethyltriazene **2** (X = *o*-CF_3). The formation of these diaryltriazenes from monomethyltriazenes must involve protolysis and fragmentation by pathways *i* and *iii* (Scheme 3), giving ArN_2^+ and $ArNH_2$, respectively, followed by coupling of the two fragments. Similar formation of diaryltriazenes and alkyldiaryltriazenes has been



SCHEME 3

observed in the reaction of *p*-nitrobenzene diazonium salt with butylamine (22*b*).

The decomposition mechanism outlined in Scheme 3 has much similarity to the reported reactions of alkyltriazenes with Lewis acids. For example, Kreher and Goth (23) obtained the secondary amine **5** as the major product of reaction of 1-aryl-3-alkyltriazenes with aluminium trihalides, analogous to pathway *ii* (Scheme 3). However when silica gel is used as the catalyst (24), the secondary amine is the minor product, the major product being the primary amine **6**, presumably formed in a manner analogous to pathway *iii*. The carbonium ion-pair mechanism (reaction 1) is favoured to account for the formation of **5**; significantly the tautomer involved here is the 3-aryl-1-methyltriazene.

[1] $Ar\cdot NH—N{=}N—CH_3 \longrightarrow \overset{-}{Ar}NH\cdot\overset{+}{C}H_3 + N_2$

Acidic alumina was found to favour decomposition of the *o*-alkoxycarbonylphenyltriazenes **2***i* by pathway *ii* (1).

The preparation of 1-(*p*-tolyl)-3-methyltriazene (**2***k*) is now described in "Organic Synthesis" (25), but success in this preparation depends upon the addition of the diazonium salt **1***k* solution *to* the methylamine solution at $-10°C$. These reaction conditions are significantly different from those used here to prepare the triazenes **2***a–h*, and when *p*-toluidine was diazotized and treated with methylamine at 0°C, no monomethyltriazene was formed. The only product obtained in this case was the diaryltriazene **4***b*, which could arise by decomposition of the monomethyltriazene **2***k* as in Scheme 3.

The corresponding reaction of benzenediazonium chloride with methylamine proved to be very difficult to reproduce. When a large excess of methylamine was added in one portion to a solution of benzene diazonium chloride, the product was the pentaazadiene **7***a*, no monomethyltriazene being evident; slow addition of methylamine gave no identifiable materials at all. For no obvious reason, the diphenyltriazene **4***a* was obtained when methylamine was added in successive portions to the diazonium salt solution. Diphenyltriazene (**4***a*) was the only product obtained when benzene diazonium chloride solution was treated with (*a*) acetamide followed by sodium acetate, or (*b*) urea followed by sodium acetate, or (*c*) sodium acetate alone.

The unwillingness of benzenediazonium chloride to couple with amides in aqueous solution does not parallel the behaviour in organic solvents. For example, reaction of *p*-chloro- or *p*-bromobenzene diazonium chlorides with formamide in ethereal suspension affords the remarkably stable 1-aryl-3-formyltriazenes **8** (26), reaction 2. The lack of formation of acyl

[2] $Ar\cdot N_2^+ Cl^- + HCO\cdot NH_2 \xrightarrow[NaHCO_3]{\text{Ether}} Ar\cdot N{=}N\cdot NH\cdot CHO + NaCl + H_2O + CO_2$

8

triazenes in the present work is not consistent with a report (27) that acetamide couples with benzenediazonium chloride in the presence of sodium hydroxide to give the *N*-acetyltriazene $CH_3CO\cdot NH\cdot N{=}NC_6H_5$. However, no reaction was observed between acetamide and the diazonium salt from sulfanilic acid (28).

The formation of diphenyltriazene from completely diazotized aniline in the absence of amino compounds can be rationalized in terms of the equilibria involved in the diazotization process (reaction 3) (29). It is generally accepted that the

[3] $Ar\cdot NH_2 \longrightarrow \underset{\mathbf{9}}{ArNH—N{=}O} \rightleftharpoons \underset{\mathbf{10}}{ArN{=}N—OH}$

$\mathbf{9} \downarrow$ $\quad$ $\mathbf{10} \rightleftarrows$

$\underset{\mathbf{4}}{ArNH—N{=}NAr}$ $\quad$ $\underset{\mathbf{11}}{ArN{=}N^+\cdot\overset{-}{O}H}$

equilibrium **9** ⇋ **10** ⇋ **11** is present in diazonium solutions, and addition of base (*e.g.*, sodium acetate) would shift the equilibrium to the left giving a build up of $PhNH\cdot N{=}O$. Condensation of two molecules of this nitrosamine, or a reaction with PhN_2^+, could give the triazene **4**. Although the nature of the conversion **9** → **4** is not fully understood, it clearly does take place in specific cases. Primary nitrosamines have been isolated from diazotization of heterocyclic amines and can be converted into triazenes by simply warming in methanol (30).

The preparation of the *p*-bromophenyltriazene **2***l*, when *p*-bromobenzene diazonium chloride was coupled with methylamine, was accompanied by formation of the pentaazadiene **7***b*. The presence of the pentaazadiene was confirmed by the observation in the nmr spectrum of *N*-methyl resonance at 3.76 ppm, analogous to the *N*-methyl resonance of the pentaazadiene **7***a*.

Attempted purification of the mixture of triazene and pentaazadiene resulted in decomposition. Similarly attempts to prepare the *p*-chloro- and *p*-fluorophenyl-3-methyltriazenes under these conditions gave unstable materials, which could not be characterized.

Attempts to prepare monomethyltriazenes with electron-donating substituents in the aryl group, by this method, were a total failure. Treatment of the diazonium salts **1** (X = Me_2N—, HO—, MeO—, and Ph—) with methylamine at 0°C invariably produced a black oil or tar. Diazotization of *p*-aminoacetanilide and coupling with methylamine afforded a promising solid, which may have been triazene, but it decomposed immediately after filtration.

Monomethyltriazenes are useful chemically as methylating agents, and for example, readily esterify aromatic carboxylic acids (11, 25). The *p*-nitrophenylmethyltriazene **2***a* was found to esterify 3,5-dinitrobenzoic acid, but the reaction was considerably slower than expected. The rapid evolution of nitrogen that is described for the reaction of the *p*-tolyltriazene **2***k* (25) with the dinitrobenzoic acid was certainly not evident in the reaction of the *p*-nitrophenyltriazene, which does not appear to offer any particular advantage as a methylating agent.

Conclusion

These results show that the formation of monomethyltriazenes by addition of methylamine to a diazonium salt solution can be achieved cleanly only when electron-withdrawing substituents are present in the aryl group of the diazonium salt. The non-formation of pentaazadienes in these reactions suggests that the effect of the substituent is to decrease the nucleophilic reactivity of the triazene by a resonance phenomenon [4]. Delocalization of

[4] 
electron density at the alkyl-bearing nitrogen reduces the nucleophilic strength of the triazene moiety, thus rendering it less reactive in the coupling reaction. A similar electron movement, induced by the electron-attracting group, accounts for the shift in the tautomeric equilibrium towards the 3-aryl-tautomer **12** reported previously (21) [5]. A further correlation exists

[5] 
12

between these results and the protolysis experiments of Matrka and co-workers (31); the basicity of the triazene is affected similarly by changes in electron density at N-3 [6].

The passivity and overvoltage during hydrogen evolution and indium deposition of metallic indium

ALAN N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 1, 1976

ALAN N. CAMPBELL. Can. J. Chem. **55,** 1710 (1977).

The passivity and overvoltage during hydrogen evolution and indium deposition of metallic indium have been determined. Although the overvoltage to hydrogen evolution is fairly high and increases with current density in the normal manner, passivity to the solution of indium ions is almost completely absent, in contradistinction to aluminum, whose anodic passivity is complete. A tentative explanation is offered.

ALAN N. CAMPBELL. Can. J. Chem. **55,** 1710 (1977).

On a déterminé la passivité de l'indium métallique et le survoltage durant l'évolution de l'hydrogène et la déposition de l'indium. Quoique le survoltage vis à vis l'évolution de l'hydrogène est assez élevé et augmente d'une façon normale avec la densité du courant, la passivité vis à vis la solution des ions indium est complètement absente; ce comportement est en opposition avec celui de l'aluminium pour lequel la passivité anodique est complète. On offre une explication non définitive.

[Traduit par le journal]

Introduction

Little work seems to have been done on the passivity or overvoltage of metallic indium. Because of the industrial importance of these phenomena, it was thought that the subject merited systematic investigation.

Experimental

Hydrogen Overvoltage

A square sheet of metallic indium was cast in a steel mould at a temperature just above the melting point of indium. The surface was quite bright but it was treated with dilute hydrochloric acid and washed in order to remove any invisible skin of oxide. A platinum wire was embedded in the rear of the indium plate. The plate was then mounted in a frame of plexi-glass, so that the front or conducting surface of the indium was countersunk about 1/4 in. The platinum wire emerged through two sheets of plexi-glass so as to be insulated from the solution. This method ensures that there is no concentration of current on the edges of the indium plate. The area of the conducting plate was 4.94 cm^2.

For measuring the potential of the indium cathode the usual arrangement of a saturated calomel electrode, provided with a Luggin capillary, was used. The anode was a platinum gauze electrode. Various electrolytes were tried but the one finally selected was *N* acetic acid plus *N* KCl. The function of the acetic acid is to act, in conjunction with vigorous stirring, essentially as a buffer. The p*H* remains constant despite the discharge of H^+ ions. The KCl lowers the resistance. Vigorous stirring is necessary to avoid concentration polarisation, as far as possible. A source of constant current was used, an NJE Corporation Rectifier, producing up to 2.5 A at 10 V.

The equilibrium potential of the cell

$$Hg/Hg_2Cl_2 \text{ in sat. } KCl/N \text{ } HAc/H_2/In$$

is 0.3819 V, calculated from the ionisation constant of acetic acid. Current was measured as the drop in potential across a standard resistance, using a sensitive potentiometer.

Experiments were repeated with increasing and with decreasing current and varying time intervals. The results were very consistent, *i.e.* independent of the above factors.

The numerical results are to be found in the Depository of Unpublished Data.[1] The results are expressed graphically in Fig. 1.

Overvoltage of Indium Deposition

The experimental set-up was the same as in the preceding section, but the electrolyte was 0.05 *N* $InBr_3$. Using the value of E^0 for indium previously obtained (1), the emf of the combination.

$$Hg/Hg_2Cl_2, \text{ sat. } KCl/0.05 \text{ } InBr_3/In$$

is calculated to be 0.6478 V. In the present instance, the open circuit potential was found to be 0.6380 V, a difference of 0.0098 V. The hydrogen equilibrium potential is very close to this (0.657 V) but the hydrogen overvoltage at an indium surface (see preceding section) prevents hydrogen evolution.

Results

The current density was raised gradually to 1.890 A/dm^2. The overvoltage was zero up to a current density (c.d.) of 0.567 A/dm^2. It then rose slowly to a value of 0.0552 V at 1.890 A/dm^2.

The experiment was repeated using 0.1 *N* $InCl_3$ (equilibrium potential of combination with

[1]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

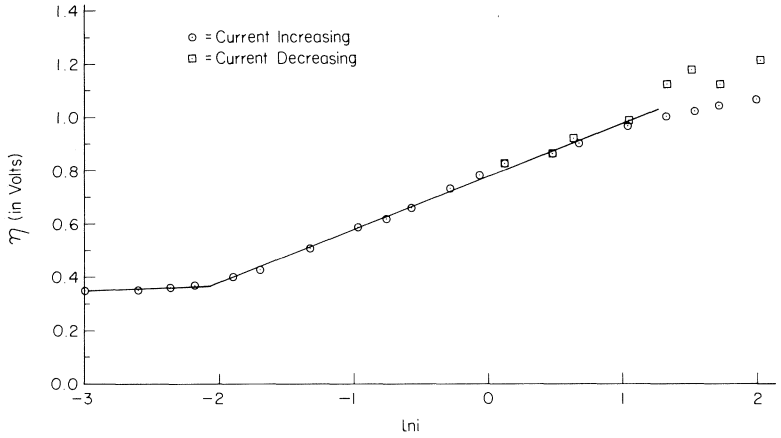

FIG. 1. Plot of η (in V) *vs.* ln *i*.

saturated calomel electrode = 0.6496 V). Again the overvoltage is very slight. A clean crystalline deposit of metallic indium was formed on the cathode (of platinum gauze). The numerical results are to be found elsewhere,[1] the results are expressed graphically in Fig. 2.

Anodic Passivity

The electrolyte first used was 0.1 *N* $InCl_3$, with a platinum gauze cathode and vigorous stirring. No passivity was observed up to a current density of 0.0750 A/dm^2. The passivity ($\eta = E_i - E_{rev}$) then rose slowly to 0.1224 V at a c.d. of 15.12 A/dm^2. The experiment was repeated with *N* $In_2(SO_4)_3$. The passivity attained a maximum value of 0.0270 V at a c.d. of 8.097 A/dm^2. The passivity is very slight.

The numerical results are to be found in the Depository of Unpublished Data.[1] The results are expressed graphically in Fig. 3.

Discussion

Hydrogen Overvoltage

When overvoltage is plotted against the logarithm of the current density (Fig. 1), the curve is seen to consist of two definite straight line portions, (*1*) from 0.0 to 0.1108 A/dm^2 and (*2*) from 0.1108 to 2.718 A/dm^2. After this upper limit, the curve loses slope and ceases to be a straight line. If the equation

$$\eta = a - b \ln i$$

(where η is the overvoltage, *i* the current

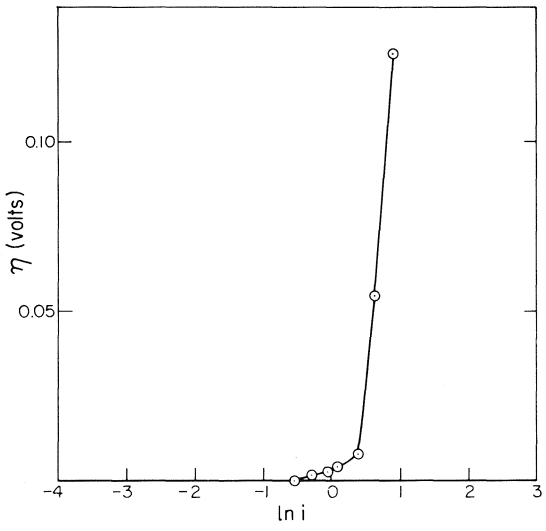

FIG. 2. Overvoltage to indium deposition *vs.* ln *i*.

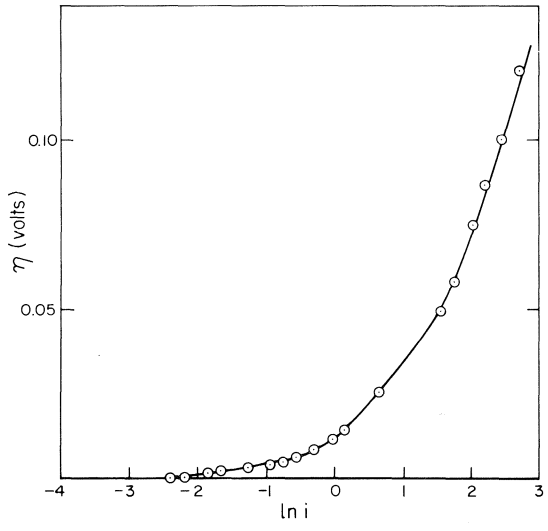

FIG. 3. Passivity of indium anode *vs.* ln *i*.

density, and a and b constants) is applied to the second (higher current density) portion, the constants result as $a = 0.78$ and $b = -0.195$.

The first part of the graph appears to be almost horizontal. If this portion of the graph is neglected, then the lowest overvoltage for hydrogen evolution is 0.37 V. Thiel and Breuning (2) give the overvoltage as 0.533 V, but they do not state the current density. Moreover, their electrolyte was $2N$ H_2SO_4 which must surely have attacked the indium chemically. According to the present results an overvoltage of 0.533 V is attained at a current density of 0.282 A/dm^2, *i.e.* it lies between those of tin and zinc.

Overvoltage to Indium Deposition

This is very slight.

Anodic Passivity

This is very slight and indeed zero up to appreciable current densities. Contrasted with the behaviour of aluminum, this is somewhat surprising. The 'valve' action of aluminum is well known: as anode, aluminum will not pass current up to very high positive potentials. This is no doubt due to the existence on all but recently cut aluminum surfaces of an oxide film (probably not the normal oxide). It has been suggested to me by Professor Sen, that the phenomenon may be due to the relative energy levels of electrons in metallic aluminum and in this aluminum oxide. It is easy to see how electrons could pass in one direction (in this case from oxide to metal) but not in the other. Since passivity is absent from indium, either an oxide layer is not formed (and there is no visual evidence that it is) or the energy levels in metal and in oxide are different from those in aluminum.

An examination of Figs. 1–3, indicates that, though the Tafel relation is obeyed over intermediate ranges of current density, the values increase rather suddenly at high current densities. This is certainly due to the impoverishment of concentration in the immediate neighbourhood of the electrode, despite the vigorous stirring. As to the various mechanisms, competing, simultaneous or successive, described in the texts, the author finds himself unable to make any worthwhile decision.

A lengthy paper by Piercy and Hampson (3), under the title "The Electrochemistry of Indium" contains many valuable references. Among other things, the suggestion is made (4) that the ionization of metallic indium or discharge of indium ion takes place in stages. This is probably true, but the results of this paper show conclusively that both the passivity of anodic solution and the overvoltage to indium deposition are very slight under the experimental conditions described in the paper.

Acknowledgment

The author is indebted to Cominco for a gift of high purity indium metal.

Received January 18, 1977

MARIE-CHRISTINE TRUDELLE, MAURICE ABRAHAM, and JAMES SANGSTER. Can. J. Chem. **55**, 1713 (1977).

Vapour pressures of the system $(Ag,Tl)NO_3 + H_2O$ have been measured at 98.5°C by the static method over the complete concentration range for Ag/Tl mole ratio = 1.14. The water activity data can be represented by a modified BET isotherm in the range $0.1 < a_w < 0.7$. The derived BET constants indicate that the salts in this system are very weakly hydrated, probably less so than (for example) $CsNO_3$. The linearity of vapour pressure with water mole ratio R_H, found previously by Tripp and Braunstein for $(Li,K)NO_3 + H_2O$, is absent in the present system. The Henry's law constant for water dissolved in molten $(Ag,Tl)NO_3$ has been deduced. The excess free energy of the system is positive at all concentrations and shows a maximum of 117 cal/mol at water mole fraction 0.66.

MARIE-CHRISTINE TRUDELLE, MAURICE ABRAHAM et JAMES SANGSTER. Can. J. Chem. **55**, 1713 (1977).

On a mesuré les pressions de vapeur du système $(Ag,Tl)NO_3 + H_2O$ à 98.5°C, par une méthode statique, pour tout le domaine de concentration en eau, le rapport molaire Ag/Tl étant fixé à 1.14. On peut représenter les données obtenues pour l'activité de l'eau par une isotherme BET modifiée, dans l'intervalle $0.1 < a_w < 0.7$. Les constantes BET que l'on en dérive indiquent que les sels constituants de ce système sont très faiblement hydratés, probablement moins que, par exemple, $CsNO_3$. Le caractère linéaire de la pression de vapeur fonction du rapport molaire R_H trouvé antérieurement par Tripp et Braunstein pour le système $(Li,K)NO_3 + H_2O$ n'apparaît pas pour le système étudié ici. La constante de la loi de Henry pour l'eau dissoute dans le mélange de sels fondus $(Ag,Tl)NO_3$ a été déduite. L'enthalpie libre d'excès de ce système est positive pour toute concentration en eau avec un maximum de 117 cal/mol pour une fraction molaire en eau de 0.66.

Introduction

Thermodynamic properties of concentrated aqueous electrolyte solutions have in general received less attention than those of dilute solutions, either experimentally or theoretically. Solubility limits have contributed to this difference. Perhaps of greater importance is the fact that there is no theory of aqueous electrolyte solutions as adequate for this concentration region as the Debye–Hückel approach is for dilute solution.

It is significant therefore that more progress in the understanding of concentrated electrolyte solutions has come from the fused salt end of the concentration scale than from the dilute (1, 2). The vapour pressures of very concentrated electrolyte solutions and of aqueous melts have been measured by the isopiestic (3*a*) and differential transpiration (3*b*) methods, mostly for the nitrates and halides of the alkalis and alkaline earths. To complement this small but growing pool of data, we describe here an apparatus for the static measurement of vapour pressures of aqueous solutions above room temperature, and report results for the system $(Ag,Tl)NO_3 + H_2O$ at 98.5°C. This system is convenient for study since, for approximately equimolar Ag and Tl in the mixture, the system is liquid around 100°C over the entire concentration range (4). The choice of this system also marks a departure from all previous work in this area (2, 3) since *both* cations in the salt mixture are probably only weakly hydrated in aqueous solution (previously used mixtures always included Li^+ or Na^+ or Ca^{2+}).

This paper will deal with the apparatus and

[1]To whom correspondence should be addressed.

experimental technique in some detail since, although the principle of the static method is simple and familiar, the components of the apparatus and their manipulation merit special attention.

Experimental

Chemicals and Procedure

The preparation, purification, and storage of the chemicals used, and a detailed description of the experimental procedure are available elsewhere.[2]

Apparatus

The apparatus is represented schematically in Fig. 1. The vacuum system (not shown) comprised a combination diffusion/rotary pump and liquid nitrogen trap. The pressure in the manifold was indicated by a Pirani gauge (Edwards High Vacuum, 10^{-4} to 1 Torr). The sample container was a 100 ml Pyrex flask. The flask was immersed in a bath of water in a Haake Circulating Pump model FS. The sample solution was stirred magnetically. The temperature of the bath was measured with a Hewlett–Packard Quartz Thermometer model 2801A, and read 98.50 ± 0.05°C.

Since the pressure gauge used (quartz spiral type, model 145, 0–50 in. Hg, Texas Instruments) operated at room temperature, an intermediate heated sensing device was necessary to avoid condensation. Thus the sample container was connected, through Pyrex and stainless steel tubing kept at 180°C by heating tape, to one side of a pressure transducer (model DP 15, Validyne Engineering Corp.) kept at 110°C in a thermostated air oven. The other side of the transducer was connected to the pressure gauge and also to a Servo Pressure Controller (model SPC, Volumetrics). Any imbalance signal from the transducer activated the pressure controller to adjust the air pressure presented to the transducer and pressure gauge simultaneously until there was null signal (zero differential pressure). At this point, the vapour pressure of the sample could be read off the pressure gauge as an absolute pressure, the reference side of the gauge being kept evacuated ($\leq 10^{-3}$ Torr) through stopcock 3.

All stopcocks were of the hollow key type; those at room temperature were lubricated with Dow Corning High Vacuum grease, and the heated ones with Apiezon type H.

The dead space above the sample solution was minimized as much as was physically possible; it was estimated to be about 80 cm^3.

The general and degassing techniques and apparatus were tested by measuring the vapour pressure of distilled water. About 25 measurements were taken at temperatures between 50 and 100°C. The values lay within one part per thousand of those in the literature (5).

Calculations

For deriving water activities, the fugacity of the vapour is required. The fugacity f was found from the pressure p by

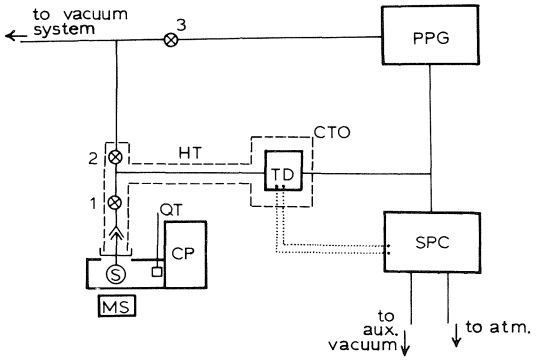

FIG. 1. Block diagram of the apparatus. MS, magnetic stirrer; S, sample flask; CP, circulating pump; QT, quartz thermometer; HT, heating tape; CTO, constant temperature air oven; TD, transducer; PPG, precision pressure gauge; SPC, servo pressure controller; 1, 2, 3, stopcocks.

$$[1] \qquad f = p \exp(Bp/RT)$$

where B is the second virial coefficient of water vapour (6) (-462 cm^3/mol at 98.5°C). Use of the third virial coefficient is not warranted in this work. If f^0 is the fugacity of pure water at 98.5°C, then the water activity $a_w = f/f^0$.

Since the data reported here cover essentially the complete concentration range, free energy parameters have been calculated on both mole fraction and molality scales. If x represents mole fraction, then the activity coefficient of water on the mole fraction scale is $\gamma_w = a_w/x_w$. On the molality scale, the osmotic coefficient ϕ is given by

$$[2] \qquad \phi = -1000 \ln a_w/2mM_w$$

where m is the total molality of salts and M_w is the molar mass of water.

The BET isotherm equation, adapted to aqueous electrolyte solutions, can be written as (7)

$$[3] \quad ma_w/55.51(1 - a_w) = 1/cr + (c - 1)a_w/cr$$

where r is the number of molecules of water adsorbed per complete monolayer on a solute molecule. The constant c is given approximately by $c = \exp[-(E - E_L)/RT]$, where E is the heat of adsorption of water molecules of the monolayer and E_L is the heat of liquefaction of bulk water.

If the mixed solute $(Ag,Tl)NO_3$ be considered as a single solute of molality m, then the measure-

ment of the water activity over the complete concentration range enables the excess free energy G^E to be calculated. Solvent and solute are both liquids in this example, and so G^E is found in the usual way (8) from the equation

$$[4] \quad G^E = x_s RT \int_{x_w=0}^{x_w} (\ln \gamma_w / x_s^2)\, dx_w$$

where $x_s = 1 - x_w$. The integral was evaluated graphically.

Results and Discussion

Vapour Pressures

The vapour pressures and derived thermodynamic parameters are presented in Table 1. Since essentially the complete concentration range is represented, the results may be discussed profitably by using both the osmotic coefficient and activity coefficient of water. Thus Fig. 2 gives the Raoult's law plot of the data; the system shows positive deviations over almost all the

concentration range. This is unusual behaviour for an aqueous electrolyte system, since the vast majority of such systems hitherto studied show strong negative deviations at all compositions (2). The exceptions to this rule are (perhaps not surprisingly) such salts as $AgNO_3$, $RbNO_3$, and $CsNO_3$. For illustration, Fig. 3 shows ϕ and γ_w in the dilute region for $(Ag,Tl)NO_3$ and also for $AgNO_3$ alone at 100°C (9). The substitution of Tl^+ for some of the Ag^+ thus significantly increases γ_w above unity.[3] The behaviour of $RbNO_3$ and $CsNO_3$ solutions is very close to that shown for $AgNO_3$ (10*a*).

Tripp and Braunstein (1, 2, 3*b*) have reported an empirical regularity for $(Li,K)NO_3$ aqueous melts which may or may not be significant for the search for an adequate theoretical model of these systems. They found that the vapour pressure (and a_w) were linear in the 'water mole ratio' R_H = moles H_2O/moles NO_3^- in the region $R_H = 0$ to 1. The same plot is shown in Fig. 4 for the present system $(Ag,Tl)NO_3 + H_2O$. Clearly there is no linearity at all, except[4] perhaps for $R_H < 0.1$. There is as yet no model (statistical or otherwise) to account for this kind of linearity (2), which may depend upon (for example) the presence of a strongly hydrated cation in the mixture.

BET Isotherm

Some time ago Stokes and Robinson (7) pointed out that very concentrated aqueous solutions of strong electrolytes could be described by a suitably adapted BET adsorption isotherm equation. At first thought this may seem quite striking, but the model it implies is a reasonable one and isotherm plots (eq. 3) show good linearity for $a_w < 0.5$ (2, 7). Figure 5 shows the BET isotherm plot for $(Ag,Tl)NO_3 + H_2O$. Also included for comparison are the data for the system $(Li,Cs)NO_3 + H_2O$ at 100°C (3*a*) and $H_2SO_4 + H_2O$ at 25°C (11).

It is noticed immediately that the $(Ag,Tl)NO_3$ isotherm is situated far above all the others (the intercept is 1.33 whereas the others (3*a*) lie below 0.3). The derived BET constants for the present system are given in Table 2, together with those

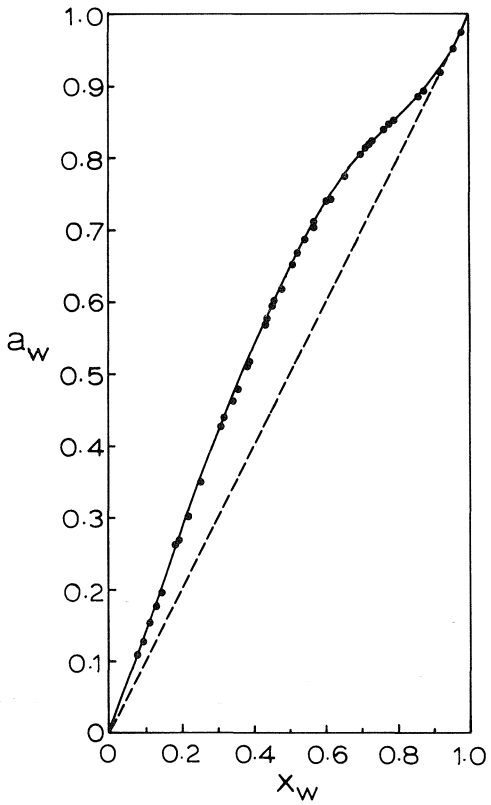

FIG. 2. Raoult's law plot for the system $(Ag,Tl)NO_3 + H_2O$ at 98.5°C. Dashed line represents ideal behaviour.

of a few other representative systems. While the Ag/Tl isotherm is valid in much the same a_w range as the others, the r and c values are very low. If the series $LiNO_3$, $(Li,Cs)NO_3$, $(Ag,Tl)NO_3$ be considered, it may be deduced that the large cations Ag^+, Tl^+, and Cs^+ are all weakly hydrated in comparison with Li^+. Thus if it is assumed that cations are hydrated preferentially over anions then the following approximate values of r at 100°C can be found: Ca^{2+}, 3.6; Li^+, 2.7; Cs^+, 1.3; Ag^+ and Tl^+, 0.3 (using the values of r in refs. 3*a* and 7).

Henry's Law

The BET equation can be written in terms of mole fractions as

$$[5]\quad a_w(1 - x_w)/x_w(1 - a_w) = 1/cr + (c - 1)a_w/cr$$

and thus in the limit as $x_w \to 0$, eq. 5 reduces (2) to

$$[6]\quad (a_w/x_w)_{x_w \to 0} = 1/cr = \gamma_w^{\infty}$$

[3]Figure 3 also suggests that, while γ_w (in contrast to ϕ) is not a sensitive indicator of non-ideality in dilute solution (10*b*), γ_w may become more useful than ϕ in the "water dissolved in molten salt" region.

[4]In the limit as $x_w \to 0$, water exhibits Henry's law behaviour where both vapour pressure and a_w *are* linear in R_H.

[a]Mole ratio Ag/Tl = 1.14.
[b]Mole ratio Li/Cs = 0.98.

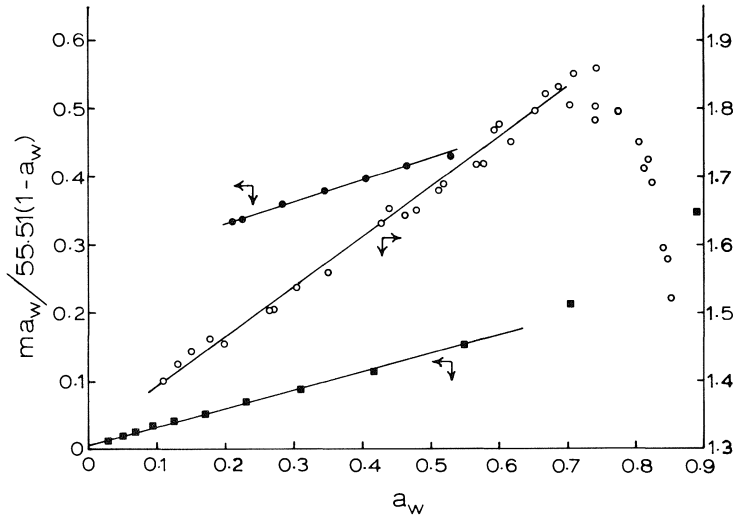

FIG. 5. BET isotherms, adapted for aqueous electrolyte solutions, for three systems: ●, $(Li,Cs)NO_3$ + H_2O at 100°C (ref. 3*a*); ○, $(Ag,Tl)NO_3$ + H_2O at 98.5°C (this work); ■, H_2SO_4 + H_2O at 25°C (ref. 11).

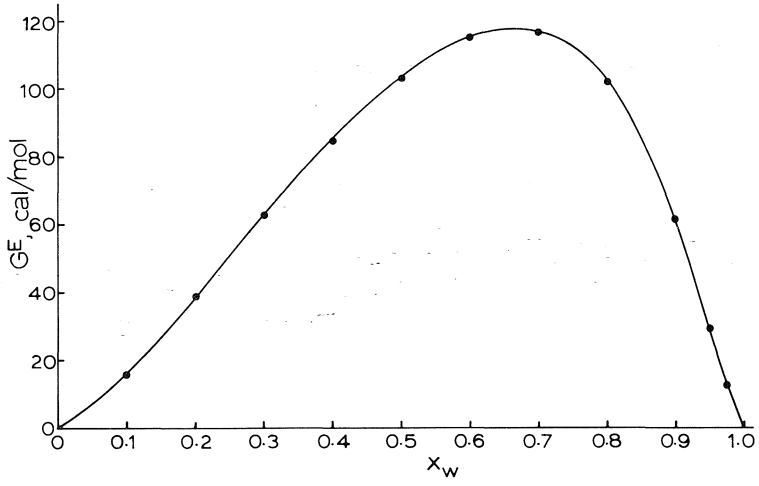

FIG. 6. Excess free energy for the system $(Ag,Tl)NO_3$ + H_2O at 98.5°C as a function of water mole fraction.

where γ_w^∞ is the activity coefficient of water at infinite dilution in molten salt (*i.e.*, the BET intercept). Converting to fugacities, we have

$$[7] \qquad f_w = f_w^0 x_w \gamma_w^\infty = K_H x_w$$

where K_H is Henry's constant for water in molten salt and f_w^0 is the fugacity of pure water. Table 3 gives K_H for water dissolved in a number of molten salts. It is seen that molten salts can differ enormously as 'solvents' for water.

It has not been pointed out previously that the theoretical limit of the BET expression $ma_w/55.51(1 - a_w)$, that is the left side of eq. 3 or eq. 5, as $x_w \to 1$ is 0.5 for 1:1 electrolytes.[5] This is shown quite clearly for dilute solutions of single electrolytes at 25°C (3*a*); it also suggests why the $(Ag,Tl)NO_3$ BET plot deviates *downward* while others (like that for LiBr) deviate *upward* as a_w increases.

[5]In general the limit is $1/\nu$ where ν is the stoichiometric number of ions per electrolyte molecule. This can be deduced easily if a_w is replaced by the 'species mole fraction' $55.51/(55.51 + \nu m)$ and noting that as $m \to 0$, $x_w \to 1 - \nu m/55.51$.

TABLE 3. Henry's law constants K_H (atm) for water dissolved in salts at 100°C calculated according to eq. 7

Salt	K_H	Reference
LiBr	0.010	3*a*
LiCl	0.017	3*a*
$Ca(NO_3)_2$	0.036	3*a*
$LiNO_3$	0.072	3*a*
$(Ca,Cs)NO_3$[a]	0.14	3*a*
$(Li,K)NO_3$[b]	0.21	3*a*
$(Li,Cs)NO_3$[c]	0.25	3*a*
$(Ag,Tl)NO_3$[d]	1.3	This work

[a]Mole ratio Ca/Cs = 0.99.
[b]Mole ratio Li/K = 1.03.
[c]Mole ratio Li/Cs = 0.98.
[d]Mole ratio Ag/Tl = 1.14. For calculating K_H, the γ_w^∞ value at 98.5°C was used.

Excess Free Energy

It is customary, when calculating excess free energies of aqueous electrolyte solutions at ordinary temperatures, to use the ideal solution represented by unity osmotic coefficient ϕ and unity mean ionic activity coefficient $\gamma_\pm$ at all concentrations (12). In this convention solvent obeys Raoult's law and solute obeys Henry's law at infinite dilution, and the pure solute is not chosen as the standard state since it is a solid of limited solubility, possessing properties too different from the solute in solution. This difficulty is absent from the present system since it is liquid at all concentrations. The activity of one component is known over the whole concentration range, and hence the Gibbs–Duhem equation may be integrated from the fused salt end quite easily.

The excess free energy G^E is given by eq. 4 and plotted in Fig. 6. To our knowledge this is the first aqueous electrolyte system to have been treated in this manner. It is seen that G^E is everywhere positive (corresponding to positive Raoult's law deviations) and is a smoothly varying function of composition. The maximum value is 117 cal/mol at $x_w = 0.66$.

Etude spectroscopique et voltammétrique de l'équilibre existant entre les acides chlorosulfurique et acétosulfurique dans l'acide acétique

BERNARD BRASME, JEAN CLAUDE FISCHER ET MICHEL WARTEL

Université de Lille I, Laboratoire de Chimie Minerale I, Bâtiment C8, B.P. 36, 59650 Villeneuve d'Ascq, France

Reçu le 19 octobre 1976

BERNARD BRASME, JEAN CLAUDE FISCHER et MICHEL WARTEL. Can. J. Chem. **55**, 1720 (1977).

L'étude des spectres Raman d'une solution d'acide chlorosulfurique dans l'acide acétique, soumise à un vide dynamique, révèle l'existence de l'équilibre:

$$HSO_3Cl + HCH_3CO_2 \rightleftarrows HSO_3CH_3CO_2 + HCl$$

dont la constante a été déterminée par l'étude du système:

$$AgCl + HClO_4 + HSO_3CH_3CO_2 + e^- \rightleftarrows Ag + HSO_3Cl + HCH_3CO_2 + ClO_4^-$$

Le traitement mathématique des résultats après affinement par la méthode des moindres carrés conduit à la valeur $K = 10^{0.8\pm0.2}$ mol ℓ^{-1}.

BERNARD BRASME, JEAN CLAUDE FISCHER, and MICHEL WARTEL. Can. J. Chem. **55**, 1720 (1977).

A study of the Raman spectra of a solution of chlorosulfuric acid in acetic acid, under a continuous vacuum, reveals the existence of the equilibrium:

$$ClSO_3H + CH_3COOH \rightleftarrows CH_3COOSO_3H + HCl$$

The equilibrium constant of this reaction was determined from the study of the system:

$$AgCl + HClO_4 + CH_3COOHSO_3 + e^- \rightleftarrows Ag + ClSO_3H + CH_3COOH + ClO_4^-$$

The equilibrium constant derived from a least-squares analysis of the data was found to be $10^{0.8\pm0.2}$ mol ℓ^{-1}.

Introduction

Dans un travail précédent (1) nous avons expliqué le caractère diacide de l'acide chlorosulfurique dans le solvant acide acétique (AcOH) en mettant en évidence par spectrométries ir et Raman et par analyse chimique la nature des composés formés lors de la neutralisation d'une solution de HSO_3Cl par une solution d'acétate de pyridinium (PyHAcO). Ce caractère diacide peut être résumé par les trois schémas suivants:

Ionisation

[1] $$HSO_3Cl + AcOH \rightleftarrows AcOH_2^+SO_3Cl^-$$

Réaction acide–base

[2] $$AcOH_2^+SO_3Cl^- + PyH^+AcO^- \rightleftarrows PyH^+SO_3Cl^- + 2AcOH$$

Réaction de complexation

[3] $$PyH^+SO_3Cl^- + PyH^+AcO^- \rightleftarrows PyH^+SO_3AcO^- + PyH^+Cl^-$$

$PyH^+SO_3AcO^-$ symbolise l'acétosulfate de pyridinium. En fait le schéma 3 met en jeu les pouvoirs donneurs de SO_3 des composés SO_3Cl^- et SO_3AcO^-.

En l'absence de la base PyHAcO un échange de SO_3 doit exister entre le chlorosulfate d'acidium acétique formé selon [1] et le solvant soit:

[4] $$AcOH_2^+SO_3Cl^- + 2AcOH \rightleftarrows AcOH_2^+SO_3AcO^- + AcOH_2^+Cl^-$$

que nous pouvons encore écrire:

[5] $$HSO_3Cl + AcOH \rightleftarrows HSO_3AcO + HCl$$

où nous ne présageons pas de l'état de solvatation des différentes espèces.

Résultats et discussion

Existence d'un équilibre entre HSO_3Cl et HSO_3AcO

L'étude par spectroscopie Raman d'une solution 5 *M* de HSO_3Cl (fig. 1, spectre 1) nous permet de mettre en évidence l'existence des espèces $AcOH_2^+$ et SO_3Cl^- et peut être HSO_3Cl par la raie à 415 cm^{-1} (tableau 1).

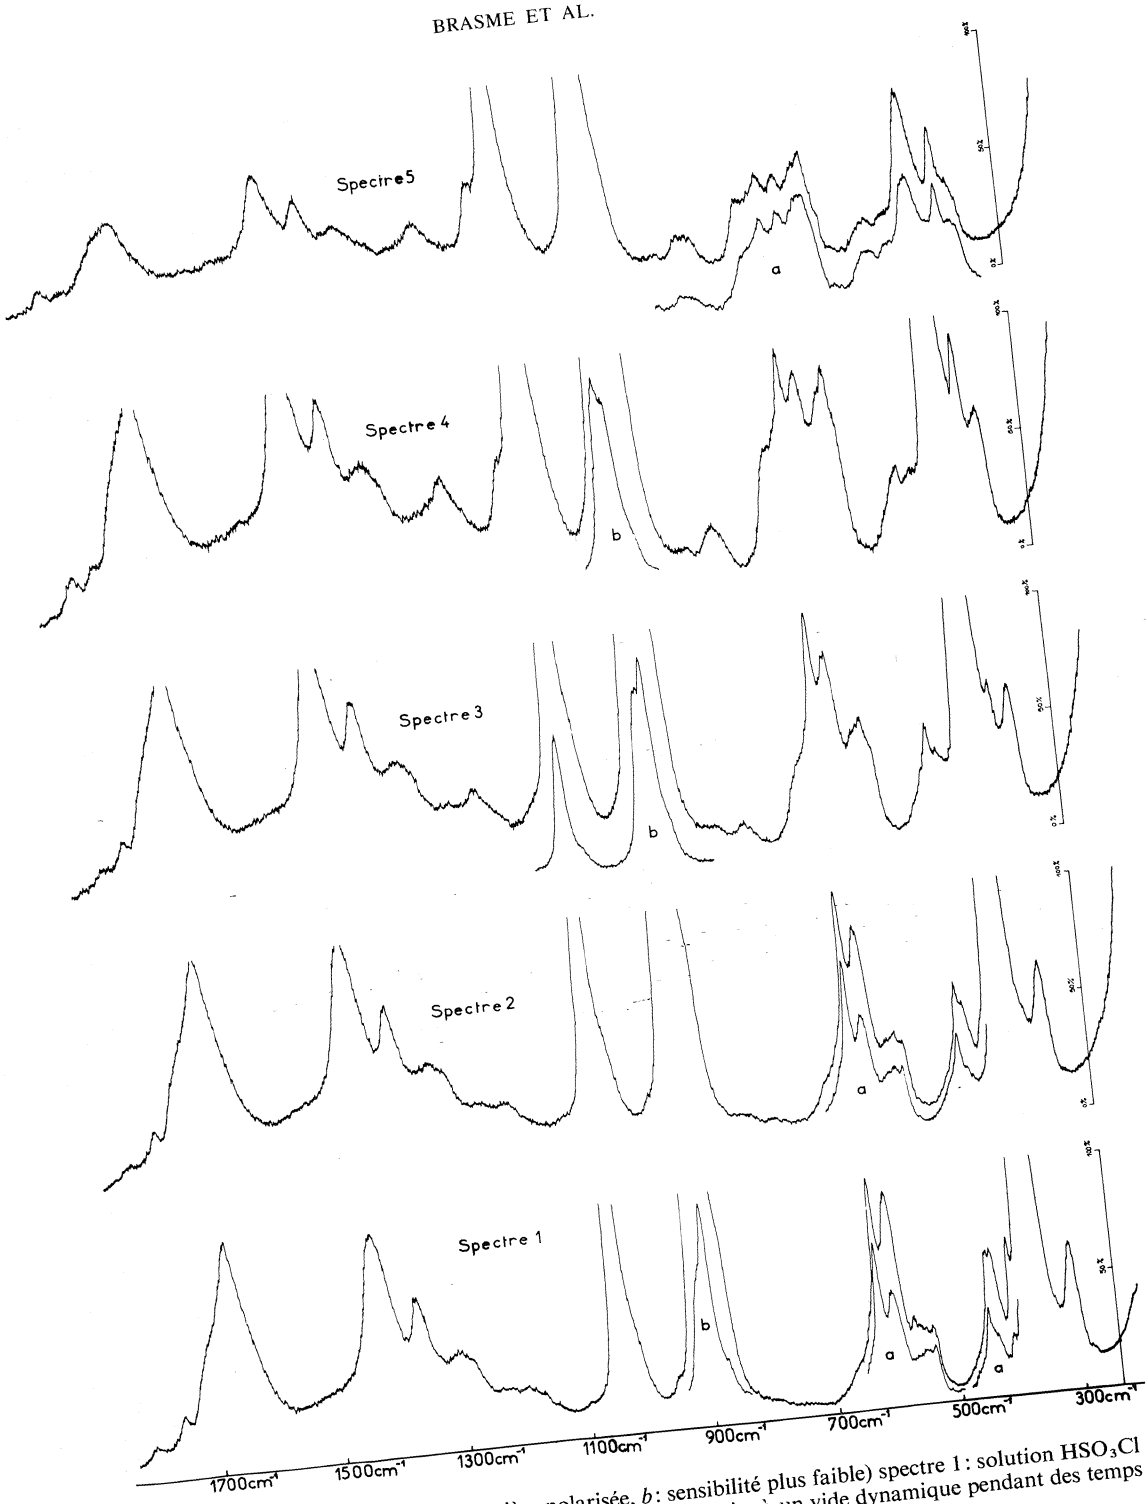

FIG. 1. Spectres Raman (*a*: lumière polarisée, *b*: sensibilité plus faible) spectre 1: solution HSO_3Cl 5 *M* dans AcOH; spectres 2, 3, 4, 5: même solution soumise à un vide dynamique pendant des temps croissants.

TABLEAU 1. Comparaison des fréquences de diffusion Raman du spectre 1 de la fig. 1 à celles du spectre des espèces: HSO_3Cl, AcOH, $AcOH_2^+$, SO_3Cl^- et $AcOSO_3^-$*

*F: forte, m: moyenne, f: faible.

L'attribution a été réalisée en s'appuyant sur les résultats obtenus par Auger *et al.* (2) et par Gerding et coll. (3, 4) pour SO_3Cl^- et par Casadevall *et al.* (5) pour $AcOH_2^+$.

Toutefois, les fréquences des raies caractéristiques les plus intenses de $AcOSO_3^-$ (regroupées dans le tableau 1) sont trop voisines de celles des raies de SO_3Cl^-, $AcOH_2^+$ et AcOH pour que nous soyons en mesure de prouver la formation d'acide acétosulfurique en quantité décelable selon l'équilibre [5]. Pour montrer que cet équilibre intervenait nous avons tenté de le déplacer vers la droite, par extraction de HCl sous pression réduite.

Nous avons donc réalisé les spectres de diffusion Raman d'une solution 5 *M* d'acide chlorosulfurique dans AcOH soumise à un vide dynamique pendant des temps croissants. Les spectres obtenus sous 10^{-2} Torr après 5 min (spectre 2), 15 min (spectre 3), 1 h (spectre 4) et 6 h (spectre 5) sont comparés à celui de la solution initiale (spectre 1) fig. 1.

Il faut noter qu'en plus du déplacement de l'équilibre, l'abaissement de la pression aura pour effet de faire varier les concentrations par élimination du solvant. Ne disposant pas d'élément de référence privilégié nous avons, au cours de notre étude, augmenté la sensibilité de notre appareillage de manière à maintenir constante dans les quatre premiers spectres l'intensité de la première raie, située vers 310 cm^{-1} (SO_3Cl^-).

Au contraire, dans le cas du spectre 5, nous avons adopté une sensibilité identique à celle utilisée pour réaliser le spectre 1 de manière à disposer d'un élément nous permettant d'ob-

server la modification de l'allure générale du spectre.

Description des spectres

Le spectre 5 comparé au spectre 1 nous permet de constater une nette diminution des intensités des raies caractéristiques de l'espèce SO_3Cl^- (en particulier la raie à 310 cm^{-1} n'apparait plus que sous forme d'un épaulement), ce qui indique un appauvrissement important en chlorosulfate.

L'abaissement de pression a aussi pour effet d'éliminer de la solution une fraction importante du solvant: diminution des intensités des raies situées à 436, 598, 619 et 892 cm^{-1} qui sont attribuables aux mouvements propres de la molécule AcOH.

L'élimination d'une partie du solvant permet d'observer une augmentation de l'intensité des raies caractéristiques de l'espèce $CH_3CO_2H_2^+$ par rapport à celles de l'acide acétique à 446 et 910 cm^{-1}. Nous notons également une augmentation de l'épaulement s'étalant de 625 à 660 cm^{-1}. La concentration de l'espèce $CH_3CO_2H_2^+$ devient suffisante pour rendre visible la raie caractéristique à 1183 cm^{-1} non identifiable sur le spectre 1.

Malgré l'élimination d'une partie du solvant nous enregistrons une augmentation des intensités des raies de diffusion à 1365 et 1427 cm^{-1} (augmentation visible par comparaison de l'intensité de ces raies à celle de la raie à 892 cm^{-1} reportée avec une sensibilité plus faible sur les spectres 1, 3 et 4 de la fig. 1). Ces raies sont attribuables aux mouvements de déformation des liaisons C—H des groupements CH_3. Cette exaltation d'intensité ne peut donc s'expliquer que par l'augmentation des concentrations d'espèces possèdant également des groupements CH_3. (L'espèce $AcOH_2^+$ pouvant être l'une d'elles.)

Même sans tenir compte de cette dernière remarque l'ensemble des résultats nous permet d'affirmer que l'espèce $CH_3CO_2H_2^+$ reste en solution avec une concentration croissante du fait de l'élimination du solvant.

L'espèce cationique $AcOH_2^+$ subsiste alors que l'espèce anionique initiale SO_3Cl^- disparait ce qui implique qu'une autre espèce anionique sera associée au cation acétique.

Cette hypothèse est confirmée par ce qui suit.

(*a*) L'apparition de raies nouvelles à 347, 550, 762 et 1800 cm^{-1}. (*i*) Celle à 347 cm^{-1} n'apparait tout d'abord (spectre 2) que sous forme d'un épaulement de la raie 380 cm^{-1} attribuable à SO_3Cl^- alors que dans le cas du spectre 5 les intensités de ces deux raies sont comparables. (*ii*) La raie à 550 cm^{-1} apparait entre les raies 536 et 570 cm^{-1} caractéristiques de l'espèce SO_3Cl^-. (*iii*) La raie située à 1800 cm^{-1} possède une intensité très faible et sa présence n'est décelable que dans les spectres 3, 4 et 5.

(*b*) Alors que les intensités des autres raies caractéristiques de l'espèce SO_3Cl^- sont artificiellement maintenues constantes (par augmentation de la sensibilité de l'appareillage), celle de la raie à 1040 cm^{-1} augmente et se déplace vers les fréquences plus élevées. Ceci est net quand on compare les intensités relatives des deux raies les plus intenses de SO_3Cl^- à 380 et 1040 cm^{-1} dans les spectres 1 et 5. On peut donc penser qu'apparait en solution une espèce présentant une raie de diffusion à une fréquence légèrement supérieure à 1040 cm^{-1}.

(*c*) Nous enregistrons une modification de l'épaulement situé entre 615 et 650 cm^{-1}. L'intensité relative de celui-ci augmente, ce qui s'explique par l'augmentation de la concentration en $AcOH_2^+$ mais on constate également une modification de sa forme qui se traduit par un élargissement vers des fréquences plus élevées, ce qui peut être expliqué par apparition d'une raie nouvelle vers 660 cm^{-1}.

En résumé: par extraction sous pression réduite: (*a*) la concentration de l'espèce SO_3Cl^- diminue, (*b*) l'espèce $AcOH_2^+$ reste en solution, (*c*) un ensemble de raies nouvelles apparait dans le spectre de la solution à 347, 550, 660, 762, 1050, 1800 cm^{-1} fréquences très voisines des raies caractéristiques les plus intenses observées dans les spectres de l'acétosulfate de sodium, de pyridinium (1) ou d'acidium acétique (6).

En conclusion, même si l'acide chlorosulfurique en solution dans AcOH se trouve sous forme de chlorosulfate d'acidium acétique (spectre 1), cette solution évolue facilement si elle est soumise à un vide dynamique. Les raies nouvelles mises en évidence sur les spectres 2, 3, 4 et 5 peuvent être attribuées à l'ion acétosulfate, malgré les légers déplacements par rapport aux fréquences notées par Commeyras et par rapport à celles des spectres des acétosulfates de sodium et pyridinium réalisés en phase solide.

L'acide chlorosulfurique, en solution dans

l'acide acétique, est donc en équilibre avec l'acide acétosulfurique. Cet équilibre peut être déplacé par une simple extraction de HCl sous pression réduite. Nous avons entrepris dans le paragraphe suivant, l'étude potentiométrique de cet équilibre.

Détermination de la constante de l'équilibre entre les acides HSO_3Cl et HSO_3AcO

L'acide acétique ayant une constante diélectrique égale à 6.2, la dissociation des paires d'ions est faible. Ne pouvant atteindre les constantes d'ionisation, nous ne pouvons déterminer que des constantes de dissociation globale. L'équilibre [5] sera donc toujours écrit sous forme moléculaire.

[5] $HSO_3Cl + AcOH \rightleftarrows HSO_3AcO + HCl$

dont la constante

$$K = \frac{[HSO_3AcO][HCl]}{[HSO_3Cl]} = K^{SO_3}_{HSO_3Cl}/K^{SO_3}_{HSO_3AcO}$$

avec

$$K^{SO_3}_{HSO_3Cl} = \frac{[SO_3][HCl]}{[HSO_3Cl]}$$

et

$$K^{SO_3}_{HSO_3AcO} = \frac{[SO_3]}{[HSO_3AcO]}$$

Ces dernières caractérisant les pouvoirs sulfonants des acides chlorosulfurique et acétosulfurique.

Dans l'acide acétique les constantes de dissociation des électrolytes sont faibles ($<10^{-5}$) (7) et les concentrations des espèces non chargées sont toujours peu élevées ($<5 \times 10^{-2}\ M$) ce qui nous permet d'assimiler activité et concentration. Pour déterminer la constante de [5] nous allons montrer par potentiométrie que l'électrode d'argent est indicatrice de [HCl] dans le solvant AcOH, et utiliser cette propriété vis-à-vis d'un donneur de HCl, l'acide chlorosulfurique.

(1) Etude potentiométrique des solutions de HCl

Les systèmes Ag/Ag^+ et Ag/AgCl sont réversibles, dans AcOH le second système ayant déjà été utilisé comme électrode indicatrice (8) ou comme électrode de référence (9, 10).

Nous avons montré que le système [6] est lui

[6] $AgCl\downarrow + HClO_4 + e^- \rightleftarrows Ag\downarrow + ClO_4^- + HCl$

aussi réversible, par dosage d'une solution ($1.22 \times 10^{-2}\ M$) de HCl par une solution de $AgClO_4$. La courbe de neutralisation, ainsi que le graphe de la transformée logarithmique correspondante sont reproduits sur la fig. 2 (x représentant le rapport $[AgClO_4]$ ajouté/[HCl] initial).

Le potentiel pris par l'électrode, pouvant être traduit par

$$E = E_{HCl}{}^0 + P \log \frac{[HClO_4]}{[HCl][ClO_4^-]}$$

où P représente le coefficient de proportionnalité dans l'équation de Nernst.

Etant données les forces relatives des acides

$HCl(pK^{H^+}_{HCl} = 8.6\,(11))$ $HClO_4(pK^{H^+}_{HClO_4} = 4.85\,(11))$

on peut admettre que $[H^+] \simeq [ClO_4^-]$ ce qui entraine

$$[ClO_4^-] \simeq \sqrt{K^{H^+}_{HClO_4}[H^+ClO_4^-]}$$

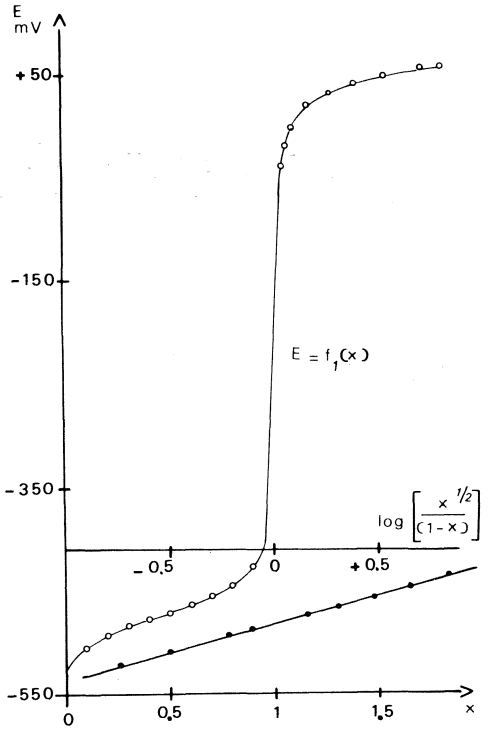

FIG. 2. Dosage d'une solution de HCl par $AgClO_4$ ($E = f_1(x)$). Analyse mathématique de la courbe potentiométrique: courbe (●).

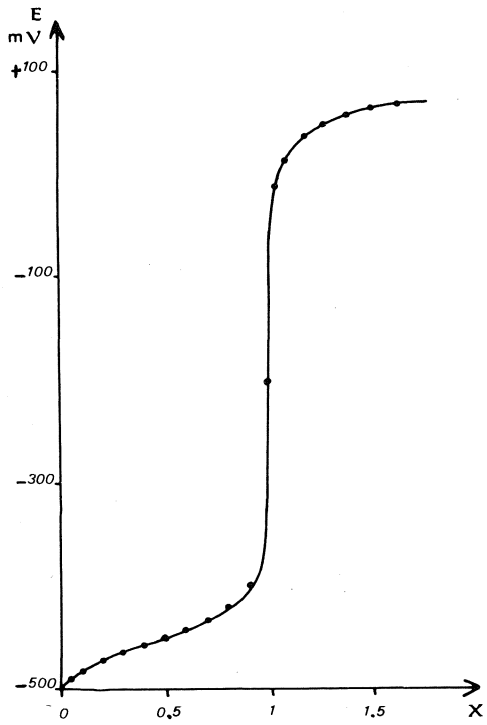

FIG. 3. Dosage d'une solution de HSO_3Cl par $AgClO_4$.

et

$$E = E_{HCl}{}^0 + P \log \left(\frac{x}{1-x}\right) - \frac{P}{2} \log (C_i K^{H^+}_{HClO_4})$$

C_i étant la concentration initiale en HCl.

Par régression linéaire nous obtenons: $P = 56$ mV/unité de log et $E^0 = -669 \pm 2$ mV. La valeur de la pente, proche de la valeur théorique: 59 mV (les manipulations étant effectuées à 25°C) justifie l'hypothèse $[H^+] = [ClO_4{}^-]$. Le système [6] est réversible et peut être utilisé pour

$$(Ag\downarrow + HCl + ClO_4{}^- \rightleftarrows AgCl\downarrow + HClO_4 + e^-)$$

le dosage de complexes donneurs de HCl tels que HSO_3Cl.

(2) Etude voltammétrique du dosage de HSO_3Cl par $AgClO_4$

Nous avons ensuite dosé une solution (2.84×10^{-2} *M*) de HSO_3Cl par une solution de $AgClO_4$ (8.17×10^{-1} *M*). La courbe de neutralisation est présentée sur la fig. 3.

Au cours de ce dosage, nous assistons à la réaction:

[7] $HSO_3Cl + AgClO_4 + AcOH \rightleftarrows AgCl\downarrow + HClO_4 + HAcOSO_3$

à laquelle correspond le système électrochimique:

[8] $AgCl\downarrow + HClO_4 + HAcOSO_3 + e^- \rightleftarrows HSO_3Cl + Ag\downarrow + ClO_4{}^- + AcOH$

L'étude mathématique de la courbe obtenue montre qu'il est nécessaire de tenir compte de l'équilibre [5], HCl libre n'étant pas négligeable devant HSO_3Cl.

En faisant l'hypothèse que SO_3 libre est négligeable devant HSO_3Cl et HSO_3AcO c'est à dire que les constantes $K^{SO_3}_{HSO_3Cl}$ et $K^{SO_3}_{HSO_3AcO}$ sont faibles nous avons: $[HSO_3Cl] + [HSO_3AcO] = C_0'$ avec C_0' concentration initiale en HSO_3Cl. La neutralité électrique donne:

$[Cl^-]$ et $[AcO^-]$ étant négligeable

$$[H^+] = [SO_3Cl^-] + [AcOSO_3{}^-] + [ClO_4{}^-]$$

$$[H^+] = \sqrt{K^{H^+}_{HSO_3Cl}[HSO_3Cl] + K^{H^+}_{HAcOSO_3}[HAcOSO_3] + K^{H^+}_{HClO_4}[HClO_4]}$$

Les résultats d'un travail en cours montrent que les acides chlorosulfurique et acétosulfurique sont tous deux de force très voisine de celle de H_2SO_4, donc non entièrement ionisés et nettement plus faibles que $HClO_4$; résultats analogues à ceux obtenus par Bessière (12) dans l'acide trifluoracétique en ce qui concerne HSO_3Cl et H_2SO_4 ($pK^{H^+}_{HSO_3Cl} - pK^{H^+}_{H_2SO_4} = 0.1$).

En prenant $K^{H^+}_{HSO_3Cl}$ et $K^{H^+}_{HSO_3AcO} = 10^{-7.2}$ constante d'acidité de H_2SO_4 (11) nous obtenons:

$$[H^+] = \sqrt{C_0' \times 10^{-7.2} + x\, C_0' \, 10^{-4.8}} \simeq \sqrt{x\, C_0' \times 10^{-4.8}}$$

si $x > 0.2$ (erreur voisine de 1%); x étant le rapport $[AgClO_4]$ ajouté/$[HSO_3Cl]$ initial.

A partir des équations

$$[HSO_3Cl] + [HSO_3AcO] = C_0'$$

$$K = \frac{[HSO_3AcO][HCl]}{[HSO_3Cl]}$$

$$[HCl] + [HSO_3Cl] = (1 - x)C_0'$$

$$[H^+] = \sqrt{xC_0' \times 10^{-4.8}}$$

la loi de Nernst appliquée au système électrochimique [8] s'écrit:

$$E = E^0 + P \log \frac{2K\sqrt{xC_0'}}{(R - xC_0' - K)\sqrt{10^{-4.8}}}$$

avec

$$R = \sqrt{(xC_0' + K)^2 + 4C_0'K(1 - x)}$$

Afin de déterminer simultanément les valeurs de E^0 et K et vérifier le coefficient de proportionnalité de la loi de Nernst, nous avons utilisé la technique d'affinement par la méthode des moindres carrés. Nous obtenons: $E^0 = -717$ mV, $K = 10^{0.8\pm0.2}$ mol ℓ^{-1}, le coefficient de Nernst = 59 mV.

La comparaison de ce potentiel normal à celui du système

$$AgCl\downarrow + HClO_4 + e^- \rightleftarrows HCl + ClO_4^- + Ag\downarrow$$

conduit à $K = 10^{0.81}$, valeur en très bon accord avec celle déterminée par traitement mathématique, et justifie les hypothèses formulées.

Partie expérimentale

Le solvant utilisé a été préparé selon la méthode déjà décrite (1). Nous n'avons pas utilisé la rectification à l'anhydride acétique (13) afin d'éviter une réaction parasite entre les traces d'anhydride acétique entrainé (14, 15) et HSO_3Cl (16).

L'acide chlorosulfurique Carlo Erba est employé sans purification car sa purification apporte plus d'impuretés (SO_2Cl_2, $S_2O_5Cl_2$, H_2SO_4) qu'elle n'en élimine (17, 18).

Les solutions anhydres d'acide chlorhydrique dans AcOH sont obtenues en faisant passer dans le solvant le chlorure d'hydrogène gazeux obtenu par action de H_3PO_4 anhydre sur NaCl.

$AgClO_4$ (produit Merck) est séché sous pression réduite en présence de P_4O_{10} à 80°C.

$PyHClO_4$ est préparé par addition de pyridine à une solution d'acide perchlorique à 70% dans l'acide acétique. Le solide est séparé par filtration et séché selon la même technique que celle utilisée pour $AgClO_4$.

Le dosage de l'eau des solutions de composés non hydrolysables est effectué par la méthode de Karl Fischer décrite par Bizot (19). La teneur en eau est généralement inférieure à 20 ppm.

L'électrode de référence choisie est l'électrode Tacussel AcHg 10.

Les mesures potentiométriques, sont effectuées sur un millivoltmètre Tacussel ISIS 20 000 couplé à un enregistreur Tacussel EPL2 permettant d'apprécier la stabilité des potentiels.

Conclusion

En conclusion, la valeur élevée de la constante K relative à l'équilibre [5] montre qu'en solution diluée un échange important de SO_3 existe entre l'acide chlorosulfurique et le solvant pour donner l'acide acétosulfurique, si l'on admet comme Casadevall et coll. (21) l'hypothèse que HSO_3AcO est très faiblement donneur de SO_3. HSO_3Cl est donc un donneur de SO_3 légèrement plus fort que l'acide acétosulfurique dans l'acide acétique.

En solution concentrée, la valeur de la constante de l'équilibre [5] déterminée par potentiométrie n'est plus valable, l'activité du solvant ne pouvant plus être considérée comme constante. La seule espèce caractérisée par spectrométrie Raman est le chlorosulfate d'acidium acétique. La formation de cette espèce ionisée est favorisée par l'augmentation du pouvoir dissociant du solvant due à une concentration élevée du soluté (5 M). Cependant, l'équilibre [5] existe encore puisque nous avons montré que par élimination de HCl sous pression réduite le spectre Raman de la solution évolue. On observe une diminution des raies correspondant au chlorosulfate d'acidium acétique et une apparition de nouvelles raies que l'on peut attribuer à l'acétosulfate d'acidium acétique.

La détermination des constantes d'acidité de HSO_3Cl et $HSO_3CH_3CO_2$ ainsi que des constantes de dissociation des sels devrait nous conduire au classement du pouvoir sulfonant de ces différents composés dans l'acide acétique et à la justification du caractère diacide de l'acide chlorosulfurique.

La constante d'équilibre azido/tétrazole de cinq azides hétérocycliques (thiazoles, benzothiazole, benzoxazole, isoxazole) dans le dioxanne a été déterminée par rmn du proton et par dipolemétrie. Cette dernière méthode utilise la comparaison des moments dipolaires électriques expérimentaux et des moments théoriques calculés pour l'azide et pour le tétrazole par les méthodes INDO, CNDO/2 et CNDO/S. L'accord est satisfaisant (surtout en utilisant la CNDO/S) aussi bien sur la constante d'équilibre que sur l'effet de la température ($\Delta S \sim 50$ J K^{-1} mol^{-1}). La valeur de l'angle C–N–N ($\alpha = 114°$) des azides est discutée sur la base des énergies, des moments dipolaires et des spectres photoélectroniques expérimentaux et calculés. On démontre la préférence pour la conformation *Z* des azidoimines hétérocycliques.

ROBERT FAURE, JEAN-PIERRE GALY, EMILE-JEAN VINCENT, JEAN-PIERRE FAYET, PIERRE MAURET, MARIE-CLAIRE VERTUT, and JOSÉ ELGUERO. Can. J. Chem. **55**, 1728 (1977).

The equilibrium constant in dioxane between azido and tetrazole isomers has been obtained for five heterocyclic azides (2-azido thiazoles, benzothiazole, benzoxazole, and 3-azido isoxazole) by proton nmr and dipole moment studies. The last method involves a comparison between experimental and calculated (INDO, CNDO/2, CNDO/S) dipole moments. The CNDO/S method gives the best equilibrium constants and entropy factor ($\Delta S \sim 50$ J K^{-1} mol^{-1}). A value of 114° for the C–N–N angle is found to account satisfactorily for certain properties (energy, dipole moment, photoelectron spectra) of aromatic azides. The heterocyclic azidoimines prefer the *Z* conformation.

Introduction

Nous avons montré que la mesure des moments dipolaires pouvait être utilisée pour déterminer la position des équilibres tautomères prototropiques (2–5). Le principe de la méthode est le suivant: pour un équilibre A ⇌ B de constante d'équilibre K_e

$$[1] \qquad K_e = [B]/[A]$$

si P_A est une propriété additive du tautomère A, P_B celle du tautomère B et P_X la propriété expérimentale du mélange en équilibre, on peut écrire:

$$[2] \qquad K_e = \frac{P_A - P_X}{P_X - P_B}$$

La propriété additive, utilisée dans les études précédentes (1–5), est le carré du moment dipolaire (7). Les valeurs des moments dipolaires de chaque forme tautomère, non déterminables expérimentalement, sont évaluées théoriquement à partir de méthodes semi-empiriques de type CNDO.

Dans le cas de la tautomérie prototropique, par suite des échanges rapides du proton entre les différents sites azotés, les constantes d'équilibre évaluées à partir de [2] ne peuvent être controlées par rmn. Afin de tester la validité de cette méthode nous l'avons appliquée au cas de l'isomérie azido ⇌ tétrazole de quelques hétérocycles pentagonaux, **1** à **5**.

[1]Cette publication est la no XXVI de la série "Systèmes aromatiques à 10 électrons π dérivés de l'aza-3a pentalène"; elle a fait l'objet d'une note préliminaire (1).

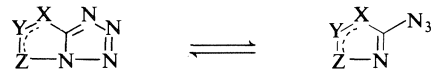
*Mesurés dans le dioxanne.

Pour ce genre d'équilibre nous avons montré (8, 9) qu'il est possible d'évaluer les proportions relatives de chacune des deux formes tautomères, par une simple étude en résonance magnétique nucléaire du proton.



a *b*

1 X = S, Y = CH, Z = CH série du thiazole
2 X = S, Y = CH, Z = C—CH_3 série du thiazole

4 X = O, Y—Z = benzo série du benzoxazole
5 X = CH, Y = C—CH_3, Z = O série de l'isoxazole

Les mesures des moments dipolaires ont été effectuées à deux températures de manière à avoir un ordre de grandeur des paramètres thermodynamiques (ΔH et ΔS) relatifs à cet équilibre. Ces valeurs sont ensuite confontrées avec celles obtenues par une étude de rmn en température variable.

Partie expérimentale

Les moments électriques ont été mesurés dans le dioxanne à la température de 25 et de 45°C. La formule de Debye a été utilisée ainsi que la méthode d'extrapolation d'Halverstadt et Kumler (10) pour le calcul de la polarisation totale du soluté. Les résultats sont donnés dans le tableau 1.

Les spectres de rmn des composés **1**, **2** et **5** ont été enregistrés sur un spectromètre Varian XL-100 à la température de 28°C et ont été analysés au premier ordre; les déplacements chimiques et les constantes de couplage sont donnés avec une précision respective de ±0.01 ppm et de ±0.05 Hz. L'analyse des spectres du tétrazolo[5,1-*b*]benzothiazole **3** et du tétrazolo[5,1-*b*]-benzoxazole **4**, enregistrés respectivement sur des spectromètres Cameca 250 MHz (T = 20°C) et Varian HA-100 (T = 28°C), a été conduite au second ordre à l'aide d'une version modifiée (11) du programme LAOCN3 (12); la déviation moyenne standart est de 0.05 Hz. Les expériences en température variable ont été réalisées sur un spectromètre Perkin-Elmer R32; la précision sur la mesure de la température est estimée à ±1°C. Les constantes d'équilibre ont été déterminées par intégration des raies de résonance relatives à chaque structure et l'erreur sur ces valeurs est inférieure à 10% (9).

Diverses paramétrisations issues du formalisme CNDO ont été appliquées à la détermination théorique des moments dipolaires de ces composés: deux modèles CNDO/2 qui diffèrent entre eux par l'introduction des orbitales *d* dans la base de description de l'atome de soufre, un modèle CNDO/S et, dans le cas des substrats oxygénés (**4** et **5**), un modèle INDO. Les méthodes CNDO/2 (13, 14) et INDO (15) ont été utilisées dans la paramétrisation originale de leurs auteurs. En ce qui concerne la méthode CNDO/S (16), les intégrales bicentriques biélectroniques γ_{AB} ont été évaluées selon le formalisme de Pariser et Parr (17), tandis que les paramètres du soufre (approximation *sp*) sont ceux proposés par Pfister-Gillouzo *et al.* (18).

A l'exception du tétrazolo[5,1-*b*]benzothiazole **3***a* qui a fait l'objet d'une étude cristallographique (19) aucune donnée structurale n'a été publiée sur ces différents composés. Aussi les géométries utilisées dans les calculs théoriques ont été choisies par comparaison avec les données de la littérature concernant des composés similaires (thiazole (20), imidazo[1,2-*b*]thiazole (21), oxadiazole-1,3,4 (22) et −1,2,5 (23)). Nous discuterons ultérieurement du choix de la géométrie du groupement azido, à savoir une structure de type linéaire ou de type angulaire.

Les synthèses des composés **1** à **4** ont été menées selon les méthodes décrites dans la littérature (24–28); l'azido-3 méthyl-5 isoxazole **5** a été obtenu par action de l'azoture de sodium sur le sel de diazonium correspondant. La structure de ce composé a été confirmée par spectrométrie de masse et par résonance magnétique nucléaire du ^{13}C (29).

Résultats et discussion

Equilibre azido/tétrazole: résultats de résonance magnétique nucléaire

Les hétérocycles étudiés dans ce mémoire (composés **1** à **5**) étant peu solubles dans le benzène, nous avons dû utiliser le dioxanne comme solvant pour réaliser les mesures diélectriques. L'étude de rmn a été conduite dans le

§Limite de détection d'une forme tautomère dans les conditions opératoires énoncées ci-dessus.

même solvant pour des raisons de cohérence évidentes.[3]

Dans ce solvant, le comportement des différents produits étudiés est très différent, ainsi que nous le montrent les valeurs expérimentales des constantes d'équilibre déterminées à partir des résultats de résonance magnétique nucléaire du proton (tableaux 2 à 4).

Le thiazolo [2,3-*e*] tétrazole **1** existe principalement sous forme azide, mais l'introduction du groupement méthyle (composé **2**), substituant donneur d'électrons, déplace l'équilibre vers la forme tétrazole (9). En ce qui concerne l'isomérie entre le tétrazolo [5,1-*b*] benzothiazole et l'azido-2 benzothiazole **3** à la température de l'expérience les deux isomères sont en proportion presque équivalente, avec une légère prédominance de la forme tétrazole. Quant aux dérivés oxygénés **4** et **5** ils n'existent que sous la forme azide quel que soit le solvant utilisé.

Par ailleurs tous ces résultats confirment les diverses études qualitatives réalisées par spectroscopie infra-rouge sur l'isomérie azido ⇌ tétrazole dans le cas des hétérocycles à système π excédentaire (24–28, 30).

Angles internucléaires du groupement azide

La détermination théorique des moments

[3]Les spectres de rmn des dérivés oxygénés **4** et **5** ont été enregistrés dans le DMSO-d_6 et le chloroforme deutérié. Dans ces deux solvants seule la forme azide est présente en solution. Nous avons montré (9) que dans le cas des systèmes hétérocycliques pentagonaux le pourcentage de forme tétrazole augmente avec la polarité du solvant. L'absence de cette forme dans le diméthylsulfoxyde est donc une preuve a fortiori de son absence dans le dioxanne.

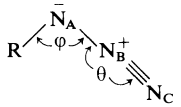
*Méthode CNDO/S.
†L'angle de la direction du moment dipolaire est compté positivement dans le sens trigonométrique direct par rapport à l'axe de *x*; cette direction du moment dipolaire, donnée par les méthodes de type CNDO, est l'inverse de celle de la définition des chimistes.
‡$ET_1 = E_{elec} + \sum_{A<B}\sum Z_A Z_B/R_{AB}$.
§$ET_2 = E_{elec} + \sum_{A<B}\sum Z_A Z_B\gamma_{AB}$.
¶Méthode CNDO/2.

dipolaires de la forme azide nécessite le choix d'une structure pour le groupement azide, c'est-à-dire le choix de l'angle φ, $\angle RN_AN_B$.



Certains auteurs (31, 32) utilisent dans leurs calculs théoriques une structure linéaire (φ = 180°), en désaccord avec les résultats expérimentaux obtenus par spectroscopie de microonde (33) ou par diffraction X (34, 35) qui indiquent un angle φ voisin de 115°.[4]

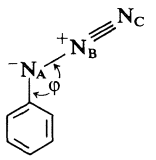
Dans l'intention de choisir la géométrie qui conduit au meilleur accord entre moments dipolaires expérimentaux et valeurs théoriques, nous avons étudié l'évolution du module et de la direction du moment dipolaire d'une molécule modèle, le phénylazide, en fonction de la variation de l'angle $\angle RN_AN_B$.

Le moment dipolaire expérimental du phénylazide est de 1.44 D (36) et sa direction est colinéaire à la liaison C—N_A puisque le *p*-bromo phénylazide possède un moment dipolaire nul (37).

Sur le tableau 5 on voit que les résultats obtenus pour un angle φ de 114° (valeur tirée de la réf. 35) sont en bon accord avec l'expérience dans le cadre de la méthode CNDO/S. Il faut cependant noter qu'une variation angulaire de 10 à 20° (par exemple pour φ = 140°) conduit à des résultats encore acceptables pour la valeur et la direction du moment dipolaire, mais la

[4]Pour l'angle θ, $\angle N_AN_BN_C$, nous avons utilisé la valeur de 172° (35).

TABLEAU 6. Spectres photoélectroniques. Comparaison entre valeurs théoriques (méthode CNDO/S) et résultats expérimentaux



Potentiels d'ionisation théoriques*				Potentiels d'ionisation expérimentaux†
φ = 114°	φ = 140°	φ = 160°	φ = 180°

†Valeurs de la réf. 32.

structure obtenue est énergétiquement moins stable (méthode CNDO/2).

Cette valeur angulaire de 114° conduit également à un excellent accord avec les résultats de spectroscopie photoélectronique (32) comme on peut le voir dans le tableau 6; les valeurs obtenues en CNDO/2 conduisent à une moins bonne concordance.

Ces résultats montrent que le choix d'une structure angulaire pour le groupement azide est parfaitement justifié; aussi tous les calculs théoriques des formes ouvertes ont été effectués en utilisant pour le groupement azido les données de la réf. 35 φ = 114°, θ = 172°.

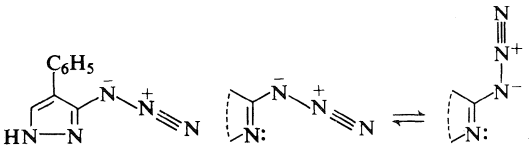
Equilibre azido-tétrazole: résultats obtenus à partir des moments dipolaires

Les constantes d'équilibre, évaluées à partir de [2], sont données dans le tableau 7 ainsi que les valeurs théoriques des moments dipolaires de chaque tautomère. Dans ce même tableau nous avons groupé les valeurs expérimentales (rmn) des constantes d'équilibre.

Les conclusions qu'on peut dégager de la comparaison entre valeurs de la constante d'équilibre déterminée par rmn et à l'aide des moments dipolaires (théoriques et expérimentaux) sont les suivantes: (*i*) l'ensemble des méthodes théoriques utilisées permet de rendre compte de l'évolution de l'équilibre azido ⇌ tétrazole, (*ii*) la méthode CNDO/S conduit aux meilleurs résultats (en ce qui concerne les structures **1**, **2** et **5** l'accord est excellent), (*iii*) ces résultats justifient, *a posteriori*, la validité des calculs des constantes d'équilibre (2–5) par cette méthode qui utilise les moments dipolaires théoriques et expérimentaux.

Conformation des azides

Dans l'article déjà cité (35) la structure radiocristallographique de l'azido-3 phényl-4 pyrazole montre que le groupement azido adopte une conformation de type *Z*, **6**. Les calculs précédents ont été réalisés en supposant une même conformation[5] du groupement azide pour les molécules **1***b*, **2***b*, **3***b*, **4***b* et **5***b*. Il est cependant possible que le fait de se trouver en solution ou le changement de noyau hétérocyclique déplace l'équilibre vers la forme *E*.



6 *Z* *E*

Nous avons choisi d'étudier le cas de l'azido-3 méthyl-5 isoxazole **5** qui existe en solution exclusivement sous la forme azide **5***b* ($K \geq 50$, tableau 7). Les résultats du tableau 8 montrent d'une part que, quel que soit le modèle énergétique et la méthode utilisée, l'isomère *Z* est toujours favorisé d'environ 0.16 eV (15 kJ mol^{-1}); d'autre part si l'on compare la valeur expérimentale (3.42 D, tableau 1) aux valeurs calculées par la méthode CNDO/S (3.31 et 5.25 D, tableau 8), on voit que l'équilibre est

[5]Nous avons supposé que l'angle dièdre formé par les plans de l'hétérocycle et du groupement azido était nul. En fait pour le produit **6** il est de 13.8° (35).

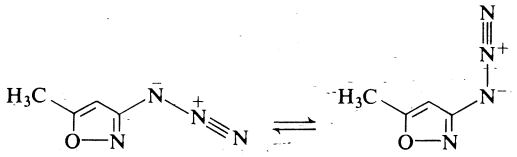
TABLEAU 8. Conformation de l'azido–3 isoxazole



Paramètre		**5***b* (*Z*)	**5***b* (*E*)
Moment dipolaire (D)	CNDO/2	2.96	4.94
	INDO	2.96	4.40
	CNDO/S	3.31	5.25
Energie totale *A** (eV)	CNDO/2	−2623.385	−2623.234
	INDO	−2518.348	−2518.154
Energie totale *B** (eV)	CNDO/2	−2734.527	−2734.397
	INDO	−2629.490	−2629.318

*L'énergie totale est la somme de l'énergie électronique et de l'énergie de répulsion des coeurs; l'énergie de répulsion des coeurs a été évaluée par *A* le modèle des charges ponctuelles, $ER_1 = \sum_{A<B}\sum Z_A Z_B / R_{AB}$ et par *B* le modèle de puits positif, $ER_2 = \sum_{A<B}\sum Z_A Z_B \gamma_{AB}$.

très fortement déplacé vers l'isomère de configuration *Z* (à titre indicatif, l'application de [2] donnerait $K_I = [Z]/[E] \sim 20$, $\Delta G_{25} \sim 8$ kJ mol^{-1}).

Equilibre azido/tétrazole: effets de la température

Les effets de la température sur l'évolution de l'équilibre azido/tétrazole sont bien connus sur le plan qualitatif (déplacement de l'équilibre vers la forme azide par élévation de température (30)), beaucoup moins sur le plan quantitatif. Dans le tableau 9 figurent les différents cas étudiés dans la littérature; à l'exception de l'azido-2 pyridine, décrite par Temple *et al.* (40)

TABLEAU 9. Effet de la température sur l'équilibre azido-tétrazole

Composé	Solvant	No de points	ΔH (kJ mol^{-1})	ΔS (J K^{-1} mol^{-1})	Réf.
Azido-2 diméthyl-4,6 pyrimidine	$CDCl_3$	4	28.2	81.6	39
Azido-2 pyrimidine	DMSO	11	21.6	47.6	40
Azido-2 purine (cyclisation sur N_1)	DMSO	5	19.7	57.3	40
Azido-2 purine (cyclisation sur N_3)	DMSO	5	11.3	46.9	40
Azido-2 chloro-6 pyridine	DMSO	3	14.6	56.9	41
Azido-2 nitro-5 pyridine	DMSO	3	7.1*	22.6	41

Azido-2 thiazole **1***b*	$C_6H_5NO_2$	8	16.0±0.3	57±1	†
Azido-2 méthyl-4 thiazole **2***b*	$C_6H_5NO_2$	8	18.0±0.3	46±1	†
Azido-2 diméthyl-4,5 thiazole **7***b*	$C_6H_5NO_2$	9	20.6±0.7	41±2	†

*La valeur, ΔH = 17.6 kJ mol^{-1}, de la réf. 41 est erronée (T. Sasaki, communication personnelle).
†Ce travail.

les autres composés ont été étudiés avec un nombre insuffisant de mesures.

Nos propres résultats, obtenus comme ceux de la littérature par simple intégration des signaux rmn, figurent également dans le tableau 9 (le domaine de température est compris entre 30 et 120°C.[6] On peut remarquer que l'entropie dépend à la fois du solvant et des substituants. Les spectres des azido-2 thiazoles **1***b*, **2***b* et **7***b*, qui avaient été déjà enregistrés à la température de 30°C dans un grand nombre de solvants (9), ont été enregistrés à la température de 70°C; dans tous les cas, la valeur de l'entropie ΔS est plus grande que zéro, et comprise entre 25 et 75 J K^{-1} mol^{-1}, ce qui interdit définitivement de traiter comme des variables indépendantes le solvant, les substituants et la température.

Nous voyons (tableau 1) que les moments dipolaires des composés **1**, **2** et **3** varient avec la temperature: on a donc un équilibre. La diminution du moment dipolaire de ces dérivés soufrés correspond à un déplacement de l'équilibre vers la forme azide beaucoup moins polaire (tableau 7). Un simple calcul, en utilisant les moments théoriques CNDO/S, conduit aux valeurs suivantes pour l'entropie: **1** ΔS = 30, **2** ΔS = 42, **3** ΔS = 34 J K^{-1} mol^{-1}, valeurs raisonnables, qui montrent une fois de plus la fiabilité de la méthode.

Pour les dérivés oxygénés (**4** et **5**) le moment ne varie pas avec la température, ce qui est en faveur de l'existence d'une seule forme. A partir des calculs théoriques on montre que la forme azide prédomine, ces résultats confirment, en les précisant, les pourcentages évalués en résonance magnétique nucléaire.

[6]A des températures plus élevées les azides se décomposent, parfois d'une façon très violente.

MICHAEL FALK and OSVALD KNOP. Can. J. Chem. **55**, 1736 (1977).

Infrared spectra of polycrystalline $K_2HgCl_4.H_2O$ at different degrees of deuteration were recorded, in the 4000–250 cm^{-1} region, at temperatures between liquid-nitrogen and 130°C. The spectra confirm the existence of a single type of water molecule, engaged in two equivalent hydrogen bonds. The value of 2548 cm^{-1} for the isolated O—D stretching frequency leads to an estimate of 3.25(3) Å for the O...Cl hydrogen-bond distance, in excellent agreement with the results of X-ray and neutron diffraction. Dynamic coupling is appreciable for stretch, bend, and librational fundamentals but is weaker than in $CuCl_2.2H_2O$ or $K_2CuCl_4.2H_2O$, in which the water molecules in the crystal are more tightly bonded.

A number of corrected values are reported of isolated O—D stretching frequencies in hydrates studied previously.

MICHAEL FALK et OSVALD KNOP. Can. J. Chem. **55**, 1736 (1977).

On a enregistré les spectres infrarouges du $K_2HgCl_4.H_2O$ polycristallin à différent degré de deutération dans la région de 4000–250 cm^{-1} et à des températures allant de celle de l'azote liquide jusqu'à 130°C. Les spectres confirment l'existence d'un seul type de molécule d'eau qui est impliqué dans deux ponts hydrogène équivalents. La valeur de 2548 cm^{-1} pour la fréquence de valence O—D isolée conduit à un estimé de 3.25(3) Å pour la distance du pont hydrogène entre O...Cl et ceci est en excellent accord avec les résultats de rayons-X et de diffraction neutronique. Le couplage dynamique est assez important pour les vibrations de valence, de déformation angulaire et de libration mais est plus faible que ceux observés dans le $CuCl_2.2H_2O$ ou le $K_2CuCl_4.2H_2O$ dans lesquels les molécules d'eau dans le cristal sont liées d'une façon beaucoup plus intime.

On rapporte un certain nombre de valeurs corrigées pour des fréquences de vibration de valence O—D isolées dans des hydrates qui avaient été étudiés antérieurement.

[Traduit par le journal]

In certain classes of inorganic salt hydrates water molecules link the metal atoms with the anions to form flat infinite chains. Such geometry is particularly favourable for a study of the water molecule in crystals by ir or Raman spectroscopy. Fifer and Schiffer (1) made use of the advantages offered by the isotopic dilution technique in their ir investigation of H_2O in $CuCl_2.2H_2O$, and a similar investigation, in the series $M_2CuCl_4.2H_2O$ (M = K, Rb, NH_4), was carried out in these laboratories (2, 3). In the present paper we describe the ir spectrum of the water molecule in another hydrate containing such chains, $K_2HgCl_4.H_2O$, and compare the results with those obtained for the other compounds.

In the metal–water–anion chains occurring in $MX_2.2H_2O$ and $M_2CuCl_4.2H_2O$ (*cf.* ref. 2) the water molecules are coordinated trigonally, while in $K_2HgCl_4.H_2O$ they are coordinated tetrahedrally (4–7) (Fig. 1). More precisely, in the Hg compound all water molecules are crystallographically equivalent and situated on twofold axes running parallel to the *c*-axis; each molecule is coordinated approximately tetrahedrally by two K and two Cl atoms. There are two types of nearest-neighbour H_2O–H_2O pairs along the chain, (*a*) those separated by the K atoms, with inter-oxygen distances of 4.1 Å, and (*b*) those separated by the Cl atoms, with inter-oxygen distances of 4.8 Å (Fig. 1). The O...O distances for water molecules in different chains are considerably larger, the shortest such distance being 6.9 Å. By contrast, in the other type of chain, one M atom performs the function of two K atoms in $K_2HgCl_4.H_2O$. The O...Cl hydrogen-

[1]NRCC No. 15821.

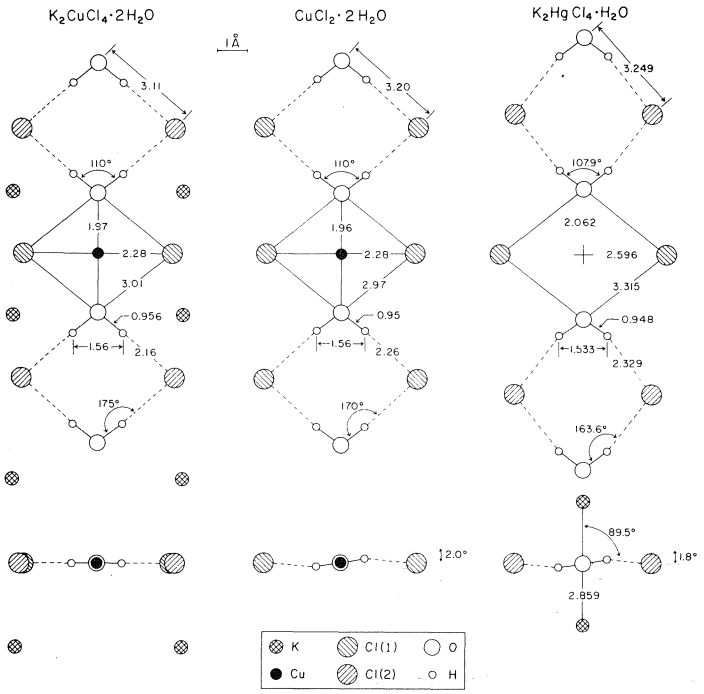

FIG. 1. Plans and elevations of the flat metal–water–chlorine chains in $K_2CuCl_4.2H_2O$ and $CuCl_2.2H_2O$ (after ref. 2) and the analogous chain in $K_2HgCl_4.H_2O$ (after ref. 7). One and a half periods are shown; the interatomic distances are in Å. The water molecule is coordinated trigonally in the Cu compounds but tetrahedrally (∠KOK, 87.7°) in $K_2HgCl_4.H_2O$. The oxygen atoms in H_2O–H_2O pairs of type *a* are separated by a Cu atom in the plane of the chain (in the Cu compounds) or by two K atoms outside that plane (in the Hg compound; the K atoms would project into a position indicated by a cross in the elevation). No metal atoms separate the two oxygens in H_2O–H_2O pairs of type *b*. The plans show the dihedral angles HOH/ClOCl and HOH/KOK.

bond contact in the Hg compound is 3.249(3) Å (7) and thus significantly larger than the corresponding O...Cl distance in $K_2CuCl_4.2H_2O$, 3.11 Å, and somewhat larger than in $CuCl_2.2H_2O$, 3.20 Å, hence hydrogen bonding in $K_2HgCl_4.H_2O$ is expected to be weaker than in either Cu compound. The difference in the hydrogen-bonding strength, in turn, would affect the magnitude of the dynamic coupling of vibrations of water molecules within the chains. Such coupling is appreciable, on evidence from the ir spectra, in the two Cu compounds (2) but not detectable in hydrates in which the water molecules are too far apart to share any nearest-neighbour atoms, *e.g.* $K_2SnCl_4.H_2O$ (8) or $K_2FeCl_5.H_2O$ (9).

Only incomplete descriptions of the vibrational spectrum of $K_2HgCl_4.H_2O$ are found in the literature. Raman lines at 1608, 3411, 3432, and 3475 cm^{-1} have been reported by Weil (10) and fifteen lines, at 415 cm^{-1} and below, by Poulet and Mathieu (11). Infrared bands at 1602 and 3390 cm^{-1} have been reported by by Chihara and Seki (12) and by Glemser and Hartert (13) respectively, and recently Barr and Goldstein (14) presented the Raman and ir spectra below about 350 cm^{-1} of the undeuterated and fully-deuterated compounds, incidental to their study of NH_4HgCl_3. Several studies by nmr also exist (15–19); the angle of inclination of the H–H vector to the crystallographic *b*-axis (*i.e.* of the plane of the water molecule to the 010 plane) obtained from the nmr experiments, 21.4°, is in reasonable agreement with the neutron diffraction result (7), 20.57°, and also with the angle deduced from the Raman spectra (10), 19°.

In addition to describing the results of our ir study of $K_2HgCl_4.H_2O$, we take this opportunity to report the newly re-measured O—D

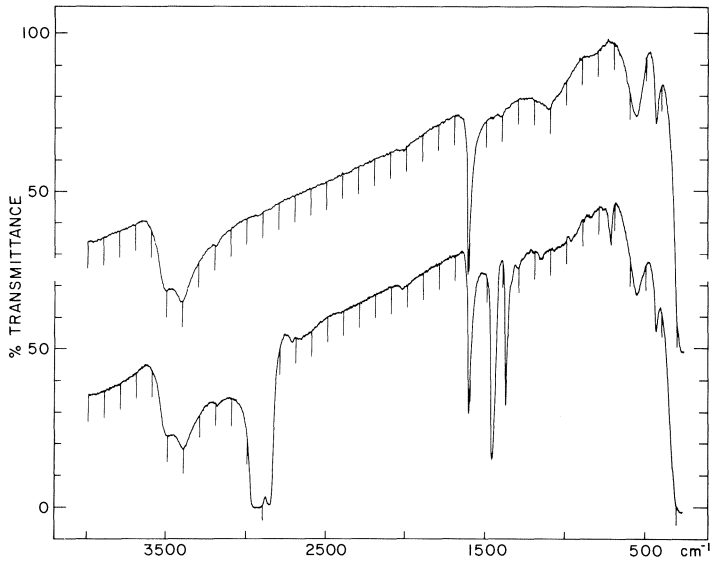

FIG. 2. Survey spectrum of undeuterated $K_2HgCl_4.H_2O$ at room temperature. (*Bottom*) Nujol mull. (*Top*) Pressed pellet of $K_2HgCl_4.H_2O$ in KCl.

stretching frequencies of several hydrates whose spectra were discussed in earlier papers of this series.

Experimental

Crystals of $K_2HgCl_4.H_2O$ were grown by slow evaporation at room temperature of a solution of 10 g KCl and 9 g $HgCl_2$ in 40 ml of a H_2O–D_2O mixture of appropriate composition. The clear colourless crystals, which had formed within a few days, were authenticated by X-ray powder diffraction. The ir spectra of the polycrystalline material dispersed in Nujol and in KCl pellets were similar (Fig. 2), indicating that the structure and composition of the compound were not modified by grinding and pressing with KCl.

In preparing samples of high D content, dry N_2 was bubbled through the solution to exclude atmospheric moisture. As a result of the accelerated evaporation crystals appeared much more rapidly. The low-temperature spectrum of the polycrystalline material obtained in this way showed additional small bands at 3599, 3564, and 3538 cm^{-1} in the O—H and at 2675, 2633, and 2627 cm^{-1} in the O—D stretching region; these small bands were barely detectable in the room-temperature spectra. It seems likely that the additional bands are due to traces of one or both of the two hydrates $KHgCl_3.H_2O$ and $KHg_2Cl_5.2H_2O$ reported by Foot and Levy (20), though we have not been able to show this conclusively. Samples obtained by slow evaporation were usually free of these admixtures.

Pressing pellets of $HgCl_2$ with excess KCl containing a trace of moisture produced H_2O spectra similar to those of $K_2HgCl_4.H_2O$ dispersed in KCl pellets but with additional bands, again presumed to be due to small amounts of the above two compounds. Pressed pellets of $K_2HgCl_4.H_2O$ in KBr gave an entirely different spectrum, similar to that obtained from pellets of $HgBr_2$ in KBr and in agreement with the frequencies reported for $KHgBr_3.H_2O$ (21).

The spectra were recorded on a Perkin-Elmer model 180 spectrophotometer using a model VLT-2 variable-temperature cell holder (Research and Industrial Instruments Company, London).

Results and Discussion

The frequencies of the major bands of H_2O, HDO, and D_2O are listed in Table 1. The spectrum gradually sharpened upon cooling the specimen to liquid-nitrogen temperature. The low-temperature frequencies are more accurate and will be used throughout in the following discussion, except where room-temperature values are required for comparison with the Raman data of refs. 10 and 11.

Bending Vibrations

At low isotopic concentrations the bending fundamentals of H_2O and D_2O are singlets, at 1612 and 1188 cm^{-1} respectively (Fig. 3). This confirms the existence of only one crystallographically distinct type of water molecule. At somewhat higher D contents a feature appears on the low-frequency side of the singlet. For D_2O it occurs at 1185 cm^{-1} and is clearly resolved. For H_2O it occurs at 1610 cm^{-1} and is not resolved from the 1612 cm^{-1} peak, but its frequency is inferred from the overall shift to low frequency with increasing H content. This feature is assigned to the out-of-phase coupled vibrations of certain H_2O–H_2O or D_2O–D_2O

[b] From refs. 10 and 11.
[c] B_{2u}, B_{3u}.
[d] Symmetry species assigned from vibrational analysis.
[e] Inactive component; frequency estimated on the assumption that the mean frequency of the factor-group components equals the isotopically isolated frequency (*cf.* refs. 1 and 2). (In an isotopically pure crystal the bending fundamental should be split into one ir-active component B_{1u}, two Raman-active components A_g and B_{1g}, and one inactive component A_u (Fig. 4). For H_2O bending the Raman-active frequencies are known from ref. 10 and the inactive frequency may be estimated after the manner of refs. 1 and 2 by assuming that the average of the frequencies of the four coupled components equals the frequency of the isolated fundamental. However, this calculated frequency, 1616(6) cm^{-1}, is of low accuracy because of combination of experimental errors of the Raman and ir measurements.)
[f] Estimated frequency, see text.
[g] Largely H in-plane motion (*cf.* Fig. 6 of ref. 2).
[h] Largely D in-plane motion.

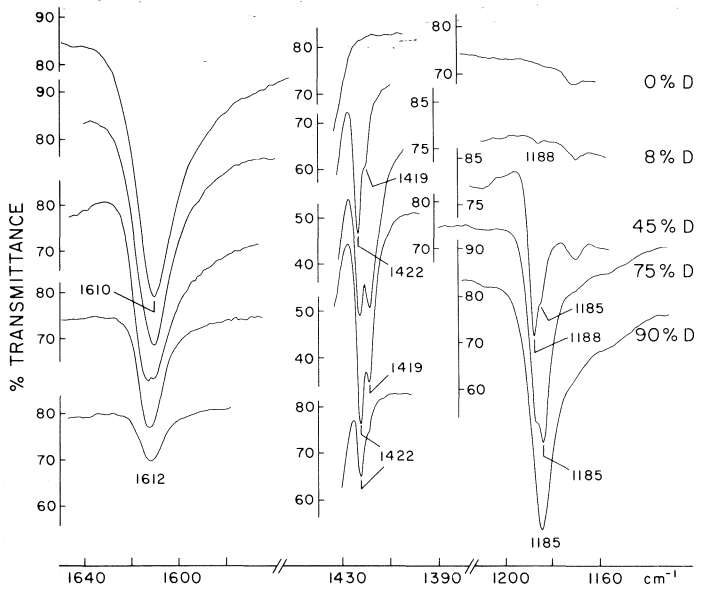

FIG. 3. Spectra of $K_2HgCl_4.H_2O$ (Nujol mulls) at −150°C in the region of the bending vibrations of H_2O, HDO, and D_2O at different D contents.

pairs. Only one feature due to coupling is detected, and the relative intensities of the coupled and uncoupled components are consistent with the coupling being appreciable for only one type of water pair. We identify the pair as one of the nearest-neighbour pairs within the chains, *i.e.* either *a* or *b* (Fig. 1). Pairs *a* and *b* are both centrosymmetric, so in either case the in-phase vibration would be ir inactive (*cf.* discussion in ref. 2).

For the isotopically pure crystals, one of the factor-group components of the bending vibration, B_{1u}, should be ir active (Fig. 4). For both H_2O and D_2O it coincides with the coupled vibration of H_2O or D_2O pairs observed at lower isotopic contents. This confirms that in this hydrate, as in $K_2CuCl_4.2H_2O$ (2) and $CuCl_2.2H_2O$ (1), the coupling of bending vibrations originates almost entirely in *one* type of water pairs within the chain. However, the magnitude of this coupling is considerably smaller in $K_2HgCl_4.H_2O$.

The bending fundamental of HDO at low isotopic concentrations is also a singlet, at 1422 cm^{-1}, which confirms the equivalence of the two hydrogens, consistent with the C_2 site symmetry of the water molecule required by the structure. At higher concentrations of HDO an additional feature, sharp and well-resolved, appears at 1419 cm^{-1}.

Since pairs of type *a* and *b* may exist, in the case of HDO, in either a centrosymmetric or a non-centrosymmetric configuration, the situation is more complex than for H_2O or D_2O pairs. The simplest interpretation of the fact that vibrational coupling results in only one sharp feature at 1419 cm^{-1} at higher HDO contents is

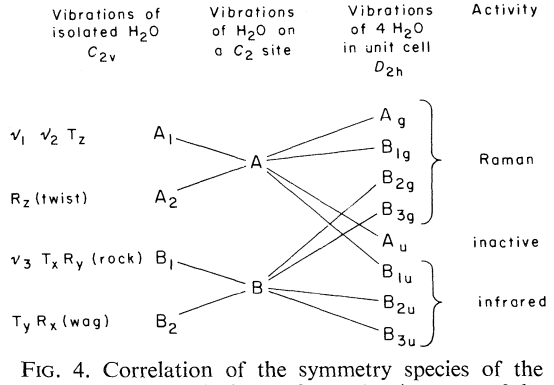

FIG. 4. Correlation of the symmetry species of the molecular (C_{2v}), site (C_2), and factor (D_{2h}) groups of the H_2O fundamentals in $K_2HgCl_4.H_2O$.

to assume that (*i*) the coupling of bending vibrations for HDO, as for H_2O and D_2O, is appreciable for only one type of water pair, *i.e.* either *a* or *b* of Fig. 1; (*ii*) the 1419 cm^{-1} band is due to the out-of-phase coupled vibrations of centrosymmetric and non-centrosymmetric pairs in near coincidence; and (*iii*) the in-phase coupled vibration of the non-centrosymmetric pairs is not observable owing to low intensity. The relative intensities of the 1422 and 1419 cm^{-1} bands at different HDO contents are fully consistent with this interpretation.

It may seem surprising that the strength of dynamic coupling can differ by what appears to be an order of magnitude for pairs of water molecules which do not differ appreciably in their inter-oxygen distances, 4.1 and 4.8 Å. However, the dominant term responsible for the coupling must be of dipole–dipole nature, and so orientation may play a decisive role.

Stretching Vibrations

The vibrationally isolated O—H and O—D fundamentals of isotopically dilute HDO gave rise to sharp singlets at 3445 and 2544 cm^{-1} respectively (Fig. 5). The singlets confirm the equivalence of the two hydrogens, consistent with the C_2 site symmetry of the water molecule.

At intermediate isotopic concentrations the spectrum in the O—D stretching region exhibits several sets of weak bands, of which the most visible are a pair at 2520 and 2565 cm^{-1}. They are assigned to coupled vibrations of HDO–HDO pairs. Unlike for the bending vibrations, the coupling of stretching vibrations appears to be appreciable for more than one type of pair. The corresponding O—H coupled modes of HDO–HDO pairs would be expected to fall near the H_2O stretching frequencies from which they are not resolved.

For undeuterated, or fully deuterated, samples the symmetric and antisymmetric stretching frequencies, ν_1 and ν_3, can be assigned unambiguously by reference to the rules of factor-group splitting (Fig. 4): the Raman bands at 3411 and 3432 cm^{-1} reported in ref. 10 are of symmetry species B_{1g} and A_g and hence must belong to the ν_1 fundamental, while the band at 3475 cm^{-1}, of symmetry species B_{3g}, must belong to the ν_3 fundamental. This establishes that $\nu_3 > \nu_1$, which is the usual order, and leads to the other assignments in the O—H and O—D stretching regions in Table 1. The overtone of

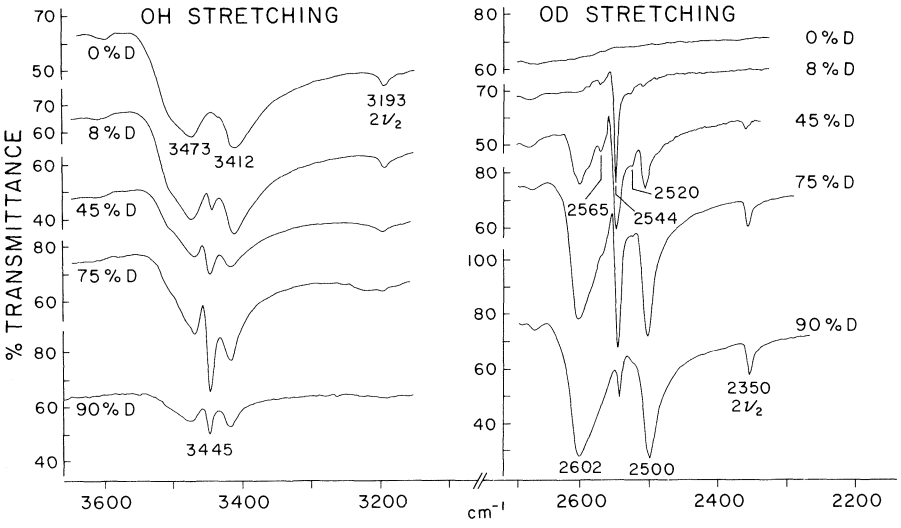

FIG. 5. Spectra of $K_2HgCl_4.H_2O$ (Nujol mulls) at −150°C in the O—H and O—D stretching regions at different D contents.

the bending vibration, $2\nu_2$, at 3193 cm^{-1} for H_2O and 2350 cm^{-1} for D_2O, is clearly enhanced by Fermi resonance with the ν_1 fundamental. The resonance is relatively weak, corresponding to case *a* in Fig. 1 of ref. 22.

We note that dynamic coupling of vibrations is also appreciable for the stretching fundamentals, as witnessed by the frequency differences between the Raman and the ir factor-group components of the ν_1 and ν_3 fundamentals.

Rotational and Translational Vibrations

In the ir spectrum of $K_2HgCl_4.H_2O$ the rocking and wagging librations should yield two, and the twisting libration one, components for a total of five bands (Fig. 6). Only two major features in the H_2O and D_2O spectrum may be assigned to librations. They occur at 571 and 451 cm^{-1} for H_2O and at 420 and 333 cm^{-1} for D_2O, which yields an H_2O/D_2O frequency ratio of about 1.36, characteristic of purely librational motions.[2] The two librations must be the rock and the wag: the twisting fundamental, which is ir inactive under the full C_{2v} symmetry of the undistorted water molecule, is rarely observed in the ir spectra of crystalline hydrates, and the factor-group splitting expected for the librations in $K_2HgCl_4.H_2O$ would be of the order of 1 to 10 cm^{-1}, as for the bending and stretching fundamentals, and certainly not of the order of 100 cm^{-1}.

In crystalline hydrates it is often difficult to decide which of the two is wag and which is rock, but in our case we are helped by the librational frequencies of HDO, 602, 431, and 373 cm^{-1}. Expected qualitative relations between the frequencies of H_2O, D_2O and those of HDO (Fig. 6 of ref. 2) lead us to assign the 571 cm^{-1} band to the wagging libration and the 451 cm^{-1} band, to the rocking libration. The usual sequence of frequencies is rock > wag (23, 24), so the present sequence constitutes another case of reversal (9, 25). The intensity sequence, however, is the usual one, wag > rock ≫ twist (9). The frequency of the twisting libration may be deduced to be approximately 630 cm^{-1} for H_2O and 440 cm^{-1} for D_2O, from a consideration of the scheme presented in Fig. 6 of ref. 2. This scheme places the frequency of the H (or D) out-of-plane libration about midway between those of the wagging and twisting librations of H_2O (or D_2O). Shoulders observed near 630 and 440 cm^{-1} may be due to the twisting mode.

The twisting motion in $K_2HgCl_4.H_2O$ thus appears to correspond to the libration of highest frequency. This is in contrast to $K_2CuCl_4.2H_2O$, in which it is the libration of lowest frequency. The difference may be explained by the forces opposing the twisting motion in a trigonally coordinated water molecule which in the Cu

[2]The intense band at 305 cm^{-1} does not shift upon deuteration, hence it does not belong to the H_2O spectrum of the hydrate.

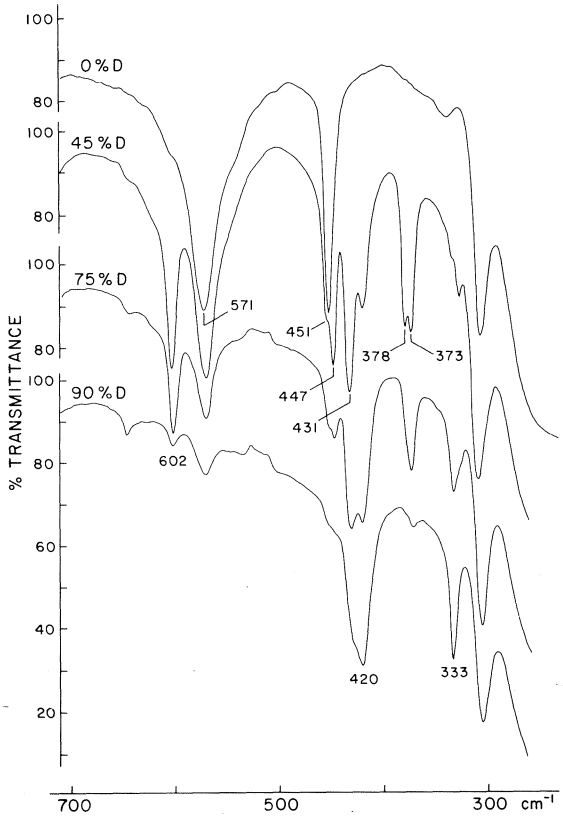

FIG. 6. Spectra of $K_2HgCl_4.H_2O$ (Nujol mulls) at −150°C in the region of the librations of the water molecules, at different D contents.

compound arise only from the hydrogen bonds. In a tetrahedrally coordinated water molecule in the Hg compound this motion is also opposed by the two K–OH_2 contacts. Further work may show whether this is a general rule for other tetrahedrally and trigonally coordinated water molecules in crystals.

Dynamic coupling of vibrations is also appreciable for the librational fundamentals. This is manifested by the difference between the Raman and ir frequencies of the wagging and rocking fundamentals (Table 1), and in the resolution, in the spectra of Fig. 6, of a 'coupled' and an 'isolated' frequency for the H_2O rocking mode at 451/447 cm^{-1}, the HDO mode at 378/373 cm^{-1}, and the D_2O mode at 333/327 cm^{-1}.

In spectra of thicker films broad bands are observed, centred at 1080 and 840 cm^{-1}. They appear to be the first overtones of the wagging and rocking librations respectively. The breadth and the complex shape of these bands show that they are the superpositions of many of the allowed overtones and binary combinations of the four factor-group components of each of these librations (*cf.* ref. 2).

The three translational fundamentals are expected to lie in the 100–300 cm^{-1} region and to give rise to five ir-active and six Raman-active factor-group components (Fig. 4). One of the ir components (at 202 cm^{-1} for H_2O and at 196 cm^{-1} for D_2O) and one of the Raman components (at 157 cm^{-1} for H_2O and at 153 cm^{-1} for D_2O) have been observed in the low-frequency spectra of ref. 14.

The O...Cl Distance

The value of the isolated O—D stretching frequency at room temperature is 2548 cm^{-1}. Using the correlation (26) between the O...X hydrogen-bond distance R and ν(OD) we obtain, for X = Cl, $R = 3.397 + 0.000840[\nu(OD) - 2727] \sim 3.25(3)$ Å, in excellent agreement with the value of 3.249(3) Å resulting from neutron-diffraction work (7). Glemser and Hartert (13) used their 'raw' value of O—H stretching frequency of H_2O, 3390 cm^{-1} (presumably ν_3), to derive, from a similar correlation, R = 3.22 Å. The use of *isolated* O—H or O—D stretching frequency leads to more accurate frequency–distance correlations.

Phase Transition in $K_2HgCl_4.H_2O$

The occurrence of a phase transition at a temperature reported to be as low as 82°C (18) and as high as 114°C (12), presumably depending on the rate of heating, has been described. The transition appears to be accompanied by marked changes in the dielectric properties (18) and by a large enthalpy change (12) but not by dehydration (12) or a volume discontinuity (18). The nature of the transition is not completely understood.

We observed no evidence of a spectral discontinuity in the above temperature region in spectra obtained from $K_2HgCl_4.H_2O$ dispersed in KCl pellets and kept at a predetermined temperature.

Structural Conclusions

1. The existence of a single type of H_2O molecule on a site of symmetry C_2, as determined by X-ray and neutron diffraction, is confirmed.

2. The spectrum of the water molecule in $K_2HgCl_4.H_2O$ grossly contrasts with that in $K_2SnCl_4.H_2O$, which was once incorrectly

TABLE 2. Corrected values of the O—D stretching frequencies (cm^{-1}) of isotopically isolated HDO in hydrates described in refs. 2, 8, 9, and 27

[a]r.t., room temperature; l.n., liquid-nitrogen temperature.

thought to be isostructural with the Hg compound (ref. 8 and other references therein).

3. The ν(OD) value of 2548 cm^{-1} for the isolated O—D stretch at room temperature leads to an estimate of 3.25(3) Å for the O...Cl distance involving hydrogen, in excellent agreement with refs. 6 and 7.

4. Dynamic coupling is appreciable for stretch, bend, and librational fundamentals. However, it is smaller in magnitude than in $CuCl_2.2H_2O$ or $K_2CuCl_4.2H_2O$. This might be expected, for the

$$O—\overset{K}{\underset{K}{}}—O$$

interaction is much weaker than the O—Cu—O interaction in the two Cu compounds, and the hydrogen bonding also is weaker.

5. The phase transition reported to occur in the 82–114°C range either does not take place in KCl matrix, and hence is associated with loss of water, or it leads to minimal structural changes in and around the water molecule, such as would not appreciably affect its ir spectrum.

Correction of Earlier Data

We have recently re-checked, using our newly acquired Perkin-Elmer model 180 spectrophotometer, the frequencies of most absorption bands reported in our earlier papers in this series (2, 8, 9, 27). It turned out that for sharp bands the new values generally agree within ± 1 cm^{-1} with the previous values obtained with a Perkin-Elmer model 521 spectrophotometer. However, one important exception was found: the previous values show a systematic error of about $+5$ cm^{-1} in the O—D stretching region, around 2500 cm^{-1}. The error was caused by a local anomaly in the frequency calibration of our model 521 instrument. Because of the importance of having accurate ν(OD) data for frequency–distance correlation purposes, we have gathered in Table 2 the previous and the new, corrected values.

Acknowledgments

We should like to thank Miss Gwen H. Thomas and Mr. P. F. Seto for assistance with the experimental work and Drs. K. Aurivillius and C. Stålhandske for providing us with a preprint of ref. 7. Extremal arrangements of points and unit charges on a sphere: equilibrium configurations revisited

THEODOR WILLIAM MELNYK, OSVALD KNOP,[1] AND WILLIAM ROBERT SMITH

Departments of Chemistry and Mathematics, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 15, 1976

THEODOR WILLIAM MELNYK, OSVALD KNOP, and WILLIAM ROBERT SMITH. Can. J. Chem. **55**, 1745 (1977).

We review the formulation and solutions of a number of extremal problems associated with points and unit charges on the surface of a sphere in E^3. For one of these problems, namely

$$U(m,n) = \tfrac{1}{2}k \sum_{p \neq q}^{m} d_{pq}^{-n} = \text{minimum}$$

where d_{pq} is the Euclidean distance between points P and Q and m is the number of points, we discuss the results for $m \leq 16$ and $1 \leq n < \infty$. For the cases $m = 5, 11, 13$–16 we find hitherto undiscovered solutions. Our solutions for $m = 5$ and 11 correct earlier results in the literature. We also sharpen the existing literature results for $m = 7$ and 10.

THEODOR WILLIAM MELNYK, OSVALD KNOP et WILLIAM ROBERT SMITH. Can. J. Chem. **55**, 1745 (1977).

On passe en revue la formulation et les solutions d'un certain nombre de problèmes extrêmes associés avec les charges ponctuelles et unitaires sur la surface d'une sphère en E^3. Pour un de ces problèmes, à savoir

$$U(m,n) = \tfrac{1}{2}k \sum_{p \neq q}^{m} d_{pq}^{-n} = \text{minimum}$$

où d_{pq} est la distance euclidienne entre les points P et Q et m est le nombre de points, on discute des résultats pour $m \leq 16$ et $1 \leq n < \infty$. Pour les cas $m = 5, 11, 13$–16, on trouve des solutions qui n'avaient pas été découvertes jusqu'à maintenant. Nos solutions pour $m = 5$ et 11 corrigent des résultats antérieurs parus dans la littérature. On précise aussi des résultats existants dans la littérature pour $m = 7$ et 10.

[Traduit par le journal]

The problem, and its equivalents and cognates, of how to arrange m points (or equivalent particles or discrete unit charges) on the surface of a three-dimensional sphere to satisfy a prescribed extremal condition, is of importance in stereochemistry (VSEPR theory of directed valency, *cf.* ref. 1) as well as in botany, virology, information theory, and elsewhere (2, 3). However, it is often not appreciated that an 'equilibrium' configuration of the points may in some cases correspond to *several*, quite different, extremal requirements which in general lead to a variety of solutions (*cf.* ref. 4). Furthermore, the extremal requirements are sometimes inadequately specified and their description is confused; it is in fact not entirely clear which particular set of extremal conditions is the most appropriate to use as a basis of stereochemical theory. In view of this and of the fact that the mathematical literature on extremal configurations is quite extensive and at times not easily accessible, we set out, in the following, the various equivalent formulations of the extremal conditions of interest and present as concisely as possible the results, exact or conjectured, that have been reported to date. Against this background we then describe the results of our own investigations of problem *B* below, the extremal problem that has received most attention by chemists.

We have investigated problem *B* for 5 to 16 points by a numerical technique. Rigorous methods (*vide infra*; refs. 2, 3, 6–8) have so far produced solutions for up to 12 points (in an isolated case, for 24 points), and then only for the so-called 'hard-spheres' case, which is of limited importance in stereochemistry. In yielding solutions for 11 and 24 points the geometric method of proof may be approaching its limit of usefulness. On the other hand, the computational time and effort required to deal with 16 points, and the increasing ease with which competing configura-

[1]To whom correspondence should be addressed.

tions can be converted into one another, give us reason to believe that further numerical work may be unprofitable.

We shall not concern ourselves with the importance, relative to other factors, of the stated extremal conditions in determining actual stereochemical configurations.[2]

In this paper, d_{pq} denotes the Euclidean distance between points P and Q on the unit sphere, s_{pq} denotes the corresponding spherical distance (in radians) measured along a great-circle segment connecting P and Q; m is a positive integer and n is a non-negative real number.

Distinct Extremal Problems and Their Formulations

A. Leech (9) posed the following problem: m particles are constrained to the surface of a sphere. Between every pair of them there acts a force which depends only on the distance between them; the law of force is the same for all particles. Which configurations are *balanced* with respect to tangential forces for *any* force law?

B. Which configurations satisfy the condition

$$[1] \quad U(m,n) = \tfrac{1}{2}k \sum_{p \neq q}^{m} {d_{pq}}^{-n} = \text{minimum}$$

If k is dimensionless, the dimension of U is (length)$^{-n}$ and the extremal condition is purely geometrical, involving distances between pairs of points. If the dimension of k is (length)^n, U is dimensionless. If the dimension of k is (energy) × (length)^n, U is the potential energy of a system of m discrete unit charges of equal sign confined to the surface of a sphere. For Coulombic repulsion, $n = 1$.

When $n \to \infty$, U is increasingly dominated by the term(s) corresponding to the smallest d_{pq} and minimizing U becomes equivalent to maximizing the smallest d_{pq}. In this limit the problem is then equivalent to the problem of *densest packing* of equal spheres (or equal circles or spherical caps) on a sphere. This is sometimes referred to as the *hard-spheres* case, while finite values of n pertain to the *soft-spheres* case.

Various equivalent formulations of the *densest-packing* problem are found in the literature (2–4, 6–8): (*1*) Which configuration of m points on a sphere maximizes the minimum distance d_{pq} or s_{pq} between any two of the points? This is the *Tammes problem* of pollen-grain orifices (*cf.* ref. 2, also for results in spaces other than E^3). (*2*) m points are placed on a sphere of radius R_m in such a way that no d_{pq} is less than unity. Find the minimum value of R_m. (*3*) The packing density ρ_m is the ratio of the total area of m equal non-overlapping circles (or spherical caps) on the surface of a sphere to the surface area of the sphere. Find the arrangement(s) of the circles that gives (give) the maximum value of ρ_m. (*4*) Find the largest angular diameter of m equal circles (or spherical caps) which can be packed on the surface of a sphere without overlapping. (*5*) How many cones of given angle can be packed around a point? (*6*) A planet is ruled by m mutually inimical dictators. How are they to distribute their residences so as to maximize the minimum distance between any two of them? (*7*) How can m fuel depots be arranged on a planet so that an accidental explosion of one of them will least endanger the rest?

C. Which configurations satisfy the condition

$$[2] \quad V(m,n) = \tfrac{1}{2}k \sum_{p \neq q}^{m} {d_{pq}}^{n} = \text{maximum}$$

D. Replace in problem *C* the Euclidean distances d_{pq} by the shortest *spherical* distances s_{pq}.

E. The problem of *thinnest covering* of a sphere by m interpenetrating equal spheres (or equal circles or spherical caps):

(*1*) Find the (complete) covering of a sphere by m congruent circles (or spherical caps) having minimum density ρ_m' (analogous to ρ_m in problem *B*(*3*)). (*2*) How should m fuel depots be arranged on a planet so as to minimize the greatest distance between a point of the planet and the nearest depot (*cf.* ref. 6)? (*3*) How should the residences of m allied dictators governing on a planet be placed so as to control the planet as well as possible (*cf.* ref. 6)?

F. How to arrange m interpenetrating equal spheres (or equal circles or spherical caps) of spherical radius s, $0 < s \leq \pi/2$, on a sphere so as to cover the greatest possible area? This case is intermediate between the densest packing and the thinnest covering.

G. How to distribute m points on a sphere so as to maximize the volume of their convex hull? More precisely, (surface of hull)^3/(volume of hull)^2 = minimum.

H. Still other extremal problems have been proposed by Whyte (4), *e.g.*, maximizing the

[2] For a discussion of these other factors see, for example, refs. 1 and 5, and the references quoted therein.

product of distances of all pairs, or finding arrangements which possess extremal properties of any kind, or finding extremal problems which lead to identical solutions.

Known or Conjectured Solutions to Problems *A* to *H* Reported to Date

In the following text and in Tables 2–7, configurations are described either by their proper names (when the configuration corresponds to a familiar convex polyhedron inscribable in a sphere, or when it is obtained by a central projection of the vertices of such a polyhedron onto the sphere)[3] or by symbols indicating the point-group symmetry of the configuration and the way in which the m points are distributed among circles formed by intersections of the sphere with consecutive planes parallel to the equatorial plane. The north–south axis coincides with the principal axis of rotation when the configuration has rotational symmetry. Thus the regular icosahedron, $m = 12$, may be described as $I_h(1:5:5:1)$, with the two single points in the poles and the vertices of the two staggered pentagons in planes parallel to the equatorial plane. Similarly, $C_{4v}(1:4:4:4)$ represents an arrangement of symmetry C_{4v} with one point in a pole and three sets of four coplanar points symmetric about the fourfold axis passing through the pole and the centre of the sphere. This nomenclature is not unique but is in common use and convenient; additional information is provided when ambiguity arises. To save space, the symbols are contracted: $I_h(1:5:5:1)$ becomes $I_h(1^15^21^1)$ and $C_{4v}(1:4:4:4)$ becomes $C_{4v}(1^14^3)$.

The positions of the points in some of the configurations are completely fixed by symmetry. In others, some of the positions vary with n while the point-group symmetry is maintained. The minimum number of n-dependent coordinates (parameters) necessary to describe completely a configuration of a particular point-group symmetry is designated by f. This quantity may be viewed as the *maximum* number of degrees of freedom of the configuration under that symmetry; it is lowered if one or several of the f variable coordinates are *a priori* assigned particular values. Thus removing a vertex of a regular octahedron $O_h(1^14^11^1)(f = 0)$ leaves a square pyramid $C_{4v}(1^14^1)$ ($\equiv$ octahedron $- 1$) in which the relative positions of the five points are completely determined and hence $f = 0$. However, this configuration is only a special case of the square pyramid $C_{4v}(1^14^1)(f = 1)$ inscribed in a sphere and in which the plane of the four points is not fixed relative to the equatorial plane, the geodetic latitude of this plane being the degree of freedom to be specified. Similarly, the removal of a vertex of a regular icosahedron $I_h(1^15^21^1)(f = 0)$ leaves a singly-capped pentagonal antiprism $C_{5v}(1^15^2)(f = 0)$, a special case of the singly-capped pentagonal antiprism $C_{5v}(1^15^2)(f = 2)$ in which the latitudes of the planes containing the two pentagons can assume any admissible values.

A. This problem has been investigated by Leech (9), with the following results. The only solutions are configurations which have rotational symmetry about every diameter through the particles, *i.e.* configurations defined by polyhedra inscribed in the sphere and having all the vertices on axes of rotation. Hence only these possibilities exist: (*a*) Regular polygons with vertices on a great circle. This includes an antipodal pair, $m = 2$. (*b*) Convex Platonic polyhedra $\mathscr{P}\ell(m)$, their duals $\mathscr{D}(m)$, and vertex-figure derivatives $\mathscr{V}(m)$.[4] (*c*) Combinations of configurations of *a* and *b* to give balanced configurations inscribed in the sphere. Construction of such configurations amounts to finding balanced sets of particles having balanced subsets which when removed leave balanced sets. At most three sets from *a* and *b* can be combined. For two sets, the possibilities are two coplanar polygons, or any binary combinations of $\mathscr{P}\ell(m)$, $\mathscr{D}(m)$, and $\mathscr{V}(m)$, or a combination of a polygon and an antipodal pair to a regular bipyramid. For three sets, the possibilities are a combination of $\mathscr{P}\ell(m)$ with its dual $\mathscr{D}(m)$ and vertex-figure polyhedron $\mathscr{V}(m)$, or two coplanar polygons and an antipodal pair combined to a regular bipyramid, or three antipodal pairs in the vertices of an octahedron.

The distinct configurations of class *b* and their combinations are listed in Table 1.

B. The configurations shown in Table 2 for $m = 2$, 3, 4, 6, and 12 are the solutions to the

[3] *Capping* adds vertices above faces perpendicular to the principal axis of symmetry of the polyhedron, *e.g.*, as in a bicapped trigonal prism. *Augmenting* adds vertices above faces perpendicular to the equatorial plane (*e.g.*, trigonal prism + 3) or, occasionally, above other faces.

[4] A dual is defined by the face-centres of a polyhedron. A vertex-figure polyhedron is defined by the midpoints of the edges of a polyhedron.

TABLE 2. Configurations corresponding to the densest packing of congruent hard spheres (solutions to problem B for $n \to \infty$)

m	Configuration	Reference
2	Antipodal pair $D_{\infty h}$	
3	Equilateral triangle D_{3h} inscribed in a great circle	2, 14
4	Tetrahedron T_d	2, 14
5	Trigonal bipyramid D_{3h} or square pyramid[a] $C_{4v}(f = 0)$	2, 14
6	Octahedron O_h	2, 14
7	$C_{3v}(1^1 3^2)$, $s_{\min} = \arccos[\cos\frac{4}{9}\pi/(1 - \cos\frac{4}{9}\pi)]$	7
8[b]	Square antiprism[c] D_{4d}, $s_{\min} = \arccos[(\sqrt{8} - 1)/7]$	7
9	$D_{3h}(3^3)$,[d] $s_{\min} = 2\arccos(\sqrt{6}/3)$	7
10[e]	$C_{2v}(2^1 4^1 2^2)^f$ (proved by L. Danzer)	[i]
11	$C_{5v}(1^1 5^2)^g$ (proved by K. Böröczki)	[i]
12	Icosahedron I_h	2, 14
14	*Not* the trisoctahedron or rhombic dodecahedron or tetrahexahedron O_h[h]	6, 9
20	*Not* the Platonic dodecahedron I_h	6
24	Snub cube O	8
30	*Not* the icosidodecahedron I_h	6, 9
32	*Not* the triacontahedron I_h	6, 9

[a]Octahedron − 1. This is the only instance known for which the solution is not unique: any arrangement between the limiting configurations D_{3h} and C_{4v} ($f = 0$) is admissible (see text).
[b]The *centrosymmetric* solution is the cube (see footnote *i* below).
[c]The triangular faces are *not* equilateral triangles.
[d]Trigonal prism + 3, or a completely truncated trigonal prism.
[e]The *centrosymmetric* solution is a pentagonal antiprism D_{5d}[i].
[f]$s_{\min} = 2\arccos[1 - (1/4R^2)]^{1/2}$, $16R^6 - 44R^4 + 34R^2 - 7 = 0$ (7).
[g]Icosahedron − 1. This is a rigid configuration.
[h]Böröczki (see footnote *i* below) in 1968 proved that this configuration is the *centrosymmetric* solution for $m = 14$.
[i]L. Fejes Tóth. Personal communication to O. Knop.

problem for *any* power law (9) and hence for all values of n. For any other values of m the dependence of the configuration on n must be investigated separately, since the *metric* properties of configurations with $f \neq 0$ change with n or else different ranges of n correspond to different configurations.

The case most extensively studied by rigorous methods is that of the *densest packing*, $n \to \infty$ (2, 10) (Table 2). One might expect, intuitively, that arrangements of the highest symmetry would be the solutions. This is known to be so for $m = 2$ to 6, 9, and 12 but not for $m = 7$, 8, 10, 11, 14, 20, and 24. Furthermore, the conjectured configurations (Table 3) suggest that with increasing m, arrangements of low symmetry are the likely solutions, though in some cases the proposed configurations are not far removed from configurations of the maximum possible symmetry. For $m = 5$, the solution is not unique: any configuration with three of the points on the equatorial circle, with $\pi/2 \leq s_{\min} \leq 2\pi/3$ between pairs, and with the other two points in the poles is equally valid, the limiting

[a]Goldberg considered alternative configurations of *axial* symmetry only, of types (w^t), (1^1w^t), and $(1^1w^t1^1)$, $w = 3$, 4, or 5.
[b]This arrangement is obtained by truncating the 4-valent vertices of the rhombic dodecahedron O_h, skewing the resulting hexagonal faces about the stationary 3-valent vertices, and placing a point inside each of the spherical hexagons. Each of these points can occupy one of two equivalent positions inside the hexagon, hence a number of equivalent configurations is possible. The maximum point-group symmetry attainable is T. The minimum spherical distance $s_{min} \sim 0.5565$.
[c]Truncated icosahedron with points above the centers of the hexagonal faces.
[d]This arrangement is derived from the rhombic triacontahedron I_h in a manner analogous to the $m = 44$ case; the truncation takes place at the 5-valent vertices. A number of configurations again are possible. The maximum symmetry attainable is C_3, $s_{min} \sim 0.3508$.
[e]Obtained by central projection of the vertices, edge-midpoints, and face centers of a rhombic triacontahedron I_h onto the sphere. However, this cannot be the best arrangement (ref. 12, erratum; ref. 2, p. 233).
[f]According to ref. 48 (quoted in ref. 47) this result is not correct.
[g]R. M. Robinson. Personal communication to M. Goldberg (unpublished note).

configurations being the trigonal bipyramid D_{3h} and the square pyramid C_{4v} (≡ octahedron − 1).

In general the total number of contacts the spheres (or circles or spherical caps) make with one another, and the average number of contacts per sphere, are rough indications of the efficiency of the densest packing, a large number of contacts at fixed m corresponding to a greater efficiency. However, this is not always so, as shown by Goldberg (11) for two of his conjectured configurations for $m = 21$.

The packing density ρ_m (*cf.* problem $B(3)$) for $m \geq 3$ can be estimated from the inequalities

$$[3] \quad 1 - (1 - g)^{1/2} \leq 2\rho_m/m \leq 1 - \tfrac{1}{2}\,\mathrm{cosec}\,[(m/m - 2)(\pi/6)]$$

where $1/g = (2\sqrt{3})(m/4\pi) + 3(m/4\pi)^{2/3} + 3(m/4\pi)^{1/3}$ (12), with the concomitant condition (13) that ρ_m is always greater than $\frac{5}{4}(2 - \sqrt{2}) \sim 0.732$ except for $m = 5$, where it is equal to this quantity. For $m \to \infty$ the upper bound of ρ_m tends to $\pi/\sqrt{12} \sim 0.907$ (2, 3, 14). The estimate of the upper bound has been sharpened by Robinson (8). Also, the values of $m = 1$ to 4, 6, 8, 9, 12, 24, 48, 60, and 120 are the only ones for which an arrangement of hard congruent spheres on a central sphere can attain its maximum *local* packing density, *i.e.* each sphere will be coordinated by the maximum possible number of like spheres and in contact with them ('maximal' packing) (15). For $m > 3$ these configurations are unique.[5]

For some values of m the known configurations are not remunerative as densest packings. For example, removal of one vertex of a regular octahedron, $m = 6$, yields the C_{4v} solution for $m = 5$: d_{min} is the same in both cases and six equal spheres can therefore be accommodated on the surface of the central sphere just as easily as five. A similar situation exists for $m = 11$. This configuration is obtained by removing one vertex of the regular icosahedron. However, unlike for $m = 5$, the configuration for $m = 11$ is rigid. Robinson (17) tried to prove, unsuccessfully, the conjecture that a similar situation also exists for

[5]The case of 12 spheres congruent with the central sphere was the subject of the celebrated 'thirteen spheres' controversy of 1694 between Newton and Gregory (2, 10). The maximum number of congruent spheres in a *second* 'coordination shell' in which each sphere touches at least one sphere of the twelve, has been bracketted by Fejes Tóth and Heppes (16) between 43 and 50.

$m = 23$, 47, 49, and 119, but that for any other m, $d_{min}(m) > d_{min}(m + 1)$.

At the other end of the n range, for $n = 1$ and $m = 2$ to 8, 10, 12, and 14, the problem was investigated by Föppl (18), at Hilbert's instigation, by methods of the variational calculus. For $m = 2$–6 (D_{3h} for $m = 5$), 8, and 12 the configurations he found were identical with those for the densest packing (Table 2; for $m = 8$, see below). The other configurations he obtained were $D_{5h}(1^1 5^1 1^1)$ for $m = 7$, $D_{4d}(1^1 4^2 1^1)$ for $m = 10$, and $D_{6d}(1^1 6^2 1^1)$ for $m = 14$. He also proposed $D_{4d}(4^1 8^1 4^1)$, $D_{4d}(1^1 4^1 8^1 4^1 1^1)$, and $D_{5d}(5^1 10^1 5^1)$ as the probable best arrangements for $m = 16$, 18, and 20, respectively. From his results he abstracted the following conditions as possible minimum general requirements for a configuration of unit charges to satisfy eq. 1 for the Coulombic case, $n = 1$: (*a*) Existence of an axis of symmetry coincident with the polar axis of the sphere and of order >2 when $m > 2$. (*b*) The charges form an antipodal pair in the polar axis, or regular polygons ('rings') in the equatorial plane or planes parallel to it, or both. (*c*) Neighbouring rings are symmetrically skewed (staggered) relative to one another. (*d*) For large m the problem may not be tractable, but for $m > 14$ that satisfy the condition $m = 2p = 2 + 4q$, where p and q are primes, the probable arrangement corresponds to the partition $1^1 q^1 2 q^1 q^1 1^1$. Such values of m are 22, 46, 94, 118 etc., the difference between successive values being 24 or 48. Five or more rings would be possible for other values of m.

Föppl's configurations must be viewed as corresponding to *local* minima of $U(m,1)$ until proven by rigorous methods to correspond to global minima. The same is true of the other results available for problem *B* so far, including our own.

King (19, 20) summed the absolute values of the Coulombic *forces* acting between pairs of charges and then sought configurations for which this sum was a minimum. His solutions thus correspond to a d^{-2} *potential* and a d^{-3} *force* law, and hence to $n = 2$. Some of the f parameters of the configurations he investigated were arbitrarily fixed and only one or two of them were adjusted to find the minimum of the objective function. Consequently the validity of the resulting configurations as solutions to problem *B* for $n = 2$ cannot be viewed as established. King examined a large number of possible arrangements for $m \leq 16$ and proposed hybrid-orbital schemes with the required point-group symmetry that could be used for bonding in such arrangements.

For $m = 5$ the trigonal bipyramid D_{3h} is believed (21, 22) to yield the lowest $U(5,n)$ for *any* finite n. Specifically, $U(5,n)(D_{3h})$ is lower than the energy corresponding to the octahedron − 1, $C_{4v}(f = 0)$ configuration for any finite n. Moreover, the ratio $U(C_{4v}, f = 0)/U(D_{3h})$ tends to $\frac{4}{3}$ as $n \to \infty$, even though *geometrically* both configurations are equally valid solutions to the *densest packing* problem.

Arrangements for $1 \leq n < \infty$ have been investigated by machine computation for $m = 7$ (21, 23) and 10 (22), with the following results. For $m = 7$, computation using the method of steepest descents (21) confirmed previous results (23) except for the range $2.5 \leq n < 5.6$, where the configuration $C_2(1^1 2^3)$ was found more favourable than $C_{2v}(1^1 4^1 2^1)$, although at $n = 5$ the energy values are equal within the number of digits quoted. The energies of the C_2, C_{2v}, and C_{3v} arrangements at $n = 5.598$ are identical within the accuracy reported in ref. 21. In a similar manner Cohn (24) obtained two arrangements for $n = 1$. For $m = 9$ the result was a trigonal prism + 3, $D_{3h}(3^3)$. His configuration for $m = 11$, $C_{2v}(1^1 2^1 4^1 2^2)$, corresponds to the $B_9C_2H_{11}$ carborane skeleton and possibly also to the $B_{11}H_{11}^{2-}$ skeleton (5).

For $m = 8$ and 9 it has been stated (1, 21, 22), without proof, that the square antiprism $D_{4d}(4^2)$ and the trigonal prism + 3, $D_{3h}(3^3)$, are the respective solutions for all values of n. Indeed, the square antiprism is the solution for $n \to \infty$ and also the arrangement found by Föppl for $n = 1$ (*cf.* also ref. 25). However, the two antiprisms, when inscribed in a unit sphere, are not congruent. A similar situation exists for $m = 9$ (19).

The case of $m = 10$ has been treated by King (20) for $n = 2$ and by Lin and Williams (22) for $1 \leq n \leq 1200$. The configurations proposed by various authors for $m \geq 7$ will be discussed below, together with our own contributions to problem *B*.

C. For $0 < n < 2$ the solution for $m = 4$ is the regular tetrahedron (26, 27). The problem of finding an upper bound of V as a function of m has been investigated by Stolarski (28). For $n = 2$ *any* centrosymmetric polyhedron inscribed in the sphere is a solution (26, 27).

D. When $n = 1$ and $m = 2r$, any centrosym-

metric configuration is a solution and all of them are equally valid (29–31). When $n = 1$ and $m = 2r + 1$, all points which have no antipodal partners must lie on a great circle in such a way that any two semicircles defined by one of the points must contain the same number of points (30; for $m \leq 6$, *cf.* also ref. 31). For $n > 1$ nothing appears to be known.[6]

E. The densest-packing and the thinnest-covering requirements in E^3 (although not necessarily in other spaces, ref. 6) lead to different sets of solutions. Exceptions are the D_{3h} configuration for $m = 5$ and the configurations for $m = 2$, 3, 4, 6, and 12 of Table 2, for which the solutions to the two problems coincide (2, 6, 32);[7] these configurations are also balanced in the sense of problem *A*. The other known solutions to problem *E* are for $m = 7$ (pentagonal bipyramid D_{5h}, ref. 33), 10 (bicapped square antiprism $D_{4d}(1^14^21^1)$, refs. 34 and 35), and 14 (bicapped hexagonal antiprism $D_{6d}(1^16^21^1)$, ref. 34). Conjectured solutions have been proposed for $m = 8$ (square antiprism D_{4d}, not congruent with that of Table 2; refs. 2 and 33), 9 (trigonal prism + 3, $D_{3h}(3^3)$, refs. 34 and 35), 16 (bicapped heptagonal antiprism $D_{7d}(1^17^21^1)$, ref. 34), 20 ($D_{6h}(1^16^31^1)$ with staggered hexagons, ref. 35), and 32 (icosidodecahedron I_h, ref. 34).

It is interesting to note that the configurations for $m = 5$ to 7 are regular bipyramids, while for $m = 10$, 12, and 14 they are bicapped antiprisms.

The *centrosymmetric* solution for $m = 8$ is the hexagonal bipyramid D_{6h}.[6] Favourable centrosymmetric arrangements have been proposed for $m = 10$, 14, and 16 (34): a bicapped tetragonal prism D_{4h} with all faces inscribable in congruent circles, the rhombic dodecahedron O_h, which is also the densest *centrosymmetric* packing arrangement, and a bicapped heptagonal antiprism D_{7d}, which is possibly a solution to problem *E* for $m = 16$.

The covering density ρ_m' for $m \geq 3$ can be estimated from the inequality

$$[4] \quad 2\rho_m'/m \geq 1 - (1/\sqrt{3})\cot[(m/m - 2)(\pi/6)]$$

(3, 32). For $m \to \infty$ the lower bound of ρ_m' from eq. 4 tends to $2\pi/\sqrt{27} \sim 1.209$. This estimate has been slightly sharpened by Fejes Tóth (34). Thus there always is at least about 21% overlap of the congruent circles or caps.

F. Solutions are known for $m = 2$, 3, 4, 6, and 12. They are the same as the solutions to problems *A*, *B*, and *E* (3) and have been referred to as *perfect* distributions of 2, 3, 4, 6, and 12 points on a sphere. It is conjectured (6) that no other values of *m* admit of perfect distributions.

G. The solutions for $m = 4$ to 7 and 12 are, respectively, the regular tetrahedron, trigonal bipyramid D_{3h}, regular octahedron, pentagonal bipyramid D_{5h}, and regular icosahedron. For $m = 8$ the best solution known is a dodecadeltahedron $D_{2d}(2^4)$ with vertex coordinates ($\pm\sin 3\alpha$, 0, $\cos 3\alpha$), (0, $\pm\sin 3\alpha$, $-\cos 3\alpha$), ($\pm\sin\alpha$, 0, $\cos\alpha$), (0, $\pm\sin\alpha$, $-\cos\alpha$), $\cos^2\alpha = (15 + \sqrt{145})/40$, and faces which are not equilateral triangles (36; *cf.* also ref. 25).

H. No investigation seems to have been made of the extremal problems proposed by Whyte (4).

Present Contribution to Problem *B*

Finding the minimum of *U* by numerical computation is complicated by the existence of *local* minima. Since in general the outcome of a minimization by a given numerical technique is predetermined by the choice of starting configuration (≡ starting coordinate values), *all* the local minima must be found and compared to find the global minimum, *i.e. the* solution to problem *B*. For larger values of *m* it is impossible to be certain that all the minima have in fact been found. We feel that, in what follows, we have examined all the local minima of any importance, but we have no proof that we have not missed a local minimum which may in reality be the global minimum of *U* for a given *m* and *n*. The local minimum with the lowest value of *U* obtained will be referred to as the conjectured solution.

