The reactions of K_2PtCl_4 with pyridine derivatives L (L = py = pyridine, pic = picoline, and lut = lutidine) were studied in dimethylformamide (DMF).

$$K_2PtCl_4 \xrightarrow[L]{-KCl} K[Pt(L)Cl_3] \xrightarrow[L]{-KCl} \textit{cis}\text{-}[Pt(L)_2Cl_2] \xrightarrow{L} \textit{trans}\text{-}[Pt(L)_2Cl_2]$$

1 **2** **3**

The complexes (**1**) were isolated and the yield decreased with the order, 2,4-lut = 2-pic > 2,6-lut > 4-pic = py, which can be correlated to the steric hindrance of the *ortho* methyl groups. The compounds (**2**) can be converted to the compounds (**3**), the free ligand acting as catalyst and (**3**) is the final product of the above reactions. The compounds (**3**) can also be obtained from a DMF solution of $[Pt(L)_4]Cl_2$ (L = py) at room temperature. A comparison of the above reactions in water and in DMF was also made.

PI-CHANG KONG et F. D. ROCHON. Can. J. Chem. **56**, 441 (1978).

Les réactions entre K_2PtCl_4 et des dérivés de la pyridine L (L = py = pyridine, pic = picoline et lut = lutidine) ont été étudiées en milieu diméthylformamide (DMF).

$$K_2PtCl_4 \xrightarrow[L]{-KCl} K[Pt(L)Cl_3] \xrightarrow[L]{-KCl} \textit{cis}\text{-}[Pt(L)_2Cl_2] \xrightarrow{L} \textit{trans}\text{-}[Pt(L)_2Cl_2]$$

1 **2** **3**

Les complexes (**1**) ont été isolés et les rendements diminuent dans l'ordre, lut-2,4 = pic-2 > lut-2,6 > pic-4 = py. L'ordre peut être relié à l'encombrement stérique des groupements méthyles en position *ortho*. Les complexes *cis* (**2**) peuvent être convertis en (**3**), le ligand agissant comme catalyseur. (**3**) est le produit final des réactions mentionnées ci-haut. $[Pt(L)_4]Cl_2$ (L = py) en solution DMF à la température ambiante se décompose pour donner également (**3**). Une comparaison entre les réactions dans l'eau et dans le DMF a été faite.

Introduction

The recent chemotherapic results of platinum compounds are very promising, and compounds with high antitumour activity, low toxicity, and better solubility in the solvents used for dissolving drugs are being sought by investigators (1). So far, most compounds tested are of the type *cis*-$[Pt(am)_2Cl_2]$ and *cis*-$[Pt(py)_2Cl_2]$ (2, 3) (am = amine, py = pyridine) with two identical neutral ligands, since they can easily be prepared from the direct reaction between K_2PtCl_4 and the base in water. If compounds with two different neutral ligands such as *cis*-$[Pt(am)(am')Cl_2]$, *cis*-$[Pt(py)(py')Cl_2]$ and *cis*-$[Pt(py)(am)Cl_2]$ (am ≠ am' and py ≠ py') could be systematically synthesized, the screening range of platinum complexes could be largely extended and antitumour activity, toxicity, and solubility could be significantly modified.

In order to prepare such complexes, one has to use $K[Pt(am)Cl_3]$ or $K[Pt(py)Cl_3]$ as a starting material and react it with another kind of amine or pyridine. However, these two compounds are not easily prepared. Although $K[Pt(NH_3)Cl_3]$ (4) and $K[Pt(py)Cl_3]$ (5) have been known for a long time, the methods used are not suitable for other amine or pyridine derivatives. Recently, Kukushkin *et al.* (6, 7) prepared some alkylamine complexes from $[Pt(DMSO)(am)Cl_2]$ (DMSO = dimethylsulphoxide) through a long process of oxidation, replacement, and reduction.

$$[Pt(DMSO)(am)Cl_2] \xrightarrow{Cl_2} [Pt(DMSO)(am)Cl_4] \xrightarrow[KCl]{HCl} K[Pt(am)Cl_5] \xrightarrow{N_2H_4} K[Pt(am)Cl_3]$$

These complexes were precipitated as $[Pt(NH_3)_4][Pt(am)Cl_3]_2$ because of the difficulty of isolating the potassium salt.

In a recent communication (8) we reported a method for preparing mononucleoside platinum complexes by the direct reaction of K_2PtCl_4 and the nucleoside in dimethylformamide (DMF). This method is also applicable to pyridine analogues. Here we report the isolation and properties of the complexes $K[Pt(L)Cl_3]$ (L = py = pyridine, pic = picoline, and lut = lutidine). The reaction between K_2PtCl_4 and the bases in DMF is also discussed.

Experimental

Microanalyses were done by Chemalytics Inc., Tempe, Arizona, U.S.A. Melting points were measured on a Fischer-Johns apparatus and are uncorrected. Nuclear magnetic resonance spectra were measured on a Perkin-Elmer R-12 spectrometer. Infrared spectra were measured on a Perkin-Elmer 621 grating spectrophotometer.

The platinum salt, K_2PtCl_4, was obtained from Johnson Matthey & Co. Limited. Pyridine, picoline, and lutidine were purchased from Aldrich and Eastman and used without further purification. Dimethylformamide, A.C.S. reagent, was purchased from Anachemia and distilled with BaO, under reduced pressure (9). $[Pt(NH_3)_4]Cl_2$ (10) and $[Pt(py)_4]Cl_2$ (11) were prepared according to the already published methods. All the complexes were dried at 65°C, under vacuum in the presence of P_2O_5.

1. (a) K[Pt(py)Cl$_3$] and (b) [Pt(NH$_3$)$_4$][Pt(py)Cl$_3$]$_2$

K_2PtCl_4 (1.245 g) and pyridine (0.277 g) were mixed in 100 ml of dimethylformamide and heated at 75°C for 3 h. The DMF was then evaporated to dryness under reduced pressure at 40°C and the residue dissolved in a minimum volume of 0.5 *M* HCl solution. The insoluble material (mainly $[Pt(py)_2Cl_2]$) was separated by filtration. (*a*) To the HCl filtrate, KCl was added till saturation and $K[Pt(py)Cl_3]$ precipitated. The precipitate was filtered and dried. It was then dissolved in acetone and filtered to remove KCl and K_2PtCl_4. The acetone filtrate was evaporated to dryness. The solid compound, $K[Pt(py)Cl_3]$, was washed with chloroform and collected by filtration. Yield 35%. (*b*) To the HCl filtrate, an excess of $[Pt(NH_3)_4]Cl_2$ was added. The precipitate consisting of $[Pt(NH_3)_4][Pt(py)Cl_3]_2$ and $[Pt(NH_3)_4][PtCl_4]$ was filtered, dried, and dissolved in DMF. $[Pt(NH_3)_4][PtCl_4]$, being insoluble in DMF, was filtered off. The DMF filtrate of $[Pt(NH_3)_4][Pt(py)Cl_3]_2$ was evaporated to dryness, and the yellow product was washed with chloroform and collected by filtration. Yield 30%.

2. (a) K[Pt(4-pic)Cl$_3$] and (b) [Pt(NH$_3$)$_4$][Pt(4-pic)Cl$_3$]$_2$

K_2PtCl_4 (1.245 g) and 4-picoline (0.326 g) were mixed in 100 ml of DMF and heated at 75°C for 3 h. The DMF was then evaporated to dryness under reduced pressure at 40°C and the residue was washed with ether and dried. It was then dissolved in a minimum volume of 0.5 *M* HCl solution and the insoluble material (mainly $[Pt(4\text{-pic})_2Cl_2]$) was separated out by filtration. (*a*) To the HCl filtrate, KCl was added till saturation and $K[Pt(4\text{-pic})Cl_3]$ was precipitated. The precipitate was filtered, washed with a saturated aqueous solution of KCl, and dried. $K[Pt(4\text{-pic})Cl_3]$ was dissolved in a minimum amount of DMF and separated from KCl by filtration. $K[Pt(4\text{-pic})Cl_3]$ was precipitated by adding the DMF filtrate to 100 ml of a mixture of acetone (20 ml) and ether (80 ml). The compound was filtered and washed with chloroform. Yield: 40%. (*b*) Same as in section 1(*b*). Yield: 35%.

3. (a) K[Pt(2, 6-lut)Cl$_3$] and (b) [Pt(NH$_3$)$_4$][Pt(2, 6-lut)Cl$_3$]$_2$

K_2PtCl_4 (0.83 g) and 2,6-lutidine (0.214 g) were mixed in 75 ml of DMF and heated at 65°C overnight. The DMF was then evaporated to dryness and the solid residue washed with ether. It was then dissolved in a minimum volume of 0.5 *M* HCl solution and the insoluble black material removed by filtration. (*a*) Same as in section 2(*a*). Yield: 60%. (*b*) Same as in section 1(*b*). Yield: 50%.

4. K[Pt(2-pic)Cl$_3$] and K[Pt(2,4-lut)Cl$_3$]

K_2PtCl_4 (1.245 g) and 2-picoline (0.290 g) (or 0.340 g of 2,4-lutidine) were mixed in 75 ml of DMF at 80°C for 3 h. The DMF was then evaporated to dryness and the crude product was washed with ether and dried. $K[Pt(2\text{-pic})Cl_3]$ (or $K[Pt(2,4\text{-lut})Cl_3]$) was dissolved in acetone and separated from KCl and K_2PtCl_4 by filtration. The acetone filtrate was evaporated to dryness, and the yellow product was washed with chloroform and collected by filtration. Yield: 83% (2,4-lut, yield: 90%).

Results and Discussion

All the complexes are yellow and decompose on heating. Their analytical data and decomposing points are listed in Table 1. They are all insoluble in chloroform and the complexes of py, 2-pic, and 2,4-lut are soluble in acetone. $[Pt(NH_3)_4][Pt(L)Cl_3]_2$ can be formed as a precipitate when $K[Pt(L)Cl_3]$ (L = py, 4-pic, and 2,6-lut) reacts with $[Pt(NH_3)_4]Cl_2$ in acidic solution.

The complexes are stable in hydrochloric acid solution and can be gradually dissolved in potassium hydroxide solution. The KOH solutions are light yellow. When an excess HCl is added to a fresh KOH solution of a complex, the solution becomes darker yellow and the complex can be recovered by evaporating the solution.

In a few hours, all the complexes $K[Pt(L)Cl_3]$, except when L = 2,6-lut, form *cis*-$[Pt(L)_2Cl_2]$ with L in aqueous solution. The aqueous solution of $K[Pt(2,6\text{-lut})Cl_3]$ and 2,6-lut only becomes turbid, even on standing for two days, and no *cis*-$[Pt(2,6\text{-lut})_2Cl_2]$ can be isolated. The typical method to prepare *cis*-$[Pt(L)_2Cl_2]$ is to isolate the precipitate from the aqueous solution of K_2PtCl_4 and L. Again, *cis*-$[Pt(2,6\text{-lut})_2Cl_2]$ cannot be prepared by this method, since the solution of K_2PtCl_4 and 2,6-lut becomes black in 3 h and no yellow precipitate appears.

From a perchloric acid solution of $K[Pt(L)Cl_3]$, $KClO_4$ crystallizes out, and $[Pt(L)Cl_2]_2$, a dimer, can be isolated by evaporating the solution. When $K[Pt(L)Cl_3]$ is treated with $AgNO_3$ in DMF, $[Pt(L)(DMF)Cl_2]$ can be isolated.

When DMF was evaporated to dryness in the isolation of $K[Pt(py)Cl_3]$ and $K[Pt(4\text{-pic})Cl_3]$, a product soluble in chloroform was found. Upon the

*Calculated value in first row.

evaporation of the chloroform, it became an oily paste which was difficult to crystallize. Its infrared spectrum showed that it contained py and DMF. However, it is not pure $[Pt(py)(DMF)Cl_2]$ which was isolated in our laboratory. It also was soluble in hydrochloric solution and can be converted at least partially to $K[Pt(py)Cl_3]$ in the presence of excess KCl.

From the Experimental section, we know that the yield in the synthesis of $K[Pt(L)Cl_3]$ is in the order:

$$2,4\text{-lut} \sim 2\text{-pic} > 2,6\text{-lut} > 4\text{-pic} \sim \text{py}$$

This order can be correlated to the steric hindrance of the *ortho*-methyl groups. During the preparation of *cis*-$[Pt(pic)_2Cl_2]$, Ivanova (12) found that 2-picoline had more difficulty entering the coordinating sphere of platinum than 3-picoline. In this work, both $K[Pt(L)Cl_3]$ and $[Pt(L)_2Cl_2]$ were isolated and the ligand difficulty in entering the platinum coordinating sphere can be determined by studying the following reactions.

$$[PtCl_4]^{2-} \xrightarrow[-Cl]{L} [Pt(L)Cl_3]^- \xrightarrow[-Cl]{L} \textit{cis}\text{-}[Pt(L)_2Cl_2]$$

Both $K[Pt(2,4\text{-lut})Cl_3]$ and $K[Pt(2\text{-pic})Cl_3]$ were produced in high yields (83–90%) and gave few by-products of $[Pt(L)_2Cl_2]$. This indicated that the second ligand, and not the first one, has difficulty in entering the coordinating sphere of the metal. However, pyridine and 4-picoline have no *ortho*-methyl groups and there is little difficulty in both steps of the above reactions. Formation of $[Pt(L)_2Cl_2]$ is at the expense of $K[Pt(L)Cl_3]$ and that is why the yield of $K[Pt(py)Cl_3]$ and $K[Pt(4\text{-pic})Cl_3]$ is low. Pearson and Muir (13) have found that the rates of the above reactions for $[PtBr_4]^{2-}$ and pyridine are comparable.

As for 2,6-lutidine, the methyl groups slow down even the first step of the above reaction and the formation of $[Pt(2,6\text{-lut})_2Cl_2]$ is almost impossible. $K[Pt(2,6\text{-lut})Cl_3]$, in DMF, decomposes slowly in the presence of 2,6-lut. This probably explains why the yield of $K[Pt(2,6\text{-lut})Cl_3]$ cannot be increased by increasing the reaction time. The steric hindrance from 2,6-lutidine can be further demonstrated by the observation mentioned in a preceding paragraph, i.e. 2,4-lut can form *cis*-$Pt(2,4\text{-lut})_2Cl_2]$ in aqueous solution with K_2PtCl_4 while 2,6-lut cannot.

Some characteristic bands of the infrared spectra of the $K[Pt(L)Cl_3]$ complexes are shown in Table 2. Quite similar to the complexes of $[Pt(L)_2Cl_2]$ (14), most bands of the pyridine ligands in $K[Pt(L)Cl_3]$ shift to a higher frequency region upon coordination. There should be three stretching modes for Pt—Cl bonds, two (sym ν(Pt—Cl) and asy ν(Pt—Cl)) for the bonds *cis* to L and one for the bond *trans* to L. The former two are generally close together in the infrared spectra and less affected by L (15). If L has a higher *trans*-effect the *trans* ν(Pt—Cl) shifts to a lower frequency and is well separated from *cis* ν(Pt—Cl), such as in the case of L = ethylene, phosphine, and carbonyl (15). With a ligand having a low *trans*-effect like pyridine the ν(Pt—Cl) is not expected to be well separated. However, some complexes show a little splitting in the ν(Pt—Cl) stretching, but we believe that it is due to crystal effect rather than to the *trans*-effect.

The chemical shifts in nuclear magnetic resonance of the protons and the coupling constants of the protons with ^{195}Pt are listed in Table 3. The upfield

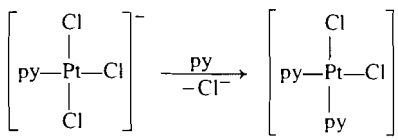
*Spectra of the aromatic protons were taken in 0.4 *M* solution of dimethylacetamide (DMA) by using CH_2Cl_2 at 5.28 ppm as standard and those of the methyl protons were taken in 0.2 *M* solution of D_2O by using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as standard. Chemical shift in δ (ppm) and coupling constant in Hz.
†Because of low solubility, the spectra were taken in 0.1 *M* DMA solution and 0.05 *M* D_2O solution respectively.

spectra were recorded in D_2O, while the downfield spectra were measured in dimethylacetamide. Couplings of both the *ortho* protons and the methyl groups can be observed; the former being larger than the latter.

The by-products, $[Pt(py)_2Cl_2]$ and $[Pt(4\text{-pic})_2Cl_2]$ largely formed in the preparation of $K[Pt(py)Cl_3]$ and $K[Pt(4\text{-pic})Cl_3]$, were found to be a mixture of the *cis* and *trans* isomers. The two isomers can be separated by their different solubility in organic solvents. They can be identified by their infrared spectra in the solid state in the region of 750–780 cm^{-1} and 320–350 cm^{-1}. In these regions the *cis*-isomer has a doublet while the *trans*-isomer has a singlet (14). The *cis*-isomer is a typical product of the reaction



because Cl has a greater *trans*-directing influence than py. The *trans* chlorine atoms destabilize each other and the *cis*-isomer is favored.

The following tests demonstrate the formation of the *trans*-isomer with catalysis of the free pyridine (16).

(*a*) The *cis*-isomer or the *trans*-isomer in DMF overnight at 80°C was found unchanged. Therefore, no isomerization reaction occurs between the *cis*- and the *trans*-isomer in the preparative conditions.

(*b*) The *trans*-isomer in DMF with pyridine at 80°C overnight was found unchanged. Tetra(pyridine)platinum chloride, $[Pt(py)_4]Cl_2$, converted in DMF, even at room temperature, to the *trans*-isomer $[Pt(py)_2Cl_2]$. Therefore, *trans*-$[Pt(py)_2Cl_2]$ is the final product of the reaction between K_2PtCl_4 and pyridine in DMF.

(*c*) *cis*-$[Pt(py)_2Cl_2]$ in DMF with pyridine at 80°C was converted to the *trans*-isomer. The addition of pyridine to the DMF solution of the *cis*-isomer produced no change in conductivity. Therefore, no ionic species are formed in the reaction between the *cis*-isomer and pyridine.

It is interesting to compare the reactions of K_2PtCl_4 and pyridine in water to the reactions in DMF (Scheme 1). (*a*) In water, *cis*-$[Pt(py)_2Cl_2]$ is first formed, which reacts further with pyridine to reach a final product, $[Pt(py)_4]Cl_2$; in DMF, the first formed *cis*-$[Pt(py)_2Cl_2]$ is converted to the *trans*-isomer by the catalysis of free pyridine. (*b*) In water, *trans*-$[Pt(py)_2Cl_2]$ is obtained by prolonged reflux of $[Pt(py)_4]Cl_2$ in concentrated HCl solution; in DMF, $[Pt(py)_4]Cl_2$ is spontaneously converted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

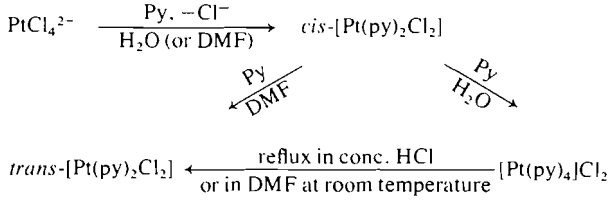

SCHEME 1

to *trans*-$[Pt(py)_2Cl_2]$ at room temperature. A method to prepare *trans*-compounds may therefore be developed by the reaction of K_2PtCl_4 and pyridine in DMF or by dissolving $[Pt(py)_4]Cl_2$ in DMF. This method would be useful to prepare *trans*-compounds of pyridine derivatives with substituent groups sensitive to acids.

Des mesures calorimétriques effectuées sur du chromate(V) de potassium, K_3CrO_4(c), et sur d'autres composés apparents ont permis d'obtenir des enthalpies conduisant à une valeur de $\Delta H_f^0 = -370 \pm 2$ kcal mol^{-1} pour le K_3CrO_4(c) à 298 K.

[Traduit par le journal]

Introduction

There is considerable contemporary interest in production of hydrogen from water by way of thermochemical processes. For example, such processes can be utilized in obtaining maximum useful energy from nuclear reactors (1). There is also potential value in using thermochemical cycles that result in decomposition of water to yield hydrogen in fields where hydrogen may be needed as a chemical reactant, such as in bitumen processing and coal gasification. Proper design and evaluation of possible thermochemical processes must be based on thermodynamic properties of the various chemicals involved in the cycle. We have therefore undertaken the investigations reported here that lead to the enthalpy of formation of K_3CrO_4, which is a promising component of one thermochemical cycle (2) for production of hydrogen from water.

We also note that results of this investigation can contribute to our understanding of the stability of chromium in the 'unusual' 5+ oxidation state.

Experimental

Potassium chromate(V), K_3CrO_4(c), may be prepared by means of any of the following reactions:

[1*a*] $Cr_2O_3 + 6\,KOH \rightleftharpoons 2\,K_3CrO_4 + H_2O + 2\,H_2$ (ref. 3*a*)

[1*b*] $4\,K_2CrO_4 + 4\,KOH \rightleftharpoons 4\,K_3CrO_4 + 2\,H_2O + O_2$ (ref. 3*b*)

[1*c*] $Cr_2O_3 + 4\,K_2CrO_4 + 10\,KOH \rightleftharpoons 6\,K_3CrO_4 + 5\,H_2O$ (ref. 3*a*)

[1]Deceased.

The choice of reaction for synthesis of K_3CrO_4 in Oak Ridge was reaction 1*a* because it readily provided for means of monitoring the course of reaction and yield of desired product. Unlike [1*c*], reaction 1*a* permits unambiguous analysis of product by means of conventional chemical methods. Reaction 1*b* presents the undesirable feature of requiring a large excess (beyond that required by stoichiometry) of KOH.

The experimental procedure in Oak Ridge consisted of heating the reagents, mole ratio of $KOH/Cr_2O_3 \cong 6.2$, to ~850°C in a tall covered cylindrical crucible of gold or platinum, under a flow of ~100 ml min^{-1} of argon until there was no more evolution of hydrogen. A tall crucible was used instead of a boat because the mixture foamed considerably during early stages of the reaction and would have spilled out of a container with low sides. The noble metal crucible was placed inside a quartz tube, which in turn was placed in a larger quartz tube that was provided with the required gas lines. This tube-within-tube arrangement was made necessary by the volatilization of KOH and subsequent reaction of this KOH with quartz that led to cracking of a single tube on cooling and thence exposure of the product to air; our double-tube arrangement made use of the inner tube as a 'getter' for KOH so that the outer tube remained intact on cooling. The exiting gases, a mixture of argon, hydrogen, and water vapor, were passed through a Drierite column and then through a thermal conductivity cell (Gow-Mac Gas Analyzer) that was calibrated for hydrogen in argon. Auxiliary equipment included thermocouples, flow meters, a wet test meter for measuring integrated gas volume, and chart read-outs for temperature and volume percent of hydrogen in exit gas.

The material resulting from the above procedure was ground in a dry box and loaded into a covered noble metal boat for further heating at ~850°C. After preliminary analysis of this material, an appropriate amount of KOH was added and the mixture subjected to final heating for 24 h at ~1000°C. Material from this third heating was sealed in evacuated glass containers to await subsequent analyses and calorimetric measurements.

Analytical characterization of the material prepared as described above was carried out in Oak Ridge as follows. Total chromium content was determined by refluxing a weighed sample in concentrated perchloric acid, followed by dilution, reduction of Cr(VI) to Cr(III) with Fe^{2+}, and back-titration

with previously standardized $KMnO_4$ solution; this procedure led to 24.9 ± 0.2% Cr. Oxidizing power was determined by adding a weighed sample to a dilute acidic solution containing excess I^-, followed by titration with a previously standardized solution of $Na_2S_2O_3$; this procedure led to 8.81 ± 0.12 milliequivalents of oxidant per gram of solid material. Flame spectrophotometric measurements led to $46._7$ ± 1.4% potassium.

The analytical data above are consistent with the following overall composition of the solid material: 85.8 ± 0.4 mass% K_3CrO_4, 9.4 ± 1.0 mass% K_2CrO_4, and 4.8 ± 0.6 mass% Cr_2O_3. The proposed presence of K_2CrO_4 is attributed to the high temperature reaction (3*a*).

$$K_3CrO_4 \rightleftharpoons K_2CrO_4 + K$$

X-Ray diffraction patterns obtained in Oak Ridge showed the presence of two polymorphs, a minor phase similar to the high temperature form of K_3CrO_4 described by Olazcuaga *et al.* (4) and a major phase with diffraction pattern very similar to that of K_3MnO_4 as described by Herbstein *et al.* (5).

All calorimetric measurements were made in Lethbridge with an LKB 8700 Precision Calorimetry System. The standard LKB 100 ml glass reaction calorimeter was used with 1 ml glass ampoules. All of our calorimetric results refer to 25.0 ± 0.1°C and are reported in terms of the defined thermochemical calorie (1 cal = 4.184 J).

A suitable sequence of calorimetric reactions involving K_3CrO_4(c) and other compounds of chromium must be one in which all reactions are reasonably rapid under practical calorimetric conditions and in which products of various reactions can be 'identified' in the sense described below. Both of these requirements present substantial difficulties because of the well known slowness of many reactions involving Cr(III) and because many aqueous species of Cr(III) are poorly characterized. We have therefore carried out a number of preliminary investigations of reactions of K_3CrO_4(c) with water and various aqueous solutions at 25°C, along with related investigations of other compounds of chromium that can be used as thermochemical references.

We have established that the reaction of K_3CrO_4(c) with aqueous acid at 25°C leads to solutions with two-thirds of the chromium in the 6+ oxidation state and one-third in the 3+ oxidation state, after allowance has been made for presence of Cr_2O_3 and K_2CrO_4 in the sample; these results are consistent with the anticipated chemical behavior of Cr(V) and with the analyses done in Oak Ridge. Unfortunately, the Cr(III) resulting from such reactions with acidic solutions was present as complicated mixtures of various complex species. Because we were unable to produce these same mixtures by starting with other chromium-containing compounds that could be used as thermochemical references, we turned to consideration of reaction sequences involving alkaline solutions.

Investigations of the reactions of K_3CrO_4(c) and various other compounds of chromium with several alkaline solutions led us to adopt 1.75 *M* KOH as the solvent for all of our calorimetric measurements. For convenience we describe Cr(III) in this solvent as 'chromite' with formula CrO_2^-; all that is really necessary is that the 'chromite' formed from K_3CrO_4(c) be the same as that formed from chromic nitrate, which we have verified by ultraviolet spectroscopic investigation of various solutions as described by Schug and King (6).

Calorimetric ampoules were loaded with K_3CrO_4(c) and sealed in a dry box with a nitrogen atmosphere.

Calorimetric samples of chromic nitrate were prepared by recrystallizing Fisher certified $Cr(NO_3)_3 \cdot 9H_2O$ from dilute nitric acid. Two different samples of recrystallized material were air dried and then stored six weeks over silica gel; these samples were gently ground and lumps were broken nearly every day during this storage period to make the samples as nearly homogeneous as possible. Weighed samples were dissolved in aqueous KOH, oxidized by H_2O_2 with the excess decomposed by boiling, followed by acidification, reduction with a known amount of Fe^{2+} and titration of the remaining Fe^{2+} with standard $Cr_2O_7^{2-}$ solution. Results of these analyses were consistent with the compositions $Cr(NO_3)_3 \cdot yH_2O$ with $y = 5.55_0$ and 7.35_0. Samples of both of these substances were dissolved in water to form solutions whose p*H* was then measured to confirm that there was no significant trapped or adsorbed nitric acid in or on the crystals. Calorimetric ampoules were loaded and sealed at the same time samples were taken for analysis and calorimetric runs were made as soon as possible afterwards to minimize the possibility of change in hydration number.

Other chemicals used in calorimetric measurements were reagent grade materials that were handled in well established ways.

Results and Calculations

All calorimetric measurements on K_3CrO_4(c) have been made on samples of material having the composition described earlier in this paper. The calorimetric measurements have led directly to enthalpies of reaction listed as Δh in Table 1. On the basis of analytical results given earlier, we have assumed that each sample contained 4.8% Cr_2O_3(c) and have further assumed that this Cr_2O_3(c) is inert to our solvent system on the time scale of our measurements. Our recovery of Cr_2O_3(c) from the calorimeter after completion of calorimetric runs was consistent with this combination of assumptions. We have also assumed that our samples contained 9.4% K_2CrO_4(c) as indicated by the analyses described earlier; our enthalpies of solution of K_2CrO_4(c) given later in this paper have been used in making an appropriate correction for presence of this substance. Finally, we have assumed that our material contained 85.8% K_3CrO_4(c) as indicated by the analyses. On the basis of all this, we have obtained the ΔH_2 values also listed in Table 1 that refer to the reaction represented by

$$[2] \quad 3\,K_3CrO_4(c) + 2\,H_2O(s) \rightleftharpoons CrO_2^-(s) + 2\,CrO_4^{2-}(s) + 9\,K^+(s) + 4\,OH^-(s)$$

in which we have used (s) to indicate that the pre-

ceding species are in solution in our 1.75 *M* KOH solvent system. We have verified by analyses of the calorimetric solutions that amounts of chromium in the 3+ ('chromite') and 6+ oxidation states were consistent with this reaction and the assumed composition of the calorimetric samples.

We have also made calorimetric measurements leading to enthalpies of reactions represented by the following equations:

[3] $K_2CrO_4(c) \rightleftharpoons 2K^+(s) + CrO_4^{2-}(s)$

[4] $Cr(NO_3)_3 \cdot yH_2O(c) + 4OH^-(s) \rightleftharpoons CrO_2^-(s) + 3NO_3^-(s) + (y + 2)H_2O(s)$

[5] $H_2O(liq) \rightleftharpoons H_2O(s)$

[6] $KNO_3(c) \rightleftharpoons K^+(s) + NO_3^-(s)$

[7] $HCl \cdot zH_2O(liq) + OH^-(s) \rightleftharpoons (z + 1)H_2O(s) + Cl^-(s)$

[8] $KCl(c) \rightleftharpoons K^+(s) + Cl^-(s)$

Results of all these measurements are summarized in Table 2 where the listed ΔH_n values are averages from three calorimetric runs of each reaction.

Appropriate combination of the seven reaction equations above and the corresponding enthalpies leads to the following:

[9] $3K_3CrO_4(c) + 3KNO_3(c) + 8HCl \cdot zH_2O(liq) \rightleftharpoons 2K_2CrO_4(c) + Cr(NO_3)_3 \cdot yH_2O(c) + (8z - y + 4)H_2O(liq) + 8KCl(c)$

[10] $\Delta H_9 = \Delta H_2 - 2\Delta H_3 - \Delta H_4 - (8z - y + 4)\Delta H_5 + 3\Delta H_6 + 8\Delta H_7 - 8\Delta H_8$

Values of ΔH_9 for the various combinations of y and z are listed in Table 3.

To derive the desired ΔH_f^0 of $K_3CrO_4(c)$ from the various values of ΔH_9 in Table 3 we need to know several enthalpies of formation as follows.

For $H_2O(liq)$ we have $\Delta H_f^0 = -68.315$ kcal mol^{-1} from NBS Tech. Note 270-3 (7). We also obtain $\Delta H_f^0 = -459.05$ kcal mol^{-1} and $\Delta H_f^0 = -592.99$ kcal mol^{-1} for $HCl \cdot zH_2O(liq)$ when $z = 6.16_7$ and $z = 8.12_0$ from this same source (7). Because the excellent NBS Tech. Note 270 series has not yet reached KCl(c) and $KNO_3(c)$, we calculate the ΔH_f^0 values for these compounds in the following way. The NBS Tech. Note 270-3 (7) does list ΔH_f^0 values for $K^+(aq)$, $Cl^-(aq)$, and $NO_3^-(aq)$; we combine these values with the standard enthalpies of solution of KCl(c) and $KNO_3(c)$ listed by Parker (8) to obtain $\Delta H_f^0 = -104.39$ kcal mol^{-1} for KCl(c) and $\Delta H_f^0 = -118.22$ kcal mol^{-1} for $KNO_3(c)$. We also use $\Delta H_f^0 = -335.4$ kcal mol^{-1} for $K_2CrO_4(c)$ from the recent review by Dellien, Hall, and Hepler (9).

We have carried out our own new calorimetric measurements leading to the desired ΔH_f^0 of $Cr(NO_3)_3 \cdot yH_2O(c)$. An equation representing the calorimetric reaction is

[11] $Cr(NO_3)_3 \cdot yH_2O(c) \rightleftharpoons Cr^{3+}(aq) + 3NO_3^-(aq) + yH_2O(liq)$

Measurements of the enthalpy of solution of the crystalline material (0.2 g in 100 ml of 10^{-2} *M* nitric acid) have led to $\Delta H_{11} = -4.50$ kcal mol^{-1} for $y = 5.55_0$ and to $\Delta H_{11} = -4.65$ kcal mol^{-1} for $y = 7.35_0$. We have estimated the enthalpy of dilution to zero concentration by analogy to other salts of similar charge type, weighting the value from NBS Tech. Note 270-7 (10) for $La(NO_3)_3(aq)$ most heavily, to obtain $\Delta H_{11}^0 = -4.9$ kcal mol^{-1} for $y = 5.55_0$ and $\Delta H_{11}^0 = -5.1$ kcal mol^{-1} for $y = 7.35_0$. Combination of ΔH_{11}^0 values with ΔH_f^0 values for $NO_3^-(aq)$ and $H_2O(liq)$ cited above and $\Delta H_f^0 = -60$ kcal mol^{-1} for $Cr^{3+}(aq)$ from the recent calorimetric investigation of Dellien and Hepler (11) leads to $\Delta H_f^0 = -583$ kcal mol^{-1} for $Cr(NO_3)_3 \cdot yH_2O(c)$ with $y = 5.55_0$ and to $\Delta H_f^0 = -706$ kcal mol^{-1} for $y = 7.35_0$.

Finally, combination of the y, z, and ΔH_9 values from Table 3 with various ΔH_f^0 values cited above leads to the ΔH_f^0 values for $K_3CrO_4(c)$ that are also listed in Table 3. We choose $\Delta H_f^0 = -370 + 2$ kcal mol^{-1} for $K_3CrO_4(c)$ in which ± 2 kcal mol^{-1} represents our estimate of the maximum likely uncertainty based on considerations of uncertainties in com-

The crystal structure of *cis*-chlorobis(triethylphosphine)-1,8-naphthyridineplatinum(II) tetrafluoroborate, $[PtCl(PEt_3)_2(naph)]BF_4$, a complex containing a monodentate 1,8-naphthyridine ligand

GORDON W. BUSHNELL, KEITH R. DIXON, AND MASOOD A. KHAN

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received July 28, 1977

GORDON W. BUSHNELL, KEITH R. DIXON, and MASOOD A. KHAN. Can. J. Chem. **56**, 450 (1978).

The crystal structure of *cis*-chlorobis(triethylphosphine)-1,8-naphthyridineplatinum(II) tetrafluoroborate has been determined by single crystal X-ray diffraction and refined to an *R*-value of 0.063. The cell dimensions are $a = 1.4246$, $b = 1.2676$, $c = 1.6530$ nm, $\beta = 115.66°$. The space group is $P2_1/c$ with 4 molecules per unit cell, and the measured density is 1.665 g cm^{-3}. The structure is essentially a 4-coordinate square planar platinum(II) complex containing monodentate 1,8-naphthyridine. Interatomic distances to platinum are: Pt—Cl, 236.6(4); Pt—P(1), 225.4(4); Pt—P(2), 225.2(4); Pt—N(1), 208.3(11); and Pt—N(2), 304.5(14) pm. The structure is discussed in relation to variable temperature nmr studies of solutions, which indicate fluxional behaviour of the heterocyclic ligand.

GORDON W. BUSHNELL, KEITH R. DIXON et MASOOD A. KHAN. Can. J. Chem. **56**, 450 (1978).

On a déterminé la structure cristalline du tétrafluoroborate du chlorobis(triéthylphosphine) naphtyridine-1,8 platine(II) *cis* par diffraction de rayon-X d'un monocristal et on a affiné la structure jusqu'à une valeur finale *R* de 0.063. Les dimensions de la maille sont: $a = 1.4246$, $b = 1.2676$, $c = 1.6530$ nm, $\beta = 115.66°$. Le groupe d'espace est $P2_1/c$ avec quatre molécules par maille et la densité mesurée est de 1.665 g cm^{-3}. La structure consiste essentiellement d'un complexe de platine(II) tétracoordonné plan carré contenant la naphtyridine-1,8 sous forme de monodentate. Les distances interatomiques vers le platine sont: Pt—Cl, 236.6(4); Pt—P(1), 225.4(4); Pt—P(2), 225.2(4); Pt—N(1), 208.3(11); et Pt—N(2), 304.5(14) pm. On discute de la structure par rapport à des études de rmn à température variable en solution qui indiquent un comportement fluxionel du ligand hétérocyclique.

Introduction

A crystal structure determination on the apparently five co-ordinate complex, *cis*-$[PtCl(PEt_3)_2phen][BF_4]$, has shown that the actual geometry is close to four co-ordinate square planar and the complex contains the first example of a monodentate 1,10-phenanthroline ligand (1).[1] This highly unusual result raised interesting questions regarding the solution behaviour of the complex since nmr studies had shown chemical equivalence of the two heterocyclic rings (2). The most likely interpretation of this result is a solution structure similar to that in the solid state but with fluxional motion of the heterocyclic ligand. Thus the platinum is bound first at one nitrogen and then at the other, with rapid interchange between the two possibilities. A more detailed nmr study (3) strongly favours this interpretation even though the lowest accessible temperatures did not yield a slow exchange limiting spectrum. Moreover, the closely related complex, *cis*-$[PtCl(PEt_3)_2(naph)][BF_4]$, naph = 1,8-naphthyridine, showed chemical inequivalence of the heterocyclic rings at low temperatures. As the temperature was raised the spectrum changed until above −30°C the two rings were equivalent. These observations suggested a fluxional process similar to that postulated for the phenanthroline complex and it was of interest to determine whether the two complexes have similar co-ordination geometry in the crystalline state.

Several previous authors have been interested in 1,8-naphthyridine complexes on the grounds that the small 'bite' of this ligand is expected to stabilize unusually high co-ordination numbers (4–8). In practice, the co-ordination geometry of the naphthyridine varies widely. For example, in $[Fe(naph)_4][ClO_4]_2$, one ligand is fairly symmetric (Fe—N = 228.4, 233.5 pm), one markedly asymmetric (Fe—N = 218.4, 275.6 pm), and the others intermediate (4). Thus, it was also of interest to determine how naphthyridine co-ordinates in a situation where even phenanthroline is essentially monodentate. Since the

[1] In this type of complex it is, of course, impossible to discount weak interactions between the platinum and the second nitrogen. However, the very asymmetric nature of the geometry is unique (Pt—N(1) = 214(2), Pt—N(2) = 284(2) pm).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

completion of our work a crystal structure determination of *trans*-[$CuCl_2$(2,7-dimethyl-1,8-naphthyridine)$_2$] showing very asymmetric naphthyridine co-ordination (Cu—N = 198.2, 280.1 pm) has been reported (8). Our complex, with Pt—N(1) = 208, and Pt—N(2) = 305 pm, seems to be even more asymmetric than this, and is essentially monodentate.

Experimental

The preparation and characterization of the complex is described elsewhere (3). Crystals were grown by a vapour diffusion method (ref. 9, p. 65) using acetone as solvent 1 and ether as solvent 2. The crystal used for intensity measurements was approximately a rectangular block with dimensions 0.14, 0.5, 0.2 mm in the x, y, and z directions respectively.

Weissenberg and precession photographs were taken with CuK_α radiation. The space group $P2_1/c$ was thus established unequivocally. A crystal was mounted on the b-axis and centred on a Picker 4-circle diffractometer. The $\theta/2\theta$ peaks were measured for 25 reflections using both $MoK_{\alpha 1}$ (λ = 70.926 pm) and $MoK_{\alpha 2}$ (λ = 71.354 pm) at 22°C. The dimensions of the unit cell were refined using the method of least squares. The results and other crystal data are given in Table 1. The density was measured by flotation in a carbon tetrachloride/bromoform solution. Intensity measurements were done manually at room temperature using MoK_α radiation and a Zr filter. Reflections were scanned in the $\theta/2\theta$ mode for 1 min at a rate of 2° min^{-1} in 2θ. The instrument was operated in the bisecting position with $\omega = 0$. The background measurements were for 30 s at each end of the scan. The orientation of the crystal was checked twice daily using a set of three reflections. One of these reflections was measured for every batch of 30 reflections and used as an intensity standard. No crystal decomposition was noted. All reflections up to 2θ = 40° were measured. A total of 2110 reflections were given observed status using the criterion that the net count must be greater than the standard deviation of the background count. The intensities were corrected for the Lorentz and polarization effects. An absorption correction was applied as a function of the angle ϕ on the diffractometer. The absorption correction function was determined experimentally using reflections at χ = 90°.

Structure Determination

The structure was solved by the heavy atom method. A set of programs supplied by Penfold (10) was used for all calculations. The atomic scattering factors of Cromer and Waber (11) were used for Pt, P, and Cl. Atomic scattering factors for F, N, C, and B were taken from the International Tables (12). All atoms were assumed to be uncharged and a correction was applied for the anomalous dispersion of Pt (13). In the full-matrix least-squares refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized. Weights were derived from the counting statistics and an experimentally determined instrument instability constant of 0.04 using the formula given by Stout and Jensen, Appendix H (9). The unobserved reflections were included in the structure factor calculations but excluded from the least-squares sums. The final agreement factors were R = 0.054, R_w = 0.058 (unobserved reflections excluded) and R = 0.063, R_w = 0.062 (all reflections). Shifts in the final cycle of refinement were less than 3% of the standard deviations. A final difference map gave no indication of any misplaced atoms, and the maximum electron density difference was 7.2×10^{-7} e pm^{-3}. Estimated standard deviations for the results are derived from the full inverted matrix. The structure factor table is in the Depository for Unpublished Data.[2]

Results and Discussion

The molecular structure with labels is shown in Fig. 1 and the crystal packing in Fig. 2. The atomic parameters are given in Table 2 and bond lengths and angles in Tables 3 and 4.

Within the triethylphosphine ligand the mean angles, C—P—C = 104.3° and P—C—C = 112°, and the mean bond length, P—C = 183 pm, are normal for this ligand, as is the mean Pt—P—C angle of 114.1°. Similarly the fluoroborate anion does not require comment. Table 5 gives the least-squares planes for the naphthyridine ligand and also for the platinum co-ordination. The χ^2 values indicate that the naphthyridine ligand is deviating slightly from planarity but this is also the case in most of the naphthyridine complexes studied previously (8) and

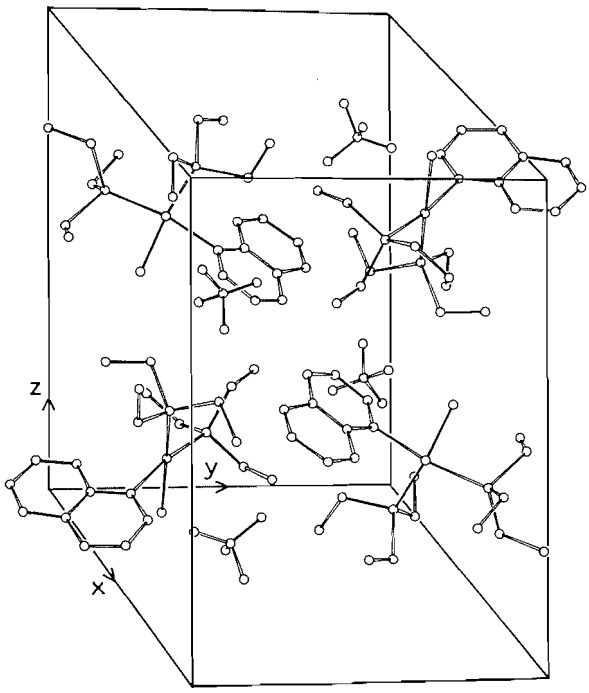

FIG. 2. The crystal packing diagram of *cis*-chlorobis(triethylphosphine)naphthyridineplatinum(II) tetrafluoroborate.

even in crystalline 1,8-naphthyridine (14).[3] The bond lengths and angles within the co-ordinated naphthyridine are similar to those in free naphthyridine and we note that the N(1)—C(13)—N(2) angle (115°) is essentially identical to the 115.3° found in the free ligand (14). A narrowing of this angle by 3.7° in $[Fe(naph)_4][ClO_4]_2$ has been attributed to decreased repulsion of the nitrogen lone pairs when they become shared pairs in the complex (14). The absence of this narrowing when the naphthyridine is essentially monodentate may therefore have some significance.

The naphthyridine ligand is almost perpendicular to the square co-ordination plane around platinum (Table 5). The platinum co-ordination is significantly non-planar with N(1) deviating furthest from the least-squares plane.

The shortest interionic contacts are of the type F---HC, the minimum F—C length being 312(2) pm. Six such contacts are less than 350 pm in length.

The bond angles around platinum are very similar to those in the analogous phenanthroline complex, the angle P—Pt—P being approximately 99° in both cases and Cl—Pt—N(1) being 83 and 81° respectively. The lengths to platinum are compared to those found in the phenanthroline complex in Table 6. The bond lengths in the square plane are identical but the Pt—N(2) distances are not the same, since the ligand structures differ.

It follows quite naturally from these structures that naphthyridine with the shorter N(1)—N(2) bite gives a longer Pt—N(2) distance. This is illustrated in Fig. 3 using hexagons, 120° angles, and the correct

[3] $\chi^2 = \Sigma_i |P_i^2/\sigma^2(P_i)|$, where P_i = perpendicular distance of atom i from the plane.

Pt—N(1) lengths. Figure 3 also shows that to change its point of attachment from N(1) to N(2) the metal atom would have to move relative to the ligand through a shorter distance for phenanthroline than for naphthyridine. To explain the fluxional and kinetic behaviour of these complexes in solution we need to estimate the order of activation energies. In Figure 3, positions A or B represent low energy co-ordinates for the platinum atom as observed in the crystalline state. The transition point of the reaction is expected to lie close to the midpoint of A, B. In the phenanthroline compound A and B are close together and it is hence unlikely that the activation energy for reaction will be high. The transition state has a five membered ring. For the naphthyridine compound, it is likely that the activation energy will be higher because A and B are further apart. Considerable distortion of the nitrogen sp^2 σ bonds from their preferred direction would be necessary in the transition state which has a four membered ring. The coalescence temperature observed by nmr spectroscopy was $-30°C$ for the naphthyridine compound, whereas the fluxional motion in the phenanthroline complex was not arrested at $-85°C$, the lowest temperature obtainable before viscosity broadening of the spectrum and crystallization of the complex spoiled the experiment.

The X-ray diffraction results for the crystalline materials thus provide insight into the processes occurring in solutions as observed by nmr, and the two techniques are in mutual accord. These results also emphasize that when the concept of ligand span

TABLE 5. Least-squares planes ($k_1x + k_2y + k_3z = k_4$) of *cis*-chloro(naph)bis(triethylphosphine)platinum(II) tetrafluoroborate[a]

Vinyl ether hydrolysis. XI. The effect of α-phenyl substitution[1]

Y. CHIANG, W. K. CHWANG, A. J. KRESGE,[2]
L. H. ROBINSON, D. S. SAGATYS, and C. I. YOUNG

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4 and Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616 U.S.A.

Received August 29, 1977

Y. CHIANG, W. K. CHWANG, A. J. KRESGE, L. H. ROBINSON, D. S. SAGATYS, and C. I. YOUNG. Can. J. Chem. **56**, 456 (1978).

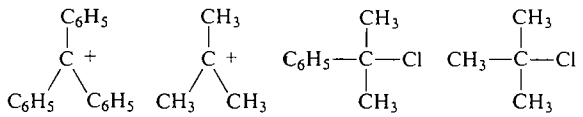
The unexpected inability of an α-phenyl group to accelerate the rate of vinyl ether hydrolysis more strongly than an α-methyl substituent, $k(CH_2{=}CPhOEt)/k(CH_2{=}CMeOEt) = 0.2$ for catalysis by H_3O^+ at 25°C, is examined and is found to be the result of two effects: (*i*) preferential initial state stabilization by phenyl and (*ii*) weak resonance interaction with the developing alkoxy carbonium ion in the transition state induced by the reactant-like character of the latter. A curved Brønsted relation for the hydrolysis of 3-methoxyindene catalyzed by carboxylic acids and monohydrogen phosphonate anions gives the Marcus theory parameters $\Delta G_0^{\ddagger} = 3 \pm 1$ kcal/mol and $w^r = 12 \pm 1$ kcal/mol.

Y. CHIANG, W. K. CHWANG, A. J. KRESGE, L. H. ROBINSON, D. S. SAGATYS et C. I. YOUNG. Can. J. Chem. **56**, 456 (1978).

Les vitesses d'hydrolyse, catalysée par H_3O^+ et à 25°C, d'éthers vinyliques substitués en α par des groupes phényle ou méthyle ne sont pas très différentes; $k(CH_2{=}CPhOEt)/k(CH_2{=}CMeOEt) = 0.2$; on a trouvé que ce résultat inattendu est dû à deux effets: (*i*) une stabilisation préférentielle de l'état initial par le phényle et (*ii*) une interaction faible de résonance avec le carbocation alcoxy qui se développe dans l'état de transition et qui est induit par le caractère ressemblant au réactif de l'état de transition. La courbe représentant la relation de Brønsted pour l'hydrolyse du méthoxy-3 indène catalysée par les acides carboxyliques et les anions monophosphate conduit à des paramètres pour la théorie de Marcus de $\Delta G_0^{\ddagger} = 3 \pm 1$ kcal/mol et $w^r = 12 \pm 1$ kcal/mol.

[Traduit par le journal]

Carbonium ions are generally stabilized to a greater extent by α-phenyl substituents than by α-methyl groups. The triphenylmethyl cation, **1**, for example, is formed from triphenylmethanol in



1 **2** **3** **4**

50% aqueous H_2SO_4 but 'superacids' such as FSO_3H–SbF_5 or HF–SbF_5 are needed to generate the *tert*-butyl cation, **2**, from *tert*-butyl alcohol (1) and cumyl chloride, **3**, undergoes solvolysis in ethanol solution 5000 times more rapidly than *tert*-butyl chloride, **4** (2).

We were somewhat surprised, therefore, when we discovered (3) that an α-phenyl group was actually *less* effective than an α-methyl group in promoting vinyl ether hydrolysis. This is a reaction which takes place via rate-determining formation of an alkoxy carbonium ion (eq. 1) (4) and yet the ratio of specific rates for R = C_6H_5 to R = CH_3 in **5** is 0.2. In this

[1] $CH_2{=}C(R)OC_2H_5 \xrightarrow[\text{slow}]{H^+}$ **5**

$CH_3\overset{+}{C}(R)OC_2H_5 \xrightarrow[\text{fast}]{H_2O} CH_3C(=O)R + HOC_2H_5$

paper we report our further study of this unexpected phenomenon.

Results and Discussion

Sigma–Rho Relationships

Phenyl groups stabilize adjacent carbonium ion centers by a conjugative or resonance mechanism; when resonance is inhibited, a destabilizing inductive effect takes over.[3] The fact that an α-phenyl group does facilitate reaction in the present case (although not as much as α-methyl): the rate ratio for R = C_6H_5 to R = H in **1** is 70 (3), indicates that some conjugative stabilization is available. To assess the magnitude of this resonance effect, we examined the influence of substituents in the *para* position of the phenyl group on the rate of methyl α-phenylvinyl ether hydrolysis catalyzed by the hydronium ion.

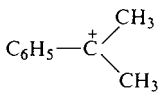
TABLE 1. Summary of rate constants for the hydrolysis of some vinyl ethers in aqueous solution at 25°C under catalysis by H^+

Substrate	k_{H^+} (M^{-1} s^{-1})
Ethyl α-*p*-nitrophenylvinyl ether	2.01[a]
Ethyl α-*p*-bromophenylvinyl ether	36.1[b]
Ethyl α-phenylvinyl ether	118[a]
Ethyl α-*p*-methylphenylvinyl ether	277[b]
Ethyl α-*p*-methoxyphenylvinyl ether	645[b]
3-Methoxyindene	57.9[b]
Methyl α-phenylvinyl ether	53.3[a]

[a]Reference 3.
[b]This work.

The results are detailed in Table S1[4] and are summarized in Table 1. They show a response to substitution, especially to introduction of methyl and methoxyl groups, which is rather less than expected for a strong resonance interaction, and the specific rates in fact correlate better with σ than with σ^+. Treatment of the data by the Yukawa–Tsuno method (6) gives 0.14 ± 0.07 for the resonance parameter *r*, which rates the conjugative effect on a scale from zero for no resonance to unity for a resonance interaction equivalent to the rather strong conjugative effect in the cumyl cation **6**. The value



6

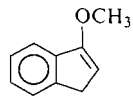
of ρ is also low: ρ = −2.23 ± 0.14. Thus, these experiments reveal a rather weak resonance interaction.

3-Methoxyindene

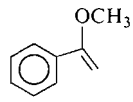
Resonance effects of phenyl groups have a strong conformational requirement, and reduced conjugation may often be traced back to steric effects which prevent the system from adopting its optimum configuration. In the present case there would seem to be no obvious interference of this kind: the α-phenylvinyl group is not a crowded one, and the benzene ring should easily be able to assume the necessary arrangement coplanar with the carbon–carbon double bond.

It is, however, a simple matter to test this idea experimentally; for example, by examining a substance in which coplanarity is forced upon the system through the presence of a small ring, as in 3-methoxyindene, **7**. We therefore measured the rate of hydrolysis of this substance. The data, detailed in Table S2[4] and summarized in Table 1, show the rate

[4]Tables S1, S2, and S3 of rate data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



7



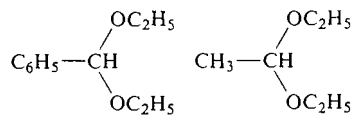
8

of this reaction to be virtually identical with that of its acyclic analog: for 3-methoxyindene k_{H^+} = 58 M^{-1}s^{-1} while for methyl α-phenylvinyl ether, **8**, k_{H^+} = 53 M^{-1}s^{-1}. Steric inhibition of resonance may therefore be ruled out as the cause of the weak resonance effect.

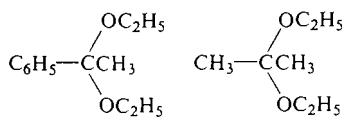
Initial State Stabilization

An additional factor which must be taken into account in the present comparison of phenyl and methyl group effects is the interaction between these groups and the carbon–carbon double bonds in the vinyl ether substrates of the initial states of these reactions. It is well known that phenyl groups stabilize double bonds; a recent study (7) puts this effect, in free energy terms, at $\delta_R G$ = 4.9 kcal/mol. Methyl groups also lower the energy of carbon–carbon double bonds but by a smaller amount: $\delta_R G$ = 3.2 kcal/mol. The difference between these two values, 1.7 kcal/mol, is the amount by which the initial state for methyl α-phenylvinyl ether hydrolysis is stabilized relative to that for ethyl α-methylvinyl ether hydrolysis. This energy difference is equivalent to a rate factor of 20 at 25°C, which is more than enough to offset the rate ratio of 0.2 actually found for these two compounds.

This analysis suggests, therefore, that an α-phenyl group is in fact better at stabilizing positive charge in an alkoxy carbonium ion than is a methyl group in the same position but this superiority is not reflected in rates of vinyl ether hydrolysis because of overwhelming initial state effects. This conclusion is supported by the fact that benzaldehyde diethyl acetal, **9**, undergoes acid-catalyzed hydrolysis 30



9 **10**



11 **12**

times faster than does acetaldehyde acetal, **10** (8). These reactions occur by rate-determining formation of alkoxy carbonium ions, eq. 2,[5] similar to those generated in vinyl ether hydrolysis but the substrates

[5]For a recent review of the evidence, see ref. 9.

[2] $$RCH(OC_2H_5)_2 \xrightarrow{H^+} RCHOC_2H_5^+ + C_2H_5OH$$

here do not contain carbon–carbon double bonds and the initial state effects found in vinyl ether hydrolysis are therefore absent. Phenyl substitution in the ketals **11** and **12**, on the other hand, is less effective at promoting hydrolysis than is methyl substitution: the rate ratio **11**:**12** is 0.3 (10). But this system is much more crowded than the acetal series **9** and **10**, and complicating steric effects may well be present (10, 11).

It is interesting also that 'inverted' phenyl to methyl rate ratios have been found in a number of other reactions involving rate-determining proton addition to carbon–carbon double bonds. In fact, of the six systems for which data are available (Table 2), only one gives a phenyl to methyl rate ratio greater than unity.

Brønsted Relation

Weak phenyl group resonance effects such as those observed here seem to be characteristic of fairly stable carbonium ions. They have been observed before in reactions which give alkoxy carbonium ions and have been attributed to a substituent saturation effect or diminished demand for additional stabilization in already quite stable species (12). Some insight into how this saturation effect operates is provided by a Brønsted relation for one of the present vinyl ether hydrolysis reactions.

This Brønsted relation was constructed using 3-methoxyindene as the substrate. Catalytic coefficients were determined for carboxylic acids and for monohydrogen phosphonate anions by measuring rates of hydrolysis in buffer solutions of these acids. The data, summarized in Table S3,[4] when treated by methods we have described before (13), give the rate constants listed in Table 3.

Here, as before in the hydrolysis of other vinyl ethers (13*c* and *d*), the monohydrogen phosphonate anions prove to be better catalysts than neutral carboxylic acids of the same acid strength; this difference may be understood as the result of electrostatic interactions in the transition states of these reactions (13*b* and *c*). The two kinds of catalysts give separate Brønsted relations (Fig. 1) of different slope, $\alpha = 0.64 \pm 0.05$ for RCO_2H and $\alpha = 0.78 \pm 0.02$ for RPO_3H^-. These may be regarded as linear segments of more extensive curved correlations, and, as before (13*c* and *d*) a single curved Brønsted relation (Fig. 2) may be obtained by a simple vertical displacement of the phosphonate anion points.

TABLE 2. Comparison of phenyl and methyl substituent effects in double bond protonation reactions

System	$k(C_6H_5)/k(CH_3)$ (Ref. No.)
$CH_2{=}CHR$	6.6 (20, 21)
$CH_2{=}C(R)CH_3$	0.26 (20, 22)
$CH_2{=}C(R)cPr$	0.065 (20)
$CH_2{=}C(R)OCOCH_3$	0.63 (23)
$CH_2{=}C(R)PO_2(OEt)_2$	0.65 (24, 25)
$CH_2{=}C(R)OC_2H_5$	0.20 (3)

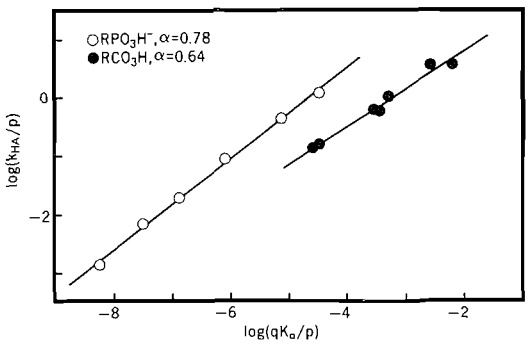

FIG. 1. Separate linear Brønsted relations for the hydrolysis of 3-methoxyindene catalyzed by carboxylic acids and by monohydrogen phosphonate anions.

This curved Brønsted relation shows that α diminishes with increasing catalyst acid strength. For an acid as strong as H_3O^+, the catalyst which was used in the rate comparisons and σ–ρ correlations discussed above, the value $\alpha = 0.39$ may be extrapolated. Insofar as Brønsted exponents may be used as a measure of the degree of proton transfer (14), this implies that the proton is only some 40% transferred, and the carbonium ion only 40% developed, in the transition states of these reactions. Resonance stabilization of this incipient carbonium ion can therefore be no more than 40% of that in a fully developed carbonium ion, and it could be less if resonance effects in carbonium ion-forming reactions lag behind proton transfer just as they seem to do in carbanion formation (14, 15). The weak resonance effects observed in these vinyl ether hydrolyses thus appear to be natural consequences of the early transition states these reactions possess.

Curved Brønsted relations such as that of Fig. 2, when analyzed using Marcus rate theory, give certain parameters by which proton transfer reactions may be characterized (15*b*, 16). This treatment in the present case provides the intrinsic barrier $\Delta G_0^{\ddagger} = 3.4 \pm 0.9$ kcal/mol and the work term $w^r = 12.2 \pm 1.2$ kcal/mol. Thus, in the hydrolysis of 3-methoxyindene, just as in most other vinyl ether hydrolysis reactions (3, 13*c*), rather more energy is required to bring the catalyst and the substrate together and form them into a reaction

complex (w^r) than is needed to surmount the kinetic barrier to proton transfer within this complex ($\Delta G_0^{\neq}$).

Experimental

Materials

Vinyl ethers were prepared from the corresponding ketones via the dimethyl or diethyl ketals. The latter were made by treating the ketones with trimethyl or triethyl orthoformate in alcohol (methanol or ethanol) solution in the presence of a catalytic amount of *p*-toluenesulfonic acid; the ketals were isolated and characterized, and alcohol was then eliminated, by heating under reflux with *p*-toluenesulfonic acid catalyst, to produce the vinyl ethers. The identity of all ketals and vinyl ethers was confirmed by their nmr and ir spectra, and satisfactory carbon and hydrogen analyses were obtained for all new substances.

Phosphoric acids were samples prepared previously for pK_a determinations (17); all other substances were best available commercial grades. Solutions were prepared using deionized water purified further by distillation from alkaline permanganate.

Kinetics

Rates were measured spectroscopically by monitoring the increase in product ketone absorption in the region 240–270 nm. Runs with half-lives greater than 2–3 min were performed using a Cary 118 spectrometer, and faster reactions were measured with a Durrum-Gibson stopped-flow spectrometer; both instruments were thermostatted at 25.0 ± 0.1°C. Rate constants were evaluated graphically, either as plots of ln $(A - A_\infty)$ vs. time (using infinite-time readings made after 10–12 half-lives) or by the Guggenheim (18) or Swinbourne (19) methods.

Vinyl ether hydrolysis. XII. Use of *cis–trans* isomerism to probe the reaction mechanism[1]

Y. CHIANG, A. J. KRESGE,[2] AND C. I. YOUNG

Department of Chemistry, University of Toronto Scarborough College, West Hill, Ontario M1C 1A4 and Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616, U.S.A.

Received August 29, 1977

Y. CHIANG, A. J. KRESGE, and C. I. YOUNG. Can. J. Chem. **56**, 461 (1978).

Rates of hydrolysis of *cis*- and *trans*-β-phenylvinyl methyl ethers, *cis*- and *trans*-β-(*p*-nitrophenyl)vinyl methyl ethers, and *cis*- and *trans*-β-cyanovinyl ethyl ethers were measured in concentrated (10–55 wt%) aqueous perchloric acids. The results show that these *cis* and *trans* isomers do not interconvert under the hydrolysis reaction conditions, and that formation of the alkoxy carbonium ion intermediate in these reactions is therefore not reversible.

Y. CHIANG, A. J. KRESGE et C. I. YOUNG. Can. J. Chem. **56**, 461 (1978).

On a mesuré les vitesses d'hydrolyse des β-phénylvinylméthyl éthers *cis* et *trans*, des β-(*p*-nitrophényl)vinylméthyl éthers *cis* et *trans* et des β-cyanovinyléthyl éthers *cis* et *trans* dans des solutions aqueuses concentrées (10–55% en poids) d'acide perchlorique. Des résultats indiquent qu'il n'y a pas d'interconversion entre isomères *cis* et *trans* dans les conditions de réaction d'hydrolyse et que la formation du carbocation alcoxy intermédiaire dans ces réactions n'est donc pas réversible.

[Traduit par le journal]

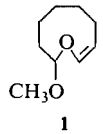
The acid-catalyzed hydrolysis of simple vinyl ethers occurs through rate-determining proton transfer from the catalyst to the substrate (eq. 1), followed by rapid hydration of the ensuing alkoxy carbonium ion (eq. 2) and subsequent fast breakdown of the hemiacetal intermediate (eq. 3). There is

$$[1]\qquad CH_2{=}CHOR + HA \rightarrow CH_3\overset{+}{C}HOR + A^-$$

$$[2]\qquad CH_3\overset{+}{C}HOR + H_2O \rightarrow CH_3\overset{OH}{\overset{|}{C}}HOR + H^+$$

$$[3]\qquad CH_3\overset{OH}{\overset{|}{C}}HOR \rightarrow CH_3\overset{O}{\overset{\|}{C}}H + HOR$$

reason to believe, however, that the hydration reaction (eq. 2) is not very much faster than the reverse of the proton transfer step (eq. 1) (1) and a change in mechanism from rate-determining protonation to rate-determining hydration has in fact been observed in the case of the difunctional cyclic vinyl ether, 2-methoxy-2,3,4,5,6,7-hexahydrooxonin, **1** (2).



1

Our interest in vinyl ether hydrolysis has prompted us to explore the borderline between these two mechanistic variations and we have already reported (1) that we were unable to obtain any evidence for a change in mechanism with substrates containing carbon–carbon double-bond stabilizing groups; such substituents would be expected to lower the free energy of activation for the deprotonation step while leaving that for hydration largely unaffected, and that might cause protonation to become reversible and make hydration rate-determining. The criteria of reaction mechanism we used in these studies consisted of isotope effects, isotopic labelling, and the form of acid-catalysis. We now report the results of applying yet another mechanistic test, *cis–trans* isomerism.

This diagnostic tool depends for its operation upon the fact that reversal of the protonation step provides a route for inversion of configuration about the vinyl ether double bond (eq. 4). This mechanistic criterion has been applied before to the hydrolysis of vinyl ethers (3), but not to substrates containing double-bond stabilizing groups.

Experimental

Materials

cis-β-Phenylvinyl methyl ether was prepared as before (1*a*) by the addition of methanol to phenylacetylene in the presence of sodium methoxide, which occurs in a stereospecific *trans* manner (4). The *trans* isomer was obtained by treating phenylacetaldehyde dimethyl acetal with an excess of *n*-butyl lithium at room temperature for 48 h; it was purified by liquid chromatography on a silica gel column using *n*-hexane to elute impurities and benzene to remove pure product. The nmr spectra of both isomers were consistent with their structures; in particular the *cis* isomer gave vinyl proton signals at

[1]For part XI see accompanying paper in this issue.

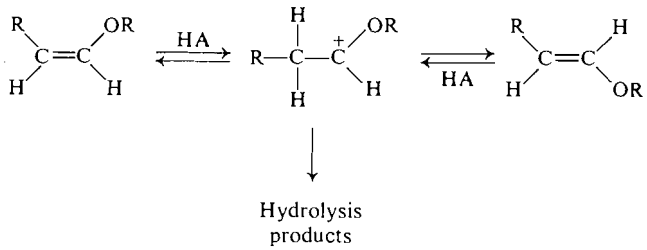
[4]



δ = 5.1 (d) and 5.8 (d) ppm with a coupling constant of J_{HH} = 7 Hz, whereas the *trans* isomer showed signals at δ = 5.7 (d) and 6.9 (d) ppm with J_{HH} = 13 Hz.

trans-β-(*p*-Nitrophenyl)vinyl methyl ether was prepared by treating β-fluoro-*p*-nitrostyrene (kindly supplied by Dr. F. Naso) with sodium methoxide (5). Irradiation of this substance with a sun lamp gave an equilibrium mixture consisting of two parts *cis*- and one part *trans*-β(*p*-nitrophenyl)vinyl methyl ether from which the pure *cis* isomer was obtained by liquid chromatography on silica gel; elution with cyclohexane containing 1% ethyl ether released the *cis* isomer first and provided good separation from the *trans*. The *cis* isomer gave vinyl proton nmr signals at δ = 6.7 (d) and 7.9 (d) ppm with J_{HH} = 8 Hz, and the *trans* isomer showed signals at δ = 5.8 (d) and 7.2 ppm with J_{HH} = 13 Hz.

A mixture of *cis*- and *trans*-β-cyanovinyl ethyl ether was prepared by decarboxylation of 2-cyano-3-ethoxyacrylic acid (Aldrich) at reduced pressure (0.5 mm) (6); this mixture was separated into pure *cis* and *trans* isomers by gas chromatography using a 20% carbowax on Chromosorb-P column. The *cis* isomer gave vinyl proton nmr signals at δ = 4.1 (d) and 4.4 (d) ppm, J_{HH} = 7 Hz, and the *trans* isomer showed signals at δ = 4.1 (d) and 4.9 (d) ppm with J_{HH} = 13 Hz.

Kinetics

Rates were measured spectroscopically by monitoring the decrease in strong vinyl ether absorption at 225 nm for *cis*- and *trans*-β-cyanovinyl ethyl ether, 260 nm for *cis*- and *trans*-β-phenylvinyl methyl ether, and 350 nm for β-(*p*-nitrophenyl)-vinyl methyl ether. Measurements were made using a Cary Model 11 spectrometer with cell compartment thermostatted at 25.0 ± 0.05°C.

Results

Each of the six vinyl ethers investigated proved to be too unreactive to hydrolyze at convenient rates in dilute aqueous acid solutions, and measurements were therefore made using concentrated perchloric acid in the range 10–55 wt%. All of the data so obtained obeyed the first-order rate law exactly. Rate constants were evaluated graphically as slopes of plots of ln $(A - A_\infty)$ vs. time, with infinite-time readings (A_∞) taken after 10–12 half-lives. The results are summarized in Tables 1–3.

It may be seen that for all three *cis–trans* vinyl ether pairs, the *cis* isomer hydrolyzed substantially more rapidly than the *trans*; *cis*:*trans* rate ratios ranged from 4.2 for β-phenylvinyl methyl ether to 5.5 for β-cyanovinyl ethyl ether. Increased hydrolytic reactivity of *cis* over *trans* vinyl ethers of this order of magnitude has been observed before (3, 7, 8) and has been attributed to preferential stabilization of the *cisoid* conformation in the transition state (*7a*) (by analogy with the eclipsed conformation of propionaldehyde (9)) and also to initial-state steric congestion in the *cis* isomer (3).

In all cases, rates of reaction increased rapidly with increasing acid concentration, and for all substrates plots of log k_{obs} vs. the H_0 acidity function were linear with slopes near unity: $d(\log k_{obs})/d(-H_0) = 0.95 \pm 0.01$ for *cis*- and 0.96 ± 0.01 for *trans*-β-cyanovinyl ethyl ether, 1.11 ± 0.01 for *cis*- and 1.13 ± 0.01 for *trans*-β-phenylvinyl methyl ether, and 1.15 ± 0.02 for *cis*- and 1.10 ± 0.01 for *trans*-β-(*p*-nitrophenyl)vinyl methyl ether. In this respect these reactions resemble the hydration of simple olefins whose rates also correlate well with the H_0 function (10).

TABLE 3. Rates of hydrolysis of *cis*- and *trans*-β-cyanovinyl ethyl ethers in aqueous perchloric acid at 25°C

wt% $HClO_4$	$-H_0$	$10^3 k_{obs}$ (s^{-1}) *cis*	$10^3 k_{obs}$ (s^{-1}) *trans*
43.28	2.62	3.44, 3.45	—
44.18	2.72	4.42, 4.44	—
45.79	2.90	6.58, 6.25	—
46.88	3.02	8.15, 8.20	1.49, 1.49
49.87	3.42	20.1, 19.9, 19.8	3.77, 3.77
50.44	3.50	—	4.70, 4.72
52.38	3.79	—	8.30, 8.20
53.42	3.96	—	12.4, 12.1
55.41	4.30	—	26.2, 25.7, 26.0

Discussion

In each of the three cases examined here, *cis* and *trans* isomeric vinyl ethers underwent acid-catalyzed hydrolysis at substantially different rates. This indicates that no mechanism for rapid isomer interconversion exists under the hydrolysis reaction conditions, for, if such a mechanism were operative, the two isomers would give a single hydrolysis rate constant characteristic of the equilibrium *cis–trans* mixture. This, in turn, shows that deprotonation of the alkoxy carbonium ion intermediates formed in these hydrolysis reactions (eq. 1) cannot be rapid relative to their rates of hydration (eq. 2).

Slow interconversion of *cis–trans* isomers under hydrolysis reaction conditions, on the other hand, would allow the two isomers to hydrolyze at different rates, at least initially. In this circumstance, however, conversion of one isomer into the other during the hydrolysis reaction would upset the smooth first-order disappearance of vinyl ether normally observed in vinyl ether hydrolysis. Some calculations we have done simulating such a system show that substantial deviations from first-order kinetic behavior occur even when the alkoxy carbonium ion intermediate partitions equally between deprotonation and hydration reaction paths. Such systems, moreover, though they show different reaction rates for the two isomers initially, settle down to identical rates of reaction after one to two half-lives. The fact that accurate first-order kinetic behavior was observed in all of the reactions investigated here, and that no tendency toward convergence to similar rate constant for members of the *cis–trans* pair could be detected, implies that no kinetically significant isomerization is occurring under the hydrolysis reaction conditions.

This conclusion is supported by additional direct examination of the reaction mixture during hydrolysis of one of the kinetic substrates, *cis*-β-phenylvinyl methyl ether. It had been found earlier, by direct equilibration studies, that this substance is less stable than its *trans* isomer (3). We corroborated that result here: using samples of both *cis*- and *trans*-vinyl ether plus catalytic amounts of mercuric acetate and following the isomerization by nmr, we found a *cis*:*trans* equilibrium ratio of 0.31 ± 0.02. We allowed this less stable isomer to hydrolyze in solution, in a 20% H_2O – 80% D_2O solvent containing 1.5 *M* perchloric acid (ca. 15 wt%), while taking samples, extracting them with an organic solvent (carbon tetrachloride) and examining the extracts by nmr. Although, as the reaction progressed, we could see *cis*-β-phenylvinyl methyl ether disappear and the product of hydrolysis, phenylacetaldehyde, appear, we could detect no *trans*-β-phenylvinyl methyl ether whatsoever; we could also not discern any of the characteristic alteration in the vinyl-hydrogen portion of the nmr spectrum which would have occurred had deuterium been incorporated into the substrate.

This total lack of evidence for reversal of the proton transfer step in these vinyl ether hydrolysis reactions is consistent with our previous experience. We were unable before to detect proton transfer reversal in the hydrolysis of β-phenyl-α-methyl vinyl ether (1*a*) and α-cyclopropylvinyl methyl ether (1*b*), despite the fact that these substrates contain phenyl and cyclopropyl groups in positions from which they can interact to stabilize the carbon–carbon double bond. We can now add cyano and *p*-nitrophenyl to the list of double-bond stabilizing groups which do not render the proton transfer step reversible. It is of particular interest that the *p*-nitrophenyl substituent does not function in this way, for the nitro group is a powerful electron acceptor. It should therefore interact strongly with the ether oxygen atom, which is a good electron donor, and set up a particularly favorable conjugated system involving the carbon–carbon double bond. In the closely analogous *N*,*N*-dimethylaniline system, for example, introduction of a nitro group into the *para* position raises the barrier to rotation about the C–N bond, which is a measure of the resonance interaction, from 5 to 8 kcal/mol (11).

It is likely that the inability of these groups to promote proton transfer reversal is related to the strong retarding effect they have upon the rate of the hydrolysis reaction. Extrapolation of the log k_{obs} vs. H_0 relationships described above gives dilute-solution hydrogen ion catalytic coefficients which range from 2.7×10^{-3} M^{-1} s^{-1} (for *cis*-β-phenylvinyl methyl ether) to 2.1×10^{-6} M^{-1} s^{-1} (for *trans*-β-cyanovinyl ethyl ether); these are lower than any values previously reported for vinyl ether hydrolysis. The slowness of these reactions implies

that they have late, product-like transition states with not much carbon-carbon double bond character; double-bond stabilizing substituents are therefore likely to have little effect on the mechanism of the reaction.

Received May 24, 1977

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, H. ERNEST HENDERSON, and RAYMOND T. HEMMINGS. Can. J. Chem. **56**, 465 (1978).

Comparative reactions of some halogenogermanes with lithium(I), lead(II), and organosilicon Group VI species have been investigated, leading to the efficient syntheses of the chalcogermanes of the formula $(Me_nH_{3-n}Ge)_2E$, where E = O, S, Se, Te; $n = 0 \rightarrow 3$. The spectroscopic properties of the new bis(methylgermyl) and bis(dimethylgermyl) chalcogenides are discussed. Germanethiols and germaneselenols, viz. $Me_nH_{3-n}GeEH$ (E = S, Se; $n = 0, 3$) are isolated as intermediates in the reaction of digermoxanes with H_2E and from equilibrium mixtures of $(Me_nH_{3-n}Ge)_2E$ with excess H_2E. Evidence is presented for the condensation of the chalcogermanes to species of the type $Me_nH_{2-n}Ge(EGeH_{3-n}Me_n)_2$ ($n = 1, 2$) and for the elimination of metallic selenium or tellurium giving digermanes of the type $(Me_nH_{3-n}Ge)_2$ ($n = 1, 2$).

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, H. ERNEST HENDERSON et RAYMOND T. HEMMINGS. Can. J. Chem. **56**, 465 (1978).

On a étudié les réactions comparatives de quelques halogermanes avec du lithium(I), du plomb(II) et des espèces du groupe VI d'organosilicium; ces réactions conduisent à des synthèses efficaces de chalcogermanes de formule $(Me_nH_{3-n}Ge)_2E$ où E = O, S, Se, Te; $n = 0 \rightarrow 3$. On discute des propriétés spectroscopiques des nouveaux bis(méthylgermyl) et bis-(diméthylgermyl)-chalcogénures. On a isolé des germanethioles et germanesélénoles, $Me_nH_{3-n}GeEH$ (E = S, Se; $n = 0, 3$), comme intermédiaires dans la réaction de digermoxanne avec H_2E et à partir de mélanges à l'équilibre de $(Me_nH_{3-n}Ge)_2E$ avec un excès de H_2E. On présente des données concernant la condensation de chalcogermanes produisant les composés du type $Me_nH_{2-n}Ge(EGeH_{3-n}Me_n)_2$ ($n = 1, 2$) et l'élimination de sélénium ou de tellure métallique conduisant à des digermanes du type $(Me_nH_{3-n}Ge)_2$ ($n = 1, 2$).

[Traduit par le journal]

Introduction

In a recent report (1) we demonstrated, via small scale preparations, the susceptibility of the Ge—N linkage in bis(methylgermanium) carbodiimides to Group VI protic species, giving bis(methylgermanium) chalcogenides. Attempts to increase the scale of production generally met with unsatisfactory results because of a variety of side reactions. Therefore, we examined a number of alternative methods of forming the germanium–chalcogen linkage and report herein the preparation of the germyl species, viz. $(Me_nH_{3-n}Ge)_2E$ (E = O, S, Se, Te; $n = 0 \rightarrow 3$), from the metathesis reactions of various halogenogermanes with lithium(I), lead(II), and organosilicon chalcogenides. The new bis(methylgermyl) and bis(dimethylgermyl) chalcogenides are identified by their ^1H nmr, infrared, Raman, and mass spectral parameters and by their cleavage reactions with known quantities of gaseous hydrogen halides. Self-condensation reactions of the methyl(hydrido)chalcogermanes and subsequent elimination of the chalcogen moiety provide further chracterization. Co-condensation with Group VI hydrides results in the formation of the monomeric chalcogermane intermediates, germanethiols and germaneselenols, which are identified by ^1H nmr and mass spectral techniques.

Experimental

Manipulations and spectroscopic measurements were as previously described (1). Halogenogermanes were either commercially obtained or prepared by literature methods (2–8). Lithium selenide and telluride were prepared from the elements: typically, powdered selenium (0.403 g, 5.10 mmol) and clean lithium wire (0.069 g, 10 mmol) were allowed to react in dry ammonia (ca. 10–15 ml) at −78°C in a reactor (ca. 70 ml) attached to the vacuum system via a Teflon-in-glass stopcock. The reaction was accelerated by occasional removal of the −78°C bath with shaking and cautious warming while monitoring the NH_3 pressure. After typically 12 h the NH_3 was pumped off. The light grey salt was heated at 150–170°C for 6 h *in vacuo* and stored under nitrogen. Hydrolysis gave typically 98% of the Se content required for Li_2Se as H_2Se, whilst ca. 80% resulted for the release of H_2Te from Li_2Te. Bis(tri-

methylsilyl)selenide and -telluride were prepared from Me_3SiCl and Li_2E (E = Se, Te) in Et_2O at 25°C. The purity of the volatile materials was confirmed by ^1H nmr and vibrational spectroscopic analysis. Hydrogen sulfide and hydrogen selenide were obtained via the hydrolysis of the respective aluminum chalcogenides (9, 10). The remainder of the materials was of commercial origin.

Reactions of Halogenogermanes with Lithium Salts

(i) With Lithium Sulfide, Selenide, and Telluride

In a typical reaction, the ampule which contained Li_2Se (ca. 0.46 g, 5.0 mmol) and which was attached to the vacuum line, was thoroughly evacuated. Then, Me_2O (ca. 10–15 ml) and Me_2HGeI (8.80 mmol) were condensed in with the ampule held at −196°C. The ampule was isolated and warmed to −78°C with occasional shaking. After ca. 96 h the ampule was opened and the volatile materials fractionated at −78 and −196°C. The latter trap retained Me_2O and traces of Me_2GeH_2 and Me_2Se which were identified spectroscopically (4, 11). The material at −78°C was further fractionated through traps at −45 and −78°C. The −45°C trap contained pure bis(dimethylgermyl) selenide, $((Me_2HGe)_2Se$, 3.90 mmol, 89%; ms peak m/e 279–294 $(C_4H_nGe_2Se)^+$). No Me_2HGeI was recovered. The analogous reactions with trimethylbromo- or trimethyliodogermane were allowed to occur at 25°C either in Me_2O or Et_2O. Details of the preparations are collected in Table 1.

(ii) With Lithium Oxide

Typically, Me_2HGeI (0.80 g, 3.47 mmol) and Li_2O (0.060 g, 2.00 mmol) were allowed to react as in (*i*). Upon fractionation of the volatile materials a mixture of $(Me_2HGe)_2O$ and Me_2HGeI (ca. 0.39 g) and small amounts of immiscible droplets of water were retained at −78°C, as identified spectroscopically (see Results and Discussion). Attempts to separate the $(Me_2HGe)_2O$ from Me_2HGeI by trap to trap fractional distillation were unsuccessful. Longer reaction times and appreciable excesses of Li_2O had little effect on the product mixture. By contrast, trimethylbromogermane, Me_3GeBr (0.58 g, 2.94 mmol) and Li_2O (0.18 g, ca. 6 mmol) in Et_2O at 25°C with continuous stirring for ca. 80 h gave $(Me_3Ge)_2O$ (0.357 g, 1.42 mmol, 98%). The purity of $(Me_3Ge)_2O$ was confirmed by the absence of the stretching vibration, ν(Ge—Br), in the Raman spectrum.

Reactions of $Me_nH_{3-n}GeX$ with Lead(II) Salts

(i) $Me_nH_{3-n}GeBr$ with PbO

Typically, MeH_2GeBr (1.56 mmol) was condensed onto PbO (ca. 14 g) contained in a reaction flask (ca. 40 ml; equipped with a Teflon-in-glass stopcock) held at −196°C. The −196°C bath was removed and the contents of the reaction flask were shaken and allowed to react at 25°C for ca. 20 min. Fractionational condensation at −78°C gave bis(methylgermyl)oxide, $(MeH_2Ge)_2O$ (0.76 mmol, 97.4%). By similar procedures Me_2HGeBr (2.98 mmol), Me_3GeBr (3.67 mmol), and H_3GeBr (0.92 mmol) reacted with PbO (12–15 g) to give $(Me_2HGe)_2O$ (1.47 mmol, 98.7%), $(Me_3Ge)_2O$ (1.83 mmol, 99.7%), and $(H_3Ge)_2O$ (0.35 mmol, 76.1%), respectively. However, when gaseous MeH_2GeBr (1.41 mmol) was allowed to pass back and forth six times at room temperature over a mixture of PbO (ca. 40 g) and a small amount of powdered glass held in a column on glass wool the recovery of MeH_2GeBr (1.39 mmol) was almost quantitative.

(ii) $Me_nH_{3-n}GeI$ with PbO

Typically, Me_2HGeI (1.46 mmol) was condensed onto excess of PbO in an analogous manner to (*i*). After ca. 15 min at 25°C, fractionation of the volatile materials through traps at −78 and −196°C gave $(Me_2HGe)_2O$ (0.45 mmol, 61.6%) in the former and Me_2GeH_2 (0.20 mmol) in the latter. Similarly, H_3GeI (0.86 mmol), MeH_2GeI (1.22 mmol), and Me_3GeI (3.67 mmol) were converted by PbO to the corresponding oxides, viz. $(H_3Ge)_2O$ (0.15 mmol, 34.9%), $(MeH_2Ge)_2O$ (0.28 mmol, 45.9%), and $(Me_3Ge)_2O$ (1.82 mmol, 99.2%).

In the alternative preparation, when $Me_nH_{3-n}GeI$ (n = 0, 1, 2) was streamed as a gas over a previously evacuated column of PbO as in (*i*) very little formation of germoxanes (5–15%) was achieved as estimated by the relative intensity of the stretching vibrations ν(Ge—O) and ν(Ge—I) in the Raman spectra.

(iii) MeH_2GeBr and Me_3GeBr with PbS

A mixture of MeH_2GeBr (1.89 mmol) and excess of PbS was allowed to react at 25°C for ca. 25 min as in (*i*). Fractionation of the volatile material gave unchanged MeH_2GeBr (1.80 mmol). No reaction occurred even when the mixture of Me_3GeBr (2.96 mmol) and excess of PbS was heated at 85°C for ca. 2 h.

(iv) MeH_2GeI and Me_3GeI with PbS

In a typical reaction, MeH_2GeI (1.03 mmol) was allowed to react with excess of PbS at 25°C for ca. 30 min. Fractionation of the volatile materials through traps held at −78 and −196°C gave a mixture of $(MeH_2Ge)_2S$ and MeH_2GeI in the former, and small amounts of $MeGeH_3$ in the latter. The conversion of MeH_2GeI into $(MeH_2Ge)_2S$ was 39% as estimated by their respective peak ratios in the ^1H nmr spectrum. Me_3GeI (2.40 mmol) at 80°C for 2 h gave $(Me_3Ge)_2S$ (0.90 mmol, 75.0%).

Reactions of Fluorogermanes with Organosilicon Chalcogenides

In a typical reaction, $(Me_3Si)_2S$ (0.24 mmol) and excess H_3GeF (0.61 mmol) were distilled into an ampule and allowed to react at room temperature for 5–10 min. The volatile materials were then fractionated at −45 and −196°C. The

former trap held $(H_3Ge)_2S$ (0.23 mmol, 96%) while the latter retained Me_3SiF (11) and unreacted H_3GeF (12), identified spectroscopically. Similar experiments using excess $MeGeH_2F$ and Me_2GeHF gave $(MeGeH_2)_2S$ (100%) and $(Me_2HGe)_2S$ (95%). The analogous reaction of $(Me_3Si)_2S$ (3.28 mmol) with excess Me_3GeF (8.15 mmol) for 45 min at room temperature gave a mixture of $(Me_3Ge)_2S$, $(Me_3Si)_2S$, and the mixed sulfide $Me_3SiSGeMe_3$ at −23°C, and Me_3SiF and MeGeF at −196°C. All species were identified by their ^1H nmr parameters (12–14). Similar product distribution was obtained with longer reaction times. However, when $(Me_3Si)_2S$ (0.14 mmol) and Me_3GeF (0.41 mmol) were allowed to react in a sealed tube at high temperature (≥80°C) and left overnight, then $(Me_3Ge)_2S$ (0.14 mmol) was formed quantitatively. Details of all preparations are collected in Table 2.

Reactions of Chalcogermanes with Hydrogen Sulfide and Selenide

In a typical reaction, $(Me_3Ge)_2O$ (1.25 mmol) and H_2S (1.28 mmol) were introduced into an ampule (ca. 7.5 ml) and isolated for 5 min at 25°C. Fractional condensation at −78°C afforded $(Me_3Ge)_2S$ (1.24 mmol, 99.2%; ms peak *m/e* 262–274 $(C_6H_{18}Ge_2S)^+$) and traces of H_2S at −196°C. Immiscible droplets of water were removed by passage of the mixture over a small amount of P_2O_5. The formation of the thiol, Me_3GeSH, resulted when excess H_2S was used as was confirmed by its ^1H nmr parameters (δ(Me) 0.56, δ(SH) −0.32 ppm, $|J_{^{13}CH}|$ 129.0 Hz). The thiol was sufficiently stable at low temperatures to permit the recording of its mass spectrum, peak *m/e* 147–155 $(CH_4GeS)^+$. Thus, with the vessel held at −78°C, H_2S was pumped away and the thiol was passed into the mass spectrometer. The identical reaction of $(H_3Ge)_2O$ with H_2S gave high yields of $(H_3Ge)_2S$, ms peak *m/e* 172–190 $(H_nGe_2S)^+$. With excess H_2S, formation of H_3GeSH resulted as was confirmed by its ^1H nmr (18) and mass spectral parameters (δ(GeH) 4.33, δ(SH) −0.23 ppm and ms peak *m/e* 102–112 $(H_nGeS)^+$. The analogous reactions with H_2Se gave the corresponding germyl selenides, $(Me_3Ge)_2Se$ (ms peak *m/e* 306–322 $(C_6H_{18}Ge_2Se)^+$) and $(H_3Ge)_2Se$ (ms peak *m/e* 216–238 $(H_nGe_2Se)^+$), and germaneselenols Me_3GeSeH (ms peak *m/e* 191–204 $(C_3H_{10}GeSe)^+$, δ(Me) 0.66, δ(SeH) −2.38 ppm, $|J_{^{13}CH}|$ 128.7, $|J_{^{77}SeH}|$ 42.55 Hz) and H_3GeSeH (ms peak *m/e* 146–162 $(H_nGeSe)^+$δ (GeH)4.26, δ(SeH) −2.23 ppm $|J_{^{77}SeH}|$ 41.1 Hz). The chalcogenols were also formed as mixtures with the sulfides and selenides with excess H_2S and H_2Se respectively and their ^1H nmr and mass spectra were recorded as above. Alternatively, the germyl selenides and selenols were formed from the sulfides with H_2Se.

Cleavage Reactions of Chalcogermanes with Hydrogen Halides

Analysis of the $Me_nH_{3-n}Ge$— moiety in the chalcogenide species, viz. $(Me_nH_{3-n}Ge)_2E$, was accomplished by protolytic cleavage of the Ge—E bond with an excess of gaseous hydrogen bromide. Typically, $(MeH_2Ge)_2S$ (1.25 mmol) and HBr (3.12 mmol) were condensed *in vacuo* into a small ampule (ca. 25 ml equipped with a Teflon-in-glass stopcock) held at −196°C. The contents were subsequently allowed to warm to room temperature for ca. 20 min. Fractionation of the products at −95 and −196°C gave MeH_2GeBr (2.46 mmol, 98%; identified by ^1H nmr (2) and vibrational (3) spectroscopy) condensing in the former and a mixture of H_2S and unreacted HBr (identified by their infrared parameters (15)) in the latter. Similar reactions with other chalcogenides provided indirect evidence for the stoichiometric and monomeric nature of $(Me_nH_{3-n}Ge)_2E$.

Results and Discussion

Heavy metal salts (16–20), as well as lithium salts (21, 22) have been widely used in the conversion of halogenosilanes and germanes into the corresponding chalcogenides. We find that iodogermanes react with lithium sulfide, selenide and telluride in ether to give high yields (Table 1) of the chalcogenides [1]. The

[1] $2Me_nH_{3-n}GeI + Li_2E \rightarrow (Me_nH_{3-n}Ge)_2E + 2LiI$
(E = S, Se, Te; $n = 0 \rightarrow 3$)

corresponding reaction of mono- and dimethyliodogermane with lithium oxide does not go to completion at −78°C, but trimethyliodo- and trimethylbromogermane afford high yields of hexamethyldigermoxane at ambient temperature. It is interesting to note that we have observed rapid exchange (on the nmr time scale) in the systems $(Me_nH_{3-n}Ge)_2O$–$Me_nH_{3-n}GeX$ (X = Br, I). Thus, the ^1H nmr spectrum shows a single, well resolved resonance intermediate to the resonance positions of the pure compounds (a 1:1 mixture of $(Me_2HGe)_2O$ (δ (Me) 0.40, δ (GeH) 5.40 ppm) and Me_2HGeI (δ (Me) 1.08, δ (GeH) 4.12 ppm) gives a well resolved doublet-septet ^1H nmr spectrum: δ (Me) 0.78, δ (GeH) 5.17 ppm). This observation places some doubt on the reported conversions of H_3GeI to $(H_3Ge)_2O$ with HgO and of $(H_3Ge)_2O$ to H_3GeI with HgI_2 (18). We also examined the use of lead(II) oxide in these syntheses. In ambient temperature reactions without the use of solvent, lead(II) oxide provides facile

For personal use only.

conversion of $Me_nH_{3-n}GeBr$ into $(Me_nH_{3-n}Ge)_2O$ in high yield. The corresponding reaction using $Me_nH_{3-n}GeI$ gives lower yields (ca. 35–60%) of $(Me_nH_{3-n}Ge)_2O$ and appreciable amounts of the decomposition by-product, methylgermane. By contrast, when iodo- and bromogermanes are passed as gases over PbO there is essentially no reaction. Bromogermanes do not react with PbS but there is partial conversion of iodogermanes into the corresponding sulfides. Nevertheless, the lower reactivity of iodogermanes towards PbS relative to Li_2S is also shown in the reactions with PbSe contrasted with Li_2Se.

However, it is essential that Li_2Se be prepared properly because, when Me_2HGeI is reacted with excess Li_2Se, where the samples still contain quantities of NH_3, Li_2NH, and $LiNH_2$ or when excess of selenium is used, a considerable reduction in the yield of bis(dimethylgermyl) selenide results with increased yields of the condensed selenide, $Me_2Ge(SeGeHMe_2)_2$ [2]. During the fractionation of these mixtures, a deposit of metallic selenium is observed with the evolution of a more volatile component, 1,1′,2,2′-tetramethyldigermane, $(Me_2HGe)_2$ (23) [3]. The latter reacts readily with hydrogen chloride or bromide without a catalyst according to reaction 4.

[2] $2(Me_2HGe)_2Se \rightarrow Me_2Ge(SeGeHMe_2)_2 + Me_2GeH_2$

[3] $Me_2Ge(SeGeHMe)_2 \rightarrow (Me_2HGe)_2 + (Me_2GeSe)_n + Se \qquad (n = 2, 3)$

[4] $2(Me_2GeH)_2 + 3HX \rightarrow Me_2HGeGeXMe_2 + (Me_2GeX)_2 + 3H_2 \qquad (X = Cl, Br)$

Pure samples of the chalcogermanes, in general, showed little evidence for condensation or elimination. However, increased condensation is observed in the telluro species, as is evident from the slow condensation of $(MeH_2Ge)_2Te$ at room temperature over an extended period of time. Moderate heating of

[5] $2(MeH_2Ge)_2Te \rightarrow MeHGe(TeGeH_2Me)_2 + MeGeH_3$

[6] $2MeGeH(TeGeH_2Me)_2 \rightarrow MeGe(TeGeH_2Me)_3 + MeGeH_2$

the condensed species in this instance leads to the elimination of tellurium and the formation of $(MeH_2Ge)_2$ (23). Similarly, condensation and elimination of tellurium are observed when tellurogermanes are sealed over extended periods (ca. 1 month) in cyclohexane solution.

The exchange reactions involving bis(trimethylsilyl) chalcogenides, viz. $(Me_3Si)_2E$ (E = S, Se, Te) and fluorogermanes, which occur in the absence of solvent, follow the general rule that the harder moiety (24*b*) prefers to be attached to silicon, so that the reactions to give Ge—S, Ge—Se and Ge—Te bonds are essentially quantitative. Attempts to prepare

[7] $(Me_3Si)_2E + 2Me_nH_{3-n}GeF \rightarrow (Me_nH_{3-n}Ge)_2E + 2Me_3SiF$

chalcogermanes by this method using the more readily available chlorides were unsuccessful because mixtures containing mixed species of the type $Me_3SiEGeMe_3$ were obtained.

The chalcogermanes are all colourless liquids with obnoxious odours. When the hydridic species are pure, they show little tendency to decompose when stored at ambient temperature. They are characterized by ^1H nmr, ir, Raman, and mass spectra and by reactions with anhydrous hydrogen halides, as well as hydrogen chalcogenides. The former cleaves the Ge—E bond quantitatively [8] to give well known compounds. Previous reports (24, 25) have shown

[8] $(Me_nH_{3-n}Ge)_2E + 2HBr \rightarrow 2Me_nH_{3-n}GeBr + H_2E$

that hydrogen sulfide and selenide react with either germylphosphine or -arsine to give $(H_3Ge)_2S$ and $(H_3Ge)_2Se$ via H_3GeSH and H_3GeSeH. These intermediates thio- and selenogermanes are also observed when digermoxane is treated with an excess of the hydrogen chalcogenide [9].

[9] $(H_3Ge)_2O + H_2E\,(\text{excess}) \rightarrow (H_3Ge)_2E + H_2O$, with H_3GeEH as intermediate

This method is quite useful for the preparation of $(Me_nH_{3-n}Ge)_2E$ when stoichiometric quantities of H_2E and $(Me_nH_{3-n}Ge)_2O$ are used (26).

Characterization of the Chalcogermanes

The ^1H nmr spectra of the chalcogermanes provide the initial characterization of the species and confirmed their purity (>99% based on the absence of any other proton containing species). The chalcogermanes, $(Me_nH_{3-n}Ge)_2E$ give first-order spectra (Table 3) consistent with free rotation about the Ge—E bonds. The chemical shifts of the germyl and methyl protons show similar changes with substituent electronegativity as do the halogenogermanes $Me_nH_{3-n}GeX$. Thus, for any series, as E = O → S → Se → Te the GeH resonance moves to high field consistent with a decrease in inductive deshielding. The accompanying downfield shift in the Me resonance may be related to anisotropic factors (14). Satellites arising from interaction with ^{77}Se and ^{125}Te are observed, indicating there is no rapid exchange of germyl groups under these conditions.

The hydridic chalcogenols, H_3GeEH (E = S, Se) give long range, first-order coupling between the three hydrogen atoms attached to germanium and the lone hydrogen attached to the chalcogen atom. The resultant doublet-quartet pattern (intensity 3:1) has been observed previously (24*a*, 25, 27). H–H coupling is not observed in the case of Me_3GeEH nor is the longer range H–H coupling observed in Me_3GeE-GeH_3 (E = S, Se, Te), where the spectra show two singlet peaks (intensity 3:1) attributable to δ(Me) and δ(GeH).[2] The condensed chalcogermanes give simple first order spectra, similar to the parent analogues. Overlap of the resonances with those of the parent compounds allows only tentative assignments to δ(Me) and δ(GeH) as follows: $Me_2'Ge(SeGeHMe_2)_2$; δ(Me) 0.31, δ(GeH) 3.73, δ(Me') 0.37 ppm; $Me'H'Ge(TeGeH_2Me)_2$: δ(Me) ca. 0.93, δ(GeH) ca. 4.12, δ(Me') 1.53, δ(GeH') 5.75 ppm; $Me'Ge(TeGeH_2Me)_3$: δ(Me) ca. 0.93, δ(GeH) ca. 4.12, δ(Me') 2.13 ppm.

The vibrational spectra of $(Me_3Ge)_2E$ and $(H_3Ge)_2E$ where E = O, S, Se, Te have appeared elsewhere (18, 22, 29–32) so we will only concern ourselves with the intermediate species (Tables 4 and 5). Assignments of the vibrational modes in $(MeH_2Ge)_2E$ and $(Me_2HGe)_2E$ are based on the aforementioned chalcogermanes and related monohalogeno- and pseudohalogenogermanes (3, 4, 33).

General features in the spectra of the chalcogermanes, which are characteristic of the Ge—E—Ge linkage, appear as follows: Ge—E stretching (2 bands) at ca. 882 (ir) and 501–480m,p (Raman) [O]; ca. 410s (ir) and ca. 371vs,p (Raman) [S]; 280s (ir) and ca. 276vs,p (Raman) [Se]; 235m (ir) and ca. 229vs,p (Raman) [Te]. The Ge—E—Ge deformation mode is clearly observed in the Raman spectra of the chalcogermanes and the resulting trend of O > S > Se > Te is a direct consequence of the weight of the chalcogen atom. Thus for $(MeH_2Ge)_2E$ we observe a shift in the Ge—E—Ge deformation as follows: 182m,p [O]; 101ms,p [S]; 84ms,p [Se]; 77ms,p [Te] which is similar to that of the $(Me_2HGe)_2E$ series, viz. 169m,p [O]; 95m,p [S]; 76m,p [Se]; 63m,p [Te]. The methyl stretching and deformation modes are clearly observed in the expected 3000–2920 cm^{-1} and 1420–1240 cm^{-1} regions as are the Ge—H stretching modes at 2080–2030 cm^{-1}. The remainder of the assignments for the $Me_nH_{3-n}Ge$— moieties (i.e. ρCH_3, δGeH_2, ρGeH_2, δGeH) are comparable to the related monohalogeno and pseudohalogenogermanes (3, 4, 33).

The mass spectroscopic data for the chalcogermanes are complicated due to the presence of polyisotopic atoms and to the stripping of hydrogen from the hydridic species, viz. $(Me_nH_{3-n}Ge)_2E$, n = 0–2. Summation of the hydrogen loss for each fragment, however, greatly reduces the complexity of the problem, resulting in 'generalized' assignments. The mass spectra of the intermediate chalcogenides, viz. $(Me_nH_{3-n}Ge)_2E$, n = 1, 2 have been analyzed and are displayed in Tables 6 and 7. The molecular ion is present in all cases although in larger abundances for the monomethyl chalcogermanes. Fragmentation along the CGeEGeC skeleton affords large abundances of ions resulting from the loss of Me, $Me_nH_{3-n}Ge$ and $Me_nH_{3-n}GeE$. The most abundant ion in the dimethyl species is due to Me_3GeH_n (n = 0, 1) suggesting a migration of a methyl group from one germanium atom to the

other. A similar rearrangement is not observed in the methylseleno and -telluro derivatives but could occur in the oxides and sulfides where the overlapping of fragments makes such an assignment speculative. The $(C_2H_nGe_2)^+$ and $(C_4H_nGe_2)^+$ fragments observed in the spectra of $(MeH_2Ge)_2Se$ and $(Me_2HGe)_2E$, where E = Se, Te, result from the effective elimination of the central chalcogen atom. For the other species in Tables 6 and 7, the *m/e* values of these fragments overlap those of other probable molecular ions. The elimination of the central atom now appears to be a common feature in the cleavage of silyl and germyl Group V and VI species (*1*, 34).

The proton nuclear magnetic resonance spectra of a reaction mixture of hydrazine and ethyl acetoacetate (EAA) in aqueous solution under flowing and stopped-flow conditions provides kinetic information concerning the rapid addition step to form the carbinolamine (CA) intermediate and the slower dehydration and cyclization steps to form the *anti* hydrazone and 3-methylpyrazol-5-one, respectively. The addition step was studied while flowing at rates faster than the dehydration and cyclization rates so that no product signal was observed. Under these conditions, a broad signal resulting from the coalescence of the CH_3 proton resonances of EAA and CA is observed. Analysis of the line shape of this broad signal yields the addition rate constant, which has a value that appears to be p*H* dependent and is of the order of $10^3\ M^{-1}\ s^{-1}$. Stopped-flow spectra provide the time dependence for the reactant and product signals. Analysis of these time dependences provides information concerning the mechanism of product formation. In contrast with hydroxylamine, CA appears to undergo dehydration and cyclization at comparable rates in the p*H* range, 8.8–9.2 when hydrazine is the nucleophile. In addition, the *anti* hydrazone cyclizes at an appreciable rate. These intramolecular cyclization rates are compared with the intermolecular values.

Les spectres de résonance magnétique nucléaire du proton du mélange réactionnel de l'hydrazine et de l'acétoacétate d'éthyle (AAE) en solution aqueuse dans des conditions de flux et de flux stoppé fournissent de l'information cinétique concernant l'étape d'addition rapide pour former l'intermédiaire carbinolamine (CA) et les étapes plus lentes de déshydratation et de cyclisation formant respectivement l'hydrazone *anti* et la méthyl-3 pyrazolone-5. On a étudié l'étape d'addition alors que les vitesses d'écoulement étaient plus grandes que les vitesses de déshydratation et de cyclisation de façon à ce que l'on n'observe aucun signal de produit. Dans ces conditions, on observe un signal large provenant de la coalescence des résonances des protons CH_3 de l'AAE et du CA. L'analyse des formes des raies de ce signal large fournit la constante de vitesse de l'addition qui a une valeur qui semble dépendre du p*H* et qui est de l'ordre de $10^3\ M^{-1}\ s^{-1}$. Le spectre à flux stoppé fournit une relation en fonction du temps pour les signaux des réactifs et des produits. Une analyse de ces fonctions fournit de l'information concernant le mécanisme de la formation du produit. Par opposition avec l'hydroxylamine, il semble que, si l'hydrazine agit comme nucléophile, la CA subit des réactions de déshydratation et de cyclisation avec des vitesses qui sont comparables à des p*H* allant de 8.8–9.2. De plus l'hydrazone *anti* se cyclise à une vitesse élevée. On compare ces vitesses de cyclisation intramoléculaire avec les valeurs intermoléculaires.

Introduction

By means of nuclear magnetic resonance spectroscopy of flowing liquids, it was possible to measure directly the rates for the addition, dehydration, and cyclization steps for the reaction between hydroxylamine and ethyl acetoacetate (EAA) (1). At p*H* 6.5 and above, the addition step to form the carbinolamine intermediate CA is much faster than the dehydration of this intermediate, permitting its detection and the measurement of the rate of addition by means of nmr line shape analysis. It was also found that cyclization of CA was not competitive with dehydration to form the *syn* and *anti* oximes. The *syn* isomer subsequently cyclizes to form 3-methylisoxazol-5-one at an appreciable rate whereas the conversion of the *anti* isomer is substantially slower. In the present paper, we report the results of a study of the reaction between hydrazine (HYD) and EAA. Hydrazine offers an interesting comparison with hydroxylamine since the intramolecular addition to the acyl carbonyl, which follows the formation of CA, involves nitrogen rather than oxygen. Unlike the hydroxylamine case, the cyclization of the CA intermediate formed from HYD appears to be competitive with the dehydration step, and no *syn* hydrazone is detected. Furthermore,

the *anti* isomer converts to the cyclic product, 3-methylpyrazol-5-one (MPY) at an appreciable rate. Since the *anti* isomer must first convert to the *syn* form before cyclizing and since no *syn* isomer is detected, the rate of cyclization of the *anti* isomer is equal to the rate of conversion of *anti* into *syn* isomer. In addition, the intramolecular addition of nitrogen to the acyl carbonyl proceeds faster than the intermolecular process.

Experimental

All chemicals except acetoacetamide were obtained from suppliers. Ethyl acetoacetate and hydrazine were distilled before use. The buffers were used without additional purification. Acetoacetamide was prepared from diketene according to the procedure used to prepare *p*-fluoroacetoacetanilide (2). This procedure was modified slightly in that the temperature was maintained between -35 and -30°C and a slight excess of diketene was used. The yield of amide was 91%, and after recrystallizing from acetone – petroleum ether, the melting point was 54–55°C. The kinetic method involved measurement of the proton nmr spectra at 100 MHz and 30.0 ± 0.3°C under static and flowing conditions using a Varian HA-100-15 equipped with a flow system as described earlier (3). The rate constant k_n for the addition step was obtained by analysis of the line shape of signals in spectra obtained while the liquid was flowing. The rate of decomposition of the tetrahedral intermediate to form products and growth of products was obtained from the time dependence of the spectra measured after the flow had been stopped. For these cases, the reaction mixture was made by mixing equal volumes of an aqueous ethyl acetoacetate and an aqueous hydrazine solution at an ionic strength of 1.0 (KCl).

The equilibrium constant K_n for the addition step was determined from the uv absorbance decrease measured with a Cary 118 when equal volumes of hydrazine and ethyl acetoacetate were mixed under the same conditions as the nmr kinetic measurements. A flow system was used for this measurement. The p*H* of the solutions was measured using a Radiometer PHM 63 digital p*H* meter with an accuracy of ± 0.02 unit. The p*H* of the reaction mixture was measured as a function of time at 5-s intervals immediately after mixing. This interval was expanded to several minutes as the reaction progressed.

Results

Sample spectra obtained under static and flowing conditions at 30°C are illustrated in Fig. 1. The spectrum labeled EAA illustrates only the proton resonance of the carbonyl CH_3 of EAA (for reference) obtained under static conditions without spinning for an aqueous solution containing 0.2 *M* EAA and 0.2 *M* diazabicyclooctane DABCO at p*H* 9.0. The complete spectrum of EAA under similar conditions has been reported earlier (1). The spectrum labeled FLOW was obtained by mixing the EAA solution with an equal volume of an aqueous solution of 0.8 *M* HYD at a flow rate of 20 ml/min. The STOP spectrum was obtained just after the flow had been stopped and the spectrum at the end of the reaction is labeled FINAL. The assignment of the

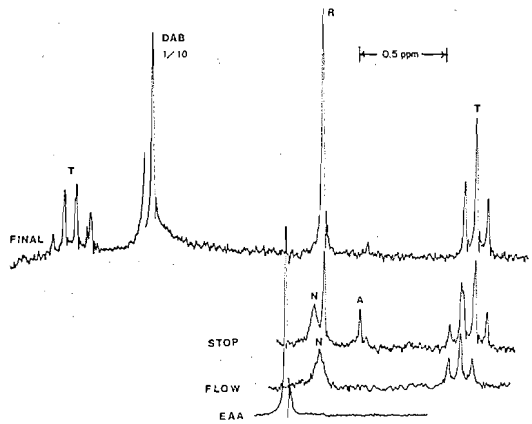

FIG. 1. Proton nmr spectra of aqueous solutions at p*H* 9.0 obtained at 100 MHz and 30°C under static and flowing conditions without spinning. Only the portion of the spectral range upfield from the water signal, which is used as the lock signal, is illustrated. The EAA spectrum is the keto CH_3 resonance of 0.20 *M* EAA. The flow spectrum was obtained after mixing the EAA solution with 0.8 *M* HYD (total). The stop spectrum was obtained immediately after stopping the flow. The final spectrum was recorded after the anti hydrazone had disappeared. For the assignment of the resonances, see the text.

signals is analogous to that given previously for the reaction of hydroxylamine with EAA (1). Thus, the triplet and quartet labeled T are due to ethanol (CH_3 and CH_2 protons, respectively); and the signals labeled R and A are due to the CH_3 protons of 3-methylpyrazol-5-one (MPY) and *anti* hydrazone of EAA, respectively. The triplets due to the ethoxy CH_3 protons of EAA and the isomeric hydrazones have identical chemical shifts (at the same position as the triplet illustrated in the flow spectrum). The signal due to DABCO (labeled DAB) was recorded at 1/10 the gain used for the rest of the spectrum. As in the case of the reaction of EAA with hydroxylamine (1), the broad signal labeled N is a coalescence of two CH_3 proton resonances, one due to EAA and the other due to the carbinolamine CA formed by the addition of HYD to the keto carbonyl carbon of EAA. Thus, in the flow spectrum obtained after mixing, the EAA signal is not observed in its original position and, instead, has moved upfield and merged with the CA signal because the equilibrium, EAA + HYD $\rightleftharpoons$ CA, is rapid on the nmr time scale (4). Consequently, although the forward and reverse rates for this equilibrium are too fast relative to the flow rates employed, they may be obtained by analysis of the line shape of N, which is related to the average lifetime τ for exchange between the CH_3 protons of EAA and those of CA (4).

The value for τ is calculated using the equation for fast exchange between two sites (4), $\Delta = p_1 p_2 \delta^2 \tau$. In the present case, the CH_3 protons are exchanging as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a group between the EAA and the CA environments. Consequently, p_1 and p_2 represent the proton fractions of the carbonyl CH_3 protons of EAA and CA, respectively, and δ is the chemical shift between the signals due to these two types of protons. For pH values of 9.0 or greater the proton fractions are calculated from the initial concentrations of EAA and HYD using K_n, the equilibrium constant for the equilibrium, EAA + HYD $\rightleftharpoons$ CA, which was determined to have a value of 0.50 M^{-1} based on the decrease in uv absorbance measured when an EAA solution was mixed with a HYD solution in a flow system. Below pH 9.0, the protonation of HYD and CA has been taken into account in the calculation of the proton fractions. This was done by considering the following equilibria to calculate the equilibrium concentrations of all the species indicated:

$$NH_2NH_3^+ \underset{H^+}{\overset{-H^+}{\rightleftharpoons}} NH_2NH_2 + EAA \overset{K_n}{\rightleftharpoons} CA \underset{-H^+}{\overset{H^+}{\rightleftharpoons}} CAH^+$$

For this purpose, 8.20 was used as the pK_a for hydrazine at 1.0 ionic strength (5). Although the pK_a for CAH^+ could not be measured, it is estimated to be 7.3, (the pK_a value of the more basic of the two possible types of protonated species), based on the values for hydrazine and 1,2-dimethylhydrazine (6) and correcting for substituent effects as discussed below. By suitable combination of all of the equilibrium constant expressions, equilibrium concentrations may be specified at any pH for given total concentrations of HYD and EAA. In practice, these calculations were programmed conveniently on an HP-65 calculator.

At pH 8.5, the extent of protonation is small so that the proton fraction for the intermediate is almost the same as that at higher pH for solutions containing the same initial concentrations of reactants. However, below this pH, protonation becomes more important, and the proton fraction of the intermediate decreases. The extent of this decrease depends on the interpretation of the details of the exchange, i.e. does the exchange with EAA involve either CA alone or CA plus CAH^+? For the former, the proton fraction of the intermediate is obtained from the concentration of CA; for the latter, it is obtained from the sum of the concentrations of CA and CAH^+. We conclude that the exchange involves the latter because the equilibrium between CA and CAH^+ is probably much faster than the one between EAA and the intermediate (CA and/or CAH^+). This conclusion is based on the following considerations. Acid–base proton transfer reactions have second-order rate constants of about 5×10^8 s^{-1} M^{-1} (7). In addition to CA and CAH^+, the solution contains the acid and base forms of the buffer and HYD, all of which can undergo proton transfer reactions with CA and CAH^+. Consequently since the concentration for acid and for base is at least 0.1 M, the lifetime for conversion of CA to CAH^+ is estimated to be about 2×10^{-8} s, which is about 4 orders of magnitude smaller than the lifetime for exchange between EAA and the intermediate (see below). Thus, the CH_3 signals due to CA and CAH^+ are coalesced and the exchange between EAA and the intermediate reduces to a two-site process in which the proton fraction for the intermediate p_I is obtained from the sum of the concentrations of CA and CAH^+. The rest of the calculation to obtain τ is the same as that used for the higher pH solutions, except that the chemical shift δ is slightly lower than the value at higher pH (90 Hz vs. 96 Hz). The value for the chemical shift of the intermediate is obtained by determining the position of the coalescence signal as a function of HYD concentration when the EAA concentration is held constant, as has been described previously (3*a*).

For each run, the value for Δ (in rad s^{-1}) is obtained from the line width of the coalescence signal by subtracting out the weighted average of the line widths in the absence of exchange for the signals due to each of the two CH_3 groups that are involved in the exchange. This line width for the CH_3 group of EAA is obtained in the absence of HYD. For the CH_3 group of CA, this line width could not be measured directly because the exchange rate could not be slowed sufficiently. Consequently, it was assumed to be the same as that for the CH_3 signal of the structurally similar carbinolamine derived from acetaldehyde (8). To account for any changes due to field homogeneity or flow rate from one run to the next, the line widths were related to the one for the CH_3 signal of methanol, which was present in all kinetic runs.

The forward k_n and reverse k_{-n} rate constants for the equilibrium are obtained from the equilibrium constant K_n and the exchange rate $1/\tau$, which is related to τ_E, the average lifetime for the CH_3 protons at the EAA site by the expression, $1/\tau_E = p_I/\tau$. Thus, since $1/\tau_E = k_n[NH_2NH_2]$ in which $[NH_2NH_2]$ is the equilibrium concentration of HYD free base, k_n may be calculated, and values are listed in Table 1 for various conditions of pH and concentration. Values for k_{-n} are not listed in the table because they are not obtained independently, i.e. k_{-n} is calculated using k_n and K_n.

Each value of k_n listed in Table 1 is an average of at least three measurements with a precision of $\pm 20\%$. For each pH, k_n appears to be independent of buffer concentration since the values do not vary

systematically and the differences are within experimental error. A similar result was found previously for the addition of hydroxylamine to EAA (1). On the other hand unlike the hydroxylamine case, k_n appears to be p*H* dependent, increasing approximately linearly as the hydronium ion concentration increases. For the hydroxylamine reaction, the absence of buffer and hydronium ion catalysis was considered to be evidence in favor of a rate limiting addition step to form the zwitterion $CA^{\pm}$ which rapidly converts to CA. For the HYD reaction, the results do not give a clear indication of the mechanistic details since the buffers do not catalyze the exchange process but the exchange rate increases with hydronium ion concentration. Unfortunately the p*H* range over which the p*H* effect is tested is small because the EAA CH_3 signal in the absence of HYD broadens for p*H* values larger than 9.2. Furthermore below p*H* 8.5, the contribution to the line width made by the EAA–CA exchange process is insufficient for accurate measurement because the small value for K_n coupled with protonation of HYD makes the proton fraction of the intermediate very small. In fact the results at p*H* 8.5 are somewhat marginal since Δ is not the dominant contribution to the line width. For example for 0.8 *M* HYD, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

largest concentration, Δ is 5.3 rad s^{-1} while the total line width is 12.0 rad s^{-1}. Consequently, the hydronium ion dependence must be considered somewhat tentative.[4] A test of the p*H* dependence for HYD addition is planned for another ketone for which K_n is appreciably larger.

The evaluation of rate constants for the formation of products from the time dependence of the coalescence signal depends upon the mechanism proposed. For the reaction of EAA with hydroxylamine, the mechanism appears to involve dehydration of the carbinolamine to form the *syn* and *anti* oximes with subsequent cyclization of the *syn* isomer (1). Cyclization via the *anti* isomer is substantially slower, and after the *syn* isomer has completely disappeared the cyclic compound and the *anti* oxime are present in about equal amounts. However in the present case with hydrazine as the nucleophile, no *syn* isomer is observed, and the *anti* isomer decays at an appreciable rate, indicating two possibilities: (*a*) dehydration of CA is faster than cyclization, and in the sequence CA → *syn* → MPY, the formation of *syn* is rate limiting; (*b*) same as *a* except CA → MPY is an additional path. To decide between these two possibilities, it is necessary to know the relative rates of formation of the *syn* and *anti* isomers. Since the cyclization step(s) cannot be slowed sufficiently to allow direct measurement of these rates, the following approach has been employed. The relative rates of formation of *syn* and *anti* hydrazones of acetoacetamide AAM were measured and assumed to be identical to those for EAA. If mechanism *a* obtains, this ratio should be identical to the ratio of MPY to *anti* isomer since all the *syn* isomer converts to MPY. For this purpose, the initial ratio of MPY to *anti*, which is obtained by extrapolation back to zero time, was used since the *anti* isomer also converts to MPY. For measurements between p*H* 8.8 and 9.2, this ratio is 1.1 ± 0.2. On the other hand, the ratio is 0.55 ± 0.03 for the hydrazones of AAM. Since the difference between these two ratios is well outside of experimental error and since mechanism *a* cannot account for this difference, it seems likely that mechanism *b* obtains, i.e. the cyclization of the carbinolamine of EAA is competitive with the dehydration step. Estimation of the rate constant for this cyclization step will be discussed below.

One question which must be considered concerns the validity of equating the ratio of rates obtained for EAA to that obtained for AAM. Fortunately, this approach can be tested with the oximes of EAA and AMM since the rate of conversion of *anti* oxime to cyclic compound is very slow in both cases, and cyclization via CA does not appear to occur for EAA (1). The ratio of rates of formation of *syn* vs. *anti* oxime was found to be identical for EAA and AAM, namely, 0.91 (1) and 0.92, respectively, at p*H* 7.0 in the presence of 0.3 *M* imidazole.

Since it appears that the carbinolamine intermediate cyclizes and dehydrates at comparable rates, the mechanism illustrated in Scheme 1 is proposed[5,6]. According to Scheme 1, the cyclic compound is formed only via intermediate CA whereas the *syn* and *anti* hydrazones are formed via intermediates CA and CAH_2^+. Cyclization via intermediate CAH_2^+ is expected to be slower than the other route since the nitrogen that is to add has no nonbonded electron pairs. On the other hand, a more complex reaction involving cyclization of CAH_2^+ after intramolecular proton transfer to the acyl carbonyl oxygen cannot be precluded. However, inclusion of this possibility makes only a minor alteration in the form of the rate expression as discussed below. Dehydration and cyclization via intermediate CAH_1^+ is assumed to occur more slowly than via the other two intermediates because the protonation is expected to make both nitrogens less electron donating. However, including this possibility does not alter the general form of the rate expression. The rate expression, which was derived to describe the rate of change of the total concentration of EAA according to this scheme, is

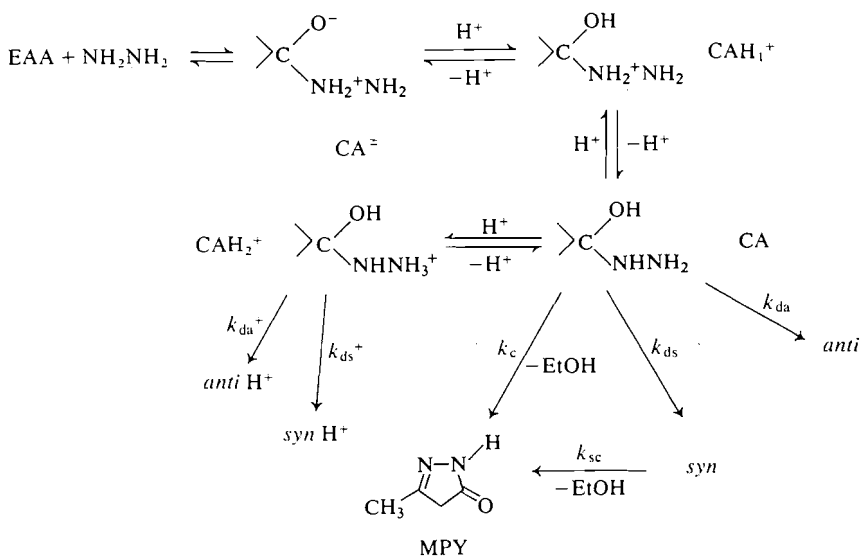
$$[1]\quad \frac{-d[EAA]_\Upsilon}{dt} = \frac{(k_d + k_d^+[H^+]/K_{a1} + k_c)K_n[N][EAA]_\Upsilon}{1 + K_n[N](L[H^+] + 1)}$$

in which the subscript d denotes dehydration to both *syn* and *anti* hydrazones, subscript Υ denotes total concentration, the superscript + denotes reaction via CAH_2^+, [N] is the equilibrium concentration of HYD free base, and $L = 1/K_{a1} + 1/K_{a2}$ in which the subscripts 1 and 2 denote CAH_1^+ and CAH_2^+,

[4]As pointed out by one of the referees, the p*H* dependence observed for k_n would require a very large third-order rate constant. In view of the possible error associated the results at p*H* 8.5, the reliability of this rate constant may be questionable.

[5]Although the reaction is written as stopping at MPY, MPY may, in fact, tautomerize to give the heterocyclic enamine. Since the ring CH proton resonance is not observed, we cannot determine whether most of the MPY converts to the enamine or only part of it does and the ring CH proton resonance is not observed because it is too broad due to rapid equilibration between the two tautomers.

[6]An intramolecular proton switch resulting in direct conversion of $CA^\pm$ to CA may also occur (see ref. 9) although we estimate that the intermolecular protonation may be somewhat faster in the present study since appreciable quantities of general acids are present.



SCHEME 1

respectively. The values for pK_{a1} and pK_{a2} are estimated to be 7.3 and 5.1, respectively, in the following manner.[7] For CAH_1^+ and CAH_2^+, 1,2-dimethylhydrazine (6) and hydrazine, respectively, are used as models and adjusted for substituent effects using σ^* values (10) and a ρ^* value of about -3 (11). For CAH_1^+, $\Delta pK = -2.45$ based on σ^* values of 0.555 for the HO—C group (10) and 0.26 estimated for the EtOOC—C—C group using the value for COOMe (10) and allowing that $\sigma_X = 2.8\sigma_{XCH_2}$ (12). For CAH_2^+, the σ^* values were estimated from those given above and assuming that the relation $\sigma_X = 2.8\sigma_{XCH_2}$ holds when the CH_2 group is replaced by the isoelectronic NH group, and ΔpK is estimated to be -0.88. In practice the sum of the rate constants, $k_d + k_d^+[H^+]/K_{a1} + k_c$, is calculated by a linear least-squares fit of the logarithm of the intensity of the coalescence signal vs. $K_n[N]t/[1 + K_n[N](L[H^+] + 1)]$ in which t is the time in seconds and [N] is determined at each t using the appropriate equilibrium constants and the total concentrations of HYD and EAA, which have been adjusted for product formation. The accuracy of this method of calculation was tested by using it to calculate the rate constant from data for the time dependence of $[EAA]_T$ that had been simulated by an incremental method using eq. 1 and specified rate constants. For this purpose, the incremental method was programmed for a HP 25 calculator to give $[EAA]_T$ and [N] for various time intervals, and it was found that time increments of 2 s or less give an accurate measure of dt. For all simulations, time increments of 0.5 s were used. It was found that the least-squares procedure gives a calculated rate constant that is always larger than the specified 'real' value and that this deviation depends upon the extent to which the concentration of one reactant exceeds that of the other. Thus, when the initial concentration of EAA is held constant at 0.1 M, the percentage error in the accuracy of the rate constant is 24.9, 10.3, and 6.0% for initial HYD concentrations of 0.1, 0.2, 0.4 M, respectively. In principle, the values calculated by the least-squares method could be corrected for this systematic error. However, the precision of the data does not warrant this correction, and the uncorrected first-order rate constants are reported as k_1 in Table 1. In addition, with the exception of one value, all the results reported in this table are derived from solutions for which the concentration of HYD is at least a factor of two larger than that for EAA so that the systematic error due to the method of calculation is 10% or less.

The values listed in Table 1 are for the sum of the rate constants, $k_d + k_d^+[H^+]/K_{a1} + k_c$. As mentioned above, product formation via CAH_1^+ and cyclization via CAH_2^+ have been neglected. Including these possibilities merely adds more terms to this sum but does not change the other parts of the rate expression and, therefore, does not alter the values in the table. The data in Table 1 do not give a clear indication concerning catalysis by the buffers. On the other hand, the rate constant k_1 increases as the initial pH is lowered from 8.5 to 7.5. Unfortunately, below pH 8.8 there is an appreciable decrease in pH during the reaction and any quantitative treatment of the pH dependence of k_1 is precluded. For

[7]We are grateful to one of the referees for pointing out this method.

For personal use only.

example, at an initial pH of 8.8, the pH decreases to a final value of 8.7, but for initial values of 8.5 and 7.5, it decreases to 8.0 and 7.0, respectively. As a result, below pH 8.8, the reported k_1 values must be considered averages over the pH change.

On the other hand, a dissection into a term for cyclization and one for dehydration is possible since the *syn* to *anti* hydrazone ratio measured for acetoacetamide appears to be identical to that for EAA, as discussed above. At pH 9.0, this ratio is 0.55 for the amide. If cyclization were occurring only via the *syn* hydrazone of EAA, the initial cyclic to *anti* ratio should also be 0.55. However, the initial cyclic to *anti* ratio is 1.1 in the pH range, 8.8–9.2, indicating that MPY is also formed from the carbinolamine intermediate. Using these two ratio (i.e. from AAM and EAA) and the expression $k_1 = k_c + k_{ds} + k_{da}$, for the EAA reaction, we find that $k_{da} = 0.48\ k_1$, $k_{ds} = 0.26\ k_1$, and $k_c = 0.26\ k_1$ in which k_c, k_{da}, and k_{ds} are the rate constants for conversion of carbinolamine to MPY and *anti* and *syn* hydrazone, respectively, with no restriction concerning protonation of the intermediate.

As discussed above, the signal due to the anti hydrazone decays at an appreciable rate with a concomitant growth in the MPY signal, indicating that the anti hydrazone converts to MPY. It is possible to calculate the rate constant k_{ac} for this conversion using a nonlinear least-squares fit of the concentration ratio $[MPY]/[EAA]_{r_0}$ vs. t according to the expression,

$$\frac{[MPY]}{[EAA]_{r_0}} = 1 - \exp(-k_1 t/X) + B(\exp(-k_{ac}t) - \exp(-k_1 t/X))$$

in which $B = k_{da}/(k_{ac}X - k_1)$, $X = (K_n[N] + 1)/K_n[N]$, t is the time, and k_{da}, which is the first-order rate constant for the formation of *anti* hydrazone from the various possible protonated forms of the intermediate, is obtained as just described. This expression was derived for the mechanism in the scheme for the case in which the pH is 8.8 or larger. For the fit, X and t are independent variables; [N] is obtained as a function of time as discussed above. The values listed in Table 1 for k_{ac} obtained in this manner have standard errors of about $\pm 10\%$ based on the fit of the data. Since the *syn* hydrazone is not detected, cyclization via this isomer is presumably faster than the *anti* to *syn* interconversion. Consequently, k_{ac} represents the first-order rate constant for *anti* to *syn* interconversion, and a comparison with k_c is not meaningful.

A measure of the effectiveness of the intramolecular cyclization steps relative to that for the analogous intermolecular nucleophilic reactions can be inferred. Since the carbinolamine is too reactive for the intermolecular study, the *O*-methyloxime of EAA was chosen as a model compound rather than EAA itself to prevent any complications resulting from nucleophilic addition to the keto carbonyl. Furthermore, since the carboethoxy group is separated from the oxime group by a CH_2 group, the rate difference caused by electronic differences between CA and the oxime of EAA is expected to be substantially less than an order of magnitude for the intermolecular process. 1,1-Dimethylhydrazine was chosen to be the intermolecular nucleophile because its primary nitrogen is expected to have a nucleophilicity similar to that for the primary nitrogen of the carbinolamine. Since these reactions were studied at pH 9.2, the ester hydrolysis rate of the *O*-methyloxime of EAA at this pH in the absence of the hydrazine was also measured as a control experiment. The rate of ester hydrolysis at this pH was found to be the same in the presence and in the absence of the hydrazine. Allowing for the fact that a 20% difference in the rate between the two solutions could have been detected, we estimate that the upper limit for the rate constant for ester hydrolysis catalyzed by 1,1-dimethylhydrazine is $4 \times 10^{-6} M^{-1}\,s^{-1}$. Since the average first-order rate constant for cyclization via the carbinolamine at pH 9.2 is about $2 \times 10^{-2}\ s^{-1}$, the lower limit for the effective molarity[8] of the nucleophile in the intramolecular process is about 10^4 M.

Since the cyclization of the *syn* hydrazone is apparently faster than the *anti* to *syn* interconversion, k_{ac} must be considered to be a lower limit to k_{sc}. Consequently comparison of the intermolecular hydrazone catalysis of the rate of ester hydrolysis with the cyclization of the *anti* hydrazone of EAA can provide only a lower limit to the effective molarity. The intermolecular catalysis of the ester hydrolysis by hydrazone was measured using a solution containing the *O*-methyloxime of EAA and the hydrazone of acetone. The oxime is expected to provide electronic effects similar to the hydrazone of EAA, and the primary nitrogen of hydrazone of acetone is expected to have a nucleophilicity similar to that for the primary nitrogen of the hydrazone of EAA. As a control, the rate of ester hydrolysis of this solution at pH 9.2 was compared to the rate for a solution that was exactly the same except that the hydrazone was absent. The rates were identical in both cases, and an upper limit for the rate constant for intermolecular hydrazone catalysis is estimated (in the same manner as described above) to be

[8]For a definition of effective molarity see ref. 13.

$4 \times 10^{-6} M^{-1} s^{-1}$. Consequently, the lower limit for the effective molarity of the primary nitrogen of the *syn* hydrazone of EAA is 10^3 *M*, based on an average value for k_{ac} at p*H* 9.2 (Table 1).

Cyclopropanediols. VII. Comportement chimique des cyclopropanediols et reactions de bis(trimethylsiloxy)-1,2 cyclopropanes

RAYMOND LE GOALLER ET JEAN-LOUIS PIERRE

Laboratoire de Chimie Organique, Université Scientifique et Médicale de Grenoble, B.P. 53, 38041 Grenoble Cedex, France

Reçu le 5 mai 1977

RAYMOND LE GOALLER et JEAN-LOUIS PIERRE. Can. J. Chem. **56**, 481 (1978).

Le texte décrit le comportement chimique des bis(triméthylsiloxy)-1,2-cyclopropanes. Les réactions de solvolyses acides et basiques, ainsi que les réactions du chlore et du brome se font avec ouverture du cycle conduisant à des α cétols, des énones et des β dicétones. Cétols et énones proviennent d'une ouverture type cyclopropanol, tandis que les β dicétones résultent de l'oxydation de siloxycyclopropanols ou de cyclopropanediols intermédiaires.

RAYMOND LE GOALLER and JEAN-LOUIS PIERRE. Can. J. Chem. **56**, 481 (1978).

The chemical behaviour of 1,2-bis(trimethylsiloxy)cyclopropanes is described. Acid and base solvolyses as well as reactions with chlorine and bromine occur with opening of the ring leading to α-ketols, enones and β-diketones. Ketols and enones arise from a cyclopropanol type ring opening while the β-diketones result from the oxidation of the intermediate siloxycyclopropanols or cyclopropanediols.

[Journal translation]

Introduction

Nous avons récemment décrit deux méthodes générales d'obtention de dérivés de cyclopropanediols (1). Nous nous proposons d'examiner ici leur comportement chimique. Les quelques cyclopropanediols libres obtenus à ce jour (2–6) sont représentés dans le schéma 1. Leur instabilité à l'air permettant difficilement l'étude de leur réactivité chimique, la littérature présente peu de données sur ce point.

Armand et Boulares (5) signalent simplement leur oxydabilité. Chen et Ainsworth (6) indiquent en outre la réaction de **3** avec le méthylate de sodium et son instabilité en milieu acide. Seuls, Curphey et coll. (3) et Reusch et coll. (4, 7, 8) ont effectué des études plus poussées sur leurs cyclopropanediols, mais ceux-ci sont exceptionnellement et anormalement stables en milieu acide (ils restent inchangés sous l'action de HCl méthanolique 2 *M*) et ne semblent donc pas représentatifs de cette classe de composés. Cette stabilité est d'ailleurs restée inexpliquée, une espèce homoaromatique ayant été suggérée, mais non confirmée. La réaction de **2** avec HCl 9 *M* fournit lentement l'α cétol **5**; par action de différents oxydants on obtient une dicétone **6**; l'action de la potasse le transforme en β cétol **7** et le chlorure d'acétyle en diacétate.

5 **6** **7** **8**

SCHÉMA 2

Les quelques réactions réalisées par Curphey et coll. (3) sur le diacétoxycyclopropane dérivé de **2** ne peuvent pas non plus être considérées comme caractéristiques du fait du squelette trop particulier. L'action de HCl méthanolique conduit au diol **2** et a des traces d'énone **8** et celle de HCl 9 *M* à l'α cétol **5** avec des traces de la même énone.

D'autre part, on sait que la réduction de Clemmensen des β dicétones conduit généralement à des α cétols et des cétones provenant de cyclopropanediols intermédiaires (9). Dans certains cas on a également obtenu des β cétols (schéma 3)

L'objet de ce travail est donc de cerner de plus près les propriétés des cyclopropanediols et éventuellement d'en dégager leur utilité en tant qu'intermédiaires de réactions, en étudiant le comportement chimique des bis(triméthylsiloxy)-1,2 cyclopropanes considérés comme des cyclopropanediols potentiels.

Resultats

Synthèse de diacétoxy-1,2 cyclopropanes

L'action du bromure d'acétyle dans l'éther sur les

SCHÉMA 3

bis(triméthylsiloxy)-1,2 cyclopropanes **9***a*–**17***a* conduit quantitativement aux diacétates correspondants **9***b* à **17***b* (schéma 4). La réaction est beaucoup plus rapide qu'avec le chlorure d'acétyle. Sans solvant et en présence d'un excès de bromure d'acétyle on obtient également des produits d'ouverture. C'est ainsi que le mélange des deux isomères de **9***a* conduit à l'acétoxy-3 méthyl-3 butanone-2 à côté des deux isomères de **9***b*. Dans tous les cas, hormis **14** les isomères cis et trans ont été séparés.

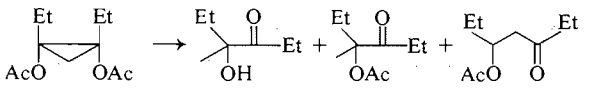
Solvolyses

Réactions induites par les acides

Les acétates de cyclopropanediols restent inchangés dans du méthanol pur, mais nous avons pu réaliser la méthanolyse de **9***b* au reflux en ajoutant un peu d'acide *p*-toluènesulfonique (TsOH). Les résultats au bout de 4 h de réaction, indiqués dans le schéma 5, montrent qu'ils diffèrent beaucoup de



10*b* **21** 47% **21***b* 50% **24***b* 3%

SCHÉMA 5

ceux de Curphey et coll. (3) et que nous avons une ouverture du cycle. Toutes ces réactions, comme les suivantes sont menées sous atmosphère d'azote.

En ce qui concerne les bis(triméthylsiloxy)-1,2 cyclopropanes, nous avons réalisé la méthanolyse dans les mêmes conditions que précédemment après avoir constaté qu'ils ne réagissent pas en milieu parfaitement neutre. Le composé de départ disparait entièrement au bout de 10 min de reflux. D'autre part, leur hydrolyse a été menée de trois façons différentes: (*i*) En milieu neutre: H_2O en quantité nécessaire et solvant[1]. Les bis(triméthylsiloxy) cyclopropanes ne sont pas affectés. La réaction a lieu dès que l'on ajoute un peu d'acide *p*-toluènesulfonique. Les résultats pratiquement analogues à ceux obtenus par méthanolyse ne dépendent pas de façon appréciable du solvant et sont résumés dans le schéma 6. (*ii*) La réaction de HCl gazeux et sec dans l'éther a été réalisée sur **9***a*, **10***a* et **17***a*. Dans chaque cas la réaction est immédiate et conduit exclusivement aux α cétols (indiqués entre crochets dans le schéma 4 pour **17***a*), sauf pour **9***a* qui donne un peu d'énone (moins de 10%). Nous n'avons pas observé de produits chlorés. (*iii*) La réaction de **9***a*, **10***a* et **17***a*, avec une solution chlorydrique N est également instantanée et conduit aux α cétols (≃80%) et aux énones (≃20%) pour **9***a* et **10***a* et à l'α cétol exclusivement pour **17***a*. Les résultats semblent donc indiquer que plus les conditions sont acides, plus on obtient d'α cétol.

D'autre part au cours de la méthanolyse de **9***a*, suivie en cpv, nous avons pu observer la formation, à côté de **19** et **20** d'un composé qui disparaît au cours de la réaction au profit de l'acétylacétone. Ce produit a été séparé par cpv préparative et identifié à partir de ses données spectroscopiques ir et rmn comme étant le monotriméthylsiloxycyclopropanol **9***c* (schéma 7). En présence d'air, même en solution dans l'éther, ce composé se transforme rapidement en acétyl acétone également obtenue seule, en présence de méthanol–eau–TsOH, c'est-à-dire dans les conditions d'ouverture des bis(triméthyl siloxy) cyclopropanes.

Réactions induites par les bases

Nous avons examiné la comportement de **9***a*, **10***a* et **17***a* dans la soude méthanolique 0.2 *M* au reflux.[2] Le produit de départ est entièrement consommé au bout de 6 heures et on obtient un mélange d'α cétols, d'énones et de composés dicarbonylés. Les résultats sont indiqués dans le schéma 8. Nous avons vérifié que les résultats ne dépendent pas de la stéréochimie des produits de départ. Cependant les proportions de produits obtenus varient sensiblement d'une expérience à une autre et les proportions indiquées au schéma 8 représentent des moyennes de plusieurs expériences. D'autre part, une expérience sur **10***a*, conduite avec de la potasse au lieu de la soude, nous

[1]MeOH, C_6H_6, diglyme et DMSO conduisent aux mêmes résultats, de même que MeOH sec. Dans tous les cas, les deux stéréoisomères donnent les mêmes résultats.

[2]Les réactions de **9***a* et **10***a* avec le méthyl lithium ont également été envisagées et aboutissent pratiquement aux mêmes résultats.

SCHÉMA 6. Resultats obtenus avec le melange H_2O–solvant en presence d'acide paratoluene sulfonique (X = —$SiMe_3$).

a permis d'isoler **10***c* qui se décompose également rapidement en β dicétone. Nous n'avons pu obtenir **10***c* en utilisant de la soude, mais la réaction semble si sensible aux conditions que nous ne pouvons en tirer de conclusion. Cette fois encore, si on remet **10***c* dans les conditions réactionnelles, on n'obtient que de la β dicétone.

Halogénations

Nous avons envisagé les réactions de **10***a*, **14***a* et **17***a* avec du chlore et du brome dans l'éther. Les réactions sont rapides et on obtient les composés halogénés du schéma 9. Ces composés séparés par chromatographie sur colonne de silice, noircissent et se décomposent rapidement, ce qui nous empêche de donner des rendements.[3] Les réactions menées avec NaOCl se sont avérées négatives.

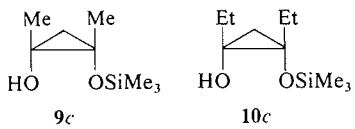

SCHÉMA 7

Discussion et conclusion

La réaction de formation des α cétols par action des acides sur les cyclopropanediols libres de Curphey et coll. (3) et de Reusch et coll. (4) est tout à fait analogue à l'ouverture acide des cyclopropanols et on accepte généralement la même conclusion pour les cyclopropanediols intermédiaires de la réduction de Clemmensen des β dicétones. En réalisant l'hydrolyse des bis(triméthylsiloxy)-1,2 cyclopropanes, nous pensions pouvoir obtenir les cyclopropanediols correspondants. En fait nous n'avons jamais pu observer ces composés même en milieu trés peu acide et nos résultats impliquent que les composés ob-

[3]Les composés chlorés sont nettement plus stables, mais il est certain que les rendements en produits isolés sont nettement plus faibles que les rendements en produits formés, la décomposition étant toujours importante.

SCHÉMA 8. Résultats obtenus par hydrolyse basique (X = $SiMe_3$).

tenus proviennent, partiellement ou totalement, des dérivés bissiloxylés et non des diols libres intermédiaires.

Le fait que les monosiloxycyclopropanols **9***c* et **10***c* se transforment uniquement en β dicétone, aussi bien en présence d'air qu'en milieu MeOH–H_2O–TsOH, montre que les α cétols sont obtenus à partir de **9***a* et **10***a*.[4]

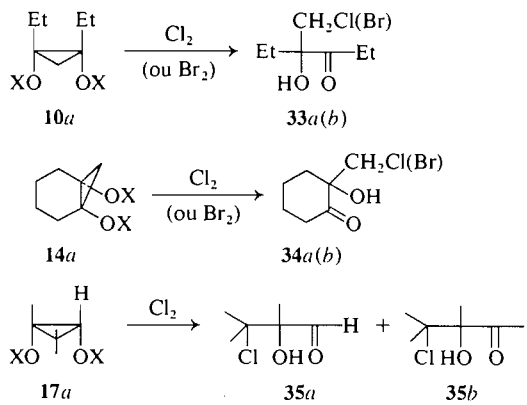

SCHÉMA 9

Il faut également noter qu'en présence d'air les bis(trimethylsiloxy) cyclopropanes présentent un comportement différent de **9***c* et sont lentement transformés (en un ou deux mois) en un mélange contenant les mêmes produits que ceux obtenus par solvolyse acide. Nous avons établi le fait que les énones ne proviennent pas des α cétols dans les conditions réactionnelles envisagées,[5] ce qui suggère que, comme les α cétols, elles sont obtenues directement à partir des dérivés bissiloxylés. Nous pensons donc que dans le cas des diéthers cyclopropaniques, les α cétols sont obtenus par un processus analogue à l'ouverture acide des cyclopropanols (2) et la formation des énones par un processus analogue à l'ouverture des tosylates de cyclopropyle, ce qui indique que la protonation peut concerner aussi bien le site cyclopropyle que le site oxygéné (schéma 10).

Les β cétols obtenus dans certains cas (ainsi d'ailleurs que dans la réduction des β dicétones) proviendraient de l'autre orientation possible de l'ouverture 'type cyclopropanol,' mais nous n'avons trouvé aucune corrélation avec la structure.

A notre avis, les β dicétones (ou le β cétoaldéhyde provenant de **17***a*) sont obtenues soit via l'intermédiaire siloxycyclopropanol soit via l'intermédiaire diol libre non isolé. Cette oxydation des cyclopropane-diols en β dicétones a été étudiée par Curphey et coll. (3*b*) et Priddy et Reusch (8) et semble analogue à l'oxydation des cyclopropanols.

En milieu basique, les résultats sont très analogues à ceux obtenus en milieu acide, avec moins de cétols et plus d'énones et de β dicétones. Ici encore le comportement de **10***c* fait penser que les α cétols et les énones sont obtenus à partir des dérivés bissiloxylés par coupure initiale d'une liaison O—Si, selon

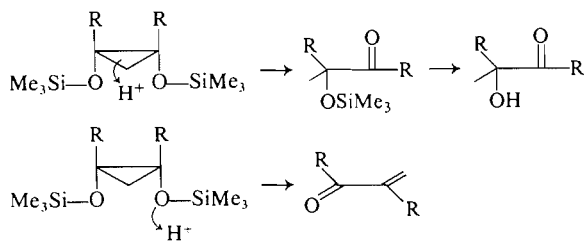

SCHÉMA 10

schéma 11, et non des diols libres. Nous avons vérifié que dans les conditions réactionnelles les cétols ne se transforment pas en énones.

La formation des composés dicarbonylés (seul produit de réaction pour **17***a*) peut être expliqué par oxydation de l'intermédiaire cyclopropanediol, non isolé. On voit cependant que quand le diol obtenu

[4]Conclusion en contradiction avec l'interprétation de Curphey et coll. (3) qui admet, dans le cas d'un diacétate, que les diols libres sont les précurseurs des α cétols.

[5]Observation en contradiction avec l'interprètation de Priddy et Reusch (7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

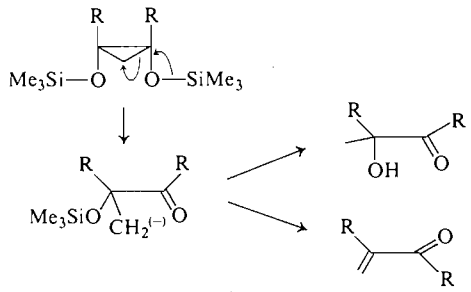

SCHÉMA 11

est moins oxydable, (i.e. non substitué en position 3) on obtient plus de cétol et d'énone et donc que dans ce cas le réarrangement serait plus rapide que l'oxydation.

En ce qui concerne les halogénations, les résultats peuvent être interprétés comme une ouverture électrophile, analogue à celle induite par les acides (schéma 12).

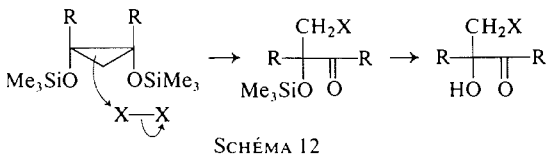

SCHÉMA 12

En conclusion, la réactivité chimique des cyclopropanediols ressemble incontestablement à celle des cyclopropanols et semble totalement différente de celles des α diols aliphatiques: les α cétols et halohydrines qui pourraient être obtenus par transposition pinacolique ne sont jamais observés et les énones sont obtenues par une toute autre voie. Dans certains cas les bis(triméthylsiloxy)-1,2 cyclopropanes peuvent constituer d'utiles synthons pour la synthèse de β dicétones dans des conditions très douces, ainsi que d'α cétols, et ils remplacent avantageusement les cyclopropanediols eux mêmes, trop instables. Nous explorons actuellement l'utilisation de ces dérivés en synthèse.

Partie experimentale

Les spectres ir ont été réalisés sur Perkin-Elmer 221 et les spectres rmn sur Perkin-Elmer R 10 ou sur Varian A60 (60 MHz). Tous les déplacements chimiques sont donnés en $\delta \times 10^6$ par rapport au TMS utilisé comme référence interne (s: singulet, d: doublet, t: triplet, q: quadruplet, h: heptuplet, m: multiplet). Les analyses en chromatographie en phase gazeuse ont été réalisées sur Aérograph 1420 et les séparations sur Aérograph autoprep A 700 équipés de colonnes Apiezon ou Carbowax.