Computation Procedure

The problem is to minimize the objective function $U(m,n)$ of eq. 1 taking $k = 1$ (without loss of generality). The distances d_{pq} are given by

$$d_{pq}^2 = 2(1 - \sin\theta_p\cos\phi_p\sin\theta_q\cos\phi_q - \sin\theta_p\sin\phi_p\sin\theta_q\sin\phi_q - \cos\theta_p\cos\theta_q)$$

where θ_p and ϕ_p are the polar and azimuthal angles, respectively, of point *P* in the spherical polar coordinate system with $r = 1$ (without loss of generality). Three degrees of freedom can be eliminated by fixing a rotational origin. One

[6] L. Fejes Tóth. Personal communication to O. Knop.

[7] For $m = 3$ the solution is not unique: the three points are on a great circle but are not necessarily equally spaced.

point and one additional ϕ coordinate can be fixed, leaving $2m - 3$ degrees of freedom for the minimization.

A computer algorithm for minimizing U was written using a modification of a rank one (R1) optimization procedure originally due to Davidon (37[8]–39). This procedure has two distinct advantages over the steepest-descents procedure used by previous authors (21, 22). In general, the convergence of the R1 procedure becomes quadratic near the local minimum, while the convergence of a steepest-descents procedure remains first-order. For our problem the R1 procedure has a special advantage in that it tends to find solutions of low symmetries, which are the most difficult ones to predict. In the steepest-descents procedure a symmetry element, once gained, will be retained from then on, whereas in the R1 procedure symmetry elements can only be gained asymptotically, allowing both the configuration and the positive-definite matrix associated with the procedure, to gain the symmetry element together.

For each value of m an initial configuration containing no symmetry elements was generated by placing the m points on an approximate spiral. Starting from this configuration, $U(m,n)$ was minimized, using all $2m - 3$ degrees of freedom, for two or three values of n. The dependence on n of $U(m,n)$ for the resulting configuration was then examined, within the symmetry constraints of that configuration, using a minimum set of f variable coordinates that describe the configuration. This procedure, also used by Lin and Williams (22), greatly reduces the number of degrees of freedom and the computer time required. For practical reasons the maximum value of n was taken as 400 throughout except for $m = 15$, where it was 1000.

In addition to arrangements found as a result of the minimization using all $2m - 3$ degrees of freedom, $U(m,n)$ of a number of other configurations was minimized within the symmetry constraints of the individual configurations, as above. The values of the coordinates of configurations at the minimum of $U(m,n)$ were then taken as the initial values in a minimization using all $2m - 3$ degrees of freedom at one or more values of n. If the first derivatives of $U(m,n)$ with respect to all $2m - 3$ variables were zero,[9] the configuration was deemed a local minimum and its $U(m,n)$ was then compared with other local minima for the same m and n obtained in the process.

As m becomes large, the number of such symmetry-restricted configurations becomes large. It was then impractical to examine more than a small number of likely-looking arrangements. The configurations investigated (Table 4)[10] contained at least a plane of symmetry and included the configurations conjectured by Föppl (for $n = 1$) and by other authors (for $n \to \infty$, *cf.* Table 3) as solutions of problem *B* for $m \leq 16$.

Results

The arrangements found for $m = 5$ to 16 and the ranges of n in which they are conjectured solutions, are presented in Table 5 and Figs. 1 and 2. In quoting the values (in radians) of the coordinates (θ_p,ϕ_p), the points are numbered as in Fig. 1; $\theta = 0$ corresponds to the north pole and ϕ is measured clockwise from the $+x$ axis of the projection. The θ_p,ϕ_p values at minimum U are listed only for the configurations of Table 5 and then only for one or two representative values of n (Table 6).[10] Variation with n of the minimized energies U of competing configurations is presented, in Figs. 4 to 11, in terms of the ratio $R = U(\text{LMC})/U(\text{reference})$; LMC stands for local-minimum configuration. For U(reference) the symmetry arrangement that is the conjectured solution at $n \to \infty$ is usually employed.

$m = 5$

While the fixed configuration $C_{4v}(f = 0)$ gives a U value which is higher than $U(D_{3h})$ for *any* n (*cf.* above), a C_{4v} configuration with one degree of freedom becomes more favourable than D_{3h} when n exceeds 15.04808, contrary to common belief. The values of the ratios $U(C_{4v}, f = 1)/U(D_{3h})$ and $U(C_{4v},f = 0)/U(C_{4v},f = 1)$ tend to $\frac{2}{3}$ and 2 respectively as $n \to \infty$ (Fig. 4). The minimum of $U(D_{3h})/U(C_{4v},f = 1)$ is at $n \sim 8$. Variation of $\theta_2(C_{4v},f = 1)$ with $1/n$ is shown in Fig. 3.

$m = 6$ and 12

As stated above, the regular octahedron $O_h(1^14^11^1)$ $(f = 0)$ and icosahedron $I_h(1^15^21^1)$ $(f = 0)$ are the respective solutions for all values of n. Figure 5 shows how their $U(m,n)$ vary with n relative to some LMC's.

[8]For discussion of some modifications, see refs. 38 and 39.

[9]Any value less than $10^{-7} \times U$ was considered zero.

[f] $d_{77'}$ (~36.86 > n), d_{68} (~36.86 < n).

m = 7

The result obtained by Föppl (18) for $n = 1$ was confirmed but a few minor discrepancies were discovered in the work of Claxton and Benson (21). The cross-over values of n, at which the conjectured solution changes configuration, given by the latter authors have been sharpened. A comparison of values of $U(5,n)$ at the minimum for different configurations is shown in Fig. 6. The C_2 configuration is a local minimum

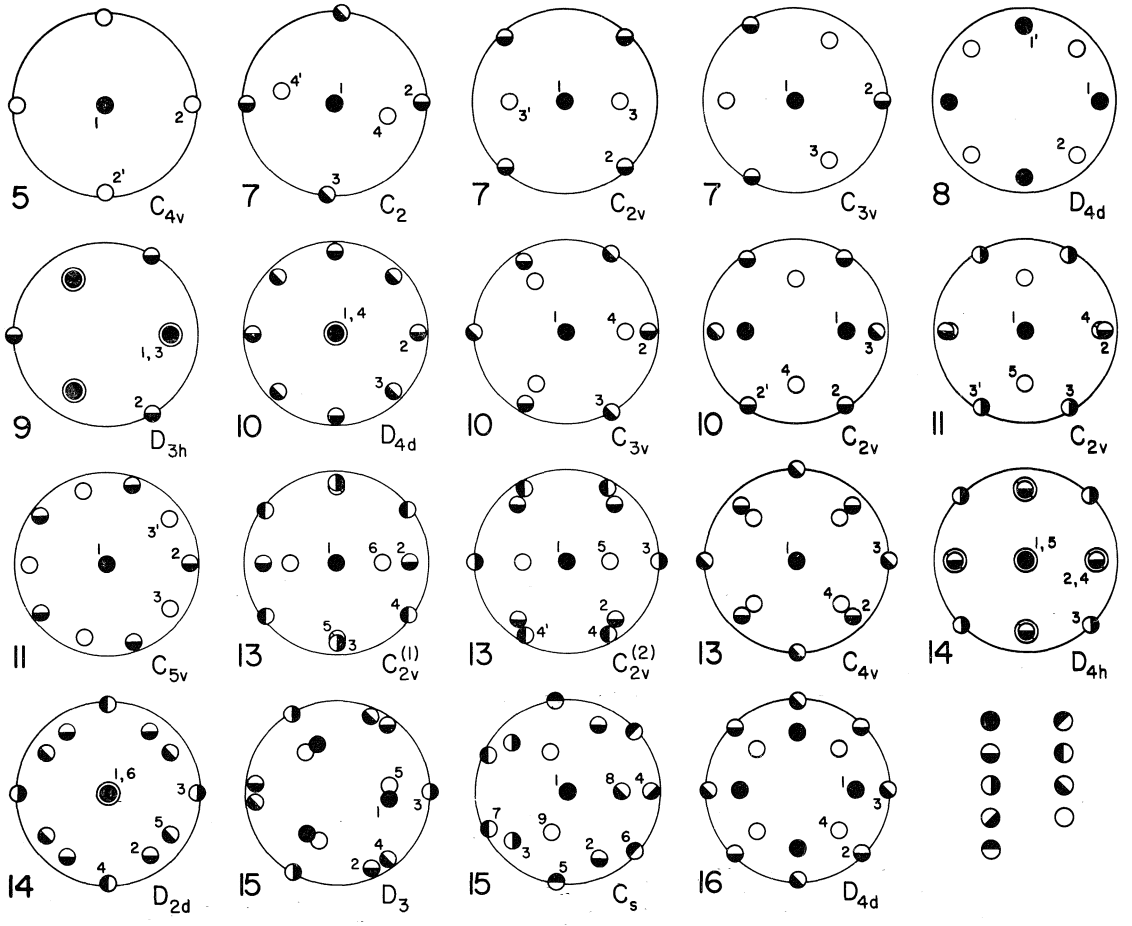

FIG. 1. Parallel projections, along the principal axis of symmetry, of the configurations of Table 5. The coordinates of the highest point on the sphere (the 'north pole') are $\theta = 0$, $\phi = 0$. The points are numbered in the increasing order of θ; the numbering corresponds to that in the text.

in a restricted range of n only. As n decreases, this configuration approaches D_{5h} symmetry and becomes asymptotically indistinguishable from the D_{5h} configuration to one part in 10^{12} in U by $n = 2.00$ and to 1×10^{-8} rad in angular coordinates by $n = 1.84$. With increasing n the C_2 configuration approaches C_{2v} symmetry and becomes asymptotically indistinguishable from the C_{2v} configuration to one part in 10^{12} in U by $n = 4.88$ and to 1×10^{-8} rad in angular coordinates by $n = 5.00$. The C_{2v} configuration remains the lowest minimum ($\equiv$ conjectured solution) until $n \sim 5.59791$, at which point (A of Fig. 6) the C_{3v} configuration becomes the conjectured solution. The angular data given for C_2 by Claxton and Benson (21) were confirmed at $n = 4.0$ but could not be reproduced at $n = 2.0$ and 5.6. Their data for the C_{2v} and C_{3v} configurations were confirmed at these n values.

m = 8

The square antiprism $D_{4d}(4^2)(f = 1)$ is the best arrangement for all values of n (Figs. 3 and 5), confirming previous conjecture.

m = 9

The best arrangement for all values of n is the trigonal prism + 3, $D_{3h}(3^3)(f = 1)$ (Fig. 3), confirming earlier conjectures. At $n = 1$, $\theta_1 \sim 0.790277$, in complete agreement with ref. 24.

m = 10

The three arrangements reported by Lin and Williams (22) have been confirmed and the crossover values of n sharpened (Figs. 3 and 7).[11] The configurations for $n = 1$ and 400 agree with

[11]The angular data given by Lin and Williams for the C_{3v} configuration at $n = 100$ are in fact the correct data for $n = 200$. The value of $U(C_{3v})$ given for $n = 100$ is correct.

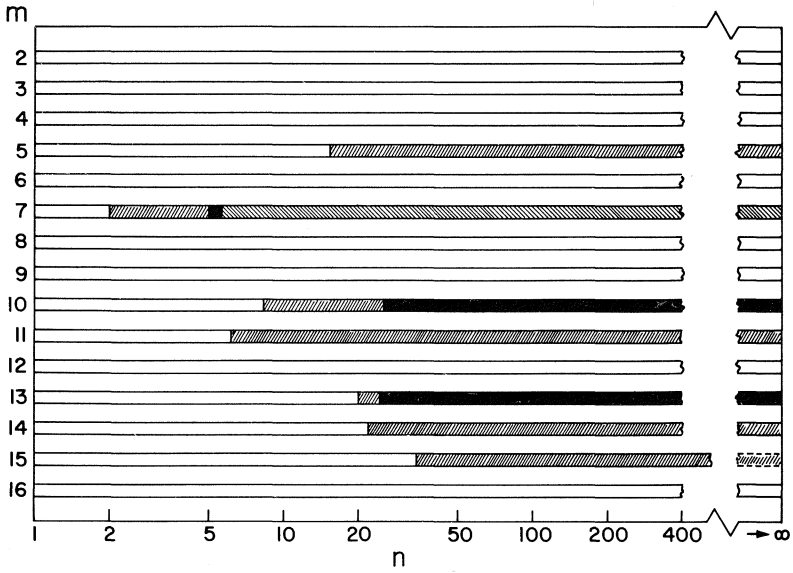

FIG. 2. Synoptic presentation of the ranges of n (on an $n^{-1/2}$ scale) for the solutions, or conjectured solutions, to problem *B*.

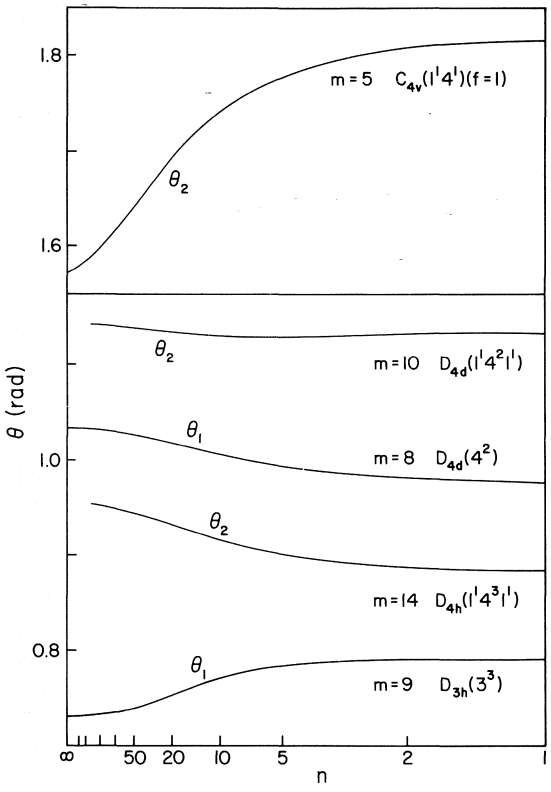

FIG. 3. Variation of θ (rad) with $n^{-1/2}$ for the one-parameter ($f = 1$) configurations of Table 5 at minimized U.

those proposed by Föppl and by Danzer (for $n \to \infty$), respectively.

m = 11

Contrary to the conjecture of Lin and Williams (22) that the densest-packing solution persists for *all* values of n, *two* configurations are solutions at different values of n. At low values, the best arrangement was found to be the $C_{2v}(1^12^14^12^2)$ ($f = 5$) configuration reported for $n = 1$ by Cohn (24), whose numerical results were confirmed. At larger values of n the configuration of minimum $U(11,n)$ is the singly-capped pentagonal 'antiprism' $C_{5v}(1^15^2)(f = 2)$ (Fig. 8); this configuration approaches the icosahedron − 1, $C_{5v}(1^15^2)(f = 0)$ as $n \to \infty$ (*cf.* Table 2). Better than $C_{5v}(1^15^2)(f = 2)$ at low values of n, but not as good as $C_{2v}(1^12^14^12^2)$, is a hitherto unreported configuration of low symmetry, $C_s(1^12^21^12^21^1)$ ($f = 10$). This configuration takes on C_{5v} symmetry at $n \sim 6.144$ and continues with this symmetry for larger values of n (*cf.* inset, Fig. 8).

m = 13

Of the three conjectured solutions found (Figs. 1 and 9), that for large values of n coincides with the $C_{4v}(1^14^3)$ arrangement proposed for $n \to \infty$ by Schütte and van der Waerden (7). The two C_{2v} configurations have not been reported previously.

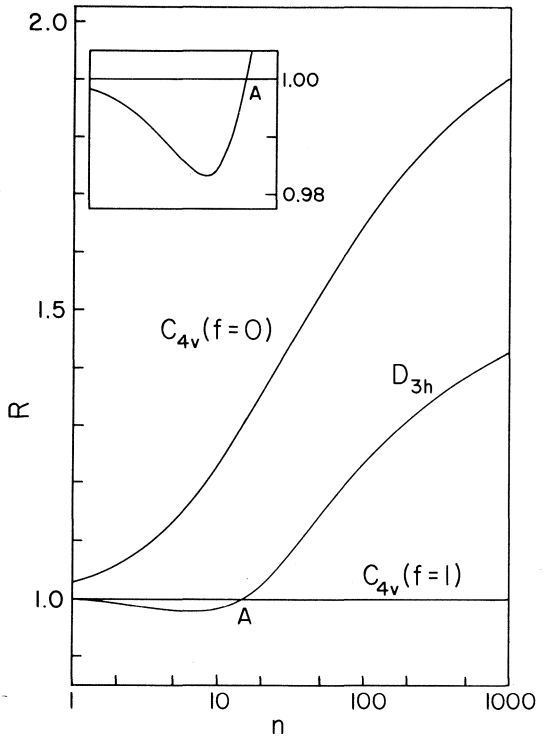

FIG. 4. Variation of $R = U(\text{LMC})/U(C_{4v}, f = 1)$ with $\log n$, $m = 5$. Inset: $U(D_{3h})/U(C_{4v}, f = 1)$ on an expanded scale.

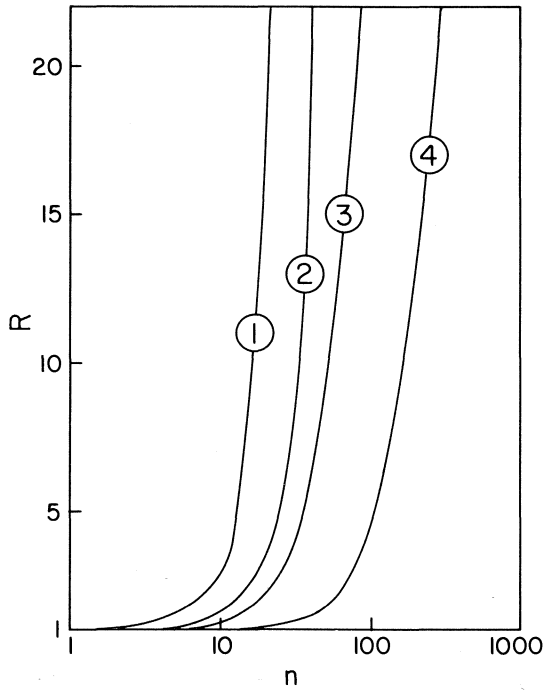

FIG. 5. Variation of $R = U(\text{LMC})/U(\text{MC})$ with $\log n$, $m = 6$, 8, and 12. (*1*) $m = 6$, $U(C_{5v}, f = 1)/U(O_h)$. (*2*) $m = 6$, $U(D_{3h}, f = 1)/U(O_h)$ (trigonal prism *vs.* octahedron). (*3*) $m = 8$, $U(\text{cube } O_h, f = 0)/U(D_{4d}, f = 1)$; $m = 12$, $U(\text{cuboctahedron } O_h, f = 0)/U(I_h, f = 0)$. The two curves are indistinguishable on the scale of this drawing. (*4*) $m = 8$, $U(D_{2d}, f = 2)/U(D_{4d}, f = 1)$.

m = 14

The bicapped hexagonal antiprism $D_{6d}(1^1 6^2 1^1)$ ($f = 1$) found by Föppl for $n = 1$ turned out not to be the best configuration at low n, a bicapped square prism + 4, $D_{4h}(1^1 4^3 1^1)$ ($f = 1$), being better for $n < 21.66607$ (Figs. 1 and 10). At high exponents the D_{2d} configuration proposed by Schütte and van der Waerden (7) for $n \rightarrow \infty$ was confirmed. Interestingly, with decreasing n this configuration became worse than the bicapped hexagonal antiprism at $n \sim 12.60203$ and then disappeared as a local minimum in favour of the latter at $n \sim 11.5110$ (point *C*, Fig. 10). The rhombic dodecahedron $O_h(1^1 4^3 1^1)(f = 0)$ is not the solution at any n.

m = 15

At small values of n the best arrangement is $D_3(3^5)(f = 4)$ (Fig. 11). The $C_3(3^5)$ arrangement proposed by Schütte and van der Waerden (7), in which the central plane of three points is not the equatorial plane, is better than the $D_3(3^5)(f = 4)$ configuration for large n and converges to the D_3 arrangement as n decreases; at $n \sim 54.268$ the U values are indistinguishable to within one part in 10^{12} and the coordinates to within 1.0×10^{-6} rad. However, a new, low-symmetry configuration $C_s(1^1 2^2 1^1 2^3 1^1 2^1)(f = 14)$ was found to be better than both $D_3(3^5)$ and $C_3(3^5)$ for $n > 34.027944$. As n becomes large, the energies of the C_3 and C_s configurations approach each other again and it appears that they might cross over in the range of $n \sim 2000$, which would agree with Schütte and van der Waerden's proposal that C_3 is the solution for $n \rightarrow \infty$.

m = 16

The best arrangement for all values of n is $D_{4d}(4^4)$ ($f = 2$). This is in agreement with the configuration proposed for $n \rightarrow \infty$ by Schütte and van der Waerden but not with Föppl's proposal, $D_{4d}(4^1 8^1 4^1)$, for $n = 1$. The minimized value of U of $D_{4d}(4^1 8^1 4^1)(f = 1)$ exceeds that of $D_{4d}(4^4)(f = 2)$ by about 0.33% at $n = 1$, by 2.6% at $n = 2$, and by 7% at $n = 4$.

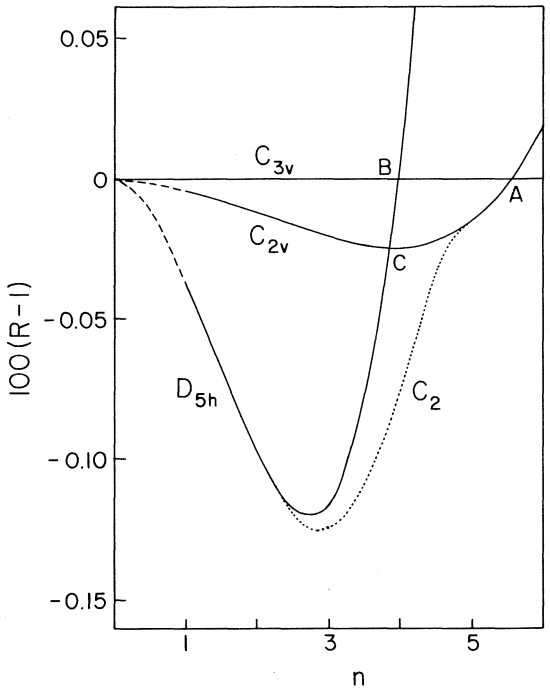

FIG. 6. Variation of $R = U(\text{LMC})/U(C_{3v}, f = 2)$ with n, $m = 7$; $n(A) \sim 5.59791$, $n(B) \sim 3.96$ (this work); $n(C) \sim 3.84165$ (ref. 21).

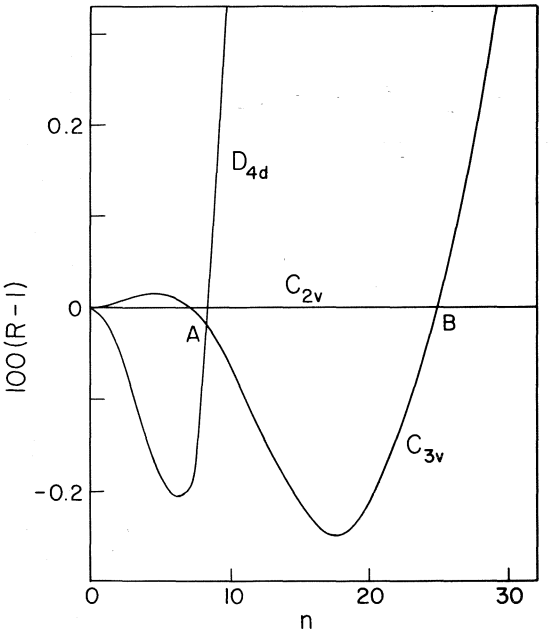

FIG. 7. Variation of $R = U(\text{LMC})/U(C_{2v}, f = 5)$ with n, $m = 10$; $n(A) \sim 8.22402$, $n(B) \sim 24.91438$.

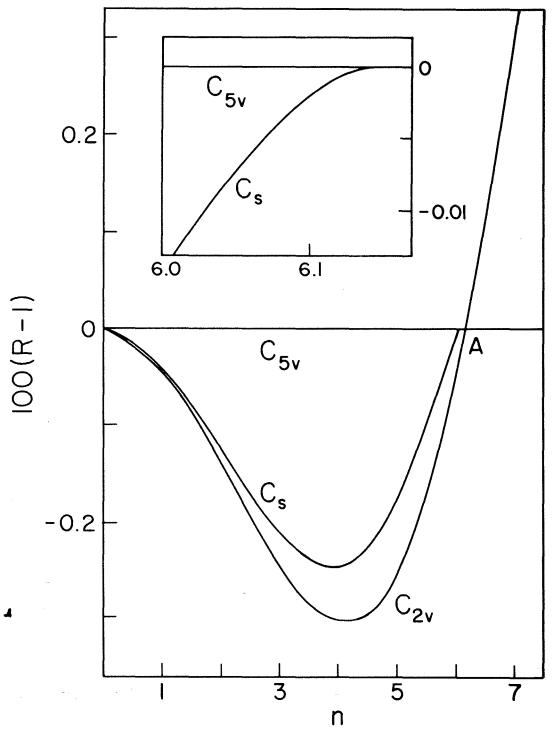

FIG. 8. Variation of $R = U(\text{LMC})/U(C_{5v}, f = 2)$ with n, $m = 11$; $n(A) \sim 6.16566$. Inset: $U(C_s)/U(C_{5v})$ on an expanded scale.

Some Observations on the Results

With one exception the configurations obtained at $n = 400$ always agree with the known or conjectured solutions of problem B for $n \to \infty$, and the $d_{\min}$ and ρ_m values at $n = 400$ and $n \to \infty$ differ, on the average, by only about 0.1–0.2% and by much less for some values of m (Table 7).[10] It is therefore assumed that the configurations listed for $n = 400$ in Table 5 remain valid for $n > 400$. The exception is $m = 15$, where U was minimized up to $n = 1000$, with the result described above.

The configuration found by Föppl for $m = 14$, $n = 1$, does not correspond to the lowest $U(14,1)$, and his prediction of the best configuration for $m = 16$, $n = 1$, has turned out to be wrong. It would seem that his prescription contains too much symmetry, while the solutions to problem B at $n = 1$, and at other values of n, tend to lose elements of high symmetry as m increases.

For $n \to \infty$, where geometrical arguments can be employed, a number of conjectured configurations have been proposed (Table 3). How-

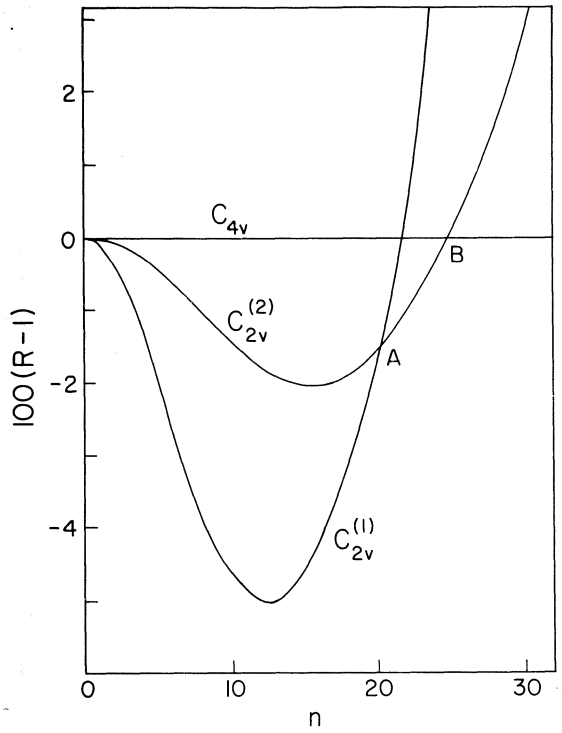

FIG. 9. Variation of $R = U(\text{LMC})/U(C_{4v}, f = 3)$ with n, $m = 13$; $n(A) \sim 19.95657$, $n(B) \sim 24.70475$.

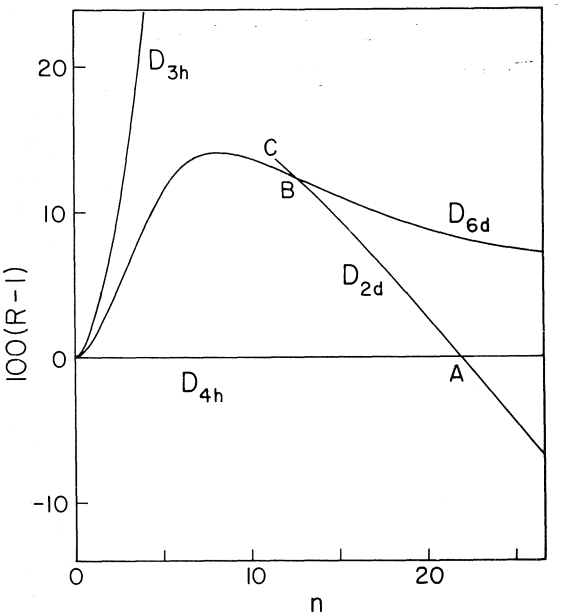

FIG. 10. Variation of $R = U(\text{LMC})/U(D_{4h}, m = 3)$ with n, $m = 14$; $n(A) \sim 21.66607$, $n(B) \sim 12.60203$, $n(C) \sim 11.5110$.

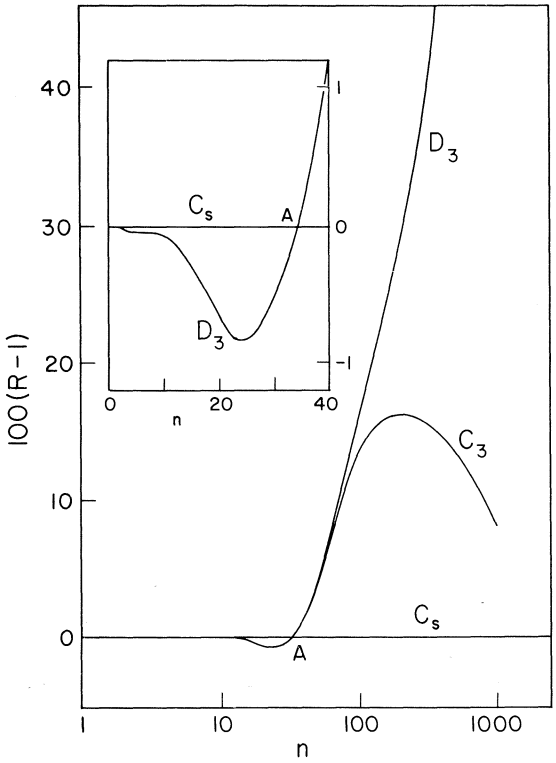

FIG. 11. Variation of $R = U(\text{LMC})/U(C_s, f = 14)$ with $\log n$, $m = 15$; $n(A) \sim 34.02794$.

ever, for *finite* values of n no method of predicting the best configurations for $m > 16$ seems to exist, and the irregular distribution of the cross-over points for $m < 16$ (Fig. 2) makes the possibility of prediction of the validity ranges seem quite remote.

The difference in U between the best and the next-best configurations for a given m,n pair is sometimes very small. Noteworthy are the $D_{5h}|C_2$ and $C_{2v}|C_2$ pairs ($m = 7$) in the $n = 2$ to 5 range (Fig. 6), the triplet $D_{4d}|C_{3v}|C_{2v}$ ($m = 10$) in the region of point A ($n \sim 9$, Fig. 7), the $C_{2v}|C_2$ pair ($m = 11$) between $n = 1$ and 3 and between $n = 5$ and 6, and $D_3|C_s$ ($m = 15$) between $n = 1$ and 10. In the Coulombic case in particular the differences in U between local-minimum and best configurations are seldom pronounced. At the cross-over points the dependence of the arrangement on n is of course critical.

Variation of the *mean* energy of interaction between two charges,

$$[5] \qquad \bar{U}(m,n) = \left[U(m,n) \Big/ \left(\frac{m}{2}\right) \right]^{1/n}$$

in the best configurations is shown in Fig. 12.

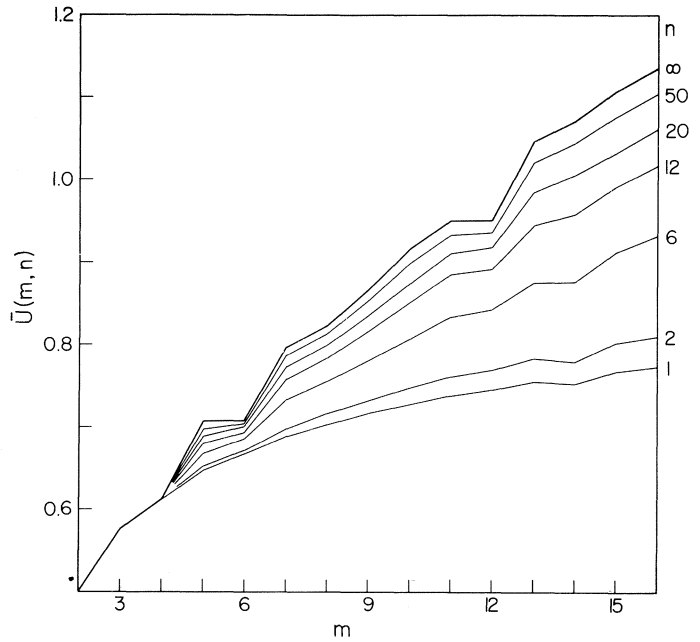

FIG. 12. Variation of the mean energy of interaction $\bar{U}(m,n)$ between two charges in the configuration of minimum $U(m,n)$ (*cf.* eq. 5).

Summary

In this paper we have reviewed the various formulations of a number of extremal problems associated with point charges on the surface of a sphere in E^3 which have appeared in the literature to date. We have summarized existing results for these problems and presented new results for one of these, problem *B*. In that case we have found new solutions for 5, 11, 13, 14, 15, and 16 point charges. We have also sharpened the existing results for $m = 7$ and 10.

Acknowledgments

We thank Professor L. Fejes Tóth and Dr. M. Goldberg for helpful comments on the subject, and the National Research Council of Canada for financial assistance.

NOTE ADDED IN PROOF

The following results reached us too late to be incorporated in the body of the text.

B. In many, though not all, of the previously reported configurations for $n \to \infty$, p of the vertices are arranged on a spiral with the North–South line as axis. Rotating the spiral successively by $2\pi/k$ about this axis produces a set of kp vertices; one or two additional vertices may be located at the poles, giving rise to $m = kp$, $kp + 1$, or $kp + 2$ and configurations of axial (rotational) symmetry C_k or D_k. This observation was used by Karabinta (46, 49)[12] and by Székely (47) to generate, and optimize by computer, a number of conjectured configurations (Table 8), some of them supplanting previous proposals, others for values of m considered for the first time. In a few cases the proposed configurations do not follow the principle of the spiral completely, in that extra points can be accommodated on the sphere in a manner inconsistent with the order of rotation of the generating spiral (*e.g.* for $m = 35$, 40, 59).

It is noteworthy that, when Székely (47) replaced the configuration $C_3(3^{15})$ proposed for $m = 45$ in ref. 46, by an improved configuration $C_4(1^14^{11})$, $s_{\min}$ increased by less than 0.04%, in spite of the complete change of rotational symmetry. This, together with similar though somewhat larger increases for several other m in ref. 47, indicates that with increasing m there will be an increasing number of local extrema and an increasing probability that the global minimum will be of low symmetry, parallelling our findings for small m and intermediate n values. This raises the question of whether a construction principle which presupposes rotational symmetry of order 3 or higher does not from the outset lead to

configurations containing too much symmetry and not likely to correspond to a global minimum of U.

The Tammes problem has been generalized by Molnár (50 and refs. therein), who introduced the idea of *space-claim*, SC. The SC is a domain associated with each of the m congruent circles C to be packed on the sphere. It consists of one or more circles tangent to C, congruent or incongruent among themselves, though in general the SC can be an arbitrary point set (51). An SC may overlap other SC's but not the C's; it may be viewed as a domain of influence (exclusion) of its C. For one SC per circle the centres of the C's in the extremal arrangements are at the vertices of the five convex Platonic solids, m = 4, 6, 8, 12, 20; the snub cube $O(4^6)$, m = 24; and the snub dodecahedron $I(5^{12})$, m = 60. For two congruent SC's per circle, with all three centres on a great circle, the cuboctahedron $O_h(4^3)$ and the icosidodecahedron $I_h(5^210^15^2)$ are the solutions for m = 12 and 30, respectively. For three SC's per C, two of them congruent and the third smaller, the truncated icosahedron $I_h(5^210^45^2)$ is the solution for m = 60. The icosidodecahedral arrangement for m = 30 and two nonisomorphic arrangements of I_h symmetry constructed by Molnár for m = 180 appear to correspond with the disposition of the features visible on the surface of certain spherical viruses. Molnár remarks that the symmetry of these packings for m = 180 is the direct consequence of the "economy principle", *i.e.* the densest-packing requirement.

The notion that the surface structure of small spherical viruses may be related to the Tammes problem was first explored by Goldberg (44).

C. Computer solutions for n = 1 and m = 5 to 10 have recently been reported by Berman and Hanes (52). The respective configurations coincide with the solutions to B for n = 1 (Table 5) except at m = 7, for which the configuration is a pentagonal bipyramid $C_1(1^7)$ having no symmetry but closely approaching $C_s(1^12^11^12^11^1)$. The $V(7, 1)$ of the $C_1(1^7)$ arrangement differs by only 0.001% from that of the $D_{5h}(1^15^11^1)$ configuration. It is interesting to compare this situation with the configurations of minimum $U(7, n)$ under B (Table 5 and Fig. 6): the configuration corresponding to $U(7, 1)_{\min}$, $D_{5h}(1^15^11^1)$, goes over smoothly into $C_2(1^12^3)$ as n increases, the difference of $U(7, 2.4)$ for the two configurations being less than 0.0007%. The θ_1 value for m = 8, 0.9659 rad, is *below* that of the $D_{4d}(4^2)$ configuration of B for any $n \geq 1$, while θ_1 for m = 9, 0.7911 rad, is *above* that of the $D_{3h}(3^3)$ configuration of B for any $n \geq 1$. For m = 10, the $V(10, 1)$ value quoted in ref. 52 yields a θ_1 comparable with that of the $D_{4d}(1^14^21^1)$ configuration of B at $n \sim 200$.

An estimate of the upper bound of $V(m, 1)$ is given in ref. 53. Additional references relating to C are 53–56.

G. Klee has conjectured that the solution for m = 9 is an augmented trigonal prism $D_{3h}(3^3)$. This configuration has been optimized by Schoen (57):

$$\theta_1 = \arccos [1 - (4/3)c^2]^{1/2} = 0.8213275 \text{ rad}$$

where

$$c = 2(a^2 + b^2)^{1/6} \cos \{[\pi - \arctan(-b/a)]/3\} - (4\sqrt{3})/9$$

$$a = -(121\sqrt{3})/972$$

and

$$b = [(41/54)^3 - 3(121/972)^2]^{1/2}$$

The θ_1 is greater than the corresponding θ_1 for B for any $n \geq 1$.

MEINDERT BOOY and THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 1762 (1977).

Aqueous H_3NTA, H_2MIDA, H_2IDA, and their anions decompose under hydrothermal conditions (400–580 K) according to first order kinetics by successive decarboxylations, oxidation by O_2 being unimportant except at the highest temperatures. In the presence of added H^+, the species H_4NTA^+ and, to a lesser extent, H_3MIDA^+ (but not H_3IDA^+), provide significant decomposition pathways through elimination of a —CH_2COO— group (deacetylation). For $H_nNTA^{(3-n)-}$, first order rate coefficients k_n for decomposition are $k_0 = 4.5 \times 10^{-7}$, $k_1 \sim 1 \times 10^{-6}$, $k_2 \sim 7 \times 10^{-5}$, $k_3 = 2.1 \times 10^{-4}$, and $k_4 = 1.0 \times 10^{-2}$ s^{-1}, at 503 K and ionic strength 2.0 *m*, the spread in rates being due to differences in ΔS^* rather than ΔH^*. H_2MIDA and H_2IDA are comparable in reactivity to H_3NTA, while their anions are much less reactive than the NTA species of the same charge. The good thermal stability of aqueous NTA commends it as a reagent for boiler servicing and for decontamination of water-cooled nuclear reactors. A potentiometric method for the estimation of mono-, di-, and tribasic aminoacids in aqueous mixtures of these is described.

MEINDERT BOOY et THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 1762 (1977).

Des solutions aqueuses de H_3NTA, H_2MIDA, H_2IDA et de leurs anions se décomposent, dans des conditions hydrothermiques (400–580 K), suivant des cinétiques du premier ordre par des décarboxylations successives; l'oxydation par O_2 n'est pas importante exceptée aux plus hautes températures. En présence d'ions H^+ additionnés, les espèces H_4NTA^+ et à un degré moindre H_3MIDA^+ (mais pas H_3IDA^+) fournissent des voies importantes de décompositions par élimination d'un groupe —CH_2COO— (déacétylation). Pour $H_nNTA^{(3-n)-}$, les coefficients de vitesse du premier ordre k_n pour la décomposition sont: $k_0 = 4.5 \times 10^{-7}$, $k_1 \sim 1 \times 10^{-6}$, $k_2 \sim 7 \times 10^{-5}$, $k_3 = 2.1 \times 10^{-4}$ et $k_4 = 1.0 \times 10^{-2}$ s^{-1} à 503 K et une force ionique de 2.0 *m*, les écarts dans les vitesses étant dus à des différences dans les ΔS^* plutôt que dans le ΔH^*. Les H_2MIDA et H_2IDA ont des réactivités comparables à celles du H_3NTA alors que leurs anions sont beaucoup moins réactifs que les espèces NTA ayant la même charge. La bonne stabilité thermique du NTA en solution aqueuse fait qu'on peut le considérer comme un bon réactif pour nettoyer les bouilloires et pour décontaminer des réacteurs nucléaires refroidis à l'eau. On décrit une méthode potentiométrique pour évaluer les aminoacides mono-, di- et tri-basiques dans des mélanges aqueux.

[Traduit par le journal]

Introduction

Our investigations of reagents suitable for high temperature aqueous chemistry (1, 2) have led us to a study of the hydrothermal chemistry of aminopolycarboxylate chelating agents, particularly nitrilotriacetate (NTA). These systems are of potential importance in the nuclear energy field, since chelating agents having high hydrothermal stability could be of use in the on-line removal of cobalt-60 deposits from the heat-transfer circuits of water-cooled nuclear power reactors ("decontamination") (3, 4). It has also been claimed (5, 6) that the addition of chelating agents to boiler water reduces rates of corrosion.

We have therefore examined the products, kinetics, and mechanism of the decomposition of aqueous NTA as functions of temperature and p*H*. The kinetic data also permit the calculation by extrapolation of an upper limit to the thermal lifetime of NTA in natural waters, which may be of interest to environmentalists in the context of the controversy surrounding the use of NTA as a substitute for polyphosphates in detergents (7–10).

Venezky and co-workers studied the rates of decomposition of aqueous ethylenedinitrilotetraacetic acid (H_4EDTA) (11, 12) and H_3NTA (13) and their sodium and lithium salts at 473 K.

[1]Present address: University Chemical Laboratory, the University of Kent, Canterbury, England CT2 7NH.

[2]To whom correspondence should be addressed.

They showed that the salts are more hydrothermally stable than the acids, the rates of decomposition decreasing markedly with increasing pH, and that the EDTA species decompose much more readily than their NTA analogues, this being associated with the presence of internal C–N bonds in EDTA. The hydrothermal decomposition of EDTA, NTA, and nitrilotrimethylenephosphonic acid at pH_{298} 9.5 was studied by Wilson and co-workers (14, 15) using proton magnetic resonance.[3] NTA possessed the highest hydrothermal stability of more than 20 reagents tested, decomposing above 533 K by decarboxylation to *N*-methyliminodiacetate (MIDA) according to first order kinetics. Dioxygen has been reported to cause the oxidation of aqueous EDTA, but not NTA, at 473 K (16), although NTA is oxidized at pH_{298} 8.5 to iminodiacetate (IDA), CO_2, and some oxalate by O_2 at temperatures as low as 358 K in the presence of a palladium–carbon catalyst (17). In the present study, therefore, attention has been given to the influence of the presence of O_2 upon the rate of hydrothermal decomposition of NTA.

Experimental

Materials

Distilled water, further purified by passage through Barnstead deionizer and organic cartridges was used throughout these experiments. All chemicals were reagent grade. Solutions were in general made up by weighing solids and adding water or aqueous acid or alkali with a pipette, and concentrations are therefore expressed on a molal basis (mol kg^{-1}, *m*).

Sodium hydroxide solutions were standardized with potassium hydrogen phthalate solutions using phenolphthalein as indicator. Acids were standardized using red mercuric oxide. Nitrilotriacetic acid (Eastman Kodak) and iminodiacetic acid (Matheson, Coleman, and Bell) were recrystallized from water and dried *in vacuo* for several hours. Hydroxyacetic acid (Fisher) was recrystallized from diethylether. Trifluoromethanesulfonic acid (HTFMS) (3 M Company) was distilled under vacuum. This acid was chosen because it is highly dissociated in water, a poor complexing agent, nonoxidizing (unlike $HClO_4$), and resistant to hydrolysis except at temperatures above about 550 K (2). *N*-Methyliminodiacetic acid (Aldrich), sarcosine hydrochloride (Baker), *N*,*N*-dimethylglycine (K & K), and trisodium nitrilotriacetate hydrate (Aldrich) were used as received. The reactions were carried out in capped Teflon vessels (inner diameter 25 mm, height 36 mm, thickness of walls 1.2 mm) inside stainless steel autoclaves. A Teflon ring provided a seal. These vessels were found suitable for use with aqueous solutions up to 580 K, above which temperature Teflon deformed appreciably. The vessels were filled with 10 ml solution for experiments at 480 K and lower. This left a free volume of 7.7 ml. At higher temperatures, because of the expansion of water, only 5 ml of solution were used, in which case the free volume was 12.7 ml. Unless otherwise stated, the reactions were carried out under air (90 kPa at 294 K, when the vessels were sealed).

Solutions under dinitrogen were prepared by using solvents saturated with N_2, closing the vessels in a glovebox filled with dinitrogen (90 kPa at 294 K). Solutions under dioxygen were made up from solvents saturated with O_2, flushing the vessel with O_2, and capping the vessel quickly, a method which could only give approximate results. The ionic strength was maintained at 2.0 *m* in acid solutions by sodium trifluoromethanesulfonate prepared by neutralizing HTFMS with NaOH and recrystallizing the salt from water, and in alkaline solutions by NaCl.

Thermostating of the pressure vessels was achieved with a Blue M Conwate CW-160HF-1 forced convection oven. The reaction temperature was measured with an iron constantan thermocouple in conjunction with a Leeds-Northrup 7554K4 potentiometer. The cold junction reference was provided by a Thermoelectric 80020 Automated Ice Point Reference. The pressure within the vessels at the reaction temperatures was that of the solvent vapor plus the pressure of the gas present in the free volume on sealing. At selected intervals, vessels were removed from the oven and immediately immersed in cold water.

Gas Liquid Chromatography (glc)

Analyses by glc were performed by the method of Warren and Malec (18). Tabsorb^R (Regis Chemical Company) was used as column material. It was found that this method, employing the *N*-trifluoroacyl derivatives of the butyl esters of the amino acids, did not give quantitatively reproducible analyses for the tertiary amino acids methyliminodiacetate (MIDA) and *N*,*N*-dimethylglycine (DMG). Accordingly, glc was used only for qualitative purposes.

Titration Techniques

All pH measurements and titrations were performed at room temperature (294 K) with a Beckman 39502 combination electrode, standardized against Beckman buffer 22331 (pH = 6.86) and 0.05 *M* potassium diphthalate (Fisher) (pH = 4.01).

The analyses were performed with a Radiometer Model 11 Titrator coupled to a Radiometer Model 28 pH meter. A Radiometer G202 C glass electrode and a K401 saturated calomel electrode were used. The rate of delivery of titrant from a buret was regulated by a magnetic valve and was proportional to the difference of the measured pH and a set endpoint.

Complexometric titrations were performed with copper(II) nitrate and copper(II) chloride solutions standardized against 0.05 *M* Na_2H_2EDTA (Fisher) with murexide (Fisher) as indicator at pH = 8.5 with 0.05 *m* $Na_2B_4O_7 \cdot 10H_2O$ as buffer (19). Solutions in which NTA was dominant gave sharp endpoints. When appreciable

[3]The symbol pH_T refers to the pH of the solution as measured at temperature T kelvins, rather than the reaction temperature.

amounts of di- and monobasic amino acids were present, the colour change was much less distinct.

A potentiometric titration technique was therefore developed for the analysis of mixtures of mono-, di-, and tribasic amino acids, based on the work of Schwarzenbach and Biedermann (20), and Pinzer and Stewart (21). The method utilizes differences in the stability constants of complexes of Ca^{2+}, Zn^{2+}, and Cu^{2+} with the various chelating agents (22). The product solution was washed into a volumetric flask (usually 25 ml) and diluted to the mark. Three aliquots were pipetted, diluted to 40 ml, and neutralized (pH about 6.2) with dilute sodium hydroxide or nitric acid. This left one ionizable proton on the nitrogen atom of each molecule.

To the first aliquot was added an excess of 0.1 *m* copper(II) nitrate solution (pH = 4.15) over the total amount of amino acid expected to be present. The Cu^{2+} ion was able to displace the last proton from all species and neutralization of the liberated protons with 0.1 *m* NaOH gave the total number of moles of amino acid.

To the second aliquot a small excess of 0.1 *m* zinc(II) nitrate (pH = 5.1) was added. This released the protons on nitrogen from di- and tribasic acids only, and these protons were again titrated with 0.1 *m* sodium hydroxide. Pinzer and Stewart (21) used $Pb(NO_3)_2$ instead of $Zn(NO_3)_2$, but Pb^{2+} gave problems with the combination electrode we used, presumably due to precipitation of $PbCl_2$.

To the third aliquot was added an excess of 0.1 *m* $Ca(NO_3)_2$ solution (pH = 5.40). Calcium ion released the last proton only from $HNTA^{2-}$ under these conditions. Neutralization gave the amount of nitrilotriacetate present. The accuracy of the determination of NTA after addition of Ca^{2+} was 99 ± 1%, even when large amounts of dibasic acids were present. The accuracy of the analysis of the dibasic acids MIDA and IDA with Zn^{2+} was 98 ± 2%.

In the cases in which carbon dioxide was expected to be present, the reaction mixture was acidified and heated on a steam bath for 15 min. This was sufficient to remove interfering amounts of carbon dioxide, which caused unsharp endpoints.

Proton Magnetic Resonance Methods

Proton magnetic resonance spectra were obtained on a Varian HA-100 Spectrometer operated in the field sweep mode. The water resonance was used as the lock signal. As the chemical shifts of the methyl and methylene groups are very pH dependent, the solutions of the reaction products were made either alkaline with 3 *m* NaOH or acidic with 2 *m* HCl. Identifications were made by comparing chemical shifts and adding an extra amount of reagent and observing which peaks increased in size.

The use of water as a lock signal had the disadvantage that large amounts of energy were absorbed by the water, which distorted the other signals, so that reliable quantitative measurements could not be made in this way. Analysis of weighed mixtures of aminopolycarboxylates showed deviations from the calculated intensities, measured by integration or by the height of the peaks, by as much as 10%. Martell *et al.* (15) avoided this problem by exchanging hydrogen for deuterium in several steps, and obtaining spectra in D_2O.

Other Analytical Methods

Formaldehyde was detected as its 2,4-dinitrophenylhydrazone and estimated by titration with acid after addition of sulphite (23). Carbon monoxide was detected by mass spectroscopy after correction for the contribution to $m/e = 28$ due to the decomposition of CO_2^+ to CO^+ (2).

Results

1. Products

(*a*) *Gas–Liquid Chromatography*

After heating a solution of 0.10 *m* H_3NTA for 17 h at 473 K IDA, MIDA, GLY, and sarcosine (SARC) were identified as products. Decomposition of H_2IDA under the same conditions produced mainly SARC and some GLY. The spectrum of the decomposition products of methyliminodiacetic acid showed a broad peak at low retention time attributable to *N*,*N*-dimethylglycine (DMG), but small amounts of GLY, SARC, and IDA were also detected. The last compound was probably formed through decomposition of the ammonium salt of MIDA in the chromatograph.

(*b*) *Nuclear Magnetic Resonance*

At low pH IDA, MIDA, formaldehyde, and some formic acid were found as products of the decomposition of NTA. The ratio [IDA]/[MIDA] increased with increasing $[H^+]$, as did the yield of formaldehyde, and the ratio [IDA]/[MIDA] in 2.3 *m* acid was equal to the ratio of the yield of CO to that of CO_2 as determined by mass spectrometry. This indicates that MIDA was formed by decarboxylation, and IDA by a process leading eventually to CO and HCHO. The survival of relatively large concentrations of IDA indicated that its decomposition was markedly slower than that of NTA in acidic solutions. For $pH_{294} > 1.5$ the main mode of decomposition of NTA was decarboxylation, and there was no accumulation of the corresponding product MIDA, which showed that the rates of decarboxylation of MIDA and NTA are similar. Oxidation of NTA by dioxygen resulted in IDA, formaldehyde, and CO_2, but was unimportant except at temperatures above 500 K.

2. Kinetics

It must be recognized that, because of experimental and analytical difficulties, together with complications due to the protonation equilibria and (except at the highest and lowest pH) the

change of p*H* as the decompositions proceeded, the kinetic data reported here are to be regarded as only semiquantitative, except for those referring to NTA^{3-}, $HIDA^-$, and $HMIDA^-$, for which precision was better. They suffice, however, as keys to the mechanism of the reactions, and as empirical guides to the kinetic stability of NTA, IDA, and MIDA over wide ranges of temperature and p*H*.

(*a*) *Isoelectric Species*: *H_3NTA, H_2IDA, and H_2MIDA*

Since ΔH for the acid dissociation of these species is close to zero, and the acids are fairly "weak" at 293 K (22), it was assumed that solutions of the stoichiometric amino acids above contain the isoelectric species to the virtual exclusion of species containing more or fewer protons (*e.g.*, H_4NTA^+, H_2NTA^-), even at ~500 K. Subsequently, it was confirmed that decomposition pathways involving the cationic or anionic species could not contribute significantly to the initial decomposition rate in such solutions, so that the values of the rate coefficients k_{obs} listed in Table 1 under [HTFMS] = 0 can be identified with those governing the decompositions of the isoelectric species themselves.

In these solutions, the fractional extent of decomposition of a given amino acid over a given time interval t was independent of the initial amino acid concentration c_0 for $0.02 < c_0 < 0.3\ m$; thus, the reactions were first order in amino acid concentration. However, the accumulation of basic decomposition products resulted in a rise in p*H* which caused appreciable deviations from the integrated first order rate equation beyond about 40% reaction. This effect was also observed for NTA by Venezky and Moniz (13), who found essentially the same time dependence of [NTA] as reported here except for an "induction time" attributable to solubility problems associated with $c_0 \sim 0.3\ m$. The pseudo-first order rate constants k_{obs} were therefore calculated from the slope of the initially linear parts of plots of $-\ln([NTA]_t/[NTA]_0)$ *vs.* time (Table 1 and Fig. 1). The uncertainties quoted are fairly large because of the pronounced increase in p*H* for the experiments at high temperatures and the large influence of errors in the analyses of experiments at low temperatures in which only the first few percent of reaction could be measured. The presence of dioxygen (up to 90 kPa at 294 K) did not affect the rate of disappearance of the isoelectric or cationic forms of NTA, except at the highest temperature (503 K) with a small volume of solution and an excess of O_2 over NTA.

The temperature dependences of the values of k_{obs} listed in Table 1 under [HTFMS] = 0 for the decompositions of the isoelectric species H_3NTA, H_2IDA, and H_2MIDA (to MIDA, sarcosine, and dimethylglycine, respectively) yield the corresponding values of 106 ± 5,

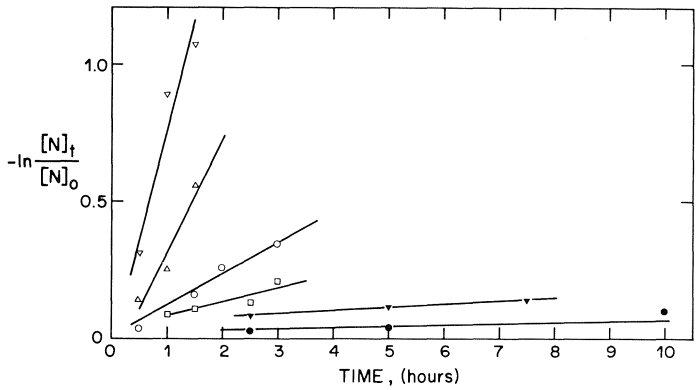

FIG. 1. First order plots of $-\ln [NTA]_t/[NTA]_0$ *vs.* time for the decomposition of H_3NTA; $C_0 = 0.10\ m$; $I = 2.0\ m$ with NaTFMS. ●, 418 K; ▼, 433 K; □, 453 K; ○, 473 K; △, 487 K; ▽, 503 K.

120 ± 14, and 92 ± 9 kJ mol^{-1} for the enthalpies of activation ΔH^* and -109 ± 10, -79 ± 29, and -144 ± 19 J K^{-1} mol^{-1} for the entropies of activation ΔS^*. The kinetic stabilities of these isoelectric acids are thus similar, the slightly lower reactivity of H_2MIDA becoming more evident at the higher temperatures.

(*b*) *Cationic Species*: H_4NTA^+, H_3IDA^+, and H_3MIDA^+

Addition of H^+ to solutions of H_3NTA, H_2IDA, and H_2MIDA produces significant concentrations of the cationic species H_4NTA^+, H_3IDA^+, and H_3MIDA^+ respectively (22), so that both isoelectric and cationic species need to be considered as contributing to the decomposition kinetics of NTA, IDA, and MIDA in solutions containing added acid. Under such conditions, the rate of decomposition of NTA can be described by (Fig. 2)

$$[1] \quad \frac{-d[NTA]}{dt} = \frac{(k_3 + k_4K_4[H^+])[NTA]}{(1 + K_4[H^+])} = k_{obs}[NTA] \text{ at a given } [H^+]$$

adopting a convention whereby k_n is the first-order decomposition rate coefficient of an amino polycarboxylate species having n ionizable protons, and K_n is the nth protonation constant. When $[H^+] > 0.26\ m$, the term involving k_3 may be neglected, and eq. 1 may be linearized to

$$[2] \quad (1/k_{obs}) = (1/k_4) + 1/(k_4K_4[H^+])$$

Plots of k_{obs}^{-1} *vs.* $[HTFMS]^{-1}$ gave good straight lines, and yielded the values of k_4 and K_4 listed in Table 2. On fitting the experimental data for $0.26 \leq [HTFMS] \leq 1.08\ m$ at 473 K and ionic strength 2.0 m to eq. 1 by regression analysis, the values $k_4 = 7.1 \times 10^{-4}$ s^{-1} and $K_4 = 1.7\ m^{-1}$ were obtained, in good agreement with those of Table 2. Values of the decomposition product ratio $[IDA]_t/[MIDA]_t$, calculated on the basis of these kinetic parameters and the assumption that H_4NTA^+ decomposes exclusively to IDA and H_3NTA to MIDA, agreed satisfactorily with those observed experimentally, and served to justify the assumption. The temperature dependence of k_4 (Table 2) gives $\Delta H^* = 150 \pm 14$ kJ mol^{-1} and $\Delta S^* = 11 \pm 32$ J K^{-1} mol^{-1} for the decomposition of H_4NTA^+.

The rates of decomposition of IDA and MIDA in acidified solutions (to sarcosine with traces of glycine, and to a mixture of dimethylglycine and sarcosine, respectively) were also first order in the original amino acids for $c_0 = 0.1$ to $0.3\ m$ at least, and dioxygen did not affect the rates even in 2 m HTFMS. The rate of decomposition of MIDA increased slightly with increasing [HTFMS], and the data of Table 1 suggest $k_3 \sim 2 \times 10^{-4}$ s^{-1} and $K_3 \sim 10\ m^{-1}$ at 503 K. For IDA, however, addition of HTFMS resulted in a *decrease* in the decomposition rate, indicating $k_3 < k_2$, and the values of k_{obs} in Table 1 suggest $K_3 \sim 2\ m^{-1}$ at 470–500 K with $k_2 \geq 10\ k_3$.

(c) Decomposition of the Sodium Salts of NTA, IDA, and MIDA

Solutions of Na_3NTA with initial concentrations from 0.03 to 0.20 m were decomposed at 560 K for 2 h at ionic strength 2.0 m with NaCl under dinitrogen. The slope of a plot of $\ln(-dc_0/dt)$ *vs.* $\ln c_0$ was 0.97 ± 0.07, indicating first order kinetics in Na_3NTA. This correlation was not valid when reactions were carried out under air as the oxidation by dioxygen was fairly rapid relative to these very slow rates of decarboxylation of NTA^{3-}, and all O_2 present was consumed within two hours. Proton magnetic resonance spectra showed much larger amounts of IDA for reactions carried out under pure O_2 than for those under air at the same pressure.

No significant yields of dibasic amino polycarboxylate anions were detected, when aqueous NTA^{3-} was decomposed in the absence of O_2, so that their rates of decomposition were comparable to or faster than that of NTA^{3-}. Semilogarithmic plots of $[NTA^{3-}]$ as time showed a rapid rate over the first few % reaction, presumably due to the presence of traces of oxygen, but subsequently were linear, and first order rate coefficients k_{obs} calculated from the linear portion are listed in Table 3. These coefficients were independent of both ionic strength and $[OH^-]$ for [NaOH] > 0.1 m, so that there was no significant reaction pathway involving nucleophilic attack by OH^- on NTA^{3-}. The data of Table 4 give $\Delta H^* = 103 \pm 5$ kJ mol^{-1} and $\Delta S^* = -166 \pm 8$ J K^{-1} mol^{-1} for the decomposition of NTA^{3-} at ionic strength 2.0 m.

Semi-quantitative experiments showed that the monoprotonated anion $HNTA^{2-}$, prepared in solution by addition of the stoichiometric amount of HCl to Na_3NTA, underwent decarboxylation more rapidly than NTA^{3-} by a factor of about 3 at 541 K and 4 at 575 K (ionic strength 2.0 m). Similar experiments showed that the doubly protonated ion H_2NTA^- was much more reactive, decomposing about one-third as rapidly as H_3NTA at 503 K. Thus,

[b]Initial [chelant] = 0.2 m.

extrapolation of the data of Tables 2 and 3 shows that the relative decomposition rates of NTA^{3-}, $HNTA^{2-}$, H_2NTA^-, H_3NTA, and H_4NTA^+ are $1:3:150:470:2 \times 10^4$ approximately, at 503 K and ionic strength 2.0 *m*.

For IDA^{2-} and $MIDA^{2-}$, the decomposition rates were again very slow but were poorly reproducible. The monoprotonated ions $HIDA^-$ and $HMIDA^-$, however, were respectively some 40 and 20 times more reactive than the dinegative anions at 573 K, and gave the reproducible ($\pm 5\%$) first order rate coefficients k_{obs} of Table 4, from which we calculate $\Delta H^* = 150 \pm 12$ and 148 ± 4 kJ mol^{-1}, and $\Delta S^* = -54 \pm 22$ and -62 ± 7 J K^{-1} mol^{-1}, for the respective decarboxylations.

Rate coefficients for the decomposition of NTA, obtained using both the conditions (566 K, pH_{294} 9.3) and method of computation of Martell *et al.* (15), were somewhat smaller (1.4×10^{-5} s^{-1}) than those reported by these authors (5.3×10^{-5} s^{-1}). It may be that the unlined titanium vessels used by Martell *et al.* (15) caused some catalysis of the reaction, especially since titanium is known to be attacked by alkaline water at high temperatures (4), but the discrepancy is not considered to be serious.

Discussion

This study confirms that the chelating agent NTA possesses good kinetic stability under hydrothermal conditions, especially at high p*H* in the absence of dioxygen. Its decomposition products include MIDA, IDA, DMG, SARC, and GLY. which are also chelating agents but which decompose at rates comparable to that of NTA and do not accumulate in high concentrations as NTA degrades. The ultimate products are CO, CO_2, HCHO, and various methylamines.

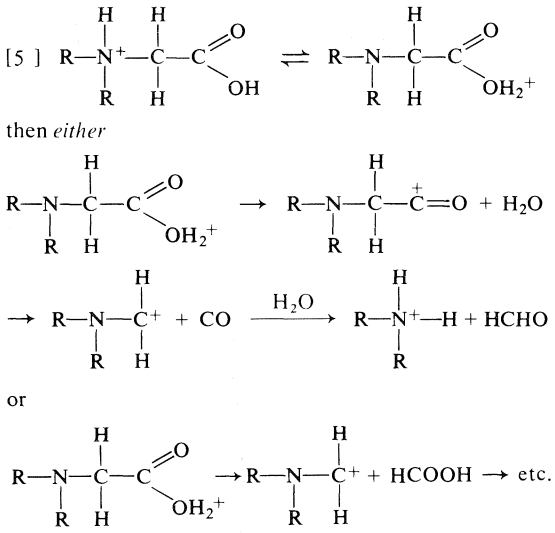
The species NTA^{3-}, $HNTA^{2-}$, H_2NTA^-, and H_3NTA all decompose *via* initial elimination of a CO_2 molecule (decarboxylation), but, while the decomposition rate of $HNTA^{2-}$ is only about three times that of NTA^{3-}, and H_3NTA about three times that of H_2NTA^-, H_2NTA^- is fully 70 times more reactive than $HNTA^{2-}$ (at 503 K). Similarly, $HMIDA^-$ is about 40 times less reactive than H_2MIDA, and $HIDA^-$ some 80 times less than H_2IDA at 503 K (from Tables 1 and 4). These observations indicate that decarboxylation is facilitated if at least two ionizable protons are present; since the N atom in an aminopolycarboxylate is always protonated in preference to a $—COO^-$ group, this means that protonation of a $—COO^-$ function is necessary if relatively facile decarboxylation is to occur. This is not surprising, as a proton transfer either within a $—CH_2COOH$ group

[3] 
or to $—CH_2COO^-$ from a neighboring $—CH_2COOH$ group

[4] 
would obviate the development of a carbanion when CO_2 separates. Mechanism 4 seems more likely, especially since protonation of *all* N and $—COO^-$ sites results in a change of mechanism from decarboxylation to deacetylation (from C—C bond fission to C—N bond fission) and, in the case of IDA, a marked *decrease* in reactivity on going from H_2IDA to H_3IDA^+.

The high kinetic stability of NTA^{3-} is due to the strongly negative entropy of activation (-166 J K^{-1} mol^{-1}), as ΔH^* is much the same as for the other decarboxylations (~ 110 kJ mol^{-1}). Conversely, H_4NTA^+ is relatively reactive by virtue of its positive ΔS^* for deacetylation ($\sim +11$ J K^{-1} mol^{-1}), and indeed ΔH^* is rather higher (150 kJ mol^{-1}) than for most comparable decarboxylations, presumably as a result of the difference in mechanism.

The decomposition of aminopolycarboxylic acids by deacetylation might be expected to yield glycollic acid, $HOCH_2COOH$, if direct hydrolysis of the $N—CH_2COOH$ bond were the initial step, but in no case could glycollic acid be detected amongst the decomposition products. Formaldehyde and carbon monoxide were major products, but it was established independently that glycollic acid yields only minor amounts of HCHO under the conditions of these experiments. Formic acid, on the other hand, decomposes extensively to CO and water under these conditions. Thus, the crucial step in these decompositions probably involves the separation of either CO or HCOOH, followed by the release of HCHO.



A somewhat similar process has been proposed for the decomposition of glutaric acid (the carbon analogue of IDA) in dilute sulfuric acid (24). Variants of mechanism 5 in which the initiating step is nucleophilic attack of H_2O on the α-carbon atom can be readily devised, but not distinguished operationally.

The formation of the familiar reducing agents, carbon monoxide and formaldehyde, in this pathway serves to emphasize that any organic matter is to be regarded as a potential reductant in aqueous systems at high temperatures, where kinetic barriers are likely to be overcome (2). Similarly, the emergence of dioxygen as an aggressive oxidant in water at high temperatures is illustrated by this work. On the other hand, the high temperature protonation constants K_n estimated here, though approximate, are not very different from those measured at room temperature (22).

Finally, noting that the rate of decomposition of $HNTA^{2-}$, the predominant form of NTA at the pH of natural waters, will be roughly that of NTA^{3-} at low temperatures, we can estimate from the data of Table 3 that the thermal halflife of aqueous NTA in the environment would be on the order of eight million years, since we have shown that oxidation by O_2 is competitive with decarboxylation only at the highest temperatures. Thermal decarboxylation or oxidation of free NTA therefore cannot compete with the photolysis of NTA transition-metal chelates (25, 26) or with biodegradation (18) as mechanisms for the elimination of pollutant NTA from rivers or lakes.

Chelating agents in high temperature aqueous chemistry. 2. The thermal decomposition of some transition metal complexes of nitrilotriacetate (NTA)

MEINDERT BOOY[1] AND THOMAS WILSON SWADDLE[2]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received November 10, 1976

MEINDERT BOOY and THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 1770 (1977).

The kinetics and mechanism of decomposition of NTA complexes of Fe^{III}, Fe^{II}, Co^{II}, Ni^{II}, and Cu^{II} under hydrothermal conditions (425–573 K) have been examined. The relative rates at 573 K are $Co^{II}NTA^- < NTA^{3-} \lesssim Fe^{II}NTA^- < Ni^{II}NTA^- < Fe^{III}NTA^0 < H_3NTA^0 < Cu^{II}NTA^- < H_4NTA^+$. Aqueous $Co^{II}NTA^-$ and $Fe^{II}NTA^-$, like NTA^{3-}, decomposed at 573 K by decarboxylation, precipitating $Co(OH)_2$ and Fe_3O_4 respectively; $Ni^{II}NTA^-$ precipitated $Ni(OH)_2$ initially but subsequently Ni metal. At 530 K, $Fe^{III}NTA^0$ solutions precipitated $Fe^{II}{}_3(NTA)_2 \cdot H_2O$, but at higher temperatures Fe_3O_4 formed, the NTA ligand being reduced to HCHO and iminodiacetate (IDA) rather than decarboxylated. Similarly, $Cu^{II}NTA^-$ gave IDA and HCHO at temperatures as low as 425 K, forming first Cu^I (which precipitated as CuCl in the presence of Cl^-) and then metallic Cu. The applicability of NTA to corrosion control in boilers and to ^{60}Co removal from water-cooled nuclear reactors is briefly considered. The half-life of $Fe^{III}NTA$ in the hydrosphere is estimated at 80 years (*cf.* 8×10^6 years for free NTA), in the absence of photolysis or biodegradation.

MEINDERT BOOY et THOMAS WILSON SWADDLE. Can. J. Chem. **55**, 1770 (1977).

On a déterminé la cinétique et le mécanisme de décomposition des complexes de NTA avec Fe^{III}, Fe^{II}, Co^{II}, Ni^{II} et du Cu^{II} dans des conditions hydrothermiques (425–573 K). Les vitesses relatives à 573 K sont $Co^{II}NTA^- < NTA^{3-} \lesssim Fe^{II}NTA^- < Ni^{II}NTA^- < Fe^{III}NTA^0 < H_3NTA^0 < Cu^{II}NTA^- < H_4NTA^+$. Comme le fait NTA^{3-}, des solutions aqueuses de $Co^{II}NTA^-$ et de $Fe^{II}NTA^-$ à 573 K se décomposent par décarboxylation et provoquent respectivement la précipitation de $Co(OH)_2$ et de Fe_3O_4; au début de la réaction avec $Ni^{II}NTA^-$, il y a précipitation de $Ni(OH)_2$ mais au fur et à mesure que la réaction progresse, il y a précipitation de nickel métallique. A 530 K, des solutions de $Fe^{III}NTA^-$ provoquent la précipitation de $Fe^{II}{}_3(NTA)_2 \cdot H_2O$ mais à des températures plus élevées, il y a formation de Fe_3O_4 puisque le ligand NTA est réduit en HCHO et iminodiacétate plutôt que d'être décarboxylé. De la même manière, $Cu^{II}NTA^-$ conduit à IDA et HCHO à des températures aussi basses que 425 K conduisant à la formation en premier de Cu^I (qui précipite sous forme de CuCl en présence de Cl^-) et ensuite de Cu sous forme métallique. On a considéré les possibilités d'appliquer le NTA pour contrôler la corrosion dans des bouilloires et pour enlever du ^{60}Co des réacteurs nucléaires refroidis à l'eau. On estime que le temps de demi-vie du $Fe^{III}NTA$ dans l'hydrosphère est d'environ 80 ans (par opposition à 8×10^6 ans pour le NTA à l'état libre) en l'absence de photolyse ou de biodégradation.

[Traduit par le journal]

Introduction

The possibility of using chelating agents, in particular nitrilotriacetate (NTA), in the control of corrosion processes in boilers (1, 2) and of cobalt-60 transport in water-cooled nuclear reactors (3) prompted our study (4) of the kinetics of decomposition of aqueous NTA over a wide range of temperature and p*H*. That study provided incidentally an upper limit to the environmental half-life of free NTA reaching the hydrosphere through its use as a builder in detergents; such NTA may present a biological hazard through mobilization of heavy metals, or through decomposition to secondary amines and thence to carcinogenic *N*-nitrosamines (5–9). The kinetic data provided by the study (4) would not, however, be directly applicable to conditions in boilers, nuclear reactors, or the hydrosphere if the decomposition of NTA were significantly accelerated or retarded by chelation of the metal ions which would inevitably be present.

Accordingly, the present article describes a semi-quantitative study of the effect of chelation of iron(II), iron(III), cobalt(II), nickel(II), and copper(II) upon the kinetics and mechanism of thermal degradation of aqueous NTA. The

photochemical decomposition of $Fe^{III}NTA$ (10, 11) has been shown to proceed by deacetylation (loss of $—CH_2COO—$) rather than by decarboxylation (loss of CO_2), and the photochemical degradations of $Cu^{II}NTA^-$ (12) and Fe^{III}-$EDTA^-$ (13, 14) have also been examined. The thermal decomposition of aqueous NTA complexes, however, seems to have been little studied, although extensive research in the U.S.S.R. has shown that EDTA complexes of many metal ions have half lives of several hours in water at 473 K, the relative kinetic stabilities being $Na_2CaEDTA \sim Na_2MgEDTA > Na$-$Fe^{III}EDTA > Na_2H_2EDTA > Na_2CuEDTA$ (15, 16), and it has been found (2) that hydrothermal decomposition of iron chelates in boilers can produce corrosion-resistant coatings of magnetite on steel surfaces.

Experimental

Experimental procedures were in general those described previously (4). Unless otherwise stated, analytical grade hydrated transition metal chlorides were used, and shown to be of acceptable purity by complexometric analysis using EDTA. Iron was determined by titration with $K_2Cr_2O_7$ after reduction to iron(II) with $SnCl_2$ (17). Metal chelates were prepared according to Rajabalee (18). Reaction mixtures were made up by weighing the reagents into the PTFE-lined autoclaves, and adding deoxygenated deionized water and closing the vessels under dinitrogen.

For analysis of the chelating agents after reaction, the transition metal ions were removed by addition of sodium hydroxide solution and filtration with a sintered glass funnel. Copper(II) was removed by reduction with a small excess of hydrazine and removal of the yellow product on a sintered glass filter, but the buffer action of the excess hydrazine limited the use of this preliminary procedure to the determinations of di- and tribasic acids using zinc(II) (4), where the endpoints of the titrations are at pH 6.0.

Results

1. Nitrilotriacetatoiron(III)

This complex decomposed readily above 530 K with reduction of iron(III) to iron(II), yielding the solid $Fe^{II}_3(NTA)_2 \cdot H_2O$ (see below) at 530 K, and magnetite at higher temperatures. The rate of reaction was the same whether the starting material was $Fe^{III}NTA \cdot H_2O$ or an equimolar mixture of $FeCl_3$ with Na_3NTA, *i.e.*, it was unaffected by the presence of Na^+ or Cl^-. The proton magnetic resonance spectrum of a solution, initially 0.3 m in each of $FeCl_3$ and Na_3NTA, showed after 2 h at 563 K that iminodiacetate (IDA, formed by deacetylation) and decarboxylation products (notably *N*-methyliminodiacetate, MIDA) were present in small but approximately equal amounts. This indicated that deacetylation was of comparable importance to decarboxylation (in contrast to the decomposition of Na_3NTA, etc. (4)), a conclusion which was verified by the identification of formaldehyde as a major product, and that IDA and MIDA decomposed at rates similar to $Fe^{III}NTA$ and therefore did not accumulate as reaction products.

The rates of disappearance of NTA were first order in $[Fe^{III}NTA]$, and first order rate coefficients k were estimated ($\pm 20\%$) for solutions initially 0.1 m in $Fe^{III}NTA$ and ionic strength 2.0 m (with NaCl) from the expression

$$[1] \qquad kt = \ln([NTA]_0/[NTA]_t)$$

where $[NTA]_t$ represents the total NTA concentration at time t. Values of $10^4 k$ (s^{-1}) of 0.22, 0.60, 0.94, 1.1, and 1.4 were obtained at temperatures of 503, 540, 554, 562, and 573 K respectively, and are represented to within the experimental uncertainty by the enthalpy ΔH^* and entropy ΔS^* of activation given in Table 1.

When $Fe^{III}NTA$ was prepared in solution at 503 K using $Fe(NO_3)_3$ rather than $FeCl_3$, or when $NaNO_3$ was added as such in 1.5:1 molar ratio to $Fe^{III}NTA$, the rate of disappearance of NTA increased about tenfold, the solution of products being bright yellow (due to iron(III)) and a red, non-ferromagnetic precipitate (presumably α-Fe_2O_3) being formed. This occurred even though $NaNO_3$ had no effect on NTA in the absence of iron(III), which indicates that the role of nitrate in promoting the decomposition of $Fe^{III}NTA$ consisted in maintaining the iron in the trivalent state.

In an equimolar mixture of $FeCl_3$ and H_3NTA, decomposition was almost complete in 4.5 h at 503 K, and almost all the iron was reduced to iron(II). Thus, hydrogen ion facilitates the redox (deacetylation) decomposition pathway, the decomposition being only about one-third complete for $Fe^{III}NTA$ alone under these conditions.

2. Nitrilotriacetatoferrate(II) Ion

On heating at 503 K, a solution 0.1 m in $FeCl_2$ and H_3NTA deposited the white solid $Fe_3(NTA)_2 \cdot H_2O$, which was identified by titration and by its infrared spectrum (18), whereas a similar solution of $FeCl_2$ and Na_3NTA precipitated a small amount of a black solid. The

black ferromagnetic solid product obtained at higher temperatures was identified by X-ray diffraction as magnetite, and was seen under the scanning electron microscope to be in the form of good octahedra up to about 50 μm across. The rate of disappearance of NTA was greater when $[Na_3NTA]:[FeCl_2]$ was 2:1 rather than 1:1.

For a variety of initial $[Fe^{II}NTA^-]$, the fractional extent of loss of NTA over a given time interval was the same, at a given temperature, so that the decomposition was first order in $[Fe^{II}NTA^-]$. Unfortunately, a meaningful representation of the time-dependence of the concentration of NTA surviving in solution in terms of the integrated first order rate equation could not be obtained, since the main slow phase of the disappearance of NTA from the solution was preceded by an apparent accelerated initial stage (probably due to the deposition of a small amount of $Fe_3(NTA)_2 \cdot H_2O$, as noted above) and followed by a second accelerated phase. The latter probably originated in heterogeneous catalysis of the decomposition reaction by the precipitated magnetite, as it was established separately that aqueous Na_3NTA decomposed to the extent of 35% in 2 h at 573 K under N_2 in the presence of added magnetite, but only 9% in its absence. This effect was not observed in the decomposition reactions of $Fe^{III}NTA$, which were relatively rapid and qualitatively different from those of $Fe^{II}NTA^-$.

On the other hand, the yield of Fe_3O_4, determined by dissolving the black precipitate in concentrated HCl and analyzing it for total iron (17), indicated that the dissolved iron content declined smoothly in accordance with the integrated first order rate equation, with rate coefficient $k = (1.6 \pm 0.2) \times 10^{-5}$ s^{-1} at 566 K. This rate of decomposition is of the same order of magnitude as that reported by Castle and Thompson (19) for the decomposition of iron(II) hydroxide in aqueous suspensions at 573 K according to the Schikorr reaction

$$[2] \qquad 3Fe(OH)_2 \rightarrow Fe_3O_4 + H_2 + 2H_2O$$

The ^1H nmr spectrum of solutions, initially 0.3 m in each of Na_3NTA and $FeCl_2$, decomposed at 571 K for 2 h, showed the presence of decarboxylation products such as MIDA in small amounts, but no deacetylation products such as IDA could be detected except when the reaction had been carried out under air (when iron(III) was formed). These observations confirmed that deacetylation in non-acidic solutions is associated with oxidation of the ligand by the metal ion.

The addition of HCl or NaOH to solutions of $Fe^{II}NTA^-$ produced modest increases in the rate of disappearance of NTA; thus, at 571 K for solutions initially 0.1 m in $FeCl_2$ and Na_3NTA, 20% NTA was lost after 2 h, as compared with 35% with addition of an equimolar amount of HCl and 42% with NaOH.

3. Nitrilotriacetatocobaltate(II) Ion

The initial decomposition of Co(II)–NTA complexes showed the same behaviour as that of Fe(II)–NTA complexes. At 503 K, $CoCl_2$ + H_3NTA gave $Co_3NTA_2 \cdot H_2O$. Small amounts of

brown solid, most likely oxidized $Co(OH)_2$, were formed upon heating solutions of $CoCl_2$ + Na_3NTA at temperatures above 500 K. After 44 h at 573 K only 10% of the initial amount of cobalt was precipitated. In each case, direct complexometric titration showed that the extent of decomposition of NTA was equal to the extent of formation of $Co(OH)_2$. The ^1H nmr spectrum after reaction for 8 h at 573 K showed the presence of NTA but only very small amounts of decarboxylation products and IDA, the latter most likely due to traces of dioxygen. The precipitation of Co(II) by hydroxide in the analytical procedure (4) was incomplete, and reliable analyses for chelating agents could not be obtained following attempts to remove cobalt(II) by this method. However, all other evidence showed that the $Co(II)NTA^-$ complex was kinetically the most stable of the complexes studied.

4. Nitrilotriacetatonickelate(II) Ion

When solutions containing equimolar amounts of Na_3NTA and $NiCl_2$ were heated at 573 K under N_2, $Ni(OH)_2$ was precipitated initially, but was subsequently reduced to metallic nickel. After 44 h, over 80% of the nickel had been precipitated as the metal, and the solution was almost colorless. Complexometric titrations showed that the NTA content of the solutions was only slightly in excess of the remaining nickel(II) at any time, that is, that the reduction of nickel(II) proceeded at essentially the same rate as the decomposition of NTA, and the two reactions are probably causally connected. The hydrothermal reduction of nickel(II) to the metal by the chelating agents ethylenediamine and diethylenetriamine at about 570 K has been observed in our laboratory by J. C. Arnold.

5. Nitrilotriacetatocuprate(II) Ion

Of the divalent transition metal ions, copper(II) has the highest stability constant for the formation of an NTA complex, and this strong interaction manifests itself (for example) in the dissolution of copper tubing by aqueous NTA at $pH \sim 11$ at room temperature, giving $NaCuNTA \cdot H_2O$ (20). Thus, although copper(II) often acts as an oxidant, *e.g.* of aliphatic amines (21), copper(I) complexes usually disproportionate to copper metal and their copper(II) analogues because of the high thermodynamic stability of the latter (22).

It was therefore not surprising that aqueous $Cu^{II}NTA^-$ decomposed readily at 425 K to deposit essentially pure copper metal; the color of the solution changed from blue to green to yellow as the reaction proceeded. Solutions of $CuCl_2$, similarly treated, showed no change other than the precipitation of a small quantity of a basic copper(II) chloride. When the solutions of $Cu^{II}NTA^-$ were made up from solid $NaCuNTA \cdot H_2O$ (20), the hydrothermally produced copper metal took the form of a fine powder, whereas solutions made from equimolar amounts of Na_3NTA and $CuCl_2$ yielded initially solid CuCl and subsequently large particles of copper metal. The presence of Cl^- also slowed the reduction to copper metal significantly; at 433 K, the amounts of copper produced in 5 h in the presence of 0.0, 0.2, and 1.8 *m* NaCl were 56, 52, and 21% respectively. In a highly acidic solution (initially 0.1 *m* in each of H_3NTA and $CuCl_2$; pH_{293} 1.2), however, the solid product was CuCl (20%) and about 80% of the copper(II) remained in solution after 2 h at 473 K, in which time the decomposition of NTA was about 50% complete; in this case, therefore, the latter reaction proceeded mainly by a pathway *not* involving reduction of copper(II).

An excess of copper(II) over complexing agents in the products was also observed for mixtures of $CuCl_2$ and Na_2H_2EDTA ($pH_{293} = 2$, and also when $pH_{293} = 6$ with NaOH). CuCl was the main product but some Cu metal was also present. Non-oxidative pathways were apparently predominant and the decomposition of $Cu^{II}EDTA^{2-}$ was faster than the decomposition of Cu(II)NTA under the same conditions. Iminodiacetatocopper(II) gave CuCl and Cu metal in a ratio 2:1. The rates of decomposition at 433 K decreased in the order EDTA $\gg$ IDA $>$ NTA.

The decomposition of the organic part of the complexes gave formaldehyde, and the mass spectrum of the gaseous products showed CO_2 and some CO. We also found that at 473 K aqueous $CuCl_2$ was reduced to CuCl by formaldehyde (23). ^1H nmr spectra indicated IDA as the major product and MIDA as a minor product. Only in the case of $H_4Cu(NTA)_2$ at $pH_{293} \sim 2.5$ were significant amounts of aminomonocarboxylic acids (mainly sarcosine) and methylamines (mainly dimethylamine) detected.

The amount of aqueous NTA that was

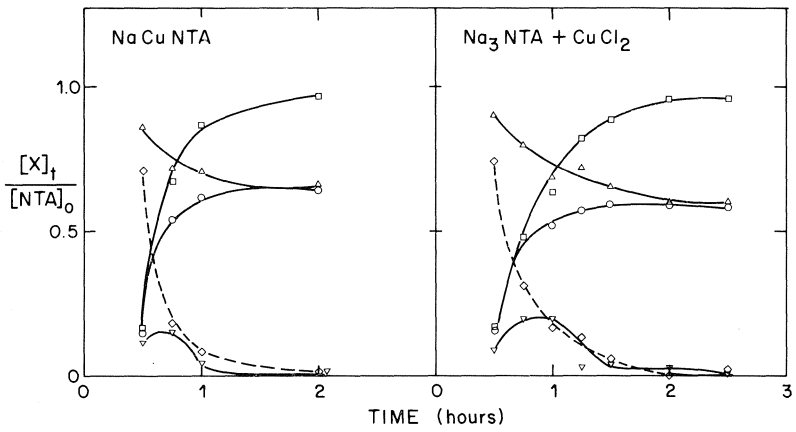

FIG. 1. The decomposition of $Cu^{II}NTA^-$ at 473 K. $[Cu^{2+}]_0 = [NTA^{3-}]_0 = 0.1\ m$. □, $[Cu(0)]_t$, copper metal formed; △, $[L]_t$, total amount of chelating agent; ○, $[L]_t - [Cu(II)L]_t$, uncomplexed chelating agent; ◇, $[Cu(II)]_t = [L]_t - ([L]_t - [Cu(II)L]_t)$; ▽, $[Cu(I)]_t = 1.0 - [Cu(0)]_t - [Cu(II)]_t$.

oxidized by an initially equimolar amount of solid CuCl in 2 h at 473 K was about half that oxidized by the same molar amount of copper(II). The decomposition of 2CuCl + Na_3-NTA progressed somewhat further than for $CuCl_2$ + Na_3NTA after 5 h at 433 K and no CuCl was detected among the products, but for 4CuCl + Na_3NTA considerable amounts of CuCl were still present after the reaction.

In the decomposition of aqueous NaCuNTA, or of $CuCl_2$ + Na_3NTA, complete reduction of copper(II) to the metal resulted in 75% loss of NTA, the remaining 25% of the reduction being accounted for by the further oxidation of the products IDA, HCHO, etc. This is consistent with the stoichiometry

$$[3]\quad Cu^{2+} + \begin{matrix}\diagdown\\ \diagup\end{matrix}\overset{+}{N}H{-}CH_2COO^- + H_2O \rightarrow$$

$$Cu + CO_2 + \begin{matrix}\diagdown\\ \diagup\end{matrix}NH_2^+ + HCHO + H^+$$

which also accounts for the observed initial fall in pH; eventually, however, the pH again rose because of the incursion of non-oxidative degradation of the aminoacids (*e.g.*, decarboxylation). The kinetics of the decompositions were followed at 433, 453, and 473 K (470 K in the last case for $CuCl_2$ + Na_3NTA) with respect to various reactants and products, and are illustrated by Fig. 1. The amount of Cu(II) remaining in solution was calculated from the difference between the total amount of complexing agent (determined after precipitation of copper ions with hydrazine by potentiometric titration after addition of $Zn(NO_3)_2$) and the amount of free ligand (from direct titration of the reaction mixture with $CuCl_2$ and murexide as indicator). The disappearance of Cu(II) followed closely the formation of copper metal. Formally, [Cu(I)] can be expressed as the amount of copper not accounted for by copper metal and Cu(II), and Fig. 1 shows clearly the initial build-up and subsequent decay of copper(I) expected of it as an intermediate in a series of consecutive reactions.

The formation of copper metal followed first order kinetics in $[Cu^{II}NTA^-]$ to 80% conversion with an induction time of about 0.4 h. The rate for this process was faster for NaCuNTA than for $CuCl_2$ + Na_3NTA, presumably because solid CuCl was formed as an intermediate in the latter case and its rate of disappearance was of the same order of magnitude as that of its formation. The rates of formation of copper metal were used to provide approximate first order rate coefficients k (±15%) for the decomposition of $Cu^{II}NTA^-$. For NaCuNTA, $10^4\ k$ (s^{-1}) was 0.7, 2.6, and 10 at 433, 453, and 473 K; for Na_3NTA + $CuCl_2$, $10^4\ k$ was 0.5, 2.5, and 6 at 433, 453, and 470 K.

Discussion

Of the transition metal NTA complexes considered here, only $Co^{II}NTA^-$ decomposed by simple decarboxylation of the ligand and deposition of $Co(OH)_2$, without net reduction or oxidation of the central metal atom. This complex showed remarkable thermal stability, being

less reactive than NTA^{3-} itself by an order of magnitude (Table 1). Thus, in the absence of complicating redox processes, coordination stabilizes the NTA^{3-} ligand.

Nitrilotriacetatoferrate(II) decomposed exclusively by decarboxylation, as did the cobalt(II) complex, but the product $Fe(OH)_2$, being unstable in aqueous systems near 570 K, decomposed to magnetite (19), which appeared to catalyze further decomposition of the NTA to a moderate extent. At low p*H*, $Fe(OH)_2$ formation would be suppressed, and indeed we found the solid product formed under acidic conditions to be $Fe_3(NTA)_2 \cdot H_2O$, which presumably resulted from reaction of $FeNTA^-$ with the $Fe^{2+}(aq)$ released as the ligand decomposed.

Iron(III) oxidized the NTA ligand with the formation of IDA, formaldehyde, and CO_2, whereupon the iron(II) product yielded magnetite as above. The oxidation is rapid relative to the decarboxylation of NTA^{3-}, etc., because the very favorable enthalpy of activation outweighs the strikingly negative entropy of activation in the temperature range of interest.

The decomposition of $Cu^{II}NTA^-$ clearly proceeded via a copper(I) intermediate, which in the presence of chloride yielded solid CuCl but otherwise disproportionated

$$[4] \qquad 2Cu^{II} \rightarrow 2Cu^{I} \begin{cases} \rightarrow Cu^0(s) + Cu^{II} \\ \xrightarrow{Cl^-} 2CuCl(s) \end{cases}$$

Solid CuCl would act as a buffer for Cu(I) in solution. As noted above, the disproportionation of copper(I) is favored by interaction with ligands such as NTA which strongly stabilize copper(II). The stability constant of $Cu^{II}IDA^0$ is much smaller than that of $Cu^{II}NTA^-$ (by a factor of at least 200, at 298 K (24)), so that the IDA formed by oxidation of NTA not only cannot compete effectively with the remaining NTA for coordination to copper(II) but is also less conducive than NTA to reaction 4 even when coordinated. Consequently, IDA accumulated as the chief oxidative degradation product, while the products of lower molecular weight (sarcosine and dimethylamine) were formed by decarboxylation rather than further oxidation of IDA. The oxidation of the NTA ligand in $CuNTA^-$ and in $FeNTA^0$ probably proceeded through successive one-electron transfers, the first being rate determining, and indeed a mechanism of this type has been proposed by Carey and Langford (14) for the photochemical degradation of $Fe^{III}EDTA^-$.

The product distributions in the oxidations of NTA by metal ions were in accordance with the schemes proposed by Langford and co-workers for the photolysis of $Fe^{III}NTA$ (10) and $Cu^{II}NTA^-$ (12), if it is recognized that their experiments were carried out under air and reoxidation of the reduced metal ions could occur (and, in particular, no copper(I) was isolated).

The studies described here and elsewhere (4) demonstrate that the high hydrothermal stabilities of NTA^{3-}, $Fe^{II}NTA^-$, and especially $Co^{II}NTA^-$ augur well for the application of NTA as a decontaminating reagent for the removal of cobalt-60 ferrite deposits in the heat transfer systems of water-cooled nuclear reactors under operating conditions of relatively high temperature and p*H* in conjunction with reducing conditions. Furthermore, the slow deposition of magnetite, copper, and nickel from NTA complexes in solution may lead to the formation of cohesive protective coatings in place of mobile particulate corrosion products. On the other hand, heterolytic catalysis of NTA decomposition on magnetite surfaces was suggested by some of our observations, and radiolysis of aqueous NTA has not been considered. Complete recovery of dissolved $^{60}Co^{II}NTA^-$ from solution may also prove to be technically difficult. It is perhaps more likely that NTA will find application in corrosion control in conventional steam-raising.

Finally, the activation parameters of Table 1 predict that, while NTA itself is expected to have a thermal half-life of some 8 million years in the hydrosphere (assumed 288 K, p*H* 7) (4), complexing with the ubiquitous iron(III) will reduce its environmental half-life to about 80 years as a consequence of the low ΔH^* for decomposition of $Fe^{III}NTA$. The corresponding half-life for $Cu^{II}NTA^-$ is 3000 years. By contrast, photochemical degradation of $Fe^{III}NTA$ or biodegradation of the free ligand should, when available, consume NTA pollutants in a matter of weeks (5–14).

Far infrared absorption and rotational vibrations of the guest molecules in structure I clathrate hydrates between 4.3 and 100 K

JOHN E. BERTIE AND STEPHEN M. JACOBS

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 15, 1976

JOHN E. BERTIE and STEPHEN M. JACOBS. Can. J. Chem. **55**, 1777 (1977).

The infrared spectra between 330 and 15 cm^{-1} of the structure I clathrate hydrates of ethylene oxide, cyclopropane, and trimethylene oxide, at 4.3 K are presented. The spectra have an unusually high signal-to-noise ratio made possible by a Michelson interferometer and a silicon bolometer detector which operates at 1.2 K. Rotational vibrations of the guest molecules were observed at 65.0 and 35.6 cm^{-1} for ethylene oxide and at 69 and 50 cm^{-1} for trimethylene oxide. Inter-guest coupling of rotational vibrations is small and the two frequencies are assigned to vibrations about different inertial axes. The resulting force constants are 487 and 264 ferg rad^{-2} for ethylene oxide and 1190 and 1130 ferg rad^{-2} for trimethylene oxide and are discussed in relation to the barriers to reorientation of the guest molecule. The bands due to these vibrations are fairly sharp at 4.3 K, but are broad and poorly defined at 100 K. The guest and water vibrations interact predominantly through their transition dipoles, although the main contribution to the force constants of the rotational vibrations is from steric forces. The absorption by the water vibrations above 100 cm^{-1} is very similar for ethylene oxide and cyclopropane hydrates but significantly different for trimethylene oxide hydrate. Strong objections exist to the obvious interpretations of this difference which remains unexplained.

JOHN E. BERTIE et STEPHEN M. JACOBS. Can. J. Chem. **55**, 1777 (1977).

On présente les spectres infrarouges, à 4.3 K et entre 330 et 15 cm^{-1}, de la structure I des hydrates de clathrate de l'oxyde d'éthylène, du cyclopropane et de l'oxyde de triméthylène. Les spectres ont un rapport signal à bruit qui est anormalement élevé et qui est rendu possible par un interféromètre de Michelson et un détecteur bolomètre de silice qui opère à 1.2 K. On a observé les vibrations rotationnelles des molécules hôtes à 65.0 et 35.6 cm^{-1} pour l'oxyde d'éthylène et à 69 et 50 cm^{-1} pour l'oxyde de triméthylène. Le couplage des vibrations de rotation entre hôtes est faible et on peut attribuer les deux fréquences à des vibrations autour d'axes d'inertie différents. Les constantes de force qui en résultent sont de 487 et 264 ferg rad^{-2} pour l'oxyde d'éthylène et de 1190 et 1139 ferg rad^{-2} pour de l'oxyde de triméthylène et on les discute par rapport aux barrières de réorientation de la molécule hôte. Les bandes dues à ces vibrations sont assez précises à 4.3 K mais sont plus larges et mal définies à 100 K. Les vibrations de la molécule hôte et de l'eau interagissent d'une façon prédominante par l'intermédiaire de leurs dipoles de transition quoique la contribution principale des constantes de force des vibrations rotationnelles provient de forces stériques. L'absorption par les vibrations de l'eau au-dessus de 100 cm^{-1} est très semblable pour l'oxyde d'éthylène et les hydrates de cyclopropane mais diffère d'une façon importante pour l'hydrate d'oxyde de triméthylène. Des objections très fortes existent au sujet des interprétations qui paraissent évidentes pour ces différences qui demeurent inexpliquées.

Introduction

The far-infrared spectra of the structure I clathrate hydrates (1) of ethylene oxide (2) and cyclopropane (3) at 100 K have been reported (4, 5). The rotational vibrations of the ethylene oxide molecules yield diffuse absorption between 100 and about 50 cm^{-1} (4, 5). At 100 K the water molecules have essentially fixed orientations (6) but the ethylene oxide molecular dipoles reorient at about 6 GHz (7). At 4.3 K the ethylene oxide molecules also have essentially fixed orientations (8) so that the clathrate hydrate has an essentially static structure with the water molecules and, probably, the guest molecules (8) orientationally disordered. It was of interest, therefore, to see if the absorption by the rotational vibrations of the guest molecules is sharper at 4.3 K than at 100 K and, if it is sharper, to obtain from the absorption frequencies a measure of the intermolecular forces acting on the guest molecules in the cages of water molecules.

This paper presents the spectra between 120 and about 15 cm^{-1} of the structure I clathrate hydrates and deuterates of ethylene oxide, cyclopropane, and trimethylene oxide (9–11) between

4.3 and 100 K, and spectra between 330 and 120 cm^{-1} of these compounds at 4.3 K.

No previous reports of the far-infrared spectra of structure I hydrates below 100 K exist. While this work was in progress, spectra were reported between 65 and 4 cm^{-1} of the structure II hydrate of tetrahydrofuran between 80 and 17 K (12) and between 100 and 10 cm^{-1} of the mixed structure II hydrates of hydrogen sulfide with carbon tetrachloride, chloroform, and methylene chloride, between 45 and 95 or 290 K (13).

Experimental

The preparation and characterization of the hydrates and deuterates of ethylene oxide (composition used: 6.7 $C_2H_4O{\cdot}46H_2O$ (or D_2O)) and cyclopropane ($6C_3H_6{\cdot}46H_2O$) have been described (4, 5). Structure I trimethylene oxide hydrate and deuterate were prepared by rapidly cooling to 77 K, in vacuum, de-gassed solutions of composition $6C_3H_6O{\cdot}46H_2O$ (or D_2O), then holding them at $-27°C$ for about two weeks before recooling them to 77 K for study (14). X-ray powder diffraction photographs and mid-infrared spectra (5, 14–16) showed the hydrates (deuterates) to be pure. To keep them pure, they were kept under liquid nitrogen and manipulated in a dry, 77–100 K, nitrogen atmosphere.

Spectroscopic pellet samples were made by mixing powdered hydrate and 0.50 g of adamantane in a 0.75 in. diameter piston and cylinder pressure vessel at 77 K, then pressing the powder into a pellet at $-30°C$, $-40°C$, or $-45°C$, all $\pm 5°C$, for ethylene oxide, cyclopropane, or trimethylene oxide hydrates, respectively. A pressure of 1000 bar was applied for at least $1\frac{1}{2}$ h, occasionally releasing it for 5 min. The pellet was cooled to 77 K under pressure to prevent shattering at the adamantane phase transition (17, 18). The pistons were removed and the cylinder, which held the pellet firmly, was placed in the copper sample holder of the infrared cell in a 77 K dry nitrogen atmosphere. The face of one piston of the pressure apparatus was cut at 89.7° to the axis of the piston, to bevel the pellet to reduce interference fringes. Other infrared samples, including all those for study above 120 cm^{-1}, were made by mixing powdered hydrate into 3-methyl pentane at 120 ± 10 K, in a teflon or TPX (Imperial Chemical Industries Ltd. trademark for methyl pentene polymer) cup which was 0.025 in. deep and had a bevelled (4.5°) base. The temperature was then lowered to 77 K and the 3-methyl pentane set to a glass containing powdered hydrate. The cup containing the sample was loaded into the copper sample holder at 77 K. Background spectra (4) were of adamantane pellets or 3-methyl pentane glasses which contained no hydrate, at the same temperature as for the sample spectra.

The infrared cell was a Janis Research Corporation, Inc. model 8DT variable low-temperature research Dewar. In this cell, the copper sample holder is suspended in an atmosphere of helium gas at the bottom of a central tube. At 4.3 K the sample is just above the surface of liquid helium in this tube. At higher temperatures liquid helium is vaporized by a heated diffuser plate and the gas cools the sample. The sample temperatures were measured by factory-calibrated platinum resistance and germanium resistance thermometers mounted in the copper sample holder. The temperatures were controlled to ± 0.1 K at 4.3 K and ± 2 K at higher temperatures, with the aid of two heaters mounted in the copper sample holder and a Cryogenic Research Model TC103 temperature controller which was modified to incorporate a precise decade resistance box. The cell was fitted with windows of crystal quartz for spectra below 120 cm^{-1}, or sapphire for spectra below 330 cm^{-1}, both cut perpendicular to the unique axis and sealed by Indium O-rings against the cold central tube. TPX windows were sealed by buna-N O-rings against the outer jacket of the cell. The cell was kept mounted in the spectrometer and was loaded while cold by carrying the copper sample holder immersed in liquid nitrogen to the cell, then quickly inserting it into the central tube.

Far-infrared spectra were recorded on a modified Beckman-RIIC FS-720 Interferometer described elsewhere (4). The detector was initially a Golay detector but a Molectron Corporation Model D1.5S-720 Silicon Bolometer Cryostat System was used for most of the work. This detector operates at 1.2 K and was found to be reliable, simple to use, and far superior to the Golay.

Results

The Janis cell transmitted far less radiation than the liquid nitrogen cell used previously (4, 5), and the spectra had a very poor signal-to-noise ratio when the Golay detector was used. Curve *a* of Fig. 1 shows a typical absorbance spectrum obtained from a single pair of sample and background interferograms using the Golay detector, and curve *b* shows the average of 14 such spectra. The better performance of the silicon bolometer is illustrated by curve *c*, which was obtained from a single pair of interferograms. Curves *d* and *e* of Fig. 1 show the spectra of 3-methyl pentane glass and an adamantane pellet at 4.3 K.

Figures 2 to 4 show unsmoothed averages of 3 to 5 spectra below 130 cm^{-1} of the structure I hydrates and deuterates of cyclopropane, ethylene oxide, and trimethylene oxide in adamantane pellets between 4.3 and 100 K. The frequencies of the reproducible features at 4.3 K are given in Table 1. In spectra of very strongly absorbing samples the absorbance decreases uniformly from the lowest feature listed to 15 cm^{-1}. The feature (Figs. 2 to 4) at 78, 76.5, or 74 cm^{-1} at 4.3, 50, or 100 K, respectively, is due to imperfect subtraction of the adamantane peak (Fig. 1). The features previously reported (5) at 23, 46, and 68 cm^{-1} for cyclopropane hydrate at 100 K were spurious (Fig. 2). The bands are clearly sharper at 4.3 K than at 100 K, but more detail is observed for ethylene oxide hydrate and deuterate at 100 K (Fig. 3) than was reported previously (4). This is due to the better detector *and*

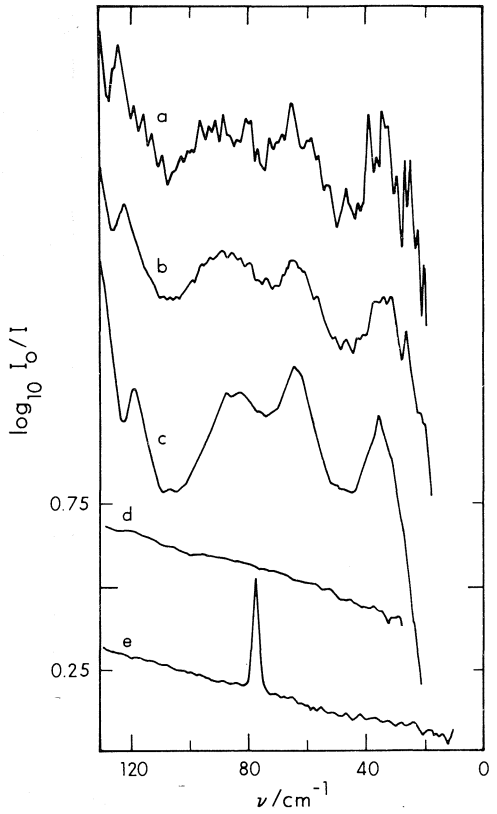

FIG. 1. Curve *a*: spectrum from one pair of sample and background interferograms recorded using the Golay detector. Curve *b*: the average of 14 spectra like curve *a*. Curve *c*: as curve *a* but recorded using the silicon bolometer detector. Curve *d*: spectrum of 3-methyl pentane glass, about $1\frac{1}{4}$ mm thick, at 4.3 K. Curve *e*: spectrum of a 2 mm thick adamantane pellet at 4.3 K. Resolution: 1.5 cm^{-1}. The curves have been offset for clarity.

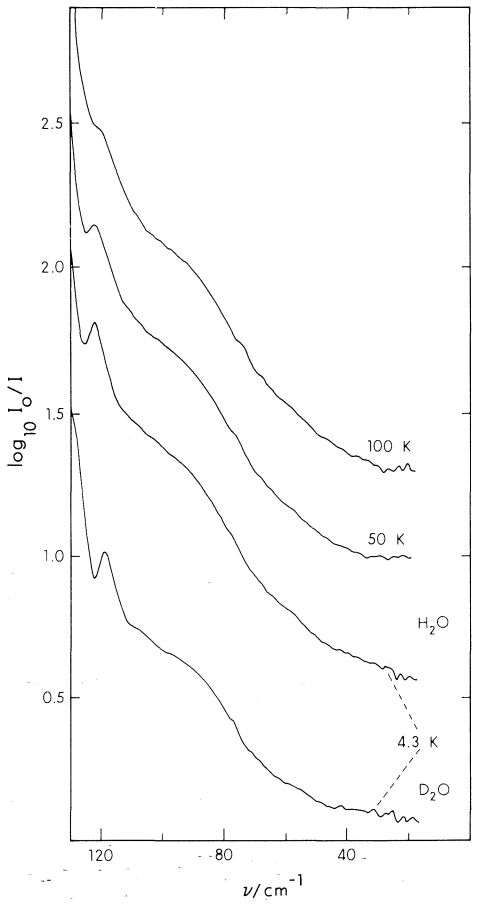

FIG. 2. Spectra of structure I cyclopropane deuterate at 4.3 K (bottom curve) and hydrate at 4.3, 50, and 100 K (top). Resolution: 1.8 cm^{-1}. The hydrate curves have been raised by 0.5 (4.3 K), 0.85 (50 K), and 1.20 (100 K) units for clarity.

to the pellet and glass techniques which allow much more strongly absorbing samples to be used than is possible with mulls (4). The assignment of the peaks and shoulders to water or guest vibrations (Table 1) is based on the isotope shifts, with slight ambiguity in the case of trimethylene oxide hydrate.

The temperature dependences of the spectra of trimethylene oxide hydrate and cyclopropane and ethylene oxide deuterates are similar to those shown (Figs. 2–4). The features above 100 cm^{-1} are all about 2 cm^{-1} lower in frequency at 100 K than at 4.3 K. The temperature shifts of the other features are ± 2 cm^{-1} or less, except for the 65 cm^{-1} band of ethylene oxide hydrate which shifts about 5 cm^{-1} (Fig. 3), and are probably due to increased breadth of the overlapping bands at high temperature.

The following evidence shows that the hydrates did not decompose during the preparation of the adamantane pellets. (*1*) The spectrum of cyclopropane deuterate dispersed in 3-methyl pentane glass at 4.3 K was identical to that of Fig. 2, except that the weak shoulders at 108 and 58 cm^{-1} were about half as prominent. (*2*) A 12.7 mol% aqueous solution of ethylene oxide in a Teflon cup was crystallized completely to yield $6.68C_2H_4O{\cdot}46H_2O$ (19); the Teflon cup was loaded into the cell and yielded spectra of the hydrate identical to those in Fig. 3. (*3*) Cyclopropane and trimethylene oxide hydrates were subjected to the pelleting procedure without adamantane, and were shown to be unchanged by X-ray powder photography (5, 14).

Figure 5 shows unsmoothed averages of three

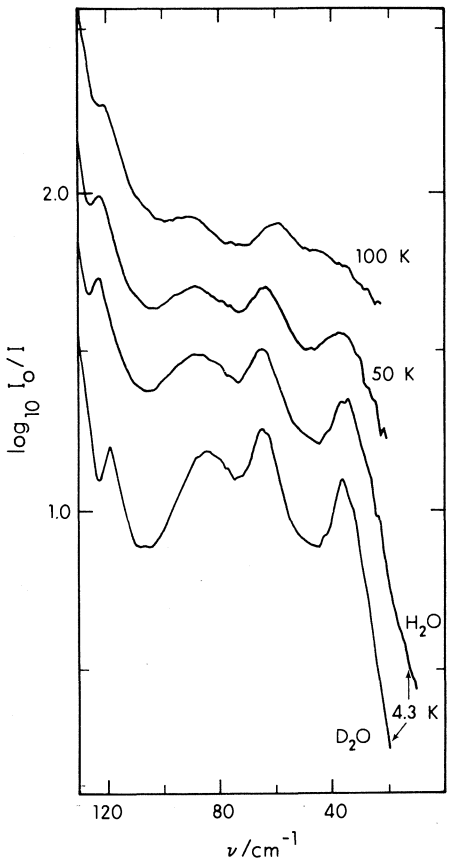

FIG. 3. Spectra of structure I ethylene oxide deuterate at 4.3 K (bottom curve) and hydrate at 4.3, 50, and 100 K (top). Resolution: 1.8 cm^{-1}. The hydrate curves have been raised by 0.4 (4.3 K), 0.65 (50 K), and 0.90 (100 K) units.

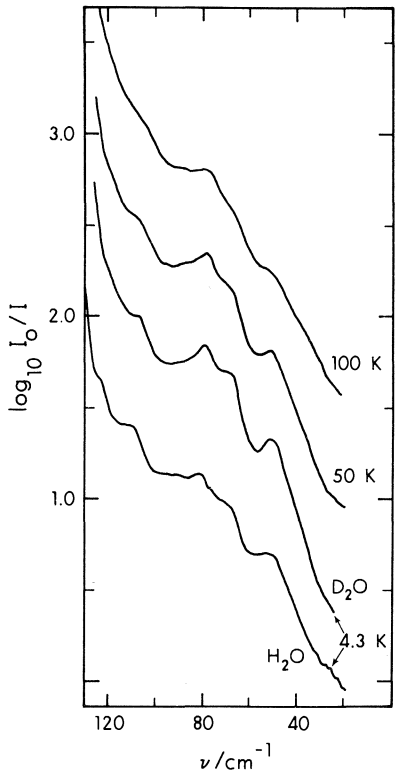

FIG. 4. Spectra of structure I trimethylene oxide hydrate at 4.3 K (bottom curve) and deuterate at 4.3, 50, and 100 K (top). Resolution: 1.8 cm^{-1} for hydrate, 2.8 cm^{-1} for deuterate. The deuterate curves have been raised by 0.25 (4.3 K), 0.75 (50 K), and 1.25 (100 K) units.

spectra of cyclopropane, ethylene oxide, and trimethylene oxide hydrates at 4.3 K between 330 and 100 cm^{-1}. The frequencies of the reproducible features are given in Table 2, with those of the deuterates. Curves *c* and *d* in Fig. 5 are both of cyclopropane hydrate and show that the relative intensity of the main peak is very sensitive to the size of the hydrate particles, increasing with decreasing particle size. The spectrum of very well ground ethylene oxide hydrate at 100 K is the same as reported previously (4, 5) except that the main peak has greater relative intensity. Thus, the frequencies are higher and more structure is resolved when the compounds are at 4.3 K. Curves *c* and *d* also show that the band shapes between 260 and 330 cm^{-1} are uncertain because of different amounts of 3-methyl pentane (curve *e*) in the sample and background glasses. Curve *e* proves that condensation of ice upon the samples was not a problem. Figure 6 shows several spectra of ethylene oxide hydrate at 4.3 K between 220 and 100 cm^{-1}, to prove the existence of the many weak features listed in Table 2.

Discussion

Relaxation data (7, 8, 11, 20, 21) for the hydrates studied (Table 3) indicate that the molecular reorientation rates are below far-infrared frequencies at 100 K. Thus, the perturbed "free" rotation invoked by Hadni and co-workers (13), to explain a band at 40 cm^{-1} in double clathrates, cannot contribute to the present spectra, which must, therefore, be due to absorption by translational (rattling) and rotational vibrations of the guest molecules superimposed on the broad, disorder-allowed absorption by the translational vibrations of the water molecules (4, 5). Whether the absorption by the guest mole-

[a]Frequencies are in cm^{-1} and their accuracy is ±0.5 if quoted to 0.1 or ±1 otherwise, except as noted in parentheses; sh, min, p, cos, and b, indicate shoulder, minimum, peak, change of slope, and broad.
[b]w, water vibration; G, guest vibration.

cules is observed and well-resolved depends on its intensity relative to that of the water molecules.

It is useful to assume that the vibrations of the guest and water molecules do not interact. In this approximation, the water absorption is constant for all structure I hydrates, apart from frequency shifts related to changes in the lattice parameter (5), because it is the density of vibrational states of the empty hydrate lattice weighted by an intensity function (4, 5). It is also useful to assume that the rotational vibrations of each guest molecule occur about the principal axes of inertia of the free molecule. In this case, two of the rotational vibrations of ethylene oxide and trimethylene oxide (22, 23) reorient the dipole moment, and absorb much more radiation than the other four intermolecular vibrations of each guest whose dipole moment derivatives arise solely from intermolecular forces (12). Klug and Whalley (12) analysed the absorption below 70 cm^{-1} by the structure II hydrate of tetrahydrofuran using these assumptions, which appear to hold for that case (24).

It is clear from Figs. 2 to 5 and Tables 1 and 2 that the first assumption holds rather well above 100 cm^{-1} for ethylene oxide and cyclopropane hydrates, but not for trimethylene oxide hydrate. Further, it is not good below 100 cm^{-1}, since the peaks at 87.5 and 82 cm^{-1} in the spectra of ethylene oxide and trimethylene oxide hydrates are sensitive to the water isotope but are replaced

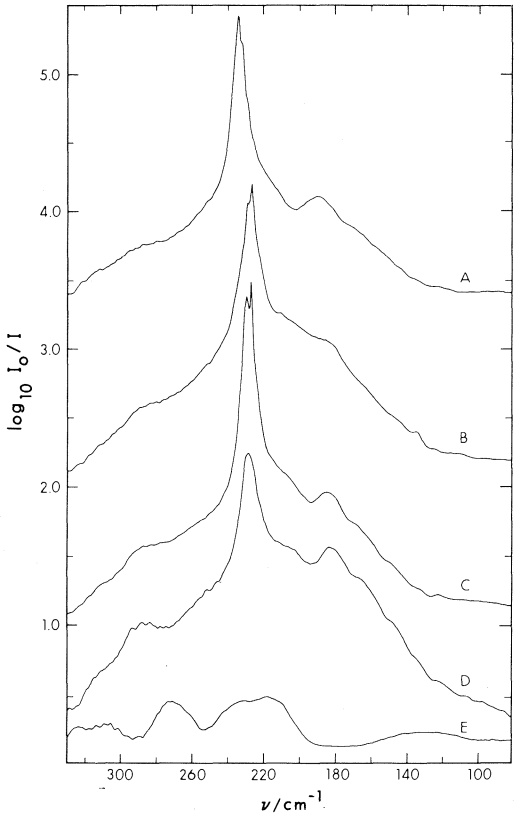

FIG. 5. Spectra of *a*, ethylene oxide hydrate (raised $3\frac{1}{4}$ units), *b*, trimethylene oxide hydrate (raised 2 units), *c*, cyclopropane hydrate (raised 1 unit), *d*, a less-well-ground sample of cyclopropane hydrate (raised $\frac{1}{4}$ unit), and *e*, 3-methyl pentane glass, ($\sim\frac{3}{4}$ mm thick), all at 4.3 K. Resolution: 2 cm^{-1}.

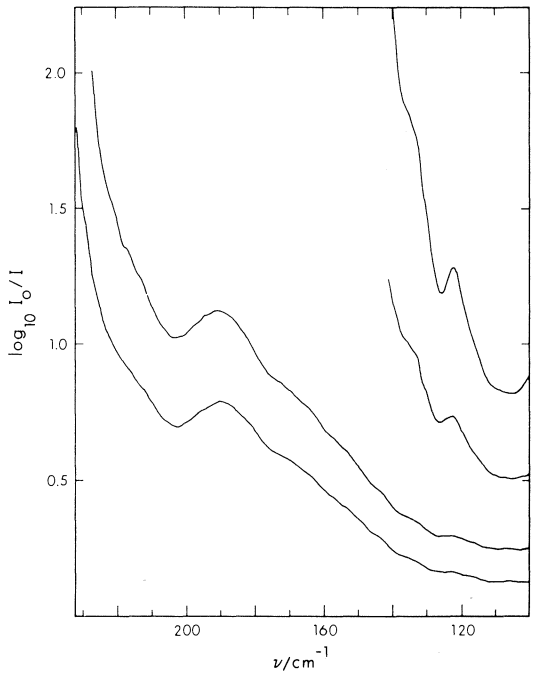

FIG. 6. Spectra of ethylene oxide hydrate at 4.3 K. The curves have been offset for clarity. Resolution: 2 cm^{-1}.

by a broad shoulder in the spectrum of cyclopropane hydrate. They are assigned to translational vibrations of the water which have gained intensity by interacting with the rotational vibrations of the guest. The second assumption is good for these hydrates, since two features in the spectrum of each hydrate with a dipolar guest can be assigned to the vibrations which rotate the dipole, while the other four intermolecular vibrations of each guest molecule are undetectable above 15 cm^{-1}.

The higher and lower frequency guest bands (Table 1) are assigned to the vibrations about the axes of lower and higher inertia, respectively, neglecting intermolecular coupling for the moment. With this assignment and the moments of inertia, *I*, in Table 3, the force constants, *k*, for the two rotational vibrations are calculated from $\nu = (2\pi c)^{-1}[kI^{-1}]^{1/2}$ to be 487 ± 7 and 264 ± 5 ferg rad^{-2} for ethylene oxide hydrate and 1190 ± 20 and 1130 ± 25 ferg rad^{-2} for trimethylene oxide hydrate.

The nearest-neighbor guest–guest intermolecular coupling force constant, *f*, must take a range of values if the orientations of the guest molecules are disordered. The limits of this range are $\pm 2\mu^2/r^3$ in the point-dipole approximation (12), where μ is the dipole moment of the guest molecule (Table 3) and *r* is the distance between the dipoles. For structure I hydrates, each guest molecule in a tetrakaidecahedral cage has two nearest-neighbor guest molecules, in the cages which share a six-sided face with its own cage. Thus, *r* is half of the cubic lattice parameter (Table 3) if the dipoles are central in the cages, and the limits of the interaction constant, *f*, are ±34 and ±35 ferg rad^{-2} for ethylene oxide and trimethylene oxide hydrates, respectively. If the interaction constants were all equal, the nearest-neighbor coupling would yield a range of frequencies from each molecular vibration, the frequencies given in the harmonic approximation by $\nu = (2\pi c)^{-1}[KI^{-1}]^{1/2}$ where *K* varies from $k + 2f$ to $k - 2f$. With the limiting interaction constants given above, these ranges are 60 to 69 cm^{-1} and 31 to 40 cm^{-1} for ethylene oxide hydrate and 66 to 70 and 49 to 52 cm^{-1} for trimethylene oxide hydrate. The ranges for orienta-

tionally disordered guest molecules must be much smaller than these, probably by a factor of two. Thus, it is clear that inter-guest coupling can only contribute to the breadth of the bands and cannot invalidate the assignments given.

The interaction between the guest and water vibrations precludes a detailed analysis of the shapes of the guest bands such as that of Klug and Whalley (12). However, the bands must also be broadened by static and dynamic forces between the guest and water molecules; that is, by the disorder in the orientations of the water molecules, which causes the force constants, k, of the guest vibrations to vary from cage to cage (12), and by the interaction between the vibrations of the guest and water molecules. This latter interaction also causes the enhanced intensity of the water vibrations near 85 cm^{-1}, and appears to be greater in ethylene oxide hydrate than in trimethylene oxide hydrate. This indicates the predominant dynamic interaction to be between the transition dipoles of the guest (proportional to $\mu/I^{1/2}$) and water vibrations, and not steric interactions. In contrast, Klug and Whalley (12) have argued that the main static forces are non-electrostatic, with repulsive forces between hydrogen atoms on the guest and water molecules being important; the much larger force constants for trimethylene oxide than for ethylene oxide support their conclusion.

The force constants show that for ethylene oxide, trimethylene oxide, and tetrahydrofuran (606 and 465 ferg rad^{-2} (12)) in their hydrates (structures I, I and II, respectively) the rotation of the molecule in its plane meets less resistance than the rotation about the non-dipolar axis in the plane. Further, the force constants for ethylene oxide are both smaller than those for tetrahydrofuran. Thus the curvatures of the potential energy of the molecule with respect to its orientations in the cage are smaller for ethylene oxide, even though the barrier to reorientation of the ethylene oxide dipole (Table 3) is larger than that of the tetrahydrofuran dipole (0.92 kcal/mol (17)). A more quantitative comparison can be made by following Klug and Whalley (12) in assuming that the potential to guest reorientation about each axis is sinusoidal with period $2\pi/n$, and determining n by relating the vibrational quantum to the barrier height by an approximation (12) that is useful if the barrier is large compared to the vibrational quantum. For the in-plane and out-of-plane rotational vibrations, one calculates n to be 3.8 and 4.3 for tetrahydrofuran, using the data in ref. 12, 3.9 and 4.0 for trimethylene oxide, and 2.3 and 3.1 for ethylene oxide; alternatively, the geometric mean frequencies and moments of inertia yield n equal to 4.1 (12), 4.0, and 2.7, respectively. The four-fold potential calculated for tetrahydrofuran in the hexakaidecahedral cages suggested (12) that the guest molecule has minimum energy when its dipole is perpendicular to the four hexagonal faces of the cage, which are tetrahedrally disposed. No such physically appealing conclusions about the equilibrium orientations of ethylene oxide and trimethylene oxide in the tetrakaidecahedral cages are evident from the above values of n and the available approximate calculations (8, 11, 25). The four-fold potentials calculated for the in-plane and out-of-plane motions of trimethylene oxide suggest that the oxygen atom and the methylene groups are indistinguishable to the cage, and that axial and equatorial (8, 11, 25) configurations are equally favoured. Neither of these suggestions is compatible with the calculations (11) or with the existence of an ordering transition (11). For ethylene oxide hydrate, calculations suggest (8) that axial and near-equatorial orientations of the guest molecule are equally likely and it is unclear how two-fold and three-fold barriers arise from this. Thus, the sinusoidal potential is probably too great an approximation for these systems, except to yield the correlation that the relative periodicities calculated for trimethylene oxide and ethylene oxide undoubtedly reflect the large size of trimethylene oxide for the tetrakaidecahedral cage.

The broadening of the guest bands with increasing temperature is of the same magnitude as that observed for tetrahydrofuran hydrate (12), and is greater than is observed (24) for simple molecular crystals under the same conditions. It must arise from the three factors discussed previously (12). Of these, molecular reorientation is too slow (Table 3) to contribute more than about 1 cm^{-1} to the breadth at 100 K. Thus the broadening is due to the anharmonicity of the guest–host interaction potential, which is greater than that of the intermolecular potential of simple molecular crystals. The temperature dependence between 4.3 and 200 K of the spectrum of trimethylene oxide hydrate gave no evidence of the partial ordering transition (11) nor of the ring puckering vibration (23, 26).

Previous discussions of the spectra of ethylene oxide and cyclopropane hydrates between 300 and 100 cm^{-1} (4, 5) apply equally to the present

results. The extra details that are resolved when the samples are at 4.3 K are sufficiently similar in spectra of the two hydrates (Table 2, Figs. 5, 6) to indicate that they arise from features in the density of translational vibrational states of the hypothetical empty hydrate lattice. There are 138 branches of dispersion curves for this lattice so no simple description is possible and the exact origin of the features can only be determined by a calculation of the density of states. Such calculations have been made (27) but further refinement is needed and should be helped by the new data.

The spectra between 330 and 100 cm^{-1} of trimethylene oxide structure I hydrate and deuterate are presented for the first time (Fig. 5). The frequency of the strong central peak is very close to that in the spectrum of cyclopropane hydrate, reflecting (5) the nearly identical lattice parameters of the two hydrates (Table 3). But the spectra of the two hydrates differ between ~200 and 100 cm^{-1}, indicating that trimethylene oxide modifies the absorption by the water molecules. Two possible sources of this modification are evident, but there are strong objections to both. The ring puckering vibration, or an intermolecular vibration, of trimethylene oxide is an unlikely possible source, since its absorption intensity can surely not exceed that of a rotational vibration of trimethylene oxide, which is at least a factor of 10 weaker than the water absorption near 200 cm^{-1} (Figs. 4, 5). The second possible source is that the combination of the large size and the dipole moment of trimethylene oxide perturbs the lattice of water molecules but does not change the lattice parameter significantly from that of cyclopropane hydrate (Table 3). If this were the case, the absorption by the O—D stretching vibrations of HDO molecules isolated in a H_2O lattice, ν_{OD}(HDO), should reflect it. In fact the absorption by ν_{OD}(HDO) at 100 K indicates that both ethylene oxide and trimethylene oxide perturb the water lattice slightly from that of cyclopropane hydrate (14, 16), but gives no indication that trimethylene oxide has a greater effect. Trimethylene oxide structure I hydrate undergoes a partial ordering transition of the guest molecules at ~80 K (11), but neither the ν_{OD}(HDO) absorption nor any other mid-infrared absorption shows any significant change between 100 and 60 K (14). Thus the reason for the modification by trimethylene oxide of the water absorption between 200 and 100 cm^{-1} is unclear.

An improved synthesis of ishwarane: conversion of bicyclo[2.2.2]octenes to tricyclo[3.2.1.$0^{2,7}$]octanes via reductive homoallylic cyclization

RONALD B. KELLY AND SANDRA J. ALWARD

Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

Received January 10, 1977

RONALD B. KELLY and SANDRA J. ALWARD. Can. J. Chem. **55**, 1786 (1977).

Conversion of the alcohol **4** into the mesylate **5** and reduction of the latter with $LiAlH_4$ under mild conditions afforded ishwarane **1** in 65% yield, thereby providing a further demonstration of the synthetic utility of such reductive, homoallylic cyclizations and a substantially improved synthesis of ishwarane.

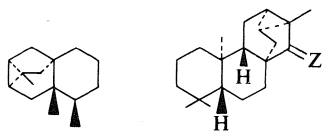
RONALD B. KELLY et SANDRA J. ALWARD. Can. J. Chem. **55**, 1786 (1977).

La transformation de l'alcool **4** en son mésylate **5** et la réduction de ce dernier par $LiAlH_4$ dans des conditions douces fournit l'ishwarane **1** avec un rendement de 65%; cette synthèse fournit une démonstration supplémentaire de l'utilité en synthèse de telles cyclisations homoallyliques réductrices et une synthèse sensiblement améliorée de l'ishwarane.

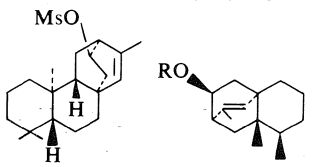
[Traduit par le journal]

The presence of the tricyclo[3.2.1.$0^{2,7}$]octane system as a structural feature of the terpenoids ishwarane **1** and trachylobane **2** has recently stimulated considerable interest in devising synthetic methods for the construction of this system (1–5). In connection with our total syntheses of ishwarane (1) and trachylobane (2–4) we have described three methods for the conversion of bicyclo[2.2.2]octane systems, readily available by synthesis, into tricyclo[3.2.1.$0^{2,7}$]octanes.[1] All of these methods have been utilized in our total syntheses of trachylobane (2–4) but our reported (1) synthesis of ishwarane involved only the most lengthy of these.

The most convenient synthesis of trachylobane **2** involved reductive, homoallylic cyclization of the mesylate **3** directly to trachylobane (60%) by treatment with $LiAlH_4$ under mild conditions (ref. 4, *cf.* ref. 6). We now wish to bring our synthetic work on the bicyclo[3.2.1.$0^{2,7}$]octane system to a conclusion by reporting the application of this type of cyclization to an improved synthesis of ishwarane **1**. Thus, conversion of the alcohol **4**, the synthesis of which has already been described (1), into the mesylate **5** followed by reduction of the latter with $LiAlH_4$ under mild conditions (refluxing ether, 5 h) afforded ishwarane **1** in 65% yield. The fact that we were successful in converting 47 mg of the alcohol **4** into ishwarane **1** in 65% yield (see Experimental) attests to the amenability of this procedure to small-scale preparations.



1 **2** Z = H,H; **6** Z = O



3 **4** R = H; **5** R = Ms

Since the alcohol **4** is a totally synthetic intermediate encountered in our former synthesis of ishwarane **1** (1), its conversion into ishwarane, as just described, represents a new total synthesis of this sesquiterpene. In our former synthesis (1), the conversion of the alcohol **4** into ishwarane **1** required six steps and was accomplished in 23% yield. Hence, the conversion of **4** into ishwarane via the homoallylic cyclization of the mesylate **5** represents a substantially improved total synthesis of this sesquiterpene and further demonstrates the synthetic utility of such cyclizations.[2]

[1]For a discussion of such conversions, with emphasis on mechanism and stereochemistry, see ref. 4.

[2]For another useful type of homoallylic cyclization whereby the mesylate **3** was converted into the ketone **6** see refs. 3 and 4.

Experimental

A solution of 47 mg of the alcohol **4** in 3.5 ml of dry pyridine was cooled to 0°C then treated with 0.13 ml of methanesulfonyl chloride. The solution was left, under nitrogen, at −15°C for 66 h then at 15°C for a further 24 h. Ice was added to the reaction mixture and the resulting cold solution was extracted three times with ether and the ether extracts were washed with cold 1 *N* hydrochloric acid and finally with cold brine. Evaporation of the dried ether extracts afforded 60 mg of the mesylate **5**; ν_{max}(neat) 3020, 1655 and 800 cm^{-1} (olefin), 1345 and 1175 cm^{-1} (mesylate); nmr ($CDCl_3$), δ 0.74 (d, J = 6.5 Hz, 3H, secondary methyl), 0.98 (s, 3H, angular methyl), 1.78 (d, J = 2 Hz, 3H, vinylic methyl), 2.98 (s, 3H, mesylate), 4.75 (m, 1H, SO_2O—C—H), 5.74 (m, 1H, vinylic proton). The mesylate was used directly for the next step.

A solution of 60 mg of the mesylate **5** in 4 ml of ether was added over a period of 30 min to a stirred suspension of 60 mg of lithium aluminum hydride in 4 ml of ether under nitrogen. The mixture was then refluxed for 5 h, cooled, treated with 0.4 ml of brine, stirred for 1 h, then dried by addition of anhydrous sodium sulfate and filtered. Evaporation of the filtrate and purification of the residue by tlc on silica gel with hexane as solvent afforded 28 mg (65%) of (±)-ishwarane. The synthetic sesquiterpene was identical with an authentic sample of ishwarane obtained from natural sources by the following criteria: identity of ir and nmr spectra, single peak on glc when coinjected with an authentic sample.[3]

Reaction of alkyl (aryl) sulfonyl chlorides and sulfonic acid anhydrides with pyridine in the presence of sodium borohydride afford *N*-sulfonyl-1,4-dihydropyridines (**1**) and *N*-sulfonyl-1,2-dihydropyridines (**2**). The ratio of products (**1**:**2**) was dependent upon solvent and temperature. Reaction of **2***d* with 4-phenyl-1,2,4-triazoline-3,5-dione (**4**) afforded the *endo*-adduct **5**.

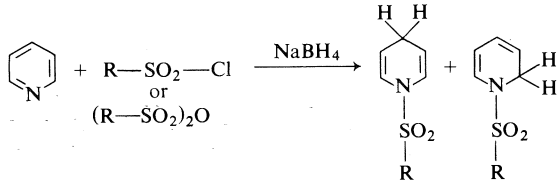
EDWARD E. KNAUS et KINFE REDDA. Can. J. Chem. **55**, 1788 (1977).

La réaction des chlorures d'alkyle (aryle) sulfonyles et des anhydrides d'acides sulfoniques avec la pyridine en présence de borohydrure de sodium conduit aux *N*-sulfonyldihydro-1,4 pyridines (**1**) et aux *N*-sulfonyldihydro-1,2 pyridines (**2**). Le rapport des produits (**1**:**2**) dépend du solvant et de la température. La réaction de **2***d* avec la phényl-4 triazoline-1,2,4 dione-3,5 (**4**) conduit à l'adduit *endo* **5**.

[Traduit par le journal]

The use of pyridinium salts as precursors for the synthesis of pharmacologically active agents provides an attractive route to reduced pyridine heterocycles. Although the antibacterial activity of some *N*-sulfonylpiperidine derivatives have been studied (1), the preparation of *N*-sulfonyl-1,2-dihydropyridines has not been reported. The synthesis of *N*-benzene (methane) sulfonyl-1,4-dihydropyridine from cyclopentadiene was recently described (2). Many of the benzenesulfonamides already prepared and tested as antibacterial agents possess five- and six-membered heteroaromatic rings as N^1-substituents (1). It would be of interest, therefore, to develop a one-step synthesis of benzenesulfonamides in which the N^1-sulfonamide nitrogen is part of a 1,2- or 1,4-dihydropyridyl ring system. Treatment of a mixture of pyridine and sodium borohydride with alkyl (aryl) sulfonyl chlorides and sulfonic acid anhydrides, using a modification of the procedure reported by Fowler (3) for the preparation of *N*-methoxycarbonyl-1,2-dihydropyridine, now provides a convenient route to *N*-sulfonyl-1,4-dihydropyridines (**1**) and *N*-sulfonyl-1,2-dihydropyridines (**2**).

Reaction of pyridine with methanesulfonyl chloride in methanol at −65°C in the presence of sodium borohydride afforded *N*-methanesulfonyl-1,2-dihydropyridine (**2***a*, 32.1%) as the sole product. A similar reaction employing methane sulfonic anhydride gave **2***a* (37.2%). On the other hand, reaction with benzenesulfonyl chloride using the same conditions, gave rise to an isomeric mixture of **1***b* and **2***b* in a ratio of 1:8 as determined from the integrals of the H-4 and H-2 absorptions at δ 2.68 and 4.16 for the respective compounds.[1] The reaction of benzenesulfonyl chloride with pyridine (both solvent and reactant) in the presence of sodium boro-



a, R = Me-
b, R = Ph-
c, R = *p*-Me-C_6H_4-
d, R = *p*-MeCONH-C_6H_4-

hydride at 25°C was investigated to determine if the isomeric product ratio **1**:**2** was dependent upon solvent and temperature. Reaction under these conditions gave rise to an isomeric mixture of **1***b* and **2***b* in a ratio of 5:4.[1] The results of similar reactions employing benzenesulfonic anhydride are shown in Table 1.

The reaction of *p*-toluenesulfonyl chloride with pyridine (solvent) at 25°C in the presence of sodium borohydride afforded an isomeric mixture of **1***c* and **2***c* in a ratio of 1:1.[1]

Structure–activity studies of benzenesulfonamides have shown that a N^4-amino group or a group such as a N^4-acetamido group which can

[1]This ratio was determined for the unpurified reaction product since 1,2-dihydropyridines **2** undergo considerable decomposition upon purification.

undergo metabolic biotransformation to a N^4-amino group *in vivo* is required for antibacterial activity. It was therefore of interest to investigate this reaction employing *N*-acetylsulfanilyl chloride. Reaction with pyridine using methanol as solvent at −65°C did not occur probably due to the low solubility of *N*-acetylsulfanilyl chloride. When the reaction was carried out using pyridine as solvent at 25°C an isomeric mixture of **1***d* and **2***d* in a ratio of 2:1 was obtained.[1] The presence of both **1***d* and **2***d* was substantiated further since catalytic reduction with palladium–charcoal and hydrogen gave **3** as a single product which was identical with the product obtained from the reaction of piperidine and *N*-acetylsulfanilyl chloride (4).

3

A successful separation of **1***d* and **2***d* could not be achieved using column or thin layer chromatography. However pure **1***d* can be obtained by treating a mixture of **1***d* and **2***d* with 4-phenyl-1,2,4-triazoline-3,5-dione (**4**). The 1,2-dihydro isomer **2***d* reacts readily via a ($\pi 2 + \pi 4$) cycloaddition reaction with **4** to give 5-*endo*-*p*-acetylsulfanilyl-2,3,5-triazabicyclo[2.2.2]oct-7-ene-2,3-*endo*-dicarboxylic acid *N*-phenylimide (4) which is consistent with the reported reaction of **2***b* with **4** (5). Compounds **1***d* and **5** are readily separated by preparative thin layer chromatography. Both acidic and alkaline hydrolyses of the N^4-acetamido group of **1***d* to liberate the free amine gave rise to intractable tar even though acidic hydrolysis of the N^4-acetamido group of **3** is known to proceed smoothly (6).

TABLE 1. Isomeric product ratio's of 1,4- and 1,2-dihydropyridines

Product mixture	Reactant	Solvent	Reaction temp. (°C)	Reaction time (h)	Ratio **1**:**2**[a]	Ratio **1**:**2**	Yield **1** (%)	Yield **2** (%)
1*b* and **2***b*	$PhSO_2Cl$	MeOH	−65	1.5	1:8	1.8:5.8[b]	1.8[b,d]	5.8[b,d]
1*b* and **2***b*	$PhSO_2Cl$	C_5H_5N	25	15	5:4	12:5[c]	17[c,d]	7.1[c,d]
1*b* and **2***b*	$(PhSO_2)_2O$	MeOH	−65	1.5	4:29	1:5[c]	6.7[c,d]	33.6[c,d]
1*b* and **2***b*	$(PhSO_2)_2O$	C_5H_5N	25	15	7.5:4	3.4:1[c]	23.7[c,d]	7.0[c,d]
1*c* and **2***c*	*p*-Me-C_6H_4-SO_2Cl	C_5H_5N	25	15	1:1	7:5[b]	7.7[b]	6.3[b]
1*d* and **2***d*	*p*-MeCONH-$C_6H_4SO_2Cl$	C_5H_5N	25	15	2:1	4:1[c]	16.7[c]	4.2[c]

[a]Determined from the integrals of the C_2-H and C_2-H of **1** and **2**, respectively, for the unpurified reaction mixture.
[b]Determined from percentage yields of purified isolated products **1** and **2**.
[c]Determined from the integrals of the C_4-H and C_2-H for a purified mixture of **1** and **2**, respectively, eluted from a neutral alumina column.
[d]There is considerable loss of both **1** and **2** during column purification since only 40–60% of **1** and 25–40% of **2** is recovered.

The reduction of *N*-sulfonylpyridinium salts appears to be dependent upon solvent and temperature. Attack by hydride anion occurs predominately or exclusively at the 2-position to give *N*-sulfonyl-1,2-dihydropyridines **2** using methanol as solvent at −65°C whereas attack at the 4-position is usually favoured slightly when pyridine is employed as solvent at 25°C (see Table 1).

The broad spectrum pharmacological screening of **1***d* is presently in progress.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform, unless otherwise noted, with TMS as internal standard with a Varian A-60 or HA-100 spectrometer. Infrared spectra (in potassium bromide unless otherwise noted) were taken on a Unicam SP-1000 spectrometer. Mass spectra were measured with an AEI-MS-9 or MS-50 mass spectrometer and these exact mass measurements are sometimes used in lieu of elemental analyses.

*N-Methanesulfonyl-1,2-dihydropyridine (**2***a*)

General Procedure A

Sodium borohydride (0.8 g) was added to a solution of pyridine (1.58 g, 0.02 mol) in methanol (7.5 ml) pre-cooled to −65°C. A solution of methanesulfonyl chloride (2.29 g, 0.02 mol) in dry ether (5 ml) was added dropwise during 15 min. After stirring for 1.5 h at −65°C the reaction mixture was poured onto crushed ice (75 ml) and allowed to come to room temperature. Extraction with chloroform (3 × 30 ml), drying (Na_2SO_4), and removal of the solvent *in vacuo* gave a yellow oil which was chromatographed on a 2.5 × 15 cm neutral alumina column. Elution with 300 ml chloroform gave 1.02 g (32.1%) of **2***a* as a yellow oil: ir (film) 1350, 1160 cm^{-1} (SO_2); nmr δ 6.24–6.62 (1H, m, C_6-H), 5.8–6.18 (1H, m, C_4-H), 5.3–5.73 (2H, m, C_3-H, C_5-H), 4.25 (2H, d ($J_{2,3}$ = 4 Hz) of d ($J_{2,4}$ = 1.5 Hz), C_2-H), 2.92 (3H, s, Me). *Exact Mass* calcd. for $C_6H_9NO_2{}^{32}S$: 159.0354; found: 159.0355.

When the reaction was carried out as described above using 3.48 g (0.02 mol) methanesulfonic anhydride 1.18 g (37.1%) of **1***b* was obtained.

*N-Benzenesulfonyl-1,4-dihydropyridine (**1***b) and N-Benzenesulfonyl-1,2-dihydropyridine (**2***b)*

Sodium borohydride (0.8 g) was added to a solution of pyridine (1.58 g, 0.02 mol) in methanol (20 ml) pre-cooled to −65°C. A solution of benzenesulfonyl chloride (3.52 g, 0.02 mol) in dry ether (10 ml) was added dropwise during 15 min and the reaction was completed as described under procedure A. The reaction product was then chromatographed on a 2.5 × 15 cm neutral alumina column. Elution with benzene (400 ml) gave 0.591 g (13.37%) of an isomeric mixture of **1***b* and **2***b* which was purified further by tlc using five 8 × 8 in. silica gel PF 254 plates, 0.5 mm in thickness, with benzene as development solvent. Extraction of the fraction having an R_f of 0.55–0.6 gave 0.078 g (1.8%) of **1***b*: mp 83–85°C (lit. (2) mp 86–89°C); ir 1352, 1175 cm^{-1} (SO_2); nmr δ 7.58 (5H, m, Ph), 6.47 (2H, d ($J_{2,3}$ = $J_{5,6}$ = 8.5 Hz) of d ($J_{2,4}$ = $J_{4,6}$ = 1.5 Hz), C_2-H, C_6-H), 4.88 (2H, m ($J_{2,3}$ = $J_{5,6}$ = 8.5 Hz), C_3-H, C_5-H), 2.68 (2H, m, C_4-H). *Exact Mass* calcd. for $C_{11}H_{11}NO_2{}^{32}S$: 221.0511; found: 221.0506.

Extraction of the fraction having an R_f of 0.3–0.5 gave 0.257 g (5.8%) of **2***b*: mp 68–69°C; ir 1360, 1340, 1175 cm^{-1} (SO_2); nmr δ 7.62 (5H, m, Ph), 6.63 (1H, d ($J_{5,6}$ = 7.75 Hz) of d ($J_{4,6}$ = 0.8 Hz), C_6-H), 5.8 (1H, m, C_4-H), 5.34 (2H, m, C_3-H, C_5-H), 4.16 (2H, d ($J_{2,3}$ = 4 Hz) of d ($J_{2,4}$ = 1.5 Hz), C_2-H). *Exact Mass* calcd. for $C_{11}H_{11}NO_2{}^{32}S$: 221.0511; found: 221.0506.