Substrats

Les bissiloxy 1,2-cyclopropanes ont été préparés au laboratoire (1) et purifiés par cpv préparative. Le chlore a été préparé par réaction de HCl concentré sur $KMNO_4$, puis séché sur H_2SO_4. L'azote a été séché sur P_2O_5, puis KOH avant de traverser une solution d'hydroquinone dans l'éther. Les autres réactifs sont des produits commerciaux utilisés tels quels.

Préparation des acétates de cyclopropanediol

Les diacétates **9***b*–**17***b* sont obtenus quantitativement en faisant réagir 1 g de bis(triméthylsiloxy) cyclopropane sur 0.6 g de bromure d'acétyle dans 5 ml d'éther anhydre au reflux. Au bout de 30 min, le produit initial ayant totalement disparu, l'éther est évaporé et les diacétates séparés par cpv (Carbowax). Ont été ainsi obtenus:

9*b cis*: ir: 1750 et 3010 cm^{-1}; rmn (CCl_4) δ: 1.45 (s, 6H), 1.92 (s, 6H), 51 et 60 Hz A–B, J = 8.5 Hz. **9***b trans*: id sauf A_2 à 0.82 (2 H). *Anal.* calc.: C 58.06, H 9.67; trouvé: C 58.15, H 9.48.

10*b* isomères non séparés: ir: 1745 et 3030 cm^{-1}; rmn (CCl_4) δ: 1.00 (t, 6H), 1.7 (q, 4H), 1.95 (s, 6H), 0.75 (2H). *Anal.* calc.: C 58.06, H 9.67; trouvé: C 58.15, H 9.48.

11*b*: ir: 3040, 1750 cm^{-1}; rmn (CCl_4) δ: 1.94 (s, 6H), 1.2–1.8 (m, 8H), 0.8–1.15 (8H). *Anal.* calc.: C 64.46, H 9.09; trouvé: C 63.98, H 9.09.

12*b cis*: ir: 3040 et 1745 cm^{-1}; rmn (CCl_4) δ: 1.98 (s, 6H), 1.4 (h, 2H), 1.1 (d, 12H), 0.8–1.2 (m, 2H). Dans le benzène le AB analysable indique δ A 32 Hz, δ B 54 Hz, J = 6 Hz.

12*b trans*: id sauf A_2 à 0.8 (2H). *Anal.* calc.: C 64.46, H 9.09; trouvé: C 64.18, H 9.21.

14*b*: ir: 1655 cm^{-1}; rmn (CCl_4) δ: 1.95 (s, 6H), 1.8–2.2 et 1.1–1.8 (2 massifs, 18H), 1.00 (s, 2H); dans le benzène on lit δ A 36.2 Hz, δ B 53.4 Hz et J_{AB} = 8 Hz.

15*b cis*: ir: 1750 cm^{-1}; rmn (CCl_4) δ: 0.9 (s, 3H), 0.97 (s, 3H), 1.39 (s, 6H), 1.95 (s, 6H). **15***b trans*: 1.09 (s, 6H), 1.39 (s, 6H), 1.95 (s, 6H). *Anal.* calc.: C 61.68, H 8.41, O 29.91; trouvé: C 61.67, H 8.85, O 30.33.

16*b*: rmn (CCl_4) δ: 7.3 (massif, 5H), 2.1 (s, 3H), 1.1 (s, 3H), 1.3 (s, 3H). *Anal.* calc.: C 74.58, H 6.5; trouvé: C 74.48, H 6.32.

17*b*: rmn (CCl_4) δ: 0.90 (s, 3H), 0.95 (s, 3H), 1.25 (s, 3H), 2.45 et 2.84 (2s, 1H). *Anal.* calc.: C 60.00, H 8.00; trouvé: C 60.15, H 8.43.

Hydrolyse de 10

On porte au reflux pendant 4 h 1 g du produit dans 10 ml de méthanol additionné de quelques mg de TsOH, puis les produits obtenus sont séparés par cpv. On obtient: 50% d'acétoxy 3, méthyl-3 hexanone-4 (ir: 1735 et 1690 cm^{-1}, rmn δ: 0.85 (t, 3H), 2.4 (q des CH_2—C(=O)—, 2H)) 47% de **21** et 3% d'acétoxy-5 heptanone-3 identique au produit obtenu par estérification de **24**.

Hydrolyses des bissiloxy 1,2-cyclopropanes en milieu acide

Nous avons utilisé quatres méthodes que nous décrivons ici à titre d'exemple pour **9***a*.

(*a*) On porte au reflux 1 g de **9***a* dans 10 ml de méthanol en présence de 5 mg d'acide paratoluènesulfonique, sous atmosphère d'azote. La réaction est suivie en cpv et en chromatographie sur plaque jusqu'àdisparition totale de **9***a*. On observe à côté de **19** et **20** la formation de **9***c* qui disparait rapidement ($t_{\frac{1}{2}}$ = 12–13 min). Ce produit, séparé sur colonne Apiézon recueilli dans du CCl_4 et maintenu sous atmosphère inerte montre en ir des bandes à 3450–3500, 1250 et 840 cm^{-1}, et en rmn δ: 0.05 (s, 9H), 0.3–0.5 (doublet d'intensité 1, représentant la partie A des protons cyclopropaniques, la partie B étant masquée par le $SiMe_3$), 0.98 et 1.03 (2s, 6H), plus le proton hydroxylique variant avec la dilution. Ce produit isolé se transforme uniquement en **20**, et on obtient en fin de réaction 40% de **19** et 60% de **20** (étalon interne: diphényl éther).

(*b*) A 1 g de **9***a* (0.004 mol) on ajoute 72 µl de H_2O (0.004 mol) et 10 ml de solvant (méthanol, ou bien benzène plus méthanol jusqu'à ce qu'on obtienne une solution homogène,

For personal use only.

ou bien DMSO). Le mélange est ensuite chauffé au reflux pour les deux premiers cas, à 80°C pour le troisième. La réaction est suivie en cpv et en chromatographie couches minces. Les études rmn réalisées en cours de réaction, après évaporation du solvant sous vide et remplacement par $CDCl_3$ ne nous ont pas permis de conclure à la présence de diol. Les composées **19** et **20** sont ensuite séparés en cpv et comparés à des échantillons authentiques.

(*c*) On fait arriver un courant de HCl sec dans une solution éthérée de **9***a*. La réaction est instantanée et **19** et **20** sont identifiés par cpv dans le rapport 9:1.

(*d*) On ajoute 1 ou 2 gouttes d'acide chlorhydrique N à une solution méthanolique de 1 g de **9***a*. La réaction est instantanée et conduit à **19** et **20** dans le rapport 8:2.

Les produits obtenus ont été identifiés sans ambiguité par comparaison avec des échantillons authentiques sauf **9***c* et **10***c* et par les analyses spectrales rapportées ci-dessous:

19: ir: 3450, 1625 cm^{-1}; rmn ($CDCl_3$) δ: 2.03(3H), 1.4(6H).

20: ir: 3090, 1685, 1640 cm^{-1}; rmn (CCl_4) δ: 1.87(3H, s), 2.3(3H, s), 5.75 et 5.81 (1H et 1H s et s).

21: ir: 3480 et 1705 cm^{-1}; rmn ($CDCl_3$) δ: 1(6H, 2t), 2(2H, q), 2.5(2H, q), 2.3(3H, s).

22: ir: 3105, 1690, 1640 cm^{-1}; rmn (CCl_4)δ: 1 et 1.05: (2 t, imbriqués, 3H et 3H), 2.27 (q, 2H), 2.67 (q, 2H), 5.9 et 5.61 (1H et 1H).

23: ir: 1710–1720, 1600 cm^{-1}; rmn (CCl_4) δ: 1.15 (t, 6H), 2.3 (q, 4H), et s à 5.4 et 3.5 (1H).

24: ir: 3540 et 1610 cm^{-1}; rmn ($CDCl_3$) δ: 1.05 (t, 6H), multiplets à 1.4(2H), 2.4(2H), 3.9(1H).

25: ir: 3430 et 1685 cm^{-1}; rmn ($CDCl_3$) δ: 1.1 (t, 3H) -s-(6), 2.9 (q, 2H).

26: rmn ($CDCl_3$) δ: 0.95 (t, 3H), 1.3 (s, 3H), 2.3 (q, 2H) 2.6 (s, 3H).

27: ir: 1675, 1630, 3125 cm^{-1}; rmn (CCl_4) δ: 1.1 (t, 3H), 2.7 (q, 2H), 1.88 (s, 3H), 5.8 et 6 (s, 1H et 1H).

29: ir: 3470 et 1730 cm^{-1}; rmn ($CDCl_3$) δ: 1.4 (s), 1.75–2.5 (6H et 2H).

30: ir: 3450 et 1605 cm^{-1}; rmn ($CDCl_3$) δ: 2.12 (s, 3H), 3.91 (d 1H), 1.4 (m 1H), 0.7, 1.1 (2d, 3H et 3H).

31: rmn δ: 1.3 (d, 6H), 1.42 (s, 3H), 2.4 (h, 1H), 9.7 (s, 1H).

Hydrolyse en milieu basique

(*a*) On porte au reflux 10 ml d'une solution de soude méthanolique 0.2 *M* (ou soude 0.2 *M* dans le glyme à 80°C) contenant 1 g de produit cyclopropanique. Le produit disparait au bout de 6–10 h. La réaction est suivie par cpv et en chromatographie sur plaques de silice. Des analyses rmn en cours de réaction ne nous ont pas permis de conclure à la présence de cyclopropanediols.

Dans le cas de **10***a* on observe l'apparition d'un composé qui disparait au cours de la réaction en se transformant en dicétone. Ce produit séparé en cpv Apiézon présente en ir une bande OH à 3450 cm^{-1} des protons cyclopropaniques à 3080 cm^{-1} et les bandes caractéristiques du groupement $SiMe_3$ à 1250 et 830 cm^{-1}.

(*b*) *L'action du MeLi*—L'action du MeLi obtenu à partir de MeI en solution éthérée est très lente: on porte au reflux 1 g de produit cyclopropanique dans la quantité nécessaire de MeLi. La réaction dure 10–15 h. On obtient les mêmes produits que précédemment.

Action du chlore—On fait barbotter du chlore sec, dans une solution éthérée de produit. Après évaporation de l'éther les produits obtenus sont analysés en chromatographie sur plaque de silice.

Action du brome—On ajoute du brome sur le produit en solution dans l'éther. Il est rapidement consommé (20–30 min) et il y a noircissement rapide. Les produits sont séparés par chromatographie colonne.

33*a*: rmn ($CDCl_3$) δ: 1.1 et 1.2 (2t imbriqués, 6H), 1.65 (massif, 2H), 2.5 (q, 2H), 3.65 (AB, 2H (CH_2Cl) inéquivalents).

34*b*: ir: 3450 et 1720 cm^{-1}; rmn δ: 2 massif cyclohexane à 1.4 et 2.3 (6H), et 2.4 et 2.7 (2H), protons AB à 3.66 J = 8 Hz δA 212 Hz et δB 230 Hz.

35*a*: rmn δ: 9.7 (s, 1H), 1.6 (s, 3H), 1.25 et 1.3 (s, 3H et 3H).

35*b*: rmn δ: 2.2 (s, 3H), 4.1 (s, 1H), 1.1 et 1.2 (s, 3H) et 3H).

Oligoribonucleotide synthesis. XI.[1] Improved preparation of 2′-*O*-tetrahydropyranyl derivatives of guanosine and adenosine necessary for insertion in phosphotriester synthesis

RENE J. GREGOIRE AND THOMAS NEILSON

Department of Biochemistry, McMaster University, Hamilton, Ont., Canada L8S 4J9

Received July 18, 1977

RENE J. GREGOIRE and THOMAS NEILSON. Can. J. Chem. **56**, 487 (1978).

Treatment of N^2-benzoyl-2′,3′,5′-*O*-triacetylguanosine and 2′,3′,5′-*O*-triacetyladenosine with buffered hydrazine gave equilibrium mixtures of N^2-benzoyl-2′(3′),5′-diacetylguanosine and 2′(3′),5′-diacetyladenosine, greatly enriched in the desired 3′-acetates. Fractional crystallization effected recovery of pure 3′,5′-diacetates in 60% yields. From these were prepared the 2′-*O*-tetrahydropyranyl derivatives required for guanosine and adenosine insertion in phosphotriester oligonucleotide synthesis.

RENE J. GREGOIRE et THOMAS NEILSON. Can. J. Chem. **56**, 487 (1978).

La réaction de la N^2-benzoyl tri-*O*-acétyl-2′,3′,5′ guanosine et de la tri-*O*-acétyl-2′,3′,5′ adénosine avec de l'hydrazine tamponnée conduisent à des mélanges à l'équilibre de N^2-benzoyl diacétyl-2′(3′),5′ guanosine et diacétyl-2′(3′),5′ adénosine, dans lesquelles les acétates-3′ désirés ont été grandement enrichis. La cristallisation fractionnée permet de récupérer des diacétates-3′,5′ purs avec des rendements de 60%. Utilisant ces derniers, on a pu préparer les dérivés *O*-tétrahydropyranyl-2′ requis pour l'insertion de la guanosine et de l'adénosine dans la synthèse d'oligonucléotides de phosphotriestères.

[Traduit par le journal]

Introduction

All successful polymer syntheses are dependent on (*i*) convenient supply of monomers and (*ii*) efficient coupling. Recent improvements in phosphotriester oligoribonucleotide synthesis in these areas include (*i*) new nucleoside protecting groups such as alkylsilyl ethers (2) and levulinic esters (3), and (*ii*) more efficient internucleotide coupling with various mesitylene sulfonamides (3, 4).

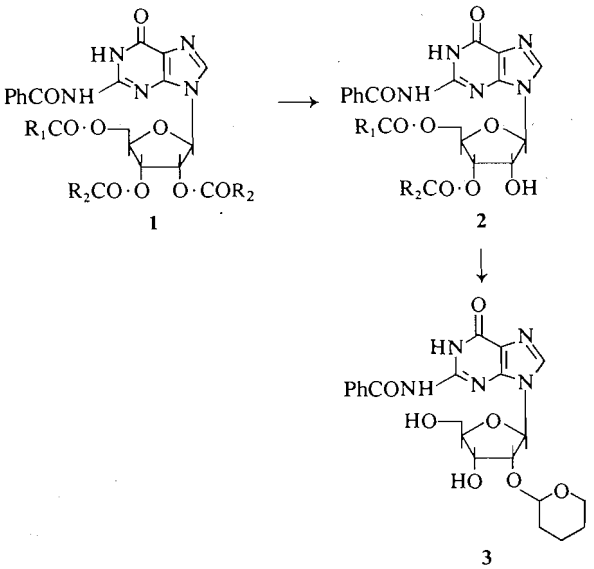
Several oligoribonucleotides of biological significance (1, 5, 6) have been prepared by the general synthesis developed in this laboratory. This communication describes an improved, convenient synthetic route to two purine ribofuranoside monomers widely used in oligoribonucleotide synthesis.

Guanosine is presently inserted as N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**3**), obtained by a synthesis (7) containing (*a*) two acidic steps leading to loss via depurination and (*b*) a wasteful fractional crystallization from an approximately 1:1 isomeric mixture of 3′(2′)-*O*-acetates.

A recent report of supposed regioselective hydrazinolysis (8) of 2′-*O*-acyl groups in fully acylated purine ribofuranosides was of interest, since such a scheme would eliminate the acid-catalyzed 2′,3′-orthoacetate ring opening. Difficulty was experienced in ^{1}Hmr monitoring of the hydrazine-catalyzed debenzoylation of N^2,2′,3′,5′-*O*-tetrabenzoylguanosine (**1**: $R_1 = R_2 =$ Ph). Also, crystallization of N^2,3′,5′-*O*-tribenzoylguanosine (**2**: $R_1 = R_2 =$ Ph) was unsuccessful. Deacetylation of N^2-benzoyl-2′,3′,5′-*O*-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$) on the other hand, was convenient to monitor by ^{1}Hmr, and the 3′-acetyl product (**2**: $R_1 = R_2 = CH_3$) crystallized well.

N^2-Benzoyl-2′,3′,5′-*O*-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$) was prepared from N^2-benzoylguanosine (**1**: $R_1 = R_2 =$ Ph). Also, crystallization of N^2,3′,5′-*O*-tribenzoylguanosine (**2**: $R_1 = R_2 =$ Ph) was unsuccessful. Deacetylation of N^2-benzoyl-2′,3′,5′-*O*-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$) on the other hand, was convenient to monitor by ^{1}Hmr, and the 3′-acetyl product (**2**: $R_1 = R_2 = CH_3$) crystallized well.

N^2-Benzoyl-2′,3′,5′-*O*-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$) was prepared from N^2-benzoylguano-



SCHEME 1

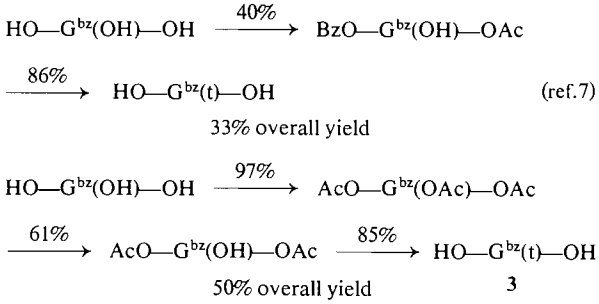
For personal use only.

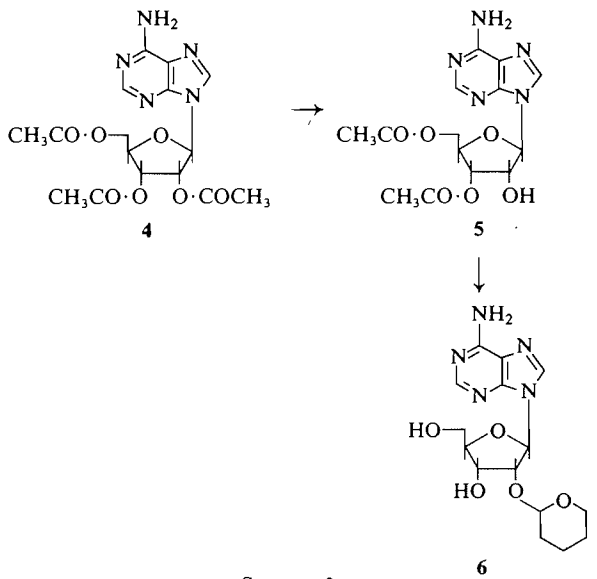
sine (9) and treated with buffered hydrazine solution (8). Work-up gave N^2-benzoyl-3′,5′-*O*-diacetylguanosine (**2**: $R_1 = R_2 = CH_3$) as the major product, in 61% yield, from an equilibrium mixture of 2′- and 3′-acetates enriched (ca. 5:1) in the latter. Compound **2** was successfully converted to **3** (Scheme 1).

Scheme 2 summarizes the overall yields of **3** from the present and previous methods. Elimination of depurination and crystallization of **2** from an enriched isomeric mixture allows the overall yield of **3** to rise from 33 to 50%.

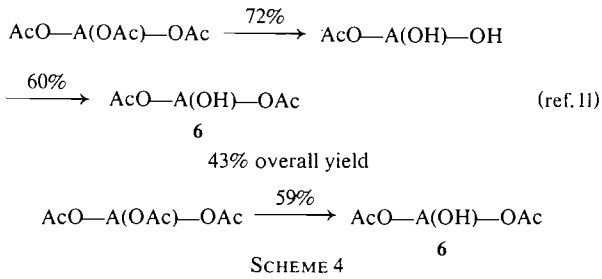


SCHEME 2

The improved synthesis of **3** prompted us to consider a parallel synthesis for the adenosine analogue (**6**) (Scheme 3). Similar hydrazinolysis (8) on 2′,3′,5′-*O*-triacetyladenosine (**4**) (10) gave a similarly enriched (ca. 5:1) mixture of isomers, from which 3′,5′-*O*-diacetyladenosine (**5**) was recovered in 59% yield. This offers some improvement in yield over the previously published method (11), as shown in Scheme 4. Conversion of **5** to **6** remained as before (12).



SCHEME 3



SCHEME 4

Although hydrazinolysis is deemed to be regioselective (8), base-catalyzed acetyl migration is also in operation. The resulting equilibrium mixture of 2′(3′)-acetates favours the 3′-acetate isomer by ca. 5:1, which improves fractional crystallization of the desired isomer.

Composition of acetate samples was readily determined from ^{1}Hmr spectra. Table 1 compares the ^{1}Hmr data of the 2′- and 3′-acetates. Chemical shifts (ppm) of the anomeric proton are typically less for the 3′-acetate, whereas the $J_{1',2'}$ coupling constants (Hz) of the 3′-acetates are larger (13).

Experimental

Proton magnetic resonance spectra were recorded on a Varian T60 spectrometer in DMSO-d_6/D_2O/CD_3COOD (0.5 g/0.05 ml/0.05 ml) solutions. Silica gel (Baker Analyzed Reagent) was used for column chromatography, and Analtech prescored silica gel plates for tlc. The plates were developed in 10% methanol in methylene chloride mixtures, then sprayed with 1% (w/v) $H_4Ce(SO_4)_4$ in 10% (v/v) aqueous sulfuric acid and heated to 300–400°F for detection.

*N²-Benzoyl-2′,3′,5′-O-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$)*

Cold acetic anhydride (146 ml, 1.55 mol) was added, portionwise, over 30 min, to an ice-cold stirring solution of N^2-benzoylguanosine (9) (18.29 g, 47.2 mmol) in dry pyridine (500 ml). The mixture was cooled for 60 min, then warmed to room temperature. Acetylation (R_F 0.07 → 0.30 → 0.55 → 0.70) was complete after 2½ h. The reaction was cooled briefly and quenched with excess methanol. After 30 min, the mixture was reduced to ca. 450 ml, and extracted from water (200 ml) into methylene chloride (3 × 150 ml). Combined organic extracts were washed with water (150 ml), then saturated sodium bicarbonate solution (3 × 150 ml) and water (150 ml). This was followed by evaporation *in vacuo* to a reddish-brown foaming oil for chromatography on silica gel (150 g) in methylene chloride. The product (**1**: $R_1 = R_2 = CH_3$), a yellowish white foam (23.43 g, 97%) was eluted with 3–4% methanol in methylene chloride. A pilot reaction had previously yielded 1.57 g (95%) of foam from 1.2 g of starting material.

The ^{1}Hmr spectrum of the material showed signals (δ TMS) at 8.26 (1H, sharp s, 8 proton of G), 8.10–7.60 (5H, m, C_6H_5CO protons), 6.20 (1H, d, $J \simeq 6.0$ Hz, 1′ anomeric sugar proton), 2.08 (3H, sharp s, CH_3CO protons), and 2.00 ppm (6H, sharp s, 2 CH_3CO protons).

*N²-Benzoyl-3′,5′-O-diacetylguanosine (**2**: $R_1 = R_2 = CH_3$)*

Hydrazine hydrate (2.44 ml, 50.4 mmol) was added to a solution of the N^2-benzoyl-2′,3′,5′-*O*-triacetylguanosine (**1**: $R_1 = R_2 = CH_3$) (23.43 g, 45.8 mmol) prepared above, in a 4:1 pyridine – acetic acid mixture. After overnight stirring at

where G is guanosine and A is adenosine.

room temperature, tlc indicated a trace of starting material, diacetylated products (R_F 0.50, ca. 90%), and monoacetylated by-products (R_F 0.30, ca. 10%). The reaction was quenched with acetone. After 30 min, the yellowish brown mixture was partially evaporated and extracted from water (150 ml) into methylene chloride (4 × 150 ml). The combined organic extracts were washed with water (2 × 100 ml), then saturated sodium bicarbonate solution (4 × 100 ml), and water (2 × 100 ml). Combined organic extracts were evaporated *in vacuo* to a green foam for chromatography on silica gel (150 g) in methylene chloride. The diacetate mixture was eluted with 5–6% methanol in methylene chloride. The ^{1}Hmr analysis of the crude diacetate mixture showed a mixture of 2′-and 3′-acetates as indicated by the additional anomeric doublet ($J \simeq 5.0$ Hz) at 6.18 ppm. Integration of the anomeric doublets showed an approximate 1:5 mixture of 2′(3′)-acetates. Crystallization of the yellow foam (14.92 g) from warm methanol yielded as a single crop, N^2-benzoyl-3′,5′-*O*-diacetylguanosine (**2**: $R_1 = R_2 = CH_3$) (13.1 g, 61%) as a fluffy white solid (mp 131–133°C). Thin-layer chromatography indicated only trace quantities remaining in the mother liquor. A pilot reaction had previously yielded 1.92 g (60%) of the desired isomer from 3.5 g of starting material.

The ^{1}Hmr spectrum of the material (**2**: $R_1 = R_2 = CH_3$) showed signals (δ TMS) at 8.30 (1H, sharp s, 8 proton of G), 8.16–7.60 (5H, m, C_6H_5CO protons), 5.98 (1H d, $J \simeq 7.0$ Hz, 1′ anomeric sugar proton), 3.67 (2H, sharp s, H_2O protons), 2.12 (3H, sharp s, CH_3CO protons) and 2.05 ppm (3H, sharp s, CH_3CO protons). *Anal.* calcd. for $C_{21}H_{21}N_5O_8 \cdot H_2O$ (mol. wt. 489.444): C 51.53, H 4.74, N 14.31; found: C 51.39, H 4.91, N 14.32.

N^2-*Benzoyl-2′-O-tetrahydropyranylguanosine (3)*

A solution of *p*-toluenesulfonic acid monohydrate (142 mg, 0.75 mmol) in dry *p*-dioxan (15 ml) containing molecular sieves (500 mg) was cooled on ice, to solidification. 2,3-Dihydro-4*H*-pyran (5 ml, 59.6 mmol) was then added dropwise, with stirring, causing partial melting of the frozen solution. N^2-Benzoyl-3′,5′-*O*-diacetylguanosine (**2**: $R_1 = R_2 = CH_3$) (1.4 g, 2.98 mmol) suspended in dry *p*-dioxan (10 ml) was added portionwise, with stirring. After 45 min, the reaction was allowed to warm to room temperature. Reaction (R_F 0.50 → 0.70) was ca. 60% complete after 6 h, and finished by standing at room temperature overnight. After brief chilling, and neutralization with concentrated ammonia, ammonium tosylate was filtered off and washed with methylene chloride. Filtrate and washings were evaporated *in vacuo* to a yellow-green oil, which was dissolved in absolute ethanol (15 ml) and pyridine (10 ml). To this rapidly stirred solution was added a mixture of aqueous 2 *N* sodium hydroxide (7.5 ml) and ethanol (7.5 ml). Reaction (R_F 0.68 → 0.45 and 0.35) was quenched after 5 min by neutralization with Dowex 50W-X8 resin (pyridinium form). After filtration, and washing with ethanol, the filtrate and washings were evaporated *in vacuo* to a yellow-green foam for chromatography on silica gel (25 g). The two diastereoisomers of **3** (R_F 0.35 and 0.45) eluted as a mixture (755 mg) with 3–4% methanol in methylene chloride. Pure low R_F **3** (490 mg) eluted with 4–6% methanol. Combined yield of the two isomers corresponds to 85%, compared to 86% (7) starting from 3′-*O*-acetyl-N^2,5′-*O*-dibenzoylguanosine (**2**: R_1 = Ph, $R_2 = CH_3$). The ^{1}Hmr spectrum of the low R_F product was identical to that obtained previously from **2**: R_1 = Ph, $R_2 = CH_3$ (7).

2′,3′,5′-O-*triacetyladenosine (4)*

Adenosine was acetylated with a five-fold excess of acetic anhydride in dry pyridine. 2′,3′,5′-*O*-Triacetyladenosine (**4**) was recovered in 90% yield as white crystals, mp 172–173°C (lit. (10) mp 174°C) from toluene.

3′,5′-O-*diacetyladenosine (5)*

Hydrazine hydrate (1.36 ml, 28 mmol) was added to a solution of 2′,3′,5′-*O*-triacetyladenosine (**4**) (10 g, 25.5 mmol) in a 4:1 pyridine – acetic acid mixture (8). After overnight reaction, tlc indicated unreacted material (R_F 0.65, ca. 10%), diacetylated products (R_F 0.45, ca. 85%) and monoacetylated by-products (R_F 0.25, ca. 5%). Reaction was quenched with acetone (10 ml, 134 mmol). After 30 min, the mixture was partially evaporated *in vacuo* and continuously extracted into methylene chloride (2 × 300 ml). Combined extracts were evaporated *in vacuo* to a foaming oil for chromatography on silica gel (150 g) in methylene chloride. Unreacted triacetate eluted with 3% methanol in methylene chloride. The diacetate mixture eluted with 4–6% methanol.

The ^{1}Hmr spectrum of the crude diacetate mixture showed a mixture of 2′- and 3′-acetates, as indicated by the additional anomeric doublet ($J \simeq 4.0$ Hz) at 6.20 ppm and additional acetyl singlets at 2.08 and 1.98 ppm. Integration of the anomeric protons indicated an approximate 1:5 mixture of 2′(3′)-acetates.

The ^{1}Hmr spectrum of the material (**5**) showed signals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(δ TMS) at 8.38 (1H, sharp s, 8 proton of A), 8.25 (1H, sharp s, 2 proton of A), 6.00 (1H, d, $J \simeq 6.0$ Hz, 1′ anomeric sugar proton), and 2.12 and 2.02 ppm (3H, 3H, sharp s, two CH_3CO protons). Crystallization of the yellow foam (6.60 g) from warm ethanol yielded 3′,5′-*O*-diacetyladenosine (**5**) (5.27 g, 59%) as white crystals, mp 146–148°C. This compared favourably with a yield of 43% previously obtained by 2′,3′-orthoacetate ring opening (11).

Sesquiterpene lactones from *Centaurea linifolia* Vahl[1]

A. G. González, J. Bermejo, J. M. Amaro, G. M. Massanet, A. Galindo, and I. Cabrera

Department of Organic Chemistry and Biochemistry, University of La Laguna, Instituto de Productos Naturales Organicos del CSIC, Tenerife, Spain

Received July 19, 1977

A. G. González, J. Bermejo, J. M. Amaro, G. M. Massanet, A. Galindo, and I. Cabrera. Can. J. Chem. **56**, 491 (1978).

Three new sesquiterpene lactones, linichlorins A, B, and C were isolated from the aerial parts of *Centaurea linifolia* Vahl and their structures were determined by physical and chemical methods. The sesquiterpene lactones chlorohyssopifolins A, B, C, D, E, aguerin B, and vahlenin were also isolated from the same plant.

As part of our studies of the chemical constituents of the genus *Centaurea* (Compositae) we examined *Centaurea linifolia* Vahl, endemic to the Iberian peninsula. The plant was gathered in July at Los Monegros (Zaragoza) and extracted as usual (see Experimental). By column chromatography 10 sesquiterpene lactones were separated and 7 were identified, by comparison with authentic samples, as centaurepensin (chlorohyssopifolin A) (**1***b*), acroptilin (chlorohyssopifolin C) (**2***b*), chlorohyssopifolins B (**1***a*), D (**1***c*), and E (**1***d*), vahlenin (**4***e*), and aguerin B (**3***e*), isolated from other species of *Centaureae* (1–6). The other three lactones were chlorinated guaianolides found for the first time and were named linichlorin A (**1***e*), B (**3***b*), and C (**5***b*).

Linichlorin A (**1***e*): $C_{19}H_{23}O_6Cl$, mol. wt. (ms) 382, mp 153–155°C, $[\alpha]_D$ +89°. The ir spectrum showed bands at 3450 (OH), 1740 (α,β′-unsaturated γ-lactone), 1710 (ester), and 1640 cm^{-1} (double bonds). Its nmr (Table 1) and mass spectra clearly show that it is a methacrylic acid ester (doublets at δ 6.20 and 5.65 (J = 2 Hz), singlet of a vinyl methyl at δ 2.0, and prominent peaks at m/e 296 ($M^+ - C_4H_6O_2$) and 69 (C_4H_5O)). A pair of doublets at δ 4.35 and 3.95 (J = 11 Hz) is attributable to a —C—(OH)—CH_2Cl group at C-4, a pair of lowfield doublets at δ 6.20 and 5.60 (J = 3 Hz) confirms the presence of an exocyclic methylene in **1***e* while two signals at δ 5.10 and 4.80 represent a methylene at C-10.

From these data, linichlorin A was assigned the formula **1***e*. $NaBH_4$ reduction led to the corresponding 11,13-dihydroderivative (**6***e*), with a new doublet at δ 1.25 (J = 9 Hz) typical of a secondary methyl. This compound proved to be the same as 8α-metacryloyl-11,13α-dihydrochlorohyssopifolin B, obtained in this laboratory (7) by treating centaurepensin with a zinc–copper couple.

Linichlorin B (**3***b*): $C_{19}H_{23}O_6Cl$, mol. wt. (ms) 382, mp 144–146°C, $[\alpha]_D$ +95° has an ir spectrum similar to that of linichlorin A. Its nmr shows signals in the vinyl region which correspond to three methylenes, at C-4, C-10, and C-11 (Table 1). A β-chloro-α-hydroxyisobutyric group is indicated by nmr (pair of doublets at δ 3.90 and 3.65 (J = 11 Hz), singlet at 1.50 (—C—(OH)*Me*—CH_2Cl)) and by ms (m/e 244 ($M^+ - C_4H_7O_3Cl$)). These data suggest the formula **3***b* for linichlorin B. By $NaBH_4$ treatment of **3***b*, the 11,13α-dihydroderivative (**7***b*) was obtained (8α,β-chloro-α-hydroxyisobutyrate of 11,13α-dihydrocynaropicrin) plus its saponification product **7***a* (11,13α-dihydrodeacylcynaropicrin). Both of these had been obtained in this laboratory from centaurepensin, the structure and stereochemistry of which, in its turn, had previously been established by González *et al.* (7) by dehalogenation and saponification, thus giving the deacyldihydrocynaropicrin derivative of cynaropicrin for which the assymetrical centres C-1 [α-H], C-5 (α-H), C-6 (β-H), and C-7 (α-H) have been rigorously established. By reductive elimination of the spiroepoxide at C-4 with $MgBr_2$–(H_g)Mg (8), **3***b* can be obtained from acroptilin (**2***b*), further confirming the structure of this lactone as **3***b*.

Linichlorin C (**5***b*): mp 160–162°C, $[\alpha]_D$ +83°, $C_{21}H_{27}O_9Cl$ from its elemental analysis and ms (fragment at m/e 427 ($M^+ - CH_2OH$)), shows bands of hydroxyl groups, of an α,β′-unsaturated γ-lactone, esters and double bonds in its ir. Its nmr and ms reveal an acetyl group (singlet at 2.20 and peak at m/e 43 (C_2H_3O)) and a β-chloro-α-hydroxy-

[1]Part 35 of the series "Chemical constituents of the *Compositae*." For Part 34 see ref. 6.

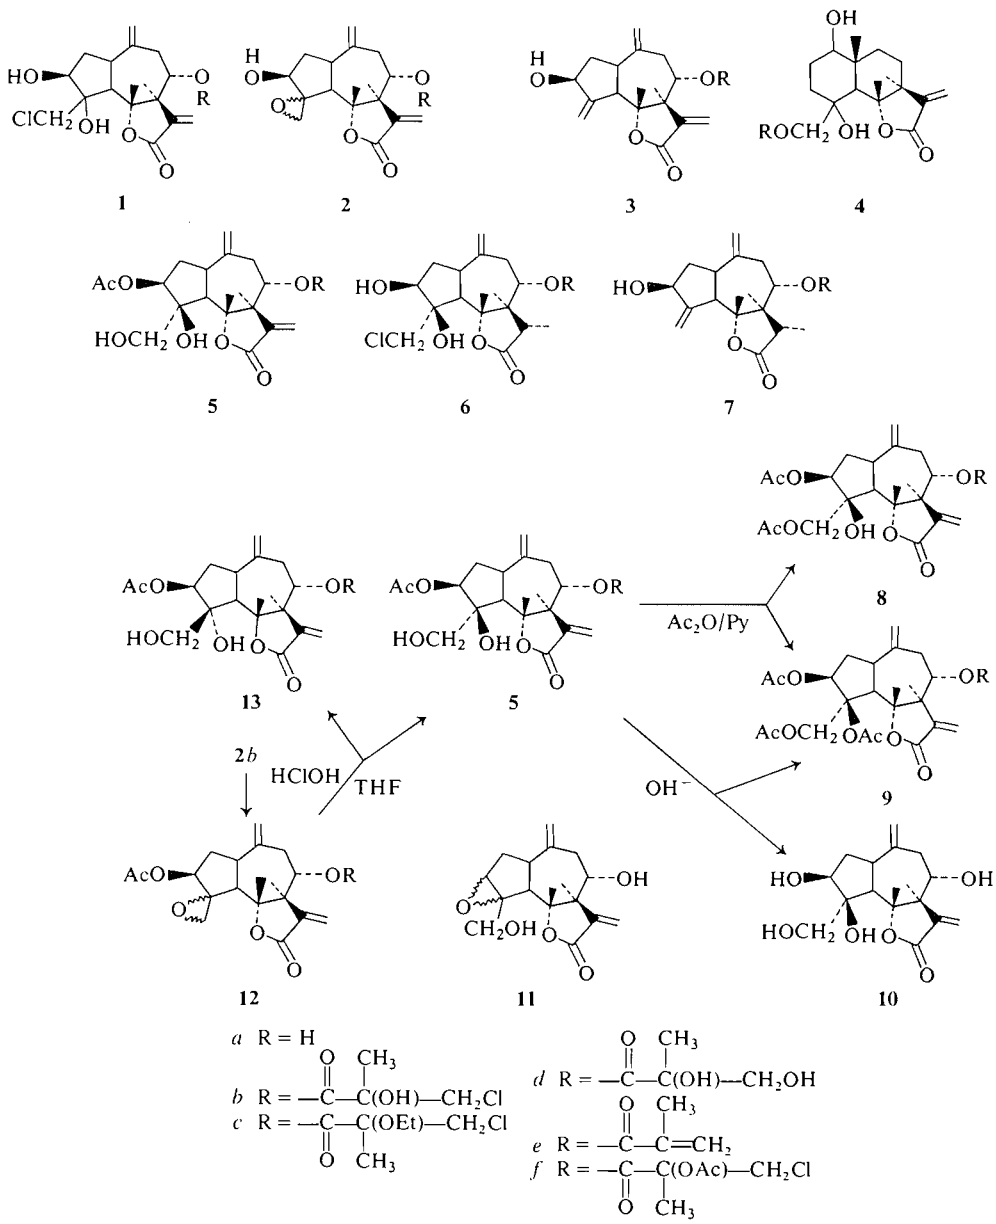
For personal use only.



isobutyric grouping. A prominent peak in its ms spectrum at *m/e* 31 (CH_2OH) suggests the existence of a primary hydroxyl group in the molecule. By mild acetylation **8***b* was formed with a paramagnetic shift of 0.5 ppm from the CH_2OH signals recorded in the nmr of **5***b*. Protracted treatment produced **9***f*. Alkaline hydrolysis of **5***b* gave **10** as major product and **11** in lower yield. Compound **11** proved to be identical (nmr and mp) to the compound obtained by Rybalko *et al.* (9) upon saponifying acroptilin. Compound **8***b* showed no reaction on treatment with Jones' reagent, leading to the assumption that the acetate group in **5***b* esterified the hydroxyl at C-3. This was confirmed when **5***b* was obtained from acroptilin. In fact the acetylation at 0°C of **2***b* yielded a mixture of **12***b* and **12***f* and treatment of **12***b* with $HClO_4$ at room temperature (10) caused the opening of the oxiran ring to give a mixture of diols (**5***b*) epimeric at C-4 and identical to **5***b* and **13***b*. A comparison of the nmr spectra of both diols showed a downfield chemical shift of the H-6 in **5***b* relative to **13***b* ($\Delta\delta = +0.30$ ppm probably due to the 1–3

†Acyl group C(1')—C(2')Me—C(3').

diaxial interaction between the β H-6 and the C-4 OH. This suggests a β orientation for the C-4 OH in **5***b*.

Experimental

Melting points were taken on a Kofler block and are uncorrected. Optical activities were measured in $CHCl_3$, ir spectra in $CHCl_3$ on a Perkin–Elmer spectrophotometer, and nmr spectra in $CDCl_3$ with TMS as internal standard on a 90 MHz Perkin–Elmer instrument.

Extraction and Separation

The dried plant (12 kg) collected at Los Monegros (Zaragoza) in July was chopped and exhaustively extracted with EtOH in a Soxhlet. The extract was filtered, concentrated to 500 ml and, after adding $Pb(OAc)_2$ (15 g) in hot H_2O (500 ml), was left for 24 h. It was then filtered, concentrated until free of EtOH and the residue (630 g) was extracted with $CHCl_3$ and chromatographed on a column of silica gel. Elution with benzene – ethyl acetate yielded, in order of increasing polarity, linichlorin A, aguerin B, chlorohyssopifolins A, D, and C, linichlorin B, chlorohyssopifolins B and E, vahlenin, and linichlorin C.

Linichlorin A (**1***e*) was purified by preparative tlc with petrol – ethyl acetate (7:3) (six elutions) and crystallized from chloroform – isopropyl ether: mp 153–155°C, $[\alpha]_D$ +89° (*c* 0.58); ir (KBr) ν_{max}: 3450, 1740, 1710, 1630, and 740 cm^{-1}; ms *m/e*: 382 (M^+), 296, 278, 260, 69. *Anal.* calcd. for $C_{19}H_{23}O_6Cl$: C 59.60, H 6.01, Cl 9.28; found: C 59.81, H 6.24, Cl 9.32.

Linichlorin B (**3***b*): mp 144–146°C (EtOAc–petrol), $[\alpha]_D$ +95° (*c* 0.45); ir ν_{max}: 3560, 3540, 1760, 1740, and 1640 cm^{-1}; ms *m/e*: 382 (M^+), 296, 278, 260, 69. *Anal.* calcd. for $C_{19}H_{23}O_6Cl$: C 59.60, H 6.01, Cl 9.28; found: C 59.59, H 6.13, Cl 8.98.

Linichlorin C (**5***b*): mp 160–162°C (EtOAc–petrol), $[\alpha]_D$ +83° (*c* 0.36); ir (KBr) ν_{max}: 3550, 3360, 1760, 1720, and 1660 cm^{-1}; ms *m/e*: 427 ($M^+ - 31$), 391, 368, 320, 302, 260, 242, 93, 57, 43. *Anal.* calcd. for $C_{21}H_{27}O_9Cl$: C 55.02, H 5.89, Cl 7.75; found: C 54.79, H 6.11, Cl 7.77.

*$NaBH_4$ Reduction of **1***e*

Sodium borohydride (600 mg) was added to compound (**1***e*) (300 mg) dissolved in methanol (50 ml) and the solution was stirred for 10 min at 0°C. The solution was evaporated and the residue acidified with 5% hydrochloric acid and extracted with ethyl acetate. The resulting solid was chromatographed on silica gel, yielding the product (**6***e*): mp 164–167°C, $[\alpha]_D$ +33.4° (*c* 0.25); ir ν_{max}: 3540, 1760, and 1640 cm^{-1}; ms *m/e*: 298 ($M^+ - 86$), 280, 262, 91, and 69.

*$NaBH_4$ Reduction of **3***b*

A solution of compound (**3***b*) (500 mg) in methanol (30 ml) was treated with sodium borohydride (100 mg). Under the same conditions as above, a mixture of two products was obtained which was separated by preparative tlc with petrol – ethyl acetate (4:6). Derivative **7***b*, oil: $[\alpha]_D$ +88° (*c* 0.24); ir ν_{max}: 3460, 1770, 1730, and 1640 cm^{-1}; ms *m/e*: 384 (M^+), 264, 246, 93. Derivative **7***a*: mp 134–136°C (EtOAc–petrol), $[\alpha]_D$ +70° (*c* 0.27 in MeOH); ir (KBr) ν_{max}: 3330, 1730, and 1635 cm^{-1}; ms *m/e*: 264 (M^+), 246, 218, and 200.

*Treatment of **2***b* with $MgBr_2$–Mg(Hg)*

A solution of **2***b* (500 mg) in THF (20 ml) was added to magnesium amalgam (Hg 3.53 g, Mg 0.072 g) under argon atmosphere. A solution of $MgBr_2$ (180 mg) in THF was then introduced and the mixture was continually stirred for 1 night under argon atmosphere. It was filtered, the solvent being eliminated, poured into water, and extracted with ethyl acetate. By chromatography on silica gel (petrol – ethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

acetate 6:4), two products were separated, one proving to be linichlorin B (**3***b*).

*Diacetate (**8***b*)

A solution of **5***b* (300 mg) in pyridine (0.2 ml) and Ac_2O (1 ml) was left standing for 2 h at room temperature. By silica gel chromatography (petrol–EtOAc 7:3) monoacetyllinichlorin C (**8***b*) was obtained, oil: $[\alpha]_D$ +82° (*c* 0.43); ir ν_{max} 3530, 1770, 1740, and 1640 cm^{-1}; ms *m/e*: 464 ($M^+ - 36$), 427, 462, 302, 242, 93, and 43.

*Tetraacetate (**9***f*)

Treatment of **5***b* (150 mg) with Ac_2O (3 ml) in pyridine (0.2 ml) at room temperature during 48 h yielded a liquid tetraacetate (**9***f*) which was purified by silica gel chromatography (benzene – ethyl acetate 1:1), $[\alpha]_D$ +56° (*c* 0.36); ir ν_{max}: 1770, 1740, and 1640 cm^{-1}; ms *m/e* 524 ($M^+ - 60$), 481, 421, 404, 284, 241, 224, 93, 43.

*Alkaline Hydrolysis of **5***b*

A solution of compound (**5***b*) (500 mg) in methanol (10 ml) was treated with aqueous 5% potassium carbonate (50 ml) during 48 h at room temperature. The soln was acidified with 5% hydrochloric acid until p*H* 6, saturated with NaCl and continuously extracted with EtOAc. The crude product (350 mg) was eluted on a column of silica gel (benzene–EtOAc 1:4). Crystallization from EtOAc–petrol gave a solid (**11**): mp 164–166°C, $[\alpha]_D$ +61° (*c* 0.2); ir (KBr) ν_{max}: 3460, 1760, and 1640 cm^{-1}; ms *m/e* 278 (M^+), 260, 247, 231. The other product was an amorphous solid (**10**): $[\alpha]_D$ +32° (*c* 0.64 in MeOH); ir (film) ν_{max}: 3500–3300, 1740, and 1640 cm^{-1}; ms *m/e* 296 (M^+), 278, 265, 248, 229. *Anal.* calcd. for $C_{15}H_{20}O_6$: C 60.80, H 6.80; found: C 60.88, H 6.82.

Treatment of Diacetate with Jones' Reagent

Diacetate **8***b* (250 mg) was dissolved in acetone (20 ml) and Jones' reagent (8 ml) was added in drops. The solution was stirred for 1 h at 0°C and then brought to room temperature and kept overnight. Excess reagent was destroyed with MeOH and the solution was filtered and evaporated at reduced pressure. The residue was extracted with EtOAc, dried on Na_2SO_4, and concentrated, recovering the starting material.

*Acetylation of **2***b*

Treatment of **2***b* (500 mg) with Ac_2O–Py at 0°C produced a mixture of acetates (480 mg) separated by silica gel chromatography (petrol–EtOAc 6:4). Monoacetate (**12***b*): mp 173–176°C (CH_3Cl – isopropyl ether), $[\alpha]_D$ +79° (*c* 0.48); ir ν_{max}: 3540, 1765, 1740, and 1650 cm^{-1}; ms *m/e* 440 (M^+), 380, 370, 302, 93, 43. Diacetate (**12***f*): mp 111–112°C, $[\alpha]_D$ +72° (*c* 1.75); ir ν_{max}: 1765, 1735, and 1640 cm^{-1}; ms *m/e* 302 ($M^+ - 180$), 259, 242, 91, 43.

*Treatment of **12***b* *with $HClO_4$*

One millilitre of 3 *N* $HClO_4$ was added to a solution of **12***b* (300 mg) in THF (15 ml) and the mixture was left at room temperature. The reaction was followed by tlc until the starting material was virtually eliminated (1 h). The products were extracted with $CHCl_3$, dried, distilled, and the residue was separated by preparative tlc with $CHCl_3$–Me_2CO (8:2) (three elutions). Diol **5***b*: mp 160°C, $[\alpha]_D$ +83° (identical with natural linichlorin C (mixture mp, ir, nmr, and chromatography results)). Diol **13***b*: $[\alpha]_D$ +41° (*c* 0.53); ir ν_{max}: 3520, 1760–1710, and 1640 cm^{-1}; ms *m/e* 427 ($M^+ - 31$), 368, 321, 302, 260, 242, 229, and 93.

Received June 16, 1977

E. J. McAlduff, B. M. Lynch, and K. N. Houk. Can. J. Chem. **56**, 495 (1978).

The photoelectron spectra of the following substituted benzamides have been determined: *p*-CH_3O, *p*-CH_3, *p*-Cl, H, *p*-F, *p*-CN, *p*-NO_2, *m*-CH_3O, *m*-CH_3, *m*-Cl, and *m*-NO_2. The first six ionization potentials have been assigned with reference to the phenyl and amide moieties. As an aid to the assignment CNDO/S calculations have been performed on the methoxy, methyl, and nitro benzamides. Linear relationships have been shown to exist between the first phenyl IP of disubstituted and monosubstituted benzenes. The slopes of these relationships have been shown to be related to the electron releasing ability of the substituent.

By comparison of the pes data with nmr chemical shifts, the first phenyl IP has been shown to be related to the electron density at the position of substitution of the amide group. Likewise, the amide IP centered on the nitrogen has been shown to be related to the electron density on nitrogen.

E. J. McAlduff, B. M. Lynch et K. N. Houk. Can. J. Chem. **56**, 495 (1978).

On a déterminé les spectres photoélectroniques des benzamides substituées suivantes: *p*-CH_3O, *p*-CH_3, *p*-Cl, H, *p*-F, *p*-CN, *p*-NO_2, *m*-CH_3O, *m*-CH_3, *m*-Cl et *m*-NO_2. On a attribué les six premiers potentiels d'ionisation en se référant aux portions phényle et amide. Afin d'aider à l'attribution, on a effectué des calculs CNDO/S sur les benzamides substituées par des groupements méthoxy, méthyle et nitro. On a montré qu'il existe des relations linéaires entre le potentiel d'ionisation du premier phényle de benzènes disubstitués et monosubstitués. On a démontré que les pentes de ces relations sont reliées à l'habilité du substituant à donner des électrons.

En effectuant une comparaison de données de spectres photoélectroniques avec des déplacements chimiques en rmn, on a montré que le potentiel d'ionisation du premier phényle est relié à la densité électronique au niveau de la position de substitution de groupe amide. De la même manière le potentiel d'ionisation de l'amide centré au niveau de l'azote est relié à la densité au niveau de l'azote.

[Traduit par le journal]

Introduction

Electronic effects of substituents upon reactivity have been empirically quantified in Hammett relationships and other extra thermodynamic treatments (1). Various experimental and theoretical criteria have been used to divide gross substituent effects into polar, steric, and resonance effects but experimental reactivity probes, with the exception of ion cyclotron resonance studies (2), are always subject to uncertainties involving solvent effects or uncontrollable variables. Until recently theoretical treatments (3) were too inexact to yield reliable results.

Photoelectron spectroscopy can be used to measure directly the influence of a substituent upon the elementary ionization event, and upon the relative energies of the ground state and various radical cation states of the molecule. By the investigation of substituent effects upon ionization potentials of substituted benzenes, we hoped to determine how the presence of a substituent on the benzene ring influences the ability of a second substituent to stabilize or destabilize the radical cation states formed by ionization.

Finally, through Koopmans' theorem (4), we can utilize the information obtained from photoelectron spectroscopy to map the electron densities in filled molecular orbitals of substituted benzenes.

By determining the photoelectron spectra of a series of *para* and *meta* substituted benzamides we hoped to study a range of substituents from strong donors to strong acceptors and their effect on the phenyl IP values of benzamides. In addition, the amido substituent is particularly significant in that its influence is secondary to the other substituents. It is also useful to determine the photoelectron spectra of benzamides since three of the IP values can be associated with the amide moiety and thus the in-

fluence of substituents on the ring on the energy of an orbital not effectively connected with the ring can be determined.

A number of investigators (5–9) have studied the photoelectron spectra of mono- and disubstituted benzenes. In monosubstituted benzenes the substituent interacts with the phenyl moiety to remove the degeneracy of the e_{1g} π orbitals of benzene. At the point of substitution one of the benzene orbitals (b_1 in C_{2v} symmetry) has its maximum electron density whereas the other orbital (a_2 in C_{2v} symmetry) has a node. As can be seen from Fig. 1, electron releasing substituents interact conjugatively with the phenyl orbital, e_{1g} (S) via a high lying occupied lone pair orbital to produce a new π ionization substantially shifted to lower IP. The other phenyl orbital e_{1g} (A) (termed Ph_A in this discussion) is found essentially unchanged from its position in benzene. Electron withdrawing groups shift both bands to higher IP values. The location of the first ionization potential in substituted benzenes which will be termed Ph_S in this discussion has been correlated with the σ constants of the substituent (9).

In disubstituted benzenes Turner and co-workers (5, 6) have pointed out that the separation between the two highest π levels is nearly equal to the sum of the separations in the corresponding monosubstituted benzenes. Rao (9) has pointed out that this approximation fails in the case of substituents interacting strongly with the phenyl π system. Rao has correlated all three π ionization potentials of substituted benzenes with the Hammett σ constants (10) of the substituent. Lindberg *et al.* (11) have correlated esca shifts of *meta* and *para* carbon in disubstituted benzenes with Hammett σ constants and have established the fact that esca shifts can be treated as linear free energy relationships.

The photoelectron spectra of formamide and acetamide have been determined (5) and the spectra of similar alkyl carbonyl compounds extensively described (12).

In this investigation we have studied the effect on the photoelectron spectrum of combining the phenyl and amide moieties in benzamide and the perturbation on its energy levels by a variety of substituents in the *meta* and *para* positions.

Results and Discussion

The photoelectron spectra of *m*-benzamides and benzamide are shown in Fig. 2. Figure 3 contains the photoelectron spectra of the *p*-benzamides. The IP values for the various band maxima and their

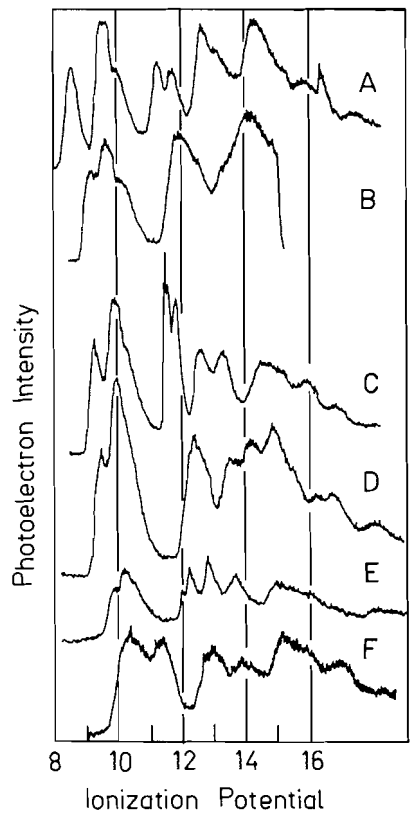

FIG. 3. Photoelectron spectra of *para* benzamides: (*A*) p-OCH_3; (*B*) p-CH_3; (*C*) p-Cl; (*D*) p-F; (*E*) p-CN; (*F*) p-NO_2.

assignments are listed in Table 1. Using the energy level designation which is applied to the constituent moieties, three of these levels are related to the phenyl group and are designated Ph_S, Ph_A, and Ph. The other three are derived from the amide group and are termed n_0, π_0, and $\pi_{C=O}$.

In considering the photoelectron spectrum of benzamide (Fig. 2*D*) it can be seen that the first band at 9.45 eV has shoulders at 9.78 and 10.20 eV. In addition the band with maximum at 12.16 eV has a shoulder at 14.16 eV. When a strong donor group such as OCH_3 or CH_3 is introduced into the *para* position of benzamide the first band is separated from its shoulder components (Fig. 3*A* and *B*) with its maximum appearing at 8.62 and 9.14 eV in p-OCH_3 benzamide and p-CH_3 benzamide, respectively. The peak which appeared at 9.78 eV in benzamide is destabilized to a smaller extent and appears at 9.57 and 9.62 in p-OCH_3 benzamide and p-CH_3 benzamide. Thus the first band at 9.45 eV is assigned to the Ph_S orbital which is characterized by high electron density at the position of substitution and *para* to it. The shoulder at 9.78 eV in benzamide is assigned to Ph_A. This orbital is generally less influenced by donor substituents and is characterized by high electron density in the *ortho* and *meta* positions and a node at the position of substitution and *para* to it. The substituent effect of $CONH_2$ on benzene is analogous to that of other electron withdrawing groups in that it has affected the Ph_A orbital to a larger extent than Ph_S. Ph_S has been stabilized by 0.21 eV and Ph_A by 0.54 relative to benzene. In benzonitrile (7) Ph_S is stabilized by 0.48 and Ph_A by 0.90 and in nitrobenzene (15) Ph_S is stabilized by 0.75 eV and Ph_A by 1.08. The amide group being less strongly electron withdrawing than the cyano or nitro results in less stabilization of the phenyl orbitals but the trend of $Ph_A > Ph_S$ is maintained.

In the amide moiety, the n_0 orbital corresponds to the oxygen lone pair on the carbonyl group. The analogous lone pair in formaldehyde at 10.88 is lowered to 10.20 in acetaldehyde by methyl substitution (12). Phenyl substitution in benzaldehyde lowers it further to 9.69 eV (14). Thus the phenyl substituent effect is 1.75 times as great as methyl. The n_0 IP in formamide at 10.32 eV is lowered to 9.96 eV in acetamide. If the phenyl substituent effect on the oxygen lone pair observed in benzaldehyde is duplicated in the case of benzamide the oxygen lone pair IP might be expected to occur in the region of 9.7 eV. This result together with the fact that the Ph_A band is considerably larger in area than Ph_S in the *para* substituted benzamides leads to the assignment in which n_0 is assumed to be accidentally degenerate with Ph_A of benzamide at 9.78 eV. In the *meta* benzamide this accidental degeneracy is removed.

The orbital designated π_N is largely located on the N atom and is an antibonding combination of the carbonyl π and the nitrogen p orbital. In formamide this IP occurs at 10.52 eV (5) and in acetamide it is found at 10.32 eV. If the phenyl substituent effect on π_N is assumed to be of the same order of magnitude as was observed for n_0 (i.e. 1.75 times the CH_3 substituent effect) the π_N IP might be expected to be found in the region of 10.17 eV. For this reason the

shoulder at 10.20 eV in the benzamide spectrum is assigned to the π_N orbital.

The band at 12.16 eV in benzamide is assigned to the phenyl orbital which has been stabilized from 11.67 eV in benzene. This stabilization is comparable to that observed for the Ph_A orbital. The shoulder in this band at 14.16 eV is assigned to $\pi_{C=O}$ which has been destabilized from 14.5 eV in formamide. This is comparable to the destabilization observed in the π_N orbital from formamide to benzamide. The $\pi_{C=O}$ orbital is the bonding combination of $\pi_{C=O}$ and the nitrogen lone pair. There is more uncertainty associated with the latter two ionization potentials than with the others because they are located in broad bands which probably include overlapping σ components and orbitals from the substituents.

Substituent Effect on Phenyl Orbitals

Electron releasing groups such as OCH_3 and CH_3 increase the Ph_S level of benzamide by 0.83 and 0.31 eV, respectively, whereas electron withdrawing groups such as CN and NO_2 lower the Ph_S level of benzamide by 0.54 and 0.88 eV, respectively. As expected the magnitude of the destabilization or stabilization is an indication of the electron releasing or withdrawing ability of the substituent. Figure 4 shows a plot of the Ph_S IP of *para*-substituted benzamides vs. the Ph_S IP of the corresponding substituted benzenes. As can be seen, a linear relationship is observed with a slope of 1.04. The significance of this slope will be considered when Ph_S IP values of

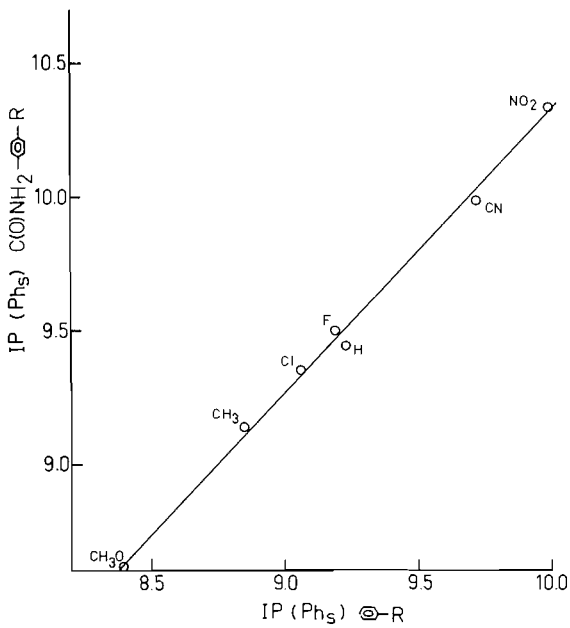

FIG. 4. Ph_S IP of *para* benzamides vs. Ph_S IP of substituted benzenes.

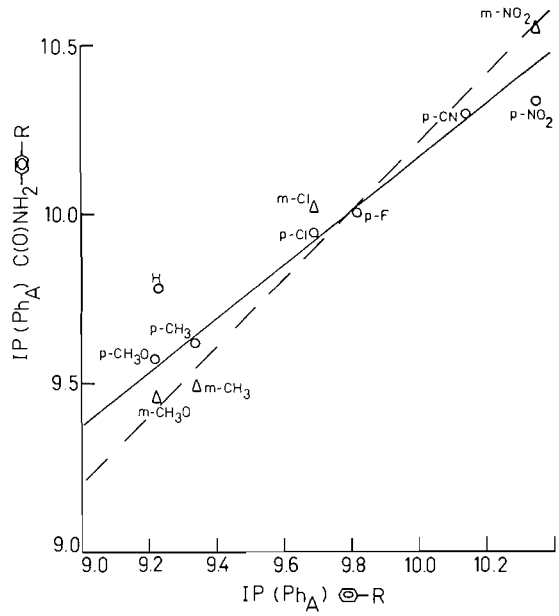

FIG. 5. Ph_A IP values of *para* ○ and *meta* △ benzamides vs. Ph_A IP of substituted benzenes.

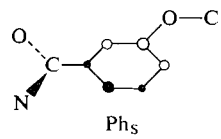
other disubstituted benzenes are discussed. The Ph_S IP's of the *meta* substituted benzamides are identical to the *para* substituted benzamides within experimental error. In contrast to this the Ph_A orbitals are found to be separated by at least 0.1 eV in *para* and *meta* benzamides. Discussion of this distinction will be considered after the Ph_A data are presented.

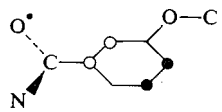
Figure 5 shows a plot of Ph_A IP values for substituted benzamides vs. those for the corresponding substituted benzenes. As in the case of Ph_S orbital linear relationships between substituted benzamide and substituted benzene IP's are found. Unlike the Ph_S orbital, there is a significant difference between the Ph_A IP's for *meta* and *para* substituted compounds. The shapes of the Ph_S and Ph_A orbitals obtained from CNDO/S calculations on *m*-OCH_3 benzamide are shown in Schemes 1 and 2.



Ph_S

SCHEME 1

The strong donor or strong acceptor substituents used in this study exert the major 'orbital orienting' effect, that is, determine the effective C_{2v} symmetry of the disubstituted molecules. In Schemes 1 and 2 the size of the circles at each position is approximately proportional to the coefficient of the wave function at that position. As can be seen in Scheme 2, as one shifts the amido substituent from the *para* to



Ph_A

SCHEME 2

the *meta* position one goes from essentially a node to a position of high electron density. The actual coefficients from the calculation are 0.043 and −0.467 for the Ph_A orbital for the carbons *para* and *meta* to the methoxy group. From Scheme 1 it is obvious that the change is not so dramatic for Ph_S as the amido group is moved from *para* to *meta* to the OCH_3 group. The calculated coefficients for the Ph_S orbital at the *para* and *meta* positions are 0.511 and 0.215, respectively. Since the square of the coefficient is assumed to be proportional to the extent of interaction then if the large change in the *para* and *meta* coefficients for Ph_A is only producing a change in the energy level of 0.1–0.2 eV, it would be impossible to observe any change in Ph_S energy level as one changed the amido substituent from *para* to *meta* where the relative change in coefficient size is much smaller.

The phenyl orbital IP values are listed in Table 1 and the general trend of increasing orbital energy with increasing electron donating ability of the substituent is also observed. Because the IP of the phenyl orbital increases for electron withdrawing groups it moves up into the region of the σ bands. In *p*-CN benzamide it becomes impossible to assign the Ph orbital.

Substituent Effect on Amide Orbitals

The substituent effect on the n_0 orbital is shown in Fig. 6 where its IP is plotted against the σ value of the substituent. Separate linear relationships are found for both *para* and *meta* substituted benzamides. Thus, the inductive effect of the substituent is being transmitted to the carbonyl oxygen from either the *meta* or *para* position. The influence of substituent on n_0 IP is obviously less than that on an orbital such as Ph_S which is directly associated with the phenyl group. Thus, the n_0 orbital changes by 0.76 through the series from *p*-CH_3O benzamide to *p*-NO_2 benzamide whereas Ph_S changes by 1.71 eV over the same series of compounds.

The dependence of π_N on substituent is also shown in Fig. 6. The π_N IP is also linearly related to the σ value of the substituent with *para* and *meta* substituents showing parallel trends. The change in π_N IP from *p*-CH_3O benzamide to *p*-NO_2 benzamide is 0.67 eV which is comparable to that observed for the n_0 orbital. As observed for all orbitals discussed thus far, the introduction of donor groups results in higher energy levels (decrease in IP's) and acceptor

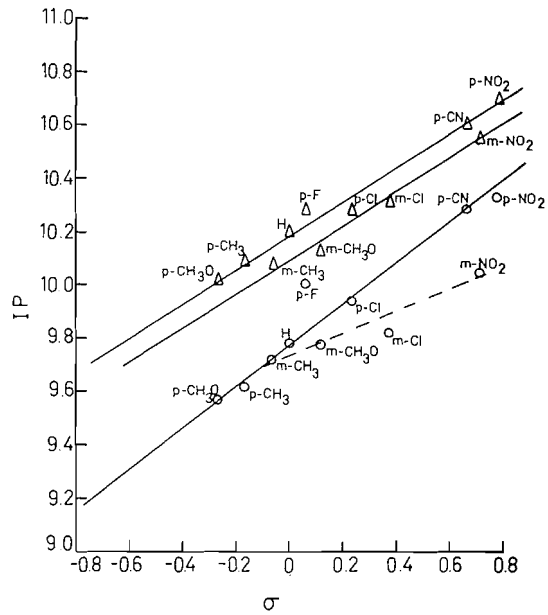


FIG. 6. n_0 IP of benzamides ○ and π_N IP of benzamides △ vs. σ of substituents.

group introduction lowers the energy levels (increases IP's). There is a general trend of decreasing $\pi_{C=O}$ IP with electron donating ability of the substituent. However, both *p*-CH_3O and *m*-CH_3O seem to be exceptions to this trend in that the $\pi_{C=O}$ IP for them is higher than the corresponding IP in *p*-CH_3 and *m*-CH_3 benzamide. Thus, there is less of a correlation between IP and substituent than there was for some of the lower IP's.

Other Levels

Ionizations from other orbitals which can be identified in the photoelectron spectra in Figs. 2 and 3 are principally due to lone pairs on the various substituents. In *p*-CH_3O benzamide and *m*-CH_3O benzamide the IP's at 11.27 and 11.21 eV, respectively, are assigned to ionization from the nonbonding oxygen of the methoxy group. The analogous IP is at 11.06 eV in anisole (7). In *p*-Cl benzamide the peaks at 11.52 and 11.83 eV are assigned to the nonbonding chlorine orbitals. In *m*-Cl benzamide these two levels occur at 11.62 and 11.79 eV. The analogous levels in chlorobenzene are located at 11.42 and 11.76 eV (6). The chlorine lone pair orbital which is perpendicular to the plane of the phenyl ring would be expected to interact more strongly with the phenyl π electrons. As a consequence it should be lowered and its IP should be slightly higher than that of the orbital which is in the plane of the phenyl ring. The orbital with the higher IP should have lost some of its nonbonding character and should be broader than the one at lower IP. As

TABLE 2. CNDO/S calculated ionization potentials for benzamides

	Ph_S		Ph_A		n_0		π_N	
	$IP_{(calcd)}$	Ratio	$IP_{(calcd)}$	Ratio	$IP_{(calcd)}$	Ratio	$IP_{(calcd)}$	Ratio
p-CH_3O	9.13	0.944	10.07	0.950	10.20	0.938	11.36	0.882
m-CH_3O	9.25	0.930	9.87	0.957	10.24	0.954	11.46	0.884
p-CH_3	9.51	0.961	10.05	0.957	10.20	0.943	11.43	0.882
m-CH_3	9.64	0.945	9.90	0.958	10.22	0.951	11.47	0.879
H	9.83	0.961	10.09	0.970	10.26	0.953	11.50	0.887
p-NO_2	10.50	0.984	10.68	0.967	10.44	0.989	10.78	0.992
m-NO_2	10.46	0.983	10.65	0.965	10.37	0.969	10.81	0.976

can be seen from the spectra of the chlorobenzamides this is the case. In *p*-CN benzamide there are three levels whose IP's are 12.20, 12.82, and 13.54 eV. Two of these levels are probably the C≡N π orbitals whose IP's are 11.84 and 12.11 eV in benzonitrile (7). If the first two are assigned to the C≡N π orbitals then the third at 13.54 eV seems unusually high for a phenyl orbital as compared to other phenyl orbitals in the series. Alternatively 13.54 eV seems unreasonable for C≡N π, when compared to benzonitrile. Thus, a definite assignment of these three levels cannot be made. In *p*-NO_2 benzamide and *m*-NO_2 benzamide the IP's at 11.34 and 11.33 eV are assigned to nonbonding oxygen orbitals of the nitro group. These are located at 11.15 and 11.30 eV in nitrobenzene (15). No splitting of the nitro group orbitals into two levels is observed here as in the nitrobenzene case.

Calculations

As an aid in assignment of the photoelectron spectra of the benzamides CNDO/S calculations (16) have been performed on several of the compounds under investigation. Table 2 shows the results of these calculations for the first four ionization potentials. These values were obtained by the use of Koopmans' theorem (4) in which the negative of the calculated molecular orbital energy is equated to the ionization potential. The halogen substituted benzamides are not included since the program is not equipped to handle halogen orbitals. Standard geometries were used throughout the calculation. Ionization potentials beyond the first four are not included for two reasons: (*i*) the program begins to overestimate the orbital energies of σ levels and places them in this range and (*ii*) the Ph and $\pi_{C=O}$ levels are mixed with other levels so that they become difficult to distinguish.

The ratio of IP_{exp}/IP_{calcd} is also included in Table 2 for comparison purposes. The calculated IP is always larger than the experimental. It is also worth noting that with the exception of the nitrobenzamides the ratio of the experimental to calculated IP's is virtually constant for each type of orbital: 0.95 for Ph_S, 0.96 for Ph_A, 0.95 for n_0, and 0.88 for π_N. This relative constant deviation between calculated and experimental IP's can be used as an aid in assignment. If an IP is assigned incorrectly for one compound in the series the ratio will show a large deviation from the remainder of the series.

In the benzamides for which calculations were performed, the trends in calculated IP's parallel those of the experimental values. Thus, the Ph_S IP undergoes the greatest change from the parent benzamide to *p*-CH_3O benzamide. Ph_A IP's are more affected by substituents in the *meta* position than in the *para* position. The calculated and experimental π_N IP change by a comparable amount from *p*-CH_3O benzamide to benzamide. One notable exception to these trends in the n_0 orbital whose calculated IP is virtually unchanged from *p*-CH_3O benzamide to benzamide whereas the experimental IP changes by 0.21 eV over this series of compounds. Another significant difference between calculated and experimental IP's appears when one compares the Ph_S IP's of the *para* and *meta* substituted compounds. Experimentally, these IP's are identical whereas calculationally they differ by ~0.1 eV with the *meta* compound having the higher IP. In summary, the use of semiempirical molecular orbital calculations aids qualitatively in assignment of the photoelectron spectra of the benzamides in this investigation.

Ionization Potential Relationships in Disubstituted Benzenes

As discussed previously the photoelectron spectra of series of dimethylanilines (8), nitrobenzenes (8), acetophenones (8), and nitrosobenzenes (17) have been determined. In each case linear correlations between phenyl π IP and σ for the substituent have been obtained. In view of the fact that we have obtained a linear relationship between the Ph_S IP of substituted benzamides (Fig. 4) and the Ph_S IP of the corresponding substituted benzenes, we have attempted a similar correlation for the above series of disubstituted benzenes. The results are shown in Fig. 7.

The Ph_S IP's for substituted benzenes have been compiled from various sources and these values together with the sources are listed in Table 3. As can be seen from Fig. 7, a linear relationship is found for each series of compounds. The slope of this linear relationship is approximately unity for all series of compounds except the *N,N*-dimethylanilines. In the latter case the slope is 0.40.

An analogous plot is shown in Fig. 8 for substituted anilines, chlorobenzenes, and benzonitriles. The Ph_S IP's of substituted anilines and benzonitriles are not available directly but Rao (9) has tabulated the changes in first IP of substituted benzenes brought about by substituting amino and cyano groups in the *para* position. Thus, we have added these group contributions to the Ph_S IP's of monosubstituted benzenes in Table 3 to obtain the data for anilines and benzonitriles in Fig. 8. The substituted chlorobenzene data is listed in Table 3. All three series of compounds in Fig. 8 show linear relationships with slopes of 1.06 for benzonitriles,

0.92 for chlorobenzenes, and 0.67 for anilines. As previously observed in Fig. 7, it is only a strong electron releasing group ($—NH_2$) which shows a slope much less than unity.

To investigate further the generality of this relationship between phenyl IP's of disubstituted and monosubstituted benzenes it was decided to examine the phenyl IP's of substituted toluenes and anisoles. The results are shown in Fig. 9 for toluenes and Fig. 10 for anisoles. Since several sources of IP's are used, the values of the IP's used in Figs. 9 and 10 and their sources are listed in Table 3. A linear relationship with a slope of 0.95 exists between the Ph_s IP of substituted toluenes and the Ph_s IP of substituted benzenes. Figure 10 demonstrates similar behavior for the *para* substituted anisoles with the slope being 0.69. Thus, it seems that electron releasing groups such as CH_3, OCH_3, NH_2, and $N(CH_3)_2$ have a distinct influence on the Ph_s IP of benzene. Electron withdrawing groups do not display this effect and show slopes of $COCH_3$ 1.01, $CONH_2$ 1.06, CN 1.06, NO_2 1.12, and NO 1.20. It is of interest to note that the slopes exhibited by the electron releasing groups are in the order of their electron releasing abilities with the furthest deviation from unity being the most electron releasing viz. 0.9 for CH_3, 0.7 for OCH_3, 0.67 for NH_2, and 0.40 for $N(CH_3)_2$.

Donor substituents are known to interact with the e_{1g} orbital of benzene through high lying occupied lone pair orbitals producing the phenyl $S(b_1)$ and phenyl $A(a_2)$ levels of substituted benzenes. The fact that a second electron releasing substituent produces

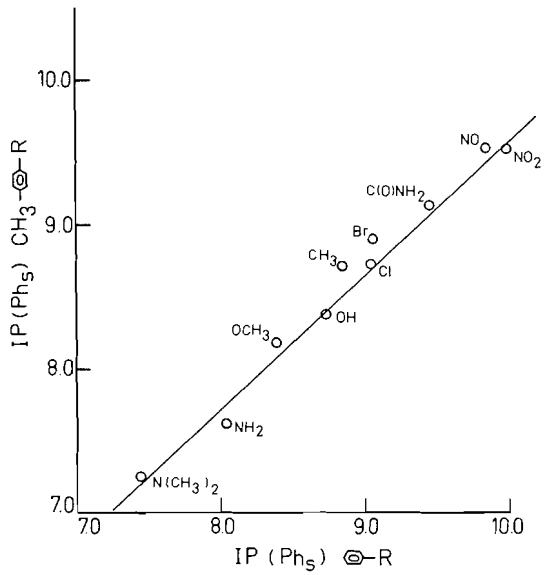

FIG. 9. Ph_s IP for substituted toluenes vs. Ph_s IP for substituted benzenes; IP values from Table 3.

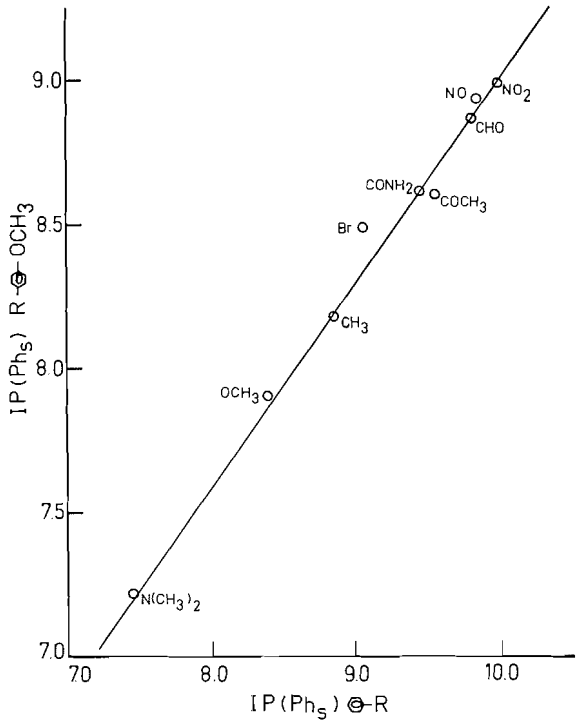

FIG. 10. Ph_s IP for substituted anisoles vs. Ph_s IP for substituted benzenes; IP values from Table 3.

less of an effect on Ph_s than the first can be attributed partly to the fact that there is a larger separation, hence decreased interaction, between Ph_s of the monosubstituted benzene and the lone pair of the substituent than between the benzene e_{1g} orbital and the lone pair of the substituent. The nitrogen lone pair in dimethylamine occurs at 8.9 eV (18). The interaction between this orbital and one of the e_{1g} orbitals of benzene at 9.24 eV produces a destabilization of 1.78 eV in *N,N*-dimethylaniline (Table 3). When a second dimethylamino group is introduced, the interaction is a much weaker one between the lone pair orbital at ~8.9 and the Ph_s at 7.45 eV and produces a destabilization of 0.61 to 6.84 eV (8). In addition the HOMO of substituted benzene has less benzene character i.e. all the coefficients are smaller than in the benzene HOMO.

The energy consideration above would suggest that acceptors should lower Ph–donor orbitals more than they lower Ph—H, since the acceptor LUMO is involved and will be closer in energy to the Ph–donor HOMO. The combination of inductive withdrawal plus the low lying vacant π orbital in acceptors is responsible for producing a larger effect than anticipated when an acceptor is added to a donor substituted benzene. The smaller slope observed for donor substituents can then be considered to result from both decreased interaction by a second donor and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

enhanced interaction when the second substituent is an acceptor group.

An additional feature of the plots of Ph_S IP values of disubstituted benzenes vs. those of monosubstituted benzenes is that the graphs can aid in assignment of photoelectron spectra of some of these compounds. Two conflicting assignments have been reported for the photoelectron spectrum of nitrobenzene. Kobayashi and Nagakura (7) and Egdell and co-workers (8) have proposed an inversion of the b_1 and a_2 levels in nitrobenzene. Rabalais (15) has concluded that the normal ordering of substituted benzene levels is followed and b_1 is the HOMO with a_2 at a lower energy. If one uses the inverted assignment the b_1 or Ph_S point does not fall on the curve for nitrobenzenes (Fig. 7). A prediction of inversion of energy levels for nitrosobenzenes (17) has also been made, whereas Rabalais and Colton (14) have predicted the normal ordering in their assignment. Again an attempt to use the second highest IP in nitrosobenzene to represent Ph_S results in a point which does not correlate with the remainder of the nitrosobenzene curve (Fig. 7). In an independent study[2] the normal ordering (b_1 or Ph_S above a_2 or Ph_A) in nitrobenzene has been confirmed from the photoelectron spectra of *p*-NO_2 styrene and *m*-NO_2 styrene.

Photoelectron Spectra Correlations with Nuclear Magnetic Resonance Data

Figure 11 shows a plot of the IP's assigned to Ph_S in the *para* benzamides vs. chemical shifts of C-4 carbon (19). In this designation the C-4 carbon represents the carbon at which the amide group is substituted. As can be seen a linear relationship is observed between IP and chemical shift which is to be expected since the extent of chemical shift is proportional to the electron density and the Ph_S orbital is expected to be one in which there is high electron density at the position of substitution of the amide. This high electron density results both from actual charge donation and polarization of the benzamide HOMO by substituents. As pointed out by Santiago *et al.* (20), the higher in energy the HOMO, the more it has mixed with the donor orbital and the more polarization towards the *para* carbon occurs. Acceptor substitution does the opposite with polarization towards the substituent taking place. This polarization will influence the chemical shift of the *para* carbon in the direction observed with larger values of the chemical shift associated with acceptor substituents. Figure 12 shows a correlation of the π_N IP's of *para* benzamides with ^{15}N chemical shifts as determined by Randall and co-workers (21). In their studies an acceptor group produced a low field shift (i.e. to higher frequency) and a donor group produced a high field shift. The ^{15}N shifts correlate well with the IP of the orbital with high electron density on the atom to which the shift is referred and the substituents which act to remove electron density from that atom provide both a large chemical shift and high IP.

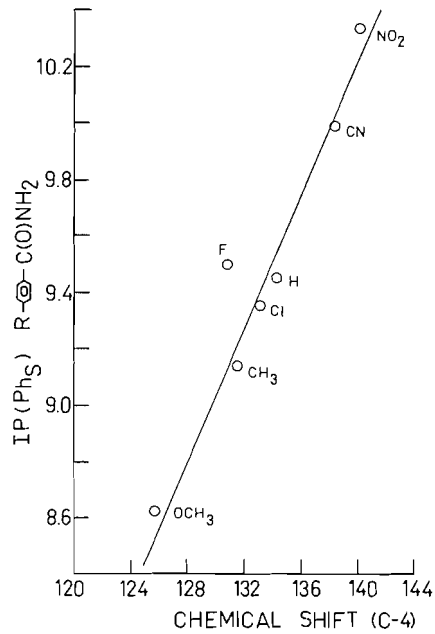

FIG. 11. Ph_S IP *para* benzamides vs. chemical shift (carbon-4) (ref. 20).

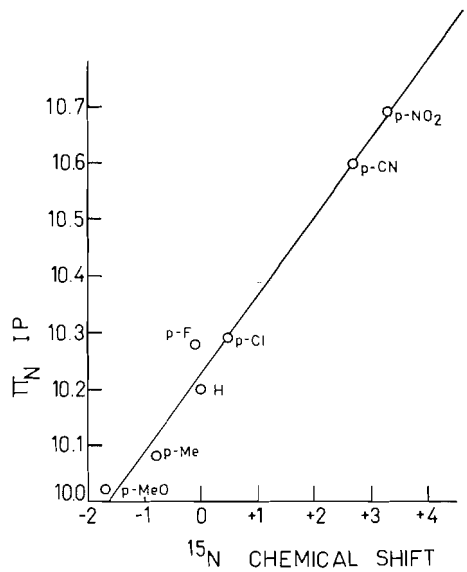

FIG. 12. π_N IP *para* benzamides vs. ^{15}N chemical shift (ref. 22).

Experimental

Photoelectron spectra were recorded on a Perkin-Elmer Ltd., PS-18 Photoelectron Spectrometer with heated probe. A mixture of xenon and argon was used as internal calibrants and the recorded peak positions represent an average of five determinations. Resolution as measured on the argon peak at 15.76 eV was 25–30 meV. The substituted benzamides were prepared by ammonolysis of the commercially available benzoyl chlorides using a standard procedure (22).

Preparation of cyclobutenones and cyclopent-2-enones via epoxy sulfone cyclizations

BERNARD CORBEL,[1] JOHN M. DECESARE, AND TONY DURST

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received July 29, 1977

BERNARD CORBEL, JOHN M. DECESARE, and TONY DURST. Can. J. Chem. **56**, 505 (1978).

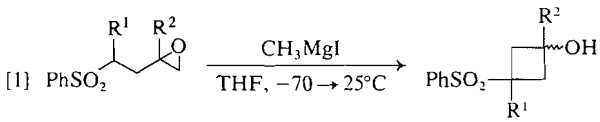
Epoxysulfones of the type $PhSO_2(CH_2)_nCH\overset{O}{\frown}CH_2$ (n = 1, 2) react with about 2 equiv. of CH_3MgI in THF to give 3-phenylsulfonylcyclobutanols and 3-phenylsulfonylcyclopentanols in good to excellent yields. 3-Alkyl-3-phenylsulfonylcyclobutanols and -cyclopentanols can be obtained either from the appropriately substituted epoxides or by alkylation of the dianion of the parent 3-phenylsulfonylcycloalkanols. Oxidation of these alcohols with Jones' reagent followed by treatment of the crude ketones with triethylamine leads to 3-substituted cyclobutenones and cyclopent-2-enones.

BERNARD CORBEL, JOHN M. DECESARE et TONY DURST. Can. J. Chem. **56**, 505 (1978).

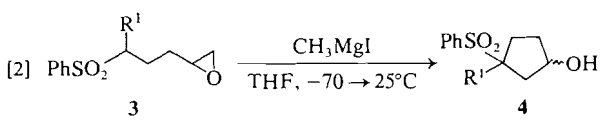
Les époxysulfones du type $PhSO_2(CH_2)_nCH\overset{O}{\frown}CH_2$ (n = 1,2) réagissent avec environ 2 équiv. de CH_3MgI dans le THF pour conduire aux phénylsulfonyl-3 cyclobutanols et aux phénylsulfonyl-3 cyclopentanols avec des rendements allant de bon à excellent. On peut obtenir des alkyl-3 phénylsulfonyl-3 cyclobutanols et cyclopentanols soit à partir des époxydes substitués d'une façon appropriée soit par alkylation du dianion des phénylsulfonyl-3 cycloalkanols correspondants. L'oxydation de ces alcools par le réactif de Jones, suivi par un traitement des cétones brutes par la triéthylamine, conduit aux cyclobutenones et aux cyclopentène-2 ones substitués en position 3.

[Traduit par le journal]

We have shown in a recent communication (1) that γ-epoxysulfones **1** can be effectively cyclized to 3-phenylsulfonylcyclobutanols **2**. We would now like to report the conversion of the homologous δ-epoxysulfones **3** to cyclopentanols **4**, and the conversion of **2** and **4** in good overall yield to cyclobutenones and cyclopent-2-enones, respectively. This route adds significantly to the synthetic methodology available



1 **2**

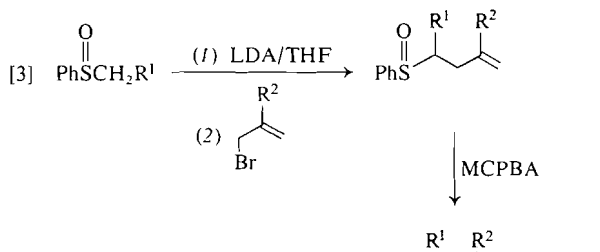


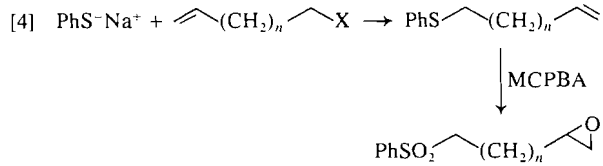
3 **4**

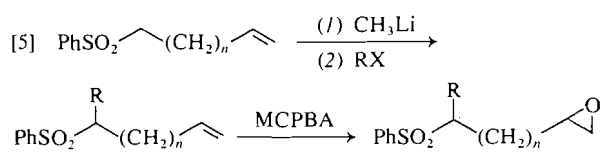
for the preparation of cyclobutenones, especially those having substituents only in the 3 position (2).

The starting materials **1** and **3** required for the cyclization reactions were readily prepared by several simple routes outlined in eqs. 3–5. For details, see the Experimental.

The cyclizations of the epoxysulfones were carried out in dry THF, initially at −70°C and then at room temperature over a 24 h period, using about 2 equiv. of Grignard reagent. The yields of chromatographically pure cyclized material were usually in the good to excellent range (Table 1). The structures of these compounds were confirmed by their nmr, ir, and analytical data (see Table 1). The mechanism of the cyclization reactions, which involves initial opening of the epoxide to a haloalkoxide, subsequent formation of an α-sulfonyl Grignard reagent







[1]NRCC–France exchange visitor 1975–1976.

TABLE 1. Physical characteristics of cyclobutanols and cyclopentanols from the cyclization of epoxy sulfones

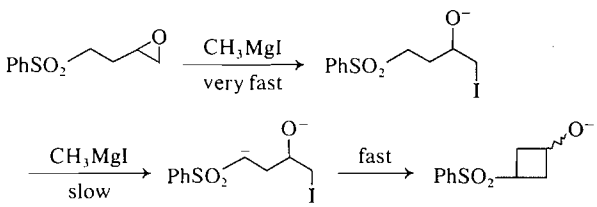


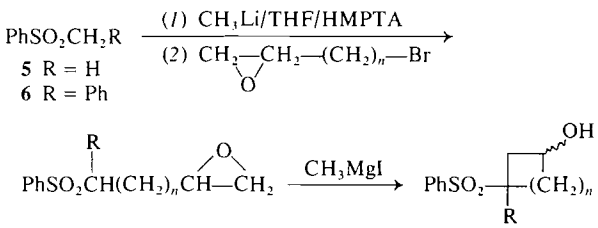
SCHEME 1. Mechanism of cycloalkanol formation from epoxy sulfones.

and finally cyclization has been discussed (1) (Scheme 1).

The preparation of both the β-phenylsulfonylcyclobutanols and -cyclopentanols could also be carried out under 'one-pot' conditions according to Scheme 2. Thus reaction of phenyl methyl sulfone **5** (R = H) with 1 equiv. of CH_3Li in THF containing 5% of hexamethylphosphoramide (HMPTA) at −70°C followed by sequential addition of epibromohydrin and CH_3MgI and warming to room temperature overnight gave **2** ($R^1 = R^2 = H$) in 46% isolated yield; the cyclobutanol **2**, R^1 = Ph, R^2 = H, was similarly prepared from benzyl phenyl sulfone (**6**, R = Ph) in 60% yield. Replacement of epibromohydrin by 4-bromo-1,2-epoxybutane in the above sequence lead to the formation of 3-phenylsulfonylcyclopentanol and 3-phenyl-3-phenylsulfonylcyclopentanol in 35 and 75% yield, respectively.

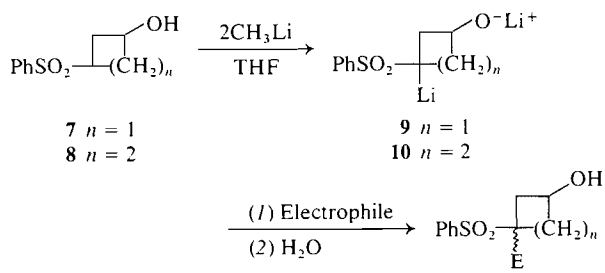
The parent ring compounds **7** and **8** could readily be alkylated, halogenated or sulfenylated at the 3 position via the dianion **9** and **10** (Scheme 3). The yields of product derived from these reactions are remarkably high considering the fact that a quaternary system is being generated (Table 2). Interestingly, in the cyclization of the epoxysulfones only one isomer was detected by nmr examination of the product, whereas two isomers were obtained in nearly equal amounts from the alkylation procedure. The stereochemical assignments of the isomers has not as yet been made and thus no explanation can be offered for the high stereoselectivity in the epoxysulfone cyclization.

Oxidation of the cyclobutanols or cyclopentanols with Jones' reagent led in excellent yield to the corresponding ketones (Scheme 4, Table 3). The



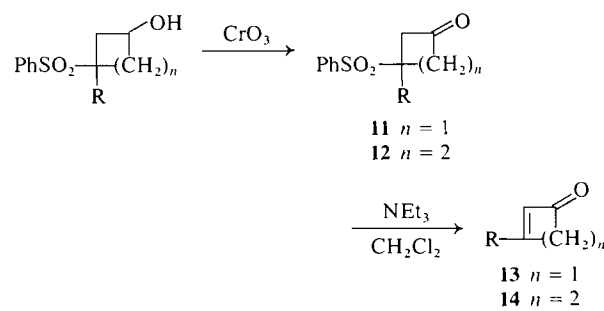
SCHEME 2. 'One-pot' formation of 3-phenylsulfonylcycloalkanols.

β-sulfonylcyclobutanones **11** were generally isolated and purified. Subsequent treatment with triethylamine in CH_2Cl_2 at room temperature furnished the cyclobutenones. Because of the ease of elimination of the phenylsulfonyl group from the cyclopentanones **12**, these compounds were directly converted to cyclopentenones without attempts at their purification. The facile β-elimination of a phenylsulfonyl moiety to yield αβ-unsaturated ketones is well known (3).



SCHEME 3

The 3-phenylsulfonyl substituted cyclobutanones were identified by their analytical data, nmr spectra (see Experimental) and the characteristic carbonyl frequency, 1780–1800 cm^{-1}, in the infrared. The cyclobutenones showed the carbonyl frequency at about 1760 cm^{-1}. In their nmr spectra these substances each had two slightly broadened singlets at about δ 3.2 (2H) and 5.8–6.0 (1H) assignable to the remaining methylene and olefinic hydrogen in the



SCHEME 4

ring. For **13** (R = Ph) these absorptions occurred at δ 3.54 and 6.40 (4). 3-Benzylcyclobutenone (**13**, R = CH_2Ph) readily isomerized in the presence of triethylamine to benzylidenecyclobutanone (nmr δ: 3.9–4.0 (m, 4H), 6.6 (m, 1H) and 7.3 (s, 5H)). In the presence of D_2O/NEt_3 all non-aromatic ring hydrogens underwent H–D exchange. The various 3-alkylcyclopentenones each showed a one proton multiplet in the δ 5.9–6.0 region (5).

Experimental

General Comments

All nmr spectra were recorded on a Varian T-60 or HA-100 Spectrometers using $CDCl_3$ – 1% TMS as solvent; the chemical shifts are reported in ppm downfield from TMS. Infrared spectra were obtained as thin films or $CHCl_3$ solution on a Beckman IR-20 instrument. Melting points are not corrected. Usual work-up refers to washing the reaction mixture with water, drying the organic extracts with $MgSO_4$, and evaporating the organic solvent on a rotary evaporator. The intermediates epoxysulfones and their precursors were not subjected to elemental analysis. Their structures follow unambiguously from their method of synthesis and are supported by the nmr spectra.

Preparation of Epoxysulfones

General Procedures

Via eq. 3—The anion of an alkyl phenyl sulfoxide was generated by reaction with 1.1 equiv. of lithium diisopropylamide (LDA) in THF at either −70 or 0°C. One equivalent of an alkyl halide was then introduced and the reaction mixture was then allowed to warm to room temperature. Usual workup gave the crude sulfoxide olefin which was generally purified by silica gel chromatography. The purified product was then oxidized with slightly more than 2 equiv. of *m*-chloroperbenzoic acid (MCPBA) in refluxing CH_2Cl_2 (overnight). The reaction mixture was then washed with 10% NaOH and then water. The crude product was purified by chromatography on silica gel or recrystallization.

Via eq. 4—Potassium phenyl mercaptide was generated in CH_3OH and reacted with slightly less than 1 equiv. of alkyl halide usually by refluxing the methanol solution for up to 18 h. The sulfide was isolated by diluting the reaction mixture with water and extracting several times with CH_2Cl_2. The organic phase was then processed in the usual manner. The crude sulfide, which was generally sufficiently pure for further use was oxidized in one of two ways. The use of 2 equiv. of MCPBA in CH_2Cl_2 at room temperature furnished only olefin sulfones whereas epoxysulfones could be obtained directly by reacting the sulfide olefin for 18 h with >3 equiv. of MCPBA in refluxing CH_2Cl_2. In each instance the reaction was processed as described above.

Via eq. 5—The phenylsulfonylalkenes $PhSO_2CH_2(CH_2)_n$ $CH{=}CH_2$ obtained via eq. 4 above were dissolved in dry THF at 0°C, treated with 1.1 equiv. of CH_3Li and the resultant anion was then alkylated. After a 15–30 min reaction time the reaction mixture was diluted with water and extracted with CH_2Cl_2. The crude organic products isolated in the usual way were purified by column chromatography.

4-Phenylsulfonyl-1,2-epoxybutane

This compound was prepared in 85% overall yield starting with 5.4 g of 4-bromobut-1-ene according to eq. 4. The nmr spectrum of the epoxysulfone showed peaks at δ 1.7–3.5 (m, 7H) and 7.4–7.8 (m, 5H).

2-Methyl-4-phenylsulfonyl-1,2-epoxybutane

Alkylation of the anion derived from 2.45 g (17.5 mmol) of phenyl methyl sulfoxide and 20 mmol of LDA with 2.5 g methallyl bromide gave after purification by silica gel chromatography 2.23 g (66%) of 2-methyl-4-phenylsulfinyl-but-1-ene; nmr δ: 1.84 (s, 3H), 2.1–3.1 (m, 4H), 3.7–3.9 (m, 2H) 7.4–7.8 (m, 5H).

Oxidation of this material with 2.2 equiv. of MCPBA gave 2.33 g (84%) of the desired epoxysulfone whose nmr spectrum showed peaks at δ 1.32 (s, 3H) 1.7–2.2 (m, 2H), 2.60 (s, 2H), 3.1–3.3 (m, 2H), and 7.5–8.0 (m, 2H).

4-Phenyl-4-phenylsulfonyl-1,2-epoxybutane

This compound was prepared according to eq. 3. Thus 4.15 g (19.2 mmol) of benzyl phenyl sulfoxide in 70 ml of THF at −20°C was converted to its lithio salt by reaction with 21.5 mmol of CH_3Li. The yellow anion solution was then quenched with 40 mmol of allyl bromide. The yield of 4-phenyl-4-phenylsulfinyl-but-1-ene was 86%.

The sulfide-olefin was refluxed overnight in CH_2Cl_2 with 2.5 equiv. of MCPBA. The yield of epoxysulfone, mp 98°C (CH_2Cl_2–hexane) was 90%; nmr δ: 2.2–3.2 (m, 6H), 4.2–4.4 (m, 1H), 7.0–7.6 (m, 10H).

5-Phenyl-4-phenylsulfonyl-1,2-epoxypentane

Via eq. 5: 4-phenylsulfonylbut-1-ene (7.5 mg, 3.64 mmol) was dissolved in 25 ml THF and 1 ml hexamethylphosphorus triamide (HMPTA) at −70°C and then converted to its α-sulfone anion with CH_3Li. The resultant anion was reacted with 1.5 equiv. of $PhCH_2Br$ and the reaction mixture allowed to warm to room temperature workup, followed by column chromatography on silica gel gave 780 mg (77%) of a clear oil whose nmr spectrum showed peaks at δ: 2.3–2.6 (m, 5H), 4.9–5.9 (m, 3H), 7.0–8.0 (m, 10H).

The above alkene was oxidized with MCPBA in refluxing CH_2Cl_2. The yield of epoxide, mp 67°C, was 95%; nmr δ: 1.5–2.3 (m, 3H), 2.4–3.0 (m, 3H), 3.1–3.6 (m, 2H), 7.1–7.4 (m, 5H), 7.5–8.0 (m, 5H).

4-Phenylsulfonyl-1,2-epoxyundecane

Via eq. 5: alkylation of the lithio salt from 1.12 g of $PhSO_2CH_2CH_2CH{=}CH_2$ with 1-bromoheptane in THF–HMPTA (25:1) at −70°C followed by warming to room temperature gave 1.18 g (76%) of 4-phenylsulfonylundec-1-ene; nmr δ: 0.8–2.0 (m, 15H), 2.1–2.7 (m, 2H), 2.8–3.1 (m, 1H), 4.9–6.0 (m, 3H), 7.5–8.0 (m, 5H). This latter upon oxidation with MCPBA in the usual manner furnished, after column chromatography (4:1 hexane – ethyl acetate), a 92% yield (1.15 g) of epoxysulfone; nmr δ: 0.8–2.2 (m, 17H), 2.4–2.6 (m, 1H), 2.7–2.9 (m, 1H), 3.0–3.4 (m, 2H), 7.5–8.0 (m, 5H).

4-Phenylsulfonyl-1,2-epoxyoctane

Via eq. 5: 4-phenylsulfonyl-but-1-ene (2.09 g) dissolved in 35 ml THF and 2 ml of HMPTA at −70°C was converted to its anion with CH_3Li and then reacted with excess 1-bromobutane. The crude product was chromatographed to yield

1.86 g (77%) of alkene sulfone; nmr δ: 0.8–2.0 (m, H), 2.1–2.7 (m, 2H), 2.8–3.2 (m, 1H), 4.9–6.0 (m, 3H), 7.5–8.0 (m, 5H).

Epoxidation of the above intermediate with MCPBA gave 92% of the desired epoxysulfone after purification on silica gel column (4:1 ethyl acetate – hexane); nmr δ: 0.8–2.2 (m, 17H), 2.4–2.6 (m, 1H), 2.7–2.9 (m, 1H), 3.0–3.3 (m, 2H), 7.5–8.0 (m, 5H).

5-Phenylsulfonyl-1,2-epoxypentane

4-Penten-1-ol (9.9 g) was dissolved in 150 ml CH_2Cl_2 containing 14 g of triethylamine. To this mixture, cooled to 0°C was added dropwise 11.4 g of CH_3SO_2Cl dissolved in 50 ml of CH_2Cl_2. The reaction mixture was washed successively with water and 5% HCl solution and the organic extract was dried and evaporated. The crude yield of mesylate was 18.0 g (96%); nmr δ: 1.5–2.3 (m, 4H), 2.92 (s, 3H), 4.0–4.3 (2H), and 4.7–6.0 (m, 3H).

The crude mesylate was added to a methanol solution containing PhS^-K^+ and stirred overnight. The reaction mixture was then diluted with H_2O and extracted with 5 × 100 ml of CH_2Cl_2. The combined organic extracts were washed with 4 × 100 ml of 5% NaOH, dried, and evaporated yielding 17.8 g (97%) of 4-phenylthiopent-1-ene; nmr δ: 1.4–2.4 (m, 4H), 2.79 (t, J = 7 Hz, 2H), 4.7–6.0 (m, 3H), 7.0–7.4 (m, 5H).

Oxidation of 16.3 g (92 mmol) of the above sulfide-alkene with 70 g (330 mmol) of MCPBA in refluxing CH_2Cl_2, overnight, followed by washing with 5% NaOH solution and further usual work-up gave 18.0 g (90%) of the desired epoxy-sulfone, mp 120–121°C; nmr δ: 1.2–2.2 (m, 4H), 2.4–3.4 (m, 5H), and 7.3–8.1 (m, 5H).

Reaction of Epoxysulfones with CH_3MgI Preparation of Cyclobutanols and Cyclopentanols. General Procedure

Epoxysulfone (2 mmol) was dissolved in about 25 ml of THF at −70°C. The solution was then treated with 4–5 mmol of CH_3Mg (~2.5 M) in ether. A white solid precipitated immediately. The reaction mixture was allowed to warm to room temperature and stirred for about 4–18 h depending on convenience. The crude product obtained in the usual manner was purified by silica gel chromatography (see Table 1).

Alkylation of 3-Phenylsulfonylcyclopentanol. General Procedure

A solution of 3-phenylsulfonylcyclopentanol was dissolved in THF at −70°C and converted to the dianion upon treatment with 2.1 equiv. of CH_3Li. The dianion formation was allowed to proceed for 5 min and 1 equiv. of the alkyl halide was introduced. The acetone – Dry Ice bath was then removed and the reaction stirred until the disappearance of starting material (tlc). Work-up, as described for the formation of 3-phenylsulfonylcyclopentanol gave the crude products which were purified by chromatography using 1:2 ethyl acetate – hexane as eluent (see Table 2).

'One-pot' Preparation of Cyclobutyl- and Cyclopentanols

3-Phenyl-3-phenylsulfonylcyclopentanol

Benzyl phenyl sulfone 786 mg (3.3 mmol) was dissolved in 25 ml of THF containing 1 ml of HMPTA. The solution was cooled to −70°C and reacted with 3.6 mmol of CH_3Li followed by 543 mg (3.6 mmol) of 4-bromo-1,2-epoxybutane. The reaction mixture was warmed to room temperature and kept until the starting material had disappeared. The reaction mixture was then cooled to −70°C and treated with 2.1 equiv. of CH_3MgI, warmed to room temperature and stirred for 48 h. Work-up was accomplished by pouring the reaction mixture into saturated NH_4Cl solution, extracting with ether and then CH_2Cl_2, drying the organic extracts, and evaporating the solvents. The crude product was purified by chromatography using 1:2 ethyl acetate – hexane as eluent. The yield of viscous oil was 750 mg (75%); ir: 3500 (broad), 1300(s), 1130(s) cm^{-1}; nmr δ: 2.0–3.4 (m, 6H), 3.4–3.8 (1H, OH), 4.2–4.6 (m, 1H), 7.0–7.6 (m, 10H). *Anal.* calcd. for $C_{17}H_{18}O_3S$: C 67.55, H 5.96; found: C 67.33, H 6.10.

Also prepared by this route were 3-phenylsulfonylcyclopentanol (35%); 3-phenylsulfonylcyclobutanol (46%), and 3-phenyl-3-phenylsulfonylcyclobutanol (60%).

Oxidation of Cyclobutanols to Cyclobutanones

(a) 3-Phenylsulfonylcyclobutanone

3-Phenylsulfonlycyclobutanol (270 mg, 1.29 mmol) was dissolved in 6 ml of acetone and reacted with 2 ml of Jones' reagent (6) for 3 h at room temperature. The reaction mixture was diluted with CH_2Cl_2 and then washed successively with 10% $NaHSO_3$ and 10% $NaHCO_3$. Chromatography of the crude reaction product yielded 148 mg (56%) of 3-phenylsulfonylcyclobutanol as colorless crystals, mp 99–100°C; ir: 1790 cm^{-1}; nmr δ: 3.1–4.1 (m, 5H), 7.5–8.0 (m, 5H.) *Anal.* calcd. for $C_{10}H_{10}O_3S$: C 57.13, H 4.79; found: C 57.11, H 4.92.

(b) 3-Phenyl-3-phenylsulfonylcyclobutanone

The precursor cyclobutanol 560 mg (1.94 mmol) was dissolved in 5 ml of acetone and treated with 2 ml of Jones' reagent. After a 30 min reaction time the reaction was worked up as above. Recrystallization of the crude product gave 450 mg (80%) of cyclobutanone, mp 144°C from 95% ethanol; nmr δ: 3.4–3.7 (m, 2H), 4.1–4.4 (m, 2H), 6.9–7.8 (m, 10H).

(c) 3-Benzyl-3-phenylsulfonylcyclobutanone

The precursor alcohol (140 mg, 0.48 mmol) was oxidized as above in 5 ml of acetone with 1.5 ml of Jones' reagent for 1 h. Recrystallization gave 134 mg (94%) of 3-benzyl-3-phenylsulfonylcyclobutanone, mp 134°C (CH_2Cl_2–hexane); ir: 1800(s), 1310(s), and 1150(s) cm^{-1}; nmr δ: 219–3.3 (m, 2H), 3.26 (s, 2H), 3.6–3.9 (m, 2H), 6.9–8.1 (m, 10H).

(d) 3-Butyl-3-phenylsulfonylcyclobutanone

This compound was prepared in 92% yield after column chromatography on silica gel (1:5 ethyl acetate – hexane); colorless viscous oil; ir: 1800(s), 1305(s), 1150(s) cm^{-1}; nmr δ: 0.8–2.0 (m, 9H), 2.8–3.2 (m, 2H), 3.6–4.0 (m, 2H), 7.5–8.0 (m, 5H). The crude sample was contaminated with some of the enone.

(e) 3-Heptyl-3-phenylsulfonylcyclobutanone

Oxidation of 205 mg (0.68 mmol) of the precursor alcohol as above gave 196 mg of a viscous oil whose nmr indicated a mixture of cyclobutanone and cyclobutenone. The two compounds were separated by column chromatography. Yield of 3-heptyl-3-phenylsulfonylcyclobutanone, 152 mg (74%), ir 1800(s), 1305(s), 1150(s); nmr δ: 0.7–2.0 (15H), 2.8–3.2 (m, 2H), 3.7–4.0 (m, 2H), 7.5–8.0 (m, 5H); 3-heptylcyclobutenone (22 mg, 20%) was obtained in an earlier fraction.

Cyclobutenones

(a) 3-Phenylcyclobutenone

3-Phenyl-3-phenylsulfonylcyclobutanol (1 mmol) was dissolved in CH_2Cl_2 and stirred with 10% Na_2CO_3 solution containing a small amount of benzyltriethylammonium chloride. After 20 min of reaction time, work-up yielded 140 mg (>98%) of 3-phenylcyclobutenone; nmr δ: 3.54 (s, 2H), 6.40 (s, 1H), 6.2–6.8 (m, 1H); ir: 1770 cm^{-1} (4).

(b) 3-Benzylcyclobutenone

3-Benzyl-3-phenylsulfonylcyclobutanone (80 mg) was dissolved in 3 ml of CH_2Cl_2 and reacted with 0.5 ml of triethylamine for 30 min. After the usual work-up the reaction mixture was separated into two components by column chromatography using 1:5 ethyl acetate – hexane as eluent. The faster moving fraction (23%) was identified as 3-benzylidene cyclobutanone on the basis of its ir and nmr spectra; ir: 1760(s),

1585(s) cm^{-1}; nmr δ: 6.5 (m, 1H), 3.90 (m, 4H), and 7.2–7.6 (aromatic H). 3-Benzylcyclobutanone had a strong ir peak at 1802 cm^{-1} and nmr bands at δ 3.18 (2H), 3.90 (2H), 5.92 (1H), and 7.2–7.6 (5H). The combined yield was about 90%.

In a second experiment an 82% yield of a 1:1 mixture of conjugated and unconjugated enones was obtained. The compounds decomposed on standing and were not analyzed.

(c) 3-Butylcyclobutenone

3-Butyl-3-phenylsulfonylcyclobutanol 250 mg (0.93 mmol) was oxidized with 1.2 ml of Jones' reagent in 5 ml of acetone for 1 h. The crude product obtained from the typical oxidation reaction work-up was dissolved in 6 ml of CH_2Cl_2 and reacted with 0.15 ml of triethylamine for 30 min at room temperature. Usual work-up followed by filtration through silica gel using CH_2Cl_2 as eluent afforded 92 mg (80%) of 3-butylcyclobutenone; ir: 1770(s) and 1590(m) cm^{-1}; nmr δ: 0.91 (m, 3H), 1.2–1.9 (m, 4H), 2.62 (t, 2H), 3.10 (s, 2H), 5.88 (s, 1H).

(d) 3-Heptylcyclobutenone

This compound was obtained in 83% yield from 200 mg of 3-heptyl-3-phenylsulfonylcyclobutanol using the same procedure as for the 3-butyl derivative; nmr δ: 0.85 (m, 3H), 1.1–2.0 (m, 10H), 2.57 (t, 2H), 3.15 (s, 2H), and 5.87 (s, 1H).

(e) 3-Isopropylcyclobutenone

This compound was obtained in 80% yield from 261 mg of 3-isopropyl-3-phenylsulfonylcyclobutanol using the same procedure as the other 3-alkyl derivatives; nmr δ: 1.16 (d, J = 7 Hz, 6H), 2.4–3.0 (m, 1H), 3.1 (s, 1H), 5.8 (broad s, 1H).

Conversion of 3-Phenylsulfonylcyclopentanols into Cyclopent-2-enones. General Procedure

About 500 mg of the 3-phenylsulfonylcyclopentanol was dissolved in 5 ml of reagent grade acetone at room temperature and reacted with 1.1 equiv. of Jones' reagent (6); dropwise addition was carried out over 10 min. The progress of the reaction was followed by tlc and most oxidations were complete within 30 min. Excess oxidizing agent was destroyed by addition of 10% Na_2SO_3 solution. The reaction mixture was then poured into saturated NH_4Cl solution and extracted with 2 × 50 ml of CH_2Cl_2. The organic layer was dried over $MgSO_4$ and concentrated to a few milliliter on a rotary evaporator. To this crude product was added about 1 ml of triethylamine. The reaction was followed by tlc. When complete, the product was isolated by washing with 2 × 25 ml of 5% HCl solution, drying, and evaporating the organic solvent. The cyclopentenones were purified by column chromatography using 1:4 ethyl acetate – hexane as eluent: (*a*) 3-phenylcyclopent-2-enone: colorless oil, yield 75%; ir: 1690(s), 1610(m) cm^{-1}; nmr δ: 2.5–2.7 (m, 2H), 2.9–3.2 (m, 2H), 6.52 (narrow spaced triplet, 1H), 7.2–7.7 (5H); (*b*) 3-benzylcyclopent-2-enone: colorless oil, 87%; nmr δ: 2.3–2.7 (m, 4H), 2.74 (s, 2H), 5.88 (broad s, 1H), 7.1–7.5 (m, 5H); (*c*) 3-butylcyclopent-2-enone: colorless oil 86%; nmr δ: 0.98 (t, J = 7 Hz, 3H), 1.2–1.8 (m, 4H), 2.3–2.8 (m, 6H), 5.86–5.98 (m, 1H); (*d*) 3-heptylcyclopent-2-enone: colorless oil, 75%; nmr δ: 0.7–2.8 (m, 13H), 2.3–2.7 (m, 6H), 5.85–5.95 (m, 1H). *Anal.* calcd. for the DNP derivative: C 60.00, H 6.66, N 15.55; found: C 59.89, H 6.76, N 15.44.

γ-Sultines having an aryl substituent α to the oxygen atom have been shown to undergo photochemically induced loss of SO_2 via radical intermediates. In the case of the monocyclic derivatives, arylcyclopropanes are formed in excellent yield. 3-Phenylbenz-2,1-thiole-2-oxides yield fluorene derivatives as the major photolysis product.

TONY DURST, JOHN C. HUANG, NARENDRA K. SHARMA et DAVID J. H. SMITH. Can. J. Chem. **56**, 512 (1978).

On a montré que les γ sultines possèdant un substituant aryle en α de l'atome d'oxygène subissent des pertes de SO_2 induites photochimiquement; ces réactions se produisent par des intermédiaires radicalaires. Dans le cas de dérivés monocycliques, il y a formation d'arylcyclopropanes avec d'excellents rendements. Les phényl-3 benzthiazol-2,1 oxydes-2 conduisent à des dérivés fluorènes comme produits majeurs de la photolyse.

Several years ago we reported the thermal extrusion of SO_2 from β-sultines **1** to yield alkenes. In addition, several examples of the formation of phenylcyclopropanes from the photolysis of 5-phenyl-1,2-oxathiolan 2-oxides (γ-sultines) **2**, were also described (1).

We have since investigated several aspects of the photochemical reaction. Structurally, only those sultines which have an aryl group α to the ring oxygen atom undergo SO_2 elimination and cyclopropane formation; no photochemistry was observed for sultines such as **4** or **5** which do not have this feature. Since the sultine **4** has no uv absorption near 253 nm ($\lambda_{max} \sim 225$, $\varepsilon < 500$), the 5-aryl group appears to be required for energy absorption and not simply to stabilize a radical at that carbon. From the two

examples which we have studied, the γ-sultine route represents a viable three-step process for converting epoxides to cyclopropanes. The overall yields in the sequence approach 80%.

The photochemical behavior of γ-sultines is similar to that of the structurally related γ-lactones. The latter compounds have been studied quite thoroughly by Givens and Oettle (2) who have shown that a variety of aryl substituted γ-lactones of the type **7** yield arylcyclopropanes. The yields were generally under 50% and are thus considerably lower than those obtained from the sultines.

The reverse of eq. 2, i.e., the preparation of γ-sultines by photolysis of mixtures of arylcyclopropanes and sulfur dioxide in the presence of visible light has recently been accomplished. Such reactions which

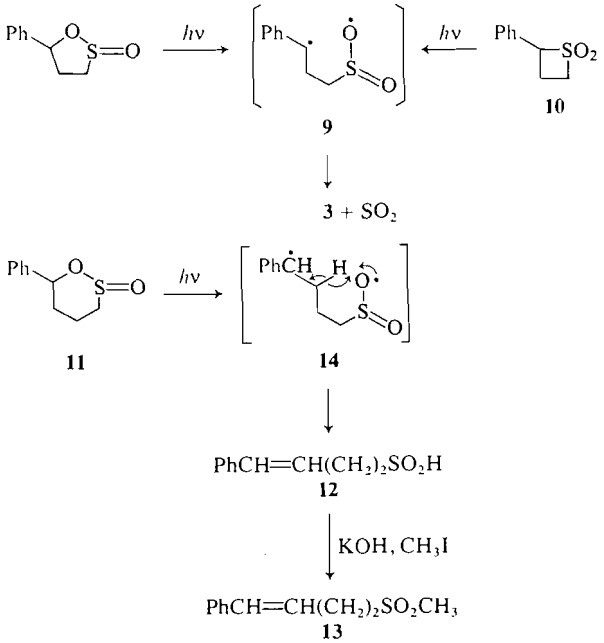
[3] 
involve initial excitation of SO_2 occasionally also give thietan *S,S*-dioxides **8** in addition to γ-sultines (3).

[4] 
8

The mechanism of the sultine photolysis has not been studied in detail. The available evidence is completely consistent with initial generation of the diradical **9**, which loses SO_2 and couples to give cyclopropanes.[1] In agreement with this, is the observation that 2-phenylthietane *S,S*-dioxide, **10**, also yields phenylcyclopropane (>95%) on photolysis in methanol with **9** being a reasonable intermediate.[2] Furthermore, irradiation of the δ-sultine **11** rapidly afforded the unsaturated sulfinic acid **12** which was isolated and identified as the methyl sulfone **13**. The formation of **12** via the diradical **14** is easily visualized.



The photolysis of the benz-fused sultines **15** was then studied as a potential route to benzocyclopropenes. Depending on the substitution pattern desired, these compounds were synthesized by one of the two following routes. The parent, dimethyl, and diphenyl derivatives were most easily prepared by controlled oxidation of the mercaptoalcohols **16** using SO_2Cl_2 in acetic acid (4). These intermediates in turn were readily available by reduction of *o*-mercaptobenzoic acid with $LiAlH_4$ in the case of **15***a*, and reaction of methyl *o*-mercaptobenzoate with excess methyl- or phenylmagnesium bromide for **15***b* and **15***c*, respectively. All the mercaptoalcohols were highly susceptible to air-oxidation and were best processed further without undue delay. The diastereomeric monosubstituted sultines, **17***a* and *b*, were obtained via a more arduous route based on our earlier sultine synthesis (5). Thus, *o*-mercaptobenzoic acid was alkylated with α-phenethyl bromide, esterified, and reduced with lithium aluminum

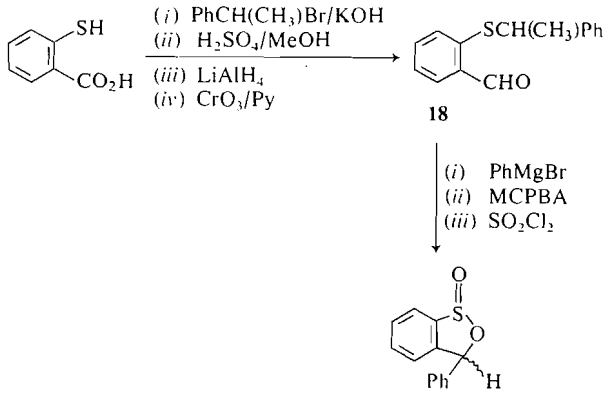
hydride. The resultant alcohol was oxidized with CrO_3–pyridine to give the aldehyde **18**. This aldehyde was then treated with PhMgBr and the product oxidized and cyclized with SO_2Cl_2. The diastereomeric alcohols were easily separated by column chromatography. Their spectroscopic properties are described in the Experimental. Individual stereochemical assignments have not been made conclusively. The less polar isomer, **17***a*, mp 122–123°C, shows the benzylic hydrogen at δ 6.57 whereas in the more polar one **17***b*, this proton resonates at δ 7.06. On the basis of the generally observed *trans*-annular deshielding by a *syn*-S=O bond (6) we assign the S=O and C—H *cis* relationship to the latter isomer. The chromatographic behavior of the isomers, in which the isomer having the S=O and C—H groups *cis* would be expected to be more polar because of the greater steric accessibility of the S=O group than when the S=O and phenyl groups are *cis*, supports the assignments (7).

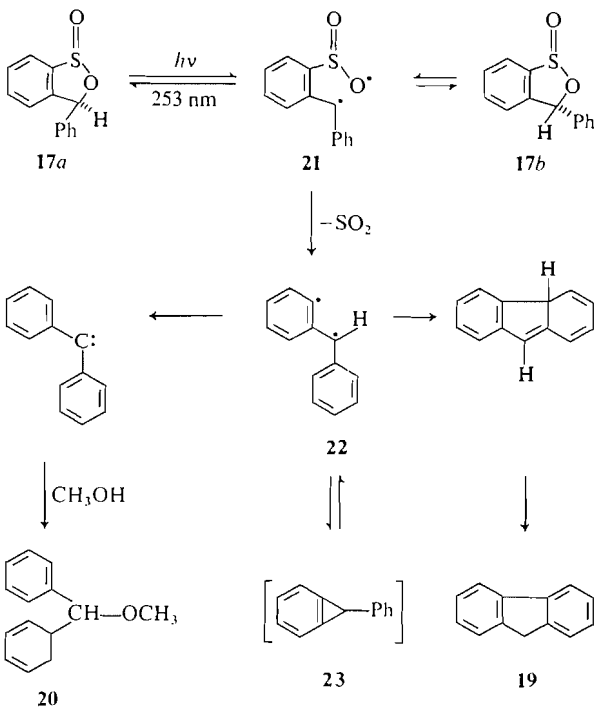
Upon photolysis of the compounds **15***b* and **17**, two types of products were isolated, neither of which requires the intermediacy of benzocyclopropenes, but suggest that possibly under appropriate experimental conditions, e.g. lower temperatures, benzocyclopropenes might be obtainable (8). Thus, irradiation of either of the diastereomeric monophenyl sultines **17** in CH_3OH resulted first in epimerization, a result consistent with a diradical intermediate which can collapse back to starting materials with loss of stereochemistry at both sulfur and carbon. Prolonged irradiation of **17** led to a mixture from which

[1]The photochemical decarboxylation likewise has been shown to involve radical intermediates (2).

[2]D. J. H. Smith and J. Finlay. Private communication.



fluorene (**19**) and diphenylmethyl methyl ether (**20**) were isolated in 27 and 32% yields, respectively. The rationalization of fluorene formation via the diradicals **21** and **22** is shown below. The benzocyclopropene **23**, if formed, would not have been expected to be stable under the reaction conditions and be converted to fluorene (9). The isolation of **20** suggests the intermediacy of diphenylcarbene; examples of the trapping of this carbene by methanol to form **20** are well documented (10).



The diphenyl sultine **15***c* gave 9-phenylfluorene as the only isolable product in 42% yield. Its genesis must be similar to that of fluorene from **17**. In contrast to these reactions, the parent benz-fused sultine **15***a* and the dimethyl derivative **15***b* were quite unreactive and gave, after prolonged irradiation (>48 h), unidentifiable decomposition products.

The six- and eight-membered ring sultines **24** and **25**,[3] when photolyzed in CH_3OH gave, respectively, the sulfone **26** and 9,10-dihydrophenanthrene (**27**). The photolysis of **24** to **26** required about 1 h at 25°C; this interconversion can also be accomplished thermally at 80°C (11).

Experimental

All proton nmr spectra were recorded on either Varian T-60 or HA-100 spectrometers using $CDCl_3$ – 1% TMS as solvent; shifts are reported in ppm (7) downfield from TMS. Infrared spectra were obtained on a Beckman IR-20 either neat, or as $CHCl_3$ solutions. Melting points are not corrected.

Usual work-up of reactions refers to partitioning of the reaction mixture between CH_2Cl_2 and water, drying the organic phase over $MgSO_4$, and evaporating the solvent using a rotary evaporator.

The structures of most intermediates were assigned on the basis of spectroscopic data. Key compounds were also sent for elemental analysis and/or exact mass spectral measurements. Sultines **2** (R = H and R = CH_3), **4**, **5**, **11**, and **15***a* have been described (5).

o-Mercaptobenzyl Alcohol (16a)

This compound was prepared in 80% yield by reduction of *o*-mercaptobenzoic acid with $LiAlH_4$ in THF. The crude reaction product was a slightly orange oil; nmr δ: 3.26 (broad s, OH and SH), 4.60 (s, 2H), 7.0–7.4 (m, 4H); ir 3360 and 2530 cm^{-1}.

2-(o-Mercaptophenyl)propan-2-ol (16b)

A stirred solution of 4.89 g of methyl *o*-mercaptobenzoate (prepared by H_2SO_4-catalyzed esterification of the corresponding acid) was dissolved in 200 ml of dry ether at 0°C under N_2 and reacted with 50.5 ml of 1.7 *M* CH_3Li. The reaction was stirred for 5 min, then washed with 200 ml of 10% HCl. The separated aqueous layer was saturated with NaCl and re-extracted with ether. The combined organic extracts were dried and evaporated to yield 4.22 g (86%) of the desired product as a yellowish oil; nmr δ: 1.74 (s, 6H), 2.74 (1H, OH), 4.12 (1H, SH), and 6.9–7.5 (m, 4H). The substance was considered sufficiently pure for the next transformation.

(o-Mercaptophenyl)diphenylmethanol (16c)

Phenylmagnesium bromide (~80 mmol) was prepared in 100 ml of ether. To this solution was added 4.6 g (27.2 mmol) of methyl *o*-mercaptobenzoate. The solution was stirred for about 30 min at room temperature. The usual Grignard work-up gave 8.2 g (95%) of crude thiol alcohol; ir: 3480, 2540 cm^{-1}, no C=O. The crude product was sufficiently pure for the next step.

3H-2,1-Benzoxathiole 1-Oxide (15a)

To a solution of 5.71 g. of mercaptobenzyl alcohol in 100 ml of a 9:1 mixture of CH_2Cl_2 and acetic acid at 0°C was added dropwise 4.4 ml of SO_2Cl_2 in 20 ml of methylene chloride. The mixture was stirred for 1 h and washed with 200 ml of 10% Na_2CO_3. The organic extracts were dried and the solvent evaporated. The crude brown oil was chromatographed on

[3]The authors would like to thank Mr. K. Steliou and Prof. D. N. Harpp (McGill University) for a sample of this compound.

24 6 25 27

300 g of silica gel. The sultine was eluted with 1:5 ethyl acetate – hexane; yield, 2.60 g, 40%. The ir and nmr spectra were identical to those of the compound previously prepared by a different route (5).

*3,3-Dimethyl-2,1-benzoxathiole 1-Oxide (**15c**)*

To a mixture of 0.511 g. of *o*-mercaptophenylpropan-2-ol and 2 ml of acetic acid in 25 ml of CH_2Cl_2 at 0°C was added dropwise 0.25 ml of SO_2Cl_2 in 5 ml of CH_2Cl_2. The reaction was subsequently stirred for 1 h and then worked up as in the case of **15***b*. The crude product was chromatographed on 30 g of silica (hexane). The yield of sultine **15***c*, colorless oil, bp 125°C/4.5 Torr, was 0.274 g (50%); nmr δ: 1.67 (s, 3H), 1.83 (s, 3H), 7.05–7.75 (m, 4H); ir: 1130 and 1105 cm^{-1} (S=O); ms calcd. for $C_9H_{10}O_2S$: 182; found 182; other peaks (relative intensities) were: 182(78), 167(32), 148(88), 134(52), 118(100), 103(68), 91(52), 77(78).

*3,3-Diphenyl-2,1-benzoxathiole 1-Oxide (**15b**)*

A solution of 0.56 ml (6.9 mmol) of sulfuryl chloride dissolved in 10 ml of CH_2Cl_2 was added dropwise with stirring to 2.03 g (6.9 mmol) of (*o*-mercaptophenyl)diphenyl methanol in 70 ml of CH_2Cl_2 and 10 ml of acetic acid at 0°C. The reaction mixture was stirred for 1 h after completion of the addition, then washed with 10% Na_2CO_3 until the p*H* of the aqueous layer was 8. The crude organic product was chromatographed on 150 g of silica gel using hexane – ethyl acetate as eluent. The sultine **15***b* was obtained as colorless crystals, 0.651 g (30%), mp 125–126°C; nmr δ: 7.1–7.8 (m); ir: 1110 and 1120 cm^{-1} (S=O); ms calcd. for $C_{19}H_{14}O_2S$: 306; found 306; other peaks (relative intensity), 258(4), 242(100), 197(44), 165(76), 118.5(40), 105(47), 77(62).

*2-(1-Phenylethylthio)benzaldehyde (**18**)*

2-(1-Phenylethylthio)benzyl alcohol (5) (14.0 g) was dissolved in dry pyridine (87 ml) and reacted with 35 g of CrO_3 using the procedure of Ratcliffe and Rodehurst (13). The yield of the aldehyde **18** was 10.0 g (72%), pale yellow oil; nmr δ: 1.67 (J = 7.5 Hz, 3H), 4.33 (q, J = 7 Hz, H), 7.2–7.4 (m, 5H), 7.4–7.6 (m, 3H), 7.7–8.1 (m, 1H), 10.4 (s, 1H); ir: 1685 cm^{-1}.

2-[(1-Phenylethylsulphinyl)phenyl]methanol

The above aldehyde (3.5 g) dissolved in 10ml of dry ether was added to a solution of PhMgBr prepared from 4.3 g of bromobenzene, 1.8 g Mg in 50 ml of dry ether. The reaction mixture was stirred for an additional hour after completion of the addition then poured into 50 ml of H_2O. Separation, drying and evaporation of the organic extracts gave 3.3 g (72%) of alcohol; ir: 3440 cm^{-1}; nmr δ: 1.57 (d, J = 7 Hz, 3H), 2.3 (s, 1H), 4.00 (q, J = 7 Hz, 1H), 6.10 and 6.13 (2s, 1H), 7.0–7.5 (m, 14H). To this alcohol, dissolved in 100 ml of ethyl acetate at −30°C was added dropwise with vigorous stirring 2.09 g of MCPBA in 30 ml of ethyl acetate. The reaction mixture was kept at −30°C for 2 h, washed with 100 ml of 10% $Na_2S_2O_3$, and 2 × 100 ml of 10% NaOH solution. The crude oily product was chromatographed on 250 g of silica gel. Elution with CH_2Cl_2 gave 2.0 g (57%) of one isomer mp 124–125°C, from methylene chloride – hexane; nmr δ: 1.30 (d, J = 7.5 Hz, 3H), 4.1 (q, J = 7.5 Hz, 1H), 5.63 (1H, OH), 7.0–7.6 (m, 14H), 7.7–8.0 (m, 1H). *Anal.* calcd. for $C_{21}H_{20}O_2S$: C 75.00, H 5.95, S 9.52; found: C 74.91, H 6.07, S 9.68.

*3-Phenyl-2,1-benzoxathiole 1-Oxide (**17a and b**)*

To a solution of 2.0 g of 2-[(1-phenylethylsulfinyl)phenyl]-methanol in 70 ml of CH_2Cl_2 at 0°C was added dropwise 0.80 g of SO_2Cl_2 in 15 ml of CH_2Cl_2. The reaction mixture was kept at 0°C for 1 h and then the solvent was removed on the rotary evaporator. Chromatography on 150 g of silica gel provided, on elution with 4:1 hexane – ethyl acetate, both isomers. Isomer **17***a*: 41% yield mp 122–123°C (CH_2Cl_2–hexane); ir: 1125 cm^{-1}; nmr δ: 6.57 (s, 1H), 7.1–7.8 (m, 9H). *Anal.* calcd. for $C_{13}H_{10}O_2S$: C 67.92, H 4.35, S 13.91; found: C 67.59, H 4.44, S 13.70. Isomer **17***b*: 32% yield; mp 102°C from CH_2Cl_2–hexane; ir: 1125 cm^{-1}; nmr δ: 7.06 (s, 1H) 7.1–7.8 (m, 9H). *Anal.* found: C 67.99, H 4.48, S 13.83.

Photolysis Reactions

These were carried out using a Rayonet-type photochemical apparatus, unless otherwise stated. The photolyses were carried out under N_2 until tlc indicated the disappearance of starting material.

5-Phenyl-1,2-oxathiolane 2-Oxide

Sultine (1.40 g) was dissolved in 40 ml of benzene and 10 ml of acetone and photolyzed using a 450 W Hannovia lamp (immersion apparatus) for 14 h. The yield of phenylcyclopropane, identified by a comparison of the nmr with the published spectrum, was 850 mg (93%).

3-Methyl-5-phenyl-1,2-oxathiolane 2-Oxide

Sultine (250 mg) was photolyzed as above for 4 h. Vapour phase chromatographic analysis indicated a 98% yield of 2-methyl-1-phenylcyclopropane. The nmr of the product obtained after evaporation, 180 mg (~98%) showed absorption from δ 0.5–2.1 (m, 7H) and 6.8–7.3 (m, 5H).

Sultines **4** and **5** were photolyzed under identical conditions to **2***a* and *b* for 36 h. No indication of cyclopropane formation was observed and the starting materials were largely recovered.

Photolysis of 6-Phenyl-1,2-oxathian 2-Oxide

Sultine (0.25 g) was photolyzed in 40 ml of benzene and 10 ml of acetone using a 450 W Hannovia lamp under the above conditions for 3 h. Thin-layer chromatography indicated the disappearance of starting material and the formation of a single very polar product identified as **12** by nmr δ: 2.5–3.0 (m, 4H), 5.3–5.6 (m, 2H), 7.2 (m, 5H), and 9.8 (broads, 1H, OH).

The sulfinic acid was characterized as the sulfone **13** by stirring with methanolic KOH and CH_3I overnight. The reaction mixture was worked-up in the usual manner and the product chromatographed on silica gel using benzene as eluent.

The yield of the sulfone **13** was 180 mg (82%), mp 112°C; nmr δ 2.90 and 3.0 (two s, 3H), 3.0–3.4 (m, 4H), 5.3–6.6 (m, 2H) 7.2 (5H); ir 1120 and 1300 cm^{-1}. *Anal.* calcd. for $C_{11}H_{14}O_2S$: C 50.81, H 5.82, S 13.23; found: C 50.65, H 5.89, S 13.51.

*Photolysis of Sultine **15b***

Sultine (363 mg) was dissolved in 120 ml of anhydrous methanol and photolyzed at 253 nm in a Rayonet apparatus for 14 h. Nitrogen was passed through the reaction mixture during the photolysis. At the end of the photolysis period, the reaction mixture was foggy yellow. The solvent was removed on a rotary evaporator and the product chromatographed on 80 g of silica gel. Elution with 1:1 hexane – ethyl acetate gave two fractions. The less polar material was identified as 9-phenylfluorene, mp 182°C, 42% yield, by comparison with an authentic sample prepared by reduction of 9-hydroxyphenylfluorene with zinc in acetic acid (13). The more polar fraction (61 mg) of yellowish oil was not identified; nmr δ: 7.06–7.83 (m).

Photolysis of 3-Phenyl-2,1-benzoxathiole 1-Oxide in Methanol

Sultine (107 mg, mixture of isomers) was irradiated for 19 h in 120 ml of anhydrous methanol under N_2 as above. The reaction mixture changed from colorless to foggy yellow. The solvent was evaporated and the dark brown paste was chromatographed. The less polar product, 20 mg (27%), had nmr peaks at δ 3.90 (s, 2H) and 7.1–7.9 (m, 8H) and was identified as fluorene by comparison of its spectrum with that of a standard sample (14). Further elution furnished 29 mg (32%) of a colorless oil; nmr δ: 3.3 (s, 3H), 5.2 (s, 1H) and 6.9–7.5 (m, 10H); ir: 1090 cm^{-1}, which was identified as diphenylmethyl ether.

In a second experiment, the photolysis of a single isomer was interrupted after approximately 5 h. Nuclear magnetic resonance investigation of the crude reaction product indicated the presence of approximately equal amounts of both isomers, together with some fluorene and diphenyl methyl ether.

*Photolysis of **24***

A solution of 260 mg of **24** in 30 ml benzene and 10 ml of acetone was photolyzed in the immersion apparatus for 1 h. The solvent was removed and the product identified as the five-membered ring sulfone **26** (11). The yield was essentially quantitative.

*Photolysis of Sultine **25***

A solution of 302 mg of sultine in 120 ml of CH_3OH was photolyzed as above under a stream of N_2 for 18 h. During the photolysis the solution changed from colorless to yellow and the walls of the reaction vessel became coated with polymer. The solvent was evaporated and the brown paste obtained was chromatographed. Elution with hexane gave 161 mg of a 1:1 mixture of 9,10-dihydrophenanthrene and phenanthrene (nmr analysis). In another experiment, the solution was initially purged with N_2, then photolyzed for 17 h. The product obtained was a mixture of 9,10-dihydrophenanthrene and phenanthrene in about a 10:1 ratio.

Synthesis of dehydrocycloroyleanone

ROBERT H. BURNELL and MICHEL RINGUET
Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received July 18, 1977

ROBERT H. BURNELL and MICHEL RINGUET. Can. J. Chem. **56**, 517 (1978).

A degradation product (**14**) obtained during the elucidation of the structure of lycoxanthol has been synthesized from podocarpic acid. Several model series of experiments are also described, leading to quinones and furan derivatives.

ROBERT H. BURNELL et MICHEL RINGUET. Can. J. Chem. **56**, 517 (1978).

On a synthétisé, à partir de l'acide podocarpique, un produit de dégradation (**14**) obtenu au cours de l'élucidation de la structure du lycoxanthole. On décrit aussi plusieurs séries d'expériences modèles permettant d'obtenir des dérivés de quinones et de furannes.

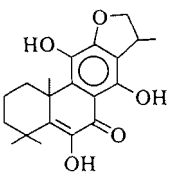
During work on the non-alkaloidal constituents of *Lycopodium lucidulum*, we isolated a diterpenoid hydroquinone (lycoxanthol) which was shown (1) to be **1**. One of the degradation products arising from



1

the hydrogenolysis of lycoxanthol was assigned the structure **14** (dehydrocycloroyleanone) and the synthesis of this compound, which contains the intact carbon skeleton of lycoxanthol seemed a desirable corroboration of the structures proposed.

Since the final synthesis would be effected from podocarpic acid (**9***a*) and the reduction of the carboxylic acid function to a methyl group is laborious (2), we used the suitably substituted dimethylanisole **2***a* for model studies. Our intention was to oxidize the latter to the known quinone **3***a*, hydrolyze the methoxyl to give the hydroxyquinone **3***b* and then effect a free-radical (Fieser type) annelation (3) to construct the dihydrofuran ring. The hydrolysis step did not afford satisfactory results although hydrolysis had evidently occurred, so it was decided to try the same sequence using a protecting group removable under neutral conditions. Peracid oxidation (4) of the *O*-benzylxylenol **2***b* lead to the *O*-benzylquinone **3***c* but rather than remove the protecting group at this stage, the quinone was subjected to reductive acetylation to give the *O*-benzyldiacetoxyxylenol **4***a*. While this product was readily hydrolyzed to **4***b*, the latter was even more readily oxidized in air to give back the quinone **3***c*. By using conditions whereby simultaneous hydrolysis and methylation are possible the diacetoxy derivative was converted to the dimethoxy compound **4***c* but the reaction was far from complete. Hydrogenolysis of the *O*-benzyl residue in **4***a* afforded the phenol **4***d* which was hydrolyzed to **4***e*, too unstable to isolate but quantitatively oxidized to hydroxyquinone **3***b*. The dimethoxy phenol **4***f* was obtained by similar hydrogenolysis of **4***c*.

Hoping that manipulation of the products might prove easier on the larger molecule, we performed most of these operations on the podocarpane

skeleton. We originally followed published methods (2) to reduce the carboxyl moiety of podocarpic acid **9** to the methyl group (as in **9***d*). Recently however we have found that the photochemical reduction of esters described by Deshayes *et al.* (5) for certain acetates, formates, and benzoates:

$$[1]\quad R^1COOR^2 \xrightarrow[HMPT\text{–}H_2O]{h\nu} R^2H(\text{major}) + R^1OH(\text{minor})$$

can be applied to convert the methoxy-*O*-acetyl compound **9***c* to the podocarpane derivative **9***d*. While this reaction is only moderately successful (42%), the only other product is the primary alcohol **9***b* (46%) which can be acetylated and recycled. The methoxypodocarpane **9***d* was then oxidized with peracid and the methoxyquinone **10***a* obtained in 18% yield after chromatography over deactivated alumina. Hydrolysis of the methoxyl proved as unmanageable in this case as in the simpler model **3***a*. Oxidation of the benzyloxypodocarpane **9***f* gave the quinone **10***b*.

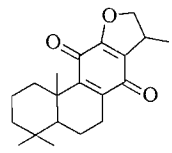
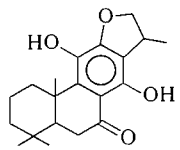
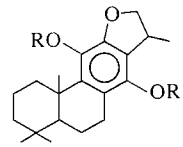
13



14



15



16

In a parallel series of experiments on the model xylenol establishment of the dihydrofuran ring was found to be much simpler. The *O*-acetylxylenol **2***c* was subjected to a Fries rearrangement and gave almost exclusively the properly oriented acetylxylenol **5***a*. Ethyl bromoacetate in the presence of sodium carbonate afforded the ester **5***b* which was hydrolyzed to the acid **5***c*. The latter, on heating in acetic anhydride containing sodium acetate, cyclized and decarboxylated affording the benzofuran **6** which readily absorbed hydrogen in ethanol containing palladium-on-charcoal to give the dihydrofuran **7**. Exploratory peracid oxidation of the small quantity of product available at this stage was shown to be successful both by the required colour change during the reaction and the spectra of the isolated product **8**. The nmr spectrum of this material (and that of **7**) bore a striking resemblance to that of lycoxanthol in the δ 3–4 region.

Applying this sequence in the podocarpane series necessitated certain experimental modifications. Fries rearrangement of the *O*-acetylpodocarpane **9***c* could not be effected so the acetyl residue was introduced by Friedel–Crafts acylation of the methoxypodocarpane **9***d* and the methoxyl group (in **11***a*) was then hydrolyzed by the aluminium chloride technique (6). *O*-Alkylation of the phenol **11***b* with bromoacetate and hydrolysis of the product **11***c* afforded the acid **11***d*. Cyclization and decarboxylation gave the furan **12**. Unlike the model furan **6**, this podocarpane derivative was only sluggishly hydrogenated even in the presence of perchloric acid. The dihydrofuran product **13** contains a newly established asymmetric centre but no evidence suggested the presence of two epimers. Peracid oxidation of the benzodihydrofuran **13** followed by careful chromatography afforded a yellow glass which showed very similar spectral properties and identical tlc behaviour to dehydrocycloroyleanone **14**. Repeated thick-layer chromatography finally removed traces of a minor product affording a synthetic product identical with the dehydrocycloroyleanone **14** obtained previously from lycoxanthol (**1**).

Monache[1] has informed us that this quinone **14** is also a transformation product arising from the naturally occurring ketone **15** and both our synthetic and natural quinones (**14**) are identical with the sample obtained from this source. Despite repeated experimentation we have been unable to proceed further towards synthesis of Monache's ketone **15** or lycoxanthol **1** due to the reluctance of hydroquinone derivatives such as **16** (R = H, Me, or Ac) to Ring B

oxidation. Other workers have described similar difficulties (7).

Experimental

The normal conditions and instruments for the spectra quoted are: optical rotations, chloroform solutions ($c = 1.0$); uv ethanol solutions (ε in parentheses), Beckman DK-1A; ir Perkin Elmer 457 and Beckman IR 12; nmr deuteriochloroform solutions with internal TMS standard, coupling constants in Hz, Varian A60 and Bruker HX 90; mass spectra, Varian M66. Elemental analyses by Chemalytics, Arizona.

4-Benzyloxy-o-xylene **2b**

To 3,4-dimethylphenol (6.11 g) in dioxane (40 ml) under nitrogen was added potassium hydroxide (2.81 g) in water (3 ml). The mixture was heated to 100°C and benzyl chloride (7.03 g) was added drop by drop then the heating was continued for 36 h. After cooling, pouring into water (90 ml), ether extraction and washing with 2 *N* sodium hydroxide, the benzyl ether was obtained as a colourless oil (6.4 g, 60%) which crystallized slowly on standing, mp 39–40°C: λ_{max}: 278 (1800) and 283 nm (1700); δ: 2.18 and 2.22 (s's, aromatic methyls), 5.00 (s, —O—CH_2—), 6.87 (m, 3H, aromatic protons), 7.45 (bs, 5H). *Anal.* calcd. for $C_{15}H_{16}O$: C 84.87, H 7.60; found: C 84.68, H 7.85.

*5-Benzyloxy-2,3-dimethyl-*p*-benzoquinone* **3c**

Sulfuric acid (10 ml) was added to acetic anhydride (920 ml) at 0°C followed by the dropwise addition of hydrogen peroxide (400 ml of 30%) at 5°C. The benzyloxy-*o*-xylene **2b** (30 g) was added in acetic anhydride (60 ml) and the reaction mixture stirred in darkness for 20 h. The product which precipitated when the mixture was poured into cold water was filtered and recrystallized from methanol (3.2 g, 9.5%) mp 134–135°C; λ_{max}: 270 (21 500) and 370 nm (450); ν_{KBr}: 3050, 1680, 1650, and 1610 cm^{-1}; δ: 2.00 (s, C-methyls), 5.00 (s, —O—CH_2—), 5.95 (s, vinyl proton), 7.35 (s, phenyl). *Anal.* calcd. for $C_{15}H_{14}O_3$: C 74.36, H 5.83; found: C 74.52, H 5.83.

4-Benzyloxy-3,6-diacetoxy-o-xylene **4a**

The *p*-quinone **3c** (1.5 g) was dissolved in acetic anhydride (7.5 ml). Powdered zinc (1.5 g) and sodium acetate (0.3 g) were added and the mixture heated until the yellow colour disappeared and then for 1 min longer. Acetic acid (6 ml) was added and after boiling for several minutes the solution was decanted. The residue was washed with hot acetic acid and the combined supernatant was diluted with water to a faint turbidity when cooling in ice gave the hydroquinone derivative **4a** (1.5 g, 75%) mp 118–120°C (from ethanol): λ_{max} 276 nm (1800); ν_{KBr} 2950, 1770, 1635, 1600, 1230, and 1200 cm^{-1}; δ: 2.00 and 2.10 (s's, aromatic methyl), 2.35 and 2.37 (s, CH_3CO), 4.98 (s, —O—CH_2—), 6.55 (s, aromatic proton), 7.35 (s, phenyl). *Anal.* calcd. for $C_{19}H_{20}O_5$: C 69.50, H 6.14; found: C 69.76, H 6.12.

2,5-Diacetoxy-3,4-dimethylphenol **4d**

The benzyloxy derivative **4a** (500 mg) was dissolved in a 9:1 mixture of ethanol–toluene (100 ml) and added to 10% palladium-on-charcoal (200 mg) in ethanol (10 ml). Hydrogenation was continued at 3 atm for 30 min. Filtration and evaporation afforded the phenol **4d** (290 mg, 80%) after crystallization from ether–hexane, mp 115–117°C: λ_{max} 278 nm (2100); ν_{KBr} 3400, 3050, 2930, 1745, 1630, 1230, and 1190 cm^{-1}; δ: 1.98 and 2.04 (s's, aromatic methyls), 2.27 (s, 6H, CH_3CO), 5.9 (bs, D_2O, phenolic OH), 6.75 (s, aromatic proton). *Anal.* calcd. for $C_{12}H_{14}O_5$: C 60.50, H 5.92; found: C 60.54, H 5.89.