General Procedure B

Sodium borohydride (0.8 g) was added to a mixture of pyridine (10 ml) and benzenesulfonyl chloride (3.53 g, 0.02 mol) pre-cooled to 0°C with stirring. The reaction was allowed to proceed for 15 h at 25°C after which it was poured onto crushed ice (100 ml). Extraction with chloroform (4 × 100 ml), drying (Na_2SO_4), and evaporation of the solvent *in vacuo* afforded a brown oil which was subjected to chromatography on a 2.5 × 26 cm neutral alumina column. Elution with benzene (700 ml) afforded 1.06 g of an isomeric mixture composed of 0.75 g (17%) of **1***b* and 0.312 g (7.1%) of **2***b* as determined by the integrals of the C_4-H and C_2-H of **1***b* and **2***b*, respectively.

Reaction of benzenesulfonic anhydride (5.86 g, 0.02 mol) with pyridine (1.58 g, 0.02 mol) in the presence of sodium borohydride (0.8 g) as described under procedure A and purification of the reaction mixture as described above afforded 1.78 g of an isomeric mixture consisting of 0.3 g (6.7%) of **1***b* and 1.49 g (33.6%) of **2***b* as determined by the integrals of the C_4-H and C_2-H of **1***b* and **2***b*, respectively.

Reaction of benzenesulfonic anhydride (5.86 g, 0.02 mol) with pyridine (10 ml) in the presence of sodium borohydride (0.8 g) as described under procedure B and then elution from a neutral alumina column as described above gave 1.36 g of an isomeric mixture composed of 1.05 g (23.7%) of **1***b* and 0.31 g (6.95%) of **2***b* as determined by integrals.

*N-p-Toluenesulfonyl-1,4-dihydropyridine (**1***c) and N-p-Toluenesulfonyl-1,2-dihydropyridine (**2***c)*

Sodium borohydride (0.8 g) was added to a mixture of pyridine (10 ml) and *p*-toluenesulfonyl chloride (3.81 g, 0.02 mol) pre-cooled to 0°C with stirring. The reaction was completed as described under procedure B to give a brown semi-solid which was subjected to chromatography on a 2.5 × 26 cm neutral alumina column. Elution with benzene (250 ml) gave 0.36 g (7.7%) of **1***c*: mp 93–95°C; ir 1370, 1345, 1170 cm^{-1} (SO_2); nmr δ 7.68 (2H, d (J = 8 Hz), *ortho* phenyl hydrogens), 7.38 (2H, d (J = 8 Hz), *meta* phenyl hydrogens), 6.44 (2H, d ($J_{2,3}$ = $J_{5,6}$ = 8.5 Hz), of d ($J_{2,4}$ = $J_{4,6}$ = 1.5 Hz), C_2-H, C_6-H), 4.86 (2H, m ($J_{2,3}$ = $J_{5,6}$ = 8.5 Hz), C_3-H, C_5-H), 2.7 (2H, m, C_4-H), 2.42 (3H, S, CH_3). *Exact Mass* calcd. for $C_{12}H_{13}NO_2{}^{32}S$: 235.0667; found: 235.0659.

Further elution with benzene–ether (1:1 v/v) (250 ml) gave 0.297 g (6.32%) of **2***c*: mp 59–61°C; ir 1350 and 1170 cm^{-1} (SO_2); nmr δ 7.67 (2H, d (J = 8 Hz), *ortho* phenyl hydrogens), 7.38 (2H, d (J = 8 Hz), *meta* phenyl hydrogens), 6.58 (1H, d ($J_{5,6}$ = 7.75) of d ($J_{4,6}$ = 0.8), C_6-H), 5.8 (1H, d ($J_{3,4}$ = 8 Hz) of d ($J_{4,5}$ = 4.5 Hz) of d ($J_{2,4}$ = 1.5 Hz), C_4-H), 5.36 (2H, m, C_3-H, C_5-H), 4.12 (2H, d ($J_{2,3}$ = 4 Hz) of d ($J_{2,4}$ = 1.5 Hz), C_2-H), 2.42 (3H, s,

CH_3). *Exact Mass* calcd. for $C_{12}H_{13}NO_2{}^{32}S$: 235.0667; found: 235.0659.

*N-p-Acetylsulfanilyl-1,4-dihydropyridine (**1d**), N-p-Acetylsulfanilyl-1,2-dihydropyridine (**2d**), and 5-endo-p-Acetylsulfanilyl-2,3,5-triazabicyclo[2.2.2]-oct-7-ene-2,3-endo-dicarboxylic Acid N-phenylimide (**5**)*

Sodium borohydride (0.8 g) was added to a mixture of pyridine (10 ml) and *p*-acetylsulfanilyl chloride (4.67 g, 0.02 mol) pre-cooled to 0°C with stirring. The reaction was completed as described under general procedure B to give a reddish semi-solid which was chromatographed on a 2.5 × 26 cm neutral alumina column. Elution with ether–methanol (6:1 v/v) (300 ml) gave 1.198 g of an isomeric mixture consisting of 0.96 g (16.7%) of **1***d* and 0.24 g (4.2%) of **2***d* as determined from the integrals of the C_4-H and C_2-H of **1***d* and **2***d*, respectively. 4-Phenyl-1,2,4-triazoline-3,5-dione (0.069 g, 0.392 mmol) in methylene chloride (10 ml) was added dropwise with stirring to a solution of 0.543 g of the above mixture of **1***d* and **2***d* (containing 0.109 g, 0.392 mmol of **2***d*) in methylene chloride (20 ml) pre-cooled to 0°C. The reaction was allowed to proceed 1 h, after which the solvent was removed *in vacuo* to give a white solid. Preparative tlc on four 8 × 8 in. silica gel PF 254 plates, 0.5 mm in thickness, with ethyl acetate as development solvent afforded 0.094 g of **1***d* having an R_f of 0.86: mp 138–140°C; ir 1705, 1690 (C=O), 1350, 1168 cm^{-1} (SO_2); nmr δ 9.78 (1H, s, NH, exchanges with deuterium oxide), 7.81 (2H, m, *ortho* phenyl hydrogens), 7.58 (2H, m, *meta* phenyl hydrogens), 6.38 (2H, d ($J_{2,3} = J_{5,6} = 8.5$ Hz) of d ($J_{2,4} = J_{4,6} = 1.5$ Hz), C_2-H, C_6-H), 4.86 (2H, m ($J_{2,3} = J_{5,6} = 8.5$ Hz), C_3-H, C_5-H), 2.67 (2H, m, C_4-H), 2.16 (3H, s, CH_3). *Exact Mass* calcd. for $C_{13}H_{14}N_2O_3{}^{32}S$: 278.0725; found: 278.0721.

Extraction of the fraction having R_f 0.27 gave 0.06 g of **5**: mp 200–204°C; ir 1700 (C=O), 1372, 1160 cm^{-1} (SO_2); nmr (DMSO-d_6) δ 10.5 (1H, s, —NH, exchanges with deuterium oxide), 7.25–8.0 (9H, m, phenyl hydrogens), 5.3–6.68 (3H, m, C_4-H, C_7-H, C_8-H), 4.96 (1H, m, C_1-H), 4.5 (2H, m, C_6-H), 3.15 (3H, s, CH_3). *Anal.* calcd. for $C_{21}H_{19}N_5O_5S$: C 55.63, H 4.19, N 15.45; found: C 55.66, H 4.21, N 15.62.

*N-p-Acetylsulfanilylpiperidine **3***

Catalytic hydrogenation of a 4:1 mixture of **1***d* and **2***d* (95 mg) in methanol (30 ml) was carried out in the presence of palladium-on-charcoal (30 mg) and hydrogen gas at 50 psi for 72 h. Removal of the charcoal by filtration and evaporation of the solvent under reduced pressure afforded 0.055 g (57.1%) of **3** as a white solid, mp 156°C (lit. (5) mp 156°C), identical ir and nmr, with the authentic sample.

Multilayer oxidation of polycrystalline platinum

ROBERT J. BERRY

Division of Physics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received March 2, 1977

ROBERT J. BERRY. Can. J. Chem. **55**, 1792 (1977).

The formation of a visible oxide film on polycrystalline Pt foil and wire is reported, and positively identified. The conditions for growth and dissociation of the oxide are outlined, and the energy of decomposition is estimated.

ROBERT J. BERRY. Can. J. Chem. **55**, 1792 (1977).

On rapporte et identifie positivement la formation visible d'une couche d'oxyde sur des lames et des fils de platine polycristallins. Les conditions sous lesquelles l'oxyde croît et désassocie sont exposées, et l'energie de décomposition est estimée.

Introduction

Wohler (1), in 1903, reported that Pt black (powder), Pt sponge (finely divided), and smooth Pt foil (all of unstated purity) could be oxidized and indeed visibly darkened in the latter two cases by prolonged heating near 420°C in dry oxygen (pressure unstated, but presumed to be about 1 atm). Since then the oxidation of finely divided Pt has been confirmed by Busch (2) using 1 atm of oxygen at 550°C. However the surface oxidation of Pt foil (or wire) could not be confirmed by Betteridge and Rhys (3) (1961) on high purity Pt, leading them to suggest that Wohler's discolouration of Pt foil might be due to the oxidation of impurities on the Pt surface. Several other authors have concurred with this explanation and the prevailing opinion up to now (*e.g.* ref. 4) has been that heating Pt foil or wire in oxygen or air below 500°C produces only a strongly adherent atomic layer or two of oxygen (or Pt oxide) on its surface.

Under widely different conditions of temperature, pressure, and Pt surface structure than were used by Wohler, there is considerable evidence that Pt will oxidize. For example: Pt foil and wire are known to form a volatile oxide above 800°C in air or oxygen (3); Pt sponge and wire have been oxidized under oxygen pressures of 40–180 atm at 450°C (5); Pt single crystals are reportedly oxidized to the few atomic layer levels under 10^{-8} Torr oxygen at 840°C (6); and evaporated Pt films are reportedly oxidized under about 0.5 Torr oxygen at 400°C (7). Finally we note that, under radically different conditions than Wohler's, Pt has been oxidized when used as electrodes in electrolytic cells (8), and when it has been sputtered onto substrates in oxygen–argon mixtures (9).

In this paper we wish to briefly outline new work that shows conclusively that modern high purity Pt foil and wire will oxidize beyond the few atomic layer levels under something approaching the conditions used by Wohler, and, of interest to thermometrists, under something approaching the conditions often encountered with Pt resistance thermometers.

Results

In our experiments polycrystalline Pt wire (99.99% pure) and Pt foil (99.98% pure), obtained from Sigmund Cohn Corp., U.S.A., have been heated at 450–550°C inside fused silica tubes filled with research grade oxygen at about 1 atm pressure. Within a few days a surface discolouration is visible, and after 1 month or more the surface film is of sufficient thickness (estimated to be about 50–100 atomic layers) that it appears dark blue or black to the naked eye. Microscopic examinations reveal that the surface has a granular colour pattern, indicating that different crystal faces are reacting at different rates.

Evidence that we are dealing with an oxide film is given by the fact that its growth rate depends strongly on oxygen pressure, becoming virtually zero at pressures as low as 10 Torr. In addition, heating a blackened specimen at 600°C or higher in 1 atm of air causes the Pt surface to return to its original bright metallic appearance, undoubtedly due to the dissociation of the oxide film.

To demonstrate conclusively that the film is

not due to the oxides of impurities on the Pt surface, we have stripped the film off a sample of oxidized foil (0.015 mm thick) by immersing it in hot aqua regia. The film was left in the acid for 2 days to ensure that all unoxidized Pt was dissolved, following which it was washed in distilled water many times. A semi-quantitative analysis of the film by the Analytical Chemistry Section of the National Research Council of Canada using optical emission spectroscopy revealed that the only metallic element present beyond the trace impurity level was Pt, which is what one would expect for a Pt oxide film.

This oxidation process was first detected here about two years ago during high precision (0.1 ppm) electrical resistance measurements on Pt resistance thermometers that were specially filled with oxygen to a pressure of 500 Torr (at 22°C). The ice point resistance, $R(0°C)$, was found to increase rapidly when the Pt sensing wire (0.1 mm diameter) was heated in the 450–550°C range and then decreased rapidly in the 600–700°C range. Similar resistance changes have been observed by others during surface oxidation of other metals (4). The usual explanation is that part of the metal is converted into a poorly conducting oxide skin thus reducing the effective cross-sectional area of the metal and increasing its electrical resistance. It was first suspected that we were not dealing with oxidation of trace impurities in the Pt when the measured resistance ratio, $R(100°C)/R(0°C)$, was found to remain constant within ± 15 ppm while $R(0°C)$ changed by up to 0.2%. This resistance ratio is normally very sensitive to changes in the concentration (or oxidation state) of impurities in the Pt (10); however, if the Pt itself is oxidizing one expects the ratio to remain practically unchanged because essentially only the size of the conductor is changing.

It can be readily shown that the change in resistance should be proportional to the thickness of the oxide film to a first approximation (11). Hence by following this very sensitive parameter we have obtained a great deal of information about the surface oxidation of Pt.

Four main points will be mentioned here. Firstly during the initial stages of oxidation the film growth follows the standard logarithmic dependence on time (4). Secondly the heat of decomposition of the oxide has been determined by measuring the temperature for reaction equilibrium (*i.e.* zero oxide growth rate just prior to the onset of dissociation) at a number of oxygen pressures. Using the standard thermodynamical relationships between the dissociation pressure, temperature, and heat of decomposition (12) we estimate the latter to be about 41 ± 2 kcal per mol of oxygen in the region 450–600°C. This value is in reasonable agreement with a value of 32 ± 10 given for solid PtO_2 at 25°C in the "Oxide Handbook" (13). Thirdly, it is also possible to oxidize the Pt in $\frac{1}{2}$ to 1 atm of air at about 450°C at a rate which is easily detected in Pt resistance thermometers. Fourthly the comparatively small oxygen-activated thermal cycling effect found earlier in Pt resistance thermometers in the 0–450°C range by the author (11) is almost certainly due to an initial fractional monolayer of oxide formed on the Pt surface.

A detailed description of the experiments and results outlined here is being prepared for publication. Also further work on the identification of the particular form of oxide involved, and its crystalline structure, is in progress.

Acknowledgments

The author would like to thank Mr. D. G. Kearney for his assistance with the measurements on Pt resistance thermometers, Mr. D. S. Russell and Mr. P. Tymchuk for their spectrographic analysis, and Dr. D. F. Mitchell of the Metallic Corrosion and Oxidation Section for helpful comments on the manuscript.

JOSHUA JORTNER and ARIEL GAATHON. Can. J. Chem. **55**, 1801 (1977).

In this paper we shall be concerned with the energetics of selective ionization processes in simple nonpolar fluids and with the nature of electron localization in polar fluids, studied over a wide density range. The static features of bound Wannier states and of the conduction band in simple solid and fluid insulators were monitored by vacuum-ultraviolet absorption spectroscopy and photoemission studies providing quantitative information concerning the energy of the bottom of the conduction band, impurity ionization potentials, and adiabatic polarization energies. Electron localization in subcritical and supercritical water and ammonia was studied by pulse radiolysis methods. A critical, temperature dependent, density ρ_C for electron localization in ND_3 was observed. The weak density dependence of the maximum of the absorption band of the localized electron in D_2O and ND_3, and the temperature and density dependence of ρ_C in ND_3, provide compelling evidence for the crucial role of density fluctuations on electron localization in polar fluids.

JOSHUA JORTNER et ARIEL GAATHON. Can. J. Chem. **55**, 1801 (1977).

Dans cette publication on est intéressé à l'énergie des processus d'ionisation sélective dans des fluides non-polaires simples et avec la nature de la localisation électronique dans des fluides polaires qui sont étudiés sur un grand écart de densité. On a déterminé les caractéristiques statiques des états Wannier liés et des bandes de conduction dans des solides simples et dans des isolants fluides en faisant appel à la spectroscopie d'absorption dans l'ultra-violet lointain et par des études de photoémission fournissant des informations quantitatives concernant l'énergie au minimum de la bande de conduction, les potentiels d'ionisation des impuretés et les énergies de polarisation adiabatique. On a étudié, par des méthodes de radiolyse pulsées, la localisation d'électrons dans de l'eau et de l'ammoniac à l'état sous-critique et supercritique. On a observé une densité critique, ρ_C, dépendant de la température, pour la localisation d'électrons dans ND_3. La faible dépendance sur la densité du maximum de la bande d'absorption des électrons localisés dans D_2O et ND_3 et les dépendances sur la température et la densité de ρ_C dans ND_3 fournissent des implications importantes sur le rôle crucial des fluctuations de densité sur la localisation des électrons dans des fluides polaires.

I. Introduction

The understanding of the nature of excess electron states in fluids (1–3) provides a challenging problem in the general area of the physics and chemistry of disordered materials. In the past decade there has been substantial experimental and theoretical progress in the elucidation of the electronic structure and of electron transport in polar and in nonpolar

[1]Present address: Department of Biological Sciences, Columbia University, New York, NY, U.S.A.

liquids with regard to the molecular composition, the static structure, and the dynamic properties of the medium. An attempt to provide a general classification of excess electron states in fluids is presented in Table 1. The gross features of the quasi-free electron state (3–5) (class 1) as well as localized excess electron states resulting from bubble formation in nonpolar fluids (3–5) (class 5) and via the formation of the solvated electron in polar fluids (1, 2; for a recent review, see ref. 6) (class 6) are well understood. On the other hand, the nature of 'intermediate type' excess electron states with regard to temporal (time-resolved) and structural aspects of electron localization are not yet well established. These include 'quasi-localized' states (class 2) originating from fluctuations in the local electron–medium potential which may result in Anderson localization (3, 7) of the excess electron, self-trapping by small configurational fluctuations (8) (class 3), and electron localization by pre-existing traps (9–11) (class 4). The present paper will be concerned with physical information concerning:

(*1*) The energetics of ionization processes and the features of the quasi-free excess electron states in simple nonpolar solids and fluids. Spectroscopic techniques, utilizing vacuum-ultraviolet optical absorption spectroscopy and electron photoemission to probe energy levels, were applied to these problems.

(*2*) Electron localization in polar fluids, studied by monitoring the yields of localized excess electrons. Conventional time-resolved absorption spectroscopy combined with pulse radiolysis methods for determination of the yields of localized electrons were utilized.

While most of previous studies of excess electron states in fluids focused attention on electrons in liquids, the results of the work reported herein will provide pertinent information regarding the effects of phase density on ionization processes and on electron localization, studied over a broad density range.

II. Selective Ionization Processes in Solids and in Dense Fluids

The optical absorption spectra of pure and of lightly doped simple insulators, such as solid and liquid rare gases, can be analyzed in terms of stable exciton or impurity states converging to the bottom of the conduction band (13, 15; for a recent review see ref. 12). The relative simplicity of these exciton and impurity states makes it possible to gain detailed information regarding ionization processes in a dense medium. The sources of experimental information regarding such selective ionization processes are:

(*A*) Identification of Wannier bound states in pure materials and of Wannier atomic or molecular impurity states in doped insulators by absorption spectroscopy. The Wannier series converges to the bottom of the conduction band.

(*B*) From the convergence limit of the Wannier series studied by absorption spectroscopy one can obtain the band gap, E_G, in the pure substance or the impurity ionization potential, E_G^i, of the impurity in the medium.

(*C*) The energetics of the Wannier states, monitored by absorption spectroscopy, result in basic information regarding the characteristics of the conduction band. In particular, from the effective Rydberg constant of the Wannier series one can deduce the effective mass of the electron near the minimum of the conduction band.

(*D*) The threshold for photoconductivity in the pure solid or liquid results in a direct measurement of E_G, while the photoconductivity threshold E_G^i of the doped insulator yields the ionization potential of the impurity in the medium.

(*E*) The threshold for external photoemission from the pure material, E_{TH}, or from the doped insulator, E_{TH}^i, results in the external ionization potentials. From the combination of optical spectra and photoemission yields in pure or in doped insulators one can determine the energy V_0 of the bottom of the conduction band relative to the vacuum level.

In what follows we shall consider first the energetics of ionization processes in solids where Wannier series are now well documented. Subsequently, we shall consider the application and implication of these results for fluids over a wide density range.

In pure insulators low-lying stable excitons originate from Bloch states near the top of the valence band and in the vicinity of the bottom of the conduction band (16–18). Impurity excited states below interband threshold can be considered in terms of a hole in the energetically flat impurity band correlated with electron states, which are constructed from levels near

TABLE 1. Excess electrons in fluids*

Definition	Physical state of fluid	Nature of electron–fluid interaction	State of excess electron	Time scale	Characteristic systems and physical properties
1. Quasi-free	Structure of fluid unperturbed	Single scattering by fluid structure factor $s(\boldsymbol{Q})$ Multiple scattering off density fluctuations (?)	Extended	Adiabatic injection in *all* fluids Long t scale when $V_0 < E_t^B$	$\mu \geq 10^2\ V^{-1}\ cm^2\ s^{-1}$ All fluids short time Heavy rare gases Ar, Kr, Xe Low density nonpolar (He) and polar (H_2O, NH_3) fluids
2. Quasi-localized	Structure of fluid unperturbed	Strongly changing local potentials	Localized (Anderson model) (?) or extended	Long t scale	$0.1 \leq \mu \leq 10\ V^{-1}\ cm^2\ s^{-1}$ T activated motion Some hydrocarbons (?) Transition range in He gas (?)
3. Self-trapped by small density and/or structural fluctuations	Small configurational fluctuations induced by e	Local attractive potential (homopolaron)	Localized (?)	$t \geq \tau_{MM}$	$0.1 \leq \mu \leq 10\ V^{-1}\ cm^2\ s^{-1}$ T activated Some hydrocarbons (?)
4. Localized by pre-existing 'traps'	Unperturbed pre-existing configurational fluctuations	Local attractive potential of 'trap'	Localized	$t \sim \sigma\langle v\rangle n_{trap}$ $t \leq \tau_{DR}$	$\mu \leq 0.1\ cm^2\ V^{-1}\ s^{-1}$ Polar liquids 'short' times $\tau_{DR} \sim 10^{-10}$–10^{-12} s Polar molecular clusters in hydrocarbons. Polar gases
5. Localized by bubble formation	Formation of microscopic cavity, large configurational changes	Essentially repulsive $V_0 > E_t^B$	Localized	$t \gg \tau_{MM}$	$\mu \sim 10^{-2}$–$10^{-3}\ cm^2\ V^{-1}\ s^{-1}$ Volume expansion Optical spectra Liquid He, Ne
6. Localized by large local configurational changes	Radial and orientational changes induced by e	Bound polaron in polar liquids	Localized	$t \gtrsim \tau_{DR}$	$\mu \sim 10^{-3}\ cm^2\ V^{-1}\ s^{-1}$ Optical spectra, etc. solvated electron in polar liquids

*V_0 = Energy of quasi-free electron (qfe) state; μ = electron mobility; σ = cross section for trapping of qfe by a pre-existing cluster; E_t^B = energy of ground state energy of localized electron (class 5 or 6) in the same fluid; τ_{MM} = time scale for molecular motion; τ_{DR} = dielectric relaxation time.

the bottom of the conduction band. In insulators such as solid rare gases, we are primarily concerned with deep exciton and impurity states, where pseudopotential theory was invoked to rationalize the observation of Wannier states (18). Such highly excited deep exciton and impurity states can be described in terms of the effective mass equation (18, 19). If the edges of both valence and conduction band occur at some point $\boldsymbol{k}_0$ in the Brillouin zone (BZ) and the interband transition is dipole allowed, one is concerned with direct excitons. For impurity excitations $\boldsymbol{k}_0$ corresponding to the minimum of the conduction band and direct impurity excitations are always encountered. In simple insulators $\boldsymbol{k}_0$ correspond to the Γ point in the BZ. The high exciton levels E_n and impurity levels $E_n^{\,i}$ (see Figs. 1 and 2) are described in terms of a hydrogenic series converging to the bottom of the conduction band,

$$E_n = E_G - G/n^2 \quad [1]$$

$$E_n^{\,i} = E_G^{\,i} - G^i/n^2 \quad [2]$$

where E_G corresponds to the interband gap at $\boldsymbol{k}_0$ while $E_G^{\,i}$ is the impurity energy gap (see Figs. 1 and 2). The latter energetic quantity, which in the chemist's language just corresponds to the ionization potential of the impurity in the solid, is given by

$$E_G^{\,i} = I_g + P_+ + V_0 \quad [3]$$

where I_g is the impurity gas phase ionization potential, P_+ is the (adiabatic) medium polarization energy by the impurity positive ion, and V_0 designates the energy of the bottom of the conduction band relative to the vacuum level. G and G^i in [1] and [2] correspond to the effective Rydberg constants for the exciton and for the impurity hydrogenic series, respectively, which are given by

$$G = 13.6(\mu/\varepsilon^2)\ \text{eV} \quad [4]$$

$$G^i = 13.6(m^*/\varepsilon^2)\ \text{eV} \quad [5]$$

$$\mu = m^* m_h/(m^* + m_h) \quad [6]$$

where m^* is the electron effective mass near the bottom of the conduction band, m_h is the hole effective mass, again near $\boldsymbol{k}_0$, while ε is the static dielectric constant of the solid. In view of the large value of m_h we expect that G is close to G^i.

High exciton and impurity states, characterized by the quantum number $n \geq 2$, do not reveal any relation to the atomic or molecular excited states of the constituents in the gas phase, and should be viewed as one-electron excitations of the dense medium below the direct interband threshold. Relevant examples for Wannier exciton states in pure rare-gas solids are presented in Figs. 3 and 4. Focusing attention on Wannier impurity states the following quantitative information concerning the static properties of the conduction band emerges.

(*1*) From the effective Rydberg constant G^i, [5], together with the static dielectric constant, one can deduce m^*. These values are invariant

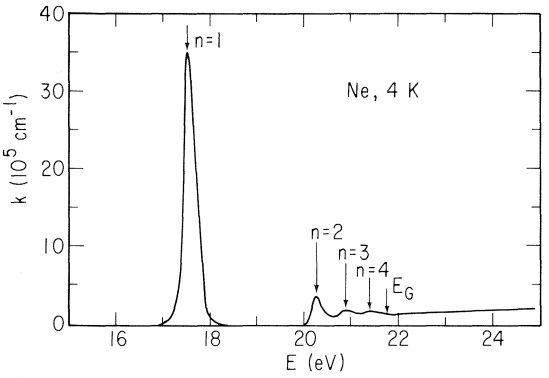

FIG. 3. The absorption spectrum of solid Ne (15, 29).

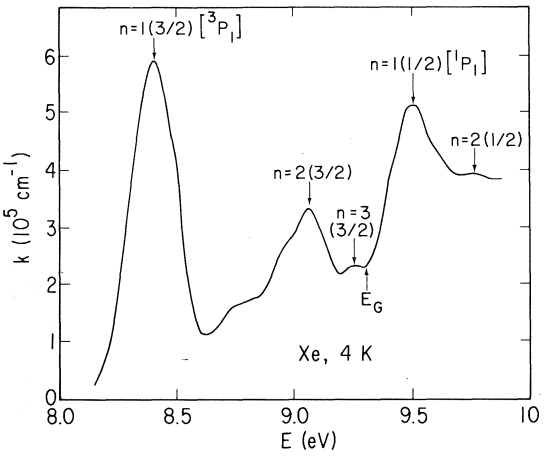

FIG. 4. The absorption spectrum of solid Xe (55).

with respect to the nature of the particular impurity.

(*2*) The convergence limit of the impurity Wannier series results in E_G^i, the impurity ionization potential in the insulator.

(*3*) A direct and reliable approach to derive V_0 rests on the combination of spectroscopic data for E_G^i with photoemission yield data from lightly doped insulators. The photoemission threshold, E_{TH}^i, is

$$E_{TH}^i = I_g^i + P_+ \quad [7]$$

whereupon from [3] and [7] we obtain

$$V_0 = E_G^i - E_{TH}^i \quad [8]$$

An analogous relation of the form

$$V_0 = E_G - E_{TH} \quad [9]$$

holds for the pure solid and liquid insulator.

III. Wannier-type Impurity States in Solid Insulators

We now turn to a brief survey on Wannier impurity states in simple solids. The best known example involves dilute rare-gas alloys (20–22, 14). Typical examples for the absorption spectra of such atomic impurity states (14) are reproduced in Fig. 5. The observation of hydrogenic Wannier impurity states is not limited to rare-gas solids and Xe impurity states were observed in other molecular crystals (23, 24) such as solid H_2, D_2, and CF_4 (Fig. 6). All these spectra pertain to large-radius atomic impurity states. Analogous molecular excitations are also amenable to experimental observation, whereupon extravalence excitations of a molecular impurity in an insulator should exhibit Wannier-type states originating from an electron wavepacket interacting with a molecular positive ion (14). The identification of such molecular excitations is complicated by congestion of vibrational structure, overlap of extravalence

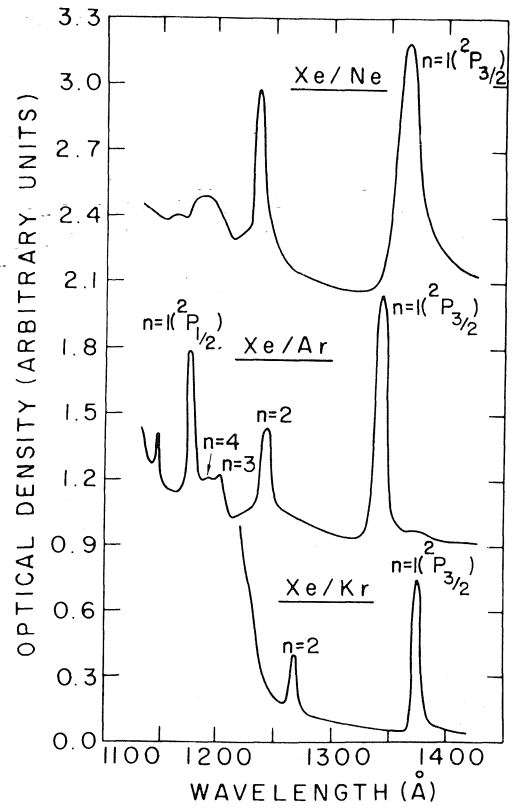

FIG. 5. The absorption spectra of dilute solid rare-gas alloys (14).

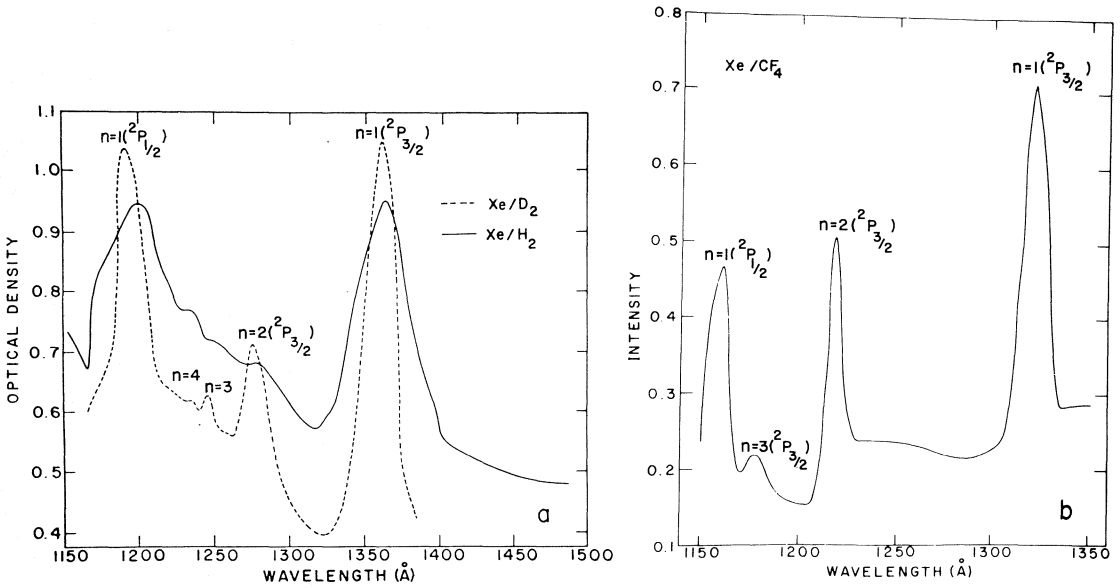

FIG. 6. Absorption spectra of Xe impurity in molecular crystals. (*a*) The absorption spectra of Xe in solid H_2 and D_2 at 6 K. (*b*) The absorption spectrum of Xe in solid CF_4 at 6 K (23).

and intravalence excitations, overlap of extravalence excitations with photodissociative continua, as well as additional line broadening originating from intramolecular electronic relaxation. A typical example for extravalence excitations of the benzene molecule (14) in rare-gas solids is presented in Fig. 7. Analysis of these data according to [2] is demonstrated in Fig. 8.

The physical information derived from solid state absorption spectroscopy is supplemented by the results of photoemission yields from pure solids and from lightly doped insulators (25–30). Figure 9 portrays the energy dependence of the photoemission yield (30) from pure Xe at 20 K. The weak peak at 1380 Å originates from extrinsic effects, while intrinsic photoemission is exhibited below ~1300 Å. Intrinsic photoemission data from atomic and molecular impurity states (26–28) (characterized by $E_{TH}^{i} < E_{TH}$) are presented in Figs. 10–12. Square root extrapolation of the photoemission yield *vs.* energy results in the photoemission thresholds.

In Table 2, we summarize the energetic data characterizing ionization processes in solid rare gases. The following observations are pertinent.

(*a*) E_G^{i} is determined by the nature of the impurity state, according to [3] (see Section II).

(*b*) E_{TH}^{i} is determined by the nature of the impurity state as is evident from [7].

(*c*) The effective Rydberg constants for impurity ionization G^{i} are independent of the nature of the impurity as these are determined by the host dielectric constant and by the features of the conduction band according to [5].

(*d*) The observation that $G^{i} \simeq G$ implies, according to [4]–[6], that $\mu \simeq m^*$, *i.e.* the hole effective mass m_h is large.

(*e*) The V_0 value derived from [8] for doped solids and from [9] for the pure solids corresponds to an intrinsic property of the solid. V_0 is identical, within experimental uncertainty, for the pure and for the doped solids and for the latter it is independent of the nature of the impurity. The self-consistency of the V_0 data provides strong evidence for the validity of the assignment of exciton and Wannier impurity states in insulators.

IV. V_0 Scale for Solid and Liquid Rare Gases

The combination of spectroscopic and photoemission data results in a reliable V_0 scale for solid rare gases. In Table 3, we compare these V_0 values with the experimental data for liquid rare gases recently determined by Tauchert (31). It is apparent that in all cases V_0 in the solid is higher than in the corresponding liquid, indicating that in the former case the contribution of short-range repulsive interactions is

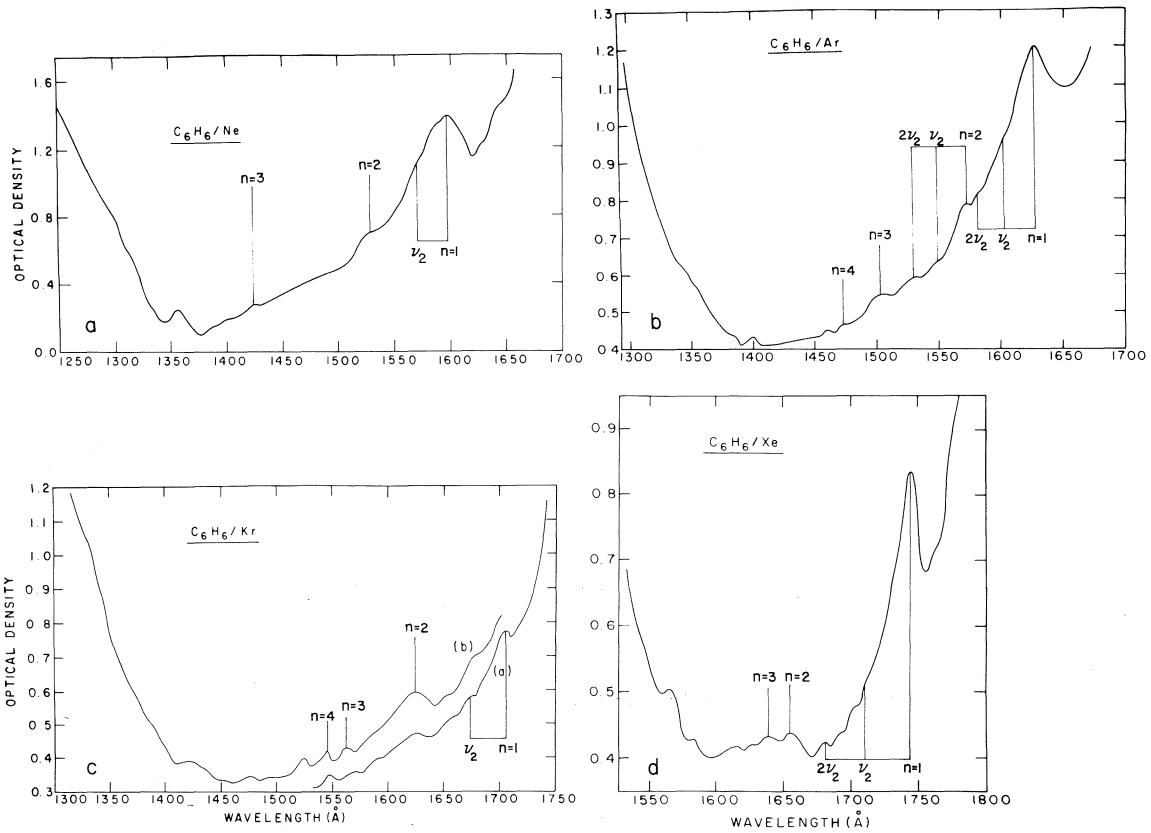

FIG. 7. Extravalence excitations of benzene in solid rare gases (14). (*a*) C_6H_6/Ne; (*b*) C_6H_6/Ar; (*c*) C_6H_6/Kr; (*d*) C_6H_6/Xe.

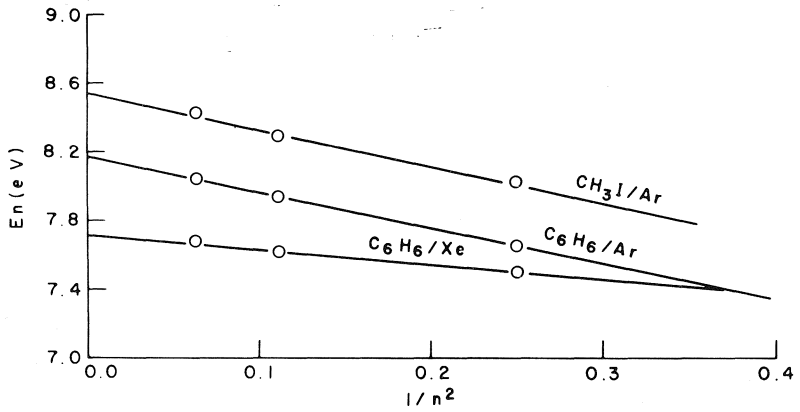

FIG. 8. Plots of E_n *vs.* $1/n^2$ for Wannier molecular impurity states in rare-gas solids.

somewhat higher. It is of interest to confront the experimental V_0 data with the prediction of the simple SJC theory (5). As is well known, the energy of the conduction band minimum for the excess electron consists of two contributions, the background polarization potential U_P and the kinetic energy term T arising from multiple scattering from nearest neighbors, so that $V_0 = T + U_P$. The SJC model provides a simple recipe for the estimate of U_P including

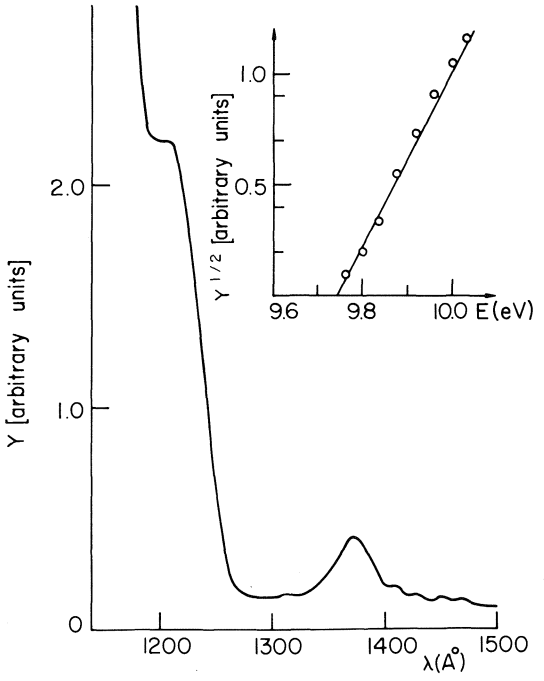

FIG. 9. Photoemission spectrum of pure Xe and 20 K (27, 30).

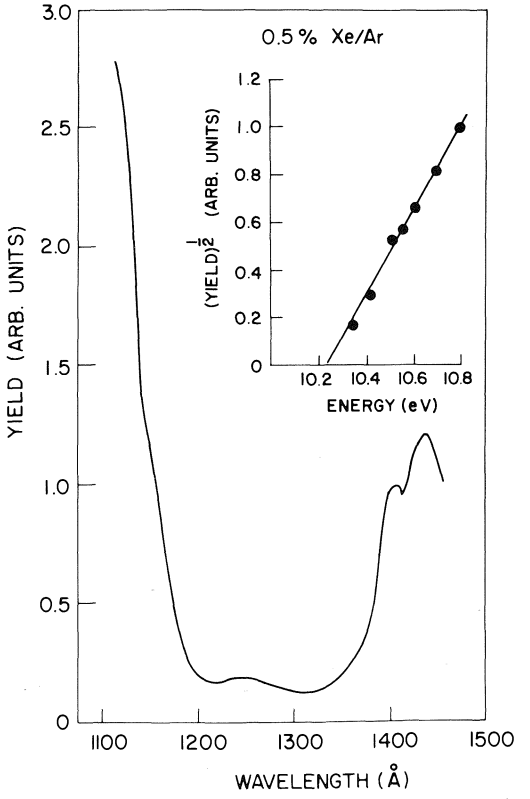

FIG. 10. Photoemission spectrum of Xe in solid Ar (28).

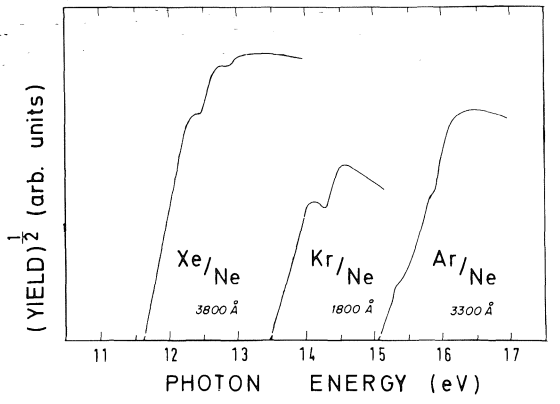

FIG. 11. Photoemission yields of atomic impurities in solid Ne (29).

the screened polarization field of the surrounding atoms and for the evaluation of T by the Wigner–Seitz approximation. Table 4 summarizes the results of such calculations, where the scattering length a of the Hartree–Fock atomic field for He and Ne was taken from theoretical scattering data (5), while for Ar, Kr, and Xe, the value of a was adjusted to fit the liquid V_0 value. These semiquantitative theoretical estimates of V_0 are fraught with difficulties as Table 4 emphasizes how much smaller V_0 is than the T and the U_P terms. These theoretical estimates clearly indicate that the increase of T in the solid is somewhat higher than the corresponding decrease in U_P; however, the SJC model underestimates the relative increase of the short-range repulsive interactions in the solid as is apparent from the result for Ar. Thus this semiquantitative approach (5) should not be considered as an ultimate theory and further theoretical work in this field is required.

V. Impurity Ionization Potentials in Solids

In Table 5 we summarize the available experimental data for the ionization potentials E_G^i of atomic and molecular impurities in solid rare gases obtained from spectroscopic determinations of the convergence limit of Wannier impurity states. Another piece of useful energetic data involves the adiabatic polarization energy of the medium by the positive ion which can be obtained from the relation $P_+ = E_{TH}^i - I_g^i$ provided that the photoemission threshold is known or, alternatively, from [3], $P_+ = E_G^i -$

TABLE 2. Energetic data for pure and doped solid rare gases

System	E_G or E_G^i (eV)	G or G^i (eV)	E_{TH} or E_{TH}^i (eV)	V_0 (eV)
Ne (pure)	21.69	5.24	20.6	1.0 ±0.2
Ar/Ne	16.23	5.27	15.16	1.07±0.1
Kr/Ne	14.76	5.27	13.56	1.2 ±0.1
Xe/Ne	(12.63)		11.67	0.97±0.2
Ar (pure)	14.2	2.4	13.9	0.3 ±0.1

Xe/Kr	10.1	1.7	10.3	−0.2 ±0.1
Xe (pure)	9.28	0.88	9.74	−0.46±0.1

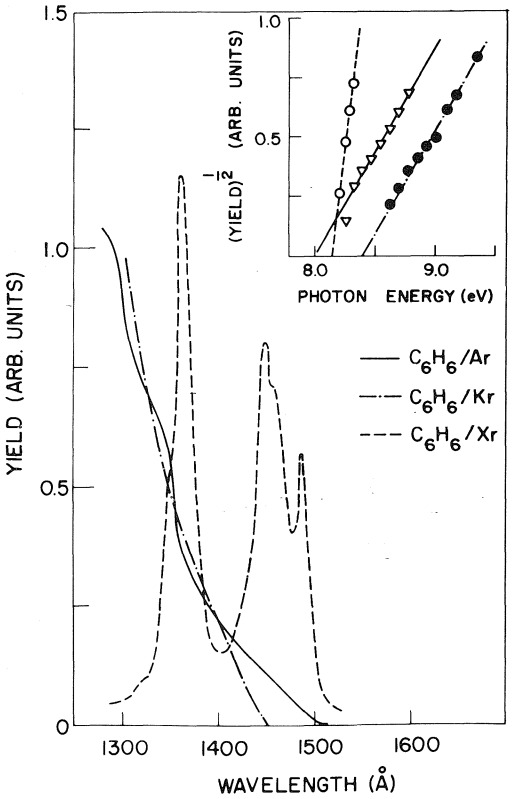

FIG. 12. Photoemission spectra of benzene in solid rare gases (28).

$I_g^i - V_0$ utilizing the experimental V_0 scale (Table 3). The resulting P_+ values are also given in Table 5. From these results we conclude that:

(*A*) The impurity ionization potential in the solid can exceed the gas phase ionization potential provided that V_0 is positive and large. This is the situation for atomic impurity states in solid Ne where $E_g^i > I_g^i$.

(*B*) In a solid characterized by a small positive value of V_0, such as Ar, or where $V_0 < 0$, as is the case for Kr and for Xe, we expect that $P_+ + V_0 < 0$, whereupon $E_g^i < I_g^i$.

(*C*) As $P_+ < 0$ one expects that the external photoemission threshold, [7], is always lower than the gas phase ionization potential, *i.e.* $E_{TH}^i < I_g^i$. This point was discussed by Chia and Delahay (32).

(*D*) For a given impurity in different hosts P_+ roughly increases with increasing optical dielectric constant. A rough approximation for P_+ involves the Born charging energy $P_+ \simeq (e^2/2R)(1 - (\varepsilon_{op})^{-1})$, where R is the effective radius of the impurity. It should be noted that the Born relation does not provide a quantitative account for the experimental P_+ data. Thus, for benzene in Ne, Ar, Kr, and Xe, P_+ exhibits only a weak dependence on the host matrix. Short-range repulsive interactions are of some importance as is evident from the fact that P_+ for Ar^+/Ne is lower than the corresponding values for Kr*/Ne and for

Xe*/Ne, while P_+ for the latter two systems is practically identical.

VI. Excitons in Fluids

While one-electron excitations in crystalline insulators are quite well understood, the nature of analogous excitations in fluids is not yet elucidated. It was suggested (33) that large-radius Wannier-type exciton states are amenable to experimental observation in a dense fluid where electron–medium interaction is sufficiently weak. Liquid rare gases provide suitable candidates for the search for such electronic excitations which are of considerable interest in relation to general problems of electronic states in disordered materials as well as in the context of deriving quantitative information concerning ionization processes in simple liquids. From the experimental point of view evidence has been reported (34, 35) for the identification of the $n = 2$ exciton in liquid Xe and the $n = 2$ impurity state of Xe in liquid Ar (36). In order to establish the nature of Wannier states in dense simple fluids it will be interesting to obtain a continuous description of the electronic excitations of a guest atom or molecule in a host fluid where the fluid density is varied over a broad density range. One has to distinguish carefully between intravalence excitations, low extravalence impurity excitation, and high extravalence impurity excitations, all of which are exhibited at low and intermediate densities of the host medium, and sort out the large Wannier states which may appear in the high density fluids. The general characteristics of different types of impurity excitations in a host fluid are summarized in Table 6.

Messing (37) has recently studied the absorption spectra of atomic and molecular impurity states in simple dense fluids over a wide density range. The absorption spectra of the Xe/Ar system from the atomic limit up to the solid one is presented in Figs. 13 and 14. At low and at moderate Ar densities (ρ = 0–0.6 g cm^{-3}) five 'atomic' excitations are exhibited (Fig. 13) in the range 1150–1300 Å.

(I) $6s'$ [1/2] $J = 1$ located in the atomic limit at 1296 Å.

(II) $5d$ [1/2] $J = 1$ located in the atomic limit at 1250 Å.

(III) $5d$ [5/2] $J = 3$ which is symmetry forbidden in the isolated atom, being pressure induced around 1210 Å.

(IV) $5d$ [3/2] $J = 1$ located at 1192 Å in the atomic limit.

TABLE 6. Medium effects on absorption spectra of a guest atom in a host fluid and solid*

States of perturbing medium	Guest atomic states		
	(*1*) Intravalence excitations	(*2*) Lowest extravalence $\Delta n_A = 1$ excitations	(*3*) High extravalence $\Delta n_A \geq 2$ excitations
(*A*) Spectral perturbations by a foreign gas at low and at moderate densities	(*a*) Spectral shifts (small red or blue) and line broadening (*b*) Appearance of 'red' or 'blue' satellites (*c*) Symmetry breaking, induction of forbidden transitions	(*a*) Shifts (red at low densities, blue at higher densities) and line broadening (*b*) Appearance of 'red' or of 'blue' satellites (*c*) Symmetry breaking, induction of forbidden transitions	(*a*) Spectral shifts (red or blue) (*b*) States converges into (perturbed) ionization potential
(*B*) Spectral effects of high density fluid or liquid	Same as *1A*	(*a*) Large spectral shifts (blue) (*b*) Satellites disappear, merge with main line into a broad band (*c*) Forbidden transitions exhibited	(*a*) States 'disappear' (*b*) Appearance of high Wannier $n \geq 2$ states (*c*) Wannier states converge into bottom of conduction band
(*C*) Spectral effects in a solid	(*a*), (*b*), (*c*) same as *1A* (*d*) Crystal field splitting of degenerate excited states	Same as *2B*	Same as *3B* Wannier states well resolved due to line narrowing relative to liquid

*n_A, atomic or molecular one-electron quantum number (qn); n, qn for Wannier states.

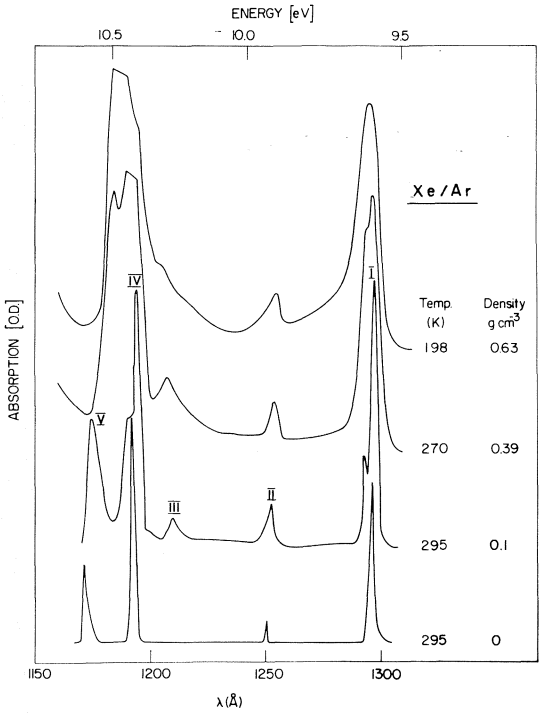

FIG. 13. The absorption spectra of Xe in fluid Ar at low densities (37).

(V) 7*s* [3/2] $J = 1$ located at 1170 Å in the atomic limit.

In the high Ar density region (Fig. 14) the absorption band in the range 1225–1250 Å exhibits an appreciable enhancement for $\rho > 0.8\ \mathrm{g\ cm^{-3}}$. In Fig. 15 we present Messing's results for the intensity ratio of this absorption relative to the intensity of transition I. The intensity enhancement of the 1225–1250 Å band in the Xe/Ar system is entirely different from the behavior of the Xe/Ne system where this intensity ratio reveals only a weak density dependence. Messing (37) assigned the strong absorption band located around 1250 Å in the Xe/Ar system of high Ar densities $\rho > 0.8\ \mathrm{g\ cm^{-3}}$ to the $n = 2$ Wannier impurity states in fluid Ar. Making use of [3] one can then provide an estimate for the Xe impurity ionization potential in liquid Ar assuming that the electron effective mass m^* in the liquid is equal to that in the solid. We then obtain $E_G^{\,i} = 10.9$ eV for Xe in liquid Ar and $P_+ = 1.0 \pm 0.2$ eV for the polarization energy of the liquid.

It is of considerable interest to obtain information regarding the density dependence of the ionization potential of an impurity in a

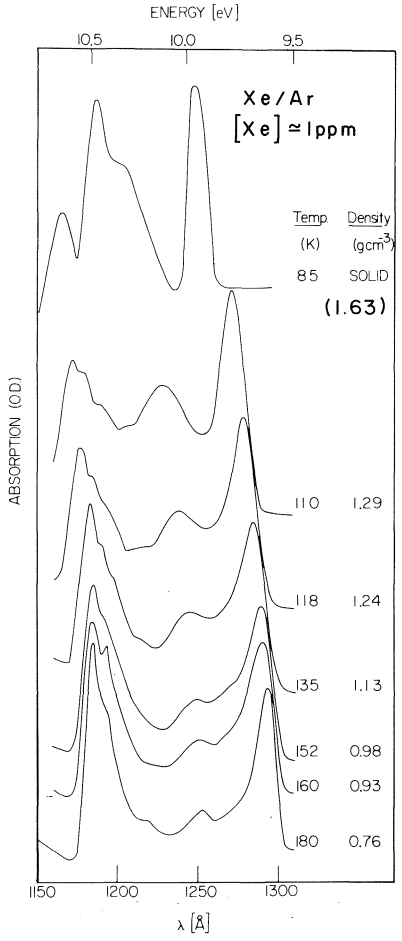

FIG. 14. The absorption spectra of Xe in fluid Ar at high Ar densities (37).

fluid. Messing (37) has studied the vacuum-ultraviolet spectra of CH_3I in Ar over a broad density range. At low densities six Rydberg series are exhibited, three of which converge to the first ionization potential (38). In the Ar density range $\rho = 0$–$0.5\ g\ cm^{-3}$ five members $n = 1$–5 of the Rydberg series could be clearly observed (37). Analysis of these data using the isolated molecule quantum defects (38) results in $G^i = 9.6\ eV$ and $E^i = 9.2\ eV$ for CH_3I at $\rho = 0.34\ g\ cm^{-3}$. In Table 7 we summarize the available experimental information derived from spectroscopic data concerning atomic and ionization potentials in fluids (37). These results demonstrate the gradual decrease of the impurity ionization potential with increasing fluid density. Such a pattern will be exhibited in any fluid where $V_0 < 0$ as is the case for Ar. It is also worthwhile to note that P_+ in the liquid is considerably lower than in the solid, a difference which cannot be reconciled just by the 15% change in the dielectric constant. Obviously, these interesting areas of electronic excitations and ionization processes in fluids deserve further experimental and theoretical effort.

Up to this point we have been concerned with some of the intrinsic features of one-electron excitations in solid and liquid insulators which provide information concerning the energetics of ionization processes in fluids and some static characteristics of the conduction band in such systems. We shall now proceed to discuss some dynamic aspects of electron localization in dense fluids.

VII. Electron Localization in Polar Fluids

Excess electrons in He gas at low temperatures undergo a sharp 'transition' from the quasi-free state to a localized bubble state with increasing density (3, 39–41). Levine and Sanders (39) have demonstrated that the mobility of electrons injected into He gas exhibits a dramatic drop of some four orders of magnitude over a density range of $\sim 10\%$. The nature of the electronic states and electron transport in the transition region were described in terms of the Anderson model (3) by the percolation picture (42) and by a phenomenological model where extended and localized states coexist (43, 44). Electron localization in subcritical and in supercritical polar fluids at sufficiently high densities is expected to be a general phenomenon, while at low densities of a polar fluid the quasi-free excess electron state will be energetically stable. One thus expects that in a polar fluid, as in the case of He, a 'transition' from the localized state to the quasi-free state will be exhibited with decreasing fluid density (45). The problem of electron localization in polar fluids as a function of density (and other thermodynamic variables of state) is of considerable interest (45–49). The following questions are relevant in this context.

(*1*) Can one observe a 'critical' density, ρ_C, for the 'transition' between localized and quasi-free excess electron states in a polar fluid?

(*2*) What are the physical properties of the localized excess electron in a polar fluid over a broad density range where the localized state is thermodynamically stable?

Points *1* and *2* require basic experimental

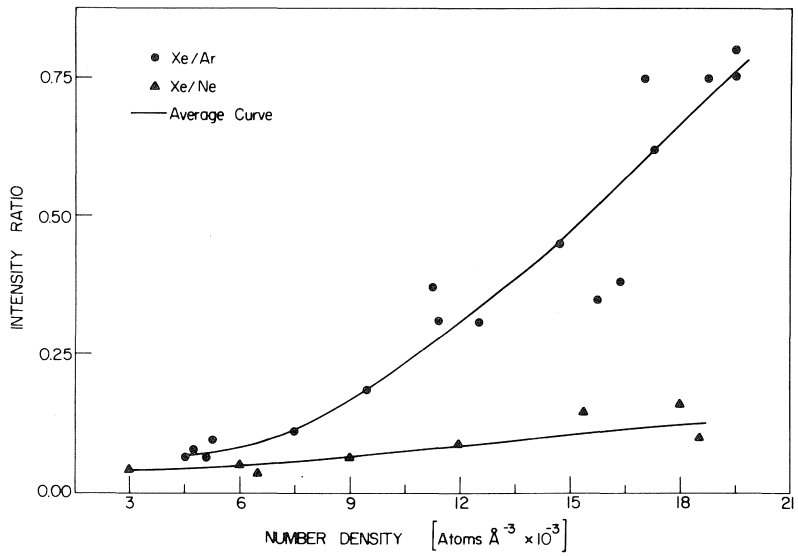

FIG. 15. The density dependence of the intensity ratio of the 1250 Å absorption to the $^1S_0 \rightarrow {}^1P_1$ transition (band I) in Xe/Ar and in Xe/Ne (37).

TABLE 7. Ionization potentials of some atomic and molecular impurities in fluid Ar (from ref. 37*a*) (solid state data are given for comparison)

Guest	Host	E_G^i (eV)	I_g^i (eV)	G (eV)	$P_+ + V_0$ (eV)	P_+ (eV)
Xe	Liquid $\rho = 1.35$ g cm^{-3}	10.9	12.13	(3.0)	−1.23	−1.03
Xe	Solid $\rho = 1.7$ g cm^{-3}	10.54	12.13	2.4	−1.59	−1.79

CH_2O	Liquid $\rho = 1.24$ g cm^{-3}	10.2	10.88	3.8	−0.68	—

information. Supplementary theoretical work should be directed towards the elucidation of the following problems.

(*3*) The electron localization process in polar fluids with respect to the role of configurational fluctuations, pre-existing traps, etc.

(*4*) A proper theoretical description of localized excess electron states with regard to the role of short-range and long-range interactions.

A theoretical study of the properties of localized excess electrons and of their thermodynamic stability in a *homogeneous* polar fluid was conducted by Gaathon and co-workers (48, 49). He considered the molecular model for the localized excess electron incorporating short-range attractive and repulsive interactions with the first 'molecular' coordination layer, which consists of N molecules, and long-range polarization interactions with a medium characterized by the mean fluid density beyond the first coordination layer. This homogeneous model results in the following predictions.

(*a*) The critical densities for electron localization in H_2O and NH_3 (Table 8) are obtained

from a modified energetic stability criterion which incorporates entropy changes accompanying the formation of the first coordination layer.

(*b*) The density dependence of the absorption band maximum $h\nu_{max}$ exhibits three distinct regions. (b.1) At high densities (ρ = 1.2–1.0 g cm^{-3} for H_2O) $h\nu_{max}$ drops fast with decreasing ρ. (b.2) Over a broad density range (ρ = 1.0–0.1 g cm^{-3} for H_2O) $h\nu_{max}$ exhibits a weak ρ dependence. (b.3) At lower densities ($\rho < 0.1$ g cm^{-3} in H_2O) $h\nu_{max}$ decreases fast with decreasing ρ.

Experimental studies of the absorption spectra and the yields of localized excess electrons in subcritical and supercritical water and ammonia were conducted by Schindewolf and co-workers (46, 47) and by Gaathon (45, 48, 49). Extensive experimental data for electron localization in D_2O, NH_3, and ND_3 were obtained (49) in the density range $\rho = 1.0\text{–}8 \times 10^{-3}$ g cm^{-3} (p = 1–400 atm, T = 273–670 K) for D_2O and ρ = 0.6–10^{-2} g cm^{-3} (p = 1–200 atm, T = 273–430 K) for NH_3 and ND_3. Pulse radiolysis techniques were employed.

Figures 16 and 17 portray typical absorption spectra (49) of localized electrons in subcritical and supercritical D_2O. The experimental density dependence of $h\nu_{max}$ (corrected for temperature effects) is presented in Fig. 18. In this figure these experimental results are confirmed with the theoretical predictions (Section *b*). We note that the experimental density dependence in region b.1, where a sharp drop of $h\nu_{max}$ is predicted, and in range b.2, where $h\nu_{max}$ exhibits a weak density dependence, is in reasonable agreement with the trend predicted by the homogeneous model. However, in the low density range $\rho < 10^{-1}$ g cm^{-3} the experimental values of $h\nu_{max}$ are practically independent of the fluid density in marked contrast to the expectations based on the homogeneous model which envisions a fast drop of $h\nu_{max}$ with decreasing density in range b.3.

The yields for the formation of localized excess electron states in D_2O and in ND_3 were determined by two independent methods (49). First, time-resolved absorption of the localized electron was found to obey second order decay kinetics and extrapolation of these results to $t = 0$ resulted in the yield. Second, the absorption of the localized electron was monitored during electron pulses of the duration of τ = 0.3 μs and τ = 1.5 μs, the data being analysed

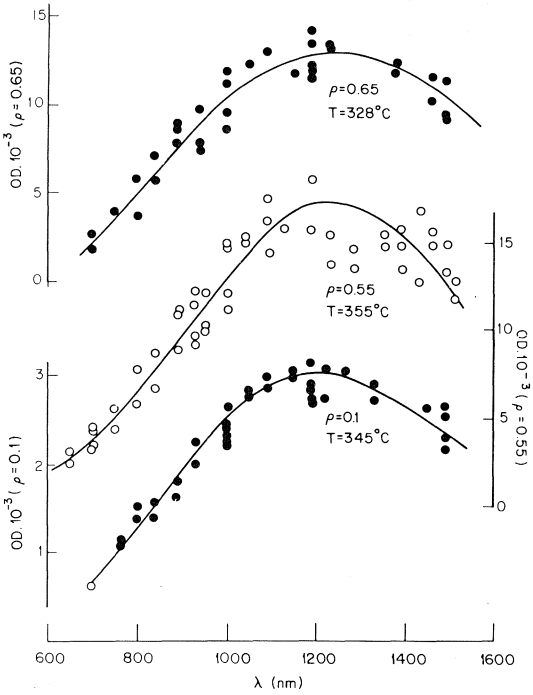

FIG. 16. The absorption spectra of the localized electron in subcritical D_2O (49).

according to the relation $d[e_l]/dt = \alpha\rho I - k[e_l]^2$ where α is the yield of the localized electrons, I is the intensity of the electron beam, ρ is the fluid density, and k is the bimolecular recombination rate constant. The experimental procedures for the determination of the yields of the localized electron provide proper corrections for the 'kinetic instability' of the localized state, originating from efficient recombination, and result in reliable experimental data for the initial yields. The density and temperature dependence of the yields α in D_2O and in ND_3 are displayed in Figs. 19 and 20. From these results we conclude that:

(*1*) In D_2O the localized excess electron state is stable throughout the entire density range 8×10^{-3} g cm$^{-3} < \rho < 1.0$ g cm^{-3} and up to T = 673 K. Thus in supercritical D_2O $\rho_C < 8 \times 10^{-3}$ g cm^{-3}. This experimental result is in conflict with the theoretical prediction of the homogeneous model (Table 8).

(*2*) Electron localization in ND_3 (Fig. 20) exhibits a more complex and more interesting behavior. Near the liquid–vapor coexistence curve (CEC) electron localization is observed up to the lowest density $\rho \simeq 5 \times 10^{-3}$ g cm^{-3}

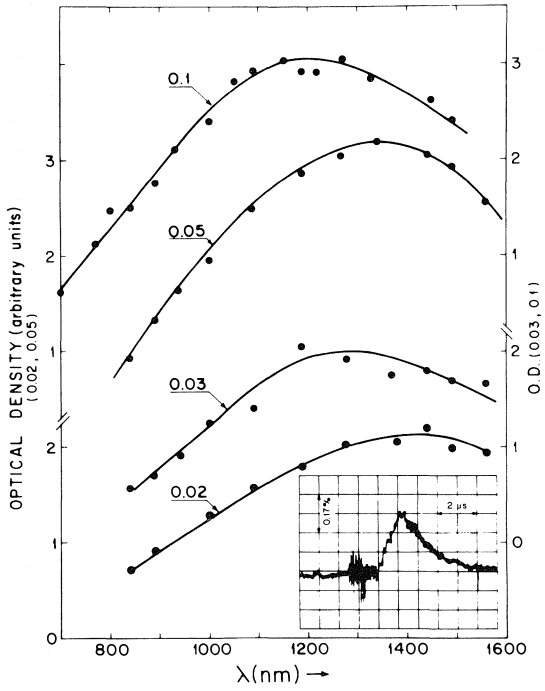

FIG. 17. Absorption spectra of the localized electron in D_2O vapor. The vapor densities (relative to the liquid at 4°C) are indicated by the numbers above the curves (48, 49). FIG. 18. The density dependence of the band maximum of the localized electron in D_2O (49). Solid curve represents the experimental data at 623 K (corrected for temperature dependence). The dashed curve (49) portrays the prediction of the homogeneous model.

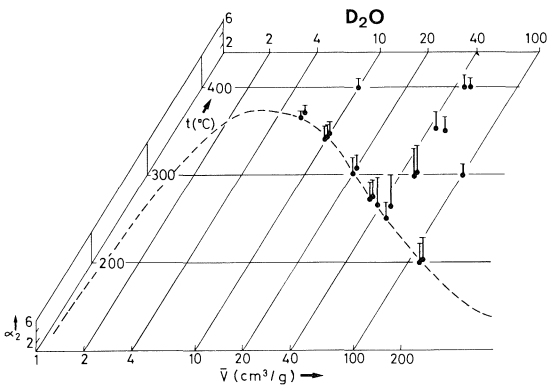

FIG. 19. Density and temperature dependence of the yields and of the localized electrons in D_2O (49). The solid dots represent (ρ, T) points for which experiments were conducted. The vertical lines represent the values of α in arbitrary units. The dashed curve is the liquid–gas CEC. Densities represented in terms of specific volumes $\rho = (\bar{v})^{-1}$.

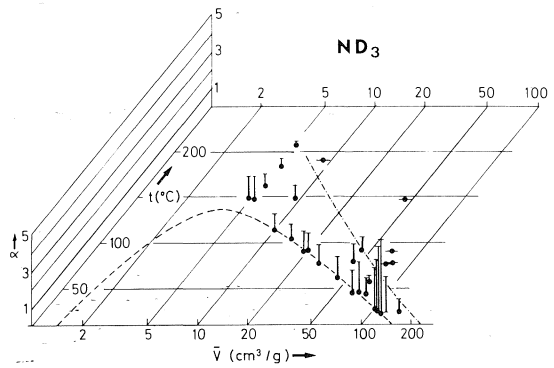

FIG. 20. Density and temperature dependence of the yields of localized electrons in ND_3 (49). Presentation of data identical to those in Fig. 19. Points represented by (—) correspond to ρT values where localized electrons could not be detected. Dashed curve is the liquid–gas CEC. Dotted-dashed curve corresponds to a rough segregation of the ρT plane to two regions where localized states exist and where localized states are thermodynamically unstable.

studied by us, whereupon $\rho_C < 10^{-2}$ g cm^{-3} near the CEC. This observation is again inconsistent with the prediction of the homogeneous model. At high temperatures above the CEC the yield of localized electrons vanishes. In Fig. 20 we have drawn a line in the ρT plane which segregates the range of electron localization from the thermodynamic range where the quasi-free electron state is stable. For these experimental results it is apparent that in supercritical ND_3 ρ_C is determined not only by density but also by the temperature.

TABLE 8. Critical densities for electron localization in polar fluids

	Model calculations		Experimental
	N	ρ_C (g cm^{-3})	ρ_C (g cm^{-3})
H_2O	4	0.044–0.03	$<5\times10^{-3}$
$T = 660$ K	6	0.07–0.05	
NH_3	4	0.08–0.065	$<10^{-2}$ near CEC
$T = 470$ K	6	0.14–0.11	~0.1 40°C above CEC

Although the thermodynamic stability criterion used in the homogeneous model involves a temperature dependence originating from an entropy contribution, the experimental results cannot be accounted for in terms of such a model and in particular the low value of ρ_C near the CEC is striking. On the other hand, at high temperatures above the CEC the predictions of the homogeneous model are not too bad; for example, at 40°C above the CEC $\rho_C \simeq 0.1$ g cm^{-3} in agreement with the observation of Olinger *et al.* (47), in accord with the theoretical prediction (Table 8). However, this minor success does not reconcile the serious discrepancies between the experimental observations and the expectations of the homogeneous model.

These discrepancies between the theoretical homogeneous model and the facts of life can be summarized as follows.

(I) The weak dependence of $h\nu_{max}$ on ρ at low ($\rho < 0.1$ g cm^{-3}) densities is in conflict with the prediction for a sharp drop of $h\nu_{max}$ in that range. This theoretical result originates from the decrease (at $\rho < 0.1$ g cm^{-3}) of the polaron coupling parameter $\beta = \varepsilon_{op}^{-1} - \varepsilon_s^{-1}$ which determines the long-range polarization potential.

(II) The low values of ρ_C observed for D_2O over the entire ρT range and for ND_3 near the CEC. The high value of ρ_C predicted by the homogeneous model originates from the following three causes. First, a cluster of $N = 4$ solvent molecules does not localize the excess electron. Second, the sharp decrease of β with decreasing density at low ρ results in a decrease of the ground state energy. Third, the entropy contribution resulting from formation of the first coordination layer from the homogeneous gas is crucial in determining the thermodynamic stability of the localized state.

(III) The strong temperature dependence of ρ_C for ND_3 is inconsistent with the prediction that the density alone is the primary thermodynamic variable of state which determines the stability of the localized state. We are forced to conclude that the homogeneous model is inadequate and propose that the role of pre-existing density fluctuations is crucial in the electron localization process in polar fluids.

We propose that in polar supercritical fluids of polar molecules the quasi-free electron is trapped by density fluctuations. These density fluctuations can be envisioned as pre-existing clusters which act as electron traps. Similar ideas for dynamics of electron localization in liquids were recently advanced by Kenney-Wallace and Jonah (10) and by Baxendale and Sharpe (11). We address ourselves to a more general problem; as in our one-component system the fluid density can be continuously varied, we inquire when is the amplitude of density fluctuations sufficiently low (*i.e.* the size of the pre-existing clusters is too small) so that electron localization will not occur.

To determine the probability of electron capture by density fluctuations two cardinal points have to be elucidated.

(*A*) What is the minimal size of a pre-existing cluster to insure electron capture?

(*B*) What is the probability for density fluctuations of appropriate amplitude to satisfy condition *A*?

To provide a semiquantitative answer to point *A* we have carried out (49) calculations of the ground state energy of an electron localized in a cluster which consists of $N = 4$ molecules in the first coordination layer and N_D molecules in the second coordination layer. These calculations were conducted (49) using a modified version of Iguchi's method (50). We find that the localized excess electron is stable in a cluster of water molecules consisting of $N = 4$ and $N_D \simeq 2$, while for a cluster of ammonia molecules energetic stability is insured for $N = 4$ and $N_D \simeq 6$. Next we turned to point *B* and utilized (49) the simple thermodynamic fluctuation theory to evaluate the probability distribution for density fluctuations consisting of $N_T = N + N_D$ molecules. This probability distribution is determined by the mean density,

by the isothermal compressibility, by the temperature, and by N_T. Detailed calculations will be presented elsewhere and only some conclusions of this analysis will now be mentioned. As the compressibility is high near the CEC the probability of density fluctuations characterized by a large amplitude is always sufficiently large to insure electron localization both for D_2O and for ND_3 in that region. As $N_T \simeq 10$ for ND_3 and $N_T \simeq 6$ for D_2O we expect that the probability for sufficiently large density fluctuations in the latter case will be large enough over the entire ρT range studied by us. On the other hand, for ND_3 the value of N_T is sufficiently high so that at sufficiently low densities high above the CEC (where the compressibility is low) the probability for the occurrence of large ($N_T \simeq 10$) clusters is low and electron localization will not occur. All these expectations agree with the experimental observations.

We thus conclude that the role of density fluctuations is crucial in determining the energetics and dynamics of electron localization in polar fluids. We have experimentally followed the life story of the electron in the polar fluid on a long (μs) time scale. Thus, the spectroscopic information obtained by us does not pertain, of course, to the initial state of the localized electron trapped in the pre-existing cluster. Following the initial process of electron localization several dynamic processes will be exhibited which will result in further energetic stabilization of the localized state. These will include dielectric relaxation (10, 11) (induced by the field of the localized charge) of the external polar medium. In low density polar fluids ($\rho < 0.1$ g cm^{-3}) this long-range effect may be less important than in normal liquids. More interesting is the possibility of further clustering of polar molecules around the initially formed charged cluster. Such a 'snowball effect' will result in the formation of a trapped electron localized in a large cluster of polar molecules, which is characterized by a high local density. The 'snowball effect' is reminiscent of electrical stabilization of liquid drops in supersaturated vapors.

One of the compelling reasons for the study of excess electron states in fluids is that excess electrons can be used as probes for the study of molecular geometry and molecular dynamics in normal liquids and in subcritical and supercritical fluids. The results reported herein, as well as the recent investigations of the dynamics of electron localization in He gas (39–44) and in normal liquids (9–11, 51, 52), provide the first steps towards that goal.

Discussion

L. Kevan: Do you think the "snowball" effect for electron localization should occur in nonpolar liquids doped with polar molecules? In recent experiments on glassy mixtures of alkanes with alcohols we have not yet found evidence for such an effect. And in liquid mixtures I believe Professor Baxendale also does not find such evidence. It may be that the critical experiment has not yet been performed since alcohol forms clusters in alkanes. What is needed is a polar molecule that does not cluster on nonpolar media.

J. Jortner: The proposed "snowball" effect in subcritical and supercritical polar fluids at moderately low densities involves a formation of a localized state by electron attachment to a (sufficiently large) pre-existing cluster, followed by subsequent attachment of polar molecules to that charged cluster. Such effect will not be observed in glasses because of the low diffusion coefficient of the polar molecules. In liquid mixtures of polar and nonpolar molecules at a low concentration of the former such effects can be exhibited. However, the time scale is unknown.

G. A. Kenney-Wallace: Jonah and I have carried out picosecond pulse radiolysis experiments on alcohols diluted in alkanes and, to quote one example, electron solvation in butanol–*n*-hexane (1:5 mol ratio) mixtures definitely appears to be slower than that in pure butanol, by a factor of about 2. The stable spectrum appears within tens of picoseconds, not nanoseconds as might have been expected for a diffusion process; however, even in this concentration range we expect to have large alcohol clusters and so an adequate number of alcohol molecules are already present and available for the solvation sheath. In order to see any "snowball" effects, as Jortner has suggested, we would have to go to much lower concentrations of alcohol.

J. Jortner: Obviously picosecond studies of the systems investigated by you and by Baxendale at low alcohol concentrations are required to settle the point whether 'condensation' of additional polar molecules on a charged cluster occurs.

A. O. Allen: Conductivity studies of dilute (0.01 *M*) methanol in hydrocarbons shows that an equilibrium exists between mobile electrons and methanol-solvated electrons. The evolution of solvation in time is therefore due (at least in part) to passage from smaller to larger clusters through the conductive (unsolvated) state which exists in thermal equilibrium.

J. Jortner: The peaceful coexistence between extended and localized states at thermal equilibrium in methanol–hydrocarbon mixtures bears a close analogy to the recent experiments of Klaus Schwarz on electron drift velocities in He gas where 'slow' and 'fast' electrons were identified.

N. R. Kestner: Whether or not the "snowballing" effect can be observed after the initial cluster is formed (say in Baxendale's experiments) depends on how long range is the effect of the electron on the fluid. If that potential is reasonably short range, the optical spectra may not change significantly after the initial trap is formed especially if the snowballing involves, say, a third or further coordination layer. We now believe that, in fact, the old theoretical models had a potential which was much too long range.

J. Jortner: The "snowball" effect resembles Thompson condensation of charged droplets occurring on a microscopic scale. One has to distinguish carefully between the nature of the potential acting on the localized electron at long times, whose long-range part is affected by density fluctuation, and the interaction of the charged cluster with polar molecules leading to cluster growth. The invariance of the optical spectrum in D_2O in the density range 0.8–0.01 g cm^{-3} reflects the result of a long time experiment where clustering has been already completed.

L. Onsager: Let me argue for the proposition that the "snowball" forms from the outside in. If we regard the trap formation as a process of dielectric relaxation around a delocalized electron, this will proceed at a rate given by the longitudinal relaxation time $\tau_L = \tau_D\varepsilon_\infty/\varepsilon_0$ in the distant part of the fluid (outside the counteracting region of localization), and the equilibrium polarization in the immediate vicinity is established last.

J. Jortner: Your interesting proposal implies that the initial step in electron localization involves the fast response of the polar medium to a large polaron in an extended state and that the long-range polarization field builds up on a time scale which is considerably shorter than the Debye relaxation time. A few years ago Rentzepis, Jones, and myself proposed that the initial step in electron localization in a polar liquid (water) involves the build-up of the long range dipolar polarization field. However, in low density supercritical polar fluids near the liquid–vapor coexistence curve we have to consider the role of pre-existing clusters (originating from density fluctuations), which act as electron traps.

Photoionization energies: liquids and solutions versus gases (Extended Abstract)

LADISLAV NEMEC, LUCILLE CHIA, AND PAUL DELAHAY
Department of Chemistry, New York University, New York, NY, U.S.A. 10003

Received November 22, 1976

We compare the external ionization energies of neutral and ionic species in liquids with the ionization energies of these species in the gas phase. The experimental liquid–gas shifts in ionization energy thus obtained are estimated from simple models.

The external ionization energies for liquids and solutions were obtained by photoelectron spectroscopy by means of a recently developed method (1). The *second* derivative of the quantum yield, with respect to the kinetic energy T of electrons emitted into vacuum, was measured as a function of T. Second derivative curves (sdc) exhibit one or several maxima, each of which corresponds to a photoionization process. The external ionization energy I is related to T_{max} at each sdc maximum by

$$[1] \qquad I = E - T_{max} - 0.52w_{1/2}$$

where E is the photon energy and $w_{1/2}$ is the half-width of the sdc segment on the high-energy side of the maximum. The $w_{1/2}$ correction arises from energy transfer from quasi-free electrons to the liquid medium and is rather small ($w_{1/2} \approx 0.5$ eV).

The energy I for *neutral substances* is lower in the liquid than in the gas phase. The *red shift* (1 to 2 eV) from gas to liquid arises (1) in a major part from the difference between the energies stored in the electrical field of the ion (produced by photoionization) in the liquid and vacuum. This shift depends primarily on the *optical* dielectric constant of the substance being photoionized and does not vary markedly from one substance to another.

Conversely, the energy I for *ions* is higher for solutions than in the gas phase. The *blue shift* from gas to liquid ($\approx$2 to 3 eV) is accounted for, in a major part, by the energy of solvation of the ion. This energy depends on the *static* dielectric constant of the solvent, and consequently the shift for ions can vary appreciably with the nature of the solvent. Detailed experimental results and calculations are presented for a variety of substances.

This work was supported by the National Science Foundation and the Office of Naval Research.

Discussion

J. Jortner: The general feature of the ionization potential (IP) of a neutral molecule in solution which is red-shifted relative to the gas phase IP pertains to external photoemission to the vacuum. For an internal ionization process the shift can be red or blue depending on the sign and magnitude of V_0.

P. Delahay: Your statement corresponds to my equation for the liquid

$$I_{internal} = I_{external} + V_0$$

where the I's are positive by convention and V_0 is taken with its sign. This relationship does not include the surface potential which was assumed to be zero. V_0 does not matter in the comparison of $I_{external}$ for the liquid with I_{gas} since the final state of the electron is the same in both cases.

A. Henglein: Ionization energies determined by photoelectron spectroscopy are vertical ionization energies which exceed the thermodynamic ones by the reorganization energy of the cation formed (including its solvation shell). The thermodynamic free energies ΔG_i of ionization are important for the understanding of chemical reactions in which an electron is abstracted from a solvent molecule (by a free radical or excited molecule). Free energies of ionization have recently been published (see table) for

Solvent	ΔG_i (eV)	E^0 (V)
Water	7.9	3.4
Ethanol	6.4	1.9
Acetone	6.5	2.0

a few solvents (A. Frank, M. Grätzel, and A. Henglein. Ber. Bunsenges. Phys. Chem. **80**, 593 (1976)). These free energies can be converted into standard redox potentials E^0 using the relation

$$E^0 = -4.5 + \Delta G_i$$

-4.5 V being the potential of an electron in the gas phase on the standard redox potential scale. The standard redox potential of the redox couple H_2O^+/H_2O is 3.4 V.

Effect of temperature and phase on the photoionization energy threshold of TMPD in hydrocarbon solvents

Received September 27, 1976

J. BULLOT and M. GAUTHIER. Can. J. Chem. **55**, 1821 (1977).

The temperature dependence of the TMPD photoionization energy threshold, I, in a set of eight hydrocarbon solvents has been systematically studied, from room temperature down to 77 K. For this purpose ion-pair formation is detected either by measuring the photocurrents in the liquid phase or by measuring the recombination luminescence intensity in the solid phase. It is found that I(liquid) increases linearly when the temperature is decreased down to the liquid–solid transition temperature. At this temperature I undergoes an abrupt increase of 0.2–0.6 eV depending on the hydrocarbon and the nature of the phase transition. Any subsequent solid–solid phase change is accompanied by a new shift towards higher energy. In the low temperature phase of all the studied crystals, I(solid) has a constant value down to 77 K. Glass-forming liquids have a very different behavior: I varies linearly in the liquid and the straight line extrapolates to the I(glass) value at 77 K. The applicability of the two methods is discussed. From the present data it is concluded that the conduction state energy, V_0, is constant in the low-temperature phase of crystals. By calculating the polarization energy due to the $TMPD^+$ cation and from data on the temperature dependence of V_0 in the liquid phase, we have estimated V_0 in crystalline *n*-hexane (0.64 eV) and 2,2,4-trimethylpentane (0.44 eV) and in the plastic phase of cyclohexane (0.47 eV) and 2,2-dimethylbutane (0.01 eV). Finally a correlation of I with the medium density is described.

J. BULLOT et M. GAUTHIER. Can. J. Chem. **55**, 1821 (1977).

Nous avons étudié la variation en fonction de la température du seuil de photoionisation, I, de la TMPD dans huit hydrocarbures, depuis la température ambiante jusqu'à 77 K. La formation des paires d'ions est détectée soit par la mesure des photocourants en phase liquide, soit par la mesure de l'intensité de la luminescence de recombinaison en phase solide. I(liquide) augmente linéairement quand la température décroît, et ceci jusqu'à la température de transition liquide–solide. A ce point I augmente brutalement de 0.2 à 0.6 eV, suivant l'hydrocarbure étudié et la nature de la transition de phase. Toute autre transition de phase solide–solide s'accompagne d'une nouvelle augmentation de I. Dans la phase basse température des cristaux étudiés, I(solide) a une valeur constante jusqu'à 77 K. Les liquides qui donnent des verres ont un comportement très différent: I varie linéairement dans le liquide et les valeurs extrapolées coïncident avec la valeur mesurée à 77 K dans le verre. A partir de ces données on peut conclure que le bas de la bande de conduction, V_0, a une valeur constante dans la phase basse température des cristaux. A partir du calcul de l'énergie de polarisation du cation $TMPD^+$ et des données sur la variation de V_0 en fonction de la température en milieu liquide, nous avons estimé la valeur de V_0 dans les cristaux de *n*-hexane (0.64 eV) et de triméthyl-2,2,4 pentane (0.44 eV) et dans la phase plastique du cyclohexane (0.47 eV) et du diméthyl-2,2 butane (0.01 eV). Enfin nous décrivons une corrélation entre I et la densité du milieu.

1. Introduction

It has long been known that the ionization potential of a solute molecule in a condensed phase is lowered relative to the value measured in the gas phase I_g. Indeed this has been experimentally checked (1–6) by measuring the photoionization threshold of the solute molecule TMPD[1] in some liquid, I(liq.), and in some crystalline or glassy solvents, I(sol.).

[1] *N,N,N′,N′*-Tetramethylparaphenylenediamine.

The early interpretation of Lyons and coworker (7, 8) emphasizes the importance of the polarization of the medium, P_+ around the cation and the ejected electron. More recently, the theoretical model developed by Springett *et al.* (9) for rare gases permits a direct calculation of the energy V_0 of the excess electron in a quasi-free state, which enters the equation giving the photoionization threshold:

$$[1] \qquad I(\text{liq.}) \text{ or } I(\text{sol.}) = I_g + P_+ + V_0$$

This model has been extensively used and extended in the past few years to elucidate some properties of the excess electron in hydrocarbons such as the temperature dependence of V_0 (10, 11), localization criterion (11, 12), and mobility (13–15).

The experimental measurement of I made with TMPD as a solute in various hydrocarbons has shown that I(sol.), measured in the crystal at 77 K, is always higher than I(liq.) measured at room temperature (3). The difference ranges from ~0.6 to 1 eV from one solvent to another. Recently both I(liq.) and V_0 have been found to increase when the temperature is decreased (4*a*, 10), but the V_0 variations are too low to account for the difference, I(sol.) − I(liq.), previously observed.

Therefore it was of interest to study the temperature dependence of the photoionization threshold in the crystal and to look for a specific effect of phase transitions. Some preliminary results (16) have already been published. In the present paper, we report the systematic determination of the TMPD photoionization threshold in various hydrocarbons with special attention (*i*) to the variation of I with temperature either in the crystal or in the liquid and (*ii*) to the effect on I of phase transitions. The solvents have been chosen to cover several types of phase changes, namely liquid–crystal, liquid–glass, and crystal–crystal.

2. Experimental

The experimental techniques used to determine the biphotonic ionization threshold and to detect the ions by the neutralization luminescence have been previously described in detail (1, 16).

In the liquid phase, two photoconduction cells have been used. Each may be fitted into a 10 mm square silica absorption cell C (Fig. 1). In the first cell (Fig. 1*A*), the two stainless steel electrodes E are held 4 mm apart by means of a stumatite[2] spacer ST. The light beam emerging from the monochromator enters through the front silica window S, and is then perpendicular to the applied electric field direction. This set-up was used for most liquid phase measurements. In the second cell (Fig. 1*B*), the electrodes E and G are 1 mm apart. The light enters the cell through the silica window S, fitted into the front stainless steel holder H; the front electrode G is made of a 0.03 mm thick nickel grid welded onto H. This cell was used for some solid-state measurements. Usual care was taken for shielding the measurement cell. The high voltage applied across the sample was taken from a set of batteries, the applied electric field being ~1.5 kV cm^{-1}. The photocurrents were measured by means of a 602 Keithley electrometer. Temperature of the sample was varied by admitting an adjustable flow of cooled nitrogen gas close to cell C. Temperature was known to ±0.2 deg.

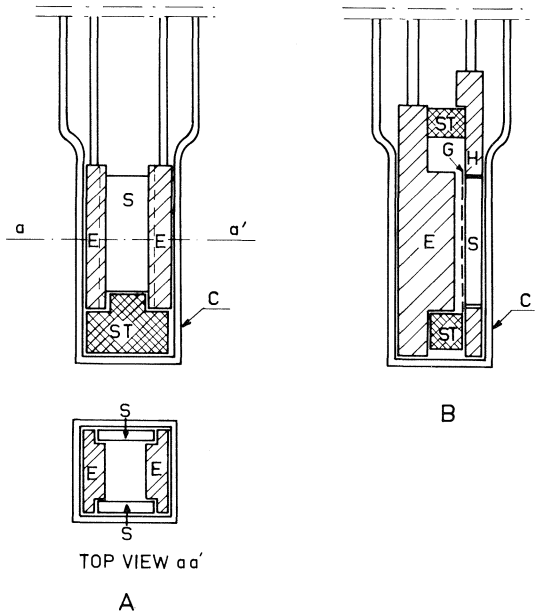

FIG. 1. Details of the photoconduction cell (see text).

The light emerging from a Kern WHS 200 deuterium lamp is passed through a M 25 Huet grating monochromator whose band width is 12 nm This set-up enables accurate measurements up to 195–200 nm. Relative values of the photon flux F *vs.* wavelength were obtained by measuring the fluorescence emitted by a concentrated alcoholic solution of rhodamine B. Absolute values were determined by comparison with the signal obtained at 310 nm with a Kipp thermopile. In the energy range of interest F decreases slowly from 2×10^{12} photons s^{-1} at 270 nm to 0.09×10^{12} photons s^{-1} at 200 nm.

2.1. Chemicals

TMPD (Eastman-Kodak) was liberated from the hydrochloride and sublimated just before use.

The following hydrocarbons (Fluka) were used: 2,2,4-trimethylpentane (TMP); 2,2-dimethylbutane (DMB); *n*-hexane (*n*-Hex); cyclohexane (cy-Hex); neopentane (neo P); tetramethylsilane (TMSi); 3-methylpentane (3-MP); and methylcyclohexane (MCH). They were purified by keeping them at least 24 h on activated molecular sieves (3A + 5A + 13X Linde) in a vacuum system. Afterwards they were slowly distilled into a storage bulb. The efficiency of the treatment was tested by absorption and emission spectroscopy. For photoconductivity measurements, the solution was rapidly prepared in the presence of air, just before use, and poured into the cell C, dehydrated with silica gel. The measurements were done in the presence of air.

[2]Stumatite is a natural lava which, when properly machined, is baked at ~1200°C. The resulting material is hard and has good insulating properties. We had recourse to this material after having experienced great difficulties with Teflon as an insulator which, when immersed in liquid hydrocarbons, yields large dark currents.

3. Results

3.1. The Ionization Efficiency Curves in Liquid and in Solid Hydrocarbons

The shape of the ionization efficiency curves is similar for all the solvents studied. Typical examples are shown in Fig. 2 for liquid MCH and in Fig. 3 for solid cy-Hex. Both refer to the same number of exciting photons at each wavelength.

In the liquid, the concentration has been chosen high enough (5×10^{-4} *M*) to give total absorption whatever the wavelength and it has been verified that for this concentration, the light absorption by the solvent is always negligible, even at short wavelengths. The shape of the curves is consistent with the results reported earlier by Holroyd and Russell (4) but some discrepancies appear in the low and high energy range when comparing the present curves with those of Peterson *et al.* (17).

These authors emphasize the existence of a residual photocurrent in the long wavelength region. Indeed, we observed such currents only in solvents like TMSi or TMP leading to especially high ionization yields. The use of a high pass filter (J280 from MTO which transmits 42% at 280 nm and 67% at 300 nm) reduces the photocurrent measured at 300 nm by a factor of about 20 in TMSi. Since the transmission of the filter becomes negligible only below 230 nm, it appears that the current observed at 300 nm might be totally accounted for by short wavelength stray light which is strongly reduced but not totally cut off by the filter.[3]

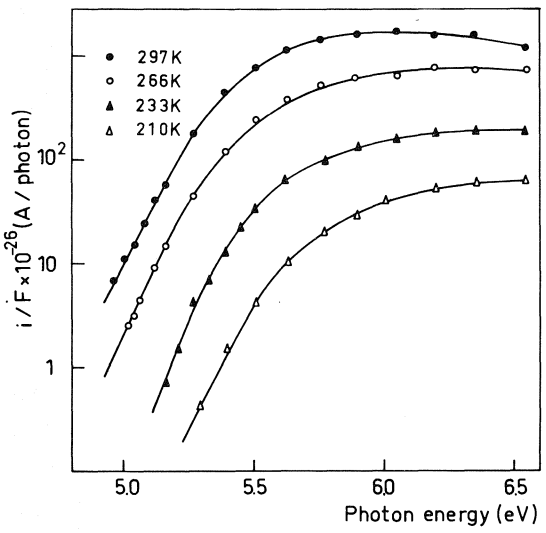

FIG. 2. Photocurrent *vs.* energy curve for liquid MCH at various temperatures.

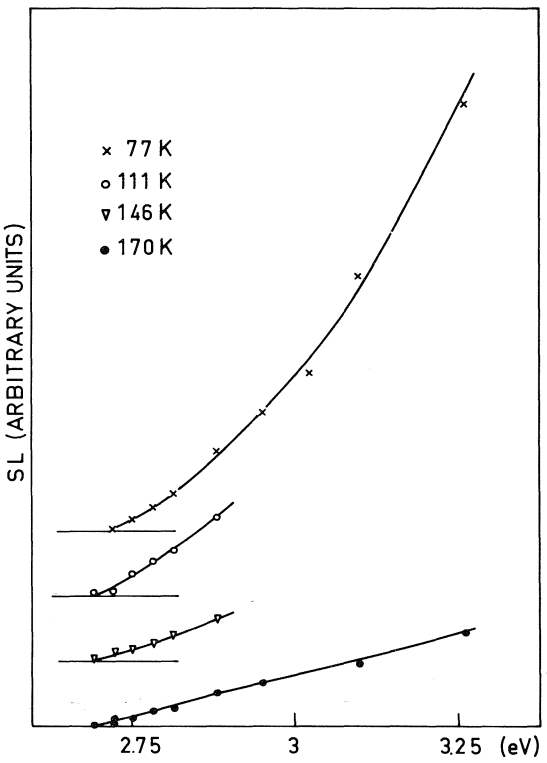

FIG. 3. Neutralization luminescence intensity *vs.* second beam energy curve for crystalline cy-Hex at various temperatures. For sake of clarity the curves have been shifted along the vertical axis. I(sol) is given by $E_T + E_{th}$, where E_T is the energy of the TMPD triplet state (2.8 eV) and E_{th} is the second beam energy threshold.

On the other hand, at high energies, Peterson *et al.* (17) found in every case a drastic decrease of the ionization yield and claimed that it is related to the onset of the third absorption band of TMPD around 6 eV. This fact is not so clear from Holroyd's results (4). In most of our experiments, a maximum has indeed been observed but its wavelength depends on experimental conditions. It has been found that the maximum occurs at a shorter wavelength every time the

[3]It may also be noted that, with a cell fitted with Teflon as an insulator, a monophotonic current was always observed in the 280–350 nm range with a maximum at 305 nm. It was not due to stray light, did not depend on the applied voltage, and its rise time was very long (of the order of minutes). The origin of this signal has not yet been elucidated, but it appears as an experimental artifact since it has never been observed when stumatite was used instead of Teflon.

ionization yield is lowered either by decreasing the temperature or by using solvents in which the ionization yield is low. In a few cases, no more maximum is observable at low temperature and the current rises continuously up to 6.5 eV which corresponds to the maximum of the third absorption band of TMPD. Such an example is shown in Fig. 2 for MCH at 210 K. Thus there is no correlation between the absorption spectrum of TMPD and the photoionization curve. In our opinion, the changes of the shape of the latter may well not be real but may originate from volume recombination effects (4) whose importance increases with ionization yield. Being more interested in the ionization threshold than in the ionization yield, we did not try to overcome this effect.

In the solid, part of the light is scattered by the polycrystalline sample. It is thus quite difficult to determine the number of absorbed photons. It may just be noticed that the incident number of photons is kept constant by adjusting the monochromator slits at each wavelength, and that the *T–T* extinction coefficient being approximately constant in the 400–500 nm range, the curves shown in Fig. 3 truly represent the variation of the ionization efficiency *vs.* energy (6). The increase near the threshold is very rapid; however, due to the small energy range available (it is limited by the onset of the ground state absorption at $\sim$3.3 eV), it is not possible to speculate whether the increase is exponential as in the liquid.

The variations of the ionization yield *vs.* temperature are strikingly different in liquid and solid phases. In the liquid, the yield decreases rapidly with temperature (see Fig. 2 and ref. 4). In the crystal, the variation is more complex. The yield is approximately constant at low temperature and suffers an abrupt decrease in the premelting range. A similar behavior has been observed for all the crystalline solvents studied, the decrease occurring about 10 to 30 deg below any phase transition temperature. It originates in the decrease of the matrix rigidity which shortens the lifetime of the triplet state intermediate and decreases the stability of the trapped electrons which can no longer be detected after excitation.

3.2. *Temperature Dependence of the Photoionization Threshold*

As explained in the experimental section, in the liquid phase the ions were detected by means of the photoconduction technique. In the solid phase, the ions were detected by means of the stimulated luminescence following a biphotonic ionization, except in those cases where the monophotonic ionization of the solute molecule could be detected by means of the photoconduction technique.

The photoionization threshold values given below correspond to the lowest photon energy for which a signal may be detected. In the solid, the detection sensitivity is limited by the intensity and reproducibility of the signal obtained when the first beam is acting alone (1). In the liquid, the detection sensitivity is limited by the value of the dark current ($\sim 3.5 \times 10^{-13}$ A at room temperature) and its stability; typically the lowest detected signals are $\sim 10^{-14}$–10^{-13} A at room temperature, down to 10^{-15}–10^{-14} A at low temperature. Such an approach is justified, in the present work, since we are only concerned with the shift of the photoionization threshold when the temperature is varied and when a new phase is formed. Any other possible definition remains somewhat arbitrary until a better understanding of the meaning of the ionization potential of a solute molecule in a condensed medium is reached.

Plots of I *vs.* temperature for the various solvents are shown in Figs. 4–6. As seen we find that the photoionization threshold in the liquid increases linearly when the temperature is decreased down to the melting point. In the solid phase the I behavior is strikingly different. Within experimental uncertainty ($\sim \pm 0.05$ eV), I(sol.) does not vary with temperature, in a given crystalline phase. This point is clearly seen by examining Figs. 3–5.

In Table 1 are presented the numerical data. In the liquid phase we report the I(liq.) value near room temperature (columns 2 and 3) and in column 4 the slope, $-\mathrm{d}I(\mathrm{liq.})/\mathrm{d}T$; it is seen that the slope changes by ~ 5 when going from a liquid like TMSi, which exhibits quasi-free electron behavior, to glass-forming liquids like 3-MP or MCH in which localized states are anticipated. In the solid phase we report (*i*) the I(sol.) data (columns 5 and 6) obtained by means of the photoconduction method (see Section 3.3) and (*ii*) the average value of I(sol.) measurements (columns 7 and 8) obtained by means of the luminescence method. In columns 9 and 10 the phase transitions are described.

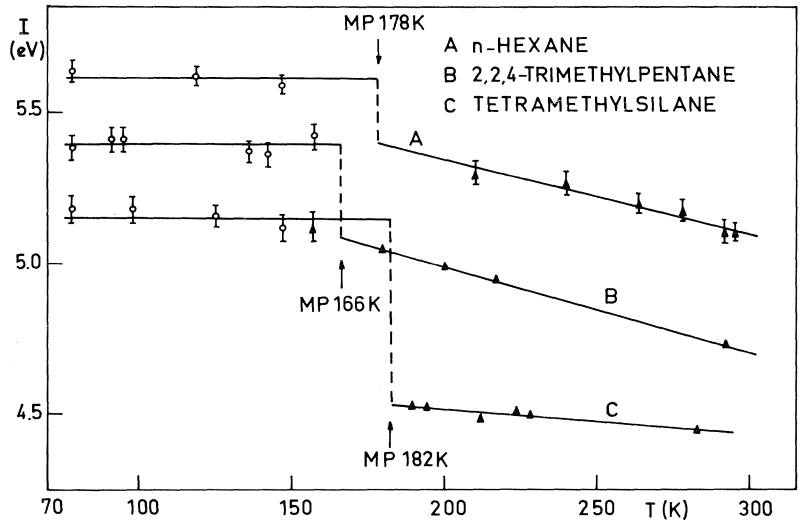

FIG. 4. Temperature dependence of the photoionization threshold energy for TMPD in TMSi, *n*-Hex, and TMP: (▲) data obtained by the photoconduction method; (○) data obtained by the neutralization luminescence method.

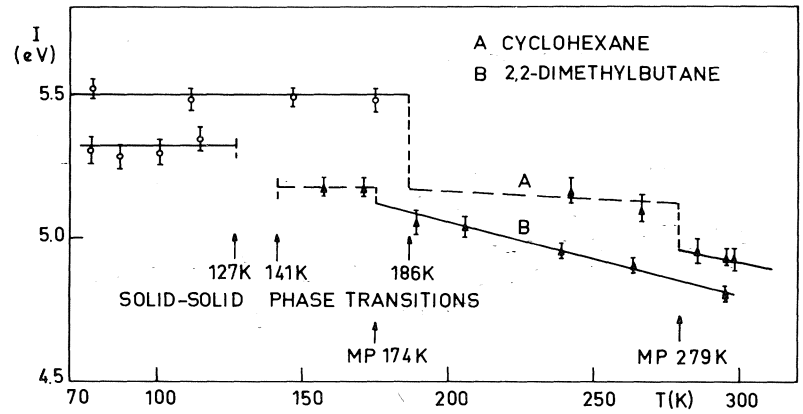

FIG. 5. Temperature dependence of the photoionization threshold energy for TMPD in DMB and cy-Hex. See Fig. 4 for meaning of symbols. For DMB no data could be obtained in the region between the two solid–solid phase transitions.

3.3. Variation of the Photoionization Threshold at a Phase Transition

From Figs. 4 and 5, concerning crystal-forming liquids, it appears that the I *vs.* T curves show discontinuities when the solvent undergoes a phase transition. However, it is necessary to ascertain that the two different methods used for the two phases do not give systematically different values of I at a given temperature and that the observed I shift at a phase transition is not an artifact reflecting some basic difference in the experimental techniques.

Takeda *et al.* (5) stated that, in the liquid phase, mono- and biphotonic ionization yield the same ionization energy values. We have reported before (16) an attempt to measure the TMPD monophotonic threshold in crystalline DMB at 77 K by means of the luminescence technique. However, the accuracy was poor and no conclusion could be drawn.

Evidently, the best method would be to measure the temperature dependence of I from room temperature down to 77 K using the same technique. Unfortunately this is not generally feasible due to the inherent limitations of both experimental methods.

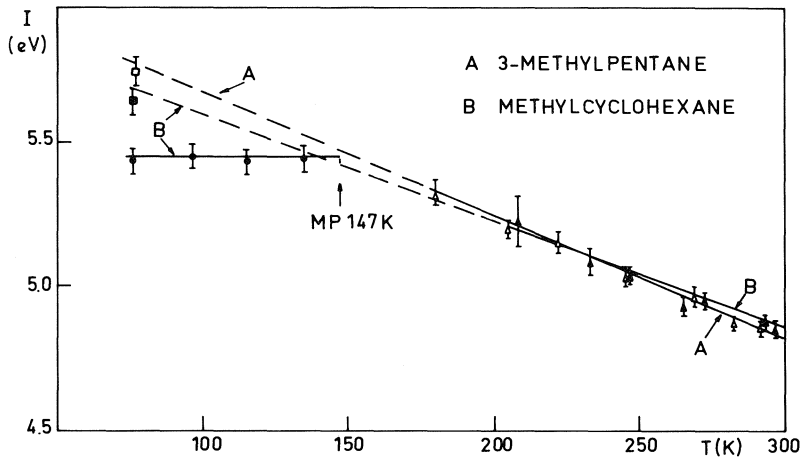

FIG. 6. Temperature dependence of the photoionization threshold energy for TMPD in 3-MP and MCH. Data obtained by the photoconduction method in the liquid: (△) 3-MP; (▲) MCH. Data obtained by the neutralization luminescence method in the glass: (□) 3-MP; (■) MCH; or in the crystal (●) MCH.

As discussed before (Section 3.1), the luminescence technique has a narrow range of applicability and any extension at a higher temperature is precluded. Difficulties are also encountered in extending the photoconduction method to low temperature measurement. As a matter of fact, in most solvents the photocurrent decreases very rapidly with temperature and a further abrupt decrease is expected upon crystallization since most electrons become trapped in the crystal and cannot travel to the electrodes, even in a very thin sample. Finally it is worth noting that since I(sol.) values are significantly higher than I(liq.) ones, the threshold is expected to lie at ~220 nm in solid linear alkanes, *i.e.* within an energy range where the photon flux is dramatically low.

Nevertheless, photocurrents in the solid phase were detected in three favorable cases: TMSi, cy-Hex, and DMB, and the photoionization thresholds could be measured.

In TMSi, for which the photoionization yield is particularly high, a current as high as 8×10^{-13} A at 205 nm could be detected at 156 K, *i.e.* 26 deg below the melting point. A threshold of 5.13 eV was obtained, identical to the average value obtained by means of the biphotonic luminescence technique (Fig. 4). At lower temperatures, the photocurrent intensity decreases rapidly, noise is large, and no accurate measurements could be carried out.

It is well-known that upon crystallization, cy-Hex and DMB give plastic crystals; that is crystals in which molecular reorientation is easy, so that electron trapping is not possible. Moreover, these crystals are almost transparent to light, while at low temperatures opaque polycrystalline samples are obtained. The currents measured at 220 nm were 4×10^{-14} A at 267 K and 5×10^{-13} A at 181 K in cy-Hex and DMB respectively and I(sol.) could be measured (see Table 1). Although a direct comparison with the luminescence technique is not possible in this case, it is important to note that a discontinuity at the melting point is also observed when both liquid and solid I values are obtained by photoconductivity (Fig. 5).

Thus we feel fairly confident in drawing the following conclusions.

(*i*) I(sol.) is always higher than I(liq.). At the liquid–solid phase transition, the I *vs.* T curve presents a discontinuity and the difference $(\Delta I)_{SL} = I(\text{sol.}) - I(\text{liq.})$ is some tenths of an eV. It is larger for rigid crystals (TMSi; *n*-Hex; TMP (16)) than for plastic crystals (cy-Hex; DMB).

(*ii*) From cy-Hex and DMB data it is seen that I(sol.) is higher for the low temperature phase than for the plastic crystal. In cy-Hex there is a discontinuity in the I *vs.* T curve at the solid–solid transition temperature.

(*iii*) For the glass-forming liquids 3-MP and MCH, the I values obtained in the liquid fit a straight line which extrapolates nicely to the I value measured in the glass without any discontinuity at the glass transition temperature.

4. Discussion

4.1. *Ionization Potential and Photoionization Threshold of a Solute Molecule*

The definition of the ionization potential of a molecule in the gas phase—the lowest energy needed for ejecting an electron to infinity with no excess kinetic energy—is no longer valid in a condensed phase. In effect the electron is readily slowed down and gets thermalized in the Coulomb field of the parent cation, and the ionization threshold is related to the ionization potential IP by I(liq. or sol.) = IP(liq. or sol.) + E_c where E_c is the Coulomb energy.

The result is that the energy needed for charge separation is no longer single valued, but reflects the distribution of cation – thermal electron separation distances.

The implication of such a picture may be somewhat different according to the ultimate fate of the electron and according to the detection technique. Let us mention here (*i*) that the only detectable electrons by means of the photoconduction technique are those which have escaped geminate recombination and for which E_c is negligible; and (*ii*) that in a solid matrix the electrons are trapped at such distances that $E_c \simeq 0.1$ eV to 0.2 eV in a glass (1); still lower values are expected in crystals where the density of traps is lower.

Finally we wish to allude to the specific problem of the photoionization threshold and of the shape of the photocurrent *vs.* energy curve. It is indeed a fundamental problem to understand the meaning of the spectral response curve because it contains some basic information concerning the interaction between a solute molecule and the environment. Moreover the proper theoretical description of this curve should provide a clear definition of what the photoionization threshold is, a problem we had to face all along the course of this work.

We are aware of two approaches by Delahay *et al.* (18, 19) and by Peterson *et al.* (17), but no definite conclusion has been reached and no clear definition of the photoionization threshold obtained.

4.2. *The Conduction State Energy V_0 in the Crystal Phase of some Hydrocarbons*

Our experimental results show unambiguously that the photoionization threshold, I(sol.), is constant in the low-temperature crystal phase of all the studied hydrocarbons. In the plastic phase

TABLE 1. Effect of temperature on TMPD photoionization energy threshold

Solvent	Liquid phase			Solid phase					Phase transitions	
				Photoconduction method		Luminescence method				
	T (K)	I(liq.) (eV)	$-dI(liq.)/dT$ (eV K^{-1})	T (K)	I(sol.) (eV)	Temperature range studied (K)	I(sol.) (eV)		T (K)	Nature*

of DMB and cy-Hex, data are too scarce to draw any definite conclusion. Restricting then our discussion to the former well-established result, we wish to comment on the meaning of the constancy of I(sol.).

I(sol.) is related to V_0 and P_+ by [1]. The polarization energy P_+ due to the cation may itself be written as

$$[2] \qquad P_+ = -\frac{e^2}{2r_0}\left(1 - \frac{1}{\varepsilon}\right)$$

where ε is the optical dielectric constant and r_0 the $TMPD^+$ cation radius. In the low temperature phase of crystalline hydrocarbons, the density ρ is not expected to vary much with temperature. Indeed, X-ray crystallographic measurements in the monoclinic phase of cy-Hex at 175 K and 115 K give the same value (20). Then, from the Clausius–Mosotti equation

$$(\varepsilon - 1)/(\varepsilon + 2)M/\rho = P$$

where M is the molecular weight and P the molar polarization, ε may be considered as constant, and consequently P_+ does not vary. Hence from [1] the conclusion is reached that *V_0 is itself constant in the low-temperature phase of hydrocarbons.*

It is of course quite interesting to get an estimate of V_0 in the solid phase. Noda *et al.* (11) and Grand (6*a*) have calculated V_0 in some polar and nonpolar glasses at 77 K, from I(sol.) data published by Bernas *et al.* (1–3) and by Santus *et al.* (21). Bernas and Grand (6*b*) have used the same approach for crystalline hydrocarbons. In refs. 10 and 6 eq. [1] is used: I(sol.) is known and P_+ is calculated from [2]. This indirect way of determining V_0 is straightforward, once the radius r_0 of the $TMPD^+$ cation, which enters [2], is known. Several values have been proposed; Holroyd and Russell (4) deduced an average value $r_0 = 2.49$ Å, while Noda *et al.* (11) used $r_0 = 1.93$ Å. With the latter value these authors calculated $V_0 = 1.20$ and $V_0 = 1.24$ eV in glassy 3-MP and MCH respectively. By using our I(liq.) data for 3-MP (Table 1) and the density data published by Dietrich (22),[4] we obtained a straight line $V_0(T) = 1.60 - 5.44 \times 10^{-3}T$, which extrapolates at 77 K to the $V_0 = 1.20$ eV value given in ref. 11.

A modified version of this indirect method is used below to estimate V_0 in the crystal phase of hydrocarbons. As seen above, an abrupt change $(\Delta I)_{SL}$ of the photoionization threshold energy is observed at the melting point (mp). As a consequence of [1], it may be written that

$$I_{sol} - I_{liq} = P_{+(sol)} - P_{+(liq)} + V_{0(sol)} - V_{0(liq)}$$

or

$$(\Delta I)_{SL} = \Delta P_+ + V_{0(sol)} - V_{0(liq)}$$

where the subscripts sol and liq mean that I, P_+, and V_0 refer respectively to the solid and the liquid at the *melting temperature*. Thus

$$[3] \qquad V_{0(sol)} = V_{0(liq)} + (\Delta I)_{SL} - \Delta P_+$$

From [3], V_0(sol) may be calculated. Here, V_0(liq) is obtained by extrapolating at mp the available liquid V_0 data (10), $(\Delta I)_{SL}$ is measured experimentally, and

$$\Delta P_+ = \frac{e^2}{2r_0}\left(\frac{1}{\varepsilon_{sol}} - \frac{1}{\varepsilon_{liq}}\right)$$

obtained from [2], may be calculated once ε_{sol} and ε_{liq} are known. In the following, ε_{liq} at 293 K is taken as the square of the refractive index. To calculate ε_{liq} and ε_{sol} at mp, first a value of the molar polarization P is obtained from ε_{liq} at 293 K and the known density at 293 K by means of the Clausius–Mosotti equation. Then, using the same equation, the procedure is reversed and ε_{liq} and ε_{sol} at mp are obtained from known values of the fluid density.

One question arises concerning the applicability of [2] giving P_+ in the solid phase. Lyons and Mackie (8) have calculated the energy of the polarization by a positive charge in a crystal by summing over ion-induced dipole interactions and over secondary interactions between induced dipoles. Provided the crystal structure is known, the total polarization energy may be obtained. They found for crystalline *n*-Hex: $P_+ = -1.7$ eV. When we use [2] and calculate ε_{sol} and ε_{liq} for *n*-Hex by the procedure just described, we get $P_+ = -1.65$ eV when choosing $r_0 = 2.49$ Å and $P_+ = -2.13$ eV with $r_0 = 1.93$ Å. Though the situation is different in the case treated in ref. 8—ions are *n*-hexane cations localized at the nodes of the crystal lattice—we simply wish to emphasize that the calculated values of P_+ are of the same order of magnitude.

The above method for calculating V_0(sol) may be used provided the density in the crystal is known. Unfortunately such determinations are

[4]We thank Professor J. E. Willard for kindly supplying these data.

TABLE 2. Calculated values for V_0 in hydrocarbon crystals*

Solvent	T (K)	$(\Delta I)_{SL}$ (eV)	V_0(liq.) at mp (eV) from ref. 5	ΔP_+ (eV)		V_0(sol.) (eV)	
				(*b*)	(*c*)	(*b*)	(*c*)

*(*a*) Plastic phase; (*b*) for $r_0 = 1.93$ Å; (*c*) for $r_0 = 2.49$ Å; (*d*) V_0 has been calculated as explained in the text.

scarce for hydrocarbon crystals. As far as we know, the only data available for the compounds we used are for *n*-Hex (23), cy-Hex (20, 24), and plastic DMB from X-ray studies (23), for TMP and *n*-Hex from pressure–temperature phase diagrams (25), and for plastic cy-Hex from densitometry (26). The results are presented in Table 2. The P_+ calculation has been carried out with two r_0 values 2.49 and 1.93 Å, as discussed above; two sets of V_0(sol.) values result as shown in columns 7 and 8 of Table 2. As no V_0(liq.) data are available for cy-Hex, we have used [1] and [2] to estimate V_0(liq) at mp taking $I_g = 6.6$ eV, $r_0 = 1.93$ Å, and $\varepsilon(293\ \text{K}) = 2.035$.

The method we used to calculate V_0(sol.) from measured $(\Delta I)_{SL}$ escapes the difficulty due to the scattering of data on the gas phase ionization potential of TMPD (27–31). However, due to experimental uncertainties in determining both I and V_0(liq.), the absolute values shown in Table 2 are, in our opinion, a rough estimate. Nonetheless, considering that relative values are meaningful, the following remarks are justified: (*1*) ΔP_+ does not vary much with r_0; (*2*) ΔP_+ is significant but always lower than $\Delta V_0 = V_0(\text{sol}) - V_0(\text{liq})$; (*3*) V_0 suffers an abrupt change when the liquid undergoes crystallization, ΔV_0 being smaller when the liquid yields a plastic phase as in DMB and cy-Hex, than when the liquid directly yields a rigid crystal as in *n*-Hex and TMP.

4.3. *Density Dependence of the Photoionization Threshold*

Previous work on the properties of an excess electron in a fluid or in a solid has demonstrated that they are governed by the density ρ of the medium. This point is clearly evidenced by many experimental results in liquid and solid rare gases (32, 33). The Springett, Jortner, and Cohen model (9) predicts that in rare gases exhibiting quasi-free electron behavior, the energy of the excess electron V_0 is due to two terms: U_p the polarization energy due to the electron and T a kinetic energy term. Both depend upon r_s, the radius of the Wigner–Seitz sphere, defined as $r_s = (3/4\pi\rho)^{1/3}$.

As far as the photoionization threshold is concerned we have seen in the preceding section that P_+, the cation polarization energy in a nonpolar medium, is a function of ρ alone.

All these reasons call for a plot of the photoionization threshold as a function of the density. Such a plot is shown in Fig. 7 for 3-MP, cy-Hex, *n*-Hex, DMB, and TMP. Though our I data do not cover the whole density range (for obvious experimental reasons), it is seen that the I(liq.) data fit a straight line which extrapolates nicely to the point corresponding to the low-temperature crystal phase. In the case of *n*-Hex and cy-Hex the fit is poorer and possibly a different relationship is underlying the density dependence of the photoionization threshold.

The striking difference in the slope between a glass-forming liquid like 3-MP and other crystal-forming hydrocarbons should also be noted.

Undoubtedly such a dependence, though it is not clearly understood at the present time, points out the fundamental role played by the density of the medium upon the properties of the free electron in nonpolar hydrocarbons. Introduction of the molecular quantity $(r_s - a)$, where a is the hard-core radius, used in the SJC model, has been made for correlating V_0 at different temperatures for various hydrocarbons (10) and attempted for I (16). But care should be taken because, as stressed by Jortner (34), in those hydrocarbons where the mobility is low, the electron cannot be considered as quasi-free and the SJC model is inapplicable. The idea underlying Kestner and Jortner's (13) model of a microscopically inhomogeneous fluid, containing 'transparent' and 'opaque' regions regarding electron transport, is very likely a first step to-

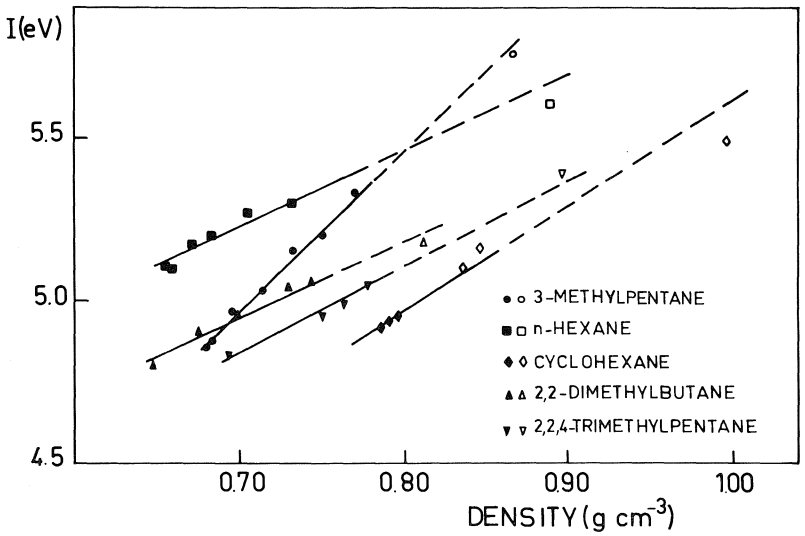

FIG. 7. Plot of the photoionization energy threshold as a function of the medium density.

wards a full understanding of these nonpolar fluids.

Discussion

J. K. Baird: I noted in your paper that you regarded V_0 to be the energy needed to transfer an electron from a condensed phase to the vacuum. In Professor Delahay's paper, he mentioned a surface energy term which I regarded to be due to a kind of image force. Does his surface term have to be included in your analysis?

M. Gauthier: The results I have presented concern internal photoionization. So a surface energy term has not to be considered. Professor Delahay's results concern photoemission or external photoionization.

J. Jortner: The 'surface polarization' term does not enter into the energetics of either internal or external photoionization process. For an internal ionization V_0 which determines the IP in a dense medium incorporates bulk polarization energy. For external photoemission image charge effects are neglected, of course, for an insulator. The 'surface polarization' energy which was so popular with electrochemists cancels out in the Born–Haber cycle which can be used to describe the energetics of external photoionization.

J.-P. Dodelet: In various hydrocarbon solvents, the IP of TMPD varies with the temperature in the liquid phase. What would be the expected variation of IP of the solvent molecules themselves with the temperature in liquid phase?

M. Gauthier: It has been previously shown that the lowering, with respect to the gas phase, of the ionization potential in a condensed medium is a characteristic of the solvent. So I would say that the same $I_g - I_{liq}$ value is expected for the solvent molecule itself. It amounts to 1 to 2 eV and is expected to vary with temperature in the same way as for TMPD.

G. R. Freeman: The density of the liquid was changed by changing the temperature. Can you distinguish between density and temperature effects?

M. Gauthier: So far we cannot distinguish between temperature and density effects. To that end, it would be necessary to determine the ionization threshold as a function of pressure.

G. Ascarelli: You measured the energy gap of the solid by means of photoionization. If the crystals are not cubic the apparent gap should depend on the direction of incidence of the photon and its polarization with respect to the crystal axis. Did you have single crystals? If so what is the crystal structure of the solidified liquids?

M. Gauthier: All the measurements were done with polycrystalline samples. At any rate, if one attempts to use single crystals, the local perturbation due to the presence of the TMPD impurity molecule would preclude any possibility of studying anisotropy effects. To my knowledge, the crystal structure has been determined only in a few cases. DMB and cyHex are cubic in their high temperature phase. cyHex at low temperature and *n*-Hex are monoclinic.

L. Kevan: In regard to Freeman's question, the changes in ionization energy with temperature depend on the temperature dependence of V_0. Within the framework of the Springett–Jortner–Cohen theory of V_0 this is purely a density effect.

Yield and properties of solvated electrons created by the γ radiolysis of hexamethylphosphorotriamide

M. C. LEBAS, J. SUTTON, AND A. M. KOULKES-PUJO[1]

DRA/SRIRMa and CNRS, Centre d'Etudes Nucléaires de Saclay, 91190 Gif-sur-Yvette, France

Received September 27, 1976

M. C. LEBAS, J. SUTTON, and A. M. KOULKES-PUJO. Can. J. Chem. **55**, 1832 (1977).

According to various authors, the value of the yield of the solvated electron in the pulse radiolysis of hexamethylphosphorotriamide (HMPT) varies from 1.2 to 2.4 and increases to 4.2 or 3.1 in the presence of NaBr. We exposed this compound to γ rays after purification and saturation with N_2O. N_2 was formed with a yield $G(N_2) = 4.4 \pm 0.4$. After elimination of a certain number of processes which might also lead to N_2 formation, it was concluded that this $G(N_2)$ corresponds to the total yield of electrons. This value was confirmed by measuring $G(Br^-)$ obtained by radiolysis of HMPT with *p*-bromophenol as a scavenger. The yield of N_2 remains constant whenever solutes generally known as good electron scavengers are added (H^+, CH_3COCH_3, NO_3^-). An interpretation of the results leads to the suggestion of the formation of a dielectron in this medium.

M. C. LEBAS, J. SUTTON et A. M. KOULKES-PUJO. Can. J. Chem. **55**, 1832 (1977).

Suivant divers auteurs, la valeur du rendement d'électrons solvatés lors de la radiolyse pulsée du HMPT varie de 1.2 à 2.4 et augmente jusqu'à 4.2 ou 3.1 en présence de NaBr. On a soumis ce composé à des rayons γ après purification et saturation avec N_2O. Il y a formation de N_2 avec un rendement de $G(N_2) = 4.4 \pm 0.4$. Après l'élimination d'un certain nombre de processus qui peuvent aussi conduire à la formation de N_2, on a conclu que $G(N_2)$ correspond au rendement total en électrons. On a confirmé cette valeur en mesurant $G(Br^-)$, obtenu par radiolyse de HMPT additionnée de *p*-bromophénol comme capteur d'électrons. Le rendement de N_2 demeure constant quels que soient les solutés ajoutés, connus comme étant de bons capteurs d'électrons (H^+, CH_3COCH_3, NO_3^-). Une interprétation des résultats conduit à la suggestion qu'il y a formation d'un biélectron dans ce milieu.

[Traduit par le journal]

Hexamethylphosphorotriamide (HMPT) is an interesting solvent in that it is polar but also aprotic, *i.e.* it forms no hydrogen bonds. Because of the dipole charge distribution it is also a poor solvating medium for anions but leads to the formation of stable solvated electrons by dissolution of alkali metals. Thus we decided to study the formation and reactions of the solvated electrons formed by γ radiolysis of this compound.

Several previous papers (1–4) on the pulse radiolysis of HMPT give values of the solvated electron yield $G_{e_s^-}$ which vary between 1.2 (1) and 2.3 (2, 4). Moreover addition of NaBr appears to increase this yield to 3.1 (4) and to 4.2 (1).

In view of this disagreement it appeared justifiable to use the classic method of γ radiolysis of the solvent with and without reactive solutes in order to obtain independent information on the solvated electron yield by analysis of final products. We have therefore used N_2O and *p*-bromophenol, taken separately, which lead to the formation of N_2 and Br^- respectively by reaction with solvated electrons. We also radiolyzed solutions containing N_2O plus acid ($HClO_4$, H_2SO_4, HCl), N_2O plus $LiNO_3$, and N_2O plus acetone.

Experimental Method and Results

The experiments were carried out on solutions which were deaerated by saturating with either argon, N_2O, or mixtures of known composition of these two gases at atmospheric pressure. The solvent (Merck) was doubly distilled under vacuum, first over sodium to eliminate H_2O and any chlorinated residues left from the HMPT synthesis. The middle fraction of the second distillation, boiling at 90°C at 4 Torr, was stored in a glove box under dry argon and in the absence of light. The preparation of samples for irradiation was done in the glove box so that the solutions never came in contact with air. The dose rate was $2.7 \pm 0.1 \times 10^{18}$ eV h^{-1} cm^{-3}. The concentration of N_2O in the solution was determined by gas chromatography (column

[1]Author from whom reprints may be obtained.

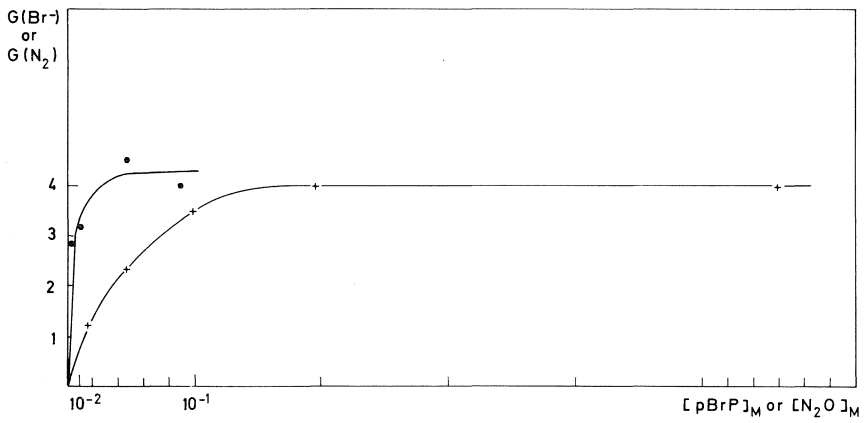

FIG. 1. Yields of N_2 (●) or Br^- (+) *vs.* N_2O or *p*-bromophenol concentrations.

Porapak Q; carrier gas helium). For pure N_2O at atmospheric pressure, it is 9×10^{-2} *M* at 25°C; for mixtures of N_2O/Ar at 1%, 10%, or 50% of N_2O, Henry's law was obeyed and the concentrations in the solutions were respectively 0.9, 9, and 45×10^{-3} *M*. The nitrogen formed by radiolysis of these solutions was determined by gas chromatography.

The radiolysis of solutions of *para*-bromophenol(*p*-BrP) lead to the formation of Br^-, the concentration of which was determined by potentiometric titration using an Orion 801 potentiometer and a specific bromide ion electrode. Although NaBr is fully dissociated in HMPT (5), it was necessary to add water before the titration to obtain a correct response of the electrode with a slope obeying the Nernst's law.

The quantities of N_2 and Br^- formed by irradiation are proportional to the dose over a large range (maximum dose 5.2×10^{19} eV cm^{-3}). The curves representing $G(Br^-)$ and $G(N_2)$ *vs.* the concentration of *p*-BrP or N_2O are presented in Fig. 1. The yields at the plateaux are the same within the limits of experimental error and equal to 4.4 ± 4.0. The addition of 10^{-1} *M* isopropanol or 10^{-1} *M* NaBr to the solutions containing 9×10^{-2} *M* N_2O or *p*-BrP did not change the yields of N_2 or Br^-. We tried to establish a competition between N_2O and H^+ by adding $HClO_4$ or H_2SO_4 which are known to be entirely dissociated in HMPT (6). However, on adding up to 0.35 *M* acid to the solutions containing 9×10^{-4} or 9×10^{-2} *M* N_2O, no variation in the N_2 yield was observed. Thus, if H_s^+ reacts with e_s^-, we can only conclude that the rate constant is very much lower than that of N_2O with e_s^-, contrary to the result obtained in most other solvents. The proton behaviour in this case would be similar to that of the proton in liquid ammonia (7).

Although HCl is not a strong acid in pure HMPT (8), we used this compound in H_2O–HMPT mixtures where it is probably more dissociated. The Cl^- ions so introduced are able to react either with the parent positive ion $HMPT^+$ or with the radical HMPT(-H).

In this case also (0.36 *M* HCl plus 9×10^{-2} *M* N_2O), $G(N_2)$ remained unchanged. These results suggest that Cl^-, contrary to Br^- (which gives Br_2^- on pulse radiolysis (1–4)), does not react with the radicals or ions deriving from $HMPT^+$; however, this seems very unlikely. It is more probable that the electron is scavenged by N_2O and that any other reaction cannot compete with this one. This assumption was supported by the results obtained with solutions containing N_2O and 10^{-1} *M* NaBr, where the N_2 yield again remained constant. We also tried $LiNO_3$ as a second scavenger of electrons in N_2O solutions, but the N_2 yield remained constant.

Acetone (Ac) employed as an electron scavenger represents a special case. Although the addition of 0.47 *M* acetone to solutions containing 9×10^{-2} *M* N_2O did not change $G(N_2)$, addition of the same concentration to a solution containing 9×10^{-4} *M* N_2O increased the value of $G(N_2)$ from 2.3 to 4.4, probably by the intervention of the radical ion Ac^-.

Discussion

Since the plateau value of 4.4 ± 0.4 obtained for $G(N_2)$ or $G(Br^-)$ in the experiments described does not vary on addition of alcohol, it would appear that these products are formed by

reaction of N_2O or *p*-BrP respectively with electrons only and that hydrogen atoms and free radicals make no contribution to these yields. The high G values lead us to assume that N_2O and *p*-BrP at the concentrations employed in the plateau region react with electrons in the spurs before their diffusion. This conclusion is supported (*i*) by the results of Mal'tsev *et al.* (1) who, using pulse radiolysis, directly observed an electron yield of 4.2 in HMPT + 0.3 *M* NaBr and (*ii*) by the fact that addition of 10^{-1} *M* NaBr to 9×10^{-2} *M* N_2O in HMPT leads to no increase in $G(N_2)$. Indeed Shaede *et al.* (4) have given a value $k_{N_2O + e_s^-} = 1.4 \pm 10^{10}$ M^{-1} s^{-1} in HMPT, notably higher than the rate constant for the same process in many other media.

The results obtained by Shaede *et al.* (4) with pyrene as scavenger are more difficult to correlate with ours, the value of $G(Py^-) = 2.4$ remaining constant for pyrene concentrations varying from 3.2×10^{-4} to 1.2×10^{-1} *M*. If N_2O can suppress any recombination of electrons with $HMPT^+$ or HMPT(-H), it seems difficult to admit that Py^- formed by capture of intraspur electrons may undergo a more rapid charge neutralization than the electron itself. In this context the effect of Br^- addition on the yield of Py^- in HMPT may provide valuable information.

Using the theory of Mozumder (9) it is possible to calculate an escape probability for the electron of approximately 0.9 for an effective dielectric constant of 14 (10), *i.e.* approximately 47% of the static dielectric constant. This probability may be compared with that of the hydrated electron (0.5) for an effective dielectric constant in the same proportion. This may be an explanation for the high electron yield found with an appropriate scavenger.

Furthermore, the constancy of the hydrogen yield even in the presence of high concentrations of efficient scavengers of both e_s^- and H lead us to eliminate an overall stoichiometry of the type $2e_s^- \rightarrow H_2 + 2HMPT(-H)^-$. This conclusion is also supported by the stability of the electron in metal–HMPT solutions.

Taking these facts into account, one may suppose that two different forms of electron are produced in HMPT both of which react with N_2O and *p*-BrP but that only one reacts with pyrene. This idea has led us to consider the formation of dielectrons in spite of the uncertain evidence for their existence (except in the case of Eu–NH_3 solutions (11)) and the controversy that arose concerning these species (12). We may admit that they react with N_2O, *p*-BrP, Ac but not rapidly enough with pyrene, anthracene, or biphenyl. In fact, the slow formation of Py^{2-} was recently shown by Engdahl and Rämme (13).

Assuming that the dielectron is formed by successive trapping of two electrons in the same large cavity because of the favourable properties of HMPT, especially its surface energy (33.8 erg cm^{-2} at 20°C) and its molecular volume (207 $Å^3$), we suggest the following mechanism for the radiolysis of this solvent which is consistent with our results and those of other workers.

$$HMPT \xrightarrow{\gamma} HMPT^*$$
$$HMPT \rightarrow HMPT^+, e^-, e_2^{2-}$$
$$HMPT^* \rightarrow H_2 + \text{products}$$
$$HMPT^+ + HMPT \rightarrow HMPT(-H) + HMPT, H^+$$
$$n\text{-}HMPT + e^- \rightarrow e_s^-$$
$$e_2^{2-} + n\text{-}HMPT \rightarrow (e_2^{2-})_s$$
$$e_s^- + HMPT(-H)^\bullet \rightarrow HMPT(-H)^-$$
$$(e_{2_s}^{2-}) + HMPT(-H)^\bullet \rightarrow HMPT(-H)^- + e_s^-$$
$$HMPT(-H)^- + HMPT, H^+ \rightarrow 2HMPT$$
$$HMPT(-H)^\bullet \rightarrow \text{products}$$
$$e_s^- \rightarrow \text{products}$$

Discussion

D. C. Walker: A question about the total electron yield: Do you envisage the proposed reaction between the dielectron and N_2O to give two N_2 molecules?

A. M. Koulkes-Pujo: Yes.

D. C. Walker: With regard to the relative importance of the reactions $e_s^- + e_s^- \rightarrow (e_2^{2-})_s$, $e_s^- + S^+ \rightarrow S$ and $e_s^- + R \rightarrow R^-$ (where R is a radical or molecule product of radiolysis): in the paper by Shaede *et al.* (4) we concluded that the last reaction was most important because when HMPT containing a steady state $[e_s^-]$ from dissolved Na was pulse irradiated, there was an overall net loss of e_s^-. If the first two reactions dominated the decay of e_s^- after radiolysis there would have been no net change in the steady state $[e_s^-]$.

A. M. Koulkes-Pujo: This experiment is perhaps not significant for the presence or absence of e_2^{2-} because your solution contains Na^+ ion and you may have for example other species like e^-, Na^+ pairs.

Effects of very high dose-rates on solvated electron yields (Extended Abstract)

STEFAN KAROLCZAK[1] AND DAVID C. WALKER
Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1W5
Received October 13, 1976

Upon replacing the electron tube of a 600 kV Febetron 706 accelerator with the dual-tube output attachment of the model 708, a relatively uniform radiation dose can be administered to a sample of thickness-density ~0.45 g cm^{-2}. This enables conventional pulse radiolysis – spectrophotometric studies to be made. Radiation cells were used in which the dose per pulse could readily be changed, as could the optical path length of irradiated solution, so that the same absorbance could be achieved for quite different doses. With the pulse duration fixed at 3 ns, doses from 10^3 to $>10^5$ rad, with dose-rates up to 10^{14} rad s^{-1}, were selected by means of beam attenuators.

For doses less than about 6000 rad the yield of hydrated electrons and their subsequent decay rates in the presence of concentrated electron scavengers were normal and in agreement with published data. At these low doses, too, the formation of CO_3^- in 3 *M* Na_2CO_3/0.3 *M* KNO_3 solutions (due to reaction of OH radicals with CO_3^{2-}) was complete within the 3 ns time resolution of the detector (1P28 photomultiplier) plus oscilloscope (HP 183).

However, at higher doses the yield of e_{eq}^- in water was nonlinear with dose. In fact *G* decreased progressively with increasing dose. Furthermore the absorbance increased after the end of the pulse for 50 to 100 ns, with this post-pulse absorbance often accounting for 30–40% of the maximum observable absorbance. When the product of a hydrated electron reaction, such as Cd^+ in 0.1 *M* Cd^{2+} solutions, was monitored at 300 nm its absorbance showed an analogous effect, namely some immediate and some delayed absorbance. Its yield was also nonlinear with dose. Finally, the CO_3^- radical ion which should be formed in ~10^{-9} s from OH radicals in a 3 *M* Na_2CO_3/0.3 *M* KNO_3 solution also showed delayed absorbance.

In searching for an explanation of these effects we have eliminated the obvious possible electronic or optical artifacts, including (*i*) nonlinear response of the detectors (photodiode and photomultiplier); (*ii*) very rapid shock-wave effects; (*iii*) optical saturation behaviour; or (*iv*) inhomogeneities arising from the beam attenuators. Nor can we find any satisfactory rationalisation for these results in terms of delayed formation of both e_{aq}^- and OH. We could explain all our results, however, if there was significant 'channelling' of the electron beam at high dose-rates. By this we envisage the possibility of electron tracks funnelling together into super-tracks, as a result of the enormous dose-rates and dose from relatively low energy electrons.

If such super-tracks existed they would contain very high concentrations of e_{aq}^- such that these regions would be opaque to visible light, while the surrounding solution was fairly transparent. For 50 or 100 ns after the pulse, these regions would enlarge, due to diffusion of e_{aq}^-, thereby extending the volume of strongly absorbing species and causing a further increase in the measured absorbance. An electron scavenger such as Cd^{2+} at 10^{-2} *M* could capture only a fraction of e_{aq}^- within 5 ns, but over the next decade of time could capture e_{aq}^- as they emerged from the super-track. In this way the absorbance would be essentially constant over about 50 ns before decreasing rapidly, as observed. The very high concentrations of e_{aq}^- and OH in the track will lead to low *G* values as with particles having high LET tracks.

We hesitantly offer this as a possible explanation for the considerable range of data we have on these high dose-rate effects, without knowledge about the plausibility of its physical basis. We know of no information at compara-

[1]On leave from Institute of Radiation Chemistry, Technical University of Łódź, Poland.

ble dose-rates and electron energies which would offer guidance as to whether channelling of electron tracks is expected under these conditions.

Discussion

W. F. Schmidt: From work on breakdown in dielectric liquids it is known that turbulences are created in the liquid due to momentum transfer of charge carriers to the molecules of the liquid. It has also been observed that high energy electron beams create shock waves in the material they are traversing. Isn't it possible that the growing-in of the absorption after the pulse is due to a relaxation of turbulences or other density changes which were created by the high power electron beam and which perturbed the absorption measurement?

S. Karolczak: Shock waves originating at the front of the cell travel across the cell at about the speed of sound, arriving in the observation region after delayed absorbance is complete ($>1\,\mu s$). These temperature/pressure fronts cause a change of refractive index and distort the light beam but such effects occur much later than the phenomena being studied.

Effect of density on the total ionization yields in X-irradiated argon, krypton, and xenon[1]

SAM S.-S. HUANG AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 27, 1976

SAM S.-S. HUANG and GORDON R. FREEMAN. Can. J. Chem. **55**, 1838 (1977).

The amounts of ionization produced by absorption of X radiation in the liquids xenon, krypton, and argon are respectively 1.5, 1.4, and 1.2 times greater than those produced by the absorption of the same energy in the corresponding low density gases. The yields of free ions in the irradiated liquids were measured at applied electric fields 1–40 kV/cm and extrapolated to infinite field strength. The total number of ionizations per 100 eV absorbed was $G_{tot} = 6.6$ in xenon, 6.0 in krypton, and 4.5 in argon. The reason that the ionization yield is larger in the liquid than in the corresponding low density gas is partly that the energy gap E_g between the top of the valence band and the bottom of the conduction band in the liquid is smaller than the gas phase ionization potential IP. The ratio $IP/E_g = 1.36$ for xenon (Roberts and Wilson), 1.27 for krypton, and 1.17 for argon (from data of Jortner *et al.*). An extra source of ionization in the liquid might be reaction of the higher excited states, $M^* + M \rightarrow [M_2^+ + e^-]$.

SAM S.-S. HUANG et GORDON R. FREEMAN. Can. J. Chem. **55**, 1838 (1977).

Les quantités d'ionisation produites par absorption de radiation X dans le xénon, le krypton et l'argon liquide sont respectivement de 1.5, 1.4 et 1.2 fois plus grandes que celles produites par l'absorption de la même énergie dans les gaz correspondants de faible densité. On a pu mesurer les rendements en ions libres dans les liquides irradiés à des champs électriques appliqués de 1 à 40 kV/cm et les extrapoler à une force de champ infinie. Le nombre total d'ionisations par 100 eV absorbés est $G_{tot} = 6.6$ dans le xénon, 6.0 dans le krypton et 4.5 dans l'argon. Le fait que le rendement d'ionisation est plus grand dans le liquide que dans le gaz correspondant de faible densité provient en partie de la différence d'énergie E_g qui existe entre le sommet de la bande de valence et le bas de la bande de conduction du liquide et qui est plus petite que le potentiel d'ionisation en phase gazeuse IP. Le rapport $IP/E_g = 1.36$ pour le xénon (Roberts et Wilson), 1.27 pour le krypton et 1.17 pour l'argon (à partir de données de Jortner *et al.*). Une source additionnelle d'ionisation dans le liquide peut être la réaction des états excités plus élevés $M^* + M \rightarrow [M_2^+ + e^-]$.

Introduction

A problem in radiation chemistry is to know the amount of ionization produced in a liquid or solid exposed to high energy radiation. A useful parameter is W, the average amount of energy expended per ion pair formed. In low density gases the value of W (1–6) is usually about double the first ionization potential (2, 7). Ionization potentials in the condensed phases are often about 2 eV lower than those in the gas phase, due to electronic polarization of the medium around the newly created charges (8–16). One might therefore find an approximately 20% decrease in the value of W on going from the normal gas to the liquid phase, if ionization processes are similar in the two phases.

Product yields from the radiolysis of solutions of an electron scavenger in alcohols (17, 18) and saturated hydrocarbons (19, 20) indicate that the W values in the liquids, ~20 eV, are indeed about 20% lower than those in the corresponding low density gases, ~25 eV (3–6). In aqueous solutions the value of W also appears to be ~20 eV (21–23), whereas the gas phase value is 30 eV (3, 4, 6). This corresponds to an ~33% reduction in W with increasing phase density. The energy gap between the valence and conduction bands in liquid water was recently estimated to be ~9 eV (24), which is ~30% lower than the 12.6 eV gas phase ionization potential (7).

Although the above results indicate that W is smaller in the liquid than in the low density gas there are two major sources of uncertainty in addition to the experimental difficulties. (*a*) The liquid phase values were determined for solutions rather than for pure solvents. If excited neutral

[1]Assisted by the National Research Council of Canada.

molecules react with the solutes the apparent W values would be too small. (*b*) The definition of an ionization in dense phases is ambiguous and not always readily distinguished from that of a highly excited neutral state. For practical purposes we define an ionization as an event during which an electron separates from an ion or molecule, and after which the electron may be considered to have a separate existence for a finite time. This includes geminate ion – electron pairs, in which the electron has not escaped the Coulomb field of the ion but the wave function of the electron is not centered on the ion. If the electrons form localized states they can be detected by optical absorption spectroscopy before they react with geminate ions or other species that happen to be present. However, it has not yet been possible to obtain the value of W for a pure solvent by a spectroscopic method, because it has not been possible to estimate the amount of geminate neutralization that occurs at times shorter than the resolution time of the measurement (including neutralization prior to solvation).