Hydrolysis and Oxidation of **4d**

The acetylated hydroquinone **4d** (500 mg) was dissolved in methanol (25 ml). One drop of concentrated hydrochloric acid was added and the mixture was heated on the steam bath for 30 min. The solution was evaporated *in vacuo* at 40°C leaving an oil which crystallized on standing. Without purification the unstable product **4e** was taken up in water (50 ml) and oxidized with ferric chloride (9.7 g) in water (10.7 ml) containing concentrated hydrochloric acid (10.7 ml). After 30 min the hydroxyquinone **3b** (160 mg, 50%), was isolated in the usual manner (ether), mp 115–116°C (lit. (8) mp 115–116°C).

4-Benzyloxy-3,6-dimethoxy-o-xylene **4c**

The diacetoxy compound **4a** (0.328 g) was dissolved in methanol (3 ml) under nitrogen and dimethyl sulfate (0.5 g) was then added. The flask contents were cooled to, and maintained at, 5°C while a solution of sodium hydroxide (0.5 g) in water (0.5 g) was added. The mixture was stirred for 2 h, diluted with water (3.5 ml) and stirring continued for 1 h. Concentrated ammonia (0.02 ml) was then added and the mixture extracted with benzene. The crude product was chromatographed over silica gel and the benzene eluate contained the dimethoxy derivative **4c** (0.13 g, 48%), white needles, mp 54–55°C: λ_{max} 283 nm (2500); δ ($CDCl_3$): 2.08 and 2.21 (s's, aromatic methyls), 3.72 and 3.78 (s's, O-methyls), 5.11 and 7.39 (bs, 2H, 5H, O—CH_2—Ph), 6.42 (bs, lone aromatic proton). *Anal.* calcd. for $C_{17}H_{20}O_3$: C 74.97, H 7.40; found: C 74.93, H 7.20.

2,5-Dimethoxy-3,4-dimethylphenol **4f**

Hydrogenolysis of the benzyl residue in **4c**, as described for **4d**, afforded the phenol **4f** (76%), mp 70–71°C: λ_{max} 284 nm (2480); δ ($CDCl_3$): 2.02 and 2.15 (s's, aromatic methyl), 3.67 and 3.71 (s's, O-methyls), 5.67 (bs, D_2O, OH), 6.38 (s, aromatic proton). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.91, H 7.74; found: C 65.96, H 7.95.

2-Hydroxy-4,5-dimethylacetophenone **5a**

Aluminium chloride (4 g) was added in small portions to the 4-acetoxy-*o*-xylene **2c** (25 g) and the mixture heated at 160°C for 2 h. Good yields depend on the exclusion of moisture. After cooling, the hard mass was broken up and added to ice (100 g). Dilute hydrochloric acid (200 ml, 13%) was added and finally the precipitated acetophenone **5a** was filtered and recrystallized from hexane (17.1 g, 68%), mp 69–72°C: λ_{max} 263 (13 000) and 333 nm (4000); ν_{KBr} 3050, 1655, 1630 cm^{-1}; δ: 6.82 and 7.63 (s's, aromatic methyls); 11.62 (s, chelated OH). *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.14, H 7.34; found: C 73.17, H 7.14.

The Ester **5b**

Under nitrogen, the hydroxyacetophenone **5a** (3.4 g) was dissolved in acetone (100 ml), anhydrous potassium carbonate (2.4 g) was added and the mixture heated to gentle reflux. Ethyl bromoacetate (4.5 g) was added dropwise and after 2 h a further portion (1.5 g) of bromoacetate was added and refluxing was continued until a ferric chloride test was negative (ca. 2 h). After cooling, the solid was filtered off, the volume reduced and the solution filtered again before evaporating. The white residue was recrystallized from ethanol–water (5.2 g, 90%), mp 89–90°C: λ_{max} 255 (11 800) and 310 nm (4800); ν_{KBr} 1760, 1660, 1605, and 1270 cm^{-1}; δ: 1.28 (t, $J = 7.0$ Hz), 4.26 (q, $J = 7.0$ Hz), and 4.68 (s, CH_3CH_2OOC—CH_2—O—), 2.16 and 2.33 (s's, aromatic methyls), 2.66 (s, CH_3CO), 6.65 and 7.58 (s's, aromatic protons). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.30, H 7.37.

The Acid **5c**

The acetophenone **5b** (5 g) was heated on a steam bath with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

aqueous sodium hydroxide (100 ml, 4%) for 1 h, then cooled and neutralized with dilute hydrochloric acid. The acid **5***c* was filtered, washed with cold water, and recrystallized from ethanol (4.25 g, 95%) mp 185–187°C: λ_{max} 255 (9800) and 312 nm (4400); ν_{KBr} 3200, 1720, and 1660 cm^{-1}; δ: 2.39 and 2.47 (s's, aromatic methyls), 2.95 (s, CH_3CO), 5.04 (s, —O—CH_2—), 7.00 and 7.85 (s's, aromatic protons). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.55, H 6.28.

3,5,6-Trimethylbenzofuran ***6***

The acid product **5***c* (4.4 g), sodium acetate (17.6 g), and acetic anhydride (60 g) were refluxed for 1.5 h and then cooled and poured onto ice (400 g). The ether extract was evaporated to a small volume then poured into ice water causing the low melting product to crystallize. The benzofuran **6** was sublimed (2.9 g, 90%), mp 40–42°C: λ_{max} 248 (10 300), 278 (3000), 284 (3000), and 290 nm (3600); δ: 2.07 and 2.25 (s's, aromatic methyls), 2.12 (d, J = 1.0 Hz, furan methyl), 7.19 and 7.28 (bs, s, aromatic protons), 7.22 (d, J = 1.0 Hz, furan proton). *Anal.* calcd. for $C_{11}H_{12}O$: C 82.46, H 7.55; found: C 82.42, H 7.55.

3,5,6-Trimethyl-2,3-dihydrobenzofuran ***7***

The benzofuran **6** (5.35 g) in acetic acid (50 ml) was added to prehydrogenated palladium charcoal (500 mg) in acetic acid (10 ml). After the uptake of 1 mol of hydrogen (ca. 1 h), the catalyst was removed and the solution evaporated. The residue was taken up in water, extracted with ether which was washed with sodium bicarbonate solution. The dihydrofuran was finally distilled, (5.0 g, 92%) bp 45–46°C/0.3 Torr; λ_{max} 287 nm (3800); δ: 1.25 (d, J = 7.0 Hz), 3.43 (m), 3.98 (dd, J = 7.0 and 8.5 Hz), and 4.60 (dd, J = 8.5 and 8.5 Hz, CH_3—CH—CH_2—O—), 2.16 (s, 6H, aromatic methyl), 6.57 and 6.87 (s's, aromatic protons). *Anal.* calcd. for $C_{11}H_{14}O$: C 81.44, H 8.70; found: C 81.58, H 8.81.

The Quinone ***8***

The peracid solution was prepared as described for **3***c* using acetic anhydride (9.2 ml), sulfuric acid (0.1 ml), and hydrogen peroxide (4 ml of 30%). To this solution, the dihydrobenzofuran **7** (2.5 g) was added in acetic anhydride (0.8 ml). After 3 h in darkness, the reaction mixture was poured into cold water (25 ml) and was extracted with methylene chloride. After washing with sodium bicarbonate (5%), the residue obtained by evaporation was lyophilized to give an orange oil from which the quinone **8** (90 mg) was obtained by repeated preparative tlc; mp 101–104°C: λ_{max} 285 (19 000) and 420 nm (400); ν(CCl_4): 2950, 1680, 1655 and 1645 cm^{-1}; δ: 1.29 (d, J = 8.0 Hz), 3.57 (m), 4.26 (dd, J = 8.0 and 9.0 Hz), and 4.74 (dd, J = 9.0 and 9.0 Hz, CH_3—CH—CH_2—O—), 1.98 (s, 6H, quinone methyls); *m/e* 192 (M^+, 100), 177 (80), 160 (40), 149 (50), 145 (25), 95 (20), and 53 (30).

12-Methoxypodocarpa-8,11,13-trien-16-ol ***9b***

The primary alcohol was prepared from methyl podocarpane methyl ether following essentially the procedure of Zeiss *et al.* (9) ($LiAlH_4$ in ether), yield 90%, mp 89–91°C (lit. (9) mp 91°C).

The *acetate* **9***c* was prepared by reacting **9***b* (1 g) with acetic anhydride (2 ml) and pyridine (1 ml) at 25°C for 40 h; yield 0.95 g (82%), mp 72–74°C (from hexane), $[\alpha]_D^{25}$ +65.99°: λ_{max} 280 (2700) nm; ν_{KBr} 1730 and 1240 cm^{-1}; δ($CDCl_3$): 1.02 and 1.19 (s's, *C*-methyls), 2.04 (s, CH_3CO), 2.81 (m, benzylic CH_2), 3.63 (s, *O*-methyl), 4.14 (ABq, J = 11 Hz, —CH_2—O—), 6.77 (m, aromatic protons, 3H). *Anal.* calcd. for $C_{20}H_{28}O_3$: C 75.91, H 8.92; found: C 75.98, H 8.78.

12-Methoxypodocarpa-8,11,13-triene ***9d***

By Irradiation of the Acetate ***9c***

The acetate **9***c* (0.5 g) was dissolved in HMPT (95 ml) and water (5 ml) and the solution irradiated with a low pressure mercury lamp (254 nm) in a quartz vessel for 3 h. After evaporation, the residue was taken up in ether and washed well. The oily product was separated by chromatography over silica gel affording the primary alcohol **9***b* (0.19 g, 46%) which followed the reduced product **9***d* (0.17 g, 42%), mp 30–31°C (lit. (9) mp 30.5–31.5°C), $[\alpha]_D^{25}$ +71.8°: δ: 1.03, 1.27, and 3.86 (s, methyls). *Anal.* calcd. for $C_{18}H_{26}O$: C 83.66, H 10.14; found: C 83.87, H 10.40.

12-Hydroxypodocarpa-8,11,13-triene ***9e***

Under nitrogen, the methoxy derivative **9***d* (6.0 g) was dissolved in dry methylene chloride (180 ml) which was then cooled to −70°C. Drop by drop, a solution of boron tribromide (6.0 g) in methylene chloride (20 ml) was added and the temperature allowed to rise to ambiant during 16 h of stirring. Water (100 ml) was added and the organic layer yielded the phenol **9***e* (5.0 g, 88%) in the usual manner, mp 139–141°C (lit. (10) 140–141°C).

The *O-benzyl ether* ***9f*** was prepared in 65% yield using the procedure described for **2***b*. Colorless oil, n_D^{20} 1.5745, $[\alpha]_D^{25}$ +67.2°: λ_{max} 278 (3000) and 283 nm (2600); ν_{film} 3050, 2960, 1620, 1590, 1510, 1460, 1390, 1260, 1200, 1080 and 1040 cm^{-1}; δ: 0.95 (s, 6H, *gem*-dimethyl), 5.05 and 7.42 (s, bs, —O—CH_2—Ph), 6.95 (m, other aromatic protons); *Anal.* calcd. for $C_{28}H_{30}O$: C 86.18, H 9.04; found: C 86.01, H 9.08.

The *O-acetyl derivative* ***9g*** was prepared from the phenol **9***e* (9.7 g) by heating at 70°C with anhydrous sodium acetate (0.7 g) in acetic anhydride (125 ml) for 2 days. The acetate **9***g* (10.2 g, 90%) was recrystallized from methanol, mp 75–77°C (lit. (4) 75–76°C).

12-Methoxypodocarpa-8,12-dien-11,14-dione ***10a***

A peracid solution was prepared as described for **3***c* (acetic anhydride 40 ml, sulfuric acid 0.5 ml and 30% hydrogen peroxide 20 ml). The methoxypodocarpatriene **9***d* (2.4 g) in acetic anhydride (5 ml) was added and the mixture stirred in darkness for 20 h and then poured into cold water (125 ml). Methylene chloride extraction, washing with sodium bicarbonate solution, and evaporation gave a yellow oil which was chromatographed over alumina (deactivated by adding 5% by weight of 10% aqueous acetic acid). Petroleum ether elutes starting material (0.7 g) but the petroleum ether – benzene (1:4) eluate was the yellow methoxyquinone **10***a* (320 mg), mp 168°C (lit. (4) 171°C), $[\alpha]_D^{25}$ +89.6°: λ_{max}: 272 (20 700) and 370 nm (645); ν_{KBr}: 1670, 1645, and 1595 cm^{-1}; δ: 0.95, 1.31, and 3.83 (s's, methyls), 2.64 (m, —CH_2—C=C), 5.86 (s, vinyl proton). *Anal.* calcd. for $C_{18}H_{24}O_3$: C 75.0, H 8.4; found: C 75.2, H 8.6.

Further elution of the column (benzene–ether 1:1) gave 8β-hydroxypodocarpa-9(11),13-dien-12-one (0.5 g).

12-Benzyloxypodocarpa-8,12-dien-11,14-dione ***10b***

The benzyl ether **9***f* (1.4 g) was oxidized as described above but the orange crude product was chromatographed over silica gel affording the crystalline benzyloxyquinone **10***b* (160 mg, 10%) in the hexane–benzene (7:3) eluate, mp 232–233°C, $[\alpha]_D^{25}$ +85.3°; λ_{max}: 272 (17 000) and 360 nm (500); ν_{KBr}: 1675, 1655, and 1605 cm^{-1}; δ: 0.93 (s, 6H, *gem*-dimethyl), 1.32 (s, angular methyl), 5.00 and 7.40 (bs, s, —O—CH_2Ph), and 5.88 (s, vinyl proton). *Anal.* calcd. for $C_{24}H_{28}O_3$: C 79.09, H 7.74; found: C 79.10, H 7.84.

13-Acetyl-12-methoxypodocarpa-8,11,13-triene ***11a***

To a stirred cooled solution of the methoxy compound **9***d* (2.0 g) and acetyl chloride (1.17 ml) in nitrobenzene (25 ml) was added aluminum chloride (2.05 g) in small portions over a 30 min period (12). The mixture was stirred for 20 h and then hydrolyzed with cold 10% hydrochloric acid (200 ml). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

nitrobenzene was removed by steam distillation and the residue extracted with ether to give the acetyl compound **11***a* (1.7 g, 75%) after crystallization from hexane, mp 76–77°C, $[\alpha]_D^{25}$ +69.9°: λ_{max} 258 (10 700) and 318 nm (4200); ν(CCl_4). 2840 and 1670 cm^{-1}; δ (CCl_4): 6.75 (s, H) and 7.33 (s, C(14)-H) *Anal.* calcd. for $C_{20}H_{28}O_2$: C 79.95, H 9.39; found: C 79.72, H 9.44.

13-Acetyl-12-hydroxypodocarpa-8,11,13-triene ***11b***

This preparation is adapted from the method of Cambie *et al.* (6). Under nitrogen, the methoxy compound **11***a* (0.75 g) in methylene chloride (15 ml) was refluxed for 15 h with aluminum chloride (1.0 g). The cooled reaction mixture was poured into cold dilute hydrochloric acid. The organic layer was extracted with 0.5% sodium hydroxide and the phenolic product **11***b* isolated in the usual manner, mp 129–130°C (from hexane), $[\alpha]_D^{25}$ +83.4° (0.6 g, 85%): λ_{max} 263 (14 500) and 340 nm (4200); ν(CCl_4) 2950, 2860, 1655 and 1585 cm^{-1}; δ: 0.93, 0.94 and 1.17 (s's, methyls), 2.54 (s, CH_3CO), 6.83 and 7.35 (s's, C(11)-H, C(14)-H, aromatic protons), 11.82 (s, chelated OH). *Anal.* calcd. for $C_{19}H_{26}O_2$: C 79.68, H 9.15; found: C 79.60, H 9.38.

13-Acetyl-12-(carbethoxymethoxy)podocarpa-8,11,13-triene ***11c***

To phenol **11***b* (1.75 g) and anhydrous potassium carbonate (5.4 g) in dry acetone (50 ml) was added ethyl bromoacetate (1.8 g). The mixture was refluxed 12 h and after cooling and filtering, evaporation afforded a yellow oil (2.0 g, 88%) which resisted crystallization after chromatography over silica gel, n_D^{20} 1.5436, $[\alpha]_D^{25}$ +54.9°: λ_{max} 255 (10 000) and 312 nm (3450); ν_{film} 1755, 1670 and 1610 cm^{-1}; δ: 0.90, 0.92 and 1.15 (s's, methyls), 1.28 (t, J = 7.5 Hz), 4.27 (q, J = 7.5 Hz), 4.65 (s, $CH_3CH_2OOC—CH_2—O$), 2.63 (s, CH_3CO), 6.73 and 7.45 (s's, C(11)-H, C(14)-H, aromatic protons). *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.16, H 8.66; found: C 74.26, H 8.60.

13-Acetyl-12-(carboxymethoxy)podocarpa-8,11,13-triene ***11d***

The ester **11***c* (1.9 g) in ethanol (20 ml) was hydrolyzed by refluxing for 1 h with 10% sodium hydroxide (12.5 ml). The cooled mixture was poured into ice water, acidified (5% hydrochloric acid) and the precipitated acid was filtered off (gummy) and then taken up in ether. Silica gel chromatography afforded the acid **11***d* (1.7 g, 97%) as a yellow glass which has never crystallized: λ_{max} 255 (11 800) and 315 nm (4300); ν_{film} 3400, 2500, 1730, 1675 and 1615 cm^{-1}; δ(CCl_4): 0.90 (s, 6H, *gem*-dimethyl), 1.13 (s, angular methyl), 2.57 (s, CH_3CO), 4.64 and 11.65 (s, bs, $O—CH_2—COOH$), 6.75 and 7.38 (s's, aromatic protons). *Anal.* calcd. for $C_{21}H_{28}O_4$: C 73.22, H 8.19; found: C 73.15, H 8.21.

3,7,7,10aβ-Tetramethyl-5,6,6a,7,8,9,10,10a-octahydrophenanthrofuran(2,3,b) ***12***

To the acid **11***d* (1.7 g) in acetic anhydride (35 ml) was added anhydrous sodium acetate (7.0 g) and the mixture was refluxed for 3 h. After cooling and pouring into ice water (200 ml), the gummy precipitate was taken up in ether and washed with dilute sodium bicarbonate. Evaporation gave a yellow oil (**12**) which was purified by short path distillation, bp 140°C/0.15 Torr, n_D^{20} 1.5671 (1.2 g, 86%), $[\alpha]_D^{25}$ +66.0°; λ_{max} 253 (13 500), 286 (5500) and 295 nm (5100); δ: 0.95 (s, 6H, *gem*-dimethyl), 1.19 (s, angular methyl) 2.16 (d, J = 1.0 Hz, furan methyl), 3.00 (m, benzylic CH_2) 7.10 and 7.31 (s's, C(11)-H, C(14)-H) aromatic protons, and 7.24 (d, J = 1.0 Hz, furan). *Anal.* calcd. for $C_{20}H_{26}O$: C 85.05, H 9.28; found: C 84.76, H 9.40.

3,7,7,10aβ-Tetramethyl-2,3,5,6,6a,7,8,9,10,10a-decahydrophenanthrofuran(2,3,b) ***13***

The furan **12** (0.5 g) was hydrogenated at 3 atm. for 12 h in acetic acid (200 ml) containing a small drop of perchloric acid. The residue obtained by evaporating the filtered solution was taken up in hexane and washed with dilute sodium bicarbonate. The usual workup afforded the dihydrofuran **13** as a colorless oil (0.48 g, 95%), n_D^{20} 1.5877, $[\alpha]_D^{26}$ +72.1°: λ_{max} 292 nm (5100); δ: 0.91 (s, *gem*-dimethyl), 0.93 (s), 1.15 (s, angular methyl), 1.28 (d, J = 7.0 Hz), 3.35 (m), 3.95 (dd, J = 8.5 and 8.5 Hz), and 4.58 (dd, J = 8.5 and 8.5 Hz, $CH_3—CH—CH_2—O—$), 6.61 and 6.72 (s's, C(11)-H and (C14)-H, aromatic protons). *Anal.* calcd. for $C_{20}H_{28}O$: C 84.45, H 9.92; found: C 84.48, H 9.94.

Dehydrocycloroyleanone ***14***

To a peracid solution, prepared as described for **3***a* using acetic anhydride (80 ml), sulfuric acid (0.5 ml) and 30% hydrogen peroxide (35 ml), was added the dihydrofuran **13** (4.4 g) in acetic anhydride (20 ml). After stirring in darkness for 2.5 h the mixture was poured into ice water (250 ml) and extracted with chloroform. After rigorous washing with 1% sodium hydroxide, the crude product was chromatographed over Florisil and the yellow band eluted with benzene was rechromatographed over alumina deactivated with 10% acetic acid (5% by weight). The yellow fraction (303 mg) still showed a slight impurity (weak acetate peaks in the infrared) which could only be removed by repeated preparative tlc. The quinone **14** was finally sublimed, mp 142–143°C: identical in all respects with the dehydrocycloroyleanone obtained by hydrogenolysis of lycoxanthol (1): λ_{max} 285 (21 000) and 380 nm (400); δ($CDCl_3$): 0.89 (s, 3H), 0.92 (s, 3H), 1.25 (s, 3H), 1.30 (d, J = 8.0 Hz, 3H), and dihydrofuran protons centred at 3.49, 4.18, and 4.71 (J = J = 8.5 Hz); *m/e* 314.1880 (M^+, $C_{20}H_{26}O_3$ requires 314.1882).

This ^{1}Hmr study initiates our examination of the conformations of dinucleoside monophosphates possessing ribo 2′- or 3′-nucleotidyl units linked to 5′-nucleotidyl units possessing the 2′-deoxyribo sugar. The syntheses of uridylyl-3′,5′-2′-deoxythymidine (3′,5′-UpdT) and its 2′,5′-isomer, 2′,5′-UpdT, were carried out with standard techniques. The ^{1}Hmr data were obtained at frequencies up to 270 MHz and used to derive the dominant conformation of the dimers in aqueous solution. Comparison with data for the component mononucleotides reveals that dimerization does not lead to drastic changes in the molecular conformation. Literature data for dimers possessing only the ribo sugar (3′,5′-UpU) and the 2′-deoxyribo sugar (3′,5′-d(TpT)) are also presented. The results indicate that, at least for our dipyrimidine dimers, the molecular conformation of a particular fragment is not critically dependent on the nature (ribo or 2′-deoxyribo) of the other nucleotide unit.

JAMES PEELING, FRANK E. HRUSKA, et PETER C. LOEWEN. Can. J. Chem. **56**, 522 (1978).

Cette étude par rmn ^{1}H marque le début de nos travaux sur les conformations de monophosphates de nucléosides possédant des unités ribo 2′- ou 3′-nucléotidyles qui sont liées à des unités 5′-nucléotidyles possédant un sucre 2′-déoxyribo. On a effectué des synthèses d'uridylyl-3′,5′ 2′-déoxythymidine (3′,5′-UpdT) et de son isomère 2′,5′-UpdT, en faisant appel à des techniques standards. On a obtenu des données de rmn ^{1}H à des fréquences allant jusqu'à 270 MHz et on les a utilisées pour déterminer la conformation prédominante des dimères en solution aqueuse. Une comparaison de ces données avec celles obtenues pour les composants mononucléotides indique que la dimérisation ne conduit pas à des changements importants dans la conformation moléculaire. On présente aussi des données provenant de la littérature au sujet de dimères ne possédant que le sucre ribo (3′,5′-UpU) et le sucre 2′-déoxyribo (3′,5′-d(TpT)). Les résultats indiquent, au moins pour nos dimères dipyrimidines, que la conformation moléculaire d'un fragment particulier ne dépend pas d'une façon critique de la nature (ribo ou 2′-déoxyribo) de l'autre unité nucléotide.

[Traduit par le journal]

Introduction

Conformational studies of oligonucleotides in solution have been directed mainly at molecules containing solely either the ribose or 2′-deoxyribose sugar (1–6) though structures with covalently linked ribo- and 2′-deoxyribonucleotides are known (7). Maurizot *et al.* (8) examined the temperature dependence of the circular dichroic spectra of the four possible hybrid dinucleoside-3′,5′-monophosphates of adenine, i.e., ApA, dApA, ApdA, and d(ApA),[2] with a view to elucidating the conformational role of a 2′-hydroxyl group, and suggested that the observed spectral differences were most likely due to an intramolecular hydrogen bond to the adjacent 3′-phosphate. Kondo *et al.* (9) carried out uv, cd, and proton nmr of these same molecules, and concluded that the mode and extent of intramolecular base stacking was influenced by the 2′-hydroxyl group but they suggested that its effect is exerted through steric hindrance.

In the earlier nmr studies of the hybrid dimers (9), spectral parameters obtainable from the bands of the base, the H_1' and H_2' protons were considered, and thus, though comments about base stacking and sugar pucker could be made, no information about the conformational situation about the $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ bonds was obtained. Here we present proton nmr data for the hybrid dimer, uridylyl-3′,5′-2′-deoxythymidine (3′,5′-UpdT) (Fig. 1) as well as for its isomer possessing the 2′,5′-phosphodiester linkage (2′,5′-UpdT). Dimers containing only the pyrimidine bases (U, T) were chosen for our initial studies; since base stacking is

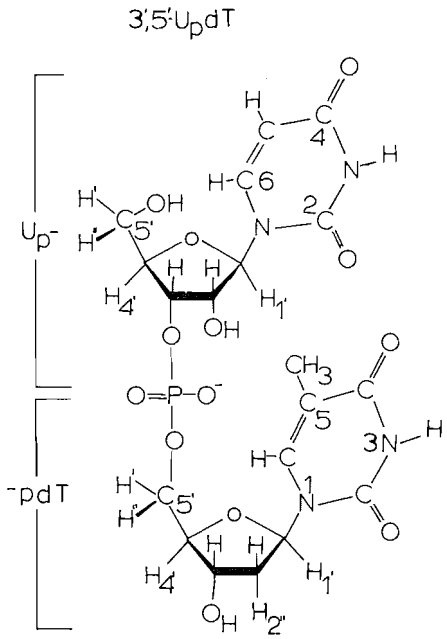

FIG. 1. Structural formula of uridylyl-(3',5')-2'-deoxythymidine or 3',5'-UpdT. Up- and -pdT refer to the 3'- and 5'-linked fragments, respectively.

expected to be less important here than in purine-containing dimers, the interpretation of the data is simplified but forms the basis for extension of the work to the more complex situation of stacked dimers.

Experimental

3',5'-UpdT and 2',5'-UpdT were prepared following the procedure of Lapidot and Khorana (10). Details of the preparation and purification are available upon request.

Proton spectra were obtained on a variety of spectrometers (Bruker WH-90DS, Manitoba; Bruker WH-270, Madison; Varian HA-100, Manitoba; Varian HR-220, Canadian 220 MHz Centre) operating in the CW or FT modes. Sodium-3-trimethylsilylpropionate, 2,2,3,3-d_4 (TSP) was used as an internal ^{1}Hmr reference. Solutions (0.05 *M* or less) were freeze-dried three times and dissolved in 100% D_2O. For the dimers the p*D* of the solution was adjusted to neutrality with NaOD and DCl; for the monomers the solution p*D* was adjusted to about 5.0. In all instances, then, the phosphate is monoanionic. Calibration of the spectra was carried out by standard methods. Spectral analysis was carried out using LAME (11) and computer simulated spectra were generated as a final test of the data. A sample spectrum of 3,5-UpdT is shown in Fig. 2.

The chemical shift (δ) and coupling constant (*J*) data for the *ribose* and *2'-deoxyribose* fragments of the hybrid dimers are listed in Tables 1 and 2, respectively. For purposes of comparison data for the mononucleotide, 5'dTMP, and the homodimers, 3',5'-UpU and 3',5'-d(TpT), are included in the appropriate table; the source of these data is indicated in the footnotes to the tables.

Results and Discussion

Spectral Assignment and Chemical Shifts

The assignment of the spectral bands of the Up- and -pdT fragments was accomplished by comparison with published spectra of mono- and oligonucleotides (1, 3, 12, 13). Following the work of Ritchie and Perlin (14) on selectively deuterated adenosine and that of Remin and Shugar (15) and Davies and Rabczenko (16), the low-field portion of the $H_{5'}$,$H_{5''}$ bands was assigned to $H_{5'}$ for all ribose and 2'-deoxyribose fragments (Fig. 3).

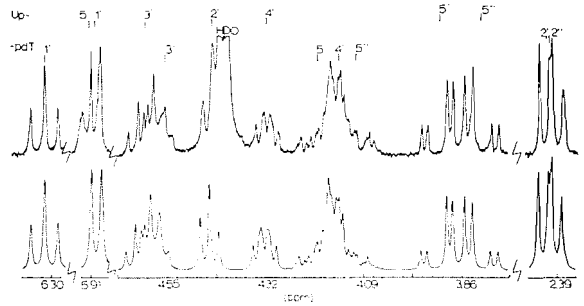

FIG. 2. (*a*) Single scan, continuous wave, 220 MHz spectrum of the ribose protons 3',5'-UpdT (p*D* = 6.8, 65°C, ~0.05 *M* in D_2O). Sweep width 250 Hz. (*b*) Computer simulated spectrum.

In the -pdT unit of 3',5'-UpdT there exists a substantial shift between the 5'- and 5''-hydrogens (0.13 ppm at 20°C; Table 2). In contrast $H_{5'}$ and $H_{5''}$ in -pdT of 2',5'-UpdT are nearly isochronous. Furthermore, the $\delta_{5'}$ and $\delta_{5''}$ values of -pdT (2',5'-isomer) are similar to those of the monomer 5'dTMP. This is not the case in either 3',5'-UpdT or 3',5'-d(TpT) where large deshielding effects (up to 0.19 ppm, relative to 5'dTMP) are evident in the $\delta_{5'}$ and $\delta_{5''}$ values of the -pdT units. Thus, incorporation of 5'-dTMP into a dimer induces magnetic nonequivalence in the $H_{5'}$,$H_{5''}$ pair if the second fragment is 3'-linked, the magnitude of the induced effect being dependent on the nature (ribo or 2'-deoxyribo) of the 3'-linked fragment. Ezra *et al.* (4) have seen an analogous situation for the ribose homodimers 2',5'-CpC and 3',5'-CpC. In the -pC fragment of the former the $H_{5'}$,$H_{5''}$ hydrogens are isochronous whereas in that of the latter they are separated by 0.22 ppm.

It is interesting to note that, whereas the $\delta_{5''}$ values for the -pdT units of 3',5'-UpdT and 3',5'-d(TpT) differ by only 0.03 ppm, the $\delta_{5'}$ values differ by a larger amount, 0.09 ppm. Thus, the $H_{5'}$ hydrogen on the -pdT fragment appears to be more sensitive to the nature (hydrogen or hydroxyl) of the *exo* substituent on the $C_{2'}$ carbon of the 3'-linked nucleotidyl fragment. This supports our assignment of the $H_{5'}$,$H_{5''}$ hydrogens in the -pdT fragment of both dimers and provides as well some conformational information. (See below).

The $H_{2'}$ and $H_{2''}$ of the -pdT units of 3',5'-UpdT,

[a]Chemical shifts reported in ppm from TSP. Coupling constants in Hz. Estimated error: J, ±0.2 Hz; δ, ±0.01 ppm.
[b]Data from ref. 3; pD = 7.4, 0.05 M.
[c]$\Sigma = J_{4'5'} + J_{4'5''}$.

3′,5′-d (TpT) and 5′dTMP are nearly isochronous. Furthermore, $\delta_{2'}$ and $\delta_{2''}$ fall in the narrow range from 2.37 to 2.41 ppm from TSP. This constancy of the $\delta_{2'}$ values on the one hand and of $\delta_{2''}$ on the other, for these three molecules, is perhaps predictable from space-filling models of the dimers in either the extended (unstacked) conformation or in the right-handed stacked arrangement. In both conformations the $C_{2'}$ hydrogens on -pdT are distant from the 3′-linked unit.

In contrast with 5′dTMP and the 3′,5′-dimers, a substantial chemical shift (0.06 ppm) exists between the $H_{2'}$ and $H_{2''}$ protons of the -pdT fragment of 2′,5′-UpdT, a consequence of the differential shielding effect induced by the formation of the 2′,5′-phosphodiester bond. Thus, relative to 3′,5′-UpdT, $H_{2'}$ and $H_{2''}$ of the 2′,5′-isomer are shifted upfield by 0.10 and 0.04 ppm, respectively. (Our assignment of the $H_{2'}$ and $H_{2''}$ hydrogens is based on the observation that $J_{2'3'}$ is generally larger than $J_{2''3'}$ (1, 12, 13).) This shielding effect is not simply explained. It could be due to changes in the sugar-base torsion angle (χ) (4, 17) of the -pdT unit which determines the disposition of $H_{2'}$ and $H_{2''}$ relative to the magnetically anisotropic 2-keto oxygen of the base. (In this regard it is relevant to point out that $H_{1'}$ is also shifted (upfield) in -pdT of 2′,5′-UpdT relative to the 3′,5′-isomer.) The need for change in χ could in turn be traced to the stacking properties of the 2′,5′- and 3′,5′-isomers, but further comment here would require extensive cd measurements.

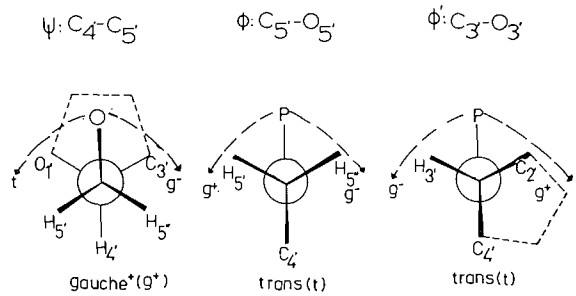

FIG. 3. Newman projections of the dominant conformations viewed along the $C_{4'}$—$C_{5'}$, $C_{5'}$—$O_{5'}$, and $C_{3'}$—$O_{3'}$ bonds. Definitions according to ref. 18.

The Sugar-base Torsion Angle (χ)

A variety of methods have been employed for evaluating χ. One method is based on the characteristic shielding changes observed for the $H_{2'}$ and $H_{3'}$ protons when, in the *syn* conformation, the 2-keto oxygen is located over the sugar ring (19, 20). Following the reasoning outlined (19), we propose on the basis of the chemical shifts (Table 2) that the *syn* ⇆ *anti* balance is not drastically altered by incorporation of the monomers into the dimer molecules. The general consensus is that in solution pyrimidine nucleosides prefer the *anti* conformation but the *syn* can be significantly populated (2).

[i]Not measurable.

Sugar Pucker

The conformation of a ribose or 2′-deoxyribose ring, described in terms of the pseudorotational parameters (P), the amplitude of pucker (τ_m), and the populations of the 2′*endo* (S) and 3′*endo* (N) puckers in the N ⇆ S blend (21), can be evaluated from the magnitudes of the vicinal couplings ($J_{1'2'}$ etc.) (22, 23). In Table 3 are presented the % 3′*endo* values for the entries in Table 1, calculated according to Davies and Danyluk (22).

A striking feature of the $J_{1'2'}$, $J_{2'3'}$, and $J_{3'4'}$ data (Table 1) is their similarity in the monomer, 3′UMP, and the 3′-linked uridylyl fragments of 3′,5′-UpU and 3′,5′-UpdT. Clearly, the sugar pucker of the 3′-linked uridine fragment is not critically dependent on whether its 5′-linked pyrimidine nucleotidyl partner is a ribose or 2′-deoxyribose derivative. The data in Table 3 show a slight bias for the 3′*endo* conformation which is little affected by temperature change.

With few exceptions, 2′-deoxyribose derivatives display a preference for the 2′*endo* pucker, both in the crystal and solution states (18, 24). The -pdT fragment of 3′,5′-UpdT is not, in this respect, exceptional. Calculations (Table 3) show contributions of 32 and 39% from the 3′*endo* pucker at 20 and 65°C, respectively, results which are similar to those of the -pdT unit of 3′,5′-d(TpT) and to that of the monomer, 5′dTMP. Thus the pucker of a -pdT unit is not critically dependent on the nature (ribo or 2′-deoxyribo) of its 3′-linked pyrimidine nucleotidyl partner. (At 20°C the magnitude of the sum $J_{1'2'} + J_{1'2''}$ is 12.4 and 13.8 Hz for the -pdT units of 3′,5′-UpdT and 3′,5′-d(TpT), respectively. Thus, some dependence on the nature of the 3′-linked unit is indicated; however, it is difficult to assess since only the sum, and not the individual couplings, could be obtained owing to the chemical shift equivalence of $H_{2'}$ and $H_{2''}$.)

The data for the 2′-phosphorylated uridine fragments provide some contrast. For 2′UMP there is a shift, relative to 3′UMP, in the 3′*endo* bias (Table 3).

Furthermore, dimerization of 2′UMP to yield the Up- unit of 2′,5′-UpdT results at 20°C in a decrease in $J_{1'2'}$, $J_{2'3'}$, and $J_{3'4'}$. This decrease in $J_{2'3'}$ is indicative of an increase in the amplitude of pucker (21) and is not observed upon dimerization of 3′UMP. Dimerization also leads to a slight increase in the 3′*endo* contribution (Table 3). Elevation of the temperature to 65°C leads to an increase of 1.2 Hz in the magnitude of $J_{2'3'}$, indicating a decrease in the τ_m value of 65°C. This pronounced decrease in τ_m with increasing temperature is not observed for the Up- unit of 3′,5′-UpdT (Table 3) or of 3′,5′-UpU (3). Ezra *et al.* (4) have found that 2′,5-dimerization of 2′CMP to yield 2′,5′-CpC leads to an increase in $J_{2'3'}$ (decrease in τ_m) at 20°C, results which contrast with our results for 2′,5′-UpdT. It seems therefore, that a systematic study of the influence of the base, sugar, temperature, etc., is warranted for the 2′,5′-isomers.

Conformation about the $C_{4'}$—$C_{5'}$ (ψ) and $C_{5'}$—$O_{5'}$ (ϕ) Bonds

Contributions from $g^+(\psi)$ and $t(\phi)$ conformers (Fig. 3), calculated[3] by the usual methods, are listed in Table 3. The following comments can be made about the $C_{4'}$—$C_{5'}$ conformation of the uridine units. (*a*) The data define a range from 53 to 70%, indicating a bias for $g^+(\psi)$ over $t(\psi)$ and $g^-(\psi)$ in all instances. (*b*) 3′-Elongation of 3′UMP with either a U fragment or a dT fragment enhances % $g^+(\psi)$ (7–11%). Thus, the ψ conformer distribution is not strongly dependent on the nature (ribo or 2′-deoxyribo) of the 5′-nucleotidyl unit. (*c*) Relative to 3′UMP the bias for $g^+(\psi)$ is reduced in 2′UMP. This reduction is probably a reflection of the shift in the 3′*endo* ⇆ 2′*endo* balance (Table 3) which is known (24) to influence the ψ conformer distribution. Elongation of 2′UMP with a dT unit (2′,5′-UpdT) leads to a slight increase in % $g^+(\psi)$. It is interesting that our 2′,5′- and 3′,5′-dimerization effects are in line with observations on 2′,5′- and 3′,5′-CpC (4); in both isomers dimerization leads to an increase in % $g^+(\psi)$.

Ezra *et al.* (4) have noted a significant magnetic nonequivalence for $H_{5'}$ and $H_{5''}$ of -pC of 3′,5′-CpC and that this pair of hydrogens are, along with $H_{4'}$ of -pC, essentially isochronous in the 2′,5′-isomer. In like fashion, we observe magnetic nonequivalence for $H_{5'}$ and $H_{5''}$ of -pdT of 3′,5′-UpdT but a collapse of $H_{5'}$, $H_{5''}$, and $H_{4'}$ in the 2′,5′isomer. Thus, in this respect, a parallel behavior exists for the 5′-nucleotidyl units of the CpC and UpdT isomers. An unfortunate consequence of this spectral collapse is that the couplings required for discussion of the ϕ,ψ conformational features of the 2′,5′-isomers cannot be obtained.

However, we may make the following comments about the $C_{4'}$—$C_{5'}$ (ψ) and $C_{5'}$—$O_{5'}$ (ϕ) conformer distributions for the -pdT unit of 3′,5′-UpdT. (*a*) The $g^+(\psi)$ conformer is dominant in 5′dTMP (Table 3). (*b*) The magnitude of % $g^+(\psi)$ is enhanced to about 65% when (at 20°C) 5′dTMP is incorporated into 3′,5′-UpdT and 3′,5′-d(TpT). With dimerization of 5′dTMP there occurs also an increase in % t (ϕ) regardless of the nature (Up- or dTp-) of the 3′-unit. It is, then, clear that neither the ϕ nor the ψ conformer distribution of -pdT is dependent on the nature of the sugar moiety of the 3′-unit. This, of course, need not be the case for purine derivatives nor for that matter in pyrimidine dimers in the fully stacked conformation. (*c*) Increasing temperature leads to decreases in % $g^+(\psi)$ and % $t(\phi)$. This is also the case for -pdT of 3′,5′-d(TpT) (4) and -pU of 3′,5′-UpU (3). It seems, however, that Σ' is somewhat more sensitive to temperature in 3′,5′-UpdT than in the other dimers, increasing by 3.7 Hz in the 20–65°C interval. In the 18–65°C range Σ' increases by about only 1 Hz for -pdT of 3′,5′-d(TpT) (14) and by 0.9 Hz for -pU of 3′,5′-UpU in the 20–85°C interval (3). Thus, the ϕ orientation is not entirely insensitive to the nature of the 3′-linked sugar.

The long-range $^4J_{P4'}$ couplings provide information about the $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ conformer distribution (26, 27) although, owing to their small size, they may be less reliable than Σ and Σ' as conformational probes. However, the magnitudes of the observed $^4J_{P4'}$ couplings for the 5′-nucleotidyl fragments (1.6–1.8 Hz, Table 2) are in line with our observations based on Σ and Σ', namely, that $g^+(\psi)$ and $t(\phi)$ are the dominant conformations.

[3]% $g^+(\psi) = (13 - \Sigma)/10$ where $\Sigma = J_{4'5'} + J_{4'5''}$ and % $t(\phi) = (25 - \Sigma')/21$ where $\Sigma' = J_{P5'} + J_{P5''}$ (12, 25).

Conformation about $C_{3'}$—$O_{3'}$ and $C_{2'}$—$O_{2'}$

Information about the conformations about these bonds in 3′- and 2′-nucleotidyl units may be obtained from $^3J_{P3'}$ and $^3J_{P2'}$. On the basis of steric considerations and a wealth of X-ray data (18), the $g^+(\phi')$ conformation (Fig. 3) may be excluded from consideration. However, the $H_{3'}$ ($H_{2'}$) and P atoms are *gauche* in the two remaining possibilities, $g^-(\phi')$ and $t(\phi')$, and thus no unambiguous distinction between the two can be made on the basis of ^1H–^{31}P couplings alone. They provide, however, the following important information about our 3′(2′)-uridylyl units if we assume the applicability of eq. 1 (25).

$$[1] \qquad {}^3J_{PH}\,(\text{Hz}) = 18.1\cos^2\theta - 4.8\cos\theta$$

where θ is the dihedral angle in the relevant H—C—O—P fragment. Note that $\theta = 60°$ corresponds to the classical $g^-(\phi')$ and $t(\phi')$ staggered conformers whereas $\theta = 0$ corresponds to the conformation in which $H_{2'}$ (of the 2′-nucleotidyl units) and $H_{3'}$ (of the 3′-nucleotidyl units) eclipse the phosphorus atom, i.e. $\phi' = -120°$.

The $^3J_{P3'}$ and $^3J_{P2'}$ values (Table 1) are significantly larger than expected for the classical $g^-(\phi')$ and $t(\phi')$ conformers (ca. 2 Hz) and since the $g^+(\phi')$ conformation is excluded (expected $^3J_{P3',2'} = 23$ Hz), a substantial bias towards the $\phi' = -120°$ situation is indicated. In this conformer which separates the g^- and t ranges, the phosphorus and $H_{2'}$($H_{3'}$) atoms are eclipsed ($\theta = 0°$) and a large (13.3 Hz) ^1H–^{31}P coupling is expected. Using eq. 4 we obtain $\theta \simeq 35°$ for 2′- and 3′-UMP and the Up- units of 3′,5′UpU and 3′,5′UpdT from the low temperature data, corresponding to ϕ' angles of -85 and $-155°$ in the g^- and t conformer range, respectively. Increasing temperature leads to a small decrease in $^3J_{P3'}$ and an increase (ca. 1°) in θ for the 3′-units of the dimers. For Up- of 2′,5′-UpdT $\theta \simeq 30°$, corresponding to $\phi' = -90$ and $-150°$. It appears then that in the 2′,5′-dimer the $C_{2'}$—$O_{2'}$ bond is somewhat more constrained towards the eclipsed ($\phi' = -120°$) situation than is the $C_{3'}$—$O_{3'}$ bond in the 3′,5′-isomer. (A similar trend has been noted (4) for the Cp- units of 2′,5′-CpC ($^3J_{P2'} = 9.1$ Hz) and 3′,5′CpC ($^3J_{P3'} = 8.3$ Hz).) Thus 3′,5′-dimerization appears to have little influence on $^3J_{P3'}$, regardless of the nature (ribo or 2′-deoxyribo) of the 5′-nucleotidyl unit. 2′,5′-Dimerization appears to bias the angle about the $C_{2'}$—$O_{2'}$ bond towards the $\phi' = -120°$ situation but again the nature of the 5′-linked sugar is unimportant.

The bias towards the $\phi' = -120°$ eclipsed conformer is consistent with X-ray data. Thus, in Sundaralingam's review (18), we note that for 3′-nucleotides (five entries) the ϕ' values lie in the range from -91 to $-165°$, with one entry, 3′AMP, having a ϕ' value of $-123°$, just 3° from the $H_{3'}$–P eclipsed situation.

In general, the $^3J_{P3'}$ values for the Up- units are considerably larger than those measured for dTp- units (6.8 Hz for dTp- of 3′,5′-d(TpT) (4) and 6.1–6.4 Hz for the dTp- units of 3′,5′-d(TpTp) (16) and 3′,5′-d(TpTpA) (1)). Thus, the bias towards the eclipsed conformer is less pronounced in the 2′-deoxyribo units ($\theta \simeq 44°$; $\phi' = -76, -164°$). This greater bias for $\phi' = -120°$ in the ribo units is most likely due to steric interactions involving the 2′-hydroxyl group. Support for this contention is provided by the observation (28) that 2′-*O*-methylation of the Ap- unit of ApA results in an increase of 1.4 Hz in $^3J_{P3'}$.

The similarity in the $^3J_{P3'}$ values suggests that the ϕ' conformer distribution is similar for the Up- units of 3′,5′-UpdT, and 3′,5′-UpU and for 3′UMP itself. This suggestion is supported by the chemical shift data. In the $g^-(\phi')$ conformer $H_{4'}$ is near to the charged nonester oxygens of the phosphate while $H_{2''}$ is distant; in $t(\phi')$, the converse is true. Thus, changes in the $g^-(\phi') \rightleftarrows t(\phi')$ blend should be manifest in $\delta_{2''}$ and $\delta_{4'}$. However, in Table 1 we note a remarkable constancy for these species in, on the one hand, $\delta_{2''}$, and, on the other hand, $\delta_{4'}$, which is inconsistent with major differences in the conformer weighting.

Conformation about the $O_{3'}$—P and $O_{5'}$—P Bonds

Our measured coupling constants cannot provide information on the orientations about the internucleoside O—P bonds. Recently, however, variations in the $H_{5'}$ shift of the 5′-unit of 3′,5′-ribodimers have been related (3) to the proximity of $H_{5'}$ to the 2′-hydroxyl of the 3′-unit. When the $O_{3'}$—P and $O_{5'}$—P bond are g^-, as in the right handed (g^-g^-) stacked conformation, van der Waals contact between these atoms is possible and appears to lead to a specific deshielding of $H_{5'}$ (3). These effects are best discussed in terms of the dimerization shifts, Δ, defined as the shift of a proton in the dimer relative to its shift in the corresponding mononucleotide, with positive values indicating increased shielding at the dimer level. For the -pdT fragments we obtain from the low temperature data in Table 2: $\Delta_{5'}$ ($\Delta_{5''}$ in brackets) in ppm: -0.10 (-0.04), -0.19 (-0.07), -0.02 (-0.03) for 3′,5′-d(TpT), 3′,5′-UpdT, and 2′,5′-UpdT, respectively. For 3′,5′-UpdT a significant deshielding effect upon dimerization is noted for the $H_{5'}$, that for $H_{5''}$ being greatly attenuated. Following the reasoning outlined (3), we conclude that $H_{5'}$ is located in the vicinity of the 2′-OH of the Up- unit for a significant fraction of the time and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

therefore, that the g^-g^- conformer makes a significant (but quantitatively undeterminable here) contribution to the time-averaged conformation of 3′,5′-UpdT. It is important to point out, however, that a large (ca -0.10 ppm) $\Delta_{5'}$ value is observed for -pdT of 3′,5′-d(TpT), but the effect is certainly smaller than that noted for the mixed dimer. Clearly factors other than the proximity of the 2′-OH of the 3′-unit can contribute to the $\Delta_{5'}$ values and thus the interpretation of these Δ values in quantitative terms will be difficult. Interestingly, the $\Delta_{5'}$ and $\Delta_{5''}$ values are small (less than -0.03 ppm) for the 2′,5′-isomer. In the g^-g^- conformer of a 2′,5′-dimer $H_{5'}$ does not approach any position of the furanose moiety of the 3′-unit and thus the appearance of this conformer may not be reflected in the $\Delta_{5'}$. However, with molecular models one may construct a compact, g^-g^- stacked arrangement of a 2′,5′-dimer in which $H_{5'}$ is placed in juxtaposition with the magnetically anisotropic 2-keto oxygen of the pyrimidine base on the 3′-unit. The minimal value of $\Delta_{5'}$ for 2′,5′-UpdT cannot, therefore, be unambiguously interpreted; it could be a reflection of the virtual exclusion of the g^-g^- arrangement or it may be a consequence of an insensitivity of $\Delta_{5'}$ to the orientation of the O—P bonds.

Comparison of some other chemical shift data (Table 1) provides some evidence for base-base interaction in the 2′,5′-dimer. Thus, in particular, the large (0.17 ppm) upfield shift (relative to 3′UMP) experienced by the 5-hydrogen of the uracil base is only reasonably explained if some stacking of the U and T bases occurs. For the 3′,5′-isomer an upfield shift (0.06 ppm) for the H_5 hydrogen of the uracil is observed, in line with the evidence given above for some contribution from the g^-g^- conformer. That the H_5 dimerization shift is larger for the 2′,5′-UpdT isomer could be a consequence of more extensive base stacking as well as to alternations in the spatial arrangement of the bases in the stack.

Conclusions

The ^{1}Hmr data of mixed dimers 3′,5′-UpdT and 2′,5′-UpdT are compared with data for the component mononucleotides, 3′UMP, 2′UMP, and 5′dTMP, and for the dimers 3′,5′-UpU and 3′,5′-d(TpT), and discussed in terms of their molecular conformations in aqueous solution. For the greater part the conformations (sugar pucker and the $C_{4'}$—$C_{5'}$, $C_{5'}$—$O_{5'}$, and $C_{3'}$—$O_{3'}$ conformer distributions) of the 3′- and 5′-linked dimer units are similar to those of the corresponding mononucleotides. Furthermore, the sugar phosphate conformation of a particular nucleotidyl unit (3′- or 5′-linked) does not appear to be critically dependent upon the nature (ribo or 2′-deoxyribo) of the other unit. This conclusion is, of course, restricted to our dipyrimidine dimers which exist to a large extent in an extended rather than stacked orientation.

Acknowledgements

This research was supported by operating grants from the National Research Council of Canada and Rh Institute of Manitoba. We thank the NRCC, the University of Manitoba, and its Faculty of Graduate Studies for capital grants for purchase of a Bruker WH-90 spectrometer. We thank Dr. A. A. Grey of the Canadian 220 MHz centre and Dr. W. A. Gibbons of the University of Wisconsin (Madison) for obtaining 220 MHz and 270 MHz spectra, respectively. We are grateful to Dr. Donald Wood for his generous aid in the spectral analysis, and to Mr. A. George and W. Niemczura for obtaining spectra for 2′UMP.

The microwave spectrum and structure of cyclopropyl carbinol. II. Four deuterated forms

W. V. F. BROOKS AND C. K. SASTRI

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received August 31, 1977

W. V. F. BROOKS and C. K. SASTRI. Can. J. Chem. **56**, 530 (1978).

The microwave spectra of four deuterated species of cyclopropyl carbinol have been studied. The rotational constants *A*, *B*, and *C* (in MHz) are: $C_3H_5CH_aD_bOH$, 11 742.86, 3205.17, 2830.41; $C_3H_5CD_aH_bOH$, 11 853.44, 3188.10, 2878.28; $C_3H_5CH_aD_bOD$, 11 321.30, 3145.87, 2762.23; $C_3H_5CD_aH_bOD$, 11 433.85, 3129.30, 2809.81. The measured dipole moments of $C_3H_5CH_aD_bOH$ and $C_3H_5CH_aD_bOD$ are, respectively, 1.91 and 1.873 D. This confirms the essential details of the conformation proposed in an earlier paper.

W. V. F. BROOKS et C. K. SASTRI. Can. J. Chem. **56**, 530 (1978).

On a étudié les spectres de microonde de quatre espèces deutérées de cyclopropylcarbinol. Les constantes de rotation *A*, *B* et *C* (en MHz) sont: $C_3H_5CH_aD_bOH$, 11 742.86, 3205.17, 2830.41; $C_3H_5CD_aH_bOH$, 11 853.44, 3188.10, 2878.28; $C_3H_5CH_aD_bOD$, 11 321.30, 3145.87, 2762.23; $C_3H_5CD_aH_bOD$, 11 433.85, 3129.30, 2809.81. Les moments dipolaires mesurés pour $C_3H_5CH_aD_bOH$ et $C_3H_5CH_aD_bOD$ sont respectivement 1.91 et 1.873 D. Ces résultats confirment les détails essentiels de la conformation proposée dans une publication antérieure.

[Traduit par le journal]

Introduction

An earlier paper (1) hereafter referred to as I, reported the microwave spectra and dipole moments of cyclopropyl carbinol ($CH_2—CH_2—CH—CH_2OH$) and a deuterated (—OD) form, and proposed a conformation of the molecule which is diagrammed in Fig. 1. Note that the diagram shows only one of two forms; the mirror image conformation is identical in its spectroscopic properties. Note also that the two hydrogens labelled *a* and *b* are not equivalent. The microwave spectra of species deuterated at these *a* and *b* positions may be used to test the validity of the proposed conformation, and to determine some of the structural constants (interatomic distances and angles) more precisely.

Experimental

The deuterium labelled molecules were prepared by oxidizing cyclopropyl carbinol (Aldrich Chemical Company) to the aldehyde (2), reducing the aldehyde to the sodium salt with $NaBD_4$, and adding H_2O to the reaction mixture. The doubly deuterated (C_3H_5CHDOD) forms were made by allowing the singly deuterated substance to exchange with excess D_2O in the cell of the microwave spectrometer. The purity and composition of the intermediate aldehyde and singly deuterated product were checked with infrared, mass, and nmr spectra.

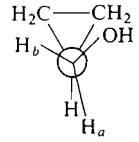

FIG. 1. Newman projection of gaseous cyclopropyl carbinol.

Microwave spectra and Stark coefficients were measured as described in I.

Spectra

All samples contained at least two separate species (D in the *a* and D in *b* positions). The predicted spectra, calculated from the structure of I, made the assignment easy. Enough isolated lines were available to clarify assignment problems and a few Stark coefficients were measured (measured and calculated coefficients are given in Table 2).

Four species were identified, two singly deuterated (on the carbinol C atom) and two doubly deuterated. More than 20 lines for each species[1] (mostly *a*-type R and *c*-type Q with *J* values from 0 to 8) were assigned, measured, and used in a least-squares determination of the rotational constants (listed in Table 1). Only lines for which observed and calculated values differed by less than 0.5 MHz were used in the final least-squares computations. No attempt was made to identify vibrationally excited states or other conformational species.

Structure and Discussion

The dipole moment results (Table 3) are in excellent agreement with the previous measurements except for the large value of μ_c for $C_3H_5CH_aD_bOH$ (this component is very poorly determined by the data available). The rotation of the principal axes due to deuterium substitutions are small enough that

[1]The assigned and measured line measurements are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

the components can be compared directly without considering rotation.

The rotational constants of all four species are sufficiently close to the predicted values that the proposed conformation of the molecule may be regarded as confirmed. The 12 new pieces of data were combined with the earlier 6 to determine the structure more precisely. The most interesting structural questions concern the amounts of rotation of the CH_2OH and OH groups about the C_{ring}—$C_{carbinol}$ and $C_{carbinol}$—O bonds respectively, the C—O—H angle and the distortion of the ring due to the unsymmetrical interaction between the ring and the carbinol group.

Using the same fitting procedure as described in I, we first tried adjusting the dihedral angles H—C_{ring}—$C_{carbinol}$—O, C_{ring}—$C_{carbinol}$—O—H, and the C—O—H angle as these were the items of greatest interest in the proposed structure. The new best least-squares values changed H—C—C—O from $\pm$124.2 to $\pm$123.7°, C—C—O—H from $\mp$32.3° to $\mp$32.9° and C—O—H from 116.7° to 117.8°. These changes seem insignificant. We also tried several adjustments of coordinates that either move the carbinol carbon into a less symmetrical position with respect to the ring or make the ring less symmetrical. No adjustments of these gave any significant improvement of the fit between calculation and observation. We conclude, therefore, that the carbinol carbon must lie very close (within 0.1 nm) of the plane that is perpendicular to and bisects the ring.

Penn and Boggs (3) consider another type of ring distortion due to substitution on the ring; the ring bond opposite to the point of substitution is shortened or lengthened. This effect is fairly easily measured when the substituent group and the ring have a common plane of symmetry. The lack of symmetry in this molecule makes the problem more difficult; we have not been able to extract any information about such a distortion from our data. Thus the remaining differences between observed and calculated rotational constants (Table 1) must be due to a combination of experimental and model errors (the rigid rotor model plus all the assumed distances and angles). A more precise determination of the ring shape will require isotopic substitution on

The ionic reaction of CH_3CHO^+ with trioxane in acetaldehyde–trioxane mixtures has been studied using a time-of-flight mass spectrometer. The product ions, $C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$, were formed by condensation–elimination reactions, which involve the elimination of a formaldehyde molecule. The dissociation of the intermediate-complex, $CH_3CHO(CH_2O)_3^{+*}$, leads to the formation of the product ions. The structure of the complex is linear with localized positive charge. Rearrangement of hydrogen atoms occurs in the complex but not extensive scrambling. From the distribution of the isotopic product ions in acetaldehyde-d_4–trioxane mixtures it was proposed that the origins of the product ions are the acetaldehyde molecule (reactant ion) and fragments from trioxane. The rate constants for the product ions formed in acetaldehyde (or acetaldehyde-d_4)–trioxane mixtures were obtained.

MINORU KUMAKURA, KAZUO ARAKAWA et TOSHIO SUGIURA. Can. J. Chem. **56**, 533 (1978).

Faisant appel à un spectromètre de masse à temps de vol, on a étudié la réaction ionique de CH_3CHO^+ avec le trioxanne dans des mélanges d'acétaldéhyde–trioxanne. Les ions qui se forment comme produits, $C_3H_5O_2^+$, $C_3H_6O_2^+$ et $C_3H_7O_2^+$, proviennent de réactions de condensation–élimination qui impliquent l'élimination d'une molécule de formaldéhyde. La dissociation du complexe intermédiaire, $CH_3CHO(CH_2O)_3^{+*}$, conduit à la formation des ions. La structure du complexe est linéaire avec une charge positive localisée. Dans le complexe, il se produit des transpositions des atomes d'hydrogène, mais il ne se produit pas d'une manière importante de répartition au hasard. En se basant sur la distribution isotopique dans les ions qui se forment comme produits dans des mélanges d'acétaldéhyde-d_4–trioxanne, on propose que les produits ioniques ont comme origine la molécule d'acétaldéhyde (ion réactif) et des fragments provenant du trioxanne. On a évalué les constantes de vitesse pour les formations des ions obtenus comme produits dans des mélanges d'acétaldéhyde (ou acétaldéhyde-d_4)–trioxanne.

Introduction

In an earlier work the reaction of ethylene oxide molecular ion with trioxane in ethylene oxide–trioxane mixtures was studied as a part of our program for examination of the thermal ion–molecule reactions occurring in binary mixtures of oxygen-containing molecules (1). From the distribution of isotopic product ions in the mixture it was concluded that the intermediate-complex formed has a cyclic structure and delocalized positive charge (1). The ion–molecule reactions in ethylene oxide and acetaldehyde have been studied in order to obtain information concerning the behavior of structural isomers in oxygenated fragment ions such as CHO^+ and $C_2H_4O^+$ (2, 3); it was found that the reactions are intimately related to the structure and properties of the neutral molecules. It was felt that a study of the ion-molecule reactions in acetaldehyde–trioxane mixtures is important to obtain information to elucidate any structure effect of the reactant ion in the reactions involving structural isomers of oxygen-containing cyclic molecules. The ion–molecule reactions in acetaldehyde have been studied by several workers (4–8); however, reactions in binary mixtures of acetaldehyde and large-ring cyclic ether molecules, such as trioxane, have not been studied containing cyclic molecules. The ion–molecule thus far. The behavior of protonated molecular ions resulting from proton and hydrogen atom transfer reactions in acetaldehyde–trioxane mixtures has been studied at low pressures (9). Since the condensation–elimination reactions involving the acetaldehyde molecular ion in acetaldehyde have been studied at elevated pressures (3), the present work is concerned with exploring the structural consequences of the condensation–elimination reaction of the acetaldehyde molecular ion with trioxane on the ion chemistry of acetaldehyde–trioxane mixtures at elevated pressures.

Experimental

The instrument used was a Bendix Model 12-101 time-of-flight mass spectrometer which has been modified to study

ion–molecule reactions as described in a previous paper (2). A Hewlett-Packard 214A pulse generator and a pulse generator (Sanwa Denshi Production Co. Ltd.) were used as the source of the ionizing and ion withdrawal pulses. The retarding potential differential technique (rpd) was adopted for appearance potential and ionization efficiency curve measurement and a detailed description of this technique was reported earlier (10). The measurement of the ionization efficiency curves of two ions was performed simultaneously by a two-channel ion detection method. The ion current of two different ions was recorded with a three-pen recorder. A gas-sample inlet system consisting of a dual leak and a dual reservoir was used. The samples were introduced individually into the ionization chamber through two separate leaks from separate reservoirs. The partial pressure of the two samples was measured with an MKS Baratron 90-X RP-2 capacitance manometer and the pressure was calibrated by the known rate constant (1.11×10^{-9} cm^3 molecule^{-1} s^{-1}) for the formation of CH_5^+ in methane. Acetaldehyde and acetaldehyde-d_4 were obtained from Merck Sharp and Dohme of Canada and trioxane from Celanese Chemical Co. Ltd. These samples were used after vacuum distillation.

Results and Discussion

Delay Time and Pressure Dependence

The delay time dependence of major fragment and product ions in a 1:1 mixture of acetaldehyde and trioxane at 2.65×10^{13} molecules cm^{-3} is shown in Figs. 1 and 2. $C_3H_5O_3^+$ (*m/e* 89), $C_2H_5O_2^+$ (*m/e* 61), CH_3O^+ (*m/e* 31), and CHO^+ (*m/e* 29) are fragment ions from trioxane, while CH_3CHO^+ (*m/e* 44), CH_3CO^+ (*m/e* 43), and CHO^+ (*m/e* 29) are those from acetaldehyde. The molecular ion from trioxane

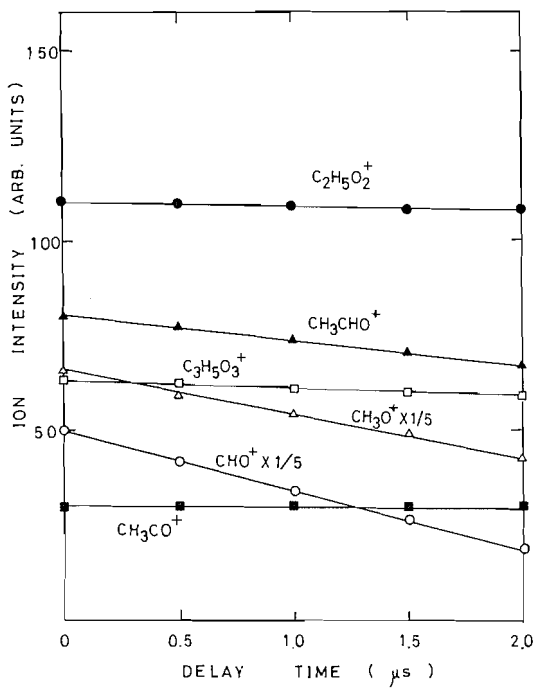

FIG. 1. Delay time dependence of major fragment ions in acetaldehyde–trioxane mixtures.

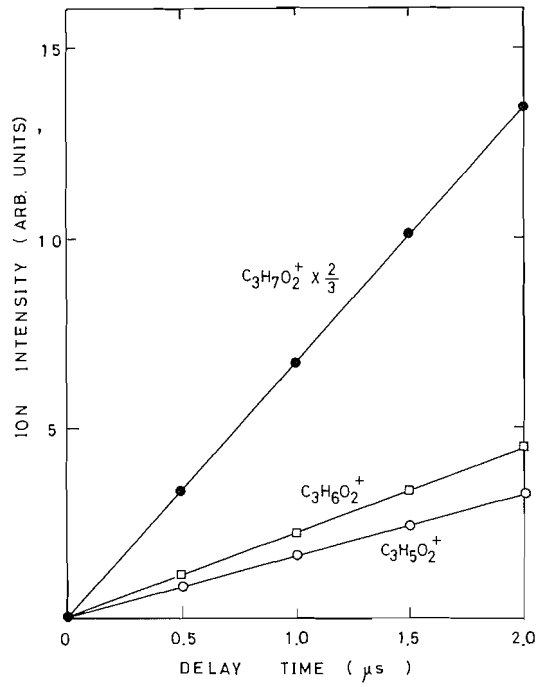

FIG. 2. Delay time dependence of product ions in acetaldehyde–trioxane mixtures.

was less abundant and its ion intensity was comparable with the ion intensity of the ^{13}C isotope of $C_3H_5O_3^+$. The remarkable decrease of the ion intensities of CHO^+ and CH_3O^+ with increasing delay time was due to the participation of these ions in proton transfer reactions (9). Since the behavior of the product ions (homo-reaction product ions) formed in each individual system has been described previously (3), these ions are not shown in Fig. 2. New product ions of $C_3H_5O_2^+$ (*m/e* 73), $C_3H_6O_2^+$ (*m/e* 74), and $C_3H_7O_2^+$ (*m/e* 75) were observed in acetaldehyde–trioxane mixtures at elevated pressures and long delay times. In order to clarify the formation mechanism and the structures of the product ions, the ion–molecule reactions in acetaldehyde-d_4–trioxane mixtures were studied under the same conditions as for acetaldehyde–trioxane mixtures. The delay time dependence of the product ions is shown in Fig. 3, and the isotopic product ions ($C_3H_2D_3O_2^+$ (*m/e* 76), $C_3HD_4O_2^+$ (*m/e* 77), $C_3H_2D_4O_2^+$ (*m/e* 78), and $C_3H_3D_4O_2^+$ (*m/e* 79)) correspond to the ions ($C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$) formed in acetaldehyde–trioxane mixtures.

The ion intensity variation of the product ions with pressure in each gas was examined in order to clarify the contribution of both compounds (acetaldehyde and trioxane). The dependence of the product ions ($C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$)

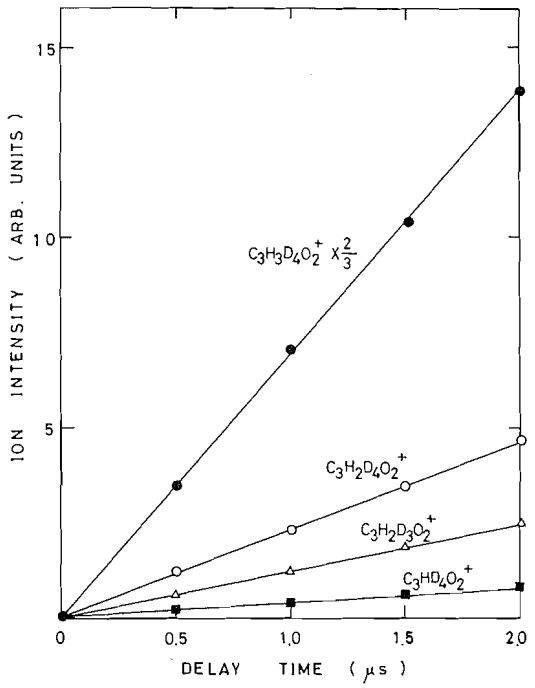

FIG. 3. Delay time dependence of product ions in acetaldehyde-d_4–trioxane mixtures.

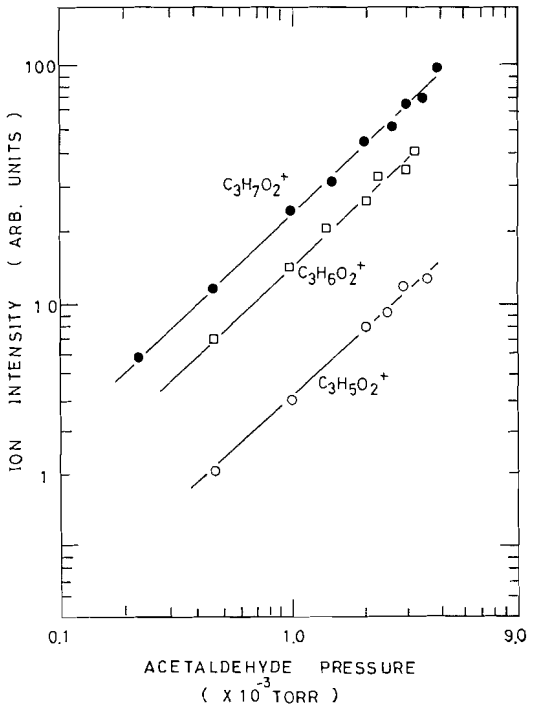

FIG. 4. Pressure dependence of product ions on acetaldehyde at 2.0 μs.

on acetaldehyde pressure, shown in Fig. 4, was obtained by variation of the acetaldehyde pressure using the dual leak at constant trioxane pressure and at a delay time of 2.0 μs. Similarly, the pressure dependence of the product ions in trioxane at constant acetaldehyde pressure is shown in Fig. 5. In Figs. 4 and 5, the product ions are first order in acetaldehyde and trioxane, indicating that these ions result from a cross reaction (reaction between ions of one compound and the molecules of the other) in acetaldehyde–trioxane mixtures.

Ionization Efficiency Curve

The appearance potentials and ionization efficiency curves of the fragment and product ions were measured to determine the precursors (reactants) of the product ions. The fragment ion whose appearance potential lies closest to that of the product ion generally is taken to be the precursor. If more than one fragment ion is responsible for the formation of a given product ion, a change in the slope of the ionization efficiency curve will often denote the onset of the reaction involving a different precursor. The ionization efficiency curves of major fragment and product ions ($C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$) in acetaldehyde–trioxane mixtures are shown in Fig. 6. All the ionization efficiency curves of the product ions coincide in onsets as well as shape. This indicates that the product ions have a common precursor. The onsets of the ionization efficiency curves

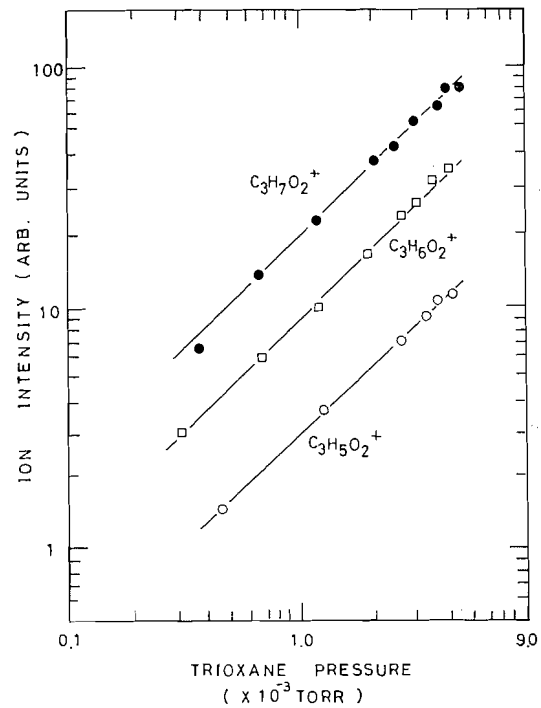

FIG. 5. Pressure dependence of product ions on trioxane at 2.0 μs.

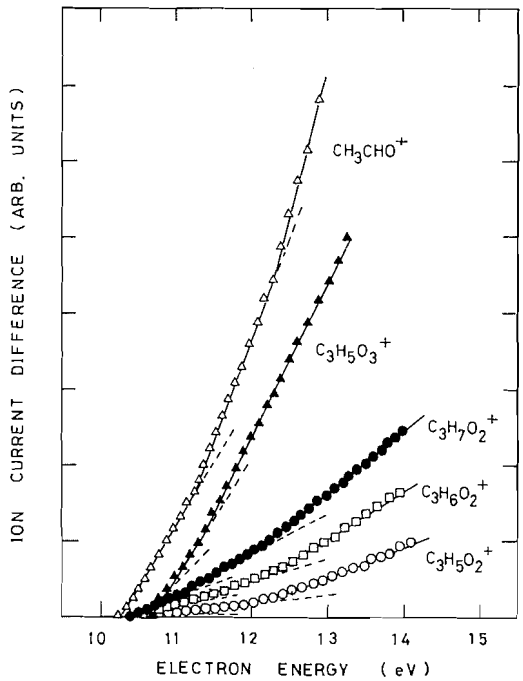

FIG. 6. Ionization efficiency curves of major fragment and product ions in acetaldehyde–trioxane mixtures.

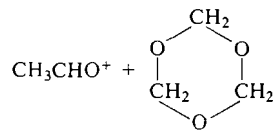
of the product ions agree with the ionization potential (10.32 ± 0.05 eV) of acetaldehyde. The break points in the ionization efficiency curves of the product agree with those of acetaldehyde molecular ion. The onsets and break points in the ionization efficiency curves of the product ions did not agree with that of $C_3H_5O_3^+$ from trioxane. The appearance potentials of the fragment ions, CH_3CO^+, CHO^+, and CH_3^+, from acetaldehyde were 11.42 ± 0.05, 12.12 ± 0.05, and 14.32 ± 0.05 eV (3), while the appearance potentials of $C_2H_5O_2^+$, CH_3O^+, and CHO^+ from trioxane were 10.79 ± 0.05, 11.49 ± 0.05, and 13.59 ± 0.05 eV, respectively (10). Thus, the appearance potentials of these fragment ions were considerably higher than those of the product ions, and the break points in the ionization efficiency curves of the product ions did not agree with those in the curves of these fragments. CHO^+ and CH_3O^+ did not participate in the formation of the product ions in acetaldehyde–trioxane mixtures. The CHO^+ was generated from acetaldehyde as an intense fragment ion; however, $C_3H_5O_2^+$ was not formed in the ionic reactions in acetaldehyde. The CHO^+ and CH_3O^+ are proton donor ions which participate in proton transfer reactions (9). From the results of the ionization efficiency curve measurement it is concluded that the acetaldehyde molecular ion is the precursor of the product ions.

Reaction Mechanism and Ion Structures

The product ions result from the condensation–elimination reaction of CH_3CHO^+ with trioxane. From the distribution of the isotopic product ions in acetaldehyde-d_4–trioxane mixtures it is proposed that the product ions are formed by means of the dissociation of an unstable intermediate-complex resulting from the reaction of CH_3CHO^+ with trioxane (Scheme 1). The rate constants for the



$$\rightarrow CH_3CHO{-}CHO^+ + C_2H_5O_2 \quad m/e\ 73 \quad (1)$$

$$\rightarrow CH_3CHO{-}CH_2O^+ + C_2H_4O_2 \quad m/e\ 74 \quad (2)$$

$$\rightarrow CH_3CHO{-}CH_2OH^+ + C_2H_3O_2 \quad m/e\ 75 \quad (3)$$

SCHEME 1

product ions in acetaldehyde (or acetaldehyde-d_4)–trioxane mixtures are given in Table 1. The sum of the rate constants for $CD_3CO{-}CH_2O^+$ and $CD_3CDO{-}CHO^+$ formed in acetaldehyde-d_4–trioxane mixtures is nearly equal to that for $CH_3CHO{-}CHO^+$ formed in those of acetaldehyde–trioxane. In addition, the rate constants for $CD_3CDO{-}CH_2O^+$ and $CD_3CDO{-}CH_2OH^+$ in acetaldehyde-d_4–trioxane mixtures are comparable with those for $CH_3CHO{-}CH_2O^+$ and $CH_3CHO{-}CH_2OH^+$ in those of acetaldehyde–trioxane. From the distribution of the isotopic product ions in both systems, the empirical formulae for the product ions shown in Table 1 are reasonable. The origins of the product ions are the acetaldehyde molecule (reactant ion) and fragments from trioxane. This suggests that the formation of the product ions involves an abstraction reaction by CH_3CHO^+ in the complex. From the formula of the product ions, it is probable that the complex resulting from the reaction of CH_3CHO^+ with trioxane has the linear structure shown in Fig. 7. As can be seen in Fig. 3, the ion intensity of $CD_3CDO{-}CH_2OH^+$ increased with increasing delay time and the rate constant for its formation was the largest of those for that of any of the product ions observed. The formation of $CD_3CDO{-}CH_2OH^+$ involves the rearrangement of a hydrogen atom in the complex. The rate constant for $CD_3CDO{-}CHO^+$ resulting from CHO^+ transfer in the complex is relatively small. From the empirical formulae of the product ions we estimate that extensive scrambling does not occur in the complex.

TABLE 1. Rate constants of the reactions in acetaldehyde (or acetaldehyde-d_4)–trioxane mixtures

Reactant ion			Product ion					$k \times 10^{10}$ (cm^3 molecule^{-1} s^{-1})
CH_3CHO^+	+		$CH_3CHO—CHO^+$ *m/e* 73	+	$2CH_2O$	+	H	0.51
			$CH_3CHO—CH_2O^+$ *m/e* 74	+	$2CH_2O$			0.75
			$CH_3CHO—CH_2OH^+$ *m/e* 75	+	CH_2O	+	CHO	4.30
CD_3CDO^+	+		$CD_3CO—CH_2O^+$ *m/e* 76	+	$2CH_2O$	+	D	0.37
			$CD_3CDO—CHO^+$ *m/e* 77	+	$2CH_2O$	+	H	0.10
			$CD_3CDO—CH_2O^+$ *m/e* 78	+	$2CH_2O$			0.71
			$CD_3CDO—CH_2OH^+$ *m/e* 79	+	CH_2O	+	CHO	4.10

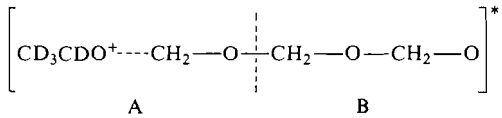


FIG. 7. Possible structure of the intermediate-complex.

It is well known that ring opening of trioxane occurs by means of positive species and radiation (11). It is presumed that the ring of the trioxane molecule is subsequently opened after the reaction of acetaldehyde molecular ion with trioxane. The constituent atoms of the product ions consist only of those in the A-site in the complex (Fig. 7) and the ion having the atoms of the B-site is not observed. This indicates that the positive charge is mainly localized on the site of the acetaldehyde molecule in the complex. The complex would be dissociated to the product ions due to the cleavage of the C—O bond in the trioxane molecule site, in which the neutral products involving a formaldehyde molecule are eliminated. If the complex has a cyclic structure, some product ions containing fragments from both origins (acetaldehyde and trioxane) would be formed as observed in the condensation–elimination reaction in ethylene oxide–trioxane mixtures (1). It would be impossible that a formaldehyde molecule is abstracted from trioxane by a stripping mechanism. The structure of the complex elucidated in acetaldehyde–trioxane mixtures is different from that in ethylene oxide–trioxane mixtures (1). Thus is is found that the nature of the condensation–elimination reaction involving a cyclic ether is related to the structure of the reactant ion.

X-ray photoelectron spectra of C_6F_5X compounds (X = CH_3, CF_3, CN, CHO, OH, OCH_3, NH_2, NO_2)

BARRY C. TRUDELL AND S. JAMES W. PRICE[1]

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received August 4, 1977

BARRY C. TRUDELL and S. JAMES W. PRICE. Can. J. Chem. **56**, 538 (1978).

The gas phase photoelectron spectra, XPS, were observed for the series C_6F_5X (X = CH_3, CF_3, OCH_3, OH, CHO, NO_2, NH_2, CN). Binding energies were determined from the spectra by using computer curve fitting. Charge calculations were carried out using CNDO/2 and ACHARGE techniques. The CNDO/2 analysis led to the following correlation for the C 1*s* binding energies and the atomic charges, q_i

$$E_i, (\text{C } 1s) = 290.01 + 23.74q_i + \sum_{i \neq j} q_i/R_{ij}$$

Correlations were also obtained for O 1*s* and N 1*s*:

$$E_i, (\text{O } 1s) = 538.12 + 9.59q_i + \sum_{i \neq j} q_i/R_{ij}$$

$$E_i, (\text{N } 1s) = 405.99 + 24.26q_i + \sum_{i \neq j} q_i/R_{ij}$$

These equations are based on only four and three points respectively. However, the N 1*s* values cover a wide range (E_i, 402 to 419 eV; q_i, −0.2 to 0.5) and show a better correlation than those for oxygen.

BARRY C. TRUDELL et S. JAMES W. PRICE. Can. J. Chem. **56**, 538 (1978).

On a déterminé les spectres photoélectroniques en phase gazeuse, XPS, pour la série C_6F_5X (X = CH_3, CF_3, OCH_3, OH, CHO, NO_2, NH_2, CN). On a déterminé les énergies de liaison à partir des spectres en faisant appel a une correspondance de courbe effectuée par ordinateur. On a calculé les charges à l'aide des techniques CNDO/2 et ACHARGE. L'analyse CNDO/2 a conduit à la corrélation suivante pour les énergies de liaison des atomes de C 1*s* et les charges atomiques q_i

$$E_i, (\text{C } 1s) = 290.01 + 23.74q_i + \sum_{i \neq j} q_i/R_{ij}$$

On a aussi obtenu les corrélations pour O 1*s* et N 1*s*:

$$E_i, (\text{O } 1s) = 538.12 + 9.59q_i + \sum_{i \neq j} q_i/R_{ij}$$

$$E_i, (\text{N } 1s) = 405.99 + 24.26q_i + \sum_{i \neq j} q_i/R_{ij}$$

Toutefois ces équations ne sont basées respectivement que sur quatre et trois données. Toutefois les valeurs de N 1*s* couvrent un spectre plus grand (E_i 402 à 419 eV, q_i −0.2 à 0.5) et présentent une meilleure corrélation que celles obtenues pour l'oxygène.

Introduction

We have shown in a recent paper (1) that charge distributions in molecules of the type C_6F_5X (X = F, Cl, Br, I, H) can be calculated from XPS data and compared with CNDO/2 calculations successfully. This paper presents a similar study of C_6F_5X compounds where X = OH, CHO, NO_2, CN, OCH_3, NH_2, CF_3, CH_3.

Experimental

All of the C_6F_5X compounds were obtained from the Imperial Smelting Corporation with the exception of C_6F_5OH which was obtained from Bristol Organics Ltd. The chemicals were distilled twice, with only middle fractions taken for use. Boiling points agreed with literature values (2).

Spectra were measured (1) using a McPherson Esca 36 spectrometer[2] employing MgK_α radiation (1253.6 eV). Spectra for each level were run a minimum of three times and were reproducible to within ±0.1 eV.

Results and Discussion

The binding energies of the various levels in each of the compounds are reported in Table 1. The areas calculated were used in some cases to decide how many, but not which, carbons were to be assigned to a particular binding energy (e.g. $C_6F_5OCH_3$ 6:1).

	N 1*s*	406.2	219(11)	

[a]All binding energy values relative to argon $2p_{3/2} = 248.62$ eV.
[b]Relative values. Values in parentheses are uncertainties calculated by computer curve fitting.

The binding energies of the carbon atoms varied over a wide range (290.0–299.3) depending on the particular environment. The pattern for the chemical shifts of the carbon atom joined to the substituting group was found to be OH > OCH_3 > NO_2 > CN > CF_3 = NH_2 > CHO > CH_3. The position of CH_3 in this series is consistent with the idea that the first seven groups are all −I groups while CH_3 is +I. Each of these groups also has the capability of a resonance effect (either +R or −R) on the ring system. The pattern of chemical shifts for the carbon atoms on the C_5F_5 portion of the ring was found to be CN = NO_2 = CF_3 > CHO > OH > CH_3 > OCH_3 > NH_2. The first four groups are all −R groups while the last four are +R groups which is consistent with the overall ordering. (The method by which carbon atoms were assigned to particular binding energy values will be discussed later in the paper.) There were no separate peaks seen for the fluorine atoms in any of the molecules, although the fluorine in the aliphatic side chain in $C_6F_5CF_3$ did lead to peak broadening.

In all cases where comparison was possible, the binding energies of all atoms of the C_6F_5X series are higher than in the corresponding C_6H_5X (3) series in accordance with the idea that the fluorine atoms are largely −I moderated by a small +R effect.

CNDO/2 Calculations and Chemical Shifts

The use of the electrostatic potential model to correlate binding energies of atoms in molecules with their respective CNDO/2 charges is well documented (3–8). The technique involves an equation of the type,

$$[1] \qquad E_i - \sum_{i \neq j} q_j/R_{ij} = E_0 + k_A q_i$$

A plot of the term on the left vs. q_i, the CNDO/2 charges, should allow calculation of k_A and E_0 which are parameters necessary for ACHARGE analysis of the molecules.

The CNDO/2 charge calculations for the series of molecules in this present paper were carried out using QCPE No. 290.[3] The program was discussed in a previous paper (1) and no alterations were made. The CNDO/2 charges are reported in Table 2. In three cases (X = OH, CHO, OCH_3) the optimized geometry (minimum energy) predicts an unsymmetric configuration. The values listed in Table 2 for these three molecules are for this minimum energy structure.

If one substitutes these CNDO/2 values for q_i in [1] along with the necessary R_{ij} values which were derived from the optimized geometry calculated by QCPE No. 290, the plot shown in Fig. 1 is obtained. This plot is for the carbon atoms only. As can be seen the correlation for these values is excellent. A least-squares calculation returns the values 289.93 eV and 23.80 eV/e for E_0 and k_c respectively. If points from previous calculations of similar molecules are included, the following equation is obtained.

$$[2] \quad E_i(\text{C } 1s) = 290.01 + 23.74q_i + \sum_{j \neq i} q_j/R_{ij}$$

In the case where the assignment of a particular binding energy to a particular carbon atom in the molecule was not clear, e.g. $C_6F_5OCH_3$, Fig. 1 was used as an aid to work out the problem. In $C_6F_5OCH_3$ there is one carbon atom with a binding energy higher than all the rest. It is impossible to determine whether it is the C_1 carbon or the CH_3

[a]M.P. ≡ molecular potential.
[b]$k_0 = 9.2$.
[c]$k_0 = 11.5$.
[d]$f_0 = 10.5$.
[e]Minimum energy states unsymmetric. Charge on C_3 and C_5 nearly equal but in C_6F_5CHO and C_6H_5OH the charge on C_6 exceeds that on C_2 by 0.008 and 0.015 respectively. F_7–F_{11} charges all −0.148 to −0.184 with in general F_7 and F_{11} more negative than F_8–F_{10} by 0.01 to 0.02 charge units.

carbon by inspection. However, if the two sets of assignments are made it is found that in one case both of the points fall well off the line, while the second choice leads to excellent correlation indicating correct assignments have probably been made. This procedure was also adopted for C_6F_5CHO.

Although the molecular potential terms are not dominant in all cases, in every case it certainly adds or subtracts a significant amount to or from the chemical shift. Only in molecules where there is no significant charge distribution, e.g. C_6H_6, could the molecular potential term be successfully left out.

In order to be able to carry out the ACHARGE analysis for this series of molecules, it is necessary to have values for E_0 and k_A for carbon, fluorine, nitrogen, and oxygen (suitable values for fluorine were used in a previous paper (1) and the values for carbon have already been discussed). In order to obtain the values for nitrogen and oxygen, plots similar to that of Fig. 1 for carbon were made for nitrogen and oxygen. These are shown in Figs. 2 and 3.

The nitrogen plot contains only three points (NO_2, NH_2, CN) but gives a reasonable correlation over a wide range of binding energies (402–419 eV) and atomic charges ($-0.2 \rightarrow 0.5$). The corresponding parameters were found to be 406.0 eV for E_0 and 24.26 eV/e for k_N.

The oxygen plot although having four points

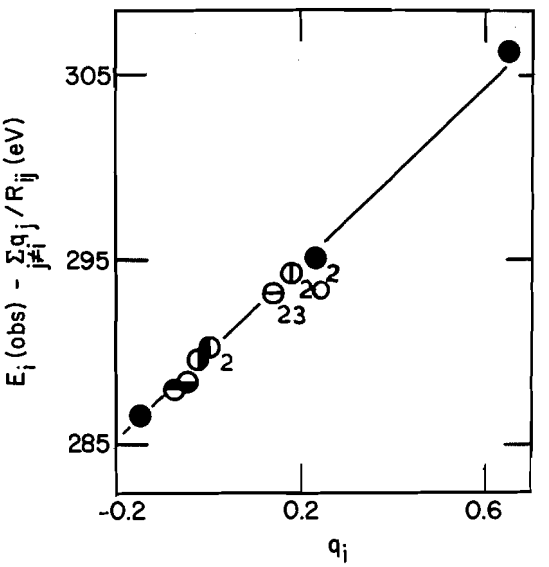

FIG. 1. Binding energies of C 1*s* electrons in C_6F_5X (X = CF_3, CH_3, NH_2, OH, OCH_3, CN, NO_2, CHO) corrected for interatomic potentials vs. the charge on the respective carbon atom. All *q* values are from CNDO/2 calculations. ● $C_6F_5CF_3$, ◐ $C_6F_5CH_3$, ◑ C_6F_5CN, ◒ $C_6F_5NO_2$, ◓ C_6F_5CHO. Subscripts indicate number of C 1*s* values averaged to obtain the given point. For the two multicompound points contributions are as follows (X, number of C 1*s* values from C_6F_5X): ⊕ CF_3, 1; CH_3, 2; NO_2, 5; CN, 6; CHO, 6. ⊖ CF_3, 2; CH_3, 3; NH_2, 6; OH, 6; OCH_3, 6.

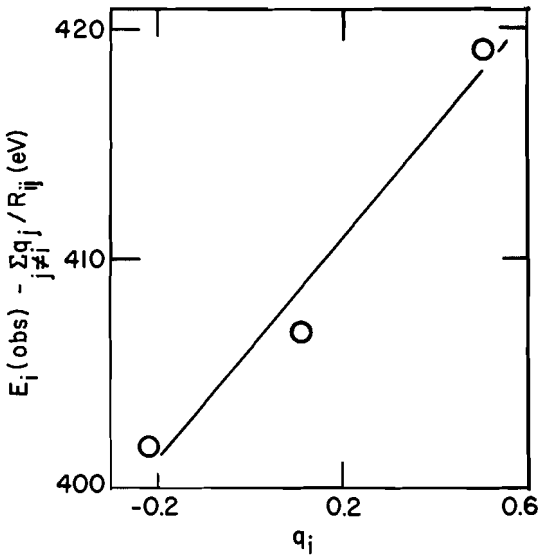

FIG. 2. Binding energies of N 1*s* electrons in C_6F_5X (X = NH_2, CN, NO_2) corrected for interatomic potentials vs. the charge on the respective nitrogen atom. All *q* values are from CNDO/2 calculations. Points from left to right are for $C_6F_5NH_2$, C_6F_5CN, and $C_6F_5NO_2$ respectively.

(NO_2, CHO, OH, OCH_3) gave a poorer correlation. This was probably due to the narrow range of binding energies (538.5–540.3 eV) and charges ($-0.31 \rightarrow -0.17$). The necessary values were calculated as 538.1 eV for E_0 and 9.59 eV/e for k_0. The value for k_0 of oxygen was lower than expected although other experiment slopes have varied from roughly 8 (9, 10) to 26 (11) eV/e. Accordingly, it was thought that the value of 9.59 eV/e was probably acceptable for ACHARGE calculation on these molecules.

ACHARGE Analysis

Using chemical shift data and a knowledge of molecular geometry, atomic charges can be calculated by ACHARGE Analysis (3–7).

In the preceding section E_0 and k_A values for carbon, nitrogen, and oxygen were established. Values for fluorine have been documented (1, 7). Thus, if we assume only that all hydrogens in the molecules have an equal charge (e.g. the hydrogen in $C_6F_5CH_3$) and that the molecule is neutral, the calculation can be carried out.

The charge densities calculated by the ACHARGE technique are shown in Table 2.

In most cases the correlation between these 'experimentally' determined charge densities and the CNDO/2 result is excellent. In the case of

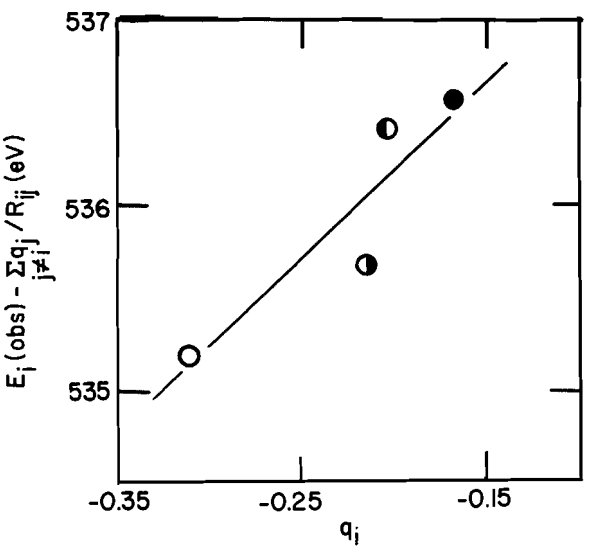

FIG. 3. Binding energies for O 1*s* electrons is C_6F_5X (X = NO_2, CHO, OH, OCH_3) corrected for interatomic potentials vs. the charge on the respective oxygen atom. ○ $C_6F_5NO_2$, ◑ C_6F_5CHO, ◐ C_6F_5OH, ● $C_6F_5OCH_3$.

$C_6F_5OCH_3$, C_6F_5CHO, and C_6F_5OH, because of the lower precision in the value for k_0 slightly different values ranging from 9.2 to 11.5 eV/e were used to give the best fit. It was found that the charges on the oxygen atom and its immediate neighbours were extremely sensitive to the values of k_0 used. The fact that E_0 for oxygen may also be in error is considered but the effect on the charge densities was less pronounced.

Acknowledgements

The authors would like to thank Mr. R. Lazier for his assistance in running the spectra, Mr. R. M. Baillageon for his co-operation in setting up the programmes used in this paper, and Dr. C. S. Lin for many fruitful discussions. This work was supported by a grant from the National Research Council of Canada.

The effect of *p*, *d*, and *f* Gaussian polarization functions on the computed one-electron properties of AH_n oxygen and sulfur hydrides

RAYMOND POIRIER AND ROY KARI

Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received August 12, 1977

RAYMOND POIRIER and ROY KARI. Can. J. Chem. **56**, 543 (1978).

A series of LCAO-MO-SCF calculations, using various basis sets of Gaussian-type functions, has been made in order to study the effects of *p*, *d*, and *f* polarization functions on calculated one-electron properties for a 10-electron isoelectronic series of oxygen hydrides and for an 18-electron series of sulfur hydrides. Conclusions from these results suggest that several one-electron properties have a predictable, although not monotonic convergence pattern. Except for calculated field gradients, *f* GPF's have only a small effect on the calculated values.

RAYMOND POIRIER et ROY KARI. Can. J. Chem. **56**, 543 (1978).

On a effectué une série de calculs LCAO-MO-SCF, faisant appel à divers ensembles de base de type Gaussien, de façon à étudier les effets des fonctions de polarisation *p*, *d* et *f* sur les propriétés uniélectroniques calculées pour une série isoélectronique de 10 électrons d'hydrures d'oxygène, et pour une série de 18 électrons d'hydrures de soufre. Les conclusions que l'on peut tirer de ces résultats suggèrent que plusieurs propriétés uniélectroniques possèdent un type de convergence qui peut être prèdit mais qui n'est pas monotone. A l'exception des gradients de champs calculés, *f* l'effet des valeurs GPF sur les valeurs calculées est minime.

[Traduit par le journal]

Introduction

Physical properties may be divided into two general classes: those that involve energy, specifically energy differences such as ionization potentials and proton affinities, and those that represent molecular properties other than energy. In this paper, attention will be focussed on certain properties of the latter class, namely properties such as dipole and quadrupole moments, which may be computed as expectation values of one-electron operators (one-electron properties).

The sources of error in *ab initio* calculations may be divided into four distinct categories: (*1*) Born–Oppenheimer and relativistic effects, (*2*) variation with internuclear distance, (*3*) correlation effects, and (*4*) finite expansion basis set effects. The purpose of this article is to examine the fourth category in detail for it is well known (1) that a deficiency in the SCF basis will not be corrected by subsequent beyond Hartree–Fock calculations.

The importance of *d* Gaussian polarization functions (GPF's) in molecules containing first and second row atoms and *p* GPF's on molecules containing hydrogen in the determination of molecular properties have been the subject of many investigations (2, 3). However, these investigations have been confined usually and only to those properties involving energy, which generally converges monotonically and relatively quickly with the addition of GPF's. On the other hand, molecular one-electron properties converge more slowly and furthermore do not usually converge to their limiting values in a monotonic manner. This makes it difficult if not often impossible to predict limiting values for one-electron properties. Also, although one property may be adequately represented by a given basis set, this does not imply that any other property will be equally well represented.

Recognizing the relative intractability of computed one-electron properties, the present study included an analysis of the importance of *f* GPF's in determining one-electron properties for oxygen and sulfur hydrides. The inclusion of a *f* GPF also allows a comparison to be made with a parallel study (3) undertaken to determine the energetic effects of GPF's.

Calculations

In order to investigate the basis set dependence of each operator, two series of calculations were performed on three isoelectronic oxygen hydrides OH^-, OH_2, and OH_3^+ and on three isoelectronic sulfur hydrides SH^-, SH_2, and SH_3^+. The first series included as *s* only basis set on the hydrogens and a *sp*, then *spd*, and finally an *spdf* basis set on either oxygen or sulfur. The second series repeated the oxygen or sulfur basis set but this time each hydrogen was represented by an *sp* basis set. The basis sets will be hereafter abbreviated by the symbols (*sp*/*s*), (*spd*/*s*), etc., where the letters before the solidus indicate the basis set used to represent the heavy atom while the letters after the solidus indicate the basis set used to represent each hydrogen atom.

The actual basis sets used incorporated 10^s, 5^p, 1^d, and 1^f GTO's contracted to 4^s, 2^p, 1^d, and 1^f GTO's

on oxygen, 12^s, 9^p, 2^d, and 1^f GTO's contracted to 6^s, 4^p, 2^d, and 1^f GTO's on sulfur, and finally 4^s and 1^p GTO's contracted to 2^s and 1^p GTO's on hydrogen. Due to the nature of Gaussian functions, the six *d*-type functions will combine to form linear combinations which correspond to the traditionally accepted five 3*d*-AO and one 3*s*-AO. Similarly, the 10 *f*-type Gaussians will produce seven 4*f*-AO and three 4*p*-AO. No attempt was made to separate the Gaussians into the more traditional forms. The oxygen α exponent (0.706328) and the sulfur *d* exponents (0.25 and 1.3225) were chosen so as to describe electron densities for both ionic and neutral species. The *f* exponent was arbitrarily set equal to unity. As a result of these compromises, none of the GPF exponents are optimum for any one species. However, because the dependence of expectation values on the choice of exponent values is small (3, 4) relative to their dependence on the actual inclusion of one or more polarization functions, it is not expected that the present choice of exponents will cause any qualitative discrepancies in the relative results and conclusions presented here. The reader is referred to previous publications (3–6) for more specific details about the basis sets and the nuclear geometries for all of the species investigated. It should be noted that the nuclear geometries used here were not necessarily identical to experimental geometries. Hence, the values of the properties calculated here are not directly comparable to experimentally determined values in so far as these values vary with small changes in the internuclear distances or valence angles.

All of the one-electron properties calculations were performed via the POLYATOM (version 2) system of programs (QCPE # I99). The one-electron properties package was locally modified to compute properties over *f* Gaussian-type orbitals.

Balanced Basis Sets

Mulliken (7) introduced the terms physical and formal balance to describe the nature of basis sets. A physically balanced set is one which gives reasonable calculated values for well defined experimental quantities. A formally balanced set exists when reasonable charges are calculated for atoms. Both of these definitions are somewhat arbitrary in that one must define what is meant by reasonable. For discussion purposes, it will be assumed that the (*spdf*/*sp*) basis set Mulliken populations display formally balanced charge distributions.

The absolute effect of GPF's on Mulliken population is illustrated in Fig. 1 for oxygen and sulfur hydrides. For convenience, these have been shown relative to the (*sp*/*sp*) basis set. The relative effect of adding GPF's in the order *d*, *p*, and *f* is given in Table 1. Assuming that the (*spdf*/*sp*) basis set is formally balanced, the addition of *d* or *f* GPF's on the heavy atom will exaggerate the charge on the heavy atom. Figure 1 reveals a simple rule. Electron density will flow to the nuclear centre where the GPF is added. Therefore, in order to obtain a formally balanced basis set when adding *d* and *f* GPF's to the heavy atom, a *p* GPF must be included in the hydrogen basis set. In Fig. 1 and Table 1, *p* and *f* GPF show a significantly larger effect for the oxygen hydrides than for the sulfur hydrides while the reverse is true for addition of a *d* GPF.

Mulliken population is an excellent example of predictable convergence where the addition of GPF's on a given centre increases the population at that centre and addition at a second centre will lower the population at the first centre.

Although physical balance requires that the basis set produce reasonable results for well defined experimental quantities, Fig. 3 shows that the dipole moments, for example, do not exhibit a simple or predictable convergence. As a result, one basis set may accidentally give a reasonable result for one quantity but may also give an unreasonable description of another property. For this reason, a discussion of physical balances would seem inappropriate unless consideration is simultaneously given to many different physical properties. One method of incorporating all of the calculated properties is to discuss the basis set in terms of their relative effects on negative, neutral, and positive species.

On addition of *d*, *f*, and *p* GPF's to an (*sp*/*s*) basis set, the minimum change in the dipole moment was noted for the anion and the maximum change was noted for the cation. Table 2 indicates similar maximum and minimum changes for all of the other one-electron properties. If it is assumed that the (*spdf*/*sp*) basis set is the most physically balanced basis set, then any other basis set which is equally balanced should exhibit a similar minimum and maximum effect for each property. For example, if the (*spd*/*s*) basis set were as balanced as the (*spdf*/*sp*) basis set, then we would expect the addition of a *d* GPF to least affect the dipole moment of the anion and to most affect the dipole moment of the cation. A summary of the mismatches which were observed for the (*spd*/*s*), (*sp*/*sp*), (*spd*/*sp*), and (*spdf*/*s*) basis sets is listed in Table 3. From this table, it may be concluded that the (*sp*/*sp*) basis sets for both the oxygen and sulfur hydrides and the (*spd*/*s*) basis set for oxygen hydride are furthest from physical balance and the (*spd*/*sp*) and (*spdf*/*s*) are closest to physical balance.

TABLE 1. Percentage[a] effects of *d*, *p*, and *f* GPF's on the calculated Mulliken population of oxygen or sulfur atom

Species	Basis set[b]	Percentage effect
OH^-	*d*	0.57
	p	−198
	f	58
OH_2	*d*	1.22
	p	−212
	f	48
OH_3^+	*d*	0.70
	p	−598
	f	122
SH^-	*d*	1.01
	p	−85
	f	16
SH_2	*d*	2.48
	p	−83
	f	9
SH_3^+	*d*	4.16
	p	−78
	f	3

[a]For a definition of percentage effect see text.
[b]Symbols *d*, *p*, and *f* refer to (*spd*/*s*), (*spd*/*sp*), and (*spdf*/*sp*) basis sets respectively.

Relative Effects of Polarization Functions

In order to measure the relative effects of GPF's, an order of addition of GPF's was assumed. Thus, the basis sets were built up in the order; (*sp*/*s*), (*spd*/*s*), (*spd*/*sp*), and (*spdf*/*sp*). As the addition of a *d* GPF to a (*sp*/*s*) basis set will change the calculated expectation value of any operator, the value of this change (Ad) may be defined as

$$\mathrm{Ad} = \langle spd/s \rangle - \langle sp/s \rangle$$

where $\langle sp/s \rangle$ and $\langle spd/s \rangle$ refer to the expectation values of an operator as calculated with (*sp*/*s*) and (*spd*/*s*) basis sets respectively. As well, the value of a similar change on addition of *p* (Ap) or *f* (Af) GPF's may be defined as

$$\mathrm{Ap} = \langle spd/sp \rangle - \langle spd/s \rangle$$

$$\mathrm{Af} = \langle spdf/sp \rangle - \langle spd/sp \rangle$$

For convenience, the percentage effect of adding a *d* GPF was defined relative to the change calculated with the (*sp*/*s*) basis set while the percentage effects of additional *p* and *f* GPF's was defined relative to the change occurring on addition of a *d* GPF. That is,

$$\text{Percentage effect of a } d \text{ GPF} = \frac{\mathrm{Ad}}{\langle sp/s \rangle} \times 100\%$$

$$\text{Percentage effect of a } p \text{ GPF} = \frac{\mathrm{Ap}}{\mathrm{Ad}} \times 100\%$$

$$\text{Percentage effect of a } f \text{ GPF} = \frac{\mathrm{Af}}{\mathrm{Ad}} \times 100\%$$

TABLE 2. Species for which the minimum (min) and maximum (max) effects were observed on addition of *p*, *d*, and *f* polarization function to an (*sp*/*s*) basis set. The species are identified by the symbols A for anion, C for cation, and N for neutral

[b]Symbols *d*, *p*, and *f* refer to (*spd/s*), (*spd/sp*), and (*spdf/sp*) basis sets respectively.

A summary of the percentage effects of *p*, *d*, and *f* GPF's is listed in Tables 4 and 5 for a variety of operators. A few of the calculated expectation values are also illustrated in Figs. 2 and 3. In these figures, all values are shown relative to the expectation value as calculated with the (*sp/s*) basis set which is indicated by the *p* line under the s column for each species. Actual computed one-electron property values for the (*spdf/sp*) basis set are listed in Tables 6 and 7. Persons interested in obtaining additional computed values for the various other basis sets may do so by writing to one of the authors (RK).

Energy

The absolute and relative effects of GPF's on the energy have been fully discussed in a previous publication (3) but are summarized for convenience in Table 4. Here, it may be noted that the percentage effect on the energy of added *d* GPF's is relatively small, for example 0.04% for OH_2 and 0.01% for SH_2. Similarly, a *p* and a *f* GPF both have very small additional effects and the GPF's cause a monotonic convergence of the energy to the Hartree–Fock limit. The general preference for the addition of polarization functions is in the order $d > p > f$.

TABLE 5. Percentage[a] effects of *d*, *p*, and *f* Gaussian polarization functions on the calculated potentials $\langle 1/r \rangle$, electric fields $\langle 1/r^2 \rangle$, and field gradients $\langle 1/r^3 \rangle$ of sulfur and oxygen hydrides

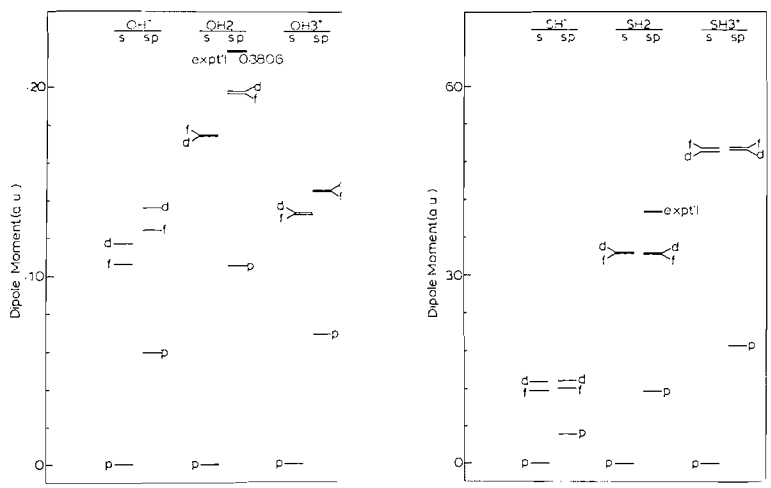

FIG. 2. The calculated dipole moments of oxygen and sulfur hydrides.

Dipole Moment

The absolute effect of GPF's on the calculated dipole moment is illustrated in Fig. 2 for the oxygen and sulfur hydrides respectively. The percentage effect of adding GPF's in order *d*, *p*, and *f* is given in Table 4. Whereas *d* GPF's had little effect on the energy this is not the case for the dipole moment. For example, the dipole moment changes by 13.36% for OH_2 and by 13.96% for SH_2. For the oxygen hydrides there is a small effect when a *p* GPF is added but a *f* GPF has relatively no effect. For the sulfur hydrides neither *p* nor *f* GPF's have significant effects on the calculated dipole moments. Figure 2 shows that for OH_2, addition of a *f* GPF to the (*spd*|*sp*) basis set will not cause any further convergence towards the experimental dipole moment (8). Similarly for SH_2, the addition of a *p* or *f* GPF will not cause any further convergence towards the experimental dipole moment (9). The poor agreement between the calculated and experimental dipole

moment in the case of OH_2 may be due to any one or all of the following reasons: poor (*sp*/*s*) basis sets, incorrect geometry, or electron correlation effects.

Second Moment

The relative effect of adding GPF in the order *d*, *p*, and *f* is given in Table 4. The effect of adding *d* GPF's is much smaller than for the dipole moment but again larger than for energy, for example 0.71% of OH_2 and 2.03% for SH_2. The effect of *d* GPF have a larger percentage effect for all hydrides, although somewhat exaggerated in an absolute sense by the small affect of a *d* GPF. Table 4 reveals for both OH_2 and SH_2 a convergence of the second moment except for the addition of *f* GPF to the (*spd*/*sp*) basis set, which causes a divergence. In

general the relative importance again appears to be in the order $d > p > f$.

Third Moment

From Table 4, the percent effect of adding *d* GPF's is generally greater for the third moment than it is for the second moment.

Overall, dipole, and third moments are the most affected while the second moment is least affected by the addition of GPF.

Potential, Electric Field, and Field Gradient at the Heavy Atom

The absolute effects of GPF on the potential as calculated at the heavy atom are illustrated in Fig. 3. The relative effects of adding GPF in the order *d*, *p*, and *f* are given in Table 5 for all of the above properties. The potential is almost invariant to the addition of GPF's. The reason for this invariance is that the potential operator ($\langle 1/r \rangle$) is part of the Hamiltonian and the wavefunction is initially designed to represent this property optimally. Figure 3 also illustrates the oscillatory convergence of the potential. There are no obvious rules for the order of addition, which varies from species to species.

Very large effects are observed for the calculated electric field on addition of a *d* GPF with 90.02% change for H_2O and 46.24% change for SH_2. The total force on the nuclei, like energy, decreases monotonically to the H–F limit of zero. As seen from Table 4, *p* and *f* GPF's have a significant additional effect on the net force on the nuclei for the oxygen hydrides but no significant effect on the sulfur hydrides. For oxygen hydrides the preferable order of addition is $d > p > f$ and for sulfur hydrides addition of a *d* GPF appears sufficient.

For field gradients, *d* GPF also have a large effect. For example, the effect is 5.42% for OH_2 and 31.49% for SH_2. As with electric field, *p* GPF have a minimal effect on field gradient, but this effect is somewhat larger than was the case for electric field. In addition it may be noted that *f* GPF have a substantial and unpredictable effect on the calculated field gradient. For example, the field gradient of OH_2 at the oxygen is increased by 17% on addition of a *p* GPF to an (*spd*/*s*) basis set but increased by 170% on

For personal use only.

addition of an *f* GPF. For SH_2 the effect of a *p* GPF is plus 11% whereas the subsequent effect of a *f* GPF is −25%.

In summary, Table 4 shows that the general trend for the effect of *d* GPF is electric field ($\langle 1/r^2 \rangle$) greater than field gradient ($\langle 1/r^3 \rangle$) much greater than potential ($\langle 1/r \rangle$). This may be contrasted with the general trend dipole moment ($\langle r \rangle$) approximately equal to third moment ($\langle r^3 \rangle$) much greater than second moment ($\langle r^2 \rangle$) noted before.

Potential, Electric Field, and Field Gradients at the H Atom

It is generally expected that the addition of a GPF to a particular nuclear centre will affect a property calculated at another nuclear centre. As shown in Table 5, the relative effect of *d*, *p*, and *f* GPF's on the properties calculated at the sulfur or oxygen atoms is consistent with this expectation. However, the properties calculated at the hydrogen atom are generally more affected by the addition of a *d* GPF to sulfur or oxygen than by the addition of a *p* GPF to hydrogen. Only four exceptions may be noted: the potential for OH_3^+ and the electric field for OH_2, SH_2, and SH_3^+.

The general trend for the effect of a *d* GPF is electric field approximately equal to field gradient much greater than potential. As well, the potential at the hydrogen atom is more affected by the *d* GPF than was the potential at the sulfur or oxygen atom. This indicates that the *s* basis set for hydrogen atom is not as adequate as the *sp* basis set for the heavy atom and also agrees with previous studies on optimal basis sets (4, 10). The *f* GPF is of little importance for the calculation of potential or electric field at the hydrogen. Although, *f* GPF's contribute from one-third to one-half as much as *p* GPF's, *f* GPF's are of less importance here than they were in the calculation of field gradients at the heavy atom nucleus.

Conclusions

Energy

While the energy decreases monotonically as it must for the addition of GPF's to a given centre, GPF's should be added in the order *d*, *p*, and *f* for maximum effectiveness.

Convergence of One-electron Properties

Both Mulliken population and net force (electric field) have a predictable convergence behaviour. In a Mulliken population analysis, the charge flows to the centre where the GPF is added. The convergence pattern for the net force on the nuclei is monotonic and similar to the pattern observed for total energy.

Although the multipole moments (dipole, second, and third moments) do not converge in a monotonic manner, if the basis sets are considered in the order (*sp*/*s*), (*spd*/*s*), (*spd*/*sp*), and (*spdf*/*sp*) there is an observable pattern. For all neutral and anionic species the value of the moment either increases or decreases when proceeding through the series (*sp*/*s*), (*spd*/*s*), (*spd*/*sp*). The value then reverses slightly on addition of a *f* GPF to the (*spd*/*sp*) basis set. For cationic species, a similar pattern can be observed for the (*sp*/*s*) to (*spd*/*sp*) series but on addition of a *f* GPF the value continues to either increase or decrease as before. That is, the *f* GPF reinforces the effect of *d* and *p* GPF's for cationic species. These patterns indicate that GPF's have a tendency to increase the magnitude of the electronic component of the dipole moment which in turn indicates increased charge separation. Increased charge separation cannot be obtained from a Mulliken population analysis with certainty except when changing an (*sp*/*s*) basis set to an (*spd*/*sp*) basis set.

The other one-electron properties have an unpredictable convergence behaviour. For example, although the field gradients of OH^-, OH_2, and OH_3 are all increased on addition of a *d* GPF, the subsequent addition of a *p* GPF causes an increase for OH^- and OH_2 but a decrease for OH_3^+. The final addition of an *f* GPF causes an increase for OH_2 and OH_3^+ but a decrease for OH^-. In addition the sulfur hydrides display a pattern different from the above.

Effectiveness

In almost every case there is a substantially greater effect when adding a *d* GPF rather than a *p* GPF. This suggests that an (*spd*/*s*) basis set is both more effective and more efficient than an (*sp*/*sp*) basis set.

Addition of a *d* GPF to an (*sp*/*s*) basis set has a larger absolute effect on the sulfur hydrides than on the oxygen hydrides. However, these effects are similar in percentage terms.

Except for the calculated field gradients, *f* GPF's have a small effect on the calculated properties of neutral and positively charged species.

The effect on the calculated properties of anions is substantially greater. Previous studies (11, 12) on anionic species have shown that additional diffuse *s* and *p* basis functions have a marked effect on the energy of anionic species but only a minimal effect on the neutral or positively charged species. Hence, it has been concluded that diffuse *s* and *p* basis functions are required to adequately represent anions. Here, the additional effect of an *f* GPF on the anion properties is likely due to the lack of such diffuse functions rather than the intrinsic need for an *f* GPF. For neutral and positively charged molecules, there appears to be little obvious advantage to

including *f* GPF in the basis set. The addition of an *f* GPF to an (*spd*|*sp*) basis set of OH^- increases the number of integrals to be evaluated from 26 796 integrals for the (*spd*|*sp*) basis set to 123 256 integrals for the (*spdf*|*sp*) basis set. Taking into account that *f* integral computation is approximately twice as slow as *d* integral computation and considering that the addition of one *f* GPF increases the integral computation time for OH^- by 720%, there is little economic justification for using *f* GPF's.

In terms of balance, reliability, and effectiveness, the best basis set to use for either oxygen or sulfur hydrides is an (*spd*|*sp*) basis set. For sulphur hydrides, the (*spd*|*s*) basis set will give relatively good results except for Mulliken population. The (*sp*|*sp*) basis should never be used.

GÉRALD PERRON, DANIEL JOLY, JACQUES E. DESNOYERS, LÉVON AVÉDIKIAN, and JEAN-PIERRE MOREL. Can. J. Chem. **56**, 552 (1978).

The thermodynamic pair interaction parameters of the ternary systems electrolyte (alkali halides and tetraalkylammonium bromides) – nonelectrolyte (*n*-alcohols and *tert*-butylalcohol) – water were measured at 25°C through enthalpies of solution, of mixing and of dilution, densities and heat capacities per unit volume. Some freezing point and electromotive force data were also combined with previously published data to obtain free energies. From these pair parameters the complete thermodynamics of the salting in and salting out of alcohols can be derived and were used to test various theoretical approaches. Most results are consistent with the cosphere overlap structural model, and the various trends can also be correlated through the scaled-particle theory.

GÉRALD PERRON, DANIEL JOLY, JACQUES E. DESNOYERS, LÉVON AVÉDIKIAN et JEAN-PIERRE MOREL. Can. J. Chem. **56**, 552 (1978).

Des mesures, effectuées à 25°C, d'enthalpie de dissolution, de mélange et de dilution, de densité et de capacité calorifique permettent le calcul des paramètres thermodynamiques d'interaction par paire dans les systèmes ternaires: électrolyte (halogénures alcalins, bromure de tétraalkylammonium) – non-électrolyte (alcools normaux et alcool *tert*-butylique) – eau. Certaines mesures d'abaissement du point de fusion et de force électromotrice conduisent, en utilisant des résultats déjà publiés, aux valeurs des enthalpies libres. Des paramètres d'interaction par paire, on peut déduire la thermodynamique complète du relargage des alcools et vérifier diverses théories. Les résultats proposés sont en accord avec ceux prévus par le modèle structural de recouvrement des cosphères d'hydratation. L'allure des variations des différentes grandeurs peut aussi être prédite par la théorie des particules calibrées (scaled particle).

Introduction

Electrolytes are known to modify the properties of nonelectrolytes in water. An example of this is the familiar salting effect. The several reviews (1–3) written in the last 25 years illustrate the large quantity of data that has been cumulated on this topic. Still, our understanding of these phenomena is far from satisfactory, and recently a number of vastly different theoretical approaches have been proposed with the claim that they can account at least semi-quantitatively for the experimental data (4).

The main difficulty with our understanding of the interactions between electrolytes and nonelectrolytes is that most investigations have been limited to free energies. Other thermodynamic properties can readily be obtained provided the nonelectrolytes are sufficiently soluble for direct measurements. This excludes most gases and alkanes, but alcohols are usually considered good substitutes in view of the similarity of the OH group with water.

Any property which measures the activities of the electrolyte, of the nonelectrolyte, or of water can be used in principle to determine the non-ideal free energies. For example, freezing point (4, 5) electromotive forces (6, 7), vapor pressures (8, 9), and distribution (10) measurements have all been used successfully to study ternary aqueous systems.

The purpose of the present study is to report enthalpies, heat capacities, and volumes of alcohols with alkali halides and tetraalkylammonium bromides in water. Some free energy data were also measured and combined with previously published data. The complete thermodynamics of the interactions between typical nonelectrolytes and electrolytes could then be derived.

Theoretical Relations

The usual way of expressing thermodynamic properties of ternary systems is in terms of transfer functions. For any function F the transfer of a nonelectrolyte N from pure water W to an electrolyte E solution can be expressed as $\Delta F_N(W \rightarrow W + E)$. If the component N is in the standard state (hypothetical ideal 1 mol kg^{-1} or infinite dilution), we

refer to standard transfer functions. In the particular case of free energies the standard function is related to the salting constant k_S by

$$[1] \qquad \Delta G_N^0(W \rightarrow W + E) = RTk_S m_E$$

provided the molality m_E of the electrolyte is relatively low (4). The factor 2.303 is usually added on the right-hand side of eq. 1.

To generalize to all thermodynamic functions it is advantageous to use a virial expansion in m (11–15) which related the non-ideal contribution of any total thermodynamic function to a series of pair (f_{NE}, f_{NN}, f_{EE}), triplet (f_{NNN}, f_{NNE}, ...), and higher order interaction parameters. For a transfer function it can readily be shown that

$$[2] \quad \Delta F_N(W \rightarrow W + E) = 2\nu f_{NE} m_E + 3\nu^2 f_{NEE} m_E^2 + 3\nu f_{NNE} m_E m_N + \ldots$$

where m_E and m_N are the molalities defined per kg of pure water and ν is the number of ions into which E dissociates. In many instances ν is included in the interaction parameters. For simplicity in deriving the equations E is not separated into its ionic components. A similar equation can be written for the converse transfer function,

$$[3] \quad \Delta F_E(W \rightarrow W + N) = 2\nu f_{NE} m_N + 3\nu f_{NNE} m_N^2 + 3\nu^2 f_{NEE} m_N m_E + \ldots$$

For standard functions the higher terms in m_N or m_E on the right-hand side of eqs. 2 and 3 vanish, and the limiting slopes of the standard transfer function, $2\nu f_{NE}$, must be identical for the two converse functions. This has been verified experimentally (16). For free energies it immediately follows from eqs. 1 and 2 that

$$[4] \qquad RTk_S = 2\nu g_{NE}$$

The pair and triplet interaction parameters are all readily measurable experimentally for any thermodynamic function. Most of the free energy data were obtained from the freezing point depression θ for the ternary and binary systems (4, 5) using the expression

$$[5] \quad \frac{RT\{\theta(m_N, m_E) - \theta(m_N) - \theta(m_E)\}}{1.858 m_N m_E} = 2\nu g_{NE} + \text{terms in } m_N \text{ and } m_E$$

or from the emf of a cell using a specific ion glass cathode and a silver – silver halide anode as described by Pointud *et al.* (7). In this latter technique the emf is measured for the electrolyte in water and also after the addition of N. Then it follows that the standard emf variation ΔU^0 is given by

$$[6] \quad -\mathcal{F}\Delta U^0/m_N = \Delta G_E^0(W \rightarrow W + N)/m_N = 2\nu g_{NE} + 3\nu g_{NNE} m_N + \ldots$$

where $\mathcal{F}$ is the Faraday.

For enthalpies, the parameters are derived either from enthalpies of solution or enthalpies of mixing and of dilution (15). In the first instance standard enthalpies of transfer are calculated from the standard enthalpies of solution of the solute in the binary mixture and in pure water;

$$[7] \quad \Delta H_N^0(W \rightarrow W + E)/m_E = 2\nu h_{NE} + 3\nu^2 h_{NEE} m_E + \ldots$$

and

$$[8] \quad \Delta H_E^0(W \rightarrow W + N)/m_N = 2\nu h_{NE} + 3\nu h_{NNE} m_N + \ldots$$

With the second technique, solutions in pure W, initially at molalities m_N and m_E, are mixed and the final molalities are $d_N m_N$ and $d_E m_E$, where d_N and d_E are the dilution ratios (d_N is equal to the weight of W in the initial solution of N divided by the weight of W in the final solution). From the enthalpy of mixing ΔH_M, expressed in J per kg of W in the final mixture, and the corresponding integral enthalpies of dilution of both components it follows that

$$[9] \quad \left\{\Delta H_M\begin{pmatrix} m_N \rightarrow d_N m_N \\ m_E \rightarrow d_E m_E \end{pmatrix} - d_N m_N \Delta H_N(m_N \rightarrow d_N m_N) - d_E m_E \Delta H_E(m_E \rightarrow d_E m_E)\right\} \Big/ d_N d_E m_N m_E = 2\nu h_{NE} + 3\nu h_{NNE} m_N + 3\nu^2 h_{NEE} m_E + \ldots$$

For volumes and constant pressure heat capacities the parameters are given by the apparent molal quantities at low m_N in the ternary and binary systems (17, 18);

$$[10] \quad \{\phi_{V_N}(m_E, m_N) - \phi_{V_N}(m_N)\}/m_E = 2\nu v_{NE} + 3\nu^2 v_{NEE} m_E + \ldots$$

and

$$[11] \quad \{\phi_{C_N}(m_E, m_N) - \phi_{C_N}(m_N)\}/m_E = 2\nu c_{NE} + 3\nu^2 c_{NEE} m_E + \ldots$$

Similar equations can be written for the apparent molal quanities of E in solution of W + N.

The pair interaction parameters are related to each other in the usual way. Assuming c_{NE} to be independent of temperature, the enthalpic pair parameter at temperature T is given by

$$[12] \qquad h_{NE}^T = h_{NE}^{T_0} + c_{NE}(T - T_0)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where T_0 is a reference temperature, usually 298.15 K. From the Gibbs–Helmholtz equation it also follows that the free energy parameter $g_{NE}{}^T$ at any temperature is given by

$$[13] \quad g_{NE}{}^T = (T/T_0)g_{NE}{}^{T_0} + \frac{T_0 - T}{T_0} h_{NE}{}^{T_0} - \left\{T_0 - T + T \ln \frac{T}{T_0}\right\} c_{NE}{}^{T_0}$$

Depending on the units of $c_{NE}{}^{T_0}$ the last term of eq. 13 is sometimes divided by T_0. Similarly the value of $g_{NE}{}^P$ at any pressure is given by

$$[14] \quad g_{NE}{}^P = g_{NE}{}^{P_0} + v_{NE}(P - P_0)$$

For a large range of pressures, compressibility parameters would also have to be considered. From a knowledge of $g_{NE}{}^T$ and $g_{NE}{}^P$ and eq. 4, the salting constant can be calculated over a large range of temperature or pressure (5). From the parameters g_{NE} and h_{NE} it is also straightforward to obtain the entropies,

$$[15] \quad s_{NE} = (h_{NE} - g_{NE})/T$$

Experimental

The procedure for the measurement of free energies has been described elsewhere (4, 7). The freezing point technique is in general quite reliable for differential measurements (4) but can lead to larger uncertainties with *n*-pentyl alcohol. This alcohol has a strong tendency to unmix especially in the presence of NaCl and it was hard to reproduce the freezing temperatures. In addition triplet interactions become important at relatively low concentrations with the long-chain alcohols, and again this may lead to larger uncertainties in the determination of g_{NE}.

Enthalpies have been measured with an LKB precision calorimeter and a flow microcalorimeter as described elsewhere (15). In the heat of mixing technique corrections have to be made for enthalpies of dilution of both binary systems. In general this presented no difficulty and the parameter h_{NE} was determined with reasonable precision. For alcohols the heats of dilution were remeasured but for the electrolytes literature values were used (22, 23). With a few alkali halides the heat of dilution had not been measured previously in our laboratory and it was more difficult to estimate the uncertainty on these literature data. The largest uncertainty arises with the large alcohols and R_4NBr since here the corrections for the enthalpies of dilution become quite important. Still, as it will be shown in the next section, the agreement with the enthalpy of solution method is in general quite satisfactory.

The volumes and heat capacities (19–21) presented no special problem. In all cases the densities and heat capacities per unit volume were repeated for the corresponding binary systems to minimize sources of errors. In all cases where data on the binary systems were available in the literature the agreement of the new data was within the experimental error.

The origin and purification of chemicals and general procedure for the preparation of solutions have all been given elsewhere (4, 5, 7, 24, 25).

Results

In this study on ternary aqueous sytems the chosen nonelectrolytes were alcohols and the electrolytes were alkali halides and tetraalkylammonium bromides. For *tert*-butylalcohol (TBA) the effect of additivity of the pair parameters and the effect of ionic size were investigated. With NaCl the effect of nonelectrolyte size was examined. The following solutes were therefore used: alkali chlorides (MCl), KI, KBr, sodium halides (NaX), the five first symmetrical tetraalkylammonium bromides (R_4NBr), the first five normal alcohols (ROH) and TBA.

The free energies obtained from freezing point data (4, 5), electromotive force (6, 7), and distribution studies at 20°C (10) are compared in Table 1. The parameters g_{NE} at the freezing point were corrected to 298.15 K with eq. 13. Some discrepancy was observed between the different sets of data, especially with RbCl and CsCl. These measurements were repeated by both techniques[2] (freezing point and emf) and the differences essentially disappeared. The only disagreement remaining which is probably larger than the experimental uncertainty is with NaCl and NaBr. Although they were repeated g_{NE} still differ by 40 J mol^{-2} kg. However, the trends in g_{NE} with ionic size are hardly affected by this difference.

The enthalpies of mixing[2] were determined for variable m_N and m_E in the range 0.1 to 1 mol kg^{-1}. For most systems the enthalpies of transfer of both N and E were measured for the same concentration range of the variable component. Some examples of the function $\Delta H^* = 2v h_{NE} + 3v h_{NNE} m_N + 3v^2 h_{NNE} m_E + \ldots$ are shown in Fig. 1 for the enthalpies of mixing and enthalpies of solution. The agreement is quite good considering that with the enthalpies of solution one of the components is at a much lower concentration than in the mixing experiments. Both sets of data were analysed separately. The enthalpies of transfer were assumed to be standard values (final concentration is of the order of 0.01 mol kg^{-1}) and the pair parameters were obtained through a least-squares treatment using eq. 7 or eq. 8. For the mixing data the function ΔH^* was treated by least-squares using a function of the type $Z = a + bx + cy$. The parameters h_{NE}, given in Table 1 for both sets of data, are in excellent agreement. On the other hand the agreement is less satisfactory for the triplet interaction parameters derived from both approaches and in some cases even the signs are different. These

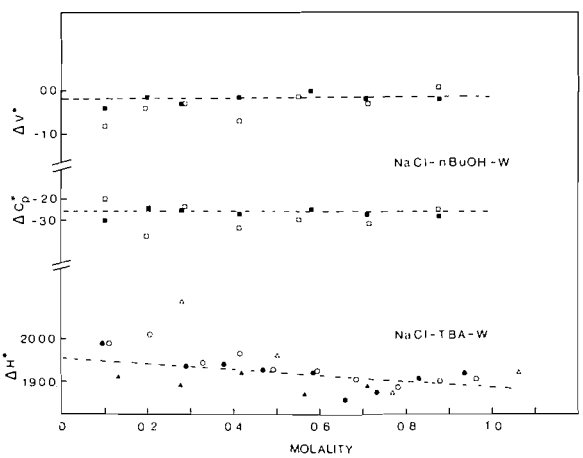

FIG. 1. Dependence of the functions $\Delta F^* = 2vf_{NE} + 3vf_{NNE}m_N + 3vf_{NEE}m_E + \ldots$ on m_N and m_E at 25°C: □, *n*-BuOH in NaCl (variable component); ■, NaCl in *n*-BuOH; ○, mixing of NaCl with TBA, NaCl variable; ●, mixing of NaCl with TBA, TBA variable; △, enthalpies of solution of TBA in NaCl; ▲, enthalpies of solution of NaCl in TBA.

parameters are in general small and are associated with a large uncertainty. All we can say at this stage is that h_{NNE} is zero or negative with all the systems investigated while h_{NEE} are also small but sometimes positive and sometimes negative.

The volumes and heat capacities were measured for a fixed m_N (0.25 mol kg^{-1}) and a variable m_E between 0.1 to 1 mol kg^{-1}. It has been verified that under these conditions the triplet terms $3vv_{NNE}m_N$ and $3vc_{NNE}m_N$ contribute little to the overall data. Examples of the functions $\Delta V^* = 2vv_{NE} + 3v^2v_{NEE}m_E + \ldots$ and $\Delta C^* = 2vc_{NE} + 3v^2c_{NEE}m_E + \ldots$ are shown in Fig. 1. The original data for densities and heat capacities per unit volume are also available elsewhere.[2] The pair interaction parameters obtained from a least-squares fit are given in Table 1. The entropic pair parameters derived from g_{NE} and h_{NE} using eq. 15 are also given in Table 1.

The pair parameters should, by definition, be additive for various ionic pairs. The additivity test was verified for g_{NE} at the freezing temperature elsewhere (4). The values from emf measurements also show very good additivity although the differences between various pairs are slightly different for both sets of data. The parameters h_{NE}, v_{NE}, and c_{NE} show little ionic size dependence and the differences between pairs are therefore rather small. Still the additivity test, combined with a comparison of parameters obtained by various techniques, serves as an indication of the accuracy of the parameters: g_{NE}, ±20 J mol^{-2} kg; h_{NE}, ±20 J mol^{-2} kg; v_{NE}, ±0.05 cm^3 mol^{-2} kg; c_{NE}, ±1 J K^{-1} mol^{-2} kg.

Discussion

It was shown that the salting out (4) and salting in (5) of alcohols by alkali halides and tetraalkylammonium bromides follow the same general pattern as typical nonelectrolytes such as benzene or alkanes. It is therefore reasonable to expect that the trends observed with all the thermodynamic parameters will be similar to those of nonpolar nonelectrolytes.

The pair parameters for the NaCl–ROH–W system are plotted against the standard partial molal volumes of the alcohols $\bar{V}^0_{ROH}$ (26) in Fig. 2. Inside the experimental uncertainty all the parameters are linear function of $\bar{V}^0_{ROH}$ of normal alcohols and pass through the origin. This is the kind of behavior we would expect from the McDevit and Long theory (1). Electrostatic type theories (3) and the scaled-particle theory (6, 27–29) also predict a strong dependence on the size of the nonelectrolyte but the functions do not necessarily pass through the origin. The data for TBA or *n*-PenOH are slightly out of line. It could be that a better linear function exists with the $\bar{V}^0$ of MeOH, EtOH, *i*-PrOH, TBA, etc. but the uncertainty on the data is too large to prove this.

The pair parameters for the system MCl–TBA–W, NaX–TBA–W, and R_4NBr–TBA–W are given as a function of the cationic and anionic size in Fig. 3; g_{NE}, h_{NE}, and Ts_{NE} are not shown for NaX for clarity of presentation. The data points for the variable anions are very similar to the cationic size dependence. While g_{NE} shows a significant ionic size dependence, becoming negative with the R_4NBr, the other parameters shown relatively little size dependence with the alkali halides. On the other hand, h_{NE}, c_{NE}, and v_{NE} show a very large dependence on the cationic size of R_4NBr. These trends are remarkably similar to the transfer functions of electrolytes from water to urea–water (U + W) mixtures and to D_2O (D) (30–36). These transfer functions are also rather insensitive to the ionic size with alkali halides (except with Li^+ and I^- which are usually out of line) and very dependent on the size of the R_4NBr. The simplest way of seeing the similarities and differences between these functions is to compare the pair parameters for TBA and U with the transfer functions $\Delta F^0_E(W \rightarrow D)$ for the three electrolytes NaCl, Me_4NBr, and Bu_4NBr; pair interaction parameters were derived from the transfer functions $\Delta F^0_E\{W \rightarrow W + U)$.

It is interesting to compare these three systems since TBA is usually considered a typical hydrophobic structure maker, U a structure breaker, and D_2O more structured than H_2O, at least at low temperatures.

The first observation we can make from the data in Table 2 is that for all alkali halides the sign of the

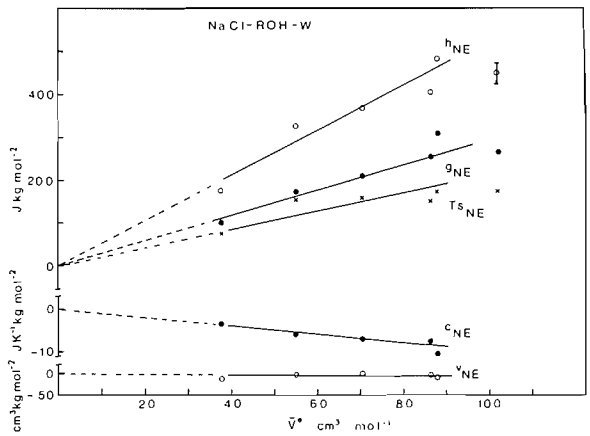

FIG. 2. Dependence of pair functions of NaCl on the standard partial molal volumes of the alcohols.

pair parameters f_{NE} for TBA are always opposite f_{NE}(U) and of the same sign as $\Delta F^0_E(W \rightarrow D)$. This is also true for Me_4NBr for all the properties except for the parameter g_{NE}(TBA) which is slightly negative. The situation is more complex with Bu_4NBr (and the other large R^4NBr). The parameters v_{NE}(TBA) and c_{NE}(TBA) are again opposite those for U and the same as $\Delta V^0_E(W \rightarrow D)$ and $\Delta C^0_E(W \rightarrow D)$. Such relations do not exist with free energies, enthalpies, and entropies; h_{NE}(TBA) and s_{NE}(TBA) now have the same sign as U and opposite sign to the transfer functions to D_2O, and g_{NE}(TBA), g_{NE}(U), and $\Delta G^0_E(W \rightarrow D)$ are all negative.

Although h_{NE} and s_{NE} for the systems TBA–Bu_4NBr and U–Bu_4NBr have the same sign, they are not reflecting similar interactions. It was shown (36) that $\Delta H^0_{Bu_4NBr}(W \rightarrow W + U)$ decreases rapidly with temperature and probably changes sign above 50°C. The opposite was observed with $\Delta H^0_{Bu_4NBr}(W \rightarrow D)$ and $\Delta S^0_{Bu_4NBr}(W \rightarrow D)$. On the other hand, the temperature dependence of h_{NE} can readily be calculated from eq. 12 and, as seen from Fig. 4, it increases significantly with temperature with the more hydrophobic R_4NBr. If the temperature dependences of c_{NE} were known, h_{NE} would most probably show some curvature as a function of temperature.

It is relatively easy to find a model or theory that can account for the sign, magnitude, and trends if only one property and one chemical system is examined. It is much more difficult to find such a model or theory if we try to account for all the thermodynamic properties with typical hydrophobic and hydrophilic, ionic and non-ionic solutes.

The parameters f_{NE} represent the contribution to the thermodynamic function F when the two solutes N and E approach each other from infinity to some critical distance. Contributions will arise from inter-

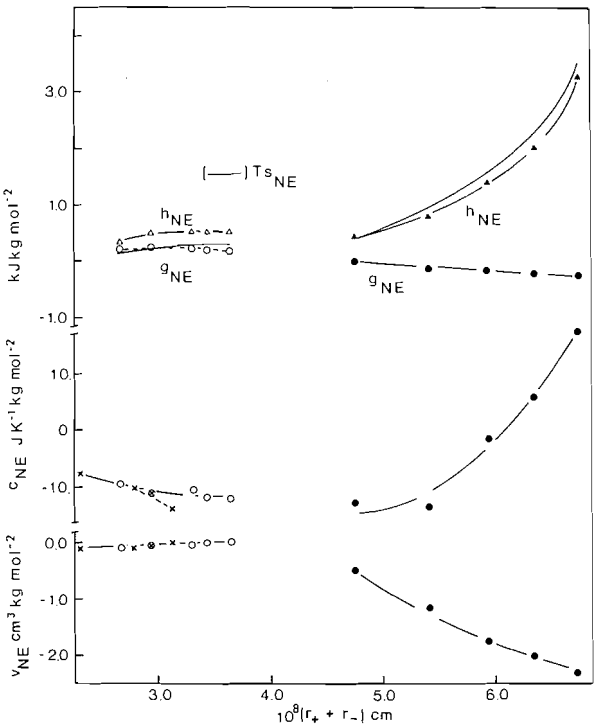

FIG. 3. Dependence of pair functions of TBA on the sum of ionic radii: △ and ○, MBr; ×, NaX; ▲ and ●, R_4NBr; data not shown for the NaX with g_{NE}, h_{NE}, and Ts_{NE} (see text).

actions such as charge-dipole, polarization, and dispersion forces and also from modification of the solute–solvent interactions.

Most electrostatic theories of the salting effect can explain reasonably well the dependence of g_{NE} or k_S on the charge and size of the ions and on the size and polarity of the nonelectrolytes (1–3). However, they fail to account for the salting in by R_4NBr (5) of solutes which lower the relative permittivity of the solvent and which are salted out by inorganic salts. They also generally fail to account for the trends, magnitude, and sometimes even the sign of the other functions, h_{NE}, s_{NE}, v_{NE}, and c_{NE}. The probable explanation for this failture is that while electrostatic interactions may be the leading contribution to g_{NE}, these interactions do not vary significantly with temperature and pressure. On the other hand, structural hydration interactions (related to the modification of the overall solute–solvent interactions) do not have a large contribution to g_{NE} or k_S but, being quite temperature dependent, rapidly becomes the leading effect with the other functions.

The concept of structural interactions, introduced by Frank and Robinson (37) in 1940, has been used successfully by many authors to explain the anomalous concentration dependence of thermodynamic functions of electrolytes in water (24, 38). The same

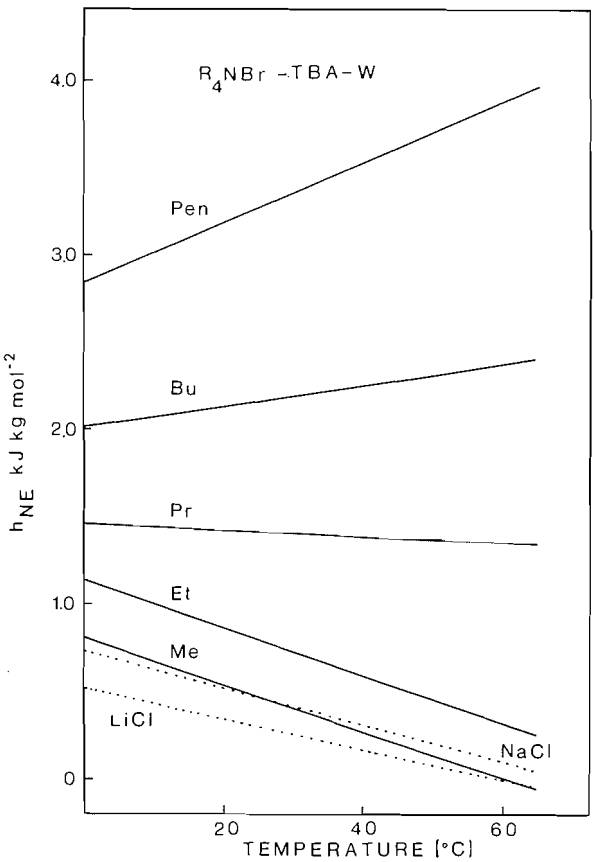

FIG. 4. Dependence of h_{NE} for the systems R_4NBr–TBA–W on temperatures.

idea was used to interpret salting in by R_4NBr (39), the transfer functions of electrolytes to TBA–W mixtures (17) and to U–W mixtures (30). For example h_{NE} for the two hydrophobic solutes Bu_4N^+ and TBA will have the same sign as the pair parameters h_{NN} and h_{EE} (obtained from enthalpies of dilution) since they are all reflecting hydrophobic–hydrophobic interactions. This explains why h_{NE} has a sign different from $\Delta H^0_E(W \rightarrow D)$ since this latter function is reflecting differences in solute–solvent interactions. A general discussion of these structural interactions is given elsewhere (18). The signs of all the pair parameters can be explained with this approach. In most cases, the overlap of the cospheres are destructive in that the net effect is the reduction of the hydration contribution of both solutes. Pair functions related to second derivatives of the free energy (heat capacities, expansibilities, and compressibilities) are more complicated in that they cannot be accounted for with a simple destructive overlap approach; new interactions must be called upon.

Friedman and co-workers (38, 40) have treated structural interactions quantitatively by introducing a contribution (Gurney term) to the potential of average force, from which the solute pair correlation function is obtained, using the hypernetted chain equation. Franks and co-workers (41, 42) have extended this approach to mixtures of alcohols and their results are not inconsistent with the existence of some cooperative effects. Unfortunately there is at present no way of predicting the Gurney terms which must be derived from the experimental data. While this is a small term with excess free energies of electrolyte solutions, it becomes the leading term with excess heat capacities of R_4NBr (43) and with ternary systems (40). Therefore, although the statistical thermodynamic theories in terms of a potential of average force between the solute molecules is the logical approach to account for the pair interaction parameters, these theories are not very useful at present since we cannot predict from basic principles the Gurney terms.

The most successful theories for the prediction of the pair interaction parameters are, probably at present, those based on a thermodynamic approach. McDevit and Long (1) have related the salting out effect to the energy necessary to create a cavity in a medium characterized by ion–solvent interactions. This theory has been refined recently by Cross (44), and it can account for the salting out of various nonelectrolytes up to very concentrated KOH solutions. However, this theory fails to account for salting in by R_4NBr (5), and it is also difficult to extend it to thermodynamic functions other than free energies.

The scaled-particle theory (SPT), as applied to aqueous systems by Pierotti (45), was shown to account for the salting out and salting in of gases (27, 28), and of alcohols (6, 10) and for the temperature dependence of the salting effect (5, 29). Using reasonable values for the size parameters, Philip and Jolicoeur (46) have shown that this theory explains most of the transfer functions of R_4N^+ from H_2O to D_2O and Desrosiers and Desnoyers (47) applied it to the transfer functions of Bu_4N^+ from water to TBA–W and U–W mixtures. In all cases the agreement with experiment is amazingly good. In this approach the thermodynamic functions are calculated in three steps: formation of a cavity in the solution, transfer of the solute in the cavity, and interaction of the solute with the molecules in the solvent. For g_{NE} and h_{NE} the interaction terms are important but for the other functions the cavity term rapidly becomes the leading one.

The SPT is probably the only theory which can predict nearly quantitatively the pair interaction parameters and many transfer functions over a large concentration range of cosolvent for polar and nonpolar nonelectrolytes, for simple and hydrophobic

electrolytes, and for all thermodynamic functions. Still this theory is not ideal and can be criticized on many aspects. It is very sensitive to the choice of the molecular diameters of the various components and the interaction energy parameters required are not always easy to evaluate. However, the main drawback of this theory is that the experimental mixed-solvent density is introduced to account for the attractive forces in the system, and, as a result, much of the information on solute–solvent and solute–solute interactions is lost in the process. The SPT is therefore more of a correlation device between thermodynamic properties of ternary and binary solutions (g_{NE} is related to the apparent molal volume ϕ_V of the electrolyte solution, h_{NE} to the apparent molal expansibility ϕ_E, and c_{NE} to $d\phi_E/dT$), and sometimes the binary data ($d\phi_E/dT$) might be more difficult to measure than the ternary data (c_{NE}).

The thermodynamic theory based on surface tension (10) is also successful but f_{NE} are not correlated to factors that are readily accessible and such an approach again does not give us much insight on the interactions on the molecular level.

Crystal structure of methyl,2-mercaptopyrimidinatomercury(II)

CHUNG CHIEH

Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received August 19, 1977

CHUNG CHIEH. Can. J. Chem. **56**, 560 (1978).

Methyl,2-mercaptopyrimidinatomercury(II) was synthesized from methylmercuric hydroxide and 2-mercaptopyrimidine in aqueous solution. The crystal is orthorhombic with $a = 4.063(2)$, $b = 9.901(4)$, $c = 18.808(15)$ Å, $D_m = 2.88(1)$, $Z = 4$, $D_c = 2.867$ g cm^{-3}, space group $P2_12_12_1$. The structure was solved by the heavy atom method using 605 diffractometer measured reflections. The final R factor was 0.069. The key bond lengths and angles are: Hg—S, 2.39(2) Å, Hg—CH_3, 2.13(6) Å, ∠SHgC, 174°. The CH_3HgS— group bends out of the plane of the pyrimidine ring and the Hg atom interacts rather strongly with one of the ring nitrogens with an Hg—N distance of 2.83 Å. However, the Hg...N interaction is very labile in solution, since the two hydrogen atoms in the *meta* positions are equivalent from the ^{1}H nmr spectra in both $CDCl_3$ and DMSO solutions. The solution of the compound is not optically active.