The amount of ionization in a low density gas is measured by applying an electric field across the gas and collecting the charges at electrodes. After an ionization event in a low density gas the electron escapes sufficiently far from its parent ion that geminate neutralization is negligible (25), so essentially all of the charges can be collected at practicable field strengths. This method cannot be used for most liquids because geminate neutralization is not completely eliminated by the application of fields up to 10^5 V/cm. Dielectric breakdown occurs before all the initially formed electrons can be drawn away from their parent ions. Ionization yields measured at high fields may be extrapolated to infinite field strength with the aid of a model (26, 27) based on early work of Onsager (28).

The extrapolation is relatively short when the electrons are able to penetrate relatively long distances from their parent ions. This occurs in liquids made of spherical molecules, such as argon (29–31), krypton, and xenon (31). Unfortunately, the answers obtained by different techniques do not agree with each other (30–33). The problem has therefore been reinvestigated.

Experimental

Materials and Sample Preparation

The stated purities of the gases obtained from Matheson were 99.995% for xenon and krypton, and 99.999% for argon. The same purity of xenon was also obtained from Linde.

The materials were handled in a vacuum rack that was initially evacuated to 0.1 mPa (1×10^{-6} Torr). The gas cylinders were connected to the rack through a vacuum-tight valve that was welded to a piece of flexible stainless steel tubing, which was in turn welded to a Kovar seal. The tubes and rack were flushed twice with gas from the cylinder, then evacuated to 0.1 mPa again with the exception of one portion; the cylinder valve and steel tubing were kept at a pressure in excess of 1 atm (> 100 kPa) by way of a 1 m long manometer tube (2 mm id) that dipped 4 cm beneath the surface of a pool of mercury.

Argon was passed through a 60 cm × 1.5 cm Pyrex U-tube column of activated Molecular Sieves 3A (Fisher Scientific Co) at −78°C, then a 60 cm × 2 cm quartz U-tube of 6–14 mesh activated coconut charcoal (Fisher) at −78°C. The adsorbants had each been activated for 6 days at < 1 mPa, the Molecular Sieves at 290°C, and the charcoal at 600 °C. Upon cooling the adsorbants to −78°C the pressure in the system fell to < 0.1 mPa. The conductance cell was flushed once with purified argon, then filled, using liquid argon refrigerant.

Krypton and xenon were passed through the above type of Molecular Sieves (3A for Kr and 4A for Xe) columns at −78°C. Fresh Sieves were used for each batch, and they were activated for 5 days under 0.1 mPa at 290°C. The purified gas was condensed in one of three potassium-mirrored traps with liquid nitrogen as refrigerant. A slush bath (−150°C isopentane for Kr and −100°C moist ethanol for Xe) was placed around the trap to liquify the material and allow impurities to react with or adsorb on the potassium mirror. After 3 h the krypton or xenon was distilled to a different trap containing a new mirror. Each trap contained a lump of potassium in the bottom; mirrors were regenerated by evacuating the trap to 0.1 mPa and heating the potassium while continuing to evacuate. After 15 three hour treatments some of the material was used to flush the cell, then the rest distilled into it with liquid nitrogen coolant.

The cells were sealed with a flame.

The vacuum line was grease free and was separated from the mercury diffusion pump by two liquid nitrogen traps.

Physical Properties of the Liquids

These are summarized in Table 1. Values were taken or estimated from data in refs. 34–36. The dielectric constant ε was calculated from the polarizability α and the density d, using the Clausius–Mosotti equation (36).

Conductance Cells

The cell used for argon was described in ref. 37. The electrode spacing was $L = 0.49$ cm and the effective area of the collecting electrode was $A = 1.16$ cm^2.

The cell used for krypton and xenon is shown in Fig. 1*b* of ref. 31: $L = 0.30$ cm, $A = 1.77$ cm^2. The exterior of the top half of the cell, which was the collector electrode side, was coated with aquadag and grounded.

The cell constants (L/A, cm^{-1}) were measured conductiometrically, using standard KCl solutions (38).

Cooling Baths

The argon cell was immersed in liquid argon at atmospheric pressure, 87 K.

TABLE 1. Properties of materials

	Ar	Kr	Xe	
T (K)	87	129	164	183
Liquid d (g/cm^3)	1.39	2.34	3.06	2.93
ε	1.50	1.63	1.93	1.87
Vapor pressure (atm)	1.0	2.0	1.0	2.5
Gas α (Å^3)	1.63	2.47	4.01	4.01
IP (eV)	15.7	14.0	12.1	12.1

The krypton and xenon cell was cooled by a regulated stream of cold nitrogen gas in a Styrofoam box. A calibrated thermocouple was glued to the side of the cell. Another thermocouple was placed near the cell and connected to the temperature controller.

Determination of the Free Ion Yields

The free ion yield G_{fi} is the number of pairs of ions and electrons that can be collected at electrodes per 100 eV of energy absorbed by the liquid. The value at a given applied field strength E is designated $G_{fi}{}^{E}$.

The measurement technique was similar to that in ref. 31. Briefly, a 100 ns pulse of 1.7 MeV X rays delivered 1–2 × 10^{10} eV/cm^3 to the sample. The free ions generated by the radiation were swept to electrodes by applying fields of 0.5 to 45 kV/cm. The charge from the sensitive volume ($L \times A$) was integrated and divided by the radiation dose absorbed. The measuring circuit was the same as that in Fig. 2 of ref. 31, except that the 'current integrator and interface circuitry' were replaced by an ultralow bias current integrator (39). The integrator calibration was based on a General Radio type 1422-CD standard capacitor and a Fluke DC Transfer Standard model 731A.

The signal integration time was varied from 50 ms to 5 s, increasing with decreasing applied field and, to a small extent, with decreasing temperature.

Each point in Figs. 1–3 represents the average of 16 signals, from which the average of 16 blanks (no pulse from the accelerator) has been subtracted. Signal and blank measurements alternated each other. This method was developed for other systems in which there was a significant amount of electrical leakage through the sample. The blanks were always zero in argon, krypton, and xenon. Signal averaging was done by a Fabritek model 1062.

The negative power supply used for xenon and krypton was limited to 6 kV.

Dosimetry

The most probable source of error in measuring W or G_{fi} values is in the determination of the amount of energy absorbed by the sample. The energy absorbed per pulse is too small (0.3 ncal) to be measured directly. The dosimetric method must therefore be considered in detail.

X rays were generated by 1.7 MeV electrons striking a gold target. The magnitude of each radiation pulse was monitored by integrating the electron current that flowed from the target to ground. To insulate the target from ions generated in the air, the 3 mm × 50 mm diameter gold disc was glued with epoxy cement into a polystyrene holder that snugly covered one face and the rim. The other face, which received the electron beam, was insulated with Letraset protective coating spray (Letraset Canada Ltd.). The polystyrene holder was mounted into the end of the stainless steel drift tube of the accelerator. A BNC fitting penetrated the holder to make contact with the target. The exterior of the holder was coated with aquadag and thoroughly grounded, as was the accelerator drift tube and the body of the BNC connector. Aquadag was not put on the Letraset coating.

The X rays were roughly collimated by passing through a 10 cm × 10 cm hole in a 10 cm thick lead shield. They then passed through a K filter to remove X radiation emitted from the K shell of the gold target. In the K filter the radiation passed successively through 5.0 mm Pb, 0.4 mm Sn, 0.25 mm Cu, and 1.0 mm Al (41). The ~80 kV radiation from gold or lead would be much more strongly absorbed in xenon than in lithium fluoride and would cause apparent values of G_{fi} in xenon to be too large. An adequate K filter was not used in our earlier experiments (31, 42).

The primary standard for determination of energy absorption was the Fricke dosimeter (40). With it the γ beam from a low intensity ^{60}Co source was calibrated. Doses of 10^{17}–10^{18} eV/g were used for accurate measurement with the Fricke solutions.

The γ beam was then used to calibrate the lithium fluoride crystals of a Harshaw model 2000 thermoluminescent dosimeter. The lowest doses that could be obtained accurately from the γ source, 10^{13}–10^{14} eV/g, were used.

The lithium fluoride crystals served to calibrate the X-ray pulse monitor. The crystals were given 10^{13}–10^{14} eV/g by delivering 10^3–10^4 pulses of X rays, while integrating the total electron current that flowed from the target to ground. The pulse rate was 4/s to assure stability of the system. The ratio (Harshaw reading)/(target monitor reading) sometimes varied for pulse rates > 10/s, so the pulse rate was kept < 10/s.

The dosimeter crystals were used in sets of three or four, contained in thin, flattened glass tubes or wrapped in aluminum foil. The precision of measurement with the crystals was ±2%. Our previous main difficulty had been the estimation of the amount of photoelectric absorption in the high atomic number liquids. We have now used powders of salts that have the same average atomic number as the noble elements to simulate the liquids: KCl for Ar, RbBr for Kr, and CsI for Xe. A hole was drilled in the side of a duplicate cell, the cell was half filled with the appropriate powder, Al foil wrapped LiF crystals were placed midway between the electrodes, and the cell was filled with more powder. The packing densities of the powders were about 25% less than the liquid densities, but an experiment with CsI powder (2.4 g/cm^3) and a large CsI crystal (4.5 g/cm^3) with a small hole drilled into it showed that the density of the salt had little effect on the LiF dosimetry in the geometry used. The rate of generation of primary electrons per unit volume in the salt is proportional to the density, but the electron range is inversely proportional to the density, so the 'equilibrium' flux of high energy electrons is the same.

Results

The measured free ion yields were all in the range $G_{fi}{}^{E}$ = 3 to 7 ion pairs per 100 eV, in-

creasing with applied field strength and increasing from argon to krypton to xenon (Figs. 1–3).

Measurements were made by applying both positive and negative voltages to the high tension electrode. The yields measured with positive applied voltages were larger than those measured with negative voltages; the relative difference increased with increasing voltage (Figs. 1–3). The reason for the difference is not known, but it is not observed for liquids in which electron mobilities are low. It is also smaller when the cell 'dead volume' is smaller. We favor the values obtained with negative voltages because it is easier to think of artifacts that would make the apparent yield too large than too small. For example, positive field penetration into the region between the collector and guard electrodes might draw highly mobile electrons out of that volume, leaving positive ions in the dead volume to drift to the collector and guard. Reversing the field would draw extra electrons into the dead volume, but they would not find extra positive ions to neutralize. The extra electrons would ultimately diffuse to the guard and collector electrodes, relatively unaffected by having entered the dead volume. It is curious that this problem is not discussed in the literature, yet most authors report having used negative applied voltages.

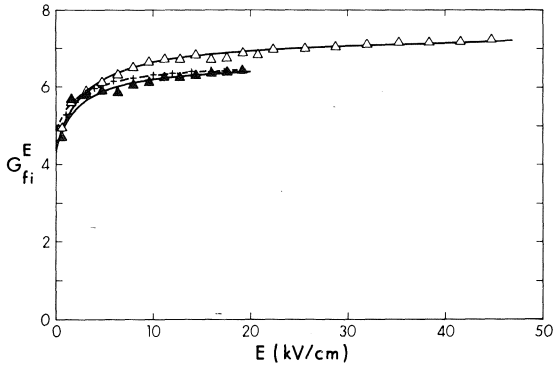

FIG. 1. Free ion yields $G_{fi}{}^{E}$ as a function of applied electric field strength E in liquid xenon at 164 K. △, positive voltage; ▲, negative voltage; +, results for 183 K from ref. 33, negative voltage. The curves were calculated from [9] and [10], using the parameter values in Table 2.

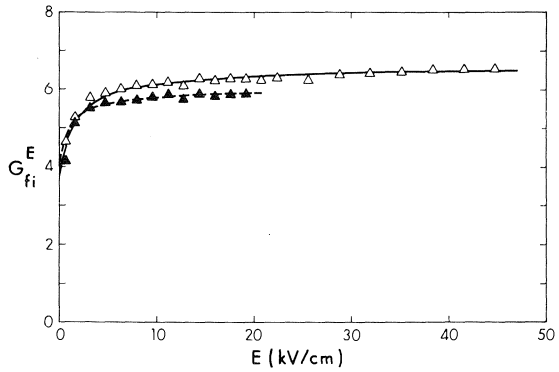

FIG. 2. Free ion yields $G_{fi}{}^{E}$ as a function of applied electric field strength E in liquid krypton at 129 K. △, positive voltage; ▲, negative voltage. The curves were calculated from [9] and [10], using the parameter values in Table 2.

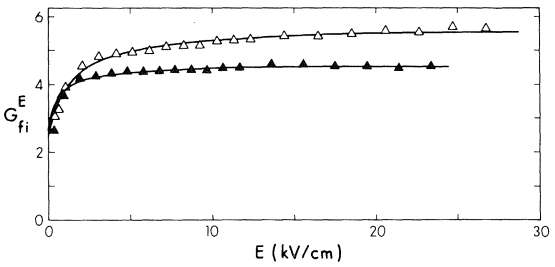

FIG. 3. Free ion yields $G_{fi}{}^{E}$ as a function of applied electric field strength E in liquid argon at 87 K; △, positive voltage; ▲, negative voltage. The curves were calculated from [9] and [10], using the parameter values in Table 2.

Total ionization yields were obtained by extrapolating the measured yields to infinite voltage. The method (26) was based upon early work of Onsager (28) and is discussed below.

Model

In an irradiated system free ions are generated by the following reactions.

[1] $\quad M \rightsquigarrow [M^+ + e^-]$

[2] $\quad [M^+ + e^-] \rightarrow M$, geminate neutralization

[3] $\quad [M^+ + e^-] \rightarrow M^+ + e^-$, free ions

The wiggly arrow in [1] signifies the ionizing radiation. The square brackets indicate that the electron may become thermalized sufficiently close to the ion that the Coulombic attraction between them is not negligible compared to kT. The Coulombic force may draw the ion and electron back together to undergo geminate neutralization (reaction 2). For pairs in which the Coulombic force is not too great, the random thermal motions of the ion and electron may cause them to drift apart (reaction 3). Free ions are those that are sufficiently far apart that the

interaction between them is negligible compared to kT.

The Coulombic energy of attraction E_c between an ion and electron separated by a distance y in a medium of dielectric constant ε is

$$[4] \qquad E_c = \xi^2/\varepsilon y$$

where ξ is the electronic charge.

In the absence of an external field the fraction $\phi(y, 0)$ of ion pairs produced in [1] that become free ions is (28)

$$[5] \qquad \phi(y, 0) = \exp(-E_c/kT)$$

where k is Boltzmann's constant and T is the absolute temperature. Actually, all pairs do not possess the same separation y, so

$$[6] \qquad \phi(0) = \int_0^\infty F(y)\phi(y, 0)\,dy$$

where $F(y)\,dy$ is the fraction of thermalized electron-ion pairs with initial intrapair separation distances between y and $y + dy$.

Application of an external field diminishes the average field between the ion and electron in the randomly oriented pairs. This decreases the extent of geminate neutralization and thereby increases the yield of free ions. The field effect in fluids subjected to densely ionizing radiation, such as alpha particles, was earlier described by Jaffe (43). This model and a later modification of it (44) have sometimes been erroneously applied to systems subjected to sparsely ionizing radiation, such as X rays and high energy electrons. The latter systems were treated by Onsager (28), whose model has been refined through several stages (26, 27, 45). In the presence of an applied field E, the fraction $\phi(y, E)$ of pairs with a given initial separation y that become free ions is

$$[7] \qquad \phi(y, E) = e^{-r/y}\left[1 + e^{-\beta y}\sum_{n=1}^{\infty}\frac{(\beta y)^n}{(n+1)!} \times \sum_{j=0}^{n-1}(n-j)\frac{(r/y)^{j+1}}{(j+1)!}\right]$$

where $r = \xi^2/\varepsilon kT$ and $\beta = \xi E/300kT$.

Averaging over the y distribution one obtains

$$[8] \qquad \phi(E) = \int_0^\infty F(y)\phi(y, E)\,dy$$

The free ion yield is given by

$$[9] \qquad G_{fi}{}^E = \phi(E)G_{tot}$$

where G_{tot} is the yield of reaction 1 and equals $100/W$.

The distribution function $F(y)$ was taken to have the form [10], designated YGP (27).

$$[10] \qquad \begin{cases} F(y) = 0.96\text{YG} & y < 2.4b_{GP} \\ F(y) = 0.96[\text{YG} + 0.5b_{GP}{}^2/y^3] & y > 2.4b_{GP} \end{cases}$$

where 0.96 is a normalization factor, YG is the three dimensional Gaussian function $(4y^2/\pi^{1/2}b_{GP}{}^3)\exp(-y^2/b_{GP}{}^2)$, and b_{GP} is the most probable value of y. The parameter b_{GP} represents an average penetration range of the low energy electrons into the liquid, away from their parent ions, during thermalization.

Equations 9 and 10 were fitted to the experimental data in Figs. 1–3 by using G_{tot} and b_{GP} as adjustable parameters. The value of G_{tot} is somewhat sensitive to the form assumed for $F(y)$. The true form of the distribution is not known, although YGP was devised to fit the experimental field effect on $G_{fi}{}^E$, within this model, in many diverse systems (27). When the range parameter b_{GP} is large, as in the present systems, YGP is practically indistinguishable from the Gaussian YG. A simple exponential form is sometimes used for $F(y)$ (46). It leads to a higher estimate of the value of G_{tot} than does YGP (47).

In the absence of an applied field the free ions neutralize each other and no current is collected on the electrodes.

$$[11] \qquad M^+ + e^- \rightarrow M, \text{ random neutralization}$$

However, at the low radiation doses used, essentially all of the free ions are collected at the electrodes when E is greater than 1 kV/cm. At $E > 1$ kV/cm reaction 11 is negligible, and the increasing yields with field strength are due to the enhancement of reaction 3 at the expense of [2].

Discussion

The values of G_{tot} obtained for xenon, krypton, and argon are listed in Table 2, along with those of the other relevant parameters. Positive applied voltages lead to estimates of G_{tot} that are 10–20% greater than those from negative voltages. The latter are preferred, for reasons given above.

TABLE 2. Parameters of [9] and [10] for curves in Figs. 1–3

Liquid	V	T (K)	ε	G_{tot}	$G_{fi}{}^0$	b_{GP} (Å)
Xe	+	164	1.93	7.3	4.5	1080
	−	164	1.93	6.6	4.4	1300
	−	183	1.87	6.6	4.8	1600
Kr	+	129	1.63	6.5	3.9	1530
	−	129	1.63	6.0	4.0	2030
Ar	+	87	1.50	5.6	2.5	1540
	−	87	1.50	4.5	2.7	2470

The most recent results of Takahashi and coworkers on the ionization of liquid xenon by high energy electrons (33) were converted to $G_{fi}{}^E$ values and included in Fig. 1 for comparison. Negative applied voltages were used and agreement between the two sets of results is satisfactory. Takahashi *et al.* preferred to take the yield $G = 6.4$ measured at 17 kV/cm as the saturation value, although extrapolation to infinite voltage by a yield^{-1} *vs.* V^{-1} plot gave $G = 6.5$ (33). Extrapolation by our method gives $G_{tot} = 6.6$.

In Table 3 ionization energies obtained from the present work are compared with those reported by Takahashi *et al.* (32, 33). The corresponding ratios of gas to liquid energies, W_g/W_l, are listed in Table 4. The value of W_g/W_l decreases slightly on going from xenon to krypton to argon. The ratio for xenon reported in ref. 32 is lower than that in ref. 33, which by the above arguments may itself be too low. By analogy, all of the values in ref. 32 may be low.

The energy gap E_g between the top of the valence band and the bottom of the conduction band in liquid xenon is 8.9 eV (15), which is 0.4 eV smaller than that in solid xenon (11, 16). The values of E_g are 11.6 eV in solid krypton and 14.2 eV in solid argon (16). The electron photoemission threshold energy E_{thresh} drops upon melting the solid, by 0.14 eV in argon and 0.25 eV in krypton (48). The threshold energy corresponds to that required to elevate an electron from the top of the valence band into a vacuum (16),

$$E_{thresh} = E_g - V_0 \quad [12]$$

where V_0 is the energy of the bottom of the conduction band relative to the vacuum level. The value of V_0 in liquid argon, −0.33 eV, is 0.63 eV lower than that in the solid, +0.3 eV (16), so in the liquid phase E_g is (14.2 − 0.14 − 0.63) = 13.4 eV. The value of V_0 in liquid krypton may also be assumed to be lower than that in the solid, due to the decreased repulsive interaction in the less dense phase (16). Hence, $E_g \approx 11$ eV in liquid krypton.

TABLE 3. W_l, the average energy expended per ionization in the noble liquids

[a]Values for negative voltages, from Table 3.
[b]See text.
[c]W from ref. 2, ionization potentials from ref. 7.

The ratio W_l/E_g is analogous to the gas phase ratio W_g/IP, where IP is the ionization potential. The former appears to be slightly lower than the latter (Table 5). In the liquid phase the higher excited states might react by [13], followed by the usual competition between geminate neutralization and free ion formation (*cf.* reactions 2 and 3).

$$M^* + M \rightarrow [M_2^+ + e^-] \quad [13]$$

The energies of the excited states are given by the Wannier equation (8, 11)[2]

$$[14] \quad E_n = E_g - (G/n^2) \qquad n = 1, 2, 3,...$$

where G is a Rydberg-like constant. The value of G in the solids is $\sim$2.1 eV for argon, 1.7 eV for krypton, and 0.9 eV for xenon (11) and should be similar in the liquids. The binding energy of the neutral M_2^* is $\sim$1 eV in the heavier noble solids (49), and that of the ions M_2^+ should be somewhat greater. It is therefore conceivable that states with $n > 1$ contribute to ionization.

The average radii a_n of the excited states are (11)

$$[15] \quad a_n\,(\text{Å}) = 0.53\varepsilon n^2/\mu$$

where $\mu^{-1} = (m_e^*)^{-1} + (m_h^*)^{-1}$, while m_e^* and m_h^* are respectively the effective masses of the electron and positive hole. Assuming that the values of μ in the noble liquids are similar to those in the solids (0.43 in Ar, 0.41 in Kr, and 0.31 in Xe (11)), the value of a_n reaches about 60 Å for $n = 6$ in argon and krypton, and $n = 5$ in xenon. The extent of field induced dissociation of excited states would not be greater than that of geminate pairs with a similar radial distribution. Using an exponential distribution function YE (47) with an inner cut-off at 20 Å, it appears that at $E < 100$ kV/cm there would be $<10\%$ of field induced dissociation of excited states with $a_n < 60$ Å. Field induced dissociation might be a fate alternative to [13] for the highest states at high fields, but the total ionization yield would not be affected.

Discussion

L. G. Christophorou: A mechanism similar to the one you propose ($M^* + M \rightarrow M_2^+ + e^-$) to account for the extra source of ionization in the liquid noble gases has been suggested by myself (L. G. Christophorou. Atomic and molecular radiation physics. Wiley-Interscience, New York, NY. 1971. Chapt. 2) for the noble gases, to partially account for the increased ionization for the noble gases compared to molecular vapors.

G. R. Freeman: The binding energy of M_2^+ is about 1 eV so the reaction is also possible for the higher Rydberg states in the gas phase. The question is whether a larger fraction of the total number of excited atoms generate ions in the liquid than in the gas.

R. C. Hughes: Could you comment on the fact that in semiconductors like Si and Ge, the energy required for each electron–hole pair is three times the band gap, and for wide band gap materials Rotwarf has predicted that two times the band gap would be required? Your values are even less than two times the band gap.

G. R. Freeman: The gas phase values are also less than two times the ionization potential. Perhaps the semiconductor values were not obtained by extrapolation to infinite field strength, in which case some geminate neutralization might have occurred. This would increase the apparent W values. Furthermore, Si and Ge are already chemically bonded systems, so the equivalent of $M^* + M \rightarrow M_2^+ + e^-$ would not occur in them.

G. Ascarelli: Do you expect field ionization of the excitons?

G. R. Freeman: We have estimated the extent of field induced dissociation of excitons with $n = 6$ in Ar, Kr, and Xe liquids. The fraction that would dissociate at 100 kV/cm would be less than 10%. The highest excitons could be dissociated by high fields, but this process would compete with the bimolecular ionization reaction and would not enhance the total ionization yield.

R. F. Firestone: The proposed contribution of additional free-ion pairs by Hornbeck–Molnar ($Ar^* + Ar \rightarrow Ar_2^+ + e^-$) reactions which you tentatively attribute to the liquid/gaseous phase difference should be observable in the gaseous phase alone. The rate constant for such reactions in the gas is $\sim 10^{-9}$ cm^3 atom^{-1} s^{-1} at room temperature. The radiative decay constant will likely be of the order 10^8 s^{-1} for Ar*. Thus, at 200–300 Torr and 300 K, extra ions from this process will be observed alternative to production of lower excited atomic states. We observe this effect on yields of Ar species in pulse radiolysed Ar gas at 300 K. Thus, it seems unlikely that extra ions will form only at densities characteristic of the liquid phase.

G. R. Freeman: The gas phase W values were probably measured at a few hundred Torr. Although there are the experimental uncertainties that I mentioned in our results, it appears that the reaction is more extensive in the liquid. Ar* refers to a whole manifold of states. The density dependence of the competition between the ionization reaction and other processes may be different for different states.

J. Jortner: Your proposed mechanism for 'Penning type' ionization of bound electron – hole Wannier excitons ($n = 2$) $\rightarrow M_2^+ + e$ (where M is a rare gas atom) is fraught with some difficulties, as the efficiency of this process is determined by the lifetime, τ, of the $n = 2$ state with respect to the $(n = 2) \rightarrow (n = 1)$ nonradiative multiphonon relaxation. Optical emission studies of solid and liquid Ar, Kr, and Xe conducted by us indicate that $\tau \approx 10^{-12}$ s and this expectation is borne out by theoretical calculation.
To the best of my knowledge there is no experimental evidence for extrinsic photoconductivity in liquid Xe below E_g. A search for such effect will provide a conclusive proof for the validity of your suggestion.
Finally, it is possible that cross sections for excitation of metastable exciton states above E_g are higher than the corresponding cross section for excitation of autoionizing states in the gas phase.

G. R. Freeman: Optical emission is a relatively slow reaction on the picosecond time scale and is not a test of the occurrence of the ionization reaction. The geminate neutralization reaction $[M_2^+ + e^-] \rightarrow M_2^*$ could occur in the time range $10^{-12} - 10^{-9}$ s. The longer times correspond to the greater electron penetration ranges; these pairs would be most easily dissociated by the applied fields, so the shorter time neutralizations are the ones that remain at high fields.
The definition of an ionization process in dense phases is ambiguous and not always readily distinguishable from that of a highly excited neutral state. For practical purposes we define an ionization as an event during which an electron separates from an ion or molecule, and after which the electron may be considered to have a separate existence for a finite time. Although the electron has not escaped the Coulomb field of the ion in a geminate pair $[M^+ + e^-]$ we include the pair under the definition of ionization because the wave function of the electron is not centered on the ion. Such electrons are observable in hydrocarbon glasses and in polar liquids and glasses.
Roberts and Wilson did observe photoconductivity in Xe below E_g, but they attributed it, probably correctly, to impurities. However, they made the measurements at rela-

tively low field strengths and would not have dissociated many geminate pairs. Our values were obtained by extrapolation to infinite field strength.

W. F. Schmidt: Klassen and myself have measured saturation currents in liquid argon irradiated with high energy X rays (Can. J. Chem. **47**, 4286 (1969)). Our W value was close to 25 eV and in agreement with data reported by Ullmaier (see above reference) and with those reported by Takahashi *et al.*

G. R. Freeman: We question whether you obtained a saturation current at 13 kV/cm, that is, whether you reduced the amount of geminate neutralization to zero. We had reported G(ionization) ≈ 5, or $W \lesssim 20$ eV (J. Chem. Phys. **51**, 1276 (1969)). Your value agrees with the 1974 value of Takahashi and co-workers. The 1974 value of Takahashi for xenon is higher than that from their more extensive work reported in 1975. If they made the same errors for xenon, krypton, and argon in 1974, all the W values from that study would be too high.

W. F. Schmidt: With respect to the xenon values I should like to ask how dosimetry was performed and whether the Bragg–Gray principle was fulfilled in your experiment.

G. R. Freeman: In the dosimetry we used a powdered salt that has the same average atomic number as the noble liquid in question; CsI for Xe. The samples were thick enough to satisfy the Bragg–Gray principle.

W. F. Schmidt: The difference in currents with positive and negative polarity of the high voltage electrode is, to a large extent, due to irradiation of the dead volume behind the collector electrode – guard ring assembly. Proper shielding reduces this effect to less than 5% difference; sometimes it vanishes completely.

G. R. Freeman: We have a grounded shield behind the collector electrode, at a potential less than 1 mV different from that of the collector. It is difficult to explain the difference in results obtained from positive and negative voltages.

J. W. Warman: I would question the use of the Onsager expression under conditions where the field strengths are high enough (*e.g.* >40 V cm^{-1} in liquid xenon) that the electrons are no longer in thermal equilibrium with the medium. This heating of the electrons should be taken into account as an effective variation of the temperature, *i.e.* the relevant temperature is T_e, the temperature of the electrons not the temperature of the medium.

G. R. Freeman: We have not considered this problem, but will do so. (Using T_e much greater than the liquid temperature increases the value of G_{tot} required to fit the results. See the note added at the end of the article.)

Electron energy loss processes at subelectronic excitation energies in liquids

JOHN L. MAGEE

Chemistry Department and Radiation Laboratory,[1] University of Notre Dame, Notre Dame, IN, U.S.A. 46556

and

Lawrence Berkeley Laboratory, Berkeley, CA, U.S.A. 94720

Received September 27, 1976

JOHN L. MAGEE. Can. J. Chem. **55**, 1847 (1977).

The theory of the processes by which subexcitation electrons lose energy in molecular liquids is considered. It is convenient to classify such losses as resulting from 'indirect' and 'direct' interactions; the former interactions arise from the transient electric field of the electron and the latter from the short range quantum mechanical forces occurring in direct collisions. Indirect processes are considered at some length; Monte Carlo trajectories for electrons are generated and the Fourier spectrum of the electric displacement obtained from which energy loss to dipolar relaxation and infrared-active vibrations are estimated. A tight binding scheme is used to derive an expression for the rate of energy loss to single-phonon excitation in direct collisions; the same theoretical framework is used to discuss electron trapping by the molecules of the liquid. Finally, some attempt is made to relate the loss mechanisms considered to experimentally known facts. It is concluded that the 'direct' processes are probably dominant and that knowledge of elastic scattering is of primary importance for the construction of a satisfactory theory.

JOHN L. MAGEE. Can. J. Chem. **55**, 1847 (1977).

On considère la théorie des processus par lesquels des électrons de subexcitation perdent de l'énergie dans des liquides moléculaires. Il est opportun de classifier de telles pertes comme résultant d'interactions "directes" et "indirectes"; les premières interactions proviennent de champs électriques transitoires de l'électron et les dernières proviennent de forces mécaniques quantiques à courtes distances se produisant lors de collisions directes. On considère longuement les processus indirects à longues distances; on génère des trajectoires de Monte Carlo pour les électrons et on obtient des spectres de Fourier des déplacements d'électron à partir desquels on a pu estimer les pertes d'énergie vers des relaxations dipolaires et les vibrations actives en infrarouge. On utilise un schéma d'association intime pour dériver une expression pour la vitesse de perte d'énergie vers une excitation à phonon simple dans les collisions directes; on utilise le même environnement théorique pour discuter du piégeage des électrons par des molécules du liquide. Enfin on fait quelques essais pour relier les mécanismes considérés pour les pertes avec les faits expérimentaux connus. On en conclut que les processus "directs" sont probablement dominant et que la connaissance de la dispersion élastique est de première importance pour la construction d'une théorie satisfaisante.

[Traduit par le journal]

1. Introduction

Subexcitation electrons can lose energy only in the excitation of the motion of nuclei, *i.e.*, in condensed systems to phonons, and thus in liquids all loss processes must depend upon the electron–phonon coupling. In all molecular media energy can be lost in *direct* or in *distant* or *indirect* collisions. The first mechanism is associated with short-range interactions and is usually the most important loss mechanism. The second mechanism is associated with the transient electric field generated by the motion of the electron. In dipolar media which have large static dielectric constants, under conditions favorable for dielectric relaxation the indirect loss can be very large; in molecular media which have no dielectric relaxation, infrared-active vibrational modes can absorb energy by this mechanism. The indirect loss processes establish a minimum rate of energy loss for electrons in molecular media.

Many investigations of the loss processes of low-energy electrons have been carried out for materials in the solid state, for gases, and for rare gas liquids, but few studies have been made on molecular liquids of interest in radiation chemistry. One of the principal problems of radiation chemistry is the configurations of

[1]Operated under contract with the US Energy Research and Development Authority. This is an ERDA Document NDRL-1706.

charges created by energy deposits immediately after thermalization has been attained. Much effort has been made to infer such configurations from experimental data such as free ion yields, the effect of external fields on free ion yields, the results of scavenger experiments, etc.

The distribution of subelectronic energies in liquids is not known. The function

$$[1] \qquad N(E) = \frac{8I^2}{3(E + I)^3} \qquad 0 \leq E \leq I$$

was proposed for low-energy electrons in molecular media by Magee and Burton (1). Here $N(E)$ is the number of electrons per unit energy interval at E and I is the ionization potential; the spectrum is normalized to unity. This distribution was suggested by a theoretical prediction of the distribution of electrons from photoionization of atoms. A formula for the absorption coefficient of an atom above the ionization limit widely used in opacity calculations of astrophysics was given by Kramers (2) on the basis of quite general considerations. It is

$$[2] \qquad \sigma = C/\nu^3 \qquad h\nu \geq I$$

where C is a constant which depends upon properties of the atom but is of no further relevance to this discussion. The energy of the photoejected electron is given by

$$[3] \qquad h\nu = E + I$$

and so the distribution function of [1] is clearly obtained. Of course, the distribution of electrons arising from particle impact processes is not necessarily expected to be the same and the usefulness of the formula for subexcitation electrons of radiation chemistry had to be established by analyzing experimental data. Platzman (3) investigated the distribution function for gases; it has not been possible to make a meaningful analysis of the data of other phases.

Platzman (3) called attention to the fact that the subexcitation electron spectrum is cut off on the high side at the lowest excited state of the medium, E_x, rather than the ionization potential, I. He analyzed experimental data in rare gases to derive spectra of 'subexcitation' electrons and found functions quite similar to $N(E)$ of [1] except that the high energy limit was E_x instead of I.

According to the distribution function $N(E)$, the average value of E is given by

$$\langle E \rangle = I/3$$

or

$$\langle E \rangle = E_x/3$$

if E_x is substituted for the upper limit. The lowest excitation potentials of molecular liquids are around 6 eV. Radiation chemists think of subexcitation electron energies in the vicinity of 2–3 eV and perhaps this is as reasonable as one knows at the present time.

According to Birkhoff and co-workers (4) and Ritchie *et al.* (5) the absorption of energy from high-energy electrons occurs primarily through a resonant process which forms a plasmon at around 20–24 eV. The case of water has been investigated rather extensively and the plasmon energy has been given as 22 eV; the complex dielectric constant has been obtained throughout this energy region; it is said that the initially created plasmon decays with a mean lifetime of around 10^{-16} s and presumably one of the products is a subexcitation electron. There is no reason to believe that the energy distribution would be given by [1]; in fact, on general grounds it would appear that a Gaussian distribution function would be more reasonable, but no one has considered the matter explicitly.

Interest in the 'initial' geometrical arrangement of the thermalized charged particles in tracks began with Lea (6) and Gray (7, 8). These authors speculated that a subexcitation electron would reach a separation from its parent positive ion of about 150 Å in water before becoming attached to a molecule to form H_2O^- which would subsequently dissociate to the products $H + OH^-$. No calculation of the range or even a consideration of the energy loss mechanisms was made. The value 150 Å was based somehow on interpretation of experimental results for α particles in hexane by Jaffe (9) and no attempt was made to justify the application of this result to water. The first theoretical consideration of the energy loss of a subexcitation electron was made by Fröhlich and Platzman (10). This treatment estimated the loss in *distant* collisions by excitation of polar vibrational modes, *i.e.*, dipolar relaxation. This very sophisticated treatment is not entirely free from objection, however, as we point out in section 2. Samuel and Magee (11) suggested that the energy loss mechanism of subexcitation electrons in water was due to *direct* collisions with the water molecules. These

authors did not present a theoretical treatment in the sense of Fröhlich and Platzman (10), but used gas phase data on fractional energy loss per collision to obtain an estimated loss rate which was large enough to be consistent with parent-ion recapture. The radical diffusion model was beginning to have great success in the explanation of experimental data and it was generally accepted that the reducing entity was the H-atom. Parent-ion recapture seemed to be necessary to explain the initial radical distributions.

After the hydrated electron was discovered a much more elaborate radical diffusion model was constructed by Schwarz (12); all parameters were chosen to be consistent with experimental results and there was no attempt to relate the initial separations of charges to thermalization mechanisms.

In recent years, interest in the behavior of low-energy electrons in organic liquids has been very great. Mozumder and Magee (13) made a study of the free ion yield in hexane which contained an elaborate discussion of the thermalization process for subexcitation electrons. In other studies most authors have been more concerned with the nature of distribution functions which must be assumed in order to obtain agreement with experimental results. Such distribution functions contain indirect information on low-energy electron ranges in the liquids. Mozumder and co-workers (14–16), Abell and Funabashi (17), Hummel (18), Freeman and co-workers (19–22), and Holroyd *et al.* (23), have made many studies of this nature.

Free ion yield studies in molecular liquids involve the difficulty that the amount of energy required to form a primary charge pair is not well known. On general principles it is expected that the energy required is somewhat less for a given compound in the liquid state than in the gas. The situation with respect to the noble gases and their liquids is better understood and has been presented by Huang and Freeman (24).

Most papers treat the high-energy electron track as if it were composed entirely of charge pairs, or that track entities such as short tracks do not exist although on general grounds it is known that they do. All authors are actually aware of the problem, but at the present time there is no real understanding of the role of higher track entities. Mozumder (25) considered the problem explicitly. Mozumder and Magee (13) demonstrated in the case of hexane that the latter had to be taken into account to explain the free ion yield, but many later studies have continued to use the approximation of entities with charge pairs only.

In spite of the various uncertainties regarding energy distribution of subexcitation electrons and track structure, most authors have assumed that it is possible to obtain electron ranges and 'stopping power' information from experimental data. In part this belief is supported by the success of the treatment of electron scavenging and escape using the Smoluchowski and Onsager equations. The question of importance now is this: how do electrons starting at energies from 1 to 5 or 6 eV thermalize in going a distance of 60–100 Å in molecular liquids?

In this paper, we are primarily concerned with the mechanisms of energy loss of subexcitation electrons. The use of the mechanisms to generate range energy relations has not been accomplished.

2. The Theory of Energy Loss: Indirect Processes

The loss of energy by means of the transient electric field generated by the motion of the electron has been considered by Magee and Helman (26). These authors took into account the random motion of the electron as it moves through the molecular medium and made explicit estimates of rates of energy loss to dipolar relaxation and to infrared-active vibrational modes.[2] The earlier treatment of the indirect loss process by Fröhlich and Platzman (10) had been restricted to the dipolar loss mechanism and the electron trajectory had been approximated as linear.

The total energy loss (per unit volume) to a molecule located at a position $\boldsymbol{R}$ in the vicinity of an electron trajectory is given by

$$[4] \qquad L(\boldsymbol{R}) = \frac{1}{4\pi}\int_{-\infty}^{\infty} \boldsymbol{E}(\boldsymbol{R},t)\cdot\frac{\partial \boldsymbol{D}}{\partial t}(\boldsymbol{R},t)\mathrm{d}t$$

where $\boldsymbol{E}$ is the electric field intensity, $\boldsymbol{D}$ the electric displacement, at $\boldsymbol{R}$. It is clear that the energy lost to the molecule depends upon an integral over the entire trajectory of the electron;

[2]This problem has also been considered by H. Sano (unpublished results) using a space–time autocorrelation function. His result is in qualitative agreement with this section.

the interaction pattern of the trajectory cannot be divided into separate 'collisions'.

Fourier transforms of $\boldsymbol{E}$ and $\boldsymbol{D}$ are used and a complex dielectric constant

$$\varepsilon = \varepsilon_1 + i\varepsilon_2$$

introduced. The integration over time can be performed to yield

$$[5] \quad L(\boldsymbol{R}) = \int_0^\infty \frac{\varepsilon_2(\omega)}{\varepsilon_1^2(\omega) + \varepsilon_2^2(\omega)} \boldsymbol{D}_\omega \cdot \boldsymbol{D}_\omega^* \omega d\omega$$

where the following symmetry in the Fourier transforms

$$[6] \quad \begin{aligned} \boldsymbol{D}_\omega &= \boldsymbol{D}_{-\omega}^* \\ \boldsymbol{E}_\omega &= \boldsymbol{E}_{-\omega}^* \\ \varepsilon_\omega &= \varepsilon_{-\omega}^* \end{aligned}$$

has been used (10, 26).

It is clear from [5] that the track enters the calculation only through the Fourier transform of the electric displacement. Magee and Helman (26) consider three kinds of tracks.

(*a*) A random track in which the electron starts at an initial position (on a molecule!) and then jumps to neighboring molecules in a random manner. A Monte Carlo routine is used to obtain such tracks.

(*b*) A random track in which the electron hesitates on 10% of the molecules for an average of five jump times. The significance of this type of track is an approximation of the effect of resonances which are believed to exist; in the energy region of subexcitation electrons most such resonances probably arise from the energy level structure of the electron in the disordered molecular system (27). This track is of course also obtained by a Monte Carlo procedure.

(*c*) A linear track in which the electron jumps from one molecule to the next along a line. The significance of this track is twofold. In the first place a check of the technique is desired and analytical calculations are available for the linear case. In the second place, the linear track provides an estimate of the minimum energy loss by the indirect mechanism; it is the lower limit for large mean free path.

The electric displacement is given by

$$[7] \quad \boldsymbol{D} = \frac{e}{|\boldsymbol{R}_n - \boldsymbol{R}|^3} (\boldsymbol{R}_n - \boldsymbol{R})$$

where $\boldsymbol{R}_n$ is the position of the electron at the nth jump in the track. A track is composed of N jumps and time is related to the jump so that zero time occurs in the middle of the track, *i.e.*

$$[8] \quad t = (n - N/2)\tau_J$$

where τ_J is the jump time.

Equation 5 shows that the spectrum $\omega \boldsymbol{D}_\omega(\boldsymbol{R}) \cdot \boldsymbol{D}_\omega^*(\boldsymbol{R})$ is the important quantity to determine. First this spectrum is obtained for particular tracks and then it is averaged over an ensemble; it is finally integrated over all $\boldsymbol{R}$ to obtain

$$[9] \quad \omega J_\omega = 4\pi \int_0^\infty R^2 \langle \omega \boldsymbol{D}_\omega(R) \cdot \boldsymbol{D}_\omega^*(R) \rangle dR$$

where J_ω is defined by the equation. Figure 1 shows ωJ_ω for ensembles of random tracks of 256 jumps for the three types *a*, *b*, and *c*.

Magee and Helman (26) considered the application of these results to the energy loss of electrons in water. Following Fröhlich and Platzman (10) they took

$$[10] \quad \varepsilon_1(\omega) = \varepsilon'(\omega) + \frac{\varepsilon_s - \varepsilon_{ir}}{1 + \omega^2\tau^2}$$

$$[11] \quad \varepsilon_2(\omega) = \varepsilon''(\omega) + \frac{(\varepsilon_s - \varepsilon_{ir})\omega\tau}{1 + \omega^2\tau^2}$$

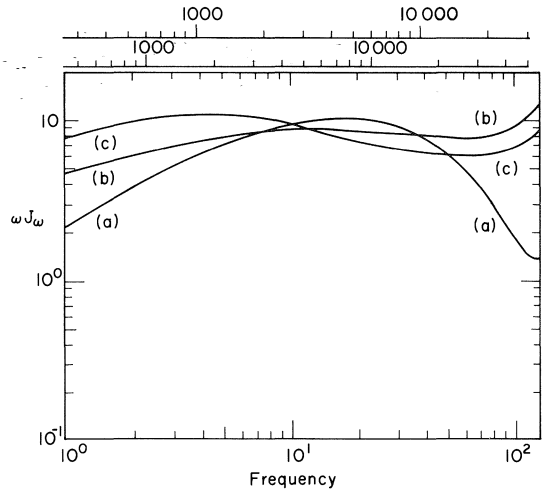

FIG. 1. The quantity ωJ_ω *vs.* frequency for tracks of 256 jumps normalized to an effect per jump. The abscissa is the frequency (*i.e.*, $\omega/2\pi$) in units of the smallest frequency calculated, $(256\ \tau_J)^{-1}$; three cases are shown: (*a*) linear trajectory; (*b*) simple random walk; (*c*) random walk with hesitation for an average of five jump times on 10% of sites. Two scales are shown above the plot which relate frequency to wave numbers for $\tau_J = 5 \times 10^{16}$ s, top scale, and for $\tau_J = 3 \times 10^{16}$ s, lower scale.

where τ is the relaxation time, ε_s is the static dielectric constant, and ε_{ir} is the dielectric constant at frequencies sufficiently lower than the lowest principal infrared absorption frequency ω_{ir}. The quantity $\varepsilon''(\omega)$ gives the absorption due to ionic oscillation in the infrared and any other resonant absorption processes at higher frequencies; $\varepsilon'(\omega)$ gives the corresponding dispersion.

These formulas have quite general validity for substances which have Debye-type relaxation. For water at 20°C, $\tau = 10^{-11}$ s. The frequency range of our calculation involves only $\omega\tau > 10^3$; thus we can take

$$[12] \qquad \varepsilon_1^2 + \varepsilon_2^2 \approx \varepsilon_1^2 \approx n^4$$

and

$$[13] \qquad \frac{(\varepsilon_s - \varepsilon_{ir})\omega\tau}{1 + \omega^2\tau^2} \approx \frac{\varepsilon_s - \varepsilon_{ir}}{\omega\tau}$$

The integrand of [7] when ensemble averaged and integrated over space becomes

$$[14] \qquad \frac{\varepsilon_s - \varepsilon_{ir}}{n^4\tau} J_\omega$$

The loss expression for Debye-type relaxation becomes

$$[15] \qquad W = \frac{\varepsilon_s - \varepsilon_{ir}}{n^4\tau} \int_0^\infty J_\omega d\omega$$

In order to get numerical values for the energy loss, explicit values for all quantities must be taken. We have used $\varepsilon_s - \varepsilon_{ir} = 75$, $n^4 = 3$; in the random walk $l = 3$ Å and the electron velocity 10^8 cm/s which gives $\tau_J = 3 \times 10^{-16}$ s.

Table 1 gives the values of W calculated for the three tracks whose spectra are shown in Fig. 1. According to the calculations the random track has a larger loss rate than the linear track and the track with hesitation has an even larger loss rate. The linear track as calculated by the approximate procedure has a loss rate somewhat larger than the loss rate given by the analytical calculation (about 15%). The value of the total loss in a track is found to vary with the track parameters as

TABLE 1. Energy loss rate to dipolar relaxation in H_2O

Track	Loss in eV per jump	Loss in eV/s
Random	0.0041	1.37×10^{13}
Random with hesitation	0.0049	1.63×10^{13}
Linear	0.0032	1.06×10^{13}

$$[16] \qquad W \propto \frac{\tau_J}{l}\Delta$$

where Δ is a dimensionless measure of the integral over J_ω; it is obtained numerically and is independent of the parameters. The average rate of energy loss is

$$[17] \qquad \frac{W}{256\tau_J} \propto \frac{\Delta}{256l}$$

and is *independent* of the velocity, in agreement with Fröhlich and Platzman (10).

Magee and Helman (26) also considered the indirect loss to infrared-active molecular vibrations. The problem of the frequency-dependent dielectric constant of a system which has resonance absorptions has been discussed by Van Vleck and Weisskopf (28) and Fröhlich (29, 30). The absorption in such resonances is expected to be less important than that to dipolar relaxation if the latter mechanism exists. Consider a system which has no dipolar relaxation; in a spectral region in which there are infrared absorptions at κ frequencies $\omega_1, \omega_2, \ldots, \omega_j, \ldots, \omega_\kappa$, the dielectric constant can be written as

$$[18] \qquad \varepsilon_1(\omega) - \varepsilon_{ir} = \sum_{j=1}^{\kappa} 2\pi\rho_j \frac{q_j^2}{M_j\omega_j^2}\left[\frac{1 + \omega_j(\omega + \omega_j)\tau_j^2}{1 + (\omega + \omega_j)^2\tau_j^2} + \frac{1 - \omega_j(\omega - \omega_j)\tau_j^2}{1 + (\omega - \omega_j)^2\tau_j^2}\right]$$

$$[19] \qquad \varepsilon_2(\omega) = \sum_{j=1}^{\kappa} 2\pi\rho_j \frac{q_j^2}{M_j\omega_j^2}\left[\frac{\omega\tau_j}{1 + (\omega + \omega_j)^2\tau_j^2} + \frac{\omega\tau_j}{1 + (\omega - \omega_j)^2\tau_j^2}\right]$$

where ρ_j is the number density of oscillators of the jth type which has an effective charge of q_j and a reduced mass of M_j; and τ_j is the effective collision time for the damping of the jth oscillator. The latter quantities are to be obtained from experiment; unfortunately the theory of infrared absorption is not developed far enough to be useful in predicting such parameters.

The energy loss is to be obtained from [5] and it is clear that all of the terms of the summations

TABLE 2. Infrared intensities and track absorptions in benzene for tracks of 256 jumps

Mode	Frequency (cm^{-1})	Γ (cm^2/mol)	Energy absorbed from track (eV)		
			Linear	Random	Random with hesitation

Sum of line absorptions			0.063	0.089	0.1316
Rate of energy absorption (eV/s)			4.92×10^{11}	6.95×10^{11}	1.03×10^{12}

of [18] and [19] are involved in the integration. The fact that each term of ε_2 has a resonance allows a simplification; we assume that no other frequency dependence is important and the integration over the resonance term becomes

$$[20] \quad \int_0^\infty \frac{\omega\tau_j \boldsymbol{D}_\omega \cdot \boldsymbol{D}_\omega^* \omega d\omega}{1 + (\omega - \omega_j)^2\tau_j^2} \approx \pi\omega_j^2 \boldsymbol{D}_{\omega_j} \cdot \boldsymbol{D}_{\omega_j}^*$$

In most cases

$$\varepsilon_2(\varepsilon_1^2 + \varepsilon_2^2)^{-1} \approx \varepsilon_2/\varepsilon_{ir}^2$$

to a good approximation and we can write for the energy loss per unit volume at a molecule located at $\boldsymbol{R}$

$$[21] \quad W = \sum_{j=1}^{\kappa} W_j = \sum_{j=1}^{\kappa} \frac{2\pi^2\rho_j}{\varepsilon_{ir}^2} \frac{q_j}{M_j} J_{\omega_j}$$

Magee and Helman (26) show how q_j^2/M_j can be eliminated using experimentally determined absorption strengths. The energy loss is given by

$$[22] \quad w = \sum_j \left(\frac{\rho_j}{N}\right) \frac{\Gamma_j}{\varepsilon_{ir}^2} c\omega_j J_{\omega_j}$$

where Γ_j is the integrated absorption of the jth transition in cm^2/mol. Thus the energy absorption by infrared-active oscillators can be obtained from experimental data on integrated absorptions. Such experimental information is not readily available but data on the absorption in gas phase benzene have been published (31) and they have been used to obtain the estimates of electron loss given in Table 2. Absorption is stronger in the liquid. The calculated energy losses for the various tracks using gas phase data are perhaps minimal values.

Aliphatic hydrocarbons are of great interest in radiation chemistry but neither absorption intensities nor complete analysis of the vibrational spectra are available for these molecules. On the other hand, the vibrational spectrum of polyethylene is quite well understood and in some approximations it can be taken as a prototype for the aliphatic hydrocarbons. The basic unit is —CH_2—CH_2— which in the crystalline state is very symmetric, with a center of symmetry; there are 18 degrees of freedom and only six infrared-active frequencies (31) (one of these is strictly inactive in the crystal).

Table 3 shows the absorption of electrons in polyethylene as significantly larger than in benzene. One factor is that the mean free path, l, is taken to be 5 Å in benzene and 3 Å in polyethylene. The latter value was used because the calculation made for water used 3 Å and the unknown mean free path in polyethylene was taken to be the same.

The energy loss to a particular absorption line at ω_j over the entire track is found to vary as

$$[23] \quad W_j \propto \frac{1}{l}\tau_j^2\Delta_j'$$

where Δ_j' is a quantity proportional to the spectrum shown in Fig. 1. To a rough approximation it can be taken as independent of frequency for the random track; thus the contribution of the jth line to the *rate* of energy absorption is

$$[24] \quad \frac{W_j}{256\tau_j} \propto \frac{\tau_j}{l}\Delta'$$

where we take Δ' as a constant, and the absorption of the line varies *directly* as the jump time or *inversely* as the velocity. This dependence is approximately valid for all lines in the region 500 to 3500 cm^{-1}.

3. Theory of Energy Loss: Direct Processes

The theory of loss processes involving short-range interactions requires the use of wave

[a]This mode is inactive in the crystal.

functions. The low-energy electrons are initially in extended states as they lose energy in the 1–6 eV region and we shall assume that the extended states can be made up of superpositions of negative ion states of the molecules; in other words, the tight-binding approximation is used. The electrons are in very low concentrations (in fact, we consider a system which only has *one* electron and N molecules with $N \sim 10^{22}$) and so the molecules vibrate in the potential function of the neutral ground state. The negative ion potential function is, of course, also important. As the electron moves about there is a tendency for the nuclei of the molecule which contains the electron to relax from the vibrational structure of the neutral molecule to that of the negative ion. The general theory of this process has not been worked out and we consider two limiting cases.

(*a*) The weak interaction limit in which no relaxation develops about the negative ion. The interaction produces excitation of vibrations in the neutral molecules.

(*b*) The strong interaction limit in which localization occurs in a single event and is followed by a large transfer of energy into vibrations.

It is likely that many loss processes can occur in molecular liquids in the spectrum between these two limiting cases. However, the most probable processes should be the special cases themselves.

According to the 'random phase model' (RPM) used in solid state physics (33, 34), under certain conditions the wave functions of extended states for electrons can be expanded in terms of localized functions (Wannier-like) centered on atoms, the latter having completely random phases. This type of model would seem to be in keeping with the requirements of subexcitation electrons in some of the molecular media of interest in radiation chemistry and we explore its use in the energy loss to phonons in the mechanism called (*a*). At the outset it should be stated that the RPM is not expected to be of universal validity for this problem and the range of applicability needs to be explored.[3]

Another matter of importance for subexcitation electrons is the spatial distribution as the energy approaches thermal. The use of a wave function is of course necessary for an adequate treatment and in this case we require a superposition of the extended wave functions to form a wave packet which spreads out as the energy is lost. This problem is also not considered at this time.

The electron wave function is assumed to be (34)

$$[25] \qquad |k\rangle = \sum_{n=1}^{N} a_{nk}\phi_n(\boldsymbol{r} - \boldsymbol{R}_n)$$

where the ϕ_n are located on the molecules and the a_{nk} have random phases.

The Hamiltonian of the system is taken as

$$[26] \qquad H = \sum_q \hbar\omega_q a_q^{+} a_q + H_{el} + H_{int}'$$

which consists of the Hamiltonian for the unperturbed phonon field of the neutral molecules, the electron Hamiltonian, and an interaction term between the phonons and the electron; a_q^{+} and a_q are creation and annihilation operators, respectively, and q goes over all phonon

[3]The Random Phase Model should be distinguished from the Random Phase Approximation also used in solid state theory. See ref. 35.

modes; the electron Hamiltonian operates on the wave function as follows:

$$[27] \qquad H_{el}|k\rangle = \varepsilon_k|k\rangle$$

The interaction Hamiltonian H_{int}' is taken to be of the deformation potential type (36, 37)

$$[28] \qquad H_{int}' = \sum_j E_{1j}\Delta \boldsymbol{u}_j$$

where E_{1j} is a constant with dimension energy which applies to the jth coordinate of the system and Δ is the dilation due to the phonons. It is the divergence of the local displacement $\boldsymbol{u}_j$ which is taken to be a continuous function for this purpose.

The system considered contains N molecules in a volume V. Most of the 'phonons' of interest are actually to a good approximation vibrations of individual molecules. Say that each molecule has p vibrations (three times the number of atoms minus six); we shall at first consider only the excitation of these vibrations, for the total system equal to Np. The other six degrees of freedom combine to form acoustical modes and a few additional 'optical' modes; these neglected modes are in fact active in the exchange of energy with thermal electrons and are certainly of importance in the latter stage of thermalization.

The excitations we consider are those of the normal vibrations of individual molecules; the $\boldsymbol{u}_j$ of [28], therefore, belongs to a single molecule and H_{int}' is composed of N terms each containing the p normal vibrations of one molecule.

The rate of energy loss is to be obtained through the use of the 'Golden Rule' and we need matrix elements of H_{int}' between arbitrary electron states k' and k. The phonon field is not explicitly involved in this consideration.

$$[29] \qquad \langle k'|H'|k\rangle = \sum_{n',n} a_{n'k'}{}^* a_{nk}\langle n'|H'|n\rangle$$

where

$$\langle k'|H'|n\rangle = \int \Phi_{n'k'}(\boldsymbol{r} - \boldsymbol{R}_{n'})H'\Phi_{nk}(\boldsymbol{r} - \boldsymbol{R}_n)\mathrm{d}\boldsymbol{r}$$

We assume that the Wannier-like states Φ_n are orthogonal and so we have the relationship (34)

$$[30] \qquad \sum_n a_{nk'}{}^* a_{nk} = \delta_{k'k}$$

We shall always assume that ensemble averages are to be used; we have from [30] for $k' = k$

$$[31] \qquad \begin{aligned} \sum |a_{nk}|^2 &= 1 \\ |a_{nk}|^2 &= 1/N = v/V \end{aligned}$$

where v is the volume of a molecule. We require the absolute values of the square of the matrix element

$$[32] \qquad |\langle k'|H'|k\rangle|^2 = \sum_{\substack{n',n \\ m',m}} a_{m'k'}{}^* a_{mk} a_{n'k'}{}^* a_{nk}\langle m'|H'|m\rangle\langle n'|H'|n\rangle$$

Because of the random phases, only terms which have $m' = n'$, and $m = n$ fail to vanish. Use of this fact and [31] allows us to write

$$[33] \qquad |\langle k'|H'|k\rangle|^2 = \left(\frac{v}{V}\right)^2 \sum_{n,n'} |\langle n'|H'|n\rangle|^2 = \left(\frac{v}{V}\right) \sum_{n'} |\langle n'|H'|n\rangle|^2$$

In our particular problem the 'phonons' are vibrations of individual molecules and so the matrix elements of the interaction Hamiltonian only involve single molecules. Thus we have

$$[34] \qquad |\langle k'|H'|k\rangle|^2 = \frac{v}{V}|\langle n|H'|n\rangle|^2$$

which means that the molecules of the medium all contribute equally and one only has to perform the calculation for one of them.

Let us now consider the energy loss to phonons. We require the matrix element

$$\langle k', n_q + 1|H_{int}'|k, n_q\rangle$$

where n_q is taken to represent all of the p modes and in general $n_{q'}$, the number of phonons initially present in a mode, can be taken as zero. The displacement of the nth molecule is (38)

$$[35] \qquad \boldsymbol{u}(n) = \sum_{j=1}^{p} \boldsymbol{u}_j(n)Q_j(n)$$

The internal condition of a molecule can be given in terms of the p normal modes and $\boldsymbol{u}_j$ are vectors in the directions of the modes; [35], therefore, has only a single sum

$$[36] \qquad Q_j = \left(\frac{\hbar}{2M_j\omega_j}\right)^{1/2}(a_j{}^+ + a_j)$$

Use of [35] and [36] with [28] gives

$$[37] \qquad |\langle k', n_q + 1|H'|k, n_q\rangle| = \sum_{j=1}^{p} \frac{(E_j q_j)^2 \hbar v}{2M_j\omega_j V}$$

where E_j has been substituted for E_{1j} and we have used

$$[38] \qquad |\langle n|\Delta u_j|n\rangle|^2 = q_j^2$$

for the matrix element of the dilation.

The rate of energy loss is given by

$$[39] \quad \left(\frac{\partial\varepsilon}{\partial t}\right) = \frac{2\pi}{\hbar}\frac{(E_j q_j)^2 \hbar v}{2M_j\omega_j}\hbar\omega_j\left[n_j\frac{\nu(\varepsilon_k + \hbar\omega_j)}{V} - (n_j + 1)\frac{\nu(\varepsilon_k - \hbar\omega_j)}{V}\right]$$

where $\nu(\varepsilon_k + \hbar\omega_j)$ is the number of states per unit energy interval for the electron with energy $\varepsilon_k + \hbar\omega_j$; it is proportional to V. The average numbers of vibrational quanta present initially can be taken as zero for almost all the molecular vibrational modes; the only surviving term is an energy loss term

$$[40] \quad \left(\frac{\partial\varepsilon}{\partial t}\right) = -\sum_{j=1}^{p}\frac{\pi\hbar}{\rho_j}(E_j q_j)^2\frac{\nu(\varepsilon_k - \hbar\omega_j)}{V}$$

where $\rho_j = M_j/v$ is a 'density', *i.e.*, mass per unit volume.

The difficulty with the use of [40] is the appearance of potential functions of both the neutral molecule and negative ion, the wave function for the electron and the density of states, quantities which are not known.

Consider a classical oscillator which is subjected to a transient force $-\partial U/\partial x$ for a short time τ. The momentum given the oscillator is

$$[41] \qquad P = -\int\left(\frac{\partial U}{\partial x}\right)dt \simeq -\left(\frac{\partial U}{\partial x}\right)\tau$$

and its energy increase is

$$[42] \qquad \Delta E = \frac{P^2}{2M} = \frac{1}{2M}\left(\frac{\partial U}{\partial x}\right)^2\tau^2$$

The *rate* of energy increase is

$$[43] \qquad \frac{\Delta E}{\tau} = \frac{1}{2M}\left(\frac{\partial U}{\partial x}\right)^2\tau$$

In [40] the quantity $E_j q_j$ is essentially $\partial U/\partial x$; the other terms of [40] can be identified with [43] as follows:

$$M = M_j$$

$$\tau = \frac{hv}{V}\nu(\varepsilon_k - \hbar\omega_j)$$

To some extent one can adopt the pictures of oscillators subject to excitation by transient negative ion fields.

Let us attempt to estimate the parameters involved in [40]. It has never been customary to attempt a calculation of a deformation potential when that model is used in solid state calculations; values of 1–10 eV are usually assumed and so let us take 1 eV; q_j has to be of the *order* of 10^8 (one reciprocal angström). The density ρ_j is smaller than the liquid density because M_j is one of the reduced masses; let us assume $\frac{1}{6}$ as a reasonable guess. The density of states is very uncertain but a number to assume is perhaps the free electron value, $\nu(\varepsilon_k - \hbar\omega_j) \simeq 7 \times 10^{21}$ if the argument is 3 eV. Use of these values gives

$$[44] \qquad \left(\frac{\partial\varepsilon}{\partial t}\right) = -1.4 \times 10^{12}\ \text{peV/s}$$

Although the uncertainties are great, [40] is not incompatible with an energy loss of 10^{14} eV/s. The dependence of the rate of energy loss on E_j is as the *square* and just one degree of freedom with $E_j \sim 10$ would give $\partial\varepsilon/\partial t \sim 10^{14}$ eV/s; the potential functions for H_2O^- calculated by Claydon, Segal, and Taylor (39) suggest that $E_j q_j \sim 10$ is reasonable. Because this mechanism involves essentially one molecule at a time, the gas phase data of Christophorou *et al.* (40) should be applicable. Use of their Fig. 3 and a linear correction for density allows an estimate of 5×10^{13} eV/s for the rate of loss of an electron in water at energy 1 eV.

For hydrocarbons in the hexane class, $p \sim 50$. Substitution of this value in [44] (which assumes $E_j q_j \sim 1$) gives a loss rate of 7×10^{13} eV/s.

The strong interaction limit (*b*) in which the negative ion state is actually attained is in many ways like the capture of the electron in a scavenger (41). Of course in this case the scavenger is a molecule of the principal component. 'Capture' means that a configuration is attained which prevents continued migration of the electron and all of the excess energy is transformed into vibrational excitation of one molecule. Such a molecule is very 'hot' and cools through loss of vibrational quanta to its immediate neighbors. The electron becomes thermalized at this point and only continues its migration as a thermal electron.

The initial state is the same as before with

the wave function of [25]. There are N final states, the N possible negative ions of the system. For the purpose of this treatment the fact that there is a weak resonance between these negative ion states can be ignored.

We are interested in the probability that the electron is captured per unit time, which can be written as:

$$[45] \qquad P = \frac{2\pi}{\hbar}|H_{if}'|^2\rho_E$$

where H_{if}' is the matrix element of the appropriate perturbation operator between the initial and final states and ρ_E is the density of final states. The transition is from the ground vibrational state of the neutral molecule to an excited vibrational state of the negative ions. Funabashi and Magee (41) have made an elementary consideration of the capture of an electron from an extended state in a liquid to a scavenger which dissociates. In that case the perturbation operator is shown to be the matrix element of the electron with respect to the electronic interaction with scavenger molecule, *i.e.*

$$[46] \qquad \beta_{21} = \langle\Phi_2 V_s \Phi_1\rangle$$

where Φ_2 is the negative ion wave function; Φ_1 is the extended state wave function; and V_s is the operator for the interaction of the electron with the scavenger. The matrix element in [45] for this case is

$$[47] \qquad H_{if}' = \langle\eta_2\beta_{21}\eta_1\rangle$$

where η_2 is the wave function for the nuclear motion of the negative ion and η_1 is that of the neutral scavenger molecule.

Funabashi and Magee (42) have shown that the same treatment can be applied approximately to the capture of electrons by the molecules in a homogeneous liquid. In this case there are many degrees of freedom and so wave functions for all of the vibrational modes of the system must be included; the term β_{12} is a function of all coordinates. In general the neutral molecule and the negative ion will have different potential functions and different normal modes. An analysis can be carried out in a formal manner (42) but it will not be presented at this time.

For the sake of orientation consider the magnitude of P given in [45] for the case of a dissociative capture by a molecule. It is probable that such a process is actually important as an energy loss mechanism for subexcitation electrons; the interpretation of experimental results of Hamill and co-workers (43) which bear on this point is discussed in the next section. The process considered is

$$e(k) + RX \rightarrow R + X^-$$

where RX is a hydrocarbon molecule, X^- is H^-, CH_3^-, etc., and k is a measure of the momentum. The value of the square of the matrix element of [45] is

$$[48] \qquad |H_{if}'|^2 \simeq E'^2 S^2 a/R$$

where E' is an electronic integral which is perhaps of the order of magnitude of an electronvolt; S is the overlap integral for all of the vibrational degrees of freedom which may be fairly small; a is a distance of the magnitude of a bond dissociation distance (10^{-8} cm), and R is a macroscopic distance arising out of the normalization of the dissociated state.

The density of states per unit energy interval is given by

$$[49] \qquad \rho_E = \left(\frac{2MR^2}{Eh^2}\right)^{1/2}$$

where M is the reduced mass for the dissociation and E is the relative kinetic energy in the dissociated state. It is clear that the constant R cancels from the calculation and if we take $E = 1$ eV and $M = 1$ atomic mass we obtain

$$[50] \qquad P \simeq 4 \times 10^{16} E'^2 S^2 a \text{ s}^{-1}$$

where a is to be taken in units of Å, and E' in eV.

This consideration does not establish the order of magnitude of P but it shows that the mechanism is not incompatible with a process which must have a specific rate of the general magnitude 10^{14} s^{-1}. It is reasonable to expect E' and a to be of the order of unity, and S^2 could easily be $(400)^{-1}$ or perhaps larger.

One thinks of dissociative processes as having large specific rates because of the high density of final states. A system of oscillators also has a high density of states which increases exponentially as the excitation increases. It is easily possible that there are polyatomic molecules for which the negative ion formation processes by the non-dissociative route dominate the energy loss mechanisms.

4. Discussion

This paper has been concerned only with theoretical aspects of the energy loss of subexcitation electrons. Unfortunately, the best understood mechanisms are the least important for systems of interest in radiation chemistry. The indirect loss mechanism described in section 2 can be developed in an elegant manner but there may be no cases in which it is the dominant process. All mechanisms act concurrently and so the more effective energy loss processes determine the experimentally observed phenomena. An entirely adequate theory would not consider the two mechanisms separately; they would both be contained within a single unified treatment.

Most subexcitation electrons probably have energies in the range below the threshold for dissociation processes and both mechanisms (*a*) and (*b*) of section 3 are effective. These are most probably the dominant subexcitation energy loss mechanisms in molecular media. Further development of the theory presented in section 3 requires quantum mechanical studies of the wave functions and energies of excess electrons in molecular systems.

There is a tendency for radiation chemists to think of energy loss in terms of one phonon at a time; this intuition leads to the process of section 2 and process (*a*) of section 3. On the other hand, many experimental results demand the type of process in which essentially all of the energy of a subexcitation electron is available for one purpose, such as a molecular dissociation (43, 44). Clearly the energy cannot be given up by the excitation of single phonons at a time. To be consistent with experimental results, mechanism (*b*) (of section 3) must compete favorably with mechanism (*a*). For the case of irradiated thin films of alkanes at 77 K, Hamill and co-workers (43) have made chemical studies of the products. The dissociation process which has the lowest threshold energy ($\sim$3.8 eV) is

$$e + RH \rightarrow R + H^-$$

and chemical products are observed at about this electron energy. Hamill[4] reports that the total observed product yield for electrons somewhat above threshold but below the energy required to excite the lowest electronic state requires that there is a G value for dissociation of 2 or 3. Say the electron energy is 5 eV, 20 electrons are required to give up 100 eV and 3 of these must produce dissociations. The effectiveness of an excited negative ion in dissociation as compared with energy loss to the environment without dissociation is unlikely to be as much as 50%; if there are 6 localized vibrationally-excited ions created per 20 electrons, this means that about one third of the loss processes proceed through route (*b*) as contrasted with (*a*). In any case, the two processes compete on something like an equal footing.

Other work by Hiraoka and Hamill (45, 46) on characteristic losses and luminescence indicates that energy of subexcitation electrons is available in larger quantities than single phonons at a time. On the other hand, in this same work a prominent energy loss occurs at about $\frac{1}{2}$ eV, and it is likely to be due to a single phonon.

In sections 2 and 3 the formal theory was developed in terms of a scattering mean free path explicitly or implicitly equal to a molecular diameter. The theory was developed so that the two mechanisms would be consistent. However, the transmission of the electrons through thin films depends upon the scattering mean free path and if the latter were as small as a molecular diameter, the transmission to backscattering ratio (T/B) would be very small for films as thick as 100 or 200 Å. Experimentally it is known (44, 46, 47) that the T/B ratios are the order of unity and not very sensitive to film thickness. These facts indicate that the mean free path for scattering is much larger than molecular dimensions. The results of Chang and Berry (47) give values of 'mean free path' which are 20–50 Å for a great many alkanes at 77 K; Huang and Magee (48) have shown that the results of Hamill are consistent with those of Chang and Berry.

Unfortunately the results of experiment are not well enough known so that the requirements of experiment on the theory presented here can be precisely stated at this time. In particular, the 'initial distributions' which are the most interesting to radiation chemists of all the experimental data are unknown quantities; uncertainties in subexcitation electron distribution, track entity distribution, etc., make them impossible to define precisely. In a general way, however, we know many things. Effective mean

[4]W. H. Hamill, private communication.

free paths for the electrons must be fairly large, 20–50 Å, and energy loss processes very efficient. Many results seem to indicate that the distribution is very broad (with a long tail), which might imply that a process such as 3(*b*) dominates but a significant fraction of loss is due to 3(*a*) and low-energy electrons have less efficient loss processes.

The principal defect of the theory as presented here is that the implied mean free path is too short. The theory can be restated in terms of the concept 'coherence length' for the wave function instead of requiring the wave function to be coherent only on each molecule. Relaxation processes may not be associated with single molecules, but may also involve intermolecular motions. Such processes arise naturally in a treatment which has a longer coherence length. Funabashi (49) has discussed this topic and the application to the present problem has been considered by Funabashi and Magee (42).

Phenomena resulting explicitly from disorder in molecular systems have also been neglected. Funabashi and Kajiwara (27) have shown that the effect of such disorder on electron scattering is important.

Acknowledgments

Discussion

G. R. Freeman: In calculations of the electric field effect on free ion yields, two electron–ion separation distance distributions are commonly assumed. One is a simple exponential function and the other is a Gaussian. Is the straight path assumed by Platzman associable with the exponential distribution (attenuation of a plane wave), and the random path assumed by you associable with the Gaussian?

J. L. Magee: The random path is of course compatible with a Gaussian distribution function. The straight line trajectory is a good approximation in any case where the mean free path is large. Simple exponential distributions are also obtained for some conditions of multiple scattering but the linear trajectory would probably be applicable.

G. R. Freeman: What is the mechanism of electron hesitation between jumps? Does it involve transient negative ion states?

J. L. Magee: Transient negative ion formation is the only physical mechanism I know which would cause a hesitation in the motion. The actual hesitation used (a delay of five jump times in 10% of the jumps) was chosen arbitrarily and does not actually mimic any known case of negative ion formation.

J. M. Warman: Over what range of electron energies are your calculations applicable?

J. L. Magee: The objective was to cover the entire subexcitation range from 6 eV or so to epithermal energies. However, there is no explicit use of energy in either consideration. The indirect loss mechanism employed a hopping of the electron from one molecule to another and the intermolecular distance combined with the jump time determine a kinetic energy. I think this calculation is reasonably consistent down to energies of 1 eV or so. The direct mechanism can be used for lower energies with an appropriate deformation potential. Of course it is understood that there are threshold energies for the molecular vibrations which must be treated properly.

G. R. Freeman: Did you consider processes that would be important below about 0.3 eV? They should be very important in hydrocarbons.

J. L. Magee: In principle the treatment of the direct effect can be used at low electron energies. The main excitations may not be the vibrations of individual molecules in this case, however, and a deformation potential for intermolecular vibrations must be used.

P. Delahay: The energy loss due to dielectric relaxation is inversely proportional to the relaxation time according to Platzman and Frohlich. This loss is $\sim 10^{13}$ eV s^{-1} for water, but it would be nearer to 10^{12} eV s^{-1} for other liquids (or even lower). Hence, the loss due to vibrational excitation would be dominant for other liquids than water for the indirect mechanism. Is this conclusion correct?

J. L. Magee: Yes, I think this is a correct conclusion. However, I think that in most cases the direct mechanism is actually responsible for the loss.

P. Delahay: Could you comment on the dependence of the energy loss on the kinetic energy for the *direct* mechanism?

J. L. Magee: There is no explicit dependence on the kinetic energy of the electron. In a general way the loss should be larger as the velocity decreases, but the perturbation Hamiltonian depends upon the details of the potential energy functions of the ion and neutral molecule. I don't think a generalized statement is possible.

U. Sowada: I would like to comment on the order of magnitude which you get out of your calculation about the rate of energy loss to nonpolar molecules (around 10^{12} eV/s) at liquid densities. There have been performed measurements in our laboratory concerning this topic (see this issue and Phys. Rev. A, **14**, 438 (1976)). For the case of methane the extrapolation to the liquid density is possible. For electron energies around 0.5 eV the product of the energy loss per drift distance (slightly above 10^5 eV/cm) with the thermal velocity for electrons of this energy (approximately 10^7 cm/s) the same order of magnitude as from your calculation is obtained.

J. L. Magee: This is an interesting result. Your electrons are just at the lower limit of validity of the calculation and at the moment I am not sure that my mechanism is responsible for your findings, although it may be.

J. Jortner: Concerning the inelastic electron scattering accompanied by excitation of intramolecular vibrations, let me point out that the process bears a close analogy to optical Raman scattering. In this context, let me inquire whether you have considered second-order contributions to this mechanism, which may be important.

J. L. Magee: I have not made a thorough study of this problem. A preliminary estimate of the effect seemed to indicate that it would be less important than the first order process, but a more careful examination should be carried out.

Photoelectric determination of V_0 values and electron ranges in some cryogenic liquids

WOLFGANG TAUCHERT, HELMUT JUNGBLUT, AND WERNER F. SCHMIDT

Bereich Strahlenchemie, Hahn-Meitner-Institut für Kernforschung Berlin GmbH, D 1000 Berlin 39, Germany

Received September 27, 1976

WOLFGANG TAUCHERT, HELMUT JUNGBLUT, and WERNER F. SCHMIDT. Can. J. Chem. **55**, 1860 (1977).

Conduction state energies V_0 were measured for liquid neon, argon, krypton, xenon, liquid nitrogen, liquid methane and ethane, and mixtures of methane and ethane by means of photoeffect on a metal electrode. A lower limit of V_0 for liquid hydrogen was estimated. From the dependence of the photocurrent on the electric field strength electron penetration ranges could be deduced.

WOLFGANG TAUCHERT, HELMUT JUNGBLUT et WERNER F. SCHMIDT. Can. J. Chem. **55**, 1860 (1977).

On a mesuré les énergies d'états de conductivité V_0 pour du néon, de l'argon, du krypton, du xénon liquide, pour de l'azote liquide, du méthane et de l'éthane liquide et pour des mélanges d'éthane et de méthane en faisant appel à l'effet photoélectrique sur une électrode métal. On a estimé la limite inférieure de V_0 pour l'hydrogène liquide. A partir de la dépendance du courant photoélectrique sur la force du champ électrique, on a pu déduire des limites pour la pénétration électronique.

[Traduit par le journal]

1. Introduction

Photoemission of electrons or holes into an insulator from a metal electrode can be employed for obtaining information on the electronic energy levels in the material. This technique has been used for the investigation of solid insulators and semiconductors (1–5) and in 1971 it was introduced for the study of electronic levels in non-polar liquids by Holroyd and Allen (6).

The experiment consists of the determination of the work function of a suitable metal electrode in a vacuum and in the liquid. The work function in the liquid ϕ_L is different from that in the vacuum ϕ_{vac} by a value V_0, the energy necessary to bring an electron from the vacuum into the liquid

$$[1] \qquad \phi_{liq} = \phi_{vac} + V_0$$

Negative V_0 values mean that energy is released.

Photoemission from a metal electrode in a vacuum was treated theoretically first by Fowler (7) who derived the dependence of the normalized photocurrent density j on the light frequency ν. Experimentally (6) and theoretically (8) it was shown that the Fowler formula can also be applied for the photoemission into an insulator with a low dielectric constant.

The work function is obtained from the experimental data either by numerical comparison with the Fowler function with the aid of a computer or simply by plotting $j^{1/2}$ as a function of ν which represents a straight line and yields $\nu_g = \phi/h$ at $j = 0$. The normalized photocurrent is obtained as i/I with i the measured photocurrent and I the light intensity measured with a calibrated photomultiplier.

If the measurements are carried out in a vacuum, saturation currents can be obtained. Injection into a liquid leads to thermalization of electrons near the cathode due to energy losses. Under the influence of the field of the image charge a certain fraction of the injected electrons returns to the cathode and the measured current is smaller than in vacuum at the corresponding wavelength where the same excess electron energy is obtained. The photo-response i_L/i_V ($i_{L,V}$ photocurrents in liquid and vacuum, respectively) depends on the applied electric field. Due to the image force a potential barrier is generated near the metal electrode and the escape probability for such a one-dimensional case has been derived by several authors (9–11). The photo-response is then given by

$$[2] \qquad i_L/i_V = \int_0^\infty P(x_0)D(x_0)\,dx$$

where

$$[3] \qquad P(x_0) = \frac{\int_0^{x_0} \exp\left(\frac{eV(x)}{k_B T}\right) dx}{\int_0^{\infty} \exp\left(\frac{eV(x)}{k_B T}\right) dx}$$

and

$$[4] \qquad V(x) = -Fx - \frac{e}{4\varepsilon x}$$

x_0 is the thermalization distance of the injected electron, F is the electric field strength, e electron charge, and ε the dielectric constant of the liquid. $D(x_0)$ is a range distribution and various distribution functions can be used in analogy to the treatment of ion yields in γ-irradiated liquids (12–14). It was found by Holroyd *et al.* (9) that with a one-dimensional Gaussian distribution

$$[5] \qquad D(x_0) = \frac{2}{b\sqrt{\pi}} e^{-x_0^2/b^2}$$

with a suitably chosen b the experimentally observed photo-response data in several hydrocarbons followed the field strength dependence given by [2].

Interest in V_0 values and ranges of low energy electrons exists from various problems of electron transport in liquids. In the theory of excess electron states in simple liquids by Springett *et al.* (15) a criterion of localization is derived in which the magnitude of V_0 determines whether an extended or a localized state of the electron in the liquid is energetically the most favorable one. Experimentally it was found that electrons in liquid helium (16) exhibited a low mobility in agreement with the V_0 value (17) which predicted a localized state. In liquid argon, krypton, and xenon high electron mobilities were observed (18) and the reported V_0 value for argon (19) favors the extended electron state. In liquid neon low electron mobilities have been reported (20–22) but V_0 values had not been measured. In liquid hydrocarbons many V_0 values and electron mobilities μ_{el} were reported by several groups and a relation was thought to exist between V_0 and μ_{el} (23–26).

The present experiments were carried out in order to obtain those V_0 values for liquefied rare gases and some other liquids which had not been measured yet and to obtain V_0 values for methane–ethane mixtures where electron mobilities as a function of composition had been measured previously in this laboratory (27).

2. Experimental

The set-up was essentially that of Holroyd and Allen (6). The measurement cell was placed in a cryostat. For the measurement of the light intensity a calibrated photomultiplier was used. The photocathode consisted of a brass base on which first a layer of gold and then a second layer of zinc were vacuum deposited.

Measurements were carried out on the following liquids: neon, argon, krypton, xenon, nitrogen, mixtures of methane and ethane for the whole range of composition, and liquid hydrogen.

The gases were high purity grades (99.95 vol.% minimum) and they were purified further by passage through columns of activated molecular sieve (Linde 3Å) and charcoal). The vacuum work function was measured before and after the measurement with the liquid and the vacuum work functions obtained this way agreed within ± 0.03 eV.

3. Results

The normalized photocurrents as a function of the light frequency (Fowler plot) for a zinc electrode in vacuum and in liquid methane, ethane, and neon are shown in Fig. 1. While the Fowler plots for vacuum and liquid ethane agree quite well with those published by Noda *et al.* (28) our plots for methane disagree with the results by Noda and Kevan (29). In their experiment the photocurrents at comparable excess energies above the work function were almost two orders of magnitude lower than the vacuum currents. The high excess electron mobility in liquid methane, however, favors escape from the electrode and leads to higher currents. We repeated the methane experiments also with a gold electrode and found the same relative magnitude of the Fowler plots for the vacuum and the liquid as with the zinc electrode. There was, however, a definite influence of the electrode material on the V_0 value which has been also reported by Holroyd and Allen (6). Gold gave more negative values. The vacuum work functions for zinc and gold were in the range of values reported in the literature. The temperature dependence of V_0 in liquid methane is shown in Fig. 2. Although the slope of the decrease of V_0 with increasing temperature is approximately the same for the different set of data, there is considerable discrepancy in absolute terms.

The temperature dependence of V_0 in liquid ethane is given in Fig. 3. The values for the methane–ethane mixtures were measured with a gold electrode at $T = 100 \pm 2$ K and are summarized in Table 1 together with the data for liquid neon, argon, krypton, and xenon, nitrogen,

and an estimate for hydrogen. In hydrogen no injection currents could be obtained with a zinc electrode and the lower limit given in Table 1 is the short wave limit of the lamp. Also with a sodium electrode no injection currents could be obtained in liquid hydrogen.

The photo-response of a gold electrode in the methane–ethane mixtures as a function of the electric field strength is shown in Fig. 4, while for the other liquids some data are compiled in Fig. 5. The photo-response i_L/i_V is determined by the distance b the electrons penetrate into the liquid. The solid lines in Fig. 4 represent i_L/i_V values obtained from [2] with the b values given in parentheses. The agreement is rather good.

No distribution function $D(x_0)$, however, could be found to fit the data of Fig. 5. The temperature dependence and the dependence on the electron energy of the b parameter in methane and ethane are shown in Figs. 6 and 7.

4. Discussion

Conduction state energies of excess electrons in liquefied rare gases have been calculated by Springett, Jortner, and Cohen (15) who adapted the Wigner–Seitz model by introducing a pseudo-

TABLE 1. V_0 values

Liquid	T (K)	V_0 (eV)	Electrode

potential which excludes the electrons from the hard core radius of the atoms. By applying their theory to our experimental V_0 values, hard core radii were obtained which are slightly smaller than the values from other physical experiments (30, 31). The positive V_0 value for neon predicts localized electron states to be stable (15) which is

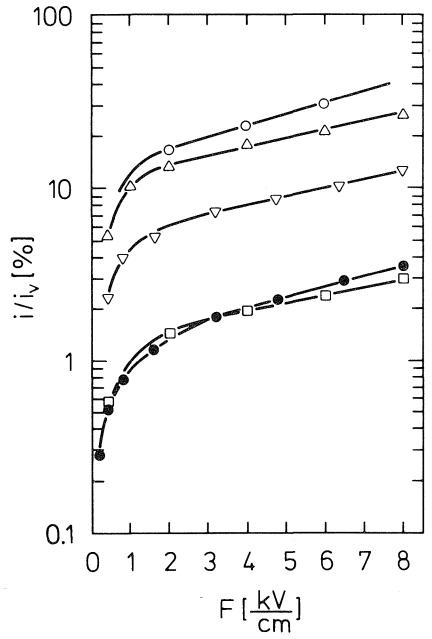

FIG. 5. Photo-response of zinc electrode in several liquids: ○ xenon, $T = 161$ K, $\varepsilon = 0.54$ eV; △ krypton, $T = 120$ K, $\varepsilon = 0.50$ eV; ▽ argon, $T = 85.5$ K, $\varepsilon = 0.54$ eV; ● nitrogen, $T = 77$ K, $\varepsilon = 0.49$ eV; □ neon, $T = 25$ K, $\varepsilon = 0.55$ eV.

supported by the low electron mobilities reported in the literature (20–22). The estimated lower limit for V_0 in liquid hydrogen and the low electron mobilities observed (32) indicate that the excess electron state is localized.

Miyakawa and Dexter (33) assumed localization of the electrons in liquid hydrogen and neon in bubbles and estimated for neon $V_0 = +0.45$ eV and for hydrogen $V_0 = +2$ eV.

Quantum field theory was applied by Tankersley (34) to the problem of the energy barrier for electron penetration into liquefied rare gases. V_0 is calculated in terms of the static structure factor of the liquid. Although his treatment is primarily concerned with liquid helium and treats the simultaneous interaction of two He atoms with the electron his results give also for neon and argon (where interaction with more than two atoms should be considered) V_0 values in fair agreement with our measured data.

Low electron mobilities were measured in liquid nitrogen (35) while the V_0 value would predict a delocalized state according to the localization criteria of Springett *et al.* (15) or

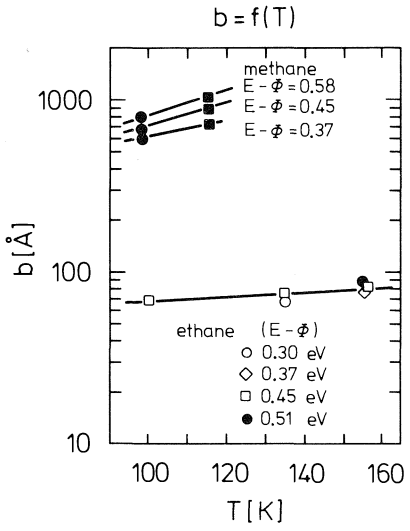

FIG. 6. Dependence of the electron range (parameter b of a Gaussian distribution) on the temperature ($E - \phi$ is the energy of the photoelectrons).

Noda *et al.* (28). Mobility measurements with nitrogen, however, might suffer from contamination with oxygen. The measurements with the methane–ethane mixtures were carried out in order to test a μ_{el}–V_0 relationship proposed by Kestner and Jortner (26) based on percolation theory and by Schiller *et al.* (25) based on an equilibrium between localized and extended states. Electron mobilities had been measured previously for this system (27). It was not possible, however, to obtain agreement between experimental results and theory with any set of physically realistic parameters.

The ranges of photoelectrons estimated in these experiments should be compared with data obtained from the radiation induced conductivity. High free ion yields G_{fi} were observed in methane yielding a large separation distance between positive ion and electron while small G_{fi} values were reported for liquid ethane (36). The photoelectric ranges show the same influence of the molecular shape with ethane slowing down subexcitation electrons more efficiently than methane.

Application of the diffusion model (eqs. 2–5) on the photo-response data of the liquefied rare gases (Fig. 5) did not yield electron ranges since no agreement could be obtained with various distributions $D(x)$. It is possible, however, that the diffusion model does not apply for liquefied

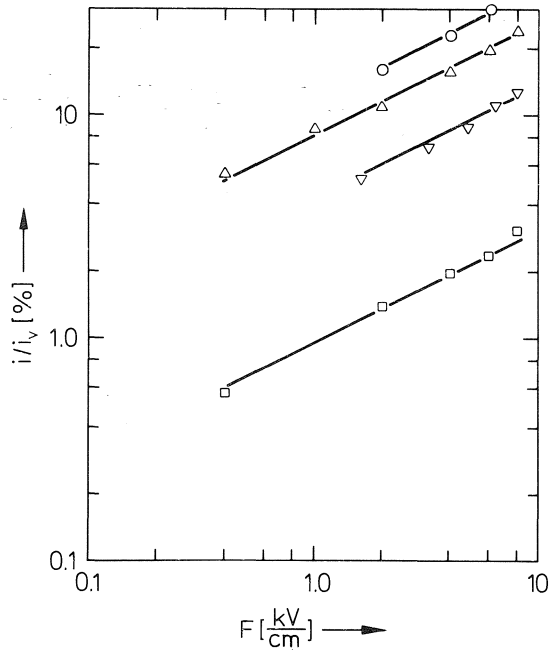

FIG. 8. Photo-response data of Fig. 5. The solid lines exhibit a slope of 0.5.

rare gases where the electrons lose energy very inefficiently in elastic collisions and travel large distances. Furthermore, at the field strengths applied here they do not reach thermal equilibrium with the liquid but the mean electron energy is greater than thermal. Electron loss from the conduction current can occur due to backscattering. Smejtek *et al.* (37) have discussed this mechanism for the injection of electrons into gaseous argon of high pressure. They found that the photo-response should be given approximately by

$$[6] \qquad \frac{i}{i_L} \approx \frac{1}{2}\pi^{1/2}\left(\frac{eF\lambda}{E_0}\right)^{1/2}$$

where E_0 is the energy of the injected electrons and λ is the mean free path for momentum transfer. The data of Fig. 5 follow this $F^{1/2}$ dependence quite well as is shown in Fig. 8. It may be concluded that in liquefied rare gases backscattering of electrons is the main factor which limits the photo-response. A more detailed evaluation would require more photo-response data at different electron energies E_0.

Discussion

L. Kevan: Do you understand the difference in the magnitude of your V_0 values in methane obtained with zinc and with gold electrodes?

W. F. Schmidt: Not at this time. A detailed investigation should take into account the experimental conditions of the generation of the surface and the effect of impurities in the liquids.

L. Kevan: For your V_0 value in liquid nitrogen have you used the stability criterion that Noda, Fueki, and I (J. Phys. Chem. **79**, 2866 (1975)) suggested to see whether an extended or localized state is predicted.

W. F. Schmidt: Yes, your criterion as well as that of Springett, Cohen, and Jortner predict the extended state to be stable. Mobility measurements gave low values (in the range of 10^{-3} cm^2 V^{-1} s^{-1}). These experiments might have suffered from traces of oxygen, however.

P. Delahay: With reference to the effect of the electrode, it is to be noted that you measure the algebraic sum of V_0 and the surface potential. This potential undoubtedly varies from one metal to another, and consequently an electrode effect is not so surprising. This contribution from the surface potential renders values of V_0 somewhat approximate (independently of experimental errors).

W. F. Schmidt: This is correct, although the origin of this surface potential may be either an intrinsic property of the particular metal–liquid interface; it may, however, also be generated by impurities. On occasions it was observed that different V_0 values were obtained, when the purification of the liquid was carried out less vigorously.

P. Delahay: Did you examine the field effect in terms of backscattering of emitted electrons?

W. F. Schmidt: No, we did not, since good agreement was obtained in the case of hydrocarbons with the one-dimensional escape probability.

D. E. Brodie: Could the difficulty with electrodes be checked for a possible effect due to contamination by using two different inert metals for electrodes, say gold and platinum?

W. F. Schmidt: In the usual photoemission set-up a limitation arises from the absolute value of the work function which is ~5 eV for Pt. In order to determine V_0 it is desirable to follow the emission over a certain range of electron excess energy. The intensity of the xenon lamp decreases drastically below 250 nm making it difficult to get photocurrents with a Pt electrode.

Ion recombination processes in rigid solutions[1,2]

JOHN R. MILLER
Chemistry Division, Argonne National Laboratory, Argonne, IL, U.S.A. 60439
Received October 12, 1976

JOHN R. MILLER. Can. J. Chem. **55**, 1867 (1977).

It is known that the free ion yield is small in irradiated aromatic hydrocarbon liquids. This study uses pulse radiolysis to observe anions of aromatic solutes in matrices at 77 K. In aliphatic matrices, trapped electrons tunnel to aromatic solutes and the anion yield is observed to grow with time. If the concentration of aromatic solute is large (0.1 *M*) or if the matrix is aromatic, ion recombination via tunneling dominates the anion kinetics, and long lived triplet states are observed to grow in. These results and the effects of other charge scavengers indicate that just a few percent of added aromatic material can dramatically increase the probability of charge recombination in aliphatic media, and that this effect involves decreased charge separation distances. The same effect apparently also occurs in alkane liquids at room temperature.

JOHN R. MILLER. Can. J. Chem. **55**, 1867 (1977).

Il est bien connu que le rendement d'ions libres est petit dans les hydrocarbures aromatiques liquides irradiés. Cette étude utilise la radiolyse pulsée pour observer les anions des solutés aromatiques dans des matrices à 77 K. Dans des matrices aliphatiques, les électrons piégés sont transferés aux solutés aromatiques par un effet de tunnel et on observe que le rendement en anions augmente avec le temps. Si la concentration du soluté aromatique est grande (0.1 *M*) ou si la matrice est aromatique, la recombinaison ionique par un effet de tunnel domine la cinétique de l'anion et on observe que les états triplets de longue vie croissent. Ces résultats et les effets d'autres agents qui peuvent piéger des charges indiquent que l'addition de quelques pourcents de composés aromatiques peut produire une augmentation dramatique de la probabilité de recombinaison de charge dans un milieu aliphatique et que cet effet implique une diminution des distances de séparation des charges. Il semble que le même effet se produit aussi dans des alcanes liquides à la température de la pièce.

[Traduit par le journal]

Introduction

Ionizing radiation produces solvated electrons in liquids and trapped electrons in glasses. In most alkane liquids ion pairs are thermalized with a wide distribution of geminate ion separation distances. The ion separation distance distributions are thought to peak at about 75 Å (1–3). A few percent are thermalized beyond the Onsager distance (4), which is about 300 Å at room temperature, and become free ions. In rigid hydrocarbon glasses where diffusion is eliminated, electrons trapped within the coulomb field of the positive ion may still have very long lifetimes, because the only decay mechanism available is electron tunneling to the positive ion. The distance distributions in the glasses are thought to be roughly similar to those in liquids, but they may be shifted to slightly larger distances (2).

Electron acceptors added to the matrix capture trapped electrons by the tunneling mechanism (5). In this study it appears that high concentrations ($\approx 2\%$) of an aromatic solute prevent separation of charges to large distances. Most of the anion–cation pairs appear to be separated by less than 50 Å, and recombine by tunneling in the time range 10^{-7} to 10^{2} s.

Experimental

Aldrich 3-methylhexane (3-MHX) was allowed to stand over Linde 13X molecular sieve, which had been activated by heating at least 2 h at 250°C. Aldrich 3,3-dimethylbiphenyl, Eastman cumene, Phillips (research grade) 2-methylpent-1-ene, Fluka triethylamine, and Matheson Coleman and Bell 1-chloropropane were used as received. Samples were degassed in cells with silica windows, and sealed off under vacuum. Samples were frozen by immersion in liquid nitrogen and were subjected to 2 to 10 ns pulses of 12 ± 3 MeV electrons, which pass completely through the cell, leaving a trail of ionization events.

To prevent optical bleaching, analyzing light from a xenon arc-lamp passed through a monochromator and a

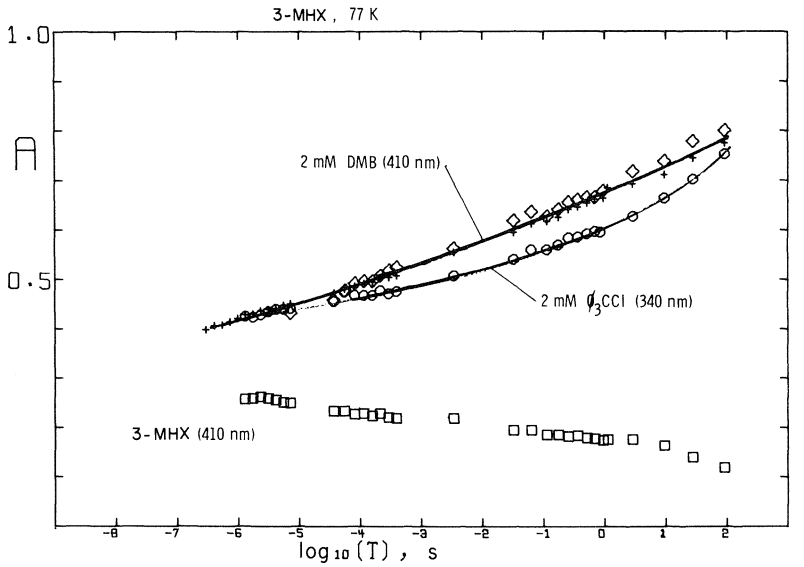

FIG. 1. The growth of absorbance (in arbitrary units) at 410 or 340 nm as trapped electrons in 3-methylhexane glass are captured to form dimethylbiphenyl anions (+ normal analyzing light intensity; ◇ analyzing light intensity on sample reduced by a factor of 15) or to form triphenylmethyl radicals (○). There is a background absorbance in the pulse irradiated 3-MHX matrix (□).

light chopper (open 5% of the time) before reaching the sample. The signal from an EMI 9781R photomultiplier was recorded by a computer-controlled Biomation 8100 transient recorder from 10^{-7} to 10^{2} s. Time resolution was often degraded to *ca.* 10^{-6} s by large amounts of fluorescence, especially if the sample contained cracks. More experimental details are given in ref. 6.[3]

The stated molar concentrations apply at 77 K, and are corrected for the fact that 3-MHX contracts by $\approx$17% as it is cooled from room temperature.

Results

Anion Growth by Electron Tunneling

Figure 1 shows the growth of absorbance of the 3,3′-dimethylbiphenyl (DMB) anion at 410 nm and the triphenylmethyl radical ($\phi_3C^{\bullet}$) at 340 nm, when 2 m*M* solutions of DMB or triphenylmethyl chloride in 3-MHX are pulse irradiated at 77 K. The growths of these products are the result of capture of trapped electrons by a tunneling mechanism (5). Slightly less than half of the trapped electrons are captured at 10^{2} s (5). It is possible for electrons captured by DMB to recombine by tunneling to the positive ion, but this is not possible in the case of a dissociative capture product such as $\phi_3C^{\bullet}$.

The similarities of the growth curves for DMB^{-} and $\phi_3C^{\bullet}$ suggest that there is little ion recombination. At higher concentrations of DMB we shall see much ion recombination.

A report by Kroh *et al.* (7) has indicated that there is no growth of the biphenyl anion under similar conditions. These authors claimed that biphenyl anion growth could only occur by bleaching of the trapped electron by the spectrometric analyzing light (7). But the growths in Fig. 1 are real and unaffected by the analyzing light, which was monochromatic (6 nm half height band width at the sample) and was chopped to reduce the average intensity by a factor of 20 (6). A further reduction of a factor of 15 by filters showed no effect on the kinetics of DMB^{-} growth (see Fig. 1). Further, the spaces between 0.5 and 3 ms and between 3 and 33 ms (Fig. 1) are times during which the chopper prevented any analyzing light from reaching the sample, but DMB^{-} growth continued unabated.

The apparent growth of DMB^{-} was reduced if the light passing through the sample was deliberately made more intense. The intense analyzing light bleached DMB^{-}. This probably is the explanation for the failure of Kroh *et al.* (7), to observe biphenyl^{-} growth. They did not use a monochromator before the sample, but used filters of 80 nm band width (7) *vs.* 6 nm in the present work. Because they did not use a monochromator before the sample to disperse

[3]Copies of the supplementary material for ref. 6 are available from the first author or from the journal.

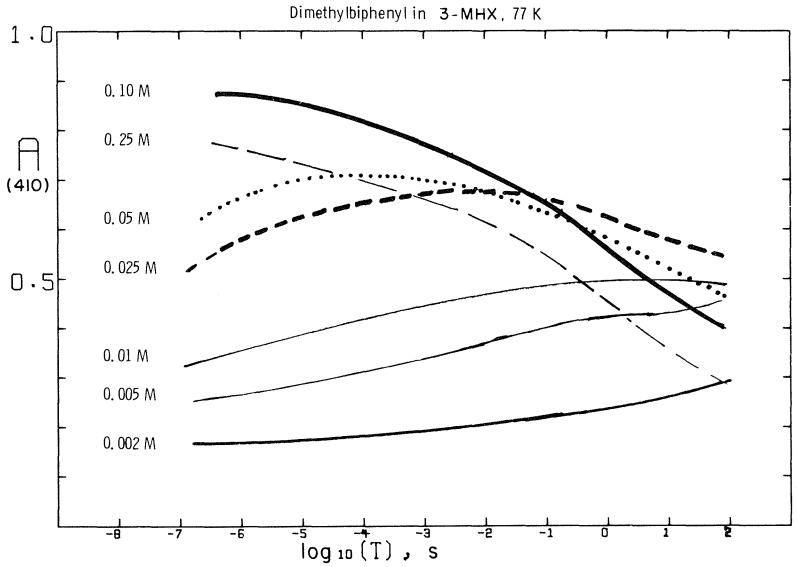

FIG. 2. The kinetics of DMB^- anions for DMB concentrations between 0.002 and 0.25 *M* in 3-MHX at 77 K.

the light, an image of the arc was probably formed in the sample, further aggravating the bleaching problem.

In the present work in 3-MHX at 77 K, anion growths have been observed for DMB, biphenyl, pyrene, and triphenylethylene. Similar anion growths have been reported by Klassen, Gillis, and Teather (8). Richards and Thomas (9) reported pulse radiolysis work at *ca.* 10^{-6} s which showed that a much greater fraction of trapped electrons survived capture by biphenyl at 10^{-6} s than at *ca.* 5 min after gamma irradiation. Because exposure to light was negligible in the gamma irradiation experiments (10, 11, 5), electron capture clearly cannot be due to bleaching as Kroh *et al.* (7) claim.

Ion Recombination at High Solute Concentrations

The growth of anions at low solute concentrations is well established. At higher concentrations, a remarkable behavior is observed: Instead of growing to a plateau, the anion yield decays with time (see Fig. 2). At the highest concentration, 0.25 *M*, almost all of the anions decay, giving the lowest final (10^2 s) absorbance at 410 nm of any of the concentrations used. The relative anion yield in 0.25 *M* DMB is probably even lower than apparent in Fig. 2, because no anion peak is seen in the spectrum at 100 s (see Fig. 3). Most of the final absorbance is probably

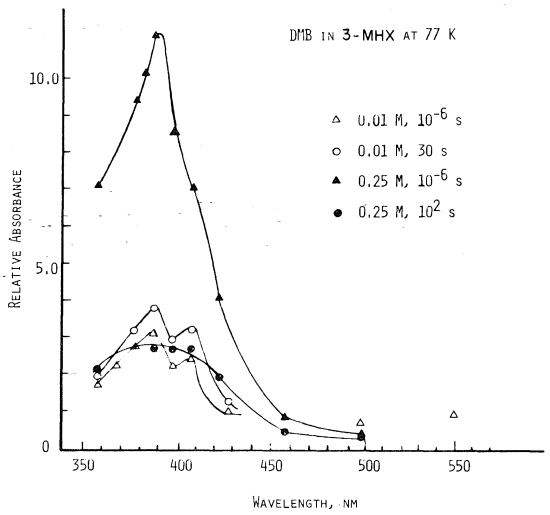

FIG. 3. Absorbance spectra for 0.01 and 0.25 *M* DMB at 10^{-6} and 10^2 s. After the triplet state (390 nm peak) in 0.25 *M* DMB has decayed out, it is still not possible to detect a 410 nm peak due to the anion.

due to various DMB and solvent radicals, which have not been identified here.

The yield of trapped electrons per 100 eV of absorbed energy (the *G* value) is 0.9 in 3-MHX glass (12). The yield of biphenyl anion (ϕ_2^-) is 1.6 if 0.015 *M* ϕ_2 is added to 3-MHX glass (12). Comparing these results with those in Fig. 2, and recalling that the final (10^2 s) absorbance in

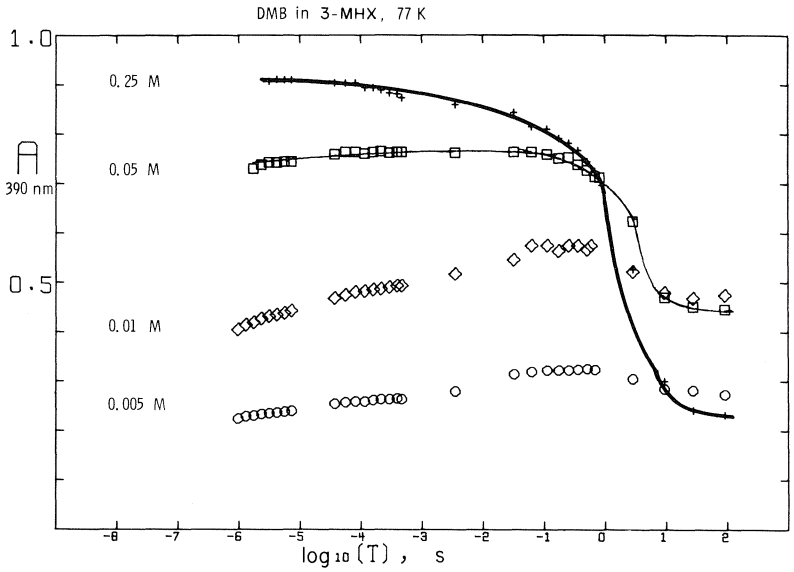

FIG. 4. Kinetics of the absorbance (in arbitrary units) at 390 nm, the peak of the triplet state absorption.

0.25 *M* DMB is due mainly to species other than DMB^-, we see that the final yield of DMB^- in 0.25 *M* DMB is much lower than the yield of trapped electrons in pure 3-MHX glass.

The disappearance of DMB^- in the more concentrated solutions of DMB appears to lead to substantial yields of triplet (T_1) states of DMB. The triplet absorption, peaking at 390 nm, dominates the spectrum at 10^{-6} s in 0.25 *M* DMB (Fig. 3). Unlike the anion which decays by the bimolecular process of ion recombination, the triplet decay is a unimolecular, first order process, which appears almost as a step function in log *t* (Fig. 4), with a triplet lifetime of about 3 s. This is quite similar to the phosphorescence lifetime of biphenyl, which is 3.7 s (13). The triplet state of biphenyl has an absorption peak at about 375 nm as measured in this work, and 367 nm as reported elsewhere (14, 15). So the DMB triplet has a slight red shift, as is usual for methyl substituted aromatics (15). The absorbance at 390 nm is not entirely due to the triplet, since by analogy to biphenyl, both DMB^+ and DMB^- are expected to absorb strongly at 390 nm (see ref. 16, Fig. 8). Because the absorbance at 410 nm (Fig. 2) shows little 'step function' behavior at 3 s, we may conclude that the triplet does not seriously interfere with measurement of DMB^- at 410 nm.

Effects of Charge Scavengers

Figure 5 shows the effect of a positive charge scavenger, triethylamine (TEA) and a negative charge scavenger 1-chloropropane on the DMB^- kinetics. The positive charge scavenger, TEA, appears to slightly increase the DMB^- yield, but does not slow its decay. Apparently ion recombination is almost as effective when TEA^+ is the cation.

The effect of the same scavengers on the triplet yield at *ca.* 3 s are given in Table 1. Both positive and negative ion scavengers reduce the triplet yield as expected if the triplets result from ion recombination. The triplet yield is

TABLE 1. Effect of additives on dimethylbiphenyl triplet yields* in 3-MHX at 77 K

Solute	Relative absorbance at 390 nm
0.25 *M* DMB	1.0
0.25 *M* DMB + 1.0 *M* TEA	0.6
0.25 *M* DMB + 1.0 *M* chloropropane	0.4
0.25 *M* DMB + 1.0 *M* TEA + 1.0 *M* chloropropane	0.4
0.025 *M* DMB + 1.0 *M* chloropropane	0.1

*Anions and cations of DMB also absorb at 390 nm and decay with the logarithm of time (Fig. 2). The first order (in time) decay of the triplet gives almost a 'step function' change of absorbance at 3 s on the log *t* plot, and is easily separated out from the DMB^- and DMB^+ absorbances.

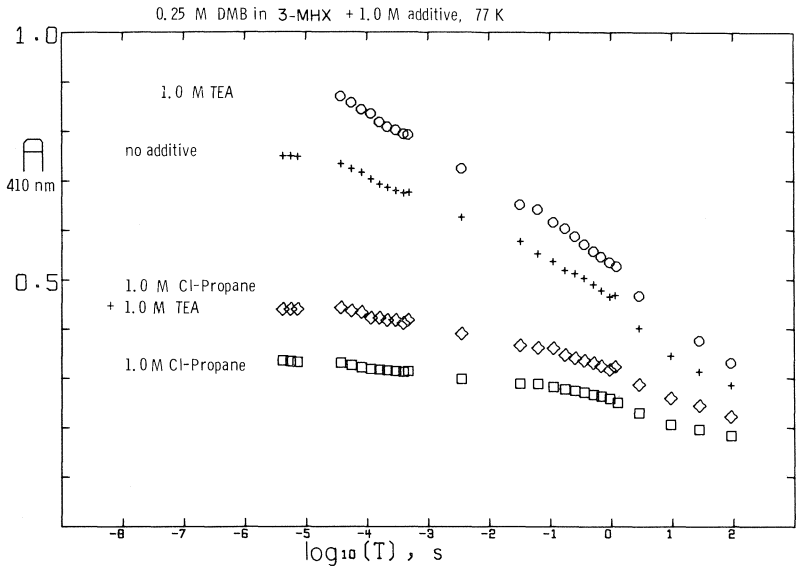

FIG. 5. Effects of 1.0 *M* concentrations of the positive charge scavenger triethylamine (TEA), and the electron scavenger 1-chloropropane on DMB^- kinetics in 0.25 *M* DMB solutions in 3-MHX at 77 K.

quite small in 0.025 *M* DMB + 1.0 *M* chloropropane. This result shows that production of triplet states by reabsorption of Cerenkov radiation is small. At 0.025 *M*, DMB will absorb almost all Cerenkov light within the DMB absorption band, so that little increase can be obtained by raising the DMB concentration. This assumes that the average light path for Cerenkov absorption is about 1 mm. It has been noted before (17) that internal absorption of Cerenkov light by solutes is essentially complete at low solute concentrations. This is true for the case of 0.025 *M* DMB because about 95% of the oscillator strength (>200 nm) is in regions where the molar absorption coefficient (18) $\varepsilon > 400\ M^{-1}\ cm^{-1}$.

Figure 6 shows that in 0.01 *M* biphenyl (ϕ_2) in 3-MHX at 77 K, the small yield of ϕ_2 triplets is decreased by addition of 2-methyl-1-pentene (2-MP-1), and is increased by addition of cumene (isopropylbenzene). Correspondingly, large concentrations of 2-MP-1 do not seem to increase the decay of ϕ_2^-, while cumene greatly increases ϕ_2^- decay. Cumene and 2-MP-1 both have lower ionization potentials than 3-MHX, so both are expected to capture positive charge. Both also have lower lying electronic states than 3-MHX. But cumene, unlike 2-MP-1, can capture electrons, as can benzene (11, 5). This may point to the role of electron capture in increasing ion recombination.

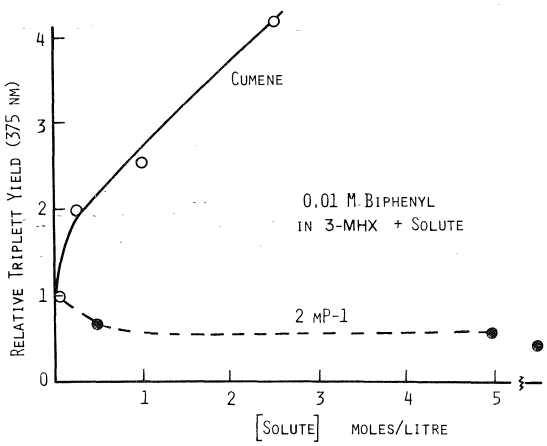

FIG. 6. The effects of 2-methyl-1-pentene and cumene on the absorbance step at 3 s (*e.g.*, see Fig. 4) due to the triplet state of biphenyl (ϕ_2) in 0.01 *M* ϕ_2 in 3-MHX at 77 K.

Figure 7 shows the ion recombination in cumene glass containing 0.1 *M* pyrene. Pyrene is very soluble in cumene, but sparingly soluble in 3-MHX. The anion, cation, and triplet state of pyrene can be observed almost independently.

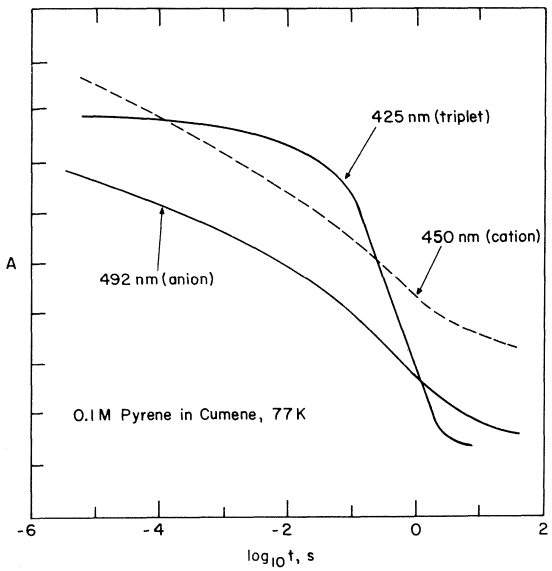

FIG. 7. Kinetics of the anion, cation, and triplet state of pyrene in cumene (isopropylbenzene) glass at 77 K.

Both the anion and cation decay with the log t kinetics typical of tunneling reactions over a range of distances. The pyrene triplet was observed to the red of its maximum, and is probably overlapped by cation absorption.

Pulse radiolysis of 0.15 M biphenyl in cumene glass seems to produce a large ϕ_2^+ absorption, which decays as does pyrene$^+$ in cumene. Substantial triplet yields are also obtained, but the yield of ϕ_2^- seems to be no more than one fifth as large as the yield of the cation. Perhaps ϕ_2^- can capture holes, but not electrons from the cumene matrix, which probably has a substantial electron affinity.

Discussion

General Conclusions: Ion Separation Shortening by Capture of Hot Electrons

The following tentative conclusions will be discussed: (*1*) Aromatic solutes capture trapped electrons in alkane glasses by electron tunneling. The anions which grow in show little decay at low solute concentrations ($\approx 10^{-3}$ M). (*2*) The probability of ion recombination (DMB^- + DMB^+) is dramatically enhanced at solute concentrations of 0.1 M ($\approx 1.5\%$) or greater. The triplet state of the solute is a major product. (*3*) The major reason for increased ion recombination appears to be shortening of ion separation distances so that most ion pairs are separated by less than 45 Å. (*4*) The solute molecules must act on the separating charges while they are 'hot'. (*5*) To enhance ion recombination, the solute molecule must be able to form a stable negative ion state.

The first two conclusions seem to be firmly established by the data, while the last three conclusions are tentative. These tentative conclusions are discussed below.

It was shown a few years ago that electron capture by solutes in hydrocarbon glasses could be accounted for by electron tunneling, which occurs after the electrons are thermalized and trapped (5). Inefficient processes for mobile electron capture (requiring solute concentrations substantially greater than 10^{-2} M) remained a possibility.

The rates of electron tunneling reactions depend exponentially on the distance between the electron donor and acceptor (19). A simple and useful expression for reasonably efficient tunneling reaction gives the distance a (in Å) over which the tunneling reaction can occur in a time t (in s)

$$[1] \quad a = a_0 + 2.26B^{-1/2}(15 + \log_{10} tF)$$

where B (in eV) is the binding energy of the electron on the electron donor and F is a nuclear overlap (Franck–Condon) factor for the reaction. We will assume that F is of the order of magnitude of unity. The quantity a_0 corrects for the finite size of the reactants and is about 5 Å. Equation 1 predicts that trapped electrons, which appear to be bound by about 0.5 eV in alkane glasses such as 3-MHX, can tunnel about 30 Å in 10^{-6} s and about 55 Å in 1 min. In a random distribution of distances, we expect growth kinetics to extend over many orders of magnitude in time, as observed in Fig. 1.

If ion recombination with DMB^- in rigid hydrocarbons proceeds by tunneling, we must use the binding energy of DMB^-. This is probably similar to the value of 1.6 eV found for the photobleaching threshold of biphenyl anion in 3-methylpentane glass (5). If we assume that the effect of the coulomb potential in the ion recombination reaction in hydrocarbons can be represented reasonably in the WKB approximation, then [1] will be a reasonable approximation for distances greater than 20 Å if we take a_0 to be about 12 Å. We then expect the ion recombination reaction of DMB^- + DMB^+ to

occur in about 10^{-6} s for ion pairs separated by 28 Å, and in about 10^{2} s for ion pairs separated by 43 Å.

Because the yield of DMB^- in 0.25 *M* DMB in 3-MHX is very small at 10^2 s, we conclude that almost all of the ion pairs are separated by less than about 45 Å.

This conclusion is tentative. If it is correct then DMB must have acted on the separating charges while they possessed energy in excess of thermal. Had the charges been thermalized at 45 Å in pure 3-MHX, they would not have been likely to separate further against the attractive coulomb potential. With a dielectic constant of 2.0, the energy required to increase the charge separation from 45 to 55 Å is 0.03 eV (= 0.17–0.14). This is more than four times thermal energy at 77 K.

The failure of large amounts of the positive charge scavenger 2-MP-1 to accelerate ion recombination pointed to the role of electron capture in the enhancement of ion recombination. Thus our tentative conclusion is that 'hot' (pre-thermal) electron capture is causing shortening of ion separation distances. This could involve a mobile, epithermal electron, or electron capture from an excited state which is a precursor to ionization. Both the concept of mobile, epithermal electron capture (20, 21), and reaction with an excited state which is a precursor to ionization (22, 23)[4] have been invoked to explain electron capture in irradiated condensed phases. Solid evidence has not been found for either concept.

Evidence for shorter ion pair separations in the presence of concentrated electron scavengers in neopentane has been seen by Schmidt and Allen (2), and in tetramethylsilane by Warman.[5] Neopentane and tetramethylsilane are unusual molecular liquids in that a very large fraction of ion pairs obtained separations greater than the Onsager distance at room temperature (300 Å) before thermalization.

Alternative Hypothesis

More Reactive Positive Ions

In the more concentrated solutions of DMB, probably most positive ions are converted to DMB^+, and DMB^+ might be more reactive toward DMB^- than is M^+, the matrix cation. This effect might explain the increased ion recombination without assuming a shortening of ion pair separations. But this effect should achieve its full impact once most positive charges (holes) have been captured by DMB. Because studies by Hamill and co-workers (10, 24, 25) have indicated that aromatic solutes such as DMB capture holes and electrons with very similar efficiencies, we would expect most holes to be captured at $\approx 10^{-2}$ *M*. Enhancement of ion recombination seems to grow most strongly at 10^{-1} *M* and above (Fig. 2). Furthermore, there is no *a priori* reason to expect DMB^+ to be more effective in ion recombination than M^+. DMB^+ and TEA^+ seem to be similar in effectiveness, since ion recombination was not appreciably slowed (Fig. 5) when about 40% of the cations were converted to TEA^+ (Table 1).

Tunneling Increases Ion Separation Distances at Low Concentrations

At low DMB concentrations, electrons are thermalized and trapped, and then tunnel tens of angströms to react with DMB. If the direction of this tunneling were completely random, the tunneling electrons would move, on the average, to farther distances from the hole. The DMB^- ions formed are probably at longer distances from the holes than were the trapped electrons from which they were formed. This effect is probably partly responsible for the fact that the ϕ_2^- yield in 0.015 *M* ϕ_2 in 3-MHX is 75% higher than the yield of trapped electrons in pure 3-MHX (12).

Two-step Tunneling

Enhanced ion recombination at high DMB concentrations might result from tunneling in two steps to the positive ion. For example, an electron on a DMB^- 60 Å from its geminate DMB^+ might tunnel 40 Å to reach another DMB, and then 35 Å to DMB^+. This two-step process would have essentially the same rate as the first (40 Å) step. Tunneling between two identical species (*e.g.* two DMB molecules) in a condensed medium is expected to be extremely slow (26), because relaxation of DMB^- and its surroundings will stabilize the anion. Were it not slow, $DMB^- \rightarrow DMB$ tunneling would set up a diffusive motion, contrary to experiment. Buxton and Kernsley, who advocate "trap to trap tunneling" (27) through a hierarchy (in increasing trap depth) of pre-existing solvent traps,

[4]H. B. Steen, unpublished results.
[5]J. Warman, private communication.

do not expect tunneling between identical species.[6]

However, the coulomb field would aid the DMB^- (60 Å) → DMB (35 Å) reaction by 0.1 eV. Simple calculations show that in 0.25 *M* DMB there is a sufficient probability of having a DMB molecule in the right region of space to allow such a two-step recombination process. There is presently not enough theoretical or experimental information to determine whether two-step (or multi-step) tunneling processes could play a significant role in the enhanced ion recombination observed here.

Even if the two-step tunneling processes do contribute to ion recombination, two pieces of experimental evidence suggest it is not the only effect: (*1*) Cumene enhances ion recombination (Figs. 6 and 7), although it has a much smaller electron affinity than DMB so that electrons could not tunnel from DMB^- to cumene. (*2*) Enhanced ion recombination also seems to occur in hydrocarbon liquids (see the following section) where ion recombination is not controlled by tunneling.

Evidence from Hydrocarbon Liquids

Thomas *et al.* (28) reported that the free ion yield for ϕ_2^- in cyclohexane at room temperature was nearly independent of ϕ_2 concentration from 10^{-3} to 3×10^{-1} *M*. On the basis of the present work, we would have expected the free ion yield to decrease almost to zero at 3×10^{-1} *M* ϕ_2. The work of Thomas *et al.* (28) may provide evidence against the conclusion that ion pair separation distances are greatly shortened by ≥ 0.1 *M* ϕ_2, at least for liquids at room temperature.

But the data of Thomas *et al.* (28) on ϕ_2^- free ion yields must be viewed with caution, because other species derived from ϕ_2 (radicals formed by H atom addition, the triplet state with $\varepsilon = 500$ at 620 nm (29)) may have been responsible for the absorbance Thomas *et al.* observed at about 600 nm. In concentrated solutions (≥ 0.1 *M*) of ϕ_2 Thomas *et al.* found a large, fast decaying ($t_{1/2} < 100$ ns) absorbance, attributed to geminate ϕ_2^-, and a much smaller absorbance, which decayed over many microseconds. At 10^{-3} *M* ϕ_2, only the small, slow decaying absorbance was present. It was shown by the use of scavengers and study of the spectrum to be predominantly due to ϕ_2^-. This same confirmation was not carried out at high ϕ_2 concentration.

I have performed this check for 0.25 *M* ϕ_2 in cyclohexane at room temperature. The small, slow decaying absorbance at $t \geq 1$ μs was not changed by adding 0.01 *M* ethyl bromide, which should have reacted with all ϕ_2^- before 1 μs. Also the spectrum at 1 μs did not correspond to the ϕ_2 spectrum, but was nearly flat between 575 and 675 nm.

The spectrum of the fast transient (about 50 ns half-life) did appear to be due to ϕ_2^-.

It thus appears that the free-ion yield in a 0.25 *M* solution of ϕ_2 in cyclohexane at room temperature is zero within experimental error. By comparison with the data of Thomas *et al.* (28), the free ion yield in 0.25 *M* ϕ_2 is no more than one fourth the yield in 10^{-3} *M* ϕ_2. This result tends to confirm the conclusion from the low temperature data that the aromatic additive shortens ion pair separations.

Closing Comments

About 2% of an aromatic solute in an alkane matrix dramatically increases the probability of ion recombination, apparently by preventing ions from separating to large distances. If this effect results from some efficient mechanism for moderation of hot electrons, then addition of a small amount of aromatic impurity to an aliphatic liquid or solid might help to prevent electrical breakdown at high voltages. Such a solution might also be more resistant to degradation by ionizing radiation, because most ions would recombine and produce excited states of aromatic solute, which usually decay without breaking bonds. Ion recombination is more probable in benzene than in aliphatic hydrocarbons. Liquid biphenyl and terphenyl are sufficiently stable toward radiation that they have been considered as working fluids in nuclear reactors (30).

Discussion

J. Jortner: Electron – positive hole recombination will result in initial singlet and triplet yields in the ratio 1/3. This will result in a trivial mechanism for fluorescence. A more interesting mechanism for fluorescence involves triplet–triplet interaction resulting in the formation of an excited singlet state. Such a process was observed by McGlynn in rigid solutions doped with phenanthrene. I would like to inquire whether you have looked for fluorescence in your systems.

J. R. Miller: Fluorescence is definitely present in substantial amounts, but I have made no quantitative measurements.

Experimental evidence for the existence of a Ramsauer–Townsend minimum in liquid CH_4 and Ar (Kr and Xe) and in gaseous C_2H_6 and C_3H_8[1,2]

L. G. CHRISTOPHOROU[3] AND D. L. MCCORKLE[4]

Received September 27, 1976

L. G. CHRISTOPHOROU and D. L. MCCORKLE. Can. J. Chem. **55**, 1876 (1977).

Experimental evidence for the existence of a Ramsauer–Townsend minimum in the electron scattering cross section for liquid CH_4 and liquid Ar (Kr and Xe) is presented and discussed. On the basis of evidence obtained from three sources: (*i*) comparisons of thermal electron mobilities in gases with those in liquids, (*ii*) changes in the electron mobility with gas density at high and very high gas pressures, and (*iii*) the dependence of the electron mobility on temperature for liquids whose V_0, the energy of the electron state in the liquid, is ≤ 0 eV, it is concluded that a Ramsauer–Townsend minimum is exhibited by the electron scattering cross section for CH_4, Ar (Kr and Xe) at all densities from a dilute gas to the liquid and that this minimum is shifted to lower energies (closer to thermal) with increasing density.

Additionally, it has been found that a Ramsauer–Townsend-type behavior is exhibited by gaseous ethane (C_2H_6) and propane (C_3H_8) with the cross section minimum located at lower energies than for methane (CH_4). For these latter molecules the measured mean scattering cross sections at thermal energies are comparable with the geometric cross sections.

L. G. CHRISTOPHOROU et D. L. MCCORKLE. Can. J. Chem. **55**, 1876 (1977).

On présente et on discute des données expérimentales supportant l'existence d'un minimum de Ramsauer–Townsend dans la section droite de la diffraction électronique du CH_4 liquide et de l'argon liquide (Kr et Xe). En se basant sur les données obtenues à partir de trois sources: (*i*) comparaisons des mobilités des électrons thermiques dans les gaz avec celles des liquides, (*ii*) changement dans la mobilité des électrons avec la densité gazeuse à haute et très haute pression de gaz et, (*iii*) la dépendance de la mobilité des électrons sur la température pour des liquides pour lesquels V_0, l'énergie de l'état de l'électron dans le liquide, ≤ 0 eV, on peut conclure qu'il existe un minimum Ramsauer–Townsend pour la section droite de la diffraction des électrons pour le CH_4, Ar (Kr et Xe) à toutes les densités (à partir d'un gaz dilué jusqu'au liquide) et que ce minimum est déplacé vers les basses énergies (plus près des énergies thermiques) lorsque la densité augmente.

De plus on a trouvé qu'un comportement de type Ramsauer–Townsend existe pour l'état gazeux de l'éthane (C_2H_6) et du propane (C_3H_8) avec une section droite minimale située à des énergies plus basses que celle du méthane (CH_4). Pour ces dernières molécules, les sections droites moyennes mesurées pour la diffraction à des énergies thermiques sont comparables avec les sections droites géométriques.

[Traduit par le journal]

I. Introduction

In this paper the experimental evidence supporting the existence of a Ramsauer–Townsend minimum in the scattering cross section for CH_4, Ar (Kr and Xe)[5] at all densities from the dilute gas to the liquid and the shifting of this minimum to lower energies (closer to thermal) with increasing density is presented and discussed. Experimental evidence is also presented showing that a Ramsauer–Townsend-type behavior is exhibited by gaseous ethane (C_2H_6) and propane (C_3H_8) with the cross section minimum located at lower energies than for methane (CH_4). For these latter molecules the measured mean scattering cross sections at thermal ener-

II. Experimental Evidence from Studies of Thermal Electron Mobilities in Gases and Liquids

Christophorou *et al.* (1, 2) have performed such studies recently, and Table 1 summarizes those of their findings which are pertinent to the present discussion. The quantity μ_L is the thermal ('zero-field') electron mobility in the liquids, and μ_G is defined by (1, 2)

$$[1] \qquad \mu_G = S' N_{torr}/N_L$$

where $S' = \mu P$, $\mu = w/E$, P is the gas pressure in torr at the temperature T, N_{torr} is the number of molecules per cm^3 per torr at the specified gas temperature, $N(= PN_{torr})$ is the gas number density, N_L is the number density of the corresponding liquid at the temperature of the liquid measurement, w is the electron drift velocity, and E is the uniform electric field in volts per cm. μ_G may be regarded as the gaseous thermal electron mobility adjusted for the change in density between the gas and the liquid.

These studies (1, 2) suggest that $\mu_L/\mu_G > 1$ for CH_4 and the heavier rare gases for which $V_0 \leq 0$ eV.[6,7] Estimates of μ_L/μ_G are $\lesssim 16$, ~ 12, ~ 4, ~ 120, and ~ 730 for CH_4, $C(CH_3)_4$, Ar, Kr, and Xe, respectively. Although these values are considered approximate because of differences in the temperature at which μ_L and μ_G were determined, the conclusions drawn are not affected. For such systems, thermal electrons are more mobile in the liquid than in the corresponding low-pressure gas. Very importantly, also, the values of μ_L/μ_G increase in the order Ar, Kr, Xe, *i.e.*, in the direction the Ramsauer–Townsend cross section minimum becomes more pronounced in the low-pressure gas. Although

[6] $V_0 = \phi_L - \phi_V$, where ϕ_L and ϕ_V are, respectively, the work functions of a metal electrode in the liquid and in vacuum.

[7] In the case of liquids with $V_0 > 0$ eV (*e.g.*, C_2H_6 ($\mu_L/\mu_G = 0.026$)), μ_L/μ_G is <1 or $\ll 1$, and $1/\mu_{torr}$ increases with N (for the cases investigated so far; see discussion in ref. 2).

these changes may be partly attributed to changes in the structure factor $S(0)$ in the low ($\varepsilon \rightarrow 0$ eV) (3) energy limit, they also reflect the change (*decrease*) in the effective scattering cross section in the liquid as compared with the low-pressure gas.[8] The existence of a Ramsauer–Townsend minimum in the scattering cross section for liquid CH_4 and the heavier liquid rare-gas atoms *at lower energies* than in the corresponding gas can provide an explanation for this behavior. Evidence for such a minimum in the cross section and for a shift in its position to lower energies with increasing density is provided in section III.

III. Experimental Evidence from the Density Dependence of the Electron Mobility at High Gas Pressures

Christophorou (2) (see also Bartels (4*a*)) has reviewed the recent work on the dependence of the electron mobility on P (or N). Christophorou *et al.* (1, 2) also have defined the quantity

$$[2] \qquad \mu_{torr} = \frac{w}{E/P}\frac{1}{P_1}$$

where E/P is in units of V cm^{-1} torr^{-1} and $P_1 =$ 1 torr. The quantity μ_{torr} is basically the electron mobility normalized to 1 torr pressure. The inverse of the value of μ_{torr} is a measure of the effective frequency for elastic collisions ν_m, defined by (5, ref. 6, p. 275)

$$[3] \qquad \frac{\nu_m}{N} = \frac{e}{m}\frac{1}{w}\frac{E}{N}$$

where e and m are the electron charge and mass, respectively. The quantity $1/\mu_{torr}$ is proportional to a function of the mean cross section for momentum transfer $\langle\sigma_m\rangle$; actually, it is (roughly) proportional to it (see [5]).

In Fig. 1, $1/\mu_{torr}$ for CH_4 is plotted as a function of the mean electron energy $\langle\varepsilon\rangle_M$, taken equal to $\frac{3}{2}(eD_L/\mu)$, where D_L is the lateral electron diffusion coefficient. At near-thermal energies $1/\mu_{torr}$ goes through a minimum due to the well-known Ramsauer–Townsend effect in CH_4 (8). Also in Fig. 1 we have plotted $1/\mu_{torr}$ for CH_4 as determined from the w *vs.* E/P measurements of Lehning (9) at 32 800 torr. It is interesting to see that these data indicate a decrease of the cross section and a downward shift of the cross section minimum with increasing CH_4 density (7). These findings cannot be accounted for by changes in the structure factor $S(0)$ with gas density since, as has been discussed earlier (10), $S(0)$ increases with N in the density range covered by the data in Fig. 1, and thus $1/\mu_{torr}$ ought to have increased rather than decreased with N. This observation is consistent with the suggestion (2) that the increase in μ_{torr} for CH_4 and the heavier rare gases Ar, Kr, and Xe in going from the gas to the liquid is due to a decrease in σ_m, at least partially due to a downward shift of the Ramsauer–Townsend minimum exhibited by these species.

Consistent with the CH_4 data are those for Ar shown in Fig. 2. The minimum in the $1/\mu_{torr}$ *vs.* $\langle\varepsilon\rangle$ function in Fig. 2 appears at a much lower (mean) electron energy $\langle\varepsilon\rangle$ (see figure captions for sources of $\langle\varepsilon\rangle$) than does the low-pressure minimum of the momentum transfer cross section $\sigma_m(\varepsilon)$ (or the total scattering cross section $\sigma_T(\varepsilon)$). The latter occurs at an electron energy ε of $\sim$0.3 eV while the former appears at mean electron energies ranging from $\sim$0.17 to $\sim$0.02 eV, depending on density. Actually, the energy, $\langle\varepsilon\rangle_{min}$, at which the minimum of the $1/\mu_{torr}$ *vs.* $\langle\varepsilon\rangle$ occurs, shifts to lower energies with increasing N as is clearly shown by the data presented in Table 2. The broken function (identified by the formula) in Fig. 2 represents (see next section) an estimate of the e–atom scattering cross section in *liquid Ar* with the effect of the structure factor removed. It is very interesting to see (Table 2) that the position of the minimum of this cross section is quite consistent with the gaseous data.[9] Furthermore, as for the case of CH_4, the effective e–atom scattering cross section decreases (and the minimum becomes sharper) with increasing N. This behavior cannot be attributed to $S(0)$ since in the density range of the gaseous data in Fig. 2 the structure factor $S(0)$ increases with N (10).

IV. Experimental Evidence from Studies on the Dependence of μ_L on T for Liquids with $V_0 \leq 0$ eV

The temperature dependence of μ_L for liquids whose $V_0 \leq 0$ eV can be used to derive information on the electron scattering cross section σ_L

[8]We calculate that the structure factors $S(0)$ for liquid CH_4 and Ar at 111 and 90 K, respectively, are 0.05 and 0.06. If it is assumed that $\mu_L/\mu_G = S(0)_{gas}/S(0)_{liquid} = 1/S(0)_{liquid}$, one obtains for this ratio 20 and 16.6 for CH_4 and Ar, respectively.

[9]Unfortunately, we have not been able so far to unfold $\sigma_m(v)$ itself from the experimental data at high P due mainly to a lack of accurate electron transport coefficients at low E/P and high P.

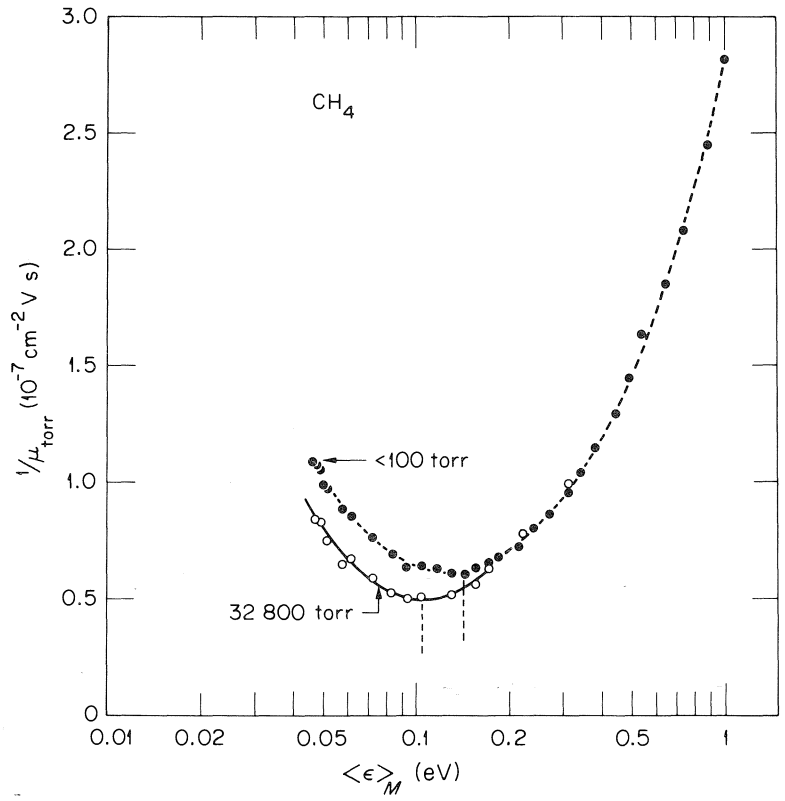

FIG. 1. $1/\mu_{torr}$ *vs.* $\langle\varepsilon\rangle_M$ for CH_4 at the indicated pressures; $T = 298$ K (from ref. 7). The vertical broken lines show the approximate position of the minima.

TABLE 2. Approximate values of $\langle\varepsilon\rangle_{min}$ for Ar at various densities $N^{a,b}$

N (10^{20} atoms/cm^3)	$\langle\varepsilon\rangle_{min}$ (eV)
0.24	0.170
5	0.128
7.5	0.120
10	0.110
12.2	0.100
15	0.090
17.5	0.085
20	0.080
22.5	0.072
25	0.066
121.5 (liquid at 151.8 K and 60.1 atm)	0.020

[a]Derived from plots such as Fig. 2 (see caption of Fig. 2 for original sources of data).
[b]The minimum in $\sigma_m(\varepsilon)$ is at $\varepsilon \simeq 0.3$ eV which is expected to be greater than the value of $\langle\varepsilon\rangle$ at which $1/\mu_{torr}$ possesses a minimum at low pressures.

in the liquid. Since when $V_0 \leq 0$ eV the electron is continuously in a quasi-free state (and not partly in it and partly in the captured (or trapped) state as in those cases where $V_0 > 0$ eV) the measured mobility μ_L is equal to the electron mobility in the quasi-free state. The temperature dependence of μ_L, therefore, reflects the changes with T of the overlap between the electron energy distribution function and $[\sigma_L(\varepsilon)]^{-1}$. Thus if the T-dependence of N_L and $S(0)$ are properly considered, the measurements of μ_L as a function of T can be employed to obtain information on $\sigma_L(\langle\varepsilon\rangle)$.

For low-pressure gas and elastic collisions (6)

$$[4] \quad w = -\frac{4\pi}{3}\frac{e}{m}\frac{1}{N_{torr}}\frac{E}{P}\int_0^\infty \frac{v^2}{\sigma_m(v)}\frac{df_0}{dv}\,dv$$

where f_0 is the spherically symmetric term in the expansion of the electron velocity distribution function, and v is the electron velocity. If we denote by $\langle\sigma\rangle$ an average of the electron scattering cross section over f_0 and assume f_0 to be Maxwellian

$$[5] \quad w \simeq \frac{2}{3}\left(\frac{2}{m\pi kT}\right)^{1/2}\frac{eE}{N}\frac{1}{\langle\sigma\rangle}$$

where k is the Boltzmann constant.

Under the assumption that [5] holds for thermal electrons drifting in a fluid with $V_0 \leq 0$ eV,

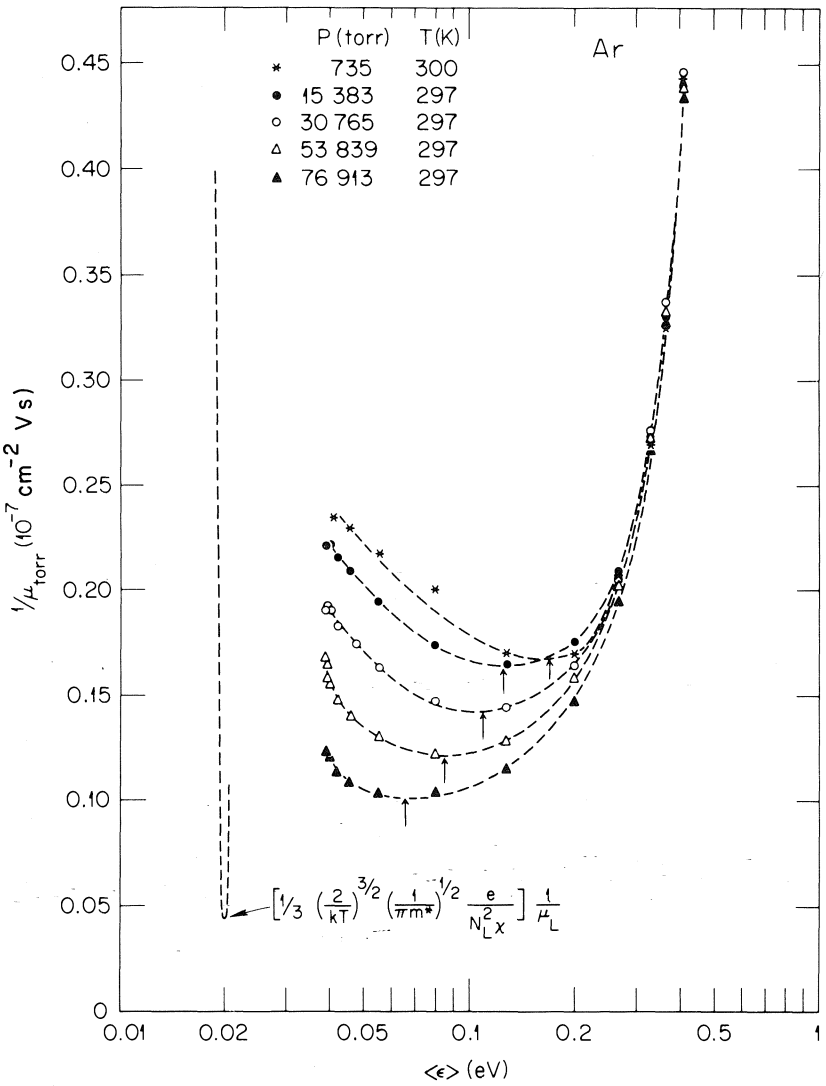

FIG. 2. $1/\mu_{torr}$ *vs.* $\langle\varepsilon\rangle$ for Ar at the indicated pressures and temperatures. Due to the low values of E/P at which the w *vs.* N measurements were made, we could not use the $\langle\varepsilon\rangle$ *vs.* E/P data listed by Christophorou (ref. 6, p. 431; see also ref. 30). Instead, we used the data on $\langle\varepsilon\rangle$ *vs.* E/P given by Frost and Phelps (31). The vertical lines indicate the approximate positions of the minima. The 735 torr data were deduced from the w *vs.* E/P measurements of Pack *et al.* (32) and the rest from the w *vs.* E/P measurements of Bartels (4*a*) at high densities. The broken line (identified by the formula) is the scattering cross section (in arbitrary units) for liquid Ar at 160 K (see text and Fig. 3).

we may express μ_L as

$$[6] \qquad \mu_L = \frac{2}{3}\left(\frac{2}{m^*\pi kT}\right)^{1/2}\frac{e}{N_L}\frac{1}{\langle\sigma\rangle_{eff}}$$

where m^* is the effective electron mass in the liquid and $\langle\sigma\rangle_{eff}$ is the mean effective scattering cross section in the liquid. Baldini (11) gives $m^* = 0.43m$ for solid argon at 20 K. In our calculation we used this value for m^* although we recognize that m^* may be density and/or temperature dependent. If we further assume that

$$[7] \qquad \langle\sigma\rangle_{eff} = S(0)\langle\sigma\rangle_L$$

and use for $S(0) = N_L kT\chi$, where χ is the isothermal compressibility, we have

$$[8] \qquad \mu_L = 0.532e[(kT)^{3/2}(m^*)^{1/2} \times (N_L)^2\chi\langle\sigma\rangle_L]^{-1}$$

For liquid Ar the quantities $\mu_L(T)$, $\chi(T)$, and

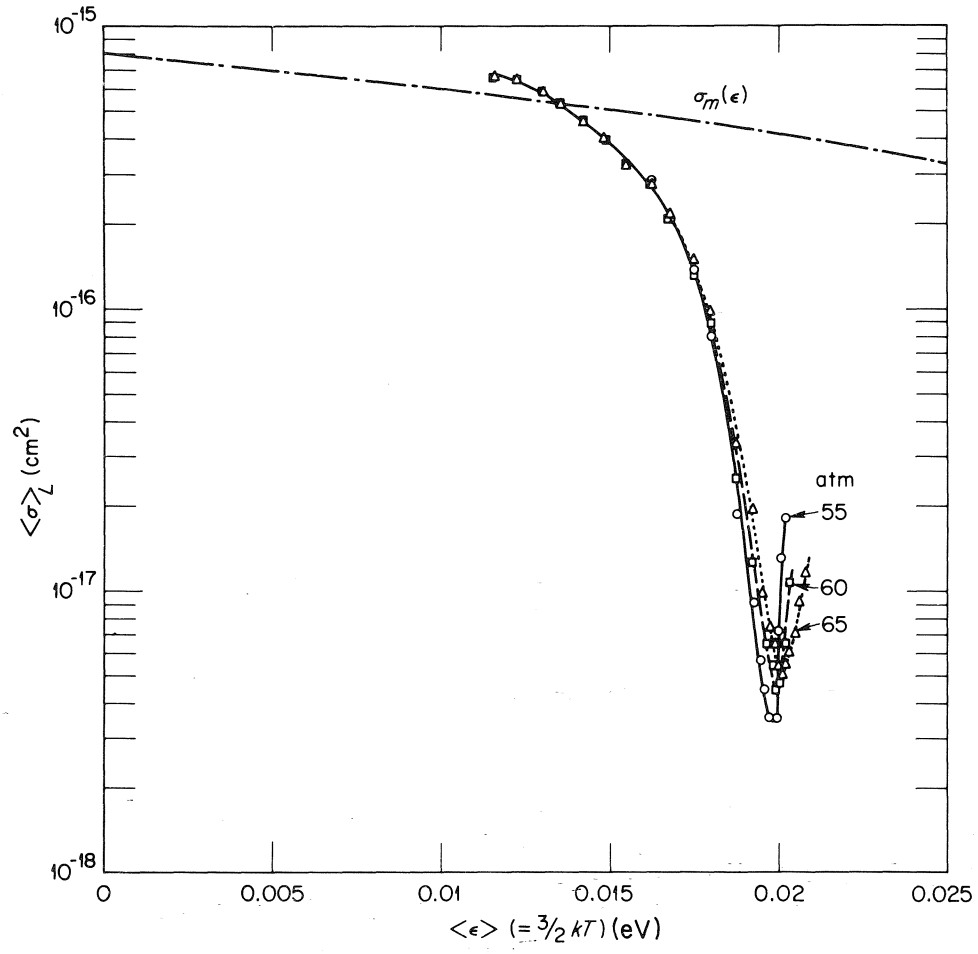

FIG. 3. $\langle\sigma\rangle_L$ *vs.* $\frac{3}{2}kT$ for liquid Ar ($90 \leq T \leq 161$ K) (see text). The broken curve is the swarm-determined momentum transfer cross section $\sigma_m(\varepsilon)$ (31). It should be noted that the $\sigma_m(\varepsilon)$ deduced (33) from recent electron beam data on Ar (34) exhibited a much sharper low-pressure Ramsauer–Townsend minimum compared with the $\sigma_m(\varepsilon)$ deduced from swarm data.