CHUNG CHIEH. Can. J. Chem. **56**, 560 (1978).

On a effectué la synthèse du mercapto-2 pyrimidinatomercure(II) de méthyle à partir de l'hydroxyde de méthylmercure(II) et de la mercapto-2 pyrimidine en solution aqueuse. Les cristaux sont orthorhombiques avec $a = 4.063(2)$, $b = 9.901(4)$, $c = 18.808(15)$ Å, $D_m = 2.88(1)$, $Z = 4$, $D_c = 2.867$ g cm^{-3}, groupe d'espace $P2_12_12_1$. On a résolu la structure par la méthode des atomes lourds utilisant 605 réflexions mesurées par un diffractomètre. Le facteur final R est de 0.069. Les longueurs de liaisons et les angles les plus importants sont: Hg—S, 2.39(2) Å, Hg—CH_3, 2.13(6) Å, ∠SHgC, 174°. Le groupe CH_3HgS se trouve à l'extérieur du plan du cycle pyrimidine et l'atome Hg interagit d'une façon assez forte avec un des azotes du cycle avec une distance Hg—N de 2.83 Å. Toutefois, l'interaction Hg...N est très labile en solution puisque les deux atomes hydrogène en position *meta* sont équivalents dans les spectres rmn ^{1}H soit en solution dans le $CDCl_3$ soit dans le DMSO. La solution du composé n'est pas optiquement active.

[Traduit par le journal]

Introduction

Numerous sulfur-substituted pyrimidines and purines have found applications as clinically useful drugs. Many sulfur derivatives of nucleic acid have shown anticarcinogenic properties (1). Because 6-mercaptopurine had been used in the treatment of acute lymphocytic and chronic mylelocytic leukemias, interest in other sulfur derivatives of purines and pyrimidines remains high (2). Recently, anticarcinogenic activities were found for palladium and bismuth complexes with 6-mercaptopurine; but the platinum complex was not active (3). We have been interested in the interaction of sulfur-containing drugs with mercurials (4) and have studied the reaction between methylmercuric hydroxide and 2-mercaptopyrimidine. The mercaptopyrimidines are interesting intermediates in many reactions (5). Methylmercury does not form stable coordination complexes with nitrogen bases such as pyridine (6). It is predictable that methylmercury will bind to the deprotonated thio-group of 2-mercaptopyrimidine, but it was not known how the nitrogen atoms on the ring will interact with the mercury.

Experimental

Methylmercuric hydroxide from Ventron, 2-mercaptopyrimidine from Aldrich Chemical and solvents of standard reagent grade were used.

When two aqueous solutions containing (not completely dissolved) 0.3 g 2-mercaptopyrimidine and 0.62 g methylmercuric hydroxide were mixed, a fine white precipitate was obtained leaving a clear colorless filtrate. The fine prismatic crystals were soluble in ethanol, chloroform, acetone, and benzene. Recrystallization by slow evaporation of an ethanol solution gave crystals of suitable size for X-ray diffraction studies. Crystals of the same form were also obtained by slow evaporation of the filtrate.

Photographic methods were used to estimate the unit cell constants. These were refined based on the 2θ (Zr-filtered Mo Kα) values of 22 reflections measured on a G.E. XRD-6 diffractometer.

Crystal Data

$C_5H_6HgN_2S$ fw = 326.7

Orthorhombic space group $P2_12_12_1$, $a = 4.063(2)$, $b = 9.901(4)$, $c = 18.808(15)$ Å, $V = 756.6$ Å^3, $D_m = 2.88(1)$ (by flotation), $Z = 4$, $D_c = 2.867$ g cm^{-3}. Systematic absences: $h00$, $h = 2n + 1$; $0k0$, $k = 2n + 1$; $00l$, $l = 2n + 1$. μ(Mo Kα) = 209 cm^{-1}; λ(Mo Kα) = 0.7107 Å.

The crystal used was approximately a cube with edges of 0.15 mm. Intensities were measured with Zr-filtered Mo Kα

radiation on a G.E. XRD-6 card-controlled diffractometer. A θ–2θ scan method at 2° m^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Backgrounds were measured at both limits of scan for 10 s. Among 819 reflections ($2\theta < 60°$) measured, 605 (74%) had net intensities greater than $3\sigma(I)$; these reflections were used throughout the structural analysis.

The Patterson map had three intense peaks at (0, 0.094, 0.5), (0.5, 0.5, 0.163), and (0.5, 0.407, 0.337). This is in agreement with the space group assignment of $P2_12_12_1$. With mercury atom alone, the agreement between calculated and measured structure factors was good, $R = 0.18$ ($\Sigma||F_o| - |F_c||/\Sigma|F_o|$). Including the sulfur in the calculation lowered R to 0.15. Poorly resolved peaks due to other atoms were not very intense in the Fourier map based on the phase from Hg and S atoms. Atoms in the pyrimidine ring were put in where both electron density and bonding appeared reasonable. Refinement based on data before absorption correction gave an R of 0.09. After this correction, according to ref. 7, the R became 0.073 with anisotropic temperature factors for all atoms. However, the bond lengths and angles from the two refinements were similar. At the final stage, a weighting function $w^{-1} = 40.0 - F_o + 0.01\,F_o^2$ was introduced. The atomic scattering factors (8) with an anomalous scattering correction for the mercury atom (9) were used. The final R and $R_w = (\Sigma w^2(|F_o| - |F_c|)^2/\Sigma w^2|F_o|^2)^{1/2}$ were 0.069 and 0.082 respectively. The final atomic coordinates are given in Table 1.[1]

TABLE 1. Final atomic coordinates with standard deviations x, y, z; $0.5 - x, \bar{y}, 0.5 + z$; $0.5 + x, 0.5 - y, \bar{z}$; $\bar{x}, 0.5 + y, 0.5 - z$

Results and Discussion

The Molecule

The crystal consists of individual molecules. The important bond distances and angles are given in Fig. 1, which is also a packing diagram. The methylmercury group is on one side of the ring plane with a dihedral angle ∠HgSCN(2) of 14.8°. This arrangement gives rise to the chirality of the molecule.

The mercury is 1.4 Å from the least-squares plane of the ring. The equation of the plane is

$$0.8877X + 0.4572Y + 0.0539Z = 4.8$$

(X, Y, and Z are coordinates in Å referred to a, b, and c axes) and the maximum displacement of the atoms from the plane is 0.10 Å. The distances are normal when compared to those in 2,4-dimercaptopyrimidine (10) within experimental error.

The Hg—N(2) distance of 2.83(3) Å indicates a rather strong interaction because the sum of the van der Waals radii for the two atoms is 3.00 Å. The ∠HgSC(4) and ∠SC(4)N(2) angles are 107.7(8) and 114(1)° respectively, whereas the corresponding angles are 109.8(1) and 125.8(3)° in dichlorobis(6-mercaptopurine)mercury(II) (11). In the latter compound, there is no Hg—N coordination; but the mercury(II) ion is coordinated to two sulfur and two chlorine atoms. Therefore, it can be concluded that the short distance is due to the affinity between the N and Hg atoms and is not a consequence of intramolecular stress. However, the coordination is very weak. The Hg—N distances are 2.13(3) and 2.06(4) Å in μ-DL-penicillaminatobis(methylmercury(II)) (12) and (DL-methioninato)methylmercury(II) (13) respectively. For both compounds, the methylmercury groups are bonded to the amino groups.

The nmr spectrum of the hydrogen attached to C(2) (see Fig. 1) is a triplet. The hydrogen atoms attached to C(1) and C(3) are equivalent for 2-mercaptopyrimidine and methyl,2-mercaptopyrimidinatomercury(II) in DMSO or chloroform solutions; the spectrum is a doublet. Since the two hydrogens at the *meta* positions are equivalent in both $CDCl_3$ and DMSO solutions, the Hg...N interaction must be labile. The chemical shifts are listed in Table 2. As expected, the bonding of CH_3Hg— to the sulfur causes a downfield shift. The net shifts are larger for the *para* than for the *meta* hydrogens. The ^{1}H nmr spectra using DMSO-d_6 as solvent indicated the presence of a small quantity of bis(2-mercaptopyrimidinato)mercury(II) in the product as described in the Experimental section. The net downfield shifts for this compound are larger than for those of methyl(2-mercaptopyrimidinato)mercury(II). However, the spectrum of bis(2-mercaptopyrimidinato)-mercury(II) was not observed when using $CDCl_3$ as a solvent, probably due to its limited solubility.

The Packing

Historically, Louis Pasteur investigated the molecular asymmetry and crystallization before crystallography was developed (14). Optically pure compounds crystallize in assymmetric space groups. The enantiomers of some synthetic compounds may grow separately in different crystals resulting in asymmetric space groups: among them, $P2_12_12_1$ is the most common with $P2_1$ being next (15). As an

example, the racemic form of (4*aRS*,4*bSR*,13*bRS*)-12-bromo-1-(*p*-brophenyl)-1,4*a*,4*b*,5,6,13*b*-hexahydro-4*H*-dipyridazino-[1,6-*a*:4,3-*c*]quinoline crystallizes in $P2_1/c$, whereas the optical pure substance crystallizes in $P2_12_12_1$ (16). There are slight but significant differences in intramolecular non-bonding distances and bonding angles in the two crystal structures. Another similar example is provided by the crystallization study of 3-benzylamino-4-hydroxypent-2-enoic acid lactone hydrobromide. This compound crystallizes from methanol solution in space group $P2_1$ and solutions of a single crystal showed positive or negative rotation of polarized light. However, the hydrochloride analog crystallizes in $P2_1/c$ (17).

Due to the very high absorption coefficient, μ, and the low accuracy of the intensities, the absolute configuration was not determined. However, neither solutions of 2-mercaptopyrimidine or methyl,2-mercaptopyrimidinatomercury(II) were optically active.

If the crystals are recognizable by hemihedry, resolution of the enantiomers may then be achieved by separating the crystals through optical observation (17). A number of heterohelicenes were obtained in optically active forms by crystal picking (18, 19). These compounds were found to show very high optical rotations due to the presence of an inherently dissymmetric chromophore. However, resolution of optical isomers is usually achieved by diastereomer formation (20).

The molecules in this structure, Fig. 1, pack in a normal way and are similar to many molecular structures such as diphenyl ditelluride and *p*-tolylsulfide do (21, 22). Only van der Waal intermolecular contacts were observed.

Crystal structure of mercury(II) bromide dithiocarbamate, $[HgBr_2(S_2CNEt_2)Hg(S_2CNEt_2)]_n$, an inorganic polymer

CHUNG CHIEH

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2M 3G1

Received September 8, 1977

CHUNG CHIEH. Can. J. Chem. **56**, 564 (1978).

A pale yellow crystal obtained from reaction of $HgBr_2$ and tetraethylthiuram disulfide (TETD) has the composition of $HgBr_2{\cdot}Hg[S_2CN(C_2H_5)_2]_2$. TETD was reduced to dithiocarbamate. The molecules are polymeric chains with $HgBr_2$ and Hg^{2+} alternately bridging to dithiocarbamate ions and vice versa. The crystal is monoclinic: a = 10.421(7), b = 15.244(13), c = 14.649(8) Å, β = 113.3(1)°; space group $P2_1/c$. The final R factor for 2085 observed reflections is 0.083. There are two types of coordination geometries for the mercury(II) ions in the crystal: the coordination for one is digonal with two short Hg—S distances of 2.385(11) and 2.365(10) Å. The coordination for the other is tetrahedral with two Hg—S, 2.552(10) and 2.569(10) Å, and two Hg—Br, 2.640(4) and 2.552(7) Å, bonds. The average C=S distance is 1.72(4) Å.

CHUNG CHIEH. Can. J. Chem. **56**, 564 (1978).

Un cristal jaune pâle obtenu par réaction de $HgBr_2$ avec le disulfure de tétraéthylthiurame (TETD) a la composition $HgBr_2{\cdot}Hg[S_2CN(C_2H_5)_2]_2$; le TETD a été réduit en dithiocarbamate lors de la réaction. Les molécules existent alors sous forme de chaînes de polymères contenant en alternance $HgBr_2$ et Hg^{2+} qui servent de pont aux ions dithiocarbamates et vice versa. Le cristal est monoclinique a = 10.421(7), b = 15.244(13), c = 14.649(8) Å, β = 113.3(1)°; groupe d'espace $P2_1/c$. Le facteur d'accord R pour 2085 réflexions observées est de 0.083. Il y a deux types de géométrie de coordination pour les ions mercure(II) dans le cristal: la coordination dans l'un est digonale avec deux distances Hg—S courtes de 2.385(11) et 2.365(10) Å. La coordination de l'autre est tétraédrique avec deux Hg—S, 2.552(10) et 2.569(10) Å, et deux Hg—Br, 2.640(4) et 2.552(7) Å. La distance moyenne C=S est de 1.72(4) Å.

[Traduit par le journal]

Introduction

The conversion of tetraethylthiuram disulfide, $R_2NCS_2S_2CNR_2$, and dithiocarbamate, $R_2NCS_2^-$, is relatively easy according to the equation: $2R_2NCS_2^- \rightarrow R_2NCS_2S_2CNR_2 + 2e$. Oxidation of dithiocarbamato complexes of mercury with halogen results in the oxidation of the ligand yielding thiuram disulfide complexes (1). However, the reactions of mercury(II) halides with tetraethylthiuram disulfide (TETD) often yield dithiocarbamato complexes (2, 3). The reaction of mercury(II) bromide and TETD yielded colorless and pale-yellow crystals. The former is $HgBr_2{\cdot}$TETD which is isostructural with $HgI_2{\cdot}$TETD. The orthorhombic cell constants for $HgBr_2{\cdot}$TETD are: a = 13.050, b = 13.593, c = 22.373 Å.

Crystallographic results indicated that the pale-yellow crystal is a compound of composition $Hg_2Br_2[S_2CN(C_2H_5)_2]_2$. This paper reports the crystal structure.

Experimental

When two ethanolic solutions of $HgBr_2$ and TETD were mixed at 25°C, a white precipitate was obtained. Recrystallization of the precipitate in ethanol–chloroform (1:1 by volume) gave two kinds of crystals. One was colorless and the other pale yellow. The latter were subjected to crystallographic studies. The space group was determined from preliminary photographs. Cell constants were estimated from the same, and then refined by least-squares methods from the 2θ values of 38 reflections measured on a G.E. XRD-6 diffractometer, which was used to measure the intensities of the reflections. Crystal data are as follows.

$Br_2C_{10}H_{20}Hg_2N_2S_4$ fw = 857.4

Monoclinic, a = 10.421(7), b = 15.244(13), c = 14.649(8) Å, β = 113.3(1)°, V = 2137.3 Å^3. D_o = 2.65 (by flotation), Z = 4, D_c = 2.664 g cm^{-3}. Systematic absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$; space group $P2_1/c$ (C_{2h}^5, No. 14). μ(MoKα) = 189.8 cm^{-1}. λ(MoKα) = 0.7107 Å.

The crystal used for intensity measurements was a thin square plate with dimensions of 0.18 × 0.20 × 0.06 mm along a, b, and c directions. It was mounted with b^* along the ϕ axis of the goniometer. The faces developed were {110} and {001}. These data were used for absorption corrections (4). The range of μR is 1.1 to 3.9. There were 2085 observed among 3744 reflections with 2θ(Zr-filtered MoKα) < 50° measured. The scan rate was 2° per min with a range of $\pm(0.95 + 0.85 \tan\theta)$. The majority of unobserved reflections, $I < 3\sigma(I)$, had 2θ > 40°. The structure was solved by the heavy atom method; refinement procedures were similar to those described recently (5). The weighting scheme was $w^{-1} = 60 - F_o + 0.001F_o^2$. The final R ($= \Sigma||F_o| - |F_c||/\Sigma F_o$) and R_w were 0.083 and 0.108, respectively, on refinement of F. The difference Fourier map showed no other atoms. In the final cycle of refinement, the maximum parameter shifts were 0.5σ. Atomic coordinates are given in Table 1. Structure and temperature factors were deposited.[1]

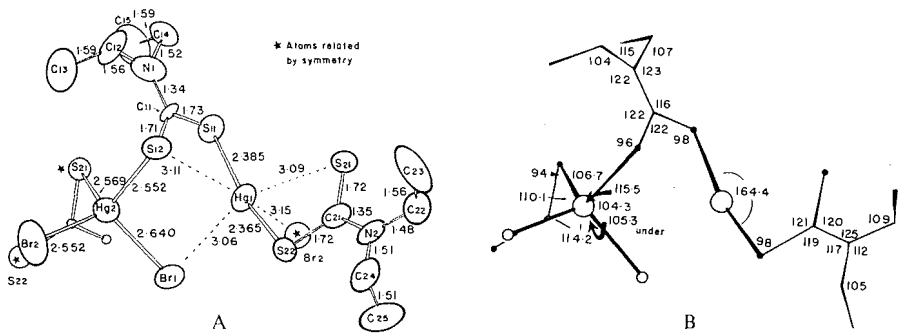

FIG. 1. Bond distances and angles for $[HgBr_2(S_2CNEt_2)Hg(S_2CNEt_2)]_n$. Estimated standard deviations: Hg—Br, 0.005; Hg—S, 0.010; C—S, 0.04; C—N or C—C, 0.05 Å. ∠BrHgBr, 0.1; ∠BrHgS, 0.2; ∠SHgS, 0.3; ∠SCS, 1.0; ∠CNC etc., 2.0°.

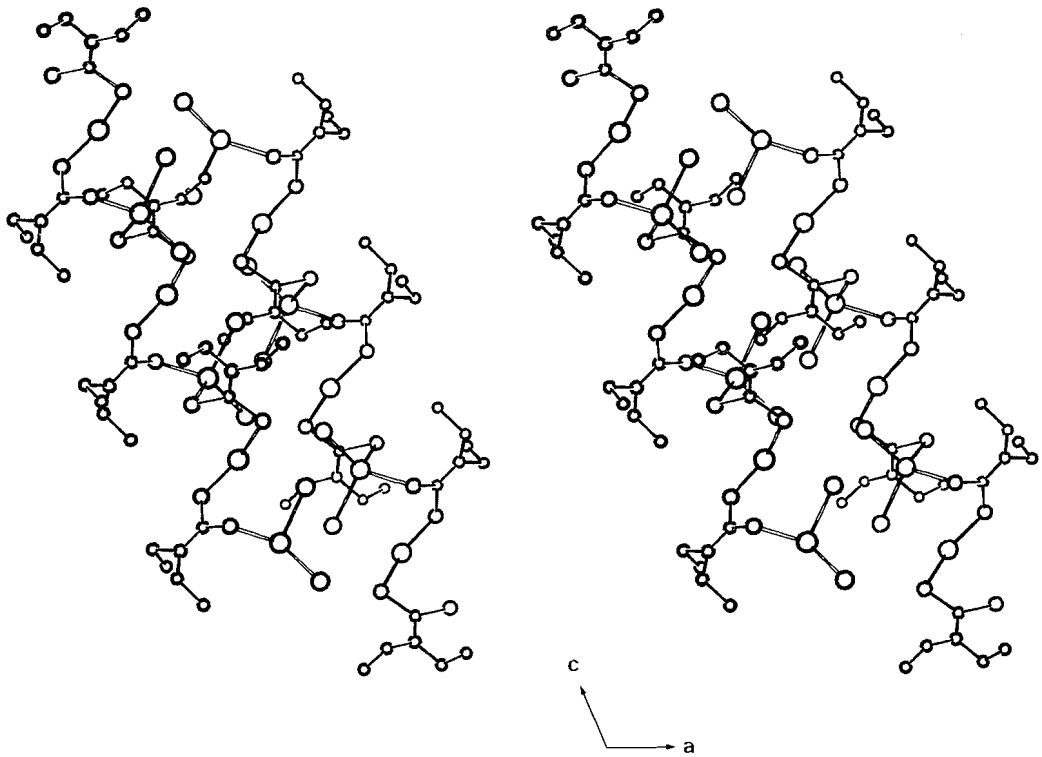

FIG. 2. Stereo pair for the chains looking along the *b*-direction. Two chains are antiparallel. They are related to each other via a centre of symmetry. Sizes of atoms increase with atomic numbers.

Results and Discussion

The compound can be formulated as $[HgBr_2(S_2CNEt_2)Hg(S_2CNEt_2)]_n$. There are two mercury(II), two bromide, and two dithiocarbamate ions per asymmetric unit, which repeats itself by a *c*-glide plane forming a chain. The important bond distances and angles for the basic unit are given in Fig. 1.

A unique and interesting feature in the structure is the existence of two coordination geometries for mercury(II) in one crystal. The coordination for one, Hg_1, is digonal with two short almost linear Hg—S bonds of 2.385(11) and 2.365(10) Å; the angle ∠SHgS is 164.4(3)°. For Hg_1, additional contacts of Hg...S or Hg...Br are of the order of 3.1 Å. The coordination for the other, Hg_2, is tetrahedral with 2 Hg—S (2.552(10) and 2.569(10) Å) and 2 Hg—Br (2.552(7) and 2.640(4) Å) bonds. The bond angles around this ion range from 104.3 to 115.5°. For both mercury ions, the bond lengths and angles are in good agreement with those in the literature (6). Two Hg—Br distances are significantly different resulting from the secondary Hg...Br interactions.

Each dithiocarbamate ion is bonded to one Hg^{2+}

and one $HgBr_2$ via the sulfur. Chains are formed through the mutual bridging between dithiocarbamates and $HgBr_2$ or Hg^{2+} units. In contrast, molecules of the stoichiometric iodo analogue, $[1Hg(S_2CN(C_2H_5)_2]_2$, pack as dimers in the crystal (3). The bridging of the dithiocarbamate is more symmetric in the title compound than in the iodo analogue. Although the Hg—S distances around the two mercury(II) ions are different because the coordination geometries are not the same, the C—S bond lengths are indistinguishable. The average value is 1.72(4) Å. Similar values appeared for one of the dithiocarbamates in the structure of α-mercury(II) dithiocarbamate (7). The configurations for the dithiocarbamate ions are normal with respect to other complexes (1–3).

The packing of this compound presents a typical model for linear polymers. The *c*-glide plane is responsible for extending the chains. Figure 2 is a stereo pair of the chains looking along the *b*-direction. The chains are antiparallel. Parallel chains form layers which stack up along the *b* axis as shown in Fig. 3. The crystals grown from ethanol are thin square plates with a general thickness of 0.06 mm, which is approximately the length of the chains. In this case, the chains contain 9×10^5 basic units and have a molecular weight of 7×10^8.

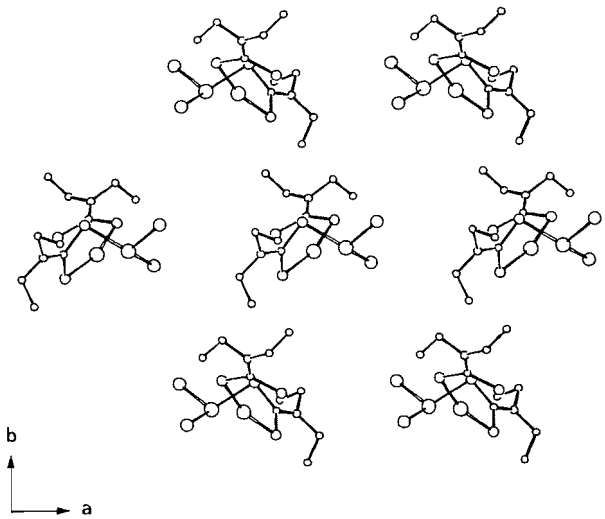

FIG. 3. Packing of the chains looking along *c**-direction.

Because of the polymeric nature of dithiocarbamato mercury(II) complexes, their solubilities are usually low, especially in water.

Dielectric relaxation in 2-acetylnaphthalene and related compounds

J. CROSSLEY, M. A. MAZID, C. K. MCLELLAN,
P. F. MOUNTAIN, AND S. WALKER
Chemistry Department, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received August 29, 1977

J. CROSSLEY, M. A. MAZID, C. K. MCLELLAN, P. F. MOUNTAIN, and S. WALKER. Can. J. Chem. **56**, 567 (1978).

The dielectric absorption of 2-acetylnaphthalene and 2- and 3-acetylphenanthrene has been studied in *p*-xylene solution at several microwave frequencies and in a polystyrene matrix at low frequencies. Acetyl group relaxation has been established from both sets of data. A clear separation of the dielectric absorption of the molecule and the group has been achieved for both 2- and 3-acetylphenanthrene in the matrix. The Eyring activation parameters have been established for acetyl relaxation in these molecules in the matrix. The free energy of activation values for group relaxation increase in the sequence acetophenone < 2-acetylphenanthrene < 3-acetylphenanthrene < 2-acetylnaphthalene. For the *p*-xylene solution data the weight factor for group relaxation, C_2, is appreciably lower than the theoretical value, so that $C_2 < C_1$, bearing out the findings of Fong and Smyth for 2-acetylnaphthalene. In polystyrene matrices, the data for 2- and 3-acetylphenanthrene also indicated that $C_2 < C_1$. The enthalpy of activation for acetyl relaxation in 2- and 3-acetylphenanthrene is similar to that for acetophenone and 1,4-diacetylbenzene whereas that for 2-acetylnaphthalene would seem somewhat larger.

J. CROSSLEY, M. A. MAZID, C. K. MCLELLAN, P. F. MOUNTAIN et S. WALKER. Can. J. Chem. **56**, 567 (1978).

On a étudié l'absorption diélectrique de l'acétyl-2 naphtalène et des acétyl-2 et acétyl-3 phénanthrènes en solution dans le *p*-xylène à plusieurs fréquences de microondes et dans une matrice de polystyrène à de basses fréquences. On a établi la relaxation du groupe acétyle à partir des deux groupes de données. On a pu obtenir une séparation nette de l'absorption diélectrique de la molécule d'une part et du groupe d'autre part pour chacun des acétyl-2 et acétyl-3 phénanthrènes dans la matrice. On a évalué les paramètres d'activation de Eyring pour la relaxation du groupe acétyle dans ces molécules dans la matrice. Les valeurs d'énergies libres d'activation pour la relaxation du groupe augmentent lorsque l'on passe de l'acétophénone < acétyl-2 phénanthrène < acétyl-3 phénanthrène < acétyl-2 naphtalène. Pour les données en solution dans le *p*-xylène, le facteur de poids pour la relaxation du groupe, C_2, est beaucoup plus faible que la valeur théorique; C_2 est donc plus faible que C_1 et ce résultat est en accord avec les conclusions de Fong et Smyth pour l'acétyl-2 naphtalène. Dans des matrices de polystyrène, des données pour les acétyl-2 et acétyl-3 phénanthrènes indiquent aussi que $C_2 < C_1$. L'enthalpie d'activation pour la relaxation du groupement dans les acétyl-2 et acétyl-3 phénanthrènes est semblable à celle observée pour l'acétophénone et le diacétyl-1,4 benzène alors que celle pour l'acétyl-2 naphtalène semblerait plus élevée.
[Traduit par le journal]

Introduction

Dielectric relaxation in 2-acetylnaphthalene, 4-acetylbiphenyl, and 4-acetyl-*o*-terphenyl has been studied by Fong and Smyth (1–3) in benzene solution. Their data analyses in terms of two relaxation times consistently yielded a weight factor $C_2 \simeq 0.14$ for the acetyl group relaxation process. This value is markedly less than the C_2 of 0.6 ± 0.1 reported by Farmer *et al.* (4) for acetophenone. Theoretical calculations for acetophenone based on group moments or bond moments yield expected C_2 values of 0.67 and 0.49, respectively.

Dipole moments of 2-substituted naphthalenes tend to be slightly greater than those of their substituted benzene analogues (e.g., 2-bromonaphthalene, 1.70 D, and bromobenzene, 1.57 D (5)), but this effect is much too small to account for such a large difference in C_2 values between 2-acetylnaphthalene and acetophenone. Moreover, it could not explain the low C_2 values for 4-acetylbiphenyl and 4-acetyl-*o*-terphenyl.

In order to examine these findings further we have measured the dielectric properties of *p*-xylene solutions of 2-acetylnaphthalene and of 2- and 3-acetylphenanthrene, employing a greater number of microwave frequencies than was available in the Fong and Smyth work. In this way we should obtain improved analyses of the data, which ought to give a better indication as to the validity of the low C_2 values.

Fong and Smyth suggested that the reduced contribution (i.e., smaller C_2 value) from acetyl group rotation might be linked to an increased energy barrier to such motion in 2-acetylnaphthalene as compared to acetophenone. At room temperature,

the molecular (τ_1) and group (τ_2) relaxation times of these acetyl compounds in benzene solutions differ by less than one order of magnitude. In such cases where C_2 is small, the error in τ_2 is considerable (6), and it is not possible to obtain reliable activation energies from Eyring plots of log ($T\tau$) vs. ($1/T$). Recent work (7–12) has indicated that intramolecular relaxation may be well separated from that of the molecule if the compound is examined in a polystyrene matrix at low temperatures (7–13). The energy barriers to substituent group rotations obtained by this technique have compared favourably with estimates based on other methods (10–13). Therefore we have undertaken such a study of 2-acetylnaphthalene and of 2- and 3-acetylphenanthrene to determine whether the acetyl group definitely relaxes in such compounds, and, if it does, to determine the Eyring activation parameters. Of particular interest is the enthalpy of activation for group relaxation since, as Fong and Smyth (1) have pointed out, this is related to the resonance energy which governs the group rotation. Thus any appreciable enhanced conjugation of the acetyl group with the ring in 2-acetylnaphthalene and 2- and 3-acetylphenanthrene (which may be looked upon as substituted 2-acetylnaphthalenes) ought to be reflected in enhanced ΔH_E values over that found in acetophenone.

Experimental

The apparatus and techniques used to obtain dielectric constant (ε') and loss (ε'') data at up to nine microwave frequencies between 0.8 and 35 GHz for the acetyl compounds in liquid solutions have been described previously (14, 15). Low-frequency dielectric constants (ε_0) were measured at 2 MHz on a WTW Dipolmeter.

Dielectric measurements of solutes in polystyrene matrices and subsequent data analyses in terms of the Fuoss–Kirkwood and Eyring equations were carried out as before (9, 11). The solute concentration in the matrices was approximately 5% (weight), which is sufficiently low to avoid solute concentration effects (8, 16).

Experimental Results

The microwave data from solutions generally gave a smooth, depressed-centre Cole–Cole plot and were computer-fitted (17) to the Cole–Cole equation (18) to obtain mean relaxation times (τ_0), distribution parameters (α), and high-frequency dielectric constants (ε_∞). In addition, the same data were fitted (6, 19) to the Budó equation (20) to obtain discrete relaxation times, τ_1 and τ_2, together with their respective weight factors, C_1 and $C_2 = 1 - C_1$. Table 1 shows the results of these analyses along with the dipole moments obtained in *p*-xylene solutions. The results compare well with the Fong and Smyth (1) results for 2-acetylnaphthalene in benzene.

As an alternative to the Budó analysis technique, rough estimates of the two relaxation times may be obtained sometimes from the equation:

$$[1] \qquad \varepsilon' = \varepsilon_0 - \tau(\varepsilon''\omega)$$

Figure 1*a* shows a plot based on [1] for 3-acetylphenanthrene in *p*-xylene at 298 K, yielding the results shown in Table 1. Figure 1*b* shows the data for a solution containing Nujol mineral oil to increase the macroscopic viscosity to 9.0 cP.

The dielectric loss data from the polystyrene matrices were analyzed via the Fuoss–Kirkwood equation (21). The Cole–Cole distribution parameter, α, was estimated from the Fuoss–Kirkwood β value (22), and the matrix dielectric constants (ε') were analyzed via the Cole–Cole equation (18) to yield ε_∞.

The mean relaxation time, $\tau = 1/2\pi f_{max}$, from Fuoss–Kirkwood analyses of data gathered over a wide range of temperatures was analyzed via Eyring plots of log ($T\tau$) vs. ($1/T$) to yield activation enthalpies and entropies as described previously (9, 11, 12), and these results are summarized in Table 2.

Figure 2 shows plots of dielectric loss factor (ε'') vs. the logarithm of frequency for 3-acetylphenanthrene in a polystyrene matrix at four temperatures. A General Radio bridge was used at the two lower temperatures and a Hewlett-Packard Q-meter at the two higher temperatures. It may be noted that each curve appears symmetric. A second completely separate set of absorption curves was observed above room temperature. This may be contrasted with the data for 2-acetylnaphthalene in polystyrene for which Fig. 3 shows the curves at four temperatures. In these latter cases it would appear that the overall dielectric loss curve is composed of two overlapping contributions. Preliminary attempts were made to analyze such curves in terms of two separate curves each described by the Fuoss–Kirkwood formulation, eq. 2, employed previously (7, 12).

$$[2] \qquad \cosh^{-1}(\varepsilon''_{max}/\varepsilon'') = \beta \ln(f_{max}/f)$$

However, this necessitates the evaluation of six parameters at each temperature, three (ε''_{max}, β, and f_{max}) for each of the two peaks. The results of such attempts were inadequate. A more approximate type of approach is to analyze the data at each temperature in terms of a single absorption of the Fuoss–Kirkwood type. The resultant data are shown in the Eyring graph of Fig. 4 fitted to the two solid lines. This bears out that the overall absorption is dominated by different processes in the limits of lower and higher temperatures. For comparison, Fig. 4 also contains a dotted line fitted to the data for the lower-temperature absorption for 3-acetyl-

phenanthrene, for which the loss curves were symmetric.

Discussion

Figure 1 shows clearly that there are two distinct relaxation processes for 3-acetylphenanthrene, the shorter relaxation time being relatively insensitive to the macroscopic viscosity of the solution. This would appear to justify the use of Budó analyses of the data in liquid solutions in terms of two relaxation times. Further, there is reasonable agreement in Table 1 between the τ_2 values from Budó analyses and those obtained graphically by means of [1]. The graphical $\tau_2 = 8.5 \times 10^{-12}$ s for acetophenone in pure Nujol is also in agreement with the value of $\tau_2 = 7.8 \times 10^{-12}$ s in cyclohexane at 298 K (4).

Clearly, the acetyl group in 3-acetylphenanthrene does rotate and is characterized by a relaxation time appreciably longer than in acetophenone. Similarly longer τ_2 values resulted from Budó analyses of the microwave data for 2-acetylphenanthrene and 2-acetylnaphthalene. Further, the results in Table 1 agree with those of Fong and Smyth (1–3) with respect to the low values of C_2, the weighting factor associated with the group relaxation process. This suggests that acetyl group rotation in these compounds is somewhat modified, and Fong and Smyth (1) have suggested enhanced resonance of the keto group with the conjugated ring in comparison with acetophenone may be responsible.

Molecular and intramolecular relaxation energy barriers may be obtained with reasonable accuracy from dielectric measurements of solutes in polystyrene matrices (10–13). Table 2 shows such results for 2-acetylnaphthalene, 2- and 3-acetylphenanthrene, and 2-acetyl-1-tetralone, along with some previously published results included for purposes of comparison. In acetophenone, 1,4-diacetylbenzene, and 4-acetylbiphenyl, acetyl group relaxation was

characterized by $\Delta H_E \simeq 29$ kJ mol^{-1} and $\Delta S_E \simeq 30$ J K^{-1} mol^{-1} while ΔG_E at 200 K was ~23 kJ mol^{-1}. Further, molecular relaxations of 4-acetylbiphenyl and 4-nitrobiphenyl gave much larger values for both ΔH_E and ΔG_E. This would appear to establish a set of reference values for the activation parameters of acetyl group relaxation in aromatic compounds in the absence of appreciable enhanced conjugation.

For 4-acetylbiphenyl both the group and molecular relaxation processes were detected; the latter process is characterized by the Eyring parameters $\Delta H_E = 68$ kJ mol^{-1} and $\Delta G_{E(200)} = 62$ kJ mol^{-1}. 2- and 3-acetylphenanthrenes also exhibit two relaxation processes (see Table 2), and the higher temperature process yields Eyring parameters significantly greater ($\Delta H_E \sim 85$ kJ mol^{-1}) than those for 4-acetylbiphenyl but of the order to be anticipated for these somewhat larger molecules. Certainly, the lower temperature process with a ΔH_E of 28 kJ mol^{-1}, which is, in fact, a typical value for acetyl group relaxation in aromatic ketones, could not be ascribed to the molecular relaxation process. There-

fore we allot the higher temperature data to the molecular process and the lower one to group relaxation. It must be stressed that the absorption of relaxation. It must be stressed that the absorption of the group and molecule has been separated completely for both the 2- and 3-acetylphenanthrenes in a polystyrene matrix.

Only one relaxation process has been detected for 2-acetyl-1-tetralone, with $\Delta H_E = 61$ kJ mol^{-1} and $\Delta G_{E(200)} = 46$ kJ mol^{-1}, and this corresponds fairly closely with the data for 2-cyanonaphthalene ($\Delta H_E = 54$ kJ mol^{-1} and $\Delta G_{E(200)} = 45$ kJ mol^{-1}), a molecule closely similar in shape and size.[1] Further, the temperature range of observation is higher than that found for the other acetyl group relaxation processes. It is concluded for 2-acetyl-1-tetralone that either the process is totally molecular or is a mixture of group and molecular with the latter predominating.

Although acetyl group relaxation in the two phenanthrenes yielded ΔH_E values similar to the three reference compounds, the ΔS_E values were appreciably lower, with the result that at 200 K ΔG_E values were considerably greater than in the first three compounds. For 2-acetylnaphthalene the trend in ΔS_E was continued, and ΔH_E appeared to be greater, resulting in a very much larger ΔG_E of 38.3 kJ mol^{-1} at 200 K. The higher-temperature data for this compound yielded $\Delta H_E = 82 \pm 8$ kJ mol^{-1} and $\Delta S_E = 180 \pm 30$ kJ^{-1} mol^{-1}, yielding $\Delta G_{E(200)} = 46$ kJ mol^{-1}, in excellent agreement with the value of 45.7 kJ mol^{-1} for 2-acetyl-1-tetralone for which mainly molecular relaxation appears to have been observed, as discussed earlier. These data indicate clearly that, at these temperatures, the dielectric absorption of 2-acetylnaphthalene is dominated by molecular relaxation.

The sequence of increasing ΔG_E values at 200 K for acetyl group rotation in acetophenone, 2- and 3-acetylphenanthrene, and 2-acetylnaphthalene was 24.4, 27.4, 29.3, and 38.3 kJ mol^{-1}, respectively. This sequence is reflected in the stretching frequencies of the carbonyl group ($\bar{\nu}_{C=O}$) shown in Table 3 for these compounds in CCl_4, being 1691, 1689, 1688, and 1678 cm^{-1}, respectively. A decrease in the $\bar{\nu}_{C=O}$ value is in harmony with greater conjugation of the carbonyl group with the ring. Thus, both $\Delta G_{E(200)}$ and $\bar{\nu}_{C=O}$ suggest appreciably enhanced conjugation of the C=O group in 2-acetylnaphthalene in comparison with acetophenone.

Davies and Swain (8) employed Debye and Fuoss–Kirkwood relationships to estimate from their polystyrene matrix data the effective dipole moment, μ, associated with the relaxation process observed. While these were low at the measurement temperatures, they found that a linear extrapolation of μ vs. temperature yielded, on the whole, values comparable to liquid solution results at temperatures between 300 to 320 K. We have followed their procedures for our matrix data for 4-acetylbiphenyl and 2- and 3-acetylphenanthrene. In each of these molecular and acetyl group relaxations were observed to be well separated, and we have evaluated the two dipole moments separately, the data being shown in Table 4. From these data we have calculated the total dipole moment from [3] and the weight factor for molecular relaxation, C_1, from [4] and [5].

$$[3] \qquad (\mu_{tot})^2 = (\mu_{\parallel})^2 + (\mu_{\perp})^2$$

$$[4] \qquad C_1/C_2 = (\mu_{\parallel}/\mu_{\perp})^2$$

$$[5] \qquad C_1 + C_2 = 1$$

Table 4 also includes the extrapolated μ_{tot} for 2-acetylnaphthalene for which the overlap of the two absorption processes prevented separate evaluation of $\mu_{\parallel}$ and $\mu_{\perp}$.

2-Acetylnaphthalene			3.10	3.13	

*Reference 5.

For 4-acetylbiphenyl and 2-acetylnaphthalene the μ_{tot} values are in good agreement with literature data (5). One may expect similar values (~ 3 D) for the two phenanthrenes, and the experimental extrapolated results are in reasonable agreement, bearing in mind that at best the error is of the order of $\pm 10\%$. Such agreement suggests that the component dipole moments so obtained are reasonably reliable, and hence that the C_1 values derived are similarly meaningful. Therefore, it is noteworthy that 2- and 3-acetylphenanthrene which contain the 2-acetylnaphthalene unit yielded C_1 values significantly greater than that of acetophenone ($C_1 \sim 0.33$) (4) while 4-acetylbiphenyl, which has more structural similarity with the latter molecule, gave a C_1 (0.38) similar to that of acetophenone. These results bear out the solution studies in the microwave region; hence, there can be little doubt that some factor is at play which diminishes the value of C_2 in these compounds which contain the 2-acetylnaphthalene unit. The actual values of C_2 by both approaches are prone to considerable error. However, both the matrix and the solution studies being taken into account, it would seem that for the three molecules the C_2 value is something of the order of 0.3 ± 0.15.

The ΔH_E value for acetyl group relaxation in 2-acetylnaphthalene would seem about 6 kJ mol^{-1} greater than that for the other aromatic ketones in Table 2. However, the possibility exists that the ΔH_E value for 2-acetylnaphthalene is in greater error since in this case there may be some overlap of the dielectric absorptions of the group and molecular processes. From the magnitude of the weight factor, though, the main point would appear to be that, although the C_2 values for acetophenone and 2- and 3-acetylphenanthrene differ significantly, the cause of the discrepancy is not to be sought in terms of ΔH_E values. It is possible that the sequence of ΔG_E values for group relaxation offers a more promising lead. It is also to be noted for the microwave data in Table 1 that the τ_2 values for 2-acetylnaphthalene and the 2- and 3-acetylphenanthrenes are all appreciably longer than those for acetophenone; this, of course, again is in line with a lower free energy of activation for group relaxation in acetophenone than in the other three acetyl compounds.

Conclusions

Group relaxation has been established for the acetyl group in dilute solution in nonpolar solvents and in a polystyrene matrix for 2-acetylnaphthalene and 2- and 3-acetylphenanthrene. Both in the liquid solutions and in the matrices we have found that $C_2 < C_1$. The Eyring activation parameters have been determined for these group relaxations in a polystyrene matrix.

It would seem possible that there is enhanced conjugation of the acetyl group in 2-acetylnaphthalene compared with that in acetophenone as Fong and Smyth (1) postulated, and that this is borne out by the ΔH_E values and the carbonyl stretching frequency. However, this enhanced conjugation alone does not account for the low weight factor for group relaxation in 2-acetylnaphthalene since 2- and 3-acetylphenanthrene have similar weight factors but exhibit no sign of an enhanced enthalpy of activation for group relaxation. The ΔG_E values at 200 K for acetyl relaxation follow the sequence: acetophenone < 2-acetylphenanthrene < 3-acetylphenanthrene < 2-acetylnaphthalene, and this is the order of increased conjugation as assessed by the carbonyl stretching frequency. However, the variation in $\bar{\nu}_{C=O}$ amongst the first three is only ~ 3 cm^{-1} whereas between acetophenone and 2-acetylnaphthalene the shift is 13 cm^{-1}.

Diffusion coefficients and viscosities in glycol and glycerol solutions

JOHN E. EVANOFF AND WALTER E. HARRIS

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 6, 1977

JOHN E. EVANOFF and WALTER E. HARRIS. Can. J. Chem. **56**, 574 (1978).

Diffusion coefficients have been measured polarographically in media with a wide range of viscosities. The range covers five orders of magnitude up to the limits of high viscosity possible by normal polarographic means. The diffusion coefficients obtained are nearly inversely proportional to the viscosity. The diffusion coefficients are in the range of interest to chromatography theory.

JOHN E. EVANOFF et WALTER E. HARRIS. Can. J. Chem. **56**, 574 (1978).

On a mesuré les coefficients de diffusion, d'une façon polarographique, dans des milieux de viscosité très variable. Les écarts de viscosité couvrent cinq ordres de grandeur jusqu'aux limites supérieures de viscosité possibles par les méthodes polarographiques normales. Les coefficients de diffusion obtenus sont, à toutes fins pratiques, inversement proportionnels à la viscosité. Les coefficients de diffusion sont dans les écarts d'intérêt de la théorie de chromatographie.

Rates of diffusion of small solute molecules in viscous solvents are important in gas chromatography because of their influence on resistance to mass transfer and hence on plate height and column efficiency. In van Deemter curves (1) of plate height against carrier-gas velocity, the band broadening at high flow rates is attributed largely to resistance to mass transfer, particularly in the stationary phase. The slow rates of mass transfer to and from the liquid and moving-gas phases is caused mainly by a low rate of diffusion of solute molecules in the liquid phase. Accordingly, a knowledge of diffusion coefficients in viscous liquids should contribute to the quantitative understanding of the factors involved in column efficiency.

In this study diffusion coefficients in viscous media were measured polarographically. The polarographic method is one of the simplest methods and is applicable to dilute solutions. Since measurements of diffusion coefficients by any method are likely to require experimental finesse, it would be convenient if a generally applicable relation could be established between diffusion coefficients and a more simply measurable property such as viscosity.

Several nitro compounds were chosen for the study because of their well established polarographic behaviour and their well defined current–voltage curves (2). Their polarographic reduction proceeds through a four-electron step to form a corresponding hydroxylamine.

Experimental

Fisher reagent-grade ethylene glycol and glycerol were used as solvents with 0.1 *M* lithium chloride as indifferent electrolyte. Several difficulties arising from the high viscosities, particularly of glycerol, had to be overcome. First of all, it was found best to prepare the solutions by weight to give dilute solutions of known concentration about 10^{-3} *M*. Removal of dissolved oxygen took more time (30 min) than for aqueous solutions. Loss of solute during removal was minimized by presaturating the purified nitrogen with a part of the solution to be examined, before passing it into the electrolytic cell, and also by using a low temperature (0°C for glycol, 25°C for glycerol). After treatment the solutions, particularly of glycerol, were milky in appearance from the many small bubbles of nitrogen. The procedure adopted for removal of these bubbles involved storage for up to 12 h in a nitrogen atmosphere prior to making measurements. At the lowest temperature, especially again in glycerol-based solutions, the viscosity is beyond the limit at which normal polarographic measurements can be made. The mercury drops would not fall free from the electrode and would sometimes merge with the next drop to form. A slight extension of the viscosity limit was possible by grinding the electrode tip as shown in Fig. 1. With such a tip the individual drops no longer interfered with each other though they fell extremely slowly, as can be seen from the figure. At temperatures in excess of about 40°C erratic drop formation was observed, which appeared to result from retreat of the mercury column up the capillary after a drop had broken free. This effect disappeared after the inside of the capillary was coated with silicone (3).

The reference electrode used in the polarographic cell was silver – silver chloride, and the electrolytic cell a 29- × 75-mm tube. Viscosities were determined with routine Cannon–Fenske calibrated viscometers; they were chosen so that the efflux time was between 200 and 600 s. The viscometers were charged with the sample solutions, and five efflux time determinations were carried out on each solution and at each temperature. Densities at the various temperatures of the 0.1 *M* lithium chloride – glycol or – glycerol solutions were determined by the pycnometer technique. Capillary constants were measured over the temperature range used. Diffusion coefficients were computed from the Ilkovic equation and the measured diffusion currents.

Results and Discussion

The current–voltage curves obtained for the various nitro compounds were well formed and

FIG. 1. Instantaneous photograph showing ten consecutive mercury drops in 0.1 *M* LiCl – glycerol at 1°C. Drop time 4.5 s; viscosity approximately 107 P.

symmetrical in both ethylene glycol and glycerol at high and at low temperatures (Fig. 2). All the nitro compounds tested showed a linear relation between diffusion current and concentration in the millimolar range and in the temperature range from 0 to 100°C. The capillary constant over the temperature range of 100°C was relatively constant. It varied from 1.54 to 1.50 $mg^{2/3}\ s^{-1/2}$ in 0.1 *M* LiCl – ethylene glycol and from 1.62 to 1.74 $mg^{2/3}\ s^{-1/2}$ in 0.1 *M* LiCl – glycerol. Diffusion coefficients were calculated from the Ilkovic expression ($I_d = 607nD^{1/2}Cm^{2/3}t^{1/6}$); the results are summarized in Table 1. It is evident from the table that diffusion coefficients were measured that cover the range from values typical of ions in aqueous solution (with glycol at 100°C) to values about five orders of magnitude smaller (with glycerol at 0°C).

Since the measurement of diffusion coefficients by polarographic means is experimentally tedious, an attempt was made to correlate the coefficients to the more simply measurable properties of viscosity and the molecular characteristics. If the viscosities and diffusion coefficients in Table 1 are plotted as a function of each other, we can see a nearly (but not exactly) inverse relation between the two, over several orders of magnitude (Fig. 3).

For the diffusion of spherical macromolecules or particles in a solvent, the Stokes–Einstein relation (4) is valid, that is, the diffusion coefficient is equal to $kT/6\pi\eta r$, where k is Boltzmann's constant, T is absolute temperature, η is viscosity, and r is the radius of the diffusing species. The factor 6π is

based on the assumption that the medium can be regarded as homogeneous.

For self-diffusion, that is, diffusion of solvent within itself, hydrodynamic theory (5) indicates that the 6π is replaced by 4π. For spherical, nonsolvated molecules the radius can be expressed in terms of molar volume of the substance, and the Stokes–Einstein relation is modified to

$$[1] \qquad D_{\text{liq}} = \frac{k}{2\pi}\left(\frac{N}{V}\right)^{1/3}\frac{T}{\eta}$$

where N is Avogadro's number and V is the molar volume. Experimentally, the values corresponding to the constant 2π (6.3) were found by Li and Chang to vary between 5.4 and 8.3 (5).

It would not be surprising should a relation similar to that shown in eq. 1 be found to apply for the diffusion of small molecules in a solvent consisting of larger molecules, but with an adjustment of the factor 2π. It seems reasonable, from our knowledge of the diffusion rates of particulates and of self-diffusion, that the factor 2π should be somewhat smaller. Figure 4 compares the diffusion co-

efficients of nitrobenzene measured polarographically and those calculated from eq. 1, with 2π replaced by 1.4π. The trends and general agreement are such that useful estimates of diffusion coefficients could be expected from viscosity information. Even though the agreement is not perfect, the results obtained should be applicable to a range of typical solutes and solvents of interest to gas chromatography.

J. F. BAGLI and M. ST-JACQUES. Can. J. Chem. **56**, 578 (1978).

The ^{13}Cmr spectra of a series of 2-substituted tropones were analysed using a combination of methods including specific deuteration, multiplicities in coupled ^{13}Cmr spectra and proton off-resonance decoupling techniques. The published ^{13}C assignment for tropolone acetate was proven wrong and was corrected. Substituent parameters were defined and shown to exhibit two linear relationships with the corresponding substituent parameters for analogous monosubstituted benzenes. The significance of the results is discussed.

J. F. BAGLI et M. ST-JACQUES. Can. J. Chem. **56**, 578 (1978).

On a analysé le spectre rmn ^{13}C d'une série de tropones substituées en position 2 en faisant appel à une combinaison de méthodes comprenant la deutération spécifique, les multiplicités des spectres rmn ^{13}C couplés et des techniques de découplage du proton. On a démontré que les attributions publiées pour le ^{13}C de l'acétate de tropolone sont incorrectes et on les a corrigées. On a défini des paramètres de substituants et on a montré qu'ils présentent deux relations linéaires avec les paramètres de substituants correspondants pour les benzènes monosubstitués analogues. On discute de la signification de ces résultats.

[Traduit par le journal]

Tropone derivatives constitute a class of naturally occurring nonbenzenoid aromatic substances, several of which could be of potential pharmaceutical interest (1). Structural assignment and isomer characterization of synthetic derivatives are often difficult by proton magnetic resonance (^{1}Hmr) spectroscopy owing to the small chemical shift range for the various strongly coupled nonequivalent ring protons; these often exhibit second-order multiplets (2, 3) which are tedious to analyse completely.

By contrast, because of the larger chemical shifts and greater spectral simplicity, proton decoupled carbon-13 magnetic resonance (^{13}Cmr) spectroscopy appears to be a more promising tool of structure elucidation. Because of our interest in tropone chemistry, it became important for us to determine the advantages and limitations of ^{13}Cmr spectroscopy in this area.

Although the ^{13}Cmr spectra of tropone (**1**) (4), thiotropone (4), and of a few simple derivatives (5) have been reported, very little information exists on the effect of substituents on the ^{13}Cmr parameters of tropone derivatives. This paper describes the analysis of the ^{13}Cmr spectra of a series of 2-substituted tropones (**2**-X, where X denotes the nature of the substituent). All of the compounds studied were prepared using published procedures or modifications thereof as described in the experimental section. By providing a description of the substituent effect on each ring carbon, our investigation has enabled us to reassign unequivocally the carbon signals of tropolone acetate (**2**-$OCOCH_3$) (*5a*).

Results and Discussion

Spectral Assignments

The published assignment (4) of the spectral lines of tropone (**1**), the reference compound in our study, has been confirmed by our work (*vide infra*) and the carbon shifts are reported in Table 1.

The spectral analysis of the various 2-substituted tropones (**2**-X) required a combination of arguments: intensity differences owing to relaxation effects, specific deuteration, carbon–hydrogen coupling constants, and proton off-resonance decoupling techniques (6).

Excluding the substituent signals, which are readily assignable, two groups of lines are easily distinguished in the proton decoupled ^{13}Cmr

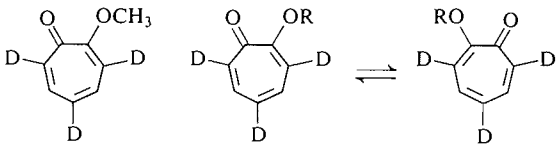
spectra: two less intense lines associated with the nonprotonated C-1 and C-2 and five more intense lines associated with the five protonated ring carbons. It is for this latter group that special assignment techniques were required including the preparation of 3,5,7-trideuterio-2-methoxytropone (**3**), 3,5,7-trideuteriotropolone (**4**) and its acetyl derivative **6**.



3 **4** (R = H) **6** (R = $COCH_3$) **5** (R = H) **7** (R = $COCH_3$)

Tropolone-d_3 (**4**), which is known to undergo rapid tautomerization (**4** ⇌ **5**) at room temperature, gave a ^{13}Cmr spectrum showing only one protonated carbon line whose chemical shift is in accord with the published (7) value for the signal of the equivalent C-4 and C-6 of tropolone. This observation therefore confirms the assignment based on charge density calculations.

The comparison of the proton decoupled ^{13}Cmr spectra of **2**-OCH_3 (Fig. 1A) and its deuterated derivative **3** (Fig. 1B) allowed the partial assignment of the protonated carbon lines by identifying two sub-groups of lines, namely those arising from C-3, C-5, and C-7 now appearing as weak triplets (because of coupling with the directly bonded deuterium atom) and those arising from C-4 and C-6 still observed as intense singlets.

Charge density arguments similar to those used for tropolone (7) are much less conclusive when used to assign C-4 and C-6. Consequently we proceeded to make an unequivocal assignment through a combination of the following techniques: the analysis of

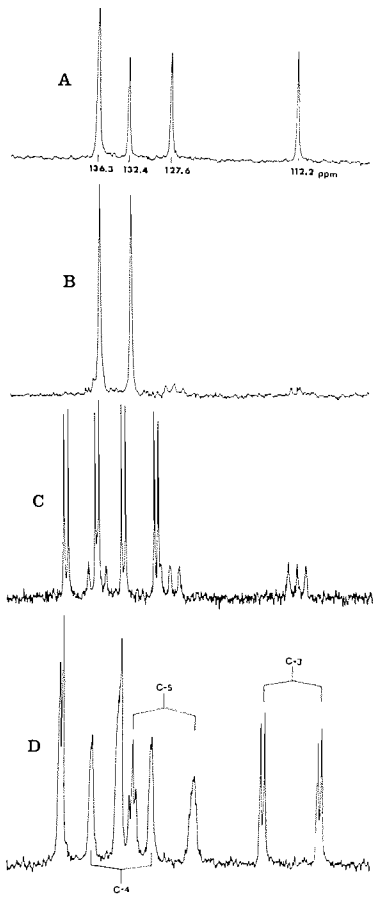


FIG. 1. Proton decoupled and coupled ^{13}Cmr spectra of **2**-OCH_3 (A and D, respectively) and of **3** (B and C).

coupled (i.e. non-proton-decoupled) spectra, the determination of residual splitting in off-resonance decoupled spectra, and selective proton decoupling (6).

The coupled ^{13}Cmr spectrum of **3** (Fig. 1C) shows

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

that both the C-4 and C-6 signals consist of two doublets arising from a large $^1J_{CH}$ and a smaller $^3J_{CH}$. Three signals (C-3, C-5, and C-7) are clearly seen as triplets in accord with one bond C–D couplings and small (unresolved) two-bond carbon–hydrogen couplings as in benzene (8). The pertinent carbon–hydrogen coupling constants obtained from a first-order analysis are reported in Table 2.

Proton decoupling experiments (9–11) with a stepwise variation of the irradiating field frequency provided evidence for the unambiguous assignment of the C-4 and C-6 signals from the analysis of the residual splitting (J_r) arising from coupling only to directly bonded protons (i.e. $^3J_{CH}$ effects are eliminated) as described next.

Bertelli *et al.* (3) reported that the computer simulation of the second-order proton spectrum of **2**-OCH_3 in C_6D_6 revealed a chemical shift difference of 14.8 Hz (100 MHz; $^4J_{HH}$ 1.1 Hz) for H-4 and H-6 whereas our analysis of the first-order 100 MHz deuterium decoupled ^{1}Hmr spectrum of **3** in $CDCl_3$ gave 13.8 Hz ($^4J_{HH}$ = 1.0 Hz). The agreement thus supports the authors' conclusion (3) that H-4 absorbs at higher field than H-6.

The off-resonance proton decoupled spectrum of **3** showed two doublets with J_r larger for the lower field ^{13}C signal when the irradiating field was located upfield from both the H-4 and H-6 resonances whereas the larger splitting was observed for the upfield ^{13}C doublet when the decoupling field was placed downfield from both H-4 and H-6. It is therefore evident that the upfield ^{13}C signal relates with the upfield proton line (and vice versa) and it follows (9) that C-4 is upfield from C-6 in **3** and in **2**-OCH_3 as reported in Table 1.

The coupled ^{13}Cmr spectrum of **2**-OCH_3 is shown in Fig. 1D. First-order patterns arising mainly from $^1J_{CH}$ and $^3J_{CH}$ couplings are not always observed because of the small proton chemical shifts (6). Although second-order effects complicate the spectral analysis, it is nevertheless possible to identify the C-5 multiplet because it is the only carbon atom expected to show multiplicity arising from two relatively large (between 10 and 13 Hz) but not necessarily equal $^3J_{CH}$ couplings. The lowfield component of the C-5 multiplet is sufficiently first order to give a triplet (such is not the case for the upfield component) and thus allow clearcut identification of the C-5 signal. The C-1 signal also gives a triplet because of similarly large three-bond couplings with H-3 and H-6. All the $^1J_{CH}$ values of the protonated carbon atom are given in Table 2.

TABLE 2. Carbon–proton coupling constants[a] for **2**-OCH_3

	J_{CH}				
Nuclei	H-3	H-4	H-5	H-6	H-7
C-3	~153				
C-4		158.9		10.3	
C-5			~162		
C-6		11.8		155.8	
C-7					~160

[a]The $^1J_{CH}$ and $^3J_{CH}$ values (in Hz) obtained from the spectral analysis of **3** are reported with a decimal point. The other $^1J_{CH}$ values were obtained from measurements on the coupled spectrum of 2-OCH_3 and are believed to be accurate within 2 Hz. Furthermore, $^3J_{C\text{-}1,H\text{-}6}$ = 12.5 was obtained from the analysis of **3**.

Proton decoupled off-resonance spectra with variable irradiating field frequency (9) was used to confirm the assignment of the C-3 and C-7 signals by relating these two signals with the assigned (3) proton resonances of H-3 (upfield) and H-7 (downfield). By setting the proton decoupling field upfield from H-3 and then downfield from H-7, the appreciable difference in J_r observed for the appropriate ^{13}C doublets confirmed that C-3 is the most upfield ring carbon. Selective irradiation (11) at the H-3 frequency collapsed the most upfield ring carbon signal and thus confirmed the above assignment.

The coupled ^{13}Cmr spectrum of tropone also revealed that the upfield component of the signal centered at 134.4 ppm (Table 1) is a triplet in accord with the existence of two large $^3J_{CH}$ values for the equivalent C-4 and C-5 atoms responsible for that signal (4).

It has been reported (*5a*) that **2**-$OCOCH_3$ (tropolone acetate) undergoes rapid intramolecular acetyl exchange at room temperature for which $\Delta G^{\neq}$ is 10.8 kcal/mol. Consequently a nonaveraging spectrum can be recorded below −60°C. The protonated ring carbon line in the ^{13}Cmr spectrum of **6** (δ_C = 133.7 in $CDCl_3$ at room temperature) splits into a doublet with components at 136.8 and 131.5 ppm at −72°C in accord with the slowing down of the acetyl exchange **6** ⇌ **7**. This observation demonstrates that the published assignment for the C-3, C-7, and C-4, C-6 pairs is wrong and should be reversed. The correct line assignment is given in Table 1.

The identification of the C-5 signal from the coupled spectra of **2**-NH_2, **2**-$NHCH_3$, and **2**-$NHCOCH_3$ together with the expectation that C-3 should have the smallest methine chemical shift allowed the assignment of the ring carbon signals as reported in Table 1.

Because the spectral lines of the five methine carbons of **2**-Cl and **2**-CH_3 are closely spaced (e.g. 138.3, 135.6, 135.3, 133.9, 131.2 ppm for **2**-Cl), their assignment is less straightforward. The off-resonance doublets for the lines at 138.3, 133.9, and 131.2 ppm were easy to recognize so that J_r could be measured with the proton irradiating field at the higher and at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the lower field sides of all the methine proton resonances. But because of the closeness of the lines at 135.6 and 135.3 ppm it was impossible to make an unambiguous assignment from J_r values alone. From the knowledge (3) that the proton chemical shifts of **2**-Cl follow the order: H-3 > H-7 > H-6 > H-5 > H-4 it was easy to selectively decouple H-3 and H-7 and show that the chemical shifts of C-3 and C-7 are 135.3 and 135.6 ppm, respectively. The combined use of J_r values, selective decoupling and the analysis of the coupled spectrum of **2**-Cl led to the complete assignment given in Table 1.

The C-5 line of **2**-CH_3 was identified from the coupled ^{13}Cmr spectrum and the other lines were assigned to the various carbons as shown in Table 1 from an analogy with the spectrum of **2**-Cl.

Analysis of the coupled and decoupled spectra of **2**-SCH_3 together with the expectation that C-3 should be upfield (C-5 cannot because it is identified in the coupled spectrum) led to the probable assignment given in Table 1.

The chemical shifts (not reported in Table 1) of the carbon atoms of the various substituents were readily assigned from simple model compounds (12) as follows: OCH_3 (55.9), $OCOCH_3$ (168.0, 19.7), $NHCH_3$ (29.2), $NHCOCH_3$ (169.3, 25.3), CH_3 (22.4), SCH_3 (14.8).

Substituent Effects

The shielding changes observed for the ring carbon nuclei along a series of substituted aromatic compounds are believed to be primarily related to a redistribution of electron density brought about by the substituent change (13). Although charge density correlations in monosubstituted benzenes have been more successful for *para* carbons (14), it is now widely accepted that the empirically obtained substituent chemical shift parameters for all ring carbons are very useful for spectral and structural assignment purposes (6).

Consequently, as a prelude to any correlation with calculated π- and σ-electron densities (as well as bond orders) (14), we first sought to characterize substituent effects in tropone derivatives by a comparison to the known effects for analogous benzene derivatives through an approach somewhat similar to that used previously (15) for pyridine derivatives.

Using the tropone carbon chemical shifts as reference, a set of substituent parameters was derived from the data in Table 1 as summarized in Table 3.

The C-2 shift parameters of the tropone derivatives were then plotted against the substituted carbon (C-X) shift parameter of each corresponding monosubstituted benzene in Fig. 2. A similar plot of the C-5 parameters (tropones) against the *para*-carbon

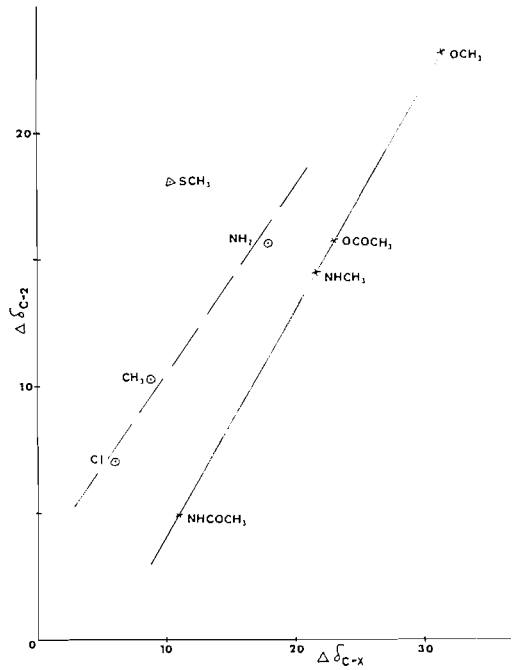

FIG. 2. Substituent parameters of the substituted carbons (C-2 vs. C-X) in 2-substituted tropones and monosubstituted benzenes.

parameters (benzenes) is shown in Fig. 3 while Fig. 4 illustrates the plot of the C-3 parameters versus the *ortho*-carbon parameters. Owing to the very small chemical shift spread of the *meta* carbons for the substituents investigated in our work, a plot against C-4 is not reproduced. It was not possible to obtain data for the non averaging tropolone and consequently the OH group does not appear in our analysis.

Figure 2 (substituted carbons) reveals a very interesting feature which suggests that the substituents (except SCH_3) fall into two categories each appearing to exhibit a linear relationship i.e. OCH_3, $OCOCH_3$, $NHCH_3$, and $NHCOCH_3$ (that is -X-Y type) as the first group and NH_2, CH_3, and Cl (that is -X type) as the second group; SCH_3 evidently behaves differently. Figure 3 (C-5 vs. C-*p*), on the other hand, appears to show a reasonably good single line correlation for all substituents except SCH_3. It is interesting to note, however, that the points for the two categories fall on the same side of the line as they did in Fig. 2. Finally, Fig. 4 (C-3 vs. C-*o*) shows an intermediate behaviour whereby the two groups of substituents each exhibit a characteristic correlation line slightly separated one from the other.

Attention is now drawn to the two major features revealed from our analysis of the data: (*i*) The existence of significant differences in the substituent

[a]In ppm, calculated from Table 1 relative to the resonances of tropone taken as reference.
[b]The values given in parentheses are the well known substituent effects of the four carbons (X, *o*, *m*, and *p*) of monosubstituted benzenes. Taken from ref. 13, p. 244.
[c]Taken from ref. 26. Data converted using δ_C 128.5 for benzene.

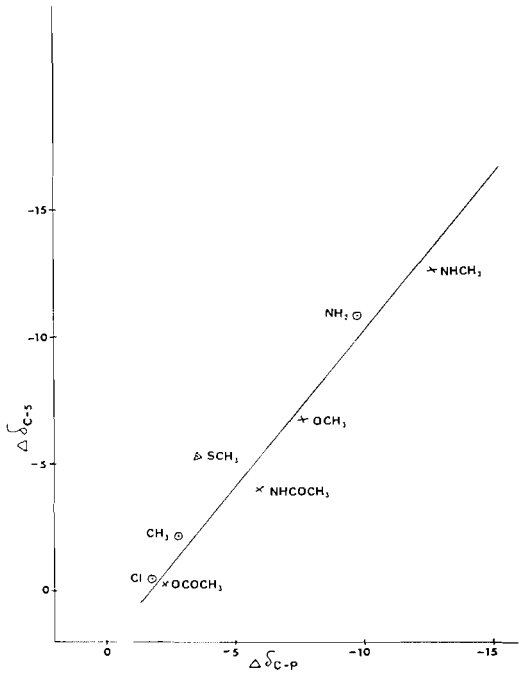

FIG. 3. Substituent parameters of C-5 in 2-substituted tropones and *para* carbons in monosubstituted benzenes.

parameters of the tropones compared to analogous substituted benzenes. (*ii*) The apparent existence of two categories of substituents each characterized by parameters exhibiting a linear relationship with those of benzene derivatives.

The magnitude of substituent effects is usually a composite of several factors whose relative importance is very difficult to establish quantitatively (16). The realization that tropones actually exhibit bond alternation characteristic of polyenones (3) could easily account for the differences in the magnitude of substituent parameters relative to benzenes. In fact the presence of the carbonyl group and the possibility of 'through' conjugation with the electron donating substituents (i.e. **8** ↔ **9**) could account for some of the differences involved, notably for C-4 whose parameters encompass a much larger range than for the corresponding *meta* parameters.

8 **9**

It is now fairly well recognized that π-electron redistribution through mesomeric effects is very important for substituted benzenes (14) and the linear relationships observed for tropones suggest that this mechanism is also very important. But other factors must contribute appreciably as evidenced by the two categories of substituents and the apparent abnormality of SCH_3.

The difference between the two lines representing the two categories of substituents (i.e. -X vs. -X-Y) appears to decrease with distance from the site of substitution. Because C-2 is β to Y and C-3 is γ to it, one would expect some difference if the proximity of the carbonyl group modified the conformational properties of the -X-Y substituents compared to the situation in substituted benzenes. Because of the vastly different nature of the substituents it is difficult to identify clearly the origin (steric or electrostatic) of the rotational conformational perturbation. It is nevertheless clear that this modification causes changes in electron densities by a mechanism other than (although not necessarily exclusively) resonance but which we are unable to identify unambiguously at this time (17).

The apparent abnormality of the SCH_3 substituent together with the realization that no strongly electron attracting substituent has been investigated suggest some caution in extrapolations from the available data although it is hoped that our observations will be a useful starting point for the utilization of ^{13}Cmr spectroscopy for the structure elucidation of more complex substituted tropones.

Experimental

The 100 MHz ^{1}Hmr spectra were recorded on a JEOL JNM-4H-100 spectrometer (Université de Montréal) equipped with a JEOL Hetero Spin Decoupler model JNM-SD-HC. The ^{13}Cmr spectra were recorded at 22.63 MHz with a Bruker WH-90 spectrometer (Université de Montréal) equipped with the standard Bruker variable temperature accessories. Heteronuclear ^{1}H–^{13}C double-resonance experiments were carried out using the standard proton decoupler of the WH-90.

All ^{13}C spectra were obtained in the Fourier transform mode using 10 mm diameter sample tubes. The field–frequency lock was provided by the deuterium resonance of the solvent $CDCl_3$. The decoupler power was calibrated by proton off-resonance decoupling of a methanol sample (6). The flip angle was set at about 45° (6 μsec) and the number of accumulations depended on the concentration of the samples which varied according to the amount available. The coupled spectra were obtained through the gated decoupling technique (6) using the standard procedure for WH-90 spectrometers equipped with the Nicolet model 293 I/O Controller.

Synthesis of the 2-Substituted Tropones

The tropolone required for this work was prepared by the method reported by Steven *et al.* (18). The derivatives **2**-OCH_3 (19), **2**-$OCOCH_3$ (20), **2**-$NHCOCH_3$ (21), **2**-Cl (22), and **2**-SCH_3 (23) were prepared essentially as reported. We succeeded in preparing **2**-NH_2 with an 84% yield, much better than previous reports (21) through a modification of Doering and Knox's (20) procedure. Using milder conditions we were able to substantially increase the yield of **2**-$NHCH_3$ over that previously obtained (21) as described below.

*2-Aminotropone (**2**-NH_2)*

2-Methoxytropone (4.0 g) was dissolved in methanol (20 ml) and cooled to −30°C in a pressure bottle. Ammonia was passed into it for 5 min. The bottle was closed, and heated to 90°C for 2 h. The reaction mixture was then cooled and the resulting solution evaporated to dryness. The residue was taken in methanol, treated with charcoal and filtered through Celite to yield 2-aminotropone (2.9 g) mp 94–96°C (lit. (20) mp 100–101°C). All the spectroscopic data, (ir, uv, ms) were in agreement with the structure.

*2-Methylaminotropone (**2**-$NHCH_3$)*

A solution of 2-methoxytropone (3.77 g) in methanol (10 ml) was cooled to −50°C and methylamine was bubbled through it for about 10 min. The reaction mixture was then brought to room temperature, the solvent was removed under vacuum, and it was flushed twice with methanol. The residue was crystallized with ether to yield pure product (3.5 g) mp 80–82°C (lit. (21) mp 83°C).

*2-Methyltropone (**2**-CH_3)*

2-Methyltropone was synthesized by a modification of a previously described procedure (24).

Deuterations

3,5,7-Trideuteriotropolone (**4**) was prepared using the procedure described by Forbes (25). Compounds **3** and **6** were prepared from **4** by the same procedures as used for the non deuterated **2**-OCH_3 and **2**-$OCOCH_3$.

Chemical behavior of charge-transfer complexes. VII. Solvolysis of alkyl arenesulfonate donors in the presence of aromatic acceptors[1]

ALLAN K. COLTER[2] AND ROBERT E. C. TURKOS

Department of Chemistry, Carnegie-Mellon University, Pittsburgh, PA 15213, U.S.A. and Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 19, 1977

ALLAN K. COLTER and ROBERT E. C. TURKOS. Can. J. Chem. **56**, 585 (1978).

Rates of solvolysis of several ethyl and 2-propyl arenesulfonates having π donor leaving groups were measured in the absence of acceptor and in the presence of the π acceptors 1,3,5-trinitrobenzene (TNB) and 2,4,7-trinitrofluorenone (TNF). With four of the nine combinations investigated, added acceptor produced small but measurable rate enhancements. Ester–TNF 1:1 association constants were measured spectrophotometrically at 20, 30, and 40°C in acetic acid for 2-propyl 4-methoxy-1-naphthalenesulfonate (**3***b*), 4,8-dimethoxy-1-naphthalenesulfonate (**4**), 3,7-dimethyl-1-naphthalenesulfonate (**5**), and 1-pyrenesulfonate (**6**). From the equilibrium and kinetic data, the reactivity of the 1:1 ester–TNF complex relative to that of the uncomplexed ester (k_c/k_u) in acetolysis at 85.73°C was estimated to be *less than* 4.2 and 1.4 for **3***b* and **4**, respectively, 4.4 ± 2.0 for **5**, and 2.8 ± 0.4 for **6**. The value of k_c/k_u for **6** determined from analysis of the kinetic data alone is 2.7 ± 0.8.

ALLAN K. COLTER et ROBERT E. C. TURKOS. Can. J. Chem. **56**, 585 (1978).

On a mesuré les vitesses de solvolyse de plusieurs arènesulfonates d'éthyle et de propyle-2 possédant des nucléofuges donneurs d'électrons π; ces mesures ont été effectuées en l'absence d'accepteur et en présence des accepteurs d'électrons π trinitro-1,3,5 benzène (TNB) et trinitro-2,4,7 fluorénone (TNF). Dans quatre des neuf combinaisons étudiées, l'addition d'un accepteur à provoquée des augmentations faibles mais mesurables des vitesses. On a mesuré d'une façon spectroscopique les constantes d'association 1:1 ester–TNF; on a effectué ces mesures à 20, 30 et 40°C dans de l'acide acétique pour les sulfonates suivants: méthoxy-4 naphtalènesulfonate-1 (**3***b*), diméthoxy-4,8 naphtalènesulfonate-1 (**4**), diméthyl-3,7 naphtalènesulfonate-1 (**5**) et pyrènesulfonate-1 (**6**) de propyle-2. En se basant sur les équilibres et les données cinétiques, on a évalué que la réactivité du complexe 1:1 ester–TNF par rapport à celle de l'ester non complexé (k_c/k_u) lors de l'acétolyse à 85.73°C est respectivement plus faible que 4.2 et 1.4 pour **3***b* et **4**, 4.4 ± 2.0 pour **5** et 2.8 ± 0.4 pour **6**. La valeur de k_c/k_u pour **6**, déterminée uniquement à partir d'une analyse de données cinétiques, est de 2.7 ± 0.8.

[Traduit par le journal]

There are three main classes of reactions where catalysis by molecular complexing as a consequence of enhanced charge-transfer interaction in the transition state should be observable (1). A reaction of a π acceptor in which the transition state (or at least that portion of the structure responsible for its acceptor properties) is more electron-deficient than the reactant should be facilitated by complexation with a nonreacting donor. This type of catalysis by π donors has been amply demonstrated in solvolytic reactions of 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate and related compounds (2). Reactions involving extension of a conjugated system in the transition state should be catalyzed by either π donors or π acceptors, depending on the reactant. This prediction has again been confirmed by catalysis of racemization of biaryl donors by π acceptors (3).

The third class is reactions of π donors having an electron-rich transition state, where catalysis by a nonreacting π acceptor might be anticipated. For several reasons, attempts to observe catalysis of this kind have been less successful. For example, rates of basic hydrolysis of *N*-(3-indoleacryloyl)imidazole, *p*-nitrophenyl 3-indoleacrylate, and *p*-nitrophenyl 3-indoleacetate in aqueous solution were decreased by complexation with 3,5-dinitrobenzoate ion (4), possibly owing to electrostatic repulsion of the approaching hydroxide or to steric hindrance to the nucleophilic attack. While aromatic nucleophilic substitution is strongly facilitated by electron-withdrawal on the aryl halide, it is difficult to design a substrate having appreciable π donor properties which will undergo nucleophilic substitution under conditions where any of the common strong π acceptors will survive (5). Furthermore, electronic effects due to complexing are likely to be outweighed by unfavorable steric effects. The clearest examples of catalysis due to electron-withdrawal by complexation are the small rate enhancements produced by 1,3,5-trinitrobenzene and other π

acceptors in the reaction of several π donor acids with 4-chlorodiphenyldiazomethane (6). Any steric effects in these reactions are apparently of minor importance.

As part of our continuing investigation of the chemical effects of charge-transfer complexing, we have sought additional evidence for appreciable electron transfer in weak π–π donor–acceptor complexes. We have therefore investigated the influence of π acceptors on the rates of solvolysis of several alkyl arenesulfonates having π donor leaving groups. Any rate enhancements in such reactions are expected to be very small since the π donor properties of the arenesulfonate ion (and hence the partially-developed arenesulfonate ion in the transition state) are expected to be only slightly enhanced over those of the ester itself. Nevertheless, even very small rate enhancements would have qualitative significance since the reaction should be free from complicating steric effects and side reactions of the acceptors.

Results

The arenesulfonate esters **1–6** were synthesized by standard methods. Rates of ethanolysis of esters **1***a*,

[a]Concentrations of esters at 85.73°C: 9.4×10^{-3} M.
[b]At 85.73°C.

By analogy with earlier work (2), the simplest mechanism for catalysis by added acceptor, A, is as represented by [1], where RX is the arenesulfonate

[1]
$$\begin{array}{ccc} RX + A & \overset{K}{\rightleftharpoons} & RX\cdot A \\ \downarrow k_u & & \downarrow k_c \\ \text{Products} & & \text{Products} \end{array}$$

ester donor, k_u and k_c are rate constants for acetolysis of uncomplexed ester and 1:1 ester–acceptor complex, respectively, and K is the 1:1 ester–acceptor association constant. Under conditions where the stoichiometric concentration of acceptor, c_A, is much greater than the concentration of 1:1 complex, RX·A, this mechanism leads to [2] (1), where k_{obs} is the observed rate constant in the presence of c_A M

[2] $$1/(k_{obs} - k_u) = 1/(k_c - k_u) + 1/K(k_c - k_u)c_A$$

acceptor. In theory, therefore, both k_c and K can be obtained by measurement of k_{obs} at two or more acceptor concentrations and analysis of a plot of $1/(k_{obs} - k_u)$ vs. $1/c_A$. In practice, however, such an analysis requires substantial rate enhancements over

[a]Extrapolated from data at 20, 30, and 40°C.

a range of acceptor concentrations corresponding to a substantial variation in the fraction of ester which is complexed, and in the present work was marginally possible only for acetolysis of **6** in the presence of TNF. The analysis leads to $K = 3.1 \pm 1.4$ ℓ mol^{-1}, $k_c = 3.3 \pm 1.0 \times 10^{-4}$ s^{-1}, and $k_c/k_u = 2.7 \pm 0.8$.

To confirm this result, and to gain further information about the effects of complexation with the other systems, ester–TNF association constants were measured spectrophotometrically for esters **3***b*, **4**, **5**, and **6** in acetic acid at 20, 30 and 40°C. The results are summarized in Table 3, together with an estimate of the complexation constants at 85.73°C, obtained by extrapolation. The associated thermodynamic quantities ΔH^0 and ΔS^0 (30°C) are, respectively: **3***b* -9.7 ± 1.5 kcal mol^{-1}, -29.1 ± 5.0 cal deg^{-1} mol^{-1}; **4** -2.2 ± 0.7 kcal mol^{-1}, -4.5 ± 2.4 cal deg^{-1} mol^{-1}; **5** -7.4 ± 2.2 kcal mol^{-1}, -22.5 ± 7.2 cal deg^{-1} mol^{-1}; **6** -8.9 ± 0.8 kcal mol^{-1}, -22.7 ± 2.6 cal deg^{-1} mol^{-1}. The extrapolated value of K for **6** (2.9 ± 0.7 ℓ mol^{-1}) is in good agreement with the value (3.1 ± 1.4 ℓ mol^{-1}) obtained by analysis of the kinetic data alone.

From [1], k_{obs} at a particular set of ester and acceptor concentrations is given by [3], where F_c is the fraction of ester which is complexed and F_u

$$[3] \quad k_{obs} = k_u F_u + k_c F_c = k_u + (k_c - k_u)F_c$$

($= 1 - F_c$) is the fraction uncomplexed. Under conditions where the acceptor is in large excess over the ester and/or the complexation constants for the ester and arenesulfonate ion product do not differ greatly, F_c will be very nearly constant over the course of the reaction and strict first order kinetics are expected. In the present work, no deviations from first-order behavior were detectable over two half lives.

Rearrangement of [3] yields an expression for k_c/k_u [4]. Using the values of K at 85.73°C obtained

$$[4] \quad k_c/k_u = \frac{k_{obs} - k_u + k_u F_c}{k_u F_c}$$

by extrapolation (Table 3), c_A, and initial ester concentration (Table 2), values of F_c were calculated for the conditions of each rate measurement in the presence of TNF. These values of F_c were then combined with the appropriate values of k_{obs} and k_u (Table 2) to calculate k_c/k_u using [4]. The values of k_c/k_u so obtained are 4.4 ± 2.0 for **5** and 2.8 ± 0.4 for **6**. Values of k_c/k_u for **6** calculated from the rate data at four different TNF concentrations were 2.8 ± 0.5, 2.9 ± 0.5, 2.8 ± 0.4, and 2.8 ± 0.4 for 0.0187, 0.0233, 0.0280, and 0.0374 M TNF, respectively. This agreement and the close agreement with k_c/k_u obtained from analysis of the kinetic data alone (2.7 ± 0.8) supports the reliability of the results for **6**.

Using the standard deviations in k_u, k_{obs} and K, minimum and maximum values of k_c/k_u were estimated from minimum and maximum values of $(k_{obs} - k_u)$ and maximum and minimum values of K, respectively. In this way, we estimate for **3***b*, $k_c/k_u = 1.6$ (maximum range, 0.6 to 4.2) and for **4**, $k_c/k_u = 0.9$ (maximum range 0.6 to 1.4). Thus it is possible that the chemical effect of complexation by TNF in acetolysis of **3***b* is similar to that estimated for **5** and **6**, but that measurable rate enhancements were not observed because of the very small extent of complexation. In contrast, the behavior of **4**, where k_c/k_u is *less than* 1.4, appears to be distinctly different.

Discussion

With four of the nine solvolyses of π donor – alkyl arenesulfonates investigated, added TNB or TNF produced measurable rate enhancements. We have interpreted the rate increases in terms of a mechanism involving complexation between donor ester and acceptor to form a 1:1 complex which is more reactive than uncomplexed ester. The most plausible explanation for the increased reactivity of the 1:1 complex is electron withdrawal by the complexed acceptor, and we consider the results to provide further evidence for significant charge transfer in weak π–π donor–acceptor complexes.

The absence of measurable rate enhancements in several systems where the extent of complexation is expected to be very small (particularly acetolysis of **1***b* and **2***b* in the presence of TNF) argues strongly against some general more specific medium effect not involving complexing. For the acetolysis of **3***b* in the presence of TNF, we estimate from independent

spectrophotometric measurements that an increase in ester reactivity due to complexation (k_c/k_u) less than 4.2 would not lead to a significant rate enhancement under the conditions of our experiments. The extent of complexation is almost certainly smaller for esters **1***b* and **2***b* + TNF in acetic acid.

The increase in ester reactivity due to complexation by TNF (k_c/k_u) estimated for esters **5** and **6** is small as expected. In the absence of rate data for acetolysis of a series of substituted 2-propyl 1-naphthalenesulfonates and 1-pyrenesulfonates, only a very approximate comparison between the electron-withdrawing effect of a complexed TNF and those of typical electron-withdrawing substituents can be made. In the 1-naphthalenesulfonate series the rate-retarding effect of a 4-methoxy group (i.e., **3***b* vs. **1***b*) is very close to that of a *p*-methoxy group in acetolysis of cyclohexyl benzenesulfonates at 70°C (7). If the influence of a 3-substituent in the 1-naphthalenesulfonate series is similar to that of a *meta* substituent in the benzenesulfonates, the rate enhancing effect of a complexed TNF in acetolysis of 2-propyl 1-naphthalenesulfonates (4.4) is between that expected for 3-Cl (~3.0) and 3-CN (~5.3) substituents. Measured in this way, this effect is very similar in magnitude to that of a complexed TNB on the acidities of several donor carboxylic acids (6).

The results for ester **4** are unusual in two ways. The association constant determined spectrophotometrically is unusually insensitive to temperature changes, both the enthalpy decrease ($-\Delta H^0$) and entropy decrease ($-\Delta S^0$) accompanying complexation being unusually small. We have previously observed unexpectedly small complexation constants for dimethoxynaphthalene donors and 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate in acetic acid (8). It is possible that a methoxy group may sterically hinder complexation in the same way that an ethyl group does (9). It is interesting that *both* $-\Delta H^0$ and $-\Delta S^0$ are smaller for complexation of I_2 (10) and ICl (11) with hexaethylbenzene than with hexamethylbenzene. The smaller $-\Delta H^0$ and $-\Delta S^0$ values measured for **4** may therefore reflect a looser complex, possibly as a result of steric hindrance from the two methoxy groups and the alkoxysulfonate group. The second unusual result with **4** is the absence of any increase in reactivity on complexation with TNF. This result could also be a consequence of a looser complex. Alternatively, complexation may sterically hinder solvation of the developing sulfonate anion in the transition state.

Experimental

All melting points are corrected. Microanalyses were performed by Galbraith Laboratories, Knoxville, Tennessee, U.S.A. Infrared spectra were measured using a Perkin-Elmer model 137B spectrophotometer, and nuclear magnetic resonance spectra with a Varian A-60 spectrometer.

Reagents and Solvents

1,3,5-Trinitrobenzene was Fisher highest purity, used without further purification. 2,4,7-Trinitrofluorenone was prepared as described by Woolfolk and Orchin (12) and had mp 175.5–176°C (lit. (12) mp 175.2–176°C). Anhydrous ethanol was prepared by heating reagent grade absolute ethanol for 12 h at reflux over magnesium ethoxide, followed by distillation under anhydrous conditions. Anhydrous acetic acid, and standard (0.01 *M*) sodium acetate in acetic acid were prepared as previously described (13). Standard alcoholic sodium hydroxide (0.02 *M*) was prepared by dilution of 0.2 ml of a filtered solution of reagent grade sodium hydroxide in 7 ml of distilled water, to 1 ℓ with absolute ethanol, and standardization using a potassium hydrogen phthalate primary standard.

Synthesis of Esters

The esters were synthesized by reaction of ethanol or 2-propanol with the appropriate acid chloride, either commercially available (1- and 2-naphthalenesulfonyl chlorides) or obtained by reaction of the corresponding potassium arenesulfonate with thionyl chloride. The arenesulfonate salts were prepared by sulfonation of pyrene or the appropriate substituted naphthalene.

Arenesulfonate Salts

Sulfonation of 1-methoxynaphthalene, 1,5-dimethoxynaphthalene (8), and 2,6-dimethylnaphthalene is illustrated by the following procedure. To a cooled (0°C), stirred, solution of 0.20 mol of substituted naphthalene in 500–700 ml of CH_2Cl_2 was slowly added 0.22 mol of distilled chlorosulfonic acid. After complete addition the solution was stirred for an additional 6–9 h at 0–5°C. Cold water (200–250 ml) was added and stirring continued for 1 h. The aqueous layer was separated and the CH_2Cl_2 solution extracted with water. The aqueous extracts were combined and K_2CO_3 carefully added until the solution was slightly basic. The resulting suspension was heated on a steam cone until solution was complete. The salt which separated on cooling was filtered, dried, washed with ether or methylene chloride, and dried again at 120°C. Potassium 4-methoxy-1-naphthalenesulfonate was obtained in 94% yield; ir (Nujol): 1198, 1182, 1059, 687 cm^{-1} ($—SO_3^-$); *p*-toluidide mp 211–212°C. Potassium 4,8-dimethoxy-1-naphthalenesulfonate was obtained in 86% yield, ir (Nujol): 1199, 1176, 1059, 701 cm^{-1} ($—SO_3^-$); *p*-toluidide mp 198.5–199.5°C. Potassium 3,7-dimethyl-1-naphthalenesulfonate was obtained in 86% yield; ir (Nujol): 1205, 1183, 1058, 705 cm^{-1} ($—SO_3^-$); *p*-toluidide mp 268–269°C (lit. (14) mp 279°C).

Sodium 1-pyrenesulfonate was obtained in 98% yield by sulfonation of pyrene following the procedure of Tietze and Bayer (15) using CH_2Cl_2 as the solvent; ir (Nujol): 1198, 1181, 1062, 706 cm^{-1} ($—SO_3^-$); *p*-toluidide mp 234–236°C.

Sulfonyl Chlorides

The procedure was adapted from that of Bosshard *et al.* (16). To a stirred suspension of 0.10 mol of dry sulfonate salt in 100 ml of distilled DMF was added 36 ml (0.5 mol) of thionyl chloride over a period of 5–10 min. After stirring for an additional 10–45 min, the mixture was poured onto 800 ml of ice-water and the precipitate filtered and washed with water. The precipitate was dissolved in CH_2Cl_2, the solution dried over $MgSO_4$, and filtered. The product was isolated by evaporation and crystallization from CH_2Cl_2 – petroleum ether (bp 60–110°C). 4-Methoxy-1-naphthalenesulfonyl chloride was obtained in 85% yield, mp 98–99.5°C (lit. (17) mp 98.5°C); ir (CH_2Cl_2): 1361, 1161 cm^{-1} (SO_2). 4,8-Dimethoxy-1-naphthalenesulfonyl chloride was obtained in 86% yield, mp

118.5–119.5°C; ir (CH_2Cl_2): 1351, 1159 cm^{-1} (SO_2), nmr ($CDCl_3$) τ: 5.95 (s, 6H, methoxy), 3.20 (d, J = 9 Hz, 1H, H-3), 2.85 (doublet of doublets, J = 8 Hz, 1.5 Hz, 1H, H-7), 2.43 (t, J = 8 Hz, 1H, H-6), 2.02 (doublet of doublets, J = 8 Hz, 1.5 Hz, 1H, H-5), 1.48 (d, J = 9 Hz, 1H, H-2). *Anal.* calcd. for $C_{12}H_{11}O_4SCl$: C 50.26, H 3.86, S 11.18, Cl 12.38; found: C 50.47, H 4.08, S 11.16, Cl 12.20. 3,7-Dimethyl-1-naphthalenesulfonyl chloride was obtained in 79% yield, mp 107–108.5°C (lit. (18) mp 105–107°C); ir (CH_2Cl_2): 1361, 1176 cm^{-1} (SO_2). 1-Pyrenesulfonyl chloride was obtained in 82% yield, mp 175–176°C (lit. (19) mp 120°C); ir (KBr): 1355, 1170 cm^{-1} (SO_2); nmr ($CDCl_3$) τ: 1.78 (m, 7H, aromatic), 1.27 (d, J = 8 Hz, 1H, H-2), 0.90 (d, J = 9.5 Hz, H-10). *Anal.* calcd. for $C_{16}H_9O_2SCl$: C 63.89, H 3.01, S 10.66, Cl 11.78; found: C 63.79, H 2.93, S 10.85, Cl 11.82.

Esters

Ethyl 1-naphthalenesulfonate (**1***a*) and 2-naphthalenesulfonate (**2***a*) were prepared from the corresponding acid chlorides (Eastman Kodak, highest purity) using the method of Rodionow (20). A 74% yield of **1***a* was obtained as an oil, ir (CH_2Cl_2) 1342, 1171 cm^{-1} (SO_2). *Anal.* calcd. for $C_{12}H_{12}SO_3$: C 60.99, H 5.12; found: C 60.77, H 4.97. A 76% yield of **2***a* was obtained as an oil, ir (CH_2Cl_2) 1344, 1168 cm^{-1} (SO_2). *Anal.* calcd. for $C_{12}H_{12}SO_3$: C 60.99, H 5.12; found: C 61.10, H 5.30.

Ethyl 4-methoxy-1-naphthalenesulfonate (**3***a*) and the 2-propyl-1-naphthalenesulfonates (**1***b*, **2***b*, **3***b*, **4**, and **5**) were prepared by the usual method (21) using a 4- to 10-fold molar ratio of alcohol to acid chloride and reaction times of 2 to 3 days. Unreacted acid chloride was destroyed before work-up using aqueous NaOH (22). With the preparation of **1***b* and **2***b* the solvent was 3:10 (v/v) pyridine–benzene. The esters were crystallized from Skellysolve B (**3***a*), CH_2Cl_2 – petroleum ether (60–110°C), or $CHCl_3$ – petroleum ether (60–110°C). The 2-propyl esters were further purified before use by chromatography on Fluorosil using benzene or benzene – 1% ethyl acetate eluent. Ethyl 4-methoxy-1-naphthalenesulfonate was obtained in 27% yield, mp 118.5–119.5°C, ir (CH_2Cl_2): 1344, 1170 cm^{-1} (SO_2); nmr ($CDCl_3$) τ: 8.80 (t, J = 7 Hz, 3H, ethyl CH_3), 5.97 (quartet, J = 7 Hz, 2H, ethyl CH_2), 5.97 (s, 3H, methoxy), 3.18 (d, J = 8 Hz, 1H, H-3), 2.37 (m, 2H, H-6 and H-7), 1.77 (d, J = 8 Hz, 1H, H-2), 1.48 (m, 2H, H-5 and H-8). *Anal.* calcd. for $C_{13}H_{14}SO_4$: C 58.62, H 5.29, S 12.04; found: C 58.48, H 5.40, S 11.88. 2-Propyl-1-naphthalenesulfonate was obtained in 66% yield, mp 59–60°C, ir (CH_2Cl_2): 1340, 1171 cm^{-1} (SO_2). *Anal.* calcd. for $C_{13}H_{14}O_3S$: C 62.37, H 5.64, S 12.81; found: C 62.23, H 5.59, S 12.69. 2-Propyl 2-naphthalenesulfonate was obtained in 51% yield, mp 55–56°C; ir (CH_2Cl_2): 1333, 1168 cm^{-1} (SO_2). *Anal.* calcd. for $C_{13}H_{14}SO_3$: C 62.37, H 5.64, S 12.81; found: C 62.25, H 5.65, S 12.77. 2-Propyl 4-methoxy-1-naphthalenesulfonate was obtained in 59% yield, mp 107.5–108.5°C; ir (CH_2Cl_2): 1353, 1167 cm^{-1} (SO_2), nmr ($CDCl_3$) τ: 8.79 (d, J = 6.5 Hz, 6H, isopropyl CH_3), 5.90 (s, 3H, methoxy), 5.25 (sept., J = 6.5 Hz, 1H, isopropyl CH), 3.10 (d, J = 8 Hz, 1H, H-3), 2.26 (m, 2H, H-6 and H-7), 1.63 (d, J = 8 Hz, 1H, H-2), 1.52 (doublet of doublets, J_{ortho} = 8 Hz, J_{meta} = 2 Hz, 1H, H-5), 1.28 (doublet of doublets, J_{ortho} = 8.5 Hz, J_{meta} = 2 Hz, 1H, H-8). *Anal.* calcd. for $C_{14}H_{16}O_4S$: C 59.98, H 5.75, S 11.44; found: C 59.81, H 5.60, S 11.44. 2-Propyl 4,8-dimethoxy-1-naphthalenesulfonate was obtained in 67% yield, mp 119–120°C, ir (KBr): 1351, 1160 cm^{-1} (SO_2); nmr ($CDCl_3$) τ: 8.73 (d, J = 6 Hz, 6H, isopropyl CH_3), 5.99 (s, 6H, methoxy), 5.08 (sept., J = 6 Hz, 1H, isopropyl CH), 3.18 (d, J = 8 Hz, 1H, H-3), 2.88 (doublet of doublets, J_{ortho} = 8 Hz, J_{meta} = 1.5–2 Hz, 1H, H-7), 2.47 (t, J = 8 Hz, 1H, H-6), 2.03 (doublet of doublets, J_{ortho} = 8 Hz, J_{meta} = 1.5–2 Hz, 1H, H-5), 1.53 (d, J = 8 Hz, 1H, H-2). *Anal.* calcd. for $C_{15}H_{18}O_5S$: C 58.05, H 5.84, S 10.33; found: C 57.86, H 5.92, S 10.34. 2-Propyl 3,7-dimethyl-1-naphthalenesulfonate was obtained in 55% yield, mp 80–81°C; ir (CH_2Cl_2): 1337, 1174 cm^{-1} (SO_2); nmr ($CDCl_3$) τ: 8.78 (d, J = 6 Hz, 6H, isopropyl CH_3), 7.45 (s, 6H, aryl CH_3), 5.28 (sept., J = 6 Hz, 1H, isopropyl CH), 2.62 (doublet of doublets, J_{ortho} = 9 Hz, J_{meta} = 1.5 Hz, 1H, H-6), 2.25 (d, J = 9 Hz, 1H, H-5), 2.17 (broad s, 1H, 8-H), 1.87 (d, J = 1.5 Hz, 1H, H-2), 1.65 (broad s, 1H, H-4). These assignments are based on the paper of Garbutt *et al.* (23). *Anal.* calcd. for $C_{15}H_{18}O_3S$: C 64.72, H 6.52, S 11.52; found: C 64.58, H 6.37, S 11.53.

2-Propyl 1-pyrenesulfonate was prepared as follows. To a solution of 10.5 g (0.035 mol) of 1-pyrenesulfonyl chloride in 125 ml of dry pyridine was added 10 ml of triethylamine and 25 ml of dry 2-propanol. After shaking at room temperature for 10 min, the mixture was kept at 10°C for 20 h and then added to a separatory funnel containing 600 ml of 10% HCl and 250 ml of $CHCl_3$. After separating the $CHCl_3$ layer, the aqueous layer was extracted again with $CHCl_3$ and the combined $CHCl_3$ extracts washed with 10% HCl, water, dried over $MgSO_4$, boiled with decolorizing charcoal, and filtered. After removal of the solvent under vacuum, the ester was purified by chromatography on Fluorosil (benzene eluent) followed by crystallization from 50:50 (v/v) benzene – Skellysolve B, to yield 4.27 g (37.8%), mp 133.5–134°C; ir (KBr): 1342, 1176 cm^{-1} (SO_2); nmr ($CDCl_3$) τ: 8.80 (d, J = 6 Hz, isopropyl CH_3), 5.22 (sept., J = 6 Hz, 1H, isopropyl CH), 1.88 (m, 7H, aromatic), 1.37 (d, J = 8.5 Hz, 1H, H-2), 1.05 (d, J = 8.5–9 Hz, 1H, H-10). *Anal.* calcd. for $C_{19}H_{16}O_3S$: C 70.35, H 4.97, S 9.89; found: C 70.22, H 4.85, S 9.79.

Kinetic Measurements

Weighed amounts of ester (approximately 0.002 mol in ethanolyses, 0.001 mol in acetolyses) and acceptor were dissolved in anhydrous ethanol or acetic acid and adjusted to 100 ml in a volumetric flask. Aliquots of 6–7 ml were sealed under nitrogen in 6 in. Pyrex test tubes and placed in a constant temperature bath. After thermal equilibration ampoules were withdrawn at appropriate intervals of time, quenched thermally, and an accurately-measured aliquot (5 ml, 25°C) analyzed. In the ethanolyses, the 5 ml aliquot was dissolved in 25 ml of ethanol and titrated with standard 0.02 M ethanolic sodium hydroxide solution using Lacmoid indicator. In the presence of high concentrations of TNB, accurate determination of the end point was difficult because the solutions were already highly colored. The extent of acetolysis was determined by titration with standard 0.01 M sodium acetate in acetic acid. End points were determined potentiometrically using a Beckman model 76004 expanded scale pH meter equipped with a combination Ag/AgCl–glass electrode, estimated accuracy ±0.005 ml. Infinity determinations were carried out in triplicate after 10 half lives. Rate constants were calculated using the integrated first order rate expression, using individual titers and times (together with zero and infinity titers), and are reported as averages with standard deviations of the mean. Infinity titers were generally 97–99% of theory.

Determination of Association Constants

Optical density measurements utilized a Guilford model 200 spectrophotometer equipped with a thermostatted cell compartment. The temperature in the cell compartment was maintained to within ±0.05°C of the stated temperature by circulation of water. Four stock solutions containing close to equimolar amounts of ester and TNF in dry acetic acid were prepared, and an additional three or four solutions prepared by dilution. Concentration ranges were 5×10^{-3} to 4×10^{-2}

For personal use only.

M for **3***a*, **4***a*, and **5**, and 4×10^{-3} to 1.25×10^{-2} M for **6**. Measurements were made at 10 nm intervals from 440–460 nm with **3***b*, 430–460 nm with **4***b* and **5**, and 430–470 nm with **6**. The experimental data were analyzed by computer using an adaptation of the iterative method of de Maine and Seawright (24), described by Dewar and Thompson (25). The reported association constants are averages of the values obtained at 3 to 5 wavelengths, with standard deviations of the means.

Calculations and Error Estimates

Analysis of the kinetic data for acetolysis of **6** in the presence of TNF using [2] is based on the approximation $c_A \approx [A]$, which is only marginally valid in this case. However, stoichiometric acceptor concentrations, c_A, can be used to obtain an initial estimate of K (intercept ÷ slope), this value used to calculate initial values of [A] for the conditions of each rate measurement, and the process repeated using these values of [A] in place of c_A to obtain a second estimate of K. Values of K and k_c obtained in this way converged after two cycles.

The reported values of ΔH^0, ΔS^0, and K(85.73°C, extrapolated) were obtained by least squares analysis of a plot of ln K vs. $1/T$. Standard deviations (s) in ΔH^0, ΔS^0, and K(ext) were calculated as follows. Analytical expressions for these quantities in terms of the values of K at 20 and 40°C (and the temperatures) were derived. These were differentiated with respect to K(20°C) and K(40°C) to obtain expressions for $s_{\Delta H^0}$, $s_{\Delta S^0}$, and $s_{K(\text{ext})}$ in terms of $s_{K(20°C)}$ and $s_{K(40°C)}$. The standard deviations so obtained were larger in every case than those calculated in the usual way from least-squares analysis of the ln K vs. $1/T$ plot. The latter reflect only the degree of scatter from a perfect straight line and, for only three points, are considered less realistic.

The equilibrium expression 5 for 1:1 complexation was used

$$[5] \qquad K = \frac{[D{\cdot}A]}{\{c_A - [D{\cdot}A]\}\{c_D - [D{\cdot}A]\}}$$

to obtain an expression for F_c ($= [D{\cdot}A]/c_D$) in terms of K, c_A, and c_D. Standard deviations in F_c were then calculated in the usual way (26) from $s_{K(\text{ext})}$ by differentiation of this expression. Finally, standard deviations in k_c/k_u were obtained in the same way from $s_{k_{obs}}$, s_{k_u}, and s_{F_c} by differentiation of [4].

ROBERT N. O'BRIEN and HENRYK KOLNY. Can. J. Chem. **56**, 591 (1978).

The use of interferometry to make visible concentration gradients at working electrodes has progressed to video tape recording of interferograms. Rapid accurate analysis should be able to gain sufficient data from experimental runs where migration effects are just balanced by diffusion effects to help evolve a better mathematical formula with which to predict concentration changes at working convectionless electrodes. Data are presented showing a quasi-steady state polarization in a low current density electrolysis run with Fe^{2+} the electroactive species.

ROBERT N. O'BRIEN et HENRYK KOLNY. Can. J. Chem. **56**, 591 (1978).

L'utilisation de l'interférométrie pour rendre visible des gradients de concentrations à des électrodes en opération peut maintenant être effectuée à l'aide d'un enregistrement vidéo des interférogrammes. Une analyse précise et rapide devrait permettre d'obtenir assez de données, à partir de résultats expérimentaux où les effets de migrations sont exactement contrebalancés par des effets de diffusion, pour permettre l'élaboration d'une meilleure expression mathématique avec laquelle on pourrait prédire les changements de concentration au niveau d'électrodes opérant sans convection. On présente des données montrant un état de polarisation pratiquement statique lors d'une électrolyse à basse densité de courant impliquant du Fe^{2+} comme espèce électroactive.

[Traduit par le journal]

The idea of observing concentration gradients at working electrodes and thereby studying electrochemical transport is not of recent origin. Samarcev (1) in 1934 used a two-beam interferometer to view the diffusion layer at solid electrode and in 1938 Antweiler (2) published his classic work on the polarographic maximum in which he used a form of interferometry. In 1955 Ibl and Muller (3) published the first good two-beam interferograms of a diffusion layer at one working electrode. In 1957 O'Brien and Axon published the first multiple-beam interferogram of a complete cell showing concentration gradients from electrode to electrode (4). In the following years diffusion constants were measured (5) and also the effects of natural convection in limiting diffusion layers (6).

A first attempt to fit observed concentration gradients to theoretical curves generated for convectionless transport was reasonably successful for short times, moderate concentrations, low current densities, and electrode separations that could be considered to be semi-infinite (7). A further attempt at lower concentrations, but the same current densities, electrode separation, and electrolysis times showed much worse agreement (8). Meanwhile Tobias' group (9, 10) have shown conclusively that errors inherent in the optical set-up for interferometry are too large for its use for high current density, thick electrodes (cells), poor focussing, and long times. It is clear, however, that for low current densities (<2 mA cm^{-2}), thin cells (<0.5 cm), and hence low refractive index changes, that optical errors are smaller than other experimental errors (10).

Muller (9) has summarized progress in two-beam interferometry to 1973 (essentially to the present) and

Srivansan (11) has summarized holographic interferometry to the same date. The concentration gradient across an electrodialysis membrane by holographic interferometry has been published since Srivansan's summary (12).

In most galvanostatic studies it is assumed that steady state has been achieved at about 60 s because the potential usually has ceased to vary. This is correct if forced convection is present or at vertical (actually non-horizontal) electrodes where natural convection will limit the diffusion layer thickness and bring about a constant concentration gradient (6*c*). The exception is for horizontal electrodes where although the potential may not be perceptibly changing, the concentration contour is (7). This work was done to investigate the galvanostatic case where in the absence of convection a steady state is attained both in potential and the concentration contour, a situation at variance with mathematical solutions (8, 13). Some recent work in which the effect of a Teflon electret immersed in a KI solution was studied, where the solution was observed interferometrically, was the immediate stimulus to this work. A straight line gradient as expected in migration was first observed then the usual error function-type diffusion gradient developed and decayed (14).

Experimental

A Micro electrolysis cell which was also a Fabry-Perot interferometer giving Fizeau-type multiple beam wedge fringes similar in design to cells previously described (7, 15, 16) was used. The system in which the work was done was the $Fe/Fe(NH_4)_2(SO_4)_2/Fe$ system. The cell was 3.18 mm thick with the electrodes 8 mm apart, the solution was 0.1 *M* in $Fe(NH_4)_2(SO_4)_2$ (Mohr's Salt) and 0.1 *M* in sodium citrate at p*H* 5.1. The electrodes were Armco iron of high purity. The current density was 0.25 mA cm^{-2}.

A further series of runs was done in the system $Cu/CuSO_4/Cu$. The cathode was polycrystalline but the anode area consisted of two pieces of a single crystal with the 110 and the 111 faces exposed. The $CuSO_4$ concentration was 0.5 *M* at p*H* 4.1 at 25°C and the current density was 0.05 mA cm^{-2}. Further results with this system will be reported elsewhere.

Many runs were also done with the $Zn/ZnSO_4/Zn$ system at 0.10 *M* $ZnSO_4$ (p*H* 4.7) at 0.50 mA cm^{-2} and 0.25 mA cm^{-2}. Approximately 30 h of experiments were recorded on video tape, each experiment required about 4 min (3 min continuous taping from inception then approximately 10 s bursts for up to 1 h of electrolysis) constituting about 10^5 fields (frames) of which about 100 were analysed in detail. The data were recorded by voice on the video tape to mark times, events of experimental importance, and to record immediate impressions and values from ancillary instrumentation. The recording system consisted of a Spectra-Physics Model 122 He-Ne single mode laser as light source, a Sony Model AVC-3210 video camera, a Sony AV-3650 half-inch video recorder, and a 26 in. monitor.

Hand analysis was done by photographing the monitor with a 35 mm Nikon camera projecting the negative onto a plotting table and plotting the fringes on 30 × 50 cm transparent graph paper. Points in the drawn fringes were then converted to concentration. The conversion factor is obtained from refractive index data obtained separately with an Abbé precision refractometer or a locally designed and built interferometer using the formula:

$$[1] \qquad 2nt \cos\theta = N\lambda$$

The thickness of the interferometric cell is *t*, *n* is the refractive index of the electrolyte, θ is the angle between perpendicular incidence and the actual angle which must be so close that $\cos\theta = 1$ for good fringes, and *N* is the order of interference or twice the number of wavelengths λ in the thickness of the cell. Since *n*, *t*, and λ are known, *N* can be found and for each change of one unit (*N* is about 10^4 for the cell used) called one fringe shift, a refractive index change and hence a concentration change can be found as previously reported in detail (15, 16).

Results and Discussion

A case of steady state electrolysis for galvanostatic conditions where both the potential and the concentration contour is constant has been found and is reported here for the first time to the best of the authors' knowledge. Previously all such results occurred only when some limitation to concentration polarization such as natural or forced convection was present. It is considered that since three systems have shown this effect, two of them simple and one complex, that the effect is likely to be universal.

Figure 1 gives a plot of concentration change vs. time for the iron system typical of these 'steady-state' conditions which are achieved at about 90–120 s. Data for 3 min of the run only are shown since the remainder of the run showed only the expected experimental scatter. It is significant that constant concentration begins simultaneously (as closely as can be measured) at the electrode surface and 0.005 cm out from it. Figure 2 shows a similar plot for $Cu/CuSO_4/Cu$. The rate of anodic dissolution of the 111 plane is faster than that of the 110 plane. The effect is transferred to the part of the cathode opposite the 111 plane anode as well. Steady state is

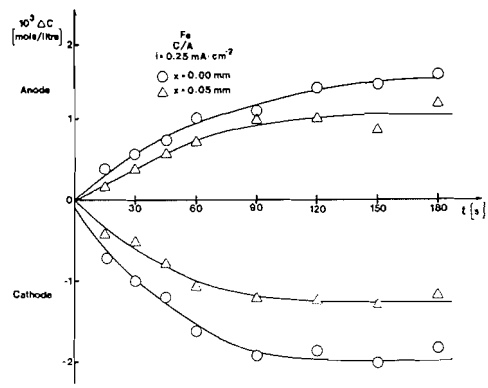

FIG. 1. The change in concentration of Fe^{2+} ion at two distances from each electrode with time of electrolysis.

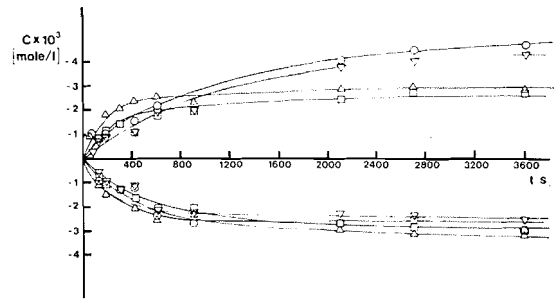

FIG. 2. The change in concentration of $CuSO_4$ at the electrode surface and 7.8×10^{-3} cm measured perpendicularly from it with time in the system $Cu/CuSO_4/Cu$. Concentration at the electrode face of the 111 and the 110 phase denoted by ○ and ▽ and at 7.8×10^{-3} cm by △ and □ respectively. The polycrystalline cathode values opposite the two anodes are marked the same way and show similar variations. The solution was 0.05 *M* $CuSO_4$, p*H* 4.1 at 25°C, and cd 0.05 mA cm^{-2}.

achieved at approximately 2000 s. The $Zn/ZnSO_4/Zn$ system showed analogous results.

The expression most commonly used to describe a non-convecting system is a solution of the differential equation (Fick's second law)

$$[2] \qquad \frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2}$$

for the boundary conditions that initially at $t = 0$ (s), $C = C_0$ the bulk concentration (mol cm^{-3}) at all x from 0 to l where $2l$ is the distance between the two electrodes (cm) and that $\Delta C = 0$, at $x = l$ for all $t > 0$ and $\partial\Delta C/\partial t$ is constant at $x = 0$ and $t > 0$. Either electrode can be taken as $x = 0$ but the case studied was the anode. When solved for these conditions by Laplace transform the expression obtained is

$$[3] \qquad \Delta C_{(x,t)} = \frac{2I\sqrt{t}}{nF\sqrt{D}}\left[\text{ierfc}\left(\frac{(2l-x)}{2\sqrt{Dt}}\right) - \text{ierfc}\left(\frac{x}{2\sqrt{Dt}}\right)\right]$$

where I is current density (A cm^{-2}), t is time (s), F is the faraday (coulombs mol^{-1}), D is the diffusion constant of the electrolyte molecule ($cm^2\ s^{-1}$), n is the number of electrons transferred in the reaction, and ierfc is the integrated error function complement tabulated by Carslaw and Yaeger (17). These are the first two terms of a series. It is usual to take into account the effect of migration by multiplying by the transport number (t_-) of the negative ion if the cation is the electroactive species as in the systems studied here. The reasoning for this procedure has been summarized by Wilke, Eisenberg, and Tobias (17). If the interest is in short times (less than 150 s) of electrolysis, the expression then becomes (8)

$$[4] \qquad \Delta C_{(x,t)} = \frac{-2It_-}{nF}\sqrt{\frac{t}{D}}\,\text{ierfc}\frac{x}{2\sqrt{Dt}}$$

It is suggested that simply multiplying by the appropriate transport number cannot give the correct concentration gradient. A solution should be sought from general transport considerations. The flux of the ith ion can be represented by

$$[5] \qquad \boldsymbol{J}_i = -D_i\left(\frac{\partial C_i}{\partial x}\right) + \mu_i v_i C_i \boldsymbol{E}$$

where all symbols have their previous meaning and μ_i is the mobility ($cm\ s^{-1}\ V^{-1}$), v_i is the charge on the ion, and $\boldsymbol{E}$ is the electric field ($V\ cm^{-1}$). When the concentration at the electrodes is constant in time at constant current density, the equation to be solved is

$$[6] \qquad \frac{\partial C_i}{\partial t} = D_i\frac{\partial^2 C_i}{\partial x^2} - \mu_i v_i \boldsymbol{E}\left(\frac{\partial C_i}{\partial x}\right) = 0$$

or

$$D_i\left(\frac{\partial^2 C_i}{\partial x^2}\right) = \mu_i v_i \frac{\partial(\boldsymbol{E}C_i)}{\partial x}$$

The statement means that rate of diffusion of ions down the concentration gradient formed by migration (the effect of the electrode field on the ion) is equal at all points to the rate of migration of ions or a steady state is reached. However, when, as is required, activities of the ions are used the solution of eq. 6 becomes very difficult.

Conclusions

The powerful method of analysis of interferometric concentration polarization data should be used to follow the onset of steady state polarization where the effects of migration are just offset by diffusion down the migration-established concentration gradient. Exact knowledge of the form of the concentration gradient should help in setting up suitable solutions to eq. 6. Clearly multiplying by the transport number does not allow eq. 4 to fit the concentration gradients observed. Intuitively, one would expect the anion transport number to approach zero as the electrode surface or more exactly the outer Helmholtz plane is approached. A mathematical solution is presently being sought.

The data and the mathematical formulations were given at the International Symposium in Ottawa July, 1976.

Transition layer model of the oxide–electrolyte interface

MICHAEL J. DIGNAM

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 9, 1977

MICHAEL J. DIGNAM. Can. J. Chem. **56**, 595 (1978).

A model of the oxide–electrolyte interface is proposed which accounts both for the Nernstian behaviour of the oxide (glass) electrode and the anomalous capacitance values of some oxides defined in terms of the change in surface charge with p*H*. The essential feature of the model is the existence of a transition layer of atomic dimensions in thickness within which is established an equilibrium between oxide and aqueous ionic species. The Nernstian behaviour of the oxide (glass) electrode is independent of the model chosen for the oxide–electrolyte double layer but requires that the oxide be conducting; the capacitance of the system, of course, is dependent on the detailed structure of the interface.

MICHAEL J. DIGNAM. Can. J. Chem. **56**, 595 (1978).

On propose un modèle pour l'interface oxyde-électrolyte qui tient compte à la fois du comportement Nernstien de l'oxyde (verre) électrode et des valeurs anormales de la capacité de quelques oxydes; ce modèle est défini en termes de changements, en fonction du p*H*, dans la charge superficielle. La caractéristique principale du modèle est l'existence d'une couche de transition dont l'épaisseur possède des dimensions atomiques et dans laquelle il s'établit un équilibre entre l'oxyde et les espèces ioniques aqueuses. Le comportement Nernstien de l'oxyde (verre) électrode ne dépend pas du modèle choisi pour la double couche oxyde–électrolyte; elle nécessite toutefois que l'oxyde soit conducteur. Il est entendu que la capacité du système dépend de la structure détaillée de l'interface.

[Traduit par le journal]

Introduction

The behaviour of the oxide/electrolyte system has for some time posed a problem, which has been tackled by many researchers who have offered as many interpretations. Ahmed (1) has recently presented a review of some of these, in addition to presenting his own. A brief summary of the situation follows.

A large number of oxide electrodes (1) that are conducting obey the Nernst equation

$$[1] \quad \psi_M - \psi_{aq} = 2.303(kT/e)(\mathrm{p}H_{zpc}{}^{(M)} - \mathrm{p}H)$$

where ψ_M is the potential of the metal in contact with the oxide, ψ_{aq} that of the aqueous electrolyte, $\mathrm{p}H_{zpc}{}^{(M)}$ the p*H* of the electrolyte for which $\psi_M - \psi_{aq} = 0$, with the other symbols having their usual meaning. Furthermore, the potential drop across a conducting glass (vitreous metal oxide) membrane follows a Nernstian relation,

$$[2] \quad \psi_2 - \psi_1 = 2.303(kT/e)(\mathrm{p}H_1 - \mathrm{p}H_2)$$

where the subscripts designate the properties of the solution on the two sides of the membrane.

On the other hand, Levine and Smith (2) have developed a detailed model of the oxide–electrolyte interface from which they deduce that the potential drop from the oxide surface to the bulk electrolyte only obeys the Nernst equation under certain limiting conditions which relate to the equilibrium constants for adsorption of H_3O^+ (henceforth H^+) and OH^- on the oxide surface. On the basis of these relations they are able to account for certain anomalies in the double layer capacitance of oxides determined from acid/base titration of high surface area oxide powders in conjunction with the Nernst equation. The acid/base titration readily yields a plot of surface charge density, σ_s^e, of H^+/OH^- as a function of solution p*H*. The total apparent or effective differential capacitance C_t^e of the oxide–solution interface is then calculated from:

$$[3] \quad C_t^e = -\frac{e}{2.303kT}\frac{d\sigma_s^e}{d(\mathrm{p}H)}$$

The 'true' total differential capacitance of the interface, defined as

$$[4] \quad C_t = d\sigma_s/d(\psi_s - \psi_{aq})$$

will equal C_t^e if and only if both the Nernst equation applies to the total double layer potential, $\psi_s - \psi_{aq}$, and the net surface charge is due solely to H^+/OH^-. Levine and Smith's approach accounts for anomalously low values of C_t^e since, for their model, the Nernst equation is not invariably obeyed. Ahmed, on the other hand, accounts for anomalously high values for $d\sigma_s^e/d(\mathrm{p}H)$ by invoking a partially compensating desorption/adsorption of the counter ions.

In this paper we outline a model which preserves the Nernst relation for all situations in which it can be tested directly, while at the same time supporting

the essential ideas advanced by both Levine and Smith and by Ahmed to account for experimental capacitance values.

Transition Layer Model – Thermodynamic Properties

Basic Concept

The basic concept behind the transition layer model is very simple, involving no more than a layer of thickness of the order of atomic dimensions between the oxide and the electrolyte, within which an equilibrium between ions originating from the oxide and from the electrolyte can be established. We examine first how such a model leads to Nernstian behaviour for the two situations in which it can be tested; a metal in contact with the oxide, and an oxide membrane separating electrolytes of different pH. We then consider in detail the molecular processes by which equilibrium (and hence Nernstian behaviour) can be established for soluble oxides, then for insoluble oxides which are respectively cationic, anionic, and electronic conductors.

The Nernst Equation

The model shown diagramatically in Fig. 1 relates to the system metal/(oxide of the metal)/electrolyte and in Fig. 2 to the system electrolyte(*1*)/oxide/electrolyte(*2*) for the case of cationic conducting oxides.

Treating the system represented in Fig. 1 by equating electrochemical potentials gives:

$$[5] \quad \frac{1}{z}\bar{\mu}(M_M^{z+}) = \frac{1}{z}\bar{\mu}(M_t^{z+}),\ K_a$$

$$[6] \quad \frac{1}{z}\bar{\mu}(M_t^{z+}) = \bar{\mu}(H_t^{+}) + \Delta\mu_b^0,\ K_b$$

$$[7] \quad \bar{\mu}(H_t^{+}) = \bar{\mu}(H_{aq}^{+}),\ K_c$$

Taking the usual approximate form for the electrochemical potential, e.g.:

$$[8] \quad \bar{\mu}(M_t^{z+}) = \mu^0(M_t^{z+}) + kT \ln [a(M_t^{z+})] + ze\psi_s$$

where ψ_s is the potential appropriate for the species in the transition layer (i.e., the potential of the oxide surface), eqs. 5 to 7 give, respectively:

$$[9] \quad [a(M_t^{z+})]^{1/2} = K_a \exp [e(\psi_M - \psi_s)/kT]$$

$$[10] \quad a(H_t^{+}) = K_b[a(M_t^{z+})]^{1/2}$$

$$[11] \quad a(H_{aq}^{+}) = K_c a(H_t^{+}) \times \exp [e(\psi_s - \psi_{aq})/kT]$$

where

$$K_a = \exp [\{\mu^0(M_M^{z+}) - \mu^0(M_t^{z+})\}/zkT]$$

$$K_b = \exp [\{1/z)\mu^0(M_t^{z+}) - \mu^0(H_t^{+}) + \Delta\mu_b^0\}/kT]$$

$$K_c = \exp [\{\mu^0(H_t^{+}) - \mu^0(H_{aq}^{+})\}/kT]$$

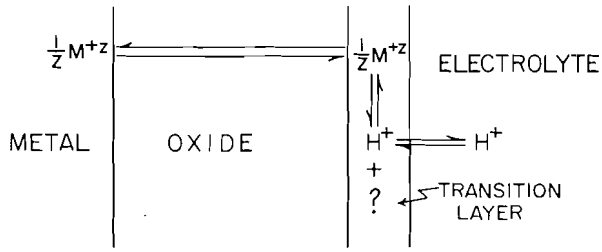

FIG. 1. Schematic diagram of the transition layer model for the system metal/metal oxide/electrolyte, showing the essential features of the equilibrium processes.

Elimination of $a(M_t^{z+})$ and $a(H_t^{+})$ from eqs. 9 to 11 gives, on taking logarithms,

$$[12] \quad \psi_M - \psi_{aq} = (2.303kT/e)[pH_{zpc}^{(M)} - pH]$$

where $pH \equiv -\log [a(H_{aq}^{+})]$ and $pH_{zpc}^{(M)} \equiv -\log (K_aK_bK_c)$.

In practice, a counter electrode must be used, whose electrostatic potential with respect to the solution is independent of pH, to give for the overall cell potential,

$$[13] \quad \psi_M - \psi'_{ref} = \text{const} - (2.303kT/e)pH$$

where ψ'_{ref} is defined to include the difference in Fermi level for the electrons in the two metals so that the $\psi_M - \psi'_{ref}$ is an observable. Note that this result, which represents Nernstian behaviour, is independent of the model chosen for the double layer. It rests, however, on being able to construct a transition region having the desired properties.

In precisely the same way, the equilibria depicted in Fig. 2 lead to

$$[14] \quad \psi_2 - \psi_1 = -(2.303kT/e)(pH_2 - pH_1)$$

Molecular Processes For A Soluble Ionic Conducting Oxide

We now set up a particular model for the transition layer and the molecular processes involved. For oxides which are ionic, rather than electronic, conductors, there will be only one oxidation state which need be considered. If more than one were involved, the oxide would presumably be a semiconductor. We therefore choose a model of the transition layer consisting of an approximately two-dimensional lattice or net of cation and anion sites, occupied by M^{z+}, O^{2-}, H^+, OH^-, as well as H_2O and other ions present in the electrolyte. The presence of these other ions has no effect on the Nernstian behaviour of the system but will influence the distribution of potential across the oxide, and the oxide–electrolyte double layer.

It is instructive to begin by considering the case of a soluble oxide. For equilibrium conditions to be established, the electrolyte must be saturated with

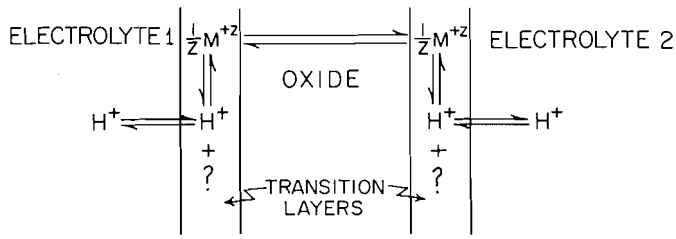

FIG. 2. Schematic diagram of the transition layer model for the system electrolyte(*1*)/metal oxide/electrolyte(*2*), showing the essential features of the equilibrium process.

respect to the oxide, so that for an acidic electrolyte

[15] $(1/2z)M_2O_z + H_{aq}^+ \rightleftharpoons (1/z)M_{aq}^{z+} + \frac{1}{2}H_2O_{(l)}$, K_s

The various molecular processes involving transition layer species presumably can be represented by the following:

[16] $(1/z)M_{aq}^{z+} \rightleftharpoons (1/z)M_{t+}^{z+}$, K_z

[17] $H_{aq}^+ \rightleftharpoons H_{t+}^+$, K_{1+}

[18] $H_2O_{(l)} \rightleftharpoons OH_{t-}^- + H_{aq}^+$, K_{1-}

[19] $OH_{t-}^- \rightleftharpoons O_{t-}^{2-} + H_{aq}^+$, K_{2-}/K_{1-}

where the subscripts t+ and t− denote species occupying cation and anion sites respectively of the transition layer.

Processes 15 to 17 lead to the following equilibrium statement

[20] $(1/2z)M_2O_z + H_{t+}^+ \rightleftharpoons (1/z)M_{t+}^{z+} + \frac{1}{2}H_2O_{(l)}$, $K_t/K_{2-}^{1/2}$ or $K_sK_zK_{1+}$

which is of the desired form, since the electrochemical potentials of M_2O_z and $H_2O_{(l)}$ are constant, or nearly so, at fixed temperature and pressure. Proceeding from Fig. 1, therefore, we obtain eq. 12, with $K_b = K_{2-}^{1/2}/K_t$, $K_c = 1/K_{1+}$ so that

[21] $pH_{zpc}^{(M)} = \log (K_{1+}K_t/K_aK_{2-}^{1/2})$

Molecular Processes For Insoluble Cationic Conducting Oxide

Equations 15, 16, 18, and 19 lead to the following equilibrium statement:

[22] $(1/2z)M_2O_z \rightleftharpoons (1/z)M_{t+}^{z+} + \frac{1}{2}O_{t-}^{2-}$, $K_t = K_sK_zK_{2-}^{1/2}$

The molecular processes represented by eqs. 17 to 19 and 22 are thermodynamically equivalent to those represented by eqs. 15 to 19, but the former processes remain viable for oxides of vanishingly low solubility, provided that a mechanism exists of sufficiently low activation energy ($\gtrsim$0.7 eV for room temperature), for transforming bulk oxide into transition layer ions at the oxide – transition layer boundary, and vice versa. This will ensure that the equilibrium represented by eq. 22 can be established in a reasonable time ($\gtrsim$1 s). We imagine this to occur via surface diffusion of M^{z+} and O^{2-} to and from lattice steps on the oxide surface, processes which would be expected to have activation energies substantially lower than that for transfer of the ions to the electrolyte phase. The high concentration of surface lattice steps existing for all but very carefully equilibrated oxide surfaces will require that ions move no more than a few lattice distances across the surface (see Fig. 3), while processes 18 and 19 combined, effectively lead to movement of O^{2-} from one site in the transition layer to another, through the aqueous phase. Processes 17 to 19 and 22 again give eqs. 20 and 21.

Molecular Processes For Insoluble Anionic Conducting Oxide

The same result is obtained for the case of an oxide which is an anionic conductor, provided again that some movement of ions at the oxide interfaces is possible so that both process 22 and an analogous process in the oxide layer at the metal–oxide interface can proceed to equilibrium. The latter process would involve the equivalent of grain boundary

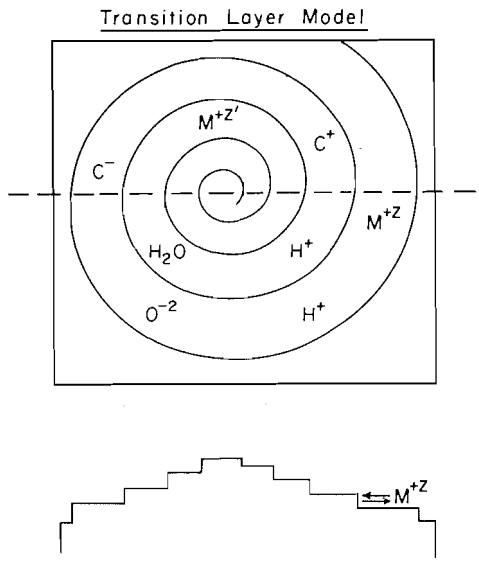

FIG. 3. Schematic diagram of a surface showing how surface steps aid in establishing the equilibrium concentration of M^{z+} in the transition layer. (C^+ and C^- represent counter ions in the transition layer.)

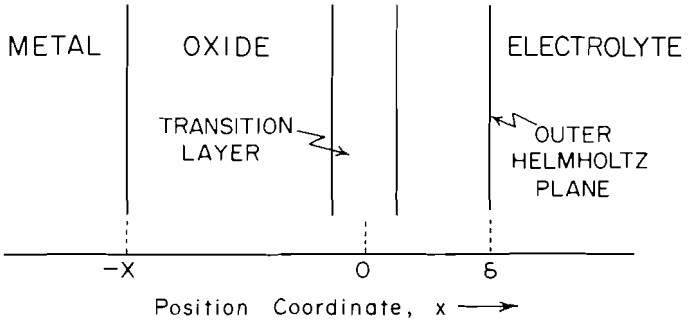

FIG. 5. Illustration of the coordinate system chosen for determining the distribution of charge and potential.

ionic diffusion, and once again, most likely low activation energies. This case is depicted in Fig. 3, and clearly leads to Nernstian behaviour. The appropriate equilibrium in the oxide–electrolyte transition layer is obtained from [17] to [19]

[23] $$H_2O_{(l)} = O_{t-}^{2-} + 2H_{t+}^{+},\ K_{1+}K_{2-}$$

to which we add the molecular processes

[24] $$(1/z)M_M^{z+} \rightleftharpoons (1/z)M_m^{z+},\ K_d$$

[25] $$\tfrac{1}{2}O_m^{2-} \rightleftharpoons \tfrac{1}{2}O_{t-}^{2-},\ K_a'$$

[26] $$(1/2z)M_2O_z \rightleftharpoons \tfrac{1}{2}M_m^{z+} + (1/z)O_m^{2-},\ K_m$$

where the subscript m designates the oxide layer next to the metal. However, [24] to [26], with [22], give

[27] $$\frac{1}{z}M_M^{z+} = \frac{1}{z}M_{t+}^{z+},\ \frac{K_mK_a'}{K_dK_t} \equiv K_a$$

which leads to eq. 5 so that eq. 21 is obtained for this case as well. Thus the final expression is independent of the molecular processes by which overall equilibrium is established, which of course must be the case if the situation being considered is a true equilibrium one. The boundary layer postulate simply provides a mechanism for the establishment of equilibrium in the case of oxides of negligible solubility. It also provides, however, a model for determining the distribution of potential across the oxide and its interfaces, which is a non-thermodynamic property (it cannot be measured) as is $\psi_M - \psi_{aq}$, though not $\psi_M - \psi'_{ref}$.

Molecular Processes For Insoluble Electronic Conducting Oxide

We next look at the case of a semiconducting oxide. Most such oxides depend for their conductivity upon the existence of two oxidation states of the metal separated by a relatively small oxidation potential. A number of different conduction mechanisms based on dual oxidation states can arise, which need not concern us, except to note that they all depend on having a significant representation of both metal oxidation states in the oxide lattice, hence presumably in the transition layer as well. We assume, therefore, the establishment throughout the oxide and the transition layer of the following equilibrium

[28] $$M^{z+} \rightleftharpoons M^{z'+} + (z' - z)e$$

Furthermore, we assume the composition of the non-stoichiometric oxide to be uniform in the vicinity of the oxide–electrolyte interface. This is most easily represented by treating the oxide as a solution of M_2O_z and $M_2O_{z'}$, the chemical potentials of M_2O_z and $M_2O_{z'}$ being constant near the transition layer. Thus equilibrium processes of the form of [22] in the transition layer lead to:

[29] $$\bar{\mu}(M_{t+}^{z+}) + (z/2)\bar{\mu}(O_{t-}^{2-}) = \tfrac{1}{2}\mu(M_2O_z)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[30] $\bar{\mu}(M_{t+}^{z'+}) + (z'/2)\bar{\mu}(O_{t-}^{2-}) = \frac{1}{2}\mu(M_2O_{z'})$

so that

[31] $\bar{\mu}(M_{t+}^{z+}) - \bar{\mu}(M_{t+}^{z'+}) = \frac{1}{2}(z' - z)\bar{\mu}(O_{t-}^{2-}) + \frac{1}{2}[\mu(M_2O_z) - \mu(M_2O_{z'})]$

However, since process 28 applies to the transition region, and electronic equilibrium is assumed throughout the system,

[32] $\bar{\mu}(M_{t+}^{z+}) - \bar{\mu}(M_{t+}^{z'+}) = (z' - z)\bar{\mu}(e_t) = (z' - z)\bar{\mu}(e_M)$

Equations 31 and 32 now give

[33] $\frac{1}{2}\bar{\mu}(O_{t-}^{2-}) = \bar{\mu}(e_M) + \frac{\mu(M_2O_z) - \mu(M_2O_{z'})}{2(z - z')}$

However

[34] $\frac{1}{2}\bar{\mu}(O_{t-}^{2-}) + \bar{\mu}(H_{aq}^{+}) = \frac{1}{2}\mu(H_2O_l)$

so that

[35] $\bar{\mu}(e_M) + \bar{\mu}(H_{aq}^{+}) = -\frac{\mu(M_2O_z) - \mu(M_2O_{z'})}{2(z - z')} + \frac{1}{2}\mu(H_2O_{(l)})$

which again leads to eq. 12 with

[36] $pH_{zpc}^{(M)} = \frac{1}{2.303kT} \times \left[\chi + \frac{\mu(M_2O_z) - \mu(M_2O_{z'})}{2(z - z')} + \mu^0(H_{aq}^{+}) - \frac{1}{2}\mu(H_2O_{(l)})\right]$

where $\chi \equiv \mu(e_M)$ is the Fermi level of the metal.

Drift of ZPC

We examine next the consequence of making the contact to the oxide using a metal not belonging to the oxide. It is apparent that in the case of ionic conducting oxides, once the metal and the oxide in contact with it establish equilibrium concentrations with respect to the two cations, the transition layer treatment of the system again leads to the Nernst equation, as long as the foreign metal ion does not reach the oxide–electrolyte interface. One would predict, therefore, a drift in the value of $pH_{zpc}^{(M)}$ with time following formation of the contact, the value ultimately stabilizing for all practical purposes. The predicted drift arises from the dependence of $pH_{zpc}^{(M)}$ on the distribution of metal ions through the metal–oxide contact. Note, however, that no such dependence exists in the case of an electronic conductor, since the only equilibrium process involving the metal–oxide interface is an electronic equilibrium between the bulk metal and the transition layer. On the other hand the value of $pH_{zpc}^{(M)}$ for an electronic conducting oxide depends directly on the composition of the oxide near the oxide–electrolyte interface, and might well be subject to drift on that account. Thus from eq. 36

[37] $pH_{zpc}^{(M)} = \frac{1}{2(z - z')} \log \frac{a(M_2O_z)}{a(M_2O_{z'})} + \text{const}$

For true thermodynamic equilibrium to be established in the case of the electronic conducting oxide, not only must the metal belonging to the oxide be used in the contact, but the oxide composition near the oxide–electrolyte interface must be that corresponding to equilibration with the metal.

Summary of Thermodynamic Properties

Conducting metal oxide systems should satisfy the Nernst equation provided that a transition layer is established, and that equilibrium between oxide and aqueous ions can be effected through the good offices of the transition layer, so to speak. We see no problem in this respect if both oxide and aqueous ionic species make significant contributions to the composition of the transition layer. If this condition is not met, we are faced with precisely the same problem we started with, which was to find a medium for effecting equilibration of oxide and aqueous ions for insoluble oxides.

The novelty of the transition layer model lies in the introduction of an interphase whose composition is variable with respect to both species resident in the aqueous phase as well as the oxide phase. Levine and Smith (2) allow only for the former while Ahmed (1) assumes, without theoretical justification, that the Nernst equation applies to the potential drop from the oxide surface to the bulk electrolyte. The transition layer model leads to exact adherence to the Nernst equation, in part in accord with Ahmed's assumption, but as we shall show shortly, it is a potential drop across the entire system, not just the electrolyte double layers, that satisfies the Nernst equation. Only under certain limiting conditions does the electrolyte double layer potential satisfy the Nernst equation, in qualitative agreement with the results of Levine and Smith.

Transition Layer Model – Charge Distribution

Surface Charge Neglecting Counter Ion Absorption

For purposes of illustrating the main features of the distribution of charge and potential across the systems metal/oxide/electrolyte and electrolyte(*1*)/

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

oxide/electrolyte(*2*), we assume that only the following ionic species in the transition layer need to be considered, M^{2+}, O^{2-}, H^+, OH^-. We choose the stoichiometry MO, and shall neglect discreteness-of-charge effects (2) and other second order energy corrections, in the interest of algebraic simplicity.

No matter which conduction mechanism is assumed, or indeed in the absence of any oxide conductivity, processes 17 to 19 and 22 are presumably operative. They lead, for the case $z = 2$, to the following

$$[38] \quad MO + 2H_{aq}^{+} \rightleftharpoons M_{t+}^{2+} + H_2O_{(l)}, \; K_{2+}$$

$$[39] \quad H_{aq}^{+} \rightleftharpoons H_{t+}^{+}, \; K_{1+}$$

$$[40] \quad H_2O_{(l)} \rightleftharpoons OH_{t-}^{-} + H_{aq}^{+}, \; K_{1-}$$

$$[41] \quad H_2O_{(l)} \rightleftharpoons O_{t-}^{2-} + 2H_{aq}^{+}, \; K_{2-}$$

If the oxide is a conductor, then we add to the above either that $\psi_M - \psi_{aq}$ is given by eq. 12, or that $\psi_1 - \psi_2$ is given by eq. 14, whichever is appropriate. That is, for a conducting oxide, the potential drop across the entire system is fixed for electrolyte(s) of fixed p*H*, being independent of the details of the double layer structure and hence of the distribution of charge throughout the system.

We next assume ideal thermodynamic behaviour for the species in the transition layer, so that for example

$$[42] \quad \bar{\mu}(M_{t+}^{z+}) = \mu^0(M_{t+}^{z+}) + kT \ln \left[\frac{\theta_{2+}}{1 - \theta_{1+} - \theta_{2+}} \right] + 2e\psi_s$$

where θ_{2+} and θ_{1+} are the fractions of the cation sites occupied by M^{2+} and H^+ respectively, and ψ_s is the potential at the oxide surface, which we define to coincide with the plane of net charge[1] in the transition layer. The form of the activity used in eq. 42 is that appropriate for species obeying a Langmuir adsorption isotherm, and can be derived from elementary statistical mechanics (2). Equations 38 to 41 now give:

$$[43] \quad \frac{\theta_{2+}}{1 - \theta_{1+} - \theta_{2+}} = K_{2+}[a(H_{aq}^{+})]^2 \exp[-2(p_s - p_{aq})]$$

$$[44] \quad \frac{\theta_{1+}}{1 - \theta_{1+} - \theta_{2+}} = K_{1+}[a(H_{aq}^{+})] \exp[-(p_s - p_{aq})]$$

$$[45] \quad \frac{\theta_{1-}}{1 - \theta_{1-} - \theta_{2-}} = K_{1-}[a(H_{aq}^{+})]^{-1} \exp[(p_s - p_{aq})]$$

$$[46] \quad \frac{\theta_{2-}}{1 - \theta_{1-} - \theta_{2-}} = K_{2-}[a(H_{aq}^{+})]^{-2} \exp[2(p_s - p_{aq})]$$

where $p \equiv e\psi/kT$ is a dimensionless potential, and θ_{2-} and θ_{1-} are the fractions of anion sites occupied by O^{2-} and OH^- respectively. Assuming that the number of lattice sites per unit area, N_s, is the same for cations and anions, and that virtually every site is occupied by an ion rather than H_2O say (i.e., $(\theta_{1+} + \theta_{2+})/(1 - \theta_{1+} - \theta_{2+}) \gg 1$ and $(\theta_{1-} + \theta_{2-})/(1 - \theta_{1-} - \theta_{2-}) \gg 1$), we obtain

$$[47] \quad \frac{\sigma_s}{eN_s} = (2\theta_{2+} + \theta_{1+}) - (\theta_{1-} + 2\theta_{2-}) \simeq \frac{1 + 2(K_{2+}a_H/K_{1+})l^{-\Delta p_s}}{1 + (K_{2+}a_H/K_{1+})l^{-\Delta p_s}} - \frac{2 + (K_{1-}a_H/K_{2-})l^{-\Delta p_s}}{1 + (K_{1-}a_H/K_{2-})l^{-\Delta p_s}}$$

where σ_s is the net charge per unit area on the oxide surface, $a_H \equiv a(H_{aq}^{+})$, and $\Delta p_s = p_s - p_{aq}$. Defining p^* and b according to:

$$[48] \quad p^* - p_{aq} = \tfrac{1}{2} \ln [K_{2+}K_{1-}/K_{2-}K_{1+}] + \ln a_H$$

$$[49] \quad b = (K_{2+}K_{2-}/K_{1+}K_{1-})^{1/2}$$

upon eliminating $(K_{2+}a_H/K_{1+})$ and $(K_{1-}a_H/K_{2-})$ from eq. 47 using eqs. 48 and 49, the result can be expressed as follows:

$$[50] \quad \frac{\sigma_s}{eN_s} = \frac{2 \sinh (p_s - p^*)}{b + b^{-1} + 2 \cosh (p_s - p^*)}$$

Now since $N_s \simeq 10^{15}$ cm^{-2}, it follows that $\sigma_s/eN_s \ll 1$. Thus if $|p_s - p^*| \gtrsim 1$ then $b + b^{-1} \gg 2 \cosh (p_s - p^*)$, while if $|p_s - p^*| \ll 1$, $2 \cosh (p_s - p^*) \simeq 2$.

Thus for all possible cases, we may approximate eq. 50 by:

$$[51] \quad \sigma_s/eN_s = \tfrac{1}{2}\alpha \sinh (p_s - p^*)$$

where $\alpha = 4/(b + b^{-1} + 2)$, or from eq. 49:

$$[52] \quad \alpha = 4\left[\left(\frac{K_{2+}K_{2-}}{K_{1+}K_{1-}} \right)^{1/4} + \left(\frac{K_{1+}K_{1-}}{K_{2+}K_{2-}} \right)^{1/4} \right]^{-2}$$

and is restricted to the range $1 \gtrsim \alpha > 0$.

Three limiting cases may be distinguished. For $b \gg 1$, the transition layer is populated almost en-

[1]That plane chosen so that the first moment of the charge displacements from the plane is zero.

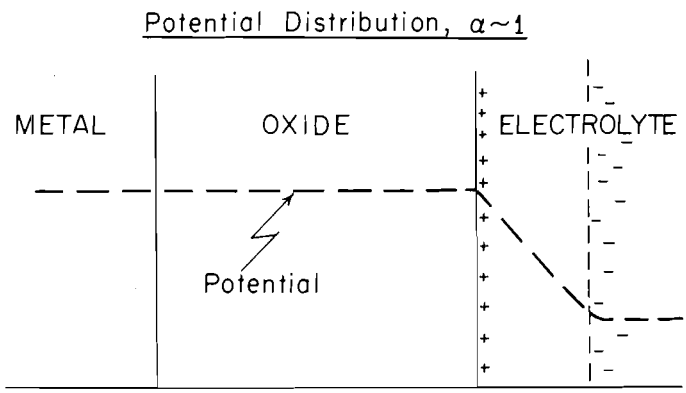

FIG. 6. Schematic representation of the potential and charge distribution for $\alpha \sim 1$.

tirely by M^{2+} and O^{2-}, while for $b \ll 1$ almost entirely by H^+ and OH^-. For $b \sim 1$, all four species occupy a substantial fraction of the available sites.

The ZPC For Free Oxide

Inverting eq. 51 and substituting for p^* from eq. 48 gives

$$[53] \quad \psi_s - \psi_{aq} = 2.303(kT/e)[pH_{zpc}^{(ox)} - pH] + (kT/e)\sinh^{-1}(2\sigma_s/eN_s\alpha)$$

where

$$[54] \quad pH_{zpc}^{(ox)} = \tfrac{1}{2}\log[K_{2+}K_{1-}/K_{2-}K_{1+}]$$

Applying eq. 53 to nonconducting free oxide particles immersed in an aqueous solution, if $\sigma_s = 0$, one must also have $\psi_s - \psi_{aq} = 0$. (In keeping with our intent to minimize algebraic complexity, we neglect the contribution of oriented water molecules to the double layer potential.) For this case, therefore, $pH_{zpc}^{(ox)}$ is the pH corresponding to the zpc for the free oxide. For sufficiently small oxide particles, even if they are conducting, the total charge within them may be neglected. We therefore regard $pH_{zpc}^{(ox)}$, given by eq. 54, as characterizing the zpc for the free oxide, whether or not it is conducting.

Distribution of Potential Across Oxide and Double Layers

We are now in a position to determine the distribution of potential for various cases. A quantitative though simplified treatment of the problem is presented in the Appendix, the conclusions being in accord with the following more qualitative treatment.

The total potential drop from metal to electrolyte is given by eq. 12 and is a property of the metal and the electrolyte pH only, being independent of the energetics of the equilibrium processes involving the transition layer species. We shall hold this potential constant, therefore, and consider the variation in the distribution of potential on varying α and the ratio of the oxide thickness, X, to the characteristic space charge length in the oxide, X_o. Three cases are illustrated in Figs. 6 to 8.