$N_L(T)$ are known (12) over the temperature range 90 to 161 K. Using these data we have determined (see Fig. 3) $\langle\sigma\rangle_L$ as a function of $\langle\varepsilon\rangle_M(\equiv \frac{3}{2}kT)$. For comparison, $\sigma_m(\varepsilon)$ for low-pressure argon has also been plotted in Fig. 3. The data in Fig. 3 clearly show the existence of a sharp minimum in $\langle\sigma\rangle_L$ at ~ 0.02 eV. This striking result is consistent with the high gas pressure behavior as can be seen from Fig. 2 and Table 2. Although the sharpness of the $\langle\sigma\rangle_L$ *vs.* $\langle\varepsilon\rangle$ function is not understood, it is not unreasonable since the electron energy distribution functions are very narrow at these low temperatures. In fact, over the temperature range 90 to 160 K the width of $\langle\sigma\rangle_L$ is comparable with the width of the electron energy distribution functions.

The results on argon are supported by the work of Bakale and Schmidt (13) on the temperature dependence of μ_L for liquid methane. In contrast to other hydrocarbon liquids for which μ_L increases with increasing T, μ_L for liquid CH_4 decreases with increasing T (13). This behavior is consistent with a cross section $\langle\sigma\rangle_L$ possessing a minimum at or below $\frac{3}{2}kT$ ($T = 90$ K; the lowest value of T for which μ_L was measured (13)), *i.e.*, far below the position of the low-pressure cross section minimum, and which increases in magnitude with increasing energy beyond $\frac{3}{2}kT$.

V. General Conclusion

From sections II to IV, it can be concluded that a Ramsauer–Townsend minimum is ex-

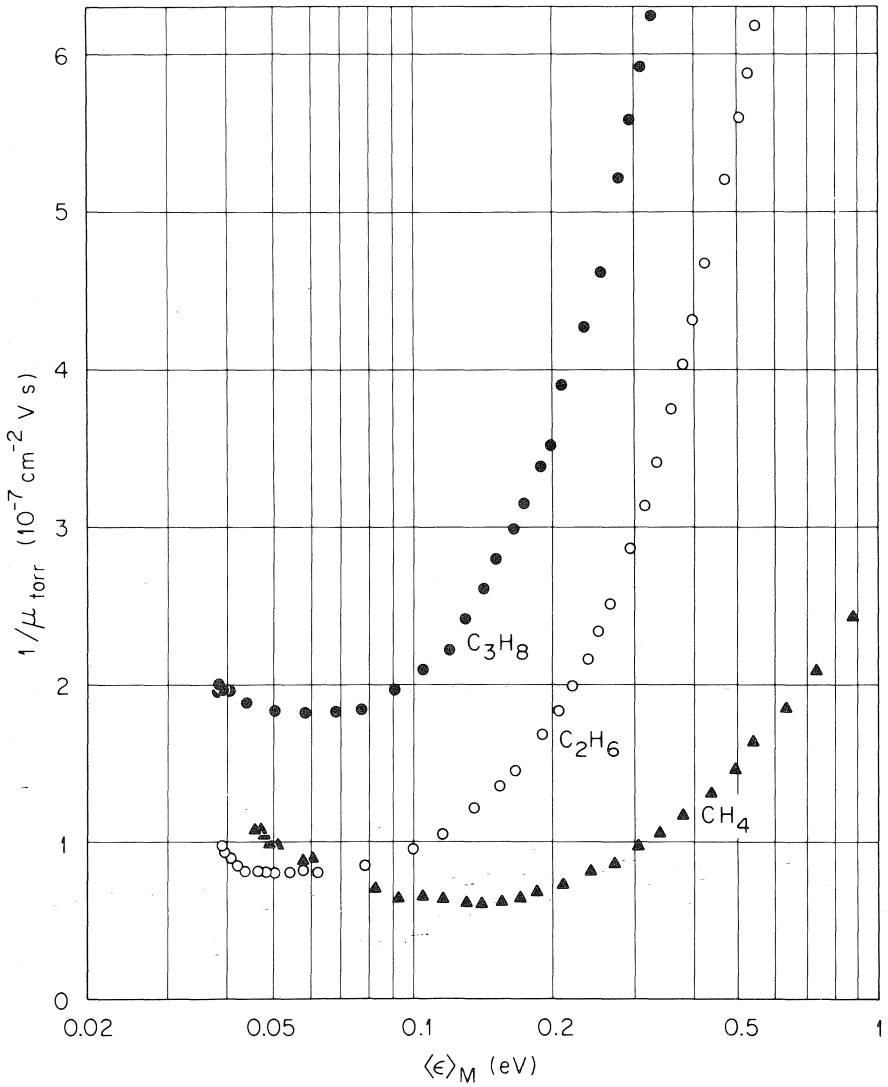

FIG. 4. $1/\mu_{torr}$ *vs.* $\langle\varepsilon\rangle_M$ for low-pressure (< 100 torr) C_2H_6, C_3H_8, and CH_4 (from ref. 7).

hibited by the electron scattering cross section for CH_4, Ar (Kr and Xe) at all densities from the dilute gas to the liquid, and that this minimum is shifted to lower energies with increasing density.

VI. Experimental Evidence for the Existence of a Ramsauer–Townsend Minimum in Gaseous C_2H_6 and C_3H_8

In Fig. 4, $1/\mu_{torr}$ for C_2H_6 and C_3H_8 is plotted (along with that for CH_4 for comparison) as a function of the mean electron energy $\langle\varepsilon\rangle_M$, taken equal to $\frac{3}{2}(eD_L/\mu)$, where D_L is the lateral electron diffusion coefficient. At near-thermal energies for all three molecules $1/\mu_{torr}$ goes through a minimum which shifts to lower energies in the order CH_4, C_2H_6, C_3H_8. This behavior would suggest that the well-known Ramsauer–Townsend minimum in CH_4 (8) is exhibited by C_2H_6 and C_3H_8 as well, but for the latter molecules it is located at energies considerably closer to thermal.

Contrary to the case of CH_4 where the mobility of slow electrons increases with increasing density of CH_4, the mobility of slow electrons in C_2H_6 and C_3H_8 decreases (14) with increasing density of C_2H_6 and C_3H_8. This behavior has been discussed recently by Christophorou (2) who argued that for C_2H_6 (also *n*-butane, *n*-pentane, and *n*-hexane) the decrease in electron

mobility with increasing density (including the liquid) results predominantly from the delaying effects of the electron capture-and-loss process.

Consistent with the behavior shown in Fig. 4 are the comparisons of mean scattering cross sections with the geometric cross sections for the *n*-alkanes reported by Christophorou *et al.* (7). Using [4], it can be shown that for thermal electrons in a low-pressure gas,

$$[9] \quad \langle\sigma_m\rangle_{exp} = 6.42 \times 10^{-9}/\mu_{torr} \quad (\text{for } T = 298 \text{ K})$$

when $\sigma_m(v)$ varies inversely with v and that

$$[10] \quad (\sigma_m)_{exp} = 4.28 \times 10^{-9}/\mu_{torr} \quad (\text{for } T = 298 \text{ K})$$

when σ_m is independent of v. The values of $\langle\sigma_m\rangle_{exp}$ and $(\sigma_m)_{exp}$ for the *n*-alkanes are listed in Table 3. Estimates of geometric cross sections for the same ten molecules are also given. These were determined from end-to-end molecular distances reported by two different sources (see ref. 7). They are seen to compare well with the experimental cross section data, and they imply that the effective range of the forces experienced by the electron is short, comparable with the mean molecular radius. A short-range and strong e–molecule interaction is required for a Ramsauer–Townsend-type behavior to be exhibited by the scattering cross section (10).

Finally, it should be noted that the existence of a Ramsauer–Townsend minimum in the scattering cross section, as well as the small magnitude of the scattering cross sections for CH_4, C_2H_6, and C_3H_8 are consistent with the relatively long electron thermalization times determined by Christophorou *et al.* (15) for these gases at low pressures. Estimates of the electron thermalization times at 1 torr pressure are given in Table 4 for CH_4, C_2H_6, C_3H_8 (and C_2H_4) where they are compared with electron ranges in the corresponding liquids (16). The longer the electron thermalization time, the longer is the electron range.

TABLE 3. $\langle\sigma_m\rangle_{exp}$ and σ_{geom} for *n*-alkanes

Molecule	$\langle\sigma_m\rangle_{exp}$ (10^{-15} cm^2) [9]	$\langle\sigma_m\rangle_{exp}$ (10^{-15} cm^2) [10]	σ_{geom} (10^{-15} cm^2) Ref. 7[a]	σ_{geom} (10^{-15} cm^2) Ref. 7[b]
Methane	0.69	0.46	0.28	0.30
Ethane	0.61	0.41	0.67	0.62
Propane	1.28	0.85	1.19	0.97
Butane	1.93	1.29	1.93	1.33
Pentane	2.52	1.68	2.57	1.69
Hexane	2.84	1.89	3.44	2.05
Heptane	3.45	2.30	4.37	2.41
Octane	4.4	2.93	5.31	2.77

Decane	5.78	3.85	7.44	3.50

[a]Values determined from data on end-to-end molecular distances given in ref. 28.
[b]Values determined on the basis of data given in ref. 29.

TABLE 4. Comparison of electron thermalization times in hydrocarbon gases (P = 1 torr; T = 298 K) with electron ranges in the corresponding liquids

Molecule	Thermalization time[a] (μs)	Density-normalized range[b] (10^{-8} g cm^{-2})
CH_4	~1.5	224 (140 K)[c]
C_2H_6	~0.5	57 (200 K)
C_3H_8	~0.5	52 (238 K)
C_2H_4	~0.15	23 (170 K)

[a]The electron thermalization times were found (15) to increase slowly with $\langle\varepsilon\rangle$ above ~0.4 eV and to decline rapidly in the energy region corresponding to the vibrational excitation thresholds. The values listed in this table were estimated at the leveling-off portions of the thermalization time *vs.* $\langle\varepsilon\rangle$ functions reported in ref. 15.
[b]Reference 16.
[c]Values in parentheses refer to temperature.

VII. Concluding Remarks

A behavior similar to that exhibited by CH_4, Ar (Kr and Xe) may be exhibited by other molecules for which $V_0 < 0$ eV such as $C(CH_3)_4$ and $Si(CH_3)_4$. Additionally, the electron scattering cross section for higher members of the *n*-alkane series may possess a minimum which is located at thermal or subthermal energies.

The results of this study show the need for a better theoretical understanding of electron motion in dense gases and liquids. Present theoretical treatments (see, for example, ref. 17) fail to predict the existence of the Ramsauer–Townsend minimum in liquid Ar.

Acknowledgments

We wish to thank Dr. A. K. Bartels for kindly providing us with a copy of ref. 4*a* and Professor N. R. Kestner for useful discussions.

Discussion

J. Jortner: You were right in pointing out the repeated failure of theoretical models in accounting for the mobility maximum (minimum in cross section) in dense Ar and other dense fluids. The reason may originate from adopting solid state models to the liquid. In particular, Lekner's calculations consider single scattering from a 'frozen' system. Such an approach may be reasonable for energetics, *i.e.* calculation of V_0, but not for dynamics of the excess electron. In the latter case the role of density fluctuations has to be incorporated.

L. Kevan: Although you do see evidence for a Ramsauer–Townsend minimum in gaseous C_2H_6, C_3H_8, and perhaps higher alkanes, you presumably do not predict that this would be observed in liquid C_2H_6 and higher alkanes, in contrast to liquid CH_4, because of the low electron mobility in liquid C_2H_6. It seems that it would be very important to directly measure the momentum transfer cross sections for electrons in liquid alkanes.

L. G. Christophorou: The data I have shown for C_2H_6 and C_3H_8 are for low pressures. At higher pressures and in the liquid although a similar behaviour to that for CH_4 may be exhibited with regard to the Ramsauer–Townsend minimum, the effect of this on the mobility must be overshadowed by the opposite one due to electron capture and loss; for both C_2H_6 and C_3H_8 the electron mobility decreases with increasing density (see L. G. Christophorou. Int. J. Radiat. Phys. Chem. **7**, 205 (1975)) and is quite low in the liquid, as you said. I agree that a direct measurement of the momentum transfer cross section in liquid alkanes is highly desirable.

G. R. Freeman: Was the increase in structure factor with density due to the increase in isothermal compressibility?

L. G. Christophorou: Yes.

G. R. Freeman: I question the use of the structure factor in this way. In the critical region the compressibility becomes very large, yet nothing much happens to the electron mobility. It seems that either the mobility model or the method of estimating the structure factor is not correct.

G. Ascarelli: The Ramsauer minimum is due to a quantum mechanical interference between the incident electron and the scatterer. The important parameter is the ratio of the electron wavelength and the size of scatterer. If the Ramsauer minimum shifts to lower energies shouldn't this imply that you have to consider some sort of a cluster rather than independent molecules?

L. G. Christophorou: Yes, perturbation by the surroundings, not necessarily a cluster.

J. W. Warman: We have also obtained evidence for Ramsauer minima in polyatomic gases by studying the absorption of microwaves in the nanosecond pulse irradiated gas at pressures where the thermalization of electrons is considerably longer than the pulse length. At the pressures used (several torr) the absorption signal is proportional to the electron collision frequency and it is found, for CH_4, C_2H_6, and C_6H_6, that the collision frequency initially decreases following the pulse as the electrons cool down, then passes through a minimum, eventually rising to a plateau value corresponding to the collision frequency for fully thermalized electrons. The importance of the Ramsauer minimum in the overall rate of thermalisation is shown by the rapid decrease of the collision frequency to the minimum value compared with the much slower subsequent increase to the thermal value.

The influence of nonelectronegative molecules on the mobility of excess electrons in liquefied rare gases and tetramethylsilane

ULRICH SOWADA, WERNER F. SCHMIDT, and GEORGE BAKALE. Can. J. Chem. **55**, 1885 (1977).

Addition of nonelectronegative molecules (*n*-alkanes, alkenes, CO, CO_2) to liquid argon, krypton, and xenon influences the drift velocity of excess electrons in an electric field. At high field strengths (10^4–10^5 V cm^{-1}), where the electrons have mean energies exceeding kT, inelastic collisions with solute molecules lead to an increase of the drift velocity above the value of the pure solvent. Analysis of this effect yields the energy dependent product of collision cross section and mean fractional energy loss per collision.

At low field strengths a decrease of the low field mobility with increasing solute concentration is observed from which the cross section for momentum transfer could be deduced. The influence of solutes on the low field mobility was also found in tetramethylsilane.

ULRICH SOWADA, WERNER F. SCHMIDT et GEORGE BAKALE. Can. J. Chem. **55**, 1885 (1977).

L'addition de molécules qui ne sont pas électronégatives (des alcanes, des alcènes, le CO et le CO_2) à de l'argon, du krypton ou du xénon liquide influencent la vitesse de déplacement des électrons en excès dans un champ électrique. A des forces de champ élevées (10^4–10^5 V cm^{-1}), où les électrons ont des énergies moyennes plus grandes que kT, des collisions inélastiques avec des molécules de soluté conduisent à une augmentation de la vitesse de déplacement au-dessus de la valeur observée pour le solvant pur. L'analyse de cet effet fournit le produit de la section droite collision, qui dépend de l'énergie, et la fraction moyenne de l'énergie perdue par collision. A des forces de champs faibles, on observe une diminution de la mobilité à champ faible avec une augmentation de la concentration du soluté à partir de laquelle des sections droites pour le transfert de moment peuvent être déduites. On a aussi trouvé l'influence des solutés sur la mobilité à champ faible dans le tétraméthylsilane.

[Traduit par le journal]

1. Introduction

The physico-chemical properties of excess electrons in liquefied rare gases have received continuing interest for more than 2 decades. On one hand electrons have served as probes for the investigation of the structure of these simple liquids, on the other hand liquefied argon and xenon have been applied in liquid ionization chambers and elementary particle detectors.

The electron transport in these liquids is understood relatively well although quantitative agreement between theory and experiment needs improvement. Cohen and Lekner (1, 2) analyzed theoretically the motion of electrons in liquid argon and found that the interaction between electrons and argon atoms could be described by two mean free paths: one related to momentum transfer Λ_P and a second one related to energy transfer Λ_0.

At low electric field strengths where the electrons are in thermal equilibrium with the argon atoms the mobility is determined by transfer of momentum while at higher field strength where the electrons are no longer in thermal equilibrium with the liquid the energy loss becomes important.

Molecular solutes in the liquefied rare gas represent additional centers for scattering and both mean free paths are influenced. The effect of some hydrocarbons on the electron drift velocity as a function of the electric field strength was investigated by Yoshino *et al.* (3) in this laboratory and the influence on the energy loss was analyzed. Changes in the low field mobility were observed but not evaluated quantitatively.

In mixtures of ethane and methane, Bakale *et al.* (4) found a decrease of the electron mobility with increasing ethane concentration.

We have extended these investigations and here we wish to report measurements on the in-

fluence of molecular solutes on the low field and high field electron mobility in liquid argon, xenon, and tetramethylsilane (TMS). The electron drift velocity as a function of the electric field strength was observed for the following solutions: (*a*) at 87 K liquid argon with methane, ethane, ethylene, propylene, carbon monoxide, and carbon dioxide, (*b*) at 165 K liquid xenon with butane, cyclopropane, and tetramethyl silane, and (*c*) in the temperature range 173 to 296 K TMS with propane, butane, pentane, octane, isooctane, cyclopropane, cyclopentane, and propylene.

2. Experimental

Measurement technique and cells have been described elsewhere (5). Argon (99.96 mol%), xenon (99.99 mol%), and methane (99.995 mol%) were passed over columns of activated molecular sieve (Linde 4 Å) and charcoal at 200 K and through a column with copper sponge at 650 K. The purified material was then condensed at 77 K in an evacuated bottle.

Ethane, ethylene, propylene, and cyclopropane (research grade quality) were degassed and purified as described above. All other hydrocarbons and TMS were passed through columns of activated silica gel and after degassing they were stored in contact with a fresh sodium mirror for at least 24 h.

Carbon monoxide was passed through columns of activated molecular sieve and charcoal and was purified further by trap-to-trap distillation in a vacuum. Carbon dioxide was condensed on activated silica gel in a vacuum and then degassed by trap-to-trap distillation.

The remaining impurity level in the purified solvents led to a lifetime of the electrons much greater than the longest drift time, which came close to 5 μs in cells with 1 mm electrode separation.

3. Results

The influence of a molecular solute on the electron drift velocity is twofold. At low solute concentration the drift velocity at low field strength remains the same as in the pure solvent while at higher field strength an increase of the drift velocity above the values of the pure solvent occurs. With increasing solute concentration a reduction of the drift velocity at low field strength occurs while at high field strength the drift velocity is increased further. Figure 1 shows as an example the data of the solution of CO in liquid argon. A stepwise increase of the drift velocity with field strength was found with ethylene and propylene as solutes. In Fig. 2 the data obtained in a solution of propylene in liquid argon are given. The increase of the drift velocity sets in above 300 V cm^{-1} and in this solution an additional steep increase occurs at 3×10^4 V cm^{-1}.

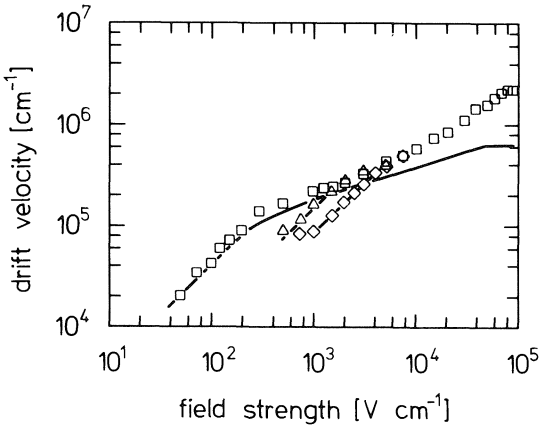

FIG. 1. The influence of carbon monoxide on the electron drift velocity in liquid argon at 87 K. CO concentration: □ 1.7×10^{19} cm^{-3}, ◇ 6.5×10^{20} cm^{-3}, △ 3.2×10^{20} cm^{-3}, — pure argon.

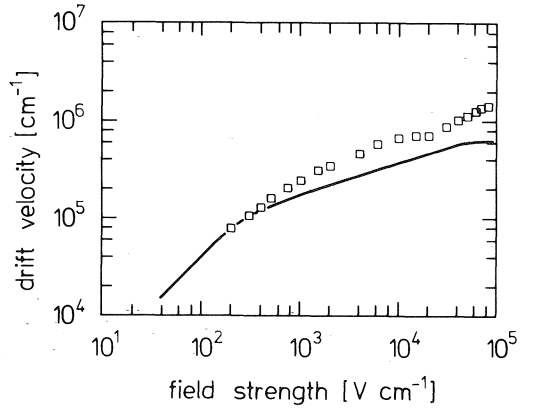

FIG. 2. The influence of propylene on the electron drift velocity in liquid argon. $T = 87$ K; 1.9×10^{19} cm^{-3}.

In solutions of methane and argon no decrease of the low field mobility with increasing methane concentration was observed. This may be due to the fact that the electron mobilities in the pure liquids are almost the same (2–4).

4. Discussion

4.1. Low Field Mobility

In pure argon, krypton, and xenon excess electrons exhibit large mobilities (Ar, 87 K, 450 cm^2 V^{-1} s^{-1}; Kr, 120 K, 1200 cm^2 V^{-1} s^{-1}; Xe, 165 K, 2000 cm^2 V^{-1} s^{-1}) and the electron is thought to move in an extended state or (in the terminology of solid state physics) in a con-

duction band (1, 2, 6, 7). The same picture may also be applied to TMS where the mobility is $\sim 100\ cm^2\ V^{-1}\ s^{-1}$.

The magnitude of the low field mobility is determined by scattering of the electron on single atoms while the scattering process is modified by the liquid structure around the scattering center (1, 2). The observed mobility μ_P is therefore correlated with a mean free path Λ_P by

$$[1] \qquad \mu_P = \frac{2}{3}\left(\frac{2}{\pi m k_B T}\right)^{1/2} e\Lambda_P$$

where m is the electron mass, e is the electronic charge, k_B is the Boltzmann constant, and T is the absolute temperature.

The addition of solutes introduces additional scattering centers and leads to a reduction of the mobility to a value μ_s. For small concentrations the scattering events are independent of each other and if the solvent structure is not changed the corresponding mean free path is given by

$$[2] \qquad \Lambda_s^{-1} = \Lambda_P^{-1} + n_s\sigma_m$$

with n_s the concentration of the solute and σ_m the cross section for momentum transfer to the solute. Combining [1] and [2] leads to an expression for σ_m

$$[3] \qquad \sigma_m = \frac{\mu_P/\mu_s - 1}{\Lambda_P n_s}$$

Plotting $\mu_P/\mu_s - 1$ as a function of n_s yields a straight line for low concentrations and σ_m is obtained from the slope. At higher solute concentrations the decrease of electron mobility with increasing concentration becomes steeper and the plot according to [3] bends upward. In Fig. 3, as an example, the reduction of the low field mobility in liquid argon at 87 K by small concentrations of ethane and carbon monoxide is given. The cross sections obtained from the various solutions are summarized in Table 1. For comparison cross sections obtained in the gas phase are also listed. σ_m(liq.) and σ_m(gas) exhibit the same order of magnitude. The embedding medium, apparently, has little influence on the scattering process. σ_m(liq.) is very small for molecules with no anisotropy of the electrical polarizability while σ_m(liq.) increases for the normal alkanes with increasing chain length. Introduction of a double bond seems to increase the cross section (*cf.* propane *vs.* propylene) while the branched isomer seems to show a

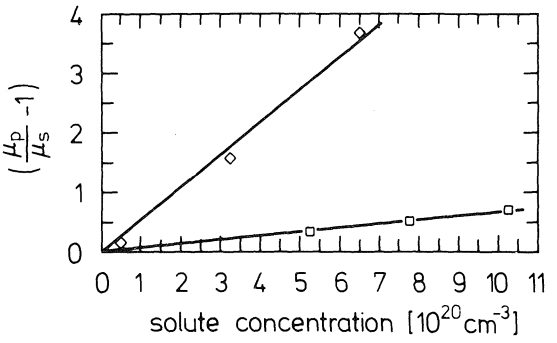

FIG. 3. Change of the low field electron mobility as a function of solute concentration; solvent: argon, 87 K; solutes: □ ethane, ◇ carbon monoxide.

smaller cross section in contrast to the gas phase, (*cf.* octane *vs.* isooctane). The carbon monoxide molecule is smaller than the ethane molecule but the permanent dipole moment of CO leads to a much greater cross section.

In general the cross section for momentum transfer seems to be correlated with the anisotropy of the polarizability (for instance, for *n*-octane $\delta^2 = 2.5 \times 10^{-2}$ while for isooctane $\delta^2 = 1.5 \times 10^{-2}$); however, other properties as, for instance, the size of the molecules may influence σ_m. Christophorou *et al.* (8) found satisfactory agreement between geometrical cross sections and σ_m(gas) for several *n*-alkanes.

4.2. High Field Mobility

At higher field strengths the drift velocity is no longer proportional to the field strength F. The electrons pick up more energy from the field between subsequent collisions than they can lose and a higher mean electron energy ε results. Addition of molecular solutes introduces new scattering centers where electrons can lose energy more efficiently than to the atoms of the solvent. In the pure liquid the rate of energy loss is determined by elastic collisions and given by

$$[4] \qquad ev_P F_P = \frac{\Delta W_{el}}{\Lambda_0/v_{el}}$$

where v_P is the drift velocity at the field strength F_P, v_{el} is the mean electron velocity, and ΔW_{el} the average energy transferred in an elastic collision.

In the solution the rate of energy loss is increased by inelastic collisions and given by

$$[5] \qquad ev_i F_i = \frac{\Delta W_{el}}{\Lambda_0/v_{el}} + \frac{\Delta W_{in}}{\Lambda_{in}/v_{el}}$$

TABLE 1. Cross section for thermal electron momentum transfer to solute molecules in liquefied rare gases and TMS

where v_i is the drift velocity in the solution at the field strength F_i, ΔW_{in} the average inelastic energy loss, and Λ_{in} the mean free path

$$[6] \qquad \Lambda_{in} = (n_{in}\sigma_{in})^{-1}$$

with n_{in} the solute concentration and σ_{in} the cross section.

From the ratio of the loss rates follows

$$[7] \qquad \frac{v_i F_i}{v_P F_P} = 1 + \frac{\Delta W_{in}}{\Delta W_{el}} \Lambda_0 n_{in} \sigma_{in}$$

Introducing the mean fractional energy loss

$$[8] \qquad f = \Delta W/\varepsilon$$

(ε mean electron energy) we obtain from [7] for σ_{in}

$$[9] \qquad \sigma_{in} \frac{f_{in}}{f_{el}} = \left(\frac{v_i}{v_P}\frac{F_i}{F_P} - 1\right) \Big/ (\Lambda_0 n_{in})$$

From [9] the product $\sigma_{in} f_{in}/f_{el}$ as a function of the mean electron energy ε can be determined.

ε is the same in the solution and in the pure liquid at field strengths where

$$[10] \qquad v_i/F_i = v_P/F_P$$

Since the mean electron energy ε is correlated with the field strength F_P, $\sigma_{in}(F_P)$ can be converted into $\sigma_{in}(\varepsilon)$. The dependence $\varepsilon(F_P)$ was calculated from the field dependence of the electron drift velocity in the pure solvent by means of the Cohen–Lekner theory (1, 2).

The elastic losses are due to collisions with argon atoms and f_{el} is given by

$$[11] \qquad f_{el} = 2m/M$$

(m electron mass, M argon mass). $f_{in}(\varepsilon)$ is not known exactly and, therefore, from the drift velocity data (*e.g.* Fig. 1) $\sigma_{in} f_{in}$ as a function of the mean electron energy was determined. The results are shown in Fig. 4.

Measurements by Christophorou *et al.* (9) in the gas phase indicate that $f_{in}(\varepsilon)$ increases steeply with energy up to 0.1 eV and then levels off above this energy with values around 0.1 for hydrocarbons. A somewhat different analysis was carried out in our previous publication (3) where the product of the energy loss quantum ΔW_{in} and the cross section $\sigma_{in}(\varepsilon)$ was obtained. In Fig. 5 the data for propylene and ethylene obtained in the present study are compared with the data for ethane and propane. The values for TMS are also given in Fig. 5.

Cross sections for energy transfer to these molecules in the gas phase have been reported by Duncan and Walker (10, 11). With plausible values for f_{in} or ΔW_{in}, respectively, values for $\sigma_{in}(\varepsilon)$ of the same order of magnitude can be obtained from Figs. 4 and 5.

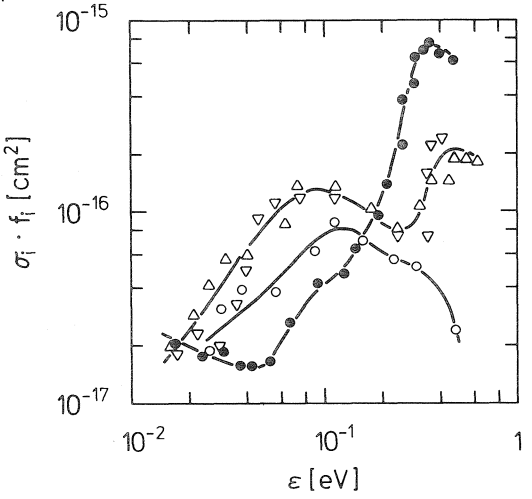

FIG. 4. Product of cross section for energy transfer and the ratio of the inelastic and elastic mean fractional energy losses as a function of the electron mean energy: ○ carbon dioxide, ● carbon monoxide, △ propylene, ▽ ethylene.

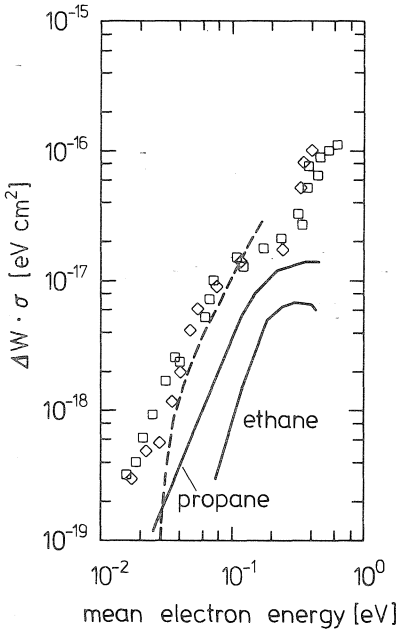

FIG. 5. Product of cross section for energy transfer and energy loss quantum as a function of the electron mean energy: □ propylene, ◇ ethylene, --- TMS; ethane and propane from ref. 3.

For TMS the energy loss as a function of the mean electron energy multiplied by the number density of the liquid at $T = 296$ K yields the energy loss per centimetre and this may be compared with the energy loss if only elastic losses given by $(2m/M)\varepsilon/\Lambda_0$ were active (M molecular mass of TMS). At thermal electron energies ($T = 296$ K) the ratio $f_{in}/f_{el} = 210$ is obtained in good agreement with the value of 230 deduced from the onset of the field strength dependence of the electron mobility in TMS (12).

Discussion

L. G. Christophorou: Could you please elaborate on your assumption that the electron energies are the same when the electron mobilities are the same?

U. Sowada: To my knowledge there is no theoretical justification. A simple physical reason why this assumption is a good one is the following: if the electrons lose energy more efficiently, the electric field strength has to be higher to end up in the same mean energy of the extra electrons. Empirically the assumption seems to be suited to account for this physical effect.

G. R. Freeman: Was it only for dilute solutions that you assumed that the electron energies were the same if the mobilities were the same?

U. Sowada: Yes. There are empirical reasons, as *e.g.* the coincidence of the results from different dilute solutions, and others, which indicate it is a good assumption.

High-speed schlieren studies of electrical breakdown in liquid hydrocarbons

P. WONG AND E. O. FORSTER

Corporate Research Laboratories, Exxon Research and Engineering Company, Linden, NJ, U.S.A. 07076

Received September 27, 1976

P. WONG and E. O. FORSTER. Can. J. Chem. **55**, 1890 (1977).

High-speed schlieren studies have been carried out on the electrical breakdown of liquid hydrocarbons using a pulsed ruby laser. The development and propagation of charge carrier trajectories were recorded photographically on prebreakdown, breakdown, and postbreakdown events occurring in very pure, oxygen-free samples of hexane, benzene, toluene, and isooctane using a parallel plate electrode geometry. The initiation of breakdown was characterized by the growth of narrow streamers the creation of which was attributed to field injected electrons at local asperities of the cathode surface. Once the streamers reached the anode, large currents were found to flow through the gap leading to formation of a plasma column. Subsequent emissions occurring at the anode were attributed to field reversal. Details of the schlieren pictures have been interpreted in terms of classical electromagnetic theory.

P. WONG et E. O. FORSTER. Can. J. Chem. **55**, 1890 (1977).

On a effectué des études de schlieren à grande vitesse sur l'éclatage électrique des hydrocarbures liquides utilisant un laser de rubis pulsé. On a enregistré d'une manière photographique le développement et la propagation des trajectoires des transporteurs de charge pour des évènements avant l'éclatage, durant l'éclatage et après l'éclatage se produisant dans des échantillons très purs et sans oxygène, d'hexane, de benzène, de toluène et d'iso-octane utilisant une géométrie d'électrode plane et parallèle. L'initiation de la dégradation est caractérisée par une croissance de flèches dont la création est attribuée à des électrons injectés par le champ au niveau d'aspérités locales de la surface cathodique. Lorsque les flèches ont atteint l'anode, on a trouvé qu'il y a une circulation de grands courants à travers la trouée conduisant à la formation d'une colonne de plasma. Des émissions subséquentes se produisant à l'anode sont attribuées à un renversement de champ. On a interprété des détails des photos de schlieren en termes de la théorie électromagnétique classique.

Introduction

An understanding of the phenomena associated with electrical breakdown occurring in dielectric liquids is very important because breakdown limits the high voltage level that can be applied to power equipment. Although numerous theories have been proposed to explain breakdown, a unified understanding of its origin is still missing because of a lack of data. Measurements related to breakdown are difficult because it is an ultrafast transient event, lasting only nanoseconds. Within that time, some quantities of interest such as conduction current can change from milliamperes to 10 000 A and higher. Moreover, even by taking the best precautions such as using isolation transformers and well-shielded cables, the electromagnetic radiation associated with breakdown has proved to strongly disturb electronic equipment. All these difficulties make an investigation of electrical breakdown events based on electrical measurements very difficult. In the present study, an optical method based on a laser schlieren system was used and the spatial development of electrical breakdown in liquid hydrocarbons was recorded photographically.

Early breakdown experiments using schlieren techniques were performed by Farazmand (1), Hakim and Higham (2), and Chaband and Wright (3). However, the electrode geometries used were of the point–point, point–plane, and sphere–sphere type, making the electrical field calculations very complicated. The work of these investigators was limited in temporal resolution by the use of conventional light sources which required rather prolonged exposures. Thomas (4) took advantage of the development of high intensity laser sources and he used a very fast laser pulse as light source for schlieren studies of prebreakdown events. (For a detailed description of the laser schlieren system see ref. 4.)

In the present study 15 ns pulses produced with a ruby laser were used to illuminate the space between two parallel plate electrodes. In

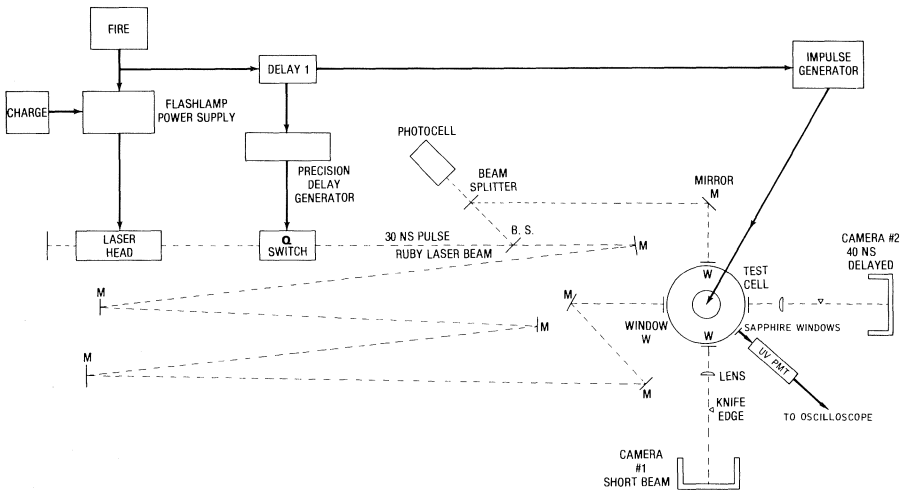

FIG. 1. Ultra high-speed electrooptical system for electrical prebreakdown in liquid hydrocarbons.

this manner it became possible to photograph density gradients produced in liquid hydrocarbons by the electronic charge carriers moving under the influence of a rapidly applied electrical stress. This paper presents some of the experimental results obtained and discusses their significance.

Experimental Technique

The experimental setup used in this investigation is basically the same as that described by Thomas (4). A simplified diagram of it is shown in Fig. 1. The *Q*-switched ruby laser was supplied by Holobeam, Inc. When the Pockel cell of the *Q*-switch is triggered, a laser pulse of 15 ns duration is generated. This pulse passes through a beam splitter and one beam is delayed with respect to the other by traversing a longer distance. The delay time can easily be adjusted by changing the optical path as defined by the mirror arrangements. The laser pulse shape is measured by using a high-speed photocell. When schlieren pictures were taken, the laser firing time is referenced to the breakdown time by displaying simultaneously the photocell output and the impulse voltage waveform on a Tektronix 556 dual-beam oscilloscope.

To produce the impulse voltage, a five stage Ferranti impulse generator was used. This instrument is of the Marx type and is capable of generating up to 275 kV. For the purpose of this study a rise time of about 1.4 μs was selected for the impulse waveform and the impulse decayed to 50% of its crest value in about 50 μs.

A parallel plane electrode system was used. The cylindrical brass electrodes had a 1 in. diameter and were spaced 6 mm apart. The edges of the electrodes were rounded (VDI type) and the surfaces were polished to a mirror finish. Since parallelism is extremely important in this plane–plane configuration, careful alignment is essential. In this setup, the upper electrode was fixed and the bottom electrode could be adjusted by means of a universal motion drive. The images of the electrodes were optically magnified onto a screen which permits monitoring of their positions for very fine adjustments.

The test liquids (toluene, benzene, *n*-hexane, isooctane) were Phillips research grade (99.9% purity). The liquids were first dried by contact with sodium ribbons for 2 days. Then they were subjected to repeated cryogenic distillations. A typical process would involve three such distillations. The liquid was then transferred to the test cell using pressurized nitrogen. Throughout the distillation and transfer process, the liquid was only in contact either with vacuum or nitrogen. The probability of having oxygen reabsorbed is estimated to be negligible.

In conjunction with the schlieren studies, a light detection system has recently been added. A RCA 4837 photomultiplier tube (PMT) was mounted just outside a sapphire window of the test cell. The latter permits the passage of uv light of wavelengths down to 200 nm. In the light emission experiment, the laser is not activated and the PMT is displayed simultaneously with the breakdown voltage waveform on the dual-beam scope. For low light-emission levels, an amplifier with an extremely fast rise time of about 1 ns was used to avoid distortion of the emitted light-pulse waveforms.

Experimental Results

The time for the collapse of the applied voltage, *i.e.* the time for the actual breakdown event, was deduced from voltage traces displayed on the oscilloscope such as the one shown in Fig. 2. From these traces it was decided that the breakdown event lasts less than 500 ns. The time lag between the instant the applied voltage reaches its crest value and the occurrence of breakdown is not reproducible in accordance with the well-known statistical nature of the breakdown mechanism. However, approximately half to one microsecond before breakdown, a sudden rise in uv light emission from the toluene

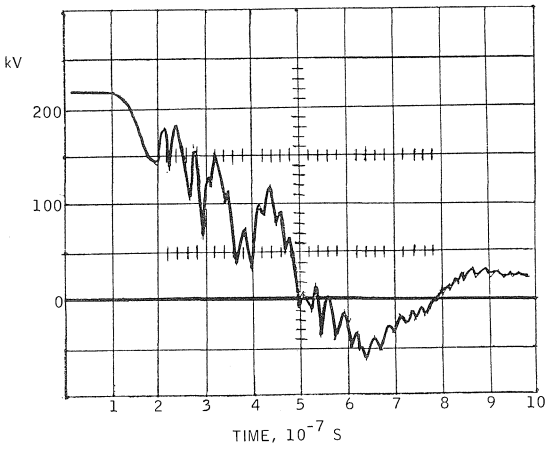

FIG. 2. Voltage trace of electrical breakdown, hexane.

sample can always be observed, as shown in Fig. 3*a*. The upper trace represents the temporal change in voltage, while the lower one represents the voltage output from the PMT. Most of the light emissions were identified as uv radiation because the light detection could be strongly attenuated if the optical window on the test cell was changed to ordinary pyrex glass (attenuation threshold at 300 nm and below). Light emission occurred as soon as the applied voltage started to increase (Figs. 3*b* and 3*c*), but a surge in intensity happened just before breakdown. This agrees very well with previous observations (5).

The schlieren photographs showed that electrical breakdown consists of three stages, which are labeled as: (*i*) prebreakdown; (*ii*) breakdown; and (*iii*) postbreakdown events. Figures 4*a* and 4*b* are a pair of photographs of the prebreakdown stage taken by the schlieren system in the crossed beam configuration. Figure 4*b* was recorded 40 ns after Fig. 4*a*. The initiation of breakdown is characterized by small, narrow cavitations near the cathode surface (see arrow in Fig. 4*a*). After 40 ns the tiny structure had developed into a well-defined streamer, propagating almost half-way between the electrodes. Hence, the velocity of the streamers is approximately 10^7 cm/s.

Typical breakdown pictures are shown in Figs. 5*a* and 5*b*. After the streamer had bridged the gap, rapid current discharge will flow through this conductive channel. By impact excitation and/or ionization, more ions will be produced and form a plasma column. It is interesting to note that the plasma columns were mostly

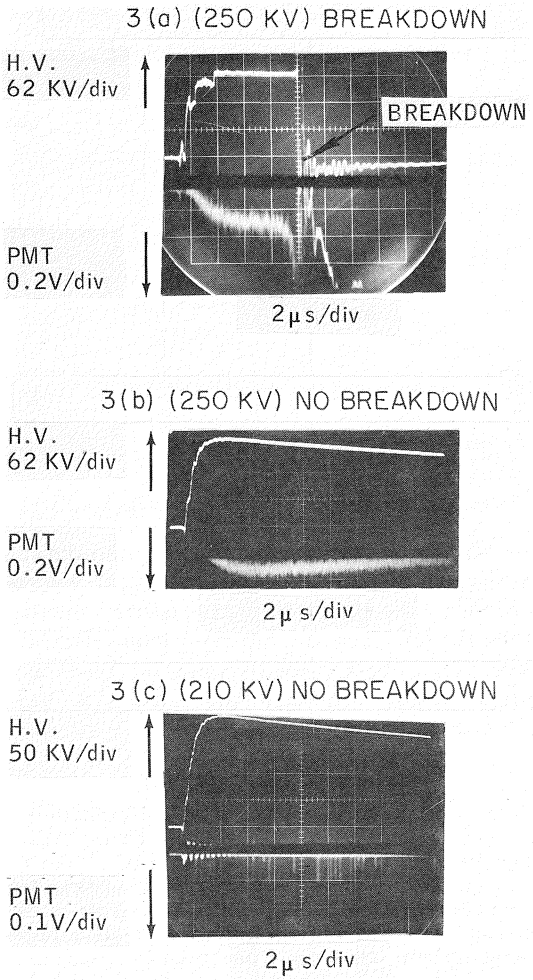

FIG. 3. Light emission from toluene.

crooked, suggesting they had been subjected to lateral forces.

In contrast to the breakdown events, the postbreakdown pictures (Figs. 6*a*, 6*b*, 6*c*, 6*d*) were marked by extensive propagation of shock waves from the plasma column. A very interesting feature was the carrier ejection from the anode electrode, moving in the cathodic direction. The structure never bridged the gap but became gradually more diffuse. (Compare Figs. 6*a* and 6*b* as well as Figs. 6*c* and 6*d*. The latter two pictures were taken more than 10 ns later with respect to the collapse of the electrical field than those shown in Figs. 6*a* and 6*b*.)

Discussion

The origin of micro-cavitation at the electrode–liquid interface has long been a topic of interest.

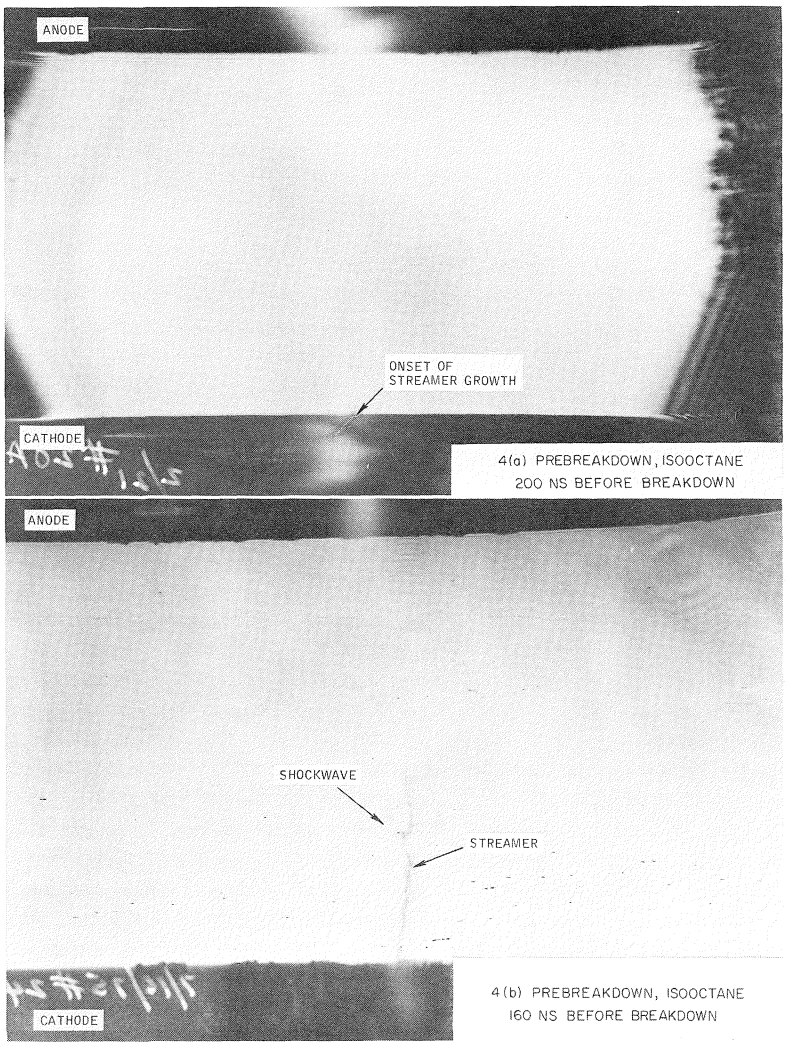

FIG. 4. Prebreakdown emission in isooctane.

Recently, a model for conduction and breakdown in liquids has been proposed by Thomas and Forster (6). The proposed scheme based on some two-dimensional calculations of Thomas (7) assumed that the electrons are being ejected from local asperities on the cathode surface by field enhancement. This agrees very well with the schlieren pictures that no streamer had been observed originating from within the liquid itself. Once the electron bombardment starts, the liquid will be heated locally. Together with an electron induced liquid motion, a region of low density will form and effectively increase the electron mean free path. The electrons, accelerated under the high electric field with fewer collisions, will gain more and more energy to cause impact excitation and/or ionization of the molecules. The excited molecules will emit light on decaying to lower energy quantum states. Within the low density region electron avalanche processes may develop leading to breakdown. The pattern of light emission will follow the growth or decay of these micro-cavities whose fate is determined by the flux of the ejected electrons.

The light emission data seem to support this growth–decay theory because the emitted light does show different degrees of intensities and occurrence rates, depending on the probability of having a breakdown. For the breakdown case,

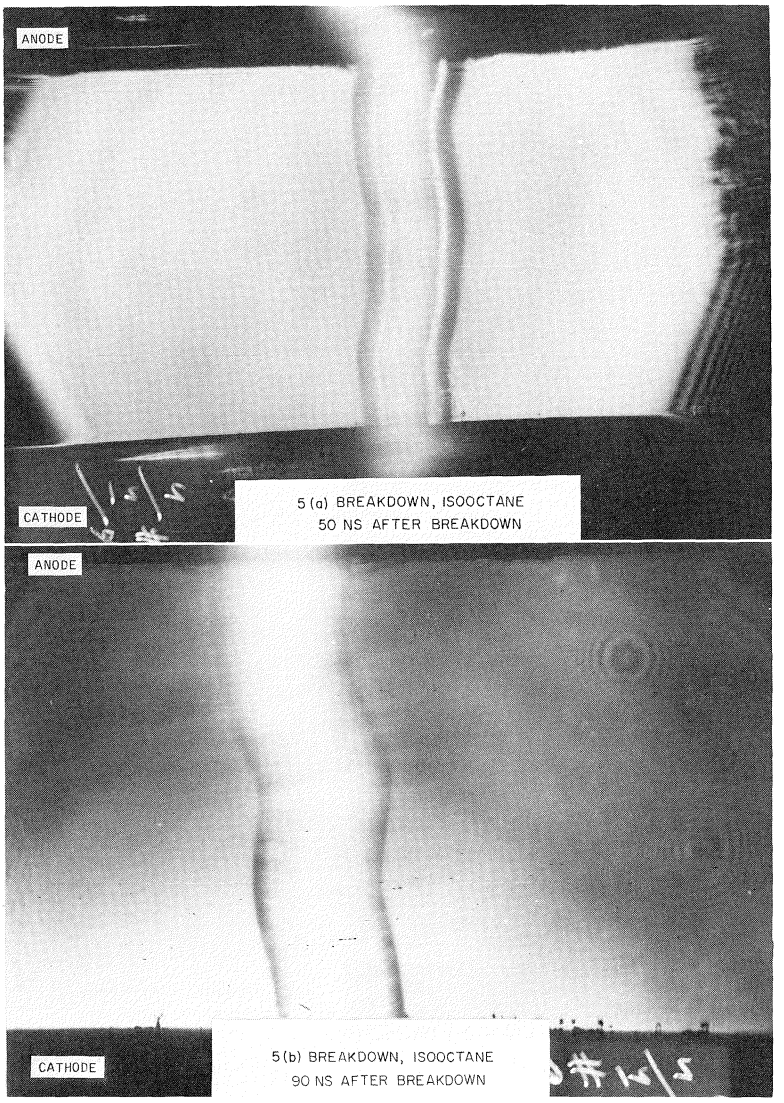

FIG. 5. Breakdown discharge in isooctane.

a rapid rise in light emission occurs just prior to breakdown. If there is no breakdown (applied voltage is the same), the light intensity will slowly decay, as shown in Fig. 3*b*. When the applied voltage is much below the breakdown strength, it is possible to observe isolated light pulses as shown in Fig. 3*c*. The last two cases indicate that the ejected electrons do not have enough energy to sustain cavitation growth long enough to create an avalanche.

When these cavities do grow, the high electric field will elongate the cavity into a streamer (a filamentary cavity with a plasma inside). Inspection of Fig. 4*b* reveals that small shock waves had already been created.

As the streamer bridges the gap and forms a highly conductive path between the electrodes, high currents will be dumped through it. The tremendous ionization and the associated energy release will expand the filament into a column as shown in Figs. 5*a* and 5*b*. The plasma columns had been distorted laterally in both cases, suggesting that the perturbing force most likely is the Lorentz force between the discharge

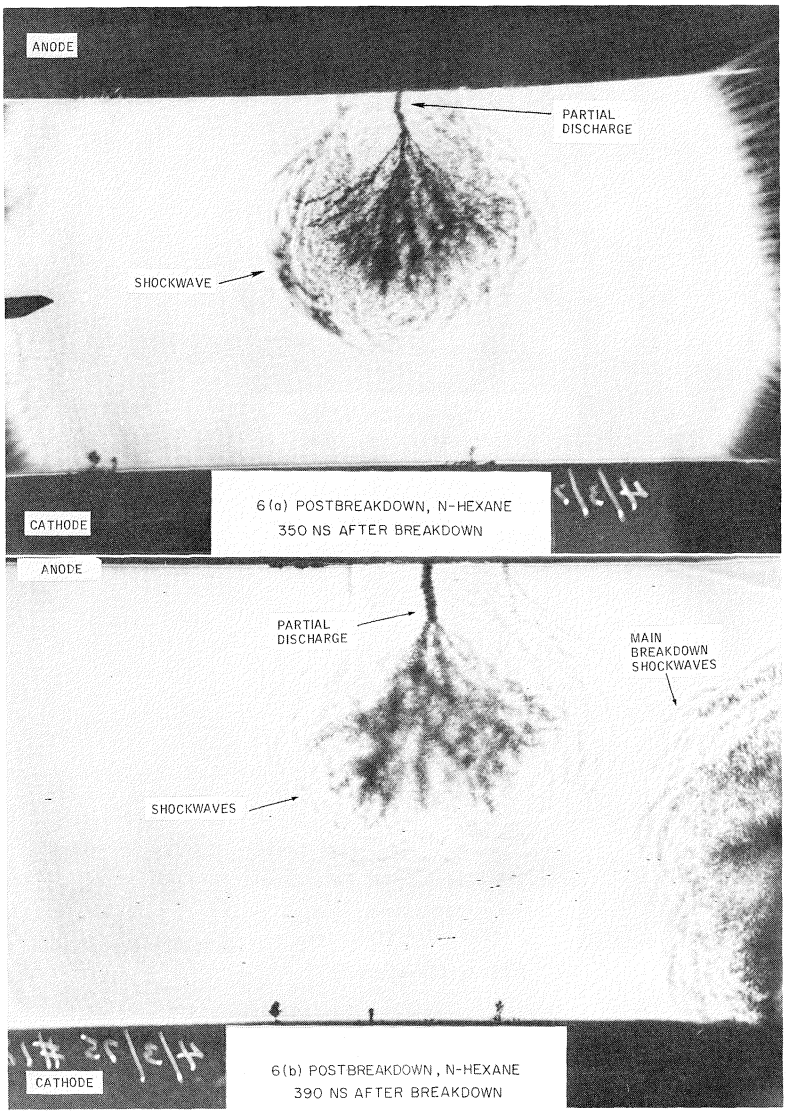

FIG. 6. Postbreakdown discharges and shock waves in *n*-hexane and in benzene.

current and the magnetic field induced by the current.

The current passing through such a column had experimentally been verified to be in excess of 5000 A. Using a diameter of 1 mm for the plasma column, the magnetic field at the column boundary was calculated to be in excess of 10 kG. The magnetic field distribution will be asymmetric if the column does not arc at the center of electrodes. The Lorentz force acting on the column will have a net force to push it outward and create a kink instability (8) in the plasma column. The physical explanation for the instability is illustrated in Fig. 7. The magnetic field is obviously stronger on the compressed side than on the stretched side, creating further asymmetry and the kink continues to grow. In the electrical breakdown case, the kink instability will eventually be limited by surface tension and hydrostatic pressure of the liquid.

The electrical breakdown is a high-power process, as evidenced by the postbreakdown photographs. By taking 3 pF as the electrode capacitance, an impulse breakdown of 250 kV

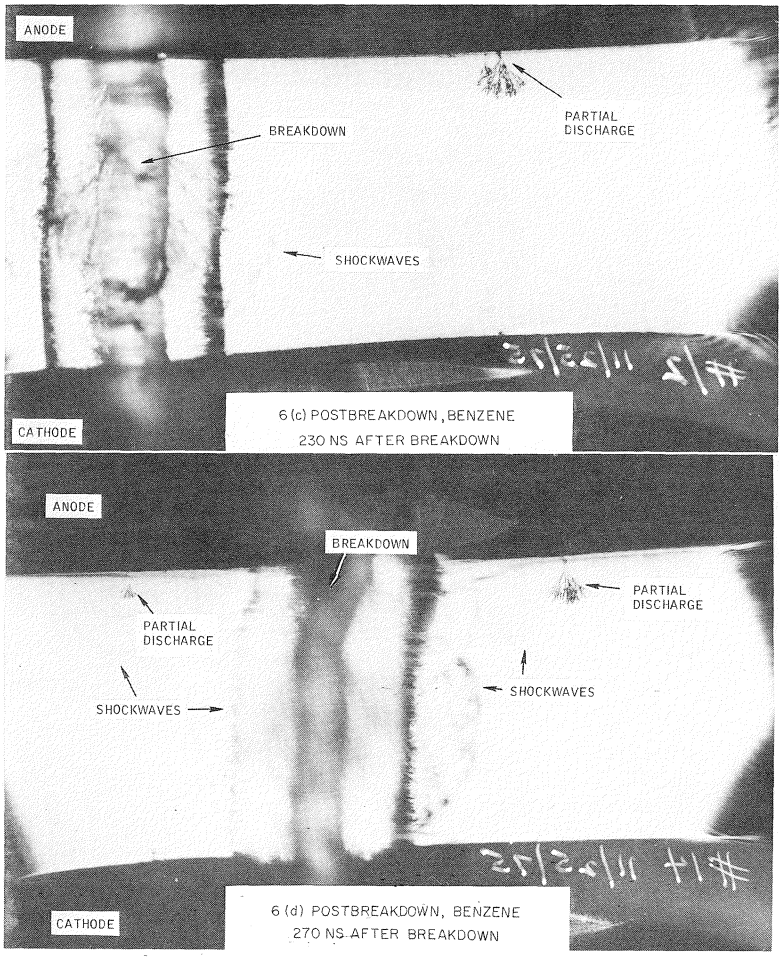

FIG. 6. (*Concluded*)

lasting 500 ns has associated with it a power of 2 MW. With that power being dissipated inside the 1 mm diameter plasma column, it is not surprising to observe significant shock waves. The Joule heating is probably extremely high. Graphitic structures had been identified by transmission electron microscopy of residues removed from the liquid after several breakdowns. This finding implies a spark temperature in excess of 1400°C.

Another noticeable feature of postbreakdown events is the electron ejection from the anode shown in Fig. 6. As shown in the Appendix, the field reversal caused by prebreakdown space charge distribution can turn the anode into a 'virtual cathode'. Curve *b* of Fig. 9 shows such a field profile. Since the negative field decreases gradually to zero at some distance away from

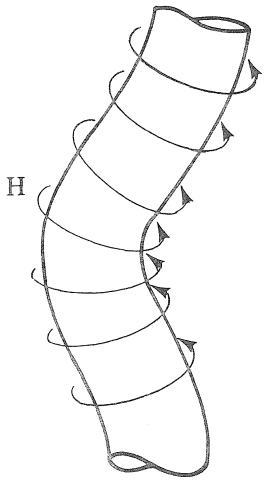

FIG. 7. Kink instability of plasma column.

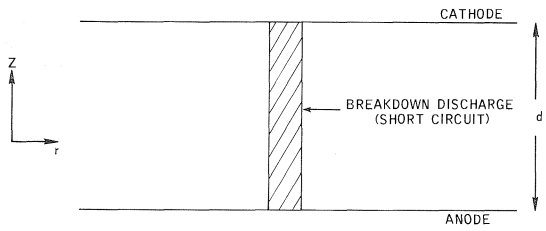

FIG. 8. Coordinate system for the plane–plane geometry.

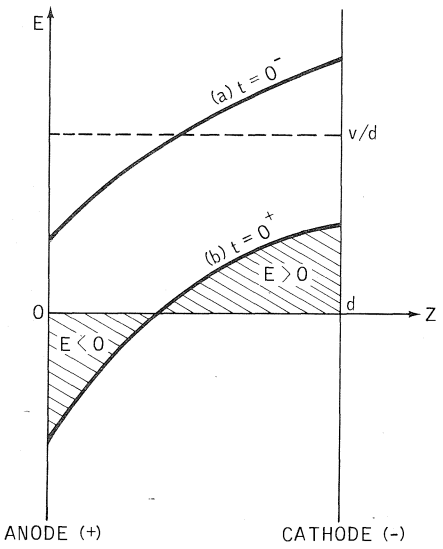

FIG. 9. Electric field distribution due to space change effects: (*a*) at $t = 0^-$, before breakdown; (*b*) at $t = 0^+$ after breakdown.

the anode, it explains very well why the propagation pattern of these ejected electrons is much slower and more diffuse than the streamers in the prebreakdown cases. Propagation of these electrons is further impeded by the decaying *E*-field because eventually $\boldsymbol{E}$ will be zero everywhere following redistribution of the space charges.

Conclusions

Although the available data are not extensive, they have shown convincingly the development of various stages of electrical breakdown in liquid hydrocarbons. While the overall patterns in these stages seem the same for the four liquids tested, it appears that there exist definite differences in the fine structures. These differences may well be due to the differences in molecular structures of the liquids. Fine details of the schlieren pictures have been explained in terms of classical electromagnetic theory. With improved instrumentation, which will include a self-triggering device based on the early light emission, it should become possible to test these explanations quantitatively.

Appendix. Field Reversal Due to Space Charge Effects

When a dielectric medium is under dc electric stress, the field strength inside the dielectric may no longer be uniform due to the pile-up of space charges. Such a nonuniform field configuration can be calculated by Poisson's equation if the charge distribution is known. For a plane–plane electrode geometry (Fig. 8), such a field distribution $\boldsymbol{E}^0(z)$ is drawn in Fig. 9 as curve *a*. Just after electrical breakdown, the applied voltage V is short-circuited by the discharge plasma column. If we denote the new electric field distribution as $\boldsymbol{E}(z)$, we arrive at the two relationships

$$[1] \qquad \int_0^d E^0(z)\,dz = V \qquad \text{at } t = 0^-$$

$$[2] \qquad \int_0^d E(z)\,dz = 0 \qquad \text{at } t = 0^+$$

Physically, it is reasonable to assume that space charges in the bulk liquid take time to redistribute themselves because of their finite mobility. Therefore, the charge distributions $q(r)$ are the same at $\tau = 0^-$ and $\tau = 0^+$. Since both $E^0(z)$ and $E(z)$ have to satisfy Poisson's equation, one obtains

[3] $$\partial E^0/\partial z = \partial E/\partial z = q(r)/\varepsilon$$

From [3], one can derive that

[4] $$E = E^0 + K$$

where K is a constant. Combining [4], [1], and [2], one obtains the final result:

[5] $$K = -V/d$$

Therefore, the new $\boldsymbol{E}(z)$ distribution will just have the same profile as $\boldsymbol{E}^0(z)$ except that it has been pulled *down* by an amount of V/d. This new distribution is plotted as curve *b* in Fig. 9. It is obvious from the curve that the condition

$$\int_0^d E\,\mathrm{d}z = 0$$

requires a negative E-field at the anode.

Discussion

P. K. Watson: The authors observe emission events at the anode, following breakdown; apparently this electrode is acting as a cathode during the post-breakdown period and this is due to field reversal in the gap. There are two possible reasons for field reversal: (*i*) internal space charge in the gap, and (*ii*) reversal of applied voltage following breakdown. There is undoubtedly a buildup of negative space charge in the gap due to the pre-breakdown electron emission, and when the applied voltage collapses at breakdown this internal space charge causes a field reversal; this is the process favoured by the authors. However, this space charge field will be very nonuniform and its effect will be most strongly felt in the vicinity of the breakdown channel; it is difficult to reconcile this with the authors' photograph which clearly shows back-discharge events occurring several millimetres away from the former breakdown channel. This suggests that the second reason for field reversal (*viz.* voltage reversal due to circuit transients) must also be included in the analysis.

G. R. Freeman: If you had a very efficient grounding of the anode, would the charge leak away fast enough that the field would not reverse?

E. O. Forster: This is a possibility. I doubt, however, whether the reversal can be reduced to zero. At present we are exploring this possibility by reducing all grounding connections to a minimum.

M. Pope: Since your electric field collapses during breakdown, what is the mechanism for the formation of additional breakdown figures during breakdown?

E. O. Forster: As discussed in the Appendix of our paper, the anode becomes a 'virtual' cathode at the surface of which electron emission occurs. Thus the mechanism of the formation of additional breakdown figures should be the same as that postulated to occur at the actual cathode in the pre-breakdown phase.

W. F. Schmidt: Why do these 'trees' have this short stem and then branch off? Why don't you see *e.g.* a bush-type?

E. O. Forster: The shape of the pre-breakdown and post-breakdown discharge channels, commonly referred to as 'trees', is a function of the electron emitting asperity (see ref. 4) as well as the molecular structure of the liquid (see ref. 5) and other parameters such as the local electrical field. For example the effect of molecular structure can be seen when comparing Figs. 6*a* and 6*b* with 6*c* and 6*d*. A closer look at the cathode surfaces shown in Fig. 6*a* and 6*b* reveal also a variety of 'tree-like' structures illustrating the influence of the structure of the emitting asperity.

L. Kevan: You showed the voltage reversing through several cycles in your initial slide. Can you see 'trees' growing from alternate electrodes with time?

E. O. Forster: No, our time resolution is inadequate for this purpose. The laser triggering technique is not, as yet, flexible enough to time in on these cycles.

L. G. Christophorou: How do electron scavengers affect the pictures you have presented?

E. O. Forster: So far we have been only concerned with very pure hydrocarbons to gain a basic understanding of the breakdown mechanism. Therefore we are unable to answer this question.

The role of electronic processes in the electrical breakdown of insulating liquids (Extended Abstract)

JOHN C. DEVINS, STEFAN J. RZAD, AND ROBERT J. SCHWABE
Corporate Research and Development, General Electric Co., Schenectady, NY, U.S.A. 12301
Received October 4, 1976

The present work has been aimed at revealing the particular electronic processes responsible for the sudden transition of an insulating liquid to a conductor under the influence of a sufficiently high electric field. This transient conducting state in the liquid can be observed by standard shadowgraphy or Schlieren optics (1–5) as a prebreakdown disturbance (streamer) with altered refractive index. We have measured, for point to plane geometries, the rate of streamer growth in a highly refined white mineral oil, Exxon Marcol 70. The voltage pulse (0.8/2500 μs) was supplied by a Marx generator and was chopped by a triggered spark gap. Observations were made between 0 to 150 μs. Steel needles were etched to a radius of approximately 1 μm. The plane was a polished stainless steel disk 10 cm in diameter with 1 cm radius edges. The electrodes were arranged in a 4 ℓ cylindrical Teflon cell provided with two optical windows, and the spacing was varied from 0.6 to 2.5 cm. The oil was generally degassed in the cell and measurements made under a 1 atm nitrogen blanket. Streamer velocities were the same with nitrogen-saturated and degassed oil (Fig. 4).

Positive and negative streamers are quite different as illustrated in Fig. 1 and Fig. 2. Typical propagation characteristics for these streamers are shown in Fig. 3, where we have plotted streamer length against time. The positive streamer velocity is remarkably constant during propagation across the gap for a given voltage suggesting a regulatory mechanism which maintains a constant field at its growing tip. On the other hand, as reported by Allan and Hizal (4), the negative streamers are much slower, and depending upon applied voltage, either develop to a constant length or speed up after crossing 50 to 60% of the gap. This is consistent with the picture proposed by Chadband and Wright (2) who approximate the negative streamer by a conducting plasma ball.

The effect of small amounts of a typical polyaromatic, 2-methylnaphthalene, is shown in Fig. 4. Both the positive and negative streamer velocities are increased with the largest concentration, *i.e.*, 7.3×10^{-2} *M*. With 7.3×10^{-3} *M*, the effect occurs only for the negative streamers.

Polyaromatics have two physical properties which may be relevant here, *i.e.*, low ionization potentials (6) and large electron trapping cross sections (7). To distinguish between these effects, we chose an additive which does not trap electrons (8), but which has an even lower ionization potential (6) than 2-methylnaphthalene (7.96 eV), *i.e.*, *N*,*N*′-dimethylaniline (DMA) (7.14 eV), and one which has a high ionization potential (9) (15.9 eV) and a large trapping cross section (7), sulfur hexafluoride. The results are shown in Fig. 5, where it is clear that the increase in negative streamer velocity is due to electron trapping. This was further substantiated using a second electron scavenger, ethyl chloride (7). It should be pointed out here that upon addition of the electron scavenger, the negative streamer becomes much more filamentary, resembling more the positive streamer. This is illustrated in Fig. 6. Neither of the electron scavengers had a measurable effect on the positive streamer velocity. The dimethylaniline, however, at concentrations above 7.9×10^{-2} *M*, accelerated the positive streamers to the same extent as did the 2-methylnaphthalene (up to a factor of *ca.* 2). Below the 7.9×10^{-2} *M* level, dimethylaniline, like 2-methylnaphthalene, did not alter the positive streamer velocity.

These results are difficult to explain in terms of the bubble mechanisms previously proposed for breakdown (10, 11), since small concentra-

tions of our additives would not be expected to show such a large influence. Similarly, collisional ionization in the liquid is unlikely because of the lack of an effect of the electron scavengers, which should markedly decrease the avalanche size. However, the important role played by low ionization potential compounds in the development of the positive streamer could well be explained in terms of field ionization (12) at the propagating streamer tip. This phenomenon requires very large fields, 10^7–10^8 V cm^{-1}. Our measurements of the diameter of the tip of the growing positive streamer (15 μm) indicate that fields of this order of magnitude will occur if the potential at the tip is of the order of that applied to the needle.

For the negative streamer, we suggest a dual mechanism in which the velocity depends upon the time spent in two modes of propagation. The electrons injected from the cathode or the growing plasma become trapped at a certain distance depending upon the scavenger concentration. As the space charge builds up, the field at the space charge boundary increases while that at the emitter decreases. This will occur faster the greater the scavenger concentration, and will determine the fraction of time spent in this injection mode. When the field outside the boundary reaches a sufficiently high value, field ionization can occur and a positive-like streamer can develop locally. When the plasma density reaches a value sufficiently high to establish conductivity further injection of electrons will occur and the first mode will be reestablished. These processes will alternate as the streamer develops. Since high conductivity is established during field ionization, the current would be expected to be discontinuous. This was found to be the case experimentally, *i.e.*, the current consisted of a series of short (< 50 ns) pulses. This is quite different for the positive streamer where the current is continuous throughout its development.

The absence of an accelerating effect of dimethylaniline on the negative streamer development indicates that the velocity is determined primarily by the time spent in the injection mode. This suggests that the addition of an electron scavenger might reduce the latter time sufficiently so that the dimethylaniline effect could be observed. Such a synergistic effect of SF_6 and DMA is indeed observed. Thus, the addition of DMA to a solution of 2.1×10^{-2} *M* SF_6 in Marcol 70 produces no effect on the negative

streamer velocity below 7.9×10^{-2}, and acceleration above this concentration, just as was observed with positive streamers.

Discussion

L. G. Christophorou: I wish to point out that in breakdown work (both in liquids and gases) one should not only consider electron scavengers but also electron thermalizers. The latter are important in that by slowing down electrons make their scavenging more efficient, while the former should be such as to capture electrons over as wide an energy range as possible (0 to ~1.5 eV).

S. J. Rzad: If only thermalisation by SF_6 and C_2H_5Cl was occurring it is very difficult to understand why the negative streamer would accelerate. If thermalisation were affecting the rate of scavenging the end result would be the same as in our experiments.

W. F. Schmidt: Couldn't the enhancement of the negative streamer velocity by the addition of a scavenger be due to a more efficient momentum transfer from the ions to the liquid as compared to electrons?

S. J. Rzad: The fact that an order of magnitude change in viscosity hardly affects the streamer velocity suggests that momentum transfer from the ion does not play an important role in determining the streamer velocity.

Electrons in fluids: the role of disorder[1]

MORREL H. COHEN

Received October 18, 1976

MORREL H. COHEN. Can. J. Chem. **55**, 1906 (1977).

I review the present status of the theory of those aspects of the theory of disordered materials which are particularly relevant to the physics of electrons in fluids. First, however, I describe a general theory of the movement of slow electrons in fluids of arbitrary complexity in which the fluid is treated as a fluctuating medium. Coupling to the fluctuations is via a set of generalized deformation potentials. It is shown that this concept permits a way out of the impasse that has been reached in understanding the mobility of slow electrons in liquid argon via Lekner's theory. Assuming that molecular motion can be neglected on the electronic time scale permits taking over various relevant results from the theory of electrons in disordered solids, which is briefly reviewed. The effect of molecular motion is studied next. It is shown that strict localization does not occur and that the quasi-localized electrons diffuse with a characteristic correlation frequency depending on electron–molecule coupling and upon the characteristic frequencies of molecular motion as well as with a correlation length related to the localization length in static problems. Under easily reached conditions, this diffusion process is faster than that giving rise to the Stokes law mobility. Finally, a discussion is given of mobility transitions in which localization by disorder is distinguished from self-trapping.

MORREL H. COHEN. Can. J. Chem. **55**, 1906 (1977).

Je présente une revue de l'état actuel de la théorie des aspects de la théorie des matériaux désordonnés qui ont un intérêt particulier pour la physique des électrons dans les fluides. Je décris toutefois en premier lieu une théorie générale du mouvement des électrons lents dans les fluides de complexité arbitraire dans laquelle le fluide est considéré comme un milieu en fluctuation. Le couplage aux fluctuations se fait par l'intermédiaire de potentiels à déformation généralisés. On montre que ce concept permet de sortir de l'impasse qui a été atteinte lorsque l'on essaie de comprende la mobilité des électrons lents dans de l'argon liquide par l'intermédiaire de la théorie de Lekner. Faisant l'hypothèse que le mouvement moléculaire peut être négligé à l'échelle de temps électronique, il est permis d'utiliser divers résultats appropriés provenant de la théorie des électrons dans des solides désordonnés que l'on passe rapidement en revue. On étudie ensuite l'effet du mouvement moléculaire. On montre que la localisation stricte ne se produit pas et que les électrons pratiquement localisés se diffusent avec une fréquence de corrélation caractéristique dépendant du couplage électron–molécule et aussi des fréquences caractéristiques du mouvement moléculaire ainsi qu'avec une longueur de corrélation qui est reliée avec la longueur de la localisation dans les problèmes statiques. Utilisant des conditions qui sont facilement atteignables, ce processus de diffusion est plus rapide que celui donnant lieu à la loi de mobilité de Stokes. Finalement, on présente une discussion des transitions de mobilité dans laquelle la localisation par le désordre peut être distinguée de l'autopiégeage.

[Traduit par le journal]

I was asked to review for this conference the theory of electronic states in disordered materials. This subject has been extensively reviewed recently (1–4), and it seems more appropriate to confine my remarks to those aspects of it most relevant to electrons in fluids. States of electrons in liquid metals and liquid semiconductors will be discussed during the conference but much has been written elsewhere about the relevant theory. Accordingly, I shall concentrate on the role of disorder in determining the states of excess electrons in fluid insulators, in molecular fluids in particular. However, it is not possible to confine oneself to disorder. Other matters must be discussed for proper perspective to arise: behavior of quasi-free electrons, self-trapped electrons, and basic conceptual questions. Accordingly, in Section I we develop a general model for describing the movement of slow electrons in fluids of arbitrary complexity. In the model, the fluid is treated as a fluctuating medium and coupling to the fluctuations is via a set of generalized deformation potentials. The model provides the basic theore-

[1]Research supported by NSF DMR75-13343, The Louis Block Fund, and the Materials Research Laboratory of the National Science Foundation at The University of Chicago.

tical framework for discussion of the issues raised above. In Section II, it is shown that such a model provides a way out of the impasse that has been reached in understanding the mobility of slow electrons in liquid argon. The central purpose of this talk, a brief review of relevant results from the theory of disorder, is met in Section III, where it is supposed that molecular motion can be neglected on the electronic time scale. Such is not always the case for thermal electrons in molecular fluids, and the effect of molecular motion is discussed in Section IV. It is shown there that strict localization no longer occurs, and the diffusion of quasi-localized electrons is discussed semiquantitatively. This dynamical localization must be distinguished from self-trapping, and in Section V we give a discussion of the consequences of these two forms of localization for mobility transitions.

In preparing this review, I was struck repeatedly by how little we really know, and how many basic questions remain unnoticed or shunted aside and unanswered in either event. This point will be well illustrated in what follows.

I. Preliminaries

We consider the motion of an excess electron added to an insulating molecular fluid. The total Hamiltonian of the system fluid plus electron is

$$[1] \qquad \mathscr{H} = \frac{p^2}{2m} + V(\boldsymbol{r};\boldsymbol{r}_i,\boldsymbol{R}) + \mathscr{H}_{\text{FLUID}}$$

in which the first term is the electron's kinetic energy, the last term is the Hamiltonian of the fluid, which need not be specified, and the second term is the interaction potential V between electron and fluid. At the present *molecular level of description*, V depends on electron position, on the set of positions $\boldsymbol{r}_i$ of all electrons bound within the molecules, and on the set of all nuclear positions $\boldsymbol{R}$.

The structure of the problem can be simplified by introducing an adiabatic approximation which has two parts. First, the internal electrons move rapidly with respect to the excess electron. This permits replacement of the instantaneous interaction in [1] by one which has been averaged over the intramolecular motion of the internal electrons in the presence of an excess electron fixed at $\boldsymbol{r}$. Second, the excess electron moves rapidly with respect to the nuclei. This permits solution for the motion of the excess electron keeping the nuclei fixed. The problem splits into two parts. In the first part, the motion of the electron is determined from

$$[2] \qquad \mathscr{H}_e(\boldsymbol{R})\,\psi(\boldsymbol{r},\boldsymbol{R}) = E_e(\boldsymbol{R})\,\psi(\boldsymbol{r},\boldsymbol{R})$$

where

$$[3] \qquad \mathscr{H}_e(\boldsymbol{R}) = \frac{p^2}{2m} + V(\boldsymbol{r},\boldsymbol{R})$$

In [2] $\psi(\boldsymbol{r},\boldsymbol{R})$ is the wave function of the excess electron, and in [3] $V(\boldsymbol{r},\boldsymbol{R})$ is the average of the potential $V(\boldsymbol{r};\boldsymbol{r}_i,\boldsymbol{R})$ in [1] over internal electronic motion for fixed $\boldsymbol{r}$ and $\boldsymbol{R}$. The potential $V(\boldsymbol{r},\boldsymbol{R})$ is only statistically defined through the probability distribution $P(\boldsymbol{R})$ of the nuclear coordinates. It is at this point that the fluid can appear as a disordered material with regard to the motion of the electron. Whether disorder is important depends on the amplitudes of the important fluctuations in $V(\boldsymbol{r},\boldsymbol{R})$ and whether one can escape with neglect of the time dependence of the nuclear positions.

The probability distribution $P(\boldsymbol{R})$ can be obtained self-consistently from the Hamiltonian governing the nuclear motion in the adiabatic approximation

$$[4] \qquad \mathscr{H}'_{\text{FLUID}} = \bar{\mathscr{H}}_{\text{FLUID}} + E_e(\boldsymbol{R})$$

where the bar over $\mathscr{H}_{\text{FLUID}}$ on the right-hand side of [4] is meant to indicate that the motion of the internal electrons has been appropriately eliminated. There are two limiting cases commonly considered. The first is that $P(\boldsymbol{R})$ is largely unaffected by the presence of the excess electron. This is the case, for example, in high mobility fluids such as liquid argon (5, 6) or when the mobility transition occurs by Anderson–Mott localization (1–4, 7, 8). The other occurs when $P(\boldsymbol{R})$ is profoundly modified as, for example, in cavity formation (9) or, more generally, self-trapping.

Suppose now that we consider solution of [2] in a nuclear configuration not very different from those most probable in the unperturbed fluid for the ground state energy and wave function, *i.e.*

$$[5] \qquad \mathscr{H}_e\,\Psi_0(\boldsymbol{r},\boldsymbol{R}) = V_0(\boldsymbol{R})\,\Psi_0(\boldsymbol{r},\boldsymbol{R})$$

where $\Psi_0(\boldsymbol{r},\boldsymbol{R})$ is the excess electron's ground state for the configuration $\boldsymbol{R}$ and $V_0(\boldsymbol{R})$ is the corresponding position of the bottom of the conduction band. Ψ_0 and V_0 still depend implicitly on all the microscopic configurational coordinates $\boldsymbol{R}$. This is both inconvenient and unnecessarily complex. Accordingly, we state

without proof that only certain local configurational coordinates $X_i(\boldsymbol{r})$ derived from these are important in determining the features of Ψ_0, V_0, and other quantities of central interest in typical experiments. We choose, for example, for the $X_i(\boldsymbol{r})$ the molecular number density $n(\boldsymbol{r})$, a unit vector specifying the mean local molecular orientation $\hat{d}(\boldsymbol{r})$ (the directrix of liquid-crystal theory) for a fluid containing symmetric aspherical molecules or an appropriate tensorial generalization for totally asymmetric molecules, the local molecular polarization $\boldsymbol{P}_M(\boldsymbol{r}')$ for a fluid containing polar molecules, and finally the local electronic polarization $\boldsymbol{P}_e(\boldsymbol{r}')$. The set $X_i(\boldsymbol{r})$ may be extended or reduced according to the microscopic character of the particular fluid.

The short distance modulations of Ψ_0 which correspond to the details of motion between and into the molecules are not among the features of specific interest to us. Rather, we are interested in variations which occur on the scale of its de Broglie wavelength, many molecular separations, that is in the 'smooth' part of Ψ_0, smooth in the sense of pseudopotential theory (10). We once again state without proof that arguments akin to those of pseudopotential theory and effective-mass theory for crystals can be found which lead to an effective Hamiltonian

$$[6] \qquad \mathscr{H}_{\text{EFF}} = \frac{p^2}{2m^*} + V_0(\boldsymbol{r}, X_i(\boldsymbol{r}'))$$

for the 'smooth' part of the wave function.

The effective Hamiltonian [6] simplifies for the case of small fluctuations $\Delta X_i = X_i - \overline{X}_i$, where $\overline{X}_i$ is the thermodynamic average of X_i in the unperturbed fluid,

$$[7] \qquad \mathscr{H}_{\text{EFF}} = \frac{p^2}{2m^*} + \overline{V}_0 + \sum_i \int V_0{}^i(\boldsymbol{r},\boldsymbol{r}') \times \Delta X_i(\boldsymbol{r}')\, \mathrm{d}^3 r'$$

The nonlocal terms in [7] give the contribution of distant polarized regions. The contributions of density and orientation fluctuations can be taken as local. For example in a simple fluid in circumstances in which the long-range contributions of the electronic polarization are unimportant, the only relevant X_i is the density n so that

$$[8] \qquad \mathscr{H}_{\text{EFF}} = \frac{p^2}{2m^*} + \overline{V}_0 + \overline{V}_0'\Delta n(\boldsymbol{r})$$

This Hamiltonian has precisely the same form as that of an electron in a crystal interacting with density variations produced by longitudinal acoustic phonons. $\overline{V}_0'$ is thus a deformation potential coefficient, and the $V_0{}^i(\boldsymbol{r},\boldsymbol{r}')$ may be regarded as generalized deformation potential coefficients.

II. Excess Electron Mobility in Liquid Argon, a Test of the Medium Description

We have sketched in Fig. 1 the potential $V(\boldsymbol{r},\boldsymbol{R})$ entering [3] in a simple liquid such as argon. Between the atoms there is a local maximum in the potential which has the average value U_0. This background potential U_0 consists primarily of a superposition of screened polarization interactions of the electrons with the individual atoms. Subtracting U_0 leaves a superposition of potentials localized about each atom which can be regarded as scattering potentials and characterized by a scattering length a, *cf.* Lekner (11). The scattering length is positive as for a repulsive potential, which can easily be understood in terms of pseudopotential theory. The value of $\overline{V}_0$ can now be easily estimated by means of the Wigner–Seitz approximation (9)

$$[9] \qquad \overline{V}_0 \cong \frac{\hbar^2 k_0{}^2}{2m} + U_0$$

where the first term is the kinetic energy associated with avoiding the molecular interiors. In the low density limit, it reduces to the optical model (12)

$$[10] \qquad \frac{\hbar^2 k_0{}^2}{2m} \xrightarrow[n\to 0]{} \frac{\hbar^2}{2m} 4\pi n a$$

Using this physical picture, Lekner (11) treated each atom as a single, independent scatterer of cross section $4\pi a^2$ and obtained an excellent fit to the full field dependence of the drift velocity

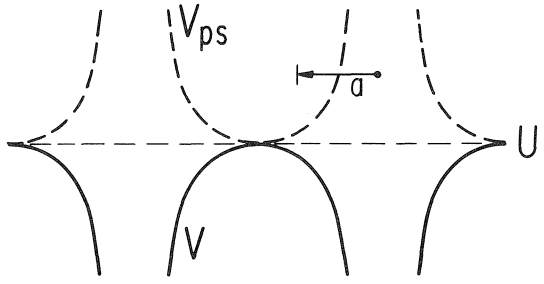

FIG. 1. The potential V within a simple liquid such as argon (schematic). U_0 is the background potential ($U_0 < 0$) above which a pseudopotential V_{ps} rises within each atom which defines a positive scattering length a for each atom in the liquid.

of excess electrons (13) in liquid argon at its triple point (84 K) (5). Jahnke *et al.* (6) extended the earlier mobility measurements of Schnyders *et al.* (5) to a wide range of densities at several pressures. They found a striking maximum in the mobility at 0.012 $Å^{-3}$. Lekner (14, 15) then proposed that a goes to zero at that density, a Ramsauer effect, and that fluctuations in a, $(\Delta a)^2$, kept the mobility finite. Jahnke *et al.* (16) searched for this effect, using Lekner's theory for the calculation of a. They found that a does not vanish in the observed range of densities and generally has the wrong density dependence to account for the data. Because this discrepancy can be interpreted as weakening the entire physical picture of electrons in fluids built up around the V_0 concept, now of central importance in the field, Basak and I have reexamined the matter.

We noted that in Lekner's theory of the scattering of an electron by the fluid (6, 13), the actual scattering occurred coherently from density fluctuations on the scale of the thermal wavelength of the electron. He therefore should have used the deformation potential in [8] as the scattering potential and not the potential associated with an individual atom; he coupled the electron incorrectly to the density fluctuations. Two errors are involved. The first is the neglect of multiple scattering included in the Wigner–Seitz energy $\hbar^2 k_0^2/2m$. The second is the neglect of the density dependence of the scattering length itself and of U_0. From the low density form of V_0, [9] and [10], we obtain

$$[11] \quad V_0' = \frac{\hbar^2}{2m} 4\pi a + \frac{\hbar^2}{2m} 4\pi n a' + U_0'$$

The first term alone, when used in the Born approximation for scattering, gives the Lekner theory. The remaining two terms are absent in the Lekner theory. In Fig. 2, the density dependence of the first term and of the total are shown. One sees that the first term is practically independent of density, whereas $|V_0'|$ has a minimum at a density equal to that of the observed mobility maximum. In calculating the terms of [11], we used the results of Jahnke *et al.* (16). Using the full Wigner–Seitz theory does not affect the conclusions.

These results give a simple physical explanation of the mobility maximum and provide the basis for a detailed semiphenomenological theory of the mobility which accounts well for the observed density dependence of the mobility. They provide an example of the utility of the medium description for long-wavelength, small-fluctuation phenomena.

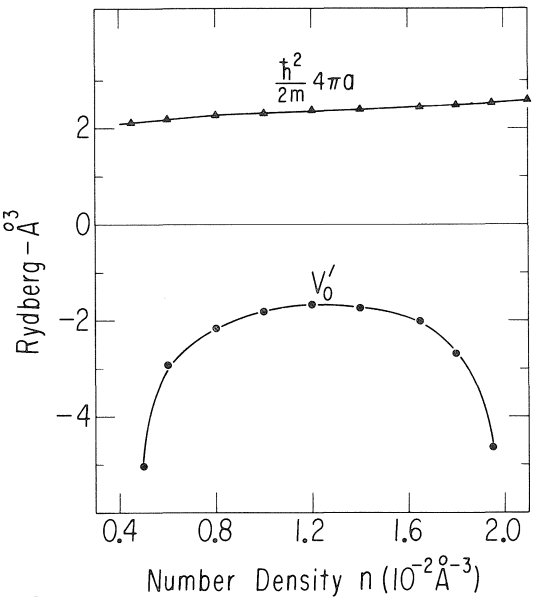

FIG. 2. Density dependence of V_0' in the optical model, [11], and of the first term, $(\hbar^2/2m)4\pi a$.

III. The Statically Disordered Medium

A. Semiclassical Theory

In the Hamiltonian [7], the $\Delta X_i(\boldsymbol{r})$ have a generalized Gaussian distribution and, as a consequence, so does the fluctuating potential. The detailed response of a long-wavelength, low-energy electron to such a fluctuating potential is unknown. However, one can make the following observations. The short-wavelength, positive fluctuations in $V_0(\boldsymbol{r})$ tend to be tunneled through, but with an amplitude reduction within the fluctuation. The kinetic energy required to follow the short-wavelength negative fluctuations tends to cancel the potential fluctuations. Thus the slow electron behaves, in effect, as though it moves within a potential which has been smoothed by averaging over some sampling length L (7, 8). Eggarter and I [2] have been able to construct explicitly for a fluid of nonoverlapping scatterers with a mean spacing significantly larger than the scattering length a smoothed wave function which satisfies a Schrödinger equation containing the smoothed

[2] T. P. Eggarter and M. H. Cohen, unpublished results.

potential. In Eggarter's original work (7, 8) he then went on to introduce a semiclassical treatment of the electron in the smoothed potential. We have been unable to justify this step explicitly. However, it is a simple matter to introduce and illustrate the basic concepts of electron motion in disordered materials via a semiclassical treatment, and we introduce one here.

The largest value of L which makes sense is one of the order of the de Broglie wavelength for an electron of a given energy. The fluctuations in the potential of shorter wavelength than L cause scattering, giving rise to a mean-free path ℓ_p for momentum transfer and one ℓ_E for energy transfer. It is the mean-free path for momentum transfer which determines the range of phase coherence of the wave function. Therefore, if $\ell_p \ll L$, we can regard the electronic properties and response functions as local on the scale of L. Similarly if $L \ll \ell_E$, we can regard the electronic motion as energy conserving on the scale of L. These are two requirements for a local, semiclassical treatment of the electronic states. The electron would then have an energy E given by

$$[12] \qquad E = \frac{p^2}{2m^*} + \mathscr{V}$$

within a given sampling region where the smoothed potential takes on the value $\mathscr{V}$. The probability distribution of $\mathscr{V}$ is Gaussian,

$$[13] \qquad P(\mathscr{V}) = \frac{\exp\left[-(\mathscr{V} - \bar{\mathscr{V}})^2/2\sigma_{\mathscr{V}}^2\right]}{(2\pi\sigma_{\mathscr{V}}^2)^{1/2}}$$

where $\sigma_{\mathscr{V}}$ relates to the corresponding quantities for the X_i, to the deformation potential coefficients, and to the sampling length L. The mobility μ takes on a local value determined by the value of $\mathscr{V}$.

If $\mathscr{V} < E$ at $\boldsymbol{r}$, then $\boldsymbol{r}$ is an allowed position, otherwise it is forbidden. Here we have supposed that L and $\sigma_{\mathscr{V}}$ are large enough that tunneling may be ignored. This defines a continuous three-dimensional percolation problem. The energy at which percolation ceases is the mobility edge E_c.

The density of states is readily calculated and sketched in Fig. 3. The position of the mobility edge is readily calculated from percolation considerations; one obtains[3]

$$[14] \qquad E_c = \bar{\mathscr{V}} - a\sigma_{\mathscr{V}} \qquad a = 1.0$$

as indicated in Fig. 3. If one ignores molecular movement, recent calculations (17) enable one to infer that the energy dependence of the mobility is

$$[15] \qquad \mu(E) = A(E - E_c)^{1.1}$$

as sketched in Fig. 4. However, molecular movement in the form of hydrodynamic drift of the localized regions, as proposed by Eggarter (8), leads to a finite mobility below the mobility edge (Fig. 5).

The mobility $\bar{\mu}$ observed in a typical experiment involves an average of $\mu(E)$ over energy:

$$[16] \qquad \bar{\mu} = \frac{\int dE n(E)\mu(E)f(E)}{\int dE n(E)f(E)}$$

The Boltzmann factor $f(E)$ decreases monotonically with energy; $n(E)$ and $\mu(E)$ both increase monotonically. Three distinct possibilities arise. First, there is a single maximum in the integrand $I(E)$ of the numerator of [16] which lies above the

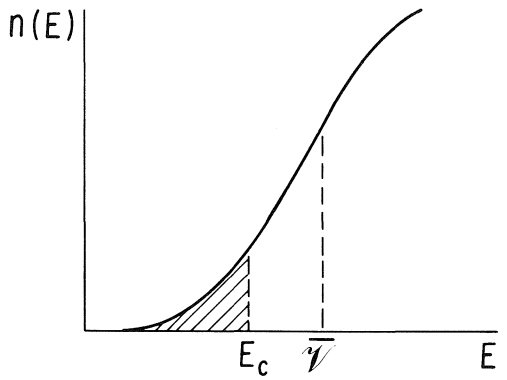

FIG. 3. Density of states in the semiclassical approximation for a Gaussian random potential, *cf.* [12] and [13]. Localized states below the mobility edge $E_c = \bar{\mathscr{V}} - \sigma_{\mathscr{V}}$ are shown shaded.

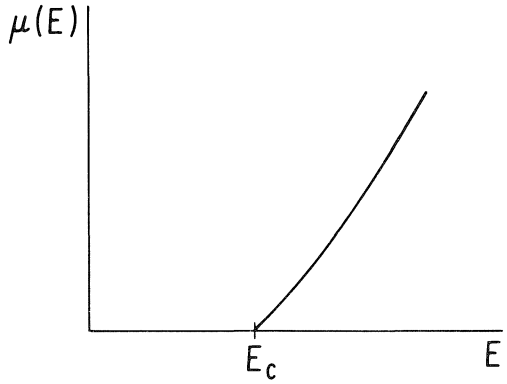

FIG. 4. Energy dependence of the mobility corresponding to Fig. 3 under the assumption of fixed nuclei.

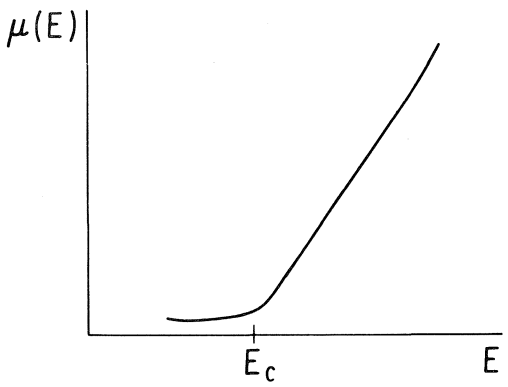

FIG. 5. Energy dependence of the mobility corresponding to Fig. 3 when hydrodynamic motion is allowed.

mobility edge. This corresponds to the case of quasi-free electrons. Second, $I(E)$ once again has a single peak but it lies well below E_c, in the region of localized states. This obviously corresponds to the case of localized electrons. Finally, there is the transitional case in which the contributions of the extended and localized states to $\bar{\mu}$ are of the same order. This can occur either as a gradual shift of a single peak in $I(E)$ from the extended to the localized states or, as occurs when the rise in $n(E)\,\mu(E)$ is large enough above E_c, there are two peaks, one in the localized region ($E < E_c$) and one in the extended region ($E > E_c$). This latter case would correspond to the simultaneous observations of a quasi-free and a slow electron by Schwarz and Prasad (18) within the mobility transition of He. These possibilities are depicted in Figs. 6 *a–c*. Thus, though oversimplified, the semiclassical model is very rich and illustrates clearly the way in which disorder affects the electronic states. Many of its features carry over into the general case.

B. Recent Developments in the General Theory

One of the major unresolved questions in the general theory of electronic states in disordered materials is the nature of the energy dependence of the conductivity or mobility in the vicinity of the mobility edge. Mott (19), in introducing his idea of the minimum metallic conductivity (20) had proposed that the mobility behaved in a step-like fashion at the edge, whereas I had proposed that it had percolation-like behavior (21, 22) as illustrated in Fig. 4. It now turns out that both are correct. Mott (23) has given an argument which shows that either can occur depending on the nature of the amplitude fluctuations in the wave functions. In the cases so far studied

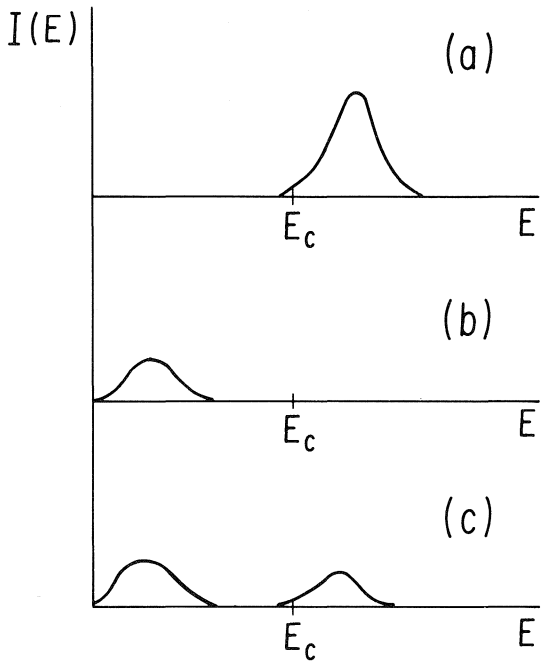

FIG. 6. The three types of weighting of the contributions of different energy ranges to the average mobility; $I(E)$ is the integrand in the numerator of [16]; (*a*) the quasi-free case, in which the weighting is above the mobility edge, (*b*) the localized case in which the weighting is below the mobility edge. A mobility transition can occur as a single such peak shifts continuously from case *a* to case *b*; or (*c*) a mobility transition occurs when the weighting splits up into two parts. Case *c* appears to occur in dense He vapor (18).

in detail experimentally, it is the step which appears to occur.[4] Wegner (24) has constructed a detailed scaling theory which provides a proof (within the limitations of a typical scaling theory) that either case can occur in three dimensions, but that only the step can occur in two.

Which case holds for slow electrons in fluids? The existing data (*e.g.* Levine and Sanders (12), Schwarz and Prasad (18)) are compatible with both. However, the existence of a step at E_c guarantees a double peak structure in $I(E)$.

IV. Dynamically Disordered Medium

In the preceding section, we treated the fluid as statically disordered. However, even in the adiabatic approximation the nuclear positions change with time, and the purely statistical approach described in Section I and used in Section III obscures some of the essential physics. Rather than use the standard Born–

[4] *Cf.* S. Pollit, work to be published.

Oppenheimer procedure which gives separate, though coupled, equations for the electronic and nuclear motion, for our present purposes it is more convenient to work in the interaction representation in which the nuclear coordinates are given their full, explicit time dependence. This can be done without making the adiabatic approximation. The electronic Hamiltonian then becomes

$$[17] \qquad \mathscr{H} = \frac{p^2}{2m^*} + V(\boldsymbol{r},t)$$

where the time dependence of the interaction V derives from the time dependence of the $X_i(\boldsymbol{r},t)$. One can show (25) that because one suppressed a large number of microscopic degrees of freedom in deriving equations of motion for the X_i, the latter undergoes a generalized Brownian motion, following a Gaussian random process in time. This last is completely characterized by the correlation functions,

$$[18] \quad \langle \Delta X_i(\boldsymbol{r},t)\, \Delta\, X_j(\boldsymbol{r}',t')\rangle \xrightarrow[\text{F.T.}]{} C_{ij}(q,\omega)$$

A frequency scale for the motion is readily established from the moments of the C_{ij},

$$[19] \qquad \omega_q{}^{ij} \equiv \frac{\int d\omega C_{ij}(q,\omega)|\omega|}{\int d\omega C_{ij}(q,\omega)}$$

Let ω_q be a typical value of the $\omega_q{}^{ij}$ for fixed q. It is an important fact that ω_q shows dispersion, *i.e.* a significant dependence on q. Let $\bar{\omega}$ be some appropriate mean value of ω_q. The phase of $V(\boldsymbol{r},t)$ will have changed irretrievably after a time $\bar{\omega}^{-1}$. Thus V remains correlated in time only for intervals $\lesssim \bar{\omega}_q{}^{-1}$.

Let us now recall the mobility theory done for the case of Fig. 6*b* where we are dealing only with localized states. We then considered that such states had a hydrodynamic (Stokes-law) mobility. However, a more chaotic mechanism, which we introduce here, can give rise to a larger mobility (26, 27). In the static picture an electron was localized in a region of spatial extent approximately equal to the localization length $L(E)$. However, the localizing potential changes in a time of order $\bar{\omega}^{-1}$. Therefore the region of localization randomly changes its position by distances at most of the order of the spatial extent of the wave function, *i.e.* $L(E)$, in times at most of order $\bar{\omega}^{-1}$. The electron thus undergoes a diffusion process. The mobility μ is related to the diffusion coefficient by the Einstein relation.

$$[20] \qquad \mu = eD/kT$$

and the diffusion coefficient has the standard form

$$[21] \qquad D = \tfrac{1}{6}\, \nu_c\, L_c{}^2$$

where the correlation frequency ν_c and correlation distance L_c can be roughly obtained from the above arguments:

$$[22] \qquad \nu_c \cong \bar{\omega} \qquad L_c \cong L$$

There results

$$[23] \qquad \mu \cong \tfrac{1}{6}\frac{e}{kT}\bar{\omega}L^2$$

Comparison of [23] with the Stokes law mobility (with slip at the boundary)

$$[24] \qquad \mu = e/4\pi\eta L$$

shows that [23] exceeds [24] whenever

$$[25] \qquad \bar{\omega}\, L^3 > 2kT/\eta$$

This condition is met if, for example, $\bar{\omega} > 10^{11}$ s^{-1}, $L > 5$ Å, $T < 300$ K, and $\eta > 1$ cP.

A consistency condition for the validity of [23] is that the time required to cross the region of localization is much less than the characteristic period, or

$$[26] \qquad \bar{v}/L \gg \bar{\omega}$$

where $\bar{v}$ is the mean speed in the localized state. If [26] is satisfied the localizing potential does not change before localization is established. If [26] is not satisfied, the mobility is that of a quasi-free electron with $\bar{\omega}$ replaced in [23] by the scattering rate τ^{-1}. As τ^{-1} is roughly equal to $\bar{v}/L$, one sees that the mobility of a dynamically localized electron as given by [23] is lower than that of a quasi-free electron by the factor $\bar{\omega}\tau$, which is $\ll 1$ whenever dynamical localization occurs.

These qualitative arguments for dynamical localization and thermal diffusion of electrons have been confirmed by a rigorous calculation for one dimension, carried out by Madhukar and Cohen (27).

There are thus two distinct processes for localized electrons, thermal diffusion and the Stokes mechanism. In developing the theory of static and dynamic localization, we here ignored the effect of the electron on the molecular configurations. When the electron–molecule interaction becomes strong enough to affect the dis-

tribution of molecular configurations significantly, the fluctuations responsible for the thermal diffusion mechanism are suppressed, and only the hydrodynamic mechanism remains.

V. Localization Versus Self-Trapping

Thus far in discussing electrons in localized states, we have had in mind only states that are localized by the disorder arising from fluctuations in the fluid, whether static (*i.e.* Anderson localization (1–4)) or dynamic. This process we call *localization*, which we distinguish from *self-trapping*. In localization, the distribution of molecular configurations can remain largely unchanged, whereas the distribution of the electron over different states associated with the various molecular configurations can change continuously. The electron can initially, before a mobility transition occurs, be found almost entirely in extended states. Then, as the mobility transition proceeds and is completed, it goes over to localized states associated with a narrow distribution of molecular configurations much like those with which a self-trapped electron is associated. In self-trapping, on the other hand, instead of a continuous change, there can be a gross change in molecular configuration to one of lower free energy. As the variable of state governing the mobility transition is changed, the self-trapped configuration can become locally stable and thereafter a mixture of the quasi-free state and the self-trapped state can occur, with relatively little probability of finding the states corresponding to intermediate stages of localization during the mobility transition. These are two alternative paths through the mobility transition. The first was emphasized by Eggarter and myself in discussing the mobility transition in He vapor, while the second was emphasized by Hernandez (28). Intermediate cases can of course occur as well.

In the preceding discussion of Anderson localization and its role in a mobility transition, we have found it convenient to use the generalized deformation-potential scheme. We have supposed both that the fluctuations are sufficiently small in amplitude that the electron–fluid interaction can be expanded to first order in the fluctuation amplitudes and that the resulting deformation potential is large enough to produce significant localization. The criterion for this is that $kT < \sigma_{\mathscr{V}}$, which can be met. This raises the question of whether the same scheme is adequate to the description of self-trapping, a convenient circumstance if so.

Jortner and I have examined self-trapping within the deformation-potential scheme by considering the configuration change illustrated in Fig. 7 for a simple liquid. A step-like increase Δn in n within a radius R is supposed to occur for negative V_0' (decrease for positive V_0'). The total energy E consists of

$$E = E_{el} + E_{dist} \qquad [27]$$

where the energy of distortion is

$$E_{dist} = \tfrac{1}{2}B\left(\frac{\Delta n}{\bar{n}}\right)^2 \frac{4\pi}{3}R^3 \qquad [28]$$

and the electronic energy is obtained as an eigenvalue of the Schrödinger equation,

$$\left[\frac{p^2}{2m^*} + (V_0'\bar{n})\frac{\Delta n}{\bar{n}}\right]\psi = E_{el}\psi \qquad r < R$$
$$\frac{p^2}{2m^*}\psi = E_{el}\psi \qquad r > R \qquad [29]$$

The surface energy is omitted from [28]; it does not change the conclusions. E_{el} was obtained in the weak-binding ($E_{el} \lesssim 0$) and strong-binding ($\psi \cong 0$, $r > R$) limits. E was then minimized with respect to the variational parameters Δn and R. The result in both cases was that the minimum value of E was positive; no stable self-trapped state could be found within the deformation-potential scheme.

Our conclusions from this study are first that self-trapping requires a large value of $\Delta n/\bar{n}$ for which the deformation-potential approximation and the simple distortion energy used above are inadequate. Second, the polarization energy is greatly modified for a bound state. It has to be

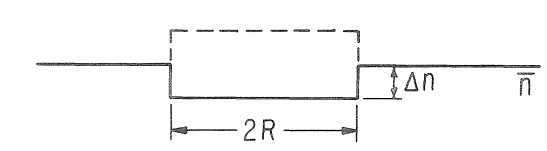

FIG. 7. Configuration change in a simple liquid employed by Jortner and Cohen to investigate self-trapping within the deformation potential approximation. A constant decrease in density of magnitude Δn (solid line) occurs within a spherical region of radius R for positive V_0'. An increase (dotted line) occurs for negative V_0'.

included explicitly into the calculation of the energy of self-trapping. Self-trapping can then occur for positive or negative V_0, positive or negative V_0', and it is important to find the explicit criteria.

The polarization energy also plays a very important role in Anderson localization, acting to provide extra stabilization of localized states in the tail of the conduction band. Thus the electron must be considered as interacting with the fluctuations and a self-induced polarization on an equal footing. The problem becomes that of a particular kind of polaron in a disordered material.

Discussion

J. R. Miller: You stated in discussing percolation theory that localized states occur only below the mobility edge. Why don't localized states co-exist with conduction states above the mobility edge?

M. H. Cohen: In a purely classical theory, they do. However, as soon as the quantum mechanics is brought back into the problem, these localized states become resonances.

J. K. Baird: You have mentioned Lekner's theory of electron mobility in liquid argon. As I understand it, Lekner proceeded as follows: (*1*) Calculated the screening of the polarization potential for a condensed phase. (*2*) Averaged this potential over the structure of the fluid using the pair correlation function. (*3*) Calculated the maximum of this potential and subtracted this maximum from the average potential. (*4*) Calculated the electron scattering form factor from the resulting potential. (*5*) Concluded that the effective scattering cross section in the liquid is this form factor multiplied by the liquid structure factor. It would seem to me that steps *3* and *4* perhaps should be omitted. Instead, I would prefer to regard step *2* as being the correct calculation of the effective potential and calculate the form factor for electron scattering from it. Then I would proceed to step *5*. Also I might note that this proposition would seem more in accord with the spirit of pseudopotential theory. The analogy is the following: In a metal, the positive ionic cores are screened by the conduction electrons. In an insulator like liquid argon, however, a core is screened by valence electrons which react to the presence of an excess electron by distorting. As I understanded it, the effective potential is pseudopotential theory is the screened potential and hence it should also be considered in liquid Ar.

M. H. Cohen: Steps *3* and *4* can be omitted only when the total potential can be represented as a simple superposition of individual atomic potentials and when the Born approximation can be used for the scattering. In the present case, the scattering potential is enormous compared to the energy of the incident electron and the Born approximation cannot be used. A **t**-matrix approach cannot be used to replace the Born approximation because the potentials from different atoms overlap and a separation into single atom **t** matrices is not possible. By performing step *3*, a background potential is defined above which a separate scattering potential appears for each atom. Thus a scattering length and cross section can be defined for an atom in the liquid which are quite different from those in the solid because of the screening of the tails of the atomic potentials and the chopping them off at the background potential level. If one stopped at step *2*, an alternative scheme equivalent to steps *3* and *4* would have to be carried out. One such scheme is the muffin-tin potential scheme, commonly used for crystals and now for liquids. It is closely related to what Lekner did.

U. Sowada: What happens to a free electron (plane wave), if the mean free path for momentum exchange becomes smaller than the de Broglie wavelength?

M. H. Cohen: Then the motion of the electron becomes diffusive and the problem of determining the mobility becomes more complex, in general, but not in the present case. Because both the de Broglie wavelength and the mean free path are much larger than the intermolecular distance, the same long wavelength limit may be taken in both cases.

U. Sowada: You were talking about phonon–electron interaction in terms of just the displacements of the atoms in the liquid. Would you call the interaction between an electron and an optically anisotropic molecule also a phonon-exchange?

M. H. Cohen: I talked about phonons only in connection with examples drawn from crystals. In the present cases we are dealing with interaction between an electron and time-dependent configuration fluctuations. The physical picture is unaffected by the optical anisotropy of the molecules. One has only to use a sufficiently general configuration coordinate.

G. R. Freeman: Could you give a physical picture of the mobility maximum in liquid argon? Beginning at low density and increasing it, why does the mobility increase, and then why does it decrease?

M. H. Cohen: Part of the initial increase is associated with decreasing compressibility, *i.e.* decreasing amplitude of density fluctuation, and with changes in the effective mass with density. However, the dominant effect is the existence of a minimum in the coupling of the electron to the density fluctuations as measured by $|V_0'|$. The two contributions to V_0', that from the kinetic energy ($\hbar^2 k_0^2/2m^*$) and that from the background potential U_0, oppose and balance at the minimum.

Experimental detection of collective modes in a polar liquid: application to the case of the solvated electron in H_2O and NH_3[1]

GIANNI ASCARELLI

Physics Department, Purdue University, West Lafayette, IN, U.S.A. 47907

Received September 27, 1976

GIANNI ASCARELLI. Can. J. Chem. **55**, 1916 (1977).

We present experimental data that confirm the predicted existence of a collective mode in a liquid corresponding to the longitudinal optical mode in an ionic crystal. The experimental investigation was carried out in nitromethane, and the results bear out all the calculated properties of this collective mode: the dipolar plasmon. The calculated frequency of the dipolar plasmon, as well as the dielectric constant at high and low frequencies, are then used to calculate *without adjustable parameters* the polaron coupling constant of the solvated electron in NH_3 and H_2O. A comparison of the calculated and measured properties of the solvated electron indicates that in either case a polaron-like continuum theory can at most account for only a fraction of the energy of the observed optical absorption.

GIANNI ASCARELLI. Can. J. Chem. **55**, 1916 (1977).

On présente des données expérimentales qui confirment l'existence, dans un liquide, d'un mode collectif dont l'existence avait été prédite antérieurement et qui correspond au mode optique longitudinal présent dans un cristal ionique. L'étude expérimentale a été effectuée dans le nitrométhane et les résultats sont conformés avec toutes les propriétés calculées pour ce mode collectif: le plasmon dipolaire. On utilise alors la fréquence calculée du plasmon dipolaire de même que les constantes dielectriques à haute et à basse fréquence pour calculer, *sans paramètres ajustables*, la constante de couplage polaron de l'électron solvaté dans NH_3 et H_2O. Une comparaison des propriétés calculées et mesurées de l'électron solvaté indique dans chaque cas qu'une théorie continue ressemblant au polaron ne peut tenir compte que de seulement une fraction de l'énergie observée pour l'absorption optique.

[Traduit par le journal]

One expects an interaction of a charged carrier with a dipolar liquid via electrostatic forces (1–3). This interaction resembles the interaction of a charged carrier with a polarizable lattice: the polaron.

In the case of solids, polarons are characterized by a dimensionless constant α that measures the strength of the coupling of the electron with a polarizable continuum whose characteristic frequency ω is that of the longitudinal optical phonons. In the case of solids

$$[1] \quad \alpha = \frac{e^2}{\hbar}\left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right)\left(\frac{m_0}{2\hbar\omega}\right)^{1/2}\left(\frac{m}{m_0}\right)^{1/2}$$

In this expression ε_∞ and ε_0 are respectively the high and low frequency dielectric constants of the solid, m is the effective mass of the electron, and m_0 the free electron mass.

Two extreme cases are well known and experimentally confirmed: (*i*) when $\alpha \lesssim 4$ the electron is mobile and (*ii*) when α is large the electron is self-trapped. The first case is that of electrons in the alkali, silver, and thallium halides (4) while the second is the case of holes in alkali halides (V_K center) and AgCl.

When α is small, perturbation theory is valid and the energy of the electron is decreased an amount $\alpha\hbar\omega$ by the localized lattice distortion that is formed around it. When the value of α is very large the depth of the well where the electron is self-trapped is instead $\simeq 0.106\alpha^2\hbar\omega$. In the intermediate range a more complex treatment is used instead. It is, however, dubious that a continuum theory is valid for self-trapped carriers because the results of the calculation predict the electron to be localized within a distance smaller than the unit cell. Neither the concept of effective mass nor that of lattice dielectric constant remains valid in such a case.

We can investigate the validity of a polaron model for a polar liquid if a collective mode equivalent to a longitudinal optical phonon can be identified. In this paper we present experimental confirmation of the existence of such a mode and then apply the polaron theory to the case of the solvated electron in H_2O and NH_3. There are no adjustable parameters in the calculation.

Collective modes in the dipolar liquids have

[1]Supported in part by the National Science Foundation Grant DMR 73-02348A01.

been predicted by Lobo *et al.* (5). These authors studied the collective oscillations of a dipolar liquid where each dipole oscillates around a position of equilibrium determined by the instantaneous field created by all other dipoles that are in turn treated as a continuum. Two types of waves were predicted to exist: longitudinal (ω_p) and transverse (ω_t). The longitudinal wave arises on account of both the lag of the Onsager reaction field with respect to the instantaneous orientation of the individual dipoles and a random walk of the individual dipole orientations. The transverse mode instead depends only on the random walk of the dipole orientation.

The predicted frequency of the longitudinal wave (ω_p) is

$$\omega_p^2 \cong \omega_t^2 + \omega_0^2 \qquad [2]$$

where

$$\omega_0^2 = 4\pi \frac{N}{V} \frac{\mu_v^2}{I^*} \frac{(\varepsilon_\infty + 2)^2}{9\varepsilon_\infty} \qquad [3]$$

$$\omega_t^2 = \frac{kT}{I^*}\left(1 + 2\frac{\tau_0}{\tau}\right) \qquad [4]$$

N/V is the density of dipoles whose dipole moment, in vacuum, is μ_v, $I^{*-1} = \frac{1}{2}(I_1^{-1} + I_2^{-1})$ is the average moment of inertia for rotations perpendicular to the dipolar axis, and ε_∞ is the high frequency dielectric constant. All the factors appearing in ω_0 are known. By contrast, the relaxation time of the random torque (τ) is an unknown to be measured in units of a time (τ_0) of the order of the Debye relaxation time.

We have studied the far infrared absorption due to the dipolar plasmon in nitromethane (NM) and solutions of nitromethane in carbon tetrachloride. The NM concentration N/V can be changed over a reasonable range thus varying ω_0 while ω_t depends on temperature and may be expected to remain approximately fixed at constant temperature if the viscosity of the liquids being mixed is similar. NM and CCl_4 are miscible in all proportions above the critical solution temperature ($T_s \sim 0°C$).

In order to be able to couple an electromagnetic (em) wave to a longitudinal mode it is necessary to have oblique incidence. An em wave polarized in the plane of incidence will couple to both a longitudinal and a transverse wave in the liquid, while a wave polarized perpendicular to the plane of the incidence will couple only to a transverse collective mode. Coupling of the em radiation to the longitudinal wave in the liquid can be enhanced with respect to the coupling of the radiation to the transverse collective mode by studying the reflection of thin liquid films on a metallic backing. The films must be thin compared to the wavelength of the light (6).

Our measurements were carried out by substituting the plane mirror of the focusing optics of a Fourier spectrometer (Beckman, RIIC Mod. 720) with a metallic cell with a transparent cover containing the liquid under study. Plastics were preferred as covers, over *e.g.* either quartz or Si, because their transmission is larger than the latter materials. The plastics were also suitable for a vacuum tight seal of the sample cell. Among the plastics, Teflon was preferred because of its chemical inertness. TPX (polymethyl pentene) was also used. It is important to emphasize that these plastics must be well annealed before each measurement to assure the absence of triboelectric fields (7) that can give rise to inhomogeneities in the NM–CCl_4 solution (8[2]).

The resulting reflection spectra of various NM–CCl_4 solutions are shown in Fig. 1. The scale on the right hand of the figure corresponds to the spectrum of the pure NM solution obtained with light polarized in the plane of incidence. On account of the flexibility of the plastic the thicknesses of the liquid films were not in general either well known or uniform. They are estimated to be of the order of 30 μm. As can be seen in the figure, the reflection spectrum changes completely with changes of polarization, thus permitting the identification of the frequency corresponding to both a longitudinal and a transverse wave. The latter is in excellent agreement with the previous results of absorption measurements at normal incidence by Kroon and Van Der Elsken (9).

The positions of the reflection minima associated with ω_p for various values of N/V as measured by the volume concentration of NM in CCl_4 are given in Fig. 2. It is clearly seen that there is excellent agreement with the functional predictions of [2].

The concentration dependence of ω_p and the polarization dependence of the reflection spectra are two of the expected properties of a longitudinal wave like the dipolar plasmon. The slope

[2]A more extensive report of the dipolar plasmon measurements is given in this publication as well as a discussion of the effects of external electric fields on the homogeneity of the solution.

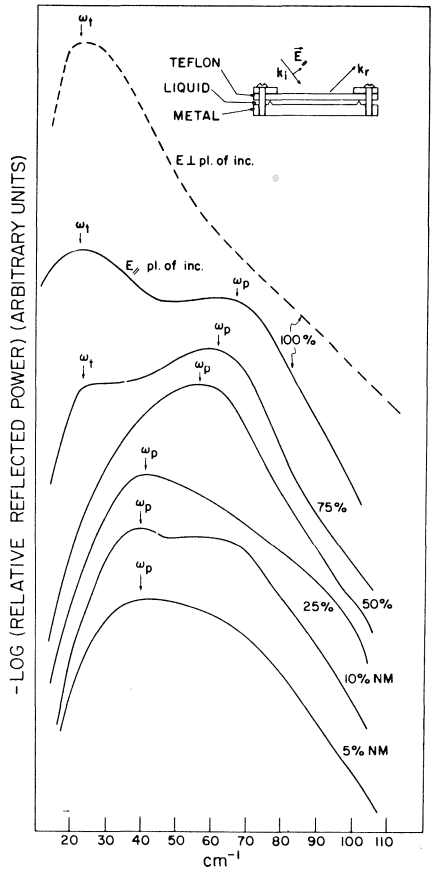

FIG. 1. Reflection spectra of solutions of nitromethane in CCl_4. The concentration of nitromethane in CCl_4 is expressed as a fraction of the total volume of the solution. R is the reflectivity of the solution. The solid line corresponds to spectra taken with radiation polarized in the plane of incidence while the broken line corresponds to a spectrum measured with light polarized perpendicular to the plane of incidence (reprinted with permission from ref. 8).

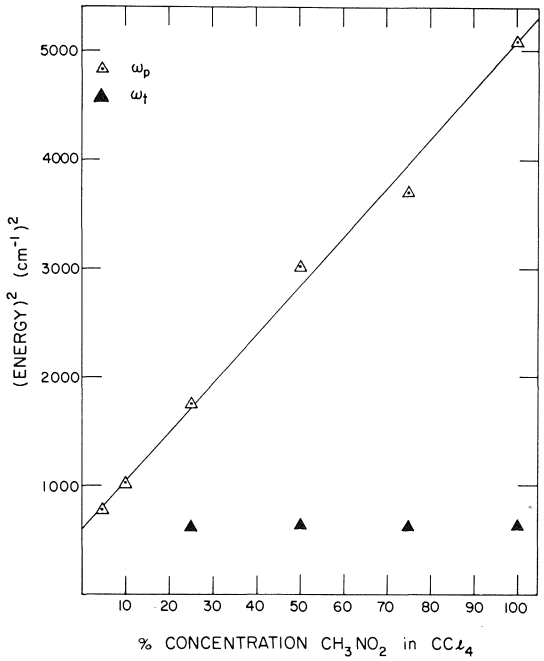

FIG. 2. Experimental relation between the square of the observed dipolar plasmon energy and the relative concentration of nitromethane in CCl_4.

of the line in Fig. 2 permits the calculation of ω_0 and a comparison with the value predicted on the basis of the known value of μ_v and I^* (10, 11). Agreement is excellent, thus confirming the calculated frequency of the dipolar plasmons.

Having demonstrated the existence of a dipolar plasmon we will apply the polaron theory (12–16) to the solvated electron problem. In order to compare the results with experiments we shall consider the case of water and NH_3. We shall use no adjustable parameters to adjust either the well depth or the well width.

We shall take $m/m_0 = 1$ in both cases and use the calculated values for ω_p (eqs. 2 and 3) to obtain α. The depth of the polaron well, *i.e.* the polaron self-energy E_p (Table 1), is obtained by interpolating between the results obtained by Shultz (14) who calculated it for several values of α using Feynman's path integral method. The extent of the electronic charge distribution (13), $\beta = 0.266\ (\hbar/2m\omega)^{1/2}$ (Table 1), corresponds to the strong coupling limit. If the solvated electron is to be described by a polaron picture the optical absorption of a polaron is an asymmetric line with a long tail toward high energies and a peak that approximately coincides with E_p (17). On the basis of a simplified configurational coordinate model the width of the optical absorption is (18)

$$[5] \qquad H_{\text{calcd}} \simeq 2.36\hbar\omega_p \frac{\alpha}{2}\left(\coth\frac{\hbar\omega_p}{2kT}\right)^{1/2}$$

A comparison of the properties of such a self-trapped electron with the experimental results (Table 1) indicates that the polaron continuum theory can at best account for half the energies of the optical absorption and of the linewidth in the case of NH_3. The agreement is even worse in the case of H_2O. In the case of NH_3 the region where the charge is concentrated agrees with the size of the cavity surrounding the solvated electron (3, 17).

The application of the polaron theory to the electron in H_2O is doubtful since the extent of the charge distribution is extremely close to the

TABLE 1. Calculated and measured properties of the solvated electron in H_2O and NH_3. The calculated values are obtained by the use of polaron theory assuming an effective mass equal to the free electron mass*

	H_2O	NH_3
ω_0	620 cm^{-1}	172 cm^{-1}
ω_p	630 cm^{-1}	200–250 cm^{-1}
α	7.9	12.3–11
E_p	0.58	0.41–0.46 eV
E_{max}	1.72 eV	0.83 eV
T	300 K	223 K
H_{calcd}	0.39 eV	0.18–0.2 eV
H_{meas}	0.92 eV	0.46 eV
β	1.8 Å	3.2–2.8 Å
$[(3/4\pi)(V/N)]^{1/3}$	1.92 Å	2.1 Å

*The meaning of the symbols ω_0, ω_p, α is discussed in the text. E_p and E_{max} are respectively the depth of the calculated polaron well and the maximum of the observed optical absorption of the solvated electron. T is the temperature at which the measurement is carried out. H_{calcd} and H_{meas} are respectively the calculated and measured width of the optical absorption. β is the polaron radius and V/N is the average volume/molecule in the solution.

intermolecular distance. In the case of NH_3 the validity of the polaron theory is not very justified either since $\beta \simeq [(3/4\pi)(V/N)]^{1/3}$. Attempts to fit the optical absorption data by introducing an effective mass $\sim 2\,m_0$ would produce an even larger discrepancy with the basic assumptions of the continuum theory, *i.e.* $\beta \gg [(3/4\pi)(V/N)]^{1/3}$.

From the above considerations it appears that the detailed description of a solvated electron in either H_2O or NH_3 will have to progress along the lines of the calculations for the V_K center in alkali halides (20, 21). Any continuum or semicontinuum theory will suffer from difficulties that are similar to those already found in the case of the F center in alkali halides (22) where there is a basic conflict between the idea of a continuum model and the calculated extent of the electronic charge distribution.

Discussion

J. Jortner: You have resurrected the old continuum model for the solvated electron using some new and interesting input data. I would like to point out the danger in the transfer of solid state concepts to the liquid state because of two major differences between electron–fluid and electron–solid interactions. First, in the polar liquid large local orientational configurational changes are induced by the localized electron. Second, the crucial role of density fluctuations have to be considered in the liquid. You cannot get away by applying a continuum model for the short range electron–solvent interactions and these have to be handled and are currently treated by a molecular model. As far as the long range polaron-type interactions with the polar fluid are concerned, one has to consider the role of density fluctuations, as argued by Kestner.

G. Ascarelli: I agree that to some extent I have resurrected an old continuum model for the solvated electron. It differs however from what has usually been considered because there are no adjustable parameters. The point I would like to stress is that even at the level of a simple polaron-like theory there are inconsistencies because the polaron radius is smaller than the nearest neighbour distance. This aspect does not seem to have been appreciated in some of the previous semicontinuum calculations where the boundary between the core potential and the long range Coulomb potential described by an ionic polarization is taken to be at a distance smaller or equal to the nearest neighbour distance. The orientational configurational changes you mention are lumped into the polarization while the density fluctuations to which you refer have no correspondence in the polaron theory.

Localized electronic states in amorphous semiconductors[1]

DAVID ADLER and ELLEN J. YOFFA. Can. J. Chem. **55**, 1920 (1977).

The experimental results pertaining to the electronic structure of covalent amorphous semiconductors are briefly reviewed. It is found that three classes of materials exist, depending on the lowest-energy coordination of the predominant chemical component. In each case, the transport properties are ordinarily controlled by the localized states in the gap resulting from the minimum-energy *defect* sites, in which the local coordination is not optimal for certain atoms. These localized states are treated in terms of a Hubbard model, in which the effective repulsion between two electrons simultaneously present on the same center is taken as positive for tetrahedrally bonded solids and negative for chalcogenide and pnictide glasses. The electronic structure is discussed in detail. It is shown that even such a simple model can account for almost all of the experimental properties of the major classes of amorphous semiconductors.

DAVID ADLER et ELLEN J. YOFFA. Can. J. Chem. **55**, 1920 (1977).

On passe brièvement en revue les résultats expérimentaux se rapportant à la structure électronique de semiconducteurs amorphes covalents. On a trouvé qu'il existe trois classes de matériaux en fonction de l'énergie la plus basse de coordination pour le composé chimique prédominant. Dans chaque cas, les propriétés de transport sont ordinairement controlées par des états localisés dans le fossé résultant des sites de défauts d'énergie minimum dans lesquels la coordination locale n'est pas optimale pour certains atomes. On traite ces états localisés en termes du modèle de Hubbard dans lequel la répulsion effective entre deux électrons présents d'une façon simultanée sur le même centre est considérée comme positive pour les solides liés d'une façon tétraédrique et négative pour les verres chalcogénides et pnictides. On discute en détail de la structure électronique. On montre que même un modèle aussi simple peut rendre compte de pratiquement toutes les propriétés expérimentales des classes majeurs des semi conducteurs amorphes.

[Traduit par le journal]

I. Introduction

Although amorphous semiconductors have been studied intensively over the past 10 years, progress in understanding their electronic structure has come slowly. As is the case for the corresponding crystalline solids, both covalent and ionic amorphous semiconductors exist (1). Because only the former materials have been investigated sufficiently that their physical behavior can be understood in some detail, we shall concentrate on them in this paper.

Three major classes of covalent amorphous solids can be differentiated, depending on the chemical nature of the predominant constituent atoms. Perhaps the most intensively investigated materials are the *chalcogenides*, those materials which contain a large percentage of the chalcogen atoms, Te, Se, or S. On the other end of the spectrum are the *tetrahedral* amorphous solids. These include not only the Group IV atoms, such as Ge and Si, but also the Group III–V materials, such as GaAs, and more complex solids with an average valence of four, such as $CdGeAs_2$. Intermediate between these two major classes are the *pnictides*, which contain predominantly the Group V atoms, Sb, As, or P.

In this paper, we analyze the experimental results on these main groups of covalent amorphous semiconductors, and summarize a model for their electronic structure which appears to be in agreement with the available data. In Section II, we discuss the major observations and contrast the three sets of materials. Section III presents an analysis of the chemistry of the lowest-energy defect centers in these solids. A

summary of an effective Hubbard model for the nature of the electronic states associated with these defect centers is given in Section IV.

II. Experimental Results on Covalent Amorphous Semiconductors

A. Optical Absorption

As is the case for all semiconductors, the optical absorption spectra of covalent amorphous semiconductors are dominated by sharp behavior in the region of the energy gap, E_g, which exists between the highest filled and lowest empty extended states (2). In most of the materials investigated, provided the short-range order is the same, the optical gap of the amorphous solid is strongly correlated with that of the corresponding crystalline solid, but many exceptions have been found, especially in the Group III–V's. There is a great deal of theoretical evidence (1, 3) that disorder should yield extensive band tails, which might be expected to manifest themselves in the optical absorption spectra, but the experimental evidence is generally ambiguous on this point. In Ge and Si, the optical absorption edge in apparently high-quality amorphous samples has been observed to be as sharp as in the crystals (4, 5), while in the chalcogenide and pnictide glasses, a comparison of the edges is masked by the so-called Urbach tails in both amorphous (6) and crystalline (7) systems. It is now believed that these tails are due to ionization of the band-edge excitons by the random electric fields present in these materials (8).

B. Electrical Conductivity

In tetrahedral amorphous semiconductors, conduction at room temperature and below is ordinarily dominated by variable-range hopping in the vicinity of the Fermi energy, ε_F (9). This indicates that there is a significant density of localized electronic states in the gap of these materials. Such a situation is not unique to amorphous semiconductors, but also characterizes partly compensated crystalline semiconductors. Conduction in such materials is generally insensitive to doping, since there are available electron and hole states at ε_F. For a particular class of amorphous Si, *viz.* that produced from silane gas (SiH_4) by an rf glow discharge, the density of localized states in the gap is relatively quite small, and conduction is dominated by thermally excited free electrons in the conduction band (10). For such material, it has proved possible to dope with ordinary donors and acceptors, and achieve extrinsic conduction (11).

The chalcogenide and pnictide glasses do not exhibit variable-range hopping near ε_F (1, 2). Conduction is predominated by thermally activated free holes in the valence band, and there is no direct evidence for a significant density of states at the Fermi energy. However, it has not yet proved possible to dope these materials to achieve extrinsic conduction.

C. Unpaired-spin Density

The tetrahedral amorphous semiconductors ordinarily exhibit an epr signal which indicates an unpaired-spin density in the range 10^{20}–10^{21} cm^{-3} (12). As the films are annealed below the crystallization temperature, the epr signal sharply decreases, although it does not disappear completely. On the other hand, no epr signal has been observed in amorphous Si prepared from glow-discharge decomposition of silane (13).

The situation is completely different for the chalcogenide glasses. No epr signal is observed at equilibrium (14) and no Curie term appears in the magnetic susceptibility (15). However, below 15 K, an epr signal can be induced by optical excitation with photons of frequency slightly below the band gap of the material (16). The resulting unpaired-spin density is of the order of 10^{16}–10^{18} cm^{-3}.

The pnictides appear to be intermediate between the other two classes. A weak epr signal, corresponding to a small spin density of the order of 10^{16} cm^{-3}, is obtained before exposure to light. This value is increased by an order of magnitude after optical excitation at very low temperatures (17).

D. Thermopower and Hall Coefficient

The tetrahedral amorphous semiconductors exhibit a nearly constant *n*-type thermopower at low temperatures, associated with the observed variable-range hopping conduction (18). At higher temperatures, more complex, history-dependent behavior is observed, although the results can be explained by superposing ambipolar band-like contributions onto the low-temperature hopping conduction. Hall-effect data has been inconsistent thus far, both *p*-type and *n*-type behavior having been obtained near room temperature (1). The existence of three parallel conduction mechanisms, as appears likely from the thermopower data, indicates the

need for controlled measurements on well-characterized samples, thus far lacking.

The chalcogenide glasses generally exhibit a nearly temperature independent, *n*-type Hall mobility (19). The discrepancy in sign between the Hall coefficient and the thermopower has received a great deal of attention (20), but it is not always observed; *e.g.* the Hall effect in $Tl_2Te{\cdot}As_2Te_3$ is *p*-type (21).

The pnictides are just beginning to be investigated, but an interesting result is that amorphous As has an *n*-type thermopower and a *p*-type Hall effect, the reverse anomaly as the chalcogenide glasses (22).

E. Photoluminescence

In tetrahedral amorphous semiconductors, photoluminescence is generally not observed (18), but, once again, glow-discharge-deposited samples behave differently. In the latter, strong photoluminescence has been found at low temperatures, with the photon energies emitted essentially equal to the exciting (band-gap) radiation (23). Any difference between the latter two quantities is ordinarily called a Stokes shift; it is small or nonexistent in glow-discharge-deposited Si.

In contrast, photoluminescence in chalcogenide glasses has been observed often (16, 24–26), although the exciting radiation is just slightly below the band gap. The luminescence appears only at low temperatures, and is significantly Stokes shifted, the emitted radiation peaking at about *half* the band gap. Initially, the luminescence is strong, and no epr signal is observed (16). As the exposure continues, the luminescence fatigues, while the epr signal grows and saturates. After exposure at low temperatures, there is also an additional optical absorption within the band gap.

F. Photostructural Changes

No photostructural effects appear to characterize the tetrahedral amorphous solids. However, chalcogenide glasses exhibit a wide range of optically induced transformations, both reversible and irreversible (27). A typical effect is photodarkening, apparently resulting from a broadening of the Urbach tail, but optically induced crystallization of the glass has also been observed (28).

G. Field-effect Measurements

The tetrahedral amorphous semiconductors prepared by ordinary techniques exhibit only a very small field effect (29), leading to the conclusion that the density of localized states in the gap is of the order of 10^{19} cm^{-3} or greater. However, the glow-discharge-deposited samples, especially those deposited on a high-temperature substrate, have a much larger field effect, providing evidence for a considerably smaller localized-state density, of the order of 10^{17} cm^{-3} (29, 30). There appear to be two peaks in the density of states in the gap, one 0.4 eV below the conduction-band edge and another about 0.4 eV above the valence-band edge (29).

Chalcogenide glasses exhibit only a small field effect (31–33), which can be interpreted to be due to a density of localized states of about 10^{18}–10^{20} cm^{-3}. The temperature dependence of the field effect is still unclear (32, 33), but there is evidence for two or more peaks in the localized-state density (32).

III. Chemistry of Defect States in Amorphous Semiconductors

Although it has been known for over 25 years that defect states control the transport properties of crystalline semiconductors, the importance of analogous states in amorphous semiconductors was not recognized until recently. This is because it was assumed that the intrinsic disorder of the amorphous state introduced a sufficiently large density of states in the gap to dominate any effects due to defect centers (3). It is now clear that this is not the case experimentally. The results on glow-discharge-deposited amorphous Si have shown that a tetrahedral amorphous solid can be prepared with a density of states in the gap sufficiently low that the Fermi level can be modulated by ordinary chemical doping (11). Consequently, the much larger localized-state density in evaporated and sputtered amorphous Si must be due to defects rather than intrinsic disorder (unless it is postulated that glow-discharge-deposited samples contain hydrogen impurities which remove intrinsic states from the gap). It is known that ordinary amorphous Si has a large density of voids, which result in dangling bonds (34). These produce what might be called *extrinsic* localized states in the gap. The fact that annealing the samples reduces the densities of both voids and localized states suggests that it is these extrinsic defects which control many of the physical properties of the material. As the defect density decreases, the epr

signal, the conductivity, and the tail of the optical absorption all decrease simultaneously.

Assuming the material is pure, the lowest-energy defects in the tetrahedral amorphous materials are vacancies and vacancy complexes (such as divacancies and larger voids). These defects lead to either strained bands or dangling bonds, the latter resulting in unpaired spins and an epr signal. Each dangling bond costs an energy E_b, depending on the bond strength, but a typical value is about 2 eV for Ge. Strained bonds cost somewhat less energy, depending on the actual configuration. Since evaporated or sputtered samples of these materials are condensed directly from the vapor phase, thermodynamic equilibrium is not reached, and a much greater density of these defects exists than would be estimated from a Boltzmann factor. Annealing the sample below its crystallization temperature does relieve some of the strains in the material, significantly reducing the defect density (perhaps by coalescing voids), but some always remain. It is evident that glow-discharge-deposited samples can have a much smaller density of defects.

In addition to increasing the ground-state energy of the sample, strained and dangling bonds also lead to localized states in the gap. In order to represent these states on a one-electron band diagram, we ask the following two questions. (*a*) How much energy does it take to remove an electron from the vicinity of the defect center and place it in the conduction (antibonding) band of the material? (*b*) How much energy does it take to remove an electron from the valence (bonding) band of the solid and place it in the vicinity of the defect? The first energy is called E_d, the second E_a. The electronic structure of the defects is then represented by placing the appropriate densities of *filled* localized states E_d below the conduction-band edge and of *empty* localized states E_a above the valence-band edge. The Fermi energy at $T = 0$ will always lie half way between the highest filled and lowest empty states; thus, ε_F will lie between the two sets of localized levels. The simplest situations, where only one type of defect exists, is shown in Fig. 1.

It might at first appear that $E_d + E_a$ should be equal to the energy gap of the semiconductor, $E_g = E_c - E_v$, in which case both sets of localized levels in Fig. 1 would coalesce. This is not the case because of the Coulomb repulsion between two electrons localized in the same

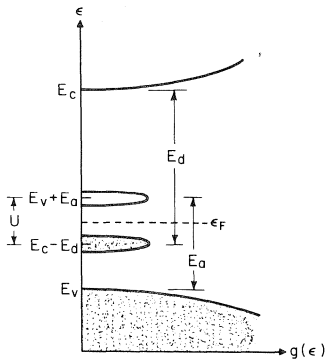

FIG. 1. Sketch of the density of electronic quasiparticle states for a semiconductor containing a single defect with effective positive correlation energy, U. Occupied states at $T = 0$ are shaded.

vicinity. When an electron is removed from the valence band and placed near a defect, it is repelled by the electron already present on that site. This repulsion is called U, the electronic *correlation* energy; thus, the two sets of localized levels are separated by an energy $U = E_d + E_a - E_g$.

If several types of defects exist or their density is very large, the defect bands can overlap, giving the situation sketched in Fig. 2. In such cases, a reoccupation of the localized states lowers the total energy, and this spontaneously occurs at low temperatures. (Any changes of correlation energy due to the effects of the redistribution of localized electrons must be taken into account in the final band diagram (35).)

It is clear that this type of approach can

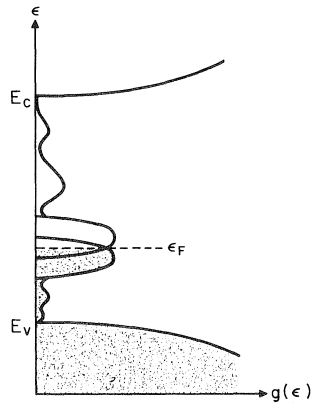

FIG. 2. Sketch of the density of electronic quasiparticle states for a semiconductor with several types of defects, in which the defect bands overlap. Occupied states at $T = 0$ are shaded.

account for all of the results thus far obtained on the tetrahedral amorphous semiconductors. The vapour-deposited samples have a large density of states at the Fermi energy resulting from the large defect densities. The dangling bonds produce a strong epr signal, while the large $g(\varepsilon_F)$ results in both the predominance of variable-range hopping at low temperatures and the lack of sensitivity of electrical conduction to doping with impurities. On the other hand, glow-discharge-deposited material can have a much smaller density of localized states in the gap. No epr signal is observable, ordinary band-like conduction can exist, and a field effect is obtained. The Fermi energy is not strongly pinned, and can be varied significantly by doping with heterovalent impurities.

The situation is entirely different in the chalcogenides (36). Since chalcogens possess lone-pair *p* electrons, the valence band of a chalcogenide glass is a nonbonding band (37). This also results in two sharp differences between chalcogenide and tetrahedral amorphous semiconductors. Firstly, since fewer bonds exist, a dangling bond tends to cost much more energy in a chalcogenide material than in a tetrahedral material; typical values are 4 eV for Se and 6 eV for S, compared to 2 eV for Ge and 3 eV for Si. Secondly, the possibility of converting a lone pair into a bonding–antibonding pair, with only a *small* loss in energy (*e.g.* 1.5 eV for Se), provides a degree of flexibility absent in other materials. These facts make the lowest-energy defect quite unique in chalcogenide glasses, and these defects control some of the major physical properties of the materials.