For $\alpha \sim 1$, eq. 53 leads to $\psi_s - \psi_{aq} \simeq 2.303(kT/e)[pH_{zpc}^{(ox)} - pH]$ while for all possible values of α we have from eq. 12,

$$\psi_M - \psi_{aq} = 2.303(kT/e)[pH_{zpc}^{(M)} - pH]$$

Thus for $\alpha \sim 1$, $\psi_s - \psi_{aq}$ satisfies the Nernst equation, while $\psi_M - \psi_s$ is independent of pH, oxide thickness, and so on. Since $\psi_M - \psi_s$ itself is not an observable but only changes in $\psi_M - \psi_s$, and since it does not change, we have set it to zero in sketching the behaviour in Fig. 6. In effect we have chosen the zero of electrostatic potential for each phase to be that corresponding to the zpc for the oxide covered metal.

For α sufficiently small, on the other hand, from eq. 53 we deduce that σ_s will be essentially zero, giving rise, therefore, to potential distributions qualitatively of the forms shown in Figs. 7 and 8. For a sufficiently thick oxide having a large X_o, virtually all of the pH dependent potential will appear across the oxide, not the double layers. These conclusions can be further justified by considering analytical solutions to the charge distribution problem (see Appendix) but they are almost self evident.

The case of an oxide membrane separating solutions of different pH can be treated in the same way. For α sufficiently large, the potential drop across the oxide is essentially zero, while each double layer potential satisfies a Nernst equation, whereas for α very small and for a thick membrane of sufficiently large characteristic space charge length, X_0, the double layer potentials are nearly zero, while the potential drop across the oxide satisfies the Nernst equation. Again for intermediate conditions, neither

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

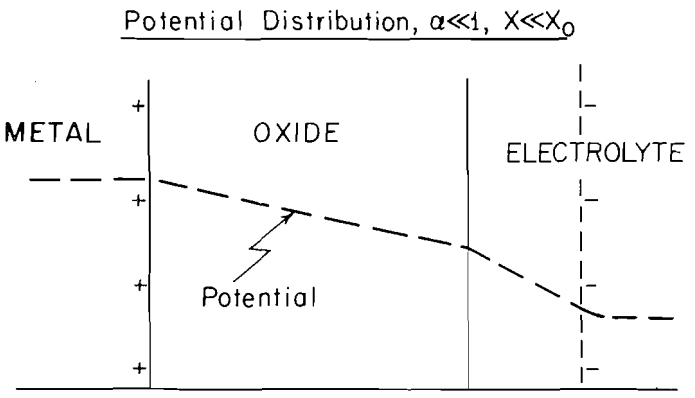

FIG. 7. Schematic representation of the potential and charge distribution for $\alpha \ll 1$ and the film thickness, X, small compared to the characteristic space charge length, X_0.

individually satisfy the Nernst equation, while their sum does.

We treat finally the case of particles of conducting oxide in the two limits, $R \ll X_0$ and $R \gg X_0$, when R is the particle radius. For $R \ll X_0$, space charge in the oxide can be neglected so that the field in the oxide particle is everywhere essentially zero. The only potential drop in this case is across the double layer which is again given by eq. 53.

For α large, $\psi_s - \psi_{aq}$ satisfies the Nernst equation, while for α very small, $\psi_s - \psi_{aq} \simeq 0$.

For $R \gg X_0$, space charge must be taken into account. But, once again, for α large, ψ_s satisfies the Nernst equation, while $\psi_{in} - \psi_s = \psi^* - \psi^* = 0$. For α very small and X_0 sufficiently large, $\psi_{in} - \psi_s$ satisfies the Nernst equation and $\psi_s \simeq 0$.

Double Layer Capacitance

The relationship between the true and apparent total differential capacitance of the double layer can be seen as follows: Differentiating eq. 53 with respect to pH, and substituting for $d(\psi_s - \psi_{aq})/d(pH)$ and $d\sigma_s/d(pH)$ using eqs. 3 and 4 gives the following result:

$$[55] \quad \frac{1}{C_t} = \frac{1}{C_t^e} + \left[\left(\frac{2\sigma_s}{eN_s}\right)^2 + \alpha^2\right]^{-1/2} \frac{1}{C_0}$$

where $C_0 = N_s e^2/2kT$ and is $\sim 3 \times 10^3$ μF at room temperature for $N \sim 10^{15}$ cm^{-2}. From eq. 55 it follows that $C_t^e > C_t$. Several realms of behaviour may now be distinguished. For $\alpha^2 \gg (2\sigma_s/eN_s)^2$, eq. 55 reduces to

$$[56] \quad \frac{1}{C_t} \simeq \frac{1}{C_t^e} + \frac{1}{\alpha C_0}$$

which in turn has two limits, $C_t \simeq C_t^e$ and $C_t \simeq \alpha C_0$ depending on the value of α. For $\alpha^2 \ll (2\sigma_s/eN_s)^2$, eq. 55 reduces to

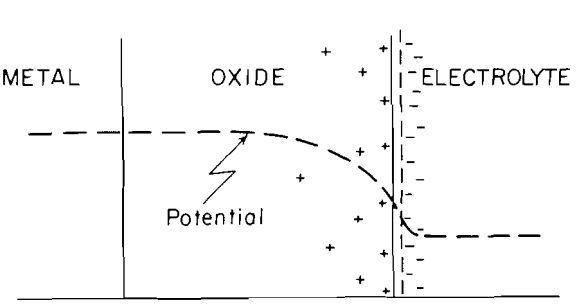

FIG. 8. Schematic representation of the potential and charge distribution for $\alpha \ll 1$ and the film thickness, X, larger than the characteristic space charge length, X_0.

$$[57] \quad \frac{1}{C_t} \simeq \frac{1}{C_t^e} + \frac{eN_s}{2\sigma_s} \frac{1}{C_0}$$

Equation 57 cannot apply, of course, close to the zpc. We see, therefore, that there are two situations in which C_t may be calculated from the results of acid/base titration of high surface area oxides and a knowledge of the zpc. When the competition between the two sets of ions for places in the transition layer is an even one (i.e., $\alpha \sim 1$) then $C_t \simeq C_t^e$, while if the competition is extremely uneven (i.e., α very small) C_t will be given by eq. 57 away from the zpc. This only applies, however, if the anion of the acid and cation of the base (i.e., the counterions) do not occupy a significant number of sites in the transition layer. If this is not the case, the calculated change in surface charge density based on H^+/OH^- titration, $\Delta\sigma_s^e$, will be in error. In particular, for a change in pH at essentially constant counter ion activities, $|\Delta\sigma_s^e| > |\Delta\sigma_s|$. Thus on decreasing the pH, some of the H^+ absorption will take place by replacing absorbed counterions, and conversely for the de-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sorbed OH^- ions. Since in practice, C_t^e is calculated from $d\sigma_s^e/d(pH)$, this effect also leads to values of C_t^e which are too large. There is an important difference, however, between the two effects. In the absence of counter ion absorption, the maximum possible value of C_t^e occurs for $\alpha = 1$ when $C_t^e = C_t = C_t^m$ where C_t^m is expected to be of the order of the capacitance of the Hg–electrolyte interface, i.e., 20 $\mu F/cm^2$. The first effect, although it gives $C_t^e > C_t$, always gives $C_t^e < C_t^m$, while the effect of counter ion adsorption will give $C_t^e > C_t^m$ for $\alpha \sim 1$ so that anomalously high values of C_t^e can result.

The above discussion is in some respects a composite of those offered by Levine and Smith (2) and Ahmed (1), except that the model of ion adsorption at the interface used here differs from their models in subtle but important ways as already noted. We will not pursue the question of surface capacitance further, however, since for this to be a worthwhile exercise would require introducing refinements and including an extensive review of relevant data, such being beyond the scope of the present paper.

Summary and Conclusions

In this paper, the consequence of assuming the existence of a transition layer of ions between the oxide and the electrolyte, such ions conforming to the oxide lattice structure, has been examined. If the oxide is a conductor, with both the ions of the oxide and those of the electrolyte (H^+ and OH^-) present in the transition layer to a significant extent at equilibrium, and if further the activation energy for surface migration of metal and oxygen ions at one or both of the oxide interfaces is $\gtrsim 0.7$ eV, then equilibrium or quasi-equilibrium conditions can be established within a few seconds for systems metal/oxide/electrolyte and electrolyte(*1*)/oxide/electrolyte(*2*) in the absence of significant oxide solubility. The transition layer acts essentially as a two dimensional medium within which equilibrium among the ions M^{z+}, O^{2-}, H^+, OH^- can be established. Equilibrium conditions for these systems lead to Nernstian behaviour with respect to the p*H* dependence of the total potential drop across the oxide and double layer(s). The double layer potential itself, however, only satisfies the Nernst equation to a good approximation if the concentrations of (M^{z+}, O^{2-}) and (H^+, OH^-) in the transition layer are comparable at equilibrium.

Use of the Nernst equation to calculate double layer capacitances from measurements of H^+/OH^- adsorbed per unit change in p*H* leads to values above the true value whenever the above condition is not satisfied. The values themselves, however, will be smaller than for the Hg–electrolyte system say. Counter ion adsorption within the transition layer, on the other hand, can lead to anomalously high capacities for H^+/OH^- adsorption. These two effects are essentially those discussed by Levine and Smith (2) and Ahmed (1) respectively. The transition layer postulate, however, effectively reconciles the apparently contradictory approaches taken by these researchers.

Appendix

Potential Distribution for a Simplified Model

The general features of the distribution of charge and potential arising from the transition layer model are determined here for a particularly simple model, but are not effected materially by model refinement.

We exclude the influence of counter ion absorption into the transition layer and employ the Gouy–Chapman model for 1:1 electrolytes, ignoring any net orientation of water dipoles adjacent to the transition layer. Apart from the inclusion of σ_s as given by the transition layer model, the treatment to follow does not differ from numerous already published treatments (see e.g., ref. 3).

We examine the system metal/oxide/electrolyte first (see Fig. 5). Charge neutrality requires that:

$$[A1] \qquad \sigma_M + \sigma_s + \sigma_{aq} + \int_{-X}^{0} \rho \, dx = 0$$

where σ_M and σ_{aq} are the net charge per unit area on the metal and aqueous phases respectively and ρ the space charge concentration within the oxide. Gauss' theorem then gives

$$[A2] \qquad \varepsilon\left(\frac{d\psi_{ox}}{dx}\right)_{x=0} = 4\pi(\sigma_s + \sigma_{aq})$$

$$[A3] \qquad \varepsilon\left(\frac{d\psi_{ox}}{dx}\right)_{x=-X} = -4\pi\sigma_M$$

$$[A4] \qquad \varepsilon_d(\psi_s - \psi_\delta)/\delta = -4\pi\sigma_{aq}$$

while the continuity condition on the electric displacement at the plane $x = \delta$ yields

$$[A5] \qquad \varepsilon_d(\psi_s - \psi_\delta)/\delta = -\varepsilon_{aq}\left(\frac{d\psi_{dif}}{dx}\right)_{x=\delta}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where ε, ε_d, and ε_{aq} are the integral dielectric constants of: the oxide phase of thickness X, the Helmholtz double-layer of thickness δ, and the diffuse layer respectively, and ψ_{dif} is the potential in the diffuse layer. The model of the diffuse layer developed by Gouy leads to the following expression for a 1:1 electrolyte:

$$[A6] \quad -\left(\frac{dp_{dif}}{dx}\right) = \frac{2}{X_{aq}} \sinh [(p_{dif} - p_{aq})/2]$$

where X_{aq} is the Debye–Hückel length for the electrolyte given by

$$[A7] \quad X_{aq} = \sqrt{\frac{\varepsilon_{aq} kT}{8\pi n_{aq} e^2}}$$

and n_{aq} is the bulk electrolyte concentration. The Debye–Hückel length is about 10 Å for a 0.1 M solution at room temperature.

Equations A5 and A6 now yield

$$[A8] \quad \frac{\varepsilon_d X_{aq}}{\varepsilon_{aq} \delta}(p_s - p_\delta) = 2 \sinh [(p_\delta - p_{aq})/2]$$

while eqs. A2 and A4 give:

$$[A9] \quad \frac{\sigma_s}{eN_s} = X_s\left(\frac{dp_{ox}}{dx}\right)_{x=0} + \frac{\varepsilon_d X_s}{\delta}(p_s - p_\delta)$$

where X_s is a characteristic length associated with the transition layer, and is given by

$$[A10] \quad X_s = \frac{\varepsilon kT}{4\pi N_s e^2}$$

at room temperature, for $N_s = 10^{15}$ cm^{-2} and $\varepsilon = 10$, $X_s = 0.014$ Å.

The Poisson–Boltzmann equation for the ionic or electronic current carriers in the oxide and the compensating immobile charged species is given by:

$$[A11] \quad \frac{d^2\psi_{ox}}{dx^2} = -\frac{4\pi n_0 z_c e}{\varepsilon}\{\exp [ez_c(\psi_z - \psi_{ox})/kT] - 1\}$$

where $-n_0 z_c e$ is the charge per unit volume due to the compensating immobile charged species, $z_c e$ the charge on the current carriers, and ψ_z the potential for which the net space charge is zero. Equation A11 may be written

$$[A12] \quad \frac{d^2y}{dx^2} = \frac{1}{X_o^2}\{1 - e^{-y}\}$$

where

$$[A13] \quad y = z_c(p_{ox} - p_z) = \frac{z_c e}{kT}(\psi_{ox} - \psi_z)$$

and

$$[A14] \quad X_o = \sqrt{\frac{\varepsilon kT}{4\pi n_0 z_c^2 e^2}}$$

Analytic solutions to [A12] are not available. Solutions can easily be found, however, for the following three limiting cases: $|y| \ll 1$, $y \gg 1$, and $-y \gg 1$. We shall pursue only the first case, however, which places a severe restriction on the quantitative applicability of the resulting expressions, but not on their qualitative applicability. Following the same procedures, more general expressions can be obtained at the expense of an enormous increase in complexity.

Expanding e^{-y} to first order eq. A13 is readily integrated to give:

$$[A15] \quad y = c \sinh\left(\frac{x - x_0}{X_o}\right)$$

where c and x_0 are the integration constants. Differentiation of eq. A15 once, then setting $x = 0$ gives

$$[A16] \quad z_c\left(\frac{dp_{ox}}{dx}\right)_{x=0} = \frac{c}{X_o} \cosh \frac{x_0}{X_o}$$

while differentiation of eq. A15 twice then setting $x = -X$ gives

$$[A17] \quad c \sinh\left(\frac{X + x_0}{X_o}\right) = \left(\frac{n_{-X}}{n_0} - 1\right)$$

where n_{-X} is the concentrate of carriers at the metal–oxide interface, which we assume to be a constant. Finally, application of eq. A16 at the two boundaries gives

$$[A18] \quad z_c(p_M - p_s) = c\left[-\sinh\left(\frac{X + x_0}{X_o}\right) + \sinh\left(\frac{x_0}{X_o}\right)\right]$$

Elimination of c and x_0 from eqs. A16 to A18 gives

$$[A19] \quad \left(\frac{dp_{ox}}{dx}\right)_{x=0} = \left[p_M - p_s + p_I\left(1 - \operatorname{sech}\frac{X}{X_o}\right)\right]\frac{\coth (X/X_o)}{X_o}$$

where $p_I \equiv (n_{-X}/n_0 - 1)/z_c$ and is a system constant. For $X \ll X_o$ this reduces to

$$[A20] \quad \left(\frac{dp_{ox}}{dx}\right)_{x=0} = -\frac{(p_M - p_s)}{X}$$

while for $X \gg X_o$ it reduces to

$$[A21] \quad \left(\frac{dp_{ox}}{dx}\right)_{x=0} = -\frac{(p_M - p_s + p_I)}{X_o}$$

Combining eqs. 51, A9, and A20 gives for $X \ll X_o$

[A22] $$\frac{\sigma_s}{eN_s} = -\frac{X_s}{X}(p_M - p_s) + \frac{\varepsilon_d X_s}{\varepsilon\delta}(p_s - p_\delta) = \tfrac{1}{2}\alpha \sinh(p_s - p^*)$$

while eqs. 51, A9, and A21 give for $X \gg X_o$

[A23] $$\frac{\sigma_s}{eN_s} = -\frac{X_s}{X_o}(p_M - p_s - p_I) + \frac{\varepsilon_d X_s}{\varepsilon\delta}(p_s - p_\delta) = \tfrac{1}{2}\alpha \sinh(p_s - p^*)$$

For moderately concentrated solutions $\varepsilon_d X_{aq} \ll \varepsilon_{aq}\delta$ so from eq. A8, $p_\delta \simeq p_{aq}$. Setting $p_\delta = p_{aq} = 0$, eqs. A22 and A23 can be written

[A24] $$\frac{\sigma_s}{eN_s} = -\frac{X_s}{X}p_M + \left(\frac{X_s}{X} + \frac{\varepsilon_d X_s}{\varepsilon\delta}\right)p_s = \tfrac{1}{2}\alpha \sinh(p_s - p^*)$$

[A25] $$\frac{\sigma_s}{eN_s} = -\frac{X_s}{X_o}(p_M + p_I) + \left(\frac{X_s}{X_o} + \frac{\varepsilon_d X_s}{\varepsilon\delta}\right)p_s = \tfrac{1}{2}\alpha \sinh(p_s - p^*)$$

while eq. 12 and eq. 48 plus eq. 54 give respectively

[A26] $$p_M = 2.303(pH_{zpc}^{(M)} - pH)$$

[A27] $$p^* = 2.303(pH_{zpc}^{(ox)} - pH)$$

For α of the order of unity, $p_s \simeq p^*$ as already noted, so that

[A28] $$\psi_s \simeq 2.303(kT/e)(pH_{zpc}^{(ox)} - pH)$$

and

[A29] $$(\psi_M - \psi_s) \simeq 2.303(kT/e) \times (pH_{zpc}^{(M)} - pH_{zpc}^{(ox)})$$

For α vanishingly small, on the other hand, we have for $X \ll X_o$

[A30] $$\psi_s = 2.303(kT/e)\left(1 + \frac{\varepsilon_d X}{\varepsilon\delta}\right)^{-1} \times (pH_{zpc}^{(M)} - pH)$$

[A31] $$(\psi_M - \psi_s) = 2.303(kT/e)\left(1 + \frac{\varepsilon\delta}{\varepsilon_d X}\right)^{-1} \times (pH_{zpc}^{(M)} - pH)$$

while for $X \gg X_o$

[A32] $$\psi_s = 2.303(kT/e)\left(1 + \frac{\varepsilon_d X_s}{\varepsilon\delta}\right)^{-1} \times (pH_{zpc}^{(M)} + pH^{(I)} - pH)$$

[A33] $$\psi_M - \psi_s = 2.303(kT/e)\left(1 + \frac{\varepsilon\delta}{\varepsilon_d X_o}\right)^{-1} \times (pH_{zpc}^{(M)} + pH^{(I)} - pH)$$

where

[A34] $$pH^{(I)} = p_I/2.303 = (n_{-X}/n_0 - 1)/2.303z_c$$

For α sufficiently large (specifically for $\frac{1}{2}\alpha \gg X_s/X$, $\varepsilon_d X_s/\varepsilon\delta$, X_s/X_o) the double layer potential, ψ_s, satisfies the Nernst equation, while the potential drop across the oxide ($\psi_M - \psi_s$) is independent of pH. For the opposite extreme in which α is so small that the final terms in eqs. A24 and A25 may be set to zero, and the oxide sufficiently thick and with a sufficiently low concentration of conducting species so that $\varepsilon\delta \ll \varepsilon_d X$, $\varepsilon_d X_o$, the potential drop across the oxide satisfies the Nernst equation while that across the double layer is independent of pH. For intermediate conditions, neither satisfies the Nernst equation, but their sum does. Three limiting cases are illustrated in Figs. 6 to 8 and have been discussed in the main body of the paper.

ARTHUR SMITH
Department of Mathematics, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received June 13, 1977

STEPHEN FLETCHER and ARTHUR SMITH. Can. J. Chem. **56**, 606 (1978).

The effect of varying the applied potential during progressive three-dimensional nucleation and growth is described. The assumed model is that due to Armstrong, Fleischmann, and Thirsk in which expanding nuclei are considered to be right circular cones distributed at random on the electrode surface. The present work extends the previous potentiostatic approach by considering that the electrode surface coverage function responds instantaneously to small changes of applied potential. Under these circumstances we show that it is possible to calculate in an exact way the theoretical response of the model to various applied potential waveforms. In particular, the linear potential sweep and the staircase potential ramp are considered, as well as feedback loops generated by uncompensated ohmic overpotential. Certain limiting cases are derived which may be tested by experiment.

STEPHEN FLETCHER et ARTHUR SMITH. Can. J. Chem. **56**, 606 (1978).

On décrit l'effet qui résulte de la variation du potentiel appliqué sur le cours de la croissance et d'une nucléation tridimentionnelle. Le modèle utilisé comme hypothèse est celui proposé par Armstrong, Fleischmann et Thirsk dans lequel on considère que les noyaux qui croissent sont des cônes circulaires droits distribués au hasard sur la surface de l'électrode. Le présent travail suggère des extensions à l'approche potentiostatique antérieure; ces extensions sont basées sur des considérations à l'effet que la fonction qui décrit la couverture de la surface de l'électrode répond instantanément à des petits changements du potentiel appliqué. Dans de telles circonstances, on montre qu'il est possible de calculer d'une manière exacte la réponse théorique du modèle à diverses formes d'onde de potentiel appliqué. On considère en particulier le balayage potentiel linéaire et la rampe de potentiel en escalier de même que des circuits de réponse qui sont générés par des surpotentiels ohmiques non compensés. On a dérivé certains cas limites pour lesquels des vérifications expérimentales peuvent être faites.

Introduction

The electrochemical formation of thick (i.e., three-dimensional) anodic films is of fundamental importance in the study of the kinetics of corrosion and passivation (1). In many cases it has been shown that reaction proceeds via a nucleation and growth mechanism, in which nuclei of the new phase appear at the electrode–solution interface under the influence of the applied electrode potential (2). Such nuclei form either instantaneously or progressively in time, and the slow step in the overall mechanism occurs at the edge of the expanding crystal lattice. This slow step, for each individual crystal face, is characterized by a potential-dependent rate constant for lattice growth (2, 3).

In order for a complete model to be described, however, assumptions have to be made regarding the geometry of the growing nuclei. Also account must be taken of the overlap of individual nuclei as they expand into each other. Avrami has shown how this may be accomplished (4–6). Provided overlap is completely random then the true surface coverage of the electrode is given by the expression

$$[0.1] \qquad s = 1 - \exp(-s_{1;ex})$$

where $s_{1;ex}$ is the fractional surface coverage calculated neglecting overlap. Application of this equation to a given geometry then allows the calculation of the current–time response expected at a given potential.

(1) The Basic Model

The model of progressive three-dimensional nucleation and growth used here is based on the work of Armstrong, Fleischmann, and Thirsk (7). Growing nuclei are considered to be right circular cones distributed at random on the electrode surface. At constant potential, following the application of a potential step, it is possible to formulate the transient current response of such a system as a function of

time. The result is

$$[1.1] \quad i = nFk_2[1 - \exp(-\pi M^2 k_1^2 A t^3/3\rho^2)] \times \exp(-\pi M^2 k_1^2 A t^3/3\rho^2)$$

where i is current density (mA cm^{-2}), F is the faraday (96 500 C mol^{-1}), n is number of electrons, k_1 is the rate constant for lattice growth parallel to the surface (mol cm^{-2} s^{-1}), k_2 is the rate constant for lattice growth perpendicular to the surface (mol cm^{-2} s^{-1}), M is gram molecular weight (g), t is time (s), ρ is density of 3-dimensional layer (g cm^{-3}), and A is a time-independent nucleation rate constant (nuclei cm^{-2} s^{-1}). Note that the growth of each individual nucleus is assumed to follow a deterministic law, whilst strictly speaking the nucleation rate constant is a stochastic quantity (8). Therefore the electrode must be sufficiently large to ensure that the current takes on its expectation value. The fractional surface coverage function corresponding to [1.1] is

$$[1.2] \quad s = 1 - \exp(-\pi M^2 k_1^2 A t^3/3\rho^2)$$

which may be calculated directly via Avrami's theorem.

A convenient form of analysis of experimental transients expected for growth of this type is in terms of the current maximum of [1.1] and the time at which the maximum occurs. Thus

$$[1.3] \quad i_m = nFk_2/4$$

$$[1.4] \quad t_m = (3\rho^2 \ln(2)/\pi M^2 k_1^2 A)^{1/3}$$

where i_m (mA cm^{-2}) is current maximum in potentiostatic transient and t_m (s) is the time taken to achieve i_m. Definition of these parameters allows the expression of [1.1] in the more convenient reduced-variable form

$$[1.5] \quad \frac{i}{i_m} = 4[1 - (\tfrac{1}{2})^{(t/t_m)^3}](\tfrac{1}{2})^{(t/t_m)^3}$$

Transients of this shape are therefore always to be expected at constant step potential. If, however, it is desired to describe the experimental response to time-varying potential waveforms then it is necessary to make some assumptions regarding the potential dependences of k_1, k_2, and A. Experimental data have indicated that these quantities are exponential functions of the applied potential (7, 9) and hence

$$[1.6] \quad i_m = 10^{(a_1 E + b_1)}$$

$$[1.7] \quad t_m = 10^{(a_2 E + b_2)}$$

where a_1, a_2, b_1, and b_2 are experimentally determined constants free of ohmic effects. Combination of eqs. [1.1] to [1.7] therefore allows the theoretical description of the effect of varying the applied potential.

The current–time responses at various constant potentials are illustrated in Fig. 1.

(2) General Considerations Regarding the Time Variation of E

It is clear that if E varies in time, then the functional forms of i and s as given in [1.1] and [1.2] will change. In order to obtain these forms a new assumption is required. Suppose [1.2] is written $s = f(t, E)$ and $S = F(t, E(t))$ when E varies in time. Then at some time t_1, $S = F(t_1, E(t_1))$. Furthermore there is a transient of identical potential E corresponding to the fixed potential $E(t_1)$ for which $s = f(t - t_1 + \tau(t_1), E)$, where s is zero at time $\tau(t_1)$ and $f(\tau(t_1), E) = F(t_1, E(t_1))$. Thus the assumption is that the gradients of $f(t - t_1 + \tau(t_1), E)$ and $F(t, E(t))$ match at time $t = t_1$. *This implies that the fractional surface coverage function S responds instantaneously to any instantaneous change in applied E.* This is only possible if there is no relaxation of nucleation i.e., the steady state values of A are always observed at given potentials. Consequently

$$[2.1] \quad f(\tau(t_1), E(t_1)) = F(t_1, E(t_1))$$

and

$$[2.2] \quad \left.\frac{df}{dt}\right|_{t=t_1} = \left.\frac{dF}{dt}\right|_{t=t_1}$$

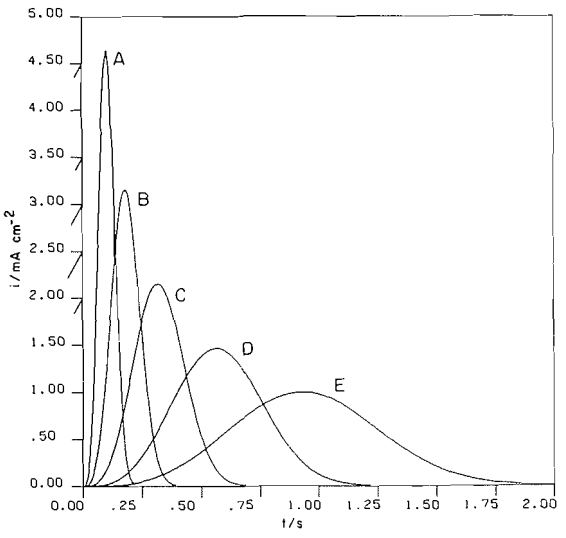

FIG. 1. Current–time transients expected for progressive 3-dimensional nucleation and growth at constant step potential. Constants are; $a_1 = 1/3$, $a_2 = -1/2$, $b_1 = b_2 = 0$, $R = 0$. (*A*) $E = 2.0$ mV, (*B*) $E = 1.5$ mV, (*C*) $E = 1.0$ mV, (*D*) $E = 0.5$ mV, (*E*) $E = 0.0$ mV.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Note that t_1 is any point in time; in general therefore

[2.3] $$f(\tau(t), E(t)) = F(t, E(t))$$

so that

$$\left.\frac{df}{dt}\right|_{t=t_1} = \frac{df}{d\xi}\cdot\frac{d\xi}{dt}$$

$$= \left.\frac{df}{d\xi}\right|_{t=t_1} = \left.\frac{\partial f(\tau(t), E(t))}{\partial \tau}\right|_{t=t_1}$$

where $\xi = t - t_1 + \tau(t_1)$ and by virtue of [2.3], [2.2] becomes

[2.4] $$\frac{\partial f}{\partial \tau} = \frac{dF}{dt} = \frac{df}{dt} = \frac{\partial f}{\partial \tau}\cdot\frac{d\tau}{dt} + \frac{\partial f}{\partial E}\cdot\frac{dE}{dt}$$

Hence

[2.5] $$\frac{d\tau}{dt} = 1 - \frac{\partial f}{\partial E}\cdot\frac{dE}{dt}\Big/\frac{\partial f}{\partial \tau}$$

Equation [2.5] may be regarded as a differential equation determining $\tau(t)$ and F via [2.3]. In the particular case that f has the functional form $f(\tau, E) = f(\tau g(E))$ for some function g then [2.5] reduces to

$$\frac{d\tau}{dt} = 1 - \tau g'(E) f'(\tau g(E))\cdot\frac{dE}{dt}\Big/ g(E)\cdot f'(\tau g(E))$$

$$= 1 - \tau\frac{dg}{dt}\Big/ g(E)$$

That is $(d/dt)(\tau g) = g$ so that

[2.6] $$f(\tau, E) = f(\tau g(E))$$

$$= f\left(\int_0^t g(E(t'))\cdot dt' + C\right)$$

The constant of integration C is given by $f(C) = f_0$ where f_0 is the value of f at time $t = 0$. The particular form of [2.6] is sufficient, for example, to find the form of S when E varies as the result of an ohmic potential drop at the electrode surface. This is an important case to consider because of the rapid rise of current as implied by [1.1].

(3) Behaviour of the Model in the Presence of Uncompensated Ohmic Potential Drop

Uncompensated ohmic potential drop is an experimental artifact which arises because of the presence of a finite resistance R (Ω cm^2) between the tip of the luggin reference probe and the working electrode (10). It may also arise in the working electrode lead. Although R may be evaluated by high frequency ac methods, exact compensation is not easy under potentiostatic conditions because its influence on the experimental data acquisition is complex. Its presence not only distorts the observed current response but also changes the applied potential waveform. Partial compensation has recently become possible by utilizing feedback circuitry incorporated into the analog potentiostat design; however, complete compensation is not usually attempted because it can result in oscillations in the operational amplifiers. Consequently there is always some residual ohmic component in the applied electrode potential. Unfortunately the profound influence of ohmic effects in measurements of electrocrystallization reactions is still not widely appreciated (see the comment of Harrison (2)). Clearly then it is desirable to consider the effect of R on the present theoretical formulation.

Uncompensated ohmic potential drop may be taken into account by the transformation $E \rightarrow E - i(t)R$ where R is a constant resistance, thus rendering E time-varying even in the transient case. The form of s in the basic model is, from [1.2], [1.4], and [1.7]

[3.1] $$s = 1 - \exp\left[-k(t10^{-a_2E})^3\right]$$

where $k = 10^{-3b_2}\ln(2)$. Thus under the transformation [2.6] and allowing for R

[3.2]

$$S = 1 - \exp\left[-k\left(\int_0^t 10^{-a_2(E(t')-i(t')R)}\,dt' + C\right)^3\right]$$

$$= 1 - \exp(-kJ^3)$$

where

[3.3] $$J(t) = \int_0^t Q(t')dt' + C$$

[3.4] $$Q(t) = 10^{-a_2(E(t)-i(t)R)}$$

The function $\tau(t)$ is determined entirely by the basic form of S and so the form of $i(t)$ is, from [1.1] and [1.2],

[3.5] $$i(t) = 4i_m(1 - S)(S)$$

$$= 4 \times 10^{(a_1(E-i(t)R)+b_1)}(1 - S)(S)$$

where S is given by [3.2]. Simplifying again [3.5] may be rewritten

[3.6] $$i(t) = PQ^{\lambda}(1 - S)(S)$$

where $P = 4 \times 10^{b_1}$, and $\lambda = -a_1/a_2$. This equation can now be used to describe the behaviour of the model in response to both linear scans of potential and potential steps, either in the absence or presence of ohmic potential drop.

Generally speaking it is the parameters a_1 and a_2 which one wishes to extract from [3.1] to [3.6]. The value of R is also of some importance. It can be controlled during a given experiment in that an additional resistance can be deliberately intro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

duced into the circuit. Mathematically it is possible to use all available data on S, i, and E to solve [3.1]–[3.6] in some way that determines the above parameters. There are, however, considerable experimental constraints. In particular deviations from the model are encountered at small values of observed current because of the presence of background reactions such as dissolution etc. Therefore the most reliable data available are the values of the peak current and the time (or when $E = \nu t$, the potential) at which this current occurs. Furthermore the asymptotic behaviour of the various parameters is worthy of investigation because simplifications occur in the mathematical analysis.

(4) Evaluation of Maximum Parameters

The description of $i(t)$ as an explicit function of time would allow the analytical prediction of the general shape of the i–t curve for a given applied potential waveform. Then from [3.6] it would be easy to solve for the maximum current simply by evaluating $\mathrm{d}i/\mathrm{d}t = 0$. The result of such an analysis is

$$[4.1] \qquad \gamma S \, \mathrm{d}E/\mathrm{d}t = (2S - 1) \cdot J^2 Q$$

Here, $\gamma = a_1 \ln (10)/3k$. It is conventional to label the current maximum as i_m in the transient case and as i_p in the voltammogram case ($E = \nu t$, where ν (mV s^{-1}) is the potential scan rate). Note that in theory it is possible to deal with the case of E being any function of time; however only the situations E = const. and $E = \nu t$ are considered here.

(5) The Case $R = 0$, $E = \nu t$

The case of $R = 0$ is simpler to deal with than $R > 0$, because the equations for S and i are not coupled. It is, however, a singular case because there is no feedback effect on the applied potential via the transformation $E \rightarrow E - i(t)R$. As a result the asymptotic forms of i_p and E_p, the potential (mV) at which i_p occurs, as $\nu \rightarrow \infty$ are entirely different from the $R > 0$ case. For $R = 0$

$$[5.1] \qquad E = \nu t$$

$$[5.2] \qquad S = 1 - \exp(-kJ^3)$$

$$[5.3] \qquad J(E) = [-(1/\nu) a_2 \ln 10][e^{-a_2 E \ln 10} - 1] + C$$

$$[5.4] \qquad Q(E) = 10^{-a_2 E}$$

so that

$$[5.5] \qquad J(E) = [-(1/\nu) a_2 \ln 10](Q - 1) + C$$

From [4.1], and denoting the parameters at the current maximum by the subscript p

$$[5.6] \qquad \gamma S_p \nu = (2S_p - 1) J_p^2 Q_p$$

Recalling [3.6] and taking logarithms

$$[5.7] \qquad \log (i) = \log (P) + a_1 E + \log (S) + \log (1 - S)$$

and hence

$$[5.8] \qquad \frac{\mathrm{d} \log (i)}{\mathrm{d}E} = a_1 + (1 - 2S) 3kJ^2 Q/S\nu$$

If $C \neq 0$ then as $\nu \rightarrow \infty$ both J and $1/S$ remain bounded and the second term of [5.8] approaches 0. Therefore

$$[5.9] \qquad \lim_{\nu \rightarrow \infty} \frac{\mathrm{d} \log i}{\mathrm{d}E} = a_1$$

In practice a_1 can be evaluated by plotting log i vs. E at high scan rates. This phenomenon is similar to Tafel-like behaviour exhibited by various reaction schemes and consequently some confusion may have arisen in practical applications in the past. However, an important diagnostic criterion of the present model is the variation of i_p with ν. From [5.5]

$$[5.10] \qquad Q/\nu = -a_2(J - C) \ln (10) + 1/\nu$$

Substituting in [5.6] when $Q \rightarrow Q_p$ and $J \rightarrow J_p$ yields

$$[5.11] \qquad \gamma S_p = (2S_p - 1) J_p^2 [-a_2 (J_p - C) \times \ln (10) + 1/\nu]$$

As $\nu \rightarrow \infty$, $J_p \rightarrow J_p^*$, $S_p \rightarrow 1 - \exp(-kJ_p^{*3}) = S_p^*$ where

$$[5.12] \qquad \gamma S_p^* = J_p^{*2} (2S_p^* - 1)(-a_2 (J_p^* - C) \ln 10)$$

The important points to note are that $S_p^* < 1$ and $Q_p/\nu \rightarrow$ a definite limit L as $\nu \rightarrow \infty$ as is clear from [5.10]. Therefore, from [3.6]

$$[5.13] \qquad i_p = P(Q_p/\nu)^\lambda S_p (1 - S_p) \nu^\lambda$$

so that

$$i_p \sim PL^\lambda S_p^* (1 - S_p^*) \nu^\lambda \qquad \text{as} \qquad \nu \rightarrow \infty$$

Therefore

$$[5.14] \qquad \log i_p \sim \lambda \log \nu + \text{constant}$$

Hence a graph of log i_p vs. log ν is asymptotically a straight line with slope $-a_1/a_2$. In a similar way it is possible to show that a plot of log E_p vs. log ν is asymptotically a straight line with slope $-1/a_2$.

The plot of log i_p vs. log ν is of particular significance in the present work because it provides a clear distinction between three-dimensional nucleation and growth, two-dimensional nucleation and growth, and diffusion-controlled reactions (in particular the dissolution–precipitation mechanism). Nicholson and Shain (11) have shown that for diffusion-controlled reactions at a stationary laminar electrode, log i_p vs.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

log v should usually have a gradient of 0.50; in the present case it is expected that $0.5 < -a_1/a_2 < 1.0$. For two-dimensional nucleation and growth the gradient of the plot should be unity, at the high scan rate, because of the constant charge required in the formation of a monolayer. It is clear therefore that 2-dimensional growth, 3-dimensional growth, and diffusion control can be simply distinguished by observing the effect of varying v on the peak parameters.

(6) The Case $R > 0, E =$ constant

In this instance [4.1] reduces to $S_m = 1/2$ so that from [3.5]

$$[6.1] \qquad i_m = 10^{(a_1(E - i_m R) + b_1)}$$

which expresses i_m implicitly as a function of E. From [6.1] it is possible to extract information about a_1 and R in various ways. Note that

$$i_m 10^{a_1 i_m R} = 10^{(a_1 E + b_1)}$$

showing that $i_m \to \infty$ as $E \to \infty$ and that

$$[6.2] \qquad R = \lim_{E \to \infty} (E/i_m)$$

Also from [6.1]

$$[6.3] \qquad \frac{dE}{d \log i_m} = 1/a_1 + \ln (10) i_m R$$

Thus a graph of $dE/d \log i_m$ vs. i_m yields a straight line, the intercept and gradient yielding a_1 and R. Note the linearity of this function even in the presence of uncompensated resistance. This is a very good experimental test provided that $dE/d \log i_m$ can be evaluated accurately. To obtain t_m (and hence a_2) is somewhat more difficult because of the coupling between the equations for i and S, and requires obtaining i as an explicit function of t. In the transient case $C = 0$ so that [3.2] becomes

$$[6.4] \quad S = 1 - \exp\left[-k 10^{-3 a_2 E} \times \left(\int_0^t 10^{a_2 i(t') R} \, dt' \right)^3 \right]$$

and from [3.6]

$$[6.5] \qquad S^2 - S + [i(t) Q^{-\lambda}/P] = 0$$

where

$$[6.6] \qquad Q = 10^{-a_2 (E - iR)}$$

From [6.4]

$$[6.7] \quad \int_0^t Q(t') \, dt' = \left[\frac{\ln (1 - S)}{k} \right]^{1/3} = h(i)$$

say, where S is obtained as a function of i via [6.5]. Then $h'(i) = Q \, dt/di$ and

$$[6.8] \quad t = \int_0^i Q^{-1} h'(i) \, di = h(i) Q^{-1} + a_2 R \ln 10 \int_0^i Q^{-1} h(i) \, di$$

When $i = i_m$, $S_m = 1/2$ so $h(i_m) = 10^{b_2}$ and

$$[6.9] \quad t_m = [10^{a_2 (E - i_m R) + b_2}] + a_2 R \ln (10) \int_0^{i_m} Q^{-1} h(i) \, di$$

To obtain $h(i)$ suppose $i \leq i_m$. Under these circumstances [6.5] can be solved uniquely for S giving

$$[6.10] \quad h(i) = 10^{b_2} \times \left[1 - \frac{\ln (1 + \sqrt{1 - Q^{-\lambda} 4i/P})}{\ln 2} \right]^{1/3}$$

From here $i(t)$ may be obtained by numerical integration. A typical result is illustrated in Fig. 2. By expansion of [6.9] and consideration of [6.1] it can also be shown, over the experimental range of i_m, that

$$[6.11] \qquad d \log (t_m)/d (E - i_m R) \simeq a_2$$

whilst from [6.1]

$$[6.12] \qquad d \log (i_m)/d (E - i_m R) = a_1$$

Thus a graph of $\log t_m$ vs. $\log i_m$ is very insensitive to the effects of R, approximating the exact relation

$$[6.13] \qquad \log t_m = (a_2/a_1) \log i_m$$

Comparison of this plot with [5.14] should therefore provide an excellent experimental value for a_2/a_1.

(7) The Case $R > 0, E = vt$

First it is necessary to show that [6.3] holds asymptotically as $v \to \infty$. Here i has the form of [5.7] and hence

$$\log i = \log P + a_1 (E - iR) + \log S + \log (1 - S)$$

giving

$$[7.1] \quad \frac{d \log i}{dE} = \left[a_1 + \frac{(1 - 2S) 3k J^2 Q}{Sv} \right] \Big/ (1 + a_1 R i)$$

As in section 5, when $v \to \infty$ the second term in the numerator $\to 0$ so

$$[7.2] \qquad \lim_{v \to \infty} \frac{dE}{d \log i} = 1/a_1 + Ri$$

which is a direct generalization of [5.9]. This equation makes a_1 and R accessible to experimental evaluation.

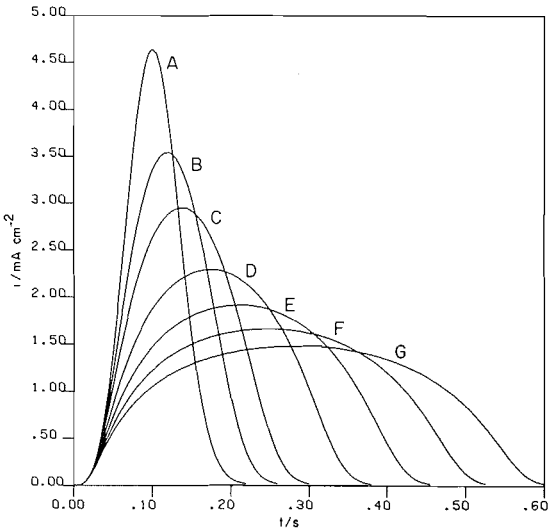

FIG. 2. Effect of uncompensated ohmic overpotential on a single, progressive 3-dimensional nucleation and growth transient. Constants are; $a_1 = 1/3$, $a_2 = -1/2$, $b_1 = b_2 = 0$, $E = 2.0$ mV. (*A*) $R = 0\ \Omega\ cm^2$, (*B*) $R = 0.1\ \Omega\ cm^2$, (*C*) $R = 0.2\ \Omega\ cm^2$, (*D*) $0.4\ \Omega\ cm^2$, (*E*) $0.6\ \Omega\ cm^2$, (*F*) $0.8\ \Omega\ cm^2$, (*G*) $1.0\ \Omega\ cm^2$.

Next to be examined is the behaviour of i_p and E_p as a function of ν and R. When $R > 0$ it is possible to deal only with asymptotic behaviour, although this is interesting in its own right. For example i_p behaves differently in the limit $\nu \to \infty$ for $R = 0$ and $R > 0$, no matter how small R may be. This is because i_p and E_p become linked through R, as $i_pR \sim E_p$. This is not the case when $R = 0$.

The analysis of the cases where R is fixed > 0, $\nu \to \infty$, and ν is fixed > 0, $R \to \infty$ is possible by rearranging the equations of section 3 and attacking the cases in conjunction. Equations 3.2 to 3.6 plus the relation $E = \nu t$ can be regarded as being five equations in S, J, Q, E, t, i, and may be considered as giving the first five quantities as functions of i. Thus

$$[7.3] \qquad Q(i) = 10^{-a_2(\nu t(i) - iR)}$$

$$[7.4] \qquad J(i) = \int_0^{t(i)} Q(t')\,dt' + C$$

so that

$$\frac{dQ}{di} = -a_2 \ln(10) Q\left(\nu \frac{dt}{di} - R\right)$$

and

$$dJ/di = Q\,dt/di$$

Thus

$$[7.5] \qquad \frac{dQ}{di}\frac{1}{\nu} = -a_2 \ln(10)\left(\frac{dJ}{di} - \frac{QR}{\nu}\right)$$

Solving for Q from [3.6] gives

$$[7.6] \qquad \frac{1}{\nu}(S(1-S))^{1/\lambda}\frac{dQ}{dt} = -a_2 \ln(10) \times \left[(S(1-S))^{1/\lambda}\frac{dJ}{di} - \left[\frac{i}{P}\right]^{1/\lambda}\frac{R}{\nu}\right]$$

Integrating [7.5] with respect to i yields

$$J = \frac{R}{\nu}\int_0^i Q\,di - (Q^{-1}/\nu a_2 \ln 10)$$

and from [3.6]

$$i = PQ^{\lambda}S(1-S) \le PQ^{\lambda}/4$$

Hence

$$[7.7] \qquad Q \ge (4i/P)^{1/\lambda}$$

Then from [7.6] and [7.7]

$$[7.8] \qquad J \ge \frac{R}{\nu}(4/P)^{1/\lambda}\frac{i^{(1+1/\lambda)}}{1+1/\lambda} - (Q-1)/(\nu a_2 \ln 10)$$

This inequality is valid at all times and in particular when $J = J_p$, $Q = Q_p$, and $i = i_p$. It allows us to show, using [4.1], that $J_p \to \infty$ as $\nu \to \infty$ unlike the $R = 0$ case. Integration of [7.6] with respect to i between the limits 0 and i_p leads to

$$[7.9] \qquad \log i_p \sim \frac{\lambda}{1+\lambda}\log \nu$$

which should be compared with [5.14]. In a similar way it is possible to estimate the effect of the variation of R at constant ν. The results are

$$[7.10] \qquad \lim_{R\to\infty}\frac{d\log i_p}{d\log R} = -\frac{\lambda}{1+\lambda}$$

$$[7.11] \qquad \lim_{R\to\infty}\frac{d\log E_p}{d\log R} = \frac{1}{1+\lambda}$$

Employing [7.10] and [7.11] in conjunction therefore allows the estimation of a_1 and a_2.

(8) The Case $R = 0$, Staircase Voltammogram

The idea of replacing the linear potential sweep with a potential staircase is due to Barker (12). The benefit of such a technique lies in the fact that it produces (at long times) a purely Faradaic response and hence eliminates the contribution of the double layer charging current to the overall observed current. This is particularly advantageous at high scan rates. The applied potential behaves according to

$$[8.1] \qquad E_n = n\nu\Delta t \qquad n = 0, 1, 2, 3 \ldots$$

where both ν and Δt are specified. Several features of this technique are of interest. In particular it is necessary to investigate the current response as $\Delta E\ (= \nu\Delta t) \to 0$. From [3.1] it is clear that

[8.2] $$S_n = 1 - \exp(-k\tau_n^3\, 10^{-3a_2E_n}) \qquad n = 0, 1, 2, 3 \ldots$$

and

[8.3] $$S_{n+1} = 1 - \exp(-k(\tau_n + \Delta t)^3 10^{-3a_2E_n})$$

which when differenced with [8.2] becomes the approximation to [2.2]. To obtain S_n note from [8.2] that

[8.4] $$S_{n+1} = 1 - \exp(-k\tau_{n+1}^3 10^{-3a_2E_{n+1}})$$

so that

$$\tau_{n+1}^3 10^{-3a_2E_{n+1}} = (\tau_n + \Delta t)^3 10^{-3a_2E_n}$$

giving

[8.5] $$\tau_{n+1} = (\tau_n + \Delta t)10^{a_2\nu\Delta t}$$

Equation 8.5 is a linear difference equation which may be solved to yield

[8.6] $$\tau_n = 10^{a_2 n\nu\Delta t}\tau_0 + \Delta t(10^{-a_2 n\nu\Delta t} - 1)/(10^{-a_2\nu\Delta t} - 1)$$

Substituting back into [8.2] gives

[8.7] $$S_E = 1 - \exp[-k(\tau_0 + \Delta t(10^{-a_2 n\nu\Delta t} - 1)/(10^{-a_2\nu\Delta t} - 1))^3]$$

where

[8.8] $$S_0 = 1 - \exp(-k\tau_0^3)$$

When $R = 0$ and $E = \nu t$ [3.2] may be solved to give S as an explicit function of time. Thus

[8.9] $$S(E) = 1 - \exp[-k((10^{-a_2\nu t} - 1)/(-a_2\nu \ln 10) + \tau_0)^3]$$

Setting $n\nu\Delta t = E$ and $\nu\Delta t = \Delta E$ shows that the finite approximation S_E given in [8.7] differs from the exact solution only in the fact that $\Delta E/(10^{-a_2\Delta E} - 1)$ replaces $1/(-a_2 \ln 10)$. But as $\Delta E \to 0$:

[8.10] $$\lim_{\Delta E \to 0} \Delta E/(10^{-a_2\Delta E} - 1) = -1/a_2 \ln 10$$

thus proving convergence of the finite approximation.[1]

When R is not zero it is not possible to obtain explicit formulae for S_n, but it is expected that convergence will still occur since the general effect of R on S (and hence $i(t)$) is to decrease gradients due to the feedback effect on the applied potential.

Conclusion

The effect of varying the applied potential on progressive three-dimensional nucleation and growth has been described. Various limiting cases have been considered on the assumption that the electrode surface coverage responds instantaneously to any instantaneous change in applied potential. A number of results are presented which may be tested by experiment.

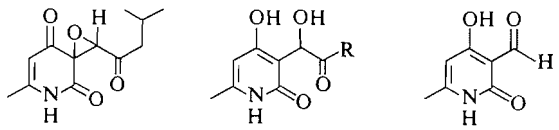
In the course of studies successfully directed at the total synthesis of the antibiotic flavipucine **1** (1) we have studied the chemistry of some 4-hydroxy-2-pyridones and now report our findings.

Of central focus has been compound **2***a*, the product of the novel condensation of 6-methyl-4-hydroxy-2-pyridone with isobutylglyoxal (2), which was eventually transformed into (±)-flavipucine **1** by the agency of *tert*-butylhydroperoxide. Initial attempts to achieve this transformation were directed by the observation of Becker *et al.* (3) that 2,4-di-*tert*-butyl-6-hydroxymethyl phenol affords the corresponding spiroepoxy-2,4-di-*tert*-butyl cyclohexadienone when treated with sodium metaperiodate in methanol at room temperature. Treatment of **2***a* and **2***b* under similar conditions resulted in cleavage at the α-hydroxy ketone site of the side chain in preference to the 1,3-enediol system and gave the aldehyde **3**. Attempts to prepare the dithioketal of **2***b* were unsuccessful and treatment with ethylene glycol in boiling benzene in the presence of paratoluene sulfonic acid gave only the tricyclic ether **4**. In support of formulation **4** the ir spectrum shows only a single carbonyl band at 1650 cm^{-1} (conjugated lactam) while mass spectral (*m/e* 223) and microanalytical data are consistent with composition $C_{11}H_{13}NO_4$ and the uv spectrum resembles those of other 3-substituted 6-methyl-4-hydroxy-2-pyridones. Further corroboration is provided by the nmr spectrum (*vide infra*).

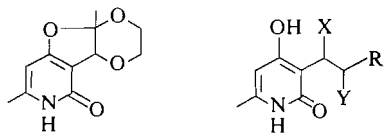
Oxidation of **2***b* with a variety of other oxidizing agents usually gave complex mixtures; however, manganese dioxide on charcoal oxidized **2***a* and **2***b* to the corresponding α-diketones **5***a* and **5***b*, respectively, in moderate yields.

Reduction of the system **2***b* was also explored and conditions were found to achieve various degrees of reduction of both side chain and nucleus. Thus,



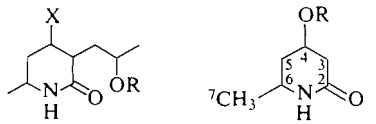
1 **2** **3**

a R = $CH_2CH(CH_3)_2$
b R = CH_3



4 **5**

a X, Y = O; R = $CH_2CH(CH_3)_2$
b X, Y = O; R = CH_3
c X, Y = OH; R = CH_3
d X = H; Y = O; R = CH_3
e X = H; Y = OH; R = CH_3



6 **7**

sodium borohydride in water smoothly converted **2***b* to the corresponding triol **5***c* in near quantitative yield, while catalytic reduction using palladium-on-charcoal at 25°C and 85 psi caused hydrogenolysis of the side-chain hydroxyl of **2***b* to furnish **5***d* in 60% yield. More vigorous catalytic reduction employing a nickel catalyst at 125°C and 1400 psi resulted in a mixture of products among which the major component (14%) was identified as 3-(2′-hydroxypropyl)-5-methyl-2-piperidone **6***a*. Reduction of the 2-pyridone nucleus has previously been achieved using

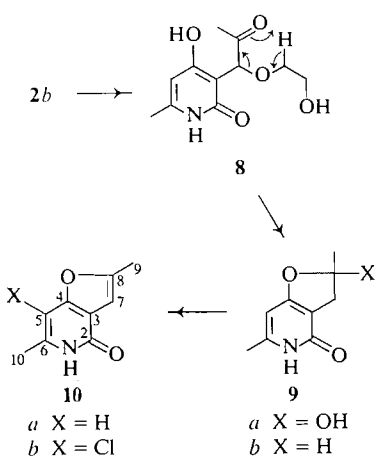
For personal use only.

Raney nickel in ethanol at room temperature to yield 2-piperidones (4) and using nickel carbonate – copper carbonate at high temperatures catalyses the hydrogenation of 2-pyridones to 2-piperidones (5). In most cases *N*-substituted substrates were employed.

We have also subjected 6-methyl-4-hydroxy-2-pyridone to catalytic hydrogenation using ruthenium-on-charcoal in ethanol at 65°C and 700 psi. The crystalline product 6-methyl-4-hydroxy-2-piperidone (**7***a*) was obtained in 60% yield and further characterized as the acetate **7***b*. Assuming that in the catalytic reduction the hydrogen is added from only one side, then the product **7***a* should have the *cis* configuration. This conclusion is consistent with the 100 MHz nmr data; however, the alternate configuration cannot be completely excluded. Attempts to oxidize the piperidone **7***a* to the corresponding ketone (or enol) were remarkably unsuccessful suggesting that the anticipated β-dicarbonyl product is highly unstable under the various conditions employed.

Ruthenium–charcoal catalyzed hydrogenation of **2***b* at elevated temperature and high pressure gave, as major product, the crystalline diol pyridone **5***e* or diol piperidone **6***b* when a large excess of catalyst was employed. The latter was transformed into the crystalline diacetate **6***c* by treatment with acetic anhydride in pyridine.

Numerous attempts to prepare an ene-trione by dehydration of **2***b* were remarkably unsuccessful and only under forcing conditions could any type of dehydration be induced and then it was accompanied by an unusual reduction and ring formation. Thus, when **2***b* was treated with *p*-toluenesulfonic acid in refluxing ethylene glycol in the presence of molecular sieve the product **10***a* was obtained whose structure is fully supported by high resolution mass spectral, ^{1}H nmr, and ^{13}C nmr data. Furthermore, the compound **10***a* has also been prepared from the more logical precursor **5***d* by treatment under the same extreme dehydrating conditions and presumably proceeding via the dehydration of the hemiacetal form **9***a*. A rationalization of the remarkable transformation **2***b* → **10***a* is portrayed in Scheme 1 in which the ether formation to give **8**, a reaction type well precedented for this system (1), is first envisaged. A reductive cyclodecomposition of **8** could lead to the ejection of glycoaldehyde and the formation of the necessary hemiacetal **9***a*. Mild catalytic hydrogenation of **10***a* gave the crystalline dihydro derivative **9***b* while treatment with sodium hypochlorite in dioxane afforded the monochlorination product **10***b*. The placement of the chlorine atom at C5 follows from a comparison of chemical shifts, coupling constants and multiplicities in the ^{13}C nmr spectra of **10***a* and **10***b*.



SCHEME 1

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Mass spectra were recorded with an Hitachi-Perkin-Elmer RMU-6D spectrometer. High resolution mass spectra were recorded with a Consolidated Electrodynamics Corporation R6-1 instrument. The nmr spectra were recorded with a Varian T-60 instrument (unless otherwise noted) using tetramethylsilane as internal standard. Line positions are reported in ppm from this standard. ^{13}C nmr spectra were obtained with a Varian XL-100-15 equipped with S1-124 Fourier transform accessory. Ultraviolet spectra were obtained with a Perkin-Elmer model 467 spectrophotometer and infrared spectra with a Perkin-Elmer model 457 grating instrument. Preparative tlc plates were of 1-mm silica gel G.

Preparation of 4-Hydroxy-6-methyl-3-carboxaldehyde-2-pyridone 3 from 2b

To pyridone **2***b* (1.97 g) in methanol (50 ml) a suspension of sodium metaperiodate (2.3 g) in water (33 ml) was added. After stirring at room temperature overnight the mixture was filtered and the filtrate evaporated yielding a white crystalline solid (1.06 g, 69%), mp 232–238°C; nmr δ_{TMS}(DMSO-d_6): 2.20 (s, 3H, CH_3—C=C) 3.2–3.8 (broad, 1H, O*H*), 5.85 (s, 1H, HC=C—), 9.15 (s, 1H, —CHO) and 11.95 (s, 1H, NH); ir ν_{max}(KBr): 1620 (conjugated lactam/dienamine), 1670 cm^{-1} (conjugated aldehyde); uv λ_{max}(ethanol): 232, 272, 337 (ε 6200, 1200, 5200); ms *m/e* 153 (M^+). *Anal.* calcd. for $C_7H_7NO_3$: C 54.90, H 4.61, O 31.35, N 9.15; found: C 54.70, H 4.65, O 31.51, N 9.02.

Preparation of 4 from 2b

A mixture of **2***b* (1 g) and *p*-toluenesulfonic acid (0.32 g) in dry ethylene glycol (20 ml) and benzene (50 ml) was refluxed for 14 h. After cooling and neutralizing with 5% sodium bicarbonate solution to p*H* 8–9 the mixture was extracted with chloroform and this extract was washed with water and evaporated giving a foam (0.99 g). Purification by preparative tlc on silica gel (chloroform–methanol 93:7) afforded white solid **4** (0.43 g, 38%), mp 183–185°C; nmr δ_{TMS}($CDCl_3$): 1.50 (s, 3H, CH_3—C—O), 2.30 (s, 3H, CH_3C=C), 3.7 (bm, 4H,

Preparation of 5a from 2a

Compound **2***a* (0.5 g) in pyridine (15 ml) was stirred with manganese dioxide on charcoal (5.59 g) at room temperature for 18 h. After filtration through Celite and evaporation of the filtrate, a yellow solid was obtained which was purified by preparative tlc on silica gel (methanol–chloroform 3:97) to furnish **5***a* (0.1126 g, 12%) as a yellow solid mp 174–180°C; nmr δ_{TMS}(Py-d_5): 1.10 (d, 6H, J = 6.5 Hz, $(CH_3)_2CH$—), 2.18 (s, 3H, CH_3—C=C—), 2.38 (m, 2H, —CH_2—CO—), 5.28 (bs, 2H, NH/OH – deuterium exchangeable), 5.92 (s, 1H, HC=C—); ir ν_{max}(KBr): 1720 (ketones), 1650, 1620 cm^{-1} (conjugated lactam); uv λ_{max}(ethanol) 207, 230, 317 (ε 8500, 8000, 8900); ms *m/e* 237 (M^+). *Anal.* calcd. for $C_{12}H_{15}O_4N$: C 60.75, H 6.37, O 26.98; found: C 60.54, H 6.28, O 27.04.

Preparation of Compound 5b from 2b

A mixture of **2***b* (0.2 g) in pyridine (10 ml) and manganese-dioxide-on-charcoal (2 g) was stirred at room temperature for 3 days. After filtration and evaporation a yellow solid was obtained which was purified by preparative tlc on silica gel (methanol–chloroform 1:9) and afforded yellow crystalline **5***b* (0.82 g, 41%), mp 128–130°C; nmr δ_{TMS}(DMSO-d_6): 1.55 (s, 3H, CH_3C=C), 2.20 (s, 3H, CH_3CO—), 5.87 (s, 1H, CH=C); ir ν_{max}(KBr): 1725 (ketones), 1640, 1610 cm^{-1} (conjugated lactam); uv λ_{max}(ethanol): 207, 230, 318 (ε 12 300, 11 900, 13 500); ms *m/e* 195 (M^+). *Anal.* calcd. for $C_9H_9O_4N$: C 55.38, H 4.68, O 32.79; found: C 55.52, H 4.41, O 32.84.

Sodium Borohydride Reduction of 2b to 5c

Sodium borohydride (0.62 g) was added to a suspension of **2***b* (2.0 g) in water (92 ml) and the mixture was stirred at room temperature for 18 h then filtered and evaporated to give a white solid (1.79 g, 88%), mp 298°C (dec.); nmr δ_{TMS}(D_2O): 1.05 (d, 3H, J = 7 Hz, CH_3—CH), 2.30 (s, 3H, CH_3C=C<), 4.3 (bm, 1H, —CHOHCH_3), 4.90 (m, 1H, >C=C—CHOH), 5.96 (s, 1H, —CH=C<); ir ν_{max}(KBr): 1630 cm^{-1} (conjugated amide); uv λ_{max}(ethanol): 218, 280 (ε 15 100, 3600); ms *m/e* 181 ($M^+ - H_2O$). *Anal.* calcd. for $C_9H_{13}NO_4$: C 54.25, H 6.58, O 32.13; found: C 54.12, H 6.49, O 32.28.

Catalytic Reduction of 2b to 5d

A mixture of compound **2***b* (2.66 g) in suspension in ethanol (210 ml) and palladium-on-charcoal (0.84 g, 10%) was hydrogenated at 85 psi and 25°C for 3 h. After filtration through Celite and evaporation, a white solid (2.2 g) was obtained which after recrystallization from ethanol yielded compound **5***d* (1.45 g, 60%), mp 209–212°C; nmr δ_{TMS}(DMSO-d_6): 2.15 (s, 3H, CH_3—), 2.28 (s, 3H, CH_3—), 4.08 (s, 2H, =C—CH_2—CO—), 6.04 (s, 1H, —CH=C); ir ν_{max}(KBr): 1720 (ketone), 1645, 1620 cm^{-1} (conjugated amide); uv λ_{max}(ethanol): 215, 280 (ε 13 300, 4500); ms *m/e* 181. *Anal.* calcd. for $C_9H_{11}NO_3$: C 59.66, H 6.12, O 7.73; found: C 59.48, H 6.01, O 7.89.

Catalytic Reduction of 2b to 6a

A suspension of **2***b* (0.49 g) and nickel catalyst (#28)* (2.16 g) in water (20 ml) was hydrogenated at 1250–1400 psi at 125°C for 40 h. After cooling, filtration through Celite, and evaporation an oil (0.38 g) was obtained which was purified by preparative tlc on silica gel (chloroform–methanol 9:1) giving **6***a* as a homogeneous oil (0.06 g, 14%); nmr δ_{TMS}($CDCl_3$ + D_2O): 1.12 (d, 6H, J = 7 Hz, $2CH_3$—CH—), 1.7 (bm, 5H), 2.4 (bm, 1H, —CH—CONH—), 3.5 (bm, 1H, —CH—NHCO—), 3.9 (bm, 1H, —CHOH—); ir ν_{max}($CHCl_3$) 3400 (hydroxyl), 1640 cm^{-1} (amide); ms *m/e* 171 (M^+).

Reduction of 4-Hydroxy-6-methyl-2-pyridone to 7a

A mixture of 4-hydroxy-6-methyl-2-pyridone (2.6 g) and ruthenium-on-charcoal (0.94 g, 5%) in ethanol (84 ml, 95%) was hydrogenated at 300–1000 psi at 58°C for 19 h. After cooling, filtration through Celite, and evaporation a white solid (2.58 g) was obtained which on recrystallization from ethanol afforded white crystalline **7***a* (1.55 g, 57%), mp 204–206°C; ir ν_{max}(KBr); 1660 cm^{-1} (amide); ms *m/e* 129 (M^+).

Anal. calcd. for $C_6H_{11}NO_2$: C 55.81, H 8.52, O 24.80, N 10.85; found: C 55.81, H 8.55, O 25.09, N 10.99.

Esterification of 7a to 7b

A mixture of **7***a* (1.02 g), acetic anhydride (14.01 g), and dry pyridine (36 ml) was stirred at room temperature for 20 h. After evaporation a yellow solid (1.37 g) was obtained which was purified by preparative tlc on silica gel (chloroform–methanol 93:7) yielding white crystalline acetate **7***b* (0.6 g, 44%), mp 138–141°C; nmr, 100 MHz, spectrum, $\delta_{TMS}(CDCl_3)$; see Table 2; ms *m/e* 171 (M^+). *Anal.* calcd. for $C_8H_{13}NO_3$: C 56.12, H 7.65, O 8.18; found: C 55.92, H 7.58, O 8.35.

Ruthenium Catalyzed Hydrogenation of 2b to 5e

A mixture of **2***b* (5 g) and ruthenium-on-charcoal (1.15 g, 5%) in ethanol (150 ml, 95%) was hydrogenated at 500–1000 psi and 85°C for 20 h. After cooling and filtration through Celite, evaporation of the filtrate yielded a white solid which was recrystallized from ethanol to give **5***e* (1.8 g, 56%), mp 273–275°C; nmr δ_{TMS}(Py-d_5): 1.50 (d, 3H, CH_3—CHOH), 2.15 (s, 3H, CH_3—C=C—), 3.35 (m, 2H, —CH_2—CHOH), 4.55 (m, 1H, —CHOH), 6.10 (s, 1H, HC=C—); uv ν_{max}(KBr): 1625 cm^{-1} (conjugated lactam); uv λ_{max}(ethanol): 215, 288 (ε 14 000, 5600); ms *m/e* 183 (M^+). *Anal.* calcd. for $C_9H_{13}NO_3$: C 59.00, H 7.15, O 26.20; found: C 58.88, H 7.20, O 26.10.

Ruthenium Catalyzed Reduction of 2b to 6b

A mixture of **2***b* (0.51 g) and ruthenium-on-charcoal (0.76 g, 5%) in ethanol (60 ml, 95%) was hydrogenated at 600–1200 psi at 80°C for 21 h. After cooling, filtering, and evaporating an oil (0.32 g) was obtained which was purified by preparative tlc on silica gel (chloroform–methanol 9:1) giving the oil **6***b* (0.08 g, 17%) which was characterized by acetylation (acetic anhydride – pyridine at room temperature for 16 h) to give the crystalline acetate **6***c*, mp 96–98°C; nmr $\delta_{TMS}(CDCl_3)$: 1.20 (d, 6H, J = 7 Hz, 2× CH_3—CH—), 2.08 (s, 3H, CH_3COO), 2.10 (s, 3H, CH_3COO) superimposed on 1.4–2.8 (multiplets, 4H, 2× —CH_2—), 3.6 (m, 1H, —CH—NHCO), 5.2 (m, 2H, —CHOAc), 6.6 (bm, 1H, deuterium exchangeable, NH); ir $\nu_{max}(CHCl_3)$: 1735 (esters), 1660 cm^{-1} (amide); ms *m/e* 171 (M^+). *Anal.* calcd. for $C_{13}H_{21}NO_5$: C 57.55, H 7.80, O 5.16; found: C 57.66, H 7.71, O 5.04.

Preparation of 10a from 2b

A mixture of **2***b* (9.0 g), *p*-toluenesulfonic acid (8.8 g) and molecular sieve (39 g, type 5Å) under dry nitrogen in dry ethylene glycol (1.59 ℓ) was refluxed for 40 h, cooled and diluted with water (1 ℓ) and filtered through Celite. The filtrate was cooled to 6°C and treated with sodium bicarbonate (50 g). Extraction with chloroform afforded a yellow solid which was chromatographed on a silica gel (155 g) column. Elution with chloroform–methanol (~200 ml) (93:3.5) gave a yellow solid which on recrystallization from chloroform–ether (1:1) gave white crystalline **10***a* (0.35 g, 5%), mp 227–229°C; nmr $\delta_{TMS}(CDCl_3)$: 2.22 (s, 3H, CH_3—C=C<), 2.32 (s, 3H, CH_3—C=C<), 6.38 (s, 1H, CH=C<), 6.77 (s, 1H, CH=C<), 12.9 (bs, 1H, deuterium exchangeable, NH); ir ν_{max}(KBr): 1670 cm^{-1} (lactam); uv λ_{max}(95% ethanol) 254, 262, 295 (ε 12 900, 12 300, 8700). *Mol. Wt.* calcd. for $C_9H_9O_2N_2$: 163.0633; found (ms) 163.0633 (100), 162.0559 (74, M^+ −H), 134.0604 (41, M^+ −H−CO).

Preparation of 10a from 5d

A mixture of **5***d* (0.5 g), *p*-toluenesulfonic acid (0.53 g), molecular sieve (4.56 g, type 5Å), and ethylene glycol (100 ml) under nitrogen was refluxed for 40 h. After cooling and filtering through Celite, the solution was cooled to 3°C and sodium bicarbonate solution (100 ml of 5%) was added. Extraction with chloroform afforded a yellow solid (0.58 g) which yielded white crystalline **10***a* (0.16 g, 23%), mp 227–229°C after preparative tlc on silica gel, identical in all respects with **10***a* obtained from **2***b* (*vide supra*).

Reduction of 10a to 9b

A solution of **10***a* (0.15 g) in ethanol (38 ml, 95%) was hydrogenated over palladium-on-charcoal (240 mg, 10%) at 27 psi for 45 h. The mixture was filtered through Celite and evaporated yielding a white solid (0.14 g) which was purified by preparative tlc using silica gel (chloroform–methanol 7:3) to give a white crystalline solid (0.07 g, 43%), mp 187–201°C. The mass spectrum *m/e* 165 (M^+). The nmr spectrum δ_{TMS} ($CDCl_3$–D_2O): 1.38 (d, 3H, J = 7 Hz, CH_3CHO—), 2.25 (s, 3H, CH_3—C=CH—), 2.2–3.4 (multiplets, 2H, —CH_2—), 4.95 (multiplet, 1H, —CHO—), 5.70 (s, 1H, —CH=C). The ir spectrum ν_{max}(KBr) 1630 cm^{-1} (v broad, conjugated lactam). The uv spectrum λ_{max}(ethanol) 223, 237(s), 294 (ε 6600, 3400, 6900).

Preparation of 10b from 10a

Sodium hypochlorite solution (3.9 g, 5% aqueous) was added to a suspension of **10***a* (0.2 g) in dioxane (4 ml) at 17°C. After stirring at ~23°C for 68 h, water (6.6 ml) was added and the white precipitate which formed was filtered off. Purification of this white solid (0.21 g) by preparative tlc on silica gel (chloroform–methanol 98:2) afforded white crystalline **10***b* (0.13 g, 53%), mp 210–232°C; nmr $\delta_{TMS}(CDCl_3)$: 2.48 (s, 3H, CH_3—C=CH), 2.54 (s, 3H, CH_3—C=C—), 6.65 (s, 1H, —CH=C—), ~9.0 (v. broad, 1H, NH); ir ν_{max}: 1680, 1600 cm^{-1}; uv λ_{max}(ethanol): 256, 264, 305 (ε 12 400, 11 400, 7400); ms *m/e* 197 (M^+). *Anal.* calcd. for $C_9H_8NO_2Cl$: C 54.68, H 4.05, O 16.20, N 7.08, Cl 17.97; found: C 54.43, H 4.13, O 16.47, N 7.00, Cl 17.51.

Intermediates in the cycloanhydrotetramerization of furan with aliphatic and alicyclic ketones

WILLIAM HAMILTON BROWN AND BRUCE JAMES HUTCHINSON[1,2]

Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 4, 1977

WILLIAM HAMILTON BROWN and BRUCE JAMES HUTCHINSON. Can. J. Chem. **56**, 617 (1978).

The acid-catalysed reaction of furan with acetone has been investigated for the presence of intermediates by vapour phase chromatography of the reaction mixture. It has been shown that 2-furyl-2-propene is a component of the furan–acetone reaction mixture. Other possible intermediates have been prepared and their reactions investigated. It is our conclusion that the alcohol, 2-furyl-2-propanol, is the initial intermediate in the condensation reaction. We have also reexamined some reactions between furan and cyclohexanone reported by other investigators.

WILLIAM HAMILTON BROWN et BRUCE JAMES HUTCHINSON. Can. J. Chem. **56**, 617 (1978).

On a étudié la réaction acido-catalysée du furanne avec l'acétone afin de déterminer la présence d'intermédiaires. Ces études ont été effectuées par chromatographie en phase gazeuse de mélanges réactionnels. On a montré que le furyl-2 propène-2 est un constituant du mélange réactionnel furanne–acétone. On a aussi préparé d'autres intermédiaires possibles et on a étudié leurs réactions. On conclut que l'alcool, furyl-2 propanol-2, est l'intermédiaire initial dans la réaction de condensation. On a aussi réétudié quelques réactions entre le furanne et la cyclohexanone qui avaient été rapportées par d'autres chercheurs.

Introduction

In view of the recent interest in the preparation of cycloanhydropolymers formed by the acid-catalysed condensation of carbonyl compounds with furan, we wish to report on our investigation of the intermediates involved in such reactions.

The acid-catalysed condensation of furan with methyl ketones was first reported by Ackman *et al.* (1). The reaction leads to the formation of porphyrinogen-like cyclic products which have been given the trivial name 'tetroxaquaterenes' (2). Brown and co-workers (3–5), extended the investigation of these reactions, using pyrrole as well as furan. Yields in most of these reactions are inherently low. However Chastrette and Chastrette (6) have reported that the yield of the tetroxaquaterene formed from furan and acetone can be raised from 18 to 45% by introducing a metallic cation such as lithium perchlorate into the reaction mixture.

Kobuke *et al.* (7) have extended the synthesis of cyclic anhydropolymers. Utilizing furan and various carbonyl compounds they have succeeded in preparing macrocyclic compounds containing six furan and six carbonyl compound residues. Hydrogenation of these macrocycles renders them capable of binding metal cations.

Interest in these cyclic compounds appears to be high. Thus, for example, compound **5**, is being produced and marketed under the name octamethylcyclotetrafurylene (8).

Results and Discussion

When furan **1** in excess is treated with acetone and concentrated hydrochloric acid, the intermediates, compounds **2**, **3**, and **4** are readily obtained. If acetone is present in excess the product is mainly the tetroxaquaterene, **5**.

The initial compound formed in the furan-acetone reaction is probably 2-furyl-2-propanol **6**, although none was detected in the reaction mixture using vpc. Brown and co-workers (1) and Katritzky and Lagowski (9) have proposed the mechanism shown in Scheme 1 for the formation of **6** and the corresponding alkene, **8**. The same reactions occur with all other simple aldehydes and ketones except chloral, where the alcohol analogous to **6** has been isolated by Willard and Hamilton (10). This result is not surprising since three electronegative chlorine atoms are on the α-carbon. To gain more information on the mechanism of this condensation reaction we prepared four possible 'alcohol' intermediates, **6**, **9**, **10**, and **11**, as well as the proposed 'alkene' intermediate, 2-furyl-2-propene, **8**. The products obtained by treating these compounds with furan or appropriate intermediates and hydrochloric acid catalyst are shown in Table 1.

Brown *et al.* (11) have reported on the acid catalysed reactions of cyclohexanone with furan and

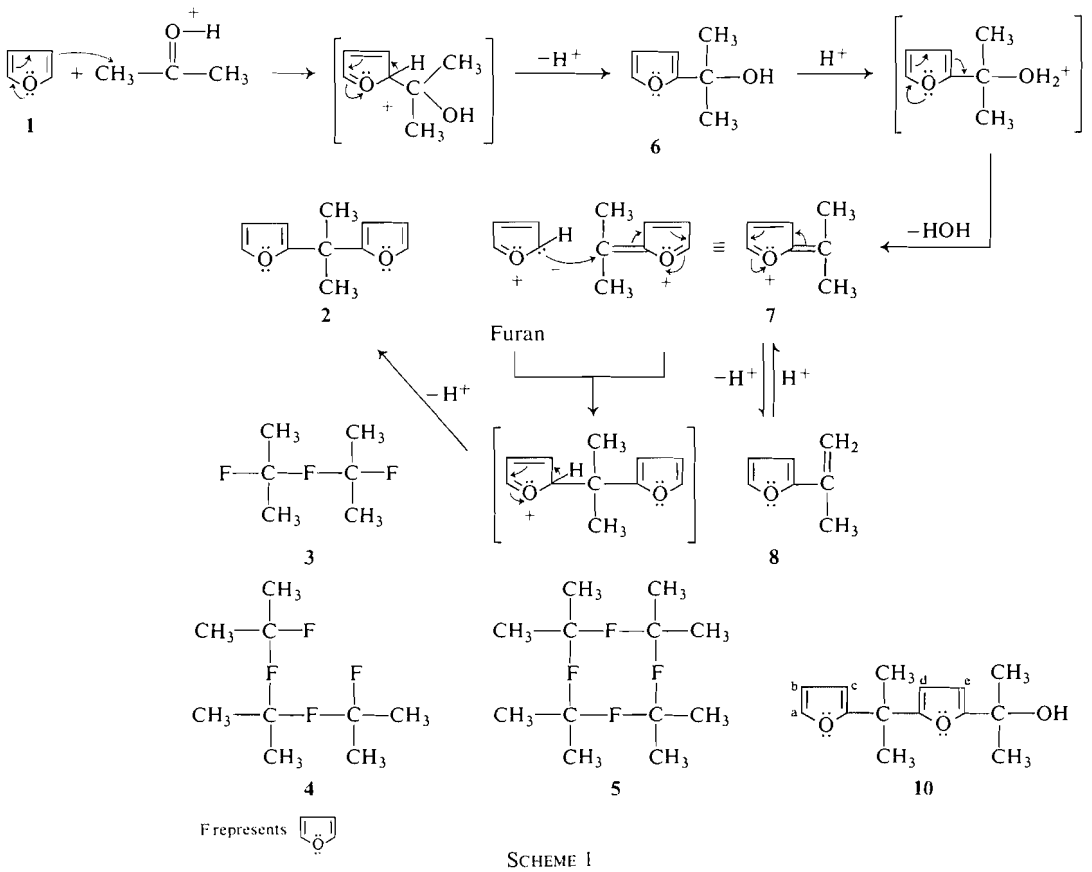
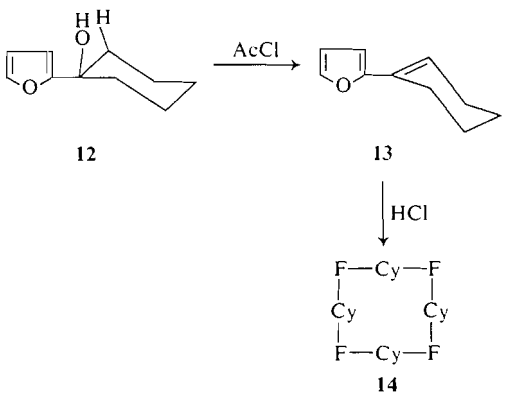


SCHEME 1

pyrrole. Some intermediates, which they isolated, were treated with the appropriate 'missing link' unit to yield the expected cycloanhydrotetramer, **14** (Scheme 2). Casy *et al.* (12) have reported the preparation of 1-(2′-furyl)cyclohexanol, **12** from furyllithium and cyclohexanone. They dehydrated by treating with acetyl chloride to form what they claimed to be 1-(2′-furyl)cyclohexene, **13**. We have repeated their synthesis and found that their chemistry is correct. However, Casy *et al.* did not determine the molecular weight of the supposed alkene **13** which we find to be 592. This value is exactly *four* times the molecular weight, 148, of the monomer 1-(2′-furyl)cyclohexene, $C_{10}H_{12}O$, **13**. Their combustion analysis results for the cyclic tetramer, **14**, of course, are correct for either the monomer $C_{10}H_{12}O$ *or* the tetramer $C_{40}H_{48}O_4$.[3]



SCHEME 2

Williams (13) cites essentially the same procedure as used by Casy *et al.* (12) for the synthesis of 2-(1′-cyclohexenyl)furan, which, if followed, would also lead to the formation of the cyclic tetramer **14**. We have also prepared authentic 1-(2′-furyl)cyclohexene **13** by following an alternate procedure also described by Casy *et al.* (12). The above alkene when catalysed by acid forms the cyclic tetramer **14** much more rapidly than the corresponding alcohol, which would support our proposal that in the case of the condensation reaction between furan and acetone, the alcohol, 2-furyl-2-propanol, **6**, is the first intermediate in this reaction.

[3]We have communicated with Dr. A. F. Casy and he has given us his kind permission to point out this oversight on their part.

Experimental

Nuclear magnetic resonance spectra were obtained on a Varian A-60-A high resolution spectrometer. For vpc analyses the gas chromatograph used was F and M model 810 with thermal conductivity detector using 1.8 m by 0.64 cm stainless steel columns. Infrared spectra were run on a Beckman IR5A instrument. Some molecular weights were determined by the Rast method while for others a Varian MAT, CH7 mass spectrometer (MS) was employed.

Vapour Phase Chromatographic Analysis of Furan–Acetone Reaction Mixture

In a three-necked 500 ml flask, fitted with reflux condenser and magnetic stirrer, were placed 34 g (0.5 mol) of furan, 29 g (0.5 mol) of acetone, and 30 ml of absolute ethanol. While this mixture was being vigorously stirred, 35 ml of 37% aqueous hydrochloric acid solution was added all at once. After 90 s reaction time stirring was stopped. A 25 ml sample of the organic (upper) layer was quenched with an excess of solid sodium bicarbonate, after which the sample was decanted and dried over anhydrous magnesium sulfate. The volume of the sample was reduced to one-half by removal of unreacted furan and acetone under diminished pressure.

The sample was then chromatographed on three different columns: (*a*) Diisodecyl phthalate; (*b*) Carbowax 20M; (*c*) SE-30 column.

On column (*a*) (Chromatographic conditions: He flow rate 40 ml/min; column temperature programmed 110–160°C at 6° per minute, injector 190°C, detector 310°C) 2-furyl-2-propene, **8**, was retained for 5.2 min. A peak in the reaction mixture sample also had a retention time of 5.2 min. The chromatogram of the sample also showed a peak at 15.2 min which is the retention time for a sample of difurylpropane, **2**.

All other vpc runs were carried out in a similar manner. The results are given in Table 2. All other reactions of the furylpropanols and 2-furyl-2-propene, **6**, **8**, **9**, **10**, and **11**, leading to the formation of compounds **2**, **3**, **4**, and **5**, were carried out as outlined above and were identified as indicated in Table 1 (14).

TABLE 2

Column	Retention time (min)	Compound identified
(*a*)	5.2	2-Furyl-2-propene **8**
	15.2	Difurylpropane **2**
(*b*)	1.8	2-Furyl-2-propene **8**
	5.6	Difurylpropane **2**
	40	2,5-bis(α,α-Dimethylfurfuryl) furan **3**
(*c*)	3.25	Difurylpropane **2**
	11.1	**3**

*Synthesis of 2-{2-[5-(α,α-Dimethyl)furfuryl]-furyl}-2-2-propanol (F-C-F-C-OH) **10**, Table 1*

An ethereal solution of methyl magnesium iodide was prepared by the reaction of 0.975 g (0.04 mol) of magnesium turnings and 5.6 g (0.04 mol) of methyl iodide in 12.5 ml of dry ether. The solution was cooled in an ice-bath, and while being stirred vigorously 8.0 g (0.0367 mol) of 2-furyl-2-(5-acetylfuryl)propane, prepared according to the method of Brown and French (15), was added dropwise over a period of 20 min. Stirring was continued for 2 h at room temperature. The complex was decomposed according to the method of Fieser (16), using saturated cold aqueous ammonium chloride. The ether solution was decanted and the solid salt in the reaction flask was washed twice with ether. The combined ether solutions were dried over anhydrous magnesium sulfate. Removal of ether yielded 7.69 g (89%) of pale yellow oil which crystallized; mp 23–27°C, bp 98.0–98.5°C (0.5 Torr); ir λ_{max} (μ): 3.0, 3.38, 6.62, 7.22, 7.85, 8.60, 9.88, 10.4, 10.72, 12.70, 13.65, (b); ^{1}Hmr 60 MHz (CCl_4) δ: 7.25 (H_a, bd, J_{obs} = 1.2 Hz), 6.20 (H_b, dd, J_{obs} = 3.2 and 1.2 Hz), 5.94 (ab q, J_{obs} = 3.5 Hz) (resonance due to H_c obscured by ab q), 2.75 (s, H on OH), 1.60 (s, 6H), 1.45 (s, 6H). Shaking with D_2O eliminated the 2.75 s. Integration accounts for 18 hydrogen atoms. Mass determined on a V.G. Micromass 7070 F using peak matching unit (6000 resolving power), calcd. for $C_{14}H_{18}O_3$: 234.1256:

found: 234.1259. *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.80, H 7.69; found: C 71.83, H 7.76.

*Reactions of 2-{2-[5-(α,α-Dimethyl)furfuryl]-furyl}-2-propanol (F-C-F-C-OH) **10**, Table 1*

(a) With Difurylpropane (F-C-F)

A solution of 1.0 g (0.0043 mol) of **10**, 7.55 g (0.043 mol) of F-C-F, and 10 ml of absolute ethanol was chilled in an ice-bath. To the stirred solution was added all at once 2 ml of 37% aqueous hydrochloric acid solution. The mixture was stirred at room temperature for 24 h and then was treated with 25 ml water and extracted with 50 ml ether. The extract was neutralized with 5% aqueous sodium bicarbonate solution and dried over anhydrous magnesium sulphate. The product was distilled after flashing off the ether. The starting material (5.43 g) boiled at 55–60°C/1 Torr. A fraction (0.47 g) boiled at 165–170°C/1 Torr. The ir spectrum of this fraction is identical with that for 2,2-isopropylidenebis(5-(dimethylfurfuryl)furan) **4**.

The product from the reaction was treated with 1.58 g (0.027 mol) of acetone, 5 ml of absolute ethanol, and saturated with dry hydrogen chloride gas. After standing for 24 h the product was removed by filtration and washed with ethanol. The white crystals melted at 220–237°C. Crystallization from benzene yielded white crystals mp 238–241°C. The melting point was not depressed on admixture with **5**, and the ir spectra of the product and **5** were identical.

(b) With Itself (F-C-F-C-OH)

This reaction was anticipated by Ackman *et al.* (1). To a stirred solution of 0.5 g (0.0002 mol) of **10** and 5 ml of absolute ethanol were added dropwise 0.5 ml of 37% aqueous hydrochloric acid solution. The mixture was stirred for 24 h at room temperature. The aqueous phase was decanted and the sticky solid washed with water. The product was washed with acetone and 0.020 g of a white solid collected mp 229.0–237.4°C. Crystallization from benzene yielded 0.01 g of product mp 238–241°C. The melting point was not depressed on admixture with **5**. The ir spectra of the product and **5** were identical.

(c) With Furan (F)

To a 25 ml Erlenmeyer flask were added 6 drops of **10**, 15 drops of furan, 0.5 ml of absolute ethanol, and 4 drops of 37% aqueous hydrochloric acid solution. The mixture was stoppered and shaken for 5 min at room temperature. The reaction was quenched with 5% aqueous sodium bicarbonate solution, extracted with ether and the extract dried over anhydrous magnesium sulphate. The sample was analysed by vpc.

(*i*) Column (*b*). Chromatographic conditions: He flow rate 70 ml/min, column isothermal 202°C, injector 250°C, detector 318°C. A peak for compound **3** occurs at a retention time of 13.2 min. (*ii*) Column (*c*). Chromatographic conditions: He flow rate 50 ml/min, column isothermal 202°C, injector 250°C, detector 318°C. A peak for 2,5-bis(α,α-dimethylfurfuryl)furan **3** was observed at a retention time of 4.6 min.

*Reactions of 2,2-bis-(1-Hydroxy-1-methylethyl-2 furyl)-2-propane (HO-C-F-C-F-C-OH) **11**, Table 1*

(a) With Difurylpropane (F-C-F)

A solution of 1.0 g (0.0034 mol) of (HO-C-F-C-F-C-OH), prepared according to the method of Brown and French (15), 0.605 g (0.0034 mol) of (F-C-F) and 10 ml of absolute ethanol in a 50 ml Erlenmeyer flask was cooled in an ice-bath. To this solution was added dropwise 0.5 ml 35% aqueous hydrochloric acid solution while swirling. The mixture was agitated for 6 h at room temperature. The product was removed by filtration and washed with 10 ml of acetone. The yield of crude white crystals was 0.16 g (10.75%) mp 235.3–239.4°C. Crystallization from benzene gave 0.090 g of white crystals mp 241–242°C. The melting point was not depressed on admixture with **5**. The ir spectra of the product and **5** were identical.

(b) With Furan (F)

To a 50 ml flask fitted with a stirrer and a condenser was added 1.0 g (0.0034 mol) of (HO-C-F-C-F-C-OH) **11**, 2.31 g (0.034 mol) of furan, 10 ml of absolute ethanol, and 2 ml of 37% aqueous hydrochloric acid solution. The mixture was stirred at room temperature for 10 h. At this time the residual furan was removed in a current of air over a period of 45 min. The residue containing **4** (F-C-F-C-F-C-F), already reported by Ackman *et al.* (1), was treated with 5 ml of acetone and stirred for 14 h at room temperature. The solid produce was removed by filtration and washed with 10 ml of cold acetone. The yield of crude product was 0.20 g. Crystallization from benzene gave 0.06 g of white crystals mp 240–242°C. The melting point was not depressed on admixture with **5**. The ir spectra of the product and **5** were identical.

*Reaction of Acetyl Chloride with 1-(2'-Furyl)cyclohexanol **12***

The preparation of 1-(2'-furyl)cyclohexanol **12** was carried out following the procedure of Casy *et al.* (12); mp 30.5°C. When 1.66 g (0.01 mol) of **12**, dissolved in 10 ml of methylene chloride in a 50 ml flask, was treated with 3.9 g (0.05 mol) of freshly distilled acetyl chloride a heat reaction set in after 5 min and at the same time a white solid began to form. When the heat reaction subsided the reaction mixture was refluxed for 1.5 h and then allowed to stand at room temperature overnight.

The resulting solid product was removed by filtration on a Hirsch funnel, then washed with a small amount of methylene chloride. The initial yield of crude solid was 1.0 g (68%). Removal of some of the methylene chloride solvent and unreacted acetyl chloride from the filtrate gave a further yield of crude solid. Overall yield of crude was 1.25 g (84%). Crystallization of the crude product from hexane gave a white substance, mp 268°C. A mixture melting point with the quaterene reported by Brown *et al.* (11) showed no depression. *Anal.* calcd. for $C_{10}H_{48}O_4$ (mol wt. 592): C 81.08, H 8.11; found (ms 592): C 81.09, H 8.44.

Received July 29, 1977

NGA HO-DUC, HUBERT DAOUST, and SERGE ST-PIERRE. Can. J. Chem. **56**, 622 (1978).

The synthesis of the sequential polypeptides $(N\text{-}\delta\text{-}Z\text{-}L\text{-}Orn\text{-}\gamma\text{-}Bzl\text{-}L\text{-}Glu)_n$ and $(N\text{-}\delta\text{-}Z\text{-}L\text{-}Orn\text{-}\beta\text{-}Bzl\text{-}L\text{-}Asp)_n$ by solution methods is described. Both polypeptides are α helical in chloroform as shown by circular dichroism. However, the conformation in this solvent is rather fragile, since small additions of TFA to a dilute solution of the polypeptides in chloroform is sufficient to cause the helix-to-coil transition, as demonstrated by cd and nmr. It is postulated that the low stability of the helical conformation is attributed, in this case, to a cooperative collapse of the ordered conformation.

NGA HO-DUC, HUBERT DAOUST et SERGE ST-PIERRE. Can. J. Chem. **56**, 622 (1978).

La synthèse en solution des polypeptides séquencés $(N\text{-}\delta\text{-}Z\text{-}L\text{-}Orn\text{-}\gamma\text{-}Bzl\text{-}L\text{-}Glu)_n$ et $(N\text{-}\delta\text{-}Z\text{-}L\text{-}Orn\text{-}\beta\text{-}Bzl\text{-}L\text{-}Asp)_n$ est décrite. Les deux polypeptides forment des hélices α comme l'indiquent les spectres de dichroïsme circulaire (dc) dans le chloroforme. Cependant, la conformation dans ce solvant est plutôt fragile car de petites additions d'acide trifluoroacétique à des solutions diluées des polypeptides dans le chloroforme suffisent pour produire la transition hélice–pelote statistique comme le montrent les spectres dc et rmn. La faible stabilité de la conformation hélicoïdale est probablement due, dans le cas présent, à l'effondrement coopératif de cette conformation.

Introduction

The synthesis (1) of sequential polypeptides with the repeating units *N*-ε-*Z*-L-Lys-β-Bzl-L-Asp (PLA) and *N*-ε-*Z*-L-Lys-γ-Bzl-L-Glu (PLG) and a study of their conformational stability (2) have been reported in two previous articles.[2] It has been shown that both copolypeptides assume the α-helical conformation in helicogenic solvents. However, this helical structure is relatively weak as compared with other helices formed by homopolypeptides and some other copolypeptides. In fact, both PLA and PLG in solution in $CDCl_3$ proceed to an helix-to-coil transition at rather low percentages of TFA (3–5%), as shown by nmr spectroscopy (2). This phenomenon has been attributed to a cooperative collapse of the ordered conformation; it is the case when the probability of H-bonding between side chains having different chemical structures is larger for the coiled than for the helical conformation. Then, the collapse of an ordered section of the main chain induces the breaking down of other sections of the chain more easily than for other types of polypeptides.

We have synthesized poly(*N*-δ-*Z*-L-Orn-β-Bzl-L-Asp) (POA) and poly(*N*-δ-*Z*-L-Orn-γ-Bzl-L-Glu) (POG) in order to keep on with our previous study on the importance of the interaction between chemically different neighboring side chains and between side chains and backbone. We have also studied the helix-to-coil transition in dilute solution of both copolymers in chloroform by nmr and cd.

Results and Discussion

The protected, activated monomers γ-benzyl-L-glutamyl-*N*-δ-carbobenzoxy-L-ornithyl *N*-succinimidyl ester and β-benzyl-L-aspartyl-*N*-δ-carbobenzoxy-L-ornithyl *N*-succinimidyl ester were prepared via a modification (3) of Goodman and Steuben's 'backing-off' procedure (4), as described in Fig. 1. The *N*-hydroxysuccinimide-activated, free-amine ornithine moiety was coupled with the amine-protected, free-carboxyl glutamyl or aspartyl residue through a mixed carbonic anhydride reaction. Isobutyl chloroformate and *N*-methyl morpholine were used for the formation of the mixed anhydride, as recommended by Anderson *et al.* (5), to minimize racemization

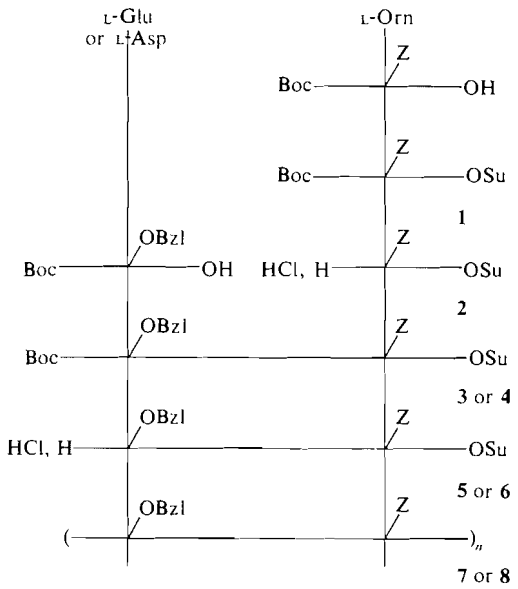

FIG. 1. Schematic description of the synthesis of sequential polydipeptide (L-glutamyl-L-ornithyl)$_n$ and (L-aspartyl-L-ornithyl)$_n$ using solution techniques for the synthesis of the monomer and *N*-succinimide group as an active ester for its polymerization.

during the coupling. This methodology had been shown adequate and very convenient for the preparation of activated peptide monomers in previous work (6, 7). The 'backing-off' method makes it possible to purify the Boc dipeptide ester via simple extraction procedures with dilute aqueous base and acid while the separation of dipeptide ester from a free-carboxyl dipeptide contaminant is much more difficult, the latter being less soluble in water. Moreover, it is safer to activate a single *N*-protected amino acid residue than a dipeptide to avoid possible racemization of the *C*-terminal residue. In a recent work on the preparation of polyheptapeptide models of muscle protein (20), it has been shown that this aforementioned series of procedures gives rise to polymeric material that is virtually free from racemization (<2%).

On the other hand, the yields of protected polydipeptides are kept below 50% because of the important formation of diketopiperazine by-product, which competes strongly with the intermolecular polymerization reaction of activated dipeptides. Fortunately, the cyclic material is easily separated from the polypeptide by washing with hot methanol (21).

The conformational stability of the two polypeptides in chloroform has been studied by both nmr and cd. Figure 2 shows the qualitative cd spectra of POA and POG in chloroform, using cells with a pathlength shorter than 0.01 cm. Cells with short path lengths were used in order to obtain spectral information down to 205 nm where the first π–π^* transition of the amide chromophore occurs. These spectra are qualitative since the thickness of the spacers between the quartz windows is not exactly known (0.001–0.005 cm). In this case, $\Delta\varepsilon$ represents the sign of the ellipticity. The qualitative spectra show that troughs around 220 and 208 nm represent, respectively, the n–π^* and the parallel π–π^* transitions of the amide chromophore indicating that both polypeptides adopt the α-helix structure in this solvent (19). When longer path lengths are used with chloroform as a solvent, the scanning has to be stopped at 215 nm because of strong noise due to the absorbance of chloroform in the uv.

The quantitative spectra of POA and POG in pure chloroform (l = 0.01 cm, c = 2 mg/ml) show the trough corresponding to the n–π^* transition at 222 nm with respective ellipticities of $-16\,000$ and $-28\,000$ deg cm^2 dmol^{-1}. The n–π^* transition of the amide chromophore allows one to follow the variation of the intensity of the trough as a function of the composition of the solvent. As in the case of PLA, the chirality of the helix is not reversed by the regular insertion of β-benzyl-aspartyl residues in the chain.

Figure 3 shows the ellipticity ratio at 220 nm of POA and POG solutions in $CHCl_3$–TFA as a function of the TFA content. The helix-to-coil transition is complete at 9% TFA for POA and at 13% for POG. A parallel study of the effect of TFA on the conformation of the chain has been made by nmr spectroscopy. Figure 4 shows the nmr spectrum of POG in $CDCl_3$; the peak at 3.96 ppm which is assigned to the α-CH proton is typical of the helical conformation of poly-γ-benzyl-glutamate (PBLG) and is reported to be 3.95 ppm (8). Unfortunately, no nmr study of poly-*N*-δ-carbobenzoxy-L-ornithine (PCLO) is reported; however, its nmr spectrum

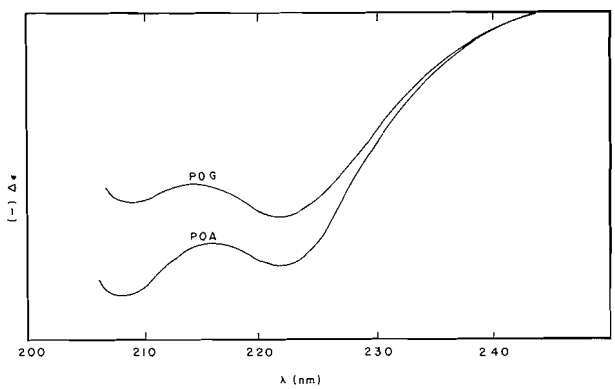

FIG. 2. Qualitative cd spectra of POA and POG in chloroform solution: $c \simeq$ 5–8 mg/ml; $l \simeq$ 0.001–0.005 mm.

For personal use only.

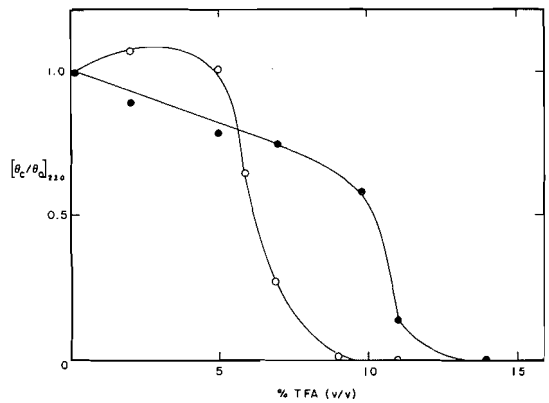

FIG. 3. The helix-to-coil transition of POA (○) and POG (●) in mixtures of chloroform: TFA as measured by circular dichroism at 220 nm; $[\theta_c/\theta_0]_{220}$ represents the ellipticity ratio at 220 nm of a peptide solution in $CHCl_3$–TFA containing respectively c and 0% (v/v) of TFA; c = 2 mg/ml; l = 0.01 cm.

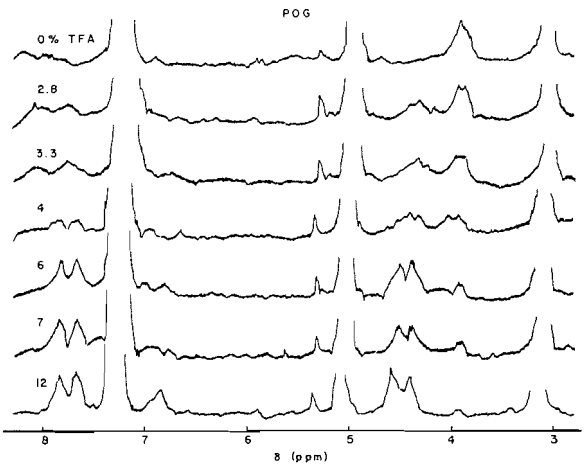

FIG. 4. The 220 MHz nmr spectra of POG in $CDCl_3$ (1% TMS) with increasing amount of TFA at 25°C.

should be very similar to the one of poly-*N*-ε-carbobenzoxy-L-lysine (PCLL); the latter shows a peak at 3.90 for the α-CH proton (8): this peak is hidden on the spectrum. Two broad peaks around 8.2 and 7.6 ppm should appear for the NH proton of the glutamyl and the ornithyl moieties, respectively. This broadening of the peak is well known and is due to molecular association or formation of liquid crystals (9). When 2.8% TFA is added, the position of the glutamyl α-CH peak remains unchanged but the peak of the ornithyl residue is shifted to 4.35 ppm. The NH peaks appear at 8.15 and 7.7 ppm, respectively, for the two residues. The pattern of the nmr spectra changes gradually as more TFA is added, up to 7% v/v: the NH proton peaks appear at 7.84 and 7.6 ppm whereas the α-CH proton peaks appear at 4.5 and 4.4 ppm for the two amino acid residues. Those chemical shifts are characteristic of the random coil conformation of most homopolypeptides (8). The helix–coil transition is complete at 7% TFA since no more changes occur in the spectrum by further addition of TFA.

Figure 5 shows a similar nmr study done with POA. This time, the transition is considered complete at 4–5% TFA. The NH proton peak moves upfield from 8.7 to 7.9 ppm and the α-CH peak is shifted downfield from 4.3 to 4.8 ppm for the aspartyl residue when the TFA content of the solution is increased from less than 1% up to 5%. The hypothesis of many authors (22), that the two peaks observed for α-CH for a given residue might come from acid solvated and unsolvated random coil residues (23) has not been retained, neither has the hypothesis that the low field resonance of α-CH might be due to protonated states of the random coil (24).

It is difficult to discuss the effect of polydispersity of the copolypeptides described here on the α-proton resonance at the transition midpoint (22) since a very small quantity of TFA is needed to complete the transition. However, in the case of POG at 3.3 and 4% TFA, as compared to 0 and 13%, a double peak which might be due to polydispersity appears.

Results obtained in the present work agree with those obtained previously (2) and indicate that the stability of helical conformation of sequential copolypeptides is lower when compared to the helical structure formed by corresponding statistical and block copolypeptides and homopolypeptides (10, 11). It has been shown that the average molecular weight of the polypeptide is an important factor that contributes to the stability of the secondary structure, in organic as well as in aqueous solutions (12). Fortunately, it can be safely assumed that this effect levels off when the chains reach a certain length, which could place the high molecular weight homo- and random copolypeptides obtained by the polymerization of their corresponding *N*-carboxyanhydrides (NCA) in a similar situation as the sequential polypeptides having comparable molecular weights.

The major difference between the four copolypeptides that have been investigated so far in this laboratory lies in the length of the side chains of their monomers. Let us now compare PLG with POG: their amino side chains differ only by one CH_2 unit. It has been shown that PCLO has a slightly more stable helical conformation than PCLL (13). Their initiation parameter, σ, which measures the difficulty of nucleating a helical region, is 1.9×10^{-5} and 1.2×10^{-5}, respectively (14, 15), indicating that destruction of PCLO helix is less cooperative. Moreover, H-bonding between two neighboring side chains in POG should be more important than for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

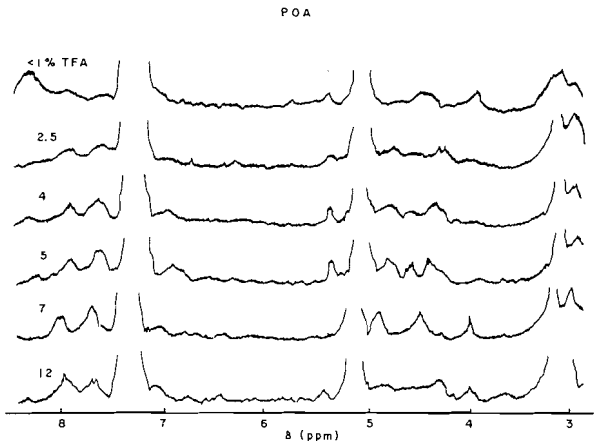

FIG. 5. The 220 MHz nmr spectra of POA in $CDCl_3$ (1% TMS) with increasing amount of TFA at 25°C.

PLG since the NH group in the ornithyl side chain faces more favorably the carbonyl group in the glutamyl side chain. Consequently, the helical conformation of POG should be reinforced by side chain – side chain interactions. However, the nmr results previously obtained for PLG (2) are very similar to those for POG, indicating that this stabilizing effect is counterbalanced by the cooperative collapsing effect due to the higher probability of forming H-bonding in the disordered conformation. The same conclusions apply when PLA and POA are compared.

In addition to side chain – side chain interactions that could increase the stability of the POG helix, we believe that POG can form stronger helices than POA because, in the latter case, of the competition that exists for hydrogen bonding between the backbone carbonyl groups and those from the aspartyl side chains. This phenomenon, which is already well known (12), tends to weaken the helical structure of POA and other aspartyl-containing polypeptides. A similar explanation can be given for the weaker stability of the helical conformation of poly (β-benzyl-L-aspartate) (PBLA) when compared to PBLG (14).

Experimental

N-α-Boc-*N*-δ-*Z*-L-Ornithine, β-Bzl-L-aspartic acid, and γ-Bzl-L-glutamic acid were purchased from Bachem Fine Chemicals (Marina del Rey, California) and were used without further purification. DCC (Aldrich Chemicals) was purified as described in a previous publication (1). *N*-Hydroxysuccinimide (Aldrich) was used without further purification. Dioxane, DMF, and triethylamine were purified according to the procedure used before (1). HCl (4 *N*) in dioxane in 10 ml ampoules was obtained from Pierce Chemical Company and diluted to 2 *N* with anhydrous dioxane. All the other solvents and reagents were of Analytical Reagent quality and used without further purification.

Melting points were determined on a Uni-Melt melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer Model 141 polarimeter at 589 nm, using a 1-dm path length microcell (0.9 ml volume). Infrared spectra of the intermediate products were recorded from KBr pellets, using a Perkin-Elmer model 621 spectrophotometer. Proton magnetic resonance spectra were taken with a Varian model T-60 spectrometer in $CDCl_3$, using TMS as an internal reference. Elemental analysis were performed by Galbraith Laboratories (Knoxville, TN). Thin-layer chromatography was carried out on precoated silica gel plates (Kodak 246 F), in the following solvent systems: 1-butanol – acetic acid – water in a ratio 4:1:5 (top phase) (BAW5) and in a ratio 4:1:1 (BAW1); chloroform – acetic acid in a ratio 95:5 (CA) and acetone – acetic acid in a ratio 98:2 (AA). Peptide spots were visualized directly under uv light or by treatment with ninhydrin spray (0.2% in acetone) and heating (free amine) or treating the plates with HCl vapors (15 min), spraying with ninhydrin, and heating (*t*-Boc amines).

N-α-*Boc*-N-δ-Z-L-*Ornithine* N-*Succinimidyl Ester (1)*

A mixture of *N*-α-Boc-*N*-δ-*Z*-L-ornithine (5 g, 0.013 mol) and *N*-hydroxysuccinimide (1.57 g, 0.013 mol) was dissolved in ethyl acetate (100 ml) and dioxane (40 ml). The solution was cooled down to 0°C and DCC (3.09 g, 0.015 mol) in ethyl acetate (5 ml) was added. The reaction was stirred at 0°C for 2 h and at 4°C for 48 h. Glacial acetic acid (5 drops) was added and after 2 h at 4°C, the DCHU was filtered off and the filtrate evaporated to an oil which was dissolved in ethyl acetate (60 ml). After standing overnight at 4°C, more DCHU was filtered, 100 ml of ethyl acetate added to the filtrate, and the organic solution was extracted, at 0°C, with 0.5 *M* $NaHCO_3$ (3 × 50 ml), washed with water, dried over $MgSO_4$, filtered, and evaporated to an oil, which was redissolved in ether and evaporated again. After repeating this operation one more time, a solid residue remained which was recrystallized in ether–hexane (5:1) to give 5.18 g (82%) of pure compound **1**, as shown by analysis: mp 80–82°C; $[\alpha]_D^{25}$ −18.44° (*c* 2, ethyl acetate); R_F^{AA} 0.82, R_F^{CA} 0.78, R_F^{BAW5} 0.65; $\bar{\nu}$ (KBr): 1805, 1780, 1685 cm^{-1}; τ ($CDCl_3$): 2.70 (5 H, phenyl singlet), 4.60 (1 H, NH), 4.72 (1 H, NH), 7.05 (4 H, singlet, CH_2 succinimido), 8.50 (13 H, multiplet, CH_2's and CH_3's). *Anal.* calcd. for $C_{22}H_{29}N_3O_8$: C 57.02, H 6.26, N 9.07; found: C 56.98, H 6.19, N 9.09.

N-*Boc*-γ-*Bzl*-L-*Glutamyl*-N-δ-Z-L-*ornithine* N-*Succinimidyl Ester (3)*

N-α-Boc-*N*-δ-*Z*-L-Ornithine *N*-succinimidyl ester (6 g, 13 mmol) was reacted with 2 *N* HCl in dioxane for 1 h. After evaporation, trituration of the residue with ether, filtration, and drying *in vacuo*, 5.2 g of hydrochloride **2** was obtained (quantitative yield). The white, hygroscopic powder was shown homogeneous by tlc (R_F^{BAW1} 0.69). Boc-γ-Bzl-L-Glutamic acid (1.72 g, 5.1 mmol) was dissolved in THF and the solution was cooled to −20°C. *N*-Methylmorpholine (0.52 g, 5.1 mmol) and isobutyl chloroformate (0.7 g, 5.1 mmol) were added and after 1 min, a cold solution containing compound **2** (2.05 g, 5.1 mmol) in DMF (4 ml) was added. Triethylamine (0.52 g, 5.1 mmol) was added dropwise to the suspension over a period of 5 min. The reaction was then stirred at −20°C for 10 min, at 0°C for 30 min, and at room temperature for 1 h. The solvents were evaporated *in vacuo*, ethyl acetate (100 ml) was added, and the insoluble salts were filtered and washed with more ethyl acetate (25 ml). The filtrate was cooled to 0°C and washed successively with 0.01 *N* HCl (3 × 25 ml), water, 0.5 *M* $NaHCO_3$ (3 × 25 ml), and with water, was dried over anhydrous $MgSO_4$ and the ethyl acetate evaporated to an oil, which was redissolved in ether and evaporated. After repeating

the last operation, a white powder was obtained which was recrystallized from acetone – petroleum ether (30–60°C); yield, 2.25 g (64%); mp 57–59°C; $[\alpha]_D^{25}$ −22.84° (*c* 2, dioxane); R_F^{CA} 0.90, R_F^{AA} 0.67. *Anal.* calcd. for $C_{34}H_{42}N_4O_{11}$: C 59.82, H 6.16, N 8.21; found: C 59.77, H 6.21, N 8.19.

N-*Boc*-β-*Bzl*-L-*Aspartyl*-N-δ-Z-L-*ornithine* N-*Succinimidyl Ester (4)*

Boc-β-Bzl-L-Aspartic acid, (1.41 g, 4.37 mmol), *N*-methylmorpholine, (0.44 g, 4.37 mmol), isobutyl chloroformate, (0.6 g, 4.37 mmol), compound **2** (1.75 g, 4.37 mmol), and triethylamine (0.44 g, 4.37 mmol) were reacted as described previously to give 1.94 g (66% yield) of compound **4**: mp 58–59°C; $[\alpha]_D^{25}$ −21.05° (*c* 2, dioxane); R_F^{CA} 0.91, R_F^{AA} 0.65. *Anal.* calcd. for $C_{33}H_{40}N_4O_{11}$: C 59.28, H 5.99, N 8.38; found: C 59.36, H 6.04, N 8.36.

γ-*Bzl*-L-*Glutamyl*-N-δ-Z-L-*ornithine* N-*Succinimidyl Ester Hydrochloride (5)*

Compound **3** (2 g, 2.9 mmol) was dissolved in 2 *N* HCl in dioxane (20 ml). After 1 h at room temperature, the solution was evaporated to an oil, under vacuum with exclusion of moisture. The oil was triturated with anhydrous ether to give a white solid, which was filtered, washed with more ether and dried *in vacuo* over KOH. Compound **5** (1.8 g) was found to be homogeneous by tlc: R_F^{BAW1} 0.68; mp 65–67°C; $[\alpha]_D^{25}$ −7.81° (*c* 2, DMF); amino acid analysis: orn/glu = 0.95. *Anal.* calcd. for $C_{29}H_{35}N_4O_9Cl$: C 56.27, H 5.66, N 9.05, Cl 5.74; found: C 56.27, H 5.70, N 9.01, Cl 5.65.

β-*Benzyl*-L-*aspartyl*-N-δ-Z-L-*ornithine* N-*Succinimidyl Ester Hydrochloride (6)*

Compound **4** (1.75, 2.6 mmol) was deprotected with 2 *N* HCl in dioxane as described above: yield, 1.58 g (quantitative): mp 75–77°C; $[\alpha]_D^{25}$ −12.76° (*c* 2, DMF); R_F^{BAW1} 0.61; amino acid analysis: orn/asp = 0.97. *Anal.* calcd. for $C_{28}H_{33}N_4O_9Cl$: C 55.58, H 5.46, N 9.26, Cl 5.67; found: C 55.50, H 5.49, N 9.23, Cl 5.80.

Poly(γ-*Bzl*-L-*glutamyl*-N-δ-Z-L-*ornithyl*) *(7)*

Compound **5** (1.5 g, 2.4 mmol) was dissolved in purified DMF (2 ml), the solution cooled to 0°C, and triethylamine (0.25 g, 2.4 mmol) in DMF (1 ml), was added. The reaction mixture solidified immediately and additional DMF (2 ml) was added. The thick suspension was kept under vigorous stirring at 4°C for 2 days. After further dilution with DMF (2 ml), the suspension was stirred at room temperature for 7 days, DMF (2 ml) being added every day. The mixture was then evaporated down to a paste on a rotary evaporator, water added, and the solid centrifuged. The water was decanted and the washing repeated several times with water; the solid was then filtered, washed with hot methanol and with ether and dried at 50°C *in vacuo* for 48 h to give 509 mg of polypeptide **7**, which was found satisfactory by infrared spectroscopy: ν (KBr pellet): 3280, 1725, 1655 and 1540 cm^{-1}. *Anal.* calcd. for $C_{25}H_{29}N_3O_6$: C 64.24, H 6.21, N 8.99; found: C 64.12, H 6.33, N 8.95.

Poly(β-*Bzl*-L-*aspartyl*-N-δ-L-*ornithyl*) *(8)*

Hydrochloride **6** (1.24 g 2.05 mmol) was used with triethylamine (0.207 g, 2.05 mmol) and the reaction carried out as described above for compound **7**: yield 0.45 g. *Anal.* calcd. for $C_{24}H_{27}N_3O_6$: C 63.58, H 5.96, N 9.27; found: C 63.40, H 6.07, N 9.21.

Characterization and Conformational Analysis of the Polypeptides

Molecular Weight Determination

The molecular weights were estimated from the intrinsic viscosity – molecular weight calibration curve of Doty *et al.* (16). Intrinsic viscosities were determined in dichloroacetic acid at 25°C with a Hewlett-Packard automatic viscometer equipped with a Cannon semimicro Ubbelhode-type viscometer. The average viscosity molecular weights are 12500 for POG and 10000 for POA.

Amino Acid Analysis

The amino acid compositions were evaluated with a Beckman 120 automatic analyser, using the procedure of Spackman *et al.* (17), after hydrolysis with 6 *N* hydrochloric acid in evacuated sealed tubes at 110°C for 22 h.

Circular Dichroism Measurements

Circular dichroism measurements were made with a Cary 60 spectropolarimeter (cd attachment Cary 6002) using 0.01-cm quartz cuvettes and quartz plates. During the measurements, the instrument was purged with nitrogen at a rate of 40 ft^3 min^{-1}. The spectropolarimeter had been previously calibrated with (+)-camphor-10-sulphonic acid (18). The mean residue ellipticity, $[\theta_\lambda]$(in deg cm^2 $dmol^{-1}$), was calculated according to the relationship $[\theta_\lambda] = \theta_\lambda$ (MRW)/10 *lc*, where θ_λ is the observed ellipticity in degrees at the wavelength λ, MRW is the average molecular weight of a residue (226.5 for POA and 233.5 for POG), *l* is the path length of the cell (cm) and *c* the concentration (g cm^{-3}).

Nuclear Magnetic Resonance Spectroscopy

The nmr spectra were obtained with a HR 220 MHz spectrometer, property of the Department of Medical Genetics, University of Toronto, Toronto, Ontario. Solvents used were $CDCl_3$ 99.8% deuterated (Merck, Sharp and Dohme, Canada Limited), and TFA (J. T. Baker). Polypeptide concentration was approximately 2% w/v and 1% TMS was added as internal reference.

Studies in decarboxylation. XI.[1] The gas phase pyrolysis of some arylacetic acids

DAVID B. BIGLEY AND RICHARD H. WEATHERHEAD
University Chemical Laboratory, Canterbury, Kent, CT2 7NH, England

Received August 5, 1977

DAVID B. BIGLEY and RICHARD H. WEATHERHEAD. Can. J. Chem. **56**, 628 (1978).

The gas phase decarboxylations of 1-naphthyl-, 2-naphthyl-, and 9-phenanthrylacetic acids all proceed through a homolytic pathway. There is no evidence for the concerted 1,5-hydrogen shift usually encountered in the decarboxylation of β,γ-unsaturated acids.

DAVID B. BIGLEY et RICHARD H. WEATHERHEAD. Can. J. Chem. **56**, 628 (1978).

La décarboxylation en phase gazeuse des acides naphtyl-1, naphtyl-2 et phénantryl-9 acétiques se produit par un mécanisme homolytique. On n'a trouvé aucune indication suggérant la présence du déplacement 1,5 d'hydrogène que l'on rencontre généralement dans la décarboxylation des acides β,γ non-saturés.

In previous papers of this series we have shown that the pyrolysis of β,γ-unsaturated aliphatic acids is a unimolecular concerted process involving a 1,5-hydrogen shift, yielding carbon dioxide and the respective alkene (2). More recently we have explored the scope and limitations of the reaction by variation of the environment of the β,γ-double bond of the acid. We have shown that β,γ-acetylenic (3), α,β,γ- and β,γ,δ-allenic (4), α,β-γ,δ-dienoic (4), and cyclopropylacetic acids (5) are all subject to a mechanistically similar decomposition. We now report our observations on the pyrolysis of some acids in which the unsaturation forms part of an aromatic system.

Experimental

The 1- and 2-naphthylacetic acid were commercial samples (Koch-Light) and were purified by sublimation; (mp 133 and 141°C, respectively (lit. (6, 7) mp 131.5 and 138°C, respectively).

We experienced considerable difficulty in the preparation of 9-phenanthrylacetic acid and in our hands the literature routes were unreliable. We were eventually successful by the oxidation of 9-phenanthrylethanol. This compound was prepared by the unusual route of Bergmann and Blum-Bergmann (8), distilled at 200°C/1 Torr and solidified in the condenser. This alcohol (7 g) was dissolved in acetone (33 ml), was cooled in an ice bath under nitrogen, and was oxidised by the dropwise addition of a cooled solution of chromium trioxide (7.5 g) in aqueous (38 ml) sulphuric acid (12 ml concentrated). The mixture was stirred at < 20°C for 45 min when it was extracted with ether (3 × 100 ml). The usual base (1 *N* NaOH) acid procedure then gave the acid as a brown powder. This was purified by vacuum sublimation to give a white crystalline powder (1 g), mp 227°C (lit. (9) mp 225°C).

Deuterium Exchange

The naphthylacetic acids were each shaken in ether solution with several portions of D_2O (99.9%) until, on evaporation of the ether, the nmr spectrum showed total loss of the carboxyl hydrogen. 9-Phenanthrylacetic acid proved to be insoluble in most of the common water immiscible solvents, but was soluble in dioxan. It was therefore precipitated from purified dry dioxan with D_2O several times, and filtered under a dry atmosphere. We could not estimate the exchange level since on removal of solvents in vacuum we found that the acid was insoluble in the normal nmr solvents.

Stoichiometry

The 1- and 2-naphthylacetic acids were pyrolysed at 300–310°C at 150 Torr pressure in break-seal tubes. The volatile products were measured in a vacuum line; in both cases CO_2 was obtained in 100% yield (absorption on soda asbestos) together with material which did not condense at liquid nitrogen temperature. Removal of the latter by a Toeppler pump showed that it constituted about 10% yield by volume. The residual involatile product in the break-seal tube was investigated by glc and was shown to comprise two major fractions, together with several minor products. Larger samples of the involatile products were obtained by flash vacuum pyrolysis (3) of the acid at 700°C and 0.01 Torr. The pyrolysis tube was found to be coated with soot after the reaction but clean products were isolated in traps in liquid nitrogen. The products from 2-naphthylacetic acid were left to stand overnight during which time a white crystalline material deposited; this was recrystallised from benzene and found to have a sharp melting point (184°C) (10) and parent ion (*m/e*) 282. This and other spectroscopic data showed the solid to be 1,2-bis-2-naphthylethane. The residual liquid was shown to be mostly 2-methylnaphthalene, with small traces of other compounds not further identified. For 1-naphthylacetic acid, the pyrolysis products were separated by preparative tlc. Two major components were similarly identified as 1-methylnaphthalene and 1,2-bis-1-naphthylethane. The amounts of involatile compounds were estimated by glc after prior standardisation of peak heights with authentic samples. 1-Naphthylacetic acid yielded 50% 1-methylnaphthalene; 20% 1,2-bis-1-naphthylethane. 2-Naphthylacetic acid yielded 65% 2-methylnaphthalene; 15% 1,2-bis-2-naphthylethane.

9-Phenanthrylacetic acid was pyrolysed in an evacuated break-seal tube at 240°C for 24 h to give a quantitative yield of carbon dioxide and no noncondensible products. The residue in the tube was vacuum sublimed and shown to be 9-methylphenanthrene $> 90\%$ yield. A small amount of dark material ($\sim 5\%$) left in the tube was not investigated further.

Kinetics

An attempt was made to measure the rates of decarboxyla-

[1]For Part X, see ref. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tion of the three acids by the pyrolysis of known weights of each acid in a series of evacuated break-seal tubes in a well thermostatted salt bath by following the amount of carbon dioxide liberated. It was shown that decarboxylation appeared to follow first-order kinetics initially but the rate slowed appreciably over the second 50% reaction. Dilution of the sample by the usual radical inhibitors, cyclohexene or toluene, had little effect on this behaviour, nor was it affected by inclusion of an inert acid, 2-ethylhexanoic acid. The reaction rate was somewhat dependent on the initial pressure but it was not possible to obtain reliable rate constants in our simple apparatus. However, approximate rate constants were estimated at several temperatures from initial slopes, to permit extrapolation to 500 K. For comparison, phenylacetic acid (range 860–995 K), $k_{500} = 5 \times 10^{-11}$ s^{-1} (relative rate 1) (12); 1- and 2-naphthylacetic acid (530–600 K), k_{500} = ca. 1×10^{-7} s^{-1} (relative rate 2×10^3); 9-phenanthrylacetic acid (500–550 K), k_{500} = ca. 1×10^{-6} s^{-1} (relative rate 2×10^4).

Nuclear Magnetic Resonance

^{13}C nmr spectra were recorded using a JEOL PS-100 spectrometer operating in Fourier transform mode and employing an internal deuterium lock. The results obtained for the various naphthalene derivatives are shown in Table 1, using the assignments of Doddrell and Welles (11). The deuterium magnetic resonance spectra of 1-methylphenanthrene showed only one peak at 204.0 Hz relative to deuteriochloroform (266.7 Hz) though peaks of less than 10% of that observed could be hidden in base-line noise.

Discussion

Our previous work had indicated that β,γ-unsaturated acids decarboxylate by a concerted 1,5-hydrogen shift to yield carbon dioxide and the α,β-unsaturated olefin. On the other hand phenylacetic (12) and diphenylacetic (13) acids, both formally β,γ-unsaturated acids, had been shown to decarboxylate by a radical mechanism. The difference probably results from the aromaticity of the latter acids. For these acids to lose carbon dioxide via the normal concerted 1,5-hydrogen shift, the activation energy would have to be sufficient to overcome the loss of aromaticity in the intermediate (114 kJ mol^{-1})[2] in addition to that for the activation of the normal β,γ-substituted-β,γ-unsaturated acid (142 kJ mol^{-1}) (14). These together would be greater than the normal bond dissociation energy, ϕCH_2—COOH (230 kJ mol^{-1}) (12). In addition the *A*-factor for dissociation into radicals will be more favourable than that for a concerted process; the homolytic mechanism shown in Scheme 1 is thus well understood.

Polycyclic aromatic compounds all contain bonds intermediate in order between the 1.5 of benzene and the full 2 of a double bond. We chose the 1,2 bond of naphthalene and the 9,10 of phenanthrene as possible candidates to show the changeover between mechanisms. There is, of course, considerable evidence for bond fixation in naphthalene: a particularly pertinent comparison is between simple *N*-alkylaniline derivatives which are recovered unchanged after thermal treatment (15) or undergo fragmentation at higher temperatures (16), and *N*-allylnaphthylamine which pyrolyses via a Claisen type of reaction (17). By analogy phenyl- and naphthylacetic acids might decarboxylate through different mechanisms. The following features of the

[2]Calculated as the difference between the resonance energies of benzene (151 kJ mol^{-1}) and hexa-1,3,5-triene (37 kJ mol^{-1}).

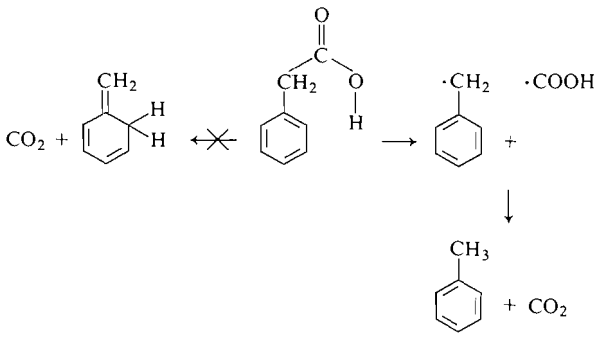
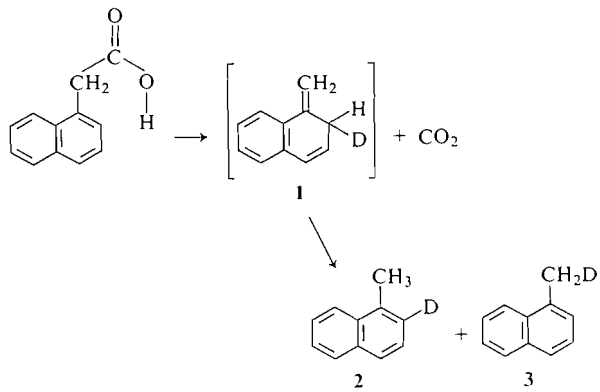


SCHEME 1

decarboxylation of both 1- and 2-naphthylacetic acids imply radical pathways: (*i*) kinetics which are not of the first order; (*ii*) appearance of noncondensible gases; (*iii*) observation of dimeric products. However the two mechanistic pathways are now closer in energy and none of the above features excludes the coexistence of both. We therefore examined the pyrolysis of the carboxyl deuteriated acids. The concerted six-centre mechanism would give rise to an intermediate (**1**), which would require a 1,3-hydrogen shift to give rise to the observed product. However for the deuteriated acid, a kinetic isotope effect would favour the transfer of a hydrogen atom rather than a deuteron and **2** would be favoured over **3** (Scheme 2).



SCHEME 2

A radical process would involve initial cleavage of the ϕCH_2—COOH bond and would be followed by abstraction by or recombination of the arylmethyl radical, and dedeuteriation of the carboxyl radical to yield carbon dioxide. Thus only **3** should be formed, although as not all products are accounted for, and the decarboxylation pathway is unlikely to be simple, it may be possible for the arylmethyl radical to obtain a hydrogen atom either from the walls of the reaction vessel or other product to give completely undeuteriated material. The ^{13}C nmr spectra of deuterio-1-methylnaphthalene obtained from the pyrolysis of carboxyl-*D*-1-naphthylacetic acid (Table 1) shows that the signal at 18.9 ppm due to the methyl group is split into a 1:1:1 triplet as expected for a —CH_2D fragment, the proton coupling being removed by noise decoupling. The value $^1J_{CD}$ = 19.5 Hz is of the expected magnitude (18). Some undeuteriated methyl group is also present in the sample as evidenced by a residual signal at 19.2 ppm. The C-2 atom of the naphthalene ring gives rise to a signal at 126.4 ppm which in the undeuteriated sample is superimposed with the signal from C-4 but is separated in the deuteriated sample. No evidence of any splitting of this signal could be obtained and it is thus unlikely that any considerable amount of **2**, the expected major component of a concerted reaction, was present in the sample. Thus the major product of the pyrolysis of carboxyl-*D*-1-naphthylacetic acid is **3** together with some undeuteriated material. This result is entirely consistent with the radical pathway but precludes, within the limits of nmr detection, the concerted mechanism.

Similarly, the ^{13}C nmr spectrum obtained from the pyrolysis product of carboxyl-*D*-2-naphthylacetic acid (Table 1) shows that the signal at 21.3 ppm due to the 2-methyl group of 2-methylnaphthalene is split into a 1:1:1 triplet with $^1J_{CD}$ = 19.5 Hz, again implying a CH_2D fragment. A residual peak due to an undeuteriated methyl group was also noted at 21.5 ppm. According to a possible concerted mechanism, it would be expected that some deuterium should appear at the C-1 position (**4**) (Scheme 3) but examination of the signal at 126.8 ppm due to the C-1 carbon shows it to be unsplit in the deuteriated sample; thus it is unlikely that the concerted reaction plays any part in the decarboxylation of this acid.

It has been estimated that the C9—C10 bond of the phenanthrene nucleus has about 90% double bond character (19). This has been demonstrated chemically by the ease of addition rather than substitution at these positions. Thus, it was hoped that the 9,10 bond in 9-phenanthrylacetic acid would act sufficiently like an isolated double bond to allow the concerted decarboxylation mechanism to proceed. No evidence for the formation of any dimer or effect of radical traps was noted on pyrolysis and high

yields of 9-methylphenanthrene (>90%) were obtained. The ^{13}C nmr spectrum of the deuteriated 9-methylphenanthrene obtained from the pyrolysis of a carboxyl-*D*-9-phenanthrylacetic acid is reported in Table 1, along with ordinary 9-methylphenanthrene. It is clear from the signal at about 20 ppm that there is considerable deuteriation at the methyl group. Without allowing for an unfavourable T_1 and nuclear Overhauser effect decreasing the intensity of 1:1:1 triplet signal for the deuteriated carbon atom as compared to the singlet for the residual undeuteriated methyl group, it may be estimated that at least 60% of deuterium from the original carboxyl-*D*-labelled acid has transferred to the 9-methyl group. Unfortunately, the various signals for the phenanthrene nucleus have not been identified with individual carbon atoms and it is not known which of the aromatic signals is due specifically to the carbon atom in the 10-position. Although the aromatic region of the ^{13}C nmr spectra is complex, there do not appear to be any extra signals characteristic of a deuterium triplet of splitting 20 Hz centred on one of the existing peaks.

To confirm the lack of deuteriation of the aromatic phenanthrene nucleus, a 13.8 MHz deuterium magnetic resonance spectrum was obtained of the deuteriated 9-methylphenanthrene. This showed only two singlet signals (204.0 and 266.7 Hz), the latter due to the deuteriochloroform solvent, and the former, calculated from the proton magnetic resonance spectrum, due to a deuterium atom in the 9-methyl group. No signals for a deuterium atom attached to the C-10 was noted, although a signal of less than 10% of that of the 9-methyl group might have been lost in the baseline noise.

It is concluded that the concerted 1,5-hydrogen shift mechanism is not significantly (<10%) involved in the decarboxylation of this acid. It will be borne in mind that had an intermediate with deuterium at C-10 been formed, a deuterium kinetic isotope effect would have favoured its retention there in place of its tautomerisation to the methyl group.

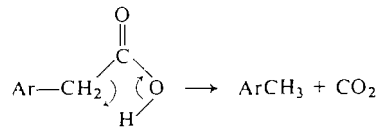
Accordingly, although no dimer is found in the product, we are bound to conclude that 9-phenanthrylacetic acid also decarboxylates via a homolytic mechanism, as integration of the ^{1}Hmr spectrum of the deuteriomethylphenanthrene showed that the methyl group was ca. 90% deuteriated.

The same general mechanism of decarboxylation may therefore be written for all five arylacetic acids investigated to date:

$$ArCH_2—COOH \rightarrow ArCH_2\cdot + \cdot COOH \rightarrow ArCH_3 + CO_2$$

The sequence of approximate rates of decarboxylation for these acids is 9-phenanthryl- > 2-naphthyl- and 1-naphthyl- > diphenyl- > phenyl-. A similar order is followed in decreasing bond order, except that the last two acids are identical in this respect. Thus although concerted mechanism would predict a fall in rates in the same general sense, it must also predict an identity of rate for the last two. Back and Sehon (12, 13) have shown this to be far from true. On the other hand the observed sequence is precisely that to be expected from decreasing stability of the substituted benzyl radical (20), further support for the homolytic mechanism.

Finally, the evidence we have presented does not rule out the thermally forbidden 1,3-hydrogen shift (Scheme 4). With the naphthylacetic acids the



SCHEME 4

reaction products indicate that such a mechanism could be at best only a contributor.

1,2-Dihydroquinolines: preparation and isolation as intermediates in the synthesis of quinolines

G. A. DAUPHINEE AND T. P. FORREST

Chemistry Department, Dalhousie University, Halifax, N. S., Canada B3H 4J3

Received August 19, 1977

G. A. DAUPHINEE and T. P. FORREST. Can. J. Chem. **56**, 632 (1978).

2,6-Dimethyl-1,2-dihydroquinoline has been isolated as an intermediate in the Doebner-Miller synthesis of 2,6-dimethylquinoline. Dihydroquinolines may be efficiently prepared by the acid catalysed elimination of water from a 4-hydroxy-1,2,3,4-tetrahydroquinoline. The analogous 4-phenylamino derivatives also undergo facile elimination of the benzylic amino group under similar conditions.

G. A. DAUPHINEE et T. P. FORREST. Can. J. Chem. **56**, 632 (1978).

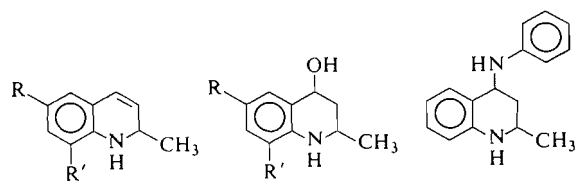
On a isolé la diméthyl-2,6 dihydro-1,2 quinoléine comme intermédiaire dans la synthèse de Doebner-Miller de la diméthyl-2,6 quinoléine. Les dihydroquinoléines peuvent être préparées d'une façon efficace par l'élimination acido-catalysée d'eau d'une hydroxy-4 tétrahydro-1,2,3,4 quinoléine. Les dérivés analogues phénylamino-4 subissent aussi une élimination facile du groupe benzylique amino dans des conditions semblables.

[Traduit par le journal]

1,2-Dihydroquinolines which are unsubstituted at the nitrogen, and have at least one hydrogen on carbon-2 are very unstable. They are rapidly oxidized by air to the quinoline, or disproportionated by trace acids to a mixture of the quinoline and the tetrahydroquinoline (1). Although difficulties have been encountered in the preparation of some 1,2-dihydroquinolines (2, 3), some have been prepared by the reduction of the corresponding quinoline with lithium aluminium hydride (2) or sodium borohydride (4), and in the case of some 2-substituted quinolines which did not respond to lithium aluminium hydride, by reduction with dialkyl aluminium hydrides (5). Reduction of quinoline by sodium in liquid ammonia was reported (6) to form 1,2-dihydroquinoline but it has recently been shown that the product is in fact 1,4-dihydroquinoline (7). The preparation of 2-alkyl-1,2-dihydroquinolines by addition of Grignard reagents to quinoline is illustrated in a recent paper (8) which also describes some facile rearrangements of 2-alkenyl-1,2-dihydroquinolines.

1,2-Dihydroquinolines are generally assumed to be intermediates in the Doebner-Miller preparation of quinolines (9) but no 1,2-dihydroquinoline has ever been isolated from this reaction, and a recent report concludes that they are not intermediates (10). We have now succeeded in isolating a 1,2-dihydroquinoline in high yield from a Doebner-Miller reaction, thus providing evidence for this intermediate and leading to a convenient method for the preparation of 1,2-dihydroquinolines.

In the normal Doebner-Miller reaction acetaldehyde and an aromatic amine are added to an aqueous acid solution and after about an hour at room temperature the mixture is heated under reflux for several hours. We have found that, if the reaction mixture is allowed to remain at room temperature for a longer period of time and the acid concentration is increased prior to heating, an excellent yield of the 1,2-dihydroquinoline is obtained after a very short reflux period. The dihydroquinoline may also be obtained by treating the aminoalcohol (**2**) or the diamine (**3**) with refluxing 6 *M* HCl for a short time.



1 **2** **3**

a R = R′ = H; *b* R = CH_3, R′ = H; *c* R = R′ = CH_3

As a method of preparation of 1,2-dihydroquinolines, the aminoalcohol provides the most convenient starting material since it may be readily prepared, can be stored indefinitely, and produces only water as the by-product of elimination. The diamine produces an equivalent amount of an aromatic amine which may be separated chromatographically. Handling of the 1,2-dihydroquinolines should be kept to a minimum since they are very sensitive to oxygen and to dilute acids; although they may be relatively stable in strongly acidic solutions, they disproportionate rapidly in dilute acid. The purity of the product from a typical preparation from the aminoalcohol may be judged from the nmr spectrum of 2,6-dimethyl-1,2-dihydroquinoline (Fig. 1), ob-

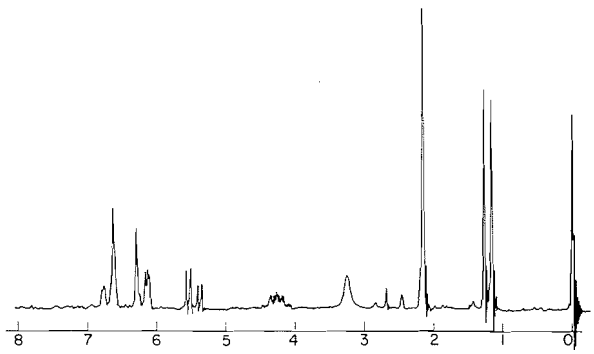

FIG. 1. Nuclear magnetic resonance spectrum of 2,6-dimethyl-1,2-dihydroquinaldine (**1***b*) from a typical preparation without further purification.

tained from a sample prepared without taking any precautions to exclude oxygen, and isolated by simple extraction of the product with ether, and removal of the solvent without further purification. The presence of a small amount of 2,6-dimethylquinoline is indicated by the peaks at δ 2.47 and 2.68 but this impurity may be kept below the detectable level (nmr) by using peroxide-free ether in the extraction and by avoiding heating the product while removing the solvent.

Experimental

Nuclear magnetic resonance spectra were determined on either of a Varian T60 or CFT20 spectrometer from solutions of about 10% solute in deuteriochloroform. Chemical shifts are reported in ppm relative to tetramethylsilane and coupling constants in Hz as line separations as measured directly from the spectra. Mass spectra were determined on a Dupont 21-220 mass spectrometer at 70 eV, infrared spectra on a Perkin-Elmer 237B spectrometer, and melting points on a Fisher-Johns apparatus.

*2,6-Dimethyl-1,2-dihydroquinoline (**1***b*) *from a Doebner-Miller Reaction*

To a solution of *p*-toluidine (1.08 g, 0.01 mol) in 2 *M* HCl (20 ml) at 5°C was added acetaldehyde (1.1 g, 0.025 mol) and the reaction mixture was stored at room temperature for 24 h. Activated charcoal (1 g) was added, the solution stirred for 5 min, and then filtered. Hydrochloric acid (14 ml of 12 *M*) was added, the solution heated under reflux for 15 min, and then poured into a cold sodium hydroxide solution (150 ml of 2 *M*). The reaction mixture was then extracted with three 50-ml portions of peroxide-free ether and the combined ether extracts stirred with activated charcoal (0.5 g), filtered, dried with anhydrous sodium sulfate, and the solvent removed *in vacuo* to yield 1.56 g of a pale yellow crystalline solid. An nmr spectrum of the product indicated that it was mainly **1***b*, contaminated by a small amount of 2,6-dimethylquinaldine and some aliphatic polymeric impurities. A portion of the product was oxidized as described below to 2,6-dimethylquinoline.

The yellow solid (0.75 g) in 75 ml of ether was vigorously stirred with 50 ml of water at room temperature while a solution of iodine in aqueous potassium iodide (0.1 *M*) was added dropwise until a brown color remained in the ether layer. With continued stirring, solid sodium thiosulfate was added until the brown color disappeared and then sodium hydroxide solution (20 ml of 2 *M*) was added. The ether layer was removed, the ether evaporated *in vacuo* and the residue steam distilled. The distillate was extracted with ether and after drying the ether was removed to yield 2,6-dimethylquinoline (83% yield based on *p*-toluidine), identical in nmr, ir, and uv spectra with an authentic sample.

*2,6,8-Trimethyl-1,2-dihydroquinoline (**1***c*) *from* cis*-2,6,8-Trimethyl-4-hydroxy-1,2,3,4-tetrahydroquinoline (**2***c*)

cis-2,6,8-Trimethyl-4-hydroxy-1,2,3,4-tetrahydroquinoline (11) (designated as the β isomer in this reference), (1 g, 5 mmol) was added to refluxing hydrochloric acid (20 ml of 6 *M*). After refluxing for 5 min the reaction mixture was poured into cold sodium hydroxide solution (100 ml of 2 *M*) and the product extracted with two 30-ml portions of peroxide-free ether. After drying with anhydrous sodium sulfate the ether was removed *in vacuo* to yield a relatively pure sample of **1***c*. Extension of the reflux time causes increasing amounts of disproportionation in this case although this was not so for 1,2-dihydroquinaldine (**1***a*) and 2,6-dimethyl-1,2-dihydroquinoline (**1***b*) in their preparation by this method. The *cis* or *trans* isomer of the starting material may be used in this reaction.

2,6,8-Trimethyl-1,2-dihydroquinoline (**1***c*), yield 96%; colorless oil; nmr δ: 1.25 (d, J = 6.5, CH_3), 1.99 (s, CH_3), 2.14 (s, CH_3), 3.71 (bs, NH), 4.28 (m, J = 6.5, 3.7, 1.6, H-2), 5.47 (dd, J = 9.7, 3.7, H-3), 6.22 (dd, J = 9.7, 1.6, H-4), 6.54 (bs, H_{arom}), 6.65 (bs, H_{arom}); ir (neat): 3440, 1640 cm^{-1}; ms: 173(18), 172(26), 171(100), 158(56).

2,6-Dimethyl-1,2-dihydroquinoline (**1***b*), prepared from *cis*-2,6-dimethyl-4-hydroxy-1,2,3,4-tetrahydroquinoline (**2***b*) (12); yield 96%; pale yellow crystals mp 60–63°C; nmr δ: 1.18 (d, J = 6.5, CH_3), 2.14 (s, CH_3), 3.61 (bs, NH), 4.22 (m, J = 6.4, 3.6, 1.6, H-2), 5.41 (dd, J = 10.0, 3.6, H-3), 6.15 (dd, J = 10.0, 1.6, H-4), 6.1–6.7 (m, H_{arom}); ir ($CHCl_3$): 3440, 1640 cm^{-1}; ms: 159(27), 158(33), 157(100), 144(87).

1,2-Dihydroquinaldine (**1***a*) (5), prepared from *cis*-2-methyl-4-hydroxy-1,2,3,4-tetrahydroquinoline (**2***a*) (11); yield 94%; colorless oil; nmr δ: 1.18 (d, J = 6.5, CH_3), 3.50 (bs, NH), 4.30 (m, J = 6.5, 3.5, 1.5, H-2), 5.43 (dd, J = 9.8, 3.5, H-3), 6.23 (dd, J = 9.8, 1.5, H-4), 6.1–7.2 (m, H_{arom}); ir (neat): 3440, 1640 cm^{-1}; ms: 145(23), 144(33), 143(97), 130(100).

*1,2-Dihydroquinaldine (**1***a*) *from* cis*-2-Methyl-4-anilino-1,2,3,4-tetrahydroquinoline (**3**)*

cis-2-Methyl-4-anilino-1,2,3,4-tetrahydroquinoline (**3**) (13), (1 g, 4.2 mmol) was added to refluxing 6 *M* HCl (20 ml) and after 10 min the reaction mixture was poured into 2 *M* NaOH solution (100 ml). After extraction with two 30-ml portions of peroxide-free ether and evaporation of the solvent, the residue, an equimolar mixture of aniline and **1***a* (by nmr), was subjected to column chromatography on silica gel (Merck G) using petroleum ether (bp 30–60°C) – benzene (50:50) as eluant. (tlc, Eastman pre-coated silica sheets using the same solvent system gave R_f values of 0.70, 0.37, and 0.05 for dihydroquinaldine, aniline, and quinaldine, respectively.) A yield of 41% (0.25 g) of 1,2-dihydroquinaldine was obtained from the column with very little quinaldine present, in spite of the fact that the column was not run under nitrogen.

Vapour pressures of aqueous solutions of (Ag,Tl,Cd)NO_3 at 98.5°C. II. Henry's law and excess free energy

MARIE-CHRISTINE ABRAHAM AND MAURICE ABRAHAM

Département de Chimie, Université de Montréal, Case postale 6210, Succursale A, Montréal (Qué.), Canada H3C 3V1

AND

JAMES MALCOLM SANGSTER[1]

Département de Génie Chimique, Ecole Polytechnique, Campus de l'Université de Montréal, Case postale 6079, Succursale A, Montréal (Qué.), Canada H3C 3A7

Received October 13, 1977

MARIE-CHRISTINE ABRAHAM, MAURICE ABRAHAM, and JAMES MALCOLM SANGSTER. Can. J. Chem. **56**, 635 (1978).