It is clear from the above discussion that the lowest-energy *neutral* defect in a chalcogenide glass is not a dangling bond (a singly coordinated chalcogen atom, which we call C_1°), but rather a threefold coordinated chalcogen (called C_3°). The former costs a bond energy, E_b, while the latter only costs the antibonding repulsive energy, which we call Δ. However, the lowest-energy defect is *not* neutral. As was shown by Kastner *et al.* (36), two C_3° centers are unstable towards the reaction

$$[1] \qquad 2C_3^\circ \rightarrow C_3^+ + C_1^- \qquad \text{Reaction 1}$$

is possible because a threefold coordinated chalcogen together with a neighboring twofold coordinated chalcogen can spontaneously transform to a neighboring singly and twofold coordinated center by breaking one of the bonds on C_3, leaving a C_1 neighbor. This is represented by

$$[2] \qquad C_3 + C_2 \rightarrow C_2 + C_1$$

The presence of an additional electron on an atomic site, as is the case with C_1^- requires an additional energy because of the Coulomb repulsion between two electrons on the same site, U_c. The approximate energies of all C_1, C_2, and C_3 states are shown in Fig. 3. It is clear that reaction 1 is exothermic, provided $2\Delta > U_c$, as appears to be the case (36). Furthermore, since positively and negatively charged centers attract one another via the Coulomb interaction, the defect centers with two oppositely charged chalcogens as nearest neighbors have the lowest energy of all. If we call the Coulomb attraction between nearest-neighboring, oppositely charged centers M, the energy of such a pair is

$$[3] \qquad U_c - M - U_p$$

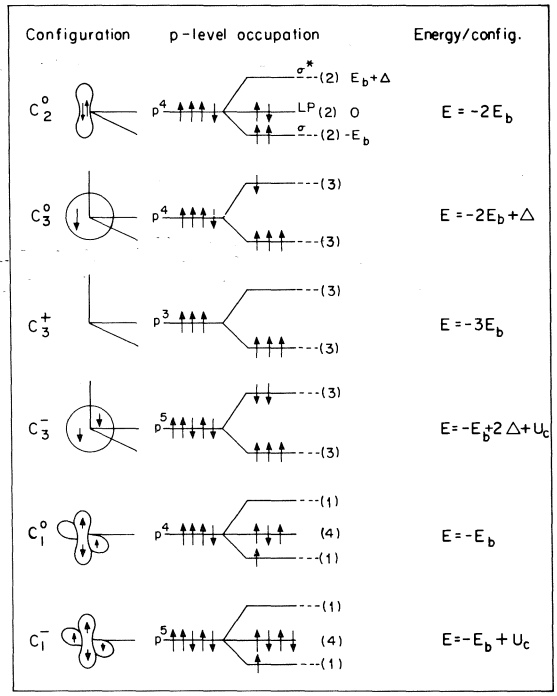

FIG. 3. Structure and energy of simple bonding configurations for chalcogen atoms in covalent amorphous semiconductors. Straight lines represent bonding (σ) orbitals, lobes represent lone-pair (nonbonding) orbitals, and large circles represent antibonding (σ*) orbitals. Each bonding electron is paired with another from a neighboring atom. The energy of a lone-pair electron is taken as the zero of energy (from ref. 36).

where U_p is the decrease in energy resulting from atomic relaxations. Reaction 1 is exothermic by an energy, $U \equiv 2\Delta - U_c + M + U_p$. Kastner *et al.* (36) called such nearest-neighboring pairs IVAP's (intimate valence-alternation pairs). Nonintimate pairs (NVAP's) are also possible, and have an energy M larger than IVAP's.

Chalcogenide glasses are made by cooling the material rapidly from the liquid state. Below the glass transition temperature, T_g, the long-range disorder is frozen in, and the amorphous state is stable. It is reasonable to estimate the density of IVAP's as

$$[4] \qquad n_I \sim n_0 \exp\left[-(U_c - M)/kT_g\right]$$

where $n_0 \sim 10^{23}\ cm^{-3}$ is the density of chalcogen atoms in the glass. For $U_c \simeq 0.55$ eV, $M \simeq 0.1$ eV, $T_g \simeq 600$ K, we obtain $n_I \sim 10^{19}\ cm^{-3}$. The density of NVAP's is then

$$[5] \qquad n_N \sim n_0 \exp\left[-U_c/kT_g\right]$$

For the same values of the parameters given above, [5] yields $n_N \sim 10^{18}\ cm^{-3}$.

For pnictides, the only lone-pair electrons are those in the lower s states. However, IVAP's become possible because of hybridization (a fourfold coordinated pnictide (P_4) can bond tetrahedrally via sp^3 orbitals). There is a slight additional cost of the s–p promotion energy and the relaxation energy, U_p, is likely to be smaller in the more rigid threefold-coordinated structure, so that relatively fewer IVAP's are present in pnictide as opposed to chalcogenide glasses. However, if the reaction

$$[6] \qquad 2P_4^{\circ} \rightarrow P_4^{+} + P_2^{-}$$

is still exothermic, IVAP's are the lowest-energy defect center.

In contrast, IVAP's are completely impossible for tetrahedrally bonded atoms, since fivefold coordination cannot occur with only s and p orbitals. This provides the explanation of why the chalcogenide and pnictide glasses have such strikingly different physical properties from the tetrahedral amorphous semiconductors.

Given the existence of about $10^{19}\ cm^{-3}$ IVAP's and $10^{18}\ cm^{-3}$ NVAP's in a typical chalcogenide glass, all of the experimental results summarized in Section II can be understood. For example, neither C_3^{+} or C_1^{-} contain any unpaired spins, so that the absence of any epr signal or Curie term in the magnetic susceptibility is clear. In addition, the existence of large densities of positively and negatively charged centers sets up strong internal electric fields which can account for the Urbach tail of the optical absorption. The photoluminescence is explained by the presence of the IVAP's, since the charged centers are efficient traps for photoexcited carriers and their spatial proximity then allows rapid luminescence. The difference between U and E_g is the observed Stokes shift.

Under nonequilibrium conditions, such as optical excitation at very low temperatures, the conversion from an IVAP to an NVAP is straightforward. Figure 4 shows how this process can occur for either chalcogenide or pnictide glasses. Upon photoexcitation and subsequent trapping of the free carriers by the charged centers, the IVAP's of Figs. 4(*a*) and 4(*c*) are transformed into the neutral, nonequilibrium configurations sketched in Figs. 4(*b*) and 4(*d*), respectively. In each case, only one bond shift occurs, at essentially no additional cost in energy. But now, since the trapped electron and hole are not sufficiently near one another, luminescence is not very probable. The centers such as C_1°, C_3°, and P_4° now have unpaired spins and thus

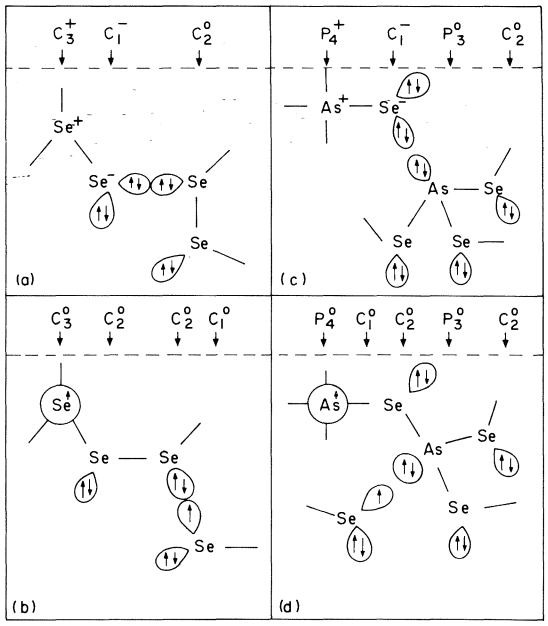

FIG. 4. Sketch of IVAP's and bond switching in Se and in As_2Se_3. C denotes a chalcogen and P denotes a pnictide atom. (*a*) An IVAP in Se. (*b*) Bond switching in photoexcited Se. (*c*) An IVAP in As_2Se_3. (*d*) Bond switching in photoexcited As_2Se_3 (from ref. 36).

yield epr signals. This further explains why the epr signal grows as the luminescence fatigues. Since only a small amount of atomic motion is involved in an NVAP → IVAP transition, the photoluminescence is restored at a relatively low annealing temperature. Even the photodarkening can be readily understood, by noting that non-radiative recombination in a material with localized optical absorption should yield intense local heating, leading to a larger density of frozen-in VAP's. In turn, the resulting increased internal electric field broadens the Urbach tail, thus darkening the sample.

Finally, we should note that the reversible electronic switching phenomena (38) which characterize chalcogenide glasses can also be a reflection of the equal densities of positively and negatively charged centers required by the VAP model (39).

IV. Effective Hubbard Model for Valence Alternation Pairs

In describing the electronic structure of localized states in a semiconductor, correlations are of vital importance and cannot be neglected. The simplest means for handling electronic correlations is the Hubbard model (40), in which only the Coulomb repulsion between electrons simultaneously localized on the same atom, U, is considered explicitly. When applying this model to localized states in the gap of a semiconductor resulting from a single type of defect, the narrow-band width limit is a good approximation (41). The Hamiltonian is then

$$[7] \qquad H = T_0 \sum_{i,\sigma} n_{i\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow}$$

where T_0 is the energy of a neutral (*i.e.* singly occupied) defect center, U is the effective electrostatic repulsion between two electrons simultaneously present in the vicinity of the same center, and $n_{i\sigma}$ is the operator which gives the number of electrons of spin σ localized on the defect i.

For the model discussed in Section III, because reaction 1 is exothermic, U is *negative*. Anderson (42) was the first to suggest that a negative U for chalcogenide glasses could account for the lack of any paramagnetism in these materials. Mott and co-workers (43, 44) showed how a single defect center, which they took as C_1, together with a negative U could also explain the photoluminescence results. We (45) previously showed that a negative U pins the Fermi energy as a function of both temperature and electronic density. The result for $kT \ll |U|$ is

$$[8] \qquad \varepsilon_F = T_0 - \tfrac{1}{2}|U| - \tfrac{1}{2} kT \ln (2n^{-1} - 1)$$

where n is the number of electrons present per defect center. A comparison of the motion of the Fermi energy with n for both positive and negative U is shown in Fig. 5. The corresponding densities of quasiparticle states are shown in Fig. 6.

In the valence-alternation-pair model of Section III, there are two types of defect pairs, IVAP's and NVAP's. (For simplicity, we are neglecting intermediate situations, when the pairs are near but not intimate.) This requires the introduction of two different values for U, with different possible densities. In the notation of Section III, the possible localized quasiparticle states are centered at $T_0 + M$, $T_0 - M$, $T_0 - |U| + M$, and $T_0 - |U| - M$. A straightforward calculation gives the results shown in Fig. 7. Only NVAP's are completely effective in pinning the Fermi energy. However, once the NVAP's are

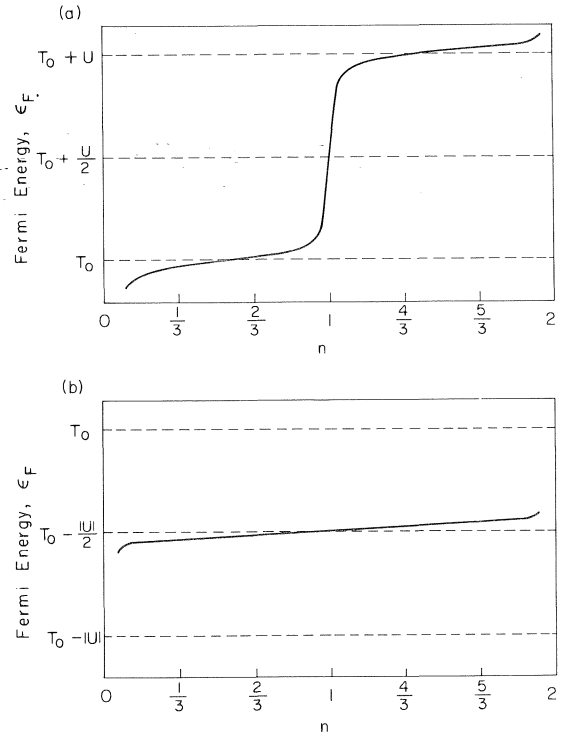

FIG. 5. Fermi energy, ε_F, as a function of localized electronic density, n, at a low but finite temperature. (*a*) $U > 0$. (*b*) $U < 0$.

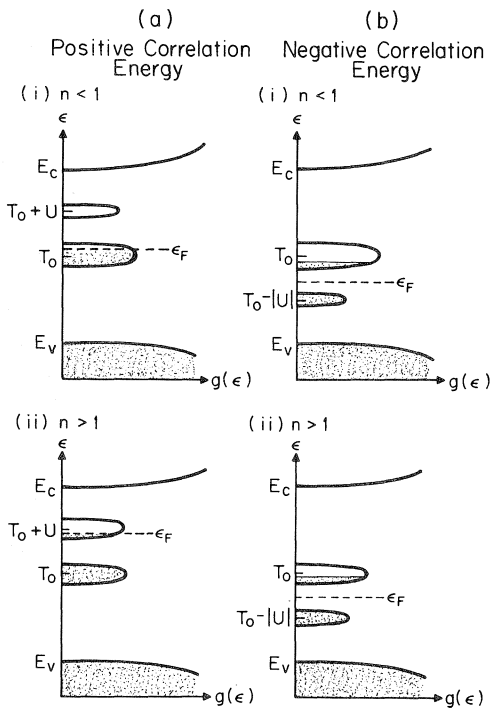

FIG. 6. Sketch of the density of electronic quasiparticle states for a semiconductor containing a single type of defect with effective correlation energy U either (*a*) positive or (*b*) negative. Occupied states at $T = 0$ are shaded.

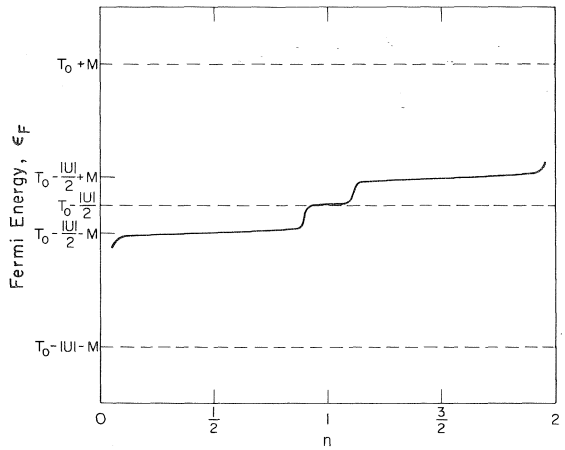

FIG. 7. Fermi energy, ε_F, as a function of localized electronic density, n, at a low but finite temperature, for a typical case where the density of IVAP's is 10 times that of NVAP's and $M = 0.1$ eV.

exhausted, as in a field-effect experiment, the considerably larger number of IVAP's pin ε_F to within a value $\pm M$ of its original value. If M is not too large, this quasi-pinning is quite effective in suppressing a sharp field effect, and, in any event, ε_F cannot be modulated nearly as much as it can when U is positive, as can be seen by contrasting Figs. 5(*a*) and 7. This explains the inability to dope chalcogenide glasses in the same way as doping of amorphous Si has proved possible. In addition, the field-effect experiments can be understood in the same way. Only after the NVAP's are saturated, will there be much modulation of the conductivity. Striking effects can be observed only after the much greater number of IVAP's are saturated.

When the effective correlation energy is negative, all transport coefficients have to be modified because of the unusual nature of the quasiparticle spectrum. In particular, the contribution to thermoelectric power from transport in the defect centers for $kT \ll |U|$ is

$$[9] \quad S = \frac{k}{e}\left[(n-1)\frac{|U|}{2kT} - \frac{1}{2}\ln\left(\frac{2}{n}-1\right)\right]$$

Thus, $S > 0$ for $n > 1$ and $S < 0$ for $n < 1$ at all temperatures. This is anomalous in the sense that for a positive effective correlation energy, S is negative for $0 < n < \frac{2}{3}$ and $1 < n < \frac{4}{3}$, while S is positive for $\frac{2}{3} < n < 1$ and $\frac{4}{3} < n < 2$ (46). Therefore, for the range $\frac{2}{3} < n < \frac{4}{3}$, S has the opposite sign from what might be expected. The Hall coefficient, R_H, for a square lattice, is negative for $n < 1$ and positive for $n > 1$, just as is the thermoelectric power. On the other hand, for a hexagonal lattice, Emin (47) has shown that anomalous signs exist for R_H, and a Hall-thermopower sign anomaly can occur. This result may be applicable to amorphous Si. However, for the chalcogenide glasses, it appears very likely that transport is predominantly band-like, in which case the pinned Fermi level required by the VAP model can account for the observed sign anomalies in a natural way (20).

V. Conclusions

The VAP model discussed in Section III makes use of the chemical nature of the atoms present in covalent amorphous semiconductors. It is simple to show that only glasses containing chalcogen or pnictide atoms are capable of exhibiting VAP's. However, when they are present, they are the most abundant defect in the material, and the fact that the centers exhibit an effective negative correlation energy leads to many unique physical properties. Among these

are the nearly complete absence of an unpaired-spin density, a pinned Fermi energy, and the lack of the ability to modulate the conductivity significantly by either doping or carrier injection. Furthermore, the model accounts for the lack of hopping conduction, the extensive Urbach edge in optical absorption, the photoluminescence and nonequilibrium epr experiments, the photostructural changes, and the switching properties of these materials. In no case are large structural rearrangements necessary for the creation of VAP's, and no large polarization energies are required beyond the electronic rearrangements implicit in the particular bond formations invoked.

Discussion

J. Noolandi: Can you estimate quantitatively the order of magnitude of the low energy states for sulphur?

D. Adler: The values of E_b, Δ, and V_c are larger for sulphur than for Se or Te. I would estimate that E_b is about 6 eV, Δ about 2.5 eV, and V_c about 1.5 eV, so that each NVAP has an energy of approximately 0.5–0.7 eV per atom above the ground state, depending on the polarization energy. For Se, E_b is about 4 eV, Δ about 1.5 eV, and V_c about 1.0 eV, reducing the additional energy per atom of an NVAP to

only 0.3–0.5 eV. For Te, these values are still further reduced. However, it is interesting to note that the glass transition temperature also decreases as we go from S to Te, so that the concentration of NVAP's may not vary much from material to material.

G. R. Freeman: You included elemental sulphur under the term chalcogenide. Does the term include both salts and the free elements of Group VI?

D. Adler: Current usage of the term 'chalcogenide glass' includes any amorphous alloy in which the major component is one or more of the chalcogen atoms, S, Se, and Te. For the purposes of this paper, I would add the requirement that the ground state of the chalcogen atoms in the glass be the twofold coordinated site, C_2°. This eliminates, for example, amorphous CdTe, which exhibits tetrahedral bonding.

M. Cutler: Why don't you allow for a Coulomb energy in the C_3^+ species? If the energy of C_3° is $-2E_b + \Delta$, it seems to me that the energy of C_3^+ would be decreased not only by $E_b + \Delta$ to give $-3E_b$ as you have it, but would also be increased by a Coulomb term to give $-3E_b$ + (Coulomb term) corresponding to the energy required to remove a charge from the neutral configuration.

D. Adler: This is a tricky point. We are really interested in the quasiparticle energy levels, in order to make contact with the one-electron density of states. In this case, the zero of energy must be set consistently. We are adopting a Hubbard model in which C_3^+ can be looked at as the ion core, and it is taken to be the zero of energy. The energy to add one electron, thus creating C_3°, is then T_0. this includes the bond energy and whatever Coulomb energy is involved. Adding a second electron, creating C_3^- then costs $T_0 + V_c$, where V_c is the *additional* Coulomb energy to place *two* electrons on the C_3^+ core. It is V_c which determines the Hubbard quasiparticle band separations. If we had broken T_0 or E_b into two components, say $E_b = E_b' + V'$, the individual terms would never be separable, and thus nothing would be gained from the decomposition except a more complicated notation. The important point is that the reaction $2C_3^\circ \rightarrow C_3^+ + C_3^-$ cost an energy V_c. This defines the separation of the quasiparticle bands.

J. Jortner: Once the chemical energetics works in your favor regarding charge separation, there are additional negative contributions to the correlation energy as V includes the polarization energy and the Coulomb interactions.

D. Adler: This is absolutely correct, and we have made it explicit in the paper. Unfortunately, I didn't have time to discuss it during my talk.

Bond equilibrium theory for Te-rich liquid Tl–Te alloys[1]

MELVIN CUTLER

Department of Physics, Oregon State University, Corvallis, OR, U.S.A. 97331

Received September 27, 1976

MELVIN CUTLER. Can. J. Chem. **55**, 1930 (1977).

Recent work has provided independent information about the behavior of the hole concentration c in Tl_xTe_{1-x} as a function of temperature T and composition x in the range $0.2 \leq x \leq 0.6$. This makes possible a critical reexamination of a molecular bond model for the structure of the alloy, in which holes are generated by broken Te—Te bonds. The earlier theory is revised to formulate an unrestricted independent bond model (ibm), for which the equations are simple and have obvious physical interpretations. This provides a good description of $c(T)$ but only a qualitatively correct $c(x)$. Using a Thomas–Fermi model for the screening interaction between holes and the acceptor ions, it is shown that the equilibrium constant can be expected to increase rapidly with c at large enough values. A modification in which the free energy of a dangling bond is decreased by proximity to a Tl—Te bond is found to significantly improve the result for $c(x)$. The thermochemical behavior is derived. The entropy of mixing is in fair agreement with experiment, but the enthalpy of mixing is grossly wrong. This reflects the neglect of intermolecular interactions in the theory, which, it seems, can easily account for the remaining discrepancies in the predicted behavior of c.

MELVIN CUTLER. Can. J. Chem. **55**, 1930 (1977).

Des travaux récents ont fourni des informations indépendantes concernant le comportement, en fonction de la température T et de la composition dans l'écart de x, $0.2 \leq x \leq 0.6$, de la concentration des trous c dans Tl_xTe_{1-x}. Ceci rend possible un réexamen critique du modèle de liaison moléculaire pour la structure de l'alliage dans lequel les trous sont générés par des liens Te—Te qui sont brisés. La théorie antérieure a été revisée de façon à formuler un modèle de liaison indépendante sans restrictions (ibm) pour lequel les équations sont simples et ont des interprétations physiques évidentes. Ceci fournit une bonne description de $c(T)$ mais seulement une valeur qualitativement correcte de $c(x)$. Utilisant un modèle Thomas–Fermi pour l'interaction d'écran entre les trous et les ions accepteurs, on montre que l'on peut s'attendre à ce que la constante d'équilibre augmente rapidement avec c pour des valeurs qui seront suffisamment grandes. On a trouvé qu'une modification dans laquelle l'énergie libre d'un lien suspendu décroît à la proximité d'un lien Tl—Te améliore d'une façon sensible le résultat pour $c(x)$. On en dérive le comportement thermochimique. L'entropie de mélange est en bon accord avec l'expérience mais l'enthalpie de mélange est très mauvaise. Ceci est un reflet du fait que l'on néglige les interactions intermoléculaires dans la théorie; il semble que ces interactions pourraient facilement tenir compte des disparités qui restent lorsque l'on prédit le comportement de c.

[Traduit par le journal]

Introduction

In the tellurium-rich range of compositions, the electronic properties of Tl–Te alloys change strongly with temperature T, as they do also in a number of other liquid chalcogenide alloys. Since the values of the electrical conductivity σ and the thermopower S indicate a semimetallic situation with the Fermi energy E_f within the valence band, the classical type of explanation for semiconductor behavior, *i.e.*, electronic excitations from states within or across a band gap, is not applicable, and the proper explanation is a question of broad interest. A molecular bonding model has been proposed for Tl_xTe_{1-x} with $x<2/3$, in which there are chain molecules of the form Tl—$(Te)_n$—Tl with variable n, and the thermal changes result from broken Te—Te bonds (refs. 1, 2, referred to, respectively, as I, II in the following text). The dangling bonds are assumed to give rise to negatively charged acceptor ions plus holes in the valence band. Critical evaluation of this model has been hampered by the absence of independent information about the structure of the valence band. This difficulty has been removed by a recent study of the thermoelectric behavior (3), in which it was shown that a rigid band model for the density of states is valid in the composition range $0.2 \lesssim x \lesssim 0.6$. Consequently it has been

[1]Work partially supported by a grant from the National Science Foundation.

possible to determine the hole concentration c^* (with an unknown constant factor) from experimental data on σ as a function of x and T in the range $x > 0.20$. This result is shown in Fig. 1.

The purpose of the present paper is to re-examine critically the molecular bonding theory introduced in II. To do this, a simplified version called the independent bond model (ibm) is derived whose equations have direct physical interpretations. The ibm is shown to reproduce the main features of the experimental results, but there are appreciable discrepancies. Complicating factors are considered, including the effect of the dangling bond concentration on the dangling bond energy (through screening), and effects of second order intramolecular and intermolecular interactions. These factors, or some combination of them, seem to be able to account for the discrepancies.

Effect of the Hole Concentration on the Energy of the Dangling Bond

The energy of formation of a dangling bond E_d can be separated into the energy E_b to break the bond (one half the energy per bond) to form a noninteracting dangling bond atom, and the energy C which results from the interaction with the valence band electrons to form a screened Te^- ion. At low concentrations, C is expected to be positive, and the extra electron is in a localized state above the band edge as shown in Fig. 2*a*. In this situation, Debye screening occurs, for which a satisfactory theory has been derived in the context of crystalline semiconductors (4). In the present problem, C is expected to be negative because of the high density of dangling bonds ($>10^{20}$ cm^{-3}), and the acceptor states are fully charged virtual impurity states below the Fermi energy as indicated in Fig. 2*b*. The negative value of C is caused by the kinetic energy necessary to keep the screening charge (holes) within the required volume. The screening particles obey Fermi–Dirac statistics, and because of the small impurity density (compared to typical metals), the screening is strongly nonlinear (5). The electronic configuration can be represented by a negative charge at the center of a spherically symmetrical 'Wigner-Seitz' (WS) cell of radius r_0 whose inverse volume is the average volume per acceptor state cN_a, where c is the hole concentration normalized to the atomic density $N_a(=2.7 \times 10^{22}$ cm$^{-3})$. The WS cell contains a distribution of positive charge (holes in the valence band) whose integrated value exactly cancels the negative charge at the center. If $\langle T \rangle$ is the average kinetic energy of the hole distribution in the WS cell and $\langle V \rangle$ is the average potential energy, $C = -\langle T \rangle - \langle V \rangle$.

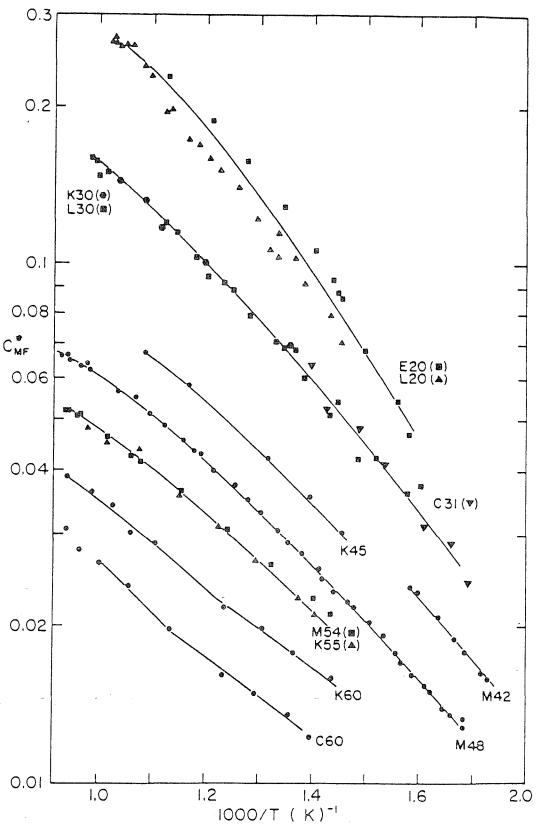

FIG. 1. Experimentally derived curves for the hole concentration c^* (to an unknown constant factor) *vs.* temperature for various compositions, indicated in at.% thallium (from ref. 3).

Useful physical insight is provided by a very rough model in which $\langle T \rangle$ is taken as the kinetic energy of a uniform free electron gas with density cN_a, and $\langle V \rangle$ is derived from a uniform positive charge distribution in the WS sphere with a dielectric constant κ. This gives

$$[1] \quad \langle T+V \rangle \cong (3\hbar^2/10m)(9\pi/4)^{2/3} r_0^{-2} - (3e^2/10\kappa) r_0^{-1}$$

As illustrated in Fig. 2*c*, this model predicts that $\langle V \rangle$ dominates at large r_0, but as r_0 decreases, the positive $\langle T \rangle$ term cancels the negative $\langle V \rangle$ term and becomes positive, causing an abrupt rise in $\langle T+V \rangle$.

The Thomas–Fermi model, which provides for

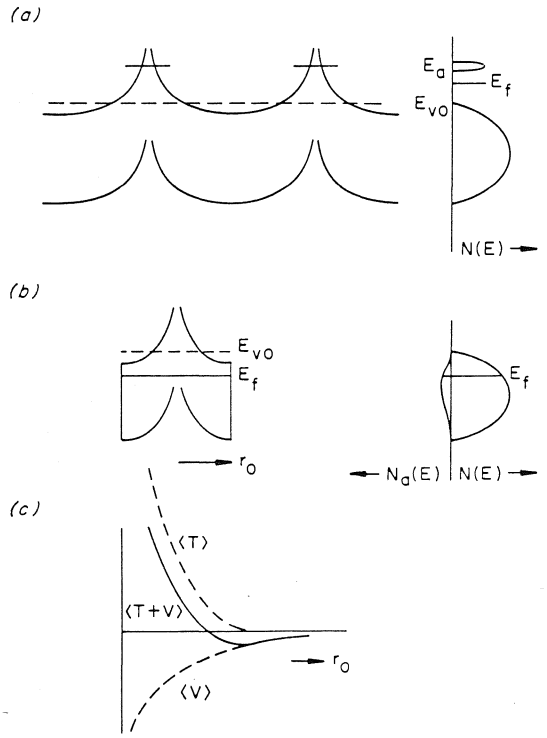

FIG. 2. Electronic behavior of acceptor impurity states due to dangling bonds. (*a*) Low hole densities. The spatial dependence of the band potential is shown on the left and the resulting density of states is on the right. The curved lines represent the local potentials of the top and bottom states of the valence band as affected by dangling bond atoms. Discrete acceptor states (E_a) are formed above the valence band edge E_{vo} (dashed line). (*b*) High hole densities. The charge and potential distribution is approximated by the Thomas–Fermi model, illustrated on the left, and the impurity state is a virtual level in the band, illustrated on the right. (*c*) Qualitative behavior of the kinetic energy $\langle T \rangle$ and the potential energy $\langle V \rangle$ and their sum as a function of r_0.

a self-consistent distribution of the screening charge, yields a better estimate for $\langle T+V \rangle$. Calculations made in previous work (5) were used to find solutions which are shown in Fig. 3, assuming $\kappa = 1$ and $\kappa = 3$. Since the equilibrium constant k_0 for broken bonds is proportional to $\exp(-C/kT)$, changes in C which are comparable to $kT(\sim 0.06$ eV) will cause large changes in k_0. The result in Fig. 3 indicates that this will occur at large enough values of c, and beyond this point k_0 will decrease rapidly with increasing c. Also, the range of c in which this occurs is sensitive to the choice of κ. The Thomas–Fermi model is still a relatively crude model since it neglects correlation and exchange

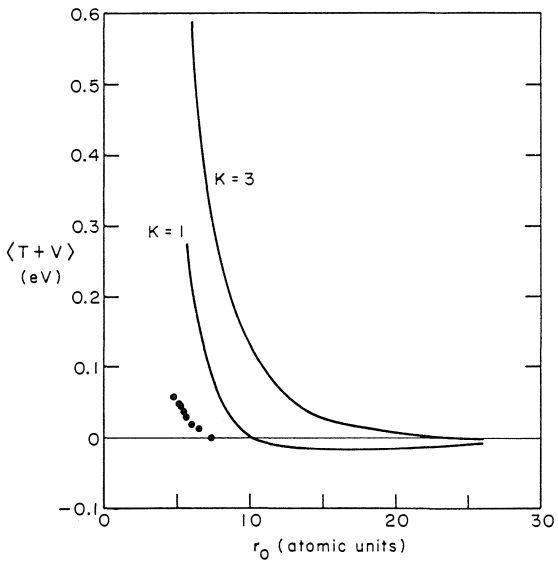

FIG. 3. Thomas–Fermi solutions for $\langle T+V \rangle$ *vs.* r_0 for $\kappa = 1$ and $\kappa = 3$. The points indicate the values of $-\Delta E_d$ required to reconcile the ibm and experimental curves for $c(x)$ in Fig. 4.

effects and it applies an electron gas approach for a relatively narrow valence band. Probably more important, the dielectric screening is treated in a very simplistic way in a range where complicated changes occur in that phenomenon. $\kappa \sim 1$ when E_f is well below the valence band edge (small r_0), but it becomes large when E_f approaches the valence band edge (large r_0) so that the true situation might be better represented by a combination of the curves shown in Fig. 2.

Bond Equilibrium Models

The Independent Bond Model

In II, equations of equilibrium were derived for a model in which there were certain constraints on what would otherwise be described as an independent bond model. The final relations are considerably simplified and their physical implications are clarified when these restrictions are removed. In what follows, parts of the original theory are repeated which are sufficient to indicate the basic assumptions and to define parameters which enter the discussion.

Three types of molecular species are assumed to be present: Tl—$(Te)_n$—Tl with concentration (per atom) a_n, Tl—$(Te)_n^-$ with concentration b_n, and $^-(Te)_n^-$ with concentration c_n. A basic assumption of the ibm is that aside from possible symmetry factors (2 or 1/2), the equilibrium con-

stant for the reaction

[2] $\text{X—Te—Te—Y} \overset{k}{=} \text{X—Te}^- + \text{Y—Te}^-$

is independent of whether X and Y is a dangling bond or any of the possible molecular groups. The second assumption is that the equilibrium constant K in

[3] $\frac{1}{2}\,\text{Te}_2 + \text{X—(Te)}_{n-1}\text{—Y} \overset{K}{=} \text{X—(Te)}_n\text{—Y}$

is also independent of X or Y, or the value of n. This immediately leads to

[4] $$a_n/a_{n-1} = b_n/b_{n-1} = c_n/c_{n-1} = y$$

where y is the product of K and the square root of the activity of Te_2. For most purposes, it is useful to think of y as a basic parameter instead of K since its value is ultimately determined from the tellurium concentration.

Application of [2] to some of the possible reactions leads to the results

[5] $$a_n = Ly^{n-1}$$
$$b_n = (2k_0Ly)^{1/2}y^{n-1}$$
$$c_n = (k_0y/2)y^{n-1}$$

where L is the concentration of Tl_2Te, and k_0 is the value of k when none of the species in [2] are symmetrical. (We are ignoring the distinction between activities and concentrations.) The constraints $x = \sum_n (2a_n + b_n)$ and $1 - x = \sum_n n \times (a_n + b_n + c_n)$ effectively determine L and y, respectively, and the total concentration of dangling bonds is $c = \sum_n (b_n + 2c_n)$, so that one obtains

[6] $$x = (2L + \sqrt{2k_0Ly})/(1-y)$$

[7] $$1-x = (\sqrt{L} + \sqrt{k_0y/2})^2/(1-y)^2$$

[8] $$c = (\sqrt{2k_0Ly} + k_0y)/(1-y)$$

From this, it is easy to derive the relations

[9] $$2k_0 = c^2/(1-\tfrac{3}{2}x - (c/2))$$

[10] $$y = 1 - (x+c)/2(1-x)$$

[11] $$L = x^2/2(1-x)$$

Since the concentration of Te—Te bonds is given by $1 - \frac{3}{2}x - (c/2)$, one can see that [9] is an expression of the law of mass action for the reaction

[12] $\text{(Te—Te bond)} \overset{2k_0}{=} \text{2(dangling bond)}$

Equation 9 is a simple quadratic equation in c which can be solved as a function of k_0 (or T) and x. Knowing this solution, [10] can be solved for y. It is interesting to note from [10] that y is equal to the fraction of Te—Te half-bonds which are neither tied to Tl atoms nor are dangling. It is also worth noting from [11] that the concentration of Tl_2Te is independent of temperature.

Comparison with Experiment

Using [8], ln c has been plotted in Fig. 4 for various values of x as a function of θ, which is defined by

[13] $$\theta = (E_d - TS_d)/kT = -\tfrac{1}{2}\ln k_0$$

These curves should correspond to those in Fig. 1 (aside from a vertical displacement determined by c^*/c) upon a linear transformation of the $1/T$ scale which fixes the values of the enthalpy (E_d) and entropy (S_d) of formation of a dangling bond. (No distinction is made here between the enthalpy and the internal energy.) As in Fig. 1, the curves in Fig. 4 are very nearly parallel,

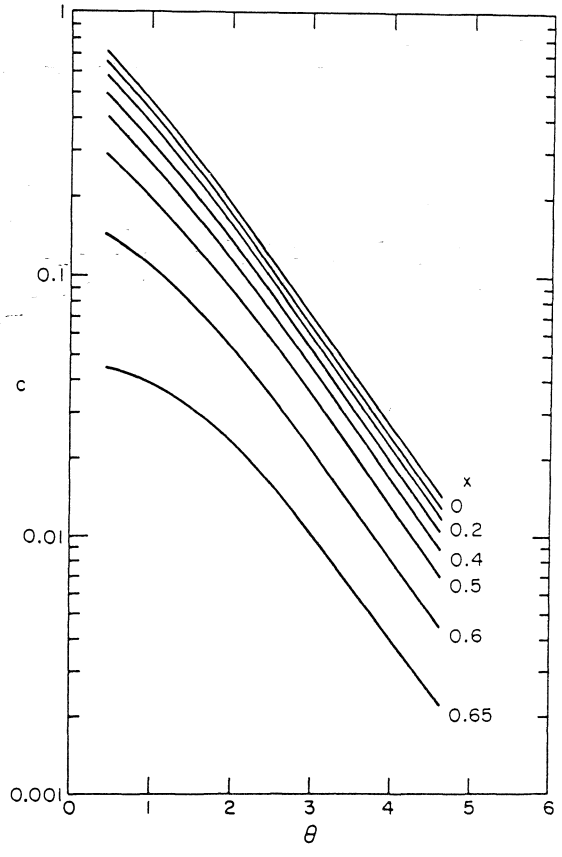

FIG. 4. Independent bond model solutions for ln c *vs.* θ for various values of x.

which indicates that values of E_d and S_d chosen to fit ln c *vs.* T^{-1} at one composition will be good at other compositions. (Actually, the experimental curves at $x \lesssim 0.30$ have a small but appreciable increase in slope not found in Fig. 4, which will be referred to later.)

A match of the theoretical and experimental curves for ln c *vs.* T^{-1} at $x \cong 0.5$ yields a very good fit (within experimental error) with $E_d = 0.23$ eV and $S_d = 2.0k$. These values don't differ much from the ones obtained previously in I. In Fig. 5, the experimental isotherm for ln c *vs.* x (marked exp) is compared with the theoretical curve (marked ibm), using the value $\theta = 1.39$ which corresponds to the experimental temperature 800 K. It is seen that there is only qualitative agreement, and the ibm curve, matched in the vicinity of $x = 0.5$ by setting $c/c^* = 3.9$, is $\sim 2x$ too small at $x = 0.20$.

The ibm is an extremely simplified model for molecular bonding, and one may ask whether reasonable modifications can improve the agreement with experiment. One reasonable modification is to allow the free energy of the dangling bond to be changed by proximity to a Te—Tl bond. This is done most simply by introducing a factor β^{-1} into the expression for b_1 in [5], which corresponds to increasing the free energy of the dangling bond in Tl—Te^- by kT ln β. This adds a term $(\beta^{-1} - 1)(2k_0yL)^{1/2}$ to the right side in [6], [7], and [8], which results in a much more complicated equation in place of [9]. If $\beta \ll 1$ over the range of temperature, the resulting curves for ln c *vs.* θ do not change much in slope, but the dependence of ln c on x is modified so that c decreases more strongly with x. In Fig. 5, the curve marked mibm was calculated with $E_d = 0.23$ eV, $S_d = 2.9k$, $E_{dl} = 0.46$ eV and $S_{dl} = -5.9\,k$, (the subscript l refers to dangling bonds on Tl—Te^- molecules), and it was fitted to the experimental curve by $c/c^* = 4.9$. It is seen that the discrepancy at low x is very much reduced.

A decrease in E_d at large c due to a change in C could also alter the shape of ln c *vs.* x in the right direction. The difference in the ibm and exp curves in Fig. 5 can be used to calculate the required change ΔE_d *vs.* c, and this result, plotted as $-\Delta E_d$ *vs.* r_0 is shown by the points in Fig. 3. It rises abruptly with decreasing r_0 as expected theoretically. But the magnitude of $-\Delta E_d$ becomes comparable to kT, and when this change is introduced into the predicted curve for

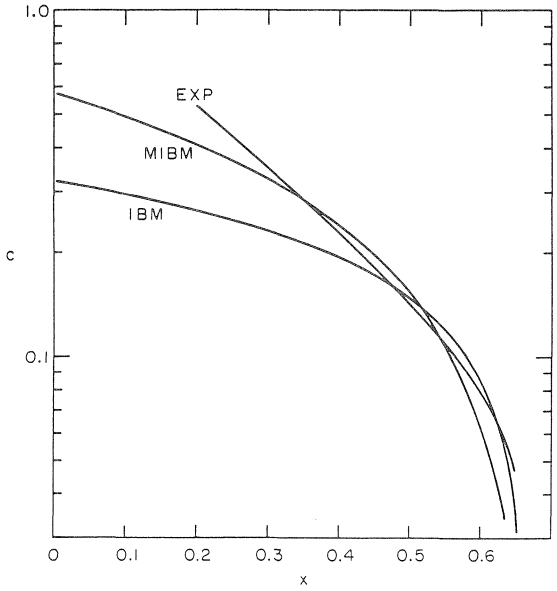

FIG. 5. Comparison of theoretical curves (ibm and mibm) for $c(x)$ with the experimental isotherm (exp).

ln c *vs.* T^{-1}, there is serious disagreement with experiment for $x = 0.30$ or 0.20. The theoretical curves rise much too fast with temperature. On the other hand the much smaller difference between the mibm and exp curves in Fig. 5 leads to much smaller values of $-\Delta E$, which actually improves the agreement with experiment for ln c *vs.* T^{-1} at $x = 0.20$.

Thermochemical Behavior

It is possible to derive the enthalpy and entropy of mixing from the ibm, and comparison with experimental results illustrates another limitation of the ibm. It will be convenient to use the entropy as ΔS_m^*, enthalpy ΔH_m^*, and Gibbs free energy ΔG_m^* of mixing of a pseudobinary alloy Te + Tl_2Te, defined by relations of the type

$$[14] \quad \Delta G_m^*(x) = G(x) - (1 - \tfrac{3}{2}x)G(0) - \tfrac{3}{2}xG(2/3)$$

The Gibbs potential $G(x)$ at composition x can be expressed in terms of the chemical potentials $\mu_i(x)$ at that composition, where i = Tl_2Te or Te, with the result

$$[15] \quad \Delta G_m^*(x) = (1 - \tfrac{3}{2}x)[\mu_{Te}(x) - \mu_{Te}(0)] + \frac{x}{2}[\mu_{Tl_2Te}(x) - \mu_{Tl_2Te}(\tfrac{2}{3})]$$

The ibm gives

[16] $\mu_{Te}(x) - \mu_{Te}(0) = RT \ln (y/y_0)$

where y_0 is evaluated at $x = 0$, and

[17] $\mu_{Tl_2Te}(x) - \mu_{Tl_2Te}(2/3) = RT \ln (L/L_0)$

where L_0 is evaluated at $x = 2/3$.

Equations 14–16 yield ΔG_m^* in terms of y and L, and ΔS_m^* and ΔH_m^* are calculated from ΔG_m^* and its temperature derivative. The results are shown in Fig. 6. The solid lines are the ibm curves and the points are from the experimental data of Nakamura and Shimoji (6). The calculated ibm values of ΔH_m^* are too small in magnitude to be distinguishable from the horizontal axis. The reason for this gross discrepancy is immediately apparent. The ibm ignores all interaction energies except those in breaking Te—Te bonds, and this is small compared to the enthalpy of mixing ($\sim RT$) caused by secondary nonbonding interactions. The result for ΔS_m^* is not so bad because the configurational entropy is taken into account, and the neglected contribution from secondary interactions is relatively small. The dashed curve in Fig. 6 represents ΔS_m^* calculated by the Flory formula (6) which also takes into account only the configurational entropy, assuming that Tl_2Te and Te are the only molecular species, and it is seen that it resembles the ibm result. The difference between theory and experiment for ΔG_m^* is simply the combined effect of the enthalpy and entropy contributions.

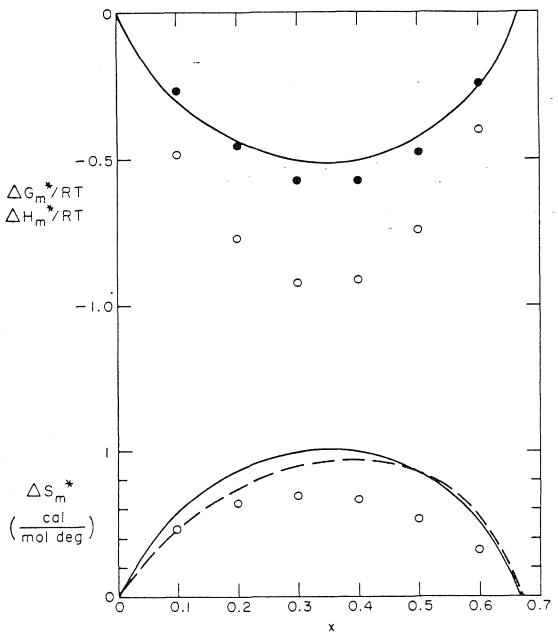

FIG. 6. Comparison of ibm theory (solid line) and experiment (open circles) for ΔG_m^* and ΔS_m^* for the pseudobinary mixture Tl_2Te + Te at 600°C. The closed circles are experimental data for ΔH_m^*. The dashed line is the theoretical curve for the ideal entropy of mixing, described by equations in ref. 6.

The neglect of intermolecular interactions undoubtedly causes an error in the calculation of $c(x,T)$. But since $E_d - TS_d$ depends on the difference between these interactions in bonded and dangling bond Te atoms, the error is much smaller than in ΔG_m^*. This effect is of course formally taken into account in chemical theory by the activity coefficients, and the discrepancies between the ibm (or mibm) and experiment seem to be well within the range to be expected from the usual variation of the activity coefficients in concentrated solutions. It is worth noting, however, that the alteration of $c(x)$ must occur largely through changes in S_d, since changes in E_d of the required magnitude would cause excessively large changes in the dependence of ln c on T^{-1}, as noted earlier.

Discussion

In II, it was noted that interactions between neighboring dangling bonds can be expected to be very strong in molecules such as $^-Te^-$ and $^-(Te)_2{}^-$, and in an effort to take these into account, constraints were introduced which led to much more complicated equations. These species play a significant role only at high T and when x is very small, so that their neglect is of little consequence in the experimental range considered here. For compositions approaching pure Te, there is evidence that configurations in which Te atoms have three bonds instead of two play an important role (7, 8). Since the ibm takes into account only twofold bonding, efforts to improve it in the range of small x are inappropriate.

A proximity effect in which $E_{dl} - E_d \gg kT$ seems to be consistent with the physical situation, since a dangling bond in a Tl—Te^- molecule places a negative charge onto a Te atom which has an extra negative charge due to the polar Te—Tl bond. Higher order proximity effects also seem to be reasonable possibilities, but their introduction into the model seems premature at the present time.

In summary, a simplified model for bond equilibrium has been considered together with

the complications which can be expected from changes in the equilibrium constant due to the electronic energy of the acceptor state, proximity of the dangling bond to Te—Tl bonds, and intermolecular interactions. The ibm provides a good explanation for the effect of temperature on c and a qualitatively correct description for the effect of composition. The deviations from experiment seem to be well within the range to be expected from the complicating factors. We therefore conclude that a molecular bond theory of the type described can account satisfactorily for the observed behavior of Tl—Te alloys in the range $0.2 < x < 0.6$, but the detailed form of it cannot as yet be ascertained.

Discussion

J. C. Thompson: What is the role of the threefold coordination of Te postulated by Adler for the chalcogenide glasses in the previous paper?

M. Cutler: Threefold bonding configurations are a possible species that can form once Te—Te bonds are broken, and they apparently occur in pure tellurium. In a recently published paper (8), I've presented arguments for believing that threefold configurations are inhibited at lower electrical conductivities because they have a large Coulomb energy, and this situation applies in Tl–Te alloys in contrast to tellurium. There are indications that the change to threefold bonding occurs between 20 and 0% thallium but the question is an open one, and needs further investigation.

An improved model of the localized electron in polar fluids

NEIL R. KESTNER
Chemistry Department, Louisiana State University, Baton Rouge, LA, U.S.A. 70803

Received September 27, 1976

NEIL R. KESTNER. Can. J. Chem. **55**, 1937 (1977).

A new model for the long range electron solvent interaction experienced by a trapped electron in a polar fluid is presented. It is an extension and modification of the work of Iguchi except that it includes a cutoff beyond which the orienting ability of the trapped electron is not strong enough to overcome other forces between the polar molecules. This potential is of finite range and supports only one bound *s* and *p* state, in contrast to the usual polaron form.

NEIL R. KESTNER. Can. J. Chem. **55**, 1937 (1977).

On présente un nouveau modèle pour l'interaction solvant électron à longue distance qui est ressentie par un électron piégé dans un liquide polaire. C'est une extension et une modification du travail d'Iguchi à l'exception de l'introduction d'une distance au-delà de laquelle la possibilité d'orientation de l'électron piégé n'est pas suffisamment forte pour surmonter d'autres forces entre les molécules polaires. Ce potentiel a des limites finies et ne supporte qu'un seul état *s* et *p* lié, ce qui est en opposition avec la forme usuelle du polaron.

[Traduit par le journal]

Introduction

In many recent papers the Copeland, Kestner, Jortner (CKS) model (1) as well as the semi-continuum model of Fueki and Kevan (see, for example ref. 2) has been observed to be incomplete especially as regards line shape and line width of the absorption spectrum of the solvated electron. For discussions on these points, see ref. 3. As Kestner and Logan (4) have pointed out the long range polaron potential in these models leads to an infinite number of bound states at quite high energy relative to the first excited state. Much experimental data such as photoelectron emission spectra suggest that the continuum is quite close to the first allowed transition (5). In this short paper we suggest a better, more molecular view of the long range electron solvent interaction which is short range and supports few bound states.

Model and Results

As stated earlier the long range electron solvent interaction used at present in almost all of the model calculations including the *a priori* work of Newton (6) becomes coulombic at large distances from the cavity center. We neglect in our discussion the obvious role of V_0, the energy of the quasi-free electron (see later comments). This term requires further study but it is not a major point of this paper. A coulombic potential means that an infinite number of bound states are supported by the potential. The estimates we have made of their location (4) and related experimental data mentioned earlier indicate that this cannot be reconciled with experimental data. Furthermore the polaron type of interaction assumes a continuum solid with no microscopic structure. Therefore our major goal must be to introduce a more molecular, microscopic approach to this electron solvent interaction.

In principle this could be done via a dielectric function approach (7) and the necessary formalism for this has been developed by Logan (8) but the dielectric function appropriate to a real polar liquid is not available even from molecular dynamics calculations in sufficient detail. Nevertheless we are continuing to explore the use of the dielectric function calculated by Lovett and Stillinger (9).

We now believe that we have a molecular model for the long range electron–solvent interaction which contains all of the essential microscopic ingredients. Basically our model is an extension and revision of the work of Iguchi (10). That work contained one major flaw and several weak points. The major flaw was in not correcting the electric field at a point far from the cavity for the standard dielectric constant screening, a fact observed previously by Gaathon (11) but never published. The weak points are its insistence on a continuum fluid at all distances from the cavity and its neglect of the importance of hydrogen bonding. The Iguchi model is

simple; it is simply the interaction of a charge distribution with a continuum dipolar fluid whose dipolar orientation is subject to thermal fluctuations via Langevin's formula. Each layer at a different distance from the cavity acts independently. The total potential at radius r is that due to all orientations beyond this.

We propose to use this model only beyond the first coordination shells. Furthermore we will cut off the interaction when the electric field is so weak that it does not have enough energy to break at least one hydrogen bond and therefore is too weak to orient the molecules. This latter point brings our thinking in line with the ideas of various people, in particular Funabashi (12). While we have arrived at that point from a totally different approach, the major philosophy is in agreement. Specifically this means that our long range potential is similar to formula [4] of Iguchi's 1968 paper (10) *i.e.*,

$$V(r)_{LR} = 4\Pi e\mu_0 n \int_r^{\infty} \left[\coth\left(\frac{\Sigma}{r^2}\right) - \frac{r^2}{\Sigma}\right] \times H\left(\frac{\Sigma kT}{r^2} - h\right) dr \quad \text{for } r > r_c$$

where μ_0 is the dipole moment of the solvent molecule, n is the number density of the solvent, r_c is the start of the continuum. The function in the integrand is

$$\Sigma = \mu_0 C_s(r)/(D_s kT)$$

where $C_s(r)$ is the charge enclosed within the radius r, and D_s is the static dielectric constant for liquid ammonia. Using a simple constant short range potential our model is (in atomic units)

$$\begin{aligned} V &= -0.039985 + V_{LR}(R = 4.25a_0) && r < 4.25a_0 \\ &= V_{LR}(R = 4.25a_0) && 4.25a_0 \leq r \leq 6.25a_0 \\ &= V_{LR}(r) && r > 6.25a_0 \end{aligned}$$

where we have set $C_s(r)$ equal to 1.0 for simplicity. The detailed potential is plotted in Fig. 1. In contrast, the potential using the polaron form of V_{LR} is $-0.523/r$ (Fig. 2). For liquid ammonia the value of Σ is 94 in atomic units, and h was selected as 0.2 kcal/mol.

In our calculations using numerical finite difference techniques we have found but one ground and one excited p-type state. The location of the states is indicated in Fig. 1. That we

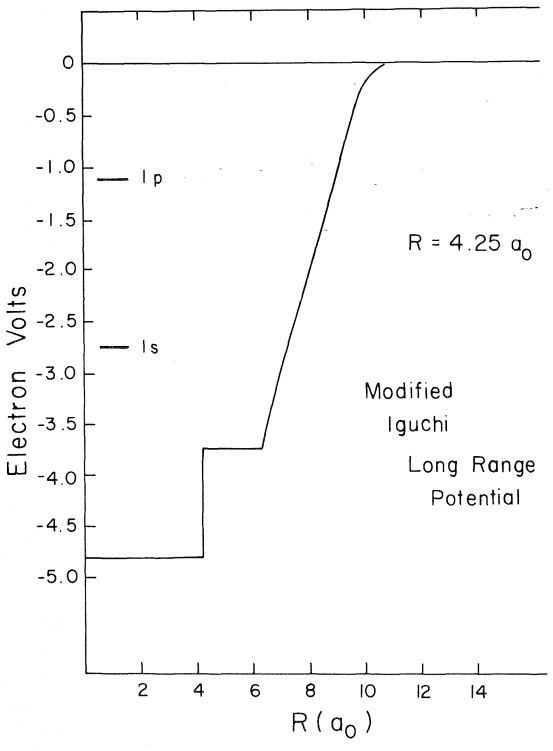

FIG. 1. Modified Iguchi long range potential for liquid ammonia. The two bound states are shown by solid lines on the left-hand side for this potential.

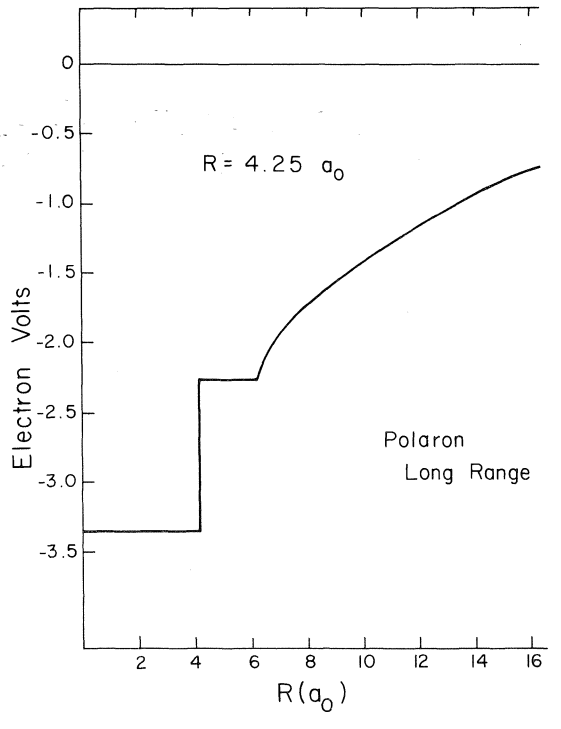

FIG. 2. Typical polaron long range potential for liquid ammonia. This potential has an infinite number of bound states.

only find one state of each type is in agreement with the rules for the number of states in a spherical box. In contrast, the polaron form would yield an infinite number of states. If V_0 were -0.5 eV in the case of ammonia, the p-type excited state would be near the ionization limit and one would expect a large contribution from the bound continuum transition in the observed line shape. Its energy should also be close to that of the bound–bound transition. The energy of the bound–bound transition is not greatly modified from our earlier model. In general a moderately negative V_0 value would bring the results of the new potential more in line with the polaron results with the only major difference being a loss of the higher excited states. We expect even less variation when the full potential is used with the proper charge enclosed, C_s. Such calculations are now underway along with the incorporation of this potential into the complete model for the calculation of the properties of electrons in fluids.

Discussion

P. Delahay: I would like to expand briefly on the evidence from photoelectron emission mentioned by Kestner with the help of Fig. 1. We have plotted the cross section for photoionization of solvated electrons in hexamethylphosphoric triamide as a function of photon energy. This result was published two years ago (J. Chem. Phys. 1974) and was discussed at the Colloque Weyl at Michigan State University last year. The main point I made at that time was that this spectrum could not be explained if one assumed a long-range Coulombic potential. I suggested that a square well, quite crudely, should be a better approximation, and I make the comparison with deuteron photodisintegration. It is interesting to note that you have come around to our point of view.

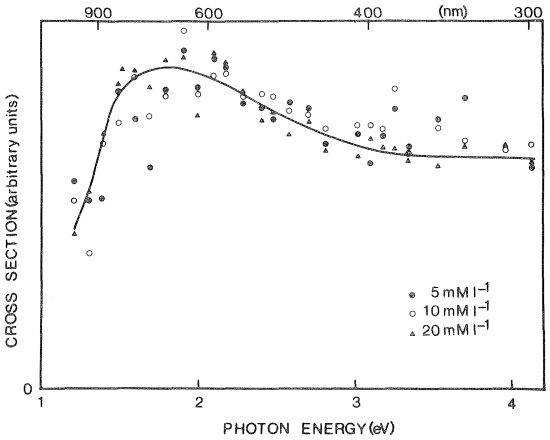

FIG. 1. Photoionization cross section of solvated electrons against photon energy for three sodium metal concentrations in hexamethylphosphoric triamide at approximately 10°C. Ordinates for the 5, 10, and 20 mM ℓ^{-1} solutions normalized in the ratios 1:1.57:2.63. Reprinted with permission from the Journal of Chemical Physics H. Aulich, L. Nemec, and P. Delahay. J. Chem. Phys. **61**, 4235 (1974). Copyright by the American Institute of Physics.

K. Funabashi: I would like to ask Professor Kestner about the possible role of *non-spherical* shape of trap potential on the line-shape of absorption spectrum of trapped electrons.

N. R. Kestner: In earlier work, especially the J. Phys. Chem. paper of 1975, we found that the role of nonspherical vibrations contributed little to the line shape. The role of permanent distortions was investigated somewhat in the same paper and found to contribute little to the line shape. However, this is a subject which should be given further attention.

J. R. Miller: In the glassy state we assume that only the polar molecules nearest the electron, which feel a large electric field strength, can reorient. Yet the absorption spectra of trapped electrons in polar glasses at 77 K are very similar to the spectra of solvated electrons in the same polar liquids (in alcohols and aqueous systems for example). This similarity may be explained by your assertion that a screened potential must be used so that polarization beyond the first or second coordination layer is only weakly operative even in the liquid.

N. R. Kestner: I agree, but one must also consider the effects of the smaller shifts in V_0 values.

A semicontinuum model with a structured first solvation shell for excess electrons in liquid and glassy alkanes

TOYOAKI KIMURA AND KENJI FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

AND

P. A. NARAYANA AND LARRY KEVAN

Department of Chemistry, Wayne State University, Detroit, MI, U.S.A. 48202

Received September 27, 1976

TOYOAKI KIMURA, KENJI FUEKI, P. A. NARAYANA, and LARRY KEVAN. Can. J. Chem. **55**, 1940 (1977).

The microdipole model for excess electrons in alkanes seems inconsistent with recent electron spin echo data. We develop a new model for electron binding in alkanes based on a semicontinuum potential framework in which the electron-polarizability energy is dependent on molecular structure by considering the electron interaction with the polarizability of each C—C bond of the first solvation shell molecules rather than with point molecules. In addition we incorporate the effect of hydrogen–hydrogen repulsion between first solvation shell molecules. This model accounts well for the variety of experimental data known for localized electrons in 3-methylpentane glass at 77 K and for electron localization or nonlocalization in various liquid alkanes consistent with electron mobility data.

TOYOAKI KIMURA, KENJI FUEKI, P. A. NARAYANA et LARRY KEVAN. Can. J. Chem. **55**, 1940 (1977).

Le modèle de microdipole pour les électrons en excès dans les alcanes ne semble pas en accord avec les données récentes obtenues par la méthode de spin écho d'électrons. On a développé un nouveau modèle pour l'attachement d'un électron dans les alcanes qui est basé sur un potentiel semi-continu à l'intérieur duquel l'énergie de polarisabilité d'un électron est reliée avec la structure moléculaire en considérant l'interaction d'un électron avec la polarisibilité de chaque lien C—C des molécules de la première couche de solvatation plutôt que des molécules ponctuelles. De plus, on a incorporé l'effet de la répulsion hydrogène–hydrogène entre les molécules de la première couche de solvatation. Ce modèle tient bien compte des disparités dans les données expérimentales qui sont connues pour les électrons localisés dans des verres de méthyl-3 heptane à 77 K et pour la localisation et la non-localisation d'électrons dans divers alcanes liquides en accord avec les données de mobilité d'électron.

[Traduit par le journal]

Introduction

Excess electron localization in many liquid and glassy alkanes is demonstrable experimentally from mobility, optical absorption, and electron spin resonance (esr) studies (1), but the theoretical understanding of this phenomenon is still quite imperfect. When an electron is initially injected into a condensed phase alkane by ionizing radiation or by photoionization of a suitable solute it becomes localized if its initial interaction energy E_t^i (transient) is more negative than V_0, the conduction state energy of the electron in the alkane. When an electron is initially localized it has not necessarily reached an equilibrium configuration with the solvent molecules. This is attained through solvation in which the electron–solvent interaction causes rearrangement of the solvent molecules around an electron to reach an equilibrium configuration with localization energy E_t.

Electron solvation in a variety of polar matrices including water, alcohol, ether, and amines has been successfully treated theoretically by a semicontinuum model (2) which gives semiquantitative agreement with experimental values of the optical transition energy, the photoionization threshold, the number of first solvation shell molecules, and equilibrium cavity sizes although it does not account for the optical absorption linewidth. The semicontinuum model has been particularly useful in accounting for trends in the experimental observables with matrix polarity. A more detailed model which incorporates the explicit molecular structure of the first solvation shell in an *ab initio* molecular orbital framework has been developed and applied to aqueous

systems (3), but it currently appears too complex to readily apply to a series of large molecular systems.

The constraints on a successful theoretical model for solvated electrons in alkanes have been significantly increased by the recent geometrical information obtained about solvated electrons in 3-methylpentane glass at 77 K from an analysis of the modulation of the electron spin echo decay envelope (4). The results of the spin echo study give an electron solvation structure characterized by 18–21 equivalent nearest neighbor protons at a distance of 3.0–3.2 Å with an isotropic coupling constant of essentially zero. To these results we must add the previously known information about the optical absorption maximum (0.8 eV) and the photoionization threshold (1.0 eV) for solvated electrons in 3-methylpentane (3MP) glass (1). The totality of this geometrical and energy level structural data must be used to assess any theoretical model for electron solvation in alkane glasses.

The model developed to treat electron localization in alkanes was oriented toward explaining the magnitude of the optical absorption data (5). This model is termed the microdipole model. It is built on the semicontinuum model formalism and incorporates the effect of local CH bond dipoles into the potential. This model requires some assumption about the structure of the first solvation shell in order to calculate the electron dipole attractive interaction and the dipole–dipole repulsive interaction. It was found that two, four, or six CH_2 groups with the carbons located symmetrically about the electron and with the geometry of a methylene group do account for electron stabilization by about 0.1–0.4 eV. However, the amount of stability decreases as the number of CH_2 groups increases. This is a serious shortcoming since the electron spin echo data indicate that there are 18–21 equivalent nearest neighbor CH interactions. A microdipole model based on nine CH_2 groups would not show appreciable stability. We have also investigated a microdipole model based on four $-(CH_2)_3-$ groups arranged symmetrically around an electron, but this gives no electron stability due to large cancellation effects as a result of the $-(CH_2)_3-$ fragment structure.[1] It therefore appears that the CH dipoles are not the key to electron stability in alkanes because of this cancellation.

[1]D F. Feng and L. Kevan, unpublished results.

In order to develop a satisfactory model for electron localization in alkanes we are influenced by the fact that electron mobilities in alkanes vary widely with molecular structure (6). This suggests that a model be built that incorporates the explicit molecular structure. Our aim is to not only account for the structural aspects of electrons in alkane glasses, but also to at least semiquantitatively account for electron localization in those liquid alkanes which exhibit a low electron mobility ($\mu \leq 1$ cm^2 V^{-1} s^{-1}) and electron nonlocalization in those liquid alkanes which exhibit a high electron mobility ($\mu \geq 10$ cm^2 V^{-1} s^{-1}). In this work we develop a new model based on the semicontinuum potential framework in which the electron-polarizability energy is structured by considering the electron interaction with the polarizability of each C—C bond rather than with a point molecule. In addition we incorporate the effect of hydrogen–hydrogen repulsions because of the large number of equivalent nearest neighbor H atoms indicated by the electron spin echo results. This structured semicontinuum model appears to be remarkably successful.

Outline of Calculation

We assume a semicontinuum model (1, 2) in which the excess electron is considered to interact with a number N of structured and specifically arranged matrix molecules in the first coordination layer by short-range attractive and repulsive potentials and with the rest of the matrix molecules beyond the first coordination layer by a long-range polarization potential. The matrix molecules in the first coordination layer are considered to be symmetrically arranged around the electron with $N = 4$, 6, and 8. We approximate the molecular structure by the carbon atom framework and distribute the molecular polarizability, α, over all the carbon–carbon bonds in a molecule.

We first consider the short-range electronic energy for molecules with zero dipole moment. The polarization potential element of the jth C—C bond for the ith electronic state is given by [1].

$$[1] \quad dV_j(i) = -(\alpha e^2/2nl\cos\theta_j)C_i(r)\,dr/r^4$$

where n is the number of C—C bonds in the molecule, l is the C—C bond length, θ_j is the angle between the jth C—C bond and a specifically defined radial direction to be described later,

and $C_i(r)$ is the excess electronic charge enclosed within the distance r from the center of the cavity for the ith state. Integrating [1] from $r_{j(\min)}$ to $r_{j(\max)}$, we obtain [2] as the effective polarization potential due to the finite length jth bond.

$$[2] \quad V_j(i) = -(\alpha e^2/6nl\cos\theta_j)[r_{j(\min)}{}^{-3} - r_{j(\max)}{}^{-3}]C_i(r_{j0})$$

where $r_{j(\min)}$ and $r_{j(\max)}$ are the minimum and maximum radial distances of the projected jth bond, and $r_{j0} = [r_{j(\min)} + r_{j(\max)}]/2$. In deriving [2] an approximation has been made that the average electric field acting on the jth C—C bond is given by the charge enclosed within the distance r_{j0}.

The electronic energy of the ith bound state for short-range attractive interactions is then given by [3].

$$[3] \quad E_e{}^s(i) = \sum_j N V_j(i) C_i(r_{j0})$$

Equation 3 reduces to $-N\alpha e^2 C_i{}^2(r_d)/2r_d{}^4$ for the point molecule model ($l = 0$) where r_d is the center of the molecule. This is readily seen for the simple case of ethane aligned so that $\theta_j = 0$;

$$E_e{}^s(\text{ethane}) = (-e^2\alpha/6)(3r_d{}^2 + l^2/4) \times (r_d{}^2 - l^2/4)^{-3} C_i{}^2(r_d)$$

The short-range medium rearrangement energy due to induced dipole – induced dipole interaction is given by the semicontinuum model as $E_m{}^s = D_N\mu^2/r_d{}^3$ where $\mu = e\alpha C_i(r_d)/r_d{}^2$ and D_N is a numerical constant calculated from the number and geometrical arrangement of the molecules (1). Here we have assumed that a point induced dipole approximation is justified because this energy term is rather small.

The nonpolar medium beyond the first coordination layer beginning at $R = r_d + r_s$ is treated as a continuous dielectric characterized by an optical dielectric constant D_{op} so that only electronic polarization is considered. The sum of the long-range electronic and medium rearrangement energies is given by [4].

$$[4] \quad E_e{}^l(i) + E_m{}^l(i) = \frac{e}{2}\left(1 - \frac{1}{D_{op}}\right) \times \left[f_i(R)\int_{r\le R}\psi_i{}^2 d\tau + \int_{r\ge R} f_i(r)\psi_i{}^2 d\tau\right]$$

where f_i is a self-consistent field potential which is obtained from Poisson's equation (1, 2).

Two other medium rearrangement energy terms have been included in the semicontinuum model (1, 2). The short-range interaction of the excess electron with the medium electrons is approximated by $E_q = V_0[1 - C_i(r_d)]$ where V_0 is the quasi-free electron energy. The energy required to form a cavity in the medium is given by $E_v = 4\pi(r_d{}^2 - r_s{}^2)\gamma$ where γ is the surface energy and r_s is the radius of the molecule.

Because of the experimental evidence for a large number of equivalent nearest neighbor protons to the solvated electron in alkanes (4), we also include in this calculation repulsive interactions between the hydrogen atoms in the different methyl groups nearest to the center of the cavity in which the electron is localized. This medium rearrangement energy term has not been included in our previous semicontinuum model calculations. The H–H interaction energy is based on high velocity helium atom scattering data and an H atom van der Waals radius of 1.25 Å; it is given by [5] (7)

$$[5] \quad E_{HH}(ev) = \sum_h g_h \times 434\exp(-4.6r_h)$$

where g_h is the number of hydrogen atom pairs separated by a distance r_h (Å).

Each methyl group is presumed rotating and one average H–H interaction distance is considered between each pair of methyl groups. A summation is taken over all different classes of methyl pairs where each class corresponds to a different r_h. For example, if the methyl groups from six alkane molecules closest to the electron are located at the vertices of an octahedron there are two classes of pairs and g_h is 12 for the adjacent methyls and 3 for the methyls located at opposite vertices.

The total energy for the ith state is then given by [6].

$$[6] \quad E_t(i) = E_k(i) + E_e{}^s(i) + E_m{}^s(i) + E_e{}^l(i) + E_m{}^l(i) + E_q(i) + E_v + E_{HH}$$

where E_k is the kinetic energy of the excess electron. This E_t is formally the same as the semicontinuum model for polar molecules plus the addition of E_{HH}. Hydrogenic wave functions are used and the variational procedure is applied to the total energy of the system to obtain the minimum energy for a given r_d. The calculational details have been described previously (1, 2). The total energy is temperature dependent via E_q because V_0 is temperature dependent and via $E_e{}^l + E_m{}^l$ because D_{op} is temperature dependent.

The energy of the conduction state consistent with the ground-state medium arrangement is given by [7].

$$[7] \qquad E_t(\text{cond}) = V_0 + E_v + E_{HH}$$

The geometrical constants defining the various configurations are listed in Table 1. For ethane, propane, *n*-pentane, neopentane, and 3MP, α is 4.9, 6.2, 10, 10, and 11.8 Å^3, respectively; γ is 8.7, 11.1, 16, 16, and 37 erg cm^{-2}, respectively; and D_{op} is 1.92 (127 K), 1.80 (182 K), 1.77 (200 K); 1.91 (179 K), 1.87 (197 K), 1.84 (211 K), 1.81 (222 K); 1.84 (296 K); 1.78 (296 K); and 2.22 (77 K), respectively. The distance r_s is taken from the center of the molecule to the hydrogen atom furthermost in the radial direction to which the C—C bond angles are referred, plus 0.5 Å (about the Bohr radius of the hydrogen atom). The C—C and C—H bond lengths are taken as 1.54 and 1.10 Å, respectively. Values of V_0 (8–11) used in the calculations are given in Table 2.

Generalized structural models for the matrix molecule in the first coordination layer are shown in Figs. 1–6. The angle parameters involved in the structural models are given in Table 1 where both planar and non-planar conformations are included. In propane (model 1), *n*-pentane (models 1–4), and 3MP (models 1–4 and 6–8), the innermost C—C bond is directed to the center of the cavity and this direction is taken as a reference radial direction. In propane (model 2) and *n*-pentane (models 6–8), the line bisecting the central C—C—C angle is directed to the center of the cavity and this direction is taken as a reference radial direction. In *n*-pentane (model 5) and 3MP (model 5), a straight line passing through three carbon atoms and the center of the cavity is taken as a reference radial direction (see Figs. 3 and 5). In ethane the C—C bond is directed to the center of the cavity. In neopentane the molecule is arranged so that one of the C—C bonds points towards the center of the cavity.

Results and Discussion

The results of the calculations are given in Tables 2–9 and Figs. 7–9. Tables 7–9 and Fig. 9 may be obtained from the Depository of Unpublished Data.[2]

Liquid Ethane

Table 3 shows the calculated properties of localized excess electrons in liquid ethane. The cavity radius at the configurational minimum is r_d^0, $h\nu(1s \rightarrow 2p)$ and $f(1s \rightarrow 2p)$ are the optical transition energy and oscillator strength for the $1s \rightarrow 2p$ transition, respectively, I is the threshold energy for photoconductivity, $h\nu_{max}$ is the transition energy at the maximum of the bound-free transition probability (12), and ΔH is the heat of solution of the excess electron. The following trends are seen in Table 4: (*a*) r_d^0 increases with

increasing N and it is nearly independent of temperature, (*b*) $h\nu(1s \rightarrow 2p)$ decreases with increasing N and temperature, (*c*) $f(1s \rightarrow 2p)$ increases with increasing N and temperature, (*d*) I and $h\nu_{max}$ decrease with increasing N and temperature, and (*e*) ΔH decreases with increasing N and decreasing temperature.

These trends are similar to those seen for polar matrices (2). The magnitudes of $h\nu(1s \rightarrow 2p)$ and $f(1s \rightarrow 2p)$ are much smaller than those calculated for solvated electrons in polar solvents and fit with the trend with decreasing matrix polarity established for polar solvents (2). The value of $I - h\nu(1s \rightarrow 2p)$ also decreases with decreasing matrix polarity in polar solvents and the small value of ~0.1 eV observed in liquid ethane also fits this trend. This means that the $2p$ level is close to the bottom of the conduction state for electrons in ethane and suggests that the optical absorption spectrum of the conduction state for electrons in ethane may not be mainly due to a bound–bound transition. This suggestion is

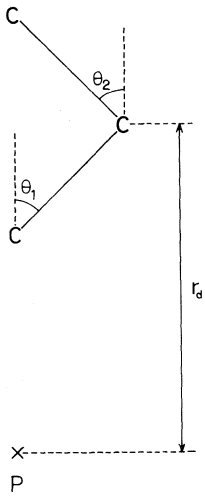

FIG. 1. Structural model for the propane molecule in the first coordination layer. Model 1 in Table 2. *P* indicates the center of a cavity.

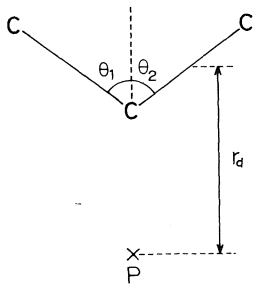

FIG. 2. Structural model for the propane molecule in the first coordination layer. Model 2 in Table 2.

reinforced by the relatively low values of $f(1s \rightarrow 2p)$, particularly at low temperature. The values of the bound–free transition energy $h\nu_{max}$ are about twice as large as those of $h\nu(1s \rightarrow 2p)$, and they fall in the near-infrared region. It is interesting to note that $h\nu(1s \rightarrow 2p)$, I, and $h\nu_{max}$ decrease significantly with increasing temperature over the temperature range studied. At present there are no experimental data available for comparison with these calculated optical properties. It would be interesting to carry out an optical absorption study of localized excess electrons in liquid ethane to test some of these predictions.

Figure 7 shows the configuration coordinate diagram for a localized excess electron in liquid ethane at 127 K. In the figure the 1*s* ground, 2*p* excited and continuum states are shown for $N = 4$, 6, and 8. The general features of the configuration coordinate curves are similar to

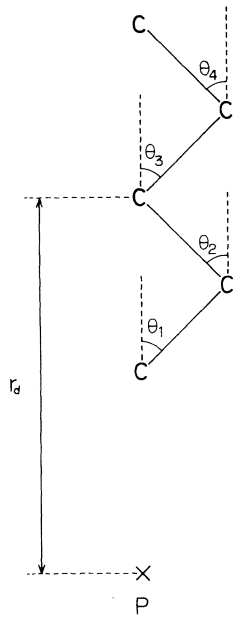

FIG. 3. Structural model for the *n*-pentane molecule in the first coordination layer. Models 1–5 in Table 2.

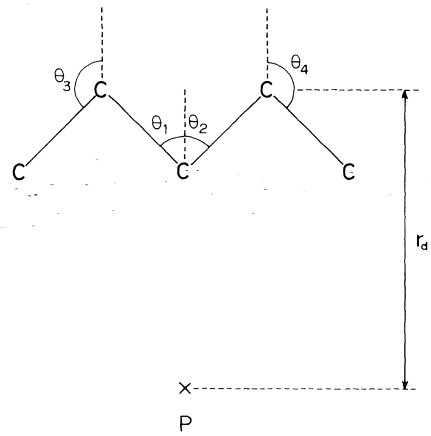

FIG. 4. Structural model for the *n*-pentane molecule in the first coordination layer. Models 6–8 in Table 2.

each other for cases of $N = 4$, 6, and 8. The ground-state energy becomes slightly higher with increasing N. The cavity radius, r_d^0, increases with increasing N. These trends are also observed in the theoretical results on solvated electrons in polar solvents (2).

Liquid Propane

Table 4 shows the properties of localized excess electrons in liquid propane calculated using the two structural models. The calculated properties and trends in Table 5 are similar to

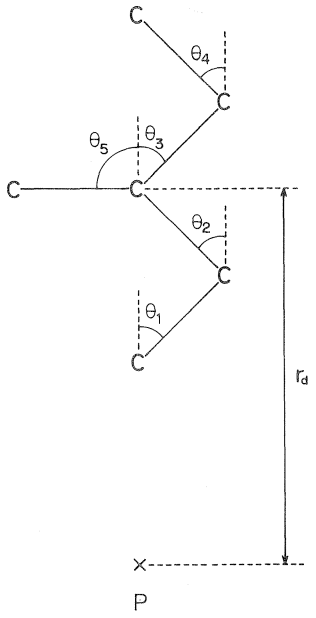

FIG. 5. Structural model for the 3MP molecule in the first coordination layer. Models 1–5 in Table 2.

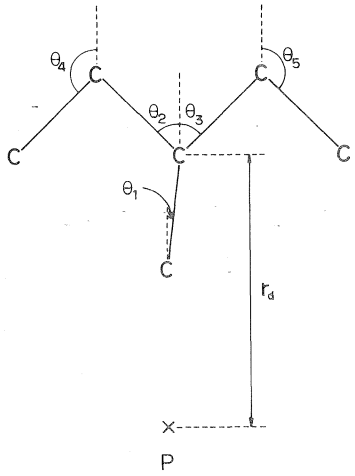

FIG. 6. Structural model for the 3MP molecule in the first coordination layer. Models 6–8 in Table 2.

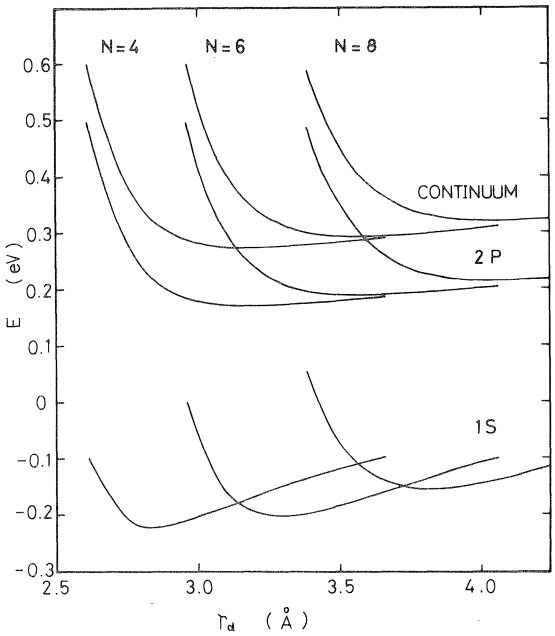

FIG. 7. Configuration coordinate diagram for the localized excess electron in liquid ethane at 127 K.

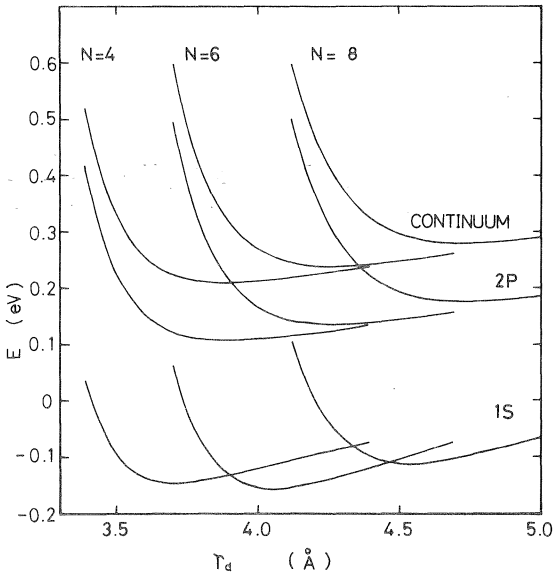

FIG. 8. Configuration coordinate diagram for the localized excess electron in liquid propane at 179 K (model 1).

those in Table 4. Model 2 with the central carbon of propane closest to the excess electron (Fig. 2) predicts $h\nu(1s \rightarrow 2p)$, I, $h\nu_{max}$, and ΔH somewhat greater than does model 1 with an end carbon of propane closest to the excess electron (Fig. 1). It is especially interesting that the ground-state energy at a given temperature shows a minimum for $N = 6$ compared to $N = 4$ and 8 in model 1 (see Fig. 8), but in model 2 the ground state is lowest for $N = 4$ as has been typically found. The optical absorption spectrum of localized excess electrons in liquid propane was observed at 88 K by pulse radiolysis techniques (13). The maximum absorption occurs at ≥ 2000 nm (≤ 0.6 eV) which is clearly higher than

$h\nu(1s \rightarrow 2p)$ but rather close to the calculated $h\nu_{max}$. It is expected that the bound-free transition may significantly contribute to the observed absorption maximum, although the calculated $h\nu(1s \rightarrow 2p)$ and $h\nu_{max}$ are both temperature dependent. Such an interpretation is also supported by the fact that the calculated $f(1s \rightarrow 2p)$ is considerably lower than unity.

The cavity radius, r_d^0, for the same N is greater in the model 1 structure of propane than in ethane by about 0.8 Å, and it is about the same in the model 2 structure of propane and ethane. This simply reflects the geometry difference between models 1 and 2.

Figure 8 shows the configuration coordinate diagram for a localized excess electron in liquid propane at 179 K (model 1). The configuration coordinate curves in Fig. 8 are similar to those

for liquid ethane (Fig. 7). However, the ground-state energy is a minimum for $N = 6$ in propane (model 1) as mentioned above.

3-Methylpentane Glass

Table 5 shows the calculated properties of trapped electrons in 3MP glass at 77 K, which includes results obtained using models 1–8 in Table 2. It is seen in Table 5 that (*a*) r_d^0 increases with increasing N, (*b*) $h\nu(1s \rightarrow 2p)$ decreases with increasing N with the exception of model 5, (*c*) $f(1s \rightarrow 2p)$ increases with increasing N and shows a relatively large increase between $N = 4$ and $N = 6$, (*d*) I is nearly independent of N, and (*e*) ΔH decreases with increasing N. The value of $h\nu(1s \rightarrow 2p)$ somewhat depends on the model used, but it is generally in reasonable agreement with the transition energy, 0.8 eV (1, 14) at the absorption maximum observed for trapped electrons in 3MP at 77 K. The relatively high value of $f(1s \rightarrow 2p)$ indicates that the $1s \rightarrow 2p$ transition significantly contributes to the absorption spectrum, although $f(1s \rightarrow 2p)$ is relatively low for $N = 4$ in some of the models. The energy difference between $h\nu(1s \rightarrow 2p)$ and I is about 0.2 eV, which is in good agreement with the experimental results on trapped electrons in 3-methylhexane glass at 77 K (1, 15). It is seen in Table 2 that the electron can be stably trapped in 3MP at 77 K and its binding energy is about 0.6 eV. The calculated value of ΔH has a negative sign for 3MP at 77 K in contrast to the positive ΔH for liquid ethane and propane. The distance of the nearest protons from the center of cavity, $r_{e^-\text{—H}}$, was calculated to be 1.9 ± 0.1, 2.3 ± 0.1, and 2.7 ± 0.1 Å for $N = 4$, 6, and 8, respectively, for all the models used for 3MP. These values are smaller than the experimental value, 3.0–3.2 Å, derived from electron spin echo data (4). However, semicontinuum models for solvated electrons in polar matrices have generally given smaller values of $r_{e^-\text{—H}}$ than observed. In order to further improve the theoretical results it would be necessary to treat short-range repulsive interactions between the excess electron and the medium electrons more adequately.

TABLE 6. Properties of trapped electrons in 3MP at 77 K for $V_0 = 0.6$ eV (model 4)

N	r_d^0 (Å)	$h\nu(1s \rightarrow 2p)$ (eV)	$f(1s \rightarrow 2p)$	I (eV)	ΔH (eV)	$V_0 - E_t(1s)$ (eV)
4	4.2	0.605	0.364	0.754	−0.012	0.588
6	4.5	0.659	0.394	0.815	−0.059	0.541
8	5.0	0.623	0.568	0.795	−0.198	0.402

	Ground state		Excited state	
N	$C_{1s}(r_d^0)$	$C_{1s}(R_0)$	$C_{2p}(r_d^0)$	$C_{2p}(R_0)$
4	0.756	0.979	0.038	0.259
6	0.789	0.982	0.060	0.330
8	0.785	0.975	0.132	0.492

Nevertheless, we consider the overall agreement between the variety of experimental data for trapped electrons in 3MP ($h\nu(1s \rightarrow 2p)$, I, $r_{e^-\text{–H}}$, and $N = 6$ depending on the configuration of the first solvation shell) and these calculations to be rather good.

Figure 9[2] shows the configuration coordinate diagram for a trapped electron in 3MP at 77 K (model 4). The general features of the configuration coordinate curves are similar to those for localized excess electrons in liquid ethane and propane.

If V_0 is decreased from 1.0 eV, which is probably an upper limit, used in Table 5, to 0.6 eV we obtain the results shown in Table 6. The main effect of making V_0 less positive is to decrease $h\nu(1s \rightarrow 2p)$ and I. This may give slightly better agreement with experiment.

Charge Distributions

The charge distributions of localized excess electrons in liquid ethane and propane were calculated *vs.* temperature. In ethane the ground state contains 0.82 of the charge within the first coordination layer at 127 K for $N = 6$. This fraction decreases to 0.67 as the temperature is increased to 200 K. The charge distribution of the excited state is much broader than that of the ground state and varies from 0.026 at 127 K to 0.018 at 200 K for $N = 6$. The charge distributions in liquid propane are similar for the various configurations considered. In 3MP at 77 K the charge is much more localized and has values of 0.97 for the ground state and 0.70 for the excited state within the first coordination layer for $N = 6$, model 1. The significant difference from ethane and propane is due in large part to the high value of V_0 for 3MP at 77 K. The narrow charge distribution of the excited state is responsible for the relatively high value of $f(1s \rightarrow 2p)$ found for 3MP at 77 K.

The detailed results for the charge distribution for all configurations are found in Tables 7–9.[2]

Criterion for Electron Localization

The criterion for excess electron localization is given by the quantity, $V_0 - E_t(1s)$; the localized electron state is stable for $V_0 - E_t(1s) > 0$ and the electron is not stably localized for $V_0 - E_t(1s) < 0$. The calculated values of $V_0 - E_t(1s)$ are given in Table 2. It can be seen that the excess electron in liquid ethane should be localized over the temperature range studied and for all cases of $N = 4$, 6, and 8. This conclusion is consistent with experiments that show a low electron mobility in liquid ethane (16, 17).

The stability of localized excess electrons in liquid propane is well established as seen in Table 2. It is interesting to note that the magnitude of the binding energy, $V_0 - E_t(1s)$, of the excess electron is comparable to the observed activation energy (~0.13 eV) (16) for the electron mobility, although the calculated binding energy is temperature dependent and somewhat higher at lower temperatures than the mobility activation energy. Since $V_0 - E_t(1s)$ contains $E_t(1s)$ which is obtained under the condition of energy minimization in the calculation while the mobility activation energy is probably associated with the energy of a transient trapped electron state, it is likely that $V_0 - E_t(1s)$ is somewhat greater than the mobility activation energy.

Calculations were also made of the stability of localized excess electrons in liquid *n*-pentane and

neopentane, in which the eight models and two values of V_0 were used for *n*-pentane and three values of V_0 were used for neopentane. The results of the calculations are given in Table 3. It can be seen that localized excess electrons are stable in *n*-pentane for almost all models. In neopentane the ground-state energy, $E_t(1s)$, of localized excess electrons is higher than V_0 for $N = 6$ and 8, and $V_0 - E_t(1s)$ is comparable in magnitude to the thermal energy kT for $N = 4$. These results indicate that in neopentane the localized excess electron is unstable and the excess electron exists as a delocalized quasi-free electron in accord with the electron mobility data (18–21).

Discussion

K. Funabashi: This calculation uses a variational technique in which the ground-state wavefunction is a hydrogenic (1*s*)-function with one parameter. But this form is approximately suitable only when one knows the ground state is *localized* before the *calculation*.

L. Kevan: We calculate the ground state energy $E_t(1s)$ relative to the vacuum level. In the alkanes thus far investigated this energy is negative, indicating stability or localization relative to the vacuum level, so hydrogenic wavefunctions are appropriate. We then compare $E_t(1s)$ to V_0 to determine whether the electron is stable or localized relative to V_0.

J. Jortner: I would like to raise a question concerning an experimental criterion regarding electron localization in some hydrocarbons. You have stated that whenever your energetic data $(V_0 - E_t(1s)) > 0$ the electron is localized and the mobility is low. However, the 'low' electron mobilities in hydrocarbons are in the range 1.0–0.1 $cm^2 V^{-1} S^{-1}$. Such mobilities are too high for a hydrodynamic drag of a localized state. You may invoke thermal excitation from the bound state to the conduction band; however, the positive values of $V_0 - E_t(1s)$ calculated by you considerably exceed the experimental activation energies of the mobility. This points to a more complex picture for electronic structure and transport of excess electrons in hydrocarbons.

L. Kevan: Our localization criterion, $V_0 - E_t(1s) > 0$, contains $E_t(1s)$ which is obtained under the condition of energy minimization by varying a configurational coordinate. However, the mobility activation energy is probably associated with the energy of a *transient* localized electron state which is expected to be less than the energy $E_t(1s)$ of the equilibrium localized electron state that we calculate in this work. We have discussed transient localized electron states in alkanes earlier (J. Phys. Chem. **79**, 2866 (1975)). Thus in general, we expect $V_0 - E_t(1s)$ to be somewhat greater than the mobility activation energy. But in some cases such as propane at higher temperatures $V_0 - E_t(1s)$ is comparable to the mobility activation energy (0.13 eV). I certainly do agree that the transport of electrons in alkanes is complex and that we do not understand it at present. In the present work we have not yet attempted to treat the dynamics of this electron transport.

A. O. Allen: It would be interesting to study further the electron energy as a function of the orientations of the surrounding molecules. The single optimum state is one of a large number of states, produced by variation of the molecular positions and orientations, in which the electron exists in thermal equilibrium. Understanding the properties of the electron must therefore require an estimation of the density of states.

L. Kevan: We do hope to study the properties of electrons in alkanes for various nonequilibrium orientations of the first solvation shell molecules. However, in the framework of our calculation as described I don't believe we can readily estimate the density of states.

H. A. Gillis: You have carried out calculations for 3-methylpentane glass at 77 K which gives reasonable agreement with the observed E_{max} of about 0.8 eV. But in fact this E_{max} is for the blue-shifted spectrum found at long times. At shorter times we found a spectrum for this glass with $E_{max} \simeq 0.6$ eV (N. V. Klassen, H. A. Gillis, and G. G. Teather. J. Phys. Chem. **76**, 3847 (1972)). Presumably this spectrum corresponds to an electron solvated in a random mixture of configurations. Can your model explain this short-time spectrum?

L. Kevan: Our calculations are for various assumed *equilibrium* configurations for the solvated electron in alkanes in which a nearest C—C bond is oriented toward the electron. The optical absorption you see at early times in pulse radiolysis corresponds to an electron in a nonequilibrium configuration. I believe we can account for this red-shifted optical absorption by making calculations for nonequilibrium configurations with varying angles between a nearest C—C bond and the electron. This would be similar to our earlier calculations of this type on electrons in ethanol where we could well account for the time dependent spectral shift observed in pulse radiolysis.

Field-dependent electron mobility in methane–ethane liquid mixtures

BAPPANADU N. RAO, ROBERT L. BUSH, and K. FUNABASHI. Can. J. Chem. **55**, 1952 (1977).

Some aspects of the mobility of excess electrons in liquid hydrocarbons are discussed. Certain salient features of the experimental data on high-field mobility in ethane–methane mixtures are explained in terms of a hopping model, in which disorder plays an important role. The disorder is compositional, like that in a binary alloy, and enters the model in the form of two distinct jump distances for hopping motion. It is shown that decreasing the coherence length for a quasi-free electron increases the binding energy of a localized electron and hence affects the activation energy and rate of hopping. The effects of temperature and impurity concentration for high-mobility liquids are shown to be consistent with a scattering model.

BAPPANADU N. RAO, ROBERT L. BUSH et K. FUNABASHI. Can. J. Chem. **55**, 1952 (1977).

On discute de quelques aspects de la mobilité des électrons en excès dans les hydrocarbures liquides. On explique quelques caractéristiques importantes des données expérimentales concernant la mobilité à haut champ dans des mélanges d'éthane et de méthane en termes d'un modèle à sauts dans lequel le désordre joue un rôle important. Le désordre a trait à la composition, comme dans un alliage binaire, et apparait dans le modèle sous forme de deux distances distinctes pour le mouvement de saut. On montre que si l'on diminue la longueur de cohérence pour un électron pratiquement libre il y a augmentation de l'énergie de liaison d'un électron localisé et ainsi un effet sur l'énergie d'activation et la fréquence des sauts. On montre que les effets de la température et les concentrations d'impureté dans le cas des liquides de grande mobilité sont en accord avec un modèle de dispersion.

[Traduit par le journal]

Introduction

Electron transport in liquid hydrocarbons has been studied extensively in recent years (1–3). The magnitudes of electron drift mobilities in these liquids vary from $\sim 10^{-3}$ cm^2 V^{-1} s^{-1} in ethane to ~ 500 cm^2 V^{-1} s^{-1} in methane (see for example ref. 4). An apparent correlation between the magnitude of the mobility and the molecular geometry has also been found among larger hydrocarbons, such as *n*-pentane and neopentane (2, 3) and butene-1 and isobutene (5).

Davis, Schmidt, and Minday (6) proposed a transport mechanism which is now called the trapping mechanism. In their picture, the mobility of an electron in a hydrocarbon liquid depends only on the probability of finding the electron in a quasi-free state; this probability is determined by the average trap depth and the trapping frequency. The electron transport is assumed to take place only in the quasi-free state, in which the mobility is about 150 cm^2 V^{-1} s^{-1} or larger. Schiller (7) and Kestner and Jortner (8) have ascribed the differences among the mobilities of hydrocarbons to differences in V_0, the energy level of the quasi-free state (9).

All these proposed models are designed to explain the entire range (10^{-3} to 500 cm^2 V^{-1} s^{-1}) of magnitudes of mobility by a unified picture with few parameters, emphasizing the role of the quasi-free electrons even for low-mobility liquids. On the other hand, the conventional transport mechanism for the low-mobility ($< \sim 1$ cm^2 V^{-1} s^{-1}) liquids and solids is electron hopping, based upon the concept of the small polaron (10).

The correct transport mechanism for excess electrons in low-mobility hydrocarbons will depend on the details of the liquid structure and the electron–phonon interaction, which are not known at this time. In the absence of this information, a model theory which explains the low-field electron mobility may be judged by its ability to explain other observed properties of the excess electron in these systems.

The purpose of this article is to discuss a hopping model for the high-field electron mobility in low-mobility liquid hydrocarbons.

[1]The Radiation Laboratory of the University of Notre Dame is operated under contract with the U.S. Energy Research and Development Administration. This is ERDA Document No. COO-38-1055.

By a hopping model we mean a model which treats electrons as tightly bound, most likely by the electron–phonon interaction, and in which the motion is by hopping in random jumps whose length is of the order of the intermolecular separation. Specifically, we shall focus on the experimental results of Bakale, Tauchert, and Schmidt (4) on ethane–methane mixtures. We shall not attempt a quantitative explanation of the magnitude of the low-field mobility as a function of methane concentration. The high-field mobilities in the high-mobility methane-rich mixtures are also outside the scope of this article. Detailed theories to describe this latter behavior have been developed by Shockley (11) and Thornber and Feynman (12).

In the next section we review experimental results for field-dependent mobilities, and propose an explanation for certain qualitative features of these results in terms of a hopping model. Our hopping model is a modification of our earlier work (13). In the following section we present a calculation which exhibits the effect of the finite coherence length of the quasi-free electron on the binding energy of a localized electron in the same system, in order to understand the change in activation energy as a function of methane concentration. We shall also present a brief discussion of wave propagation with scattering as a transport mechanism for the high-mobility regime of methane–ethane mixtures.

Field-dependent Mobility

The electron drift mobility μ is defined by

$$[1] \qquad v_D = \mu F$$

where v_D is the drift velocity (cm/s) and F is the field strength (V/cm). It is known experimentally that for most materials the mobility μ is independent of F when F is sufficiently small. When log v_D is plotted against log F, the slope is unity as long as μ is independent of F. As the field strength increases, the relationship between log v_D and log F becomes non-linear. The trend and pattern of this non-linearity depends on the magnitude of the low-field electron mobility. Figure 1 represents the field-dependent drift velocity for ethane–methane mixtures, where the pattern of non-linearity is different for different values of the zero-field electron mobility $\mu(0)$ (4). We note the following three features of Fig. 1: (*1*) the onset of the non-linearity moves toward smaller field strengths as the zero-field mobility $\mu(0)$ increases, as shown in Fig. 1 by a dotted curve; (*2*) for $\mu(0) < 1\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$, the high-field mobility increases with increasing field strength, whereas for the high-mobility regime, the mobility decreases with increasing field strength (*i.e.*, the drift velocity increases but not in proportion to the field); (*3*) the non-linearity becomes less pronounced as $\mu(0)$ increases from the lowest value to $\sim 1\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$, at which point the non-linearity *apparently* disappears.

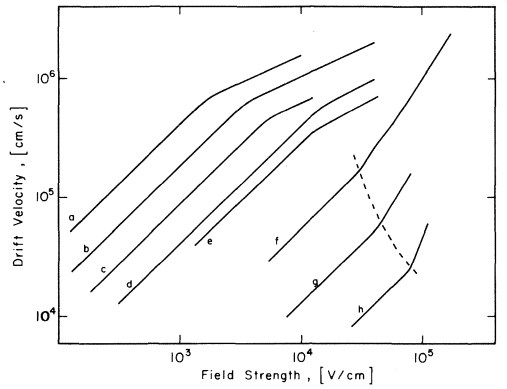

FIG. 1. Electron drift velocity v_D as a function of electron field F and concentration of ethane for ethane–methane mixtures at $T = 111$ K: (*a*) pure methane; (*b*) 4 mol% ethane; (*c*) 13 mol% ethane; (*d*) 24 mol% ethane; (*e*) 27.5 mol% ethane; (*f*) 50 mol% ethane; (*g*) 63 mol% ethane; (*h*) 74 mol% ethane.

The same three features are evident in the field-dependent electron mobility of helium as a function of pressure (14), and also in larger hydrocarbons (15), suggesting that these features may be the properties of some universal transport mechanism. We shall test the applicability of a hopping mechanism to these three features in the low-mobility regime.

The simplest theory for the non-linear mobility in the hopping model is the hyperbolic sine law (16–18):

$$[2] \qquad \mu(F) = \mu(0) \sinh\left(\frac{e\lambda F}{2kT}\right) \Big/ \left(\frac{e\lambda F}{2kT}\right)$$

where $\mu(F)$ is the electron drift mobility at the field strength F and λ is the jump distance for the hopping motion. The zero-field mobility $\mu(0)$ is given by the Einstein relationship

$$[3] \qquad \mu(0) = \frac{eD}{kT} = \frac{e\lambda^2\nu}{kT} \exp(-E/kT)$$

where ν is the jump frequency and E is the free energy barrier height for the hopping motion.

In order to explain the fact that the non-linearity sets in at smaller external fields with increasing methane concentration, the jump distance λ in [2] must increase with methane concentration. Bakale *et al.* (4) found that the jump distance increases from 10 Å for pure ethane to 50 Å for equimolar mixtures of ethane and methane. In addition to the fact that these jump distances are too large for a typical hopping motion, the increase in λ predicts that the mobility will rise more sharply with field as μ(0) increases, by [2], in qualitative contradiction to observation (*i.e.* our feature number (*3*)). In the following we present a hopping model containing disorder, which exhibits the observed behavior ((*1*)–(*3*), above) with a reasonable value for the jump distance.

The first step is to note that [2] is an approximation to the form:

$$[4]\quad \mu(F) = \mu(0)\exp\left[-(e\lambda F)^2/16EkT\right] \times \sinh\left(\frac{e\lambda F}{2kT}\right) \Big/ \left(\frac{e\lambda F}{2kT}\right)$$

which is valid for parabolic potentials, and where E is the barrier height as in [3]. Equation 4 can be derived quantum-mechanically (19, 20) or classically (21).

Let us assume for the moment that the barrier height E, which is a constant fraction of the binding energy of the polaron (22), decreases with increasing methane concentration, and both the jump frequency ν and the jump distance λ are independent of methane concentration. According to this model, the magnitude of the zero-field mobility μ(0), as given by [3], varies only as a function of E, while the high-field mobility, as given by [4], becomes more nearly constant with decreasing E. This is consistent with feature (*3*), above, but does not explain the fact that the non-linearity in v_D sets in at smaller field strengths as the methane concentration increases. In order to remedy this difficulty, we introduce some structural disorder into our model. Funabashi and Rao (13) have shown that any fluctuation in the barrier height lowers the threshold field for the non-linear drift velocity in comparison to that in a system with a constant barrier height. A similar observation has also been made by Austin and Sayer (21) and Böttger and Bryksin (23).

Before describing the nature of our specific 'disorder', we note that the lowering of the threshold field for the non-linear drift velocity as a function of the degree of disorder can be demonstrated in terms of several different models (13, 21, 23) and consequently is not a special phenomenon limited to a particular model.

In our model, we assume that all jumps in pure ethane are of length λ_1, and that adding methane introduces another jump distance λ_2, shorter than λ_1. A binary mixture of ethane and methane is therefore modeled as a linear chain of multiple barriers with jump distances λ_1 and λ_2. The fraction of jumps whose length is λ_2 is related to the concentration of methane. Clearly, there is no rigorous justification for choosing only two values for the jump distance, but we hope that this simple model may simulate some features of real binary mixtures.

The potential energy curve for hopping motion is drawn schematically in Fig. 2, where each potential is parabolic and the force constant for the potential is assumed to be the same throughout the chain. It is easy to show that the energy barrier E_i corresponding to the jump distance λ_i is given by

$$[5]\quad E_i = \alpha\lambda_i^2/8 \qquad i = 1, 2$$

where α is the force constant of the parabolic potential. Two jump distances therefore generate two values for the energy barrier.

The law of flux conservation requires

$$[6]\quad \lambda_1 \exp\left[-(ev_1)^2/16E_1kT\right]\sinh\left(ev_1/2kT\right) = \lambda_2 \exp\left[-(ev_2)^2/16E_2kT\right]\sinh\left(ev_2/2kT\right)$$

where v_1 and v_2 are the voltage drops across the jump distances λ_1 and λ_2, respectively. Because the total voltage drop across the entire system is fixed, v_1 and v_2 are related by

$$[7]\quad cv_1 + (1 - c)v_2 = [c\lambda_1 + (1 - c)\lambda_2]F$$

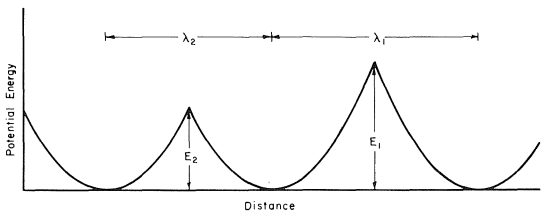

FIG. 2. Schematic diagram of potential energy *vs.* distance for a binary mixture. Note that two different barrier heights are associated with the two jump distances.

where c is the probability that a particular jump has length λ_1, and F is the external field strength as before.

The field-dependent mobility can be shown by methods analogous to those in ref. 13 to be

$$[8] \quad \mu(F) = \frac{e\lambda\lambda_1\nu}{kT}\exp\left[-\frac{E_1}{kT} - \frac{(ev_1)^2}{16E_1kT}\right] \times \frac{\sinh(ev_1/2kT)}{e\lambda F/2kT}$$

where

$$[9] \quad \lambda = c\lambda_1 + (1 - c)\lambda_2$$

For a fraction c, the voltage drop v_1 in [8] can be found from [6] and [7], and v_D can be plotted as a function of F. An example is shown in Fig. 3, where the ratio λ_2/λ_1 is taken to be 0.8 and the force constant α is assumed to decrease with a decrease in the fraction c, reflecting the physical situation that the binding energy of the small polaron decreases with the methane concentration. It can be seen in Fig. 3 that, unlike [4], [8] explains our three features ((*1*)–(*3*)) simultaneously. A comparison of Fig. 3 with the experimental results (Fig. 1) shows that the jump distance λ_1 in ethane–methane mixtures is about 10 Å, a reasonable value for the jump distance. This result implies that a hopping mechanism of electron transport properly designed is consistent with qualitative trends in the experimental results for non-linear mobility in low-mobility liquids.

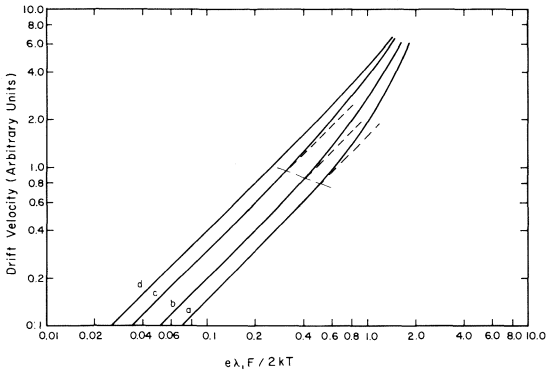

FIG. 3. Drift velocity v_D *vs.* field strength F for various concentrations c of λ_1 in a chain like that of Fig. 2, computed from eqs. 6–9. (*a*) $c = 0.64$, $\alpha = 80$ dyn/cm; (*b*) $c = 0.38$, $\alpha = 44.0$ dyn/cm; (*c*) $c = 0.15$, $\alpha = 36.8$ dyn/cm; (*d*) $c = 0.02$, $\alpha = 33.6$ dyn/cm. Here $\lambda_2/\lambda_1 = 0.8$. Comparison with Fig. 1 shows that $\lambda_1 \simeq 10$ Å in ethane–methane mixtures, a reasonable value for the jump distance.

Binding Energy of a Localized Electron

In order to provide some justification for our assumption that the binding energy of the small polaron decreases with an increase in methane concentration, we have examined the effect of a finite coherence length at the quasi-free state on the binding energy of a localized electron. Because basic information about the liquid structure and the nature of the electron–phonon interaction remains unknown, it is not possible to establish a quantitative relationship between the binding energy of a localized state and the concentration of methane. We have only investigated in a crude and qualitative way the effect of the finite coherence length on the binding energy of the localized electron and on the energy barrier for hopping motion; this finite coherence length is brought on by scattering, which varies monotonically with the concentration of methane.

Let us start with a simple tight-binding model for the electronic structure for an excess electron in molecular crystals. For example, if the crystal has a body-centered cubic (BCC) structure, the energy dispersion can be written as

$$[10] \quad E(k) = 8J\cos\theta_x\cos\theta_y\cos\theta_z$$

where the band center is chosen to be the zero of the energy scale, J is the nearest-neighbor transfer energy and

$$[11] \quad \theta_x = \tfrac{1}{2}a_l k_x \quad \text{etc.}$$

a_l being the lattice constant. When a defect potential is introduced at some site, a bound state can be realized (24) only if

$$[12] \quad V/8J > 0.722$$

where V is the diagonal matrix element of the defect potential. The situation is completely analogous to the localizability criterion for an excess electron in an attractive spherical potential; there is no bound state (25) unless $Ua^2 > \pi^2\hbar^2/8m$, where U and a are the depth and the radius of the potential, respectively. Electrons can also be localized by a sufficiently strong electron–phonon interaction (small polaron) (10). Although there is some question whether the transition from large to small polaron is continuous or sudden (26–28), the electron–phonon interaction energy must exceed one-half the band width in order for an electron to be localized as a small polaron. A finite

threshold strength for the defect or disorder potential or electron–phonon interaction is necessary to localize electrons.

In order to examine the effect of a finite coherence length, let us return to the BCC tight-binding model. For a perfect crystal all the energy levels, described by [10], correspond to completely coherent states and lie within a band of half-width $8J$. According to the general theory of electronic structure for disordered materials (29–31), fluctuation in the diagonal matrix elements, which is taken to be zero in [10], broadens the total band width, but narrows the region of extended states, so that the energy level for the lowest extended state goes up. When the energy fluctuation is sufficiently large, there are no extended states in the band (Anderson transition), as shown in Fig. 4. Since the energy fluctuation in the diagonal elements shortens the mean free path of scattering at the extended states, there is a correlation between the average binding energy of a localized electron and the finite coherence length at the quasi-free state.

Similarly, an electron–phonon interaction which is too weak to form a small polaron in the crystal could produce a small-polaron state in a highly disordered system, because of the narrowing of the band of extended states.

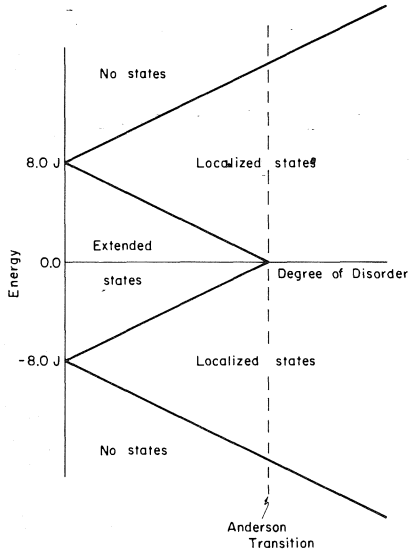

FIG. 4. Schematic diagram of the types of states which are present at various combinations of energy and randomness for a BCC lattice with nearest-neighbor interaction J and disorder in the diagonal terms of the Hamiltonian. The boundaries between the regions are not necessarily straight lines as we have drawn them. For degrees of disorder greater than that labelled 'Anderson Transition', all states are localized.

In order to show that the above argument is not restricted to the tight-binding model, let us consider the effect of a finite mean free path of scattering on the binding energy of a localized electron in a spherical potential well of depth $\hbar^2U_0/2ma^2$ and radius a. Such a potential well may be thought of as static or due to the electron–phonon interaction. We represent the fluctuating potential in the region outside the radius a by an imaginary potential $i\hbar^2U''/2ma^2$. This is a common substitution, and is used to represent such physical phenomena as widths of energy levels (optical potential for scattering) or attenuation (complex index of refraction). We expect that these features in the form of distributions of energy levels and finite mean free paths will be present in disordered systems. The presence of the imaginary potential implies, of course, that the eigenenergies will be complex. The imaginary part of the eigenenergy may be interpreted as an energy uncertainty or in terms of a mean free path.

The calculation of the binding energy proceeds as it does for the case of real potentials, except that all quantities are complex. For any complex energy ε (in units of $\hbar^2/2ma^2$) we define wavevectors p and q such that

$$[13] \qquad (p/2)^2 = \varepsilon + U_0$$

and

$$[14] \qquad (q/2)^2 = iU'' - \varepsilon$$

In terms of these, the wavefunction for the state at energy ε is

$$[15] \qquad \begin{aligned} \psi_\varepsilon(r) &= B \sin(pr/2a) && r < a \\ &= Ce^{-(qr/2a)} && r > a \end{aligned}$$

Equations 13 and 14 require a relation between p and q:

$$[16] \qquad \left(\frac{p}{2}\right)^2 - U_0 = iU'' - \left(\frac{q}{2}\right)^2$$

The requirements of continuity of the wavefunction and its first derivative at $r = a$ imply

$$[17] \qquad \frac{p}{2}\cot\frac{p}{2} = -\frac{q}{2}$$

Remembering that p and q are complex, and writing $p = p_1 + ip_2$, $q = q_1 + iq_2$, [16] and

[17] become

$$q_2^2 - q_1^2 = p_1^2 - p_2^2 - 4U_0$$
[18]
$$p_1p_2 + q_1q_2 = 2U''$$

and

$$q_1 = -\frac{p_1 \sin p_1 + p_2 \sinh p_2}{\cosh p_2 - \cos p_1}$$
[19]
$$q_2 = \frac{p_1 \sinh p_2 - p_2 \sin p_1}{\cosh p_2 - \cos p_1}$$

Equations 18 may be rewritten to show the explicit dependence of q on p:

$$q_1 = \{\tfrac{1}{2}(4U_0 - p_1^2 + p_2^2) + [\tfrac{1}{4}(4U_0 - p_1^2 + p_2^2)^2 + (2U'' - p_1p_2)^2]^{1/2}\}^{1/2}$$
[20]
$$q_2 = \{\tfrac{1}{2}(p_1^2 - p_2^2 - 4U_0) + [\tfrac{1}{4}(4U_0 - p_1^2 + p_2^2)^2 + (2U'' - p_1p_2)^2]^{1/2}\}^{1/2}$$

From this point on, the calculations to find the ground-state energy were done numerically: A value for p was chosen, and q was calculated both from [19] and [20]. Then the quantity $D \equiv (q_1(19) - q_1(20))^2 + (q_2(19) - q_2(20))^2$ was minimized by varying p_1 and p_2, using a principal axis technique (the algorithm used in a Fortran translation of procedure PRAXIS, taken from ref. 32). The initial values of p_1 and p_2 were chosen to be slightly greater than π and 0, respectively, to ensure that the eigenstate so found would be the ground state.

The result of this calculation is the ground-state energy as measured from the zero of potential. In random systems, however, a more useful number is the binding energy of the state measured with respect to the quasi-free level, the lowest conduction state. In order to satisfy the rule of Ioffe and Regel (33), that the real part of the wavevector must be greater than the imaginary part (reciprocal of mean free path), it is easy to convince oneself that the real part of the quasi-free energy must also be at least equal to the imaginary part of the potential.

The results of the calculation of the binding energy as measured from the quasi-free level are shown in Fig. 5, as a three-dimensional perspective plot. The general trend shown by this plot is that the binding energy increases with increasing U'', but not as fast as U''. That is, we observe that the energy of the ground state as measured from the zero of potential is becoming larger, but not as fast as the quasi-free level is rising. These results are also presented graphically in Fig. 6, where the separate terms are displayed for $U_0 = 2.50$ (in units of $\hbar^2/2ma^2$). There we see clearly that the term $\varepsilon_B(U_0,U'') - U''$, which is the negative of the ground-state energy measured from the zero of potential is monotonically decreasing as U'' increases. This calculation shows that a shorter coherence length at the quasi-free level increases the binding energy of localized states. As we have seen in the previous section (eq. 3), a decrease in binding energy leads to an increase in the low-field electron mobility in the hopping regime. Hence as more and more methane is added to ethane, the mean free path increases, and as a result the excess-electron mobility increases.

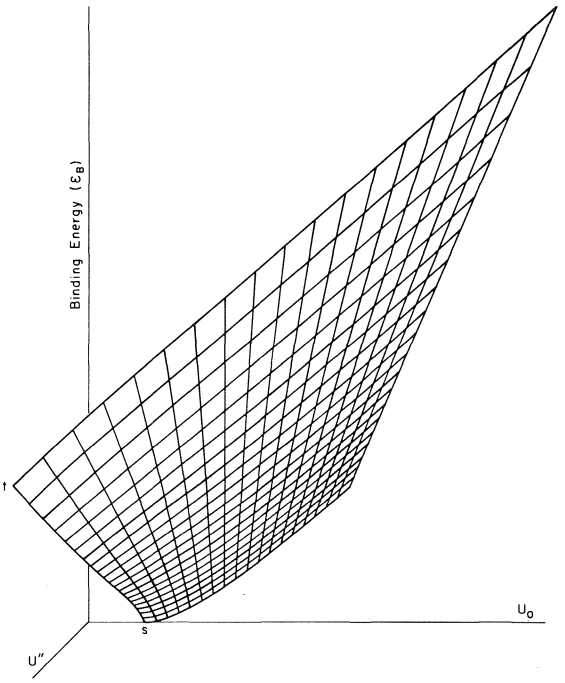

FIG. 5. Three-dimensional perspective plot of binding energy ε_B *vs.* real part of potential U_0 and imaginary part of potential U'', in the region $2.5 < U_0 < 11.5$, $0.0 < U'' < 5.0$. All energies are in units of $\hbar^2/2ma^2$ where a is the radius of the central well and m is the effective mass of the electron. Because this is the projection of a three-dimensional figure onto a two-dimensional surface, we have not shown the scales on the axes of this graph, for they would be misleading. As an example, line *st* is plotted in Fig. 6, where the scale is given.

The High-mobility Regime

We now examine briefly the high-mobility regime, and propose to show that it can be

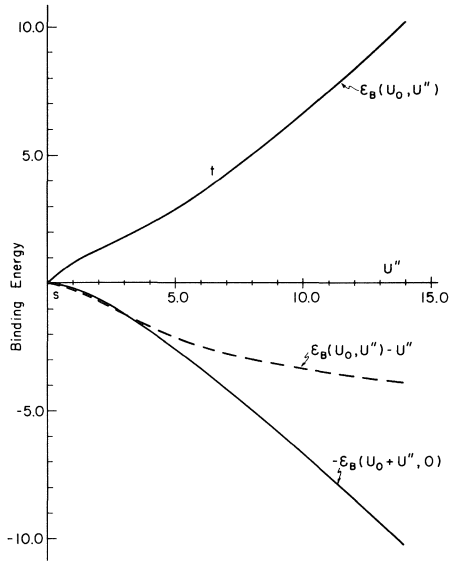

FIG. 6. Plot of the binding energy with respect to the quasi-free level $\varepsilon_B(U_0,U'')$ and the binding energy with respect to the zero of potential $\varepsilon_B(U_0,U'') - U''$ *vs.* U'' for $U_0 = 2.5$. $-\varepsilon_B(U_0 + U'',0)$ *vs.* U'' is also plotted for comparison. Here U_0 is the depth of the (real) potential well and U'' is the imaginary potential outside the well. (All energies are in units of $\hbar^2/2ma^2$ as in Fig. 5.) The line *st* corresponds to the line *st* in Fig. 5.

described adequately by a scattering model; a model containing traps and quasi-free states (6, 7) is *not* necessary in this regime. The usual argument is that the mobility is given by (34)

$$[21] \qquad \mu = \tfrac{4}{3}eL(2\pi mkT)^{-1/2}$$

where L is the mean free path. According to the proponents of the trapping model, [21] implies the mobility has a negative temperature dependence, so materials in which the mobility exhibits a positive temperature dependence cannot be described by a scattering model. This argument, however, ignores the possibility that L may be temperature-dependent. Funabashi and Kajiwara (35) have argued that L should be an increasing function of temperature in neopentane and other high-mobility hydrocarbon liquids. It is therefore possible that electron transport in high-mobility hydrocarbons may proceed via wave propagation with occasional scattering.

The scattering model also predicts the proper qualitative dependence of the mobility of ethane–methane mixtures on the ethane concentration in the high-mobility regime. For ethane concentrations of 0–20%, the mobility (4) is described by [21] with the mean free path given by

$$[22] \qquad L^{-1} = n_1\sigma_1 + n_2\sigma_2$$

where n_1 and n_2 are the numbers of molecules per unit volume for methane and ethane, respectively, and σ_1 and σ_2 are their respective cross sections. If more than 20% of the mixture is ethane, the combination of [21] and [22] no longer describes the concentration dependence of the mobility: L decreases faster than [22] predicts (4). There are two possible causes for this deviation from the simple single-scattering theory: the high density of scatterers may require a Lorentz correction such as that proposed by Landauer and Woo (36):

$$[23] \qquad L^{-1} = (n_1 + n_2)\sigma_1 + n_2(\sigma_2 - \sigma_1) \times (1 - 2n_2(\sigma_2 - \sigma_1)^{3/2})^{-1}$$

where we have assumed $\sigma_2 > \sigma_1$, and $n_2 \ll n_1$. The reason for this correction is most easily seen for hard sphere scatterers: if the incident electrons cannot penetrate into the interior of a sphere, there will be a higher current incident on other spheres. This is therefore a multiple-scattering effect, and is not restricted to hard spheres, but occurs in any medium in which the impurity cross section is larger than that of the host material. Equation 23 clearly predicts a faster decrease in the mean free path with increasing n_2 than [22] does. The second reason is that as more and more ethane molecules are added to the system they may tend to form clusters, and the cross section of a cluster of n ethane molecules may be greater than n times the cross section of a single ethane molecule. If the jth type of cluster occurs with density n_j' and the excess cross section referred to above is σ_j', then we may write

$$[24] \qquad L^{-1} = n_1\sigma_1 + n_2\sigma_2 + \sum_j n_j'\sigma_j'$$

This too will cause a more rapid decrease in L with increasing n_2. Both of these effects tend to decrease the mobility, in agreement with experiment.

Discussion

As with any model or theory, certain approximations have been made to make the mathematics tractable. The most important of these is that our model for the high-field mobility is inherently one-dimensional. A one-dimensional model gives correct results for a crystal or any other system which is uniform

or periodic in any plane perpendicular to the direction of motion. It is less clear that a one-dimensional model forms an acceptable description for disordered systems. The reason, of course, is that there is no way around a barrier in a one-dimensional system; the charge must 'go over' or tunnel through. In a three-dimensional system there may be other paths. The presence of the alternative paths reduces the effect of a small concentration of high barriers. Still, our one-dimensional model may be thought of as an idealization of the path of an individual electron through the sample in the presence of an external field, for even in a three-dimensional system, the electron's path will be over sites of randomly varying potentials. The effective width of the distribution of barrier heights may, however, be reduced. It is clear, then, that one must exercise caution when making *quantitative* comparisons between our model and experiment, although the predictions of our model should be qualitatively correct.

Although we have shown in the third section that shortening the mean free path at the quasi-free state has the effect of increasing the effective binding energy of a localized electron, we have not shown that a potential of arbitrarily small strength can bind an electron in a sufficiently highly disordered three-dimensional system. There may well be a range of values for potential strength and mean free path for which the wavefunction for an excess electron is neither localized nor extended. There is no adequate physical picture of electron transport in this regime. A number of physicists have denoted motion in this regime as electronic Brownian motion (see, for example, ref. 37) but have not provided any practical way of calculating transport properties for this intermediate range (1–10 $cm^2 V^{-1} s^{-1}$) of electron mobilities.

From what has been stated above, it is clear that the magnitude and temperature coefficient of the low-field dc mobility alone are not sufficient to determine the transport mechanism. Since other experiments such as ac conductivity, Hall effect, etc. have not yet been performed on alkane liquids, the only other available measurements of transport properties in these liquids are the high-field mobility measurements. It is on the basis of these measurements that the adequacy of models for transport must be decided.

These high-field results suggest that a simple trapping or two-state model would be difficult to apply to liquid alkanes. In the trapping model (6, 7) the observed mobility is expressed as

$$\mu = \mu_F P \qquad [25]$$

where μ_F is the mobility in the quasi-free state and P is the probability of finding the electron in the quasi-free state. The magnitude of μ_F is generally taken to be 100–150 $cm^2 V^{-1} s^{-1}$ or greater, and it is thought to be independent of the material in which the electrons are moving. The function P contains all of the information about the depth and density of the traps in a particular material. We note in passing that it is highly unlikely that a *universal* quasi-free mobility can be defined. The quasi-free mobility in a particular system depends on the amount by which electrons are scattered in the system. This in turn depends on the distribution of traps and scattering centers, a highly material-dependent quantity. Thus we expect the number and depth of traps to affect both factors in [25].

Aside from this, it appears unlikely that a reasonable functional form of P in terms of trap depth, field, temperature, etc. could be found which would predict the high-field behavior of the mobility in these liquid hydrocarbons. The functional form of μ_F can be inferred from the field dependence of the high-mobility materials: the mobility is independent of field up to $\sim 10^3$ V/cm, then decreases with increasing field. As the zero-field mobility decreases, however, the region in which the mobility is independent of field becomes larger (the lowest mobilities remain constant up to fields of $\sim 10^5$ V/cm), and the deviation changes sign: below ~ 1 $cm^2 V^{-1} s^{-1}$ the mobility *increases* with increasing field strength above the threshold. It would be difficult for the proponents of the trapping model to produce a function P which meets all these requirements and is still reasonable in terms of physical considerations such as its dependence on the trap depth and the external field. Instead of this, they could relax the requirement that the quasi-free mobility be independent of material, but then the model would be stripped of its most interesting feature.

In our model, on the other hand, we assume that transport in the high-mobility regime is by wave propagation with scattering, and in the low-mobility regime it is by hopping. In between is the uncharted region of electronic Brownian

motion. We have been able to show that the implications of these assumptions are in qualitative agreement with experimental results. It will be interesting to observe whether other experiments (ac conductivity, Hall coefficient, etc.) also produce results in agreement with our model.

A more complete treatment would be to combine the results of the trapping and hopping models, setting

$$[26] \qquad \mu = \mu_F P + \mu_H(1 - P)$$

where μ_H is the mobility due to hopping motion. The reason for this is that hopping and quasi-free motion are parallel channels for electron transport. To make such a model fit the high-field experiments, it is likely that μ_F and μ_H would have to depend on both the field strength and the choice of material, for reasons similar to those mentioned in our discussion of the trapping model above. For low-mobility materials, we would expect that P would be so small that the second term would dominate, so our treatment above would remain valid.

Discussion

G. R. Freeman: If one used a model involving an equilibrium between trapped states and a conduction band, could you estimate the field dependence of the retrapping rate from the conduction band?

K. Funabashi: If the field dependences for trapped states and conduction band are known separately, the observed field dependence should contain information on the field dependence of the retrapping rate and that of detrapping ('field-ionization').

J. M. Warman: The negative charge carrier mobility in liquid tetramethylsilane can be considerably reduced by the addition of low concentrations of a solute such as biphenyl which temporarily traps the otherwise quasifree electron. Such solutions correspond to a system in which a two state trapping mechanism is *known* to be responsible for the low mobility. A study of the field strength dependence of the mobility in such a system might therefore prove of interest with respect to the question of whether a two state trapping mechanism results in the observation of an increase or decrease in mobility at high field strengths.

W. F. Schmidt: With respect to the magnitude of the jump distance derived by us using the Bagley model we thought that the electron is not confined to say one ethane molecule but that it is spread out over a larger area and that the jump distance actually was comparable to the diameter of the trap. Values of this magnitude for trap diameters have been estimated also by Tachiya from the electron absorption spectrum of 3 MH and by Yakovlev from scavenging experiments in cyclohexane.

Experimental evidence from liquid semiconductors

J. E. ENDERBY

Department of Physics, University of Bristol, Bristol, England

Received September 27, 1976

J. E. ENDERBY. Can. J. Chem. **55**, 1961 (1977).

Two broad types of liquid semiconducting alloys will be discussed, namely those involving alkali metals (*e.g.*, the Li–Pb and the Cs–Au system) and those in which a chalcogen is involved (*e.g.*, Cu–Te or Ni–Te). It will be argued that relatively simple ionic bonding schemes in alkali metal systems must be replaced by more complicated ones in chalcogen based alloys. The close interaction between atomic structure on one hand, and the electronic structure on the other will be emphasized.

J. E. ENDERBY. Can. J. Chem. **55**, 1961 (1977).

On discutera de deux types généraux d'alliages liquides semiconducteurs soit ceux impliquant des métaux alcalins (par exemple le système Li–Pb et le système Cs–Au) et ceux dans lesquels un chalcogène est impliqué (par exemple Cu–Te ou Ni–Te). On croit que les schémas de liaisons ioniques relativement simples des systèmes métalliques alcalins doivent être remplacés par des systèmes plus compliqués dans les alliages basés sur les chalcogènes. On mettra en relief la grande interaction qui existe entre la structure atomique d'une part et la structure électronique d'autre part.

[Traduit par le journal]

Introduction

There exists a group of liquid conductors whose electronic properties are different from those of metals and are similar to those of semiconductors. Such liquids are usually referred to as 'liquid semiconductors'.[1] Two main types of liquid semiconductors have been identified, namely, those based on the *chalcogens* (for example, pure liquid Se or liquid Cu_2Te) and those liquids in which *metals* with large electronegativity differences (χ) are alloyed together (*e.g.*, liquid Mg_3Bi_2 or CsAu). Our basic understanding of these liquids is still in a very primitive state and progress continues to be painfully slow; the development of a comprehensive theoretical framework in which the various structural, electronic and thermodynamic properties of liquid semiconductors can be discussed, is now a matter of some urgency. One possible way of achieving this aim is to take some representative liquid alloy systems and to attempt, at an experimental level, to establish links between structural and electronic properties. We shall follow this course in this review.

[1]These should not be confused with the liquids formed by melting solid semiconductors. Such liquids are frequently metallic in character. A review of the electrical properties of liquid semiconductors has been given by Enderby (1).

Alkali Metal Based Semiconductors

Lithium Alloys

We first present results due to Nguyen and Enderby (2) for the resistivity, ρ, and thermoelectric power, S, for liquid lithium alloys of the type Li_xM_{1-x} where $1 < x < 0$ and M represents a metal whose valence, Z, is in the range $2 \leq Z \leq 5$. In addition, new data for the spin-flip cross-section, σ_s, for Pb and Bi in liquid lithium are given. These data were taken on dilute alloys ($x > 0.95$) so that interference effects between impurity atoms can be neglected. A summary of all the experimental results is given in Figs. 1–4.

We focus attention on the data contained in Fig. 1 which we interpret within the framework first suggested by Wignall, Enderby, Hahn, and Titman (3) and Asik, Ball, and Slichter (4). The magnitude of σ_s reflects the probability of a spin flip at an impurity site. This is dominated by the spin–orbit coupling and should, other things being equal, increase monotonically with Z. This indeed happens for $Z \leq 2$; however, as first noted by Asik *et al.* (3), for $Z \geq 3$ departures from the simple theory are evident and the new data reported here for the liquid state confirm the trend for Z values of 4 and 5.

We next consider the variation of the electronic transport parameters with composition. It is

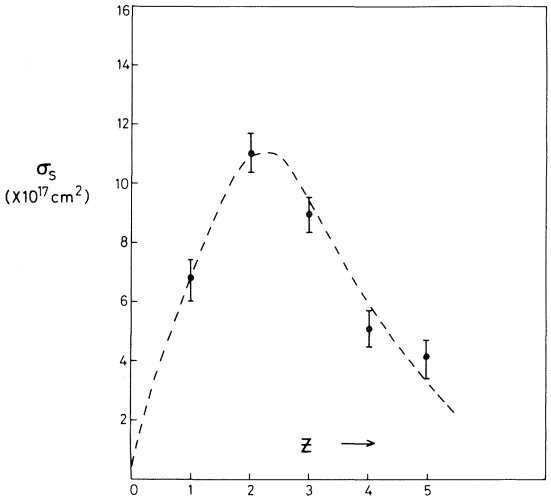

FIG. 1. Spin-flip scattering cross-sections as a function of impurity valence. The impurities were Au, Hg, Tl, Pb, and Bi.

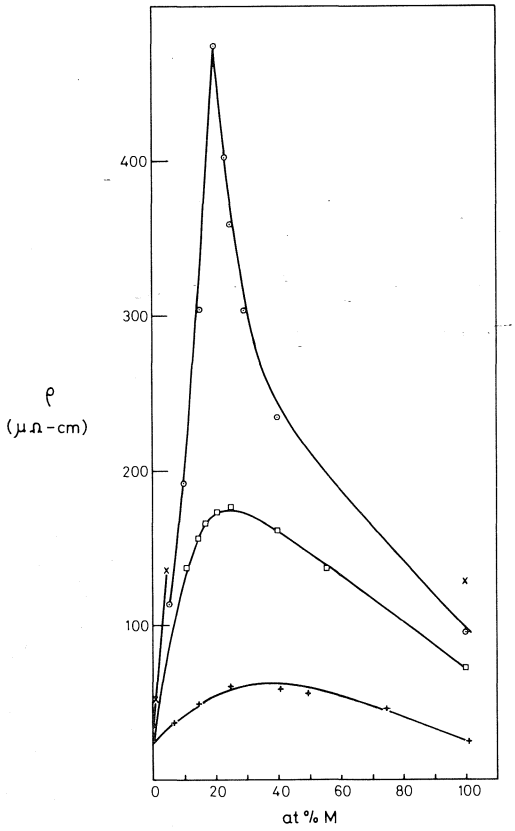

FIG. 2. Electrical resistivity of liquid Li alloys as a function of concentration: +, Li–Mg (Van Zytveld (15)); □, Li–Tl; ○, Li–Pb; ×, Li–Bi.

clear from Figs. 2–4 that this variation becomes increasingly less free electron like as $Z \geq 3$. The rapid variation in S with x around the composition Li_4Pb, for example, resembles behaviour found in other liquid alloy systems which are known to be liquid semiconductors (1).

We now assert that the anomalous electrical behaviour for $Z \geq 3$ and the reduction in σ_s which occurs at this value of Z have a common origin, namely, the formation of bound or virtually bound states at or below the bottom of the conduction band: and that for $Z \geq 3$ a progressive and actual reduction in the effective number of electrons occurs as the concentration of impurities increases. This arises first because the *s* electrons are bound to the impurity atoms and secondly because the impurity *p* orbitals fall and sharpen into virtual levels and finally, with high enough Z and χ, become bound orbitals below the bottom of the band. As noted by Flynn and Rigert (5), it is not possible, outside the one-electron approximation, to make a sharp distinction between bound and virtually bound states and the concept of an effective number of electrons is still a qualitative one. However, in this picture, it is unnecessary to invoke a pseudogap at E_F in order to explain the electrical properties for large x. Instead, attention shifts to the bottom of the conduction band. As the stoichiometric composition is approached, the density of states will fall and the possibility of localisation at E_F may then have to be considered.

The anomalies in ρ, S, and σ_s for $Z \geq 3$ are parallelled in the thermodynamic behaviour. Substantial heats of mixing develop for high (2) impurities and this reflects what is loosely called 'compound formation' at certain well-defined values of x. The most clear-cut examples are those of liquid Li–Pb (Li_4Pb) and liquid Li–Bi (Li_3Bi). We now make our second assertion, namely, that the bonding orbitals which give rise to the compound are precisely those referred to above; in asking questions about the nature of the compound, we are really asking about the spatial form of the *s* and the *p* orbitals.

The *ionic model* is one in which both the *s* and the *p* electrons are localised on the electronegative ion so that, for instance, liquid Li_3Bi consists of Li^+ and Bi^{3-} ions. In the *molecular model* the valence requirements are satisfied

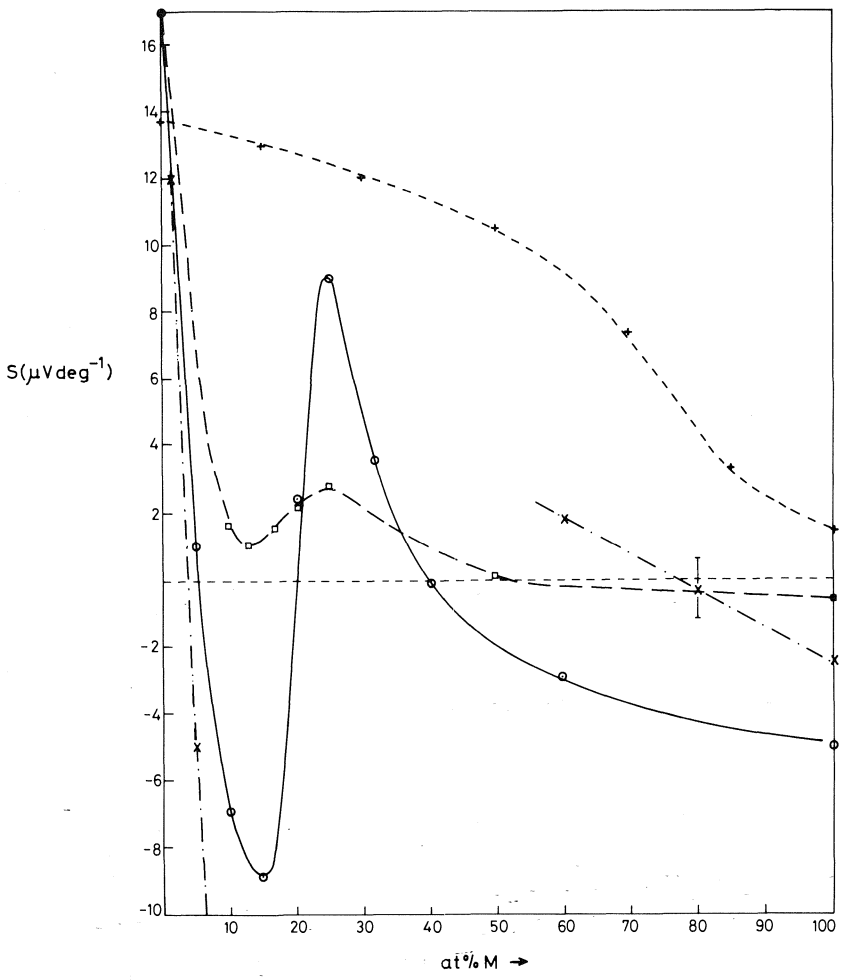

FIG. 3. Absolute thermoelectric power of liquid Li alloys as a function of concentration: +, Li–Mg (Van Zytveld (15)); □, Li–Tl; ○, Li–Pb; ×, Li–Bi.

within a molecule so that the liquid consists of electrically neutral molecules of Li_3Bi, the strong intra-molecular forces arising from *sp* hybridisation. Finally, in the *mixed bond model*, some fraction of the *s* and *p* electrons is localised on the electronegative ion and the rest are involved in an extended network of covalent bonds. We must emphasise that both Li_4Pb and Li_3Bi remain electronic conductors and that these models represent a zeroth order approximation to what is an exceedingly complex situation.

All of these models imply the presence of low-lying electron states; furthermore, the existence of ionic bonding in liquid NaCl (6) and molecular bonding in liquid $TiCl_4$ (7) is well established. Whether or not an extended network of covalent bonds can be maintained in the liquid state is not so clear, but the neutron diffraction evidence for liquid Te (8) favours this possibility.

Molecular liquids tend to be volatile and to have low freezing points. This behaviour is not at all characteristic of liquid Li_4Pb and Li_3Bi; furthermore, solid Li_4Pb is known not to be molecular and in agreement with the structural study of Ruppersberg and Egger (9) we tentatively conclude that molecules, as such, do not exist in these liquids. Of the two remaining models, the structural evidence points, albeit indirectly, to rather high co-ordination numbers (~10) for *unlike* atoms and near neighbour

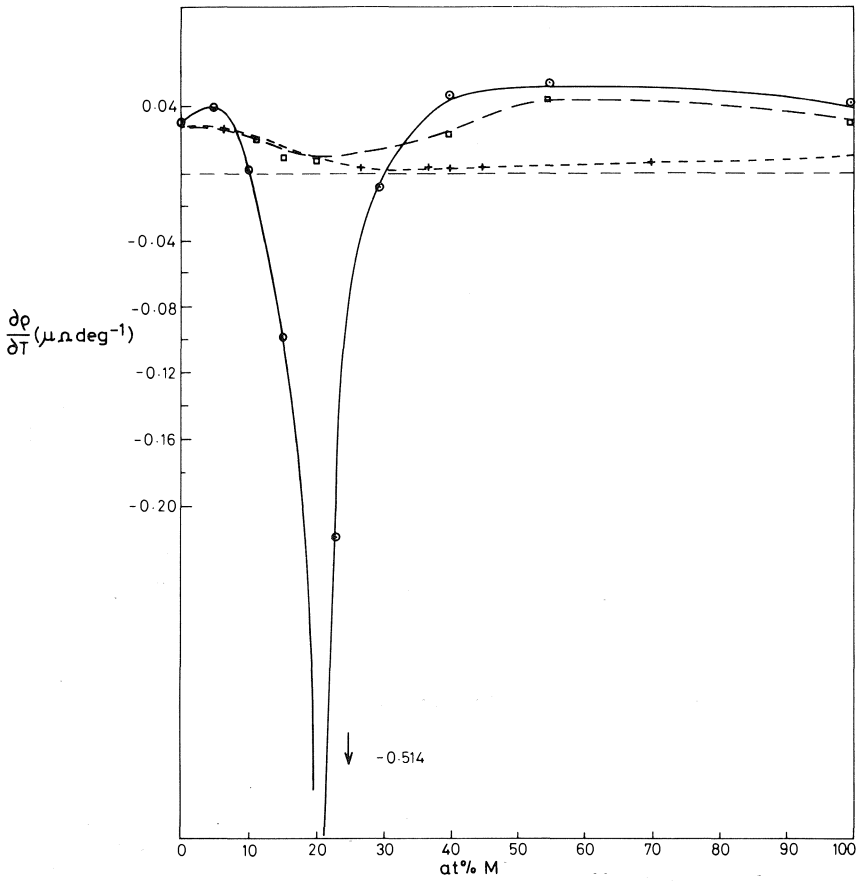

FIG. 4. $\partial\rho/\partial T$ as a function of concentration at temperatures just above the liquidus: +, Li–Mg (Van Zytveld (13)); □, Li–Tl; ⊙, Li–Pb.

distances considerably smaller than those predicted by hard sphere theory. This behaviour is consistent with the results of Edwards *et al.* (6) on molten NaCl and adds support to the ionic model.

Other Alkali Metal Systems

A detailed study of the Cs–Au system in the liquid state has recently been reported by Schmutzler, Hoshino, Fischer, and Hensel (10). Similar arguments based on electronegativitity differences used above should certainly hold for this case where χ is comparable with that of CsCl. It is found in practice that Cs–Au is indeed a liquid semiconductor, that there is a rapid increase in ρ as either Cs or Au is added to Au or Cs, and that at the stoichiometric composition, the conductivity is very low ($3\ \Omega^{-1}\ cm^{-1}$). Careful studies showed that this arises chiefly by ion-transport, that is to say, non-electronic effects. This work provides a convincing demonstration that a progressive reduction in the metallic characteristics of an alloy system can be understood in terms of increased ionicity.

Chalcogen Based Semiconductors

The electrical behaviour of these systems has been extensively studied and reviewed (see for example ref. 1). In systems like Cu–Te, Ni–Te, and Tl–Te, minima in the conductivity occur at Cu_2Te, $NiTe_2$, and Tl_2Te. A more detailed review of the present situation for Tl_2Te is given by Cutler (11). It remains, however, a matter of dispute which of the three structural models referred to above is appropriate for these cases where in general χ is less than for the alkali metal counterparts.

Let us now consider in detail the structure of

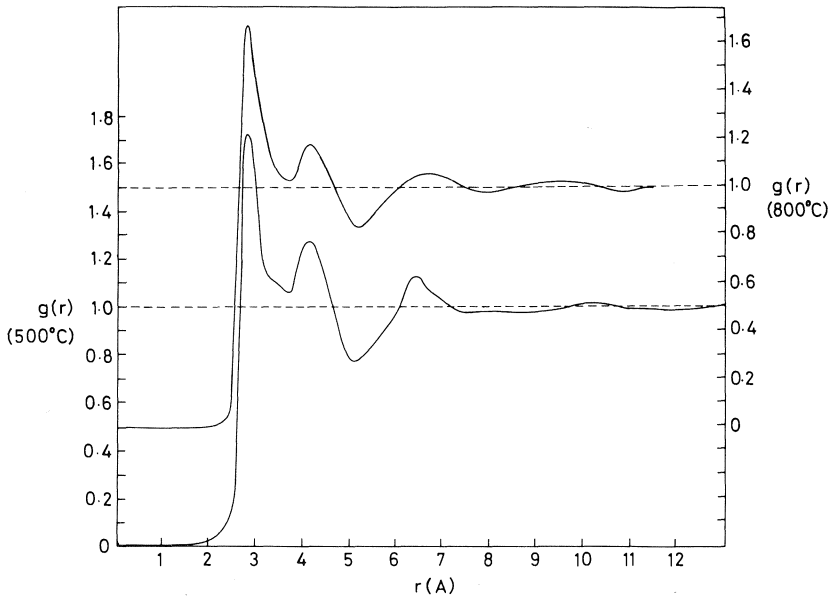

FIG. 5. The radial distribution function for pure liquid Te at 500 and 800°C.

these liquids. The quantity which can be extracted from a single diffraction experiment on a liquid containing two species, a, b is the *total structure factor* $F(Q)$ defined by

$$F(Q) = c_a^2 f_a^2 (S_{aa} - 1) + c_b^2 f_b^2 (S_{bb} - 1) + 2c_a c_b f_a f_b (S_{ab} - 1)$$

where c_a and c_b are the atomic concentrations of the two species, f_a and f_b are the neutron scattering lengths, and S_{aa}, S_{bb}, and S_{ab} are the *partial structure factors* which are related to the *radial distribution functions* $q_{\alpha\beta}$ for one atom type with respect to another atom type by

$$S_{\alpha\beta} = 1 + \frac{4\pi N}{V} \int (g_{\alpha\beta} - 1) r \sin Qr \, dr$$

α, β = a or b.

It is now accepted that the aim of structural analyses on binary systems should be to extract $S_{\alpha\beta}$ rather than $F(Q)$. This can be done by varying the scattering lengths of one or both components in such a way as to provide three total structure factors F_1, F_2, and F_3 which are sufficiently different to enable three linear equations to be solved for S_{aa}, S_{bb}, and S_{ab}. In recent experiments carried out by Nguyen[2] the variation in f was achieved by isotopic substitution since, in general, the neutron scattering length depends on the number of neutrons in the nucleus. A special study of Ni–Te was undertaken because by choosing a mixture of ^{58}Ni and ^{60}Ni, f_{Ni} could be made to be zero so that it becomes possible to study *directly* $S_{TeTe}(Q)$ as a function of concentration.

The radial distribution function for pure liquid Te at two temperatures is shown in Fig. 5. It differs from that for simple liquids in two characteristic ways: (*i*) the short range part of $g(r)$ is very hard; (*ii*) the co-ordination number is low ($\sim$4). These facts, together with other evidence of an electronic and thermodynamic character, point to the existence of an extended covalent network (8). If we now consider the Te–Te radial distribution function in the liquid semiconductor $NiTe_2$ (Fig. 6), both of these characteristic features have disappeared. Indeed, the observed $g(r)$ resembles comparable data for the Cl–Cl distribution in liquid $BaCl_2$, a liquid known to be essentially ionic in character. On the other hand, g_{TeTe} is quite different from the Cl–Cl distribution in the molecular liquid $TiCl_4$. We therefore conclude that the effect of Ni on liquid Te is to break down the extended covalent network and localise most of the charge on the Te and Ni ions. Similar experiments are in progress for the Cu–Te system and preliminary results, already reported in ref. 12

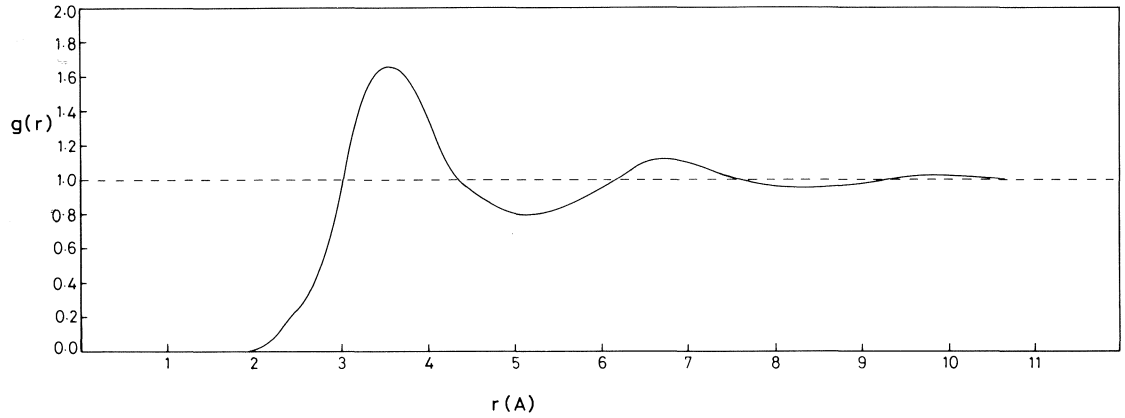

FIG. 6. The partial Te–Te radial distribution function in the liquid semiconductor $NiTe_2$ at 800°C (Nguyen, private communication).

have clearly demonstrated that substantial changes in g_{TeTe} occur with increased Cu content.

Future Developments

Apart from 'more of the same' (*i.e.* conventional electronic and structural investigations) several new techniques will need to be employed if a better understanding of these alloy systems is to be achieved. Extended X-ray absorption fine structure, EXAFS, a novel structural technique which employs synchrotron radiation, will be reviewed by Crozier *et al.* (13). Photoemission experiments will represent, when the technical problems of handling these awkward liquids are finally solved, a most powerful method of investigating core shifts and hence ionicity. Finally, nuclear spin–lattice relaxation measurements, as Warren (14) has convincingly demonstrated, yield unique information about the nature of the electron states close to the Fermi energy. Such experiments suggest, for example, that the relatively straightforward electron transfer model, though satisfactory for liquid CuTe, goes over to a mixed-bond model as the stoichiometric composition Cu_2Te is approached. This suggestion is strongly supported by the structural studies of Hawker *et al.* (12).

Discussion

N. H. March: I have a comment on the structure factor of liquid Te that you showed. Mr. B. Bhuiyan and I have recently calculated the charged hard sphere structure factor in a classical system in which, with initially localized electrons, we delocalized a very small fraction. The height of the first peak in the hard sphere structure factor $S(Q)$ increases markedly as we delocalise electrons. We believe this is relevant to the atomic structure of liquid Te, in which

the number of conduction electrons increases with increasing temperature. It indicates a sensitive interrelation between electronic and atomic structure.

J. E. Enderby: Thank you for that comment which also seems to confirm the trends we have found for the Te—Te structure factor in the Te-based liquid alloys.

G. R. Freeman: If you made an Arrhenius plot of the temperature coefficient of conductivity for liquid Li_4Pb, approximately what activation energy would you get, and at roughly what temperature?

J. E. Enderby: I do not normally make such plots because they imply the existence of a well defined energy gap. However, an effective activation energy appropriate to liquid Li_4Pb is ~0.1 eV at temperatures around 800°C.

G. R. Freeman: How does that compare with values observed in other semiconductors?

J. E. Enderby: By solid state standards, such activation energies are rather low.

Structural determinations of liquid semiconductors using extended X-ray absorption fine structure

The extended fine structure in the X-ray absorption coefficient is dominated by the interference of the photoelectron scattered by atoms in the immediate neighbourhood of the atom which absorbs the X-ray photon and thus can provide structural information about ordered or disordered systems. In this paper it is demonstrated that Extended X-Ray Absorption Fine Structure (EXAFS) measurements can be made on liquid systems at high temperatures. The technique is illustrated with results for As_2Se_3 in the liquid and amorphous states for temperatures between 100 and 773 K. A Fourier analysis of the EXAFS data reveals that a major structural rearrangement does not occur in the nearest neighbour shell when As_2Se_3 is melted. However, small structural changes do occur at the melting point which, within the limitations of the present data, suggest a slight increase in the nearest neighbour As–Se distance, a decrease in the number of nearest neighbours, and a decrease in the nearest neighbour disorder term σ_1^2.

La structure fine élargie dans le coefficient d'absorption de rayons-X est dominée par l'interférence du photoélectron dispersé par les atomes dans l'environnement immédiat de l'atome qui absorbe les photons de rayons-X et qui peut ainsi fournir de l'information structurale concernant les systèmes ordonnés ou désordonnés. Dans cette publication on démontre que des mesures de structure fine élargie d'absorption par rayons-X (EXAFS) peuvent être faites sur des systèmes liquides à haute température. On illustre la technique avec des résultats obtenus avec du As_2Se_3 à l'état liquide et dans un état amorphe à des températures allant de 100 à 773 K. Une analyse de Fourier des données EXAFS révèle qu'il ne se produit pas de réarrangement structural dans la couche voisine la plus près au moment de la fusion de As_2Se_3. Toutefois de petits changements de structure se produisent au point de fusion; à l'intérieur des limitations des données actuelles, il semble que ces changements impliquent une légère augmentation dans les distances As–Se les plus voisines, une diminution dans le nombre des voisins les plus près et une diminution dans le terme σ_1^2 de désordre des voisins les plus près.

[Traduit par le journal]

Introduction

An improved understanding of the electronic properties of liquid semiconductors requires knowledge of the fluid structure. In a disordered A–B binary system this structural information cannot be obtained from a single X-ray or neutron diffraction experiment. Enderby (16) reviewed how the partial radial distribution functions describing the A–A, A–B, and B–B correlations in a binary system can be determined from appropriate neutron diffraction experiments in alloys of different isotopic composition. In this paper we present structural data for amorphous and liquid As_2Se_3 obtained with the Extended X-Ray Absorption Fine Structure (EXAFS) technique, a technique, which it has only recently been realized, provides an important structural probe of disordered systems. In binary systems, under favourable conditions, the technique can yield the nearest neighbour distance, number, and type.

Fine structure is observed in the absorption coefficient on the high energy side of an X-ray absorption edge and in condensed phases may extend to 1000 eV beyond the edge. EXAFS refers to that fine structure in the extended range beyond ~30 eV above the edge. The structure below ~30 eV, while arising from the excitation

of a photoelectron, requires different considerations and is excluded from the discussion of EXAFS. The current theory of EXAFS for the K edge was developed and experimentally confirmed in a series of papers beginning in 1970 (1–7). The dominant absorption mechanism at usual X-ray energies is the photoelectric effect in which an X-ray with energy $h\nu$ is annihilated and a photoelectron is emitted from the atom with a kinetic energy E given by the conservation of energy as $E = h\nu - E_K$ where E_K is the initial binding energy of the electron. The photoelectron is scattered by the atoms surrounding the absorbing atom. A final state interference occurs at the origin of the absorbing atom between the outgoing part of the wavefunction of the photoelectron and the backward scattered part. This interference, which can be either constructive or destructive depending on the wavevector k of the photoelectron causes a modulation of the matrix element in which the initial state is dipole coupled to the final state. Thus the interference effect varies the photoelectric transition rate and causes the oscillation in the X-ray absorption coefficient which is referred to as the EXAFS.

Following the development of refs. 3, 4, and 5, neglecting multiple scattering effects and assuming that $kr_j \gg 1$ we write the normalized EXAFS interference term as (5)

$$[1]\quad \chi(k) = \frac{m}{4\pi\hbar^2 k}\sum_j t_j(2k)\int \frac{e^{-2r_j/\lambda}}{r_j^2} \times \sin 2(kr_j + \delta_j(k))p(r_j)\,dr_j$$

The sum is over the atoms at the distances r_j from the absorbing atom, $t_j(2k)$ is the magnitude of the amplitude for backscattering from the jth atom, λ is the meanfree path for inelastic scatterings of the photoelectron. The phase shift $\delta_j(k)$ in the sinusoidally varying term is energy dependent. It has two contributions; the phase shift produced by the absorbing atom and the phase shift produced when the photoelectron is backscattered by the jth atom. In a liquid it is convenient to specify the locations of the backscattering atoms by $p(r_j)$, the probability that the jth atom is at r_j. In a crystalline or amorphous solid it is reasonable to assume that

$$p(r_j) = \frac{1}{(2\pi)^{1/2}\sigma_j} e^{-(r-R_j)^2/2\sigma_j^2}$$

where R_j is the average position between the absorbing atom and the jth backscattering atom, and σ_j^2 is the mean square fluctuation in the interatomic distance between the origin atom and the jth atom. The fluctuation includes a dynamical term due to the thermal motion of the atoms and a static term due to structural disorder. A theoretical calculation of the structural disorder term has not yet been undertaken. In the case of the dynamical term there are two physically transparent limits. If the origin and jth atom are vibrating in phase then $\sigma_j^2 = 0$ and if they are vibrating independently then σ_j^2 is just the sum of the mean square displacements of the atoms from their equilibrium positions.

With the assumed Gaussian distribution of atoms [1] becomes

$$[2]\quad \chi(k) = \frac{m}{4\pi\hbar^2 k}\sum_j \frac{N_j}{R_j^2} t_j(2k)\, e^{-2R_j/\lambda} \times \sin 2(kR_j + \delta_j(k))\, e^{-2k^2\sigma_j^2}$$

where the sum is over the different shells of atoms whose average distance from the absorbing atom is R_j and which contains N_j atoms. In principle, by the appropriate combination of EXAFS measurements on suitable systems all the quantities in [2] can be determined for disordered solids. Analytical methods based on the Fourier transforms of the EXAFS function $\chi(k)$ are illustrated in refs. 5 and 8.

The experiments reported in this paper on As_2Se_3 were initiated to assess the feasibility of making EXAFS measurements on liquids at high temperatures. With increasing temperature the magnitude of σ_j^2 increases and the amplitude of $\chi(k)$ decreases. Utilizing the Bremsstrahlung radiation from a conventional X-ray source would necessitate taking data for a period in excess of two weeks to achieve a suitable signal-to-noise ratio in each EXAFS spectrum. Such experiments would be impractical. However the experiments were readily performed using the synchrotron radiation from SPEAR, Stanford's e^- e^+ storage ring which provides an X-ray intensity five or six orders of magnitude higher than that available from conventional X-ray sources. The As_2Se_3 system was chosen for preliminary investigations because the K edge EXAFS spectra of both the As and Se were accessible with the existing monochromator at the Stanford Synchrotron Radiation Project and because the local structure was known to remain

substantially unaltered at the melting point. Far-infrared measurements (9, 10) indicate that vibrational modes observed in the amorphous state persist into the liquid state. In this paper the EXAFS spectra are examined for changes in the first shell radii R_1 upon melting amorphous As_2Se_3 and the temperature dependence of ${\sigma_1}^2$ is determined between 100 and 773 K.

Experimental

The As_2Se_3 samples were prepared from 99.9% purity As_2Se_3 (Alfa Inorganics, Ventron, MA). The As_2Se_3 was evaporated in a vacuum of 5×10^{-5} torr from a Mo boat onto a boron nitride substrate which formed one side of the sample cell. The thickness of the As_2Se_3 films was monitored by a crystal oscillator and later determined to within 1 μm with a Reichert microscope of magnifying power 90. A film thickness of 22 μm provided suitable signal-to-noise ratio in the high k region of the EXAFS spectra. The sample cell was made from two rectangular slabs, $5.0 \times 2.5 \times 0.6$ cm, milled from BN (Union Carbide, Cleveland, OH). BN was selected as the material for the sample cell because it has a low X-ray absorption coefficient in the energy range of interest, does not react with As_2Se_3, is machinable, and does not undergo irreversible dimensional changes upon thermal cycling. To provide an X-ray window of low absorption the portion of the BN to be located in the X-ray beam was milled to a wall thickness of 0.7 mm. The loss of liquid As_2Se_3 from the cell was prevented by using a mica gasket cleaved to the same thickness as the evaporated As_2Se_3 film and by bolting the BN slabs together with BN bolts as indicated in Fig. 1. The temperature of the film was determined to within 5 K by chromel–alumel thermocouples embedded in the BN cell.

The EXAFS measurements were conducted in the symbiotic mode at the Stanford Synchrotron Radiation Project. In this mode radiation is incident on the sample cell for an uninterrupted period of approximately 3 h. The furnace indicated in Fig. 1 was designed to minimize the non-usage of available beam time. Up to three BN cells could be loaded on the translation stage indicated in the figure. One cell at a time could be heated by sliding it into a closely-fitting rectangular slot in the heating unit which consisted of BN wound with Kanthal A resistance wire. The X-ray beam passed through openings milled in the sides of the heater. The heating assembly was positioned in a cylindrical water-cooled vacuum chamber made of 304 stainless steel which was fitted with X-ray windows of 0.5 mil thick Kapton. To achieve rapid thermal cycling the chamber was evacuated and back-filled with 1 atm of helium. A cell could be heated from room temperature to 1000 K in $\frac{1}{2}$ h. In a separate assembly, which is not illustrated, low temperatures were achieved by securing the BN sample cells to a copper block which was cooled with liquid nitrogen.

A detailed description of the X-ray absorption apparatus is given elsewhere (11). Briefly, the high flux, broad band synchrotron radiation generated in the Stanford electron positron storage ring is incident on a monochromator which uses the (220) Bragg planes in a channel cut silicon crystal. The intensity I_0 of the monochromatized beam incident on the furnace housing is determined as it passes through a transmission ion chamber. After transmission through the sample the intensity I is detected by a second ion chamber. The ratio I_0/I of the digitized ion chamber currents are stored in a PDP-11/05 minicomputer. In our experiments the computer was programmed to take data in the energy range 11 450 to 14 150 eV from which could be extracted the EXAFS associated with the As and Se K edges at 11 867 and 12 658 eV, respectively. The resolution was the order of 1 eV. With the high photon flux available an integration time of 1 s per point was used for all energies. However, as will be indicated later this was insufficient for a good signal-to-noise ratio for energies 750 eV above the K edges of interest. Absorption data were taken at discrete temperatures in the range 100 to 773 K encompassing the amorphous and liquid states of As_2Se_3. One run on the absorption spectra of the As edge was taken at 867 K. Evaporation losses at this high temperature prevented our obtaining data on the Se edge.

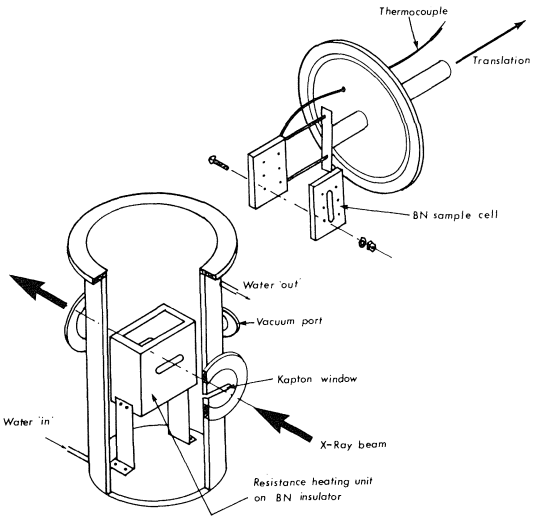

FIG. 1. Sketch of the high temperature sample cells and furnace.

The total absorption coefficient, obtained from the experimental ratio $\ln I_0/I$, contains background contributions from the furnace assembly, sample cell, and electrons in the sample as well as contributions from the K shell electrons of interest. The background contribution was found by fitting the data below the edge with a second order polynomial and extrapolating through the region of interest. This contribution was subtracted from the data leaving only $\mu(E)$, the K shell absorption coefficient (including EXAFS). The data were transformed to momentum space by taking the zero of the kinetic energy of the ejected K photoelectron to be at the K edge of interest. The EXAFS interference function $\chi(k)$ was determined by numerical procedures discussed in detail in ref. 5.

Results and Discussion

A representative plot of the EXAFS interference function $\chi(k)$ is shown in Fig. 2 for the

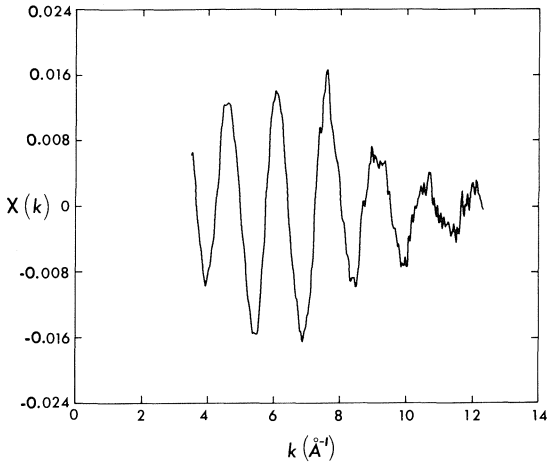

FIG. 2. The EXAFS interference function $\chi(k)$ as a function of k for the As K edge in liquid As_2Se_3 at 658 K.

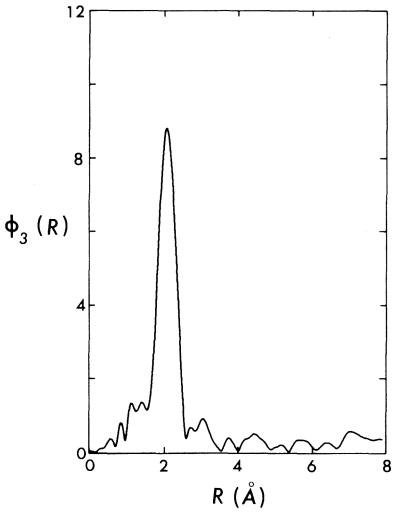

FIG. 3. The magnitude of the $\phi_3(r)$ transform as a function of r for liquid As_2Se_3 at 658 K. The absorbing As atom is located at $r = 0$. The plot was obtained by transforming the $\chi(k)$ shown in Fig. 2.

K edge of As in As_2Se_3 at 658 K (31 K above the melting point). The k-space data were truncated at 12.3 $Å^{-1}$, beyond this value the signal-to-noise ratio became unacceptable. The dominant low frequency oscillation in $\chi(k)$ is determined by interference of the photoelectrons backscattered from the nearest neighbours.

Interatomic distances are most readily obtained by taking the Fourier transform defined by

$$[3] \quad \phi_3(r) = \frac{1}{\sqrt{2\pi}} \int_{k\min}^{k\max} k^3\chi(k)\, e^{i2kr}\, dk$$

This transform is related to a pseudocharge density (3) and thus is useful for determining atom positions. The magnitude of the $\phi_3(r)$ transform obtained from the $\chi(k)$ of Fig. 2 is shown in Fig. 3 as a function of r. At the origin of the r-space is the absorbing As atom. The main peak, with a maximum value at $R_1 =$ 2.12 Å, is determined by the atoms in the nearest neighbour shell. In order to obtain the magnitude of the nearest neighbour interatomic distance R_1 must be corrected by the phase shift $\delta_1(k)$ introduced in [1]. The phase shift can be obtained (3–5) from EXAFS data in crystalline As_2Se_3. In this paper, where our interest is in structural changes at the melting point, we specify only the peak distance R_1. It is the R_1 peak which dominates the oscillations in $\chi(k)$. The shape of the R_1 peak is determined by a number of factors including the number and nature of the nearest neighbours, the disorder term σ^2, the nature of the $\phi_3(r)$ transform taken, and the finite range of the Fourier transform (which introduces a width $\Delta r \approx \pi/\Delta k = 0.36$ Å).

The magnitude of the $\phi_3(r)$ transform of amorphous As_2Se_3 at 619 K (8 K below the melting point) is shown in Fig. 4 with the absorbing As atom at the origin. A comparison of Figs. 3 and 4, and equivalent figures obtained with Se as the absorbing atom, indicates that major structural rearrangements do not occur in the nearest neighbour shells when the As_2Se_3 is melted. However some small structural changes are suggested. The mean peak in the solid at 619 K is shifted closer to the origin, the maximum value occurs at $R_1 = 2.10$ Å. This suggests that there is a slight increase in the nearest neighbour distance when the solid is melted. More extensive data with an improved signal-to-noise ratio at large k will be required to confirm this change in distance. The height of the R_1 peak in the liquid is less than that in the solid. Changes in peak heights can be attributed to changes in the number and nature of nearest neighbours and in the disorder term σ_j^2. In an earlier paper (12) the coordination numbers N_j were deduced for amorphous binary materials from an analysis of the nearest neighbour peak amplitude without including quantitatively the effect of the disorder term σ_j^2. More recent work (8) has shown that σ_j^2 can be determined separately for disordered systems. On the basis of the decrease in σ_j^2 calculated below, the

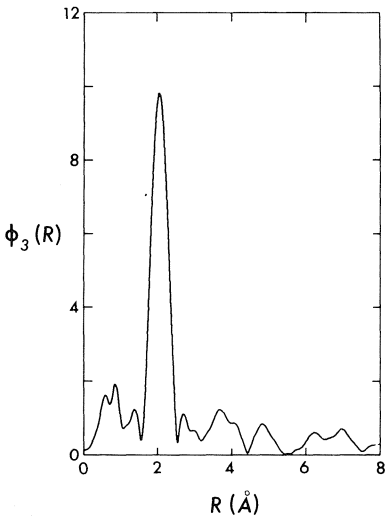

FIG. 4. The magnitude of the $\phi_3(r)$ transform as a function of r for amorphous As_2Se_3 at 619 K.

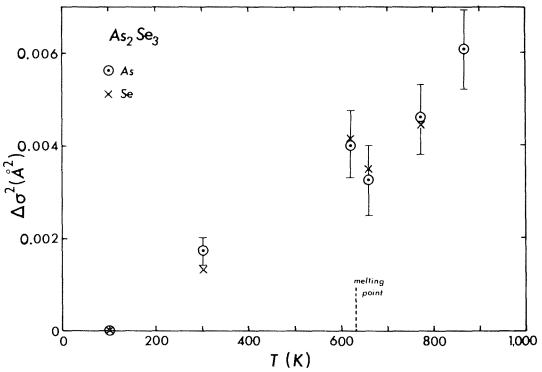

FIG. 5. $\Delta\sigma^2$ as a function of temperature. $\Delta\sigma^2$ represents the difference between σ_1^2 for amorphous or liquid As_2Se_3 at temperature T and σ_1^2 for a reference amorphous As_2Se_3 at 100 K. σ_1^2 is the mean square fluctuation in the distance between the origin atom and the nearest neighbour atoms. Data obtained with As and Se as the origin atoms are indicated by ⊙ and × respectively. For clarity error bars have been shown only for the As data. The error in the Se data is comparable.

decrease in the peak height implies a small decrease in N_j when the solid is melted.

With the present data it is not possible to distinguish unambiguously peaks arising from shells of higher radii from peaks introduced by the nature of the Fourier transform and the noise component. However a comparison of Figs. 3 and 4 does show that melting introduces differences in the peak structure at larger r. In subsequent experiments it will be determined if these differences are meaningful.

The dependence on temperature of the disorder term σ_1^2 for the first shell of atoms can be determined from a k-space analysis of the EXAFS data. With the assumptions that $\chi(k)$ is determined exclusively by the interference effect produced by backscattering from atoms in the nearest neighbour shell and that R_1 and N_1 are independent of temperature, [2] can be written as

$$[4] \qquad \chi(k, T) = \chi_1(k, 0)\, e^{-2k^2 \sigma_1^2(T)}$$

where $\chi_1(k, 0)$ is temperature independent. These assumptions must be examined more closely at the melting point (and above) where there are indications that N_1 (and possibly R_1) changes. By taking the ratio of χ at two different temperatures T_1 and T_2 we obtain

$$[5] \quad \ln\frac{\chi(k, T_1)}{(k, T_2)} = 2k^2(\sigma_1^2(T_2) - \sigma_1^2(T_1))$$

Plots of the logarithmic ratio *vs.* k^2 gave the difference $\Delta\sigma^2$ between $\sigma_1^2(T)$ for amorphous or liquid As_2Se_3 at temperature T and $\sigma_1^2(77\text{ K})$ for amorphous As_2Se_3 at 77 K. The temperature dependence of $\Delta\sigma^2$ is shown in Fig. 5 for both As and Se as the X-ray absorbing atoms.

It is seen that the disorder term σ_1^2 increases with temperature in both the amorphous and liquid states. This can be attributed to increased thermal motion increasing the dynamical contribution to σ_1^2 and a relaxation of the local structure towards a more disordered structure. It is known from conventional X-ray diffraction studies (13) that freshly deposited As_2Se_3 films of the thickness used in our EXAFS studies relax at higher temperatures to more disordered structures. Temperature dependent EXAFS studies on crystalline As_2Se_3 will assist in separating the different contributions to σ_1^2. An interesting feature of Fig. 5 is the possibility that the disorder term decreases at the melting point.

As_2Se_3 crystallizes into layer crystals. Within the layer the As and Se are covalently bonded, each As atom is threefold co-ordinated to Se atoms and each Se atom is twofold co-ordinated to As atoms. The bonding between layers is weak; the smallest interatomic separation between layers has been estimated to be 55% greater than the intra-layer As—Se bond length (14). Interpretations of optical measurements agree that the local order in amorphous and liquid As_2Se_3 is similar to that found in the crystal.

However different models have been proposed. Lucovsky and Martin (15) assume a molecular model for the amorphous state in which pyramidal $AsSe_3$ molecules are weakly coupled by bridging As—Se—As bonds. Taylor *et al.* (9) assume that the amorphous material and the liquid just above the melting point reflect the layer structure of the crystal. On the basis of either of these models, the main R_1 peak in the $\phi_3(r)$ transform measures the As—Se bond distance (when corrected for the phase shift $\delta(k)$ of [2]). Far infrared measurements (10) indicate that a band which peaks around 269 cm^{-1} in the amorphous material experiences a discontinuous decrease at the melting point of ~ 7 cm^{-1}. Arai *et al.* (10) attribute the band to a mode of the As—Se—As bridge connecting $AsSe_3$ molecules. The slight increase in R_1 at the melting point may correlate with the decrease in the frequency of the bridge mode. The decrease in σ_1^2 at the melting point may be due, in part, to changes in the bridge angles.

In conclusion, only small structural changes occur at the melting point. Within the limitations of the present data the nearest neighbour As–Se interatomic distance increases slightly, the number of nearest neighbours decreases, and the disorder term σ_1^2 decreases. Further EXAFS measurements on crystalline, amorphous, and liquid As_2Se_3 are in progress.

The number and type of nearest neighbours cannot be determined from the EXAFS data on As_2Se_3 without additional input about the assumed structure. Experiments will be undertaken on binary systems in which the backscattering amplitudes $t_j(2k)$ of the two species differ appreciably to assess if the differences in the $t_j(2k)$ will permit determination of the nearest neighbour number and type without the need for additional structural assumptions.

Discussion

G. R. Freeman: How can the degree of disorder in a material decrease when it is melted?

E. D. Crozier: I believe that this question is adequately covered in the printed text.

G. R. Freeman: If it is a relaxation process, why doesn't the disorder decrease with increasing temperature in the solid?

E. D. Crozier: The disorder term σ_1^2 is temperature dependent because of a dynamical contribution due to the thermal motion of the atoms and a static contribution due to structural disorder. When temperature dependent EXAFS studies have been made on crystalline As_2Se it will be possible to estimate the static structural disorder term and to assess its temperature dependence for relaxation processes.

J. K. Baird: You have indicated that the structure in the X-ray absorption coefficient just beyond the K-edge is caused by the backscatter of photoelectrons from neighbouring atoms. Could a monochromatic beam of X-rays be used to produce photoelectrons having a fairly well defined energy of a fraction of an electronvolt? If these electrons were sufficiently monochromatic, they might be used to sample the effective electron scattering

cross sections in the condensed phase. For example, one might look for a Ramsauer minimum in the condensed phase cross section, evidence for which has been presented in L. G. Christophorou's analysis of the electron mobilities in the liquified rare gases.

E. D. Crozier: That portion of the fine structure in the X-ray absorption coefficient referred to as extended is assumed to begin about 30 eV above the edge. Below 30 eV the interpretation of the fine structure is complicated by many body interactions, the distortion of the excited state wave function by the Coulomb field of the excited atom and the density of final states. In principle a monochromatic beam of X-rays could be used to produce in the condensed phase of interest photoelectrons with a well-defined energy. However, I am unable to state at the moment whether the complexity of the absorption fine structure seen near the edge would obscure the Ramsauer minimum in something like liquid krypton.

D. E. Brodie: Is the structure between the origin and the first coordination peak real?

E. D. Crozier: The emphasis in the *r*-space analysis of the data presented in this paper was placed on the structure associated with the first shell of radius R_1 indicated by the main peak in the magnitude of the $\phi_3(r)$ transform. Some of the structure between the origin and R_1 is an artefact of the Fourier-transform taken. Some structure may result from the analytical procedures used to extract $x(k)$ from raw experimental data. However, there is a possibility that the peak for r less than 1 Å can be attributed to scattering from valence electrons in the chemical bond. This question is under study.

K. Ichikawa: Have you considered applying the EXAFS technique to simple ionic melts such as NaCl and to ionic melts which may have complex ionic species?

E. D. Crozier: The EXAFS technique can yield local structural information about ionic melts. The K edges of Na and Cl occur at low energies and thus it is currently not feasible to do the NaCl system. A system such as KBr would be feasible. The EXAFS technique has been applied recently by Lytle and Wong to a glass containing $ZnCl_2$. Measurements were made in both the glass and liquid states.

Electrical properties of some molten ternary semiconductors

YOSHIO NAKAMURA, MASAMITSU NAOI, AND MITSUO SHIMOJI

The electrical conductivity and thermoelectric power of molten $AgTlSe_2$, AgTlSe, and Tl_2Se_3 have been measured as a function of temperature. The effect of doping with Ag, Tl, and Se on the electrical properties of molten AgTlSe has also been studied. The results are discussed in terms of the pseudogap model.

YOSHIO NAKAMURA, MASAMITSU NAOI et MITSUO SHIMOJI. Can. J. Chem. **55**, 1975 (1977).

On a mesuré, en fonction de la température, la conductivité électrique et le pouvoir thermoélectrique des $AgTlSe_2$, AgTlSe et Tl_2Se_3 à l'état fondu. On a aussi étudié l'effet de dopage avec Ag, Tl et Se sur les propriétés électriques du AgTlSe fondu. On discute des résultats en termes d'un modèle de "pseudogap".

[Traduit par le journal]

Introduction

In the previous paper (1), we have reported the electrical conductivity and thermoelectric power of some molten ternary semiconductors ABC_2 (A: Cu, Ag; B: Tl, Sb, Bi; C: Se, Te). The observed conductivity values of these compounds just above their respective melting points range from 2.5 to 2300 $ohm^{-1}\ cm^{-1}$. It has been shown that the compounds studied are classified into two groups: the electrical conduction of the one group with higher electrical conductivity can be interpreted in terms of the strong scattering model and that of the other group with lower electrical conductivity ($\lesssim 200\ ohm^{-1}\ cm^{-1}$) in terms of the pseudogap model due to Mott–CFO (2, 3).

In this study we have measured the electrical conductivity and thermoelectric power of molten $AgTlSe_2$, AgTlSe, and Tl_2Se_3. The effect of nonstoichiometric doping on the electrical properties of molten AgTlSe has also been investigated in order to test the validity of the pseudogap model.

Experimental

The experimental procedures are the same as those described elsewhere (1). The conductivity was measured by the dc four-probe method with tungsten electrodes sheathed with graphite rods. The thermoelectric power was determined from the emf's developed by temperature gradients between the two potential electrodes of the measuring cell. The purities of the elements used were 99.999% for Ag and Se and 99.95% for Tl.

Results and Discussion

Figure 1 shows the logarithm of the electric conductivity, σ, of molten $AgTlSe_2$, AgTlSe, and Tl_2Se_3 as a function of the reciprocal absolute temperature, $1/T$. The thermoelectric power, S, is also plotted as a function of $1/T$ in Fig. 2. The results fit in with the following relations:

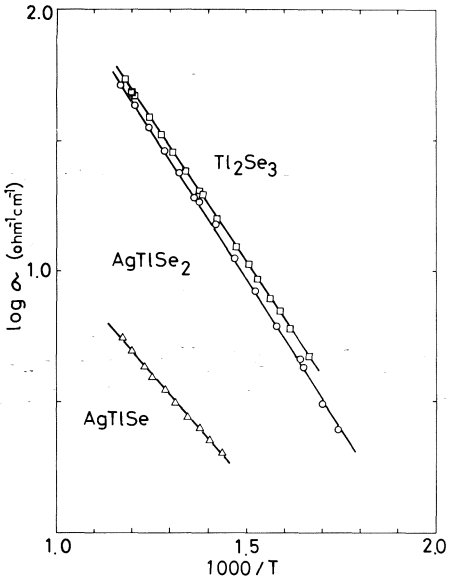

FIG. 1. The electrical conductivity of molten $AgTlSe_2$, AgTlSe, and Tl_2Se_3.

[1] $$\sigma = C \exp [- E_\sigma(0)/kT]$$

and

[2] $$S = (k/e)[E_S(0)/kT + B]$$

The observed positive sign of the thermoelectric power suggests that conduction may be dominated by holes in the extended states in the

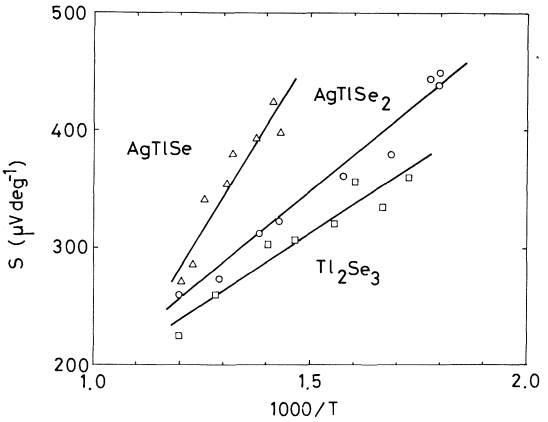

FIG. 2. The thermoelectric power of molten $AgTlSe_2$, AgTlSe, and Tl_2Se_3.

valence band. According to the pseudogap model, the hole conduction in the extended state gives rise to $E_\sigma(0) = E_S(0)$. The values of $E_\sigma(0)$ and $E_S(0)$ for $AgTlSe_2$, AgTlSe, and Tl_2Se_3 are shown in Table 1 together with those for $CuTlSe_2$, $AgTlTe_2$, and $CuSbSe_2$ reported earlier (1). We found $E_\sigma(0) > E_S(0)$, except for AgTlSe, in which $E_\sigma(0) < E_S(0)$. The inequality, $E_\sigma(0) > E_S(0)$, may be accounted for with an intrinsic two carrier model with a symmetric density of states (4). Though this may also be interpreted as originating with thermally assisted hopping conduction which has been suggested for amorphous semiconductors (5), it is reasonable to assume that conduction is dominated by carriers in extended states at such high temperatures as in the molten state. The result $E_\sigma(0) < E_S(0)$ for AgTlSe, which was also found for molten As–Se and As_2Se_3–As_2Te_3, can be explained on the basis of an intrinsic two carrier model with asymmetric density of states (6).

In the intrinsic two carrier model, the conductivity and thermoelectric power can be written as a sum of the respective contributions of electrons (subscript c) and holes (subscript v):

$$[3]\quad \sigma = \sigma_c + \sigma_v = \sigma_{0c} \exp\left[-(E_c - E_F)/kT\right] + \sigma_{0v} \exp\left[-(E_F - E_v)/kT\right]$$

and

$$[4]\quad S = \frac{\sigma_c}{\sigma} S_c + \frac{\sigma_v}{\sigma} S_v$$

S_c and S_v are given by (3):

$$[5]\quad S_c = -\frac{k}{e}\left[\frac{E_c - E_F}{kT} + A_c\right]$$

and

$$[6]\quad S_v = +\frac{k}{e}\left[\frac{E_F - E_v}{kT} + A_v\right]$$

where E_c and E_v are mobility edges of the conduction and valence bands, respectively, and E_F is the Fermi energy. The constants A_c and A_v depend on the scattering mechanism. In the symmetric density of states model (4), it is assumed that $E_c - E_F = E_F - E_v = (1/2)(E_c - E_v)$ (Fig. 3*a*). Then, if it is assumed that $E_c - E_v = E_0 - \beta T$, we have:

$$[7]\quad \sigma = (\sigma_{0c} + \sigma_{0v}) \exp\left[\frac{\beta}{2k}\right] \exp\left[-\frac{E_0}{2kT}\right]$$

and

$$[8]\quad S = \frac{\sigma_{0v} - \sigma_{0c}}{\sigma_{0c} + \sigma_{0v}} \frac{k}{e}\left[\frac{E_0}{2kT} - \frac{\beta}{2k} + A\right]$$

where $A = A_c = A_v$ is assumed. Comparing [1] and [2] with [7] and [8], respectively, we have $E_\sigma(0) = E_0/2$ and $E_S(0) = \{(\sigma_{0v} - \sigma_{0c})/(\sigma_{0c} +$

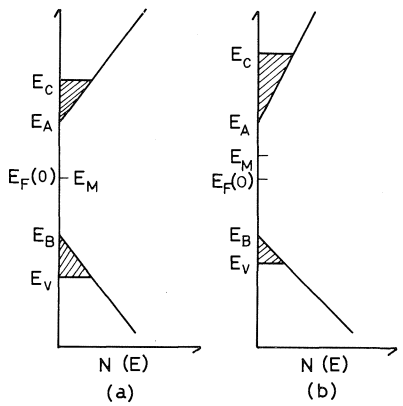

FIG. 3. (*a*) Symmetric density of states model and (*b*) asymmetric density of states model. Localized states are shown shaded. $E_M = (E_c + E_v)/2$, $E_F(0) = (E_A + E_B)/2$.

$\sigma_{0v})\}$ $(E_0/2)$. It is obvious that $E_\sigma(0) > E_S(0)$, since $(\sigma_{0v} - \sigma_{0c})/(\sigma_{0c} + \sigma_{0v}) < 1$. If A is assumed to be unity, the parameters $\sigma_{0c} + \sigma_{0v}$, σ_{0c}/σ_{0v}, and β can be determined from the experimental data (Table 1). The parameters σ_{0c} and σ_{0v} can be related to the mobility of carriers and density of states at the respective mobility edges (4).

In order to account for the inequality $E_\sigma(0) < E_S(0)$ found for molten AgTlSe, we adopt the asymmetric density of states model (6). In this model, the center of the density of states gap, $E_F(0) = (E_A + E_B)/2$, is different from the center of the mobility gap, $E_M = (E_c + E_v)/2$, as shown in Fig. 3*b*. From the observed sign of S, we assume that conduction by holes is dominant. This can be achieved, if $(E_c - E_F)$ is larger than $(E_F - E_v)$ by several kT as can be seen in [3]. The factor σ_c/σ in [4] is approximately given by

$$[9] \quad \sigma_c/\sigma \simeq \frac{\sigma_c}{\sigma_v} = \frac{\sigma_{0c}}{\sigma_{0v}} \exp\left[\frac{2(E_F - E_M)}{kT}\right]$$

which increases exponentially with temperature. This indicates that the negative term of S_c in [4] makes the positive total thermoelectric power decrease more rapidly at higher temperatures. Consequently, the obtained apparent activation energy of S, $E_S(0)$, is larger than that of the single S_v term which is equal to the conductivity activation energy, $E_\sigma(0)$. This may be the case for molten AgTlSe.

To confirm this interpretation, we have investigated the effect of the excess Tl, Ag, and Se on the electrical properties of molten AgTlSe. The results are shown in Figs. 4, 5, and 6. Ag and Tl behave quite similarly, indicating that the excess Tl acts as a monovalent metal as in molten Tl_2X (X: S, Se, Te) (7). The experimental results are summarized as follows: (*i*) the addition of Ag and Tl (up to 2 at.%) causes a slight change of the slope of ln σ *vs.* $1/T$, and a change of the sign of S (positive to negative), while the values of σ itself do not change considerably. (*ii*) the addition of Se (up to 2 at.%) causes an increase of σ by a factor of ~3–4 and decrease of the slope of S *vs.* $1/T$, while the slope of ln σ *vs.* $1/T$ and the values of S do not change significantly.

These results will be interpreted qualitatively in the framework of the asymmetric density of states model. The dissolved Ag and Tl atoms will behave as donor centers, giving valence electrons

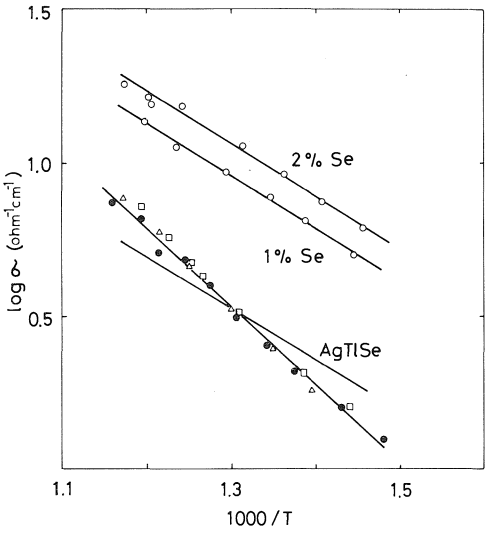

FIG. 4. The electrical conductivity of molten AgTlSe doped with Ag and Se. ●, 0.5 at.% Ag; △, 1.0 at.% Ag; □, 2.0 at.% Ag.

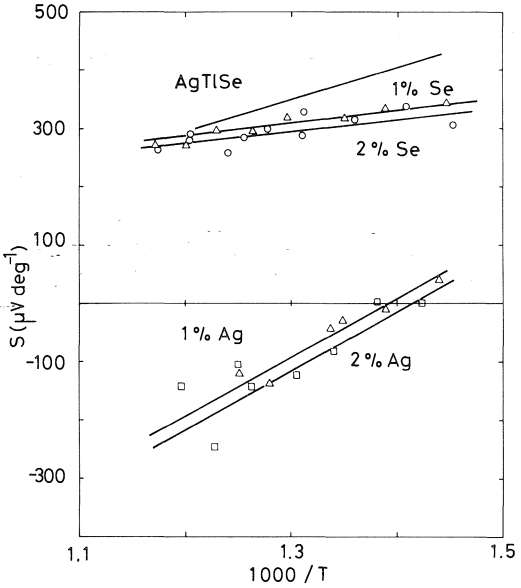

FIG. 5. The thermoelectric power of molten AgTlSe doped with Ag and Se.

to the conduction band. However, because of the localized region in the conduction band, not all of these electrons are in the extended states at lower temperatures. At the same time, the introduction of donor electrons reduces the number of holes through the well known mass-action law. Thus it appears reasonable to assume that σ_c and σ_v are compatible at the

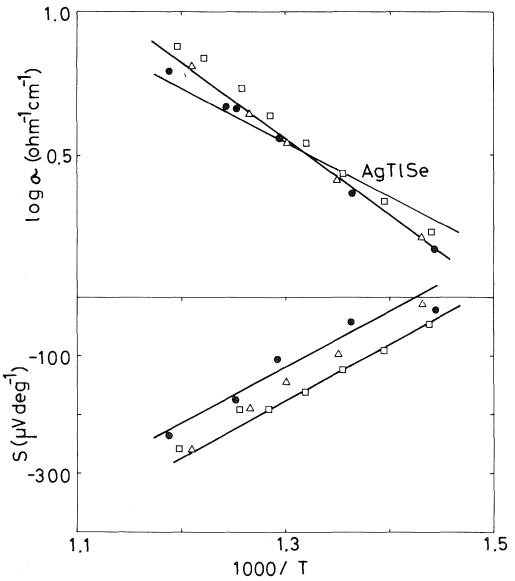

FIG. 6. The electrical conductivity and thermoelectric power of molten AgTlSe doped with Tl. ●, 0.5 at.% Tl; △, 1.0 at.% Tl; □, 2.0 at.% Tl.

lower end of the temperature range of the present study, and σ_c becomes larger than σ_v at higher temperatures. This is clearly seen from the curves of S in Fig. 5. The values of S are practically zero at lower temperatures and become large and negative at high temperatures. On the other hand, the excess Se may act as acceptor and create holes in the valence band. As these holes are in the extended states, the conductivity increases immediately. The suppression of the electron concentration by the introduction of holes would make the contribution of electrons to the thermoelectric power negligible even at higher temperatures. In consequence, the slope of S *vs.* $1/T$ becomes less steep and close to the slope of ln σ *vs.* $1/T$: for instance, we found $E_\sigma(0) = 0.33$ eV and $E_S(0) = 0.31$ eV for 1 at.% Se doped sample.

Though the arguments given above are still qualitative, we think that the present experimental data are well explained in the framework of the pseudogap model for amorphous semiconductors. For further quantitative arguments, it will be necessary to determine the contributions of both electrons and holes separately to the carrier density, mobility, etc. The determination of the band structure from optical measurements will also be needed.

Discussion

G. R. Freeman: How good is the approximation that the density of states in the band tail varies linearly with E?

M. Shimoji: It is now a very difficult task to derive accurately the density of states of real semiconducting liquids from first-principle methods, since it depends strongly on potentials, the distribution of which is highly fluctuating. Therefore, the density of states of such materials is sometimes conveniently written as a linear function of E to show schematically the relative positions of the Fermi energy, mobility edges, and band tails in an energy scale. Experimental information due to optical measurements, etc., is of course required for this problem (*cf.* N. F. Mott. Philos. Mag. **22**, 7 (1970); E. A. Davis and N. F. Mott. Philos. Mag. **22**, 903 (1970)).

L. Onsager: By common usage in solid state lore, 'electrons' are excess electrons in a conduction band, while 'holes' are unoccupied states in the valence band. In a semiconductor the proportion of such entities relative to the density of states is typically small everywhere (except for any states introduced by dopants).

M. Shimoji: Thank you very much for your pertinent comments. Because of large fluctuations of potentials the charge carriers excited to the extended states in noncrystalline semiconductors are supposed to correspond to those in a conduction (or valence) band of crystalline materials.

Electron spin resonance studies of preferential solvation in solutions of potassium in amines and ethers

R. CATTERALL

Department of Chemistry and Applied Chemistry, University of Salford, Salford M5 4WT, England

AND

J. SLATER AND M. C. R. SYMONS

Department of Chemistry, University of Leicester, Leicester 1E1 7RH, England

Received September 27, 1976

R. CATTERALL, J. SLATER, and M. C. R. SYMONS. Can. J. Chem. **55**, 1979 (1977).

Electron spin resonance spectra of solutions of potassium in tetrahydrofuran–ethylamine, tetrahydrofuran–diglyme, ethylamine–diglyme, and ethylamine–ethylenediamine mixtures are reported and compared with spectra obtained from the four pure solvents. Strong evidence for preferential solvation was observed in all mixtures, with the strength of solvation increasing in the order tetrahydrofuran < ethylamine < diglyme < ethylenediamine. Electron spin resonance spectra of mixtures containing ethylenediamine were used to investigate the nature of the single line spectrum obtained from solutions in ethylenediamine alone. It is concluded that this signal is an 'ammonia-like' time averaged spectrum arising from solvated electrons and ion-pairs.

R. CATTERALL, J. SLATER et M. C. R. SYMONS. Can. J. Chem. **55**, 1979 (1977).

On rapporte des spectres rpe de solutions de potassium dans des mélanges de tétrahydrofuranne–éthylamine, tétrahydrofuranne–diglyme, éthylamine–diglyme et éthylamine–éthylènediamine et on les compare avec les spectres obtenus à partir des quatre solvants purs. Il y a de fortes indications que l'on observe une solvatation préférentielle dans tous les mélanges alors que la force de solvatation augmente dans l'ordre tétrahydrofuranne < éthylamine < diglyme < éthylènediamine. On a utilisé les spectres rpe de mélanges contenant de l'éthylènediamine pour étudier la nature du spectre avec une seule ligne obtenu pour des solutions dans l'éthylènediamine seul. On en conclut que ce signal est un spectre moyenné dans le temps ressemblant à l'ammoniac et qui dérive d'électrons solvatés et de paires d'ions.

Introduction

Although alkali metals dissolved in amine and ether solvents ionize completely in very dilute solutions, there is strong evidence that solvated cations and solvated electrons form neutral aggregates of stoichiometry M as the concentration of metal is increased.

[1] $$M^+ + e_{sol}^- \rightleftharpoons M^+e_{sol}^-$$

Considerable controversy (1–7) has surrounded the nature of these cation–electron aggregates. Electron spin resonance spectra include contributions from both paramagnetic species and the spectra observed can be divided into two groups: those for which two signals are observed, a hyperfine multiplet from cation–electron aggregates and a central singlet from isolated solvated electrons, and those for which only a single resonance line is seen. In the latter case the spectra are described as a time-average of the two possible environments for the unpaired electron. Examples of the first class are solutions of the higher alkali metals in ethylamine and tetrahydrofuran (THF), whilst solutions in ammonia and hexamethylphosphoramide belong to the second class. Spectra of solutions of potassium in ethylenediamine have been reported (8) to consist of a single line but it is not clear whether this line is a time-averaged signal ('ammonia-like') or an 'amine-like' signal in which the hyperfine lines are broad and weak as in 1,2-propylenediamine[1] and diglyme ($CH_3O(CH_2CH_2O)_2CH_3$) solutions.

In all instances where resolved hyperfine structure from alkali metal nuclei has been resolved, the hyperfine components show a progressive broadening towards the wings of the spectra. These line-width variations and also the temperature dependence of the splitting constants have generally been attributed either to a

rapidly fluctuating hyperfine interaction involving time-dependent changes in the solvation shells surrounding the cations (10), or to an essentially static variation of the magnetic parameters with minor changes in solvation effects. Bar-Eli and Tuttle (4) refer to these as vibrational states, but their lifetimes would need to be in excess of $\sim 10^{-8}$ s to have any appreciable influence on the spectra. The importance of the solvent in a static sense is amply illustrated by the wide variation in the occupancy of metal *s*-orbital as gauged by the magnitude of the hyperfine coupling constant relative to that in the free atoms (Table 1).

Our approach to these systems has been to select a set of four solvents which differ widely in their ability to solvate cations. The four chosen were: ethylamine, tetrahydrofuran, ethylenediamine, and diglyme; two amines and two ethers. Of the two nitrogen-containing solvents, ethylenediamine is well known for its ability to chelate to metal cations, and we expect the entropy effect associated with coordination at two sites in the molecule to contribute markedly to the lifetime of solvent–metal interactions. Similarly, of the two oxygen-containing solvents, diglyme is known to be an efficient cation solvator because of its ability to chelate, whilst THF has a notoriously low solvating power. We have reported previously on solutions in ethylamine (7, 11) and THF (12, 13) and here we make a preliminary report of solutions in diglyme, ethylenediamine, and in the mixed solvent systems THF–ethylamine, THF–diglyme, ethylamine–diglyme, and ethylamine–ethylenediamine.

Experimental

High vacuum techniques were used as described elsewhere (14). Solvent mixture compositions were estimated volumetrically and converted to mole fractions using the appropriate densities and assuming no volume changes on mixing.

Electron spin resonance spectra were measured on a Varian E3 spectrometer. Temperature control was achieved using standard equipment, and field and frequency measurements were corrected by reference to standard samples.

Results and Discussion

Diglyme Solutions

Electron spin resonance spectra consisted of a quartet of broad lines which almost merged in the saturated solutions. In more dilute solutions an additional central feature was apparent which became progressively narrower at higher dilution until at the limit of detectability (no visible blue colour) the width was $\lesssim 0.1$ G. In contrast, the widths of the hyperfine lines were far less dependent upon concentration. The coupling constant varied from 2.0 to 5.0 G over the interval 15 to 35°C.

Ethylenediamine Solutions

For all metal concentrations only a single narrow line was observed. The width of this feature (~ 0.12 G at room temperature) decreased as temperature increased, but appeared to be independent of metal concentration.

Ethylamine and Tetrahydrofuran Solutions

The temperature dependence of the hyperfine coupling constants is compared with that for diglyme solutions in Fig. 1. Results for ethylamine are in good agreement with those reported in refs. 4 and 7 and we are again unable to reproduce the temperature dependence reported in ref. 10.

Mixed Solvent Systems

The dependence of the coupling constants upon solvent composition for the four systems studied is given in Figs. 2–5. In all cases the concentration of the more efficient solvating medium increases to the right and we note that A values always decrease as this solvent is added. Variations of coupling constants were always smooth functions of solvent composition and no trace of discontinuous or 'stepped' behaviour was ever observed. In all cases there was an initial rapid decrease in A value as the first few percent of the better solvating medium was added. In an early paper (7) we reported that the A value of solutions of potassium in a 1 : 1 mixture of ethylamine and butylamine was greater than that of either

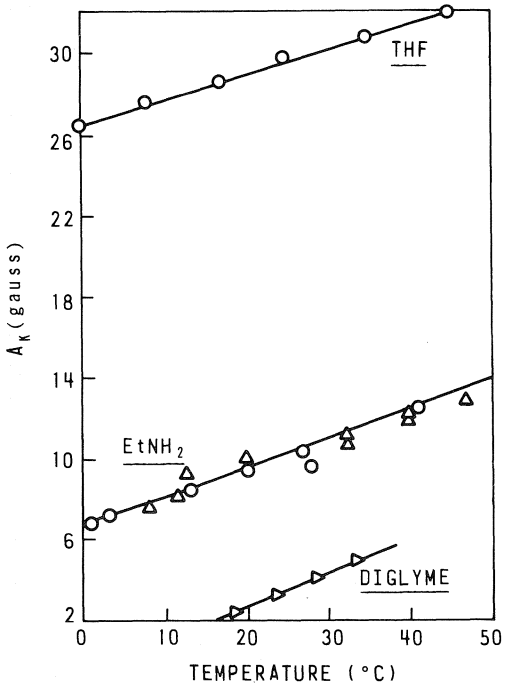

FIG. 1. The temperature dependence of the potassium hyperfine coupling constant (A_K) for solutions of potassium in tetrahydrofuran (THF), ethylamine ($EtNH_2$), and diglyme. $EtNH_2$ data: ○, this work; △, ref. 4.

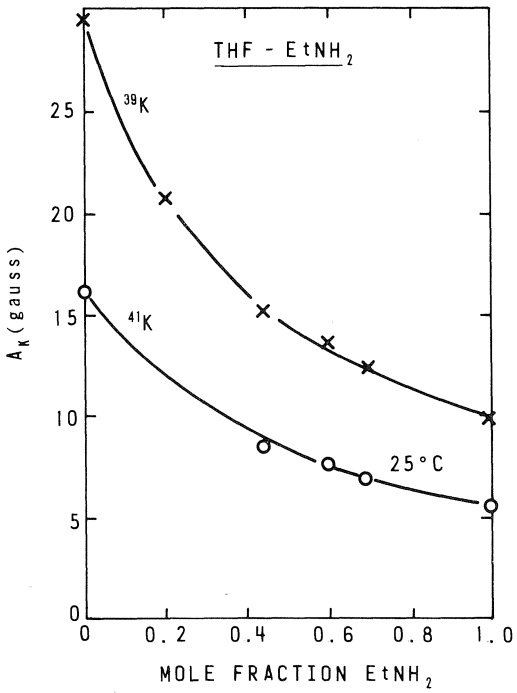

FIG. 2. The solvent dependence of the hyperfine coupling constant (A_K) to the two naturally occurring potassium isotopes in solutions of potassium in tetrahydrofuran–ethylamine mixtures.

pure solvent but approximately equal to the splitting in propylamine. No trace of this type of behaviour was observed in the present work.

For solutions in ethylamine–ethylenediamine mixtures hyperfine structure was only resolved for solutions containing less than about 20 mol% ethylenediamine (see below). Line widths of the hyperfine components were almost completely independent of metal concentration but increased rapidly with increasing concentration of ethylenediamine.

Line-widths and Time-dependent Processes

When small amounts of diglyme were added to solutions of potassium in THF, the width of the hyperfine lines increased. The rate of increase of line width was greatest for the outermost lines so that spectra with extreme linewidth variation were observed. For the outermost lines the widths in solutions containing more than 8 mol% diglyme were greater than those observed in either pure solvent. In contrast the A and g factors were always within the range of the pure solvent values. In marked contrast to these results, no significant changes in linewidths were observed when ethylamine, a solvent which cannot chelate to cations, was added to solutions of potassium in THF.

Preferential Solvation

The binary solvent systems shown in Figs. 2–5 have all been arranged so that the solvent giving rise to the highest hyperfine coupling constant is on the left. In all systems we observed an initial rapid decrease in the coupling constant as the second solvent was added, whilst the departures from linearity in the trends between the pure solvents indicate that the second solvent in each case is the more effective in determining the A value than would be expected for random solvent mixtures. A reduction in A value, indicating a lower unpaired electron spin density in the outer metal s orbital, is consistent with an increased population of the metal s orbital resulting from solvation effects such as the donation of oxygen or nitrogen lone pairs to the metal. Accordingly we attribute the observed changes in A value to a competition between different solvents for the metal cations (M^+) within the species of stoichiometry M which is responsible for the electron spin resonance spectra. The departures from linearity in Figs. 2–5 thus represent preferential

solvation of alkali metal cations. Preferential solvation as a cause of varying coupling constant was proposed for solutions of potassium in mixtures of ethylamine and methylamine (4).

The initial gradients in Figs. 2–5 can be used to establish an order of solvents reflecting the strength of the solvation forces: tetrahydrofuran < ethylamine < diglyme < ethylenediamine. As might be expected, solvents capable of forming chelate complexes with the metal ions are significantly more effective in reducing the A value than are monodentate ligands, whilst within this broad distinction, amines are more effective than ethers.

The linewidth effects observed when diglyme is added to tetrahydrofuran solutions are indicative of a slowing down of fluctuations of the hyperfine coupling constant, resulting from the tighter binding of solvent to metal in a chelate complex.

Ethylamine–Ethylenediamine Solutions

The esr spectra of solutions of potassium in mixtures of ethylamine with ethylenediamine and diglyme show significant differences. For mix-

tures with diglyme the spectra trended smoothly from one solvent to the other, but the behaviour of mixtures containing ethylenediamine was more complex and similar to that observed in solutions of potassium in mixtures of ethylamine and methylamine (4). The hyperfine coupling constant decreased rapidly (Fig. 5) as the diamine was added and all the lines broadened strongly and approximately equally until no trace of the hyperfine structure was observed at around 20 mol% ethylenediamine. Above this concentration the single line broadened and then sharpened up again over a very narrow concentration region. Since no dependence of linewidths of the hyperfine components on metal concentration was observed and no difference was observed between the broadening rates for the inner and outer lines, the fluctuation of the coupling constant to the metal nucleus cannot be the dominant electron relaxation mechanism in ethylamine–ethylenediamine mixtures. Instead we interpret these results in terms of [1]. If this equilibrium is governed by sufficiently high rate constants the coupling between the unpaired electron and the alkali metal nucleus will be randomized and as the rates increase the lines will broaden equally, coalesce, and finally sharpen up to a single line characteristic of a time averaged environment.

For this mechanism to be operative we require the rate constants governing [1] to be low in ethylamine and diglyme, but higher in ethylenediamine. The critical region is that which gives rise to effective lifetimes of the electron–cation aggregates of the order of the inverse of the hyperfine splitting constants. For ethylamine and diglyme these times are 0.36 and 1.2×10^{-7} s, respectively.

For [1], the mean lifetime (15) of the aggregates, τ_M is given by

$$[2] \qquad \tau_M^{-1} = k_1([K^+] + [e^-]) + k_1/K_{as}$$

where k_1 is the forward rate constant and K_{as} the association equilibrium constant (9):

$$[3] \qquad K_{as} = \exp(Z_e Z_M e^2/aD_s kT)$$

and k_1 is given by (15)

$$[4] \qquad k_1 = (4\pi L_0 Z_e Z_M e^2/D_s kT) \times (D_e + D_M)(K_{as}{}^{-1})^{-1}$$

where Z_e and Z_M are ionic charges, π, L_0, e, k, and T have their usual significance, D_s is the static dielectric constant of the medium, a is an ion separation parameter, and D_e and D_M are diffusion coefficients of e_{solv}^- and M^+ in the medium concerned.

We estimate D_e and D_M from values in ammonia (16) by correcting for viscosity changes. K_{as} for ethylamine we have estimated (17) from values of [e^-], [K], and total metal concentration, and reasonable estimates for K_{as} in diglyme and ethylenediamine were obtained from this value by correcting for changes in D_s. When this is done we find that the product $\tau_M A$ for ethylamine (~ 30) and diglyme (~ 7) are > 1 indicating that resolved hyperfine structure is to be expected, whilst for ethylenediamine (~ 0.04) $\tau_M A \ll 1$ indicating that a time-averaged signal is all we can hope to observe.

Discussion

U. Schwindewolf: Is there a correlation between the esr spectra and optical spectra?

R. Catterall: In recent work carried out at the Chalk River Nuclear Laboratories in collaboration with Dr. W. A. Seddon we have attempted to correlate esr spectra with transient optical absorption bands produced after pulsed electron radiolysis of solutions of alkali metal salts. A general correlation is discussed in a later paper by Dr. Seddon, Dr. J. W. Fletcher, and myself (Can. J. Chem. This issue.). For the solutions of sodium tetraphenylboron in tetrahydrofuran–diglyme mixtures we observed two bands, one at 890 nm very similar to the one produced in $NaB\phi_4$–THF and another at ~1800 nm characteristic of $NaB\phi_4$–diglyme. The relative intensity of these bands varied with solvent composition and the spectra showed an isobestic point. This appears to be strong qualitative evidence for a two-state model for the paramagnetic monomer species in THF–diglyme mixtures. However, some of the 900 nm band is present in $NaB\phi_4$–diglyme without any THF.

S. A. Rice: Would you please comment on your esr measurements and pulse radiolysis of diglyme–THF mixtures in comparison to the flash photolysis experiments on sodium–diglyme solutions of Kloosterboer *et al.* (J. G. Kloosterboer, L. J. Giling, R. P. H. Rettschnick, and J. D. W. Van Voorst. Chem. Phys. Lett. **8**, 462 (1971)).

R. Catterall: Kloosterboer *et al.* flashed the band at ~700 nm assigned to Na^- anions in solutions of sodium metal in diglyme at −60°C, and observed the formation of a band in the infrared at ~1600 nm which they assigned to the solvated electron. As this band decayed they observed the growth of a new band at ~850 nm which then slowly decayed to regenerate the original band of Na^- at ~700 nm. They assigned the intermediate band at 850 nm to an aggregate of Na^+ and e^- by analogy with the band observed in THF solutions. However, the esr spectra of potassium in diglyme reveal a hyperfine coupling of only 3.7 G (23°C) whereas we correlate an absorption band at ~900 nm with a coupling constant of ~30 G (see Seddon *et al.* Can. J. Chem. This issue.). One possible explanation might be that the band at ~1600 nm observed by Kloosterboer *et al.* was the 'ion-pair' as we suppose, and that the band they observed at ~850 nm was in fact due to K^- (produced from potassium impurity) which then slowly converted to Na^- at 700 nm. A slow conversion of K^- to Na^- such as this has been observed after pulse radiolysis of mixed metal solutions (J. W. Fletcher and W. A. Seddon. J. Phys. Chem. **79**, 3055 (1975)).

J. L. Dye: The two types of ion-pairs, one with low hyperfine splitting and an infrared absorption band, and the other with high hyperfine splitting and an absorption band nearer the visible would be better described as solvent-shared ion-pairs and contact ion-pairs, respectively. In this way, you can have both present even in *a single solvent*.

R. Catterall: I'm quite happy to accept your nomenclature. Certainly we do see evidence for two types of ion-pairs between e_s^- and Na^+ after pulse radiolysis of $NaB\phi_4$ in diglyme. The dominant band, peaking at ~1800 nm is slightly blue-shifted from its position in pure diglyme, and this we attribute to the loose ion-pair formed between a *chelated* sodium cation and a solvated electron. The weaker band that we observe at ~900 nm (which is close to that observed in $NaB\phi_4$–THF) we also attribute to an ion-pair of a Na^+–diglyme cation with a solvated electron, but in this case we envisage the glyme as being attached to the cation as a monodentate ligand. The hyperfine coupling we observe by esr (~3.7 G) is then the weighted average of the two types of ion-pair, one (900 nm) with a coupling of ~30 G and the other (~1600 nm) with a much smaller splitting, possibly $\lesssim$0.3 G.

L. Onsager: How do the symptoms of hyperfine structure correlate with the dielectric constants?

R. Catterall: For solvents which can only coordinate to metal cations in a monodentate fashion, there is an approximate correlation with dielectric constant: propylene diamine ($D_s \sim 14$, $A_K \sim 3$ G), ethylamine ($D_s \sim 12$, $A_K \sim 10$ G), isopropylamine ($D_s \sim 10$, $A_K \sim 18$ G), and THF ($D_s \sim 7$, $A_K \sim 30$ G). However, when chelating solvents are included the correlation breaks down completely: THF and diglyme have the same dielectric constant (~7), but A_K(THF) ~ 30 G, whilst A_K(diglyme) ~ 3.7 G.

Thermal emission of excess electrons from liquid hydrocarbons (Extended Abstract)

A. A. Balakin, I. A. Boriev, and B. S. Yakovlev
Institute of Chemical Physics, Academy of Sciences USSR, 142432 Chernogolovka, USSR
Received November 22, 1976

An electrical conductivity due to a liquid-to-gas electron emission has been investigated in two-phase systems. The systems consisted of a liquid hydrocarbon in equilibrium with its own saturated vapour in vacuum. Excess electrons were generated in the system by 2×10^{-7} s X-ray pulse irradiation. The conductivity cell consisted of two electrodes which were 1.5 cm diameter nickel disks separated by the distance $d = 0.7$ cm. The excess electron current was measured for the three following conditions: *a*, the liquid filled the total volume between electrodes; *b* and *c*, the liquid level was between electrodes at the distance $d' = 0.2$ cm from the lower electrode, with the potential of that electrode being negative in the case *b*, but positive in the case *c*.

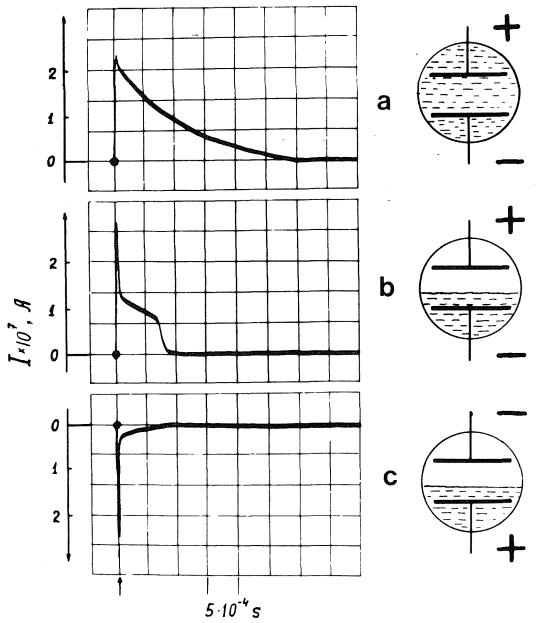

FIG. 1. Electron current *vs.* time observed in *n*-hexane at three conditions: *a* both electrodes immersed in liquid with lower electrode being negative; *b* and *c* liquid level is between electrodes, with lower electrode being negative in case *b* and positive in case *c*. Voltage between electrodes = 2000 V, $T = 296$ K.

Figures 1 and 2 show the current oscillograms for *n*-hexane and isooctane. In cases *a* and *c* the traces of current *vs.* time associated with the drift of electrons to the positive electrode in the liquid layer *d* (the case *a*) or *d'* (the case *c*), agrees with the known excess electron mobility, μ, in liquids (0.09 and 7 $cm^2\ V^{-1}\ s^{-1}$ in *n*-hexane and isooctane at 296 K). In the case *b* for isooctane and *n*-hexane the value of the current during the drift time, τ', for an excess electron to move the distance *d'* is significantly more than that in the case *c*. Corresponding measurements with tetramethylsilane (TMS) have shown that in the case *b* the current trace is the same as that in *c*.

The fact that the current value for *n*-hexane and isooctane in the case *b* was more than that in the case *c* can be connected with the transmission

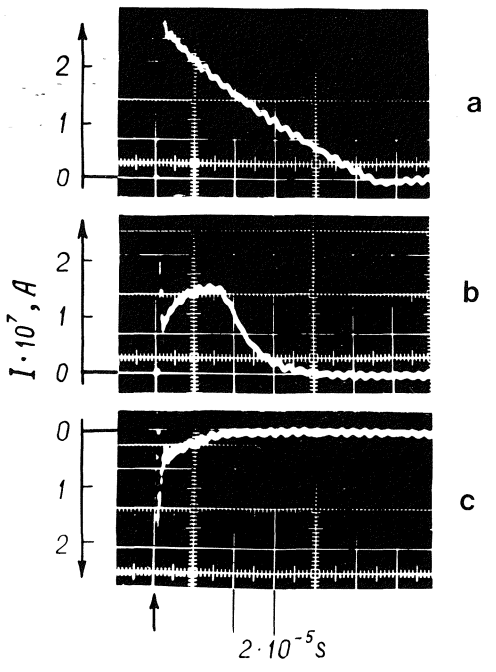

FIG. 2. Electron current *vs.* time observed in isooctane for the three conditions of Fig. 1. Voltage between electrodes = 600 V, $T = 296$ K.

of excess electrons into the vapour. (For *n*-hexane this conclusion agrees with data from ref. 1.) Comparison of the current integrals in cases *a*, *b*, and *c* showed that the bulk of electrons generated in the liquids were transferred to the vapour in a time about equal to τ'. The coincidence of currents in cases *b* and *c* for TMS is evidence of the absence of electron emission for these conditions.

The prompt increase of the current in case *b* for *n*-hexane immediately after the X-ray pulse, and its abrupt decrease at a time near τ', allowed an estimate of the delay time ($t_d < 5 \times 10^{-5}$ s) for the electron to cross the liquid surface. For isooctane the value t_d was sufficiently large to be recorded from current traces and it was inversely proportional to the electric field strength in the liquid, E, in the range 1.5×10^2 to 1.5×10^3 V/cm.

We have attempted to connect the dependence of $t_d(E)$ with the height of the surface barrier potential. The density of the emission current can be presented as $j(t) = vn_0(t)$, where $n_0(t)$ is the concentration of electrons in liquids near the liquid surface and v is the effective velocity of crossing the surface by electrons. At $t \geq d'/\mu E$ the electrons which have not yet escaped from the liquid are situated near its surface in a layer with the characteristic thickness $l = kT/eE$ (k is Boltzmann's constant, e is the electron charge), therefore

$$[1] \qquad t_d = \frac{l}{v} = \frac{kT}{eEv}$$

i.e. $t_d \sim E^{-1}$, in agreement with the experiments.

If we assume a conventional model of trap-limited transfer of excess electrons in liquid isooctane and a rectangular surface barrier potential with height V_0 for quasifree electrons then we obtain:

$$[2] \quad v = (1 - P) \int_{\sqrt{2mV_0}}^{\infty} \beta(p_z) f(p_z) \frac{p_z}{m} \, dp_z$$

Here the z axis is perpendicular to the liquid surface, β is the reflection coefficient of electrons from the barrier, $f(p_z)$ is the momentum distribution function, $P = 1 - \mu/\mu_0$ is the probability of electron localization, μ_0 is the quasifree electron mobility, and m is the effective mass of an electron. Using the experimental values of t_d, $\mu_0 = 150 \pm 50$ cm V^{-1} s^{-1}, the Maxwellian distribution function for $f(p)$ and m equal to the electron mass, we have from [1] and [2] $V_0 = -0.19 \pm 0.02$ eV for isooctane at 296 K. The measurements of t_d at 270 and 320 K allowed an estimate of $\partial V/\partial T = -8 \times 10^{-4}$ eV/deg. These values are in a fair agreement with the results obtained from metal-to-liquid electron photoemission data (2).

Discussion

P. Delahay: Did you consider backscattering of electrons in the gas phase? This type of scattering depends on the vapor pressure and the electric field in the gas phase, and the fraction (per unit of time)

$$\frac{\text{number of collected electrons}}{\text{number of emitted electrons}}$$

can be considerably smaller than unity unless the ratio field/pressure is large enough. It would seem that this effect would affect your interpretation (particularly with regard to the distribution in the liquid).

E. L. Frankevich: We did not. Actually we had no need for that as all electrons reach the electrodes within a time which is much shorter than τ. This could be seen on the *i vs. t* curve for *n*-hexane where no delay current exists and the total area under the curve (or charge collected) is independent of the voltage applied. The only type of backscattering taken into account was that due to passing of electrons over the potential barrier.

L. G. Christophorou: You assumed that all electrons in the Maxwell distribution with energies greater than V_0 escape from the liquid into the vacuum. As Professor Delahay mentioned a large fraction of these should be backscattered and this fraction should vary depending on your E/N value. Shouldn't this be reflected in your current *vs.* time curves and also in the total charge you collect?

G. Freeman: Professor Frankevich is perhaps suggesting that electrons that are reflected back into the liquid by the gas may be re-emitted into the gas.

E. L. Frankevich: They certainly do this and it is demonstrated by the independence of the total electron charge collected by the electrodes of the voltage applied. The re-emittance seems to take a very short time as no delay could be seen for the case of *n*-hexane where V_0 is positive.

U. Sowada: If backscattering were important on the time-scale of these measurements, a delayed decay should have been observed for *n*-hexane too, which was not the case. The neglect of this effect seems to be justified.

Electron localisation: evolution of optical spectra

DAVID C. WALKER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 27, 1976

DAVID C. WALKER. Can. J. Chem. **55**, 1987 (1977).

Attention is directed to experiments from several groups which bear on the origin of the electron's absorption band, particularly with regard to the spontaneous progression from metastable to equilibrated states and photoinduced spectral shifts. The absorption band is discussed as being heterogeneously broadened in both solid and liquid phases, the former being space-averaged and the latter time-averaged. This means that the proper extinction coefficients are higher than those currently in use which were evaluated on the presumption that the band was homogeneous. $E_{\lambda max}$ is seen as a generally useful measure of the solvating power of solvents.

DAVID C. WALKER. Can. J. Chem. **55**, 1987 (1977).

Cette publication permet d'orienter l'attention vers les expériences provenant de plusieurs groupes qui ont une incidence sur l'origine des bandes d'absorption d'électrons, particulièrement en ce qui a trait à la progression spontanée allant d'états métastables vers des états équilibrés et aux déplacements spectraux photoinduits. On discute de la bande d'absorption comme étant élargie d'une façon hétérogène à la fois dans les phases solides ainsi que liquides; il se produitrait une moyenne des espaces dans les premières et une moyenne dans le temps dans les dernières. Ceci implique que les coefficients d'extinction appropriés sont plus hauts que ceux utilisés actuellement et qui ont été évalués en faisant l'hypothèse que la bande était homogène. On considère que le $E_{\lambda max}$ est généralement une mesure utile du pouvoir de solvatation des solvants.

[Traduit par le journal]

1. Introduction

That the mere absence of crystalline order can, in itself, give rise to electron localisation is a notion which has emerged in the wake of extensive studies of two closely related phenomena: the trapping of electrons at vacancy or at impurity sites in crystals, and the solvating of ions in solution. It is now known that electrons may be localised (and thereby give rise to characteristic optical absorption spectra or electron spin resonance absorption) in a prodigious variety of media, including many polar and nonpolar liquids and amorphous solids, and in at least one fluid above its critical temperature. Naturally, the stability in a thermodynamic sense of the localised electron in these different environments varies considerably. Thus absorption bands are found to be centred from ~3500 to ~500 nm. Their stability with respect to chemical reaction is even more variable and is generally strongly temperature dependent at temperatures where the viscosity and diffusion coefficients change markedly. But the observed electron state, albeit often transient or metastable, also varies with temperature because of changes in the medium's relaxation and solvation rates.

There are several electron states to consider. I will use the following nomenclature: quasi-free (e_{qf}^-) for delocalised; infrared absorbing (e_{ir}^-) and weakly trapped or partially solvated for metastable states; and trapped (e_t^-) or solvated (e_s^-) for the fully equilibrated states.

2. Optical Absorption Bands of e_s^- and e_t^-

These are broad and structureless. In certain ordered solids they tend to be only ~0.2 eV wide at half height but generally range from 0.5 to 1.2 eV. In only one case (1), strongly disputed recently (2), has fine structure been reported for any of these bands. The photon energy at which the absorption band maximum occurs ($E_{\lambda max}$) for the equilibrated localised electron depends dramatically upon the composition of the chemical groups constituting the walls of the trap. Thus $E_{\lambda max}$ for monoethanolamine is the same as an equimolar mixture of monobutylamine and ethanol (1). The latter mixture, however, shows a much broader band, which suggests the broadness increases with the number of possible solvation energies that the medium can provide.

It was thought for some time that $E_{\lambda max}$ increased monotonically with the bulk dielectric

constant (D_s) of the solvating medium. Such a correlation was disproved, for instance, by the observation (3) that dimethylsulphoxide, with $D_s = 46$, had an electron absorption band in the near ir similar to that of a hydrocarbon having $D_s \sim 2$. In fact solvents like dimethylsulphoxide and hexamethylphosphorictriamide have well-defined negative stocks for strongly solvating positive ions, but the positive end of the molecular dipole is diffused over many weakly polar C—H bonds, with the result that negative ions (including solvated electrons, evidently) can be solvated to only a minor extent. $E_{\lambda max}$ is thus related to the solvation energy of the medium for negative ions. Perhaps $E_{\lambda max}$ will prove to be a more useful and broader-based factor with which to measure the relative solvating power of solvents for negative ions than the empirical parameters Y, a, Z, and E_T which are currently in use (4).

It is interesting to note that D_s was used as the principal guide to a solvent's solvating power until the dipolar aprotic solvents came to the fore (5). One of the advantages which would result from using $E_{\lambda max}$ as a measure of solvating power rather than, for instance, the pyridinium *N*-phenolbetaine anion (6) for this purpose, is that the electron's size is more flexible and therefore the correlation should apply better to small anions. Yet one finds that in liquid ammonia the electron creates, and resides in, a rather large cavity (equal to the displacement of about three ammonia molecules). On the other hand, in solvents with bulky secondary groups, steric interference among the molecules lining the walls of the trap cause the traps to be more cavernous than is found with molecules of the same basic solvating power but without bulky groups. Thus secondary and tertiary alcohols were found to have smaller values of $E_{\lambda max}$ than primary alcohols of comparable bond polarity (7).

At least two short-range factors are involved in determining $E_{\lambda max}$: The local structure and particularly the bond polarity at the walls of the trap (which in general will mean the protic character of the hydrogen atoms there) and the size of the cavity. To return momentarily to hexamethylphosphorictriamide, it has both weak polarity and an extended cavity of >8 Å diameter due to the confrontation of six methyl groups, from each of four nearest neighbour molecules (8).

Upon injecting electrons into a liquid which has been cooled to the glassy state, the absorption band is remarkably similar, though its maximum is generally shifted slightly to the blue and narrowed perceptibly when fully relaxed in the solid relative to that in the liquid phase. Electron absorption bands in solvent mixtures have also been extensively studied and seem to fall into two categories. When the solvents form relatively ideal solutions only a single absorption band is found and $E_{\lambda max}$ varies approximately linearly with volume composition between the pure components (9), even when they are of widely differing solvating power (10, 11). However, when the solutions are nonideal (as is the case for alcohol–hydrocarbon mixtures) then the equilibrated electron spectrum resembles that of the pure more-polar component over a disproportionately large range of composition in liquids (12–14); but the immediate, unrelaxed spectrum can be representative of the composition in cool viscous fluids (15), and can show two maxima in low temperature glasses (16). Small clusters of the more polar molecules seem to be acting as electron scavengers in these nonideal solutions.

3. Spontaneous Spectral Shifts

Several situations are known in which the electron absorption band is observed to change with the passage of time. Invariably the shift of the absorption band maximum is towards the blue, corresponding to a lowering of the mean energy state of the electron. The rate of transformation increases with temperature and the present extremes measured are $\sim 10^{12}\ s^{-1}$ in liquids at 295 K (17) and $<10^{-3}\ s^{-1}$ in solids at 4 K (18).

In cool liquid alcohols absorption in the near ir was observed to decay concurrently with a growth in the visible absorption band, the two bands being quite distinct (19). An absorption maximum has not yet been located for the ir band in the liquid but in solid ethanol it is at ~ 1300 nm (20). This shifting of the band from ir to visible wavelengths has also been observed in liquid alcohols at 295 K (21), in glasses at 77 K (20, 22), and in glasses which were warmed from 4 to 77 K (23). There was a significant rise-then-fall of absorption at the intermediate wavelengths in both solids and liquids (19, 20, 24). This suggests there is either (*i*) a progressive change in the overall distribu-

tion of trapped electrons or (*ii*) a sequential solvation through transient discrete, or continuously variable, states. The development of the fully solvated electron spectrum grew-in in the liquids with a single time constant which has been correlated with a relaxation time for molecular rotation over a range of temperatures (19, 21, 24, 25). This suggests electrons are digging deeper traps in the liquids. However, in glassy alcohols recent results on the effects of scavengers have been interpreted in terms of a hopping mechanism (26). As implied in Section 9, it may be more natural for electrons to be primarily 'seekers' in rigid low temperature glasses and 'diggers' in low viscosity liquids.

Spontaneous spectral shifts probably occur in most systems, the time required changing markedly with the viscosity. They have been observed in viscous hydrocarbons at low temperatures as a substantially faster decay of the infrared side of the absorption band compared to the decay rate on the visible side, which also resulted in $E_{\lambda max}$ increasing with time (27). In many aqueous glasses at 77 K a single band was observable immediately after a radiation pulse and subsequently the red edge of this band decayed (28).

But in certain other aqueous glassy systems (more on this later) a transient, separate, ir absorption band was also produced (29). In addition, there is reported to be a marked shift in absorbance from 1060 nm to 530 nm between 2 and 4 ps for electrons produced in aqueous solution at 295 K (17).

4. Origin of the Absorption Bands

It is natural for us to regard these spontaneous spectral shifts as direct observations of the electron localisation process, marking stages in the chronological development of the relaxed, equilibrated state. We can also disturb the equilibrated state photochemically and observe subsequent relaxations, or merely change the temperature and hope that we are just dilating the time scale. Eventually we focus our interpretations of these optical properties on several questions about the nature of the solvated electron.

(*i*) Is the optical transition to a bound excited state or to the quasi-free state or is some of both involved?

(*ii*) Why is the absorption band broad and structureless? Is it homogeneously broadened by phonon coupling of the excited state with a common ground state, or is it broadened through the ground state by variations in local dipoles and cavity sizes and is thus heterogeneous?

(*iii*) If it is heterogeneously broadened do we observe a time-averaged or a space-averaged spectrum?

(*iv*) Do spontaneous spectral changes to the blue arise because electrons are diggers or seekers of deeper traps?

(*v*) Is there a preferential chemical reactivity shown by electrons contributing predominantly to the red end of the band?

(*vi*) What influence does the electrolyte of aqueous glasses have?

Most of the information comes from electrons produced by radiolysis, where they start with a range of epithermal energies and are clustered together in spurs. So one should anticipate a somewhat different pattern of subsequent relaxation processes (both spontaneous and induced) for radiation-produced electrons as opposed to photochemically liberated ones. In this respect photobleaching studies of radiation-produced electrons are particularly complex.

5. Photoinduced Spectral Shifts

When a sample of trapped electrons in aqueous or alcohol glasses produced by γ irradiation at 77 K was partially bleached to rid it of trapped electrons which were close to potential reaction partners, photoinduced compensatory spectral shifts were observed (30). These were termed photoshuttling, or photoshuffling, since illumination with blue light caused loss of absorption in the blue edge of the band and a compensatory growth on the red side, and vice versa. These were permanent changes. Three significant inferences can be drawn from those observations. (*a*) One seems forced to accept the notion that the medium provides traps of different depth absorbing in different spectral regions, that is, that the band is heterogeneous. (*b*) Since it occurs equally from its blue as from its red extremities the same type of optical transition (be it bound–bound or bound–free) straddles the whole band. (*c*) The changes are permanent, so subsequent 'digging' to refurbish the original visible spectrum at 77 K did not occur. Furthermore, if refurbishing is normally accomplished by 'seeking' then photolysis must have permanently altered the distribution of available traps.

Unfortunately, photoshuttling does not directly aid in solving the bound–bound *vs.* bound–free issue. Shuttling would be a natural consequence if electrons were photobleached to the quasi-free state and then retrapped (merely by a forced net depopulation of blue traps by blue light, and of red traps by red light). But equally well, if the photoexcited state was bound, the photon energy should be dissipated, at least in part, by causing rotations of the molecules in the walls of the traps, thereby 'softening' those traps that absorbed light. The overall net effect of this would be for blue light to make deep (blue) traps shallower and red light to make shallow (red) traps deeper.

These photoinduced spectral shifts refer to rigid media at 77 K. Quite different results and inferences may be forthcoming in liquids or at higher temperatures.

6. The Visible Band in Aqueous Systems

Figure 1 shows solvated electron data from ref. 31 for aqueous 9.5 *M* LiCl pulse-irradiated at 298, 198, and 93 K and observed immediately after a 10 ns radiation pulse. Notice that the band is much narrower at the middle temperature, whereas the 298 and 93 K bands are very similar, except in intensity. At 298 K the whole band subsequently decayed without a measurable spectral shift. At 77 K a marked spectral shift occurred as indicated in Fig. 2. Absorbance was lost sequentially from the red end. The stable spectrum which was reached was similar to that found at 100 ns at 198 K. This loss was not compensated by growth elsewhere. So the questions arise: (*i*) does this represent preferential chemical reactivity by weakly trapped electrons or (*ii*) were these electrons caught in traps which were close to, and distorted by, the Coulomb field of the concomitant cation?

This loss of a short-lived red wing to the visible band is common to most aqueous glasses. But peculiar to some, including LiCl, is another transient electron absorption band much further in the ir, which will now be mentioned.

7. Infrared-absorbing Electron States in Certain Aqueous Glasses

An isolated and distinct absorption band in the ir has been found to arise in pulse-irradiated LiCl, $MgCl_2$, and ethylene glycol aqueous glasses and in D_2O ice at 77 K (29). If the lineshape is Lorentzian then the ir band maximum is indicated to be at ~3500 nm (0.35 eV) and its half-bandwidth to be ~0.38 eV. It has been shown to arise from a species with the characteristics of a weakly trapped electron. The species, designated e_{ir}^-, decays at 77 K but

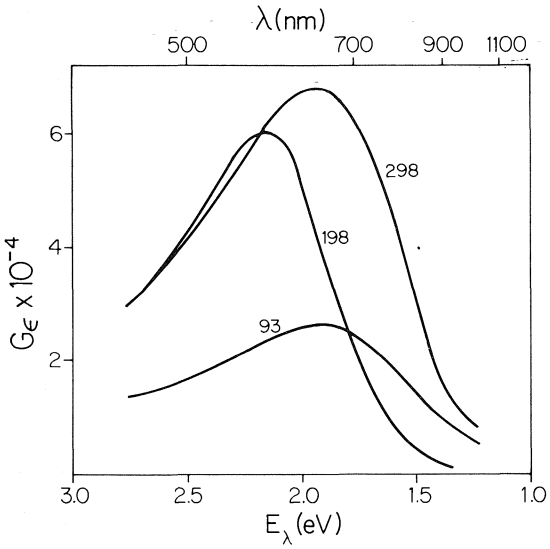

FIG. 1. Temperature dependence of the absorption spectrum of the electron in 9.5 *M* LiCl solution immediately following a 10 ns pulse at 298, 198, and 93 K (data taken from Buxton and Kemsley (31)).

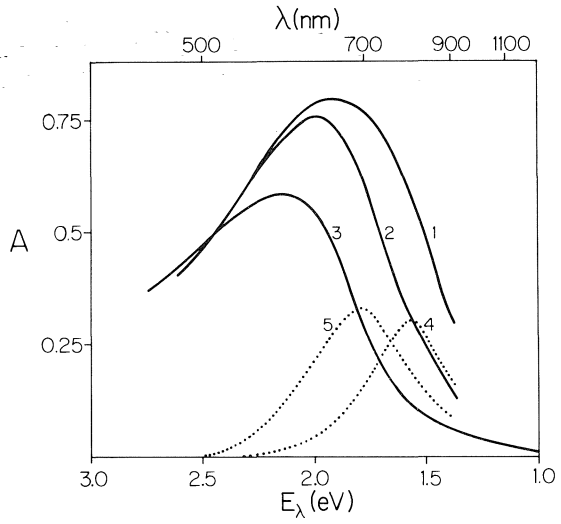

FIG. 2. Time dependence of the absorption spectrum of the electron in 9.5 *M* LiCl glass at 87 K. Curves 1, 2, and 3 were obtained 200 ns, 200 μs, and ~1 h respectively after the irradiation. Curve 4 shows the difference in absorbance between curves 1 and 2, curve 5 the difference between curves 2 and 3 (data from Buxton and Kemsley, private communication).

no compensatory absorption was observed in the visible. Instead luminescence was produced at a rate commensurate with e_{ir}^- tunneling to geminate reaction partners. e_{ir}^- was not observable under the same conditions in OH^-, K_2CO_3, $NaClO_4$, $CaCl_2$, HCOONa, $Mg(ClO_4)_2$, and $Mg(CH_3CO_2)_2$ glasses (29).

Evidently there are at least two spectral changes involved and two types of transient electron states to worry about in aqueous media at low temperatures, and at room temperature the picosecond changes (17) have to be fitted into the picture.

8. Photobleaching of e_t^- in Aqueous Glasses

Gillis and Walker (32) have recently shown that the same infrared-absorbing electron states (e_{ir}^-) as described above are produced with high quantum yield when trapped electrons in LiCl or $MgCl_2$ aqueous glasses at 77 K are subjected to 20 ns pulses of 694 nm light from a laser. These species also produce luminescence centred at ~410 nm as they decay, and are not found in K_2CO_3 or OH^- glasses. We inferred that optical excitation at 694 nm (130 nm on the red side of the band maximum) leads to quasi-free electrons (which then dispose themselves as in pulse radiolysis, but, according to the luminescence kinetics, still undergo geminate reactions). These results certainly support the view that the optical transition on the red side of the band maximum is of the bound–free type; but, as ever, it does not prove it because it is possible for the electron to be thermally released from a bound excited state, or for that state to be autoionising.

LiCl and $MgCl_2$ are the only two glasses of those studied which showed recovery of absorbance at 633 nm (8)[1] and rapid loss of absorbance at 1152 nm (34) when their stable trapped electrons were flash bleached at 694 nm. If we assume that (*a*) 1152 nm would monitor e_{ir}^- plus perhaps the short-lived red wing of the visible band which is formed during pulse radiolysis and maybe also during bleaching, while (*b*) 633 nm would also monitor this red wing plus the stable visible band and (*c*) 442 only the stable visible band, then the loss of 1152 nm absorbance concurrent with formation of 442 and 633 nm absorbance is consistent with some of the e_{ir}^- transforming spontaneously to the stable trapped electron e_t^-. This appears different from the pulse radiolysis situation (29) where growth was not seen at 633 nm as e_{ir}^- decayed; but in that situation part of the red end of the visible band was concurrently being lost.

Why should e_{ir}^- be formed in only 3 of the 10 aqueous glasses which have been studied? Is it a structural property of those particular glasses or does it have a chemical origin? Is it just a difference of time scales? What is the nature of e_{ir}^-? These are all issues currently being examined (35). It is curious that e_{ir}^- is a necessary precursor of the broad luminescence centred at ~410 nm. It is curious because one wonders why quasi-free electrons, or trapped electrons decaying from the red wing of the absorption band, or laser-bleached electrons in OH^- and K_2CO_3 glasses, or any of the melange of geminate electrons which decay during radiolysis, all do not produce luminescence in the visible or near uv which would be observable under similar conditions.

9. Heterogeneous Broadening in Liquid and Solid Phases

Whereas there is strong evidence that the absorption bands in glassy solids are heterogeneously broadened there is no such indication of this for the liquids. Consider the photobleaching results. Hydrated electrons in liquid water at 295 K showed no self-induced transparency or bleaching at 694 nm, and the time taken for the ground state to be repopulated after photoexcitation was estimated to be ≤ 5.5 ps (36). No photoinduced spectral shifts were observable either under those conditions (4). Likewise none were observed for the electron in liquid ammonia at ~220 K. When it was bleached at 610 nm the ground state was repopulated in <5 ps (37), and it was also found to be homogeneously bleached at 1060 nm with the relaxation time estimated to be $\sim 2 \times 10^{-13}$ s (38). Contrast this with various cold solid systems, where (*i*) hole-burning by monochromatic light was found in α-methyltetrahydrofuran (4, 39), ethanol (40), and various aqueous glasses (4) and (*ii*) photoinduced spectral shifts occur with the equilibrated electron spectra (30, 31, 41).

Yet it is striking how similar the electron spectra in the two phases are: as if the solid has a distribution of traps which is just the frozen-in, instantaneous distribution of polarised sites in the liquid. The initial spectra are nearly identical

[1]R. May. Unpublished data.

(see Figs. 1 and 2) and it is merely the loss of the red wing in the glass which results in the equilibrated spectra being different.

Heterogeneity in the solid implies that each electron is stabilised in a trap of a particular and relatively fixed energy. Each is thereby tinted with the characteristic absorption related to that particular energy and absorbs in only a limited region of the overall band. The overall spectrum is the envelope of this substructure. It shows the space-averaged population distribution of trapped electrons and thus parts of it may be selectively bleached.

If the liquid phase band was homogeneously broadened, in the strict sense of having a fine structure to its excited state but a single ground state, then its similarity with the solid phase would be largely fortuitous. So let us suppose the band in the liquid phase is heterogeneous also, but it is a time-averaged spectrum. That is, each electron in the liquid phase is continually and rapidly fluctuating in energy (by a factor of 2 or so) due to atomic and molecular motions of the solvent cage and due to its own wanderings. (By diffusion alone e_s^- in water is displaced, on average, a distance of $(4Dt)^{1/2}$, equal to ~ 0.4 nm, which is more than one solvent molecule away, in the time taken to rotate a solvent molecule.) The spectrum seen is thus the time-averaged, or instantaneous, distribution of these fluctuating electron energies. Since all electrons are alike and contribute equivalently to each part of the spectrum over a very short period of time, there is no possibility for hole-burning or spectral shifts, except during an exposure time which is shorter than the relaxation times of the vibrational and rotational motions which cause the fluctuations in the energy of the ground state. Only for exposure times of the order of 10^{-13} s or less could the band be observed to be heterogeneous in the liquid phase.

10. Extinction Coefficients

It has been pointed out before (4, 42) that when a band is heterogeneous because of a distribution of ground state energies, then only a fraction of the total number of species present will contribute significantly to absorption of light at any wavelength λ. Thus the real extinction coefficient at λ, ε^{hetero}, is greater than the value which is calculated on the basis of the band being homogeneous, ε^{homo}. This evidently should apply to trapped electrons in solids. It should also apply to electron bands in the liquid phase if the band is broadened through a fluctuating ground state electron energy as discussed above; for, although the excited state energy will also fluctuate, in general the transition probability will fluctuate with time, so that at any instant only a fraction of the species present will absorb significantly at λ.

If the substructure bands are narrow and essentially nonoverlapping then the overall band envelope merely shows the population distribution (4). A point on the side of the overall band then does not represent a lower ε than the peak, merely a smaller population density. The narrower the underlying bands are the larger ε^{hetero} becomes. Bleaching was found at 694 nm but not at 633 nm in aqueous and α-methyltetrahydrofuran glasses (4), so one infers substructure bands of less than 1400 cm^{-1} in a band of total width of $\sim 19\,000$ cm^{-1}. This suggests that $\varepsilon^{hetero}/\varepsilon^{homo}$ is greater than 14. Since ε^{homo} is typically evaluated to be 2×10^4 M^{-1} cm^{-1} or more at the band maximum, on the presumption that the band was homogeneous, it follows that the real values may be 3×10^5 M^{-1} cm^{-1} or more. An extinction coefficient of 3×10^5 M^{-1} cm^{-1} is equivalent to an absorption cross section of 5 $Å^2$ which, quite incidentally, is comparable to the cross-sectional area estimated for the charge distribution of the hydrated electron (33).

When should the real (ε^{hetero}) values of extinction coefficient be used? In theoretical calculations, when the oscillator strength is evaluated, ε is coupled with the bandwidth of the particular trap. In yield measurements C and ε are coupled through the $G\varepsilon$ value, so that until the concentration of a particular type of trap has been evaluated ε^{hetero} is not required. However, for photochemical processes (such as bleaching) the absolute value of ε is needed.

Discussion

J. Jortner: I would like to comment on the problem of homogeneous *vs.* inhomogeneous (heterogeneous) line broadening. Adopting the wellknown concepts of solid state physics homogeneous broadening involves line width originating from optical absorption of a single type of absorbing centre. A Gaussian line shape does not necessarily imply evidence for inhomogeneous broadening. When a single type of centre interacts with lattice (or liquid) phonons two types of electron–phonon coupling should be distinguished. In the weak coupling limit a narrow zero-phonon line is exhibited, its width being determined by T_1 (level depletion via relaxation) process, T_2 type (line broadening) processes as well as by inhomogeneous broadening. The total line width is 10^{-2}–$1\ cm^{-1}$, depending on temperature. The second limit is the strong electron–phonon coupling, a situation which we will be concerned with here. In this case the line width is Gaussian, without invoking inhomogeneous broadening. Such situations are commonly encountered in solids, *e.g.* F centres, alkali halides, and rare-gas solids. To distinguish between homogeneous or inhomogeneous broadening one can use hole burning methods or the technique of photon echoes. Hole burning experiments on trapped electrons in solids provide conclusive evidence for inhomogeneous broadening. It should, however, be recalled that the hole burned by a narrow-band optical excitation is wide, ~ 0.1 eV, which corresponds to the occurrence of bleaching of a phonon-broadened single centre. In liquids the experimental evidence for the Bell group provides evidence for homogeneous broadening of the solvated electron band in NH_3 in the range 1.6 to 0.8 μm.

D. C. Walker: My point is that the bands in liquids at 295 K and glasses at 77 K are essentially the same; so if we accept that there are traps of different depths in the solids then a comparable distribution of ground state energies seems likely for the liquids.

J. Jortner: It is apparent that the uncertainty argument for the line broadening $\sim 10^{-2}$ eV of individual 'homogeneous bonds' does not apply for the situation of strong

phonon coupling. The absorption line widths shown by Kestner for a single trapping centre are ~ 0.2 eV broad.

D. C. Walker: I should have talked only about substructure bands whose width is seen to be < 0.17 eV from bleaching studies in glasses, rather than use the only relaxation time measurement (which refers to liquid) to make deductions about the possible band widths.

J. Jortner: Finally, I would like to comment on Walker's analysis of the oscillator strengths for the optical absorption. When phonon broadening prevails the intensity has to be summed over all vibronic transitions. The sum rule for Franck–Condon vibrational overlap factors will result in the electronic term which is extracted from experiment and corroborated with theoretical calculations.

D. C. Walker: Regarding the oscillator strengths, they are calculated for each trap and refer to the substructure band. Since their band width is much less than the overall band envelope the appropriate extinction coefficient is correspondingly larger. In the limit, if one bleaches away (or preferentially destroys by reaction) all trapped electrons except those few which dominate the absorbance at λ_1 then you still have nearly the same absorbance at λ_1 but the extinction coefficient evaluated from it is based on the small concentration of traps absorbing at λ_1.

A. C. Albrecht: The idea that the broad electron (statically trapped?) absorption band actually is 'heterogeneous' and reflects a distribution of traps seems to contradict the fact that the transient photoconductivity signals (from trapped electrons in nonpolar glasses), once generated by red (or far-red) excitation, are then fully removed in the visible and near ultraviolet. This is contrary to spectral hole burning. A view consistent with both observations is to say that those electrons primarily responsible for the absorption effects are not the ones giving the transient photoelectric signals.

D. C. Walker: However, hole burning of trapped electron bands has been seen under laser excitation in nonpolar (MTHF and 3MP) media in different regions of their spectra, including 694, 1338, and ~ 2300 nm.

A. C. Albrecht: Another point is that in explaining the energy distribution in absorption spectra a bias always seems to creep in which speaks in terms of environmental effects on the ground state of the trapped electron. In fact such effects are almost certainly actually dominant in the *excited* state of the electron, quasifree, perhaps, and it is there where one should seek the origin of the spectral shifts. If the spectrally significant shifts of the ground state are to be seen (not just of the order of kT) then significant entropy changes must accompany this as well, in order to justify a detectable population of species having a spectrally important difference in ground state energies. These comments of course refer only to spectra of an equilibrated sample, not one which is still developing in time.

D. C. Walker: Yes, I agree that one should consider fluctuations in the excited state energies too; but, since small (though significant) permanent shifts in the absorption spectrum can be caused by bleaching from either extreme of the band, it seems to be possible to permanently alter the distribution of occupied traps.

P. M. Rentzepis: In relation to homogeneity, it has been shown by Huppert *et al.* that bleaching at several positions of the band of methylamine–Na between 700 to 1400 nm shows homogeneous bleaching throughout the band.

D. C. Walker: A band will appear to be homogeneous, and bleach throughout, whenever the observation time is significantly greater than the inverse of the frequency of fluctuation of the ground state energy.

S. A. Rice: Photoconductance spectra of electrons in glasses implicate excited mobile states in a continuum. In most cases the photoconductance and optical spectra either approximately coincide or the former is blue-shifted (0.2–0.5 eV) and modified compared to the latter. Thus either bound–continuum or this and bound–bound (on the low energy tail) transitions seem to occur for electrons in glasses. Such a decomposition is in agreement with the qualitative details of the analysis by P. Delahay. However, the onset of photoconductance is at much lower energies than suggested by Delahay. He used a model based on hydrogenic photoionization in an infinite medium, which Huang and Ellison have questioned.

D. C. Walker: As you know, I have not been persuaded that your photoconductivity spectra, when computed on the basis of photoconduction electrons per *absorbed* photon, are coincident with the absorption spectrum or that they show maxima which are blue-shifted. However, one could imagine each substructure band to consist of a large bound–bound part with a long, low intensity, high energy tail which is a continuum in nature. These tails would give rise to photoconductivity, with low quantum yield, *throughout* the main absorption band and sum together for the overall high energy tail which Delahay has discussed.

S. A. Rice: The experiments which have been cited to justify a large variation of trap depths for the electron in glasses are not unequivocal. Indeed the postulate of bound–bound ($1s \rightarrow 2p$) transitions in glasses (where both states depend on trap depth) to explain the absorption spectrum in terms trap depth variations requires these to be ~ 2–4 eV. Tunnelling of the trapped electron to scavengers should give a measure of the binding energy for the electrons since less deeply trapped electrons tunnel faster. There seem to be no spectral changes (with different scavenger concentration or thus of different electron concentrations (Marshall, Pilling, and Rice). Finally, if trap depths do not vary by more than $\sim 10kT$, the trapped electron absorption spectrum must either arise from the nature of the excited state or from large fluctuations in the ground electron wavefunction due to structural variations of the electron trap walls. The latter would not necessarily have a marked effect on the electron trap depth. However, the different ground state electron wavefunctions should have very different transition probabilities to the continuum states, though not necessarily for transitions to the bound states.

D. C. Walker: Certainly, as the ground state energy changes in accordance with variations in the molecular configurations in the trap walls so will the energy of the excited state vary and this must be taken into account in deducing the absorption band.

R. S. Dixon: In discussing low temperature alcohols you rightly pointed out the three different absorption spectra of electrons measured at different times, that is the broad infrared absorption attributed to weakly solvated electrons, the final spectrum attributed to fully solvated electrons, and an intermediate spectrum peaking at ~ 700 nm. The evidence for the latter is good; it has been seen in work by Baxendale and Wardman and in our own laboratories. However, you seemed to imply that this was some intermediate state in the solvation process, *i.e.* that infrared electrons first decayed to this intermediate state before finally decaying to fully solvated electrons. Do you think this is what happens?

D. C. Walker: I did not mean to imply that there was direct evidence for all electrons to pass through an intermediate state whose absorption band was centred at 700 nm, only that the overall absorption band peaks there transiently.

A pulse radiolysis study of solvated electrons in dilute solutions of polar liquids in nonpolar solvents

J. H. BAXENDALE

Chemistry Department, University of Manchester, Manchester M13 9PL, England

Received September 27, 1976

J. H. BAXENDALE. Can. J. Chem. **55**, 1996 (1977).

Measurements of the conductivities following electron pulse irradiation of dilute solutions of ethanol, *n*-propanol, *tert*-butanol, or dimethyl sulphoxide in *n*-hexane, cyclohexane, or *i*-octane are quantitatively consistent with the existence of equilibria between electrons in the hydrocarbon and electrons solvated by dimers of the polar molecules. With dimethylformamide solutions in alkanes the equilibrium could be with the monomeric anion of the solute but this assignment is not unequivocal. Absorption spectra of e_s^- in *n*-hexane solutions of ethanol and of *tert*-butanol have been obtained.

J. H. BAXENDALE. Can. J. Chem. **55**, 1996 (1977).

Des mesures de conductivité à la suite de l'irradiation pulsée électronique de solutions diluées d'éthanol, *n*-propanol, *tert*-butanol ou diméthylsulfoxyde dans les *n*-hexane, cyclohexane ou *i*-octane, sont en accord quantitatifs avec l'existence d'un équilibre entre les électrons dans l'hydrocarbure et les électrons solvatés par les dimères des molécules polaires. Avec des solutions de diméthylformamide dans les alcanes, il est possible que l'équilibre existe avec l'anion monomère du soluté mais cette attribution n'est pas sans équivoque. On a obtenu des spectres d'absorption de e_s^- dans des solutions d'éthanol et de *tert*-butanol dans le *n*-hexane.

Introduction

There is now a large body of information available on solvated electrons, e_s^-, in a wide variety of pure liquids from which it is clear that, in general, the polarity of the liquid is the major factor which determines the properties of e_s^-. Early observations (1) on mixtures of hydrocarbons and alcohols designed to produce liquids of intermediate polarity showed that as little as 4% v/v of methanol in cyclohexane gives an absorption spectrum similar to that of e_s^- in pure methanol and later work (2) showed that for e_s^- in *n*-hexane containing 2% methanol and in pure methanol the two spectra were almost indistinguishable. Most studies on such polar–nonpolar mixtures have been confined to high concentrations of alcohols in alkanes (3–5) but it has been shown in a detailed spectral examination (2) that changes in the far infrared absorption of e_s^- in *n*-hexane occur in the presence of a few tenths of 1% of *n*-propanol or of water. Simultaneously appreciable changes in ion mobility occur (6), both effects being attributed to electron solvation by the added polar molecules.

It is clear from the many thermodynamic and spectroscopic observations *on alkane–alcohol mixtures* that they do not give homogeneous liquids of intermediate polarities but that at low concentrations of the polar component, the latter forms aggregates the size of which is a function of the concentration.

The present report describes observations on the ion mobility and to a lesser extent the spectral changes occurring in the alkanes *n*-hexane, cyclohexane, and *i*-octane when small amounts of ethanol, *n*-propanol, *tert*-butanol, and several other polar materials are added. A preliminary report on some of this work has already been presented (7).

Experimental

The alkanes and alcohols were purified as described earlier (2). Dimethylformamide (DMF) was the quality 'for infrared spectroscopy' and was treated with molecular sieve 4A before use. Dimethyl sulfoxide (DMSO) was purified by distillation[1] and was shaken three times with five times its volume of alkane to give finally a saturated solution in the alkane which was used as a stock solution. The concentrations of these stock solutions were determined spectroscopically after dilution with ethanol, and for *n*-hexane, cyclohexane, and *i*-octane were found to be 34, 52, and 37 m*M* respectively at 20 ± 2°C.

The liquids were deaerated by purging and shaking with pure argon and introduced into the optical or conductivity cell by argon pressure. The apparatus and techniques for the optical and conductivity measurements

[1]Kindly supplied by Dr. A. M. Koulkes-Pujo.

have been described previously (2, 6). A 10 MeV linear accelerator introduced 5 or 10 ns pulses of radiation, electrons for *n*-hexane and cyclohexane, X rays from a tungsten target for *i*-octane. Doses of 1–2 krad were used for the optical and 0.1–0.5 krad for the conductivity measurements. All experiments were carried out at room temperature, 20 ± 2°C.

Results

Mobilities in Alcohol–Alkane Mixtures

Typical variations in the immediate post-pulse ion mobility sum as the alcohol concentration increases are shown for *n*-propanol in cyclohexane and in *n*-hexane in Fig. 1. The mobilities are calculated by extrapolating the CRO traces back to the middle of the pulse to give the immediate post-pulse conductivities. In constant experimental conditions (dose, cell geometry, and applied voltage) these conductivities are proportional to the mobility sum of the ions present and can be transformed into absolute mobilities using the known values in the pure hydrocarbons (8) as standards. The curves for ethanol and *tert*-butanol are similar, the only differences being in the effective concentration ranges. Thus to reduce the mobility sum to one half in cyclohexane requires *ca.* 45 m*M* *n*-propanol, 25 m*M* ethanol, and 100 m*M* *tert*-butanol. As previously reported (7) the behaviour of methanol is quite different. In *i*-octane little effect is produced by 40 m*M* but between 40 and 60 m*M* there is a precipitous fall in mobility to almost zero.

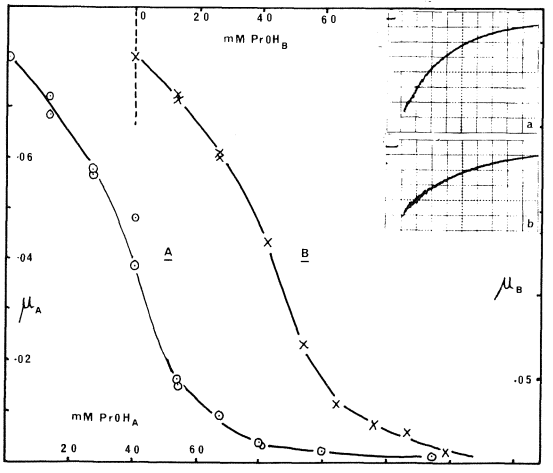

FIG. 1. Variation in mobility sum of ions, μ (cm^2 V^{-1} s^{-1}) in *n*-hexane (*A*) and cyclohexane (*B*) solutions of *n*-propanol. Inset: CRO traces on 10 mV and 100 ns/div.: (*a*) *n*-hexane + 27 m*M* propanol; (*b*) *n*-hexane + 40 m*M* propanol.

In the pure hydrocarbons it is well established that the mobility sum of the ions is determined almost entirely by the very high value of the electron mobility. When alcohols are added, the above decreases in conductivity are accompanied by changes in optical absorption (see below and ref. 2) which indicates that electron solvation by alcohol occurs. Such solvated electrons, would have the low mobility of normal ions, *i.e. ca.* 10^{-3} cm^2 V^{-1} s^{-1} compared with 0.1 to 10 for the electrons in the pure hydrocarbon. Hence even when the conductivity has been decreased to 10% of that of the pure hydrocarbon by the addition of alcohol, the contribution of the alcohol solvated electrons to this must be small. We conclude that in these conditions not all the electrons have been solvated by alcohol and the residual mobile 'hydrocarbon electrons' are still largely responsible for the conductivity. This conclusion is supported by the rates of decay of the conducting species in this range of alcohol concentrations, which are very much higher than expected from those of normal ions. The observations therefore suggest that there is an equilibrium established between electrons in the hydrocarbon and electrons associated with alcohol molecules.

Single molecules of alcohol are unlikely to be involved since the electron affinity is unfavourable and it is probable that the solvation process involves the diffusion of the electron to alcohol clusters (2). Calorimetric, infrared, and osmotic measurements (9–13) indicate that beyond *ca.* 100 m*M* alcohol tetramers are predominant. It is generally agreed that at lower concentrations more than one associated species may be present and there is specific evidence for the presence of dimers (12). Thus if solvation is by a cluster A_n we will have the equilibria

$$[1] \qquad nA \rightleftharpoons A_n \qquad K_n$$

$$[2] \qquad e_h^- + A_n \rightleftharpoons e_a^- \qquad K_e$$

where e_h^- and e_a^- are the hydrocarbon and alcohol solvated electrons. If the extent of cluster formation is small, these equations give

$$[3] \qquad [e_a^-]/[e_h^-] = K_e K_n [A]^n$$

Accepting the above conclusion that the measured mobilities at different alcohol concentrations are determined by only e_h^- and that the

reduction from μ_0 in pure hydrocarbon to μ_c at alcohol concentration c is due entirely to a reduction in $[e_h^-]$, then

$$[e_h^-]_0/[e_h^-]_c = \mu_0/\mu_c$$

From [3] above it follows that

$$[e_a^-]/[e_h^-] = (\mu_0 - \mu_c)/\mu_c = K_e K_n [A]^n$$

Figures 2, 3, and 4 and previous data (7) show that the measurements on ethanol, *n*-propanol, and *tert*-butanol in *n*-hexane or cyclohexane or *i*-octane are consistent with this interpretation for a value of $n = 2$ at least up to alcohol concentrations which reduce the mobility to one half of its original value and sometimes to higher concentrations. Deviations which occur at higher concentrations of ethanol and *n*-propanol may arise because of the increasing importance of larger clusters. Values of $K_e K_n$ derived from the lines in these figures are given in Table 1.

Although there is evidence for the presence of alcohol dimers at these low concentrations, unfortunately reliable values of K_n are not yet available because of experimental difficulties. However, it is generally agreed that the extent of dimer formation is small as required by the above analysis.

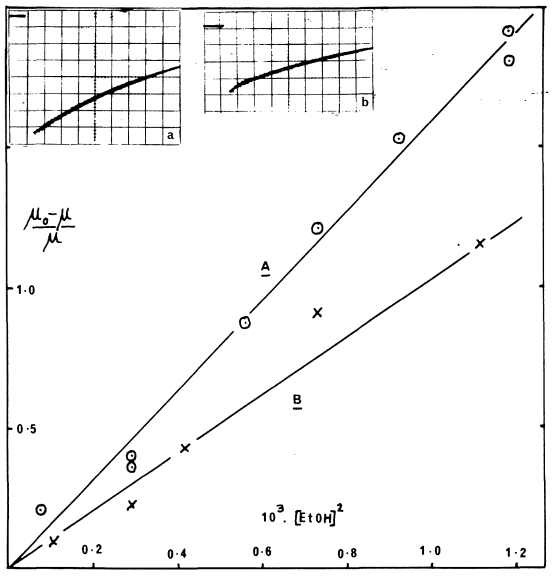

FIG. 2. Mobility – concentration relationship for cyclohexane (*A*) and *n*-hexane (*B*) solutions of ethanol. Inset: CRO traces on 50 ns, 20 mV/div.: (*a*) pure cyclohexane; (*b*) cyclohexane + 24 m*M* ethanol.

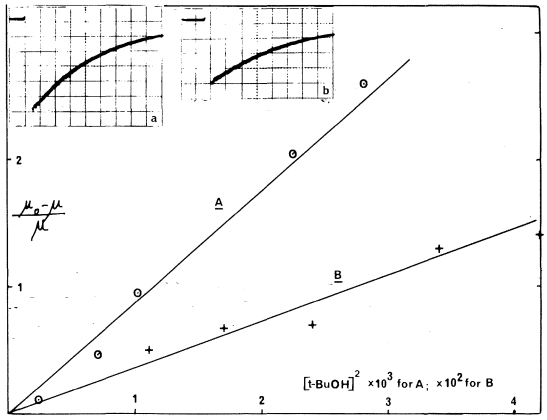

FIG. 4. Mobility – concentration relationship for *n*-hexane (*A*) and *i*-octane (*B*) solutions of *tert*-butanol. Inset: CRO traces on 20 mV and 50 ns/div.: (*a*) pure *n*-hexane; (*b*) *n*-hexane + 26 m*M* *tert*-butanol.

Spectra in Hexane–Alcohol Mixtures

The higher concentrations of e_s^- required to observe spectra in hydrocarbons reduce the lifetime of e_s^- because of their removal by the second order neutralisation reaction. With the limited response time of the present monitoring equipment, this short lifetime makes the observation of spectra difficult except for hydrocarbons such as *n*-hexane in which e^- has a relatively low mobility, and observations with alcohols have been limited to this solvent. Spectra of *n*-hexane + *n*-propanol and *n*-hexane + methanol mixtures have been reported previously (2, 7) and those of ethanol and *tert*-

TABLE 1. Values of K_eK_n for various hydrocarbon solutions

	Ethanol	*n*-Propanol	*tert*-Butanol	DMSO	DMF	H_2O
n-Hexane	1000	570	880	7.4×10^4	135	
Cyclohexane	1600	480	120	2.0×10^4	200	3.4×10^5
i-Octane	340	230	36	1.3×10^4	70	

NOTE: For DMF the values are for K_e assuming electron attachment to monomer. For H_2O the value of K_eK_n assumes the concentration is proportional to the water vapour pressure over the solution.

butanol are given in Figs. 5 and 6. The important point is that, assuming the present analysis in terms of alcohol dimers, for the concentration ranges in which solvation by the dimer is presumed to be considerable, *i.e.* where mobilities are appreciably less than those in the pure hydrocarbon, the important spectral changes occur beyond 1500 nm and are out of the range of the detection equipment. The much larger changes seen around 1000 nm must be due to solvation by larger clusters of alcohol.

Mobilities in Alkanes + DMSO

Much smaller quantities of DMSO are effective in reducing the mobility than is the case for alcohols. Thus about 7 m*M* is sufficient to halve it in cyclohexane. Again the data are consistent with solvation by a dimer of DMSO as is shown in Fig. 7 and the value of K_eK_n, which is much bigger, is listed in Table 1.

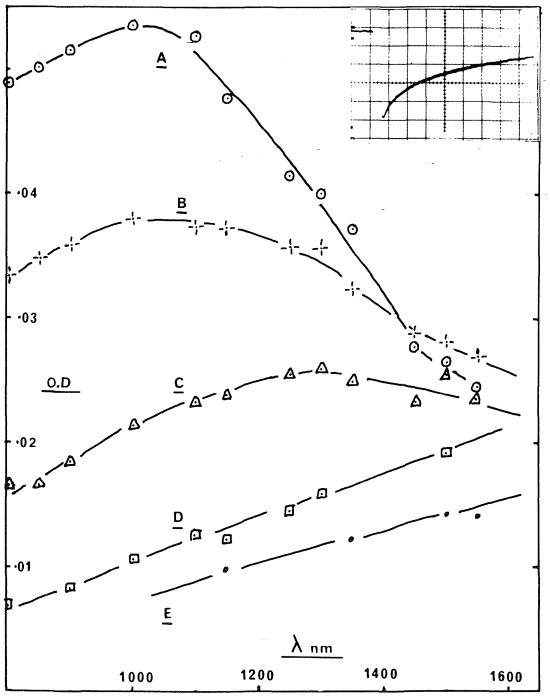

FIG. 5. Spectra of e_s^- in *n*-hexane solutions of ethanol. Inset: CRO trace at 1000 nm on 50 ns/div. for 66 m*M* ethanol.

Mobilities in Alkanes + DMF

DMF is also more effective than the alcohols as shown in Fig. 8 but in contrast to these and to DMSO the data do not fit the analysis in terms of a dimer. Figure 8 is consistent with electron capture by single molecules of DMF. Equilibrium between electrons in a hydrocarbon and electrons on a solute has been observed previously with CO_2 (14) and biphenyl (15) as solutes. However, in the present system this interpretation is not unequivocal since if for example almost all the DMF is present as a single type of cluster over the concentration range used (*i.e.* if K_n is high) then the same behaviour would be observed. Figure 8 gives the value of K_e and the value in Table 1 has been calculated assuming $n = 1$.

Water + Cyclohexane

We have previously reported (2) that appreciable spectral shifts occur in the e_s^- absorption when *n*-hexane is saturated with water even though the concentration of the latter is only *ca.* 4 m*M*. As can be seen from Fig. 9 the same is true for cyclohexane and the peak at *ca.* 1400 nm is similar to that in *n*-hexane.

Ion mobilities were also measured at various water concentrations, the latter being obtained by saturating the cyclohexane with argon containing water vapour at various water vapour pressures. The results are given in Fig. 10. It will be seen that in water saturated solution the mobility is decreased by a factor of about six. Assuming that the solution concentration is proportional to the partial pressure of water vapour and plotting as before, it will be seen that up to 60% of saturation, the data are again consistent with solvation by a dimer. However, the assumption is of doubtful validity and a reliable concentration – vapour pressure relationship is required for a more confident analysis. Data at present available are inconsistent.

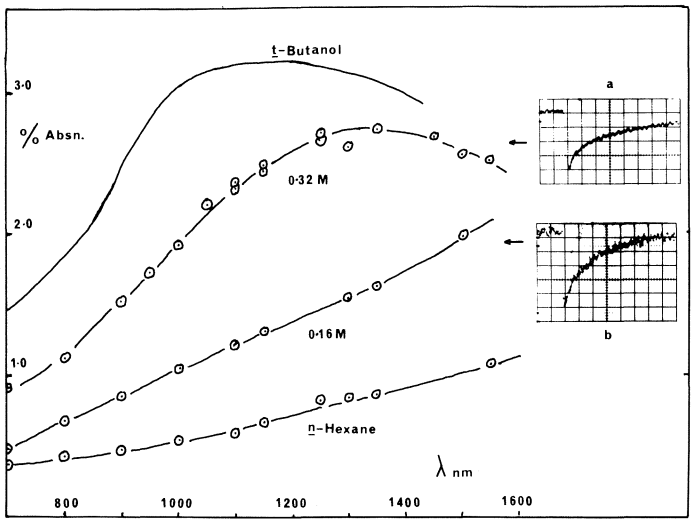

FIG. 6. Spectra of e_s^- in *n*-hexane solutions of *tert*-butanol. Inset: CRO traces at 1350 nm, 50 ns/div.: (*a*) 0.32 *M tert*-butanol, 50 mV/div.; (*b*) 0.16 *M tert*-butanol, 20 mV/div.

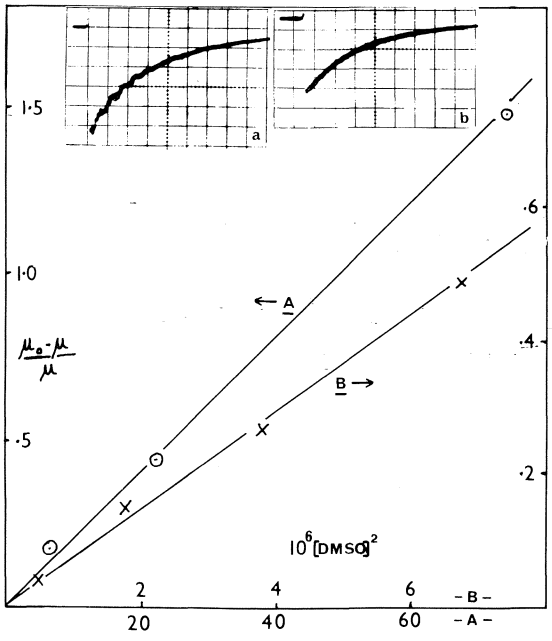

FIG. 7. Mobility – concentration relationship for DMSO in (*A*) cyclohexane and (*B*) *n*-hexane. Inset: CRO traces on 50 mV, 100 ns/div.: (*a*) pure *n*-hexane; (*b*) 2.5 m*M* DMSO in *n*-hexane.

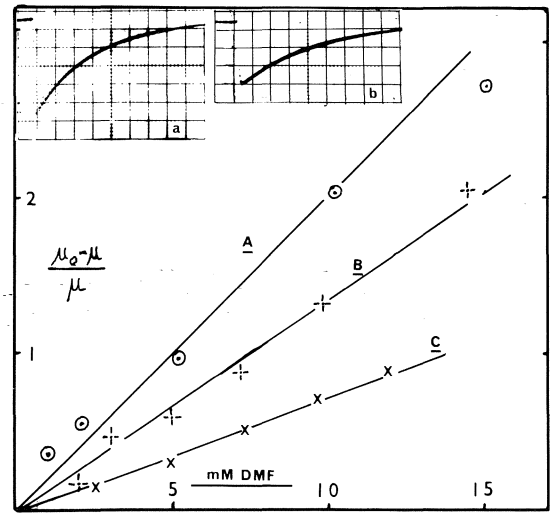

FIG. 8. Mobility – concentration relationship for solutions of DMF in (*A*) cyclohexane, (*B*) *n*-hexane, (*C*) *i*-octane. Inset: CRO traces on 100 ns/div.: (*a*) pure cyclohexane, 50 mV/div.; (*b*) 15 m*M* DMF in cyclohexane, 20 mV/div.

Other Solutes

Preliminary measurements indicate that ethyl acetate does not lower the measured mobility in cyclohexane up to *ca.* 100 m*M* while diethylamine at 1% v/v (137 m*M*) decreases the mobility to 57% of that in the pure hydrocarbon. If dimer solvation is again involved, this indicates a lower value of K_eK_n (*ca.* 40) than for any of the alcohols in cyclohexane.

Discussion

The present results strongly suggest that solvation of electrons by dimers of alcohols occurs in these dilute alkane alcohol mixtures. As mentioned above, thermodynamic and spectro-

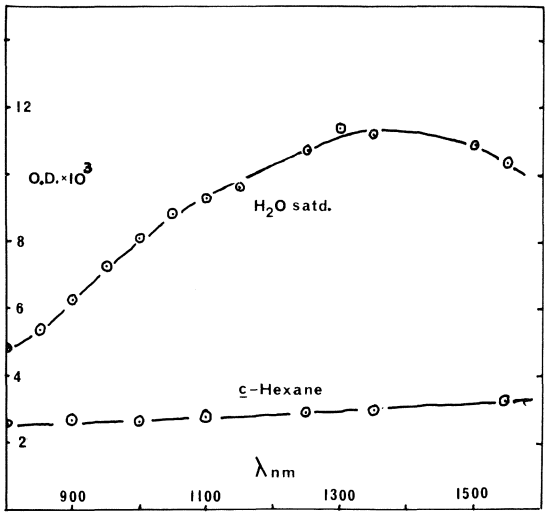

FIG. 9. Absorption spectra of e_s^- in cyclohexane and water saturated cyclohexane.

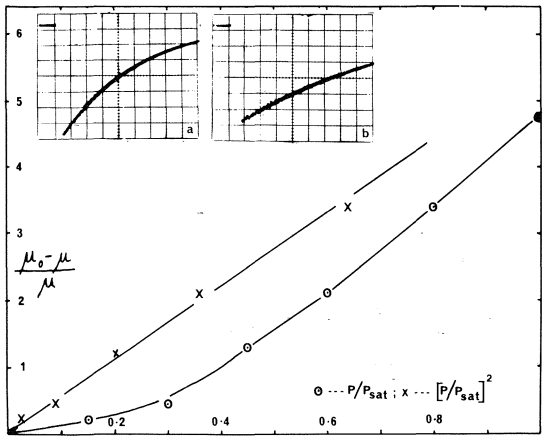

FIG. 10. Mobility variation for cyclohexane equilibrated with water vapour over a range of partial pressures P. P_{sat} is the saturated water vapour pressure. Inset: CRO traces on 50 ns/div. (*a*) pure cyclohexane, on 20 mV/div.; (*b*) cyclohexane equilibrated with 45% saturated water vapour, on 10 mV/div.

scopic investigations would support the presence of such dimers in mixtures of the concentrations used here, before the introduction of the electrons. In the spectral observations reported here the electron half-lives are at least *ca.* 100 ns in the mixtures and in this time there are no observable changes in the absorption spectra from those found immediately after the pulse. This is important since it indicates that the solvated state formed at the shortest time we can observe remains unchanged throughout the lifetime of the electron. Any subsequent aggregation of polar molecules would lead to a blue shift in the spectrum. As has been pointed out previously (2, 16) at diffusion controlled rates and concentrations of 10–100 mM of alcohol, the time required for further addition of alcohol is of the order 2–20 ns, so that the process is not restricted by the lifetime of the dimer solvated electron.

It appears (17) that theoretical calculations indicate that for water molecules in the gas phase electron solvation by four molecules would not give a stable species, and if this is the case it is very unlikely that solvation by an alcohol dimer would occur in the gas phase. Hence if the present analysis in terms of dimer solvation is correct, the stability in the hydrocarbons must derive from the interaction of the solvated species with the hydrocarbon continuum.

Although neither the alcohol dimer nor the tetramer solvated electron would appear to be stable entities in the gas phase, calculations on water (18) indicate that here the tetramer species could be more stable by *ca.* 1 eV. Hence once the dimer is formed it would be expected to acquire further alcohol molecules as envisaged by Mozumder (1b). However, it seems that this does not occur and a possible explanation is that the electron dissociation from the dimer is extremely rapid, *i.e.* the equilibrium solvated state has a short dynamic life, and the time required for aggregation is not available. Confirmation of this must await the determination of the values of K_n which will then allow K_e to be calculated and hence the electron dissociation rate.

It is interesting to note that the absorption spectrum of e_s^- in water saturated cyclohexane closely resembles that of e_s^- in D_2O vapour at 523 K when the gas density is 0.022 (17), in that it shows the same broad absorption with a peak at *ca.* 1400 nm.

In a recent treatment of the energetics of water clusters (19) the free energies of formation of various clusters have been derived from which the extent of dimer, trimer, etc. formation in the above D_2O vapour can be calculated. These data indicate that the concentrations of dimer, trimer, and tetramer present in these conditions are approximately 5 mM, 0.5 mM, and 0.01 mM respectively. It seems possible that, as suggested for cyclohexane (although still to be confirmed

by measurements of water concentrations), electrons in this vapour phase are also solvated by water dimers and that an equilibrium state exists between these and quasi-free electrons. Since at this density the bulk dielectric constant of the vapour will be of the same order as that of cyclohexane, very similar energetics and hence spectra would be expected.

It will be noted from Table 1 that with the exception of cyclohexane + ethanol the values of K_eK_n decrease in the order *n*-hexane, cyclohexane, *i*-octane, but the variation among the hydrocarbons for any one solvent except *tert*-butanol is at most a factor of six. It is to be expected that K_n will not change greatly with hydrocarbon and the same appears to be the case for K_e. A major factor determining K_e will be the free energy of solvation of the electron in the hydrocarbon (14) and it would seem that this varies little among these three hydrocarbons. The values of K_e for DMF are consistent with this conclusion.

Also, for any one hydrocarbon K_eK_n in general increases with increase in polarity of the solute which would be expected since this will increase K_e through increased electron solvation energy by the dimers, and K_n through increased association of the solute. The DMF system gives K_e directly and may lend itself to a detailed treatment such as has been carried out for CO_2 (8) to yield important thermodynamic information about the electron in these solvents.

Discussion

J. M. Warman: Have you carried out a temperature study of the effect of alcohols on the mobility since this would provide firstly very interesting thermodynamic information about the trapping site and might also give an indication as to whether the nature of the site changes with concentration?

J. H. Baxendale: Not as yet. It is not so simple since to get the interesting information, the temperature dependence of the K_a are required, and even good values at room temperature are not yet available.

J. W. Chase: What is special about methanol? Why does it have a different power law than the other additives.

J. H. Baxendale: I think it is merely a matter of the values of K_a for the clusters of various sizes. These are such that the onset of larger clusters sets in suddenly over the critical concentration range.

W. F. Schmidt: How do you exclude any influence of the added alcohol on the initial charge carrier yield, especially in the higher yield liquid isooctane?

J. H. Baxendale: We have shown previously (2) that the free ion yield in *n*-hexane is changed little by 200 m*M* *n*-propanol. In view of the parallel behaviour of the other hydrocarbons, it seems unlikely to be an important factor, but I agree this requires confirmation.

Electron in cold alcohols: a pulse radiolysis study in ethanol

L. GILLES, M. R. BONO, AND M. SCHMIDT

Centre d'Etudes Nucleaires de Saclay, DRA/SRIRMA, B.P. No. 2, 91190 Gif-sur-Yvette, France

Received September 27, 1976

L. GILLES, M. R. BONO, and M. SCHMIDT. Can. J. Chem. **55**, 2003 (1977).

The pulse radiolysis of cold ethanol near its freezing point shows 'partly solvated' states of the electron with transient spectra whose maxima vary with time. It is shown that the determination of the solvation times of the electron can depend strongly on the wavelength considered; thus an explanation could be given for the different values obtained by Chase and Hunt at $\lambda = 1300$ and $\lambda = 1050$ nm.

L. GILLES, M. R. BONO et M. SCHMIDT. Can J. Chem. **55**, 2003 (1977).

La radiolyse pulsée de l'éthanol à basse température, près de son point de fusion, montre l'existence d'électrons 'partiellement solvatés' dont les spectres d'absorption varient avec le temps. La détermination des temps de solvatation de l'électron peut donc dépendre de la longueur d'onde choisie pour en effectuer la mesure: on expliquerait ainsi les différentes valeurs obtenues par Chase et Hunt aux longueurs d'onde de 1300 et 1050 nm.

Introduction

Fueki *et al.* (1) in their semicontinuum model have pointed out the importance of the microscopic viscosity in calculating the relaxation time for orientation of the dipoles of polar molecules such as alcohols. Even though the agreement between experimental (2) and calculated values was not perfect, the theoretical curves predicted the temperature dependence observed for the solvation times of the electron, $\tau(s)$, and it appeared that the macroscopic viscosity was a good approximation to the microscopic viscosity, at least for methyl, ethyl, and *n*-propyl alcohols.

In recent papers Chase and Hunt (3) on the one hand and Kenney-Wallace and Jonah (4) on the other have shown that in normal aliphatic alcohols, $\tau(s)$ measured at room temperature increased with increasing chain length. For each alcohol, they have correlated $\tau(s)$ with $\tau(2)$, the corresponding dielectric relaxation time associated with the rotation of the free molecules.

In this case since the rotational relaxation of the unassociated molecules depends, according to the Debye equation, on the viscosity of the medium one would expect that for a given alcohol $\tau(s)$ would vary with temperature in a similar way to the viscosity. This behaviour has been observed in the case of liquid *n*-propanol at low temperatures by Baxendale and Wardman (5).

On the same basis ($\tau(s)$ linked to $\tau(2)$) one can try to correlate the solvation times for different alcohols at a given viscosity with the chain length of these molecules: for linear aliphatic alcohols (the only ones considered here) the solvation times determined at a given viscosity should increase with the chain length.

The results of Chase and Hunt (3) for methanol, ethanol, *n*-propanol, and *n*-butanol obtained in the temperature range -65 to $+60°C$ and those of Kenney-Wallace and Jonah (4) measured at room temperature for alcohols having from 2 to 10 carbon atoms allow this comparison to be made. In Table 1 the values of $\tau(s)$ measured by Chase and Hunt are listed together with the viscosities reported by Komarenko *et al.* (6) for the same temperatures. The values of $\tau(s)$ were obtained from Arrhenius plots of the rate constants determined for the decay of absorption measured at 1300 nm (methanol, ethanol, *n*-propanol) or from the increase of absorption measured at 600 nm (*n*-butanol). When measured, values of $\tau(s)$ obtained by Chase and Hunt at both 600 and 1300 nm were roughly similar, but the values measured at 1050 nm were different (Table 1), a point which will be considered later.

The results given in Table 1 for 600 and 1300 nm merit two remarks.

(1) For viscosities between 1.1 and 2.2 cP the solvation times are the same within the limits of experimental error for the first three alcohols considered or, in other words, the relaxation time of these molecules is independent of their size.

(2) For values higher than 2.2 cP the results obtained for the four alcohols at the same

[a]Values of the viscosities are from ref. 6. Values of τ(s) are from ref. 3, measured from the decay of absorbance at λ = 1300 nm or the increase of absorbance at 600 nm.

viscosity are quite different. Furthermore, the case of methanol aside, it seems that for a given viscosity the solvation time is shorter the longer the molecule. The comparison of these results with those obtained at room temperature by Kenney-Wallace and Jonah (4) for the longer chain alcohols (pentanol, octanol, decanol) which have viscosities higher than 5 cP leads to the same conclusion.

In order to obtain more evidence on these points we chose first to study the solvation times of the electron in cold ethanol (near its freezing point), with a view to comparing our results with values previously obtained by Baxendale and Wardman (5) in cold *n*-propanol at similar viscosities.

Experimental

The irradiation source is a modified Febetron 707: the electron pulse from the Febetron tube window is dispersed by an electromagnet (7*a*) and only electrons in the range 1.7 to 1.8 MeV are selected. The total pulse length is thus reduced to 16 ns with a width at half-height of 8 ns. The experimental set up (irradiation, cooling, and detection systems) is described elsewhere (7*b*) and the spectra, measured between 300 and 830 nm, are determined by normalization of optical densities to an arbitrary dose of about 10 krad.

The ethanol is 'Merck zur Analyse' grade purified by distillation. It was verified that no traces of benzene or aldehyde and ketone remained after the distillation.

Results and Discussion

At −106°C, the spectra obtained immediately after the pulse (20 ns) and later are similar to those which Baxendale and Wardman (5) obtained at −110°C. However, the minimum observed by these authors in the wavelength region of 1000 nm seems to be in the region 700–750 nm in our case.

Figure 1 shows the results we obtained at −116°C where ethanol is still liquid (melting point −117.4°C). Spectra 1–5 were respectively measured 20, 30, 50, 90, and 140 ns after the beginning of the pulse from oscilloscope traces such as those given in the insets of this figure. Curve 5 corresponds to the solvated electron spectrum with λ_{max} ~600 nm slightly different from previous results (8).

At $\lambda \leq 650$ nm, solvation times measured from the rate of increase of absorption seem to depend upon the wavelength considered: τ(s) is about 40 ns at $\lambda = 550$ nm and about 30 ns at $\lambda = 450$ nm (as seen in the inset, it would be even smaller at 650 nm). At $\lambda > 650$ nm,

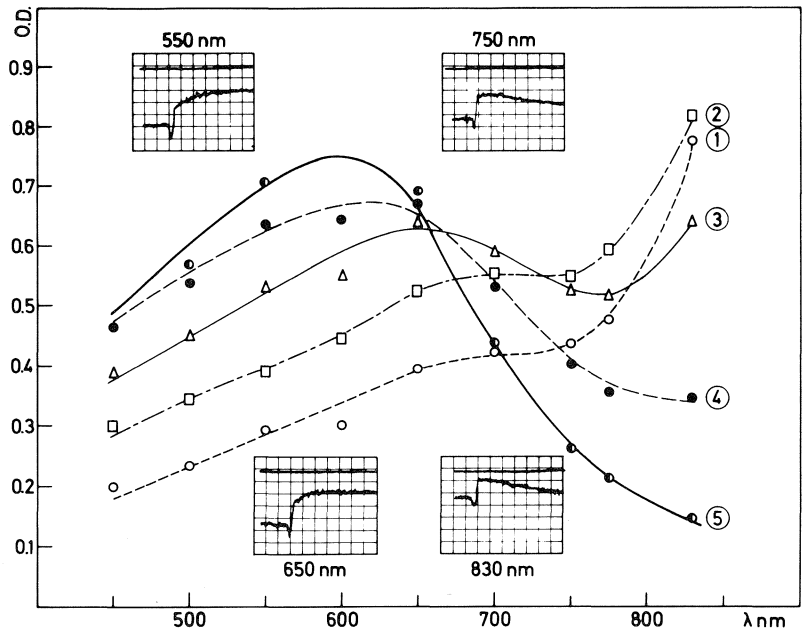

FIG. 1. Spectra observed in pulsed, Ar-purged, ethanol at −116°C. Spectra 1–5 have been obtained respectively 20, 30, 50, 90, and 140 ns after the beginning of the pulse. Optical densities were normalized to an arbitrary value of dose (~10 krad) from oscilloscope traces such as those given in the insets (20 ns/div.).

measurements become impossible as the first increase is followed by a decay of absorption.

Data obtained below the melting point at −123°C give the same kind of results with λ_{max} for e^-_{solv} at about 570 nm. At 450 nm and 600 nm $\tau(s) \approx 100$ ns whereas at $\lambda = 500$ nm and 550 nm $\tau(s) \approx 200$ ns.

These results lead to two remarks from which we will draw the necessary conclusions.

(1) Development of the Transient Spectra during the Solvation Process

Kenney-Wallace and Jonah (4) note that, at room temperature, their measured rates of increase of the absorption at 514 nm are similar to the rates measured by Chase and Hunt of decrease of absorption at 1300 nm in the cases of ethanol and *n*-propanol and of increase of absorption at 600 nm in the case of ethanol. This observation has led the authors to conclude that the passage from e^-_t to e^-_{solv} at room temperature occurs without the intervention of any intermediate solvated species of appreciable lifetime.