Curves of the water activity coefficient γ_w have been obtained as a function of water mole fraction in the mixtures $AgNO_3 + TlNO_3 + Cd(NO_3)_2 + H_2O$ at 98.5°C. It has been shown, in this study, from the BET equation itself and verified experimentally, that γ_w may pass through an extremum value for certain systems. The position of such an extremum near the fused salt end of the concentration scale can explain the appearance of a 'practical' Henry's law in a finite concentration range. The curves of the excess free energy of the system undergo rather unusual changes of shape as the cadmium content of the melt is varied.

MARIE-CHRISTINE ABRAHAM, MAURICE ABRAHAM et JAMES MALCOLM SANGSTER. Can. J. Chem. **56**, 635 (1978).

On a étudié les courbes du coefficient d'activité de l'eau γ_w en fonction de sa fraction molaire pour des mélanges $AgNO_3 + TlNO_3 + Cd(NO_3)_2 + H_2O$ à 98.5°C. On a démontré théoriquement à partir de l'équation BET, et vérifié expérimentalement, que γ_w peut passer par une valeur extremum pour certains systèmes. La position d'un tel extremum dans le domaine des solutions pauvres en eau peut expliquer l'apparition d'une loi de Henri pratique dans un intervalle fini de concentration. Les courbes de l'enthalpie libre de mélange d'excès des sels avec l'eau subissent des modifications inhabituelles quand on fait varier la concentration en $Cd(NO_3)_2$.

Introduction

In a previous article (1*b*) we presented and discussed the BET isotherm constants for the system $AgNO_3 + TlNO_3 + Cd(NO_3)_2 + H_2O$ at 98.5°C, at mole ratio Ag/Tl = 1.06 and for five Cd mole fractions in the melt, viz., 0, 0.05, 0.075, 0.1, and 0.125. The BET equation, modified for aqueous solutions (2), was found to represent the data over an unexpectedly wide water concentration range. We showed that some of these systems exhibited 'cross-over points' in their Raoult's law behaviour, and that the BET constants uniquely specified these points. The BET constants were found to follow simple additivity rules. In the present article the data are discussed in terms of the water activity coefficient, Henry's law, and the excess free energy. The symbolism and conventions used here are the same as those used previously (1).

Water Activity Coefficient

Figure 1 presents curves of the activity coefficient of water γ_w as a function of its mole fraction in each of the five melt mixtures studied, S_0, S_5, $S_{7.5}$, S_{10}, and $S_{12.5}$. The first four of these curves show maxima; this is unusual behaviour for electrolyte solutions, which generally (3) give a rising asymptote much like the one for $S_{12.5}$. The maxima are displaced toward the water end as the Cd content of the melt is increased.

Just as in the preceding article (1*b*) the rather complex Raoult's law behaviour of these systems was better understood by consideration of the BET equation, so here this equation can help to clarify Fig. 1. The equation (1*a*) can be written as

$$[1] \qquad a_w(1 - x_w)/x_w(1 - a_w) = A + Ba_w$$

where $A = 1/cr$ and $B = (c - 1)/cr$, c and r being the BET constants described previously. Insofar as the a_w data of a system can adequately be represented by an equation such as eq. 1 the maximum value of γ_w (if there is one) can be specified by the BET constants, as follows. Rearrangement of eq. 1 gives

$$[2] \quad Ax_w/a_w - Ba_wx_w + x_w(1 - A + B) - 1 = 0$$

Introducing $a_w = \gamma_w x_w$ into eq. 2 yields

$$[3] \quad A + x_w\gamma_w(1 + B - A) - B(x_w\gamma_w)^2 - \gamma_w = 0$$

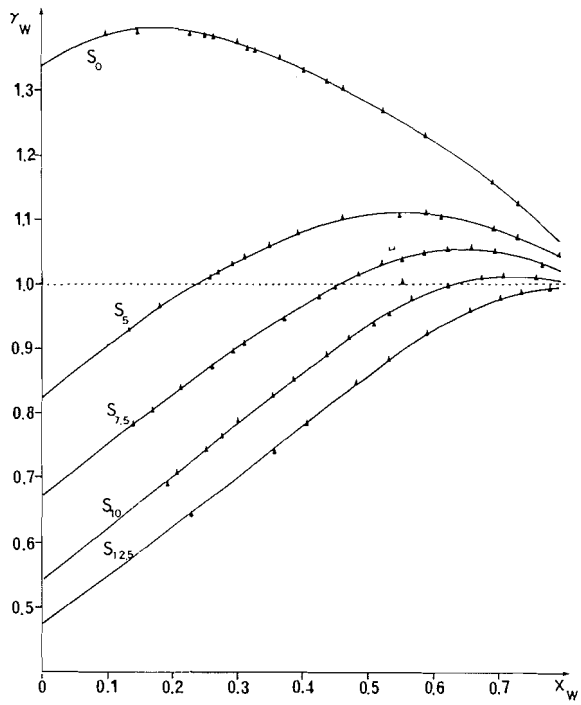

FIG. 1. Curves of γ_w vs. x_w for the system $(Ag,Tl,Cd)NO_3 + H_2O$ at 98.5°C, for five cadmium contents in the melt.

Differentiating eq. 3 with respect to x_w and remembering that, at an extremum, $d\gamma_w/dx_w = 0$, we obtain

$$[4] \qquad 1 + B - A - 2Ba_{wm} = 0$$

where a_{wm} is the water activity of the solution whose water activity coefficient is a maximum, γ_{wm}. From eq. 4 then

$$[5] \qquad a_{wm} = (1 + B - A)/2B$$

Substituting eq. 5 in eq. 2 and solving for x_w, we obtain

$$[6] \quad x_{wm} = [2AB/(1 + B - A) + (1 + B - A)/2]^{-1}$$

and thus, from eqs. 5 and 6

$$[7] \qquad \gamma_{wm} = A + (1 + B - A)^2/4B$$

where $a_{wm} = x_{wm}\gamma_{wm}$.

Experimental values of A and B for all five systems are given in Table 1, and also the derived values for x_{wm} and γ_{wm}. The x_{wm} and γ_{wm} values for S_{10} and $S_{12.5}$ are placed in parentheses since in these cases x_{wm} lies beyond the range of applicability of the BET equation (1*b*), and hence these values are not strictly valid. The values themselves are, however, of reasonable magnitude.

TABLE 1. The intercepts (A) and slopes (B) of the BET plots, with the derived extrema (γ_{wm}, x_{wm}) and Henry's law constants (γ_w^∞, K_H^∞)*

System	$A = \gamma_w^\infty$	B	x_{wm}	γ_{wm}	K_H^∞, atm
S_0	1.34	0.722	0.193	1.39	1.25
S_5	0.824	0.741	0.559	1.11	0.770
$S_{7.5}$	0.666	0.733	0.691	1.05	0.622
S_{10}	0.550	0.699	(0.804)	(1.02)	0.514
$S_{12.5}$	0.474	0.610	(0.928)	(1.00)	0.442

*Values in this table are given to three significant figures, of which the third is uncertain.

Henry's Law

The intercept A (eq. 1) of a BET isotherm plot may be equated (1*a*) to the limiting activity coefficient γ_w^∞ of water dissolved in molten salt. The corresponding Henry's law constants K_H^∞ may be calculated directly from γ_w^∞ through the relations (1*a*)

$$[8] \quad f_w = f_w^0 a_w = [f_w^0 \gamma_w^\infty x_w]_{x_w \to 0} = [K_H^\infty x_w]_{x_w \to 0}$$

where f_w is the fugacity of dissolved water and f_w^0 the fugacity of pure water. Values of K_H^∞ are also included in Table 1. It is seen that K_H^∞ decreases steadily as cadmium is added to the melt. This is what would be expected if a strongly hydrated ion such as Cd^{2+} is added to solutions of weakly-hydrated ions like Ag^+ and Tl^+. This effect has already been noted (1*a*) in the cases of Li^+ and Ca^{2+}.

Henry's law is strictly valid only at infinite dilution. There are cases, however, where the ratio f_w/x_w varies little over a finite concentration range. Depending on the error which can be tolerated and the range of concentration of interest, a 'practical' Henry's law constant K_H may be used

$$[9] \qquad f_w = K_H x_w$$

which must be distinguished from K_H^∞. The activity coefficient data (1*b*) of the series S_0 show that γ_w varies a few percent in the interval $0 < x_w < 0.3$. As Cd is progressively added to the melt, however, this interval becomes smaller. Another way of seeing this is to compare the ratio $\gamma_w(x_w = 0.3)/\gamma_w^\infty$ for all five systems: S_0, 1.03; S_5, 1.25; $S_{7.5}$, 1.35; S_{10}, 1.42; $S_{12.5}$, 1.45. What distinguishes the S_0 curve (Fig. 1) from the others is the situation of the maximum close to $x_w = 0$. Since, in the region of an extremum, a function changes little, we deduce a criterion for the existence of a practical Henry's law constant, viz., the presence of a maximum or minimum in γ in the dilute solution region of the solute of interest.

Excess Free Energy

Values of G^E were calculated for the systems S_0 to

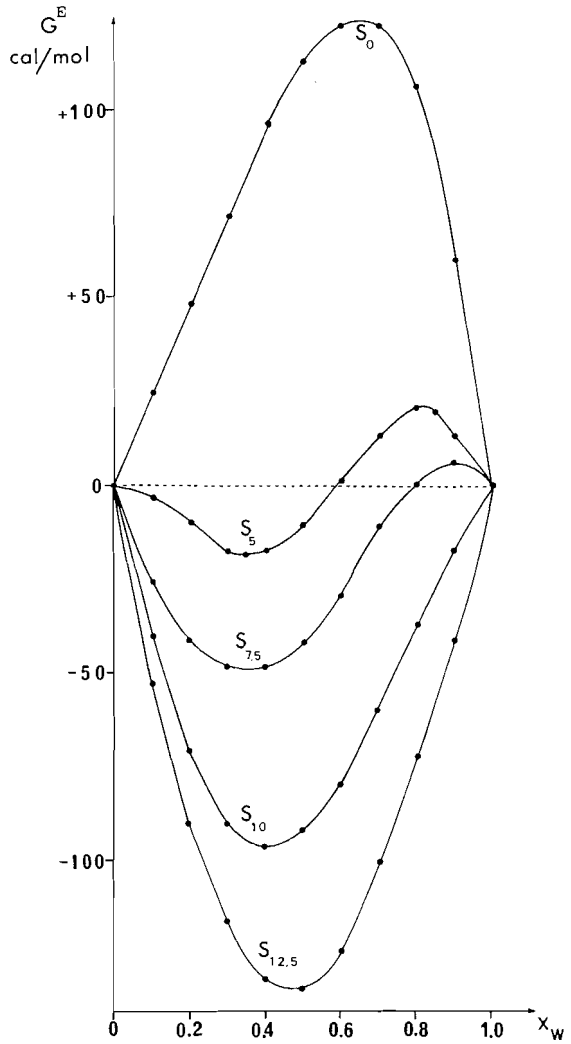

FIG. 2. Curves of G^E vs. x_w for the system (Ag,Tl,Cd)NO_3 + H_2O at 98.5°C, for five cadmium contents in the melt.

$S_{12.5}$ in the same way as previously described (1*a*). The results are given in Fig. 2. The change in orientation and shape of these curves as the Cd content of the melt changes is unusual and merits some comment. First, the presence of 'cross-over points' in the Raoult's law curves of these systems (1*b*) leads one to expect some unusual results in related thermodynamic properties. Second, the general behaviour shown in Fig. 2 is very similar to that in the following two cases: (*1*) variation of H^E at 25°C for mixtures of water and simple alcohols $C_nH_{2n+1}OH$, $n = 1$ to 3 (4); (*2*) variation of H^E for water + ethanol mixtures in the temperature range 25–110°C (5). In water + alcohol mixtures, the addition of one component to the other changes the local structure in both liquids in noticeable ways; this kind of explanation is sometimes invoked in case (*1*). As the temperature increases, the local structure in the pure components decreases, and hence their interaction also changes; this is sometimes mentioned in instances like case (*2*). Since, in the present work, water is preferentially hydrated to Cd^{2+} over Tl^+ and Ag^+, it is probable that the behaviour shown in Fig. 2 could be interpreted in terms of changes in solvent–solute interaction through the series S_0 to $S_{12.5}$.

The total synthesis of 4-deoxy-D,L-daunosamine

HING-KWOK HUNG, HING-YAT LAM, WALTER NIEMCZURA, MEI-CHING WANG, AND CHIU-MING WONG

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 12, 1977

HING-KWOK HUNG, HING-YAT LAM, WALTER NIEMCZURA, MEI-CHING WANG, and CHIU-MING WONG. Can. J. Chem. **56**, 638 (1978).

The aminosugar 4-deoxy-D,L-daunosamine and its derivatives were synthesized starting with 2,4-pentanedione which was converted to the key intermediate oxazolino-α-pyrone (**19**) by enamine formation with morpholine, oxidation with benzoyl peroxide, condensation with ammonium acetate, bromination with *N*-bromosuccinimide, nitrile formation, acid hydrolysis, and cyclization with thionyl chloride. Hydrogenation of **19** gave the δ-lactone **22** which was converted to 4-deoxy-D,L-daunosamine derivatives by reducing the lactone ring to the corresponding hemiacetal **26**.

HING-KWOK HUNG, HING-YAT LAM, WALTER NIEMCZURA, MEI-CHING WANG et CHIU-MING WONG. Can. J. Chem. **56**, 638 (1978).

On a synthétisé le sucre aminé déoxy-4-D,L-daunosamine et ses dérivés à partir de la pentanedione-2,4 que l'on a transformée en oxazolino-α-pyrone (**19**), un intermédiaire clé, grâce à une formation d'énamine avec la morpholine, une oxydation par le peroxyde de benzoyle, une condensation avec l'acétate d'ammonium, une bromation avec la *N*-bromosuccinimide, la formation d'un nitrile, une hydrolyse acide et une cyclisation par le chlorure de thionyle. L'hydrogénation de **19** fournit la δ-lactone **22** que l'on a transformée en dérivés de la déoxy-4-D,L-daunosamine par réduction du cycle de lactone en hémiacétal correspondant **26**.

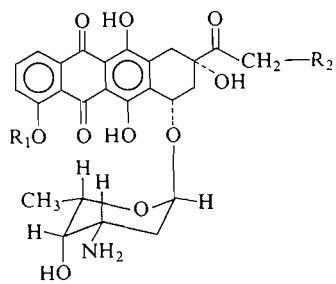
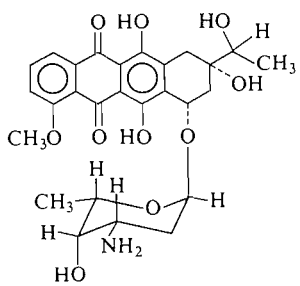
Introduction

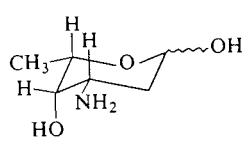
The anthracycline antibiotics daunorubicin (**1**), adriamycin (**2**), and carminomycin (**3**) have attracted much attention because of their very promising antitumor properties (1, 2). Clinical tests have clearly established their values as broad spectrum chemotherapeutic antitumor agents (3). One of their common, yet very undesirable side effects is their dose-related and progressive cardiomyopathy which is responsible for patients' death or discontinuation of chemotherapy with this group of drugs. The nature of cardiotoxicity has not been established, although morphological changes of affected heart cells indicated that interference with protein synthesis (4) and uncoupling of oxidative phosphorylation (5) could be some of the reasons. Metabolic studies of daunorubicin showed that daunorubicinol (**4**) and daunomycinone (**6**) were among the metabolites.



1 $R_1 = CH_3$, $R_2 = H$
2 $R_1 = CH_3$, $R_2 = OH$
3 $R_1 = R_2 = H$



4



5

The fate of the aminosugar portion, daunosamine (**5**), has not been well established but daunomycinone (**6**) does not seem to be responsible for the observed cardiomyopathy (6). Many aminosugars and related antibiotics interfere with protein synthesis (7) and their bacterial toxicities could be greatly modified by manipulating the stereochemistry or removing only one hydroxyl group in the molecule (8). Furthermore, the reported reduced toxicity to cultured heart cells of 4′-epiadriamycin (9) pointed to the importance of the aminosugar 4-deoxydaunosamine (**7**) in attempts to reduce cardiotoxicity of this group of drugs.

Results and Discussion

Our synthetic scheme of aminosugars is based on the early concept of relationship between aminosugars and oxazolines or pyrrolines in the Morgan–Elson test (10). The oxazolines could be considered as having amino groups in latent forms. Thus an oxazolino-α-pyrone such as **19** would be a suitable

intermediate in the synthesis of some 3-deoxy-3-aminohexopyranoses like daunosamine (11*a*), acosamine (11*b*), ristosamine (11*c*), and other related highly deoxygenated deoxyaminosugars, for example, 4-deoxydaunosamine (**7**).

The oxazolino-α-pyrone (19) was prepared in high yield in five steps starting with 3-benzoyloxy-2,4-pentanedione (**8**) (12). Refluxing **8** with ammonium acetate in glacial acetic acid gave the 2-phenyl-4-methyl-5-acetyl-1,3-oxazole (**9**) and the 1,3-diazole (**10**). The relative yield of **9** and **10** could be controlled from one extreme of forming only the oxazole **9** to the other extreme of forming only the diazole **10**, by adjusting the amount of ammonium acetate and glacial acetic acid. Photocatalyzed bromination of **9** by *N*-bromosuccinimide in carbon tetrachloride solution gave exclusively the 2-phenyl-4-bromomethyl-5-acetyl-1,3-oxazole (**11**) which was converted to the corresponding cyano compound **12** by potassium cyanide in liquid hydrogen cyanide solution. The bromo compound **11** was very unstable in basic solution and only under the hydrogen cyanide buffered condition could it be converted to the cyano compound **12** in acceptable yield. Acid hydrolysis of **12** to the corresponding carboxylic acid **13** was carried out at room temperature in aqueous acetic acid solution saturated with hydrogen chloride. This acid decarboxylated easily back to the oxazole **9** and thus only its methyl ester **14** was fully characterized. This ester was prepared in almost quantitative yield by methanolysis of **12** in anhydrous methanol solution saturated with hydrogen chloride and then converted to the acid **13** in hydrogen chloride-saturated aqueous acetic acid solution.

The crucial point at this stage was to ascertain the structure of the carboxylic acid **13**, because there was no concrete evidence to exclude the possibility of structures **16**, **17**, and **18** in the sequence of reactions described previously. The only rigorous proof came as a result of the cyclization of **13** to form the oxazolino-α-pyrone (**19**) in anhydrous alcohol-free chloroform solution containing thionyl chloride. The nmr spectrum of **19** showed a methyl doublet at 251.63 Hz, with a coupling constant of 0.80 Hz and an olefinic proton quartet at 615.76 Hz with a coupling constant of 0.80 Hz (HA-100 spectrum). This result eliminated the likelihood of structures **16**, **17**, and **18**.

Catalytic hydrogenation of **19** in the presence of Adam's catalyst in ethyl acetate solution yielded the 3-benzamido-5-hydroxyhexanoic acid lactone (**22**) and 3-cyclohexylcarbonylamino-5-hydroxyhexanoic acid lactone (**23**). Separation of these two from each other was very tedious but prolonged hydrogenation of **19** gave **23** exclusively. A small amount of hydrogenation by-product was identified as the ethyl ester **15** the quantity of which varied according to the activity of the catalyst. Very active Adam's catalyst gave good yield of **23** whereas less active catalyst such as platinum black gave a mixture of **15**, **22**, and **23**. Since the ethyl acetate had been rigorously purified, it was very likely that small amount of ethanol which opened the α-pyrone ring of **19** to form **15**, was slowly generated by hydrogenation of the solvent.

Formation of **22** and **23** involved hydrogenolysis which would indicate that the first hydrogenation

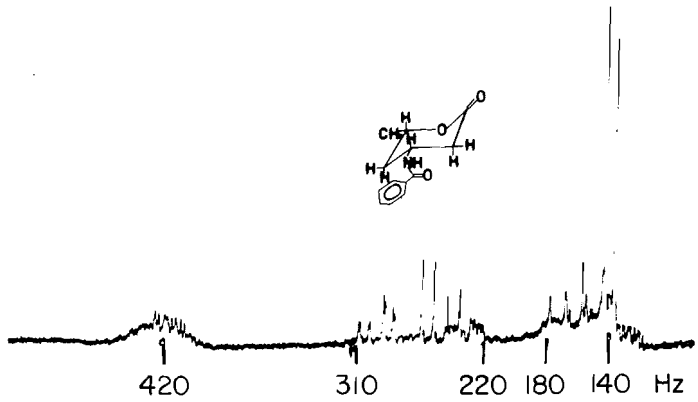

FIG. 1. The HA-100 spectrum of compound **22** (aromatic areas omitted).

product could be the oxazolinodihydropyrone (**20**) (11*a*). When hydrogenation was prematurely discontinued, a small amount of by-product presumably the dihydropyrone **21**, (m^+/e 231; ir: 3420, 1703, 1695, 1637 cm^{-1}) was isolated which because of its transient character, was not further characterized. But further hydrogenation of this compound with Adam's catalyst gave exclusively **23**.

The stereochemistry of the δ-lactone ring of **22** or **23** needed further clarification. Hydrogenation of **20** could lead to both the *cis*-1,3-disubstituted (**22**, **23**) or the *trans*-1,3-disubstituted (**24**, **25**) products. The nmr spectrum of the fully saturated lactone **23** (or **25**) was too complicated to be fully analyzed owing to the overlap of the cyclohexane ring protons over the C_4 protons of the lactone ring. However, detailed analyses of the nmr spectrum of **22** (or **24**) was possible (Fig. 1).

Conformation analysis predicts that for a *trans*-1,3-disubstituted α-lactone like **24**, the benzamido group should preferably occupy the equatorial position. Likewise, *cis*-1,3-disubstituted δ-lactone such as **22** would have both the methyl and the benzamido groups in equatorial position. This means H_5 will be in the axial position.

Table 1 gives the chemical shifts and coupling constants of the protons considered as determined from an iterative fit of the simulated spectrum against the observed line positions. Figures 2–4 show a comparison between the observed spectrum and the computer simulation using the values in Table 1. A complete simulation of the H_5, H_3 region was impractical because of the overlap of the two resonances and the inability of the program to reproduce the broad signals of H_3 because of the ^{14}N coupling and N–H proton exchange.

H_{2a} and H_{2e} were identified by the large coupling constant (17.2 Hz) usually observed between geminal protons next to a carbonyl group (13). The signals

TABLE 1. Chemical shifts and coupling constants of **22**

Chemical shifts (δ) (ppm from TMS)		Coupling constants (Hz)	
H_{2a}	2.54±0.005	$J_{2a\text{-}2e}$	−17.2±0.2
H_{2e}	2.96±0.005	$J_{2a\text{-}3a}$	8.5±0.2
H_{3a}	4.47±0.005	$J_{2e\text{-}3a}$	6.9±0.2
H_{4a}	1.60±0.005	$J_{4a\text{-}4e}$	−13.9±0.2
H_{4e}	2.34±0.005	$J_{3a\text{-}4a}$	11.3±0.2
H_{5a}	4.42±0.005	$J_{3a\text{-}4e}$	5.7±0.2
CH_3	1.36±0.005	$J_{4a\text{-}5a}$	11.7±0.2
		$J_{4e\text{-}5a}$	2.6±0.2
		$J_{5a\text{-}CH_3}$	6.5±0.2
		$J_{4e\text{-}2e}$	1.2±0.2

at δ 2.54 ppm (Fig. 2) were assigned to H_{2a} (14) which is further coupled by 8.5 Hz to H_3, indicating that the latter proton is in the axial position. The H_{2e} signals at δ 2.96 ppm in the AB pattern of Fig. 3 is also coupled to H_{3a} by the unusually large coupling constant of 6.9 Hz. This indicates that the lactone group is causing ring flattening at the C-1 end of the molecule, making H_{2a} and H_{2e} almost equivalent with respect to H_3. This is further substantiated by the additional coupling observed in the H_{2e} multiplet. Each of the four lines is further split by 1.18 Hz, apparently by H_{4e}, in agreement with an estimation based on Karplus relationships (15). This coupling establishes the resonance at δ = 2.34 ppm as belonging to H_{4e} which is further split by 13.9 Hz by H_{4a}, 5.7 Hz by H_{3a}, and 2.6 Hz by H_5. The latter value tentatively indicates that H_5 is axially oriented. H_{4a} was identified as that at δ 1.60 ppm with splittings, other than to H_{4e}, of 11.3 and 11.7 Hz attributed to H_{3a} and H_{5a}, respectively. These large values are typical of axial–axial couplings, confirming the orientation of H_3 and H_5 as axial. Using values obtained from the other protons, the H_{5a} resonance at δ 4.42 ppm was confirmed by the use of a stick diagram. Working with first-order rules

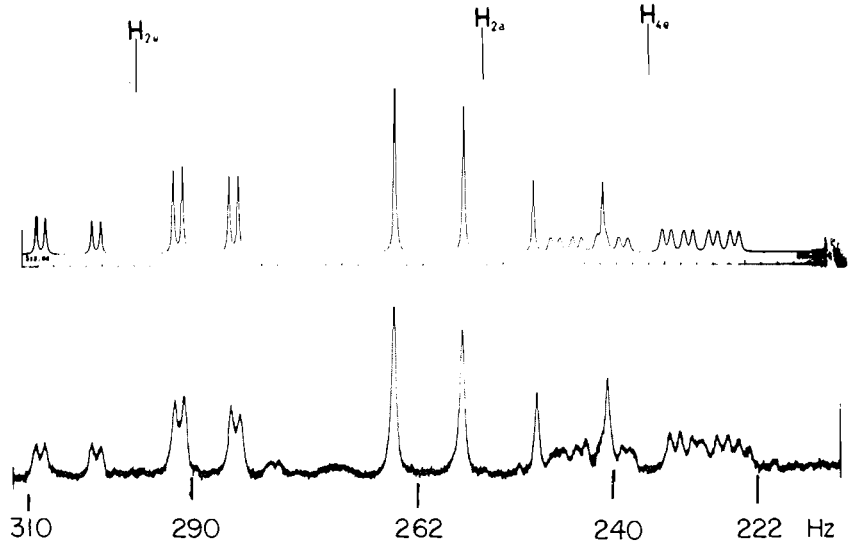

FIG. 2. The simulated (top) and recorded spectrum of H_{2a}, H_{2e}, and H_{4e} of compound **22**.

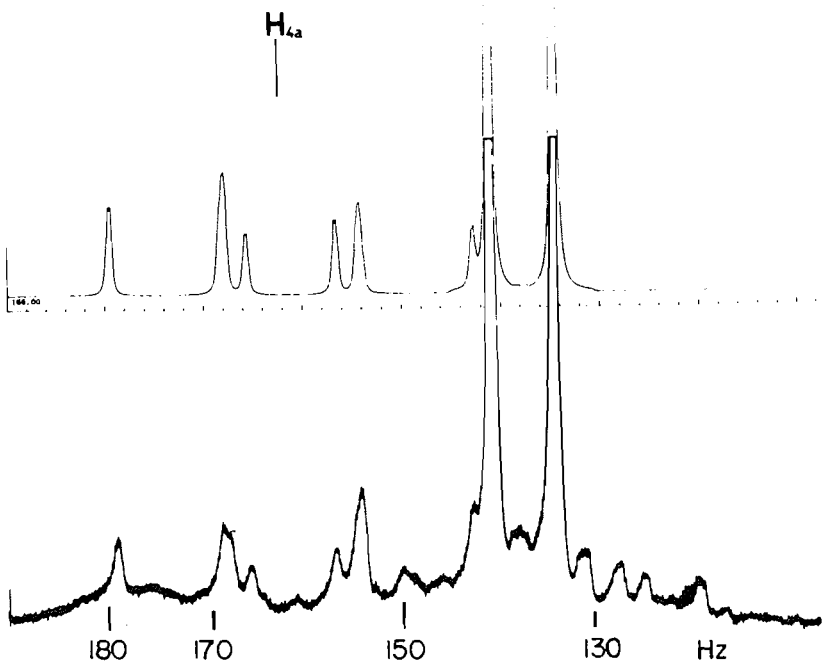

FIG. 3. The simulated (top) and recorded spectrum of H_{4a} and CH_3 of compound **22**.

and the 6.5 Hz coupling observed in the methyl resonance, the apparent splitting pattern could be very well reproduced (Fig. 4).

Having established the stereochemistry of **22**, the δ-lactone ring was then reduced to the hemiacetal **26** by the modified Red-al (*vide infra*) reagent. In large scale preparation, **19** was exhaustively hydrogenated to give exclusively **23** which was then reduced to the hemiacetal **27** as before. This operation was necessary, because **22** was always contaminated with **23** and the condition that favoured the formation of **22** always led to the formation of **15**. Hydrolysis of **26** or **27** in acetic–hydrobromic acid solution gave the hydrobromide of 4-deoxy-D,L-daunosamine (**7**).

Experimental

Most of the nmr spectra were recorded on a Varian A56/60A spectrometer using deuterated chloroform as solvent and

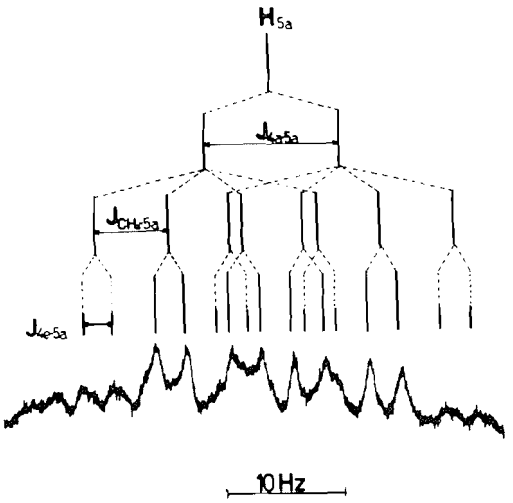

FIG. 4. The expanded spectrum of H_{5a} of compound **22**.

tetramethylsilane as internal standard. Other nmr spectra for high resolution studies were recorded on a Varian HA-100 spectrometer operating in the internal lock frequency sweep mode at a probe temperature of 31.5 ± 0.5°C. Line positions were estimated from a single calibration by periodically placing frequency markers and measuring the distance to the line positions. The analysis was performed using LAME-8 (16) (LAOCOON for eight-spins with magnetic equivalence) program.

Infrared spectra were recorded on a Perkin-Elmer infracord Model 710A spectrophotometer using methylene chloride as solvent or otherwise specified. Routine mass spectra were recorded on a Finnigan quadrupole 1015 mass spectrometer and high resolution spectra were recorded on an A.E.I. MS-9 mass-spectrometer. Microanalyses were performed by Dr. Daessle of Montreal and melting points were taken on a Fisher–Johns apparatus.

*Preparation of 2-Phenyl-4-methyl-5-acetyl-1,3-oxazole (**9**) and 1,3-Diazole (**10**)*

Acetylacetone (100 g), morpholine (90 g), and benzene (350 ml) in a 3-ℓ flask equipped with a Dean-Stark water separator and condenser was refluxed for 17 h under nitrogen. The water was removed and the solution was concentrated by removing the benzene through the Dean-Stark separator. Benzoyl peroxide (245 g) dissolved in $CHCl_3$ (1½ ℓ) was added slowly to the cooled benzene solution in 2 h keeping the temperature of the reaction mixture between 10–15°C. After stirring for 6 h at 15°C, the mixture was then warmed up to room temperature and stirring was continued for another 2 h keeping the temperature below 25°C. Water (200 ml) was added and the reaction mixture was stirred for 3 h in a 60°C hot water bath. The chloroform layer was separated, washed with water (2 × 200 ml), dried over magnesium sulfate, filtered, and evaporated under reduced pressure to give a heavy dark brown syrupy residue from which a sample was purified and the properties were comparable with those reported in the literature. To the residue was added ammonium acetate (230 g) and glacial acetic acid (1.7 ℓ) and the solution was heated to a gentle reflux for 10 h. Acetic acid (~900 ml) was removed by low pressure distillation and the residue was then diluted with water and extracted exhaustively with ether. The ether solution was washed with water (3 × 300 ml), potassium carbonate solution (10%), dried over magnesium sulfate, and evaporated to dryness to give the crude crystalline oxazole (69 g) which was purified by distillation at 115°C/0.5 Torr or recrystallization from cold ether, mp 62–63°C; ir: 1680 (ketone), 1600 (oxazole and phenyl) 1395, 1370 (methyl groups) cm^{-1}; ms m^+/e: 201; nmr δ: 2.48 (s, CH_3), 2.51 (s, CH_3), 7.45 (m, 3H phenyl), 8.03 ppm (m, 2H phenyl). *Anal.* calcd. for $C_{12}H_{11}O_2N$: C 71.64, H 5.47, N 6.96; found: C 71.72, H 5.58, N 6.70.

In another experiment, the amount of acetic acid was reduced to 500 ml and ammonium acetate was increased to 380 g. The above procedure led to the isolation of mainly 2-phenyl-4-methyl-5-acetyl-1,3-diazole (**10**) (22 g) which could be purified by recrystallization from benzene, mp 172–173°C; ir: 3420 (NH), 1665 (vinylogous amide), 1640 cm^{-1} (diazole ring); ms m^+/e: 200; nmr δ: 2.57 (s, CH_3), 2.60 (s, CH_3), 7.42 (m, 3H phenyl), 7.98 ppm (m, 2H, phenyl).

*Preparation of 2-Phenyl-4-bromomethyl-5-acetyl-1,3-oxazole (**11**)*

N-Bromosuccinimide (15 g) was added to a freshly distilled carbon tetrachloride (500 ml) solution containing **9** (16 g) in a 1-ℓ flask equipped with condenser, drying tube, and a magnetic stirring bar. The solution was heated to a gentle reflux while being irradiated for 6 h by a Hanovia Utility quartz lamp. About half of the carbon tetrachloride was removed by distillation under reduced pressure and the residual solution was cooled in cold water for 2 h. The white solid of succinimide was then removed by filtration and the solution was evaporated under reduced pressure to give a crystalline residue. Recrystallization from cold ether gave 2-phenyl-4-bromomethyl-5-acetyl-1,3-oxazole (**11**) (16 g). The mother liquor in ether solution (100 ml) was stirred with zinc dust (5 g) in the presence of acetic acid for 10 min, then filtered and washed with water and dried over magnesium sulfate. Evaporation of the ether solution to dryness as usual gave the starting oxazole **9** (3.4 g). A sample of **11** was further purified by recrystallization from ether (3×), mp 108–109°C; ms m^+/e calcd.: 280.9891; found: 280.9872; ir: 1680 (ketone), 1595 (oxazole and phenyl), 1370 cm^{-1} (—CH_3); nmr δ: 2.58 (s, —CH_3), 4.73 (s, —CH_2—Br), 7.48 (m, 3H, phenyl), 8.12 ppm (m, 2H, phenyl).

*Preparation of 2-Phenyl-4-cyanomethyl-5-acetyl-1,3-oxazole (**12**)*

Liquid hydrogen cyanide (200 ml), *N*,*N*-dimethylformamide (100 ml), and pulverized potassium cyanide (20 g) were added in sequence to a flask containing 2-phenyl-4-bromomethyl-5-acetyl-1,3-oxazole (20 g) in an ice bath. The flask was then securely stoppered and the mixture was stirred at room temperature for 4 h. The hydrogen cyanide (~100 ml) was then recovered by low pressure distillation with Dry-Ice trap. Water (200 ml) was added to the residue and the aqueous mixture was extracted with benzene (4 × 200 ml). The combined benzene solution was washed with water, dried over anhydrous magnesium sulfate, and worked up as usual to yield the crystalline 2-phenyl-4-cyanomethyl-5-acetyl-1,3-oxazole (11.8 g) a sample of which was purified by recrystallization from chloroform–ether (3×), mp 126–127°C; ir: 2300 (—CN), 1680 (ketone), 1600 (oxazole and phenyl), 1375 cm^{-1} (—CH_3); nmr δ: 2.58 (s, —CH_3), 4.10 (s, 2H, —CH_2—CN), 7.58 (m, 3H, phenyl), 8.17 ppm (m, 2H, phenyl); ms m^+/e calcd.: 226.0742; found: 226.0740.

*Preparation of 2-Phenyl-4-carbomethoxymethyl-5-acetyl-1,3-oxazole (**14**)*

To an ice-cooled anhydrous methanolic solution (500 ml) in a 1-ℓ flask containing 2-phenyl-4-cyanomethyl-5-acetyl-1,3-oxazole (19 g) was introduced anhydrous hydrogen chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

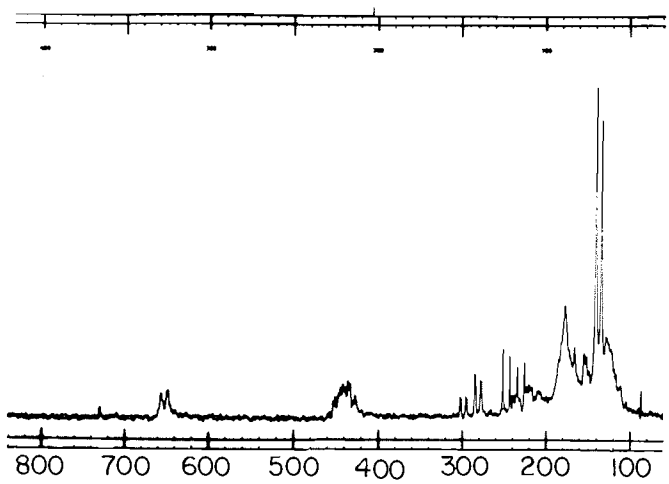

FIG. 5. The HA-100 spectrum of compound **23**.

until no absorption was visible. The flask was then securely stoppered and the solution stirred at room temperature for 24 h. The methanolic solution was evaporated under reduced pressure to give a light brown residue which was digested by chloroform (200 ml) and washed with water and bicarbonate solution (2%). The chloroform layer, dried over magnesium sulfate, was worked up as usual to give the crystalline 2-phenyl-4-carbomethoxymethyl-5-acetyl-1,3-oxazole (21 g), a sample of which was purified by recrystallization from ether, mp 98–99°C; ir: 1740 (ester), 1682 (ketone), 1600 (oxazole and phenyl), 1380 cm^{-1} (—CH_3); ms m^+/e: 259; nmr δ: 2.58 (s, —CH_3), 3.73 (s, —OCH_3), 4.05 ppm (s, 2H, —CH_2—). *Anal.* calcd. for $C_{14}H_{13}O_4N$: C 64.86, H 5.02, N 5.41; found: C 64.85, H 5.18, N 5.35.

*Preparation of 2-Phenyl-4-carboxymethyl-5-acetyl-1,3-oxazole (**13**)*

The methylester **14** (6.5 g) was dissolved in a mixture of glacial acetic acid (150 ml) and concentrated hydrochloric acid (50 ml). This solution was then saturated with hydrogen chloride and stirred for 90 h at room temperature. Under reduced pressure and at room temperature, most of the acetic acid was removed by evaporation and the residue was further diluted with water and extracted exhaustively by ethyl acetate. The ethyl acetate solution was treated as usual and evaporated to dryness at room temperature under reduced pressure to give a white solid residue (5 g) which was further purified by recrystallization from ethyl acetate, mp 194°C (dec. fast heating), ir (Nujol): 3200–2700 broad (—OH), 1735 (ester), 1690 (ketone), 1600 cm^{-1} (oxazole and phenyl). This compound was converted back to **14** by diazomethane for identification.

*Preparation of Oxazolino-α-pyrone (**19**)*

To a 2-ℓ flask was added the carboxylic acid **13** (5 g), chloroform (1-ℓ), and then thionyl chloride (25 ml). The solution was stirred at room temperature for 6 h under anhydrous conditions and evacuated occasionally to remove hydrogen chloride. The chloroform solution was then evaporated to dryness under reduced pressure and the solid residue was recrystallized from methylene chloride (3.8 g), mp 185–187°C (dec.); ir: 1730 (pyrone), 1680 and 1540 cm^{-1}; nmr δ: 2.51 (d, J = 0.8 Hz, 3H, —CH_3), 6.157 (q, J = 0.8 Hz, 1H, vinylic); ms m^+/e calcd. for $C_{13}H_9O_3N$: 227.0582; found: 227.0579.

*Preparation of 3-Benzamido-5-hydroxyhexanoic Acid Lactone (**22**) and 3-Cyclohexylcarbonylamino-5-hydroxyhexanoic Acid Lactone (**23**)*

Oxazolino-α-pyrone (**19**) (750 mg) in freshly distilled anhydrous ethyl acetone (150 ml) was hydrogenated in the presence of Adam's catalyst (400 mg) under atmospheric pressure for 4 h. After the catalyst was removed by filtration and the filtrate evaporated to dryness as usual, the clear oily residue was subjected to preparative tlc separation on silica plates developed by ethyl acetate. The top fraction at R_F 0.8 was identified as 2-phenyl-4-carbethoxymethyl-5-acetyl-1,3-oxazole (**15**) (48 mg), mp 52–53°C; ir: 1740 (ester), 1680 (ketone), 1600 cm^{-1} (oxazole and phenyl); ms m^+/e: 273; nmr δ: 1.33 (t, $3H_s$, —CH_2—CH_3), 2.58 (s, $3H_s$, CH_3), 4.04 (s, $2H_s$, —CH_2—), 4.30 (q, —CH_2—CH_3), 7.50 (m, $3H_s$, phenyl), 8.18 ppm (m, $2H_2$ phenyl). This compound is identical to the product obtained by dissolving the oxazolino-α-pyrone (**19**) in ethanol.

The second fraction at R_F about 0.5 was identified as 3-benzamido-5-hydroxyhexanoic acid lactone (**22**) overlapped with 3-cyclohexylcarbonylamino-5-hydroxyhexanoic acid (**23**). Purification by repeated separation and multiple development on silica plates with chloroform – ethyl acetate 15% and recrystallization from benzene–ether gave the lactone **22** (38 mg), mp 88–91°C; ir: 3450 (—NH), 1740 (lactone), 1675 (amide), 1610, 1590 cm^{-1} (phenyl of benzoyl compounds); nmr: Table 1 and Fig. 1; ms m^+/e calcd.: 233.1052; found: 233.1046.

From the area immediately below the fraction containing **22** was isolated the lactone **23** (270 mg) which was invisible under uv light. This compound was recrystallized from methylene chloride – ether mp 128–130°C; ir: 3450 (—NH), 1740 (lactone), 1680 cm^{-1} (amide); ms m^+/e: 239; nmr (Fig. 5) (HA-100) δ: 1.37 (d, $J_{CH_3-5_a}$ 6.2 Hz —CH_3), 2.37 (q, H_{2a}, J_{2a-2e} = 17.3 Hz, J_{2a-3a} = 8.4 Hz), 2.92 (d of q, H_{2e}, J_{2a-2e} = 17.3 Hz, J_{2e-3a} = 6.7 Hz, J_{2e-4e} = 1.2 Hz), 4.40 (m, H_{5a}) 6.52 ppm (broad d, —NH); ms m^+/e: 239. *Anal.* calcd. for $C_{13}H_{21}O_3N$: C 65.12, H 8.78, N 5.86; found: C 65.33, H 8.71, N 5.69.

Preparation of N-*Benzoyl-4-deoxy-*D,L-*daunosamine (3-Benzamido-2,3,4,6-tetradeoxy-*D,L-*threohexose) (**26**)*

To a benzene solution (20 ml) containing 3-benzamido-5-hydroxyhexanoic acid lactone (46 mg) was injected 0.4 ml of modified Red-al reagent prepared by adding isopropyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

alcohol (7 ml) slowly into a benzene solution (75 ml) containing the Red-al reagent (28 ml). The reaction mixture was stirred at room temperature for $1\frac{3}{4}$ h, washed with water and dilute hydrochloric acid, dried over magnesium sulfate, and evaporated to dryness yielding a semicrystalline residue which upon purification by tlc on silica plate developed by ethyl acetate, gave the *N*-benzoyl-4-deoxy-D,L-daunosamine (**26**) (28 mg), mp 104–109°C; ir: 3580 (—OH), 3430 (—NH), 1670 (amide), 1615 and 1590 cm^{-1} (phenyl ring of benzoyl group); ms m^+/e calcd.: 235.1208; found: 235.1213.

Similarly **23** (270 mg) was converted to the *N*-cyclohexanecarbonyl-4-deoxy-D,L-daunosamine (**27**) (180 mg) which could be purified by recrystallization from methylene chloride – ether, mp 172–176°C; ir: 3560 (—OH), 3430 (—NH), 1675 cm^{-1} (amide); ms m^+/e: 241. *Anal.* calcd. for $C_{13}H_{23}O_3N$: C 64.73, H 9.54, N 5.81; found: C 64.83, H 9.41, N 5.69.

Preparation of 4-Deoxy-D,L-daunosamine Hydrobromide

N-Cyclohexanecarbonyl-4-deoxy-D,L-daunosamine (70 mg) was heated at 100°C in a solution of acetic acid (5 ml) and hydrobromic acid (5 ml) for $1\frac{1}{2}$ h. The solution was evaporated to dryness under reduced pressure and the residue was digested with chloroform. The insoluble crystalline compound was filtered and could be recrystallized from methanol–chloroform; mp 199–210°C (slowly decomposing). This compound was converted back to *N*-benzoyl-4-deoxy-D,L-daunosamine (**26**) by reacting with benzoyl chloride and pyridine, followed by mild acid hydrolysis.

Biosynthetic studies of stress metabolites from potatoes: incorporation of sodium acetate-$^{13}C_2$ into 10 sesquiterpenes[1,2]

A. STOESSL, J. B. STOTHERS, AND E. W. B. WARD

Agriculture Canada Research Institute and the Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 12, 1977

A. STOESSL, J. B. STOTHERS, and E. W. B. WARD. Can. J. Chem. **56**, 645 (1978).

The results of incorporation studies of doubly-labelled sodium acetate-$^{13}C_2$ into the stress metabolites produced by fungal invasion of potato tubers are presented. The ^{13}C-labelling patterns for 10 sesquiterpenes have been determined by ^{13}C nmr. Two of these products have not been described previously and their structural elucidation is discussed. The biosynthetic interrelationships of these compounds are considered in detail.

A. STOESSL, J. B. STOTHERS et E. W. B. WARD. Can. J. Chem. **56**, 645 (1978).

On rapporte les résultats d'études d'incorporation d'acétate de sodium $^{13}C_2$ doublement marqué dans des métabolites de tension qui se forment sous l'effet d'une invasion fongique des rhizomes de patates. On a déterminé, grâce à la rmn ^{13}C, les types de marquage ^{13}C de dix sesquiterpènes. Deux de ces produits n'avaient pas été décrits antérieurement et on discute de l'élucidation de leurs structures. On considère en détail les rapports mutuels biosynthétiques de ces composés.

[Traduit par le journal]

Recently we reported in preliminary form, the results of incorporation of doubly-labelled acetate-$^{13}C_2$ into six sesquiterpenoidal stress metabolites of potatoes (1). Their biosynthetic mode of formation is of interest and the labelling studies provide information bearing on this question. In this paper we wish to present the full results for 10 sesquiterpenes isolated in these experiments, including 2 compounds which have not been described previously.[3]

The known compounds for which incorporation data were obtained are rishitin (**1**) (2), lubimin (**2**) (3–5), hydroxylubimin (**3**) (5, 6), phytuberin (**4**) (7, 8), desacetylphytuberin (phytuberol) (**5**) (9), solavetivone (katahdinone) (**6**) (10, 11), 15-dihydrolubimin (**7**) (4, 5), and isolubimin (**8**) (11). In general these compounds are generated by an incompatible fungus–potato interaction but other means of inducing their formation in potato tissue have been reported from several laboratories (12). The compounds are not found in any but minute traces in normal healthy potato tissue. In the present experiments, their synthesis was induced by inoculating potato tuber slices with either *Monilinia fructicola* or *Glomerella cingulata*. Sodium acetate, equally enriched to approximately 90% ^{13}C at both C-1 and C-2, was added 1 day after inoculation and the lipophilic metabolites which had been produced were extracted one day thereafter. The individual metabolites were isolated by careful chromatography on silica gel.

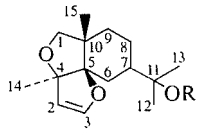
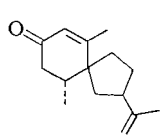
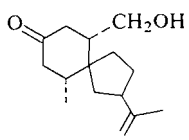
2 X = CHO, Y = H
3 X = CHO, Y = OH
7 X = CH_2OH, Y = H



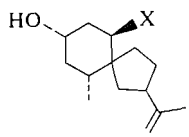
4 R = Ac
5 R = H



6



8



9 X = CHO
10 X = CH_2OH

Rishitin (**1**) was obtained in comparable amounts from both interactions but significant differences in quantity were found for the other sesquiterpenes. The *M. fructicola* interaction gave only a very small amount of **4** while **5** was probably produced in traces

[a]Data obtained for $CDCl_3$ solutions; shieldings in ppm from internal TMS and ^{13}C–^{13}C coupling constants (in parentheses) in Hz for directly bonded ^{13}C nuclei arising from a common acetate-$^{13}C_2$ unit.

but was not isolated; **6** was not detected. Two new compounds were isolated in very small amounts and were characterized as 10-epilubimin (**9**) and 15-dihydro-10-epilubimin (**10**) from the following results.

Compound **9** proved difficult to separate from **2** but was isolated as a syrup by multiple chromatography. An exact mass determination showed **9** to have the composition $C_{15}H_{24}O_2$. Its mass spectrum was strikingly similar to that of **2**. The infrared spectrum revealed the presence of a hydroxyl group, an aldehyde, and a terminal double bond. These features were all confirmed by the proton spectrum which contained absorptions for a formyl proton at 9.84 ppm as a triplet with spacings of $\sim$1 Hz, olefinic methylene protons at 4.68 ppm as a multiplet, and a carbinyl proton, 3.69 ppm, also as a multiplet. Of these patterns that for the formyl proton differs from the corresponding absorption for **2** by 0.06 ppm and in multiplicity since the latter is a doublet. The other absorptions are essentially identical for **2** and **9** and, further, a methyl doublet, 0.94 ppm, $J \sim 7$ Hz, and a broadened methyl singlet, 1.70 ppm, appear for both compounds. These data suggested that **9** is a stereoisomer of **2**, a conclusion which was strongly supported by a comparison of their ^{13}C spectra. Of the 15 signals in the decoupled spectrum of **9** those for an aldehydic carbonyl, 205.5 ppm, an isopropenyl group, 147.6, 108.5, and 21.4 ppm, a carbinyl carbon, 66.6 ppm, a secondary methyl, 17.0 ppm, and a second quaternary carbon, 46.3 ppm, were readily identified. These shieldings correspond closely with those for **2** (Table 1). From the ^{13}C spectrum of **9**-$^{13}C_x$, isolated from the enriched acetate feeding experiment, the immediate neighbors for the individual signals noted were readily identified and it was apparent that three carbons arose from C-2 of the mevalonate units since these lacked the ^{13}C satellites found for the pairs of carbons arising from intact acetate units in mevalonate. By comparison of the shieldings for **9**, with those for **2**, assignments were straightforward. The increased shieldings for the methine carbon bearing the secondary methyl group and for the carbinyl carbon, combined with the decreased shielding for C-9, constitute good evidence that **9** and **2** differ only in orientation of the aldehyde function. It is equatorial in **2** and would exert a shielding γ *gauche* effect at C-9, but if axial, the carbinyl and methine carbons (C-2 and -4, respectively) would be shielded by γ *gauche* interactions with the formyl group while C-9 would be expected to be less shielded. The remaining carbons should be little affected as is observed with the exception of C-8. The 1.9 ppm shift for this carbon is not readily explained but may reflect an alteration in the preferred conformation of the isopropenyl group. The

For personal use only.

ord curves for **2** and **9** confirmed the conclusion regarding the aldehyde orientation since **9** exhibited a distinctly negative Cotton effect while the Cotton effect for **2** was strongly positive (4).

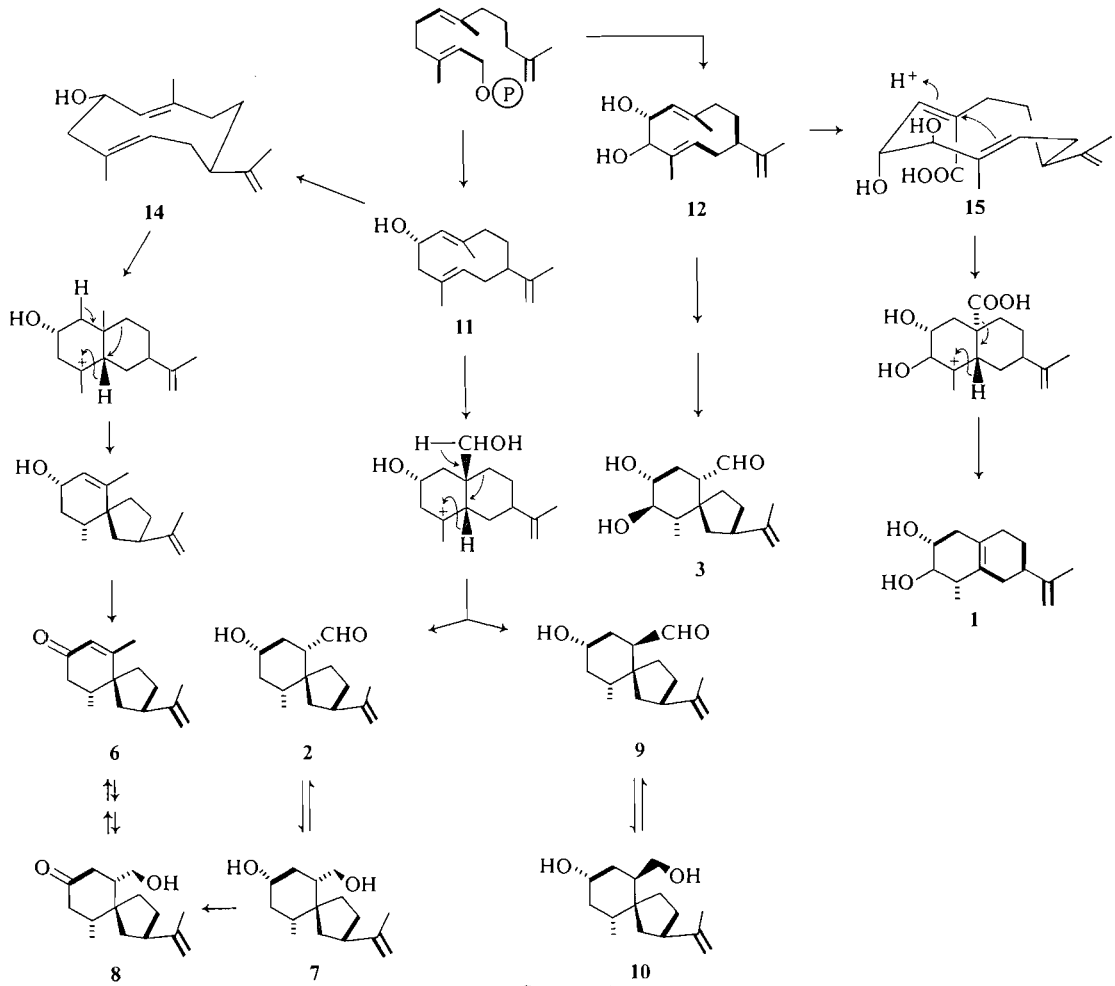
On treatment with sodium borohydride **9** furnished a diol as the major product which was found to be identical to **10** isolated from the products obtained from the *M. fructicola* interaction. Diol **10** is a crystalline compound whose mass spectrum was almost superimposable on that of **7** of which it is an isomer since an exact mass determination showed its molecular formula to be $C_{15}H_{26}O_2$. Although the two compounds are not separable by preparative tlc, pure **10** was isolated by preferential crystallization with mp 138–140°C which was depressed to 106–120°C upon admixture with **7**, mp 126–128°C. The proton spectrum of **10** was very similar to that of **7** with characteristic absorptions for olefinic methylene protons at 4.68 ppm, a vinyl methyl group at 1.70 ppm and a secondary methyl at 0.85 ppm, $J \sim 7$ Hz. A three-proton multiplet centred near 3.7 ppm could be ascribed to a single carbinyl proton and the methylene absorption of an hydroxymethyl group. The AB pattern for the hydroxymethyl group was revealed by spin decoupling at 1.65 ppm. The chemical shift difference of 0.15 ppm for these methylene protons is much smaller than that found for **7**, 0.6 ppm, and the pattern obscured the absorption of the carbinyl methine centre in contrast to the spectrum for **7**. The ^{13}C spectrum of **10** was also similar to that of **7** (Table 1). Readily identified signals included those for a carbinyl methine and hydroxymethyl group at 66.6 and 62.1 ppm, respectively, an isopropenyl group, 148.4, 108.2, and 21.5 ppm, a secondary methyl carbon, 17.2 ppm, and a second quaternary carbon at 46.4 ppm. The ^{13}C-labelled material, from the acetate-$^{13}C_2$ feeding experiment, gave a ^{13}C spectrum from which it was apparent that three signals arose from C-2 of mevalonate units and that the product contained six intact acetate units. Significant upfield shifts for C-2 and -4, as well as the hydroxymethyl carbon, together with the downfield shift for C-9, all relative to the corresponding shieldings for **7**, establish the orientation of the 15-hydroxymethyl group as axial. The formation of **10** from **9**, by analogy with the **2** → **7** reduction, confirmed the relationship between the compounds. Their absolute stereochemistries follow from the correlation with **2** which, in turn, has been related by its ord curve (6) to **3** whose full stereochemistry is known (13).

The potato – *G. cingulata* interaction gave considerably more extractable material than that with *M. fructicola* and the extract appeared to be more complex. Numerous metabolites accrued in very small amounts but **1**, **4**, **5**, and **6** were found in relatively large and readily isolable quantities. Although there was evidence of the presence of **3**, the amount was too small to allow its isolation. Lubimin (**2**) was obtained only in admixture with **8** and **9** as was readily apparent from the ^{13}C spectrum which contained three carbonyl absorptions, as well as three carbinyl carbon signals, one of which arose from a methylene carbon, and three secondary methyl signals. In addition, the appearance of signals at 50.0 and 36.9 ppm with relative intensities corresponding to those of the absorptions noted above for **8** and **9**, respectively, confirmed the presence of these compounds in the mixture since these absorptions are well separated from other peaks in the spectra of the three compounds. The remaining signals coincided with those listed for **2**, **8**, and **9** in Table 1.

These assignments were substantiated by the eventual isolation of essentially pure isolubimin (**8**) from an adjacent fraction. Compound **8** has been described previously (11) but its ^{13}C spectrum has not been reported, nor has the hydroxymethyl absorption in its proton spectrum been fully described. The latter is informative by comparison with that for **7** since the two patterns are very similar. This AB portion of an ABX pattern has $\delta_{AB} = 0.5$ ppm (cf. 0.6 ppm for **7**) suggesting the same stereochemistry for this group in both compounds since $\delta_{AB} = 0.15$ ppm for **10** having an axial CH_2OH. The ^{13}C shieldings for **8** are listed in Table 1 and the spectrum established that the material arose from six intact acetate units with three carbons from C-2 of mevalonate units.

Somewhat surprisingly, **7** was produced in the largest amount in the *G. cingulata* – potato interaction and was accompanied by only traces of its epimer **10**. The latter were revealed by the nmr spectra of mother liquors from which **7** had crystallized. There is little doubt that **7** arose primarily from fungal reduction of **2** since it is known that this process occurs readily in pure culture (14). However, it seems likely that at least a portion of **7** was formed by the action of host rather than fungal enzymes. This suggestion follows from the fact that a careful search revealed a very small quantity of **7** in *M. fructicola* – potato extracts, although this fungus does not appear to effect the reduction of **2** in pure culture (14). Biosynthetically, **7** is as likely to stand in a precursor as in a product relationship to **2**, although it may then only occur in an enzyme bound form. Of course, the two compounds may be in an equilibrium relation. A similar situation obtains for **9** and **10** and it is conceivable that the four terpenes may be dynamically related as shown in Scheme 1. These possibilities are receiving further attention.

We can now turn to a consideration of the biosynthetic information provided by this study. The



SCHEME 1

use of acetate doubly-labelled with ^{13}C and ^{13}C spectroscopy of the isolated metabolites proved to be both convenient and highly informative. A major disadvantage associated with biosynthetic studies of higher plants is that frequently only low levels of incorporation are achieved. Fortunately, this problem did not arise in these studies, nor in earlier experiments by Brooks and his associates (15) because the production of metabolites under stress conditions assured their *de novo* synthesis and, consequently, relatively high levels of incorporation. The lowest levels encountered in the present work were of the order of 0.7% enrichment and at this level useful ^{13}C spectra can be obtained on as little as 0.004 mmol of substance. The advantages of utilizing doubly-labelled acetate-^{13}C for biosynthetic studies with ^{13}C nmr techniques have been illustrated by several workers and we need only note that for terpenes the incorporation of acetate-$^{13}C_2$ into mevalonate units yields mevalonate with two intact acetate units and one carbon (C-2) which has lost its original neighbor. For sesquiterpenes formed without rearrangement or cleavage of the farnesyl chain, the ^{13}C spectrum of an enriched product contains six pairs of signals having ^{13}C satellites for each of the six intact acetate units, and three enhanced signals lacking prominent satellites which arise from C-2 of the mevalonate units. The spacing of the satellites is the ^{13}C–^{13}C coupling constant across a specific C—C bond and pairwise matching of the spacings permits unequivocal assignments of specific signals in many cases. For each of the metabolites isolated in this study, the ^{13}C shieldings and ^{13}C–^{13}C one-bond couplings have been collected in Table 1. Although the majority of these data had been reported previously it seemed worthwhile to gather these together for ease of comparison with the results for the new compounds. A few of the earlier assignments have been revised on the basis of the spectra of the enriched products. For example, the allylic methyl

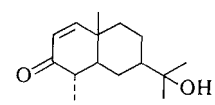
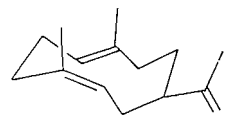
[a]From the relative intensities of the ^{13}C satellites and central signals (see text), ±0.2%.
[b]Amounts in parentheses obtained in the mixtures noted.
[c]In a mixture of **2**, **8**, and **9**.
[d]In a mixture of **7** and **10** from the mother liquors of **7**.

carbons in **6** arise from different carbons in the mevalonate precursor with C-13 from C-2 and C-15 from C-3′. Thus the latter will give rise to an absorption pattern with readily observable satellites, while the former appears as a singlet, clearly distinguishing the two and providing unequivocal assignments. In addition to revealing the biosynthetic mode of formation of the metabolites the ^{13}C spectrum of the enriched products provides a direct measure of the incorporation level from the relative intensities of the satellites and the central signal. A detailed analysis of the quantitative dependence of the intensities of multiplet lines produced by ^{13}C–^{13}C coupling as a function of ^{13}C enrichment has been published (16). In the present series, the signals for C-12, -14, and -15 readily provided the requisite data while the carbinyl patterns for a number of the examples were also analyzed. The enrichment levels determined from these absorption patterns are listed in Table 2.

With the exception of **1**, **4**, and **5**, these metabolites contained six intact acetate units (see Table 1) since prominent ^{13}C satellites were observed for 12 of the 15 signals which corresponded to the 15 singlets found for samples containing ^{13}C in natural abundance. This observation limits the possible modes of formation of the spirovetivane skeleton from a farnesyl chain, which is almost assuredly the primary C_{15} precursor. A plausible scheme to account for the genesis of **1–3** and **6–10** is illustrated in Scheme 1 in which intact acetate units are indicated by heavy bonds. On the basis of the available data for the stress metabolites of the *Solanaceae* the product of a most reasonable initial cyclization is the germacrenol **11**. Earlier we established the formation of the more highly oxidized analog **12** in *M. fructicola* – *Datura stramonium* interactions (13*a*) and preliminary tracer experiments in these laboratories indicate that **12** is not involved in the generation of **2** but does lead to **3**. The cyclodecadiene ring of **11** (and **12**) may adopt a variety of conformations and consideration of these possibilities led us to propose a scheme which accounts for the known stereochemistries of **1**, **2**, and **3** as well as that for an additional metabolite, aubergenone (**13**), formed in *Solanum melongena* (4). The question of preferred conformation and stereoselectivity in the cyclization of *E,E*-1,5-cyclodecadienes has been considered in detail by Sutherland (17). Laboratory studies support the contention that the CC conformation, in Sutherland's terminology, is highly preferred for the transition state leading to the *trans*-decalin skeleton as the major product. Such a conformation is required for our proposed route to **13** but generation of the spirovetivane skeleton appears to require the TT conformation **14** while the



13



16

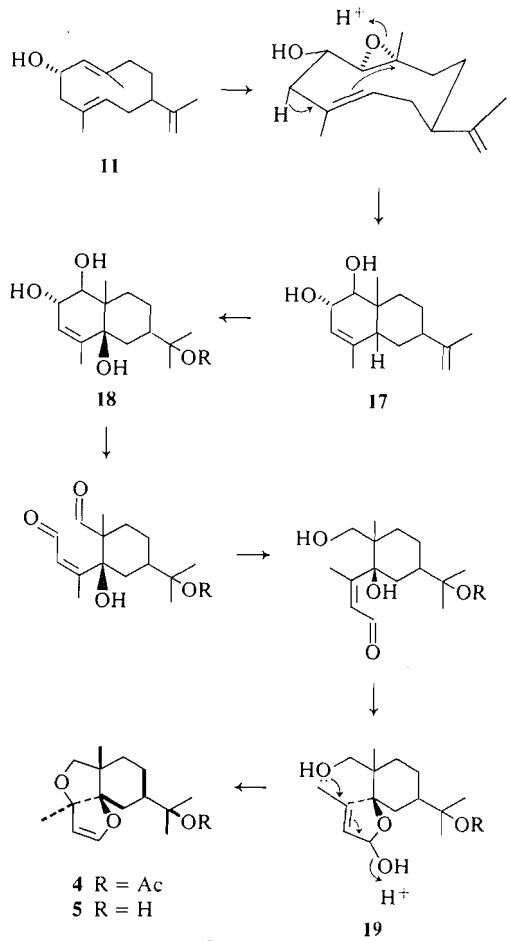
CT conformation **15** nicely accounts for a cyclization which can lead readily to rishitin. Although **14** and **15** are disfavored in laboratory studies it is not unreasonable to suggest their intermediacy in living systems involving enzymic processes, as has been noted by Coates (18). An alternative pathway, not included in Scheme 1, can be suggested, namely, isomerization to the 1*E*,5*Z* configuration followed by cyclization. In this case the CT conformation **16** would be expected to form a *cis*-decalin skeleton on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

cyclization from which the generation of the spirovetivane system is readily envisaged. It has been shown that the CT conformation is favored for the parent diene (19) in the solid state. Since **11**, however, can adopt the suitable conformation **14** it seems unnecessary to include an additional step, the isomerization, at this stage of investigation.

Cyclization of **14** to a *cis*-decalin, followed by proton loss and ring contraction as shown in Scheme 1 requires only oxidation of the allylic alcohol to the conjugated ketone to afford **6**. Analogous transformations have been discussed for closely related systems (18, 20). A corresponding cyclization of **11**, after allylic oxidation at the methyl carbon, would lead to **2** (and **9**). Proton loss from the hydroxymethyl group furnishes the enol form of the aldehyde function which upon tautomerization would be expected to produce a mixture of epimeric aldehydes **2** and **9**, with the former favored. Ring contraction by cleavage of the 9,10 carbon–carbon bond with formation of a 5,9 linkage does not rupture an intact acetate unit since C-9 originates from C-2 of mevalonate. Reduction of the aldehyde to a hydroxymethyl group gives **7** and **10** which, as suggested above, may undergo selective oxidation back to **2** and **9**, respectively. No evidence on this point is yet available. Oxidation of the secondary hydroxyl of **7**, however, provides **8** directly from which **6** could conceivably arise by dehydration and facile double bond isomerization. The reverse interconversion, **6** → **8** → **2** has been reported to occur in vivo (11) but without evidence from tracer studies. Allylic oxidation of **12** forms **15**, shown in a CT conformation, which can cyclize to a *trans*-decalin skeleton, decarboxylation of which with a hydride shift furnishes **1**. The loss of carbon dioxide cleaves a C—C bond of an intact acetate unit and four signals in the ^{13}C spectrum of **1**-$^{13}C_x$ were found to lack prominent ^{13}C satellites, as expected.

In contrast to the foregoing examples the ^{13}C spectra of the enriched samples of **4** and **5** clearly revealed only five intact acetate units. A feasible sequence leading to the phytuberin skeleton is outlined in Scheme 2 in which **11** is envisaged as the initial cyclization product in common with many of the co-occurring metabolites. Upon epoxidation of the 1,10 double bond and adoption of the CT conformation indicated the second cyclization can lead to *cis*-decalin **17**. Allylic oxidation to furnish the tertiary allylic alcohol **18** seems reasonable and has analogy in a closely related system since a *cis*-decalol derivative, β-rotunol, has been isolated from nutgrass (20*a*). It may be noted that β-rotunol readily undergoes dehydration to furnish a spirovetivone derivative (20*a*). Although hydration of the 11,12 double



SCHEME 2

bond is also included in Scheme 2 at this point, there is no evidence of the precise stage at which this occurs. It is indicated here merely to simplify the scheme but may well occur at another stage. Cleavage of the vicinal diol **18** followed by hemiacetal formation to afford **19** accounts nicely for the generation of the dihydrofuran ring having the correct stereochemistry at C-5. Furthermore, the orientation of this ring in **19** leads directly to the correct product from the final cyclization, which is essentially an S_N2' process with water as the leaving group. This sequence accounts for the formation of **4** (**5**) in a more complete fashion than our earlier proposals.

It is interesting that the level of enrichment found for **4** and **5** is distinctly lower than that observed for the other metabolites isolated from the *G. cingulata* interaction. While this may be an indication that the generation of **4** and **5** involves a sequence significantly different from that proposed with a precursor other than **11**, no other evidence is currently available. It is also remarkable that the metabolites from the *Monilinia* experiment are enriched to nearly the same

TABLE 3. Basic fractionation of metabolites from fungus–potato interactions

Fungus	Fraction	Weight (mg)	Compounds (isolated and/or characterized)	1st refractionation[b] solvent
M. fructicola[a]	13–17	8	**4**	B (tlc)
	18–25	45	**9, 2**	C
	29–32	24	**2, 1**	A

[a]On silica with solvent A [b] as described in the text.
[b]Columns of silica gel (Camag DF5, unactivated, ca. 1 g/mg substrate) were used unless tlc is specified. In the latter case, plates were activated at 120°C. Solvents were: A, MeOH–$CHCl_3$ (5:95); B, Et_2O – light petroleum (1:1); C, Et_2O; D, *sec*-BuOH–EtOAc (5:95).
[c]On silica with a succession of solvents as described in the text.

degree. It could be argued that this implies sequential elaboration of one compound from another but concurrent elaboration of the individual compounds from a common precursor cannot be dismissed. Further investigations of both of these points are clearly required. The essentially equal labelling at all sites found for each compound, as is readily seen in the previously published spectra (1), implies the nonintervention of preformed metabolic pools such as geranyl pyrophosphate and almost certainly requires an uninterrupted sequence of synthesis of farnesyl pyrophosphate on the same enzyme (21). The intensity of labelling in the isopropenyl side chains confirms the absence of allylic shifts in agreement with the earlier findings for capsidiol (22).

Experimental

General

Melting points were determined on a Kofler hot stage and are uncorrected. The spectrometers employed included a Varian MAT 311A for mass spectra, a Varian XL-100-12 for ^{1}Hmr, a Varian XL-100-15 for ^{13}Cmr and a Beckman IR20A for ir spectra. A Jasco ORD-UV5 instrument was used to obtain ord curves (path length, 0.1 dm). Solvents were redistilled before use; light petrol was of bp 30–60°C and EtOH refers to 96% EtOH.

Nuclear Magnetic Resonance Spectra

Fourier transform methods were used to obtain ^{13}C spectra with square wave modulated proton decoupling for completely decoupled spectra or with single frequency proton irradiation for off-resonance decoupled spectra. Shielding data (±0.05 ppm) are reported for $CDCl_3$ solutions (5–10%, w/v) with TMS as internal reference; coupling constants (±0.5 Hz) were measured from expanded spectra. Smaller samples of enriched material (0.5–2 mg) were examined as CD_2Cl_2 solutions in 50 µl microcells. Proton spectra were recorded for the $CDCl_3$ solutions.

Feeding Experiments

Potato tubers, 54 kg, cultivar Kennebec, grown and purchased locally and kept at 4°C until used, were scrubbed with tap water, briefly surface-sterilized with 70% ethanol and cut into ca. ½ in. slices. These were inoculated by the method of Metlitskii *et al.* (3), by scooping out several hemispherical wells (diameter, ca. 2 cm) from one surface of each slice with a melon baller. After charging the wells with a spore suspension of *Monilinia fructicola* (Wint.) Honey (2×10^5 spores/ml; 2 ml per well; ca. 4 ℓ total), the slices were incubated for 18 h at room temperature in glass-covered trays lined with moist filter paper. A solution containing sodium acetate-1,2-$^{13}C_2$ (0.984 g; 90 at.% ^{13}C) in 400 ml of water was then added (0.20 ml/well; 393 ml total). After incubating the slices for another 30 h, the liquid (the 'diffusate') was collected and the wells were rinsed with a little water. Diffusate and washings were combined (4.2 ℓ) and extracted with three successive half-volumes of ether. The ether layers were washed in turn with two small portions of water, combined, dried (Na_2SO_4), filtered, and evaporated to furnish 213 mg of crude extract.

In a similar experiment *Glomerella cingulata* (Stonem) Spauld and Schrenk (5×10^5 spores/ml; total 3 ℓ) was used to inoculate Kennebec potatoes (29 kg) 24 h before treatment with sodium acetate-1,2-$^{13}C_2$ (90 at.%; 0.714 g). Extraction of the diffusates and washings with methylene chloride after another 30 h gave 742 mg of crude extract.

Isolation and Characterization of Metabolites from the M. fructicola Interaction

The crude extract was chromatographed over a column of silica gel (Camag DF5; not activated, 350 g) in solvent A (Table 3); 64 25-ml fractions were collected. Fractions of similar composition as shown by tlc were combined (Table 3) and rechromatographed in one or more of the indicated systems. The compounds isolated in this experiment were characterized as follows.

(*a*) Phytuberin (**4**) required no purification beyond that indicated in Table 3. Except for isotope peak intensities, its mass spectrum substantially matched that of an authentic specimen kindly supplied by Professor J. Kuć. The amount of material isolated (< 1 mg) precluded a precise determination of ^{13}C enrichment by ^{13}Cmr.

(*b*) Epilubimin (**9**) still containing a trace of **2** (tlc) had ν_{max} (CCl_4): 3410 (br), 3060 (w), 2940, 2865, 2730 (w), 1645 and 892 cm^{-1}. *Exact mass* calcd. for $C_{15}H_{24}O_2$: 236.1776; found (high resolution ms): 236.1777. A dilute solution of **9** in EtOH exhibited a pronounced negative Cotton effect (λ_{min} 336, 324, λ_{max} 300 nm; for **2** λ_{max} 323, λ_0 300 nm) but insufficient material was available to permit quantitative measurements.

A small quantity (ca. 1 mg) of the substance in MeOH (1 ml) was treated with sodium borohydride (4 mg) at room temperature. Reduction was complete after 2 min (tlc). The main product, extracted with ether and purified by preparative tlc and sublimation (85°C/20 Torr) was identical with naturally occurring **10** by tlc, mp, and mixture mp.

A mixture (21 mg) of 9 and **2** in a ratio of 1:2 was also obtained by column chromatography of the crude extract (181 mg) from the interaction of potatoes (34 kg) with a *M. fructicola* suspension (3.8 ℓ) without added sodium acetate. Rechromatography (solvent D, 40 g SiO_2) afforded **9** (2.6 mg) containing only traces of **2**. This material was employed to confirm the assignments in the ^{13}C spectrum. The ord curve of this specimen did not differ in any significant aspect from that described above for enriched **9**.

(*c*) Lubimin (**2**) was purified by further preparative tlc (solvent C). Its identity was confirmed by ms comparison with authentic specimens (4, 6).

(*d*) Rishitin (**1**) was obtained as a syrup (34 mg) from fractions 33–44 by one refractionation (Table 3). More of the compound (35 mg) was isolated by rechromatography of other fractions.

(*e*) Hydroxylubimin (**3**) crystallized after preparative tlc (solvent A) of enriched fractions. Two recrystallizations from ether gave pure material, mp 95–97.5°C (6).

(*f*) 15-Dihydro-10-epilubimin (**10**) crystallized after preparative tlc (solvent D) of enriched fractions and was recrystallized from $CHCl_3$ at −10°C, mp 138–140°C. *Exact mass* calcd. for $C_{15}H_{26}O_2$: 238.1933; found (high resolution ms): 238.1936.

Compounds **7** and **10** had almost identical R_f values in most tlc solvents examined but were partially separated in *i*-PrOH–EtOAc, 1:9 (solvent E) with R_f values, ca. 0.32 and 0.30, respectively. The two materials could be further distinguished by their slightly different color reactions with a vanillin–phosphoric acid spray reagent (23) (**7**, purple fading to olive-brown; **9**, purple, fading to mauve).

The mother liquors from which **10** had crystallized contained a small amount of **7**, in addition to **10** and other compounds, as shown by tlc. Compounds **7** and **10** were also detectable in other impure fractions obtained during rechromatography of initial fractions 33–54 (Table 3). Column chromatography of the combined material (8.5 mg) in solvent E afforded a fraction (2.6 mg) which consisted of **7** and **10** in a ratio of ca. 1:2.5, to judge from the ^1Hmr and ^{13}Cmr spectra.

Isolation and Characterization of Metabolites from the G. cingulata *Interaction*

The crude extract was chromatographed over a column of silica (Camag DF5, 350 g) with solvent B (fractions 1–20), solvent C (fractions 21–50), MeOH–Et_2O, 5:95 (solvent F, fractions 51–115), and finally MeOH–Et_2O, 1:9 (fractions 116–130). Fractions (25 ml each) were combined as indicated in Table 3 and refractionated as necessary. Incorporation data for the characterized materials are listed in Table 2.

(*a*) Phytuberin (**4**) was obtained pure from the initial chromatogram and was identical with Professor Kuć's specimen by tlc, ^1Hmr, ^{13}Cmr, mass, and ir spectra.

(*b*) Solavetivone (**6**), $[\alpha]_D$ −96° (*c* 0.5, EtOH), was found to be identical with a sample provided by Dr. D. T. Coxon by tlc, uv, ir, and mass spectra.

(*c*) Desacetylphytuberin (**5**) was identified by its ^1H and ^{13}C spectra but the sample decomposed before further characterization was done.

(*d*) Isolubimin (**8**) was isolated as a syrup, ν_{max} (CCl_4): 3400 (br), 3050 (w), 2940, 2860, 1710 (s), 1640 (m), and 885 cm^{-1}. Its nmr spectral data were discussed above. *Exact mass* calcd. for $C_{15}H_{24}O_2$: 236.1776; found (high resolution ms): 236.1779.

(*e*) Lubimin (**2**) was obtained in admixture (27 mg) with **8** and **9**; these compounds were present in the ratio of 6:3:1 to judge from the ^{13}C spectrum.

(*f*) Rishitin (**1**) required further chromatography (solvent E) for final purification.

(*g*) 15-Dihydrolubimin (**7**), after recrystallization from Et_2O, was identical with material prepared by the sodium borohydride reduction of **2** (4) by mp, mixture mp, tlc, nmr, and mass spectra. The mother liquors from the recrystallization were repeatedly refractionated by tlc (solvent D and MeOH–$CHCl_3$, 1:9) to give a mixture (15 mg) which was shown to contain **7** and **10** in a ratio of 2:1 by the ^{13}Cmr spectrum.

Pyrrole chemistry. XIX. Reactions of 2-pyrrolecarbonitrile and its 4-substituted derivatives

HUGH J. ANDERSON, CYRIL R. RICHE, THOMAS G. COSTELLO, CHARLES E. LOADER, AND GRAHAM H. BARNETT

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received October 17, 1977

HUGH J. ANDERSON, CYRIL R. RICHE, THOMAS G. COSTELLO, CHARLES E. LOADER, and GRAHAM H. BARNETT. Can. J. Chem. **56**, 654 (1978).

2-Pyrrolecarbonitrile has been acylated to its 4-formyl, trichloroacetyl, ester, and thiolester derivatives. Further reactions gave other 2,4-difunctionalized compounds. These included conversion of the 2-nitriles to the corresponding 2-aldehydes. Subsequent removal of the aldehyde group afforded several 3-substituted pyrroles in good yield.

HUGH J. ANDERSON, CYRIL R. RICHE, THOMAS G. COSTELLO, CHARLES E. LOADER et GRAHAM H. BARNETT. Can. J. Chem. **56**, 654 (1978).

On a acétylé le pyrrolecarbonitrile-2 et on a ainsi obtenu ses dérivés formyle, trichloroacétyle, ester et thioester en position 4. Des réactions subséquentes permettent d'obtenir d'autres composés difonctionnalisés en 2,4. Parmi ceux-ci, on en a obtenus qui correspondent à la transformation de nitriles-2 en aldéhydes-2 correspondants. L'élimination subséquente du groupe aldéhyde permet d'obtenir, avec de bons rendements, plusieurs pyrroles substitués en position 3.
[Traduit par le journal]

Selective Friedel–Crafts 4-acylation of 2-substituted pyrroles is an essential step in the preparation of 3-acylpyrroles by the currently available methods. In an effort to improve the route to 3-substituted pyrroles we have investigated in more detail the Friedel–Crafts acylation of 2-pyrrolecarbonitrile which had been found to undergo acylation almost exclusively in the 4-position and in excellent yield (1). Recently we reported an improved synthesis of 2-pyrrolecarbonitrile (2) avoiding the rather tedious earlier synthesis (3). The newer nitrile synthesis has now been carried out on a molar scale without decrease in yield. The cyano group offers the possibilities of hydrolysis to the acid, partial reduction with aldehyde formation, as well as complete reduction to the aminomethyl group. Therefore, we decided to explore the synthesis from the 2-nitrile of 2,4-disubstituted pyrroles which were either not known or not readily available. Among the useful carbon functional groups we wished to introduce in the 4-position were the formyl, ester, and the thiol ester as well as a second nitrile group.

Treibs and Kreuzer (4) have shown that pyrrole may be trichloroacetylated easily and that a haloform type reaction then gives the carboxylic acid. The recent modification by Harbuck and Rapoport (5) affords the more useful ester group. 2-Pyrrolecarbonitrile neither reacted with trichloroacetyl chloride using the literature method nor did it undergo a mild Friedel–Crafts acylation using the aluminum chloride – nitromethane complex as catalyst. However, a normal Friedel–Crafts acylation in methylene chloride using aluminum chloride catalyst gave about 40–45% yield of 4-trichloroacetyl-2-pyrrolecarbonitrile. This compound was converted in excellent yield to the desired methyl 2-cyano-4-pyrrolecarboxylate. The same reaction sequence when applied to methyl 2-pyrrolecarboxylate gave an excellent overall yield of methyl 2,4-pyrroledicarboxylate.

Oxalyl chloride acylation was also used by Treibs (4) and the oxalyl group has found some use in earlier pyrrole chemistry (6). We expected that a regular Friedel–Crafts acylation followed by work-up with cold methanol might produce methyl 2-cyano-4-pyrroleglyoxylate. However, instead we obtained methyl 2-cyano-4-pyrrolecarboxylate in a 'one-pot' operation. This loss of carbon monoxide from oxalyl chloride in Friedel–Crafts acylation is common (7), although glyoxylic derivatives may be formed as well. Indeed, the infrared and mass spectra of the crude product indicated the probable presence of a small amount of methyl 2-cyano-4-pyrroleglyoxylate.

The thiol ester group offers the possibility of conversion to aldehyde, hydroxymethyl, and methyl (8) as well as to other acid derivatives. Alkyl chlorothiolformates have been used as Friedel–Crafts acylating agents for benzene and a number of benzene derivatives (9). We were successful in using ethyl chlorothiolformate with aluminum chloride catalyst to obtain a very good yield of ethyl 2-cyano-4-pyrrolethiolcarboxylate. If the work-up was slow, some hydrolysis to the 4-acid-2-nitrile was observed.

Friedel–Crafts type formylation using dichloromethyl butyl ether with $AlCl_3$ catalyst gave 4-formyl-2-pyrrolecarbonitrile in good yield although the reaction required carefully controlled conditions. Attempts to acylate the 2-nitrile using ethyl malonyl

chloride and aluminum chloride were unsuccessful and the nitrile was recovered unchanged. Similarly, cyanogen bromide and aluminum chloride failed to produce the 2,4-dinitrile from 2-pyrrolecarbonitrile.

We have demonstrated (10) that the 2-nitrile can be alkylated with *tert*-butyl chloride in the presence of aluminum or gallium chloride as catalyst; the latter giving the least rearrangement of 4-*tert*-butyl to 5-*tert*-butyl-2-nitrile. So this method, together with reduction of the acylated derivatives, may be used to obtain 4-alkylated 2-nitriles.

It has been reported that neither the 2-ester-4-nitrile nor the 3-nitrile itself undergo Stephen type reduction (11). We have now determined that modified Stephen type reductions will convert 4-substituted 2-pyrrolecarbonitriles to the corresponding 2-aldehydes. Of the methods tried, Raney nickel alloy in formic acid (12) was the most reliable and gave the required aldehydes in good yields. In particular, this method cleanly converted ethyl 2-cyano-4-pyrrolethiolcarboxylate to ethyl 2-formyl-4-pyrrolethiolcarboxylate without desulfurization of the thiolcarboxylate group. This provides a convenient route to 4-substituted 2-pyrrolecarboxaldehydes which are not easily obtained from 2-pyrrolecarboxaldehyde itself (1).

In our earlier work involving the replacement of the thiolester group by hydrogen, using W5 Raney nickel catalyst in a catalytic decarbonylation reaction (13) we had also observed that pyrrolecarboxaldehydes were decarbonylated under very mild conditions. Using this method, 4-acetyl-2-pyrrolecarboxaldehyde and methyl 2-formyl-4-pyrrolecarboxylate were readily decarbonylated to give 3-acetyl pyrrole and methyl 3-pyrrolecarboxylate respectively. Although catalytic decarbonylation reactions of this type are not unusual (14), in the presence of Raney nickel, 2-pyrrolecarboxaldehydes decarbonylate remarkably easily.

Thus, 2-pyrrolecarbonitrile may be converted in good yield to a number of 2,4-disubstituted pyrroles possessing useful functional group combinations. It may also be used to synthesize certain 3-substituted pyrroles.

Experimental

Melting points are uncorrected. Elemental analyses were by Alfred Bernhardt, West Germany, Atlantic Microlabs, GA, U.S.A., or by Memorial University Water Analysis Facility. The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer using potassium chloride discs. The ^{1}Hmr spectra were determined using a Varian EM 360 instrument. Values are given on the δ scale using tetramethylsilane as internal reference. Mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6E spectrometer using a direct inlet system.

2-Pyrrolecarbonitrile

This compound was prepared on a 1-mol scale in 50% yield using methyl thiocyanate instead of ethyl thiocyanate (2). Much of the unreacted pyrrole could be recovered.

Trichloroacetylation of 2-Pyrrolecarbonitrile

This reaction was carried out by normal Friedel–Crafts procedures (13) using 2-pyrrolecarbonitrile (10.0 g, 0.11 mol), trichloroacetyl chloride (25.0 g, 0.14 mol) and aluminum chloride (35 g, 0.25 mol) in methylene chloride for 2.5 h at reflux. The bright yellow reaction mixture was poured onto a mixture of ice and 6 *M* HCl and then extracted with chloroform three times. The organic layer was washed with cold water, dried ($MgSO_4$), and the solvent removed under vacuum to give a light brown solid. The solid was washed with a little cold carbon tetrachloride to remove color and unreacted 2-pyrrolecarbonitrile. The product, 4-trichloroacetyl-2-pyrrolecarbonitrile, (12.5 g, 48%) had (after sublimation) mp 138–139°C; ir ν: 1680 (CO), 2245 cm^{-1} (CN); nmr (DMSO-d_6) δ: 7.45 (m, 1H), 8.02 (m, 1H), ~13.2 (b, 1H), $J_{3,5}$ = 1.6 Hz; *m/e* 236 ($^{35}Cl_3$), 238 ($^{35}Cl_2{}^{37}Cl$). *Anal.* calcd. for $C_7H_3Cl_3N_2O$: C 35.41, H 1.27; found: C 35.55, H 1.36.

Methanolysis of 4-Trichloroacetyl-2-pyrrolecarbonitrile

Following the literature method (5) 4-trichloroacetyl-2-pyrrolecarbonitrile (0.68 g, 2.9 mmol) was added all at once to a stirred solution of sodium methoxide from sodium (0.6 g, 25 mmol) dissolved in absolute methanol (120 ml). After 30 min the methanol was evaporated to give a light brown solid which was taken up in water and extracted with ether. The water solution was acidified and saturated with salt and extracted with ether. The combined ether extracts were washed with water, dried (Na_2SO_4) and after removal of the solvent, gave a nearly white solid (0.38 g, 87%) which was sublimed to give methyl 2-cyano-4-pyrrolecarboxylate; mp 174–175°C; ir ν: 1675 (CO), 2220 cm^{-1} (CN); nmr (DMSO-d_6) δ: 3.72 (s, 3H), 7.22 (m, 1H), 7.70 (m, 1H), $J_{3,5}$ = 1.4 Hz; *m/e* 150. *Anal.* calcd. for $C_7H_6N_2O_2$: C 56.01, H 4.03; found: C 55.78, H 4.03.

Methyl 4-Trichloroacetyl-2-pyrrolecarboxylate

Following the trichloroacetylation procedure above, methyl 2-pyrrolecarboxylate (1.0 g, 8 mmol) was converted into methyl 4-trichloroacetyl-2-pyrrolecarboxylate (1.7 g, 78%), recrystallized from benzene–hexane and sublimed, mp 118–119°C; ir ν: 1700 and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 3.90 (s, 3H), 7.50 (m, 1H), 7.83 (m, 1H), ~10.2 (b, 1H); *m/e* 269 ($^{35}Cl_3$), 271 ($^{35}Cl_2{}^{37}Cl$). *Anal.* calcd. for $C_8H_6Cl_3NO_3$: C 35.52, H 2.24; found: C 35.43, H 2.26.

Methyl 2,4-Pyrroledicarboxylate

The methanolysis procedure described above was used to convert methyl 4-trichloroacetyl-2-pyrrolecarboxylate (1.0 g, 3.6 mmol) to methyl 2,4-pyrroledicarboxylate (0.5 g, 75%), mp 125.5–127°C, (lit. (14) mp 126–127°C). Spectra were in agreement with those recorded earlier (15).

Methyl 2-Cyano-4-pyrrolecarboxylate

Following the trichloroacetylation procedure above a stirred mixture of 2-pyrrolecarbonitrile (1.0 g, 11 mmol), aluminum chloride (3 g, 22 mmol) in methylene chloride (40 ml) was treated with oxalyl chloride (1.4 g, 11 mmol) at room temperature. The bright orange product was refluxed for 1 h and cooled in ice. Methanol was added dropwise until the vigorous reaction ceased and the mixture was poured onto ice. Extraction with chloroform, drying ($MgSO_4$) and evaporation gave a pale brown solid (1.4 g, 84% crude). The crude material was shown by nmr, ir, and mass spectra to be almost entirely methyl 2-cyano-4-pyrrolecarboxylate, but its ir and mass spectra indicated that a trace of methyl 4-pyrroleglyoxylate-2-carboxylate was present. Recrystallization gave pure methyl 2-cyano-4-pyrrolecarboxylate identical to that reported above.

Ethyl 2-Cyano-4-pyrrolethiolcarboxylate

Ethyl chlorothiolformate (1.4 g, 11 mmol) was added slowly to a stirred mixture of 2-pyrrolecarbonitrile (1.0 g, 11 mmol) and aluminum chloride (3.0 g, 22 mmol) in methylene chloride (40 ml) at such a rate that the reaction mixture refluxed gently (about 25 min). The deep green reaction mixture was refluxed for a further 30 min and poured onto ice – 6 *M* hydrochloric acid (about 100 g). After 1 h the layers were separated and the water layer was extracted three times with chloroform. The combined extracts were washed with water, dried ($MgSO_4$) and the solvent was removed under vacuum. The light brown solid was recrystallized from benzene to give ethyl 2-cyano-4-pyrrolethiolcarboxylate (1.4 g, 71%), mp 111–111.5°C; ir ν: 1610 (CO), 2225 cm^{-1} (CN); nmr ($CDCl_3$) δ: 1.32 (t, 3H), 3.05 (q, 2H), 7.21 (m, 1H), 7.51 (m, 1H), ~10.4 (b, 1H), $J_{3,5}$ 1.6 Hz; *m/e* 180. *Anal.* calcd. for $C_8H_8N_2OS$: C 53.32, H 4.47; found: C 53.32, H 4.47.

4-Formyl-2-pyrrolecarbonitrile

A solution of 2-pyrrolecarbonitrile (9.2 g, 0.1 mol) in dry CH_2Cl_2 (60 ml) and a solution of nitromethane (4.8 ml, 0.079 mol) in CH_2Cl_2 (20 ml) was added to a (mechanically) stirred suspension of $AlCl_3$ (23.6 g, 0.177 mol) in CH_2Cl_2 (60 ml), under N_2 at about −78°C. Dichloromethyl *n*-butyl ether (16) (21.1 g, 0.13 mol) in CH_2Cl_2 (50 ml) was then added dropwise during about 3 h in which the bath temperature was allowed to rise slowly to about −10°C. Thin-layer chromatography indicated that reaction had ceased after a further 1 h during which the bath temperature had risen to about +10°C. The reaction mixture was poured carefully with vigorous stirring onto ice-cold solid NH_4Cl. A yellow solid precipitated from the solution and after about 15 min it was collected by vacuum filtration and washed briefly with ice-cold water. The dichloromethane layer was separated from the filtrate, the yellow aqueous layer saturated with NaCl and extracted thoroughly with ethyl acetate. The ethyl acetate and CH_2Cl_2 extracts were combined, dried (Na_2SO_4) and the solvent was removed giving a yellow solid residue which was combined with the yellow precipitate collected above and recrystallized from hot water (as brown needles) to remove inorganic salts. The solid residue left after evaporation of the aqueous mother liquor was extracted continuously with petroleum (bp 100–120°C) to give more of the required pyrrole. Sublimation of the crude products gave pure 4-formyl-2-pyrrolecarbonitrile (8.9 g, 74%)[1] as a white powder, mp 173–175°C; ν (Nujol): 2235 (CN), 1660 cm^{-1} (CO); nmr (acetone-d_6) δ: 7.29 (d, 1H), 7.88 (d, 1H), 9.78 (s, 1H), $J_{3,5}$ = 1.5 Hz; *m/e* 120. *Anal.* calcd. for $C_6H_4N_2O$: C 60.00, H 3.36, N 23.32; found: C 60.16, H 3.53, N 23.35.

5-tert-Butyl-2-pyrrolecarbonitrile

This product crystallized from the mixture obtained by the $AlCl_3$ catalyzed Friedel–Crafts acylation of 2-pyrrolecarbonitrile (10). The 5-*tert*-butyl-2-pyrrolecarbonitrile was sublimed for analysis, mp 115–116°C; ir (Nujol mull) ν: 3286 (N—H), 2216 cm^{-1} (C≡N); nmr ($CDCl_3$) δ: 1.26 (s, 9H), 5.86 (m, 1H), 6.64 (m, 1H), 9.32 (b, 1H), $J_{3,4}$ 3.6 Hz, $J_{1,3}$ and $J_{1,4}$ 2.7 Hz. *Anal.* calcd. for $C_9H_{12}N_2$: C 72.94, H 8.16, N 18.90; found: C 73.36, H 8.15, N 18.98.

Conversion of the 2-Pyrrolecarbonitriles to 2-Pyrrolecarboxaldehydes

4-Acetyl-2-pyrrolecarboxaldehyde

Raney nickel alloy (2.0 g) and formic acid (75% aq, 60 ml) were mixed in a 100 ml flask. The mixture was stirred using a magnetic stirrer and heated until the mixture just began to reflux and the evolution of gas was brisk. 4-Acetyl-2-pyrrolecarbonitrile (1.00 g) was then added and the heating and stirring was maintained so that the mixture did not quite reflux but gas evolution continued. After 1 h the mixture, while still being warmed and stirred, was extracted continuously with toluene for 24 h. The toluene extract was collected and the solvent was removed to leave a brownish residue of the crude product (1.01 g). Recrystallization from ethyl acetate – petroleum mixture gave 4-acetyl-2-pyrrolecarboxaldehyde (0.84 g, 82%), mp 141.5–142°C (lit. (1) mp 136–137°C). Mixture mp with authentic material was undepressed.

Using the same procedure the following aldehydes were obtained:

Ethyl 2-Formyl-4-pyrrolethiolcarboxylate

Ethyl 2-cyano-4-pyrrolethiolcarboxylate gave ethyl 2-formyl-4-pyrrolethiolcarboxylate which was crystallized from a benzene–petroleum mixture and then sublimed to give prisms, mp 72.5–74°C, in 62% yield; nmr ($CDCl_3$) δ: 1.31 (t, 3H), 3.04 (q, 2H), 7.75 (m, 2H), 9.50 (d, 1H); *m/e* 183. *Anal.* calcd. for $C_8H_9NO_2S$: C 52.44, H 4.95; found: C 52.48, H 4.98.

Methyl 2-Formyl-4-pyrrolecarboxylate

The *product* was obtained from methyl 2-cyano-4-pyrrolecarboxylate and recrystallized from toluene–petroleum mixture as fluffy needles, (71%) mp 127–128°C after sublimation; ir (Nujol mull) ν: 1660 (CO), 1720 cm^{-1} (CO); nmr ($CDCl_3$) δ: 3.80 (s, 3H), 7.34 (m, 1H), 7.65 (m, 1H), 9.48 (d, 1H), $J_{3,5}$ 1.4 Hz, J_{CHO-5} 1.0 Hz; *m/e* 153. *Anal.* calcd. for $C_7H_7NO_3$: C 54.90, H 4.61; found: C 55.04, H 4.62.

2,4-Pyrroledicarboxaldehyde

4-Formyl-2-pyrrolecarbonitrile gave the product which was crystallized from water as brown needles (68%) mp 148–151°C after sublimation (lit. (13) mp 151.5–152°C).

4-tert-Butyl-2-pyrrolecarboxaldehyde

The *product* was extracted continuously with petroleum (bp 40–60°C) rather than with toluene, and finally sublimed (89%), mp 86.5–87.5°C; ir (Nujol mull) ν: 3227 (N—H), 1664 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 1.24 (s, 9H), 6.80 (m, 1H), 6.89 (m, 1H), 9.31 (s, 1H), $J_{3,4}$ 3.84 Hz, $J_{1,3}$ 2.4 Hz, $J_{1,4}$ 2.5 Hz. *Anal.* calcd. for $C_9H_{13}NO$: C 71.49, H 8.66, N 9.26; found: C 71.74, H 8.51, N 8.95.

5-tert-Butyl-2-pyrrolecarbaldehyde was obtained similarly (70%), mp 66–67°C; ir (Nujol mull) ν: 3281 (N—H), 1646 cm^{-1} (CO); nmr ($CDCl_3$) δ: 1.32 (s, 9H), 6.03 (m, 1H), 6.80 (m, 1H), 9.23 (s, 1H), 9.81 (b, 1H); *m/e* 151. *Anal.* calcd. for $C_9H_{13}NO$: C 71.49, H 8.66, N 9.26; found: C 71.72, H 8.49, N 9.02.

Decarbonylation of the 4-Substituted 2-Pyrrolecarboxaldehydes

Methyl 3-Pyrrolecarboxylate

A stirred mixture of methyl 2-formyl-4-pyrrolecarboxylate (500 mg), toluene (20 ml) and W5 Raney nickel (17) (about 1 g) was refluxed for 4½ h. The mixture was then cooled at room temperature and filtered through a Celite pad to remove the nickel. The nickel and pad were washed with acetone and the filtrates were combined. The solvent was then removed and the solid residue was recrystallized from chloroform–petroleum mixture (342 mg, 84%), mp 87–87.5°C (lit. (18) mp 88°C); ($CDCl_3$) δ: 3.69 (s, 3H), 6.57 (m, 2H), 7.31 (m, 1H), 9.89 (b, 1H).

3-Acetylpyrrole

Decarbonylation of 4-acetyl-2-pyrrolecarboxaldehyde (1) gave 3-acetylpyrrole in 87% yield, mp 115–116°C (lit. (1) mp 115–116°C); the mixture mp with authentic material was undepressed.

[1]Less mild conditions gave lower yields and were less selective, significant amounts of a second formylation product (nmr) being formed, presumably the result of attack at the C-5 position.

Protonated cyclopropanes. X. Studies on the deamination of *n*-butylamine-1-^{14}C and the decomposition of 3-(*n*-butyl-1-^{14}C)-1-phenyltriazene

CHOI CHUCK LEE, RANDY REICHLE, AND URSULA WEBER

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 12, 1977

CHOI CHUCK LEE, RANDY REICHLE, and URSULA WEBER. Can. J. Chem. **56**, 658 (1978).

The HNO_2 deamination of *n*-butylamine-1-^{14}C (**1**-NH_2-1-^{14}C) in aqueous $HClO_4$ gave a *n*-butyl-^{14}C alcohol (**1**-OH-^{14}C) with about 0.7% scrambling of the label from C-1 to C-2, and a *sec*-butyl-^{14}C alcohol (**2**-OH-^{14}C) which showed extensive scrambling between C-1 and C-4, as well as small amounts of rearrangement of the label into C-2 and C-3. Analysis of the data suggested that about 2.5% of the **2**-OH-^{14}C product could be derived from equilibrating protonated methylcyclopropane intermediates. The $HClO_4$ catalyzed decomposition of 3-(*n*-butyl-1-^{14}C)-1-phenyltriazene (**1**-NNNHPh-1-^{14}C) gave the unrearranged **1**-OH-1-^{14}C and a **2**-OH-^{14}C which showed only about 17–18% scrambling from C-1 to C-4. It is suggested that the different results observed in the deamination and the triazene decomposition may be due to a more ready initial formation of an ion pair in the triazene decomposition.

CHOI CHUCK LEE, RANDY REICHLE et URSULA WEBER. Can. J. Chem. **56**, 658 (1978).

La désamination nitreuse de la butylamine ^{14}C-1 (**1**-NH_2-1-^{14}C) dans de l'acide perchlorique aqueux conduit à de l'alcool butylique ^{14}C (**1**-OH-^{14}C) contenant environ 0.7% d'échange du marqueur du C-1 vers C-2 et un alcool butylique secondaire ^{14}C (**2**-OH-^{14}C) qui présente beaucoup d'échange entre les C-1 et C-4 de même que de petites quantités de réarrangement du marqueur vers les positions C-2 et C-3. Une analyse des données suggère qu'environ 2.5% du produit de **2**-OH-^{14}C pourrait provenir de l'équilibration de méthylcyclopropanes intermédiaires. La décomposition catalysée par $HClO_4$ du (butyl ^{14}C-1)-3 phényl-1 triazène (**1**-NNNHPh-1-^{14}C) conduit à du **1**-OH-^{14}C qui n'est pas réarrangé et à un **2**-OH-^{14}C qui ne présente qu'environ 17–18% d'échange entre les carbones 1 et 4. On suggère que les résultats différents observés lors de la désamination et de la décomposition du triazène peuvent être dus à une formation initiale plus facile d'une paire d'ions lors de la décomposition du triazène.

[Traduit par le journal]

The HNO_2 deamination of various D-labeled *n*-butylamines, coupled with mass spectral analysis, carried out in HOAc by Streitwieser and Schaeffer (1) and in aqueous $HClO_4$ by Karabatsos *et al.* (2), showed no detectable scrambling in the *n*-butyl product (1, 2) and scrambling in the *sec*-butyl product resulted only from reversible 1,2-hydride shifts in the *sec*-butyl cation (2). Such results indicated that protonated methylcyclopropanes are not important intermediates in these reactions. However, the scrambling data did not exclude a minor amount of involvement of such intermediates since small extents of rearrangements might be within the experimental errors of the method of measurement. Karabatsos *et al.* (2) estimated that there may be about 0.6% methylcyclopropane among the hydrocarbon products in the deamination and concluded that the only evidence for the intermediacy of protonated methylcyclopropanes in the aqueous acid deamination of *n*-butylamine was the formation of methylcyclopropane. Recently, we have shown that in the trifluoroacetolysis of *n*-butyl-1-^{14}C tosylate (3) and of *n*-butyl-1-^{14}C-mercuric perchlorate (4), the scramblings in the *sec*-butyl products can be explained only by invoking some contribution from equilibrating protonated methylcyclopropanes as intermediates. Since reinvestigations of the early work of Roberts and Halmann (5) on the HNO_2 deamination of *n*-propylamine-1-^{14}C in aqueous $HClO_4$ gave evidence in support of equilibrating protonated cyclopropanes (6, 7), we decided to carry out a study on the deamination of *n*-butylamine-1-^{14}C in order to ascertain more quantitatively the involvement of protonated methylcyclopropane intermediates. In conjunction with this work, the acid catalyzed decomposition of 3-(*n*-butyl-1-^{14}C)-1-phenyltriazene was investigated since this reaction, as in the deamination, might proceed via the alkyldiazonium ion (8).

n-Butylamine-1-^{14}C (**1**-NH_2-1-^{14}C) was prepared by the $LiAlH_4$ reduction of $CH_3CH_2CH_2{}^{14}CN$ (2, 5). That all of the ^{14}C label was located at C-1 was shown by oxidation of **1**-NH_2-1-^{14}C to CH_3CH_2-$CH_2{}^{14}COOH$ (10) followed by a Schmidt reaction to give inactive CH_3CH_2COOH. The deamination of **1**-NH_2-1-^{14}C in aqueous $HClO_4$ was carried out under the conditions used by previous workers (2, 5). The yields of the isomeric *n*-butyl, *sec*-butyl, isobutyl, and *tert*-butyl alcohols (**1**-OH, **2**-OH, **3**-OH, and **4**-OH, respectively) were determined by isotopic

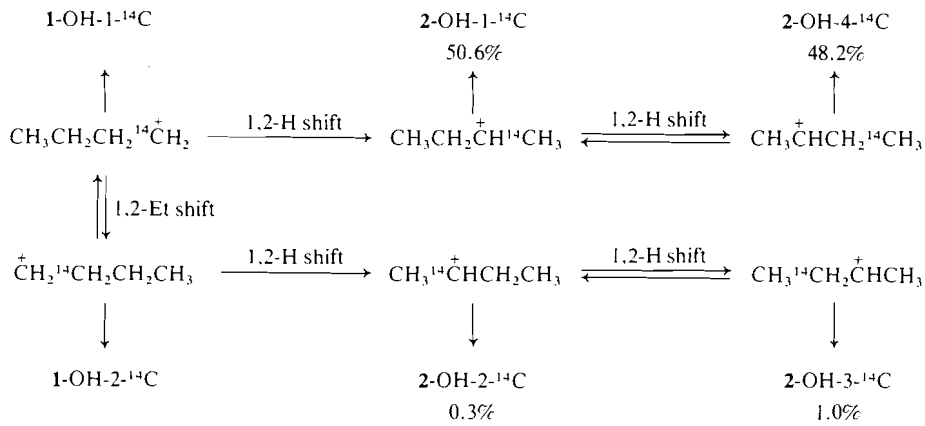
dilution (4, 9) and the results are given in Table 1. The main products, **1**-OH-^{14}C and **2**-OH-^{14}C, were degraded as described previously (4, 9) to give the ^{14}C distributions. The results are summarized in Tables 2 and 3.

n-Butyl-1-^{14}C chloride (9) was converted to the Grignard reagent and treated with phenyl azide to give 3-(*n*-butyl-1-^{14}C)-1-phenyltriazene (**1**-NNNHPh-1-^{14}C) (11). The acid catalyzed decomposition of **1**-NNNHPh-1-^{14}C was effected at room temperature with 0.1% $HClO_4$ in 90% acetone – 10% H_2O, which was one set of conditions that was used to generate triarylvinyl cations from triarylvinylphenyltriazenes (12). While the decomposition of alkylphenyltriazenes in HX–H_2O proceeds by an ionic mechanism (11, 13), it has been reported that in the absence of HX, decomposition in media such as H_2O–CH_3OH or H_2O–C_6H_6 emulsions may follow a radical process (13). To ascertain whether radicals were involved under the present conditions, the $HClO_4$ catalyzed decomposition of **1**-NNNHPh-1-^{14}C in aqueous acetone was also carried out in the presence of the radical scavenger, diphenylpicrylhydrazyl (DPPH). It was found that the added DPPH had no effect on either the yields of butyl alcohols or on the extents of isotopic scrambling. In both the presence and absence of DPPH, the decomposition of **1**-NNNHPh-1-^{14}C gave yields of 43–44% **1**-OH-^{14}C and 16–17% **2**-OH-^{14}C as determined by isotopic dilution. There were no detectable amounts of **3**-OH-^{14}C or **4**-OH-^{14}C. Degradation of **1**-OH-^{14}C showed that there was no isotopic scrambling, and this product was unrearranged **1**-OH-1-^{14}C. Degradation of the **2**-OH-^{14}C product showed that

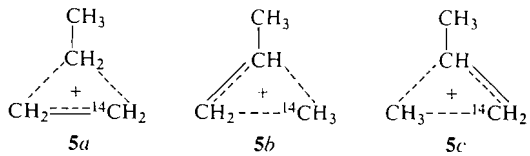


SCHEME 1

scramblings occurred only between C-1 and C-4, and the results are included in Table 3.

For the deamination of **1**-NH_2-1-^{14}C, the scrambling data may be interpreted in the same way as in the interpretation of the results from the trifluoroacetolysis of **1**-OTs-1-^{14}C (3) and **1**-$HgClO_4$-1-^{14}C (4). Consider, firstly, the ^{14}C distribution in the **2**-OH-^{14}C (Table 3). The extensive scramblings between C-1 and C-4 indicate that a major process is a degenerate 1,2-hydride shift interconverting the *sec*-butyl-1-^{14}C and *sec*-butyl-4-^{14}C cations. To account for the small amounts of ^{14}C activity at C-2 and C-3, a mechanism involving a 1,2-ethyl shift as depicted in Scheme 1 may be suggested. Since the *sec*-butyl-1-^{14}C and *sec*-butyl-2-^{14}C cations differ only in the position of the label, one would expect these ions to undergo essentially the same subsequent reactions. Thus according to Scheme 1, the ratio of **2**-OH-4-^{14}C to **2**-OH-1-^{14}C should be equal to the ratio of **2**-OH-3-^{14}C to **2**-OH-2-^{14}C. Clearly this expectation does not agree with the experimental data since 48.2:50.6 is far from equalling 1.0:0.3. The mechanism in Scheme 1, therefore, is inadequate to account for the observed results.

To account for the small amounts of scrambling into C-2 and C-3 of the *sec*-butyl product, an alternative mechanism could involve a contribution from equilibrating protonated methylcyclopropanes (3, 4). Utilizing corner-protonated methylcyclopropanes **5***a–c*, Scheme 2 shows the partitioning of the various routes leading to the ^{14}C distribution in **2**-OH-^{14}C. As suggested previously (3, 4), it is proposed that **5***b* and **5***c* could give the *sec*-butyl product directly or give rise to the more stable *sec*-butyl cation which subsequently would undergo degenerate hydride shifts. In this scheme, the equality of the product ratios derived from equilibrating *sec*-butyl cations is also maintained (47.2:50.2 $\simeq$ 0.3:0.3). The net ^{14}C contents would be 50.2 + 0.3, 0.3, 0.7 + 0.3, and 47.2 + 0.7 + 0.3 or 50.5, 0.3, 1.0, and 48.2%, respectively, for C-1, C-2, C-3, and C-4. These calculated values agree completely with the averaged, observed ^{14}C distribution in **2**-OH-^{14}C derived from the deamination of **1**-NH_2-1-^{14}C (Table 3). These results are in general accord with the conclusion of Karabatsos *et al.* (2) that there is only a minor involvement of protonated methylcyclopropane intermediates in the aqueous acid deamination of *n*-butylamine; the present work using the sensitive radioactive tracer technique has shown more quantitatively that about 2.5% of the *sec*-butyl product was derived from equilibrating protonated methylcyclopropanes.



In the *n*-butyl product, **1**-OH-^{14}C, there is about 0.7% rearrangement of the label from C-1 to C-2 (Table 2). This scrambling can be attributed to product formation from protonated methylcyclopropane **5***a*. Moreover, **5***b* and **5***c* can also give rise to the isobutyl product and a facile rearrangement of the isobutyl to the *tert*-butyl cation would account for the small amount of *tert*-BuOH among the products as recorded in Table 1.

The decomposition of RNNNHPh in aqueous acids is known to give ROH, N_2, and $PhNH_2$ as products (11, 13). If the alcohol were formed via RN_2^+ and R^+, there is an apparent similarity between the decomposition of alkylphenyltriazenes and the deamination of primary amines. As can be seen from Table 3, **2**-OH-^{14}C derived from the deamination of **1**-NH_2-1-^{14}C and from the decomposition of **1**-NNNHPh-1-^{14}C showed entirely different extents of isotopic scrambling. In the

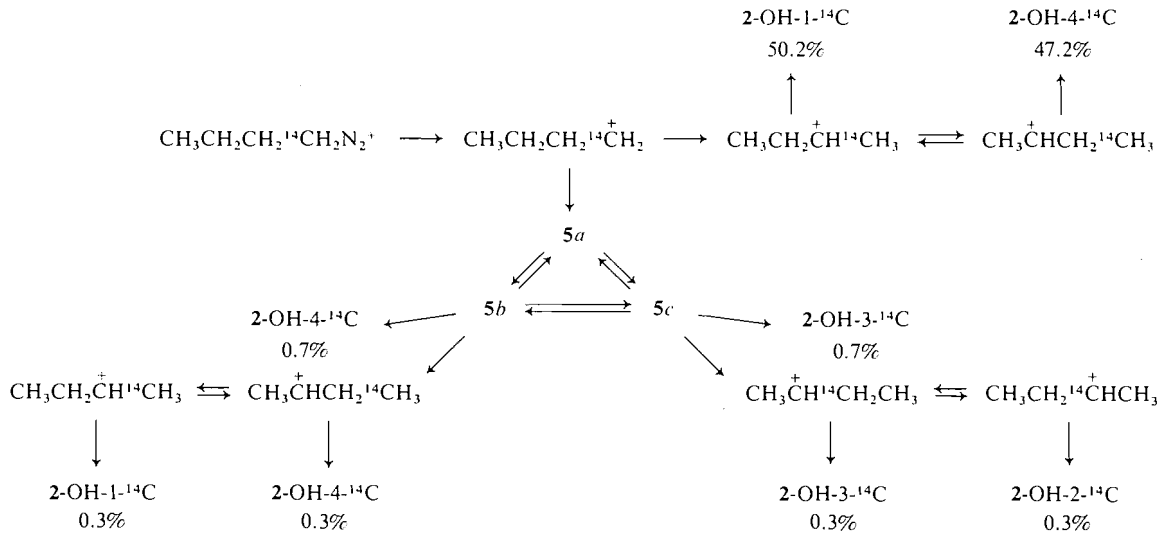

SCHEME 2

2-OH-^{14}C from the triazene decomposition, there was only 17–18% rearrangement of the label from C-1 to C-4, with no detectable amount of scrambling into C-2 and C-3. The possibility that the lesser extent of rearrangement may be due to a contribution from radical processes was eliminated since the presence of DPPH did not influence the results.

To explain the different results obtained in the deamination and triazene decomposition, it is of interest to note that Collins (14) has pointed out that ion-pairing exerts a pronounced effect on product formation in carbocationic reactions including deamination. In the present work, although there are differences in the reaction media for the deamination and the triazene decomposition, both reactions were carried out in the presence of H_2O. Any coordination or ion-pairing involving the same nucleophilic solvent is not likely to exert a sufficiently large effect to account for the differences in isotopic scrambling observed in these two reactions as recorded in Table 3. Kawanisi *et al.* (15) have reported a novel decomposition of RNNNHPh in benzene catalyzed by silica gel. Besides the usual products of ROH, N_2, and $PhNH_2$, PhNHR was also obtained and the recombination of the R group with the anilino group was found to occur with retention of configuration at the α-carbon of the R group. While the precise function of the silica gel was not known, it was proposed that the reaction mechanism involved an intimate ion-pair formed between the carbocation and the anilino ion. In the decomposition of **1**-NNNHPh-1-^{14}C in aqueous acid, possibly, there may also be an initial formation of an ion-pair between the butyl and anilino ions which could rapidly react with solvent without rearrangement. Upon further dissociation to give solvated butyl cations, more scrambling through degenerate 1,2-hydride shifts can occur. In the deamination of **1**-NH_2-1-^{14}C, there is no analogous ion-pairing with the anilino group and the net result is the occurrence of more extensive scrambling as was observed.

Experimental

Deamination of n-*Butylamine-1-*^{14}*C (1-*NH_2*-1-*^{14}*C)*

Butyronitrile-1-^{14}C, prepared from $CH_3CH_2CH_2Cl$ and $Na^{14}CN$, was reduced with $LiAlH_4$ and treated with $HClO_4$ to give **1**-$NH_2 \cdot HClO_4$-1-^{14}C using procedures similar to those reported for the preparation of $CH_3CH_2{}^{14}CH_2NH_2 \cdot HClO_4$ (5) and **1**-$NH_2 \cdot HClO_4$-1,1-d_2 (2). The deamination was carried out as described by previous workers (**1**-$NH_2 \cdot HClO_4$-1-^{14}C in 35% $HClO_4$ treated with aqueous $NaNO_2$ at 30°C) (2, 5). The reaction mixture was distilled to dryness. The distillate was acidified with HCl and distilled again to dryness. The latter distillate was saturated with KF and the organic layer was separated. The yields of the four isomeric alcohols were determined by isotopic dilution with added carriers, with purification by preparative vpc as described previously (4, 9). The major products, *n*-butyl-^{14}C and *sec*-butyl-^{14}C alcohols (**1**-OH-^{14}C and **2**-OH-^{14}C), with more carriers added if necessary, were degraded using procedures that have also been described in the previous work (4, 9).

*3-(*n*-Butyl-1* ^{14}*C)-1-phenyltriazene (1-NNNHPh-1-*^{14}*C)*

The triazene was prepared from the reaction of **1**-MgCl-1-^{14}C and phenyl azide (11, 12). The Grignard reagent, prepared from 12.5 g (13.5 mmol) of **1**-Cl-1-^{14}C in 35 ml of ether, was cooled in an ice bath. An equivalent of freshly prepared phenyl azide (16) in 35 ml of ether was added. The reaction mixture was stirred at room temperature for 2 h, treated with a solution of 10% NH_4OH – 10% NHCl, and then extracted with ether. The extract was washed with H_2O and dried over $MgSO_4$. After removal of the ether, 14.4 g (60%) of **1**-NNNHPh-1-^{14}C was recovered as a yellow oil, which was crystallized in petroleum ether in a cold room, mp 18°C (lit (17), mp 17–18°C).

Decomposition of 1-NNNHPh-1-^{14}*C*

To 3.0 g (17 mmol) of **1**-NNNHPh-1-^{14}C was added 20 ml of 90% acetone – 10% H_2O (by volume) containing 0.1%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$HClO_4$. Evolution of N_2 occurred immediately and apparently ceased within about 1 min. The reaction mixture was stirred at room temperature for 1 h and then ordinary **1**-OH, **2**-OH, **3**-OH, and **4**-OH were added as carriers. After drying over $MgSO_4$ (about 2 g), the resulting solution was filtered, the acetone removed by distillation, and the residual alcohols were purified by preparative vpc. The yields of butyl alcohols were calculated from isotopic dilution and the **1**-OH-^{14}C and **2**-OH-^{14}C were degraded as before (4, 9).

When the decomposition was carried out in the presence of DPPH, the same procedure was used except that the solvent, 90% acetone – 10% H_2O, was saturated with DPPH (about 0.1%).

Analyse des spectres de vibration de la β-alanine, de la taurine et de la ciliatine-β

CHANTAL GARRIGOU-LAGRANGE

Centre de Recherche Paul Pascal, Domaine Universitaire, 33405 - Talence, France

Reçu le 5 octobre 1977

CHANTAL GARRIGOU-LAGRANGE. Can. J. Chem. **56**, 663 (1978).

Les spectres de vibration de la β-alanine, de la taurine et de la ciliatine (forme β) à l'état solide sont analysés. Un calcul de modes normaux est effectué. Les champs de force de valence obtenus pour ces trois molécules à l'état cristallin sont très voisins et montrent que le radical $N—C_\alpha H_2—C_\beta H_2—$ est électroniquement équivalent dans les trois molécules.

CHANTAL GARRIGOU-LAGRANGE. Can. J. Chem. **56**, 663 (1978).

Infrared and Raman spectra of solid β-alanine, taurine and ciliatine (β form) are analysed. A normal mode calculation is made. The given valence force fields of the three crystalline molecules are very similar. It shows the $N—C_\alpha H_2—C_\beta H_2—$ radical is electronically equivalent in the three molecules.

La ciliatine ou acide 2-amino-éthyl phosphonique et la taurine ou acide 2-amino-éthyl sulfonique sont largement représentées dans les organismes vivants, des protozoaires aux vertébrés et à l'homme (1–4). Leur grand intérêt biologique nous a amenés à étudier leurs spectres de vibration, en liaison avec leur structure. A la suite des travaux que nous avons déjà effectués sur des acides α aminés (5, 6) et des peptides (7–10), nous avons fait un calcul des modes normaux de ces molécules. Pour comparaison, nous avons inclus dans cette étude la β-alanine ou acide 2 amino-éthyl carboxylique.

La ciliatine possède deux variétés allotropiques α et β caractérisées par leurs spectres infrarouges (11). La structure cristalline de la forme β est connue (12). On connaît également celles de la β-alanine (13) et de la taurine (14).

Une interprétation des spectres de vibration infrarouges et Raman de la β-alanine hydrogénée (15), de la taurine hydrogénée et *N* deutériée (16) à l'état solide a déjà été proposée. Par contre, aucune attribution détaillée des spectres de la ciliatine n'a, à notre connaissance, été publiée.

Dans ce travail, après avoir discuté l'interprétation des spectres de vibration de ces trois acides aminés, nous exposerons les résultats du calcul de modes normaux que nous avons effectué.

Les vibrations NH et ν OH ne sont pas envisagées dans ce mémoire: elles ne peuvent pas être localisées, les groupements NH_3^+ et OH étant très auto-associés. Quant aux vibrations ν CH, elles n'entrent pas en interaction avec les autres modes de vibration; nous n'avons donc pas cherché à les attribuer ni, a fortiori, à préciser les constantes de force correspondantes.

Analyse des spectres de vibration

Nous avons enregistré les spectres infrarouges et Raman jusqu'à 200 cm^{-1} de la β-alanine, de la taurine et de la ciliatine forme β et de leurs homologues deutériés sur l'azote et (pour la ciliatine) sur l'oxygène, à l'état solide.[1]

β-*Alanine*

L'attribution des spectres de vibration de la β-alanine hydrogénée que nous proposons sur le tableau 1 est basée sur les résultats que nous avons obtenus pour les trois variétés allotropiques de la glycine (5). Elle est en assez bon accord avec celle des auteurs précédents (15). La comparaison des spectres infrarouges des dérivés hydrogéné et *N* deutérié nous a cependant amenés à intervertir les fréquences des vibrations δ_d NH_3 et ν_a COO. En outre, nous faisons correspondre la bande observée à 1261 cm^{-1} à une vibration de torsion *t* CH_2, les vibrations de balancement *w* CH_2 étant habituellement situées à fréquence plus élevée.

Pour le dérivé *N* deutérié, la comparaison avec les glycines ND_3 (5) conduit aux attributions du tableau 1. Nous n'avons pas donné d'interprétation pour les bandes relevées entre 800 et 1100 cm^{-1}, les modes observés dans cette région dans le cas de la glycine étant très complexes.

Taurine

A l'exception de la faible raie Raman à 420 cm^{-1} relevée par Stahlberg et Steger (16) et que nous n'avons pas observée, nos résultats expérimentaux concordent avec ceux de ces auteurs. L'interprétation que nous proposons, basée sur la comparaison avec la β-alanine et indiquée sur le tableau 2, est très proche de celle donnée par les auteurs précédents (16), sauf en ce qui concerne certaines vibrations des groupements NH_3 et ND_3. Ces auteurs, en effet, attribuent quatre fréquences: 891, 961, 1103 et 1388 cm^{-1} aux deux vibrations de balancement *r* NH_3.

[1]Les spectres pourront être obtenus sur demande.

†Attribution différentes de celles données par réf. 15.

Ciliatine forme β

L'attribution présentée sur le tableau 3 a été faite par comparaison avec l'acide amino méthyl phosphonique (6, 17), la β-alanine et la taurine.

Calcul du champ de force et des modes normaux

Géométrie des ions

La géométrie utilisée est celle donnée par les rayons X (12–14). Pour les distances XH, nous avons pris les valeurs généralement admises: λ N—H = 1.03 Å, λ C—H = 1.08 Å, λ O—H = 0.97 Å.[2] Les angles autour des atomes d'azote ont été pris tétraédriques.

Coordonnées

Les coordonnées choisies sont des combinaisons linéaires de coordonnées internes correspondant aux vibrations de groupe utilisées pour interpréter les spectres. Nous les avons définies comme dans la glycine (5) et l'acide amino-méthylphosphonique (AMPh) (6), sauf pour les vibrations de torsion pour lesquelles nous avons adopté la définition utilisée dans le cas de l'acide glycylaminométhylphosphonique (Gly AMPh) (9).

Méthode de calcul

Le calcul est effectué en supposant l'ion isolé dans le réseau cristallin. Ne disposant pas de nombreuses molécules isotopiques, nous n'avons pas raffiné nos résultats, mais nous avons cherché à obtenir des champs de force aussi voisins que possible pour les trois molécules étudiées. Pour la β-alanine et la ciliatine, le champ de force de départ a été basé respectivement sur ceux de la glycine (5) et de l'AMPh (6). Pour la taurine, nous avons recherché par tâtonnements un champ de force rendant compte des fréquences du groupement SO_3 et l'avons choisi proche de celui du groupement PO_3. La comparaison avec un calcul de modes normaux effectué simultanément sur la glycyl taurine (10) nous a permis d'améliorer nos résultats. Les champs de force que nous avons finalement obtenus pour les trois molécules sont reportés sur le tableau 4.[3]

Discussion

Les fréquences calculées, accompagnées de la répartition d'énergie potentielle s'y rapportant, sont rassemblées sur les tableaux 1–3. On note que, dans l'ensemble, il y a un assez bon accord entre les fréquences calculées et les fréquences observées. Un certain nombre de bandes, non expliquées par le calcul, semblent dues à des démultiplications par interaction des différents ions dans la maille cristalline. Cette observation est contraire à l'hypothèse faite pour effectuer le calcul, mais la fréquence calculée est toujours relativement proche de celles relevées sur les spectres.

Dans le cas de la β-alanine, il a été impossible de calculer la vibration ν $C_\alpha C_\beta$ vers 850 cm^{-1} comme le laisse supposer l'aspect des spectres infrarouges et Raman et comme l'attribuent Krishnan et Katiyar (15). A cette fréquence est calculé un mode mettant particulièrement en jeu le mouvement de balancement *r* $C_\beta H_2$, mais il y a aussi une contribution importante de la vibration ν NC_α qui peut expliquer l'intensité de la raie Raman. Aucune fréquence n'a été calculée vers 320 cm^{-1} où Krishnan et Katiyar (15) situent la vibration δ $NC_\alpha C_\beta$. Cette bande pourrait être due à une vibration harmonique ou de combinaison.

Dans le cas de la taurine, on note que le groupement SO_3 se comporte pratiquement comme s'il possédait une symétrie ternaire: les deux bandes attribuées à ν_a et ν_s' SO_3 d'une part, à δ_a et δ_s' SO_3 d'autre part, pourraient également être dues à un

[2]Notons que, dans le cas de la glycine (5) et de l'AMPh (6), nous avions choisi de prendre λ N—H = 1.0 Å, λ C—H = 1.09 Å, λ O—H = 0.8 Å, ce qui peut expliquer certaines variations relevées dans les constantes de force.

[3]On peut obtenir le tableau 4, à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.) Canada K1A 0S2.

*Seules sont indiquées les repartitions supérieures à 10.

effet Davydov. Un phénomène analogue a été observé dans le cas de la glycyl taurine (10).

Les champs de force obtenus pour la partie $NC_\alpha H_2C_\beta H_2$— des trois molécules sont très proches, ce qui permet de penser que la structure électronique de ces groupements est pratiquement la même dans ces trois composés. Rappelons la valeur des angles dièdres autour de la liaison $C_\alpha C_\beta$, observés à l'état solide: β-alanine, 84°; taurine, —70.5°; ciliatine, 174°. Ainsi donc, la différence de conformation de ces trois ions n'influe pas sur le champ de force calculé, non plus que la chélation qui a été observée dans le cas de la taurine (14) entre les groupements SO_3^- et NH_3^+. Notons, enfin, que les champs de force donnés sur le tableau 4 sont très proches de ceux des molécules modèles (5, 6, 8, 9).

Certaines constantes de force d'interaction (*t* $C_\alpha H_2$, $r_\perp$ NH_3; *r* $C_\alpha H_2$, $r_\perp$ NH_3; *w* $C_\alpha H_2$, $r_\parallel$ NH_3) ont cependant pu être posées égales à zéro sans que les fréquences calculées et la répartition d'énergie potentielle soient perturbées de façon notable. En outre, dans le cas de la taurine, nous avons du annuler la constante ν $C_\beta S$, ν_s SO_3 pour pouvoir expliquer les spectres observés.

Conclusion

Ce travail donne un bon exemple de la transférabilité des champs de force entre molécules de formule voisine.

Le manque de molécules isotopiques ne nous a pas permis de raffiner les champs de force que nous avons obtenus ni de dégager les relations qui doivent exister entre les fréquences des vibrations et la conformation. Nos résultats doivent cependant pouvoir être utilisés, en particulier pour faciliter l'interprétation de molécules à liaison amide, formées à partir des acides aminés étudiés dans ce mémoire et qui font l'objet de recherches entreprises conjointement d'un point de vue conformationnel (10, 18)[4] et biochimique (19–28).

Partie expérimentale

La β-alanine est un produit Fluka, la taurine un produit Merck. La ciliatine a été synthétisée par la méthode de Kosolapoff (29). Les composés deutériés sur les atomes d'azote et (pour la ciliatine) l'oxygène ont été préparés par échanges répétés avec de l'eau lourde en excès, l'eau résiduelle étant ensuite éliminée par évaporation sous vide. La variété β de la ciliatine a été identifiée par comparaison de ses spectres infrarouges avec ceux publiés par Horiguchi et Kandatsu (11). On a vérifié, avant et après enregistrement du spectre Raman, que l'échantillon irradié par le laser était resté sous forme β. Les échantillons solides ont été examinés par spectrométrie infrarouge suivant la région spectrale considérée, en suspension dans le Nujol ou le fluorolube. Pour les spectres Raman, la poudre cristalline a été placée dans de petits tubes cylindriques en verre. Les spectres infrarouges ont été enregistrés sur un appareil à réseaux Perkin Elmer 225. Les fréquences d'absorption des bandes fines sont lues à ± 1 cm^{-1}, dans tout le domaine spectral. Les spectres Raman ont été obtenus sur un appareil Coderg PH 1, éclairé par un laser 'Spectra Physics' à Argon ionisé ($\lambda = 4880$ Å). Les lectures ont été faites à ± 3 cm^{-1}. Les calculs ont été faits sur un ordinateur CII Iris 80, en utilisant un champ de force de valence et la méthode décrite par Wilson *et al.* (30). L'énergie potentielle a été écrite dans la même approximation que la matrice d'énergie cinétique G, c'est-à-dire en posant nulles les constantes de force d'interaction entre vibrateurs sans atome commun.

Remerciements

Nous remercions Mme E. Dupart qui a préparé la ciliatine, et Mme M. Rey qui a relu et discuté ce manuscrit.

Gas phase acidic solvolysis reactions of acyl halides by ion cyclotron resonance spectroscopy

T. B. McMAHON

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received September 22, 1977

T. B. McMAHON. Can. J. Chem. **56**, 670 (1978).

A number of gas phase ion molecule reactions of protonated species with acyl halides have been examined by ion cyclotron resonance spectroscopy. A number of these reactions are found to involve an addition–elimination reaction having the character of an acidic solvolysis process. Observation of the occurrence or non-occurrence of such reactions and a consideration of appropriate thermochemical data allow a set of criteria to be formulated governing the feasibility of observing the acidic solvolysis reaction. In addition a number of mechanistic inferences are made concerning intermediates involved in the various reactions.

T. B. McMAHON. Can. J. Chem. **56**, 670 (1978).

On a étudié un certain nombre de réactions ion–molécule en phase gazeuse d'espèces protonées avec des halogénures d'acyle en faisant appel à la spectroscopie à trajectoire cycloïdale résonante. On a trouvé qu'un certain nombre de ces réactions implique une réaction addition–élimination possédant un caractère de processus de solvolyse acide. L'observation de l'existence de telles réactions et la considération de données thermodynamiques appropriées permettent de formuler un ensemble de critère concernant la possibilité d'observer la réaction de solvolyse acide. On peut de plus déduire un certain nombre d'implications mécanistiques concernant les intermédiaires intervenant dans les diverses réactions.

Introduction

The detailed mechanisms of organic reactions in solution have preoccupied physical organic chemists for several decades. Of particular interest have been the reactions of carboxylic acids and carboxylic acid derivatives because of the great synthetic utility of these compounds, the variety of reactions which they undergo and the pronounced effects of acid and base catalysis on their reactions (1–3). Of the carboxylic acid derivatives the acyl halides have been the least extensively characterized due to their extremely high reactivity (1). It has recently been shown, however, that in the case of solution reactions which proceed via ionic mechanisms a great deal of mechanistic information may be derived from the study of appropriate analogous ion molecule reactions in the gas phase (4–6). Using a variety of techniques it is possible to obtain both qualitative and quantitative information concerning the nature of the intermolecular interaction between the reacting species. In addition since in the gas phase complicating solvation phenomena are eliminated the intrinsic reactivity and stability of the ionic species of interest may be ascertained. Further, by contrasting analogous solution and gas phase reactions, it is frequently possible to elucidate the role of the solvent in the reaction.

The present work describes an ion cyclotron resonance (ICR) study of the reactions of a series of protonated molecules with several acyl halides. The observed reactions can be placed in three general categories: (*i*) proton transfer yielding protonated acyl halide, (*ii*) halide abstraction to give acylium ion, and (*iii*) addition–elimination producing a new protonated carboxylic acid derivative plus hydrogen halide. This reaction has the character of an acidic solvolysis process. A number of requirements have been formulated which allow an a priori prediction of which of the possible reaction channels may be expected. These requirements also suggest mechanistic details concerning the course of reaction and allow probable reaction intermediates to be postulated.

Experimental

The experiments described in this work were performed on a Varian V-5900 ICR spectrometer modified by Dynaspec Inc. to allow for operation in both conventional and trapped-ion modes (7). The timing and sequence of pulses to the ICR plates in trapped-ion experiments was generated by a DCC Model D-116 Minicomputer. All other ICR instrumentation and techniques were identical to those described in detail elsewhere (8, 9). Typical operating conditions are: drift voltages, 0.2 V/cm; trapping voltage, 0.2 V/cm; electron emission current, 0.01 to 1 μA; total ion current, 10^{-10} to 10^{-12} A; magnetic field sweep, 0 to 14 kG. Ion kinetic energies are all near thermal energy (less than 0.1 eV).

Approximate pressures only could be read from the ion-pump current and may be in error by a factor of two. Consequently rate constant determinations are quite approximate. In favorable cases more accurate rate constants may be inferred when a reaction is observed whose rate constant is well known. In such cases a more nearly exact pressure can be calculated from the observed experimental ion intensities.

Binary gas mixtures were prepared directly in the instrument by admitting the two reagents through separate vacuum inlet systems. Mixture ratios were determined from changes in ion pump current on introduction of each gas and again may be in error due to different ion pump response to different gases and due to modification of the flow of the gas initially admitted by the addition of flow of the second gas. Attempts to prepare binary mixtures of acyl halides with other materials in a single vessel frequently led to direct neutral–neutral reaction in the sample vessel (1). For example mixtures of methanol and acetyl fluoride always produced methyl acetate in a very short time. Since protonated methyl acetate is the species of interest in this mixture, the resulting impurity obviously invalidates the results. Thus it is imperative to use separate inlets for these experiments.

Acetyl fluoride was obtained from PCR Inc., benzoyl fluoride, acetyl chloride, and benzoyl chloride from Aldrich and methane, ammonia, methylamine, and dimethylamine from Matheson. All other materials were commercially available reagent grade chemicals.

Results

The reactions of acyl halides, RCOX, with protonated species $R'MH^+$ can be divided into three general categories as illustrated by reactions 1–3.

[1] $RCOX + R'MH^+ \rightarrow RCOXH^+ + R'M$

[2] $RCOX + R'MH^+ \rightarrow RCO^+ + R'M + HX$

(or $R'X + MH$)

[3] $RCOX + R'MH^+ \rightarrow RCOMR'^+ + HX$

Reaction 1 is simple proton transfer and can be expected to occur whenever the proton affinity of the acyl halide is greater than that of the base, R'M. Reaction 2 produces acylium ion and a pair of neutral products which may be either hydrogen halide, HX, plus base, R'M, or alkyl halide, R'X, plus a hydride, MH. In some cases both pairs of neutral products are thermodynamically possible but in others only the latter pair may be exothermically produced. Reaction 3 is an addition–elimination reaction yielding a new protonated carboxylic acid derivative plus hydrogen halide which bears a strong resemblance in many cases to observed solvolysis reactions of acyl halides in acidic solution.

The possible reactions for each of the acyl halides with protonated substrates studied are summarized in Table 1. Included are the enthalpy change for each reaction, the total observed reaction rate constant for protonated substrate with acyl halide, and the experimentally determined product distribution.

(1) Reactions of H_3O^+ and H_3S^+

From Table 1 it may be seen that the dominant reaction path for H_3O^+ and H_3S^+ with acetyl halides is acetyl cation formation. Data for a mixture of H_2S and acetyl fluoride are shown in Fig. 1 and

[4] $H_2S^+ + H_2S \rightarrow H_3S^+ + SH$

[5] $H_2S^+ + CH_3COF \rightarrow CH_3COSH^+ + HF$

[6] $H_3S^+ + CH_3COF \rightarrow CH_3CO^+ + HF + H_2S$

[7] $H_3S^+ + CH_3COF \rightarrow CH_3COFH^+ + H_2S$

[8] $CH_3COFH^+ + H_2S \rightarrow (CH_3COSH)H^+ + HF$

are typical of reactions between these species. The observed reactions occurring in this mixture confirmed by double resonance experiments are summarized below. Similar reactions are observed for H_3O^+ with acetyl fluoride and acetyl chloride and for H_3S^+ with acetyl chloride. These results establish the proton affinities of both acetyl halides to be above that of H_2S, 172 kcal/mol.

In the reactions of H_3O^+ and H_3S^+ with benzoyl fluoride no protonated benzoyl fluoride is observed even though the proton affinity of benzoyl fluoride is established to be greater than that of H_2S. It may be seen from Table 1 that the decomposition of protonated benzoyl fluoride to benzoyl cation and HF is 3 kcal/mol exothermic. Thus it is likely that no protonated benzoyl fluoride is observed since exothermic proton transfer is immediately followed by unimolecular elimination of HF to produce the abundantly observed benzoyl cation, reaction 9.

[9] $H_3S^+ + \phi COF \rightarrow H_2S + [\phi CFOH^+]^* \rightarrow \phi CO^+ + HF$

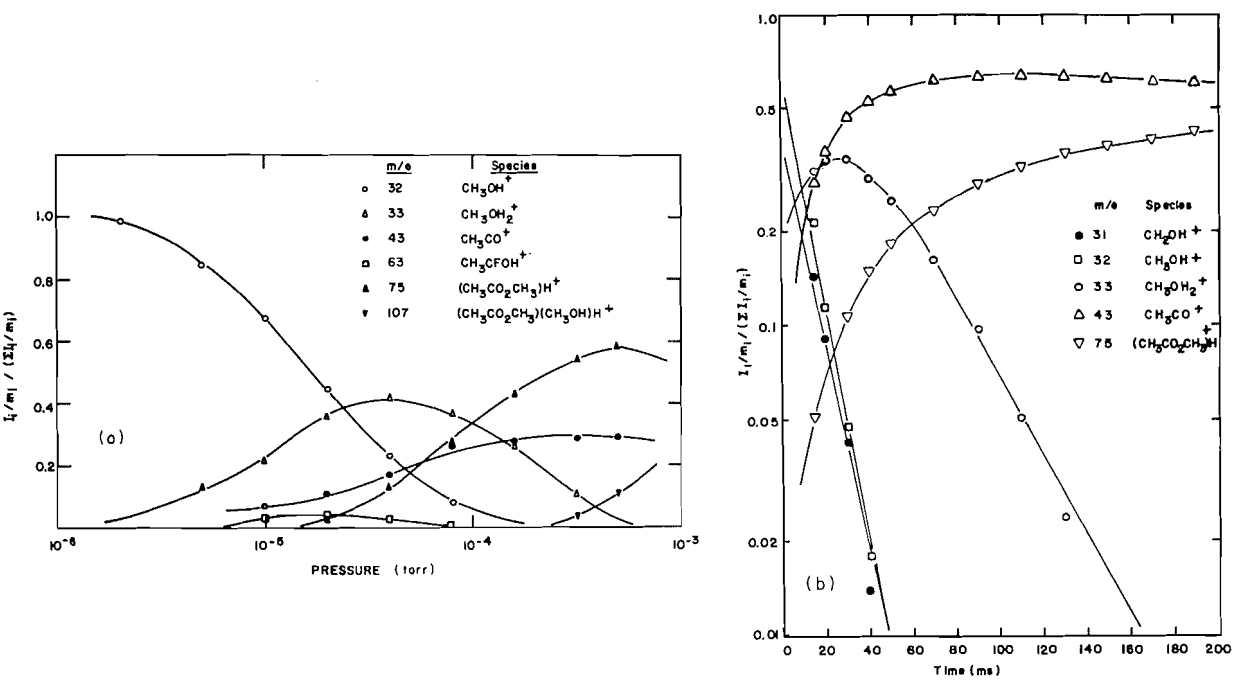

FIG. 2. (*a*) Variation of relative ion abundances with pressure in a 4.4:1 mixture of methanol and acetyl fluoride at 13 eV. (*b*) Variation of relative ion abundances with reaction time in a 2:1 mixture of methanol and acetyl fluoride at 14 eV and a total pressure of 2.4×10^{-6} Torr.

(2) Reactions of Protonated Alcohols

Protonated alcohols were found to react with acetyl fluoride and acetyl chloride to produce the corresponding protonated esters. The reactions observed in a mixture of acetyl fluoride and methanol are shown in Fig. 2 both as a function of increasing pressure and increasing reaction time to show the similarity of results from both types of experiment. Reactions observed are summarized in [10]–[14].

[10] $CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O$

[11] $CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2O$

[12] $CH_2OH^+ + CH_3COF \rightarrow CH_3CO^+ + HF + CH_2O$

[13] $CH_3OH_2^+ + CH_3COF \rightarrow CH_3CO^+ + CH_3F + H_2O$

[14] $CH_3OH_2^+ + CH_3COF \rightarrow [CH_3CO_2CH_3]H^+ + HF$

Reaction 13 is of particular interest since the neutral products have been inferred on the basis of thermochemical arguments and leads to important mechanistic considerations.

Similar results are observed in a mixture of ethanol with acetyl fluoride or acetyl chloride and methanol with acetyl chloride. In the case of ethanol and acetyl fluoride, however, another interesting product at *m/e* 87 is observed as a result of reaction of *m/e* 45, protonated acetaldehyde with the acetyl fluoride. This reaction is in principle similar to the acidic solvolysis reactions of protonated alcohols to yield protonated esters and the assumed product from protonated acetaldehyde is protonated biacetyl. This product does not appear in ethanol – acetyl chloride mixtures presumably because it does not compete favorably with acetyl cation formation. Typical data for ethanol – acetyl chloride mixtures is shown in Fig. 3.

In each of the cases where the presumed acidic solvolysis reaction is observed an alternative explanation of the reaction products is possible. In gas phase reactions of Li^+ with acetyl bromide reaction 14′ was observed which has the character of an acid induced elimination reaction producing

[14′] $Li^+ + CH_3COBr \rightarrow Li \cdots {}^+O{=}C{=}CH_2 + HBr$

an Li^+ bound to ketene (10). In analogy to this reaction it was considered possible that an alternative explanation of reactions such as [14] might be [14*a*] where the ionic product now is a proton bound

[14*a*] $CH_3OH_2^+ + CH_3COF \rightarrow$

$$CH_2{=}C{=}O \cdots \overset{+}{H}(HOCH_3) + HF$$

dimer of methanol and ketene. Since the elimination of HF from acetyl fluoride is only about 27 kcal/mol endothermic if the binding energy of protonated methanol to acetyl fluoride were in excess of 27 kcal/mol an elimination of HF such as in [14*a*] might be induced. In order to investigate this possibility

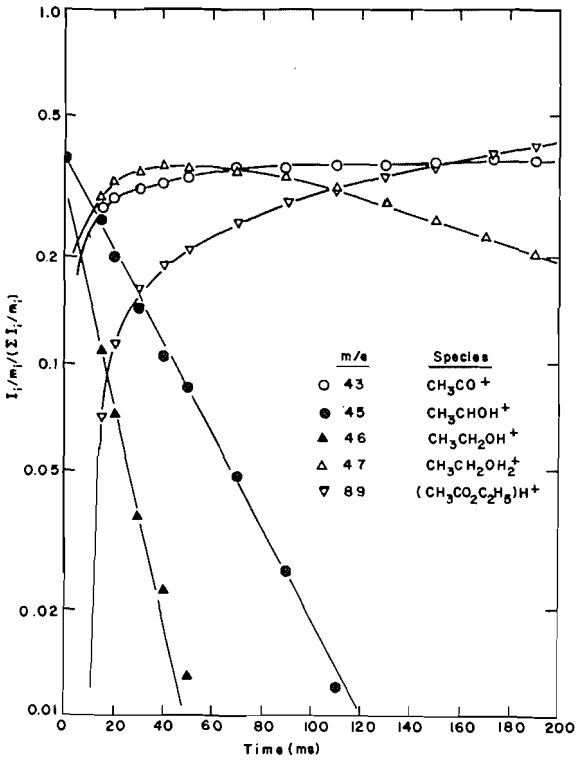

FIG. 3. Variation of relative ion abundances with reaction time in a 4:1 mixture of ethanol and acetyl chloride at 13 eV and a total pressure of 1.0×10^{-6} Torr.

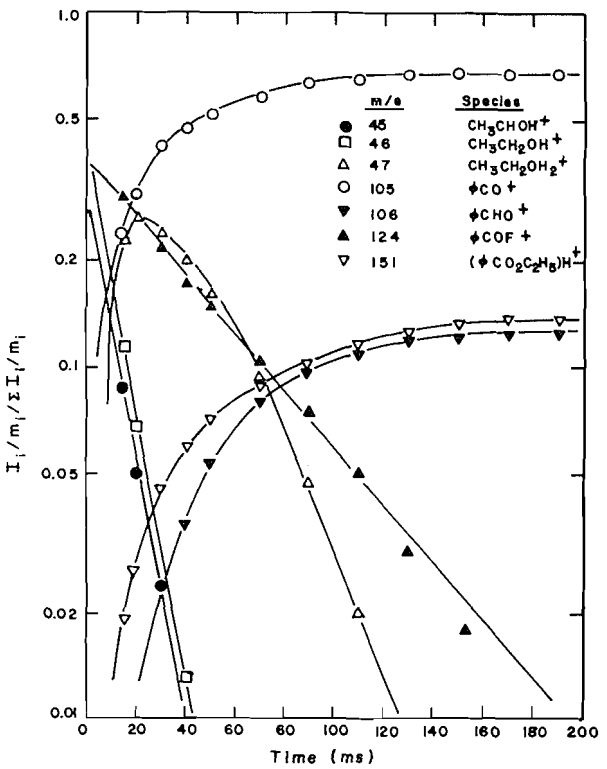

FIG. 4. Variation of relative ion abundances with reaction time in a 3.4:1 mixture of ethanol and benzoyl fluoride at 14 eV and a total pressure of 2.2×10^{-6} Torr.

the reactions occurring in a mixture of CD_3OD and CH_3COF was examined. In this case only reaction 14*b* was observed and not [14*c*].