On the contrary, the increase in absorption followed by a decrease which we observe at both −116°C and at −123°C between 650 and 830 nm cannot be explained on the basis of only two configurations of the electron, one the trapped electron e^-_t and the other the solvated electron e^-_{solv}. In fact, if such were the case only an increase or a decrease in absorption, depending on the wavelength, should be observed (which suggests also an isosbestic point at a given wavelength). In the range of temperature which we have employed where ethanol is either liquid or glassy (−123°C) our results show the existence of transient absorption spectra of which the maxima move as a function of time.

These observations are in good agreement with previous results obtained for the glassy state (77 K) by Kevan (9) and Miller *et al.* (10). As at 77 K (10), the passage from one transient spectrum to another may be attributed to the variation with time of partly solvated states of the electron.

The response time of our detection system and the pulse length furnished by the electron gun do not allow us to make accurate measurements at higher temperatures (−106°C). But it should be noted that a detailed analysis of the results obtained at various wavelengths with *n*-propanol, irradiated at −12°C, led Chase and Hunt to suggest the possibility of a displacement of the

spectrum of e^-_t during the process of relaxation to a deeper trap. Thus the results obtained with ethanol at very low temperature (77 K) and these obtained above and below the freezing point (−116 and −123°C) are of the same type as those obtained with *n*-propanol at much higher temperature (−12°C). They indicate the existence of transient states which we assign to partly solvated states of the electron. If such a conclusion were valid at room temperature, it would imply the presence of intermediate states with very short lifetimes, and thus difficult to observe, as Kenney-Wallace and Jonah have suggested, but whose existence would have consequences for the measurement of the electron solvation time (defined now as a measurement of the time necessary for the passage of the spectrum of the first state of the electron observed immediately after a pulse to the spectrum of the fully solvated electron).

(2) Measurement of the Electron Solvation Time in Ethanol at −116°C and −123°C

In order to obtain a value for the solvation time of the electron from our results we have seen that different regions of wavelength have to be considered.

(a) $\lambda \leq \lambda_{max}\ (e^-_{solv})$

In this region of wavelength the situation appears relatively simple since one only observes an increase of absorption. However, errors may arise in the wavelength region (400–450 nm) where the final stage of variation of absorption is of the same order of magnitude as the noise level on the oscilloscope traces.

In our case the most accurate values of $\tau(s)$ which we can determine are obtained in the region where the difference between the initial and final absorption is the largest, that is to say at the wavelength corresponding to the maximum of the solvated electron spectrum at the temperature in question: at −116°C: $\tau(s) = 40 \pm 4$ ns (at λ = 550–600 nm); at −123°C: $\tau(s) = 200 \pm 15$ ns (at λ = 550 nm).

(b) $\lambda > \lambda_{max}\ (e^-_{solv})$

In this region of wavelength the various spectra overlap and confusing results are obtained. For instance, as noted previously, for wavelengths immediately above λ_{max} where only an increase of absorption is observed (650 nm at −116°C (Fig. 1) and 600 nm at −123°C) the values obtained are again lower than the values of $\tau(s)$ measured at λ_{max}.

(3) Consequences

The difficulties which we have pointed out in determining the solvation time of the electron in the range of wavelengths we have considered could suggest that it is preferable to study the phenomenon in the infrared region as did Baxendale and Wardman and Chase and Hunt. At first sight indeed both at low temperatures (5) and at higher temperatures (3), the solvation times measured at 1300 nm (decrease in absorption) appear essentially similar to those measured around 600 nm (increase in absorption). However, Chase and Hunt have clearly shown that the results measured at 1050 nm are very different and that the difference increases as the temperature is lowered. It thus appears that even in the infrared region the kinetics depend on the wavelengths used for the measurements. This difference is observed for all four alcohols considered and at all the temperatures employed by Chase and Hunt. We shall see that these results may be explained by the hypothesis of partly solvated states of the electron whose spectral contributions vary with time. In fact, in the infrared region where a decrease in absorption is measured, the change in absorption indicates the transition from the first spectrum detected immediately after the pulse to the last observable at these wavelengths: this last spectrum is not necessarily that of the solvated electron but rather of the last partly solvated state which absorbs at the wavelength considered. The spectra obtained at −12°C with *n*-propanol by Chase and Hunt are in agreement with this hypothesis: the solvated electron spectrum does not extend above 1100 nm. Under these conditions the apparent rate of solvation measured at 1300 nm will be faster than the true rate.

Furthermore it should be noted that as the temperature is lowered the spectrum of the solvated electron is shifted towards the blue and the difference between the results obtained at 1300 nm and 1050 nm increases in agreement with our hypothesis.

Finally the similarity between the results obtained at 600 and 1300 nm with ethanol ($\Theta \leq$ room temperature) and with *n*-propanol ($\Theta \leq -12$°C) can only be fortuitous, for depending on the temperature considered 600 nm falls on one side or the other of the maximum of the solvated electron spectrum. We have seen the results of such a situation in our study at

-116°C and -123°C. This is particularly noticeable in the case of *n*-propanol for which, at -12°C, the absorption maximum of the solvated electron is at 600 nm.

Conclusion

The solvation of the electron in alcohols is a complex process. The recent results reported by Miller *et al.* for ethanol irradiated at 77 K are similar to those we have obtained for the same alcohol irradiated at temperatures above and below its freezing point. The interpretation of the observations in terms of partly solvated states of the electron enables certain results of Chase and Hunt to be explained. If the hypothesis is correct a complete knowledge of the various spectra obtained after radiolysis is necessary and this for all alcohols and at all temperatures considered to obtain accurate values of τ(s).

It also appears that for measurements made in the infrared a contribution due to the solvated electron must be considered (stable residual absorption) in determining the solvation time. This is clearly shown in comparing values given in Table 1. Thus any correlation between τ(s) and η becomes impossible given the present state of knowledge.[1]

Acknowledgments

The authors wish to thank J. Potier for continuous assistance in the experiments and Dr. T. B. Truong for analysis of the purified ethanol. The authors wish also to thank J. Sutton for helpful discussions during the preparation of the final manuscript.

[1]Two papers appeared after the Banff Conference. One by Kenney-Wallace (11) pointed out the importance of the polarizability and viscosity when considering the solvation times of the electron in alcohols. The other by Baxendale and Sharpe (12) gave three different rate constants for electron solvation, based on the absorption decay at 1300 nm and the absorption growth at 550 nm and 450 nm respectively for *n*-propanol irradiated at various temperatures between -119°C and -155°C. These results are in agreement with the idea we presented at the Conference and have developed in this article.

Discussion

J. W. Hunt: As discussed by Gilles and others, the changes of the absorption signals of the localized electron consist of a shift from infrared to visible wavelengths by complex decays and formations. Since the process is not one of a single jump from a shallow to a stabilized deep trap, I agree with Dr. Gilles that we must be careful in obtaining accurate values of the relaxation processes, although the values in the infrared wavelengths will probably be the best.

L. Gilles: The rate constants calculated from the decay of absorption at infrared wavelengths could appear easier to determine than those calculated from the increase of the absorption in the visible region, due to the difficulty in the latter case to determine precisely the time at which the final level is obtained. Nevertheless you will have to take care, that at the ir wavelength considered the solvated electron must absorb (*i.e.* a residual absorption must exist). Thus I don't know if the values measured at ir wavelengths will be better than those measured at the maximum of absorption of the solvated electron at the temperature considered.

L. Onsager: May I remind you again that on a simple-minded picture the pertinent dielectric relaxation time is not the Debye time τ_D, but the longitudinal relaxation time $\tau_L = \tau_D \, \varepsilon_\infty/\varepsilon_0$. This is not to assert that the concept of a simple hf dielectric constant is always appropriate. When not, then the concept represented by τ_L also must be picked apart. A good many radiation chemists do in fact know τ_L as the 'relaxation time at constant charge', as distinguished from the 'relaxation time in constant field' τ_D.

L. Gilles: In an earlier study I made with J. W. Hunt and J. E. Aldrich (2) using the stroboscopic pulse radiolysis system, we correlate the solvation times for methyl, ethyl, and *n*-propyl alcohols with τ_1', the relaxation time at *constant charge* for the breaking of hydrogen bonds. It appeared then from more recent results of Chase and Hunt on the one hand and Kenney-Wallace and Jonah on the other and also from the previous results of Baxendale and Wardman that a better relationship was found between τ(s) and τ(2) (the dielectric relaxation time of the free molecules in the liquid). As mentioned in ref. 4 modifying τ(2) to τ(2)′ would lead to times of

about 70% of $\tau(2)$ which would appear rather too fast. This observation would be even more striking in considering Baxendale's results.

L. Kevan: Your data show that the electron solvation times in methanol, ethanol, and 1-propanol are the same at the same viscosity *if* the viscosity is ≤ 2 cP. This is exactly what the simple model of Fueki, Feng, and Kevan (J. Phys. Chem. 1974 and 1976) predicts in which we equate the microscopic and macroscopic viscosities. The model does not depend on the size of the alcohol molecules. However, in glasses we know that our simple model for solvation time fails because the microscopic and macroscopic viscosities are presumably not the same. Your data seem to show that ~ 2 cP is the transition viscosity above which the microscopic and macroscopic viscosities are not equal. In this region the size of the solvent molecule becomes important. I would not be so pessimistic about defining a unique solvation time for electron solvation even though you have observed a wavelength dependence. Wouldn't you think that the solvation time determined at the farthest wavelength into the infrared is closest to the true solvation time? At shorter wavelengths the kinetics are complicated by the intermediate spectra formed during the process of solvation.

L. Gilles: I first should point out that the data reported in the table are from Chase and Hunt. From our results the wavelength dependence of the solvation time measurements could be partly due to experimental difficulties on determining a small change in the absorption level. I believe that I have shown that determination of the solvation times at the farthest wavelength into the infrared (where the fully solvated electron doesn't absorb) represents only a relaxation process towards the last partly solvated electron which absorbs at this wavelength. In that way I think that the results obtained by Chase and Hunt at 1050 nm are more representative of the solvation process than those at 1300 nm.

G. R. Freeman: The relaxation time observed at the long wavelength end of the spectrum might have a simpler interpretation than that observed at shorter wavelengths, because the former centers only decay, while the latter simultaneously grow and decay.

L. Gilles: Calculations are impossible in the region of wavelengths where the various transient spectra are overlapping. The results can be much more easily interpreted at longer wavelengths where there is only a decay of absorption.

Picosecond molecular relaxations: the role of the fluid in electron solvation

G. A. KENNEY-WALLACE

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 24, 1976

G. A. KENNEY-WALLACE. Can. J. Chem. **55**, 2009 (1977).

The role of the fluid is considered for a model of electron solvation in liquid alcohols. The events that lead to trapping and solvation of excess electrons are reconstructed from experimental data on the time and frequency-dependent electron absorptions (k_{mol}) and the appropriate molecular rotational relaxations (τ_2, τ_c), local liquid structure, viscosity (η), and orientational polarization (β) of the supporting fluid. The quasifree electron is captured at subpicosecond times in a preexisting trap in the liquid, which in alcohols is identified as an alcohol cluster whose local configurational fluctuations will be frozen in on this timescale. Rapid configurational relaxation of the cluster molecules, including multi-phonon processes, then occurs in the field of the excess electron at times $\leq 10^{-12}$ s. Finally, the molecules in the fluid layer adjacent to the initial trapping site align in the now screened field of the localized electron in a manner comparable to solvation of an ion embedded in a polar fluid. The relaxation may occur in competition with electron migration and reaction. The observed rate constant of the final step k_{mol} is shown to be proportional to $\beta\eta^{-1}$ for a range of alcohols at room temperature. The implications of this model for photobleaching experiments in liquids are briefly discussed.

G. A. KENNEY-WALLACE. Can. J. Chem. **55**, 2009 (1977).

On considère le rôle du fluide pour un modèle de la solvatation des électrons dans des alcools liquides. On reconstruit les évènements qui conduisent au piégeage et à la solvatation des électrons en excès à partir de données expérimentales sur l'absorption d'électrons (k_{mol}), qui dépend du temps et de la fréquence, et sur les relaxations rotationnelles moléculaires appropriées (τ_2, τ_c) ainsi que sur la structure locale du liquide, la viscosité (η) et la polarisation d'orientation (β) du fluide de support. L'électron pratiquement libre est capturé à des temps plus petits que la picoseconde dans un piège préexistant du liquide qui a été identifié, dans le cas des alcools, comme étant un agrégat d'alcool dont les fluctuations configurationnelles locales sont gelées sur cette échelle de temps. Il se produit alors une relaxation configurationnelle rapide des molécules agrégées, impliquant des processus multi-phonon, dans le champs de l'électron en excès à des temps $\leq 10^{-12}$ s. Finalement, les molécules dans la couche du fluide adjacente à celle du site du piégeage initial s'alignent dans le champs maintenant caché de l'électron localisé d'une façon comparable à la solvatation d'un ion imbriqué dans un fluide polaire. La relaxation peut se produire en compétition avec une migration d'électron et une réaction. On montre, pour plusieurs alcools à la température de la pièce, que la constante de vitesse observée pour l'étape finale, k_{mol}, est proportionnelle à $\beta\eta^{-1}$. On discute brièvement des implications de ce modèle pour des expériences de photodécoloration de liquides.

Prologue

Accompanying Platzman's famous statement (1) postulating the existence of the hydrated electron e_{aq}^- and its optical absorption in the red, were remarks by Onsager (1) on the formation time of such a species, which would have to be on the timescale of dielectric relaxation of water, $\sim 10^{-11}$ s (2). The subsequent experimental developments that led to the discovery and characterization of e_{aq}^-, and the properties of electrons solvated or trapped in other media, have been extensively reviewed (3, 4). However, the precise sequence of events that leads to the formation of excess electron states in fluids, and the quantum mechanical description of these states, have been and continue to be a source of lively discussion over the years (3–5).

The picosecond timescale and wavelength dependence of the electron hydration process, as revealed in the experiments of Hunt and coworkers (6, 7) and Rentzepis, Jones, and Jortner (8) were qualitatively consistent with the expectations of the role of dielectric relaxation in electron solvation. It was further suggested (8) that the initial electron localization step was governed by the long range, dipolar interactions in the liquid, following which vibrational relaxation of the newly formed solvent sheath could take place

to leave the excess electron in a fully relaxed, ground electronic state. A similar process had been envisaged for relaxation following electronic excitation of e_s^- (9). However, the recent picosecond data on electron solvation in alcohols of Kenney-Wallace and Jonah (10) and Chase and Hunt (11), clearly indicate that the dipolar relaxation in liquids occurs *after* the initial electron localization step, the time-dependence of which has so far eluded present experimental observations (10–12).

Baxendale and Wardman (13) first observed electron solvation in liquid alcohols in low temperature *n*-propanol, and discussed the role of molecular relaxation vis-à-vis electron migration to account for the observed spectral shifts. Pulse radiolysis of cool and glassy alcohols has shown that molecular reorientation is the most probable mechanism in these systems (9, 13–17). However, new results (16) on ethanol at 77 K show that a significant degree of electron migration is taking place at these low temperatures, and suggest that the mechanism for electron solvation at low temperatures is quite different from that which governs room temperature events.

In order to explain the apparent correlation of electron solvation times τ_s with τ_2, the dielectric relaxation time normally assigned to the relaxation (18) of a single molecule in a weak, external electric field, Kenney-Wallace and Jonah (10) proposed that the quasifree electron was initially localized in a cluster of hydrogen-bonded alcohol molecules, and that the observable step in the solvation process reflected the formation of a second or third solvation shell. In their study of the temperature dependence of electron solvation times in small alcohols, Chase and Hunt (11) also observed the same correlation between solvation times and the dielectric relaxation time for molecular rotation τ_2. They concluded that molecular reorientation rather than migration mechanisms, such as hopping or tunnelling between traps, was responsible for electron solvation. In subsequent developments Kenney-Wallace (19) showed a direct correlation between the fluid dynamics and electron solvation in the same media, by considering the reorganization of the medium about the cluster as a function of $\beta\eta^{-1}$, where β represented the electrostatic field in which the dipolar molecules were reoriented and η the opposing frictional force in the fluid.

In this paper we present further details on the role of the fluid in the dynamics of electron solvation and in the fast radiationless transitions that follow photoexcitation and photobleaching of e_s^- at visible wavelengths.

Experimental

The electron solvation times τ_s were derived from the observed time evolution of the stable absorption spectra of e_s^- from 450 to 765 nm, following pulse irradiation of the alcohol at 298 K with single 30 ps electron pulses from the Argonne LINAC (20). The stroboscopic pulse radiolysis facility, sampling techniques, and treatment of data have been described in detail elsewhere (10, 20). Alcohols and alkanes were obtained from Burdick and Jackson (Distilled-in-Glass) where available or the highest purity from Fisher Scientific. The ^{13}C nmr measurements of T_1 relaxations were performed on a Varian CFT-20 Fourier transform spectrometer; full details of these and the viscosity measurements will be published elsewhere (21). Laser photobleaching experiments (22) employed the output from a Q-switched 100 MW, 20 ns ruby laser for both exciting and saturating laser pulses. Solvated electrons were generated in the alcohol via the two-photon photoionization of pyrene at 347 nm with a 100 mJ frequency-doubled ruby laser pulse, and photobleached some 30 ns later.

Results and Discussion

Electron Absorption and Dielectric Data

The evolution of the visible spectrum of e_s^- in the normal alcohols appeared as an initial rapid growth followed by a slower absorption component, the duration of which increased as the size of the alcohol molecule increased. Figure 1 shows typical absorption data, in this case recorded in *n*-decanol. When analyzed (10) the slower component fitted a single exponential growth and the rate constant k_{mol} (s^{-1}) and solvation times τ_s (ps) are listed in Table 1. Comparison of these solvation times τ_s with τ_2, the relaxation time assigned to single molecule rotation in dielectric dispersion measurements (18), reveals the similarity in each fluid between the experimentally observable electron solvation time and what is, in essence, the relaxation of dipoles into a preferred alignment under the influence of a weak external field. This correlation (10, 11) invites further investigation from the perspective of the fluid dynamics. Of the many variables that may be involved in determining the response of the nearby molecules to the sudden perturbation presented by the localized electron, the local frictional forces, dipolar energy in the field of the excess electron, dipole density (which reflects the local liquid structure), and dielectric relaxation times would appear to be the major ones of in-

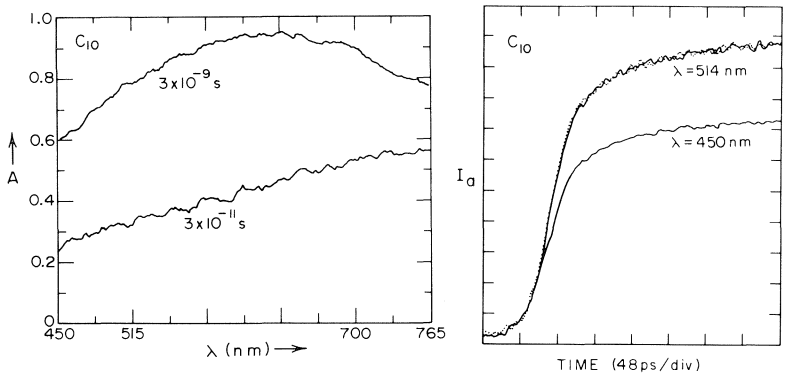

FIG. 1. The time-dependent absorption of e_s^- in *n*-decanol at 300 K: (*a*) showing the spectrum from 450 to 765 nm at 30 ps and 3 ns after the 30 ps electron pulse, where *A* is the relative absorbance; (*b*) showing the similarity in profile of the absorption signal I_a at two wavelengths by normalizing the data (10) at 450 nm to that at 514 nm.

TABLE 1. Electron solvation data

ROH	k_{mol} (10^{10} s^{-1})	τ_s (ps)	τ_2 (ps)
Methanol	9.34	10.7	12
Ethanol	5.55	18	20
Propanol	4.00	25	22
Butanol	3.33	30	27
Pentanol	2.94	34	28
Octanol	2.22	45	39
Decanol	1.96	51	48

terest. We will first consider the origin of the reaction field.

If we can envisage the initial localization step as capture of the quasifree electron by a preexisting trap due to fluctuations in the local molecular configurations in the liquid, then the subsequent step, which involves medium rearrangement about the trapped particle, can be thought of in terms of medium relaxation about an ion embedded in the fluid. The excess electronic charge will be distributed over the surface of the inner coordination shell and thus the field experienced by the dipolar molecules beyond this boundary will be much weaker than that felt by the molecules which comprise the initial trapping site. Of course the field experienced by the external dipoles will not remain constant during relaxation of the surrounding molecules. Calculations show that if the external field is kept constant, then the resulting dipole relaxation is slower than if the excess electronic charge distribution is conserved during medium relaxation (5, 23). The latter is thought to be a more appropriate basis for electron solvation and leads to the modification of the macroscopic dielectric relaxation times to $\tau' = \tau(D_{op}/D_s)$, where one is now considering a linear superposition of dielectric polarization from infinite past to the present time (23). When the τ_2' values are calculated this way there is only a 30% decrease on average from the macroscopically measured τ_2 values and thus the correlation between τ_s and τ_2 or τ_2' remains qualitatively the same (10). It is not unreasonable therefore to consider τ_s^{-1} or k_{mol} as the rate constant describing an orientational relaxation process which is the net effect of two counteracting torques: the electrostatic field and the opposing internal friction. An estimate of the distance at which the alcohol molecules no longer exhibit any preferred alignment with respect to this field shows that orientation of the dipoles is only significant up to 5 to 8 Å from the centre of the charged cluster. This is in accord with the spirit of the recent calculations of Kestner (24) whose long-range potential in fact only contributes to the stabilization energy of e_s^- at distances shorter than about 10 Å. We will approximate the field in which the external dipoles are relaxing by the orientational polarization of the alcohol molecules. Electronic polarization of these molecules has already been accomplished by the time angular rotation occurs. In Fig. 2 the rate constant k_{mol} is plotted against the reciprocal high frequency and static dielectric constants, which represent the electronic polarization α_e and the total polarization ($\alpha_e + \alpha_{or}$), respectively. By subtracting the two terms we obtain the orientational polarization α_{or}, and thus in the inset show the dependence of k_{mol} on β, where $\beta = 1/D_{op} - 1/D_s$, a familiar term for the long range potential in models of excess electron states (3–5).

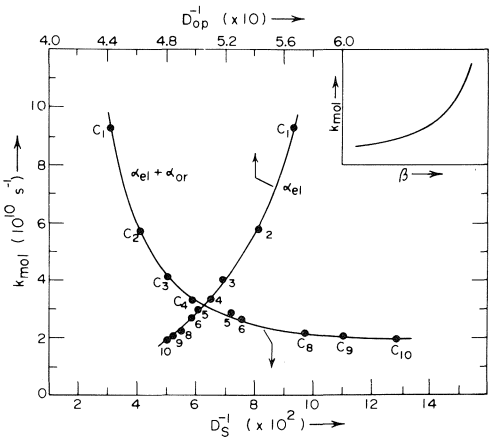

FIG. 2. The dependence of the solvation dynamics k_{mol} on the medium polarization for C_1 (methanol) to C_{10} (decanol) at 300 K (see text for discussion). Solvation data from ref. 10 except methanol (11).

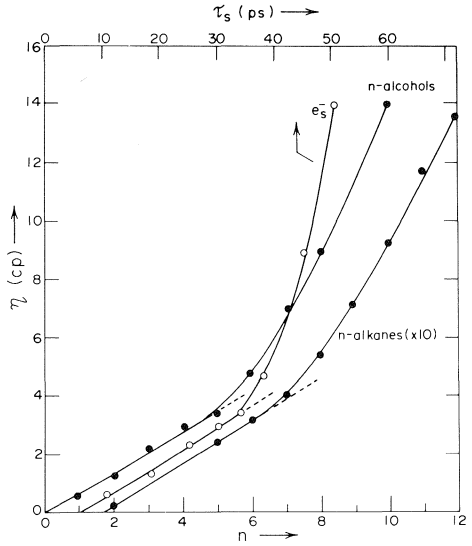

FIG. 3. ○ The dependence of the electron solvation time τ_s on η, the viscosity of the fluid; ● the viscosity as a function of carbon chain length, *n*, in *n*-alcohols and *n*-alkanes.

Viscosity Measurements

Opposing the electrostatic torque on the molecules is a frictional force which includes intermolecular forces, noticeably hydrogen-bonding in this case, and energy and momentum transfer during collisions of the rotating molecules. Clearly the motion of one molecule is coupled hydrodynamically to the motion of its neighbours in the fluid; the net angular velocity of a rotating, spherical molecule is described in the Debye–Stokes–Einstein model (2, 25) as

$$\tau_{or} = \eta V_m (kT)^{-1}$$

The orientational relaxation time τ_{or} is thus linearly proportional to the shear viscosity η, and to the hydrodynamic volume V_m swept out by the rotating molecules. To what extent do the solvation times τ_s reflect the local fluid dynamics? In Fig. 3 τ_s is plotted as a function of the fluid viscosities at 20°C for methanol to decanol. The τ_2 values exhibit the same profile, a linear dependence on viscosity up to hexanol and a sudden change in slope indicative of an additional component to the fluid viscosity. Since the alkyl end of these longer chain molecules is not a rigid extended chain but one capable of folding back over itself, it is tempting to assign the additional contribution to the viscosity to entanglement of neighbouring alkyl chains in the fluid. A plot of alcohol viscosity against chain length in Fig. 3 shows a break in the slope, again at hexanol. If the entanglement of the alkyl chains is largely responsible for this break and not the —OH bonded end of the molecule, then the viscosity of the parent alkanes should display a similar trend. The results are included on Fig. 3, and the break in slope again occurs between hexane and heptane. Subsequent ^{13}C nmr measurements of the T_1 spin–lattice relaxation times of the individual segments of the alkyl chains, in pure and alkane-diluted alcohols, confirmed the notion of chain entanglement and the inferred relationship between the autocorrelation times τ_c of each carbon moiety and the viscosity of the fluid. The full details of this work will be published elsewhere (21). All these results taken together not only add confidence to our claim that the τ_s values accurately reflect the trends in the local fluid properties, but also show that the dynamics of e_s^- may indeed be utilized in the future as a microscopic probe for local fluidity and liquid structure.

Finally, we must consider the validity of applying the Debye–Stokes–Einstein hydrodynamic model in these circumstances where the rotating molecules are probably far from spherical. In a series of picosecond laser experiments on induced dichroism, Einsenthal and Chwang (26) were able to show that the orientational relaxation time of rhodamine 6G, in the series of normal alcohols methanol to decanol, ranged from 2×10^{-10} s $< \tau_{or} <$ 2.2×10^{-9} s and scaled linearly with viscosity up to octanol. The relaxation times were apparently not influenced

by the significant changes in the hydrodynamic volume in the alcohols. The overall conclusion to be drawn from these data is that, during rotational relaxation, the solute molecule experiences a torque primarily arising from solvent–solvent interactions. Rentzepis, Struve, and Jortner (27), in their laser picosecond laser studies of solvent reorganization about a 'giant-dipole' molecule suddenly ($\leq 10^{-15}$ s) created in ethanol, also concluded that the observed orientational relaxation time reflected only the viscous rotational drag between adjacent alcohol molecules. Consequently their data could be described within the hydrodynamic model. Theoretical justification comes from recent microscopic calculations based on the generalized Langevin equation, in which orientation and angular-velocity correlation functions were calculated for a fluctuating molecular fluid (28). Expressions have been derived for rotational diffusion in which the inverse linear dependence on viscosity is retained although the formal expression is more complex than the Debye equation. Therefore we may conclude that bulk viscosity measurements do offer meaningful physical insight on the microscopic fluid interactions, and that the hydrodynamic model presents a valid framework within which to interpret these field-induced orientational relaxation times in polar fluids.

The Solvation Mechanism

The initial observation that τ_s and τ_2 were very similar raised the problem (10) of why the dipoles in the presence of a strong, inhomogeneous internal field should behave as though they were reorienting under the influence of a weak, homogeneous external field. In accepting that the correlation was not entirely coincidental, Kenney-Wallace and Jonah (10) proposed that the field of the excess electron, once trapped by a cluster, was screened by the layer of cluster molecules and that the induced-rotation of the dipoles outside of the cluster could be approximated by weak field conditions. If we assume that the rate of configurational relaxation of the molecules outside the initial trapping site is controlled by an accelerating electrostatic torque and the retarding viscous torque, and neglect affects due to variations in hydrodynamic volume (since they seem to be rather small for the alcohols in question), then we can plot k_{mol} *vs.* $\beta\eta^{-1}$ as shown in Fig. 4. The linearity of the relationship is convincing evidence that we have pinpointed the

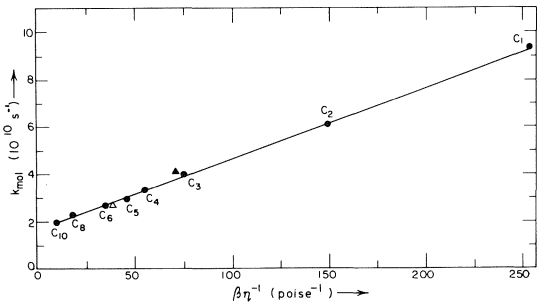

FIG. 4. The solvation dynamics k_{mol} as a function of both medium polarization β and fluidity η^{-1} for the *n*-alcohols ●, 2-propanol ▲, and 2-butanol △. Solvation data from ref. 10 except methanol (11), and normalized β values from ref. 40.

essential features of the hydrodynamic response of the fluid to the sudden perturbation in the local dipolar field and liquid structure provided by the excess electron in its initial localized state.

Although there are possibly other considerations which should be included, the most important part of this model of electron solvation which requires a quantitative time-dependence treatment is the internal field. In choosing β we have compromised between the initial and final polarizations. We are presently carrying out further experimental and theoretical work on this aspect, and on the temperature dependence of the observed solvation times for the $\beta\eta^{-1}$ correlation. Similarities in the τ_s values for small alcohols at varying temperatures but the same viscosity have been recently observed (29).

Contemporary models of electron solvation in polar liquids (30–32) have already considered the rotation of dipoles about an excess electron from different perspectives. Fueki, Feng, and Kevan (32, 33) have recently extended their semicontinuum model for solvated electrons into the time domain, and their new calculations on electron solvation explicitly incorporate dielectric relaxation of the medium beyond the first solvation layer. Their theoretical and ENDOR results imply that this relaxation must occur after the initial molecular trapping site has assumed an optimum configuration. In originally noting the $\beta\eta^{-1}$ relationship (19) we presented arguments which were used to evaluate the role of the long- and short-range interactions in determining the energetics of the solvated electron in polar fluids, and reached the same conclusion on the basis that rotational reorientation of the cluster dipoles must be accelerated in the strong

internal field of the electron due to the short-range, electron–medium interactions. Furthermore, these events probably occur on a subpicosecond timescale in liquids and may remain elusive to experimental observation. For the correlation of τ_s and τ_2 to be physically meaningful, a second relaxation process must be occurring.

Implications for Photobleaching Experiments

The nature of the electronic transition or transitions giving rise to the characteristically broad optical absorption spectrum of e_s^- remains a fruitful topic of experimental and theoretical debate (3–5). Measurements of the excited state lifetime of excess electrons in polar liquids via laser saturation (photobleaching) techniques have placed upper limits on these lifetimes ranging from 6 ps in water (34), 10 ps in several alcohols (22), 5 ps (35) and 0.2 ps (36) in ammonia to 0.2 ps in methylamine at 200 K (36). The interpretation of these values depends on both the saturating and observing wavelengths, and the degree of inhomogeneous broadening in the absorption band. A recent account of time-resolved photobleaching phenomena in solvated and trapped electrons by Walker and May (4, 37) contains a full discussion of this problem, with particular emphasis on the correct absorption coefficients ε. The latter have been recently determined (22) for our series of linear alcohols and within experimental error appear to be constant at $\varepsilon_{max} \sim 10^4\ M^{-1}\ cm^{-1}$.

Whether or not the excited state is a bound or continuum state, can in fact be examined in the context of the dynamics of electron solvation (9, 22, 34) as illustrated in Fig. 5. If, following injection of an electron into a polar fluid, the sequence of events leading to solvation can be described by an overall rate constant k_s, then the following comparison

$$e^-_{quasifree} \xrightarrow{k_s} e_s^-$$

can be made to photobleaching experiments in which the electron

$$e_s^- \xrightarrow{h\nu} e^{-*} \xrightarrow{k} e_s^-$$

is photoejected from its trap and subsequently undergoes the solvation process if chemical reaction does not occur (38).

The principle of the pulsed laser saturation technique (22, 34, 37) is to temporarily deplete the population of ground state absorbers and then to measure both the induced transparency of the system and the rate k at which the ground state acquires its normal population once more. The experimental variables are the photophysical parameters of the absorber and the amplitude and temporal profile of the transmitted laser pulse at varying incident proton fluxes, I. In a two level system, for excited state lifetimes much shorter than the laser pulse duration, it was shown that (34)

$$k = 2\varepsilon I(1 - 10^{-A})(A^0 - A)^{-1}$$

where A^0 is the linear absorption under low photon flux (Beer's law) and A is the high flux value. If following excitation and saturation of e_s^- with a photon of energy $h\nu_2$ the measured rate $k = k_2$ corresponded to the value of k_s at the same wavelength, then this would indeed be strong evidence for a continuum excited state. This is shown in Fig. 5. Excitation at lower incident photon energies ($h\nu_1$) to a bound state would lead to a rate constant k_1 where $k_1 \neq k_s$. However, if our model of electron solvation is essentially correct then it may be impossible to do such an unambiguous experiment because the initial localization step occurs on a timescale $\ll 10^{-12}$ s and is beyond direct experimental observation. Recent mobility data (39) show electrons are readily captured in alcohols by even dimers. The observed value of $k = k^*$ from photobleaching experiments will thus clearly depend on the time-window of the experiment, and the difference in absorbance will be given by the difference in the absorption coefficients of the electronically bound species in two localized states. Figure 1 suggests that this difference may not be very large, placing limitations on the sensitivity of the saturation technique. Nevertheless, one would still hope to see in k^* some contributions from orientational relaxation as indeed occur in k_s, whereas rapid vibronic relaxation k_1 from a bound photoexcited state, reached via $h\nu_1$, will not include such terms.

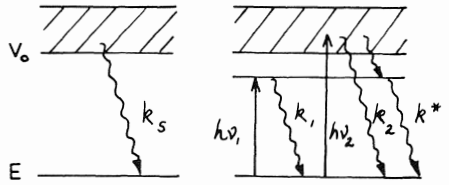

FIG. 5. Interpretations of optical photobleaching experiments (see text for discussion).

Discussion

K. Funabashi: Photo-bleaching of solvated electrons in ethanol is known to generate H from dissociation of the OH bond. If the major portion of energy relaxation arises from dipole rotation of the surrounding medium, photo-bleaching is not likely to generate H atoms. I feel that some *intra*molecular relaxation associated with the OH bond is more important in describing the solvation process than the dipole rotation mechanism.

G. A. Kenney-Wallace: The photo-bleaching effects in ethanol to which you refer have not been detected in laser saturation experiments from other groups. However, we are continuing to explore photo-bleaching in all the alcohols with picosecond laser pulses. Intramolecular relaxation of the molecules in the first solvation layer clearly occurs in times faster than we can resolve. This

was included when I stated that —OH dipole and configurational relaxation of the cluster itself occurred at times $< 10^{-12}$ s after electron localization.[1]

J. W. Chase: Your plot of k_{so1} *vs.* $\beta\eta^{-1}$ is very convincing, but have you tried this plot at different temperatures to see if this correlation still holds?

G. A. Kenney:Wallace: In order to do that we need good information on the behaviour of both β and η over a large temperature range. We have been investigating the change in fluidity of the alcohols via viscosity, and ^{13}C Fourier transform nmr measurements, at different temperatures. We are learning more about the relative degree of 'rigidity' of the carbon segments of the alkyl chain, and the origin of the initial dramatic viscosity change on dilution of alcohol in alkane. Ultimately we expect to characterize the degree of association via hydrogen bonding in the pure liquid and alcohol–alkane solutions. Once this work is completed I will be able to answer your question exactly. Over a small temperature range the correlation appears to hold.

J. Jortner: I would like to raise again the problem of the dynamics of electron localization in pure polar fluids. A few years ago Rentzepis and colleagues in their experiments on picosecond spectroscopy on electron localization in water proposed that the process occurs via the following consecutive steps: (*1*) relaxation of the long range dipolar field, (*2*) configurational changes in the vicinity of the trapping centre, reminiscent of molecular vibrational relaxation. Professor Onsager has pointed out that step (*1*) is determined by the longitudinal dielectric relaxation time which is shorter by 1 to 2 orders of magnitude (by the factor D_{op}/D_s) than the Debye relaxation time. This is an ultrashort timescale, which is on the verge of detection in some systems by the methods of picosecond spectroscopy. Recently an alternative physical picture was advanced replacing step (*1*) by trapping of the quasifree electron by 'pre-existing traps'. Evidence for such mechanism is available from Baxendale's experiments on alcohols–hydrocarbons mixture and from Gaathon's results on electron localization in supercritical polar vapors, but this evidence does not pertain directly to the pure polar solvents. I believe that crucial experiments regarding step (*1*) in the dynamics of electron localization were not yet performed.

G. A. Kenney-Wallace: I do not believe that there is any difficulty here with the points you raise, nor do they affect the correlation I reported. If you consider the case where the quasifree electron is initially localised in a pre-existing trap, such as would be created by favourable fluctuations in the local molecular configuration and, in the specific cases of the alcohols, is probably a hydrogen bonded cluster, then the rapid configurational changes in the cluster (your step *2*) must take place on a subpicosecond timescale in the strong Coulomb field. The subsequent dynamics (represented by my τ_s) appear to be governed by dipolar relaxation and the local fluidity. Certainly if τ_1 were the (Debye) relaxation time involved, the correct longitudinal dielectric relaxation time would be very much shorter, as you say. However, I am referring to τ_2 and the D_{op}/D_s modified value here is $\geq 70\%$ of the Debye time. Given the experimental uncertainties in the values of the dielectric constants, the difference between the τ_s and longitudinal dielectric relaxation time τ_2' becomes even less significant. We had already discussed this point (see Fig. 3 and text, Chem. Phys. Lett. **39**, 596 (1976)) and therefore the timescale over which the correlation is observed is the anticipated one. The order of our experimental events therefore shows that dipolar relaxation occurs as a second step, not as the initial one.

[1]NOTE ADDED IN PROOF: Recent laser saturation and photo-bleaching experiments in our laboratory clearly indicate that permanent and(or) transient photo-bleaching occurs in several alcohols at room temperature.

Correlation of optical and electron spin resonance spectra for metal–electron species in alkali metal solutions[1]

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, AND RON CATTERALL[2]

Received September 27, 1976

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, and RON CATTERALL. Can. J. Chem. **55**, 2017 (1977).

Pulse radiolysis of alkali metal cations (M^+) in amines and tetrahydrofuran has demonstrated the formation of transient optical absorption bands attributed to a species of stoichiometry M. Such bands exhibit a distinct blue shift from that of e_s^- observed in the same solvent. Comparisons with electron spin resonance (esr) spectra obtained in alkali metal solutions demonstrate that the blue shift can be correlated with the percent atomic character deduced for the species of the same stoichiometry. This correlation indicates that both the optical and esr spectra arise from the same species which, with decreasing solvent polarity, exhibits a continuous transition from well solvated ion-pairs to something approaching solvated atoms or tight ion-pairs.

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER et RON CATTERALL. Can. J. Chem. **55**, 2017 (1977).

La radiolyse pulsée de cations métalliques alcalins (M^+) dans des amines et le tétrahydrofuranne a permis de démontrer la formation de bandes transitoires d'absorption optique attribuées à des espèces de stoechiométrie M. De telles bandes présentent un déplacement distinct vers le bleu par rapport à celle observée pour e_s^- dans les mêmes solvants. Une comparaison des spectres de résonance paramagnétique électronique obtenus dans des solutions de métaux alcalins démontre que le déplacement vers le bleu peut être relié avec le pourcentage de caractère atomique déduit pour les espèces de même stoechiométrie. Cette corrélation indique que les spectres optiques ainsi que les spectres rpe proviennent des mêmes espèces qui, lorsque l'on permet à la polarité du solvant de décroître, présentent une transition continue allant des paires d'ions bien solvatés vers quelque chose approchant des atomes solvatés ou des paires intimes d'ions.

[Traduit par le journal]

Extensive investigations (refs. 1–5 and references therein) of the optical, magnetic, and conductance properties of solutions of alkali metals in amines and ethers have revealed the presence of at least three species. There is now general agreement that two of these are best described as alkali metal anions M^- and solvated electrons e_s^-. The existence of a third species of stoichiometry M, composed of an alkali metal cation and e_s^-, has been demonstrated by both optical (6–12) and electron spin resonance (esr) spectroscopy (13–16). All three are considered to be solvated to some extent and in equilibrium according to a scheme of the form

$$[1] \qquad e_s^- + M^+ \rightleftharpoons M$$

$$[2] \qquad M + M \rightleftharpoons M^- + M^+$$

However, there is considerable discussion in the literature regarding the nature of M, and indeed, it is uncertain whether there are one, two, or more different species of this composition (3, 16–20).

In order to explain, firstly, the marked temperature dependence of the hyperfine splitting constant of the multiplet esr spectrum and, secondly, the dependence of esr line widths upon nuclear configuration, it has been proposed that the observed esr spectra are in fact a time average of spectra from two or more rapidly interconverting 'monomeric' species of stoichiometry M such as tight or loose ion pairs (21), or solvated atoms (16–20). Alternatively, Tuttle (22) has suggested that the ion-pair species does not contribute to the resolved hyperfine structure but has a single line esr spectrum identical with that of e_s^- whilst only

[1]AECL No. 5662.

[2]Visiting scientist, Chalk River Nuclear Laboratories, June–September 1976. Present address: Department of Chemistry, University of Salford, Salford, England M5 4WT.

a single 'monomer' species is responsible for the hyperfine multiplet. For clarity in presentation, we subsequently designate the species responsible for the hyperfine splitting as M_{esr}.

Steady state optical spectra in such alkali metal solutions are, in general, composed of two bands attributed to metal-dependent and metal-independent species. The former or 'visible' band occurs in the region 10 000–15 000 cm^{-1} and has been attributed to the diamagnetic species M^- whereas the latter band, which extends further into the infrared ($<7000\ cm^{-1}$), has generally been identified with e_s^-.

More recently, flash photolysis (6–9) and pulse radiolysis (5, 10–12, 23, 24) techniques have been used to investigate the approach to equilibrium and have demonstrated the existence of three distinct optical bands assigned to e_s^-, M^-, and M with the latter also referred to as an ion-pair (M^+, e_s^-). It is important to recognise, however, that the notation (M^+, e_s^-) is only a convenient symbol for the transient and that no definite evidence for this structure has been obtained (9).

For solvents such as ethylamine (EA) (10), isopropylamine (IPA) (24), and tetrahydrofuran (THF) (11, 12), it is evident that the M_{opt} absorption maxima occur at wavelengths intermediate to those of e_s^- and M^-. In this context it should be recognised that at equilibrium the monomer M_{esr} is a minor, but easily detectable constituent (3) whereas in the pulse or flash techniques M_{opt} is generated on the microsecond time scale and subsequently decays to the equilibrium condition.

Hitherto, because of spectral overlap and incorrect optical assignments, early attempts to correlate optical and esr spectra have not been successful (1, 16, 25). More recently, we have reported a linear correlation between the hyperfine splitting constant (hfs) observed in potassium/EA/THF solutions and the optical band maxima ($\nu_{max}\ cm^{-1}$) for Na_{opt} in similar solvent mixtures (26). Recognising the presence of different cations we nevertheless interpreted these results as evidence that the optical and esr hyperfine spectra arose from the same type species.

If we now compare the hfs in K solutions with values for the free atom then the atomic character decreases significantly from THF (36%) to EA (~12%) (27). This is accompanied by a distinct blue shift in $\nu_{max}(K_{opt})$ from that of $\nu_{max}(e_s^-)$, the magnitude of which decreases substantially for the corresponding change in solvent (10, 12). On the other hand, in methylamine (MA) (28), ethylenediamine (EDA) (28–31), or liquid ammonia (32–34) (see later) little or no change in optical spectrum from that of e_s^- is observed on M_{opt} formation. In these cases the percent atomic character observed by esr in alkali metal solutions is small and much less than observed in EA or THF (3, 13, 18, 27).

In view of this trend we have examined all the available data relative to M_{opt} and M_{esr}. These are shown in Table 1 listing ν_{max} for M_{opt}, e_s^-, M^-, and the gaseous atoms M_g (35), along with the percent atomic character for M_{esr} for different metal–solvent combinations. Because of strong solvent absorptions room temperature values for $\nu_{max}(e_s^-)$ in MA, EA, and IPA were obtained by pulse radiolysis via the temperature coefficient $-d\nu_{max}(e_s^-)/dT = 24.0$, 23.6, and 27.8 $cm^{-1}\ deg^{-1}$, respectively, determined at temperatures ranging from 193 to 253 K. These data are plotted in Fig. 1 expressing $\nu_{max}(M_{opt})$ as a percentage blue shift from that of $\nu_{max}(e_s^-)$ in the same solvent. The relative blue shift is defined by

$$[3]\quad (\nu_{max}(M_{opt}) - \nu_{max}(e_s^-))/(\nu_{max}(M^-) - \nu_{max}(e_s^-))$$

Since with respect to the free atom value, the shift in *g*-factor for M_{esr} is negative as the atomic character increases (27, 36, 37) we have not identified the optical transition energy for the 100% limit with that of the gaseous atoms ($\nu_{max}(M_g)$). Instead, in an attempt to allow for atom–solvent interactions we assume that the term $\nu_{max}(M^-)$ in the denominator gives an approximate representation of 100% atomic character.

It can be seen that a good correlation is obtained for all solvent and metal combinations indicating that the designation M_{opt} and M_{esr} refer to the same species. No attempt has been made to correct for the slight overestimation of atomic character for M_{esr}, especially when the hfs is small (18). However, the effect is systematic and any correction simply defines a slightly different line of correlation. Similarly, use of $\nu_{max}(M_g)$ in place of $\nu_{max}(M^-)$ in [3] does not invalidate the correlation but again would

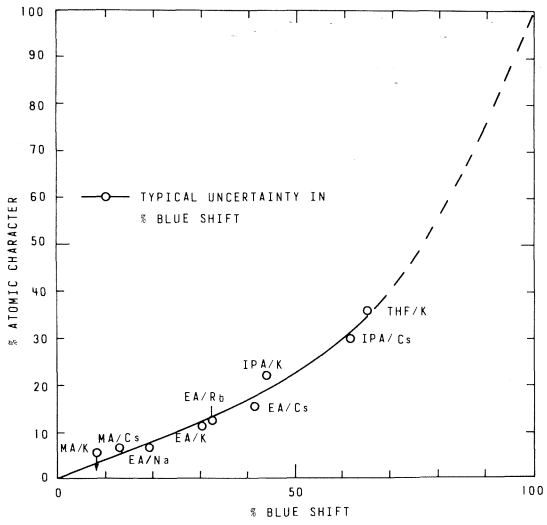

FIG. 1. Correlation of percent atomic character and percent blue shift (see text) for alkali metal solutions in amines and THF. Random errors in atomic character are expected to be small and ≤1–2%.

simply shift the curve. In no case do we attach any theoretical significance to a particular line.

Within experimental error an identical trend is observed for mixed solvents in K/NH_3/EA solutions with atomic character 3.3–11.3% (38) and blue shifts 12.6–30.5% from 20 mol% NH_3 to pure EA. For clarity these data are not shown in Fig. 1 but are listed in Table 1.

As outlined above the precise structure of the species responsible for the optical and esr spectra has been the source of much controversy and confusion in the literature (13–20, 21, 22). Thus, whilst species showing a small blue shift and low atomic character might be best described as loose ion-pairs, species such as those in K/THF having a large blue shift and high atomic character are probably better described as solvated atoms or tight ion-pairs. A significant point of Fig. 1 is the demonstration of a continuous transition between such ion-pairs and solvated atoms with decreasing polarity of

the solvent. We therefore conclude, that in agreement with Tuttle (22), a simple model involving a rapid equilibrium between a few relatively precise structures such as ion-pairs and solvated atoms (16–20, 36), is not sufficient to describe the range of species of stoichiometry M detected in these solutions. Instead we suggest that the correlation depicted in Fig. 1 illustrates a continuous desolvation process ranging from what might be regarded as well solvated dipolar ion-pairs to something approaching weakly solvated centrosymmetric alkali atoms or tight ion-pairs.

In support of this interpretation we have found that the optical band widths of the Na_{opt} species in EA–THF mixtures (26) are no broader than those in either pure solvent, whereas linear combinations of the corresponding bands from the pure solvent would show considerably greater widths.

As a final comment it is significant that in liquid ammonia the optical band attributed to the electron species shows a slight shift to the red, and not the blue, with increasing metal concentration from 10^{-3} to 10^{-2} M (40). No change in the band maximum is observed below $\sim 10^{-3}$ M and yet it is estimated from Knight shifts that $k(e_s^- + M^+) \sim 10^{12}\ M^{-1}\ s^{-1}$ (41). This is consistent with the suggestion that the spectra of e_s^- and (M^+, e_s^-) are indistinguishable and that the slight decrease in energy observed at higher concentrations represents the formation of an additional spin-paired species such as M_2 (40), rather than M^- (42). Evidence that the overall absorption band is composed of two components at equilibrium has been discussed elsewhere (34, 43, 44).

The spectrum of pulse-irradiated liquid 3-methyloctane at 127 K has maxima around 625 and 2100 nm. The latter is well-known as being due to the solvated electron (e_s^-). The former is attributed to a positive ion because it is eliminated by the addition of triethylamine, but remains in solutions of electron scavengers, and is very similar to bands observed earlier by Louwrier and Hamill in glassy solutions at 77 K of higher hydrocarbons in CCl_4 or CO_2-bubbled 3-methylpentane. At temperatures of 127 K and less the initial decay rate of e_s^- is greatly decreased by the addition of ~6 mol% triethylamine. The result is interpreted as indicating that at low temperatures the mobility of the initial hydrocarbon positive ion is much greater than that of either e_s^- or the positive ion in triethylamine solutions, and therefore the initial hydrocarbon positive ion must be the parent radical cation which moves by resonance charge transfer. As the temperature of pure 3-methyloctane is raised from 103 to 153 K, the initial $G\varepsilon_{650}$ decreases by about 30% while initial $G\varepsilon_{2100}$ almost doubles; because of these and other observations it is tentatively suggested that a second solvated electron is also produced.

HUGH A. GILLIS, NORMAN V. KLASSEN et ROBERT J. WOODS. Can. J. Chem. **55**, 2022 (1977).

Le spectre du méthyl-3 octane liquide irradié par pulsation à 127 K a deux maxima autour de 625 et 2100 nm. On sait que le dernier maximum est dû aux électrons solvatés (e_s^-). Le premier est attribué à un ion positif parce qu'il est éliminé par l'addition de triéthylamine mais demeure dans des solutions de piégeurs d'électron et est trés semblable à des bandes qui ont été observées antérieurement par Louwrier et Hamill dans des solutions d'hydrocarbures de poids moléculaires plus élevés dissous dans des verres de CCl_4 à 77 K ou de méthyl-3 pentane dans lequel on a fait barbotter du CO_2. A des températures de 127 K ou moins, le taux de décomposition initial de e_s^- diminue rapidement par addition ~6 mol% de triéthylamine. On interprète des résultats comme indiquant qu'à basse température la mobilité de l'ion positif de l'hydrocarbure initial est beaucoup plus grande que celle de soit e_s^- ou l'ion positif dans des solutions de triéthylamine et qu'ainsi l'ion positif de l'hydrocarbure initial doit être le cation radical parent qui se déplace par transfert de charge en résonance. A mesure que l'on augmente la température du méthyl-3 octane de 103 à 153 K, le $G\varepsilon_{650}$ initial diminue par environ 30% alors que le $G\varepsilon_{2100}$ initial double pratiquement; à cause de ces observations et d'autres, on suggère d'une façon non définitive qu'il y a aussi production d'une seconde espèce d'électron solvaté.

Introduction

Electrons solvated or trapped in hydrocarbons have strong absorption bands with maxima in the near infrared and they have been the subject of many optical investigations in both glasses and liquids (1–3). In hydrocarbons, especially at low temperatures, an electron is usually thermalized at a distance from a positive ion in the same spur such that the coulombic energy between the pair is greater than the kinetic energy. The ion-pair is described as geminate and will undergo geminate recombination unless one or both members of the pair is scavenged by solute. Geminate recombination was demonstrated in liquid propane at 88 K (2) and in liquid 3-methylhexane at 126 K (3) by the observation that half-lives for electron decay are independent of initial concentration.

Studies of the positively charged species participating in the recombination reaction in hydrocarbons in the condensed phase have been relatively few. Louwrier and Hamill (4) found strong absorption in γ-irradiated glassy solutions of alkanes (RH) of seven or more carbon atoms in either CCl_4 or CO_2-saturated 3-methylpentane at 77 K. The bands had λ_{max} increasing with

carbon number from 560 nm for C_7H_{16} to ~910 nm at $C_{15}H_{32}$ and higher, and were attributed to the parent radical ions, RH^+. The yield of this species was found to be a maximum around 0.5 mol% of the higher hydrocarbon in CO_2-saturated 3-methylpentane; smaller yields at higher concentrations were attributed to recombination of an appreciable fraction of all charge pairs by hole transfer of RH^+ along chains of RH. No RH^+ bands were observed in the pure hydrocarbons, presumably because recombination by hole transfer was fast enough to proceed to completion before the first observation period of some minutes after the irradiation.

Rate constants for charge transfer from solvent positive ions to solute can be calculated from the rate of formation of solute positive ions in pulse radiolysis studies. For some liquid hydrocarbons at room temperature these rate constants are more than an order of magnitude larger than expected for a diffusion controlled reaction of a molecular ion (5–8). More direct evidence for the formation of a very mobile positive ion was obtained in a recent study of pulse-irradiated liquid cyclohexane at room temperature in which electrical conductivity was studied by means of microwave absorption (9). The conductivity remaining after addition of SF_6 to convert electrons to SF_6^- or its decomposition products was more than an order of magnitude larger than expected for ions of normal mobility, and since it was greatly decreased by addition of the positive ion scavenger NH_3, was attributed mainly to the very mobile positive hole.

A functional description of the life-times of geminate electrons produced in the radiolysis of pure hydrocarbons has been derived by Rzad *et al.* (10) from the concentration dependence observed for electron scavenging. This description is

$$[1] \qquad G(t) = G_{gi} \exp(\lambda t) \operatorname{erfc}(\lambda t)^{1/2}$$

where $G(t)$ is the yield of electrons still present at time t, G_{gi} is the total yield of electrons, λ is a parameter with dimensions of frequency, and $\operatorname{erfc}(\lambda t)^{1/2}$ is the error function complement of $(\lambda t)^{1/2}$. Expression [1] was derived from experiments at room temperature, but it is not obvious that it should not also describe electron decay at low temperatures. However, in fact it is not a very good description of electron decay in 3-methylhexane at low temperatures (3).

In the present study of geminate neutralization reactions 3-methyloctane (3-MO) was chosen as the hydrocarbon medium because it was expected that reactions and yields of the positive ions as well as those of the electrons could be measured, and these should provide further information concerning the nature of these reactions. The temperature range of this work is 103–153 K. The viscosity of 3-MO has been measured between 107 and 114 K, and obeys a linear plot of log viscosity *vs.* T^{-1} over this range (11). The viscosities of other hydrocarbons give a linear plot between about 10^4 P and at least 10^{12} P (12). An extrapolation of the data for 3-MO gives a viscosity of 10^{12} P at 103 K, and indicates a viscosity of 10^4 P at 124 K. Since 153 K is in the region where linearity is no longer expected, we can say only that at this temperature the viscosity of 3-MO must be much less than 10^4 P.

Experimental

3-Methyloctane from Chemical Samples Co. was passed through a column of silica gel and Davison molecular sieve Type 4A which had been heated at 360°C for 12 h or more. The 3-MO was then degassed and stored over NaK. Triethylamine (TEA) from Matheson Coleman and Bell, CCl_4 (Fisher Spectranalysed), N_2O (Union Carbide), and SF_6 (Matheson) were used as received.

Samples were irradiated in high-purity quartz cells of 0.5 cm optical path with 35 MeV electrons from the National Research Council of Canada linac. Pulses were usually 40 ns long, and the dose per pulse was generally in the range 3–7 krad. Each sample was pulsed many times; effects due to repeated pulsing were looked for and not found. The cells were supported in a Dewar equipped with optical windows. Cold nitrogen gas was flowed through it at a rate required to give the desired temperature as measured by a thermocouple attached to the cell.

The dose per pulse was measured with a secondary emission monitor which was calibrated for each experiment by using an O_2-saturated 5 m*M* KSCN aqueous solution as a dosimeter. In correcting for differences in electron density between the 3-MO samples and the dosimeter solution, the density of 3-MO was taken to be 0.95 g ml^{-1} at all temperatures; 0.95 g ml^{-1} is the density calculated at 77 K by assuming that 3-MO shows the same percentage increase in density on cooling as 3-methylpentane does (13). Absorbance per unit energy absorbed is expressed as $G\varepsilon$ where G is the number of molecules of a particular species produced per 100 eV and ε is the decadic molar extinction coefficient in units of M^{-1} cm^{-1}.

In most experiments the intensity of the analyzing light, which was provided by a pulsed xenon lamp, was monitored simultaneously at two wavelengths. In determination of spectra one of these was fixed as the reference, usually at 650 nm, while the other was varied. The light detectors used were: for $410 \leq \lambda \leq 1000$ nm, an EG&G SHS-100 silicon photodiode; and for $\lambda > 900$ nm, a

Barnes A-100 room temperature InAs photodiode. The performance of these detectors has been described (14). The 0–98% response time of the oscilloscope–detector system was <40 ns with the silicon photodiode and <90 ns with the InAs photodiode for the conditions used in this work.

Results

Spectra of Solvated Electron and Positive Ion

The spectra of irradiated 3-MO at 127 K at different times after the start of a 40 ns pulse are shown in Fig. 1. The maximum around 2100 nm is attributed to the solvated electron (e_s^-) by comparison with our previous work (2, 15) and the maximum around 625 nm is attributed to RH^+ by comparison with the spectra of Louwrier and Hamill (4). A comparison of the three spectra of Fig. 1 indicates that at 127 K RH^+ decays somewhat faster than does e_s^-.

The spectra of an irradiated 5.7 mol% solution of TEA in 3-MO at 127 K at two times after a pulse are shown in Fig. 2. TEA is expected to scavenge RH^+ by accepting either the charge or a proton (16):

[2] $$RH^+ + (C_2H_5)_3N \rightarrow RH + (C_2H_5)_3N^+$$

[3] $$\rightarrow R + (C_2H_5)_3NH^+$$

As seen in Fig. 2 the ratio of absorption at 625 nm to that at 2100 nm is much smaller in the solution than in pure 3-MO at 100 ns, and this ratio becomes even smaller for the solution at 7 μs.

Spectra observed in solutions of known electron scavengers in 3-MO are shown in Fig. 3. Difficulties were encountered in dissolving enough scavenger in the cold 3-MO to completely remove e_s^-. Spectrum *A*, for a solution of SF_6 in 3-MO, shows a peak due to RH^+ around 625 nm and some residual absorption at longer wavelengths probably due to e_s^-. At 500 ns absorptions in this system at 2100 and 625 nm were 28% and 60%, respectively, of the corresponding absorptions at 100 ns, which is in accord with the assignment of absorption at 2100 nm to e_s^- which reacts rapidly with SF_6. Spectrum *B*, for a solution of N_2O in 3-MO,

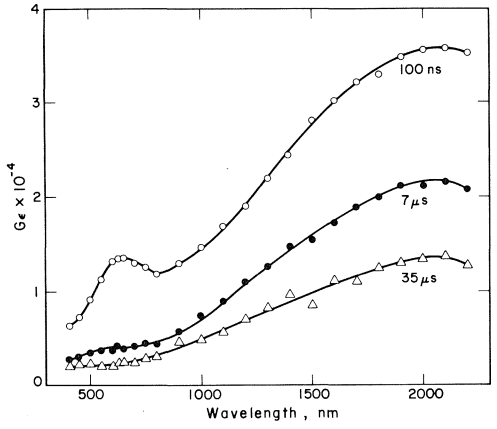

FIG. 1. Spectra observed at three times after the start of a 40 ns pulse in pure 3-methyloctane at 127 K.

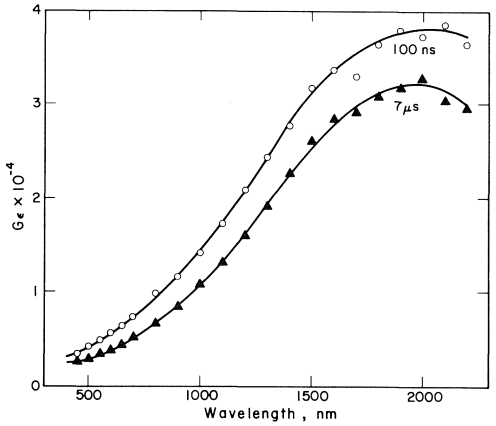

FIG. 2. Spectra observed at two times after the start of a 40 ns pulse in 3-methyloctane containing 5.7 mol% triethylamine at 127 K.

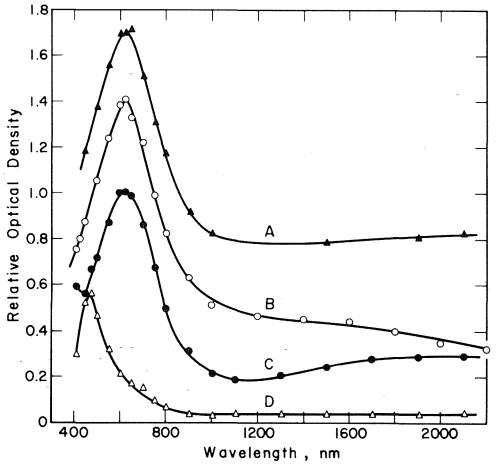

FIG. 3. Spectra observed after a 40 ns pulse in 3-methyloctane containing electron scavengers: (*A*) with 2.9 mol% SF_6, $T = 136$ K, 100 ns after start of the pulse; (*B*) saturated with N_2O at room temperature, $T = 127$ K, 60 ns after start of the pulse; (*C*) with 1.1 mol% CCl_4, $T = 127$ K, 100 ns after start of the pulse; (*D*) same as *C* except 7 μs after start of the pulse. Spectra *A* and *B* have been displaced upwards by 0.6 and 0.3 units, respectively. The magnitudes of *C* and *D* are relative to each other, but otherwise the magnitudes of the spectra are arbitrary.

shows the RH^+ peak around 625 nm and also absorption decreasing from 1000 to 2300 nm which cannot be due to e_s^-. At 7 μs, after RH^+ had largely decayed away, a peak around 425 nm remained. Spectrum *C*, for a solution of CCl_4 in 3-MO, shows the RH^+ peak around 625 nm, absorption increasing from 1000 to 2100 nm which is due to e_s^-, and an increase in absorption between 425 and 410 nm. This last feature may be due to the tail of a band assigned to CCl_4^+ and which is reported to have λ_{max} = 367 nm (17). The spectrum at 7 μs for this system, spectrum *D*, shows a peak around 470 nm which has been attributed to a charge-transfer complex, $CCl_4 \cdot Cl$, resulting from charge recombination of CCl_4^+ with Cl^- (17), though this assignment has been questioned (18). If the 470 peak is due to $CCl_4 \cdot Cl$, then it should grow in only as RH^+ decays and should not contribute significantly to spectrum *C*; in agreement with this, OD_{450}/OD_{650} for spectrum *C* is very similar to that for spectra *A* and *B*.

Effects of Solutes on e_s^- and RH^+

In Fig. 4*A* it is seen that the effect of a large concentration (6.2 mol%) of TEA on the initial yield of e_s^- in 3-MO at 109.5 K is negligible, but its initial decay rate is considerably decreased. Figure 5 shows the effect of the same concentration of TEA in 3-MO at 127 K over a greater extent of decay. At this temperature there is a small (3%) increase in concentration of e_s^- at short times in the presence of TEA. This increase is only about twice the experimental uncertainty for an individual trace but it was repeatable several times and for two different samples, and is probably not an artifact of the detector (14). However, at longer times e_s^- decays faster in the TEA solution, so that the time to reach 80% decay is the same as for pure 3-MO. Figure 6 gives results for electron decay at 141 K in the presence and absence of TEA. It is seen that at higher temperatures where electron decay is much faster in pure 3-MO, the effectiveness of TEA in decreasing the initial decay rate is much less.

The yields of trapped electrons in γ-irradiated 3-methylpentane at 77 K are increased by the addition of a few mol% TEA (1). Our work suggests that the reason is simply that the initial decay rate of the electrons is sufficiently fast in the pure hydrocarbon such that some of them disappear before the first measurement,

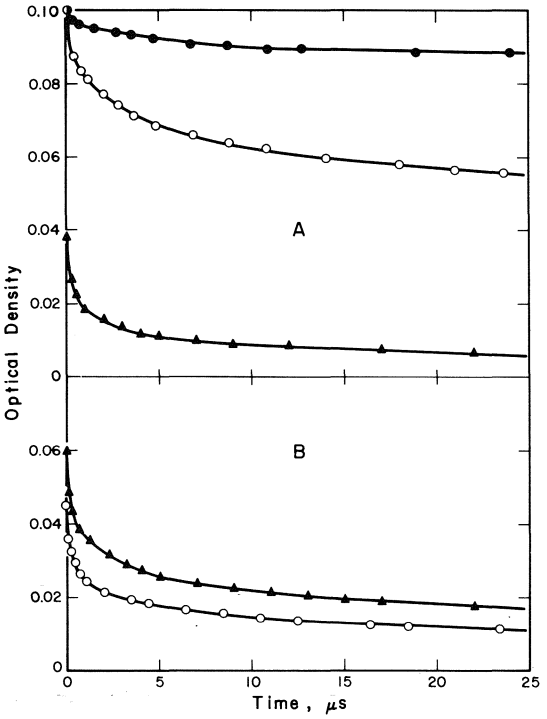

FIG. 4. Effects of solutes on electron and positive ion in 3-methyloctane at 109.5 K. Zero time refers to mid-pulse. (*A*) Optical density at 2100 nm, due to the electron, as a function of time; ○, no additives; ●, with 6.2 mol% triethylamine; ▲, with 1.22 mol% SF_6. (*B*) Optical density at 650 nm due to the positive ion (corrections have been made for electron absorption at this wavelength); ○, no additives; ▲, with 1.22 mol% SF_6.

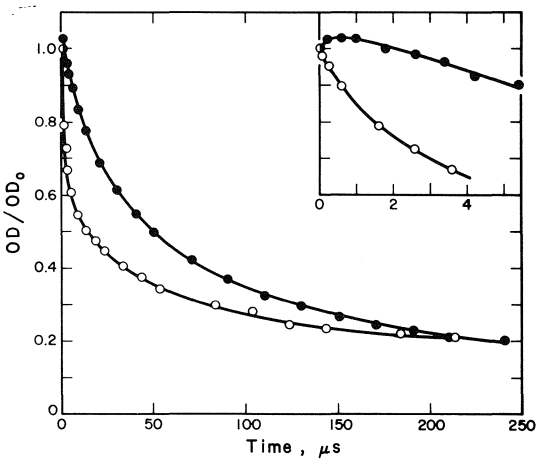

FIG. 5. Effects of triethylamine on electron decay in 3-methyloctane at 127 K: ○, pure 3-methyloctane; ●, with 6.2 mol% triethylamine. Measurements were made at 2100 nm. OD_0 is the optical density extrapolated to the middle of the 40 ns pulse. The inset shows the initial changes in optical density on an expanded time-scale.

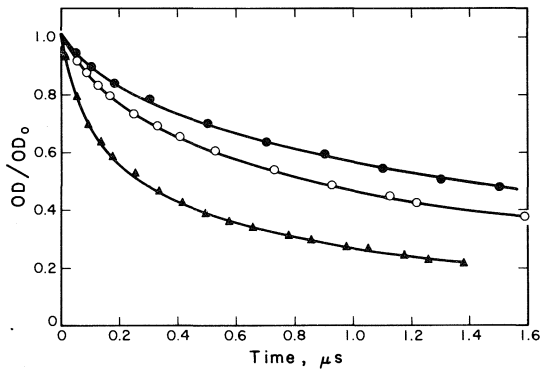

FIG. 6. Decay of electrons and positive ions in pure 3-methyloctane at 141 K, and electron decay in a 6.2 mol% triethylamine solution at 141 K. OD_0 is the optical density extrapolated to the middle of the 40 ns pulse. ●, λ = 2100 nm, triethylamine solution; ○, λ = 2100 nm, pure 3-methyloctane; ▲, λ = 650 nm, pure 3-methyloctane, corrected for electron absorption.

but the initial decay is much slower in the solutions so that fewer are lost.

Figure 4*A* shows that the effect of SF_6 on e_s^- is to considerably reduce the initial yield and greatly increase the decay rate. The effect of SF_6 on RH^+, as seen in Fig. 4*B*, is to increase the initial yield and slightly decrease the decay rate at short times. In Fig. 4*B* initial $t_{1/2}$'s for decay of RH^+ are approximately 1.7 μs in pure 3-MO and 2.8 μs in the 1.22 mol% SF_6 solution.

From a comparison of Figs. 4 *A* and *B* it is seen that in pure 3-MO at 109.5 K the decay rate of RH^+ is much faster than that of e_s^-, especially at short times. However, the fractional difference in rates becomes smaller with increase in temperature as shown by the results at 141 K given in Fig. 6.

Effect of Electron Scavengers on Yields of RH^+

The effects of SF_6 and CCl_4 on yields of RH^+ in 3-MO at two temperatures are shown in Table 1. In estimating the yields in CCl_4 solutions, it was assumed, as indicated above, that the species with λ_{max} around 470 nm found at long times makes no contribution to absorption at 650 nm at short times.

Effect of Temperature on Yields of e_s^- and RH^+

In Fig. 7 it is seen that the values of $G\varepsilon$ of e_s^- are the same in solutions of TEA as in pure 3-MO between 103 and 153 K, and the $G\varepsilon$'s almost double as the temperature is increased in this range. The $G\varepsilon$'s of RH^+ decrease by about 30% over the same temperature range. The values of $G\varepsilon$ given in Fig. 7 are those estimated

TABLE 1. Effect of electron scavengers on yields of positive ion in 3-methyloctane

T (K)	Solute	Mol%	$G\varepsilon_{650} \times 10^4$*
109.5	None	—	1.24†
109.5	SF_6	1.22	1.63†
127	None	—	1.09†
127	CCl_4	0.43	1.15†
127	CCl_4	3.61	1.24
127	CCl_4	6.51	1.35
127	SF_6	1.22	1.52†

*$G\varepsilon_{650}$ measured 100 ns after the start of a 40 ns pulse.
†After correction for electron absorption at 650 nm.

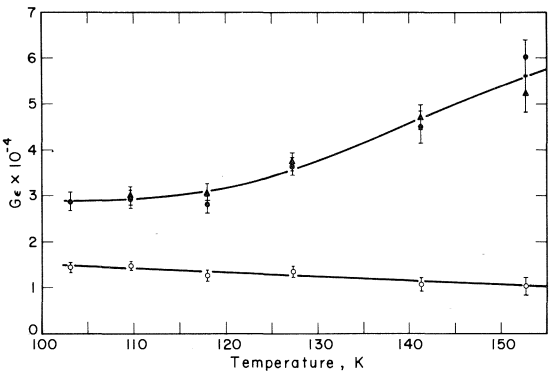

FIG. 7. Mid-pulse values of $G\varepsilon$ of electrons and positive ions as a function of temperature: ●, pure 3-methyloctane, λ = 2100; ▲, with 6.2 mol% triethylamine, λ = 2100; ○, positive ion contribution in pure 3-methyloctane at 650 nm (*i.e.* electron absorption at 650 nm has been subtracted).

from extrapolations to mid-pulse on plots of $1/OD$ *vs.* time. At the higher temperatures these extrapolations are large and therefore the uncertainties are considerable, as indicated by the error bars in Fig. 7. Thus at 153 K the estimated OD at mid-pulse (OD_0) for e_s^- is 2.3 times OD measured at 100 ns after the start of the pulse; by comparison, at 103 K OD_0 is 1.02 times OD at 100 ns.

Effect of Dose/Pulse and Light Intensity on Decay Rates

Variation of the dose per pulse and therefore OD_0 by a factor of 6.5 was found to have no effect on plots of OD/OD_0 against time at either 2100 or 650 nm for pure 3-MO at 127 K. This first order dependence on dose implies geminate reactions. Reduction of the intensity of the analyzing light by a factor of 10 also had no effect on the decay plots, so that the analyzing light was not inducing bleaching reactions.

Variation of the dose per pulse by a factor of 8.4 for a 1.22 mol% solution of SF_6 in 3-MO

at 127 K had some effect on plots of OD/OD_0 *vs.* time at 650 nm. At 1.3 μs OD/OD_0 was 0.60 and 0.50 for the low and high doses, respectively. An interpretation is that under these conditions a small part of RH^+ decays by a true second order reaction, and the rest by a reaction or reactions which are first order in dose.

Discussion

Spectra of e_s^- and RH^+

The spectra observed in irradiated pure 3-MO, Fig. 1, show maxima around 2100 and 625 nm which can be attributed confidently to the solvated electron and a positive ion, respectively. There is no indication in Fig. 1 of a shift with time in the spectrum of e_s^-. A shift with time in λ_{max} from 2000 to 1700 nm was found in 3-methylhexane glass at 76 K (15), but no such shift was found in liquid 3-methylhexane at temperatures above 112 K (3). The spectrum of the positive ion with $\lambda_{max} = 625$ nm is seen better in Fig. 3. Louwrier and Hamill (4) found $\lambda_{max} = 685$ nm for a γ-irradiated solution of 2-methyloctane in CCl_4 at 77 K and attributed it to the parent radical ion, RH^+. They also measured spectra of the parent radical ions of four methylnonanes at 77 K, and found a steady shift to the blue as the methyl group moved from the 2 to the 5 position. If it is assumed that the blue shift in going from 2-methyloctane to 3-MO is the same as in going from 2-methylnonane to 3-methylnonane, λ_{max} for 3-MO at 77 K would be expected at 650 nm. Comparison with our λ_{max} at 127 K indicates any shift with temperature is small.

Decay Kinetics for e_s^- and RH^+

The decay kinetics for e_s^- and RH^+ in pure 3-MO do not even approximately obey a log OD *vs.* time plot, but for both species the kinetics are first order in dose in that decay curves for different doses per pulse can be superimposed if normalized for dose. This demonstrates that these species are not decaying by second order reactions, and suggests that both species are undergoing geminate recombination. The decay kinetics for e_s^- in pure 3-MO are similar to those seen earlier in pure 3-methylhexane in that they happen to obey fairly well a plot of $1/OD$ against time (if the best line is drawn through the points for >50% decay, points for smaller percent decay fall below the line), but do not follow [1] (3).

However, a reaction or reactions other than recombination of e_s^- with RH^+ obviously occur also because RH^+ disappears much faster than e_s^-, as seen in Figs. 1, 4, and 6. The fractional difference in decay rates is greatest at the lowest temperature. One possibility is that, in addition to recombining with e_s^-, RH^+ dissociates or undergoes an ion–molecule reaction to form products that do not absorb in this region. However, such a reaction would be expected to obey a first order kinetics plot, and it is seen in Fig. 4*B* that successive $t_{1/2}$'s for RH^+ are very different in pure 3-MO. Instead we tentatively propose that RH^+ combines geminately with a second type of solvated electron (further evidence for this species is presented below) which presumably absorbs at $\lambda > 2200$ nm, as well as combining with e_s^-. Combination with this second type of solvated electron must be faster than with e_s^-. As well there seems to be a dissociation or ion–molecule reaction at longer times, to explain the almost complete disappearance of RH^+ by 35 μs in pure 3-MO at 127 K (Fig. 1).

In solutions of TEA where at short times the positive ion is mainly $(C_2H_5)_3NH^+$ or $(C_2H_5)_3N^+$ (16), the initial decay rate of e_s^- is very much slower than in pure 3-MO for $T < 127$ K, as indicated in Figs. 4 and 5. One possible reason is that the dominant positive ion in these solutions is $(C_2H_5)_3NH^+$ and the reaction

$$[4] \qquad e_s^- + (C_2H_5)_3NH^+ \rightarrow (C_2H_5)_3N + H$$

is very slow, just as the hydrated electron reacts slowly, if at all, with NH_4^+. However, this possibility is considered unlikely for three reasons: (*a*) if this were the case, initial electron decay would be expected to be much slower in TEA solutions than in pure 3-MO at all temperatures. In fact, as indicated in Fig. 6, the differences are smaller at the higher temperatures. (*b*) To explain why the effectiveness of TEA in increasing the yields of trapped electrons in 3-methylpentane glasses at 77 K goes through a maximum at a few percent, Hamill (1) has proposed that the decrease in effectiveness at higher concentrations is due to hole migration along chains of TEA molecules and therefore the dominant positive ion must be $(C_2H_5)_3N^+$ rather than $(C_2H_5)_3NH^+$. (*c*) If the proton affinity of $(C_2H_5)_3N$ is the same as that of NH_3, [4] is exothermic by about 110 kcal mol^{-1} in the gas phase. The energetics would be similar in a

hydrocarbon where the reactants are weakly solvated (as contrasted to the situation in water where solvation is strong) and therefore [4] would be expected to be fast in 3-MO.

A much more likely explanation for the slower initial decay of e_s^- in TEA solutions for $T \leq 127$ K is that RH^+ has a mobility which is much higher than that of $(C_2H_5)_3NH^+$ or $(C_2H_5)_3N^+$, and is also higher than the mobility of e_s^-. RH^+ must migrate by a resonance transfer of an electron from RH (hole transfer). However, at 141 K the mobilities of e_s^- and RH^+ are more similar, as indicated by the fact that TEA has a smaller effect on the decay rate of e_s^- (Fig. 6).

In pure 3-MO at 127 K, e_s^- decays more slowly at times >20 μs than in a TEA solution (Fig. 5). At these times only a small fraction of the original RH^+ remains (Fig. 1), and the remaining electrons must decay slowly with widely separated cations produced from RH^+ by dissociation or ion–molecule reactions.

A small growth of absorption at 2100 nm was seen in TEA solutions at temperatures around 127 K (inset of Fig. 5). This might be due to a conversion into e_s^- with $\lambda_{max} = 2100$ nm by a small percentage of a second type of solvated electron which was mentioned above and for which further evidence is given below.

In SF_6 solutions the decay of RH^+ is only slightly slower than in pure 3-MO (Fig. 4*B*). In these solutions the neutralization partner of RH^+ must be predominately SF_6^-. The mobility of SF_6^- has been measured in cyclohexane at room temperature, and is very much less than that of electrons in hydrocarbons like 3-MO at room temperature (19). Activation energies are not available, but at 109.5 K SF_6^- might still be expected to be less mobile than e_s^-. However, it was concluded above that at this temperature RH^+ moves much more than does e_s^- in the recombination process, so further decrease of the mobility of the negatively charged reactant is not expected to have much effect.

Yields of RH^+ and e_s^-

As the temperature is increased from 103 to 153 K, the initial $G\varepsilon$ of RH^+ decreases while that of e_s^- increases (Fig. 7). A referee has pointed out that these changes in $G\varepsilon$'s might simply reflect changes in ε at the chosen wavelengths. However, we have indicated above that any shift in λ_{max} for RH^+ between 77 and 127 K is small. A change in ε_{max} should be likewise small between 103 and 153 K since it would reflect an expected small change in band width. Earlier we found that the spectrum of e_s^- in liquid 3-methylhexane at 121 K is very similar to that of the glass at 76 K (3). Very recently small changes in λ_{max} with temperature have been reported for e_s^- in several ethers; ε_{max} was found to be practically constant with temperature (20). Therefore we cannot eliminate the possibility that the changes with temperature in $G\varepsilon$ seen in Fig. 7 are due to changes in ε, but we think they are more likely due to changes in G. A decrease in the yield of RH^+ while the yield of e_s^- increases could be explained by production of another type of initial positively charged species we have not observed, or another type of solvated electron we have not detected and which presumably absorbs at wavelengths >2200 nm. Since we have some other evidence for a second type of solvated electron, discussed above, we prefer the latter explanation. The yield of this second electron species would then decrease with increasing temperature to fulfill the presumed requirement that the yield of RH^+ equal the total yield of solvated electrons.

Only rough estimates of the extinction coefficients of e_s^- and RH^+ are available from the literature. For 3-methylpentane glass at 77 K, ε at λ_{max} ($\sim$1700 nm) has been estimated as $3 \times 10^4\ M^{-1}\,cm^{-1}$ (1). If we assume ε at λ_{max} is the same for electrons in liquid 3-MO, then $G(e_s^-)$ is 0.97 at 103 K and 1.87 at 153 K. The only estimate available for ε for RH^+ is for 2-methyldecane by Louwrier and Hamill (4), who noted that their results suggest that oscillator strengths increase markedly with carbon number. The ε_{max} for RH^+ from 2-methyldecane, $8.2 \times 10^3\ M^{-1}\,cm^{-1}$, may then be taken as an upper limit for ε_{max} for RH^+ from 3-MO. The lower limits of the initial G's for RH^+ are then calculated as 1.74 at 103 K and 1.27 at 153 K. These rough estimates suggest that if a second type of solvated electron is produced in 3-MO, its yield is appreciable at 103 K.

A second type of trapped electron with a clearly separated absorption band in the near infrared has been reported recently in a rather different type of system, three aqueous glasses and crystalline ice (21–23).

Effect of Electron Scavengers on Yields of RH^+

Our estimated initial yields of RH^+ and e_s^- are higher and lower, respectively, in the presence of SF_6 or CCl_4 than in pure 3-MO (Table 1). As indicated above, CCl_4^+ may also be produced in the CCl_4 solutions, and this may at least partly

account for the greater effectiveness of SF_6 than of CCl_4 in increasing the initial yield of RH^+. These effects can be explained by proposing that CCl_4 or SF_6 can scavenge an unsolvated, quasi-free electron (e_{qf}^-); in the absence of scavenger (S) this species can be solvated or can recombine with RH^+ very quickly, before our first observation:

[5] $$e_{qf}^- + \text{Trap} \rightarrow e_s^-$$

[6] $$e_{qf}^- + RH^+ \rightarrow RH$$

[7] $$e_{qf}^- + S \rightarrow S^-$$

Scavenging of the quasi-free electron, [7], increases the yield of RH^+ by decreasing the amount of [6], and of course decreases [5] also.

Another possible explanation is that in pure 3-MO some recombination between RH^+ and e_s^- takes place by tunnelling at very short times (24), such that our extrapolation procedure for estimating initial yields is not valid Added SF_6 or CCl_4 would interfere with this recombination by scavenging e_s^- and hence giving increased yields of RH^+ at our first observation times.

Relationship to Scavenging Experiments

If the neutralization reactions in cold hydrocarbons are as complicated as our experiments suggest and involve two types of solvated electron and a quasi-free electron, plus a mobile hole and cations produced from it by dissociation or ion–molecule reactions, then it is not surprising that decay of one type of solvated electron does not follow [1], the behaviour predicted from scavenging experiments at room temperature (10), since this prediction involves the implicit assumption that only one species reacts with electron scavengers. The situation in room temperature hydrocarbons might be much simpler in that perhaps only one electron species is important under these conditions, but at this time prediction of lifetimes of geminate electrons from scavenging experiments seems hazardous.

Discussion

R. S. Dixon: It is well-known from mass spectrometric studies that fragmentation can give rise to many different ions in the gas phase. Is it possible that you have more than one positive ion with a reasonable lifetime at low temperature in your system?

R. J. Woods: Ion fragmentation is less likely in liquid phase radiolysis than in the mass spectrometer because excitational energy of excited ions is rapidly dissipated in a condensed medium. However, we have suggested that ion fragmentation may contribute to the rapid disappearance of the positive ion which absorbs at 650 nm; carbonium ions formed by fragmentation would be expected to have a longer lifetime than the parent positive ion.

J. R. Miller: While you have shown that the positive ion in the cold liquid decays rapidly, have you studied its decay at a temperature low enough so that the system is rigid?

R. J. Woods: No. Studies have not been carried out below the glass transition point.

The yield and extinction coefficient of the solvated electron in methanol: pulse radiolysis of nitrobenzene and tetranitromethane solutions

DAVID W. JOHNSON AND G. ARTHUR SALMON

The University of Leeds, Cookridge Radiation Research Centre, Cookridge Hospital, Leeds LS16 6QB, U.K.

Received September 27, 1976

DAVID W. JOHNSON and G. ARTHUR SALMON. Can. J. Chem. **55**, 2030 (1977).

The radical anion $C_6H_5NO_2^{\cdot-}$, NB^-, which has a strong absorption spectrum from 250–500 nm, is formed by reaction of nitrobenzene with solvated electrons, e_s^-, and hydroxymethyl radical anions, $^{\cdot}CH_2O^-$, with $k_1 = (1.92 \pm 0.35) \times 10^{10}\ M^{-1}\ s^{-1}$ and $k_2 = (1.03 \pm 0.02) \times 10^{10}\ M^{-1}\ s^{-1}$.

[1] $$e_s^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-}$$

[2] $$^{\cdot}CH_2O^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-} + H_2CO$$

$G\varepsilon_\lambda$ is constant for NB^- over a wide range of nitrobenzene concentrations in basic solution. By assuming that the yields of scavengeable radicals are the same in neutral and basic solutions we obtain $\varepsilon(NB^-)_{300\ nm} = (1.66 \pm 0.02) \times 10^4\ M^{-1}\ cm^{-1}$. This value is used to evaluate the yield of e_s^- scavengeable by dilute solutions of solutes as $G(e_s^-)_{esc} = 1.20 \pm 0.03$. Extinction coefficients of e_s^-, hydroxymethyl radicals, $^{\cdot}CH_2OH$, and $^{\cdot}CH_2O^-$ and the oscillator strength of the e_s^- absorption are calculated.

The yields of e_s^- determined by previous workers are discussed in terms of dry, damp, geminate, free, spur, and escaped electrons. A model is constructed in terms of damp, spur, and escaped electrons which compares favourably with experimental scavenging results and direct measurements by optical pulse radiolysis.

DAVID W. JOHNSON et G. ARTHUR SALMON. Can. J. Chem. **55**, 2030 (1977).

Le radical anion $C_6H_5NO_2^{\cdot-}$, NB^-, qui a un spectre d'absorption très intense dans la région de 250–500 nm, se forme par réaction du nitrobenzène avec les électrons solvatés, e_s^-, et les anions radicaux hydroxyméthyles, $^{\cdot}CH_2O^-$, avec des constantes de vitesse $k_1 = (1.92 \pm 0.35) \times 10^{10}\ M^{-1}\ s^{-1}$ et $k_2 = (1.03 \pm 0.02) \times 10^{10}\ M^{-1}\ s^{-1}$.

[1] $$e_s^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-}$$

[2] $$^{\cdot}CH_2O^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-} + H_2CO$$

La valeur de $G\varepsilon_\lambda$ est constante pour NB^- à des concentrations de nitrobenzène très diverses lorsque l'on travaille en solution basique. En faisant l'hypothèse que les rendements des radicaux qui peuvent être piégés sont les mêmes en solutions neutres et basiques, on obtient la valeur $\varepsilon(NB^-)_{300\ nm} = (1.66 \pm 0.02) \times 10^4\ M^{-1}\ cm^{-1}$. On peut utiliser cette valeur pour évaluer le rendement en e_s^- piégeable pour des solutions diluées de solutés; alors $G(e_s^-)_{esc} = 1.20 \pm 0.03$. On a aussi calculé les coefficients d'extinction de e_s^-, des radicaux hydroxyméthyles, $^{\cdot}CH_2OH$, et $^{\cdot}CH_2O^-$ et la force d'oscillateur de l'absorption e_s^-.

On discute des rendements de e_s^- déterminés antérieurement par d'autres chercheurs en termes d'électrons secs, humides, géminés, libres, de grappe et qui se sont échappés. On construit un modèle en termes d'électrons humides, de grappe et qui se sont échappés qui se compare favorablement avec les résultats de piégeages expérimentaux et des mesures directes par radiolyse optique pulsée.

[Traduit par le journal]

Introduction

In a previous paper the overall scavengeable yield of solvated electrons, e_s^-, and hydroxymethyl radicals, $^{\cdot}CH_2OH$, was determined by pulse radiolysis of dilute solutions of tetranitromethane, TNM (1). Estimates of $G(e_s^-)_{esc}$,[1] the yield of e_s^- which escape from regions of high radical concentration (spurs) to become homogeneously distributed in solution, vary from 1.0–2.0 (2–14). Pulse radiolysis measurements of absorption spectra yield only the product $G\varepsilon_\lambda$,[2] thus uncertainty in $G(e_s^-)$ results in a correponding uncertainty in the extinction

[1] The G value of the designated product is the radiation chemical yield in molecules $(100\ eV)^{-1}$.

[2] $G\varepsilon(X)_\lambda$ is the product in units of $M^{-1}\ cm^{-1}$ of the radiation chemical yield and the molar decadic extinction coefficient of the light absorbing species, X, at wavelength λ.

coefficient of e_s^-. This work utilizes the strong absorption spectrum between 280 and 320 nm of $C_6H_5NO_2^{\cdot-}$, NB^- (15), generated by reaction of e_s^- and the hydroxymethyl radical anion, $^{\cdot}CH_2O^-$, with nitrobenzene by reactions 1 and 2 to obtain a more reliable value for $G(e_s^-)$ and hence determine the extinction coefficient of e_s^-.

[1] $$e_s^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-}$$

[2] $$^{\cdot}CH_2O^- + C_6H_5NO_2 \rightarrow C_6H_5NO_2^{\cdot-} + H_2CO$$

Experimental

Nitrobenzene (B.D.H. AnalaR) was washed three times with a threefold excess of triply distilled water, dried over anhydrous calcium chloride, and fractionally distilled in a nitrogen atmosphere, the middle fraction being collected at 211–214°C.

Nitrous oxide (B.O.C. 99.999%) was passed over potassium hydroxide pellets, through a trap at −80°C and either used directly or further purified by degassing at −130°C. This latter material was stored on a vacuum line and degassed again before use. Analysis by gas chromatography using a molecular sieve 5A (B.D.H.) column at 43°C with helium as a carrier gas showed no trace of any gaseous impurity.

Methanol (Wilkinson-Vickers A.R.), tetranitromethane (Koch Light, Puriss. A.R.), and argon (B.O.C. 99.995%) were purified as described previously (1).

Sodium metal (B.D.H., G.P.R. dry; or Hopkins and Williams, dry) was used as supplied.

Methods

The techniques of sample preparation, saturation with argon or nitrous oxide, and details of the pulse radiolysis apparatus have been described previously (16–18). Pulse lengths from 10 ns to 0.2 μs were chosen as appropriate.

Solutions for the determination of the reaction rate between N_2O and e_s^- were prepared by distillation *in vacuo* of a measured quantity of N_2O onto a sample of methanol which had been previously degassed at −80°C. The concentration of N_2O in solution at the temperature of the experiment was determined using values for the solubility of N_2O in methanol of 2.03×10^{-4}, 2.07×10^{-4}, and 2.99×10^{-4} M (mm Hg)$^{-1}$ at 25 (19), 20 (20), and 0°C (21), respectively. All experiments were performed at room temperature (20 ± 2°C). All errors quoted are one standard deviation of the mean (standard error).

Results

A. Nitrobenzene Solutions

I. Kinetic Studies

(a) Basic Solutions—The rate constant for reaction 1 between e_s^- and nitrobenzene was determined as $k_1 = (1.92 \pm 0.35) \times 10^{10}$ M^{-1} s^{-1} from the first order decays of the absorption of e_s^- at 580 nm in Ar saturated solutions containing $6 \times 10^{-5} \leq [C_6H_5NO_2] \leq 3 \times 10^{-3}$ M and $2 \times 10^{-2} \leq [CH_3ONa] \leq 2 \times 10^{-1}$ M. This value compares favourably with a previous measurement (5).

The rates of growth of absorption at 300 nm due to NB^- following 1.5–4.0 krad pulses measured for N_2O saturated solutions with $6 \times 10^{-5} \leq [C_6H_5NO_2] \leq 2 \times 10^{-2}$ M and $1 \times 10^{-2} \leq [CH_3ONa] \leq 1$ M conformed to first order kinetics in every case. In N_2O saturated solution the principal radical species, hydrogen atoms (H·), methoxy radicals ($CH_3O^{\cdot}$), and e_s^- are converted rapidly into $^{\cdot}CH_2OH$ with half-lives of <5 ns, 150 ns (16), and <1 ns, respectively, by reactions 3 to 5 and $^{\cdot}CH_2OH$ is in acid–base equilibrium 6 with $^{\cdot}CH_2O^-$ (22).

[3] $$H^{\cdot} + CH_3OH \rightarrow H_2 + {}^{\cdot}CH_2OH$$

[4] $$CH_3O^{\cdot} + CH_3OH \rightarrow CH_3OH + {}^{\cdot}CH_2OH$$

[5*a*] $$e_s^- + N_2O \rightarrow N_2 + {}^{\cdot}O^-$$

[5*b*] $$^{\cdot}O^- + 2CH_3OH \rightarrow H_2O + {}^{\cdot}CH_2OH + CH_3O^-$$

[6] $$^{\cdot}CH_2OH + CH_3O^- \rightleftharpoons {}^{\cdot}CH_2O^- + CH_3OH$$

Assuming that $^{\cdot}CH_2O^-$, but not $^{\cdot}CH_2OH$, reacts with nitrobenzene (as is observed in aqueous solution (15)) then the dependence of the observed first order rate constants for formation of NB^- on $[C_6H_5NO_2]$ and $[CH_3ONa]$ is given by [7]

[7] $$k_{obs} = \frac{k_2[C_6H_5NO_2]}{\left(1 + \frac{1}{K_6'[CH_3ONa]}\right)}$$

where $K_6' = K_6/[CH_3OH]$. This expression may be rearranged to [8]

[8] $$[C_6H_5NO_2]/k_{obs} = \frac{1}{k_2}\left(1 + \frac{1}{K_6'[CH_3ONa]}\right)$$

A graph of $[C_6H_5NO_2]/k_{obs}$ against $1/[CH_3ONa]$ shown in Fig. 1 gives $k_2 = (1.03 \pm 0.02) \times 10^9$ M^{-1} s^{-1} and $K_6 = 3440 \pm 250$. The latter value is to be compared with $K_6 = 2120 \pm 235$ determined previously (22). The reason for this discrepancy is not clear since under the experimental conditions employed the rate of formation of NB^- is not sufficiently rapid to be affected significantly by the rate of formation of $^{\cdot}CH_2O^-$ (22). However, the low degree of accuracy of reciprocal plots of the type employed may be responsible.

(b) Neutral Solutions—An attempt to measure the rate of reaction 9 of $^{\cdot}CH_2OH$ with nitrobenzene in N_2O saturated solutions by the increase in absorption at 300 nm was unsuccessful since no growth was observed over 20 μs

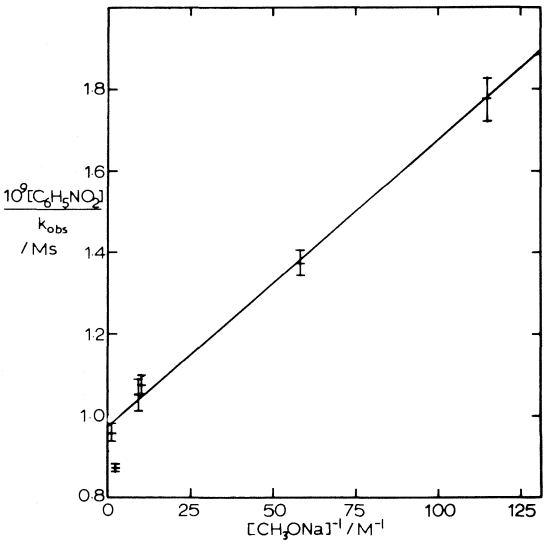

FIG. 1. Variation with $[C_6H_5NO_2]$ and $[CH_3ONa]$ of the observed first order rate constant, k_{obs}, for the formation of NB^- in N_2O saturated methanol.

at $[C_6H_5NO_2] = 3 \times 10^{-3}$ *M*. Furthermore the bimolecular decay of the

[9] $\cdot CH_2OH + C_6H_5NO_2 \rightarrow C_6H_5N(O\cdot)(O{-}CH_2OH)$

absorption of $\cdot CH_2OH$ at 320 nm (reaction 10) was unaffected by the presence of the solute. At higher concentrations of nitrobenzene absorption of light by the solute made observations

[10] $2\cdot CH_2OH \rightarrow (CH_2OH)_2$

impossible. A value for $k_9 = 3.3 \times 10^6$ M^{-1} s^{-1} has been determined in strongly acidic solutions of nitrobenzene (23). This value, and that for k_{10} (22), indicates that reaction 9 is too slow to be responsible for the disappearance of $\cdot CH_2OH$ in any solutions studied in this work.

In aqueous solution, H· and hydroxyl radicals, ·OH, react with nitrobenzene to form adducts to the aromatic ring by reaction 11 giving products which absorb strongly at 400 nm (24). There was

[11] $H(OH)\cdot + C_6H_5NO_2 \rightarrow H(OH)\cdot C_6H_5NO_2$

no evidence of any absorption at 400 nm on pulse radiolysis of an N_2O saturated solution containing 3×10^{-3} *M* nitrobenzene. It must be concluded that at this concentration of nitrobenzene reactions of H· and $CH_3O\cdot$ are too slow to compete with their reactions 3 and 4 with the solvent.

II. Spectra and Yields

(a) Basic Solutions—The spectra generated by 1.5 krad pulses in Ar and N_2O saturated solutions with $[C_6H_5NO_2] = 1$ m*M* and $[CH_3ONa] = 0.5$ *M* are identical within experimental error. The spectrum is shown in Fig. 2. This spectrum, with maxima at 295 and 420 nm, is similar to that attributed to NB^- in alkaline aqueous solution after allowance is made for the depletion of nitrobenzene (15). After the rapid formation of the absorption no decay was observed over 100 μs and only 50% of the absorption decayed over 2 min. This sets an upper limit to the decay since no allowance was made for the dilution of irradiated solution by unirradiated solution in the connecting tubing.

$G\varepsilon$ values for NB^- were determined at wavelengths from 290–320 nm for Ar saturated solutions with $6 \times 10^{-5} \leq [C_6H_5NO_2] \leq 3 \times 10^{-3}$ *M* and $1 \times 10^{-2} \leq [CH_3ONa] \leq 1.0$ *M*. The values, which were found to be independent of both $[C_6H_5NO_2]$ and $[CH_3ONa]$, are listed in Table 1. Also listed are the extinction coefficients of NB^- which were calculated on the assumption that the yield of radicals scavengeable by TNM in neutral Ar saturated solution, $G(NF^-)]_N^{Ar}$ (1), is equal to that scavenged by nitrobenzene in basic Ar saturated solution, *i.e.*,

$$[G(NF^-)]_N^{Ar} = [G(NB^-)]_B^{Ar} = [G(R\cdot)]^{Ar}$$

where the subscripts N and B refer to neutral and basic solutions and $[G(R\cdot)]^{Ar}$ is the yield of radicals scavengeable in neutral Ar saturated solutions (1). The basis for this assumption is considered in the discussion.

The variation of $G\varepsilon_{300\ nm}$ with $[CH_3ONa]$ was studied over a much larger range (1.36×10^{-4} to 1.0 *M*) for Ar and N_2O saturated solutions containing 8×10^{-4} *M* $C_6H_5NO_2$ at 3.5 krad/pulse. The large variation in yield (see Fig. 3) is due to reactions 10, 12, and 13 (22) which lead to the disappearance of $\cdot CH_2OH$ and $\cdot CH_2O^-$ in competition with their reaction with nitrobenzene.

[12] $\cdot CH_2OH + \cdot CH_2O^- \rightarrow$ } Products

[13] $2\cdot CH_2O^- \rightarrow$ }

The lines in Fig. 3 describing the dependence of the yield of NB^- on the concentration of base were calculated from [14].

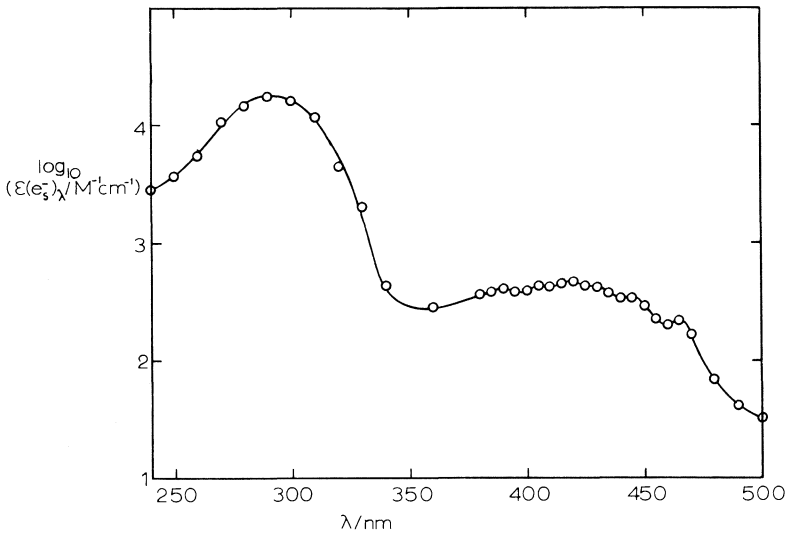

FIG. 2. Spectrum of NB^- produced by a 1.5 krad pulse in Ar saturated methanol containing 1 m*M* $C_6H_5NO_2$ and 0.5 *M* CH_3ONa.

$$[14] \qquad [G(NB^-)]_c = Z_c G(e_s^-)_0 + \frac{Yk_2[C_6H_5NO_2]}{AB} \log_e \left(1 + \frac{AB(G(R^\bullet) - Z_c G(e_s^-)_0)}{Yk_2[C_6H_5NO_2]}\right)$$

where

$$A = 2k_{10}\left(\frac{1}{1 + K_6'[CH_3ONa]}\right)^2 + \frac{2k_{12}}{B}\left(1 + \frac{1}{1 + K_6'[CH_3ONa]}\right) + \frac{2k_{13}}{B^2}$$

$$B = \left(\frac{1}{K_6'[CH_3ONa]}\right)$$

and $Y = 1.204 \times 10^6/D$. In [14], $[G(NB^-)]_c$ is the yield of NB^- at $[CH_3ONa] = c$ *M*, and $G(e_s^-)_0$ is the slowly decaying yield of e_s^- in neutral solution corrected for decay during the pulse (the 'initial' yield). Z_c is the experimentally determined ratio of the 'initial' yield of e_s^- in a solution with $[CH_3ONa] = c$ *M* to that in neutral solution and *D* is the dose delivered by the pulse in units of krads. Values of $[G(R^\bullet)]$ for Ar and N_2O saturated solutions were determined from $G\varepsilon_{300\,nm}$ at $[CH_3ONa] \geq 1 \times 10^{-2}$ *M* when scavenging of radicals by nitrobenzene is essentially complete. The results in Fig. 3 were obtained from a single experiment so that the agreement between the observed and calculated yields is good. The data used in this calculation are listed in Table 2.

(b) Neutral Solutions—On pulse radiolysis of Ar saturated solutions of methanol with $6 \times 10^{-5} \leq [C_6H_5NO_2] \leq 3 \times 10^{-3}$ *M* using 10 or 25 ns, 1–2 krad pulses an absorption spectrum with a maximum at 295 nm grew in after the pulse. The spectrum subsequently decayed rapidly over 25 μs and slowly over several hundred μs. The absorption is composed of contributions from NB^-, e_s^-, and $^\bullet CH_2OH$. In order to determine the yield of NB^-, which in neutral solution is generated by reaction between e_s^- and nitrobenzene (reaction 1), both the rate of formation and decay of NB^- must be known as well as the rate of decay of the absorption due to $^\bullet CH_2OH$. In aqueous solution NB^- is in equilibrium with the un-ionised radical $C_6H_5NO_2H^\bullet$,NBH, (equilibrium 15) (15). Although

$$[15] \qquad C_6H_5NO_2H^\bullet \rightleftharpoons C_6H_5NO_2^{\bullet-} + H^+$$

no value for K_{15} has been measured in methanol it is likely to be considerably less than its value in water ($K_{15} = 6.3 \times 10^{-4}$ *M* (15)) on account of the lower free energy of solvation of ions in

TABLE 1. Yields and extinction coefficients of NB^- in Ar saturated solution with $6 \times 10^{-5} \leq [C_6H_5NO_2] \leq 3 \times 10^{-3}$ M and $2 \times 10^{-2} \leq [CH_3ONa] \leq 1.0$ M

λ	10^{-4} $G\varepsilon_\lambda$	$10^{-3}\{\varepsilon(NB^-)_\lambda - \varepsilon(C_6H_5NO_2)_\lambda\}$*	10^{-3} $\varepsilon(NB^-)_\lambda$*
290	9.18±0.19	16.3±0.4	18.3±0.4
300	8.78±0.08	15.6±0.2	16.6±0.2
310	6.28±0.06	11.2±0.2	11.6±0.2

*Calculated assuming $[G(R\cdot)]_B^{Ar} = 5.63 \pm 0.05$.

methanol. However, in neutral methanol, for which $[H^+] = 1 \times 10^{-8}$ M, equilibrium 15 will lie towards the dissociated form. The relatively fast initial decay of absorption may be caused by reaction between H^+ formed during the pulse and NB^- forming the less strongly absorbing NBH (15).

The formation and decay of absorption can therefore be formulated in terms of [16]–[20].

$$[16] \qquad [e_s^-]_t = [e_s^-]_0 \exp(-[k_1' + k_{21}]t)$$

$$[17] \qquad [NB^-]_t = \frac{k_1[e_s^-]_0}{k_1' + k_{21} - k_{-15}'}(\exp(-k_{-15}'t) - \exp(-[k_1' + k_{21}]t))$$

$$[18] \qquad [NBH]_t = \frac{k_1'k_{-15}'[e_s^-]_0}{k_1' + k_{21} - k_{-15}'}\left(\frac{\exp(-[k_1' + k_{21}]t) - 1}{k_1' + k_{21}} - \frac{\exp(-k_{-15}'t) - 1}{k_{-15}'}\right)$$

$$[19] \qquad [C_6H_5NO_2]_t = [C_6H_5NO_2]_0 - k_1'[e_s^-]_0\left(\frac{1 - \exp([k_1' + k_{21}]t)}{(k_1' + k_{21})}\right)$$

$$[20] \qquad [\cdot CH_2OH]_t = \frac{[CH_2OH]_0}{(1 + 2k_{10}[\cdot CH_2OH]_0 t)}$$

where $[X]_0$ and $[X]_t$ are the concentrations of species X produced during the pulse and at time t after the middle of the pulse, respectively, and $k_1' = k_1[C_6H_5NO_2]$. It is assumed that the decay of NB^- by reaction with H^+ is first-order over the first few μs and that $k_{-15}' = k_{-15}[H^+]_0$. The decay of e_s^- other than by reaction with nitrobenzene is represented by reaction 21. In Ar saturated methanol it is found that the decay of e_s^- follows a first order rate law, but the observed first order rate constant, k_{21}, is dependent on the dose in the pulse (11). Hence values for k_{21} at the dose used in each experiment were determined from the decay of e_s^- in Ar saturated

$$[21] \quad e_s^- + 2CH_3OH \rightarrow \cdot CH_2OH + CH_3O^- + H_2$$

methanol. The sum of $[e_s^-]_0$ and $[\cdot CH_2OH]_0$ is calculated using $[G(R\cdot)]_N^{Ar} = 5.63 \pm 0.05$ (1).

The changes in absorption at 290 and 300 nm following a pulse were fitted to [16]–[20] at five different $[C_6H_5NO_2]$ using a linear least squares method with $G(e_s^-)_0$ and k_1 as independent variables. The extinction coefficient $\varepsilon(NBH)_\lambda$ was taken as its value in aqueous solution (15). The values for rate constants and extinction coefficients are taken from ref. 22 and elsewhere in the text. The calculated and observed absorption data were within experimental error at all concentrations of $C_6H_5NO_2$ and at both wavelengths studied. An example is shown in Fig. 4 which also shows contributions to the total absorption from each absorbing species. Since NB^- is the major component and decays only slowly, values used for the extinction coefficients of other species have little influence on $G(e_s^-)_0$. Values for $G(e_s^-)_0 = 1.20 \pm 0.03$ and $k_1 = (2.1 \pm 0.1) \times 10^{10}$ M^{-1} s^{-1} were obtained. The latter compares well with $k_1 = (1.92 \pm 0.35) \times 10^{10}$ M^{-1} s^{-1} determined in section A.*I.*(*a*) by direct observation of the decay of the absorption of e_s^-.

B. Nitrobenzene–Tetranitromethane Solutions

Pulse radiolysis of Ar saturated TNM solutions results in the formation by reactions 22 and 23 of NF^- which absorbs at 355 nm (1).

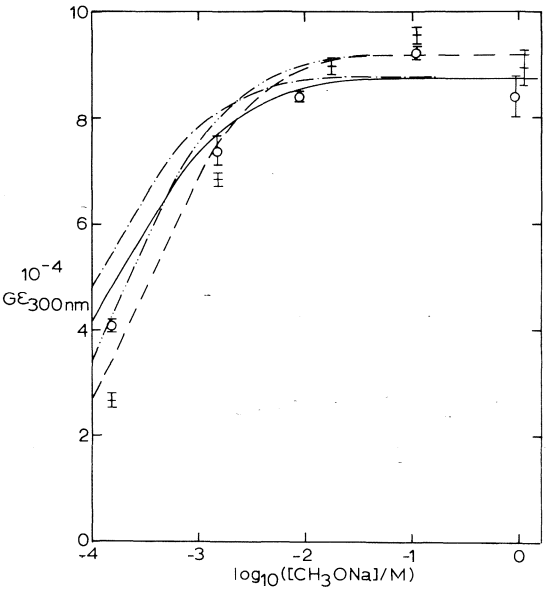

FIG. 3. Dependence of $G\varepsilon_{300\,nm}$ on the concentration of base in solutions containing 0.8 mM nitrobenzene. ○, Ar saturated; +, N_2O saturated. Curves calculated using [14] and data in Table 2. Ar saturated: K_6 = 2120, —; K_6 = 3440, -·-·-; N_2O saturated: K_6 = 2120, ---; K_6 = 3440, -·-·-·-.

Addition of nitrobenzene results in a decrease in $G\varepsilon_{355\,nm}$. This dependence of $G\varepsilon_{355\,nm}$ on $[C_6H_5NO_2]/[TNM]$ was studied in Ar saturated

[22] $e_s^- + C(NO_2)_4 \rightarrow C(NO_2)_3^- + NO_2$

[23] $\cdot CH_2OH + C(NO_2)_4 \rightarrow C(NO_2)_3^- + NO_2 + H_2CO + H^+$

solutions with $6 \times 10^{-5} \leq [TNM] \leq 3 \times 10^{-4}$

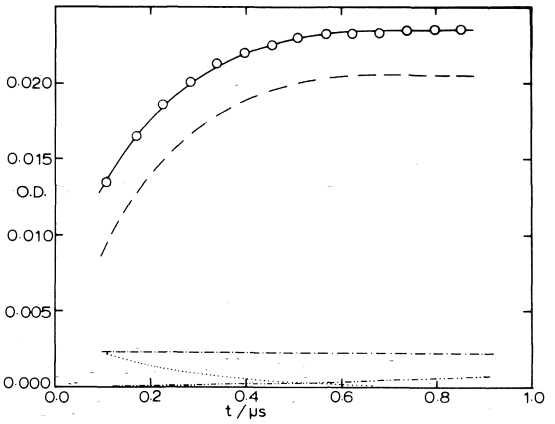

FIG. 4. Growth of absorption at 300 nm after a 10 ns, 1.6 krad pulse in an Ar saturated solution containing 3×10^{-4} M $C_6H_5NO_2$. Observed yield ○, solid line calculated from [16] to [20]. Time dependence of individual components: ---, NB^-; -·-·-·, $\cdot CH_2OH$; . . ., e_s^-; -·-·-·-, NBH.

M and $[C_6H_5NO_2]/[TNM] \geq 1$ and irradiated with 1.5–5.0 krad, 25 ns or 0.2 μs pulses. The 355 nm absorption grew in after the pulse to a plateau which was stable for at least 30 μs. The absorptions were not corrected for the absorption of NB^- since $\varepsilon(NB^-)_{355\,nm} \ll \varepsilon(NF^-)_{355\,nm}$. The dependence of $G(NF^-)$ on $[C_6H_5NO_2]/[TNM]$ is shown in Fig. 5. $G(NF^-)$ falls below its value in TMN solutions because nitrobenzene competes with TNM for e_s^- (reactions 1 and 22). Since $\cdot CH_2OH$ reacts only slowly with nitrobenzene the contribution to $G(NF^-)$ from reaction of $\cdot CH_2OH$ with TNM (reaction 23) is unaffected by nitrobenzene. Hence, at $[C_6H_5NO_2] \leq 1 \times 10^{-3}$ M, [24] applies where

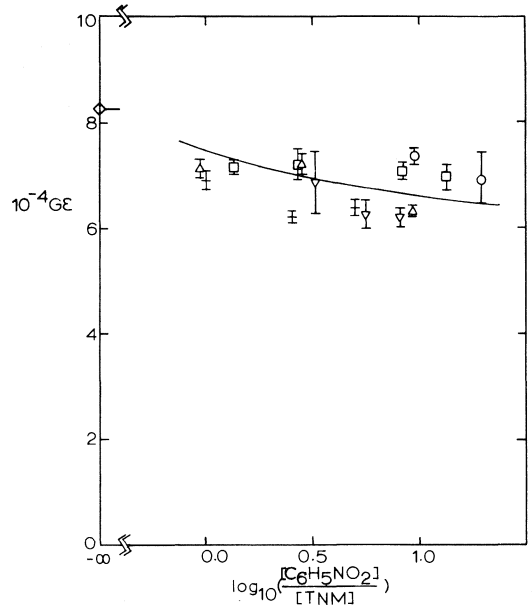

FIG. 5. Effect of nitrobenzene on $G\varepsilon_{355\text{ nm}}$ in Ar saturated solutions containing the following concentrations of TNM: ○, 6×10^{-5} *M*; □, 9.6×10^{-5} *M*; ▽, 1.15×10^{-4} *M*; +, 2.0×10^{-4} *M*; △, 2.15×10^{-4} *M*; and ◇, $3 \times 10^{-4}\ M < [\text{TNM}] < 3 \times 10^{-3}$ *M*. The solid line is calculated from [24] using $G(e_s^-)_0 = 1.38$.

$$[24]\quad [G(NF^-)]^{Ar}_{C_6H_5NO_2} = [G(NF^-)]^{Ar} - \left\{\frac{G(e_s^-)_0 k_1[C_6H_5NO_2]}{k_1[C_6H_5NO_2] + k_{22}[TNM]}\right\}$$

$[G(NF^-)]^{Ar}$ and $[G(NF^-)]^{Ar}_{C_6H_5NO_2}$ are the yields of NF^- in the absence and presence of nitrobenzene. The best value of $G(e_s^-)_0$ to fit the observed data for solutions with $[C_6H_5NO_2] \leq 1 \times 10^{-3}$ *M* is $G(e_s^-)_0 = 1.38 \pm 0.13$. Yields of NF^- calculated with this value in [24] are shown as the solid line in Fig. 5.

When the concentration of nitrobenzene is greater than 10^{-3} *M* $[G(NF^-)]^{Ar}_{C_6H_5NO_2}$ drops below the value predicted from [24] since nitrobenzene intercepts e_s^- inside spurs which would otherwise react with H^+ forming $\cdot CH_2OH$ by reactions 25 and 3.

$$[25]\qquad e_s^- + H^+ \rightarrow H\cdot$$

The absorption at 300 nm, which was corrected for the small NF^- absorption, exhibited a fast initial growth due to formation of NB^- by reaction 1 followed by a decay which was faster than found in the absence of TNM. The absence of a corresponding growth at 355 nm demonstrates that NB^- does not rapidly transfer an electron to TNM. The initial decay of NB^- may be due to reaction 26 involving nitrogen dioxide formed in reactions 22 and 23 since the electron affinities of NO_2 and $C_6H_5NO_2$, 3.10 and 0.51 eV, respectively (25), indicate that this process is energetically favoured.

$$[26]\quad NO_2 + C_6H_5NO_2^{\cdot -} \rightarrow NO_2^- + C_6H_5NO_2$$

C. Nitrous Oxide Solutions: Extinction Coefficients of $\cdot CH_2OH$ and $\cdot CH_2O^-$

The rate of reaction between e_s^- and N_2O (reaction 5*a*) was measured by following the kinetics of decay of e_s^- absorption at 630 nm following a pulse to solutions with $4 \times 10^{-4} \leq [N_2O] \leq 5 \times 10^{-3}$ *M*. The observed first order rate constants were independent of dose at each concentration of N_2O and from the variation of these rate constants with $[N_2O]$ we find $k_{5a} = (1.32 \pm 0.17) \times 10^{10}\ M^{-1}\ s^{-1}$. This value is in good agreement with those determined by Dainton *et al.* (19) and Seki and Imamura 6, 26).

The absorption spectra produced by 5–7.5 krad, 0.2 μs pulses in N_2O saturated neutral and basic ($[CH_3ONa] = 0.087$ *M*) solutions resembled those previously assigned to $\cdot CH_2OH$ and $\cdot CH_2O^-$ (19, 27) and are shown in Fig. 6. Extinction coefficients, calculated for these species using the radical yield $[G(R\cdot)]_N^{N_2O} = 6.45 \pm 0.05$ (1), are shown on the right hand ordinate of Fig. 6. In the calculation of $\varepsilon(\cdot CH_2O^-)_\lambda$, allowance was made for the incomplete dissociation of $\cdot CH_2OH$ to $\cdot CH_2O^-$ according to equilibrium 6.

The rate constant, $2k_{10}$, for disappearance of $\cdot CH_2OH$ in neutral N_2O saturated solution was determined at wavelengths from 250–320 nm from the values for $2k_{10}/\varepsilon(\cdot CH_2OH)_\lambda$ at each wavelength and the extinction coefficients taken from Fig. 6. The resultant $2k_{10}$ values were independent of wavelength within experimental error giving $2k_{10} = (2.89 \pm 0.05) \times 10^9\ M^{-1}\ s^{-1}$.

D. Argon Saturated Solutions: The Extinction Coefficient of e_s^-

The absorption spectrum produced at the end of a 0.2 μs, 5 krad pulse in neutral Ar saturated methanol is composed of contributions from e_s^- and $\cdot CH_2OH$. The absorption at $\lambda > 380$ nm due to e_s^- decayed rapidly and after 10 μs the spectrum in Ar saturated solution was normalizable to that of $\cdot CH_2OH$. At the doses

used e_s^- disappears predominantly by reaction

[27] $e_s^- + CH_3OH \rightarrow CH_3O^- + H^\cdot$

with either H^+ or methanol (reactions 25 and 27). In each case $^\cdot CH_2OH$ is formed by the rapid reaction of $H^\cdot$ with methanol (reaction 3). Therefore after complete decay of e_s^- the spectra should differ only according to the total yields of radicals which escape from the spurs in Ar and N_2O saturated solutions. In Ar saturated solutions the initial absorption at wavelength λ corrected graphically for decay during the pulse, $[G\varepsilon]_{N,\lambda}^{Ar}$, is composed of contributions from both e_s^- and $^\cdot CH_2OH$ and is given by [28].

[28] $$[G\varepsilon]_{N,\lambda}^{Ar} = G(e_s^-)_0\varepsilon(e_s^-)_\lambda + [G(^\cdot CH_2OH)]_N^{Ar}\,\varepsilon(^\cdot CH_2OH)_\lambda$$

Equation 32, for $\varepsilon(e_s^-)_\lambda$, is derived from [28]–[31].

[29] $$G(e_s^-)_0 + [G(^\cdot CH_2OH)]_N^{Ar} = [G(R^\cdot)]_N^{Ar}$$

[30] $$[G(^\cdot CH_2OH)]_N^{N_2O} = [G(R^\cdot)]_N^{N_2O}$$

[31] $$[G\varepsilon]_{N,\lambda}^{N_2O} = [G(^\cdot CH_2OH)]_N^{N_2O}\,\varepsilon(^\cdot CH_2OH)_\lambda$$

[32] $$\varepsilon(e_s^-)_\lambda = \frac{[G\varepsilon]_{N,\lambda}^{Ar} - \{[G(R^\cdot)]_N^{Ar} - G(e_s^-)_0\}[G\varepsilon]_{N,\lambda}^{N_2O}/[G(R^\cdot)]_\lambda^{N_2O}}{G(e_s^-)_0}$$

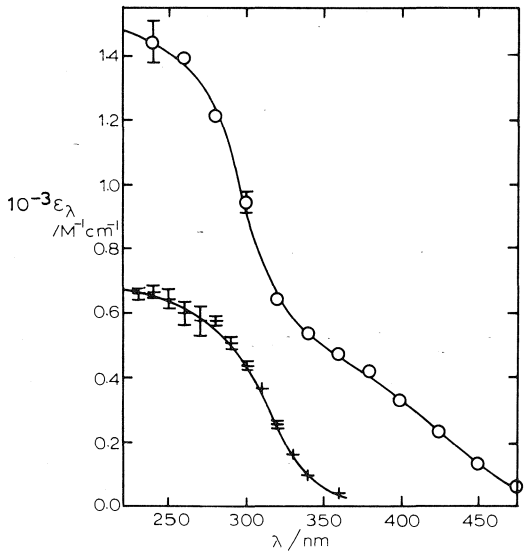

FIG. 6. Spectra of $^\cdot CH_2OH$ (+) and $^\cdot CH_2O^-$ (○) produced by 3.5–5 krad, 0.2 μs pulses of N_2O saturated solutions. +, neutral solution; ○, $[CH_3ONa] = 8.67 \times 10^{-2}$ *M*.

Values for $\varepsilon(e_s^-)_\lambda$ between 240 and 360 nm calculated using $G(e_s^-)_0 = 1.20 \pm 0.03$, $[G(R^\cdot)]_N^{Ar} = 5.63 \pm 0.05$, and $[G(R^\cdot)]_N^{N_2O} = 6.45 \pm 0.05$ are shown in Fig. 7.

Similar results were obtained in solutions containing 2.0×10^{-1} *M* CH_3ONa. Equations similar to those for neutral methanol were used to evaluate $\varepsilon(e_s^-)_\lambda$ except that $Z_cG(e_s^-)_0$ was used instead of $G(e_s^-)_0$. The values so obtained, which are also shown in Fig. 7, are slightly larger than those obtained in neutral solution. Large errors are expected for values of $\varepsilon(e_s^-)_\lambda$ computed from data for basic solutions since, especially at low wavelengths, $\varepsilon(^\cdot CH_2O^-)_\lambda \gg \varepsilon(e_s^-)_\lambda$.

The spectrum of e_s^- in neutral solution at wavelengths where $^\cdot CH_2OH$ does not absorb is in good agreement with previous determinations (10, 28, 29). The overall spectrum is shown in Fig. 7. The spectrum was extended to 850 nm

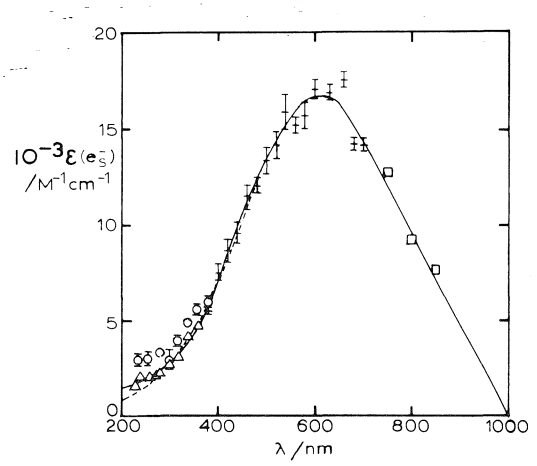

FIG. 7. Spectrum of e_s^- in neutral methanol: +, direct observation of absorption of e_s^-; △, calculated from [29] for neutral solutions; ○, calculated from [29] for solutions containing 8.7×10^{-2} *M* CH_3ONa; □, from ref. 29 normalized to 630 nm. The solid line (—) which is the best curve through the data is used for calculation of *f* (see text) and the broken line (---) a Lorentzian curve, normalized at 630 nm.

using data from ref. 29 and to longer wavelengths by graphical extrapolation. Jou and Dorfman (30) have shown that the high energy side of the spectra of e_s^- in a large number of solvents conform to Lorentzian curves. The broken line in Fig. 7 is the Lorentzian curve which fits best the data for methanol and is given by [33]. The oscillator strength of e_s^- is given by [34] (31) where $\bar{\nu}$ is in units of cm^{-1} and n_0 is the refractive index.

$$[33] \quad \varepsilon(e_s^-)_\lambda = \frac{\varepsilon(e_s^-)_{\lambda_{max}}}{1.82 \times 10^{-8}(\bar{\nu} - \bar{\nu}_{\lambda_{max}})^2 + 1}$$

$$[34] \quad f = 4.32 \times 10^{-9}[9n_0/(n_0^2 + 2)^2] \int_{\bar{\nu}_1}^{\nu_2} \varepsilon(\bar{\nu})\, d\bar{\nu}$$

A value of $f = 0.86$ was calculated from the solid line in Fig. 7, extrapolated to 200 nm, and $f = 0.90$ from the solid line at $\lambda > 630$ nm and the Lorentzian curve (to $\bar{\nu} = \infty\ cm^{-1}$) at $\lambda < 630$ nm. These values are larger than those calculated in refs. 10 and 28. In the former case $\varepsilon(e_s^-)$ at λ_{max} is similar to that obtained in this work, the higher value for f being due to the difference in shape of the spectrum at low wavelength. Any inaccuracy in the graphical extrapolation at long wavelengths will have little effect on f.

Discussion

(A) Validity of the Assumption that $[G(R^\bullet)]_N^{Ar} = [G(R^\bullet)]_B^{Ar}$

In the Results section the assumption was made that $[G(R^\bullet)]^{Ar}$ is identical in neutral and basic solutions as measured by TNM and nitrobenzene, respectively. This premise is central to our estimation of $\varepsilon(NB^-)_\lambda$ and hence $G(e_s^-)_0$. Figure 3 shows that within experimental error the yield of NB^- conforms to that expected for a constant $[G(R^\bullet)]^{Ar}$ in basic solutions with $[CH_3ONa] \geq 1.36 \times 10^{-4}$ *M*. Unfortunately the calculation of the yields of NB^- for solutions with $[CH_3ONa] = 1.36 \times 10^{-4}$ *M* is subject to large error due to their considerable dependence on the value chosen for K_6 and hence this data cannot be used to confirm the constancy of $[G(R^\bullet)]^{Ar}$ at $[CH_3ONa] < 1$ m*M*.

Further confirmation of this assumption can be drawn from the constancy of the glycol yield, which reflects the yield of radicals, between neutral and basic solutions with $[CH_3ONa] =$ 0.01 to 0.1 *M* (2, 32). It was proposed in an earlier paper (1) that the discrepancy between $[G(R^\bullet)]^{Ar}$ and $2G$(glycol) was due to the low reactivity of methyl radicals, $^\bullet CH_3$ (33), towards methanol (reaction 35) and TNM and their inability to react with TNM to form NF^-. The same arguments may be applied to the reaction

$$[35] \quad {}^\bullet CH_3 + CH_3OH \rightarrow CH_4 + {}^\bullet CH_2OH$$

of $^\bullet CH_3$ with nitrobenzene. This reaction is expected to be significantly slower than that of $^\bullet CH_2OH$ with nitrobenzene and hence can be ignored under the experimental conditions applied in this work.

The major effect of added base is to scavenge H^+ and hence to prevent geminate recombination reactions which convert e_s^- to $^\bullet CH_2OH$ (reactions 25 and 3); thus, the yield of e_s^- is increased at the expense of that of $^\bullet CH_2OH$ (11, 34, 35). This will only have an observable effect on the overall radical yield if the reactivities of e_s^- and $^\bullet CH_2OH$ in their radical–radical reactions differ. Except at the highest base concentrations it seems unlikely that the change in the overall yield of radicals escaping the spurs will be significant.

Hamill and co-workers (36–38) have proposed that base can scavenge the positive 'hole', ROH^+ (reaction 36), before this entity is stabilised by reaction with the solvent (reaction 37). The occurrence of reaction 36 may also prevent the recombination of presolvated, *i.e.* dry electrons, e^-, with ROH^+ (reaction 38) and

$$[36] \quad ROH^+ + RO^- \rightarrow ROH + RO^\bullet$$

$$[37] \quad ROH^+ + ROH \rightarrow ROH_2^+ + RO^\bullet$$

hence lead to an increase in the total radical yield. However the increase in $G(e_s^-)$ is small at

$$[38] \quad e^- + ROH^+ \rightarrow ROH$$

base concentrations where positive 'hole' scavenging is likely to be important (34) so this effect may be ignored for the base concentrations employed in this work.

(B) A Model for the Radiolysis of Methanol

Four methods have been employed to measure electron yields in methanol, namely, (*i*) the determination of the effects of solutes on the yield of hydrogen obtained by γ-irradiation (2–5), (*ii*) the measurement of the yields of species produced by dissociative electron capture by a solute (6–9), (*iii*) the determination by pulse radiolysis of $G\varepsilon$ values for radical anions produced by electron attachment to solutes (10–12),

and (*iv*) the observation of rapid conductivity changes induced by short pulses of radiation (13, 14). Following the formulation of the model by Freeman and Fayadh (39) it has become customary to associate the values given by each of the above methods with $G(e_s^-)_{fi}$, the yield of solvated electrons which escape geminate recombination. However, the disparity between the resultant values ($G(e_s^-)_{fi} = 1.0$–2.0) indicates the unsatisfactory nature of either the experimental methods employed, or the premise which suggests that each method yields $G(e_s^-)_{fi}$. We believe the latter to be the case and that the model of Freeman and Fayadh (39) is inapplicable to liquid methanol.

The probability, $P(r)$, that an electron thermalised at distance r from its counterion will escape geminate recombination with its partner is given by [39] (40),

$$[39] \qquad P(r) = e^{-r_c/r}$$

where $r_c = e^2/\varepsilon kT$, e is the electronic charge, ε the dielectric constant, k the Boltzmann constant, and T the absolute temperature. The value for r_c is dependent on the time dependence of the dielectric constant which is a function of the relaxation time of the solvent. However at times >5 ps the ordinary low frequency dielectric constant applies (41) giving $r_c = 1.7$ nm. The initial radius of a spur has been estimated as 2.3 nm (42) and is assumed to expand with time. Kevan and Chen (43) have measured a spur radius of 5.9 nm in glassy methanol at 77 K. Allowing for the greater thermalisation distances at 77 K compared to room temperature the expected spur radius is still greater than 4.0 nm so that there will be a considerable yield of e_s^- within regions of high radical concentration which do not recombine with geminate positive ions. It is proposed that these be defined as free solvated electrons, $(e_s^-)_{fi}$, whereas those combining geminately in the absence of radical–radical reactions be termed geminate solvated electrons, $(e_s^-)_{gi}$. A proportion of $G(e_s^-)_{fi}$ are expected to undergo reactions with other radicals (42, 44) and the remainder to escape into the bulk of the solution and to become homogeneously distributed. The latter category will be called 'escaped' solvated electrons, with a yield $G(e_s^-)_{esc}$, whereas the total number of electrons that undergo reactions in spurs (both geminate and free) will be termed 'spur' solvated electrons, $(e_s^-)_{spur}$. Hence, [40] applies and $G_{Tot} > G_{fi} > G_{esc}$.

$$[40] \qquad G_{Tot} = G(e_s^-)_{gi} + G(e_s^-)_{fi} = G(e_s^-)_{esc} + G(e_s^-)_{spur}$$

The existence of absorptions in the infrared region has recently been demonstrated for methanol (45) and other alcohols (45, 46). These absorptions have been assigned to partially solvated electrons. It seems necessary, therefore, to define two further types of electrons, the 'dry' electron, (e^-), and partially solvated 'damp' electron, e_{damp}^- (46). The lifetime of the former has been estimated to be about 10^{-15} s (47), *i.e.* the time taken for e^- to be thermalised, when it becomes trapped in the form e_{damp}^-. If trapping is immediate upon thermalisation it seems unlikely that e^- will participate significantly in reactions with solutes. The reactivity of e_{damp}^- with a large number of solutes has been shown to be parallel to, but greater than, that of e_s^- (45).

The total yield of fully solvated electrons at 30 ps has been measured by Lam and Hunt (48) as $G(e_s^-)_{30\ ps} = 2.0$ (based on the extinction coefficient obtained in this work). This was measured relative to $G(e_{aq}^-)_{30\ ps} = 4.0$ at 30 ps. However the stroboscopic pulse radiolysis technique does not lend itself to the accurate determination of absolute yields. Jonah *et al.* (49), using a single pulse technique enabling the observation of decays of species from 100 ps to several ns when dosimetry becomes very easy, have recently determined $G(e_{aq}^-) = 4.6$ at 100 ps. Since e_{aq}^- does not decay significantly over 300 ps (48) this value may be used for $G(e_{aq}^-)_{30\ ps}$ giving $G(e_s^-)_{30\ ps} = 2.3$ in methanol. Jha and Freeman (7) and Janovský (11) have measured scavengeable electron yields of at least 4.6 in methanol. Thus, there is a yield of electrons with $G \geq 2.3$ which do not become solvated and which presumably recombine geminately either in the form of e^- or e_{damp}^-.

(C) Comparison of the Model with Experiment

(I) Pulsed Conductivity Experiments

Fowles (13) and Busi and Ward (14) have determined $G(e_s^-)_{fi} = 2.0$ by observation of the conductivity change following a pulse of high energy radiation. Fowles concluded that the ionic conductances of e_s^- and CH_3O^- are identical so that the technique is not capable of differentiation between these species. Hence reactions of e_s^- with itself, $CH_3O^{\bullet}$, and $^{\bullet}CH_2OH$, which are known to occur in methanol (44, 50)

[41] $2e_s^- + 2CH_3OH \rightarrow 2CH_3O^- + H_2$

[42] $e_s^- + CH_3O^{\cdot} \rightarrow CH_3O^-$

[43] $e_s^- + {}^{\cdot}CH_2OH \rightarrow CH_3O^-$

to yield CH_3O^-, are not detected by this method. The method, therefore, possibly provides a measure of $G(e_s^-)_{fi}$ but not $G(e_s^-)_{esc}$. However, in the N_2O saturated solutions scavenging of dry electrons by N_2O may be expected to increase the yield of free ions, which would invalidate Fowles's conclusions.

(II) Radical-anion Formation

The reaction of e_s^- with a solute to form a radical anion may be represented by reaction 44. The yield of $X^{\cdot-}$ observed by microsecond pulse radiolysis depends on whether e_s^- originates from the $(e_s^-)_{spur}$

[44] $X + e_s^- \rightarrow X^{\cdot-}$

or $(e_s^-)_{esc}$ population. In the former case $X^{\cdot-}$ is protonated rapidly due to the high concentration of H^+ formed in spurs. This is demonstrated by the rapid decay over about 50 ns of the biphenyl anion, $C_{12}H_{10}^{\cdot-}$, absorption to a steady value (23). In contrast $X^{\cdot-}$ formed from $(e_s^-)_{esc}$ protonates by reaction with solvent or homogeneously distributed H^+ over a few μs and $G(X^{\cdot-})$ is therefore readily measurable by ns or μs pulse radiolysis. Thus the observed $G(X^{\cdot-})$ is equal to $G(e_s^-)_{esc}$ and is constant over a large concentration range of X (10, 11). Direct observation of the slowly decaying absorption of e_s^- yields $G(e_s^-)_{esc}\ \varepsilon(e_s^-)_\lambda$. Providing $\varepsilon(X^{\cdot-})_\lambda$ is known, $G(e_s^-)_{esc}$ and hence $\varepsilon(e_s^-)_\lambda$ may be calculated. Since $X^{\cdot-}$ can only be prepared by chemical methods in aprotic solvents, it has proved impossible to measure $\varepsilon(X^{\cdot-})_\lambda$ in methanol. In previous studies (10–12) $\varepsilon(X^{\cdot-})_\lambda$ has been assumed to be invariant from solvent to solvent. In this work $\varepsilon(NB^-)$ has been determined without recourse to this assumption. The agreement of the present result with those using biphenyl (10, 11) and pyrene (12) indicates that in these cases the values of $\varepsilon(X^{\cdot-})_\lambda$ do not change significantly in going from aprotic solvents (usually THF) to methanol.

(III) Dissociative Electron Capture and Reduction in Hydrogen Yields

Dissociative electron capture by N_2O (6, 7), SF_6 (8), and CH_3Br (8) has been employed to measure electron yields in γ-irradiated methanol while benzyl chloride has been used similarly in pulse radiolysis studies (9, 11). The reactions involved are of the general form of reaction 45 irrespective of whether the electrons reacting are

[45] $AB + e^- \rightarrow A^- + B^{\cdot}$

dry, damp, or solvated. More importantly, since the process is dissociative, an observable product results irrespective of whether the electrons are geminate, free, or escaped. Consequently the yield of product from reaction 45 varies continuously with [AB] and separation of the electron yield into its various components can only be achieved with prior knowledge of the reactivity and life-time distribution of each component. The effect of solutes such as nitrobenzene (5) in reducing the hydrogen yield is thought to be due to the scavenging of electrons and the interpretation of the data is therefore subject to the same complications. Jha and Freeman (5, 7) and Rzad and Fendler (8) have applied simplified treatments to their data. They have made the assumption that all geminate electrons recombine with H^+ and that free electrons all diffuse into the bulk solution and decay by a first order process. Freeman and Bolton (51) have since modified their treatment to allow for the scavenging of dry electron by the solute, but have not taken into account reaction of e_s^- with radicals. Furthermore if $\varepsilon(e_s^-)_{\lambda_{max}}$ has the value determined in the present work, it is necessary to take into account that only 50% of electrons become solvated.

We therefore propose a model which we believe to be consistent with all the known experimental observations and which, in view of the simplifications involved, provides as good a fit as can be expected to the measured yields.

The initial yield of e^- is set as $G(e^-) = 4.6$, *i.e.* equal to the maximum yield observed with high concentrations of N_2O (7). In the absence of a solute a yield, $G(e_s^-) = 2.3$ becomes solvated. It is assumed that once e^- are thermalised they can become trapped either as e_{damp}^- or e_s^-. The e_{damp}^- can undergo geminate recombination possibly by thermal excitation to the dry state. Thus the diffusion coefficient applicable to the geminate recombination is governed by the existence of shallow traps (e_{damp}^-) as is the case in hydrocarbons (52). Thus the competition between recombination (reaction 46) and solvation (reaction 47) can be expected to conform to the kinetics applied by Warman *et al.* (53) to

[46] $e^- + ROH(H)^+ \rightarrow$ Products

[47] $$e^- \rightarrow e_s^-$$

low polarity solvents. The yield of solvated electrons is given by [48]

[48] $$G(e_s^-) = G(e^-)\left(\frac{(\alpha_t)^{1/2}}{1 + (\alpha_t)^{1/2}}\right)$$

where α_t is a parameter which measures the solvation efficiency. A value for $\alpha_t = 1.0$ may be calculated from $G(e^-) = 4.6$ and $G(e_s^-) = 2.3$.

In the presence of a solute the additional reaction 49 must be considered. The yield of product, P, is then given by [50] (54)

[49] $$e^- + S \rightarrow P$$

[50] $$G(P) = G(e^-)\left\{\frac{(\alpha_t + \alpha_s[S])^{1/2}}{1 + (\alpha_t + \alpha_s[S])^{1/2}}\right\} \times \left\{\frac{\alpha_s[S]}{\alpha_s[S] + \alpha_t}\right\}$$

where α_s is the efficiency of reaction of e^- with S. The yield of e_s^- may be calculated from the corresponding equation for solvation. The assumption is made that the yield of $G(e_s^-)$ is divided into $G(e_s^-)_{spur}$ and $G(e_s^-)_{esc}$ in the same proportion as is observed in the absence of solute (*i.e.* 1.1:1.2). This approximation is not strictly valid since the electrons which travel further from the positive ion before trapping are more likely to be scavenged and also more likely to become part of the $G(e_s^-)_{esc}$ population in the absence of a solute. However, calculations show that the change in the ratio only becomes significant at values of $\alpha_s[S] > 1$ when the yield of electrons which become solvated is in any case much reduced by reaction of dry electrons with the solute (23). The rate constant for the decay of $G(e_s^-)_{esc}$ by reaction with solvent is $k_{21} = 2.2 \times 10^5\ s^{-1}$ in low dose rate γ-radiolysis experiments and is dependent on the dose rate (see section A.*II.*(*b*)) in pulse radiolysis experiments. The yield of product, P, from reaction of $(e_s^-)_{esc}$ with S (reaction 51) is given by [52].

[51] $$e_s^- + S \rightarrow P$$

[52] $$G(P) = G(e_s^-)_{esc}\left(\frac{k_{51}[S]}{k_{51}[S] + k_{21}}\right)$$

The spur decay of e_s^- has been shown both in water (49) and low temperature liquid methanol (55) to conform to [53] after an initial period, t_0, in which little decay is observed. Lam and Hunt (48) have observed that t_0 is about 350 ps for liquid methanol. Values for a and b may be determined from $G(e_s^-) = 2.3$ at t_0 and 1.65 at 7 ns (29) calculated using $\varepsilon(e_s^-)$ determined in this work.

[53] $$G(e_s^-)_{spur} = -a \log t + b$$

Thus, the rate equations for the disappearance of $(e_s^-)_{spur}$ and the formation of product are given by [54] and [55], which were integrated numerically to obtain the yield of product,

[54] $$\frac{dG(e_s^-)_{spur}}{dt} = -\frac{a}{t} - k_{51}[S]G(e_s^-)_{spur}$$

[55] $$\frac{dG(P)}{dt} = k_{51}[S]G(e_s^-)_{spur}$$

The sum of the product yields from each electron component may thus be determined. The total product yield $G(P)_{tot}$ is compared with experimental results and the one adjustable parameter α_s varied to give the best agreement between

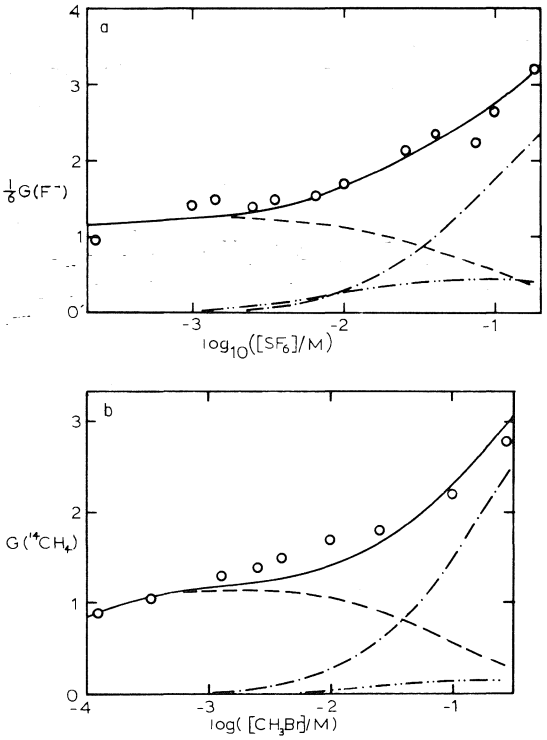

FIG. 8. Comparison between the observed dependence of product yield on solute concentration and that calculated from the model (see discussion). ○, observed data from ref. 8; —, calculated yield. Components of $G(P)$ from the various electron populations: ---, $G(P)_{esc}$ (from $(e_s^-)_{esc}$); -·-·-·-, $G(P)_{spur}$; ·····, $G(P)_{damp}$. (*a*) Sulphur hexafluoride, (*b*) methyl bromide.

TABLE 3. Values of α_s determined for dry electron reactions in methanol. Comparison with values for electron scavenging in hydrocarbons

Solute	In methanol		In cyclohexane	
	α_s (M^{-1})	Reference for scavenging data	α_s (M^{-1})	Reference
Benzyl chloride	100	9, 11, 23	39.5	57
Biphenyl	17	23	15	58
Methyl bromide	10.2	8	15.4	59
Nitrous oxide	82	7	19±2	57
Sulphur hexafluoride	17	8	6.8	60*

*Calculated from data in ref. 60.

theory and experiment. This calculation has been performed for scavenging results obtained for a number of solutes. In the case of biphenyl, the yields of $C_{12}H_{11}^{\bullet}$ measured (23) after protonation of $C_{12}H_{10}^{\bullet-}$ was complete, were used for the calculation. Data at $[S] > 3 \times 10^{-1}$ M were neglected in order to reduce any errors introduced by direct radiolysis of the solute. No allowance for encounter pair formation (56) was made since at the solute concentrations where they become important, scavenging of e_s^- is almost complete. The experimental and calculated scavenging dependences compare very well except for nitrous oxide. Figure 8 shows the results of these calculations for sulphur hexafluoride and methyl bromide. Values for α_s are listed in Table 3 where comparison is also made with the values obtained in the low polarity solvent cyclohexane where these are available. The treatment discussed here is semi-empirical but it serves to illustrate the essential features of the model.