[14*b*] $CD_3OD_2^+ + CH_3COF \rightarrow (CH_3CO_2CD_3)D^+ + DF$

[14*c*] $CD_3OD_2^+ + CH_3COF \not\rightarrow$

$CH_2{=}C{=}O \cdots D \therefore (DOCD_3) + HF$

With benzoyl fluoride protonated methanol exhibited significantly different behaviour than the other protonated alcohols. Protonated methanol was found to react with benzoyl fluoride to produce only benzoyl cation while each of the other protonated aliphatic alcohols also yielded protonated alkyl benzoates. Competitive proton transfer experiments established that the proton affinity of benzoyl fluoride was intermediate between methanol and ethanol and can be assigned a value of 184 ± 2 kcal/mol. Typical data for alcohol – benzoyl fluoride systems where acidic solvolysis occurs are shown in Fig. 4 for a mixture of ethanol and benzoyl fluoride. In addition to reactions similar to those previously observed a rather novel reaction product at *m/e* 106 was found to arise from reaction of the benzoyl fluoride molecular ion, *m/e* 124, with ethanol. A feasible explanation of this product is reaction 15.

[15] $\phi COF^+ + CH_3CH_2OH \rightarrow \phi CHO^+ + CH_3F + CH_2O$ (or $HF + CH_3CHO$)

(3) Reactions of Protonated Ammonia and Amines

Ammonium ion and all alkyl ammonium ions were observed to be unreactive towards each of the acyl halides studied. The ion molecule reactions occurring in a mixture of ammonia and acetyl chloride are shown in Fig. 5. The only reaction of interest is proton transfer from the acyl cation to ammonia, reaction 16, in agreement with recent determinations of the proton affinity of ketene from thermochemical data which establish it to be less than ammonia.[1]

[16] $CH_3CO^+ + NH_3 \rightarrow NH_4^+ + CH_2CO$

Additional interesting results were obtained in mixtures of ammonia and amines with benzoyl fluoride. Since the ionization potential of benzoyl

[1]Proton affinity of ketene calculated from $\Delta H_f^0(CH_3CO^+) = 153$ kcal/mol (30) and $\Delta H_f^0(CH_2CO) = -14.6$ kcal/mol (30).

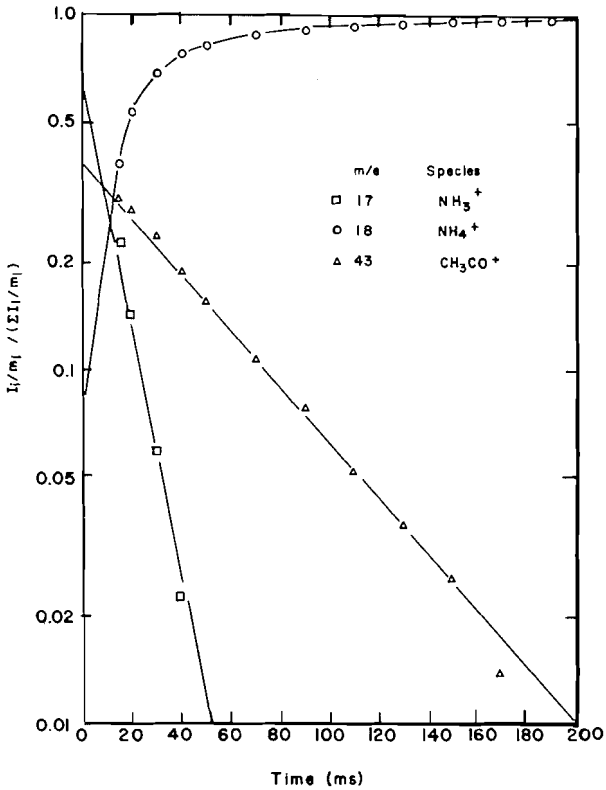

FIG. 5. Variation of relative ion abundances with reaction time in a 3:1 mixture of ammonia and acetyl chloride at 15 eV and a total pressure 2.0×10^{-6} Torr.

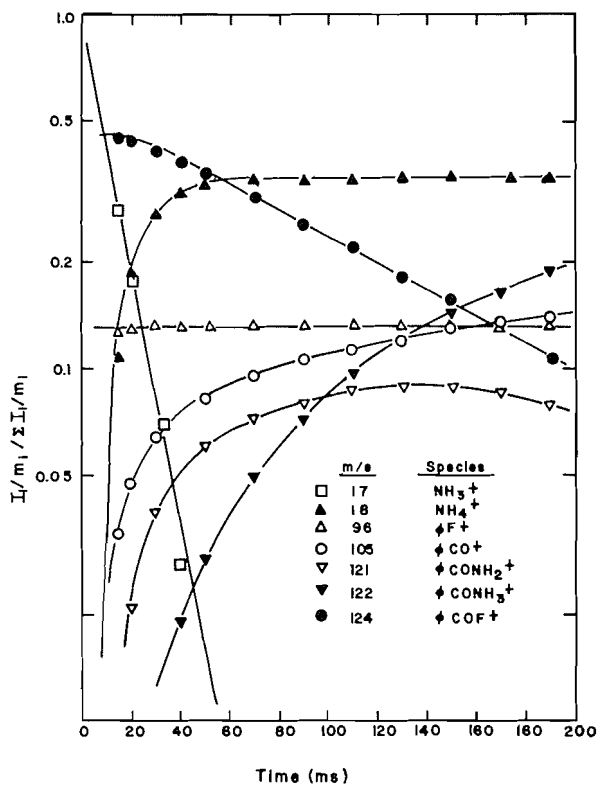

FIG. 6. Variation of relative ion abundances with reaction in a 4:1 mixture of ammonia and benzoyl fluoride at 14 eV and a total pressure of 2.0×10^{-6} Torr.

fluoride is comparable to ammonia it is necessary to operate under conditions where benzoyl fluoride molecular ion is also present. This ion initiates the sequence of reactions 17 and 18. In addition reactions 19 and 20 also occur.

[17] $\phi CFO^+ + NH_3 \rightarrow \phi CONH_2^+ + HF$

[18] $\phi CONH_2^+ + NH_3 \rightarrow \phi CONH_3^+ + NH_2$

[19] $NH_3^+ + \phi COF \rightarrow \phi CFO^+ + NH_3$

[20] $NH_3^+ + \phi COF \rightarrow \phi CO^+ + HF + NH_2$

These reactions are illustrated in Fig. 6. Analogous behaviour is observed for methyl amine – benzoyl fluoride mixtures.

(4) Reactions of Protonated Carboxylic Acids

The reactions of protonated formic acid with acetyl fluoride, Fig. 7, and acetyl chloride, Fig. 8, are noteworthy in that radically different products are formed in each case. With acetyl fluoride protonated formic acid reacts to produce a new ion at *m/e* 89 corresponding to protonated formic acetic anhydride, reaction 21. This reaction is analogous to the acidic solvolysis reactions observed above.

[21] $HCO_2H_2^+ + CH_3COF \rightarrow (CH_3CO_2COH)H^+ + HF$

In addition products also appear at *m/e* 105, 103, and 61 which may be explained by the sequence of reactions 22–24 respectively.

[22] $(HCO_2COCH_3)H^+ + CH_3COF \rightarrow (CH_3CO)_2F^+ + HCO_2H$

[23] $(HCO_2COCH_3)H^+ + CH_3COF \rightarrow ((CH_3CO)_2O)H^+ + HF + CO$

[24] $(CH_3CO)_2F^+ + HCO_2H \rightarrow CH_3CO_2H_2^+ + CH_3COF + CO$

It is interesting to note that reactions 22 and 24 constitute a chain reaction leading to the overall decomposition of protonated acetic anhydride to protonated acetic acid plus carbon monoxide, reaction 25.

[25] $(HCO_2COCH_3)H^+ \rightarrow CH_3CO_2H_2^+ + CO$

In the reactions of protonated formic acid with acetyl chloride no protonated mixed anhydride is formed. Instead the immediate product of reaction is *m/e* 61

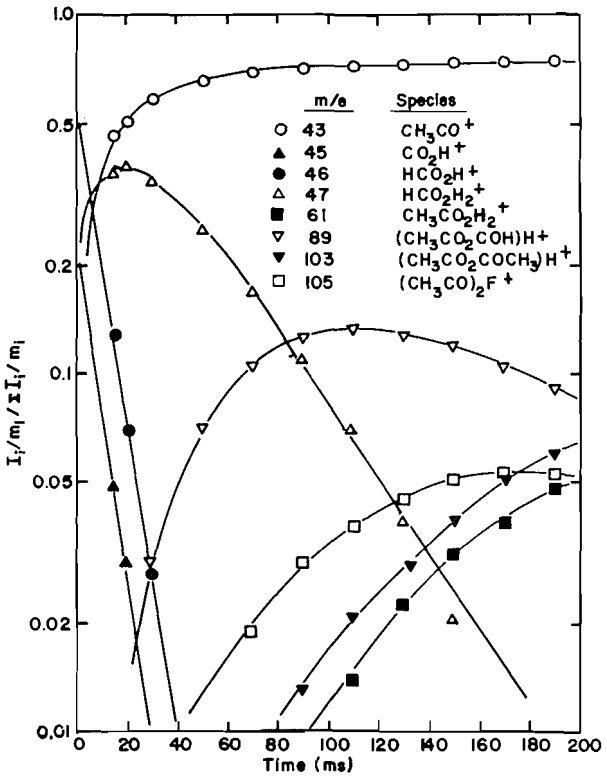

FIG. 7. Variation of relative ion abundances with reaction time in a 4:1 mixture of formic acid and acetyl fluoride at 17 eV and a total pressure of 2.0×10^{-6} Torr.

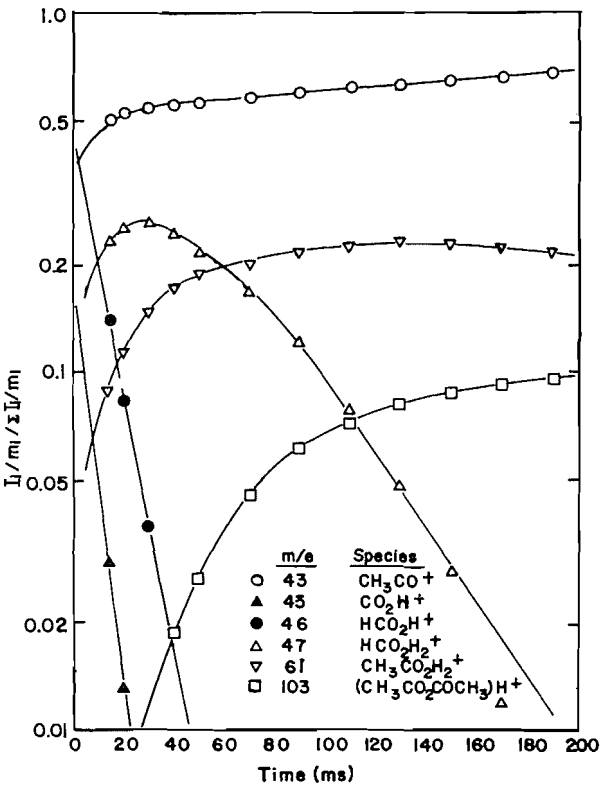

FIG. 8. Variation of relative ion abundances with reaction time in a 3:1 mixture of formic acid and acetyl chloride at 15 eV and a total pressure of 1.6×10^{-6} Torr.

protonated acetic acid, reaction 26, followed by further reaction with acetyl chloride to produce the protonated symmetric anhydride, reaction 27.

[26] $HCO_2H_2^+ + CH_3COCl \rightarrow CH_3CO_2H_2^+ + HCl + CO$

[27] $CH_3CO_2H_2^+ + CH_3COCl \rightarrow ((CH_3CO)_2O)H^+ + HCl$

Thus although protonated acetic acid leads to anhydride formation as expected from the acetyl fluoride results protonated formic acid does not, contrary to expectation. Competitive proton transfer experiments established the proton affinity of acetyl fluoride as intermediate between H_2S and formic acid and of acetyl chloride as intermediate between formic acid and methanol. These results have important mechanistic implications to be discussed below.

(5) Reactions of Other Protonated Species

In order to test the generality of the addition–elimination reaction, [1], a number of other protonated species were reacted with the acyl halides. CH_5^+, H_2Cl^+, and CH_3ClH^+ reacted only via proton transfer or acyl cation formation. Protonated alkyl ethers and ketones were completely unreactive toward the acyl halides. In addition as seen from the data presented above protonated esters and anhydrides underwent no addition–elimination reactions with the acyl halides.

Discussion

From the above data it is evident that not all protonated species will undergo the addition–elimination reaction with acyl halides. However, careful examination reveals that when the following criteria are met the acidic solvolysis reaction may be expected to occur.

(1) The reaction must be exothermic. This is a general requirement of all thermal energy ion molecule reactions (12).

(2) Proton transfer from the protonated 'solvent' molecule to the acyl halide must be endothermic. This requirement is similar to that observed for gas phase nucleophilic displacement reactions (4). For example although reactions 28 and 29 are both exothermic, [28] occurs while [29] does not since the competing reaction 30 is also exothermic. This situation does not arise in the ethylchloride case since the proton affinity of ethyl chloride is greater than that of water.

[28] $C_2H_5ClH^+ + H_2O \rightarrow C_2H_5OH_2^+ + HCl$

[29] $CH_3ClH^+ + H_2O \not\rightarrow CH_3OH_2^+ + HCl$

[30] $CH_3ClH^+ + H_2O \rightarrow H_3O^+ + CH_3Cl$

An exactly analogous situation may be seen for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acidic solvolysis reactions observed here. Thus although both [31] and [32] are very exothermic only [31] is observed since [33] dominates in reactions of protonated methanol with benzoyl fluoride.

[31] $CH_3CH_2OH_2^+ + \phi COF \rightarrow (\phi CO_2C_2H_5)H^+ + HF$

[32] $CH_3OH_2^+ + \phi COF \not\rightarrow (\phi CO_2CH_3)H^+ + HF$

[33] $CH_3OH_2^+ + \phi COF \rightarrow \phi CFOH^+ + CH_3OH$

$\rightarrow \phi CO^+ + HF + CH_3OH$

In this situation where two exothermic reaction channels are available from a common intermediate the channel involving the more extensive molecular rearrangement is less favorable. For similar reasons protonated formic acid undergoes addition–elimination with acetyl fluoride but not with acetyl chloride; H_3O^+ and H_3S^+ react only by proton transfer and ethanol and higher alcohols all undergo the acidic solvolysis reaction.

(3) The protonated solvent molecule must have at least two labile protons. This requirement arises from the observation that although reaction of protonated alcohols with acyl halides yield the corresponding protonated esters (for example reaction 14), protonated ethers are unreactive toward acyl halides. For example reaction 34 is not observed even though

[34] $(CH_3)_2OH^+ + CH_3COF \not\rightarrow$

$(CH_3CO_2CH_3)H^+ + CH_3F$

it is 20 kcal/mol exothermic. Similarly no acidic solvolysis was ever observed from protonated species with less than two labile protons. It is important to note that the two labile protons need not be bound to the same atom and need not be equivalent. For example protonated formic acid reacts with acetyl fluoride to give protonated formic acetic anhydride, reaction 21, even though the requisite two protons are on different but equivalent oxygens. In addition protonated acetaldehyde is observed to react with acetyl chloride to produce protonated biacetyl, reaction 35, even though one of the labile protons is bound to oxygen and the other to carbon. *Ab initio* calculations indicate that the hydrogen bound to

[35] $CH_3CHOH^+ + CH_3COF \rightarrow [(CH_3CO)_2]H^+ + HF$

oxygen has a formal positive charge of +0.412 while the hydrogen bound to the carbonyl carbon has a charge of +0.289 (13). It is therefore reasonable to expect a certain degree of lability from this second hydrogen.

(4) The protonated solvent must have at least one additional lone pair of electrons to participate in new bond formation. This requirement is indicated by the inability of protonated ammonia and amines to react with acyl halides to produce protonated amides even though the reactions are quite exothermic and in the case of the acetyl halides no other exothermic competing reaction channel of any kind exists. This criterion again has precedent if the ion molecule reactions of alkyl halides (14, 15), alcohols (16–18), and amines (19–21) are compared. While reactions 36 and 37 occur readily for protonated alcohols and alkyl halides the analogous reaction 38 of protonated amines is not observed at all even though it is exothermic.

[36] $ROH_2^+ + ROH \rightarrow R_2OH^+ + H_2O$

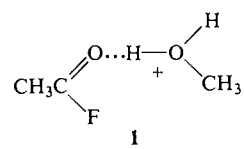
[37] $RXH^+ + RX \rightarrow RXR^+ + HX$

[38] $RNH_3^+ + RHH_2 \not\rightarrow R_2NH_2^+ + NH_3$

This result is attributable to the lack of an available electron pair on nitrogen in the proton bound dimer intermediate for the reaction. In the alcohols and halides simultaneous bond breakage and formation can occur in the intermediate since in these cases the heteroatoms have one or two nonbonding electron pairs available to participate in formation of new bonds.

On the basis of the evidence presented above the probability is high that if all four of these criteria are met an addition–elimination reaction having the character of an acidic solvolysis will occur to an observable extent. If other reaction channels are available the fraction of protonated species reacting with acyl halide via this pathway may be appreciably less than unity. In the cases examined above however wherever the suggested criteria are met some acidic solvolysis is observed.

Consideration of the above criteria and appropriate thermochemical data provides several clues to the details of the mechanisms of several of the reactions observed. On the basis of observation of reactions of protonated molecules with n-donor bases the most likely initially formed intermediate in the acidic solvolysis reaction is a linear proton bound dimer (22, 23). This geometry is supported by several *ab initio* calculations of model systems (24–26). This intermediate is typified by structure **1** for the

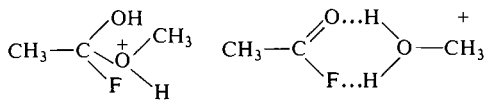


1

methanol acetyl fluoride system. In order to eliminate HF to produce protonated methyl acetate or to produce acetyl cation two further reaction intermediates are possible. The first of these, structure **2**, is a tetrahedral structure, postulated by solution organic chemists as the intermediate involved in the solvolysis of acyl halides. Structure **3** is a bent proton bound dimer which is in general considered to be less stable than a linear proton bound dimer. How-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

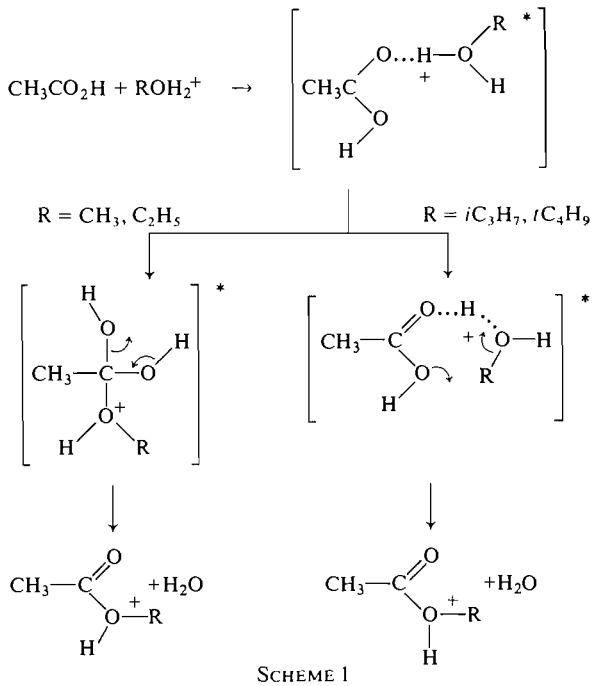
ever, Del Bene has recently carried out calculations of hydrogen bonded dimers of bifunctional carbonyl compounds and has shown that in several systems such as the dimer of urea and water two bent O—H...O and N—H...O bonds may be formed (27). This system is conceptually similar since a second weaker hydrogen bond may form to the fluorine. Both **2** and **3** are adequate to explain the formation of protonated methyl acetate. However,



2 **3**

an analysis of additional reactions which do and do not occur provides a useful indication of which of **2** and **3** is more plausible. In addition to protonated ester formation it is observed that protonated methanol reacts with acetyl fluoride to produce acyl cation. The corresponding neutral products of this reaction may be either methanol and HF or methyl fluoride and water. An analysis of thermochemical data reveals however that only reaction associated with the latter pair of neutral products is exothermic. Elimination of CH_3F from **2** suggests that formation of protonated acetic acid would also be a feasible reaction product since this reaction is exothermic by 22 kcal/mol. Since this product is in fact not observed structure **3** seems to be the more reasonable intermediate. Elimination of HF simultaneous with carbonyl carbon to alcohol oxygen bond formation facilely leads to the protonated ester. In addition rotation about the O—H...O bond allows for elimination of CH_3F and H_2O to yield acetyl cation.

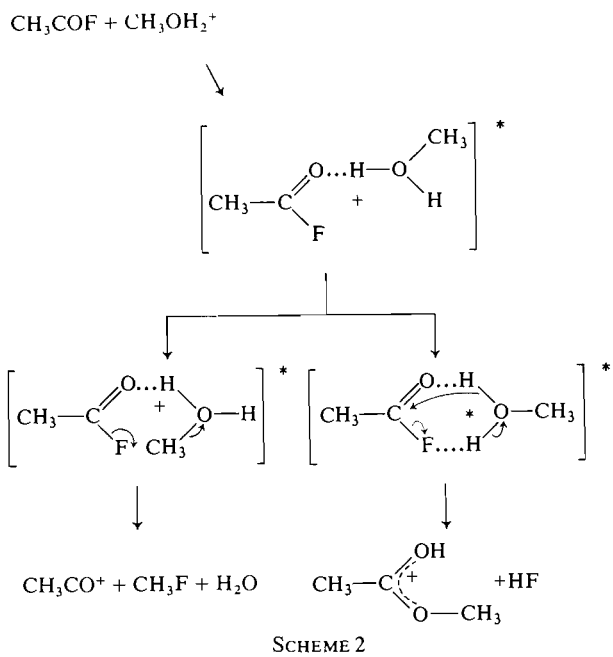
The above conjecture is supported by mechanistic studies of esterification of acetic acid using deuterium and ^{18}O labelling carried out by Beauchamp (28). In this case esterification occurs for all alcohols and acetic acids but by different mechanisms depending upon the relative proton affinities of the alcohol and the acid. The mechanistic conclusions drawn are outlined in Scheme 1. In this system the proton affinities of methanol and ethanol are less than acetic acid so that the mechanism involves proton transfer to the acid and formation of a tetrahedral intermediate followed by loss of H_2O. For isopropanol and *tert*-butanol the alcohol proton affinities are greater than acetic acid and the mechanism involves intramolecular R^+ transfer within the intermediate with loss of H_2O. This latter mechanism is exactly analogous to that proposed here for protonated species with acyl halides. The proton affinity of the acyl halide is less than the protonated species and a tetrahedral intermediate need not be formed. Using the methanol – acetyl fluoride case as an example the mechanism can be illustrated by Scheme



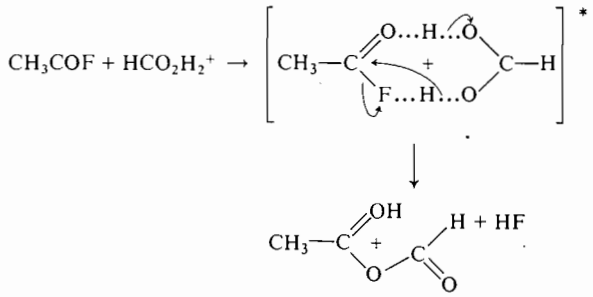
SCHEME 1

2. The evidence and precedents all tend to support this as the most reasonable mechanism for acyl halide acidic solvolysis reactions.

It is also of interest to note that in certain cases where proton transfer from the protonated species to acyl halide is exothermic reactions may occur which can be assumed to arise from a tetrahedral intermediate. For example the reactions of protonated formic acid with acetyl fluoride and acetyl chloride are markedly different. In the case of acetyl

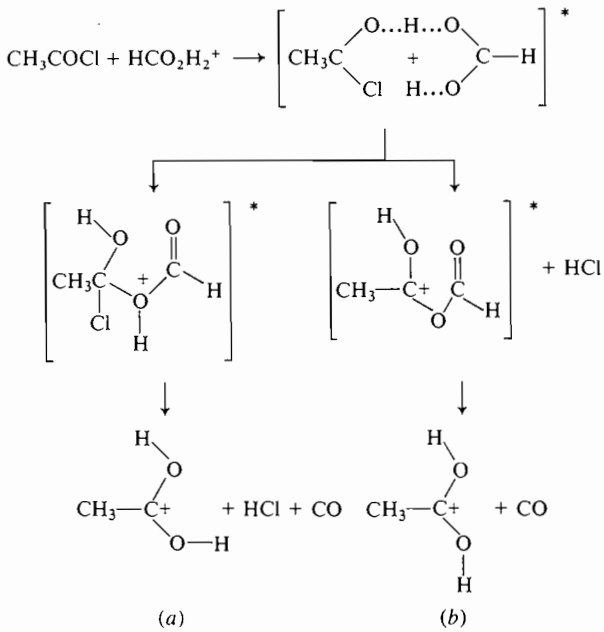


SCHEME 2



SCHEME 3

fluoride the proton affinity is less than formic acid and the acidic solvolysis product, protonated acetic-formic anhydride is formed. This reaction is illustrated by Scheme 3. However, the proton affinity of acetyl chloride is greater than that of formic acid and the observed reaction product, protonated acetic acid must arise from a different mechanism. Two reasonable mechanisms represented by Scheme 4*a* and *b* are possible. By analogy with the reactions of



SCHEME 4

protonated methanol and ethanol with acetic acid where proton transfer is accompanied by tetrahedral intermediate formation it is likely that Scheme 4*a* is the actual reaction mechanism. Although similar reaction of protonated formic acid with acetyl fluoride leading to protonated acetic acid is exothermic it is not observed, presumably because the initial proton transfer and tetrahedral intermediate formation do not occur.

Conclusions

The results and arguments presented above provide a rational basis for the general understanding of ion molecule reactions of protonated species with acyl halides. The competition between various reaction channels may be understood given the criteria described for acidic solvolysis to occur and in cases of new reactants prediction of dominant reaction pathways should be possible. In addition the gas phase ion molecule mechanism provides a first approximation for understanding the much more complex solvolysis reaction in solution.

The formation of hex-5-enopyranosides and their selective hydrolysis in methylated polysaccharides[1]

GERALD OLIVER ASPINALL[2] AND KARL-GUNNAR ROSELL

Department of Chemistry, York University, Downsview, Toronto, Ont., Canada M3J 1P3

Received October 14, 1977

GERALD OLIVER ASPINALL and KARL-GUNNAR ROSELL. Can. J. Chem. **56**, 680 (1978).

The introduction of hex-5-enopyranoside residues into methylated acidic polysaccharides is effected by reduction of uronic acid residues, followed by reaction with triphenyl phosphite methiodide, and dehydroiodination. The selective hydrolysis of hex-5-enopyranosidic linkages with characterization of the 6-deoxyglycos-5-uloses thus formed and location of the aglyconic hydroxyl groups thus exposed has been demonstrated for methylated derivatives of birch xylan and gum arabic. The reaction sequence provides a new method for linkage analysis of acidic polysaccharides.

GERALD OLIVER ASPINALL et KARL-GUNNAR ROSELL. Can. J. Chem. **56**, 680 (1978).

On effectue l'introduction de résidus hexéno-5 pyrannosides dans des polysaccharides méthylés acides en faisant appel à la réduction de résidus d'acide uronique, suivie par une réaction avec de l'iodométhylate de triphénylphosphite et une déhydroiodation. On a pu mettre en évidence l'hydrolyse sélective des liens hexéno-5 pyrannosides accompagnée d'une caractérisation des déoxy-6 glycosuloses-5 ainsi formés et de la détermination de la position des groupes hydroxyles aglyconiques ainsi exposés dans le cas de dérivés méthylés de xylanes de bouleau et de la gomme arabique. La série de réactions fournit une nouvelle méthode pour analyser la nature des liens de polysaccharides acides.

[Traduit par le journal]

In connection with the development of procedures for the selective fragmentation of polysaccharides (1, 2) we have shown that the introduction of acid-sensitive hex-5-enopyranoside units may be achieved from primary hydroxyl groups by reaction with triphenylphosphite methiodide followed by dehydroiodination with (1,5-diazabicyclo [5.4.0] undec-5-ene (DBU) (3). The hydrolysis of hex-5-enopyranosides proceeds under extremely mild conditions with no detectable hydrolysis of normal glycosidic linkages. The characterization of the 6-deoxyglycos-5-uloses thus formed by reduction with sodium borohydride and further *O*-alkylation (or *O*-acylation) has now been carried out for disaccharide derivatives. Methyl 2,2′,3,3′,4′,6′-hexa-*O*-methyl-β-maltoside (**1**) was converted into the corresponding hex-5-enopyranoside (**2**) which was hydrolyzed, reduced with sodium borodeuteride (**3**), and trideuteriomethylated. Despite the formation of products (**4**), which were epimeric at C-5, the two derivatives were separable by gas chromatography and gave identical mass spectra (Scheme 1), in which the main fragment ions indicated the site of attachment of the *O*-glycosyl substituent to the 6-deoxyhexitol unit. Furthermore, the ^{1}H nmr spectrum of the mixture of epimers (**4**) gave confirmatory evidence for the configuration of the intact glycosidic linkage.

The formation of hexopyranose residues in polysaccharides, which are substituted other than at O-6, by selective blocking and deblocking is cumbersome. However, primary hydroxyl groups are readily introduced into methylated uronic acid-containing polysaccharides by reduction with lithium aluminum hydride. We have now examined the formation of hex-5-enopyranose residues from carboxy-reduced uronic acid residues in two methylated polysaccharides and have characterized, as products of selective hydrolysis, both the liberated 'reducing'

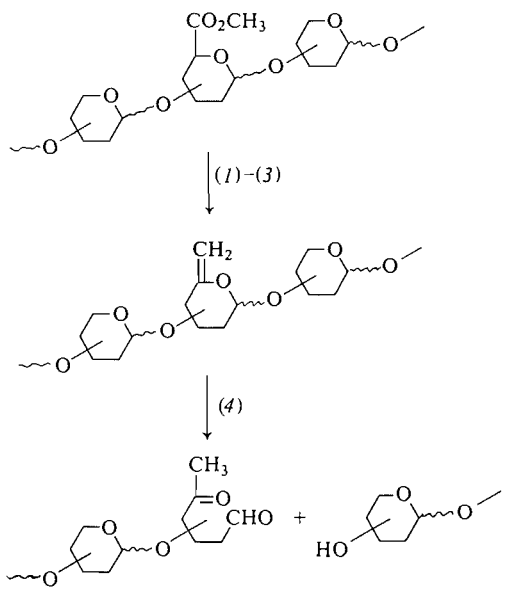
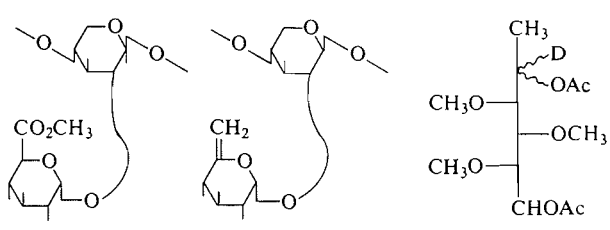
sugars and the exposed aglyconic hydroxyl groups (see Scheme 2).

The methylated polysaccharide (**5**) from birch 4-*O*-methylglucuronoxylan (4) was reduced with lithium aluminum hydride, and then treated successively with triphenylphosphite methiodide and DBU. Mild acid hydrolysis of the modified polysaccharide (**6**) gave a degraded polysaccharide and a syrupy 6-deoxyglycos-5-ulose. Reduction of the syrup with sodium borodeuteride followed by acetylation gave epimeric 1,6-di-*O*-acetyl-6-deoxy-1,5-dideuterio-2,3,4-tri-*O*-methylhexitols (**7**) which were separated by gas chromatography and gave identical mass spectra. The degraded methylated polysaccharide was then *O*-ethylated to label positions from which the modified uronic acid residues had been removed. The sugar composition of the ethylated degraded methylated polysaccharide was determined by glc analysis of the partially alkylated alditol acetates obtained from sugars formed on hydrolysis by reduction and acetylation. The compositions of the parent methylated polysaccharide, its carboxy-reduced derivative, and the ethylated degraded methylated polysaccharide are shown in Table 1. The point of attachment of glucuronic acid residues at O-2 of xylose residues in the main chain is clearly shown by the formation of 2-*O*-ethyl-3-*O*-methylxylitol triacetate, and the quantitative data indicates that the overall conversions proceeded in high yield (Scheme 3).



SCHEME 2. Formation and selective hydrolysis of hex-5-enopyranosides in methylated polysaccharides. (*1*) $LiAlH_4$; (*2*) $(C_6H_5O)_3PCH_3^+ I^-$; (*3*) DBU; (*4*) H_3O^+.



SCHEME 3. Regions of branching in methylated xylan.

A similar series of reactions was then carried out on methylated gum arabic. This polysaccharide contains a small proportion of D-glucuronic acid end groups but the majority of glucuronic acid residues are in non-terminal positions and carry α-L-rhamnopyranose residues at O-4 (**8**). Direct evidence for this linkage was obtained earlier by the isolation of rhamnose-containing oligosaccharides on partial acetolysis of the carboxy-reduced polysaccharide (5). The characterization of such partial fragmentation products from a degradation of adequate but low selectivity requires relatively large quantities of polysaccharide. Modified methylated gum arabic carrying hex-5-enopyranose residues was hydrolyzed, the reaction mixture was treated directly with sodium borohydride, and products of low molecular weight were separated from degraded polysaccharide. The nmr spectra of the mixture of alditols was consistent with the presence therein of α-L-rhamnopyranose residues (in **9**) showing signals at δ 5.10 in the ^1H spectrum assignable to H-1 (6) and at δ 99.6 in the

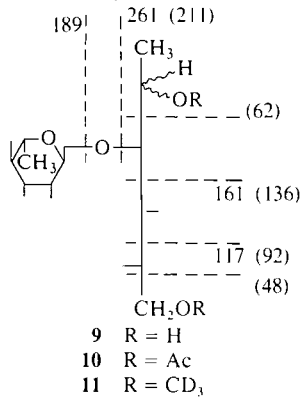
The degraded methylated polysaccharide from the above series of reactions was further alkylated with trideuteriomethyl iodide. The fully alkylated polysaccharide was analyzed for constituent sugars by



9 R = H
10 R = Ac
11 R = CD_3

SCHEME 4. Mass spectral fragmentations of derivatives of 6-deoxy-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)hexitols; *m/e* values are for ions from derivatives **10** and **11** (in parentheses where different).

conversion into methylated alditol acetates and Table 2 shows the sugar analyses for this polysaccharide derivative, the parent methylated gum arabic and its carboxy-reduced derivative. The following observations are of particular significance: (*i*) the loss of the majority of rhamnopyranose end groups; (*ii*) the absence of detectable glucose derivatives; (*iii*) no change in the overall relative proportions of arabinose and galactose methyl ethers; and (*iv*) the incorporation of trideuteriomethyl groups only at O-6 of galactose residues. These results imply that the majority of rhamnopyranose end groups in gum arabic are linked to glucuronic acid residues and are lost as fragments of low molecular weight during the selective hydrolysis of the modified sugar residues. Since base-catalyzed degradation of methylated gum

arabic results in complete loss of rhamnose end groups (8) it is known from independent evidence that all the rhamnose residues are linked to glucuronic acid. The presence of a small proportion of residual rhamnose residues in the degraded polysaccharide indicates incomplete modification of glucose residues during the overall sequence, probably from an undetected side reaction. The results of realkylation of the degraded methylated polysaccharide must be treated with some reserve. Judged by the slight excess of apparent branch points over end groups in methylated gum arabic it is not easily possible to achieve complete methylation of the interior galactose residues (for a fuller discussion on this point see the accompanying paper (9)). Consequently further alkylation of the degraded methylated polysaccharide would lead to the introduction of trideuteriomethyl groups at sites of initial incomplete methylation and at liberated hydroxyl groups exposed during the degradation. Nevertheless the detection of labelled alkyl groups only at O-6 of galactose residues is in accord with well documented evidence that glucuronic acid residues in gum arabic are linked (1 → 6) to galactose residues (10).

The experiments now reported show that uronic acid residues in methylated polysaccharides may be converted into hex-5-enopyranose residues which may be selectively hydrolyzed with the formation of 6-deoxyglycos-5-uloses. The characterization of these derivatives provides useful new structural information, especially, as in the case of gum arabic, where

For personal use only.

the cleavage of non-terminal residues gives derivatives carrying glycosyl substituents. In particular the characterization of such oligosaccharide derivatives provides information on the anomeric configuration of the intact glycosidic linkages which may otherwise be difficult to obtain unambiguously.

Experimental

Evaporations were carried out under diminished pressure at bath temperatures of 40°C or less. Optical rotations were measured with a Perkin-Elmer model 141 polarimeter at 20 ± 2°. The ir spectra were measured on a Unicam SP 200 spectrophotometer. ^{1}H nmr spectra were recorded on Varian A-60, EM-360 and HA-100 spectrophotometers in deuteriochloroform with tetramethylsilane as internal standard. ^{13}C nmr spectra were recorded on a Varian CFT-20 FT spectrometer operating at 20 MHz with an 8K 620L-100 computer. Chemical shifts were internally referenced to deuteriochloroform and are reported corrected to tetramethylsilane. Gas–liquid chromatography was performed with Hewlett-Packard model 5750 and Perkin-Elmer 990 chromatographs using columns of Gas-Chrom Q coated with (*a*) 5% of neopentylglycol adipate polyester (operating temperature 130–160°C), (*b*) 3% of silicone–polyester copolymer ECNSS-M (170–190°C), (*c*) 3% of silicone gum OV-225 (170–200°C), and (*d*) 5% of silicone gum XE-60 (160°C), and (*e*) an OV-225 S.C.O.T. column. For glc – mass spectrometry columns were attached to a Perkin-Elmer–Hitachi RMU-6 spectrometer, operated with an inlet temperature of 250°C, an ionization potential of 70 eV, and an ion-source temperature of ~250°C. Thin-layer chromatography was performed with Polygram SilG/UV$_{254}$ as the adsorbent and plates were sprayed with ethanol containing 5% sulfuric acid and heated at about 150°C. Column chromatography was carried out on MN silica gel (0.05–0.2 mm/70–270 mesh ASTM). Light petroleum refers to the fraction of bp 30–60°C.

Examination of Polysaccharides

Polysaccharides were dissolved in water, the solutions were shaken with Amberlite resin IR-120(H) to ensure complete removal of metal ions, and the solutions were filtered, concentrated, and freeze-dried. Hydrolyses of polysaccharides (including reduction of uronic acid components as their trimethylsilyl derivatives) were carried out as described by Lindberg *et al.* (11). Sugar analyses of polysaccharide hydrolyzates were carried out by reduction with sodium borohydride, followed by acetylation and glc of the resulting alditol acetates (12) on column *a*. Birch 4-*O*-methylglucuronoxylan was isolated as described previously (4) and contained 8% of uronic acid residues. The batch of gum arabic (from *Acacia senegal*) was that used in earlier studies (5), and had the composition rhamnose (14%), arabinose (28%), galactose (39%), and glucuronic acid (19%).

Preparation and Analysis of Methylated Polysaccharides

Methylation of polysaccharides was performed by the Hakomori procedure (12) as described by Lindberg *et al.* (11). Methylated polysaccharides and their derivatives were purified by chromatography on columns (15 × 1 cm) of Sephadex LH20 using chloroform–acetone (2:1) as eluant. The sugar components of methylated polysaccharides were analyzed as partially methylated alditol acetates formed on hydrolysis, followed by reduction with sodium borohydride and acetylation (13), by glc alone or glc–ms on columns *b*, *c*, or *e*. The identities of all components of different retention times (Tables 1 and 2) were confirmed by the presence of diagnostic fragment ions in their mass spectra. For separation of derivatives of 2,3,4-tri-*O*-methylrhamnose and 2,3,5-tri-*O*-methylarabinose, methylated polysaccharides were heated under reflux in methanolic 5% hydrogen chloride for 16 h, followed by neutralization with silver carbonate and examination of the resulting methyl glycosides by glc on column *a*.

Reduction of methylated acidic polysaccharides was performed by heating under reflux the sample (10 mg) in tetrahydrofuran (5 ml) containing lithium aluminum deuteride (50 mg) for 4 h. Excess reagent was destroyed by the addition of water, the mixture was acidified to p*H* 4, and reduced methylated polysaccharide was isolated by extraction into chloroform.

Preparation and Hydrolysis of Methyl 6-Deoxy-4-O-(2,3,4,6-tetra-O-methyl-α-D-glucopyranosyl)-2,3-di-O-methyl-β-D-xylo-hex-5-enopyranoside

Methyl 2,2′,3,3′,4′,6′-hexa-*O*-methyl-β-maltoside (100 mg) was kept in tetrahydrofuran (4 ml) containing triphenylphosphite methiodide (250 mg) for 18 h with continuous stirring. Thin-layer chromatography (chloroform–acetone, 7:3) showed that reaction had gone to completion, and the solution was poured into ice-water (10 ml) and extracted with chloroform (3 × 10 ml). Concentration of the dried chloroform extract afforded syrupy methyl 6-deoxy-6-iodo-4-*O*-(2,3,4,6-tetra-*O*-methyl-α-D-glucopyranosyl)-2,3-di-*O*-methyl-β-D-glucopyranoside (105 mg) (**1**); ir no absorption at 3600 cm^{-1}; ms *m/e* (% relative abundance): 550 (0.8) (M$^+$), 375 (37) (abJ_1)[3], 315 (28) (bA$_1$), 219 (32) (aA$_1$), 187 (41) (aA$_2$), 101 (92), 88 (100), and 45 (39). The iodo compound (100 mg) was kept in DBU (1 ml) at room temperature for 24 h. Thin-layer chromatography (light petroleum – acetone, 5:1) showed that reaction was complete and ice-water (10 ml) was added to the reaction mixture and the resulting suspension was extracted with ether (3 × 10 ml). The combined ether extracts were washed with water to remove DBU, dried and concentrated to give syrupy methyl 6-deoxy-4-*O*-(2,3,4,6-tetra-*O*-methyl-α-D-glucopyranosyl)-2,3-di-*O*-methyl-β-D-*xylo*-hex-5-enopyranoside (**2**) (70 mg); ν_{max} (film): 1640 cm^{-1} (C=C).

The unsaturated disaccharide **2** (60 mg) in acetone–water (1:1, 5 ml) was stirred overnight with Dowex 50(H) resin. Thin-layer chromatography (chloroform–acetone, 7:3) showed that reaction was complete with the formation of a single product, resin was removed by filtration, and concentration of the filtrate gave syrupy glycos-5-ulose (52 mg). A portion (10 mg) of the syrup in methanol–water (2:1, 5 ml) was treated with sodium borodeuteride (30 mg) for 3 h. Amberlite resin IR-120(H) was added to destroy excess reagent and to remove sodium ions, and the filtered solution was repeatedly concentrated with methanol to remove boric acid to give diastereomeric diols (**3**); ^{1}H nmr ($CDCl_3$) δ: 5.19 (d, $J_{1',2'}$ = 4 Hz, H-1′). The residue was alkylated with trideuteriomethyl iodide and sodium methylsulfinylmethanide in methyl sulfoxide (11), and analysis of the product by glc – mass spectrometry using column *e* showed the presence of two components (**4**) which were clearly separated but gave identical mass spectra with prominent fragment ions at *m/e* (% relative abundance) 273 (19), 219 (28), 213 (53), 187 (94), 137 (20), 111 (77), 101 (91), 93 (20), 88 (100), 63 (79), and 49 (17).

Modification of Methylated Birch Xylan

Methylated birch xylan (400 mg) in tetrahydrofuran (50 ml) containing lithium aluminum hydride (200 mg) was heated under reflux for 4 h, and the reduced methylated xylan (320 mg) was isolated in the usual way. Completeness of reaction was established in the ir spectrum by appearance of a band at 3600 cm^{-1} (OH) and disappearance of the band at 1735 cm^{-1} (ester C=O), and by glc examination of the methanolysis

[3]The nomenclature of fragment ions is that developed by Kochetkov *et al.* (14).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

products on column *a* which showed the formation of methyl glycosides of 2,3,4-tri-*O*-methylglucose and the absence of those of 2,3,4-tri-*O*-methylglucuronic acid. A sample of the reduced methylated xylan was also analyzed in the usual way (Table 1).

Reduced methylated xylan (300 mg) was treated with triphenylphosphite methiodide (500 mg) in tetrahydrofuran at room temperature for 20 h. Methanol (1 ml) was added to ensure complete reaction of reagent, the solution was concentrated to a syrup which was dissolved in chloroform (50 ml), and the resulting solution was washed successively with *M* sodium hydroxide, aqueous sodium thiosulfate, and dried. The chloroform solution was concentrated (5 ml) and chromatographed on a column (50 × 5.5 cm) of Sephadex LH20. Elution of the column with chloroform–acetone (1:1) afforded modified methylated polysaccharide (340 mg) which was isolated by precipitation with light petroleum and showed no hydroxyl absorption in the ir spectrum. Completeness of reaction was also shown by glc examination of the methanolysis products in which methyl glycosides of 2,3,4-tri-*O*-methylglucose were absent.

The methylated 6-deoxy-6-iodopolysaccharide (110 mg) in tetrahydrofuran (2 ml) containing DBU (2 ml) was heated on a boiling water bath for 1 h and the solution was stirred overnight at room temperature. The solution was dialyzed to remove organic solvent and reagent, and the modified polysaccharide was isolated by extraction into chloroform. The dried chloroform solution was chromatographed on Sephadex LH20 (as above) and furnished unsaturated methylated xylan (90 mg); ν_{max} (film): 1640 cm^{-1} (C=C). Unsaturated methylated xylan (90 mg) in acetone–water (1:1, 5 ml) was stirred overnight with Dowex 50(H) resin. The filtered solution was concentrated to dryness, the residue was dissolved in chloroform, addition of light petroleum afforded a precipitate of degraded methylated xylan (75 mg) (ir spectrum showed absorption at 3600 cm^{-1} (OH) but none at 1640 cm^{-1} (C=C)) and concentration of the supernatant liquid gave syrupy glycos-5-ulose. The glycos-5-ulose was reduced with sodium borodeuteride (20 mg) in methanol–water (3:1, 5 ml), and the product was acetylated. Examination of the resulting partially methylated alditols by glc – mass spectrometry on column *e* showed the presence of two compounds whose identical mass spectra showed prominent fragment ions at *m/e* 176 (19), 162 (29), 132 (72), 118 (89), 102 (89) and 43 (100), which were characteristic of 1,5-di-*O*-acetyl-6-deoxy-2,3,4-tri-*O*-methylhexitols. The degraded methylated xylan was alkylated with ethyl iodide and the resulting polysaccharide derivative was analyzed in the usual way (Table 1).

Modification of Methylated Gum Arabic

Methylated gum arabic (1 g) was successively converted into reduced methylated gum arabic (840 mg) (for analysis see Table 2), the methylated 6-deoxy-6-iodopolysaccharide (640 mg) (*Anal.* calcd. for modified methylated gum arabic: I 10.82; found: I 11.35), and unsaturated methylated gum arabic (380 mg) (ν_{max} (film): 1640 cm^{-1} (C=C)), as described for derivatives of methylated birch xylan. Unsaturated methylated gum arabic (380 mg) in acetone–water (1:1, 20 ml) was stirred overnight with Amberlite resin IR-120(H). The filtered solution was concentrated and the residue in methanol–water (3:1, 20 ml) was treated with sodium borohydride (100 mg) for 3 h. The solution was treated with Amberlite resin IR-120(H) to destroy excess of hydride and remove sodium ions, and the filtrate was repeatedly concentrated with methanol to remove boric acid. The residue was dissolved in chloroform, addition of light petroleum furnished a precipitate of degraded methylated gum arabic (270 mg) (ν_{max} (film): 3600 cm^{-1} (OH)), and concentration of the supernatant liquid gave a syrup which was purified by chromatography on a column (15 × 1.5 cm) of silica gel. Elution of the column with dichloromethane–methanol (10:1) afforded a mixture of partially methylated alditols (80 mg); ^1H nmr ($CDCl_3$) δ: 5.10 (d, 1H, $J_{1',2'}$ = 2Hz, H-1′); ^{13}C nmr ($CDCl_3$) δ: 99.6 (C-1′). The degraded methylated gum arabic was alkylated with trideuteriomethyl iodide and the resulting polysaccharide derivative was analyzed in the usual way (Table 2).

A portion of the mixture of partially methylated alditols was acetylated and examination of the resulting acetates by glc – mass spectrometry showed the presence of two pairs of diastereomeric compounds. The first pair of compounds showed identical mass spectra with prominent fragment ions at *m/e* 175 (31), 161 (41), 131 (88), 117 (89), 101 (89) and 43 (100) characteristic of 1,5-di-*O*-acetyl-6-deoxy-2,3,4-tri-*O*-methylhexitols. The second pair of compounds showed identical mass spectra with prominent fragment ions at *m/e* 321 (15), 261 (19), 189 (62), 161 (16), 117 (74), 101 (87), 88 (100), 87 (69) and 43 (88) characteristic of 1,5-di-*O*-acetyl-6-deoxy-2,3-di-*O*-methyl-4-*O*-(6-deoxy-2,3,4-*O*-methylhexopyranosyl)hexitols. A further portion of the mixture of partially methylated alditols was trideuteriomethylated and examination of the products by glc – mass spectrometry on column *e* showed two major components whose identical mass spectra contained prominent fragment ions at *m/e* 271 (8), 211 (64), 189 (88), 136 (28), 92 (29), 88 (100), 62 (87) and 48 (48) characteristic of isotopically labelled permethylated 6-deoxy-4-*O*-(6-deoxyhexopyranosyl)-hexitols.

The selective cleavage of glycopyranosiduronamide linkages in methylated polysaccharides[1]

GERALD OLIVER ASPINALL[2] AND KARL-GUNNAR ROSELL

Department of Chemistry, York University, Downsview, Toronto, Ont., Canada M3J 1P3

Received October 14, 1977

GERALD OLIVER ASPINALL and KARL-GUNNAR ROSELL. Can. J. Chem. **56**, 685 (1978).

Hofmann degradation of glycosiduronamide linkages in methylated polysaccharides furnishes pentodialdose derivatives to which any sugar residues external to uronic acid residues remain attached together with degraded methylated polysaccharides carrying aglyconic hydroxyl groups. The selective degradation has been carried out on methylated derivatives of birch xylan, gum arabic, and the capsular polysaccharide from *Klebsiella* type 47. Procedures for the degradation of methylated polysaccharides in the vicinity of uronic acid residues are assessed.

GERALD OLIVER ASPINALL et KARL-GUNNAR ROSELL. Can. J. Chem. **56**, 685 (1978).

La dégradation d'Hofmann de liens glycosiduronamides dans des polysaccharides méthylés fournit des dérivés pentodialdoses auxquels reste attachée toute portion de sucre externe aux résidus de l'acide uronique ainsi que tous les polysaccharides méthylés dégradés portant des groupes hydroxyles aglyconiques. On a effectué la dégradation sélective sur des dérivés méthylés de xylanes de bouleau, sur de la gomme arabique et sur des polysaccharides capsulaires provenant de *Klebsiella* type 47. On a évalué les procédés pour la dégradation de polysaccharides méthylés dans l'environnement de résidus d'acide uronique.

[Traduit par le journal]

Kochetkov *et al.* (1) have shown that Hofmann degradation of glycosiduronamides proceeds in high yield with cleavage of the glycosidic linkage and liberation of a pentodialdose from the uronic acid residues. In an application to a polysaccharide, reaction of birch xylan amide was shown to result in removal of 93% of the 4-*O*-methylglucuronic acid side chains. Selective bond cleavage in methylated polysaccharides (2) liberates only a limited number of reducing sugars or derivatives of known origin, and simultaneously exposes only those hydroxyl groups to which the cleaved glycosyl substituents were attached. Since more structural information is obtained from the characterization of these cleavage products than of the corresponding products from the parent polysaccharide, we have now extended the glycosiduronamide degradation to methylated polysaccharides. Two of the three methylated polysaccharides chosen for study were those resulting in the liberation of a disaccharide which was suitable for conversion into volatile derivatives, many of whose structural features could be determined using glc – mass spectrometry. Methylated birch xylan (3) was converted into the amide which was treated with sodium hypochlorite at p*H* 12.5, followed by hydrolysis at p*H* 5, to give a degraded methylated polysaccharide and a syrupy residue. The syrup was reduced with sodium borohydride and acetylated to give a single volatile component originating from cleaved glucuronic acid residues, which was characterized by glc – mass spectrometry as 2,3,4-tri-*O*-methylxylitol diacetate. The degraded polysaccharide contained no residual amide groups, and exposed hydroxyl groups were further alkylated with ethyl iodide. Sugar analysis of the alkylated polysaccharide showed that the 2-hydroxyl group of xylose was the only site of labelling and that ~90% of the branch points to which uronic acid residues were previously attached had been ethylated (see Table 1).

Methylated gum arabic amide (**1**) was similarly degraded on treatment with sodium hypochlorite, the reaction mixture was treated directly with sodium borohydride and separated to give a mixture of partially methylated alditols and a degraded methylated polysaccharide. The ^{1}H nmr spectrum of the mixture of alditols showed one signal assignable to the anomeric proton of the intact rhamnosidic linkage (in **2**) at δ 5.08 ($J_{1,2}$ 1 Hz) (4). The ^{13}C nmr spectrum likewise showed only one signal in the anomeric region whose chemical shift at 96.4 ppm, corresponded to that of a methylated α-L-rhamnopyranoside (5). Acetylation of the alditols gave two components, one with the retention time and mass spectrum of 2,3,4-tri-*O*-methylxylitol diacetate, and the other whose mass spectrum showed primary fragment ions (Scheme 1) which were consistent with the structure, 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methylrhamnopyranosyl) xylitol (**3**). Trideuteriomethylation of the alditols similarly gave a single disaccharide alditol derivative (**4**) which was

analyzed by glc – mass spectrometry. The degraded methylated polysaccharide (**5**) was realkylated with trideuteriomethyl iodide and sugar analysis of the polysaccharide derivative, before and after realkylation, showed that loss of rhamnose residues had accompanied glycosiduronamide cleavage and trideuteriomethyl groups were only detected at O-6 of some galactopyranose units, in accord with the known site of attachment of glucuronic acid residues (6). It is important, however, to consider in greater detail the significance of methylation analysis of acidic polysaccharides and their derivatives and Table 2 summarises such analyses for several derivatives of methylated gum arabic.

SCHEME 1. Mass spectral fragmentations of derivatives of 2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)-D-xylitol; *m/e* values are for ions from derivatives **3** and **4** (in parentheses where different).

Methylation of polysaccharides is most effectively performed in methyl sulfoxide using sodium methylsulfinylmethanide as base (7). Lindberg *et al.* (8) have reported many examples of the successful use of this method for the methylation of uronic acid-containing polysaccharides provided that etherification is achieved *in a single operation*. Repetition of the procedure using fresh base results in base-catalyzed degradation initiated by β-elimination from 4-*O*-substituted hexuronate residues (9, 10). Presumably in the methylation the presence of strong base ensures complete ionization of hydroxyl groups so that the weakly nucleophilic carboxylate ions fail to compete effectively with the strongly nucleophilic alkoxide ions for methyl iodide. Consequently esterification of uronic acid residues will be slow and by the time reaction is reasonably complete the diminution of base concentration is such that base-catalyzed degradation is not a significant competing reaction. However, as noted in the accompanying publication (11) it is not easily possible to achieve complete methylation of the interior galactose residues in gum arabic. It follows, therefore, that further alkylation of the exposed hydroxyl groups in the degraded methylated polysaccharide may be accompanied by alkylation of hydroxyl groups which had escaped initial methylation. In the event, however, trideuteriomethyl groups were only detected at O-6 of galactose residues.

Treatment of methylated gum arabic with sodium methylsulfinylmethanide in sulfoxide followed by direct alkylation (10) results in complete loss of uronic acid units and of sugar residues attached thereto together with alkylation of sites to which uronic acid residues were attached. The complete loss of rhamnose residues taken together with unaltered relative overall proportions of galactose and arabinose methyl ethers implies that rhamnose residues are linked only to glucuronic acid residues. It may be noted that similar base-catalyzed degradation of methylated gum arabic amide results in complete removal of rhamnose units. Analysis of the

degraded methylated polysaccharide from the Hofmann degradation showed that ~80% of the rhamnose residues had been removed. The incomplete loss of rhamnose residues during the glycosiduronamide degradation is probably accounted for by incomplete amidation or by some amide hydrolysis during the Hofmann reaction.

The capsular polysaccharide from *Klebsiella* type 47 (12) is of an entirely different structural type (**6**) but the same terminal sequence in side chains, α-L-Rha*p*-(1 → 4)-D-Glc*p*A-(1- , as in gum arabic has been proposed on the basis of various experiments including a base-catalyzed degradation which results in β-elimination of the rhamnose unit from the uronic acid residue followed by further reaction and loss of the modified uronic acid residues (9). Application of the glycosiduronamide degradation to the methylated polysaccharide amide has now provided direct evidence on this point. Treatment of the methylated polysaccharide amide with sodium hypochlorite, followed by reduction of the pentodialdose derivative and acetylation gave a disaccharide alditol, which was shown by glc – mass spectrometry to be identical to the compound (**3**) derived from gum arabic. Insufficient material was obtained to provide nmr spectroscopic evidence for the configuration of the intact rhamnosidic linkage which had been assigned as α-L- on the basis of optical rotatory data (12). SCHEME 2. Degradations of methylated acidic polysaccharides in the vicinity of uronic acid residues. *A*, hex-5-enopyranoside degradation: $—CO_2CH_3 \rightarrow —CH_2OH \rightarrow —CH_2I \rightarrow =CH_2$: H^+; $NaBH_4$; derivatization (R). *B*, glycosiduronamide degradation: $—CO_2CH_3 \rightarrow —CONH_2$; NaOCl: H^+; $NaBH_4$; derivatization (R). *C*, base-catalyzed β-elimination: $^-CH_2SOCH_3$; derivatization (R').

showed that only a small proportion of rhamnose-terminated side chains were not removed.

The glycosiduronamide degradation and the preferential hydrolysis of hex-5-enopyranosides (11) are alternative reaction sequences which may be applied to the selective cleavage of glycosiduronic acid linkages in methylated polysaccharides (Scheme 2, *A* and *B*). Both procedures after subsequent reduction yield alditols or *O*-glycosylalditols. Despite the formation of epimeric pairs of 6-deoxyhexitols from the hex-5-enopyranose degradation, derivatives suitable for glc analysis whether separable or not, give mass spectra which provide unambiguous evidence for the site of attachment of *O*-glycosyl substituents. In contrast, the glycosiduronamide degradation yields structurally symmetrical pentitols for which independent evidence would be required to distinguish between 2-*O*- and 4-*O*-substitution. The glycosiduronamide degradation involves a much simpler reaction sequence and may be performed on much smaller quantities of methylated polysaccharide than are required for the hex-5-enopyranoside degradation. Furthermore the latter degradation has been performed so far only on glucuronic acid-containing polysaccharides. The necessary transformations may prove more difficult to achieve satisfactorily for galacturonic acid-containing polysaccharides. Displacements at C-6 of galactopyranose derivatives are well known to proceed with difficulty (13) and the dehydroiodination of a 6-deoxy-6-iodogalactose derivative has been shown to occur much more slowly than for *gluco* derivatives (14). In comparison with the base-catalyzed β-elimination from 4-*O*-substituted hexuronate residues, both degradations provide more structural information since sugar residues external to uronic acid units in polysaccharide chains are isolated intact and still attached to a stub recognizably derived from the uronic acid. In base-catalyzed β-eliminations the glycosidic linkage initially broken is external to the uronic acid, and the reducing sugar unit liberated, unless protected (15), will be further degraded in the basic medium and may be entirely lost (Scheme 2, *C*) In such cases sugar analyses of the parent and degraded methylated polysaccharides indicate which sugar residues have been removed during the degradation. However, the β-elimination reaction with attendant analyses may be performed on only milligram quantities of material. Although both glycosiduronamide and hex-5-enopyranoside degradations proceed in high yield, the β-elimination reaction achieves more complete removal of uronic acid and attached glycosyl residues and the exposed aglyconic group(s) may be less ambiguously recog-

nized after further alkylation. Indeed, as recently reported, base-catalyzed degradation and further alkylation may be carried out in a single operation without intermediate isolation of the degraded methylated polysaccharide (10).

Experimental

Unless otherwise stated general experimental methods and the procedures for the preparation and examination of methylated polysaccharides were as described in the accompanying paper (11). For the conversion of esters into amides dry ammonia was bubbled through solutions of methylated polysaccharides in methanol or methanol–tetrahydrofuran (1:1) at 0°C for 0.5 h and the solutions were left overnight. Methylated polysaccharide amides were recovered by concentration, dissolution of the residue in chloroform and precipitation by the addition of light petroleum. To ensure complete amidation, methylated polysaccharide in methanol–water (1:2) was treated with Amberlite resin IR-120(H), carboxylic acid residues were esterified by treatment with diazomethane, and treatment with ammonia was repeated. Completeness of amidation was checked by disappearance of ester C=O absorption in the ir spectrum. Base-catalyzed degradations of methylated polysaccharides were performed by treatment of the methylated derivative (10 mg) in *M* sodium methylsulfinylmethanide in methyl sulfoxide (4 ml) in an atmosphere of argon for 16 h. Further alkylation was carried out by direct dropwise addition of trideuteriomethyl (or ethyl) iodide (2 ml) with stirring of the resulting solution for 0.5 h. The fully alkylated degraded polysaccharide was isolated in the usual way.

Degradation of Methylated Birch Xylan Amide

Treatment of methylated birch xylan (400 mg) with ammonia furnished methylated birch xylan amide (360 mg). Sodium hypochlorite (1.5 *M*) was added with stirring (to p*H* 12.5) to the polysaccharide amide (160 mg) in tetrahydrofuran (5 ml) under an argon atmosphere at 0°C, and the solution was kept at room temperature for 2 h and then placed in a boiling-water bath for 5 min. The cooled solution was acidified with acetic acid (to p*H* 5) and left overnight at room temperature. The solution was concentrated and the residue was extracted with boiling chloroform. Concentration of the chloroform extract to small volume followed by addition of light petroleum gave a precipitate (125 mg) of degraded methylated xylan whose ir spectrum showed absorption at 3600 cm^{-1} (OH) but none at 1650 cm^{-1} (amide C=O). The degraded polysaccharide was further alkylated with ethyl iodide and the product was analyzed in the usual way (Table 1). The supernatant liquid from the above precipitation was concentrated, the residue was reduced with sodium borohydride and then acetylated, and examination of the product by glc – mass spectrometry showed the formation of 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol as the sole volatile product.

Degradation of Methylated Gum Arabic Amide

Treatment of methylated gum arabic (800 mg) with ammonia gave methylated gum arabic amide (620 mg) (*Anal.* calcd. for modified methylated gum arabic: N 1.30; found: N 1.63). A sample of the methylated polysaccharide amide was treated with base as described above and alkylated directly with trideuteriomethyl iodide, and the product was analyzed (Table 2). Methylated gum arabic amide (600 mg) in methanol–water (2:1, 30 ml) was treated with sodium hypochlorite, as described for methylated birch xylan amide, and the product was hydrolyzed at p*H* 5. Concentration of the reaction mixture gave a residue which was extracted with boiling chloroform, and the chloroform extract afforded a product which showed no amide absorption in the ir spectrum. The reaction product in methanol–water (3:2, 20 ml) was treated with sodium borohydride (200 mg) for 16 h, Amberlite resin IR-120(H) was added to destroy excess hydride and to remove sodium ions, and the filtered solution was repeatedly concentrated with methanol. Addition of light petroleum to the residue in chloroform furnished degraded methylated gum arabic (500 mg) and from the supernatant liquid a syrupy mixture (180 mg) of partially methylated alditols was recovered; ^1H nmr ($CDCl_3$) δ: 5.08 (d, 1H, $J_{1',2'}$ = 2 Hz, H-1′), 1.25 (d, 3H, $J_{5',6'}$ = 5 Hz, H-6′); ^{13}C nmr ($CDCl_3$) δ: 96.4 (C-1′). Samples of degraded methylated gum and of the polysaccharide after further alkylation with trideuteriomethyl iodide were analyzed in the usual way (Table 2).

A portion of the mixture of partially methylated alditols was acetylated and examination of the resulting acetates by glc – mass spectrometry on column *e* showed two components. The minor product was indistinguishable (retention time and mass spectrum) from 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol, and the major product gave a mass spectrum which was characteristic of a 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(6-deoxy-2,3,4-tri-*O*-methylhexopyranosyl)pentitol with prominent fragment ions at *m/e* (% relative abundance) 307 (13), 247 (32), 189 (32), 157 (11), 117 (42), 101 (84), 88 (100), and 43 (72). A further portion of the partially methylated alditols was alkylated with trideuteriomethyl iodide and examination of the product by glc and mass spectrometry on column *e* showed a single methylated disaccharide alditol whose mass spectrum contained prominent fragment ions at *m/e* 257 (2), 197 (65), 189 (35), 157 (10), 136 (6), 101 (56), 92 (17), 88 (100), and 48 (30) which were characteristic of an isotopically labelled permethylated 4-*O*-(6-deoxyhexopyranosyl)pentitol.

Degradation of Methylated Klebsiella *Type 47 Polysaccharide Amide*

Methylated *Klebsiella* 47 polysaccharide (50 mg) was treated with ammonia and the methylated polysaccharide amide was degraded with sodium hypochlorite, as described for methylated birch xylan amide, and the product was hydrolyzed at p*H* 5. Work-up of the reaction mixture followed by reduction with sodium borohydride, as above, afforded degraded methylated polysaccharide (15 mg) (for analysis see Table 3) and a syrupy residue. The syrup was acetylated and examination of the product by glc – mass spectrometry showed a single component which was indistinguishable (retention time and mass spectrum) from the partially methylated disaccharide alditol acetate formed from methylated gum arabic acid amide.

A synthesis of 3-acetamido-3-deoxy-D-*glycero*-D-*gulo*-heptose and 3-acetamido-3-deoxy-D-*glycero*-D-*ido*-heptose from 2-acetamido-2-deoxy-D-glucose[1]

LAURE BENZING AND MALCOLM B. PERRY

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 26, 1977

LAURE BENZING and MALCOLM B. PERRY. Can. J. Chem. **56**, 691 (1978).

The reluctance of 2-acetamido-2-deoxy-D-glucose to undergo base catalyzed addition with nitromethane was overcome by using the acetamidoglycose in the form of a substituted acyclic aldehydo derivative. 2-Acetamido-2-deoxy-D-glucose diethyl dithioacetal was isopropylidenated to yield 2-acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-D-glucose diethyl dithioacetal which on demercaptalation afforded 2-acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-*aldehydo*-D-glucose. The aldehydo derivative readily underwent base catalyzed addition of nitromethane to give the expected epimers 3-acetamido 1,3-dideoxy-4,5:6,7-di *O*-isopropylidene-1-nitro-D-*glycero*-D-*gulo*-heptitol and 3-acetamido-1,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-1-nitro-D-*glycero*-D-*ido*-heptitol which, after deisopropylidenation by mild acid treatment, were converted under modified Nef reaction conditions to give 3-acetamido-3-deoxy-D-*glycero*-D-*gulo*-heptose and 3-acetamido-3-deoxy-D-*glycero*-D-*ido*-heptose, respectively.

LAURE BENZING et MALCOLM B. PERRY. Can. J. Chem. **56**, 691 (1978).

L'acétamido-2 déoxy-2 D-glucose réagit difficilement avec le nitrométhane en milieu basique; on a surmonté cette résistance en faisant appel à l'acétamidoglycose sous forme de dérivé aldéhydo acyclique. On a transformé l'acétamido-2 déoxy-2 D-glucose diéthyldithioacétal en son dérivé isopropylidène pour obtenir l'acétamido-2 déoxy-2 di-*O*-isopropylidène-3,4:5,6 D-glucose diéthyldithioacétal qui, par élimination des mercaptans, fournit l'acétamido-2 déoxy-2 di-*O*-isopropylidène-3,4:5,6 aldéhydo D-glucose. Le dérivé aldéhydo subit facilement une addition catalysée par les bases du nitrométhane pour conduire aux épimères attendus, acétamido-3 didéoxy-1,3 di-*O*-isopropylidène-4,5:6,7 nitro-1 D-*glycéro*-D-*gulo*-heptitol et acétamido-3 didéoxy-1,3 di-*O*-isopropylidène-4,5:6,7 nitro-1 D-*glycéro*-D-*ido*-heptitol qui, après élimination des groupements isopropylidènes par traitement en milieu acide dilué, ont pu être transformés respectivement en acétamido-3 déoxy-3 D-*glycéro*-D-*gulo*-heptose et en acétamido-3 déoxy-3 D-*glycéro*-D-*ido*-heptose grâce à une réaction de Nef modifiée.

[Traduit par le journal]

The base catalyzed addition of nitromethane to aldoses to produce 1-deoxy-1-nitroglycitols (1–3) which may be converted under Nef (4) reaction conditions to give aldoses provides an important method for the ascension of the glycose chain which is often of greater utility than the Fischer-Kiliani (5) cyanohydrin route to higher glycoses.

Although the nitromethane addition method can be applied to most aldoses, in some cases the addition does not proceed to a practical extent under the usual experimental conditions. Attempts to use the nitromethane addition method to effect the stepwise synthesis of *N*-acetylneuraminic acid (6) and its analogues, starting from 2-acetamido-2-deoxyhexoses, were initially hindered by the reluctance of some hexoses and synthesized higher aldose derivatives to undergo nitromethane addition. It was found for example, that 2-acetamido-2-deoxy-D-glucose and 2-acetamido-2-deoxy-D-galactose did not undergo base catalyzed addition of nitromethane. Subsequent experiments revealed that these glycoses in the form of substituted acyclic *aldehydo* derivatives underwent satisfactory addition of nitromethane. Demercaptalation of ketal substituted dialkyl dithioacetal glycoses provided a suitable method for preparing the *aldehydo*-glycoses and this note records the successful application of this approach to the addition of nitromethane to 2-acetamido-2-deoxy-D-glucose and the subsequent conversion of the resulting 1-deoxy-1-nitroheptitol derivatives to 3-acetamido-3-deoxyglycoses.

2-Acetamido-2-deoxy-D-glucose diethyl dithioacetal on acid catalyzed isopropylidenation in 2,2-dimethoxypropane–acetone mixture afforded crystalline 2-acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-D-glucose diethyl dithioacetal (**1**) (7) in almost quantitative yield. Demercaptalation of **1** with mercuric chloride and mercuric oxide in aqueous acetone afforded 2-acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-*aldehydo*-D-glucose (**2**) whose pmr and ir spectra gave peaks consistent with the presence of the *aldehydo* function. The *aldehydo*-glucose (**2**) on treatment with nitromethane in the presence of sodium methoxide afforded approx-

imately equal amounts of the expected epimeric heptitol derivatives 3-acetamido-1,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-l-nitro-D-*glycero*-D-*gulo*-heptitol (**3**) and 3-acetamido-1,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-1-nitro-D-*glycero*-D-*ido*-heptitol (**4**) which were each obtained crystalline by fractional crystallization of their mixture from methanol. The assigned configurations of **3** and **4** were based on the positive Cotton effect observed in the ord spectrum at 342 nm for **3** and the negative Cotton effect at 346 nm for **4** (8) and the assignments were further verified by the identification of the 3-acetamido-3-deoxyheptoses subsequently obtained from the respective 1-deoxy-1-nitroheptitols. Compounds **3** and **4** were deisopropylidenated by treatment with hot dilute sulfuric acid to yield crystalline 3-acetamido-1,3-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (**5**) and 3-acetamido-1,3-dideoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (**6**), respectively. The 1-deoxy-1-nitroheptitols **5** and **6** underwent a modified Nef reaction (9) to yield crystalline 3-acetamido-3-deoxy-D-*glycero*-D-*gulo*-heptose (**7**) and 3-acetamido-3-deoxy-D-*glycero*-D-*ido*-heptose (**8**) which had physical and chromatographic characteristics in agreement with those previously recorded for these compounds which were made by a route involving the addition of hydrogen cyanide to 2-acetamido-2-deoxy-D-glucose (10). Improved yields of the 3-acetamido-3-deoxyheptoses **7** and **8** were obtained by omitting the isolation of crystalline intermediates. The mixture of the nitromethane addition products **3** and **4** were hydrolyzed to yield **5** and **6** and treatment of this mixture under modified Nef reaction conditions afforded the final products **7** and **8** which were obtained in a pure crystalline form following their separation by cellulose column chromatography.

Experimental

Evaporations were performed under reduced pressure and below 40°C. Melting points were determined on a Fisher-Johns apparatus and are corrected. Optical rotations were determined at 20°C using a Perkin-Elmer Model 141 polarimeter. Optical rotary dispersion measurements (ord) were made using a JASCO model ORD/UV-5 spectrometer. Infrared (ir) spectra were obtained by the KBr disc technique using a Perkin-Elmer 237B Infracord.

Proton magnetic resonance (pmr) spectra were recorded using a Varian EM 360 spectrometer at 60 MHz with tetramethylsilane as an internal standard.

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using pyridine – ethyl acetate – water (2:5:5 v/v, top layer) as the mobile phase and sugars were detected by the dip procedure using 2% (w/v) silver nitrate in acetone followed by 3% (w/v) sodium hydroxide in ethanol (11). The mobilities of glycoses are quoted relative to 2-acetamido-2-deoxy-D-glucose (R_{GN}). Thin-layer chromatography (tlc) was done on precoated 0.25 mm silica gel 60 plates (E. Merck) using (*A*) benzene–methanol (9:1 v/v) or (*B*) butan-1-ol–acetone–water (4:5:1 v/v) mixtures as the mobile phases. Compounds were detected by spraying the plates with 10% sulfuric acid in ethanol and heating at 120°C and mobilities are quoted relative to the solvent front (R_f).

Gas–liquid chromatography (glc) was done using a Hewlett-Packard 402 gas chromatograph with a hydrogen flame detector fitted with glass U-tubes (4 ft × 6 mm × 3 mm id) packed with 3% (w/w) ECNSS-M on 100–120 mesh Gas Chrom Q and retention times are quoted relative to penta-*O*-acetyl-2-acetamido-2-deoxy-D-glucitol (T_{GN}).

*2-Acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-D-glucose Diethyl Dithioacetal (1)*

2-Acetamido-2-deoxy-D-glucose diethyl dithioacetal (12) (15 g) was added to a stirred solution prepared by adding 2,2-dimethoxypropane (60 ml) to dry acetone (22 ml) containing sulfuric acid (0.37 ml) and the mixture was kept stirred at 20°C for 90 min. The mixture was neutralized with saturated aqueous barium hydroxide and, following the addition of barium carbonate (0.2 g), it was filtered through a bed of Celite. The filtrate and water washings were treated with 2 drops of pyridine and were concentrated under reduced pressure to yield **1** (17.4 g, 93%) as a solid which gave a single spot on tlc (solvent *A*) with R_f 0.49 and it was used without purification in the next synthetic step.

An analytical sample of **1** obtained crystalline from hexane solution had mp 65–66°C and $[\alpha]_D$ −35.7° (*c* 2.1, methanol) (lit. (7) mp 66–67°C and $[\alpha]_D$ −36° (methanol)) and gave a single spot on tlc (solvent *A*) with R_f 0.49; pmr ($CDCl_3$) τ: 3.82 (1H, d, NH), 7.22 (4H, q, CH_2 of SEt), 7.92 (3H, s, $COCH_3$), and 8.65 ppm (18H, m).

*2-Acetamido-2-deoxy-3,4:5,6-di-*O*-isopropylidene-aldehydo-D-glucose (2)*

To a stirred solution of **1** (13.7 g) in acetone (230 ml) and water (12 ml) was added mercuric oxide (23 g) followed by mercuric chloride (23 g) and the mixture was kept stirred at 20°C for 48 h. The mixture was filtered and the filtrate was concentrated in the presence of mercuric oxide (1 g) and the residue was extracted with chloroform (2 × 150 ml). The chloroform extract was washed with 17% aqueous potassium iodide (150 ml) followed by water (3 × 50 ml) and the dried (anhydrous Na_2SO_4) solution was concentrated to yield **2** (5.8 g, 57%) as a syrup which gave a single spot on tlc (solvent *A*) having R_f 0.14. The product was used without further purification in the next synthetic step.

An analytical sample of **2** obtained by column chromatography on silica gel using benzene–methanol (9:1 v/v) as the mobile phase had $[\alpha]_D$ 0° (*c* 2.1, chloroform); pmr ($CDCl_3$) τ: 0.25 (1H, s, CHO), 3.65 (1H, m, NH), 7.80 (3H, s, $COCH_3$), 8.62 ppm (12H, m); ir: 1730 (CHO), 1660 (NH*CO*CH_3), and 1510 cm^{-1} (*NH*$COCH_3$).

*3-Acetamido-1,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-1-nitro-D-glycero-D-gulo-heptitol (3) and 3-Acetamido-1,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-1-nitro-D-glycero-D-ido-heptitol (4)*

To a stirred solution of **2** (5.8 g) in nitromethane (220 ml) was added 1.7 *N* sodium methoxide in methanol (18.6 ml) followed by methanol (120 ml), to dissolve precipitated material, and the mixture was further stirred at 20°C for 70 h. The reaction mixture was saturated with carbon dioxide and, following concentration under reduced pressure, the residue was extracted with warm chloroform (400 ml). Concentration of the chloroform extract gave a mixture of **3** and **4** (6.2 g, 89%) as a solid which on tlc (solvent *A*) gave two spots of equal visual intensity having R_f values of 0.23 and 0.28.

The mixture of **3** and **4** (4.3 g) was dissolved in hot methanol and the solution on cooling gave pure crystalline **3** (1.8 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which had mp 194–195°C, $[\alpha]_D$ 0° (*c* 2.0, methanol), $[\phi]_{342}$ +219° (*c* 0.09, water) and on tlc gave a single spot (solvent *A*) having R_f 0.23. *Anal.* calcd. for $C_{15}H_{26}N_2O_8$: C 49.71, H 7.23, N 7.73; found: C 49.78, H 7.29, N 7.72.

On concentration of the methanol solution it first afforded a mixture of **3** and **4** (0.2 g) followed by pure crystalline **4** (0.11 g) which, after crystallization from a mixture of chloroform and hexane, had mp 143–144°C, $[\alpha]_D$ +31.9° (*c* 0.78, methanol), $[\phi]_{346}$ −54° (*c* 0.10, water) and gave a single spot on tlc (solvent *A*) having R_f 0.28. *Anal.* calcd. for $C_{15}H_{26}N_2O_8$: C 49.71, H 7.23, N 7.73; found: C 49.53, H 7.35, N 7.71.

3-Acetamido-1,3-dideoxy-1-nitro-D-glycero-D-gulo-*heptitol (5)*

A stirred suspension of **3** (0.2 g) in 0.02 *N* sulfuric acid (10 ml) was heated on a boiling water bath for 15 min and following neutralization with barium carbonate and subsequent filtration, the filtrate was passed down a column of mixed Rexyn 101 (H^+) and Duolite A4 (OH^-) ion exchange resins (2 ml). The eluate and washings were concentrated under reduced pressure and the residue was taken up in hot ethanol from which was obtained crystalline **5** (0.15 g, 96%) which had mp 158–160°C, $[\alpha]_D$ −16.2° (*c* 2.1, water), $[\phi]_{342}$ +120° (*c* 0.11, water) and gave single spots on tlc (solvent *B*, R_f 0.64) and paper chromatography (R_{GN} 2.30). *Anal.* calcd. for $C_9H_{18}N_2O_8$: C 38.30, H 6.43, N 9.92; found: C 38.49, H 6.60, N 9.76.

3-Acetamido-1,3-dideoxy-1-nitro-D-glycero-D-ido-*heptitol (8)*

Compound **4** (50 mg) was hydrolyzed under the same conditions as those described for the preparation of **5** to yield pure crystalline **6** (40 mg), from ethanol solution, which had mp 133–134°C, $[\alpha]_D$ +38.1° (*c* 2.19, water), $[\phi]_{347}$ −41° (*c* 0.10, water) and gave a single spot on tlc (solvent *B*, R_f 0.64) and on paper chromatography (R_{GN} 2.30). *Anal.* calcd. for $C_9H_{18}N_2O_8$: C 38.30, H 6.43, N 9.92; found: C 38.12, H 6.41, N 9.87.

3-Acetamido-3-deoxy-D-glycero-D-gulo-*heptose (7)*

Compound **5** (0.28 g) dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (0.35 g) in water (6 ml) was added dropwise to a cooled solution of sulfuric acid (0.6 ml) in water (3.2 ml) and the mixture was then kept stirred for 18 h at 20°C. The neutralized ($BaCO_3$) reaction mixture was filtered and the filtrate was passed down a column of mixed Rexyn 101 (H^+) and Duolite A4 (OH^-) ion exchange resins (1 ml). The eluate and water washings were concentrated to a solid (0.15 g) which was taken up in a minimum of hot ethanol. On cooling, the ethanol solution afforded crystalline **7** (0.11 g, 44%) which had mp 192–194°C and $[\alpha]_D$ −7.4° (*c* 1.34, water) (lit. (10) mp 196°C and $[\alpha]_D$ −4.9° (water)) and on paper chromatography it gave a single spot with R_{GN} 0.92. Gas chromatography (225°C) of the reduced ($NaBH_4$) and acetylated **7** (13) gave a single peak having T_{GN} 2.03. *Anal.* calcd. for $C_9H_{17}NO_7$: C 43.02, H 6.82, N 5.58; found: C 43.24, H 6.96, N 5.53.

3-Acetamido-3-deoxy-D-glycero-D-ido-*heptose (8)*

Compound **6** (0.2 g) was treated in the same way as that described above for the conversion of **5** to **7** to yield **8** (0.1 g, 56%) which after recrystallization from ethanol had mp 185–187°C and $[\alpha]_D$ −77° (*c* 0.1, water) (lit. (10) mp 186–189°C and $[\alpha]_D$ −87.2° (water)) which gave a single spot on paper chromatography having R_{GN} 1.18 and the reduced ($NaBH_4$) and acetylated product on glc (225°C) gave a single peak with T_{GN} 1.63. *Anal.* calcd. for $C_9H_{17}NO_7$: C 43.02, H 6.82, N 5.58; found: C 43.10, H 6.95, N 5.52.

Direct Synthesis of 7 and 8

The crude mixture of 1-deoxy-1-nitroheptitols **3** and **4** (1 g) resulting from the addition of nitromethane to compound **2**, were deisopropylidenated by heating their solution in 0.02 *N* sulfuric acid (50 ml) for 15 min on a boiling water bath and, following neutralization ($BaCO_3$), were concentrated to yield a mixture of **5** and **6** (0.72 g, 92%). The mixture of **5** and **6** (0.72 g) dissolved in a solution of $Ba(OH)_2.8H_2O$ (0.9 g) in water (14 ml) was added dropwise to a solution of sulfuric acid (1.55 ml) in water (8 ml) and the stirred mixture was kept at 20°C for 18 h. The mixture was neutralized ($BaCO_3$), filtered, and the filtrate was concentrated to yield a mixture of **7** and **8** (0.46 g, 72%) which was fractionated by cellulose column (3 × 40 cm) chromatography using butan-1-ol–water (10:1 v/v) as the mobile phase. The first compound eluted was concentrated to yield crystalline **7** (0.15 g) from ethanol solution, and the second compound eluted yielded crystalline **8** (0.11 g), both compounds having identical chromatographic and physical properties with those recorded for their individual preparation.

Received September 26, 1977

HERBERT L. HOLLAND and PETER R. P. DIAKOW. Can. J. Chem. **56**, 694 (1978).

The steroid analogue 4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone was hydroxylated at C-8α, C-8β, and C-4a by *Rhizopus arrhizus*. Similar products were obtained by peracid oxidation of the corresponding enol ethers: hydroxylation of estr-4-ene-3,17-dione by the same fungus occurred at the analogous C-6 and C-10 positions. These results are consistent with a mechanism of microbial hydroxylation involving the enol form of the Δ^4-3-ketone. Data from the incubations with *R. arrhizus* of androst-4-ene-3,17-dione specifically labelled with deuterium at C-4, C-6α, or C-6β and from those of other deuterium labelled substrates have been interpreted in terms of a mechanism of C-6β hydroxylation involving a rate-determining step before enolization of the ketone, followed by rapid enolization and oxidation of the enol to give the 6β-hydroxy-Δ^4-3-ketone. The kinetic isotope effect, k_H/k_D, for the hydroxylation of androst-4-ene-3,17-dione at C-6β has been found to be 1.2 ± 0.1.

HERBERT L. HOLLAND et PETER R. P. DIAKOW. Can. J. Chem. **56**, 694 (1978).

L'hydroxylation, par le *Rhizopus arrhizus*, de l'analogue stéroïdal hexahydro-4,4a,5,6,7,8 (3*H*)-naphtalène-2-one s'effectue dans les positions 8α, 8β et 4a. On obtient des produits semblables par l'oxydation à l'aide de peracides des éthers énoliques correspondants; l'hydroxylation de l'estrène-4 dione-3,17 par le même champignon se produit dans les positions analogues 6 et 10. Ces résultats sont en accord avec un mécanisme d'hydroxylation microbiologique impliquant la forme énolique de la Δ^4 cétone-3. On a interprété des données d'incubation avec *R. arrhizus* de l'androstène-4 dione-3,17 marqué spécifiquement avec du deutérium dans les positions 4, 6α ou 6β, et à partir d'autres substrats marqués avec du deutérium, en termes d'un mécanisme d'hydroxylation en 6β impliquant une étape déterminant la vitesse antérieure à l'énolisation de la cétone, suivie par une énolisation rapide et une oxydation de l'énol pour conduire à l'hydroxy-6β Δ^4 cétone-3. On a trouvé que l'effet isotopique cinétique k_H/k_D pour l'hydroxylation de l'androstène-4 dione-3,17 en 6β est 1.2 ± 0.1.

[Traduit par le journal]

Introduction

The microbial C-6β hydroxylation of Δ^4-3-ketosteroids may involve the intermediacy of the $\Delta^{3,5}$ enol (1). Circumstantial evidence for this was obtained (2) by incubation of 4a-methyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**1***a*) with *Rhizopus arrhizus*, a microorganism known to hydroxylate Δ^4-3-ketosteroids at C-6β (3). Both C-8β and C-8α substituted products (**2***a* and **3***a*, respectively) were obtained, and their formation rationalized by stereoelectronically controlled electrophilic addition of oxygen to the *s-trans* enol **4***a*.

The observation (4) that androst-4-ene-3,17-dione-6α-T (**5***b*) was hydroxylated at C-6β by *R. arrhizus* without loss of label has been interpreted (4) in terms of a direct hydroxylation with retention of configuration, following the pattern for enzymic hydroxylation at saturated carbon (5–8), but since subsequent investigation of the enolization of Δ^4-3-ketosteroids (9–12) has established that formation of the $\Delta^{3,5}$ enol occurs with stereoelectronically controlled preference for the loss of the C-6β hydrogen relative to that at C-6α of 53:1 (2), data such as that obtained from hydroxylation of **5***b* at C-6β are not amenable to unambiguous mechanistic interpretation. This paper describes the synthesis and incubation with *R. arrhizus* of a series of specifically deuterated androst-4-ene-3,17-diones (**5***c*–**5***g*) and of the 19-norsteroid analogue **1***b* and estr-4-ene-3,17-dione (**6***a*).

19-Nor-Δ^4-3-ketosteroids are commonly hydroxylated at C-6β (13–23), C-10β (13, 14, 16, 23–26), and C-11α (13, 15, 17, 19–21, 23, 24) by microorganisms. In many cases (13–16, 20, 22, 23, 26) hydroxylations at C-6β and C-10β are concurrent or occur with the same species, and there is only one reported instance (25) of C-10β hydroxylation of a 19-nor-Δ^4-3-ketosteroid in which C-6β hydroxylation by a fungus of the same genus is unknown. The possibility therefore exists that hydroxylation at

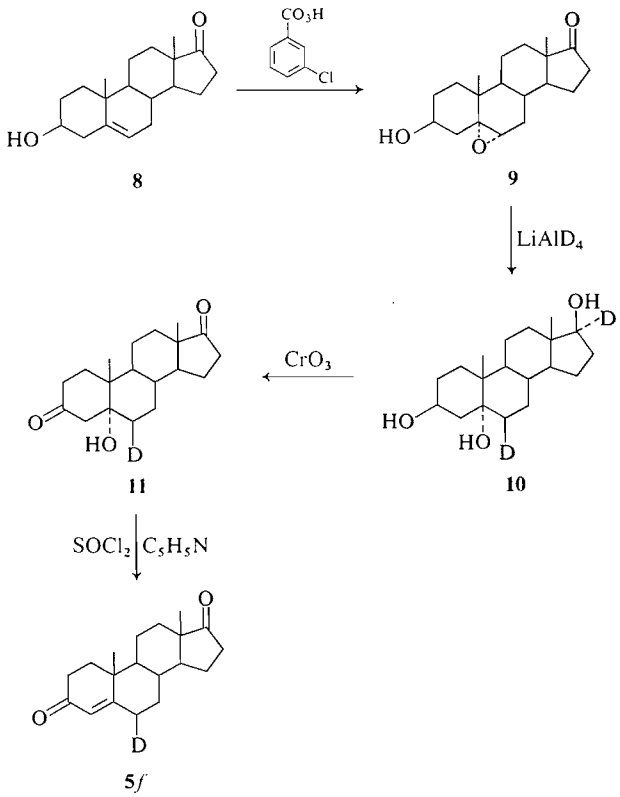
C-10β of a 19-nor-Δ^4-3-ketosteroid is a function of the C-6β hydroxylating system, operating on the *s-cis* enol analogous to **7**.

Synthesis of Labelled Substrates

Androst-4-ene-3,17-dione-2,2,4,6,6,16,16-d_7 (**5***c*), androst-4-ene-3,17-dione-4-*d* (**5***e*), and the -16,16-d_2 compound **5***g* were synthesized by standard procedures. The C-6β deuterated compound **5***f* was prepared by two routes. The existing method (10), as noted by others (27), produced considerable amounts of di- and trideuterated products; modification of this procedure gave **5***f* which was at best 14% dideuterated but which had one atom of deuterium at C-6β (d_0 content = 0%, ^{1}Hmr analysis (10, 11)). Compound **5***f* was also synthesized (Scheme 1) from epoxide **9** of established configuration. The product contained 6% undeuterated species, indicating that some dehydration of **11** to C-6 with loss of deuterium had occurred. Since thionyl chloride – pyridine dehydration takes place with stereospecific loss of hydrogen antiperiplanar to the hydroxyl (in this case C-4β or C-6β) in an E2 manner (28), any dehydration of **11** giving Δ^5 olefin with subsequent pyridine-catalysed rearrangement to the Δ^4 isomer (11, 29, 30) must involve loss of deuterium.

Androst-4-ene-3,17-dione-6α-*d* (**5***d*) was synthesized (Scheme 2) from the (5,6)β epoxide **14**, which gave (31) the **5**β alcohol **15**, oxidation of which afforded **16** which was dehydrated to give **5***d*. The latter reaction was accompanied by loss of 30% of the label. The loss of label in this step may be rationalized as follows. The C-5β alcohol of **16** is antiperiplanar only to the highly hindered C-4α hydrogen, so that elimination from **16** is E1-like (28). Accordingly, C-6α or C-6β may be lost in forming a Δ^5 olefin, or loss from C-4 occur to form



SCHEME 1. Synthesis of androst-4-ene-3,17-dione-6β-*d* (**5***f*).

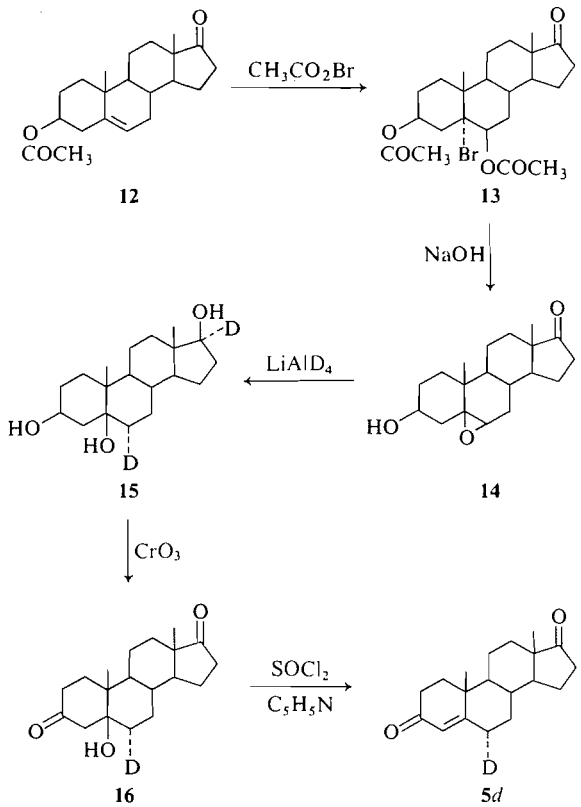
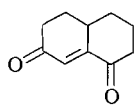


SCHEME 2. Synthesis of androst-4-ene-3,17-dione-6α-*d* (**5***d*).

5*d* directly. In the former case, subsequent base-catalyzed rearrangement (29, 30) to **5***d* must involve protonation at C-6β (11), so that any label at C-6 will ultimately occupy the α position.

Results

Incubation of **1***b* with *R. arrhizus* gave rise to three transformation products, identified as 4a-hydroxy-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**1***c*), 8β-hydroxy-4,4a-5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**2***b*), and 8α-hydroxy-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**3***b*), in the ratio 11:11:1. The structure of **1***c* follows from spectral data and comparison of physical data with published values. Mass spectra of **2***b* and **3***b* indicated the introduction of one hydroxyl group in each case, the location of which was determined by ^{1}Hmr. Signals for the methine hydrogen geminal to oxygen indicate the structures shown (2). Both **2***b* and **3***b* gave the enedione **17** on oxidation. Location of a carbonyl function at C-8 of **17** is confirmed by the downfield



17

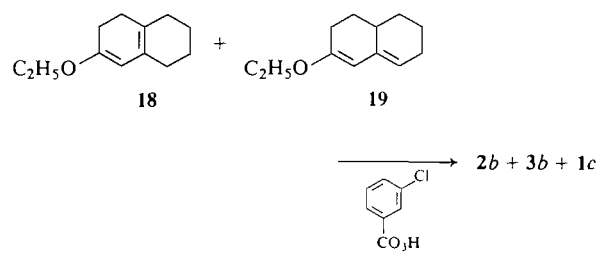
shift (relative to **1***b*) of 0.7 ppm for the resonance due to the olefinic C-1H. The relative stereochemistry of substitution at C-8 in **2***b* and **3***b* then follows from analysis of the olefinic C-1 proton absorption in both cases. In **2***b*, this appears as a narrow doublet (J = 2 Hz, $w_{\frac{1}{2}}$ = 3.4 Hz) coupled only to the methine hydrogen at C-4a (32), and in **3***b* as a broad singlet ($w_{\frac{1}{2}}$ = 4.5 Hz), with allylic couplings to both the C-4a and C-8β hydrogens.

A parallel to the microbial hydroxylation of **1***b* was observed in the peracid oxidation of the mixture of enol ethers **18** and **19** (Scheme 3). Treatment of **1***b* with ethyl orthoformate gave the unstable enol ether mixture **18** + **19** (33), oxidation of which (2) gave **2***b*, **3***b*, and **1***c* in the ratio 4:1:2.

Incubations were also performed with the monocyclic steroid analogues (**20***a*–**20***d*) and the bicyclic βγ unsaturated ketone **21**: no transformation products were observed. The failure of *R. arrhizus* to hydroxylate or even rearrange **21** is of interest in view of the observation that estr-5(10)-ene-3,17-dione (**22**) is hydroxylated only at C-11α by *R. arrhizus* and several other fungi (34, 35).

Incubation of the 19-norsteroid estr-4-ene-3,17-dione (**6***a*) with *R. arrhizus* gave the C-6β and C-10β monohydroxylated products **6***b* and **6***c*, respectively: trace amounts of 10β,17β-dihydroxyestr-4-ene-3,17-dione (**23***a*) were also formed.

The results of the incubations of the labelled substrates are summarized in Table 1. In confirmation of earlier work (4) the C-6α labelled substrate **5***d* is hydroxylated at C-6β (to give **5***h*) and C-11α (to give **5***i*) without loss of label. ^{1}Hmr analysis indicated that the position of label was unchanged. The same



SCHEME 3. Oxidation of **18** and **19** by *m*-chloroperbenzoic acid.

result was observed for C-6β and C-11α hydroxylation of substrates labelled at C-4 (**5***e*) and C-16 (**5***g*). Substrate **5***c*, with label at C-2, -4, -6, and -16, lost one atom of deuterium on hydroxylation at C-6β and none on C-11α hydroxylation.

The C-6β labelled substrate **5***f* retained ca. 12–15% of the label on C-6β hydroxylation; location of the remaining deuterium at C-6α was confirmed by

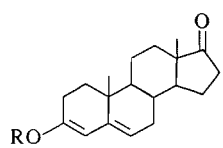
Collins and Lietzke (36, 37) gave a value of $K_H/K_D = 1.2 \pm 0.1$.

To gain information about the rate-determining step in the hydroxylation process, the metabolism of the $\Delta^{3,5}$ enol acetate **24***a* was also investigated. Incubation of **24***a* with *R. arrhizus* gave both Δ^4-3-ketone (**5***a*) and the C-6β hydroxylated product (38), although the corresponding enol ether (**24***b*) was recovered unchanged from *R. arrhizus*. Co-incubation of equimolar amounts of **24***a* and **5***g* (Table 1) suggested that **24***a* can be transformed directly to 6β-hydroxy-Δ^4-3-ketone **5***j* *without* prior conversion to **5***a*. The deuterium content of **5***j* so



24
a R = Ac
b R = Et

obtained differs substantially from the limiting value expected (d_2 39%, d_1 8%, d_0 52%) if the pathway **24***a* → **5***a* → **5***j* were mandatory.

Discussion

The concurrent formation of **2***b* and **3***b* from **1***b* in both enzymic and chemical oxidation may be rationalized by a mechanism analogous to that proposed for the hydroxylation of **1***a* (2) (*vide supra*) and formation of **1***c* in terms of electrophilic addition

of oxygen to the *s-cis* enol **7** (cf. 39, 40). The observation that **2***b*, **3***b*, and **1***c* are produced concurrently by the fungus militates against a mechanism of enzymic hydroxylation of **1***b* in which the regio- and stereospecificity of hydroxylation is determined solely by the three-dimensional relationship between the substrate and the enzyme active site, although such a mechanism operates in the case of hydroxylation at saturated carbon remote from oxygen functionality (21, 41).

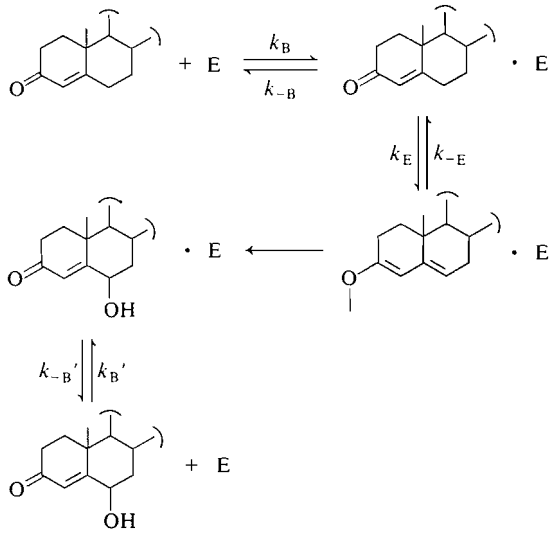
Enzymic hydroxylation of **6***a* via the *s-trans* and *s-cis* enols analogous to **4***b* and **7**, respectively, would also produce, by a stereoelectronically controlled axial addition of electrophilic oxygen, the observed products **6***b* and **6***c* (39, 40). The formation of a C-6α hydroxylated product analogous to **3***b* is prevented by the rigid conformation of ring B precluding C-6α becoming axial in a nonchair conformation (2).

The failure of *R. arrhizus* to metabolise **21** together with the observation that recovered starting material showed no loss or scrambling of label in any of the incubations performed with labelled substrates, confirm the observation (42) that nonenzymic reversible enolization with exchange of hydrogens with the medium does not occur in microbial hydroxylation of ketosteroids. The formation of both *s-cis* and *s-trans* enols from **1***b* and **6***a* implies that, although the enolization is an enzymic process, the regiospecificity of enol formation may not be under strict enzymic control.

The retention of some label at C-6α upon C-6β hydroxylation of **5***f* is inconsistent with direct hydroxylation with retention of configuration. Base-catalysed enolization of **5***f* occurs with loss of 83% of label (12), the preference for loss of the axial β deuteron being counteracted by a primary kinetic isotope effect (12). The similarity between the 17% retention observed for chemical enolization of **5***f* and the 12–15% retention observed during its microbial hydroxylation at C-6β strongly indicates that the latter process involves formation of the $\Delta^{3,5}$ enol.

Since the retention of label from C-6β at C-6 during enolization is dependent upon the existence of a primary kinetic isotope effect (chemically $k_{6\beta H}/k_{6\beta D} = 9$ (12)), the value determined for the C-6β hydroxylation (12) indicates that enolization cannot be rate determining in the enzymic process.

Since **22***a* is hydroxylated at C-6β more rapidly than **5***g*, a mechanism involving rate-determining oxidation of enol can be discounted. The mechanism proposed for C-6β hydroxylation (Scheme 4) thus involves a rate-determining step prior to enolization, such as binding of substrate to enzyme, k_B. The primary isotope effect $k_{EH6\beta}/k_{ED6\beta}$, necessary to account for the retention of some deuterium from C-6β in the product, is thus masked and direct binding of **24***a* to the enzyme bypasses the slow step.



SCHEME 4. Proposed mechanism of C-6β hydroxylation of androst-4-ene-3,17-dione by *R. arrhizus*.

An irreversible oxidation of enol to product is in accord with chemical analogies (2, 39, 43) and need not occur under enzymic control (2, 39). The detailed mechanism of this step and the existence of possible intermediates such as Δ^5-3-ketone are currently under investigation.

Experimental

Apparatus, Materials, and Methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin-Elmer 237B, ^{1}Hmr spectra with a Bruker WP-60 or Varian A-60, using $CDCl_3$ as solvent and TMS as internal standard, and mass spectra were obtained with an AEI MS30. Deuterium content was estimated by repeated scanning of the relevant ions and application of the appropriate corrections for ^{13}C; values are accurate to ±1%. Column chromatography was performed on silica gel (60–200 mesh) or alumina (basic, activity 1), thin-layer chromatography on Merck silica gel 60 F-254 or alumina F-254 type E, and preparative-layer chromatography on Merck silica gel PF-254 (containing calcium sulfate) or alumina F-254.

Microanalyses were carried out by the Pascher microanalytical Laboratory, Bonn, W. Germany.

Rhizopus arrhizus ATCC 11145 was maintained on 4.5% malt agar slopes.

Preparation of Substrates

3-Methylcyclohex-2-enone (**20***a*) was a commercial sample. Estr-4-ene-3,17-dione (**6***a*) was prepared by Jones' oxidation (44) of estr-4-ene-17β-ol-3-one (**23***c*) and gave satisfactory analytical and spectral data. The following compounds were prepared by established procedures and gave satisfactory analytical and spectral data: 3-ethylcyclohex-2-enone (**20***b*) (45), 3-*n*-propylcyclohex-2-enone (**20***c*) (45), 3-*n*-butylcyclohex-2-enone (**20***d*) (45), 4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**1***b*) (46, 47), 3,4,5,6,7,8-hexahydro-2(1*H*)-naphthal-

enone (**21**) (48), 3-acetoxyandrosta-3,5-diene-17-one (**24***a*) (49), and 3-ethoxyandrosta-3,5-diene-17-one (**24***b*) (50).

*5-Bromo-3β,6β-dihydroxy-5α-androstan-17-one 3,6-Diacetate (**13**)*

A solution of acetyl hypobromite (51) in dry carbon tetrachloride (160 ml, 0.1 *M*) at 0°C was added to a solution of 3β-hydroxyandrost-5-ene-17-one, 3-acetate (**12**) (5 g) in dry carbon tetrachloride (50 ml) at 0°C. The resulting solution was stirred at 0°C for 5 min, 5% sodium metabisulphite (5 ml) then added, and after a further 5 min the solution was washed with water (2 × 100 ml), dried over anhydrous sodium sulphate, and evaporated without heating over 40°C. Methanol (30 ml) was added to the residue and the resulting slurry filtered. The product was then recrystallized from methanol to give 4.8 g (63%) (**13**), mp 214–216°C $[\alpha]_D^{20}$ −38° (*c* 1.0, $CHCl_3$); ^{1}Hmr δ: 0.88 (3H, s, C-18 H), 1.32 (3H, s, C-19 H), 2.0, 2.08 (each 3H, s, OAc), 5.2–5.6 (2H, m, C-3α and C-6α H's). *Anal.* calcd. for $C_{23}H_{33}BrO_5$: C 58.85, H 7.09, Br 17.02; found: C 58.83, H 7.09, Br 17.06.

*(5,6β)-Epoxy-3β-hydroxy-5β-androstan-17-one (**14**)*

Sodium hydroxide (4 g) was added to a solution of **13** (4.5 g) in methanol (80 ml) and the solution then heated under reflux for 1 h. The solution was then cooled, neutralised (acetic acid), and poured onto water (300 ml). The resulting solution was extracted (chloroform) and the extract washed with water and then dried and evaporated. Crystallization from aqueous methanol afforded the product (2.4 g, 82%), mp 166–168°C (lit. (52) mp 166–167°C); ^{1}Hmr δ: 0.85 (3H, s, C-18 H), 1.03 (3H, s, C-19 H), 3.11 (1H, d, J = 2.6 Hz, C-6α H), 3.35–3.95 (1H, m, C-3α H).

*3β,5,17β-Trihydroxy-5β-androstane-6α,17α-d_2 (**15**)*

A solution of the epoxide **14** (1.5 g) in benzene–ether (80 ml, 50%) was added over 15 min to a solution of lithium aluminum deuteride (1 g) in dry ether (100 ml). The mixture was refluxed for 36 h, a mixture of ether (20 ml) and acetone (5 ml) added, the solution washed with 5% sulphuric acid (3 × 200 ml), and the washings re-extracted with ether (3 × 200 ml). The combined ethereal extract was washed with water (2 × 500 ml), dried, and evaporated. Crystallization of the residue from acetone–hexane gave the title compound (1.16 g, 78%), mp 194–197°C, (lit. (53) mp 196–198°C); ^{1}Hmr δ: 0.74 (3H, s, C-18 H), 0.98 (3H, s, C-19 H); ms isotopic composition: d_2 99%.

*5-Hydroxy-5β-androstane-3,17-dione-6α-d (**16**)*

A solution of **15** (0.75 g) in acetone (50 ml) at 0°C was oxidized with standard chromic acid reagent (44). After the usual work-up, recrystallization from acetone–hexane gave the product (0.59 g, 80%), mp 182–184°C (lit. (54) mp 183–186°C); ms isotopic composition: d_1 99%.

*Androst-4-ene-3,17-dione-6α-d (**5d**)*

Thionyl chloride (0.2 ml) was added to a solution of **16** (0.5 g) in pyridine (10 ml) at 0°C. The mixture was allowed to stand at 0°C for 5 min, poured onto water (150 ml), and extracted with ether (3 × 100 ml). The ether extract was washed (5% sulphuric acid, water), dried, and evaporated to give a residue which crystallized from ether to give **5***d* (0.42 g, 88%), identical in spectral, mp, and tlc comparisons with an authentic sample of unlabelled material; ^{1}Hmr δ: 0.93 (3H, s, C-18 H), 1.22 (3H, s, C-19 H), 5.74 (1H, br s, $w_{\frac{1}{2}}$ = 3 Hz, C-4 H); ms isotopic composition: d_1 69%, d_0 31%.

*(5,6α)-Epoxy-3β-hydroxy-5α-androstan-17-one (**9**)*

A solution of *m*-chloroperbenzoic acid (2.45 g) in dichloromethane (50 ml) was added over 1 h to a stirred solution of 3β-hydroxyandrost-5-ene-17-one (**8**) (2.45 g) in dichloromethane (50 ml) at 0°C and the resulting solution allowed to stand at 0°C for 12 h. The solution was then washed (5% sodium sulphite, 2 *N* sodium bicarbonate, and water), dried, and evaporated. The residue was crystallized twice from methanol to give **9** (2.1 g, 77%), mp 225–228°C (lit. (55) mp 227–229°C); ^{1}Hmr δ: 0.82 (3H, s, C-18 H), 1.08 (3H, s, C-19 H), 2.92 (1H, d, J = 3.6 Hz, C-6β H), 3.54–4.14 (1H, m, C-3α H).

*3β,5,17β-Trihydroxy-5α-androstane-6β,17α-d_2 (**10**)*

Reduction of **9** (1.5 g) by lithium aluminum deuteride (1 g) using the procedure described for the reduction of **14** gave the title compound (1.14 g, 76%), mp 192–195°C (diisopropyl ether) (lit. (54) mp 193–196°C); ^{1}Hmr δ: 0.74 (3H, s, C-18 H), 1.02 (3H, s, C-19 H); ms isotopic composition: d_2 99%.

*5-Hydroxy-5α-androstane-3,17-dione-6β-d (**11**)*

A solution of **10** (0.75 g) in acetone (50 ml) was oxidized by standard chromic acid reagent (44) and gave, after recrystallization from aqueous methanol, 0.67 g **11** (89%), mp 218–221°C, $[\alpha]_D^{22}$ +105° (*c* 0.8, $CHCl_3$) (lit. (54) mp 217–222°C, $[\alpha]_D$ +106°); ms isotopic composition: d_1 99%.

*Androst-4-ene-3,17-dione-6β-d (**5f**) from (**11**)*

Dehydration of **11** (0.7 g) by the procedure described above gave **5***f* (0.52 g, 79%), from ether, identified by spectral, mp, and tlc comparisons with an authentic sample of unlabelled material; ^{1}Hmr δ: 0.93 (3H, s, C-18 H), 1.22 (3H, s, C-19 H), and 5.74 (1H, s, $w_{\frac{1}{2}}$ = 1.6 Hz, C-4 H); ms isotopic composition: d_1 94%, d_0 6%.

*17β-Hydroxyandrost-4-ene-3-one-6β-d (**23b**, 6β-d)*

This was prepared from 3-ethoxy-17β-hydroxyandrosta-3,5-diene (50) by a modification of previous methods (10, 27). The enol ether (3.6 g) was added to a mixture of acetic acid-OD (20 ml) and deuterium oxide (50 ml), the suspension heated under reflux for 10 min, and the resulting clear solution stirred at 50–60°C for 3 h. The solution was then cooled to room temperature, water (300 ml) added and the mixture extracted with ether. The extract was washed (2 *N* sodium bicarbonate, water), dried, and evaporated. The resulting residue (2.8 g) was free of starting material (tlc) and was used without subsequent purification.

*Androst-4-ene-3,17-dione-6β-d (**5f**)*

17β-Hydroxyandrost-4-ene-3-one-6β-*d* (2.5 g) was dissolved in acetone (100 ml) and oxidized with standard chromic acid reagent (44) at −10°C. After the usual work-up, the product (2.2 g, 88% from ether) was identified by mp, tlc, and spectral comparisons with an authentic sample of unlabelled material; ^{1}Hmr δ: 0.93 (3H, s, C-18 H), 1.22 (3H, s, C-19 H), and 5.74 (1H, s, $w_{\frac{1}{2}}$ = 1.6 Hz, C-4 H); ms isotopic composition: d_3 1%, d_2 14%, d_1 85%.

*Androst-4-ene-3,17-dione-4-d (**5e**)*

Androst-5-ene-3,17-dione-4,4-d_2 (30) (d_2 60%, d_1 30%, d_0 10%), (1 g) was dissolved in a mixture of diglyme (200 ml) and 1 *N* HCl (20 ml). The solution was stirred at room temperature for 2 h, water (400 ml) added, and the resulting mixture extracted with ether (4 × 150 ml). The extract was washed with water (4 × 100 ml), dried, and evaporated. The residue was crystallized from ether to give **5***e* (0.6 g, 60%), identified by mp, tlc, and spectral comparisons with an authentic sample of unlabelled material; ^{1}Hmr δ: 0.93 (3H, s, C-18 H), 1.22 (3H, s, C-19 H), and 5.74 (0.5 H, br s, C-4 H); ms isotopic composition: d_1 45%, d_0 55%.

3β-Hydroxyandrost-5-ene-17-one-16,16-d_2

Tetra-*n*-butyl ammonium bromide (5 g) was added to a solution of sodium deuteroxide in deuterium oxide (100 ml,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

5%) and the resulting solution added to a solution of 3β-hydroxyandrost-5-ene-17-one (5 g) (**8**) in dry benzene (100 ml). The mixture was stirred and heated under reflux for 12 h, then cooled, and the organic layer separated and evaporated. Crystallization of the residue from ether gave the title compound, 4.6 g (92%), identified by comparison with an authentic sample of unlabelled material; ms isotopic composition: d_2 90%, d_1 10%.

Androst-4-ene-3,17-dione-16,16-d_2 *(5g)*

A solution of the above ketone (3 g) in dry toluene (80 ml) was heated and 20 ml of toluene allowed to distil from the flask. Cyclohexanone (15 ml) and freshly distilled aluminum isopropoxide (1.5 g) were then added to the flask and the mixture heated under reflux for 30 min. The solution was then cooled, water (200 ml) added, and the mixture acidified to p*H* 4 (5% hydrochloric acid). The organic layer was separated and the remaining aqueous layer extracted with ether. The combined organic extract was washed (2 *N* sodium bicarbonate, water), dried, and evaporated (rotary evaporator). Residual cyclohexanone was removed by the addition of water (100 ml) followed by steam distillation to dryness. The residue was crystallized from ether to give **5***g* (1.8 g, 60%), identified by comparison with an authentic sample of unlabelled material; ms isotopic composition: d_2 78%, d_1 16%, d_0 5%.

Androst-4-ene-3,17-dione-2,2,4,6,6,16,16-d_7 *(5c)*

This was prepared from androst-4-ene-3,17-dione (**5***a*) (1 g) by the exchange procedure described above. The product (0.78 g, 77% from ether) showed the following isotopic composition: d_7 82%, d_6 15%, d_5 2%.

*Oxidation of 4,4a,5,6,7,8-Hexahydro-2(3*H*)-naphthalenone Enol Ethers (18 + 19)*

A mixture of the enol ethers **18** and **19** (33) (3.8 g) was oxidized by *m*-chloroperbenzoic acid using the procedure described for the oxidation of 2-ethoxy-4a-methyl-3,4,4a,5,6,7-hexahydronaphthalene (2). The resulting oil (3.0 g) was applied to a column of silica gel and the column eluted with 20% ether–benzene to give **1***b* (0.21 g, 7%). Elution with ether gave a fraction (2.7 g) which by ^{1}Hmr analysis was shown to consist of a mixture of **3***b*, **2***b*, and **1***c* (1:4:2). This mixture was rechromatographed on silica gel (elution from ether to 2% methanol–ether) to give two components. The less polar material (R_f 0.26, 1% methanol–ether, silica gel) consisted of a mixture of **2***b* and **1***c*; the other (R_f 0.19) afforded *8α-hydroxy-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone* (**3***b*), 0.12 g (4%) on crystallization from hexane. Recrystallization gave pure **3***b*, mp 98–100°C; ir (KBr) ν_{max}: 1675, 3400 cm^{-1}; ^{1}Hmr δ: 0.9–2.5 (11H, C-3–C-7 H's), 3.3 (1H, br s, exchanges D_2O, OH), 3.9–4.3 (1H, m, C-8βH), 6.23 (1H, br s, $w_{\frac{1}{2}}$ = 4.5 Hz, C-1H); ms *m/e* (%): 166 (M$^+$, 93), 148 (16), 138 (91), 137 (45), 122 (43), 110 (100), 109 (93). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.20, H 8.35. 2,4-DNP mp 206–208°C (EtOH).

The mixture of **2***b* and **1***c* was rechromatographed on alumina (elution from chloroform to ethyl acetate, increments of 10% ethyl acetate) to give *4a-hydroxy-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone* (**1***c*) (0.42 g, 13%), mp 66–68°C from hexane (lit. (56) mp 67–68°C); ir (KBr) ν_{max}: 1675, 3400 cm^{-1}; ^{1}Hmr δ: 1.0–2.8 (11H, C-3–C-8 H's), 3.05 (1H, br s, exchanges D_2O, OH), 5.77 (1H, d, *J* = 1.8 Hz, $w_{\frac{1}{2}}$ = 3.2 Hz, C-1 H). 2,4-DNP mp 163–166°C (EtOH), followed by *8β-hydroxy-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone* (**2***b*), (0.82 g, 25%), bp 140–145°C/0.15 Torr; ir (film) ν_{max}: 1675, 3400 cm^{-1}; ^{1}Hmr δ: 1.0–3.0 (11H, C-3–C-7 H's), 3.86 (1H, br s, exchanges D_2O, OH), 4.36 (1H, m, C-8α H), 5.85 (1H, d, *J* = 2 Hz, $w_{\frac{1}{2}}$ = 3.4 Hz, C-1 H); ms *m/e* (%): 166 (M$^+$, 90), 148 (20), 138 (92), 137 (40), 122 (42), 110 (100), 109 (85). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.37, H 8.49.

Some epimerization of **2***b* to give **3***b* occurred during chromatography on alumina. Submission of **2***b* to the above reaction conditions resulted in near quantitative recovery of starting material, no epimerization occurring other than during chromatography.

*4,4a,5,6-Tetrahydro-2,8(3*H*,7*H*)-naphthalenedione (17)*

Oxidation of either **2***b* or **3***b* by the standard chromic acid procedure (44) gave 4,4a,5,6-tetrahydro-2,8(3*H*,7*H*)-naphthalenedione (85% from **2***b*, 80% from **3***b*), bp 135–140°C/0.15 Torr; ir (film) ν_{max}: 1700, 1675 cm^{-1}; ^{1}Hmr δ: 1.2–2.8 (11H, C-3–C-7 H's), 6.52 (1H, d, *J* = 3 Hz, C-1 H); ms *m/e* (%): 164 (M$^+$, 80), 136 (100), 108 (80). *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.15, H 7.37; found: C 73.26, H 7.18.

Incubations with Rhizopus arrhizus *ATCC 11145*

All incubations were performed as previously described (2).

*4,4a,5,6,7,8-Hexahydro-2(3*H*)-naphthalenone (1b)*

Incubation of 3.5 g gave an extract (3.1 g) which was chromatographed as described above for the oxidation products of **18** + **19** and gave **1***b* (2.6 g) and a fraction (0.13 g) which by ^{1}Hmr analysis was determined to consist of a mixture of **2***b*, **1***c*, and **3***b* in the ratio 11:11:1. Separation of this mixture was achieved as described for the analogous fraction from the oxidation of **18** + **19**.

Final purification was carried out by preparative-layer chromatography. The compounds thus obtained proved identical in spectral and analytical properties with the corresponding alcohols prepared as outlined above.

Estr-4-ene-3,17-dione (6a)

Incubation of 1 g gave an extract (1.3 g) which was chromatographed on silica gel by stepwise elution from benzene to ether (increments of 5% ether) to give *estr-4-ene-3,17-dione* (0.031 g) identical with authentic material, *10β-hydroxyestr-4-ene-3,17-dione* (**6***c*) (0.31 g from ethyl acetate – hexane), mp 197–199°C (lit. (57) mp 198–201°C, lit. (58) mp 198–211°C); ^{1}Hmr δ: 0.95 (3H, s, C-18 H), 5.80 (1H, d, *J* = 1.8 Hz, C-4 H); ms *m/e* (%): 288 (100), 270 (60), *6β-hydroxyestr-4-ene-3,17-dione* (**6***b*) (0.19 g from ethyl acetate – hexane), mp 162–164°C (lit. (17) mp 161–163°C); ^{1}Hmr δ: 0.96 (3H, s, C-18 H), 4.44 (1H, m, C-6α H), 5.91 (1H, d, *J* = 1.8 Hz, C-4 H); ms *m/e* (%): 288 (100), 273 (9), 270 (15), 259 (27), and *10β,17β-dihydroxyestr-4-ene-3-one* (**23***a*) (0.017 g from ethyl acetate – hexane), mp 208–210°C (lit. (58) mp 204–210°C); ^{1}Hmr δ: 0.82 (3H, s, C-18 H), 3.70 (1H, m, C-17α H), 5.77 (1H, d, *J* = 1.8 Hz, C-4 H); ms *m/e* (%): 290 (100), 272 (34), 262 (80). A total of 0.01 g of more polar material eluted from the column with 1% methanol–ether was not investigated further.

Androst-4-ene-3,17-dione

In all experiments described below, products were separated, purified, and identified as described for the incubation of unlabelled androst-4-ene-3,17-dione (**5***a*). Isotopic compositions are listed in the table. Although trace quantities of 11α,-17β-dihydroxyandrost-4-ene-3-one were detected (tlc) in all the following incubations, this compound was isolated only from the incubation of unlabelled material as described below.

Incubation of 1.2 g **5***a* gave an extract (0.96 g) which was applied to a column of silica gel in benzene. The column was eluted with ether–benzene (increments of 10% ether) to give in order of elution, *androst-4-ene-3,17-dione* (0.16 g from ether), identical in all respects with starting material, *11α,17β-dihydroxyandrost-4-ene-3-one* (0.014 g from ether), mp 180–182°C (lit. (3) mp 181–184°C); ^{1}Hmr δ: 0.80 (3H, s, C-18 H), 1.35 (3H, s, C-19 H), 3.5–4.0 (2H, m, C-11β and C-17α H's),

5.80 (1H, br s, C-4 H), *6β-hydroxyandrost-4-ene-3,17-dione* (0.184 g from ethyl acetate – hexane), mp 190–192°C (lit. (3) mp 191–194°C); ^{1}Hmr included signals at δ 0.95 (3H, s, C-18 H), 1.42 (3H, s, C-19 H), 4.42 (1H, m, C-6α H), 5.84 (1H, s, $w_{\frac{1}{2}}$ = 1.8 Hz, C-4 H), and *11α-hydroxyandrost-4-ene-3,17-dione* (0.37 g from ether), mp 222–224°C (lit. (3) mp 225–227°C); ^{1}Hmr δ: 0.94 (3H, s, C-18 H), 1.36 (3H, s, C-19 H), 3.6–4.3 (1H, m, C-11β H), and 5.77 (1H, br s, C-4 H). Separation of fractions containing mixtures was achieved by preparative-layer chromatography on silica gel, 1% methanol–ether.

*Androst-4-ene-3,17-dione-6α-*d *(**5d**)*

Incubation of 0.5 g gave an extract (0.53 g) which afforded *androst-4-ene-3,17-dione-6α-*d (0.082 g), *6β-hydroxyandrost-4-ene-3,17-dione-6α-*d (0.073 g), and *11α-hydroxyandrost-4-ene-3,17-dione-6α-*d (0.17 g).

*Androst-4-ene-3,17-dione-6β-*d *(**5f** from **11**)*

Incubation of 0.5 g gave an extract (0.55 g) which afforded *androst-4-ene-3,17-dione-6β-*d (0.052 g), *6β-hydroxyandrost-4-ene-3,17-dione* (0.036 g) oxidation of which by chromic acid (44) gave androst-4-ene-3,6,17-trione free from label, and *11α-hydroxyandrost-4-ene-3,17-dione-6β-*d (0.104 g), ^{1}Hmr analysis of which (10, 11, 32) indicated the presence of deuterium at C-6β.

*Androst-4-ene-3,17-dione-6β-*d *(**5f**)*

Incubation of 0.46 g gave an extract (0.5 g) which afforded *androst-4-ene-3,17-dione-6β-*d (0.033 g), *6β-hydroxyandrost-4-ene-3,17-dione* (0.038 g), chromic acid oxidation of which (44) gave androst-4-ene-3,6,17-trione of isotopic composition d_2 1%, d_1 11%, d_0 89%, and *11α-hydroxyandrost-4-ene-3,17-dione-6β-*d (0.184 g); ^{1}Hmr analysis of which indicated the presence of deuterium at C-6β (10, 11, 32).

*Androst-4-ene-3,17-dione-4-*d *(**5e**)*

Incubation of 0.45 g gave an extract (0.42 g) which afforded *androst-4-ene-3,17-dione-4-*d (0.047 g), *6β-hydroxyandrost-4-ene-3,17-dione-4-*d (0.058 g), and *11α-hydroxyandrost-4-ene-3,17-dione-4-*d (0.094 g). ^{1}Hmr analysis of the above samples indicated ca. 0.5 H present at C-4.

Androst-4-ene-3,17-dione-16,16-d_2 *(**5g**)*

Incubation of 0.45 g gave an extract (0.51 g) which afforded *androst-4-ene-3,17-dione-16,16-*d_2 (0.12 g), *6β-hydroxyandrost-4-ene-3,17-dione-16,16-*d_2 (0.024 g), and *11α-hydroxyandrost-4-ene-3,17-dione-16,16-*d_2 (0.088 g).

Androst-4-ene-3,17-dione-2,2,4,6,6,16,16-d_7 *(**5c**)*

Incubation of 0.6 g gave an extract (0.65 g) which afforded *androst-4-ene-3,17-dione-2,2,4,6,6,16,16-*d_7 (0.125 g), *6β-hydroxyandrost-4-ene-3,17-dione-2,2,4,6α,16,16-*d_6 (0.052 g) and *11α-hydroxyandrost-4-ene-3,17-dione-2,2,4,6,6,16,16-*d_7 (0.21 g).

Androst-4-ene-3,17-dione-16,16-d_2 *(**5g**)* + *3-Acetoxyandrosta-3,5-diene-17-one (**24a**)*

Incubation of 0.288 g **5*g*** + 0.328 g **24*a*** gave an extract (0.66 g) which afforded *androst-4-ene-3,17-dione-16,16-*d_2 (0.27 g), *6β-hydroxyandrost-4-ene-3,17-dione-16,16-*d_2 (0.18 g), and *11α-hydroxyandrost-4-ene-3,17-dione-16,16-*d_2 (0.043 g).

*3-Acetoxyandrosta-3,5-diene-17-one (**24a**)*

Incubation of 0.3 g gave an extract (0.25 g) which afforded *androst-4-ene-3,17-dione* (0.12 g), *6β-hydroxyandrost-4-ene-3,17-dione* (0.07 g), and *11α-hydroxyandrost-4-ene-3,17-dione* (0.015 g).

*Androst-4-ene-3,17-dione-6β-*d *(**5f**)* + *Androst-4-ene-3,17-dione-16,16-*d_2 *(**5g**)*

Incubation of a mixture of **5*g*** (0.576 g) and **5*f*** (0.488 g) gave an extract (1.1 g) which afforded *androst-4-ene-3,17-dione* (0.13 g), *6β-hydroxyandrost-4-ene-3,17-dione* (0.102 g), and *11α-hydroxyandrost-4-ene-3,17-dione* (0.174 g).

*3-Ethoxyandrosta-3,5-diene-17-one (**24b**)*

Incubation of 0.5 g gave 0.45 g of extract; tlc analysis indicated the absence of transformation products. Purification afforded only **24*b*** (0.5 g), identical with starting material.

Reçu le 11 novembre 1977

JACQUES DEVYNCK, BERNARD TREMILLON, HUGUES MENARD et GERMAIN COMARMOND. Can. J. Chem. **56**, 703 (1978).

On décrit le comportement électrochimique de Sb(III) et Sb(V) dans les mélanges eau–HF et dans HF anhydre. Une électrode à gouttes de mercure à capillaire de Teflon permettant la mise en œuvre des techniques polarographiques directement dans les mélanges eau–HF et dans HF anhydre est proposée. L'étude a montré, par polarographie classique et par polarographie à impulsions, que Sb(III) est réductible à l'état de Sb(0) comme en milieu acide non-fluoré, la réaction n'étant reversible qu'en présence d'ions Cl^- ou Br^-, I^-. Sb(V) n'est pas électroactif dans les différents milieux considérés sauf s'il est ajouté sous la forme $SbCl_5$; il présente alors deux vagues de réduction, qui disparaissent au cours du temps par suite de la formation de SbF_6^-. On discute les possibilités d'applications au dosage de Sb(III) en milieu eau–HF et dans HF anhydre.

JACQUES DEVYNCK, BERNARD TREMILLON, HUGUES MENARD, and GERMAIN COMARMOND. Can. J. Chem. **56**, 703 (1978).

The electrochemical behaviour of Sb(III) and Sb(V) in water–HF mixtures (2.5 to 50% HF) and in anhydrous HF is described. A Teflon capillary dropping mercury electrode is proposed for polarographic investigations in these fluorinated media. It is shown, by classical or pulse polarography, that Sb(III) can be reduced to Sb(0), as in acidic non-fluorinated media. The electrochemical reaction becomes reversible by addition of Cl^-, Br^- or I^-. Sb(V) is not electroactive in the various HF-media, except when it is introduced as the $SbCl_5$. In this case, the two polarographic waves of Sb(V) disappear with time because of SbF_6^- formation. Analytical applications to the determination of Sb(III) in water–HF and in anhydrous HF are discussed.

Introduction

Le fluorure d'hydrogène anhydre et ses mélanges avec l'eau sont connus comme étant de bons milieux d'attaque de minerais et de verres, et l'analyse des éléments métalliques dans ces matériaux passe très souvent par une attaque en milieu eau – fluorure d'hydrogène (1).

En raison du caractère corrosif de HF, l'analyse des éléments n'est pas effectuée directement dans le mélange eau–HF: quelle que soit la technique d'analyse employée, il est préconisé de chasser HF, opération qui peut conduire à des pertes des éléments à doser par suite d'une évaporation ou d'un entraînement par la vapeur. Des pertes de cette nature ont été évoquées notamment lors de l'analyse de l'antimoine (2).

Une application des méthodes électrochimiques directement dans les solutions d'attaque permet d'éviter ces pertes, mais elle n'est possible que si l'on dispose d'électrodes et de cellules résistant au fluorure d'hydrogène. La polarographie, en particulier, nécessite l'utilisation d'un capillaire de Teflon dont la fabrication a longtemps été reconnue comme difficile et le fonctionnement délicat (3).

Nous avons, pour notre part, réalisé un capillaire de fabrication simple et nous l'avons utilisé dans ce travail pour analyser le comportement électrochimique de Sb(III) et Sb(V) dans les mélanges eau–HF de teneur en HF supérieure à 20% (en poids) et dans HF anhydre.

L'antimoine aux degrés d'oxydation (III) et (V) a donné lieu a de très nombreuses études polarographiques (4). Il est connu que Sb(III) est réduit irréversiblement dans les milieux acides non complexants, comme les solutions de $HClO_4$ (5), et il a été montré que l'addition d'ions halogénures, Cl^- notamment,

rend le système réversible (6). L'antimoine(V) n'est, quant à lui, pas électroactif en milieu acide, sauf sous la forme de complexe $SbCl_6^-$ en milieu HCl très concentré (7). La non-électroactivité de Sb(V) est particulièrement intéressante lorsqu'il est nécessaire de doser Sb(III) à très faible concentration en présence de Sb(V) concentré: c'est précisément le cas des phases catalytiques à base de SbF_5 utilisées dans la chimie des milieux superacides (8–10).

Etant donné l'intérêt des mélanges eau–HF sur le plan analytique et les possibilités offertes par l'application directe des méthodes dérivées de la polarographie, nous avons étudié le comportement électrochimique de Sb(III) et Sb(V) dans le but de mettre au point des méthodes de dosage de l'antimoine(III).

Partie expérimentale

Cellule

Le matériel utilisé pour cette étude dérive de celui qui a été décrit pour des études du fluorure d'hydrogène anhydre et des mélanges eau – fluorure d'hydrogène (11, 13). La cellule est en voltalef (contenance: 30 ml). HF anhydre et les mélanges eau–HF très concentrés en HF sont manipulés au moyen d'une rampe spéciale (12). Les mélanges de teneur inférieure ou égale à 50% de HF sont manipulés dans un simple récipient cylindrique, en voltalef, muni d'un couvercle de Teflon dans lequel sont percées les ouvertures pour les électrodes.

Electrodes-référence

Pour l'étude des mélanges de teneur inférieure à 70% de HF, l'électrode de référence était une électrode au calomel en solution aqueuse (Tacussel, type C10) placée dans un compartiment de Teflon et séparée de la solution fluorhydrique par du Teflon poreux (11). Pour éviter la diffusion d'ions chlorure, le compartiment intermédiaire contenait une solution aqueuse de $NaNO_3$ 0.1 *M*.

Dans HF anhydre et dans les mélanges de teneur supérieure à 70% de HF, l'électrode de référence était réalisée à partir du système Cu, CuF_2, KF 0.2 *M* (14).

Electrodes à gouttes de mercure

Les capillaires de verre utilisés en polarographie sont inutilisables en présence de HF. Certaines techniques, comme l'utilisation d'une goutte fixe placée sur un support adéquat (13) ou l'utilisation d'une électrode amalgamée (or ou argent) (15) permettent de s'en affranchir. Cependant, les résultats n'ont pas la reproductibilité de ceux obtenus à l'aide d'un capillaire ou d'une électrode à goutte pendante et présentent donc peu d'intérêt analytique. Différents types de capillaires utilisables dans les mélanges eau–HF et dans HF anhydre ont été décrits, par Clifford (16), Raeen (17) et Headrige (18) puis, plus récemment, par Bond, O'Donnell et coll. (3, 19). Une mise au point sur ce sujet a été publiée par Bond et O'Donnell (3). A partir des modèles de capillaires inattaquables proposés, nous avons réalisé une électrode à gouttes différente, dont le schéma est représenté sur la fig. 1. L'électrode est composée d'un petit cylindre de Teflon dans lequel un canal de 0.1 à 0.2 mm de diamètre est réalisé par surmoulage à chaud d'un fil métallique (capillaire PFA 9705, SAIMAP, Issy-les Moulineaux). Ce cylindre de Teflon est inséré et collé dans un capillaire de verre classique (Capillaire METROHM EA671). L'espace compris entre le capillaire de verre et le cylindre de Teflon est partiellement rempli de paraffine (aspiré à l'état fondu à travers le tube de Teflon), de façon à ménager une chambre de forme sensiblement sphérique qui se remplit de mercure sans retenir de bulles d'air. L'ensemble capillaire de verre et tube de Teflon est gainé d'un tube de polyoléfine thermorétractable (gaine TTR, Compagnie française des Isolants Paris). L'électrode ainsi réalisée a été utilisée avec un dispositif de stillation forcée Tacussel, type MP03.

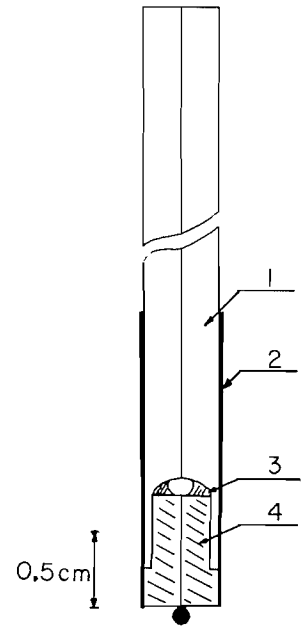

FIG. 1. Vue en coupe du capillaire de l'électrode à gouttes de mercure. (*1*) Capillaire de verre (METROHM-EA671); (*2*) gaine de polyoléfine thermorétractable; (*3*) paraffine; (*4*) tube capillaire en voltalef (ϕ intérieur: 100 à 200 μm).

L'électrode auxiliaire était un fil de platine.

Appareillage

Les courbes voltampérométriques ont été obtenues à l'aide d'un polarographe Tacussel type PRG5 et enregistrées sur table traçante Sefram type Luxytrace.

Produits

Fluorure d'hydrogène: les mélanges eau–HF de teneur inférieure à 50% ont été réalisés à partir des solutions commerciales (Merck). Cependant, ces solutions contenaient des traces d'ions chlorure qui se sont avérées gênantes pour certaines études; les mélanges ont été alors préparés par addition d'eau au fluorure d'hydrogène de haute pureté (Comhurex, Pierrelatte).

Les solutions d'antimoine (Anachemia, Reagent Grade) ont été préparées, à partir de produits purs pour analyse, dans des fioles jaugées en polypropylène (Nalgene) dont la résistance aux mélanges eau–HF s'est révélée excellente aux concentrations de HF inférieures à 50%.

Résultats

(1) Comportement électrochimique de l'antimoine(III)

(a) Dans le mélange à 40% de HF

Les solutions de Sb(III) (sous forme d'oxyde ou de fluorure) présentent une vague polarographique bien définie ($E_{1/2} = -0.540$ V/ECS) dont la hauteur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

est proportionnelle à la concentration, mais irréversible (fig. 2). Par polarographie à impulsions (fig. 3), la proportionnalité de la hauteur du pic à la concentration est bien vérifiée dans le domaine: 10^{-7} M < Sb(III) < 10^{-2} M.

L'addition d'ions chlorure (sous forme de HCl ou de KCl) provoque, comme dans d'autres solutions aqueuses acides (20), un déplacement de la vague vers les potentiels positifs. A partir d'une concentration d'ions Cl^- environ 1 M, la réduction de Sb(III) à l'état d'amalgame est devenue réversible (fig. 2). Le potentiel de demi-vague est alors $E_{1/2} = -0.358$ V/ECS. La présence d'ions Cl^- provoque simultanément l'apparition d'une vague d'oxydation du mercure. L'évolution du système Sb(III)/Sb(0) vers la réversibilité lors de l'addition de Cl^- peut également être constatée par polarographie à impulsions (fig. 3). La largeur du pic à mi-hauteur est alors de 75 mV (valeur théorique pour des impulsions de 50 mV: 54 mV d'après Parry et Osteryoung (21)).

Remarque: Les solutions d'antimoine(III) dans les mélanges eau–HF présentent, lorsqu'elles sont fraîchement préparées en l'absence d'ions Cl^- une prévague qui disparaît au cours du temps. Une telle prévague a également été observé en milieu $HClO_4$ (22) et a été attribuée à la réduction de SbO^+ formé par hydrolyse partielle de Sb^{3+}, selon la réaction:

$$SbO^+ + 2H^+ + 3e \rightarrow Sb(Hg) + H_2O$$

(b) Dans HF anhydre (+ KF 0.2 M)

Les phénomènes observés dans les mélanges eau – fluorure d'hydrogène sont un peu modifiés dans le fluorure d'hydrogène anhydre. Le polarogramme

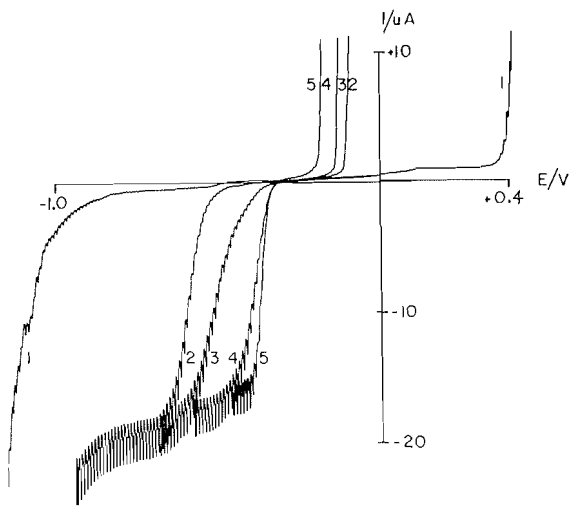

FIG. 2. Polarogrammes d'une solution de Sb_2O_3 dans un mélange eau – HF contenant 40% de HF (en poids), + KCl. (*1*) Courant résiduel; (*2*) Sb_2O_3 5 × 10^{-4} M; après addition de KCl: (*3*) 3 × 10^{-2} M; (*4*) 7 × 10^{-2} M; (*5*) 1 M.

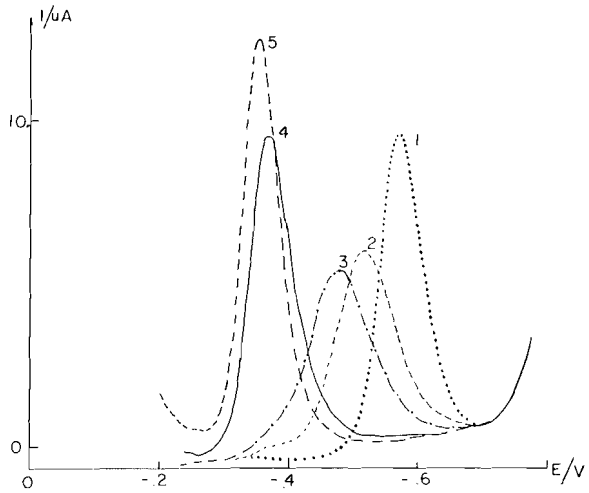

FIG. 3. Polarographie à impulsions de Sb_2O_3 3 × 10^{-5} M dans un mélange eau – HF contenant 40% de HF: influence des ions chlorure. (*1*) Sb_2O_3 seul; après addition de KCl: (*2*) 10^{-2} M; (*3*) 2 × 10^{-1} M; (*4*) 5 × 10^{-1} M; (*5*) 1.3 M. Impulsions: 50 mV, temps de goutte: 1 s.

d'une solution de Sb(III) présente également une vague de réduction non-réversible ($E_{1/2} = -0.770$ V/Cu, CuF_2). L'addition d'ions chlorure rend le système réversible, le potentiel de demi-vague est alors $E_{1/2} = -0.660$ V (fig. 4). Notons cependant que, du fait de la basicité de Cl^- et de la faible solubilité de HCl dans HF anhydre, on observe, au cours du temps, la disparition progressive de la vague réversible au profit de la vague irréversible.

(2) Comportement électrochimique de l'antimoine(V)

(a) Dans les mélanges eau–HF

Les sels de Sb(V) (Sb_2O_5 ou SbF_5) ne sont pas électroactifs dans les mélanges eau–HF. Seul le chlorure d'antimoine(V) présente une double vague de réduction (fig. 5). Les hauteurs relatives des deux vagues sont compatibles avec la mise en jeu, respectivement, de deux électrons (système Sb(V)/Sb(III) et trois électrons (système Sb(III)/Sb(0)). La dissolution de chlorure d'antimoine(V) fait immédiatement apparaître une vague d'oxydation, correspondant à l'oxydation du mercure en présence d'ions chlorure et, comme dans d'autres milieux, la réduction de Sb(V) a lieu pratiquement au même potentiel que l'oxydation du mercure; la détermination du potentiel de demi-vague de la première vague est donc impossible. Le potentiel de demi-vague correspondant à la seconde étape de réduction est: $E_{1/2} = -0.460$ V. Au cours du temps, la double vague de réduction de Sb(V) diminue, tandis que la vague d'oxydation du mercure en présence de chlorure augmente. Lorsque la vague de Sb(V) a complète-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

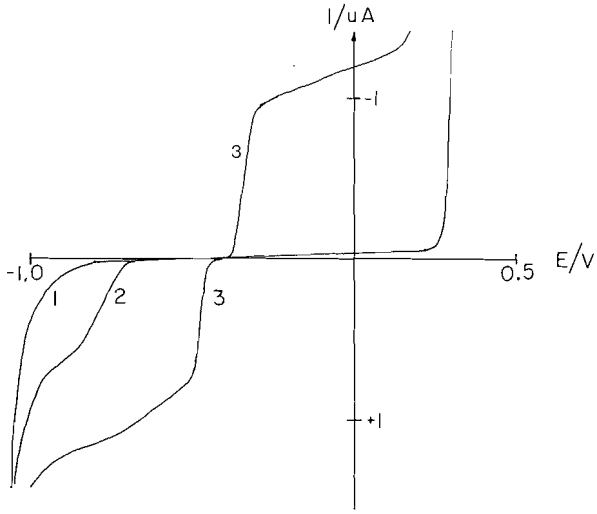

FIG. 4. Polarogramme d'une solution de Sb_2O_3 2.5×10^{-4} *M* dans HF anhydre (+KF 0.2 *M*). Influence de la concentration des ions chlorures. (*1*) Courant résiduel; (*2*) solution de Sb_2O_3 seul; (*3*) après addition de KCl 10^{-1} *M*.

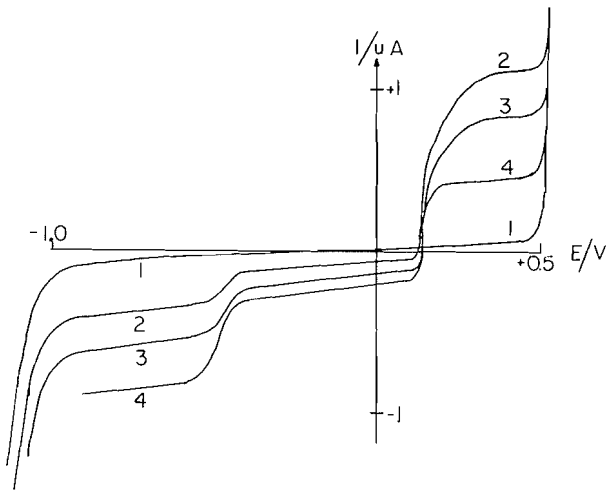

FIG. 5. Polarogramme d'une solution de $SbCl_5$ 5×10^{-4} *M* dans un mélange eau – HF contenant 40% de HF: évolution en fonction du temps *t*. (*1*) Courant résiduel; (*2*) après addition de $SbCl_5$, $t = 1$ h; (*3*) $t = 4$ jours; (*4*) $t = 6$ jours.

ment disparu, la vague d'oxydation du mercure a alors une hauteur sensiblement égale à la hauteur totale des vagues de réduction de Sb(V) en Sb(0) (fig. 5, courbe 2).

(b) Dans HF anhydre

Comme dans le cas de Sb(III), le comportement de Sb(V) diffère peu dans les mélanges eau–HF et dans HF anhydre basique. Lorsque Sb(V) est dissous sous la forme de fluorure, il n'est pas électroactif; seules les solutions de $SbCl_5$ présentent une double vague en réduction. Cette vague disparaît lentement au cours du temps (fig. 6) en même temps que la vague anodique due aux ions chlorure, du fait de la faible solubilité de HCl. Le phénomène est accéléré par un barbotage d'un gaz inerte qui entraine HCl. On obtient finalement la courbe correspondant au courant résiduel.

Discussion

Le comportement électrochimique de l'antimoine(III) dans les mélanges eau–HF de concentration en HF variable, jusqu'à HF anhydre (basique) est tout à fait comparable à celui qui avait été précédemment observé en milieu acide non fluoré. Les méthodes électrochimiques d'analyse de Sb(III) sont donc directement transposables aux mélanges eau–HF, avec des électrodes à gouttes de mercure réalisées à l'aide de matériaux résistant au fluorure d'hydrogène. Les techniques polarographiques très sensibles (polarographie à impulsions ou redissolution anodique) permettent ainsi un dosage de traces de Sb(III) directement dans les solutions d'attaque des matériaux, ce qui présente un avantage par rapport aux procédés précédemment décrits (1, 23) nécessitant l'élimination de HF.

Dans tous les mélanges eau–HF, Sb(III) présente une vague de réduction irréversible, mais l'addition d'ions Cl^- déplace cette vague de réduction vers les potentiels positifs et rend le système réversible. Outre l'intérêt qu'elle présente sur le plan analytique (meilleure "résolution" de Sb(III) en polarographie à impulsions, par exemple), cette évolution apporte quelques indications sur le comportement de Sb(III)

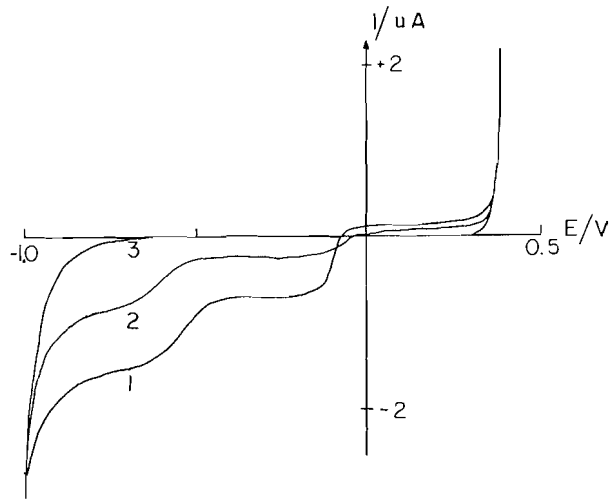

FIG. 6. Polarogramme d'une solution de $SbCl_5$ dans HF anhydre (+KF 0.2 *M*); évolution en fonction du temps. (*1*) Solution de $SbCl_5$ 3×10^{-4} *M*; $t = 1$ h; (*2*) $t = 24$ h; (*3*) courant résiduel.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

en milieu HF et sur la réactivité de ce milieu. Notons tout d'abord que les complexes chlorure de Sb(III) sont vraisemblablement peu stables dans les mélanges eau–HF: l'addition de $SbCl_3$ conduit à la libération quantitative des ions Cl^-, identifiables par la vague d'oxydation du mercure. On peut supposer que les ions halogénures X^- (Cl^-, Br^- ou I^-) sont déplacés des complexes SbX_3 par HF du fait de la stabilité des complexes fluorure et de la basicité de l'ion X^-, selon la réaction:

$$SbCl_3 + 3\ HF \leftrightarrows SbF_3 + 3HCl$$

Il n'y a donc probablement pas lieu d'invoquer la formation de complexes chlorure en solution (complexes dont on sait que la réduction est réversible pour expliquer les modifications de la cinétique de la réduction électrochimique. On observe d'ailleurs que l'addition supplémentaire d'ions halogènure au-delà de la concentration minimale nécessaire pour rendre le système réversible est sans effet sur la vague polarographique; pas de déplacement de la vague de réduction qui pourrait être attribué à la formation de complexes en solution.

Il a, en effet, été montré que des complexes fluorure de Sb(III) peuvent se former en milieu HF dilué (18–22). Cependant, il convient de noter que l'activité des ions fluorures diminue lorsque la concentration de HF augmente dans les mélanges eau–HF, du fait de la très forte solvatation de l'ion F^- par HF (24). Les complexes fluorures, s'ils existent, sont vraisemblablement de moins en moins stables quand la concentration de HF augmente et les mélanges couramment utilisés (comme le mélange à 40% de HF) sont, en fait, très peu "complexants" (25).

L'origine du phénomène responsable de la variation de la cinétique de réduction de Sb(III) lors de l'addition d'ions halogènure a donné lieu à de très nombreux travaux. Si la formation de complexes halogènures en solution a été fréquemment invoquée (4), des effets catalytiques ont aussi été avancés pour justifier l'effet des ions I^- (26), SCN^- (27), ou encore $S_2O_3^{2-}$ (28). Il apparaît ici vraisemblable que la réduction réversible de Sb(III) nécessite l'adsorption des ions halogènure X^- (ou de HX quand l'halogènure est protoné) (29). On peut, en effet, observer que la charge de la double-couche est positive dans le domaine de potentiel ou Sb(III) est réduit (par exemple, dans un mélange à 22% de HF (17)) et que la concentration nécessaire pour observer la réversibilité dans un milieu donné est d'autant plus faible que l'halogénure est plus fortement adsorbé; cette adsorption des ions halogénure en milieu eau–HF est actuellement en cours d'étude (30).

L'antimoine(V) est électroactif sous la forme de complexe chlorure ($SbCl_5$ ou $SbCl_6^-$) et présente alors dans les milieux eau–HF le même comportement qu'en milieu HCl concentré. Cependant, du fait de la très grande stabilité des complexes fluorure, l'équilibre

$$[1] \qquad SbCl_5 + 7HF \leftrightarrows SbF_6^- + 5HCl\uparrow + H_2F^+$$

est fortement déplacé vers la formation de SbF_6^-, complexe non-électroactif. On ne forme pas les complexes mixtes du type $SbCl_xF_y$ mis en évidence par Dove (31) (dans des conditions expérimentales toutefois très différentes). La réaction 1 a été mise a profit pour préparer le fluorure d'antimoine à partir du chlorure correspondant (32). Du fait du caractère non-électroactif de SbF_5 en milieu eau–HF comme dans HF anhydre, le dosage de Sb(V) n'y est pas possible par polarographie. Ce caractère peut être mis à profit pour doser Sb(III) en présence de grandes quantités de Sb(V), comme cela a été proposé pour l'analyse des produits de réduction des milieux superacides contenant SbF_5 (33).

Kinetics and mechanism of the base hydrolysis of some *trans*-dihalogeno(cyclam)rhodium(III) complexes

H. L. CHUNG[1] AND E. J. BOUNSALL

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 22, 1977

H. L. CHUNG and E. J. BOUNSALL. Can. J. Chem. **56**, 709 (1978).

The base hydrolysis of *trans*-[Rh(cyclam)XY]$^+$ (cyclam = 1,4,8,11-tetraazacyclotetradecane; X^- and Y^- = Cl^-, Br^-, and I^-) are studied in aqueous solution over a range of OH^- concentration and at various temperatures. The kinetics are done at a constant ionic strength with excess of [OH^-] (smallest ratio = 200:1) so that pseudo first order rate constants are obtained for all the determinations. All of the reactions proceed with complete retention of configuration, and no *trans*-to-*cis* isomerization is found. The kinetic *trans* effect of these complexes is $I^- > Br^- > Cl^-$ on a rate basis, but based on ΔH^*, $I^- > Br^- = Cl^-$. These Rh(III) complexes exhibit kinetic class (*b*) character on the ΔH^* basis. The results of the rate constants and the activation parameters are interpreted in terms of an S_N1CB mechanism. The behavior of these complexes is compared to that of the other analogous complexes.

H. L. CHUNG et E. J. BOUNSALL. Can. J. Chem. **56**, 709 (1978).

On a étudié l'hydrolyse basique du [Rh(cyclam)XY]$^+$ *trans* (cyclam = tétraaza-1,4,8,11 cyclotétradécane, X^- et Y^- = Cl^-, Br^- et I^-); ces études ont été effectuées en solution aqueuse à des concentrations de OH^- variables et à diverses températures. On a déterminé les cinétiques à une force ionique constante avec un excès de concentration de OH^- (plus petit rapport = 200:1) de façon à obtenir des constantes de vitesse de pseudo premier ordre pour toutes les déterminations. Toutes les réactions se produisent avec une rétention de configuration et on ne trouve aucune isomérisation *trans* vers *cis*. L'effet cinétique *trans* de ces complexes, tel que déterminé à partir des vitesses, correspond à $I^- > Br^- > Cl^-$ alors que l'ordre est $I^- > Br^- = Cl^-$ si l'on utilise le ΔH^* comme base. En se basant sur les ΔH^*, ces complexes Rh(III) présentent un caractère de cinétique de classe (*b*). Ces résultats concernant les constantes de vitesse et les paramètres d'activation peuvent être interprétés en termes d'un méchanisme S_N1CB. On compare le comportement de ces complexes avec celui d'autres complexes analogues.

[Traduit par le journal]

Introduction

The kinetics of substitution reactions in octahedral six-coordinate transition metal complexes have been extensively investigated and reviewed (1). In general, these octahedral complexes undergo acid hydrolysis and substitution reactions with other ligands at rates which are of the same magnitude and which are independent of the nature and concentration of the incoming group. Only first order kinetics are observed. In marked contrast, the hydroxide ion exhibits distinctly different behavior. Its substitution (base hydrolysis) takes place at a rate that is many orders of magnitude faster than other substitution reactions of these complexes. The base hydrolysis reactions are second order overall, first order with respect to the concentration of the complex and the hydroxide ion.

The rate of base hydrolyses of some octahedral ammine and amine complexes of Rh(III) has been reported (2). Surprisingly the hydroxide ion had little or no effect on the rate of reaction and acted like any other nucleophiles, and all reacted with complete retention of configuration.[2]

Bounsall and Koprich (4) have successfully synthesized some *trans*-[Rh(cyclam)XY]$^+$ complexes. They found that substitution reactions took place with strict retention of configuration and were independent of the nature and concentration of the incoming ligand. They also reported that these complexes were sensitive to base hydrolysis. This observation was unexpected in view of the other ammine and amine complexes of Rh(III) but identical to that found for Co(III). In view of this anomaly, it became important to study the base hydrolysis of these cyclam complexes of Rh(III).[3]

Experimental

Materials

Complexes of *trans*-[Rh(cyclam)XY]$^+$ used in this study were prepared as described previously (4). For all kinetic runs,

[1]Present address: Department of Chemistry, Michigan Cancer Foundation, Detroit, MI 48201.

[2]During the course of this work, Poe and Vuik (3) reported the base hydrolysis of *trans*-[Rh(en)$_2$X$_2$]$^+$ (en = ethylenediamine, X^- = Cl^-, Br^-, and I^-) complexes by using sufficiently high hydroxide ion concentration.

[3]The base hydrolysis of *trans*-[Rh(cyclam)Cl$_2$]$^+$ has been mentioned (5) during the course of this work.

deionized water was rendered carbon dioxide free by boiling and cooling under nitrogen atmosphere. Sodium hydroxide solutions were standardized before use. The deuterio *trans*-[Rh(D_4-cyclam)X_2]X (X^- = Cl^- and I^-) were prepared by dissolving the corresponding *trans*-[Rh(cyclam)X_2]X in hydroxide solution using D_2O as a solvent. The compounds were heated and then precipitated by adding the corresponding sodium salt.

Instruments

The electronic spectra were recorded with a Bausch and Lomb Spectronic 505 Recording Spectrophotometer. The reaction solutions were thermostatted in an oil bath with a Sargent thermo-regulator. The infrared spectra were taken on a Beckmann 10 Infrared Spectrophotometer.

Kinetics

A known quantity of the compound and the appropriate concentration of sodium hydroxide solution were prepared separately in equal volumes of water. The two solutions were previously brought to reaction temperature in a thermostatted oil bath and then mixed in a volumetric flask. Sufficient sodium nitrate was added to the sodium hydroxide solution before dilution to ensure a final ionic strength of 0.30 *M* in the reaction mixture. For the *trans*-[Rh(cyclam)I_2]$^+$ complex at 40°C, with the ionic strength adjusted to 3.00 *M*, there was a direct first order dependence on the concentration of hydroxide ion up to 2.00 *M*. (Sodium perchlorate could not be used due to the insufficient solubility of the complexes under investigation.) The final concentrations of the complexes varied from 3×10^{-5} *M* for the diiodo to 3×10^{-4} *M* for the dibromo complexes, with the lowest ratio of [OH^-] to [complex] throughout being 200 to 1, and therefore quite sufficient to ensure pseudo first order kinetics. At appropriate time intervals, aliquots were withdrawn and quenched in cold water and brought to room temperature. The reaction mixtures were analyzed immediately at suitable wavelengths for which the difference between the absorbance of the reactant and product was large.

Hydrogen–Deuterium Exchange Reactions

The reactions were done on the *trans*-[Rh(cyclam)Cl_2]$^+$ and *trans*-[Rh(cyclam)I_2]$^+$ complexes. (These two complexes were chosen because they represent the two extremes in rates, the former being the slowest and the latter the fastest in the base hydrolysis series studied.) An appropriate amount of the complex was dissolved in a solution of sodium hydroxide. The reaction mixture was heated at different times and temperatures, and the complex precipitated by addition of $NaClO_4$ and was analyzed by an infrared spectrum.

Results

Kinetics

The kinetic study of the base hydrolysis of the *trans*-[Rh(cyclam)X_2]$^+$ and *trans*-[Rh(cyclam)XY]$^+$ complexes was carried out spectrophotometrically. The reactions were studied over a temperature range of 25 to 85°C. Each complex was studied at three temperatures over 30°C to permit calculation of the activation parameters. Six different concentrations of hydroxide were employed. The reaction rate was followed for at least one half-life and usually for two or three half-lives. The rate of disappearance of the complex always followed the first order kinetic law. The pseudo first order rate constants for the reactions were determined graphically from the relationship:

$$k_{obsd} = \frac{2.30}{t} \log \frac{a}{a - x} = \frac{2.30}{t} \log \frac{A_0 - A_\infty}{A_t - A_\infty}$$

where t is the time in seconds, A_0 is the absorbance of the initial reading, A_t is the absorbance at time t, and A_∞ is the absorbance calculated from the known extinction coefficient of the product being formed. Isosbestic points were obtained in some systems in the wavelength range studied. Good first order rate plots were obtained throughout. Second order rate constants were calculated from the following expression:

$$k = \frac{k_{obsd}}{[OH^-]}$$

Excellent straight line plots of k_{obsd} vs. [OH^-] were obtained throughout over the range of [OH^-] used. No evidence of *trans*-to-*cis* isomerization was found in this study. This fact was found in the preparative work and the substitution and anation studies (6).

The activation parameters were calculated from the equation (7):

$$k = \frac{KT}{h} e^{\Delta S^\ddagger/R} e^{-\Delta H^\ddagger/RT}$$

where k is the second order rate constant at T(K), R is the gas constant, K is the Boltzmann constant, and h is the Planck constant.

The rate data were evaluated statistically using the methods of pooled variances (8). The kinetic results are given in Tables 1 and 2.

Hydrogen–Deuterium Exchange Reactions

The infrared spectra of the reaction products after the hydrogen–deuterium exchange reactions showed that the deuterium of the amine group in the complexes exchanged with hydrogen in hydroxide solution. All the four amine deuterium atoms contained in the complex could be interchanged with hydrogen. The extent of exchange depended on the concentration of the hydroxide, the temperature, and the time of the reaction. These hydrogen–deuterium exchanges were found to be faster than even the dissociative reaction step of the complex. But this was not the case in neutral and acidic solution, in which the hydrogen–deuterium exchanges were by comparison much less under the same conditions.

Discussion

The distinctive features of the base hydrolysis reactions of the cyclam complexes of Rh(III) in comparison with other substitution reactions (6*a*) are the fast rates, the large enthalpies of activation, and the large positive entropies of activation which are found

TABLE 2. Activation parameters for base hydrolysis of *trans*-[Rh(cyclam)XY]$^+$ complexes

Complex X	Complex Y	$\Delta H^\ddagger$ (kcal mol^{-1})	$\Delta S^\ddagger$ (cal deg^{-1} mol^{-1})	$10^5\,k_{55°C}$ ($M^{-1}\,s^{-1}$)
I	I	33.9±0.1	34.9±0.2	753±13
I	Br	30.8±0.2	23.2±0.4	256±4
I	Cl	29.2±0.3	17.0±0.5	121±4
Br	Br	35.4±0.2	31.5±0.4	13.8±0.4
Br	Cl	35.3±0.1	28.5±0.2	3.59±0.04
Cl	Cl	35.3±0.2	25.1±0.7	0.750±0.004

throughout the series of complexes studied. An unique feature is the high relative rate constants paralleled by high enthalpies of activation. This was a little unexpected, even though the relative rates are temperature dependent. Given a different range of temperatures the order of rate constants could be reversed.

The rate constants and activation parameters for the base hydrolysis reactions of the *trans*-[Rh(cyclam)XY]$^+$ complexes can be used to compare the kinetic *trans* effects (9) of the halogen ligands quantitatively, to classify the complexes as kinetically class (*a*) or (*b*) character (10), and to propose a reaction mechanism.

Kinetic trans *Effect*

A *trans* effect order can be found for the group *trans* to the leaving group. For the *trans*-[Rh(cyclam)XCl]$^+$ complexes with Cl^- as the leaving group, the rate constants are 121, 3.59, and 0.750 × 10^{-5} M^{-1} s^{-1} (in the ratio of 161:5:1) at 55°C for $X^- = I^-$, Br^-, and Cl^- respectively, and the values of $\Delta H^\ddagger$ are 29.2, 35.3, and 35.3 kcal mol^{-1} respectively. It is clear the *trans* effect in the *trans*-[Rh(cyclam)XCl]$^+$ complexes is $I^- > Br^- > Cl^-$, in terms of rate constants. On the $\Delta H^\ddagger$ basis, the *trans* effect is $I^- > Br^- = Cl^-$, I^- being 6.1 kcal mol^{-1} greater than Br^- and Cl^-, which are identical. With Br^- as the leaving group, with $X^- = I^-$ and Br^-, these rate constants are in the ratio of 19:1 and I^- has a $\Delta H^\ddagger$ value of 4.6 kcal mol^{-1} lower than Br^-. In other studies on octahedral complexes, on the basis of rate constants, Br^- has been found a better *trans* activator than Cl^- (10*b*).

*Kinetic Class (*a*) and (*b*) Character*

A systematic trend occurs in the case of releasing Y^- from the *trans*-[Rh(cyclam)IY]$^+$ complexes. At 55°C the rate constants for $Y^- = Cl^-$, Br^-, and I^- are 121, 256, and 753 × 10^{-5} M^{-1} s^{-1} (the ratio is 1:2:3), respectively. Based on rate constants, the complexes appear kinetically more labile as Y^- changes from Cl^- to Br^- and to I^-, and therefore of class (*a*). However, the values of $\Delta H^\ddagger$ are 29.2, 30.8, and 33.8 kcal mol^{-1} respectively and the complexes become kinetically more inert as Y^- changes from Cl^- to Br^- and to I^- by 1.6 and 3.1 kcal mol^{-1} differences which indicates class (*b*) behavior. Since the relative rate constant effect is dependent upon the temperature chosen for comparison, the $\Delta H^\ddagger$ is much more reliable. It can be concluded that the *trans*-[Rh(cyclam)IY]$^+$ complexes are kinetically of class (*b*). With $X^- = Br^-$ in the *trans* position, and Br^- and Cl^- the leaving groups Y^-, the same effect is observed: Br^- is released two times as quickly as Cl^-, but the $\Delta H^\ddagger$ of Br^- is greater than Cl^-, though only slightly (0.1 kcal mol^{-1}).

The kinetic class (*b*) character of the Rh(III) in the *trans*-[Rh(cyclam)IY]$^+$ complexes agrees with the substitution and anation results for the same complexes (6). Kinetic class (*b*) character of Rh(III) metal is common in some other Rh(III) systems, such as $[Rh(NH_3)_5X]^{2+}$ (11) and $[Rh(en_2)XY]^+$ (10*b*).

Mechanism

The mechanism of basis hydrolysis of octahedral complexes has been the subject of much discussion. Several different mechanisms have been proposed to explain the rapid base hydrolysis (12). It is normal for reactions whose rates depend on hydroxide catalysis to involve acid–base equilibria before reaction. The hydroxide ion produces an active intermediate which then reacts faster than the original substrate (13). Based on hydrogen–deuterium exchange evidence,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a conjugate base mechanism in which the hydroxide ion is involved initially in a rapid acid–base equilibrium as in this study, is consistent with Poon and Tobe's (14) base hydrolysis result of *trans*-[Co(D_4-cyclam)X_2]$^+$ (X^- = Cl^- and Br^-). Thus, the mechanism of base hydrolysis of these *trans*-[Rh(cyclam)XY]$^+$ complexes, following the S_N1CB mechanism as it is now widely accepted, can be outlined as follows:

[1] *trans*-[Rh(cyclam)XY]$^+$ + $OH^- \underset{\text{fast}}{\overset{K}{\rightleftharpoons}}$ *trans*-[Rh(cyclam-H)XY]^0 + H_2O

[2] *trans*-[Rh(cyclam-H)XY]^0 $\xrightarrow[\text{slow}]{k_{cb}}$ *trans*-[Rh(cyclam-H)X]$^+$ + Y^-

[3] *trans*-[Rh(cyclam-H)X]$^+$ + H_2O $\xrightarrow{\text{fast}}$ *trans*-[Rh(cyclam-H)X(H_2O)]$^+$

[4] *trans*-[Rh(cyclam-H)X(H_2O)]$^+$ $\xrightarrow{\text{fast}}$ *trans*-[Rh(cyclam)X(OH)]$^+$

The first step is the fast deprotonation of the amine group in the *trans*-[Rh(cyclam)XY]$^+$ to form its conjugate base. The second step is the rate-determining step of the dissociation of the leaving group. The third and the fourth steps are very fast processes. The water molecule bonds to the Rh(III) in the *trans*-[Rh(cyclam-H)X]$^+$ complex and the water proton rearranges to the amido group to form the hydroxo complex.

The normal mechanism for the base hydrolysis of octahedral ammine and amine complexes of Co(III) involves an S_N1CB mechanism in which the five coordinated intermediate takes on trigonal bipyramidal geometry. This is due to the observation that base hydrolysis is often accompanied by stereochemical change and that *cis* and *trans* isomers do not differ enormously in their reactivity. This can be understood if the main labilizing effect occurs in the transition state since, in a trigonal bipyramide, the symmetry distinction between ligands that were originally *trans* or *cis* to the leaving group is lost (5). Since stereochemical change is not observed in these Rh(III) complexes as was the case in Co(III), it suggests that any five-coordinated intermediate is square pyramide (15). The crystal field stabilization energy for the square pyramidal structure is greater in a low spin d^6 system than for the trigonal bipyramidal structure. Because of the greater crystal field strength of Rh(III) relative to Co(III), the greater loss in crystal field stabilization energy would make it easier to produce a square pyramidal structure in these Rh(III) systems.

TABLE 3. Second order rate constants, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, for the base hydrolysis of *trans*-dichloro(cyclam) complexes of Co(III), Cr(III), and Rh(III) in aqueous solution (various ionic strengths) at 25°C

Comparisons

The base hydrolysis data for the analogous cyclam complexes of Co(III) have been reported (14, 16). The base hydrolysis of these *trans* isomers studied in buffer solutions was a fast, two stage reaction. Campi *et al.* (17) have studied the base hydrolysis of *trans*- and *cis*-[Cr(cyclam)Cl_2]$^+$ complexes. They reported that a typical second order rate law was observed.

The only available data for comparison of the rates for base hydrolysis are the *trans*-dichloro(cyclam) complexes of Rh(III), Co(III), and Cr(III) and are given in Table 3. For the cyclam complexes of all three metals no steric change was observed in the course of reactions. This is not surprising as the increased rigidity of the cyclam chelate resists rearrangement in the transition state.

Based on the rates at 25°C, the sensitivity to base hydrolysis of the analogous cyclam complexes is in the order Co(III) > Cr(III) > Rh(III). The order of acidity is Cr(III) > Co(III) > Rh(III) for the amine complexes; it can be expected to be in the same order for cyclam. The electron affinity gives the order Co(III) > Rh(III) > Cr(III) and the crystal field activation energy decreases in the order Cr(III) > Co(III) > Rh(III) irrespective of the intermediate structures (18). Thus, the lowest rate for Rh(III) can be explained on the basis of a low acidity and a large crystal field activation energy, which counteracts a reasonable high electron affinity.

A greater reactivity of the cyclam complexes to hydroxide ion, compared with the tetraammine and bis(ethylenediamine) complexes of Rh(III) (2, 3), is found in this study. The tetraammine complexes have little effect on the rate of base hydrolysis. The base hydrolysis of the bis(ethylenediamine) complexes is found that the [OH^-]-dependent path leads to *trans* → *cis* isomerization and has an S_N1CB–S_N1IP mechanism. As Poon (19) concludes for the Co(III) complexes, the nephelauxetic effect is only one of

many factors, which can be explained satisfactorily in terms of the faster rate of the base hydrolysis of the cyclam complex than the analogous tetraammine and bis(ethylenediamine) complexes.

Received August 8, 1977

WILLIAM E. SANFORD, ROBERT K. BOYD, and JOHN A. RIPMEESTER. Can. J. Chem. **56**, 714 (1978).

Benzene and thiophene are known to form solid solutions over the entire composition range; the present work demonstrates the orientational freedom of thiophene molecules in solid solution with excess perdeuterobenzene, through measurements of spin–lattice relaxation times. In addition, the atom–atom approximation to intermolecular forces yielded a potential energy profile for in-plane rotation of a thiophene molecule, embedded in a benzene lattice, which is consistent with the experimental activation energy for the relaxation. The second moment of the absorption signal for thiophene in perdeuterobenzene at 80 K was determined to be 0.66 G^2, compared with a value of 0.42 G^2 computed as the intramolecular contribution only for in-plane rotation.

WILLIAM E. SANFORD, ROBERT K. BOYD et JOHN A. RIPMEESTER. Can. J. Chem. **56**, 714 (1978).

On sait que le benzène et le thiophène forment des solutions solides à toutes les compositions; dans le présent travail, on démontre la liberté d'orientation des molécules de thiophène dans une solution solide de perdeutérobenzène en excès en faisant appel à des mesures de temps de relaxation spin–réseau. De plus, l'approximation atome–atome des forces intermoléculaires conduit à un profil d'énergie potentielle pour la rotation dans le plan d'une molécule de thiophène, incluse dans un réseau de benzène, qui est en accord avec l'énergie d'activation expérimentale pour la relaxation. On a déterminé que le second moment du signal d'absorption pour le thiophène dans le perdeutérobenzène à 80 K est de 0.66 G^2 comparé avec une valeur de 0.42 G^2 calculée comme contribution intramoléculaire uniquement pour la rotation dans le plan.

It is well known that benzene and thiophene form a continuous series of solid solutions, over the entire composition range (1). In addition, it was shown by Anderson (2) using pulse nmr techniques that thiophene molecules, in solid solution with perdeuterobenzene, possess considerable rotational freedom over considerable ranges of both composition and temperature. More recently it was shown (3) that Anderson's original measurements of spin–lattice relaxation times (T_1), for pure crystalline thiophene, were suspect below 172 K; at this temperature, adiabatic calorimetry experiments (4) indicate a phase transition. Both the calorimetry (4) and the more recent (3) T_1 experiments suggest that thiophene may be readily supercooled through this transition, and that the earlier T_1 data (2) pertain to a metastable phase.

Accordingly, it was felt worthwhile to reinvestigate the motion of thiophene in solid solution with perdeuterobenzene. The thiophene was purified as described previously (3); measurements of T_1 for the protons in solid solution containing 10.1 mol% of thiophene in perdeuterobenzene were made at 60 MHz using a Bruker SXP variable frequency spectrometer. (This concentration was chosen as the lowest at which reasonable signal-to-noise ratios could be readily attained; this was done in order to approximate as closely as possible to the case where each thiophene molecule would have only benzene molecules as nearest neighbours.) The resulting T_1 values are shown as a function of temperature between 77 K and 160 K in Fig. 1. The results obtained below about 140 K are consistent with a rapid motion of the thiophene molecules; this motion is characterised by an activation energy of 4–5 kJ mol^{-1}. The decrease in T_1, observed at temperatures above about 140 K, is presumably due to the onset of appreciable motion of the benzene-d_6 molecules; by extrapolation from the work of Anderson (2), who also studied the motions of benzene in solid solution with perdeuterothiophene, it can be inferred that the motional behaviour of benzene molecules in our solid solution was little different from that in pure benzene. The

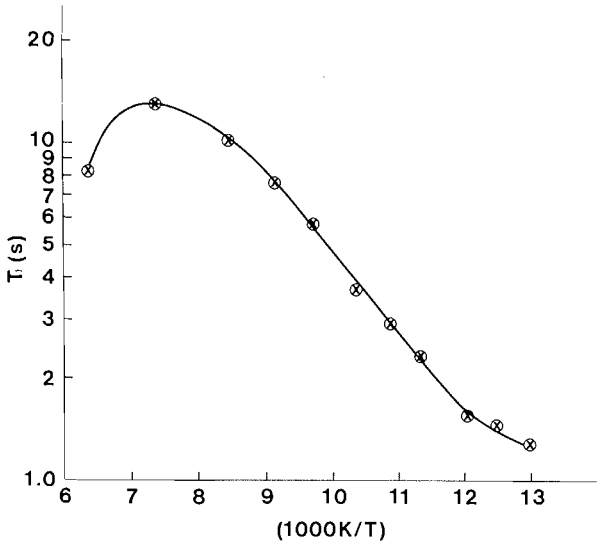

FIG. 1. Proton spin–lattice relaxation times (T_1), measured at 60 MHz, for thiophene in perdeuterobenzene; 10.1 mol% thiophene.

latter is well characterized (7), and seems consistent with the observed fall-off in T_1 at about 140 K. The mechanism could involve either ^1H–^2H (thiophene–benzene) cross-relaxation, or might be dominated by the residual protons in the sample of perdeuterobenzene. (In the solid solution used, assuming 99.5 at.% deuteration of benzene, the ratio of thiophene to benzene protons was 13:1.) No evidence of supercooling through phase transitions was detected in the present work.

For those planar aromatic molecules which display rapid spin–lattice relaxation in the solid state the molecular motion providing the mechanism for the relaxation is usually an in-plane jump between potential wells. Second-moment studies can yield useful information in this regard, and a value of 0.66 G^2 was presently obtained at 80 K for the second moment of the same solid solution as was used for the T_1 studies. This may be compared with values calculated, for the intramolecular contribution only, of 1.68 G^2 for a rigid thiophene molecule, and of 0.42 G^2 for a thiophene molecule undergoing in-plane reorientation between n potential wells, with $n > 3$. The temperature used for the experimental determination was such that the T_1 data (Fig. 1) predict that the second moment should have its high-temperature limiting value; the intermolecular contribution could not be calculated, since no crystal structure is available, so the agreement between the experimental value and the calculated value for fast motion, while reasonable and supportive of the proposed character of the motion, requires some additional evidence. Accordingly, calculations of the potential energy profile for in-plane rotation of a thiophene molecule substituted into a benzene crystal lattice, were undertaken; the general procedure, as applied to pure thiophene, was described previously (3). The present calculation considered a thiophene molecule at the origin of a unit cell, which in turn was centrally located in a 3 × 3 × 3 block of 27 unit cells of the benzene structure characterised (5) at 138 K. The thiophene molecule was substituted into this structure in such a way that the molecular plane coincided with that of the substituted benzene molecule; in addition, the centre of repulsion of the thiophene molecule was placed at the centre of symmetry of the benzene (also the crystallographic origin). The determination of this 'centre of repulsion' was described previously (3).

The computed profile thus obtained is shown in Fig. 2; the orientation corresponding to 0° rotation was arbitrarily chosen such that the sulfur atom of the thiophene molecule lay on a carbon–hydrogen vector of the substituted benzene molecule. The profile is again characterized by six potential wells, as found previously (3, 6) for pure thiophene, with energy barriers of about the correct size.

One final check was made; for one pair of nuclear spins, moving relative to one another in a plane, with a discrete number n of available sites ($n \geq 3$), T_1 may be computed by a formula due to Woessner (8):

$$(T_1)^{-1} = \left(\frac{9}{40}\right)\gamma^4\hbar^2 r^{-6} g(\omega_0, \tau_c)$$

At the minimum of the T_1 curve, $g(\omega_0, \tau_c) = (1.425/\omega_0)$; also, for more than two nuclei, the result may be obtained by summing over all pairwise interactions in the crystal:

$$(T_1)^{-1} = (1.425/\omega_0)\left[(9/40)(\gamma^4\hbar^2/N_A)\left(\sum_{i>j} r_{ij}^{-6}\right)\right]$$

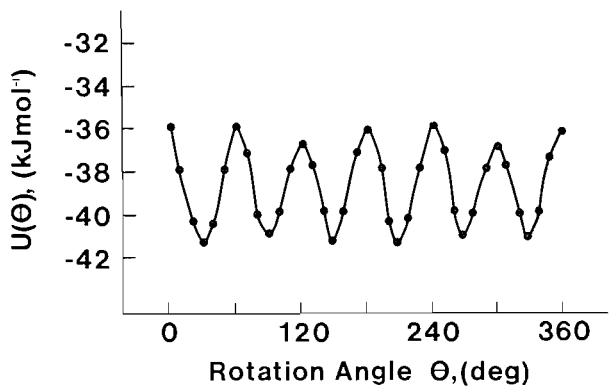

FIG. 2. Calculated potential energy profile for in-plane rotation of a thiophene molecule in a benzene lattice at 138 K.

If this is evaluated for thiophene, again including intramolecular contributions only (i.e. assuming all nearest neighbours to be perdeuterobenzene), $(T_1)_{min} = 0.44$ s at $\omega_0/2\pi = 60$ MHz; the experimental value is probably about 1 s from an extrapolation of Fig. 1. This agreement is reasonable; the discrepancy may be partly due to a distribution of correlation times τ_c, rather than a single unique value, in the sample used. For such a 10% solution, some thiophene molecules must have at least one other thiophene molecule as a nearest neighbour; this not only introduces an appreciable intermolecular contribution, but also affects τ_c.

The present work thus confirms the earlier conclusion of Anderson (2) concerning the motional freedom of thiophene in solid solutions with benzene. The question of why thiophene, a five-membered ring, should substitute for a hexagonal benzene molecule so readily, is closely related to the question discussed previously (3) as to why the potential energy profile for in-plane rotation of a thiophene molecule, in its own crystal structure, should display six rather than five potential wells. As pointed out previously (3), the general shape of such a profile is dominated by the interactions of the peripheral hydrogen atoms; the molecular geometry of thiophene is such that the four vectors, each of which is defined by the centre of repulsion and one of the four hydrogen atoms, make angles with one another all three of which are very close to 60°. Thus, rotation by 60° from an orientation corresponding to a potential energy minimum will result in three of the four hydrogen atoms occupying positions formerly occupied by hydrogen atoms prior to the rotation; this new orientation should therefore also correspond to a potential minimum though not necessarily of the same depth as the original.

WILLIAM A. AYER, LOIS M. BROWNE, JOHN R. MERCER, DAVID R. TAYLOR, and DALE E. WARD. Can. J. Chem. **56**, 717 (1978).

The isolation and structure determination of neoallocyathin A_4 (**10***a*) is described. Structures are proposed for cyathin A_4 (**11**) and cyathin C_5 (**15**). Methods for the transformation of cyathin A_3 into cyathin B_3, allocyathin B_3, and cyathin C_3 are reported. The isolation of glochidone (**22**) and ergosterol from the mycelium of *Cyathus helenae* is reported.

For personal use only.

In Part 1 of this series (2) we reported the isolation of six new diterpenoids (cyathin A_3, cyathin A_4, cyathin B_3, cyathin B_4, allocyathin A_4, and cyathin C_5) produced when the bird's nest fungus *Cyathus helenae* Brodie (strain Brodie 1500) is grown in liquid culture. The structures of two of these six, cyathin A_3 (**1**), and cyathin B_3 (**2**), and those of allocyathin B_3 (**3**) and cyathin C_3 (**4**), compounds which were not detected in our initial isolation, have previously been reported (3, 4). In this paper we wish to: (*i*) report the isolation and structure determination of another cyathin, neoallocyathin A_4; (*ii*) comment on the structures of cyathin A_4 and cyathin C_5; (*iii*) describe some interconversions of these compounds; (*iv*) report on the antibacterial and antifungal activity of some of the cyathins; (*v*) report the isolation of the triterpene glochidone as well as ergosterol from extracts of the mycelium of *C. helenae*.

Neoallocyathin A_4,[2] $C_{20}H_{30}O_4$, was first detected by mass spectrometry as an impurity present in some samples of cyathin A_3 (**1**) which had been purified (3) by silicic acid chromatography followed by preparative thin-layer chromatography (ptlc) over 10% silver nitrate – silica gel. The mass spectrum of these samples showed, in addition to the peaks for cyathin A_3 (mol. wt. 318), peaks at *m/e* 334 ($C_{20}H_{30}O_4$) and 319 ($C_{19}H_{27}O_4$). This material showed a single spot on tlc using several different solvent systems. Acetylation provided material which again could not be separated by chromatography but the mass spectrum of which showed a peak at *m/e* 418 in addition to the *O,O*-diacetylcyathin A_3 parent peak at *m/e* 402. Alternatively, treatment of the mixture with 2,2-dimethoxypropane under acid catalysis yielded a mixture of acetonides which was separable by ptlc into cyathin A_3 acetonide (**5**) and neoallocyathin A_4 acetonide, shown (*vide infra*) to possess structure **6**.

The ^{1}Hmr, ir, and uv spectra of neoallocyathin A_4 acetonide (see Experimental) are very similar to those of cyathin A_3 acetonide (**5**). Comparison of these spectra indicates the absence of hydroxyl or extra carbonyl functions in neoallocyathin A_4 acetonide and since the ^{1}Hmr spectrum does not show extra absorption associated with hydrogens geminal to oxygen, the 'extra' oxygen is present as a fully substituted ether. The absence of absorption in the δ 2.6–3.1 region of the ^{1}Hmr spectrum (in **5** the protons at C-2, C-5, and C-18 absorb in this region (2)) indicates that the C-3,C-4 double bond is not present. The fully substituted ether must thus be between C-3 and C-4, C-3 and C-5, or C-4 and C-5. Treatment of cyathin A_3 acetonide (**5**) with *one equivalent* of *m*-chloroperbenzoic acid in chloroform gave neoallocyathin A_4 acetonide (**6**) in quantitative yield, proving the presence of the C-3,C-4 oxide. The β-stereochemistry of the oxide depicted in **6** is assigned on the following basis: (*i*) examination of Drieding models indicates that the β-face of **5** is much less hindered than the α-face and, in the absence of proximate oxygen functions, peracid

oxidation usually occurs from the less hindered side (5); (*ii*) the chemical shift of the C-9 methyl protons in **6** (δ 1.24) is considerably downfield from the same methyl in **5** (δ 1.10). In the androstane series, the C-18 methyl is deshielded (δ 1.14) in the 14β,15β-oxide (**7**) and shielded (δ 0.87) in the 14α,15α-oxide (**8**) relative to androst-14-ene (**9**, δ 0.94) (6). Neoallocyathin A_4, isolated as its acetonide **6** but detected by mass spectrometry as $C_{20}H_{30}O_4$, is thus the epoxy diol **10***a*. Although **10***a* has not been isolated directly from the crude metabolites, a sample of neoallocyathin A_4 (**10***a*) has been obtained by peracid oxidation of *0,0*-diacetylcyathin A_3 (diacetyl derivative of **1**) followed by deacetylation (K_2CO_3–MeOH) of the resulting *O,O*-diacetylneoallocyathin A_4 (**10***b*).

In our earlier publication (2) we reported the isolation of two other $C_{20}H_{30}O_4$ compounds, cyathin A_4 and allocyathin A_4, of which cyathin A_4 was the more fully characterized. More recent liquid cultures of *C. helenae* Brodie (strain Brodie 1500) have failed to produce isolable amounts of these two metabolites. However, the data obtained earlier for cyathin A_4, when considered in the light of the structures since established for cyathins **1**–**4**, allow the assignment of structure **11** to cyathin A_4. Cyathin A_4 forms a triacetyl derivative **12** (2), a crystalline tri-*p*-bromobenzoate **13** (2), and an acetonide **14** (2) which on acetylation affords a monoacetyl derivative. The ^{1}Hmr spectra of the derivatives of cyathin A_4 are very similar to those of the corresponding cyathin A_3 derivatives with the exception that the signals for the isopropyl group in cyathin A_3 are replaced in cyathin A_4 derivatives by signals for the grouping $CH_3—\underset{|}{C}H—CH_2OR$. In *O,O,O*-triacetylcyathin A_4 (**12**) for example, this group appears as a doublet (J = 7 Hz) at δ 0.96 (CH_3 group), a multiplet centered at δ 3.08 (allylic methine), and an eight line signal centered at δ 3.90 for the diastereotopic methylene protons (J = 10.5 Hz) coupled (J = 7.5 Hz) to the methine proton. Simultaneous irradiation at δ 3.08 caused the methyl signal to collapse to a singlet and the methylene signal to collapse to a doublet of doublets (splitting 10.5 Hz). Since all other structural features appear to be the same as those in cyathin A_3 (**1**), cyathin A_4 is assigned structure **11**, with the stereochemistry at C-18 unspecified. Efforts to directly correlate cyathin A_4 with A_3, e.g., via the acetonide **14**, had to be abandoned when we were unable to obtain further quantities of cyathin A_4.

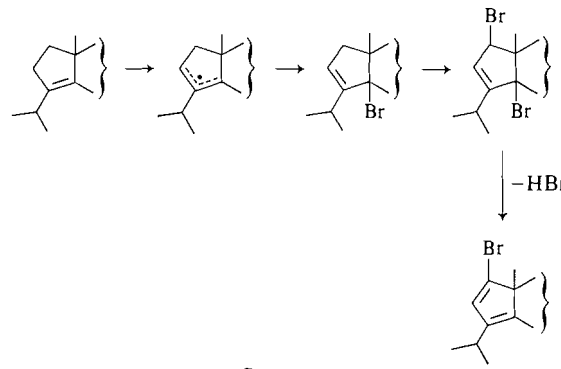
Cyathin C_5, another metabolite which has not been isolated from recent cultures of *C. helenae* but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which was well characterized (mp, ir, ^{1}Hmr, CHO analysis) in our initial paper (2), appears on the basis of its spectral characteristics to possess structure **15**. The α,β-unsaturated aldehyde system gives rise to singlets at δ 9.89 (C*H*O) and 7.27 (β-proton) in the ^{1}Hmr. The two *tertiary* methyls appear at δ 0.92 and 0.81, but the isopropyl group is not present. Instead a secondary methyl at δ 1.08 which is coupled to a quartet at δ 3.69 indicates the grouping CH_3—CH(COOH)— attached to a double bond. The presence of only two carbonyl peaks in the solid phase ir (1700 carboxylic acid, 1675 cm^{-1}, unsaturated aldehyde) indicates that cyathin C_5 crystallizes in the hemiacetal form and leads to the tentative assignment of structure **15**.

We have previously reported on the antimicrobial activity of the total crude metabolites of *C. helenae* (2). Further testing has revealed that the components which are mainly responsible for this activity are the α,β-unsaturated aldehydes cyathin B_3 and cyathin C_3.[3] Since cyathin A_3 (**1**) is the major component of the crude metabolites, it was desirable to develop methods for the transformation of cyathin A_3 (**1**) to cyathin B_3 (**2**) and to cyathin C_3 (**4**). In solution cyathin A_3 exists as a mixture of the hydroxyketone form **1** and the tautomeric internal hemiacetal **16**. Selective oxidation of the primary allylic alcohol at C-15 should be possible if the secondary allylic alcohol at C-11 is 'protected' as the hemiacetal **16**. Infrared spectra determined in $CHCl_3$ and CH_2Cl_2 indicate the presence of a considerable amount of the hydroxyketone tautomer **1** but spectra determined in ether showed essentially no carbonyl absorption. Whereas oxidation with manganese dioxide in the former solvents led to a mixture of products, oxidation of cyathin A_3 with activated manganese dioxide (7) *in ether* gave cyathin B_3 (**2**) as the only product in better than 80% yield.

The transformation of cyathin A_3 (**1**) into cyathin C_3 (**4**) involves the introduction of a double bond into ring A as well as oxidation of the primary alcohol to the corresponding aldehyde. Because of the sensitivity of the unsaturated aldehyde function to both oxidation and Michael-type additions (4) we chose first to form the cyclopentadiene system, then perform the oxidation, i.e. to proceed via allocyathin B_3 (**3**) rather than via cyathin B_3 (**2**). To protect the ring C functionality, the starting material



SCHEME 1

chosen was *O*-acetylcyathin A_3 methyl acetal (**17**) (3). Treatment of **17** with *N*-bromosuccinimide (1 equiv.) in refluxing carbon tetrachloride in the presence of a catalytic amount of benzoyl peroxide gave a mixture of two products along with recovered starting material in a ratio of ca. 1:1:1. The two products, which could be separated from starting material using $AgNO_3$ – silica gel, but which could not be separated from one another, proved to be a mixture of the desired **18** and its bromo derivative **19**. All attempts to stop the reaction at the monobromination stage were unsuccessful. However, treatment of **17** with just over 2 equiv. of *N*-bromosuccinimide led to the formation of the bromo compound **19**,[4] in good yield. The formation of the bromo diene, for which there is ample precedent (8), may involve double allylic bromination and elimination of HBr as illustrated in Scheme 1.

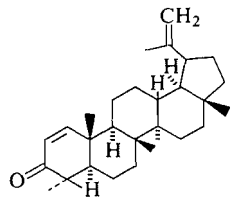
Treatment of **19** with an excess of the reagent prepared from $LiAlH(OCH_3)_3$ and CuI in THF (9) gave allocyathin B_3 methyl acetal (**20**) in 76% yield. Acid catalyzed hydrolysis of the methyl acetal **20** gave allocyathin B_3 (**3**). Oxidation of **20** with MnO_2 in ether gave cyathin C_3 methyl acetal (**21**) which on hydrolysis afforded cyathin C_3 (**4**). Cyathin C_3 (**4**) was also obtained by MnO_2 oxidation of allocyathin B_3 (**3**).

The cyathins are isolated by extraction of the culture broth of *C. helenae* after removal of the mycelium by filtration. Soxhlet extraction of the mycelium with ethyl acetate does not yield detectable amounts of cyathins but does give after chromatography a small amount of ergosterol along with larger quantities of a triterpenoid $C_{30}H_{46}O$, mp 158–160.5°C, identified from its melting point and

[3]Details of the in vitro antimicrobial activity of these compounds, determined by the Smith, Kline, French Laboratories, Philadelphia, are submitted as Appendix 1, which is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Council of Canada, Ottawa, Ont., Canada K1A 0S2. Recent results show that the activity of these compounds is not retained in vivo.

[4]Our preference for the location of the bromine at C-1 rather than at C-2 is based on ^{13}Cmr studies which reveal that the carbon carrying the bromine resonates at δ 134.5. Chemical shift assignments for the ^{13}Cmr spectra of the various cyathins and derivatives have been made and will be detailed in a separate paper. The assignment of the position of the bromine (C-1 or C-2) is not crucial for present purposes.

spectral characteristics as glochidone, **22** (10). Identity was confirmed by comparison with an authentic sample.[5]



22

Experimental

Mass spectra were recorded on an A.E.I. model MS-50, MS-9, or MS-12 mass spectrometer and are reported as *m/e* (relative intensity). Unless diagnostically significant only peaks at least 20% as intense as the base peak are reported. Infrared spectra were recorded on a Unicam SP1000 or Perkin-Elmer model 421 dual grating spectrophotometer, uv spectra on a Cary model 14M spectrophotometer, cd spectra on a Jasco model SS-20-2 spectropolarimeter, and optical rotations on a Perkin-Elmer Model 141 automatic polarimeter. Proton magnetic resonance spectra were measured using a Varian HA-100 spectrometer with tetramethylsilane as internal standard. Melting points were recorded on a Fisher-Johns melting point apparatus and are uncorrected.

Silica gel tlc plates were 0.5 mm silica gel G (E. Merck, Darmstadt) containing 1% electronic phosphor (General Electric, Cleveland); materials were detected by spraying with 30% sulfuric acid and charring. All solvents were reagent grade and were distilled before use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Isolation of Neoallocyathin A_4 Acetonide

The crude metabolites (1.01 g) of *C. helenae*, isolated as previously described (2), were chromatographed over silicic acid (Mallinckrodt, 100 mesh, 68 g) using 1.5% CH_3OH in $CHCl_3$ as eluant. Eighteen 125 ml fractions were collected. Fractions 9, 10, and 11 all showed peaks at *m/e* 334 in the mass spectrum and were combined (215 mg) and subjected to ptlc (20 × 100 cm plate, 0.5 mm layer of silica gel G (E. Merck) containing 5% added inorganic phosphor) using acetone – Skellysolve B (7:3) as the solvent system. The band centered at R_f 0.66 was removed and eluted with ether to give a clear oil (57 mg). This latter material was again subjected to ptlc (20 × 20 cm plate, 0.5 mm silica gel G impregnated with 10% $AgNO_3$) using acetone – Skellysolve B (7:3). After drying, the plate was sprayed lightly with 2′,7′-dichlorofluorescein and observed under long wave uv light. Two bands were observed, one at R_f 0.59 and one at R_f 0.50. The band at R_f 0.59 gave a clear oil (15 mg) when eluted with ether. Mass spectrometry of this fraction indicated a mixture of compounds $C_{20}H_{30}O_4$ and $C_{20}H_{30}O_3$. The material at R_f 0.50 (18 mg) was shown (ir, ms) to be allocyathin B_3 (**3**). The material of R_f 0.59 was dissolved in 2,2-dimethoxypropane (2 ml) and *p*-toluenesulfonic acid (~1 mg) added. After standing 30 min at room temperature the solution was concentrated and then applied to a ptlc plate (silica gel G) which was developed with benzene – acetone – acetic acid (75:25:1). The major fraction (R_f 0.57, 9 mg) was subjected to further ptlc (silica gel G) using Skellysolve B – acetone (4:1) as developing solvent. Bands were observed at R_f 0.59 and 0.49. Elution of the band at higher R_f gave cyathin A_3 acetonide (**5**, 5 mg) and elution of the lower R_f material gave neoallocyathin A_4 acetonide (**6**, 3 mg), mp 144.5–146°C (from ether–pentane). Mass spectrum: *m/e* 374 (45, M^+), 359 (11), 189 (26), 149 (21), 79 (25), 61 (30), 43 (100); cd (*C* 0.001 *M*, CH_3OH) $\Delta\varepsilon_{300}$ −0.18, $\Delta\varepsilon_{270}$ −0.23; ir ($CHCl_3$): 1685 (sh), 1635 (s); ^{1}Hmr ($CDCl_3$) δ: 1.03 (s, 3H, C-16 CH_3), 1.08 (apparent t, 6H, isopropyl CH_3's), 1.24 (s, 3H, C-17 CH_3), 1.40, 1.50 (each 3H singlets, acetonide methyls), 4.15–4.35 (m, 3H, C-15 and C-11 H's), 7.25 (bs, 1H, C-13 H); uv (CH_3OH) λ_{max} (ε): 232 (12 000), 322 (100). *Exact mass* calcd. for $C_{23}H_{34}O_4$: 374.2457; found: 374.2452.

Cyathin A_3 Acetonide (5)

Cyathin A_3 (**1**, 18 mg) was dissolved in 2,2-dimethoxypropane (5 ml) and a small crystal of *p*-toluenesulfonic acid added. The reaction was complete in 15 min as judged by tlc. The solvent was reduced in volume (ca. 0.5 ml) and the reaction mixture was applied directly to a 20 × 20 cm silica gel tlc plate and developed with Skellysolve B – acetone (7:3), R_f 0.51. Elution gave cyathin A_3 acetonide (**5**, 14 mg) as a crystalline solid. Mass spectrum: *m/e* 358 (100, M^+), 343 (49), 315 (25), 300 (22), 285 (88), 257 (52), 203 (40), 189 (37), 149 (30), 123 (32), 121 (31), 119 (31), 107 (30), 105 (37), 96 (50), 91 (31), 55 (45); ir ($CHCl_3$): 1660 (α,β-unsaturated ketone): ^{1}Hmr ($CDCl_3$): δ 0.98 and 1.01 (each 3H doublets, isopropyl methyls), 1.04 (s, 3H), 1.09 (s, 3H), 1.38 and 1.45 (each 3H's, acetonide methyls), 2.90 (septet, 1H, C-18 H), 4.30 (m, 2H, C-15 H's), 5.69 (bs, 1H, C-11 H).

Neoallocyathin A_4 Acetonide from Cyathin A_3 Acetonide

Cyathin A_3 acetonide (**5**, 13.5 mg) was dissolved in $CHCl_3$ (5 ml) and a solution of *m*-chlorobenzoic acid (6.5 mg) in $CHCl_3$ (6.5 ml) was added. The solution was stirred at room temperature for 5 min, then the $CHCl_3$ solution was washed with aqueous $NaHCO_3$, H_2O, and brine. Evaporation of the solvent gave a clear oil (13.6 mg) which was crystallized from ether–pentane to give colorless crystals (8 mg), mp 144.5–146°C, identical (ir, ^{1}Hmr, tlc) with neoallocyathin A_4 acetonide described above.

O,O-*Diacetylneoallocyathin A_4 (10b)*

O,O-Diacetylcyathin A_3 (3) (100 mg) in CH_2Cl_2 (5 ml) was treated with *m*-chloroperbenzoic acid (55 mg) at room temperature for 30 min, then the solution was washed (aqueous $NaHCO_3$, H_2O) and evaporated to give *O,O*-diacetylneoallocyathin A_4 (**10***b*) as an oil (93 mg); ir (neat): 1748, 1660 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.05 (s, 3H, C-16 CH_3), 1.06 (d, 3H, J = 7 Hz), and 1.07 (d, 3H, J = 7 Hz, isopropyl methyls), 1.28 (s, 3H, C-17 CH_3), 2.02 and 2.11 (acetyl methyls), 4.65 (m, 2H, C-15 H's), 5.39 (m, 1H, C-11 H), 6.13 (bs, 1H, C-13 H). *Exact mass* calcd. for $C_{24}H_{34}O_6$: 418.2355; found: 418.2355.

Neoallocyathin A_4 (10a)

O,O-Diacetylneoallocyathin A_4 (40 mg) was dissolved in CH_3OH (4 ml) and K_2CO_3 (20 mg) was added. After 30 min tlc indicated that the reaction was complete. The mixture was diluted with H_2O and extracted with $CHCl_3$ to give neoallocyathin A_4 (**10***a*) as an oil; ir (neat): 3400 br, 1642 br; ^{1}Hmr ($CDCl_3$) δ: 1.01 (s, 3H, C-16 CH_3), 1.06 (d, 3H, J = 7 Hz) and 1.10 (d, 3H, J = 7 Hz, isopropyl methyls), 1.24 (s, 3H, C-17 CH_3), 4.0–4.5 (m, 3H, C-11 and C-15 H's), 6.03 (bs, 1H, C-13 H). *Exact mass* calcd. for $C_{20}H_{30}O_4$: 334.2144; found: 334.2138.

Cyathin A_4 (11) and Cyathin C_5 (15)

These compounds and their derivatives have been described earlier (2). To further characterize cyathin A_4, the infrared

spectrum of the tribromobenzoate, and the ^{1}Hmr spectrum of the triacetyl derivative are submitted as Appendix 2. The infrared spectrum of cyathin C_5 is also included in Appendix 2. These spectra are available from the Depository of Unpublished Data.[6]

Cyathin B_3 (2) from Cyathin A_3 (1 ⇄ 16)

Cyathin A_3 (103 mg) was dissolved in ether (40 ml) and activated (7) manganese dioxide (750 mg) was added. The mixture was stirred at room temperature for 2 h, then filtered and the filtrate evaporated to yield a colorless oil (80 mg) which solidified on standing. The product was identified as cyathin B_3 by comparison (ir, ms, tlc) with an authentic sample.

O-Acetyl-1-bromoallocyathin B_3 Methyl Acetal (19)

O-Acetylcyathin A_3 methyl acetal (**17**, 75 mg) was dissolved in CCl_4 (8 ml) and *N*-bromosuccinimide (75 mg) and a trace of benzoyl peroxide (~1 mg) was added. The mixture was stirred under reflux for 3 h, then filtered, evaporated, and the residue subjected to ptlc (silica gel, Skellysolve B – acetone (3:1)) to give **19** (75 mg) as an oil which was used in the next step without further purification; ^{1}Hmr ($CDCl_3$) δ: 0.82 (s, 3H) and 0.97 (s, 3H) (C-16 and C-17 methyls), 1.04 (d, J = 7 Hz, 3H) and 1.10 (d, J = 7 Hz, 3H) isopropyl methyls, 2.09 (s, 3H, acetyl methyl), 3.21 (s, 3H, ketal methyl), 4.77 (m, 3H, C-11 and C-15 H's), 6.14 (m, 1H, C-13 H), 6.35 (s, 1H, C-2 H). *Exact mass* calcd. for $C_{23}H_{31}O_4{}^{79}Br$: 450.1405; found: 450.1399; calcd. for $C_{23}H_{31}O_4{}^{81}Br$: 452.1385; found: 452.1389.

Allocyathin B_3 Methyl Acetal 20 from 19

Lithium trimethoxyaluminum hydride (3 ml, 1.04 *M*) in tetrahydrofuran (THF) was added dropwise to cuprous iodide (290 mg) in THF (0.6 ml) at 0°C under nitrogen. After a few drops had been added, the mixture became yellowish-brown and viscous. Further THF (~0.5 ml) was added to allow efficient stirring. This process was repeated until all of the $Li(OCH_3)_3AlH$ solution had been added. The mixture was then stirred at 0°C for 15 min to give a dark brown solution. The bromodiene **19** (80 mg) in THF (0.5 ml) was added. After stirring for 5 min at 0°C the solution was allowed to warm to room temperature and was stirred for 8 h, then CH_3OH (1 ml) was added dropwise, followed by H_2O (0.1 ml). The solution was diluted with ether, filtered through Celite, and washed successively with saturated NH_4Cl solution and brine. Drying ($MgSO_4$) and evaporation of the solvents left an oil which was purified by ptlc (silica gel, Skellysolve B – acetone (3:1)) to give allocyathin B_3 methyl acetal (**20**, 45 mg), identical (tlc, ir, ms) with an authentic sample.

Cyathin C_3 Methyl Acetal (21) from (20)

Allocyathin B_3 methyl acetal (**20**, 20 mg) in ether (2 ml) was stirred with activated manganese dioxide (100 mg) at room temperature for 30 h. Filtration and evaporation of solvent gave cyathin C_3 methyl ketal (**21**, 18 mg), identical with an authentic sample.

Allocyathin B_3 (3) from 20

The ketal **20** (40 mg) was dissolved in THF (4 ml) and 1 *N* aqueous perchloric acid (0.5 ml) was added and the solution was stirred at room temperature for 5 days after which time tlc showed only the desired **3**. The solution was diluted with saturated aqueous $NaHCO_3$ and extracted with $CHCl_3$. Evaporation of the solvent gave allocyathin B_3 (**3**, 32 mg) as an oil, identical (tlc, ir, ms) with authentic material. Oxidation of **3** with MnO_2–ether as described above yielded cyathin C_3 (**4**).

Isolation of Glochidone and Ergosterol

The mycelium from 6 ℓ of culture broth, grown as previously described (2), was placed in a Soxhlet thimble and extracted for 3 days with ethyl acetate. The ethyl acetate extract was washed with water, dried ($MgSO_4$), and concentrated to give a brown oil (6.6 g). A portion (2 g) of the crude extract was chromatographed over silica gel (Woelm, < 0.063 mm). Elution with CH_2Cl_2 (1 ℓ) gave glochidone (**22**, 1.0 g), mp 158–160.5°C, (lit. (10*a*) mp 164°C), identical (mmp, tlc, ir) with an authentic sample. Further elution with methylene chloride (1 ℓ) gave ergosterol (0.03 g), identical (tlc, ir), with an authentic sample.

Received October 17, 1977

PATRICE C. BÉLANGER. Can. J. Chem. **56**, 722 (1978).

The preparation of two acidic metabolites of timolol, 2-[4-(4-morpholinyl)-1,2,5-thiadiazol-3-yloxy]acetic acid and *d,l*-3-[4-(4-morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactic acid is reported using 3-chloro-4-(4-morpholinyl)-1,2,5-thiadiazol as starting material.

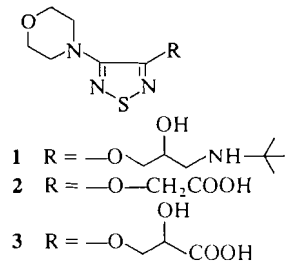
PATRICE C. BÉLANGER. Can. J. Chem. **56**, 722 (1978).

La préparation de deux métabolites acides de timolol, l'acide [(morpholinyl-4)-4-thiadiazol-1,2,5-yl-3-oxy]-2-acétique et l'acide *d,l*-[(morpholinyl-4)-4-thiadiazol-1,2,5-yl-3-oxy]-3-lactique y est rapporté en employant comme produit de départ le chloro-3-(morpholinyl-4)-4-thiadiazole-1,2,5.

Introduction

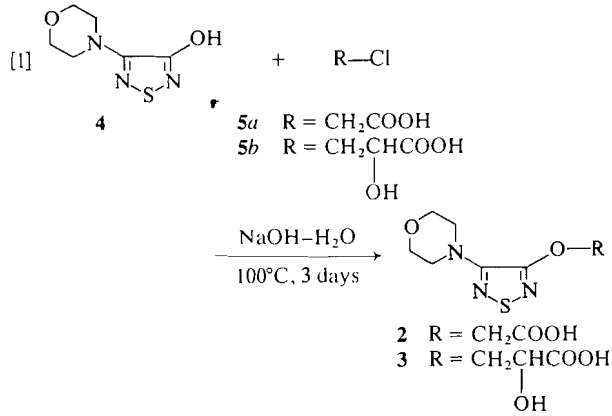
Timolol **1**, (*S*)-1[(1,1-dimethylethyl)amino]-3-{[4-(4-morpholinyl)-1,2,5-thiadiazol-3-yl]oxy}-2-propanol is a β-adrenergic blocking agent (1, 2) with antihypertensive (3) and antianginal properties (4). It is rapidly absorbed, metabolized, and excreted in man, rats, and dogs (5). The two most important sites of metabolic attack are the amine side chain and the morpholinyl group, respectively. Degradation of the (1,1-dimethylethyl)amino-2-hydroxypropoxy chain leads to the acidic metabolites **2** and **3**. Structural assignment for the metabolites was based primarily on mass spectral evidence (5) and on electrophoresis.

In this paper, syntheses of the two acidic metabolites formed by the degradation of the amine side chain, 2-[4-(4-morpholinyl)-1,2,5-thiadiazol-3-yloxy]-acetic acid **2** and 3-[(4-morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactic acid **3** are reported. The latter, while presumably an optically active metabolite, was prepared as the racemate.



Results and Discussion

Initially for the preparation of **2** and **3**, condensation of the anion of 3-hydroxy-4-(4-morpholinyl)-1,2,5-thiadiazole **4** with either chloroacetic **5***a* or β-chlorolactic acid **5***b* was attempted, using procedures previously reported for substituted phenols (6) or for metabolites of propanolol (7). The best conditions were found to be heating equimolar amounts of **4** with the corresponding halo acid **5** and 2 equiv. of aqueous sodium hydroxide for several days. Reaction (as monitored by disappearance of starting material **4**) was slow and extensive decomposition occurred. Yields of the corresponding acidic metabolites **2** and **3** were only 2 and 4%, respectively.



The low yields are probably explicable based on the reduced reactivity of the chloro substituted carboxylic acids in the anion form and on the tautomeric nature of the 4-(4-morpholinyl)-1,2,5-thiadiazol-3(2*H*)one which permits alkylation to occur on either the oxygen or the nitrogen atom. Other examples of low yields on alkylation of a hydroxy-1,2,5-thiadiazole are known.[1]

In an alternative approach, treatment of 3-chloro-4-(4-morpholinyl)-1,2,5-thiadiazole **6** with 2,2-dimethyl-1,3-dioxolane-4-methanol in DMF with potassium *tert*-butoxide as base at 110°C for 6 h led to good yields of **7**. Hydrolysis of the resulting acetonide **7** in dilute hydrochloric acid gave crystalline diol **8** in nearly quantitative yield. Cleavage of the diol **8** to the aldehyde **9** was achieved with lead tetraacetate in benzene at room temperature (8) in nearly quantitative yield. Sodium metaperiodate was

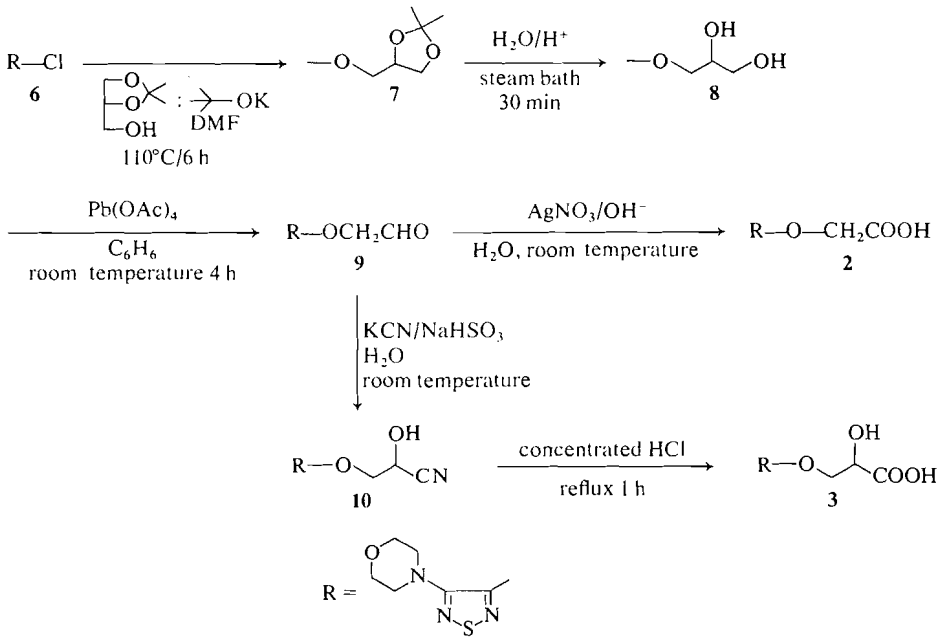

SCHEME I

also effective for the cleavage but the yields were much lower and less reproducible. The conversion of **9** to metabolite **2** occurred smoothly in 47% yield by silver oxide oxidation (9). Transformation of **9** to the racemic metabolite **3** was done through the cyanohydrin reaction followed by hydrochloric acid hydrolysis. These reactions are summarized in Scheme I; the mass spectra of synthetic **2** and **3** and the electrophoretic behavior were identical with those of metabolites **2** and **3**.

The synthetic compounds **2** and **3** were found to be inactive as β-adrenergic blocking agents or antihypertensive agents.

Experimental

Melting points were taken on a Thomas Hoover apparatus and are uncorrected. Infrared spectra were determined on a Perkin-Elmer 257 grating spectrophotometer. A Varian EM-360 instrument was used to record nmr spectra in deuteriochloroform using tetramethylsilane as an internal standard. Elemental analyses were performed by Dr. C. Daesslé. The low resolution mass spectral analyses were performed on a AEI MS 902 mass spectrometer and on an LKB 900 gc–ms spectrometer.

All reactions as well as column chromatography were monitored by tlc using precoated 0.25 mm silica gel plates (Eastman Kodak) with visualization of spots either by uv or by exposure to iodine vapors.

2-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]acetic Acid (2)

3-Hydroxy-4-(4-morpholinyl)-1,2,5-thiadiazole **4** (6.2 g, 33 mmol) and chloroacetic acid (3.2 g, 34 mmol) in 40 ml 1 *N* sodium hydroxide were heated for 3 days on a steam bath. The reaction mixture was acidified and unreacted **4** (1.7 g), mp 190°C, was recovered. On evaporation of the filtrate to half volume, crude **2** was obtained which on recrystallization from water afforded 70 mg, mp 174–176°C, homogeneous by tlc, R_f: 0.6 (chloroform–methanol–ammonia 8:4:0.5 by volume); ir: COOH 1765 cm^{-1}; ^1H nmr δ: 4.95 (2, s, CH_2CO), 3.68 (4H, m, CH_2—N—CH_2), 3.80 (4H, m, CH_2—O—CH_2); ms: M^+ 245. *Anal.* calcd. for $C_8H_{11}N_3O_4S$: C 39.18, H 4.52, N 17.14, S 13.07; found: C 39.27, H 4.74, N 17.01, S 12.93.

d,l-*3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactic Acid (3)*

Similarly, the reaction of **4** with β-chlorolactic acid led to 3.0 g of unreacted **4** and to a residue after evaporation of the filtrate to dryness. This residue was dissolved in ethanolic HCl and refluxed 3 h. On evaporation to dryness, 2.4 g of an oil was obtained and tlc analysis showed it to be a mixture of seven components. Silica gel chromatography with chloroform elution was performed, taking fractions of 10 ml. The desired ester was found to be between tubes 41 and 61. These fractions were combined and 342 mg of an oil was obtained. This ester was hydrolysed with sodium hydroxide in methanol. The residue after evaporation was acidified with aqueous HCl and the mixture extracted several times with chloroform to yield 196 mg of **3**, mp 134–135°C after crystallization from chloroform–hexane (1:5 v/v); tlc, R_f: 0.5 (chloroform–methanol–ammonia 8:4:0.5 by volume); ir: COOH, 1732 cm^{-1}; ^1H nmr δ: 3.52 (4H, m, CH_2NCH_2), 3.72 (4H, m, CH_2OCH_2), 4.60 (3H, m, CHO and CH_2O); ms: M^+ 275. *Anal.* calcd. for $C_9H_{13}N_3O_5S$: C 39.27, H 4.76, N 15.26, S 11.65; found: C 39.63, H 5.01, N 15.13, S 11.91.

4-[4-(2,2-Dimethyl-1,3-dioxolan-4-yl)methoxy]-3-(4-morpholinyl)-1,2,5-thiadiazole (7)

3-Chloro-4-(4-morpholinyl)-1,2,5-thiadiazole (10) (41 g, 0.21 mol), 2,2-dimethyl-1,3-dioxolan-4-ylmethanol (11) (28 g, 0.21 mol), and potassium *tert*-butoxide (30 g, 0.26 mol) in 200 ml dimethyl formamide were heated in an oil bath at 110°C for 6 h. The mixture was poured into water (1000 ml) and extracted twice with ethyl acetate (2 × 1000 ml). The extract after washing with water, drying over magnesium sulfate was concentrated under vacuum to give 39.6 g (66%) of **7** as an oil

that distilled at 165–170°C/1 Torr; tlc, R_f: 0.7 (ethyl acetate); ^{1}H nmr δ: 1.37 and 1.43 (6H, s, CH_3), 3.60 (4H, m, CH_2NCH_2), 3.72 (4H, m, CH_2OCH_2), 4.50 (5H, m, CH_2O, CHO); ms: M^+ 301. *Anal.* calcd. for $C_{12}H_{19}N_3O_4S$: C 47.83, H 6.37, N 13.94, S 10.64; found: C 47.41, H 6.67, N 14.08, S 10.54.

3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]-1,2-propanediol (8)

4-[4-(2,2-Dimethyl-1,3-dioxolan-4-yl)methoxy]-3-(4-morpholinyl)-1,2,5-thiadiazole (**7**) (37.3 g, 0.125 mol), water (100 ml), and concentrated hydrochloric acid (3 ml) were heated on a steam bath for 30 min until a one-phase system was obtained. The water was removed under vacuum and the yellow solid residue after trituration in 200 ml benzene gave compound **8** (31.1 g, 95.6%), mp 95–96°C; tlc, R_f: 0.2 (ethyl acetate); ir:—OH, 3380 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 3.50 (4H, m, CH_2NCH_2), 3.70 (4H, m, CH_2OCH_2), 4.40 (5H, m, CHO— and CH_2O—); ms: M^+ 261. *Anal.* calcd. for $C_9H_{15}N_3O_4S$: C 41.37, H 5.79, N 16.08, S 12.27; found: C 41.19, H 5.95, N 15.99, S 12.02.

2-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]acetaldehyde (9)

3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]-1,2-propanediol (**8**) (8.7 g, 33 mmol) and lead tetraacetate (15.5 g, 35 mmol) in 200 ml benzene were stirred at room temperature for 4 h. The solids were filtered and the filtrate washed with water, dried over magnesium sulfate, and concentrated under vacuum to yield 7.5 g of **9** as a yellow oil, homogeneous by tlc, R_f: 0.2 (ethyl acetate); ir: C=O, 1735 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.57 (4H, m, CH_2NCH_2), 3.75 (4H, m, CH_2OCH_2), 5.00 (2H, s, CH_2O), 9.80 (1H, s, CHO); ms: M^+ 229. *Anal.* calcd. for $C_{14}H_{15}N_7O_6S$: C 41.08, H 3.69, N 23.95, S 7.83; found: C 40.88, H 3.90, N 23.84, S 7.63.

2-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]acetic Acid (2)

2-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]acetaldehyde **9** (6.7 g, 29 mmol) was suspended in 100 ml water and freshly made silver oxide, prepared from 25 g silver nitrate and 100 ml 2 *N* sodium hydroxide, was added. After stirring for 20 min, the solids were removed by filtration and the filtrate evaporated to 75 ml. Following refiltration and acidification with 6 *N* HCl, compound **4** was obtained, which after washing with water and air drying, weighed 3.2 g (47%), mp 180–181°C.

(D,L)-*3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactonitrile (10)*

2-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]-acetaldehyde **9** (7.9 g, 34.5 mmol) was suspended in 100 ml water. Potassium cyanide (3 g, 45 mmol) was added, followed by sodium bisulfite (5 g, 48 mmol). After stirring 10 min at room temperature, a solid precipitated, which was filtered, washed with cold water, and air dried. 3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactonitrile **12**, (5.7 g, 65%), mp 70–71°C, was obtained. This was probably a hydrate as a dried sample melted at 101°C; tlc, R_f: 0.5 (ethyl acetate – benzene 1:1); ir: OH, 3190 cm^{-1}, CN not detected; ^{1}H nmr ($CDCl_3$) δ: 3.50 (4H, m, CH_2NCH_2), 3.82 (4H, m, CH_2OCH_2), 4.60 (2H, m, CH_2O), 4.85 (1H, m, CHO); ms: M^+ 256, base peak 229 (loss of HCN). *Anal.* calcd. for $C_9H_{12}N_4O_3S$: C 42.18, H 4.72, N 21.86, S 12.51; found: C 42.11, H 5.04, N 22.32, S 12.89.

(D,L)-*3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactic Acid (3)*

(D,L)-3-[4-(4-Morpholinyl)-1,2,5-thiadiazol-3-yloxy]lactonitrile **12** (4.1 g, 16 mmol) in concentrated hydrochloric acid (25 ml) was refluxed for a period of 1 h. The solution was poured into water (50 ml) and extracted twice with ethyl acetate (75 ml). The ethyl acetate extract was washed with water, dried over magnesium sulfate, and concentrated under vacuum to yield an oil that crystallized when triturated in petroleum ether. On filtration compound **3** was obtained (2.7 g, 61%), mp 137–138°C.

IAN W. J. STILL, NICK PLAVAC, DAVID M. MCKINNON, and MOHINDER S. CHAUHAN. Can. J. Chem. **56**, 725 (1978).

^{13}C nmr chemical shifts have been recorded for a number of uracil, thiouracil, and pyrimidine derivatives. These data are discussed in relation to what is known of the lactam–lactim tautomerism in such systems and possible correlations of chemical shifts with normal aromatic substituent chemical shift parameters. The chemical shifts for the CH_3 groups in simple methylated derivatives of uracil are very characteristic of the site of methylation and should prove useful as a tool for assigning structures to alkylated derivatives of this general type.

IAN W. J. STILL, NICK PLAVAC, DAVID M. MCKINNON et MOHINDER S. CHAUHAN. Can. J. Chem. **56**, 725 (1978).

On a enregistré les déplacements chimiques en rmn ^{13}C d'un certain nombre de dérivés de l'uracile, du thiouracile et de la pyrimidine. On discute de ces données par rapport à ce qui est connu pour le tautomérisme lactame–lactime dans de tels systèmes et pour des corrélations possibles de déplacements chimiques avec les paramètres de déplacements chimiques normaux pour des substituants aromatiques. Les déplacements chimiques des groupes CH_3 dans des dérivés méthylés simples de l'uracile sont très caractéristiques du site de méthylation et devraient s'avérer utiles dans l'attribution de structures pour des dérivés alkylés de ce type général.
[Traduit par le journal]

Introduction

As part of our continuing investigation of the ^{13}C nmr spectra of heterocyclic systems with sulfur-containing functional groups (1–4), we wish to report a study of the ^{13}C chemical shifts in a number of methylated derivatives of uracil, 2- and 4-thiouracil, and 2,4-dithiouracil. In the interests of clarity, we have categorized these compounds as uracils (*N*-methyl), pyrimidines (*O*- or *S*-methyl), or dihydropyrimidinones (methyl derivatives with only *one* formal C=O or C=S group).

Since the early pioneering work of Lauterbur (5) there have been a number of investigations of the ^{13}C nmr spectra of both pyrimidines (6–8) and uracils (9–11), as well as related ^{13}C nmr studies on both pyrimidine (12, 13) and purine nucleosides (14). In our work, in addition to a study of the effects of methyl substitution at various sites in the uracil **1** structure on ^{13}C chemical shifts, we have attempted to show the utility of these effects for structural assignment purposes. As earlier workers had already noted in the purine series (14), we have observed little difference between the chemical shifts for the ring carbon atoms (with the notable exception of C-6) in the *N*(1)-methyl-substituted uracils, compared to the analogously substituted nucleoside derivatives, and hence our conclusions are likely to be valid for any similar series of alkyl-substituted uracils or uridines.

There has been widespread interest in recent years in the tautomeric stuctures of uracil and the thiouracils (15) and other biological pyrimidines and the subject has been comprehensively reviewed recently (16, 17). The structures of the major tautomeric forms are now well established by a variety of physical methods. We believe that additional evidence in support of the tautomeric structures of uracil and the thiouracils is provided by the present work. The nature of the methylation products of uracil and related nucleic acid constituents with diazomethane has also attracted attention recently, particularly with regard to a possible relationship between the mechanisms of metagenesis and carcinogenesis (18). As we hope to demonstrate in the subsequent discussion, ^{13}C nmr chemical shifts of the CH_3 groups in methylated uracils provide a very effective way of establishing whether methylation has occurred on O-, S-, or N-sites and, in the latter case, whether at N-1 or N-3.

All our ^{13}C nmr spectra were recorded in solution in dimethyl sulfoxide. Previous workers, however,

have studied the effects of solvent on chemical shifts in uridine (19). Although these effects are not large at neutral p*H* for the series of solvents water, pyridine, dimethyl sulfoxide, the C-2 and C-4 carbonyl carbons appear farthest upfield in dimethyl sulfoxide, presumably because of decreased hydrogen bonding effects.

Experimental

Natural abundance proton decoupled ^{13}C nmr spectra were obtained on a Varian XL-100-15 spectrometer at 25.16 MHz, in the pulsed Fourier transform mode. All spectra were recorded in DMSO-d_6 solution and partially coupled spectra were also recorded in all cases. Operating temperature of the probe was 32 ± 3°C. Spectral widths of 6000 Hz were used routinely, with acquisition times of 0.666 s and pulse widths of 12 μs. (A 90° flip angle is equivalent to ca. 55 μs.)

With the exceptions noted below, compounds used in this study were available from the suppliers indicated in the tables: (Aldrich (A), Eastman (EK), Vega-Fox Biochemicals (V-F), or Sigma Chemical Co. (S)), or were synthesized following the literature procedures, also cited in the tables.

2-Chloro-4-methylthiopyrimidine

2,4-Dichloropyrimidine (2.98 g, 0.02 mol) in dimethylformamide (10 ml) and triethylamine (10 ml) was treated with excess methanethiol (~10 ml) with stirring. After 5 min the solution became turbid and a solid deposited. After 4 h the mixture was filtered under strong vacuum to remove excess mercaptan, and poured on ice. A colorless precipitate was collected and recrystallized from petroleum ether (bp 60–80°C) as colorless prisms, mp 60°C (72%); nmr ($CDCl_3$) δ:2.54 (3H, s), 7.08 (1H, d, J = 6.0 Hz, C-5 proton), 8.14 ppm (1H, d, J = 6.0 Hz, C-6 proton); *Anal.* calcd. for $C_5H_5ClN_2S$: C 37.38, H 3.12, Cl 22.12, N 17.67, S 19.94; found: C 37.45, H 3.26, Cl 21.96, N 17.61, S 20.13.

2-Methoxy-4-methylthiopyrimidine

2-Chloro-4-methylthiopyrimidine (0.4 g, 2.5 mmol) was added to a solution of sodium (0.067 g, 2.5 mmol) in methanol (10 ml) and the solution refluxed 1.5 h. The mixture was cooled, diluted with an equal amount of water, and extracted with chloroform (2 × 25 ml). The united extracts were dried over magnesium sulfate and evaporated to give a pale yellow, odoriferous oil. This was not analysed but was sufficiently pure (83%) for nmr studies; nmr ($CDCl_3$) δ:2.50 (3H, s), 3.89 (3H, s), 6.79 (1H, d, J = 6.0 Hz, C-5 proton), 8.12 ppm (1H, d, J = 6.0 Hz, C-6 proton).

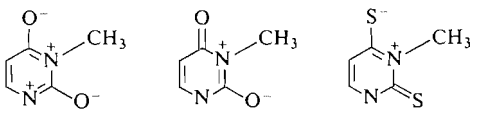
Spectral assignments have been based largely on multiplicity and chemical shift correlation arguments, although where necessary fully coupled spectra were obtained to remove any remaining ambiguity (7).

Results and Discussion

^{13}C nmr chemical shifts for a series of 14 uracil and thiouracil derivatives are listed in Table 1. This series includes the four parent uracils and thiouracils, seven of the eight possible mono-*N*-methylated derivatives, and three of the four di-*N*-methylated compounds.

Within any one of the sub-series in Table 1 (uracil, 2-thiouracil, 4-thiouracil, 2,4-dithiouracil) the changes in chemical shift of the ring carbons accompanying *N*-methylation are generally small and, with one exception, less than 2 ppm for C-2, C-4, and C-5. For the uracil derivatives these small chemical shifts were invariably to higher field, but in the various thiouracils no consistent pattern is apparent, with an apparently random distribution of small shielding and deshielding effects observed, probably as the result of competing electronic and steric strain factors.

The C-6 signal in this series of compounds, however, shows a markedly greater sensitivity towards *N*-methylation. Methylation at N-1, in uracil as well as the thiouracils, produces deshielding effects at C-6 ranging between +3.4 and +4.6 ppm. These can be attributed to the β-effect of the methyl group and are in excellent agreement with similar effects observed for *N*-methyl-2-pyridone and its 2-thione analogue (3). In contrast, methylation at N-3 produces shielding effects at C-6 ranging between −1.5 and −2.8 ppm. These may arise from a small *p*-substituent effect of the methyl group in the canonical form **1***a*.



1*a* **1***b* **1***c*

As expected, in the *N*,*N*-dimethylated derivatives the C-6 signal shows only small deshielding effects (+0.9 to +1.6 ppm), reflecting the operation of a combination of the two effects described above.

Undoubtedly the most dramatic effects in Table 1 are those observed for the *N*-methyl carbon signals and these have been summarized in Table 2. Most notably, the position of the N-3 methyl signal appears to be a very sensitive indicator of the presence of one, or two, thiocarbonyl groups at C-2/C-4 since the chemical shift ranges from a maximum of 41.2 ppm in 3-methyl-2,4-dithiouracil to a minimum of 26.4 ppm in 3-methyluracil, with 3-methyl-2-thiouracil showing an intermediate value of 32.9 ppm. Indeed, in the case of 1,3-dimethyl-2,4-dithiouracil the position of this signal reaches a value of 45.9 ppm. This astonishing range of chemical shifts, in such marked contrast to the relative insensitivity of the O—CH_3 and S—CH_3 chemical shifts (see Table 2), likely arises from a combination of the operation of steric strain factors and the anisotropies of the C=O and C=S bonds at C-2/C-4.

In the case of 3-methyluracil the very shielded position observed for this signal is probably due to the importance of canonical forms such as **1***a* and **1***b*, resulting in abnormal shielding of the *N*-methyl

[a]A range of values is quoted (ppm) where data for more than one compound with this structural feature have been obtained.

group. The *N*-methyl carbon signal in *N*-methyl-2 pyridone, for example, appears at 41.8 ppm (3). To explore this point a little farther we examined the model system, *N*-methylmaleimide **2** and found the *N*-methyl signal to occur at 23.3 ppm, in a situation where steric strain effects should be less important than in the six-membered ring case. Turning to the 2,4-dithiouracil case, because of the greater steric bulk of the sulfur atoms, or because of the lesser importance of canonical forms such as **1***c*, the nitrogen at N-3 may prefer to adopt an sp^3 pyramidal configuration. With respect to the latter, it is interesting that the chemical shift of the N-1 methyl signal in *N*-methyl-2-pyridinethione (3) at 46.0 ppm is very close to the chemical shift observed for the methyl signal in *N*-methylpiperidine, 47.9 ppm (20). Of course, since the C=S is significantly longer than the C=O bond, the much greater chemical shift observed for the N-3 methyl signal in the thiouracils may also arise from the location of the N—CH_3 (whether in a planar or a pyramidal configuration) in a deshielding, rather than a shielding, zone of the anisotropic functionality.

As indicated in the introduction, there has been considerable interest in the question of the tautomerism of uracil and related pyrimidines. Inspection of the data in Tables 1 and 3 adds further support to the large body of physical data which already exists (16, 17) in favor of the di-lactam formulation **1**. The positions of the C-2 and C-4 signals in 1,3-dimethyluracil, for example, are much closer to those in the parent compound than are the corresponding signals in 2,4-dimethoxypyrimidine (Table

[c]These values are in good agreement (within 2 ppm) with those cited in ref. 6.

TABLE 4. ^{13}C Chemical shifts of dihydropyrimidinones **4–7**

Compound	C-2	C-4	C-5	C-6	Methyl carbons	Reference No. (source)
1-Methyl-4-methoxy-1,2-dihydropyrimidin-2-one(**4**)	155.9	171.1	93.7	149.7	37.0(N—CH_3) 53.5(O—CH_3)	31
4-Methylthio-1,2-dihydropyrimidin-2-one(**5**)	154.3	177.5	101.8	143.1	11.9	33
2-Methylthio-3,4-dihydropyrimidin-4-one(**6**)	167.8	166.0	108.3	153.5	13.0	34
3-methyl-2-methylthio-3,4-dihydropyrimidin-4-one(7)	160.0	163.5	109.2	151.8	14.7(S—CH_3) 29.9(N—CH_3)	35

3). If a correctional factor for *O*-methylation of approximately 5 ppm (based on the data for C-1 in phenol and anisole, (21)) is applied, however, the distinction between the lactam and lactim tautomers at C-4 in uracil becomes rather difficult to determine on the basis of the chemical shifts. The unavailability of further model systems such as 4-methoxy-2-methylthiopyrimidine and 3-methyl-4-thiouracil also make rigorous conclusions regarding the tautomerism of the various thiouracils unwarranted, although again one can generally conclude that the thione and not the thiol tautomers appear to be favored from the data in Tables 1 and 3.

^{13}C nmr data for a number of C-2 and C-4 methoxy- and methylthio-substituted pyrimidines **3** are found in Table 3. These compounds may also be considered to be *O*-methyl or *S*-methyl substituted uracil derivatives. The chemical shift assignments were in most cases obvious from an application of shift effects and signal multiplicities. The C-2 carbon bearing an OCH_3 substituent is generally found at ca. 165 ppm but at lower field when the substituent was SCH_3. The C-4 carbon bearing either OCH_3 or SCH_3 on the other hand is consistently found at $\delta > 170$ ppm. The signal due to C-5 in this series is much more variable than that of C-6. Indeed, the C-5 chemical shifts can be predicted, with a surprising degree of accuracy (± 2.7 ppm), by using the *o*- and *p*-substituent effect parameters from the benzene series for —Cl, —OCH_3(22) and —SCH_3(2) groups at C-2 and C-4. For the other ring carbon atoms in these compounds, however, no simple correlations of this sort can be applied.

As discussed earlier, the OCH_3 and SCH_3 δ values are remarkably constant compared to those for their NCH_3 analogues. In both cases, the C-2 methyl signal is generally found slightly downfield from that at C-4, perhaps as a result of the proximity to both the ring nitrogen atoms. In either case, however, the total range encompassed is little more than 1 ppm.

Data for four compounds **4**, **5**, **6**, and **7**, whose tautomeric structures fall best into the intermediate category of dihydropyrimidinones are included in Table 4. These data require little further comment except to note in passing a relatively deshielded δ value of 14.7 ppm for the S—CH_3 group in **7** and an exceptionally large shielding effect at C-2 (-7.8 ppm), which is probably partly steric in origin, on converting **6** into its 3-methyl derivative. The δ value of 29.9 ppm for the N-3 methyl group in **7** is intermediate between the values of 26.4 and 32.9 in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

analogous monomethyl derivatives of uracil and 2-thiouracil, respectively.

Our data have demonstrated the large variation in chemical shifts of the *N*-methyl signals in uracil and the thiouracils and the way in which these shifts can be correlated with the site of methylation, at N-1 or N-3. When taken in conjunction with the well documented chemical shift parameters for *O*-methyl and *S*-methyl compounds these data provide a reliable method for identifying the site of methylation in these multifunctional compounds.

The Darzens glycidic ester condensation of indan-1-ones. A reinvestigation of the reaction

GERRY KAVADIAS[1] AND STEPHAN VELKOF

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received October 6, 1977

GERRY KAVADIAS and STEPHAN VELKOF. Can. J. Chem. **56**, 730 (1978).

The Darzens glycidic ester condensation of indan-1-one (**1***a*) with ethyl chloroacetate was reinvestigated. Contrary to previous reports, the reaction proceeded normally yielding the glycidic ester **2***a* in high yield. Similarly, 5-cyclohexylindan-1-one (**1***b*) produced the glycidic ester **2***b*. The glycidic esters **2***a,b* were converted to the corresponding aldehydes **4***a,b* by hydrolysis and decarboxylation. Oxidation of **4***b* yielded (±)-5-cyclohexylindan-1-carboxylic acid (3), a potent anti-inflammatory agent.

GERRY KAVADIAS et STEPHAN VELKOF. Can. J. Chem. **56**, 730 (1978).

On a réexaminé la réaction de condensation de Darzens entre l'indanone-1 (**1***a*) et le chloroacétate d'éthyle. Contrairement à des résultats antérieurs, la réaction se produit d'une façon normale pour conduire à l'ester glycidique **2***a* avec un très bon rendement. De la même manière, la cyclohexyl-5 indanone-1 (**1***b*) conduit à l'ester glycidique **2***b*. On a pu transformer les esters glycidiques **2***a,b* en aldéhydes correspondants **4***a,b* par hydrolyse et décarboxylation. L'oxydation de **4***b* fournit l'acide (±)-cyclohexyl-5 indancarboxylique-1, un produit anti-inflammatoire très puissant.

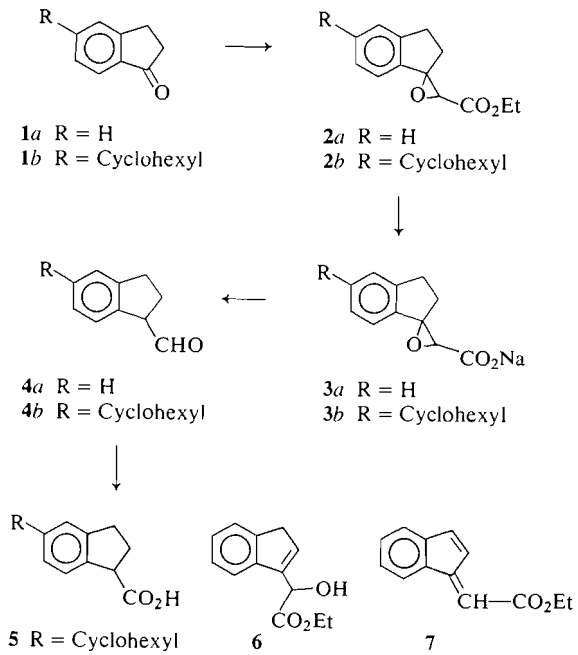
[Traduit par le journal]

The potency of (1*S*)-(−)-5-cyclohexylindan-1-carboxylic acid as an anti-inflammatory agent (3) led us to investigate an alternative synthesis for this valuable compound.

The present paper describes the synthesis of (±)-5-cyclohexylindan-1-carboxylic acid (**5**) via the glycidic ester **2***b*, the derived aldehyde **4***b* followed by oxidation (Scheme 1). It has been reported (2) that the Darzens glycidic ester condensation of indan-1-one (**1***a*) with ethyl chloroacetate in the presence of potassium *tert*-butoxide as the condensing agent yields the olefinic esters **6** and **7** instead of the expected glycidic ester **2***a*. It was concluded that this reaction with indan-1-one is of very limited practicality.

Upon repeating the above condensation reaction, a product was obtained in 94% yield which contained about 90% of the glycidic ester **2***a* as ascertained by nmr. The spectrum of this product showed a singlet at δ 3.90 for the hydrogen on the epoxide ring but no signals in the olefinic region thus establishing that the crude glycidic ester was free of olefinic esters **6** and **7**.

After completion of the reaction, it was necessary to neutralize the mixture with carbon dioxide prior to isolation of the glycidic ester **2***a*. Compound **2***a* was found to be sensitive to strong acids and bases and even when an ethereal solution was washed with dilute aqueous sodium hydroxide or hydrochloric acid, it was partly converted to the olefinic ester **6**. It was also sensitive to prolonged heating. Thus, although a small sample of crude **2***a* (8.0 g) could be distilled from a short column (Claisen head) without structural change (nmr), a larger sample (31.0 g) subjected to the same distillation gave a product (58%) which contained **2***a* and about 10% of the olefin **6** (nmr). Apparently, the partial conversion of **2***a* to **6** was the result of the longer heating period required for the larger scale experiment. When the above distillate was redistilled from a spinning band column a product was obtained (33%) which on nmr showed



1*a* R = H
1*b* R = Cyclohexyl

2*a* R = H
2*b* R = Cyclohexyl

3*a* R = H
3*b* R = Cyclohexyl

4*a* R = H
4*b* R = Cyclohexyl

5 R = Cyclohexyl

the complete absence of the glycidic ester **2***a*. The major component of the distillate was the olefinic ester **6** which was separated by column chromatography and identified. In all distillations, an appreciable quantity of residue was formed. A mechanism for the thermal conversion of **2***a* to **6** has been discussed (*2a*). Pure crystalline **2***a*, mp 56–58°C, was obtained by crystallization from ethanol.

From the above discussion, it is evident that the Darzens reaction proceeds normally in this case but care should be exercised in the isolation of the product.

The glycidic ester **2***a* was hydrolyzed by the Claisen method (4) to give the sodium salt **3***a*. Treatment of the salt **3***a* with glacial acetic acid was accompanied by a vigorous gas evolution and led to the aldehyde **4***a* (5). The above results demonstrate the usefulness of the process for the synthesis of 1-formylindanes.

Condensation of 5-cyclohexylindan-1-one (3) (**1***b*) with ethyl chloroacetate produced the glycidic ester **2***b*. The nmr spectrum of this product confirmed the structural assignment and showed no evidence of olefinic protons. Hydrolysis of **2***b* by the Claisen procedure (4) gave the sodium salt **3***b* which on treatment with glacial acetic acid yielded (±)-5-cyclohexyl-1-formylindane (**4***b*) in 52–55% yield based on the indanone **1***b*. Oxidation of the aldehyde **4***b* with the Jones' reagent in acetone (6) produced (±)-5-cyclohexylindan-1-carboxylic acid (3).

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. The ir spectra were recorded on a Unicam SP.200G grating ir spectrometer. The nmr spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform as the solvent. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalysis were performed by Micro-Tech Laboratories Inc., Skokie, Illinois, U.S.A.

Ethyl Indane-1-spiro-2′-oxiran-3′-carboxylate (2a)

The general procedure described by Johnson *et al.* (7) was followed. In a flame-dried and nitrogen-purged 500 ml three-neck flask fitted with a mechanical stirrer, dropping funnel, and nitrogen inlet tube was added 20.0 g (151 mmol) of indan-1-one and 27.0 g (220 mmol) of freshly distilled ethyl chloroacetate. The mixture was kept under nitrogen, cooled in an ice-bath, and stirred. A solution of 24.6 g (220 mmol) of potassium *tert*-butoxide (Aldrich Chemical Co.) in 250 ml dry *tert*-butanol (7) was added dropwise over 1.5 h while stirring and maintaining the temperature below 10°C. After completion of the addition, stirring at the ice-bath temperature was continued for an additional 1.5 h. The excess potassium *tert*-butoxide was decomposed by passing CO_2 through the reaction mixture and the solvent was removed *in vacuo* at 35–40°C. Ether (250 ml) was added to the residue and the mixture filtered through a bed of Celite. The Celite bed was washed with ether and the washings were combined with the filtrate and evaporated to dryness to give 31.0 g (94%) of a dark-brown oil which crystallized on standing. The nmr spectrum showed the bands required for **2***a* (see below) and in addition two extraneous single bands at δ 1.50 and 3.82 belonging to an impurity which is assumed to be *tert*-butyl indane-1-spiro-2′-oxirane-3′-carboxylate. No absorption bands for olefinic protons were observed. The crude product contained about 90% of **2***a* as estimated by nmr from the relative intensities of the bands at δ 1.30 (methyl group of **2***a*) and δ 1.50 (impurity). This material was used without further purification in the next reaction. A sample (8.0 g) was crystallized from ethanol (15 ml) to give 4.0 g of crystalline **2***a* mp 51–55°C. After one recrystallization from the same solvent, it melted at 56–58°C; ir (Nujol): 1745 cm^{-1}; nmr δ: 1.30 and 4.28 (t and q for OCH_2CH_3), 2.35 (m, 2, C-2H), 3.0 (m, 2, C-3H), 3.90 (s, 1, epoxyproton), 6.9–7.3 (m, 4, ArH). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.56, H 6.46; found: C 71.70, H 6.50. In another experiment, the crude product (8.0 g) was distilled from a Claisen head to give 6.0 g of oil, bp 106–108°C/0.1 Torr. The ir and nmr spectra showed that no change in structure had occurred.

In another experiment, crude **2***a* (31 g) (which on nmr showed no olefinic protons) was distilled from a Claisen head to give 18 g bp 120–122°C/0.2 Torr and a high boiling residue. The nmr spectrum of the distillate showed, in addition to the bands for **2***a*, a small band at δ 6.55 for the olefinic proton of **6**. The distillate contained about 10% of **6** as estimated by nmr. This distillate was redistilled using a spinning band column to give 6.0 g (33%) bp 118–122°C/0.1–0.05 Torr and a high boiling residue.

The nmr spectrum showed that conversion to **6** had occurred (olefinic proton and no absorption band for the epoxyproton). Thin-layer chromatography on silica with 5% ethyl acetate – benzene as the solvent (two immersions) showed one major spot with R_f 0.36 (**6**) and two minor ones with R_f 0.50 and 0.78. Compound **6** was separated by column chromatography on silica using 5% ethyl acetate – benzene as the eluent; ir (neat): 3450, 1740 cm^{-1}; nmr δ: 1.22 and 4.25 (t and q for OCH_2CH_3), 3.35 (m, 2, benzylic), 5.25 (s, 1, O—CH), 6.55 (m, 1, olefinic), 7.15–7.70 (m, 4, ArH). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.54, H 6.46; found: C 71.56, H 6.52.

A sample of crude **2***a* (1.0 g) was dissolved in ether (30 ml) and the solution washed with 5% sodium hydroxide (2 × 30 ml). After drying and removal of the solvent by evaporation, the residue was examined by nmr. The spectrum showed, in addition to the bands for **2***a*, bands at δ 3.35, 5.25, and 6.55 indicating that **2***a* was partly (20–30%) converted to **6**.

Ethyl 5-Cyclohexylindan-1-spiro-2′-oxiran-3′-carboxylate (2b)

The procedure described above was followed. To a mixture of 5-cyclohexylindan-1-one (3) (21.4 g, 100 mmol) and 18.3 g (150 mmol) ethyl chloroacetate was added dropwise (1.5 h) a solution of 16.8 g (150 mmol) potassium *tert*-butoxide in *tert*-butanol (200 ml). After the addition, the ice-bath was removed and the reaction mixture stirred at room temperature for 2.5 h. The product was isolated as above to give 27.0 g of crude **2***b*. The nmr spectrum showed a band for the epoxy proton at δ 3.90 and was consistent with the expected structure **2***b*. The crude product was used without further purification in the next step.

(±)-1-Formylindane (4a)

Hydrolysis of the Glycidic Ester 2a

This step was carried out according to the procedure of Claisen (4) and was as follows: To a solution of 1.69 g (0.0735 g-at.) of sodium in 30 ml absolute ethanol was added 1.32 ml (73.5 mmol) of water and the solution cooled in an ice-bath. To this was added a solution of 16.2 g (74.5 mmol) of crude **2***a* in absolute ethanol (8 ml) and the mixture stirred in the cold for 15 min and then at room temperature for 3.5 h. The solids were filtered and washed with ice-cold ethanol (10 ml) and

with ether (2 × 50 ml) to give 14.1 g (90%) of **3***a*; ir (Nujol): 1610 cm^{-1} (CO).

Conversion of 3a to 4a

Compound **3***a* (13.67 g, 64.5 mmol) was placed in a flask and 25 ml glacial acetic acid was added. A vigorous evolution of carbon dioxide occurred and after stirring at room temperature for 15 min, the reaction had subsided. The reaction mixture was then heated on a steam-bath until the evolution of gases ceased (15 min). The reaction mixture was cooled to room temperature, diluted with water (150 ml) and extracted with ether (3 × 60 ml). The combined extracts were washed with water (2 × 100 ml) and with 10% sodium bicarbonate solution (100 ml) and dried. Evaporation of the solvent gave 8.2 g of crude **4***a*. Thin-layer chromatography on silica with benzene as solvent showed one major spot R_f 0.53 and two minor ones with R_f 0.23 and 0. The ir and nmr spectra were in agreement with the expected structure **4***a*. The crude product was distilled to give 6.6 g (70%) of **4***a* bp 122–124°C/20 Torr, (lit. (5) bp 135°C/30 Torr); ir (neat): 1725 cm^{-1}; nmr δ: 2.25 (m, 2, CH_2), 2.95 (m, 2, benzylic), 3.84 (dt, 1, C-1H, J_1 = 3.0, J_2 = 7.0 Hz), 7.20 (m, 4, ArH) 9.60 (d, 1, CHO, J = 3.0 Hz).

(±)-5-Cyclohexyl-1-formylindane (4b)

Hydrolysis of the Glycidic Ester 2b

The procedure described above for the hydrolysis of **2***a* was followed. To an ice-cold solution of 2.04 g (0.089 g-at.) of sodium in 35 ml absolute ethanol was added 1.62 ml (90 mmol) of water followed by a solution of 27.0 g (90 mmol) of crude **2***b* in 10 ml ethanol. The product was separated as above to give 23.3 g (88%) of **3***b*; ir (Nujol): 1610 cm^{-1}.

Conversion of 3b to 4b

Compound **3***b* (23.3 g, 78 mmol) was treated with 30 ml glacial acetic acid and the product was isolated as above to give 14.7 g (82.5%) of crude **4***b*. This product was used as such in the next step. Thin-layer chromatography on silica with 5% ether–benzene as solvent showed one major spot and some impurities with R_f 0. A sample of 2.2 g, was chromatographed on a silica column (14 cm × 3.2 cm ID) with chloroform as the eluent and the fraction containing **4***b* (70–120 ml) was evaporated to dryness to give 1.7 g of **4***b*. This indicated that the crude product contained 78–80% of **4***a*; ir (neat):1725 cm^{-1}; nmr δ: 3.90 (dt, 1, C-1H, J_1 = 3.0 Hz; J_2 = 7.0 Hz), 9.65 (d, 1, CHO, J = 3.0 Hz). *Anal.* calcd. for $C_{16}H_{20}O$: C 84.17, H 8.83; found: C 84.00, H 8.79.

(±)-5-Cyclohexylindan-1-carboxylic Acid (5)

The Jones' reagent was prepared as described by Djerassi *et al.* (8). Chromium trioxide, 26.72 g (267.2 mmol) in 23 ml concentrated sulfuric acid was cooled in ice and diluted by careful addition of water to a volume of 100 ml. A solution of the crude aldehyde **4***b* (14.7 g, 64.5 mmol) in 100 ml of acetone was cooled in an ice-bath while stirring. When the temperature reached 4°C, 17.0 ml of Jones' reagent was added dropwise to maintain the temperature at 20–25°C. After completion of the addition (3–4 min), the mixture was stirred in the cold for 5 min, diluted with water (300 ml), and the crystalline precipitate collected by filtration and washed with water. The pale yellow crystals were dissolved in ether, the solution dried ($MgSO_4$) and evaporated to dryness to give 14.0 g of crystalline **5**. The aqueous phase after extraction with ether gave an additional 390 mg of product. The crystalline product (14.0 g) was recrystallized from petroleum ether (bp 65–75°C) to give 10.0 g of product, mp 142–145°C. The product of the extraction (390 mg) was added to the mother liquor and the solution evaporated to dryness. Recrystallization of the residue from petroleum ether gave 1.0 g of product, mp 140–145°C. This fraction was combined with the first fractions to give a total of 11.0 g of product. Recrystallization from benzene (20 ml) – petroleum ether (200 ml) gave 10.2 g of product **5** (64.5%), mp 144–146°C (lit. (3) mp 145–146°C).

Photolysis of diterpenoid quinones[1,2]

OLIVER E. EDWARDS AND PAK-TSUN HO[3]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 30, 1977

OLIVER E. EDWARDS and PAK-TSUN HO. Can. J. Chem. **56**, 733 (1978).

Photolysis of the diterpene quinone royleanone in benzene gave predominantly products resulting from both side-chain rearrangement and formation of an ether bridge to C-1. It is proposed that these arose by very specific transfer of two hydrogen atoms in a highly oriented complex between ground state royleanone and photo-excited royleanone. In contrast 7α-acetoxyroyleanone gave products of simple side chain rearrangement, with or without loss of acetic acid, probably via a spirocyclopropyl intermediate.

Royleanone methyl ether gave mainly an oxetanol in benzene but a methylenedioxy compound and an acetoxymethoxy compound in acetic acid. It is suggested that these arise from diradical and zwitterionic intermediates.

OLIVER E. EDWARDS et PAK-TSUN HO. Can. J. Chem. **56**, 733 (1978).

La photolyse de la quinone diterpénique royléanone dans le benzène conduit d'une façon prédominante à des produits provenant tant d'une transposition de la chaîne latérale que de la formation d'un pont éther vers le C-1. On suggère que ces produits proviennent d'un transfert très spécifique de deux atomes d'hydrogène dans le complexe hautement orienté entre l'état fondamental de la royléanone et de la royléanone photoexcitée. Par opposition, l'acétoxy-7α royléanone conduit uniquement à des produits provenant d'une transposition simple de la chaîne latérale accompagnée ou non d'une perte d'acide acétique probablement par l'intermédiaire spirocyclopropyle.

L'éther méthylique de la royléanone conduit principalement à un oxétanol dans le benzène alors que dans l'acide acétique il y a formation d'un composé méthylènedioxy et d'un composé acétoxyméthoxy. On suggère que ces composés proviennent d'intermédiaires diradicalaire et zwittérionique.

[Traduit par le journal]

Introduction

Royleanone **1** (R = H) is a naturally-occurring diterpenoid quinone with a structure (1) derived from the parent tricyclic diterpene abietane. Rüedi and Eugster (2) have established the presence in nature of related diterpenes coleons E and F **2** in which the side chain is a modified *n*-propyl group. Zelnik and co-workers (3) isolated and established the structure of barbatusin (**3**) in which the common isopropyl side chain now appears as a spirocyclopropyl unit. The same unit was later found (4) in cyclobutatusin **4**, and Eugster and co-workers (5) determined the structure of a series of compounds (coleons G, J, M, N, O, P, Q, and R) all of which contain this feature. Although the modified side chains of these compounds could be formed in the plants by completely ionic processes (2*a*) our interest was aroused by the possibility that they resulted from photochemical transformation of royleanone-like precursors. Indeed it was recognized by Zelnik and co-workers (4) that the cyclobutanol unit of cyclobutatusin could have a photochemical origin, and recent work (6) has shown that irradiation of barbatusin does give a product containing this feature.

In the hope that products related to the coleons and barbatusin could be obtained we undertook a study of the photolysis of royleanone **1**, 7α-acetoxy-royleanone **5** (1, 5*b*), and royleanone methyl ether **6**.

Results

Royleanone

Irradiation of a benzene solution of royleanone **1** (R = H) with light from a medium pressure mercury lamp through Pyrex, followed by acetylation (all under argon) gave a number of unusual products (in 84% yield).[4] The only predictable one isolated was the hydroquinone triacetate **7**. The other three products characterized were the cyclic ethers **8** (or **9**), **10**, and **11**. Their structures were deduced on the basis of their ^{1}H nmr spectra (see Experimental for values) and reactions.

Substance **8** (or **9**) was clearly a phenolic acetate (ν_{max} 1760 cm^{-1}) containing two aryl-alkyl ether oxygens (^{13}C nmr signals at 80.79 and 80.55 ppm) and no longer containing the isopropyl side chain. A

pair of methyl doublets at δ 1.45 and 1.5, and the related low field multiplet (δ 4.80) were readily reconciled with transformation of the original isopropyl side chain into a pair of isomers containing a methyldihydrofuran ring. The fact that the acetoxy carbonyl gave a single ^{13}C nmr signal at δ 168.13 and a single ^{1}H nmr signal (δ 2.30) makes it probable that the isomers were methyl epimers rather than having the two different ether locations (**8** or **9**). A choice as to which structure is correct would be arbitrary with the available evidence but mechanistic considerations (see Discussion) lead us to favour **8**.

Catalytic hydrogenation converted **10** into **12** which now had the ^{1}H nmr spectral characteristics of an isopropyl derivative (see Experimental for values). Similar reduction of **11** gave **13** whose ^{1}H nmr spectrum fitted the presence of a *n*-propyl group. The characteristic common feature of **8-11** was a ^{1}H quartet near δ 3.9, the magnitude of the couplings was consistent with their origin being an α hydrogen on C-1 with a 1β–11 ether bridge.[5] The gross structures of **8**, **12**, and **13** were shown to be as depicted by the action of boron trifluoride etherate in acetic anhydride leading to rearrangement to the styrene derivatives **14–16**. However, since these had an allylic methyl group (δ near 1.9) they could also have been products of methyl migration, e.g. **17**. The correct structure was established by ruthenium tetroxide oxidation of **14–16** to **18–20**, respectively. The cyclopentanone moiety was in each case evident from the infrared spectrum (ν_{max} 1740 cm^{-1}) and the acetophenone unit from the peaks near 1700 cm^{-1} and extra CH_3CO signals in the ^{1}H nmr spectra.

The irradiation of royleanone under identical conditions to the above experiments but using dimethoxyethane as solvent, led to a complex mixture with much incorporation of the solvent into products.

7α-Acetoxyroyleanone

The behavior of 7α-acetoxyroyleanone **5** on irradiation was in striking contrast to that of royleanone. The same main products were produced in benzene as in dimethoxyethane, but the conversion was more rapid in the latter solvent and the products cleaner. No significant incorporation of the ether into products was noted. The four major products after acetylation under argon were **21** (30%), **22** (34%), **23** (8.5%), and **24** (10%). It was clear from the empirical formulae and ^{1}H nmr spectra that these consisted of two pairs of compounds, one pair with the original 7-acetoxy group and the other in which this had been eliminated to give a 6,7-ene. One member of each pair had an isopropenyl side chain and the other a *trans*-1-propenyl side chain. The structure assigned to **21** was confirmed by hydrogenation to **25**, which now had an isopropyl side chain, followed by acid catalysed hydrolysis and elimination, then air oxidation to the known 6-dehydroroyleanone **26** (1). Comparable treatment of **22** gave **27** and **28** with spectral characteristics parallel to those of **25** and **26**. Accompanying the simple hydrogenation products **25** and **27** were the products **7** and **29** of hydrogenolysis of the 7-acetoxy group, a not unexpected event. Compound **7** was identical to an authentic sample prepared by reductive acetylation of royleanone.

The structures of **23** and **24** were evident from their ^{1}H nmr spectra (see Experimental for values). Confirmation was provided by hydrogenation to **7** and **29**, respectively.

Royleanone Methyl Ether

Photolysis of royleanone methyl ether **6** in a 2.5:1 acetic acid – acetic anhydride mixture under argon using radiation peaked at 254 nm gave quite rapid (2 h) conversion into products. These mainly involved the methoxyl group. After air oxidation the products isolated (yields based on unrecovered starting material) were the methylenedioxy acetate **30** (R = Ac) (17%), the acetoxymethoxyquinone **31** (10%), and a monoacetate of the hydroquinone **32** (R = H) (9%) which was tentatively assigned the 14-acetoxy structure **32** (R = Ac). The structural assignments followed from the ^{1}H nmr spectra and the following physical and chemical evidence.

The ^{13}C nmr signal at δ 99.9, the ^{1}H nmr signal at δ 5.9 and the absence of the methoxyl group made the presence of a methylenedioxy group in **30** certain. The unchanged isopropyl group (^{1}H nmr) and the phenolic acetate (ν_{max} 1750 cm^{-1}) were only compatible with the assigned structure.

The compound to which we assign structure **31** was a yellow gum with ν_{max} 1650 (quinone) and 1755 cm^{-1} (acetate). The OCH_2O group gave rise to a quartet in its ^{1}H nmr spectrum and to a ^{13}C nmr signal at 87 ppm. The characteristic ^{1}H nmr signals for the isopropyl group were present. Mild basic hydrolysis to royleanone confirmed the structure.

Compound **32** (R = Ac) was a nearly colorless oil which had an exchangeable proton (δ 5.9 in $CDCl_3$) and was a phenolic acetate (ν_{max} 1755 cm^{-1}) with an intact isopropyl group (^{1}H nmr). Treatment of the hydroquinone **32** (R = H), derived from royleanone methyl ether, at room temperature with 1:1 acetic

[5]A half-chair conformation of ring A would permit formation of a 1α–11 ether bridge, giving the same coupling constants but the all-chair product seems more probable.

acid – acetic anhydride mixture for 22 h resulted in very little acetylation. However acetic anhydride – pyridine at room temperature converted it into a mixture of mono- and diacetates. The former proved to be identical with **32** (R = Ac). The location of the acetate is made to correspond with what we consider to be the least hindered hydroxyl group.

When royleanone methyl ether was irradiated in acetic acid alone the major identifiable products were **30** (R = H) (16%) and **31** (22%). The presence of **30** (R = H) was at first missed since it had an unexpectedly high R_f on silica gel (nearly the same as **6** in C_6H_6), and the expected sharp singlet near δ 5.9 was absent in deuteriochloroform although a broad multiplet was present with this chemical shift. However addition of deuterium oxide transformed this signal into a sharp 2H singlet while a 1H singlet at δ 4.3 disappeared. In addition a complex set of signals between δ 1.5 and 3.6 resolved into the characteristic multiplet for the CH (δ 3.3) and doublet for the methyl groups (δ 1.37) of the isopropyl group. This phenomenon was reversible. The acetylation of **30** (R = H) in acetic acid – acetic anhydride or acetic anhydride alone was very slow but acetic anhydride – pyridine converted it into the **30** (R = Ac) described above. Under none of these conditions was **31** produced from **30** (R = H).

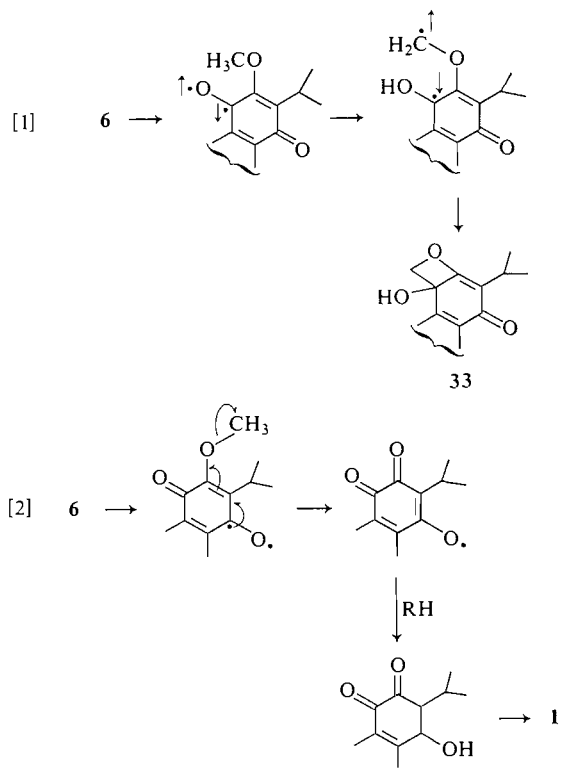
The photolysis of **6** in benzene was attempted with radiation peaked at either 350 or 300 nm. The starting material was recovered essentially unchanged. Using radiation peaked at 254 nm the quinone was slowly transformed (ca. 50% in 6 h). The products were strikingly different from those produced in acetic acid.

The major product (47% based on unrecovered **6**) was a colorless crystalline compound which has been assigned the oxetanol structure **33**. The only other product identified was royleanone (13% based on unrecovered **6**).[6] The structure of **33** was deduced on the basis of its formula, $C_{21}H_{30}O_3$, spectra, and reactions. The infrared spectrum (ν_{max} 3570, 3360, 1710, and 1622 cm^{-1}) suggested the presence of a hydroxyl group and an enone. It was inert to all but vigorous acetylation conditions, hence the hydroxyl was tertiary. The enone character was substantiated by its ultraviolet absorption (λ_{max} 248, ε 11 700 and 316 nm, ε 1770). The ^1H nmr spectrum showed the absence of a methoxyl group but the presence of a $—CH_2—O$ group (2H, dd, δ 4.90 and 5.16, J = 5 Hz) and the isopropyl group. Possible ^{13}C nmr assignments based on off-resonance decoupling and analogy (7) are indicated on structure **33**. All this evidence is consistent with the assigned structure. It was reasoned that good nucleophiles might open the oxetane ring. Action of hydroxide ion under argon on **33** did open it as illustrated in **34**. The reaction mixture was neutralized then allowed to oxidize in the air. Royleanone was produced, giving final confirmation of the structure.[7]

Discussion

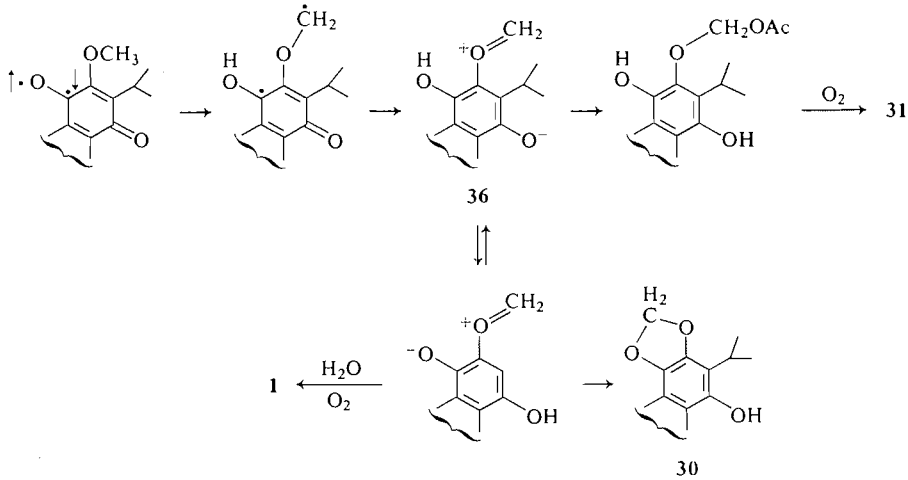
The fact that the photolysis of royleanone was much faster using lamps with peak emission at 254 nm as compared with those giving longer wavelengths indicates that the 270 nm absorption band of the quinones is involved in the reactions we have observed. This is consistent with the marked slowing of the photolysis of the methyl ether when benzene was used as solvent compared to acetic acid. Finally the fact that, although acetoxyroyleanone **5** was photolysed more slowly in benzene than in dimethoxyethane, the major products were the same indicates that the photoexcited states were the same in both solvents.

The observations on royleanone methyl ether in benzene seem best interpreted as major (eq. 1) and minor (eq. 2) homolytic processes. Clearly the



[6]Care was taken to ensure that no royleanone was present in the starting material. The benzene used had been dried over sodium wire.

[7]The structure has been confirmed and stereochemistry determined using X-ray crystallography by Drs. M. Przybylska and F. R. Ahmed.

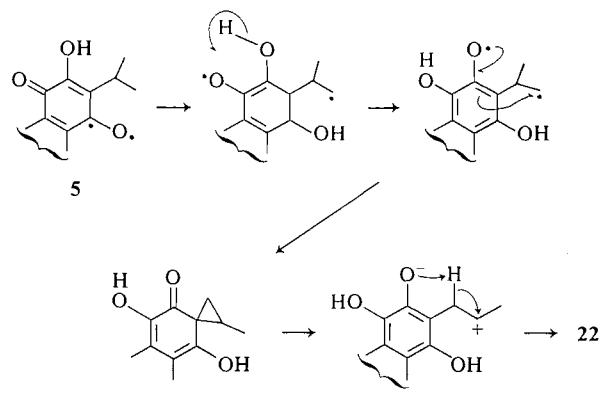


SCHEME 1

methoxyl group is the most reactive function for radical type processes. Comparable ether cleavage has been observed previously (8). Although oxetanol formation has been observed several times for methoxycyclohexenediones of type **35** (9, 10) the formation of the much more strained oxetane ring of **33** seems to be unique. A striking feature of its infrared spectrum was a peak of medium intensity at 1710 cm^{-1}. The Raman spectrum of **33** had similar peaks at 1717 (medium) and 1631 (strong) cm^{-1}. A preliminary study of the Raman spectrum in polar and nonpolar solvents indicated that the bands were of complex olefinic and carbonyl origin.[8]

The photochemical behavior of royleanone methyl ether in acetic acid or acetic acid – acetic anhydride mixtures is in striking contrast to that in benzene. If we are correct in assuming that the same excited state is involved in both solvents, the difference in reaction seems best interpreted as a rapid transition to ionic pathways as in Scheme 1 in the more polar solvents. The electron transfer could be intramolecular (analogous to Zimmerman's electron demotions) (11) or an intermolecular charge-transfer-type of electron migration. Both the formation of acetoxymethoxy and methylenedioxy groups in photolysis of a methoxy quinone in acetic anhydride were discovered recently by Baldwin and Brown (12), and the above type of ionic mechanism invoked to account for their production. Their work showed that protons are not needed to induce the ionic state, whereas ours shows that no acetylating agent is needed. It is surprising that no oxetanol is formed, i.e. that the transition to a zwitterion is so rapid and complete. The formation of the monoacetate of the methylenedioxy compound in the 1:1 acetic acid – acetic anhydride mixture seems revealing. The methylenedioxy phenol does not acetylate under these conditions, hence the reaction would seem to be capture of the phenoxide ion of **36** by acetic anhydride.

The course of photolysis of 7α-acetoxyroyleanone fits in part well-established patterns. The side-chain rearrangement and olefin formation could be readily accounted for in terms of the initial diradical formation, electron transfer to give a zwitterion, then proton abstraction to give the olefins (with or without prior methyl migration). However, the unimportance of electron transfer in benzene in the case of the methyl ether (see above), and the failure to detect dihydrofuran products, incline us to favor side-chain rearrangement via spirocyclopropyl ketones (Schemes 2 and 3). This type of intermediate was postulated by Orlando and co-workers (13) to account for side-chain rearrangement in simple quinones. Work of Farid (14) supported this con-



SCHEME 2

[8]We are grateful to Dr. P. Carey for obtaining the Raman spectrum and for advice on its significance.

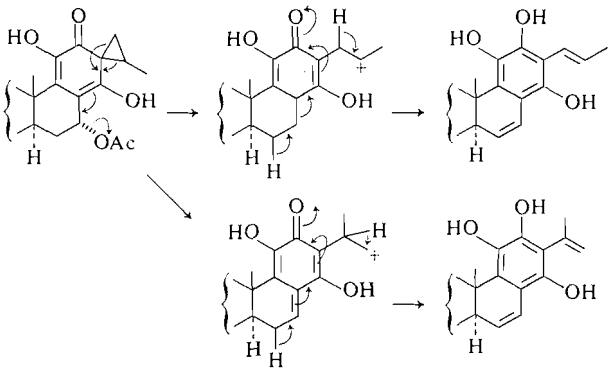


SCHEME 3

ception. But thermal [1,5] sigmatropic rearrangement of spirocyclopropyl dienones to olefins leads in all known cases (15) to *nonconjugated* olefin.[9] Hence if these are intermediates in our case, the observed opening to *conjugated* olefins would have to be by a second photolytic process[10] or by an ionic process during work-up.

Whatever the detail of mechanism, we observed none of the hoped-for spirocyclopropanes in the products of the photolysis and subsequent acetylation.

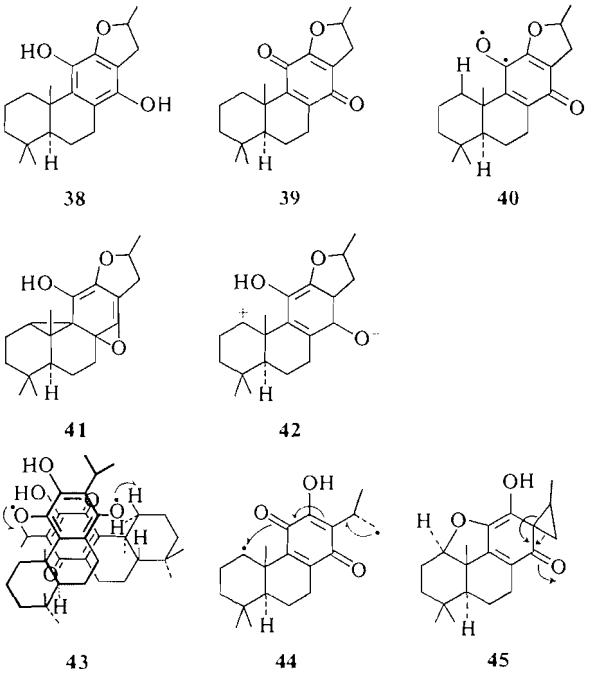
The elimination of the 7α-acetoxy group can be formulated as an alternative mode of reaction of the spirocyclopropane (Scheme 3).

The important products from photolysis of royleanone, aside from the hydroquinone, cannot arise from a simple one-photon process. In previous work on the photolysis of simple quinones (16) only minor products of similar character have been encountered and in the case of 7α-acetoxyroyleanone no comparable products were obtained.

Two interpretations of this unusual behavior seem worthy of discussion.

(*i*) A hydroquinone with a dihydrofuran ring (e.g. **38**) or unsaturated side chain could be produced in a first photochemical step. This could then be reoxidized to quinone (e.g. **39**) by parent quinone. A second photolysis of **39** could give the diradical **40** (16). This could be transformed into one of the products via a spirocyclopropane **41** and the zwitterion **42**. We discount this sequence on the following grounds. (*a*) It is not evident why more than fractional amounts of the hydroquinones such as **38** should be reoxidized by residual parent quinone. In simple models (13, 16) this is clearly a minor process. (*b*) The diradical **40** is most likely to give a cyclobutanol if hydrogen is abstracted from C-1. Indeed Zelnik *et al.* (17) have recently shown that barbatusin (**3**) does give such a cyclobutanol when irradiated. (*c*) If the cation in **42** had significant lifetime, methyl migration or ring-A contraction to give benzylic cations would have been expected. No such products were observed. (*d*) Internal oxygen radical addition to the unsaturated side chains produced in the first photolysis step should have occurred in the second (18). No products obviously derived from such events were obtained.

(*ii*) The apparent molecular weight of royleanone in 7.6×10^{-2} *M* solution in benzene was normal and no charge-transfer band was evident in its absorption spectrum. However the photoexcited state may be



38 **39** **40**

41 **42**

43 **44** **45**

more polar. We hence postulate that loose but highly oriented complexes form between photoexcited molecules and ones in the ground state (excimers). Such a complex, with minimal nonbonded interactions and stabilization by hydrogen bonding is illustrated in **43**. This is ideally oriented for double hydrogen atom abstraction leading to 1 molecule of hydroquinone and a transient diradical **44**. The latter would probably collapse rapidly to the spirocyclopropyl ether **45** (fishhooks) especially since the methylene radical of the side chain, when formed, would be orthogonal to the enone system. The spirocyclopropane **45** would give zwitterions leading to the three types of product observed (arrows).

Not only does explanation **2** account for the observations on royleanone, it can explain the fact

[9]This led Eugster and co-workers (2*a*) to postulate that spirocyclopropyl derivatives were intermediates in the biosynthesis of coleons such as **2**.

[10]Shorter wavelength light than that in the work of Orlando and Farid (13, 16) was used.

that 7α-acetoxyroyleanone, in which the axial acetoxy group would preclude the association shown in **43**, gave products accountable for on the basis of isolated photoexcited molecules.

Summary

Despite a high probability that spirocyclopropyl intermediates are involved in the photochemistry of royleanone and acetoxyroyleanone we were unable to isolate one. Hence the hoped-for route to barbatusin was not realized. However we still consider that this class of compounds may well be formed in vivo by irradiation of royleanones in the oil glands in the leaves of the appropriate plants.

Diradical states, zwitterionic states and a complex between molecules in the ground and excited states are invoked to explain the formation of the observed products.

Experimental

Infrared spectra were of chloroform solutions, ultraviolet spectra of solutions in 95% ethanol, and ^{1}H nmr and ^{13}C nmr spectra in deuteriochloroform solutions with TMS as internal reference. Thin-layer and preparative-layer chromatography was done using silica gel containing a fluorescent indicator (G_{254}).

Materials

Royleanone 1 (R = H)

This was recrystallized from methylene chloride – ethanol giving flat needles with mp 181°C; ^{1}H nmr δ: 7.3 (1Hs, OH), 3.2 (1H, m), 1.27 (9H, s), 1.16 (3H, s), and 0.93 (6H, s); λ_{max} (benzene; 1.3×10^{-3} *M*): 409 nm, ε 380. *Mol. Wt.* calcd. for $C_{20}H_{28}O_3$: 316; found (thermistor drop method, in benzene): 313.

Royleanone Methyl Ether 6

This crystallized from methylene chloride – methanol, mp 120°C; ^{1}H nmr δ: 3.90 (3H, s), 3.2 (1H, m), 1.32 (3H, s), 1.21 (6H, d, J = 7 Hz), 0.94 (6H, s).

Royleanone Acetate 1 (R = Ac)

This compound was prepared by a standard procedure for acetylation and recrystallized from ether–methanol to a constant melting point 78°C; ^{1}H nmr δ: 2.35 (3H, s), 1.30 (3H, s), 1.21 (6H, d, J = 8 Hz), 0.93 (3H, s), 0.91 (3H, s).

Royleanone

Photolysis of Royleanone 1 (R = H)

A solution of royleanone **1** (R = H) (250 mg) in anhydrous benzene (120 ml) was irradiated by a 200 W medium pressure Hanovia mercury lamp with a Pyrex filter under argon at about 10°C for 8 h, after which acetic anhydride (5 ml) and pyridine (10 ml) were added to the reaction mixture and the solution was left overnight. Evaporation of the solvent *in vacuo* resulted in a brown residue which showed four components on tlc (silica gel, 5% ether in benzene), besides the starting material as its acetate. Chromatography by preparative tlc on silica gel afforded 56 mg of the reduction product **7**, 30 mg of compound **8** (or **9**), 22 mg of compound **10**, and 23 mg of compound **11**. The photolysis gave 48% conversion to the products with 44% recovery of royleanone as its acetate (118 mg) and the total yield was 84%. The reduction product **7** was recrystallized from ethanol with mp 128°C and identified by comparison with authentic sample in all respects (mp, ir, nmr, and tlc). The other three components **8** (or **9**), **10**, and **11** were thick oils homogeneous by tlc in several solvent systems.

Compound (8 or 9)—ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 4.80 (m, 1H, —CH—O—), 3.89 (q, J = 10 Hz, J = 4 Hz, 1H, —CH—O—), 2.30 (s, 3H, —$OCOCH_3$), 1.50 and 1.45 (two d, J = 6 Hz, 3H, isomeric methyl), 1.10 (s, 3H, —CH_3), 1.03 (s, 3H, —CH_3), 0.98 ppm (s, 3H, —CH_3); ^{13}C nmr ($CDCl_3$) δ: 168.13 (—$OCOCH_3$) 142.50, 142.30, 142.21, 128.41, 116.53 and 111.33 (aromatic carbons), 80.79 and 80.55 ppm (two —O—C—). *Mol. Wt.* calcd. for $C_{22}H_{28}O_4$: 356.1991; found (high resolution mass spectroscopy): 356.1991.

Compound 10—ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 5.21 and 4.84 (two broad s, 2H, two vinylic protons), 3.95 (q, J = 11 Hz, J = 5 Hz, 1H, —CH—O—), 2.23 (s, 3H, —$OCOCH_3$), 2.20 (s, 3H, —$OCOCH_3$), 1.94 (broad s, 3H, C=C—CH_3), 1.14 (s, 3H, —CH_3), 1.03 (s, 3H, —CH_3), 0.97 ppm (s, 3H, —CH_3). *Mol. Wt.* calcd. for $C_{24}H_{30}O_5$: 398.2105; found (high resolution mass spectroscopy): 398.2096.

Compound 11—ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 6.03 (d, J = 11 Hz, 1H, —C=CH—), 5.90 (m, 1H, —C=C*H*CH_3), 3.92 (q, J = 11 Hz, J = 5 Hz, 1H, —CH—O—), 2.30 (s, 6H, two —$OCOCH_3$), 1.84 (d, J = 5 Hz, 3H, —C=CCH_3), 1.12 (s, 3H, —CH_3), 1.02 (s, 3H, —CH_3), 0.95 ppm (s, 3H, —CH_3). *Mol. Wt.* calcd. for $C_{24}H_{30}O_5$: 398.2105; found (high resolution mass spectroscopy): 398.2104.

Hydrogenation of Compound 10

Compound **10** (40 mg) was subjected to an atmospheric pressure hydrogenation in methanol (8 ml) with 10% palladium-on-charcoal (29 mg). After 3 h, the palladium-on-charcoal was removed by filtration and the solvent was evaporated to afford quantitatively crystalline dihydro derivative **12** (40 mg). An analytical sample was prepared by recrystallization from ether–*n*-hexane with mp 135–136°C; ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 3.94 (q, J = 10 Hz, J = 5 Hz, 1H, —CH—O—), 2.32 (s, 6H, two —$OCOCH_3$), 1.22 (d, J = 5 Hz, 6H, isopropyl), 1.14 (s, 3H, —CH_3), 103 (s, 3H, —CH_3), 0.94 ppm (s, 3H, —CH_3). *Anal.* calcd. for $C_{24}H_{32}O_5$: C 71.91, H 8.05; found: C 71.88, H 7.98.

Hydrogenation of Compound 11

Compound **11** (38 mg) was hydrogenated as described above for compound **10** to yield quantitatively compound **13** which was a waxy material homogeneous by tlc in several solvent systems; ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 3.95 (q, J = 11 Hz, J = 5 Hz, 1H, —CH—O—), 2.31 (s, 6H, two —$OCOCH_3$), 1.13 (s, 3H, —CH_3), 1.04 (s, 3H, —CH_3), 0.97 ppm (s, 3H, —CH_3). *Mol. Wt.* calcd. for $C_{24}H_{32}O_5$: 400.2256; found (high resolution mass spectroscopy): 400.2257.

Preparation of Compound 15

To a stirred solution of compound **12** (30 mg) in acetic anhydride (2 ml) precooled to −10°C was added freshly distilled boron trifluoride etherate (0.4 ml). The mixture was kept at −10°C with stirring for ½ h, after which it was poured into water and extracted with ether several times. The residue obtained after the combined extracts had been dried over anhydrous magnesium sulfate and evaporated in vacuo was purified by preparative tlc on silica gel. 22 mg (67%) of compound **15** was obtained as an oil homogeneous by tlc; ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^{1}H nmr ($CDCl_3$) δ: 2.36 (s, 3H, —$OCOCH_3$), 2.32 (s, 3H, —$OCOCH_3$), 2.23 (s, 3H, —$OCOCH_3$), 1.90 (broad s, 3H, —C=C—CH_3), 1.26 and 1.21 (two d, J = 6 Hz, 6H, isopropyl), 0.93 (s, 3H, —CH_3), 0.86 ppm (s, 3H, —CH_3); uv (EtOH) λ_{max}: 252 nm (ε 1.1 ×

10^4). *Mol. Wt.* calcd. for $C_{26}H_{34}O_6$: 442.2355; found (high resolution mass spectroscopy): 442.2355.

Preparation of Compound ***16***

Compound **16** was prepared from compound **13** by the same method described above for compound **15**. The yield was 69% and **16** was an oil homogeneous by tlc; ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^1H nmr ($CDCl_3$) δ: 2.36 (s, 3H, $-OCOCH_3$), 2.31 (s, 3H, $-OCOCH_3$), 2.23 (s, 3H, $-OCOCH_3$), 1.92 (broad s, 3H, $-C{=}C-CH_3$), 0.98 (t, 3H, $-CH_2CH_3$), 0.94 (s, 3H, $-CH_3$), 0.83 ppm (s, 3H, $-CH_3$); uv (EtOH) λ_{max}: 254 nm (ε 1.2×10^4). *Mol .Wt.* calcd. for $C_{26}H_{34}O_6$: 442.2355; found (high resolution mass spectroscopy): 442.2349.

Formation of Compound ***14***

Compound **14** was prepared from compound **8** under the same conditions as described above for the preparation of **15**. The yield was 70% and the oily compound **14** behaved homogeneously by tlc in several solvent systems; ir ($CHCl_3$): 1760 cm^{-1} (phenolic acetate); ^1H nmr ($CDCl_3$) δ: 4.81 (m, 1H, —CH—O—), 2.26 (s, 6H, two $-OCOCH_3$), 1.87 (broad s, 3H, $-C{=}C-CH_3$), 1.43 and 1.37 (two d, J = 6 Hz, 3H, $-CH-CH_3$), 0.87 (s, 3H, $-CH_3$), 0.80 ppm (s, 3H, $-CH_3$); uv (EtOH) λ_{max}: 251 (ε 8140), 298 nm (ε 3880). *Mol. Wt.* calcd. for $C_{24}H_{30}O_5$: 398.2099; found (high resolution mass spectroscopy): 398.2098.

Cleavage of Olefin ***15*** *to Diketone* ***19***

To a stirred solution of compound **15** (40 mg) in carbon tetrachloride (5 ml) precooled to −10°C was added dropwise a solution of ruthenium tetroxide prepared from 58% ruthenium dioxide (56 mg) in carbon tetrachloride (10 ml) and sodium metaperiodate (400 mg) in water (10 ml). The solution was stirred for 5 min, after which the black precipitate was removed by filtration. Evaporation of the filtrate to dryness resulted in a residue which was purified by preparative tlc on silica gel to give 28 mg (65%) of diketone **19** as a waxy material homogeneous by tlc; ir ($CHCl_3$): 1760 (phenolic acetate), 1740 (five-membered ring ketone), 1700 cm^{-1} (acyl ketone); ^1H nmr ($CDCl_3$) δ: 2.50 (s, 3H, $-COCH_3$), 2.46 (s, 3H, $-OCOCH_3$), 2.33 (s, 3H, $-OCOCH_3$), 2.27 (s, 3H, $-OCOCH_3$), 1.25 (d, J = 6 Hz, 6H, isopropyl), 1.18 (s, 3H, $-CH_3$), 0.80 ppm (s, 3H, $-CH_3$). *Mol. Wt.* calcd. for $C_{26}H_{34}O_8$: 474; found (mass spectroscopy): 474.

Preparation of Diketone ***20***

Olefin **16** (21 mg) was oxidized with ruthenium tetroxide under the same conditions as described above for compound **15** to give 13 mg (59%) of diketone **20** as a thick oil; ir ($CHCl_3$): 1760 (phenolic acetate), 1740 (five-membered ring ketone), 1700 cm^{-1} (acyl ketone); ^1H nmr ($CDCl_3$) δ: 2.50 (s, 3H, $-COCH_3$), 2.44 (s, 3H, $-OCOCH_3$), 2.31 (s, 3H, $-OCOCH_3$), 2.25 (s, 3H, $-OCOCH_3$), 1.13 (s, 3H, $-CH_3$), 0.94 (t, 3H, $-CH_2CH_3$), 0.83 ppm (s, 3H, $-CH_3$). *Mol. Wt.* calcd. for $C_{26}H_{34}O_8$: 474; found (mass spectroscopy): 474.

Preparation of Diketone ***18***

Olefin **14** (24 mg) was oxidized using the same method described above for compound **15** to yield 14 mg (54%) of ketone **18** as an oil which behaved homogeneously by tlc; ir ($CHCl_3$): 1760 (phenolic acetate), 1740 (five-membered ring ketone), 1705 cm^{-1} (acyl ketone); ^1H nmr ($CDCl_3$) δ: 4.92 (m, 1H, —CH—O), 2.47 (s, 3H, $-COCH_3$), 2.26 (s, 6H, two $-OCOCH_3$), 1.45 (d, J = 6 Hz, 3H, $-CH-CH_3$), 1.13 (s, 3H, $-CH_3$), 0.80 ppm (s, 3H, $-CH_3$). *Mol. Wt.* calcd. for $C_{24}H_{30}O_7$: 430; found (mass spectroscopy): 430.

Acetoxyroyleanone

Photolysis of 7-Acetoxyroyleanone ***5***

A solution of 7-acetoxyroyleanone **5** (300 mg) in anhydrous dimethoxyethane (150 ml) was irradiated using a 200 W medium pressure Hanovia mercury lamp with a Pyrex filter under argon at about −10°C for 7 h. Acetic anhydride (5 ml) and pyridine (10 ml) were immediately added to the reaction mixture and the solution was left overnight under argon. Removal of the solvent and usual work-up gave 320 mg of residue. Analysis of the residue by tlc on silica gel using 15% ether in benzene as developing solvent indicated that it consisted of two major products **21** and **22**, and two minor components **23** and **24**. Chromatography by preparative tlc on silica gel effected separation of the products. There was obtained 124 mg of starting material as its acetate, 92 mg of compound **21**, 102 mg of compound **22**, 26 mg of compound **23**, and 31 mg of compound **24** as thick oils. They behaved homogeneously by tlc in several solvent systems. The total yield was 65%.

Compound ***21***—ir ($CHCl_3$): 1770 (phenolic acetate), 1730 cm^{-1} (acetate); ^1H nmr ($CDCl_3$) δ: 6.03 (broad s, 1H, proton deshielded by acetoxyl), 5.27 and 4.92 (two broad s, 2H, vinylic protons), 2.32 (s, 6H, two acetoxy methyls), 2.23 (s, 3H, acetoxy methyl), 1.92 (broad s, 3H, vinylic methyl), 1.26 (s, 3H, tertiary methyl), 0.91 ppm (s, 6H, two tertiary methyls). *Mol. Wt.* calcd. for $C_{28}H_{36}O_8$: 500.2410; found (high resolution mass spectroscopy): 500.2412.

Compound ***22***—ir ($CHCl_3$): 1770 (phenolic acetate), 1728 cm^{-1} (acetate); ^1H nmr ($CDCl_3$) δ: 6.03 (broad s, 9H, proton deshielded by acetoxyl), 5.97 (d, J = 9 Hz, 1H, vinylic proton), 5.76 (m, 1H, vinylic proton), 2.30 (s, 3H, acetoxy methyl), 2.16 (s, 6H, two acetoxy methyls), 2.05 (s, 3H, acetoxy methyl), 1.83 (d, 3H, vinylic methyl), 1.25 (s, 3H, tertiary methyl), 0.90 ppm (s, 6H, two tertiary methyls). *Mol. Wt.* calcd. for $C_{28}H_{36}O_8$: 500.2410; found (high resolution mass spectroscopy): 500.2413.

Compound ***23***—ir ($CHCl_3$): 1772 cm^{-1} (phenolic acetate); uv (EtOH) λ_{max}: 225 (ε 11 600), 362 nm (ε 4650); ^1H nmr ($CDCl_3$) δ: 6.31 (m, 2H, vinylic protons), 5.25 and 4.90 (two broad s, 2H, vinylic protons), 2.36 (s, 3H, acetoxy methyl), 2.30 (s, 6H, two acetoxy methyls), 1.98 (broad s, 3H, vinylic methyl), 1.15 (s, 3H, tertiary methyl), 1.03 (s, 3H, tertiary methyl), 0.98 ppm (s, 3H, tertiary methyl). *Mol. Hydrogenation of Compound ***23*** *to the Tetrahydroderivative* ***7***

Compound **23** (30 mg) was hydrogenated in methanol (10 ml) with 10% palladium-on-charcoal (30 mg) for 4 h. The palladium-on-charcoal was filtered off and the methanolic solution was evaporated to dryness. The product **7** was crystallized from ethanol and melted at 129°C. The yield was quantitative. Identity was established by comparison with an authentic sample in all respects (mp, ir, nmr); ir ($CHCl_3$): 1770 cm^{-1} (phenolic acetate); ^1H nmr ($CDCl_3$) δ: 2.34 (s, 3H, acetoxy methyl), 2.30 (s, 6H, two acetoxy methyls), 1.26 (s, 3H, tertiary methyl), 1.15 (d, J = 5 Hz, 6H, isopropyl), 0.93 ppm (s, 6H, two tertiary methyls). *Anal.* calcd. for $C_{26}H_{36}O_6$: C 70.24, H 8.19; found: C 70.15, H 8.24.

Hydrogenation of Compound ***24*** *to the Tetrahydroderivative* ***29***

Compound **24** (20 mg) was hydrogenated under the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

conditions used in the preparation of **7**. Crystallization from ethanol–water yielded **29**, mp 94°C, in a quantitative yield; ir ($CHCl_3$): 1770 cm^{-1} (phenolic acetate); ^1H nmr ($CDCl_3$) δ: 2.36 (s, 3H, acetoxy methyl), 2.26 (s, 6H, two acetoxy methyls), 1.24 (s, 3H, tertiary methyl), 0.91 (s, 6H, two tertiary methyls), 0.89 ppm (t, 3H, methyl). *Anal.* calcd. for $C_{26}H_{36}O_6$: C 70.24, H 8.19; found: C 70.36, H 8.24.

Hydrogenation of Compound 21

Compound **21** (100 mg) was hydrogenated in methanol (15 mg) with 10% palladium-on-charcoal overnight. The product was a mixture of two compounds which could be separated by preparative tlc on silica gel to yield the crystalline compound **7** (11 mg, 13%) and compound **25** (82 mg, 80%). Compound **25** was recrystallized from ethanol and showed mp 172°C.

Compound 25—ir ($CHCl_3$): 1770 (phenolic acetate), 1730 cm^{-1} (acetate); ^1H nmr ($CDCl_3$) δ: 5.97 (broad s, 1H, proton deshielded by acetoxyl), 2.30 (s, 9H, three acetoxy methyls), 2.03 (s, 3H, acetoxy methyl), 1.24 (s, 3H, tertiary methyl), 1.13 (d, J = 6 Hz, 6H, isopropyl), 0.89 ppm (s, 6H, two tertiary methyls). *Anal.* calcd. for $C_{28}H_{38}O_8$: C 66.99, H 7.63; found: C 67.06, H 7.70.

Hydrogenation of Compound 22

Compound **22** (48 mg) which was hydrogenated under the same conditions used for **21** yielded a mixture of two compounds. Preparative tlc on silica gel resulted in separation of the mixture to give 6 mg (14%) of crystalline compound **29** and 38 mg (80%) of compound **27**. Crystallization of **27** from ethanol–water gave an analytical sample, mp 144–146°C.

Compound 27—ir ($CHCl_3$): 1770 (phenolic acetate), 1730 cm^{-1} (acetate); ^1H nmr ($CDCl_3$) δ: 5.89 (broad s, 9H, proton deshielded by acetoxyl), 2.20 (s, 9H, three acetoxy methyls), 1.99 (s, 3H, acetoxy methyl), 1.21 (s, 3H, tertiary methyl), 0.92 (s, 6H, two tertiary methyls), 0.90 ppm (t, 3H, methyl). *Anal.* calcd. for $C_{28}H_{38}O_8$: C 66.99, H 7.63; found: C 67.12, H 7.74.

Conversion of Compound 25 to 7-Dehydroroyleanone 26

A mixture of compound **25** (40 mg) and *p*-toluenesulfonic acid (140 mg) in aqueous methanol (10 ml) was heated under reflux and under nitrogen for 2 days. The reaction mixture was diluted with water and extracted with chloroform three times. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a reddish brown residue. Purification by preparative tlc on silica gel and recrystallization from ethanol–water yielded the product **26** (11 mg, 48%), mp 168°C, and unchanged on admixture with an authentic sample. Identity was also established by comparison of ir, nmr, and tlc.

Conversion of Compound 27 to the Quinone Derivative 28

Compound **27** (38 mg) was converted to compound **28** under the same conditions used in the preparation of **26**. There was obtained after purification and recrystallization from ethanol–water 12 mg (54%) of the quinone **28** as red needles, mp 93°C; ir ($CHCl_3$): 3380 (hydroxyl), 1640 cm^{-1} (carbonyl); uv (EtOH) λ_{max}: 214 (ε 15 300), 247 (ε 7344), 330 nm (ε 6579); ^1H nmr ($CDCl_3$) δ: 7.28 (s, 1H, hydroxyl, exchanged with D_2O), 6.70 (m, 2H, vinylic protons), 1.03 (s, 9H, three tertiary methyls), 0.96 ppm (t, 3H, methyl). *Anal.* calcd. for $C_{20}H_{26}O_3$: C 76.46, H 8.34; found: C 76.58, H 8.41.

Royleanone Ether

Royleanone Methyl Ether (6) in Benzene

A solution of 316 mg of royleanone methyl ether **6** in 80 ml of dry benzene was flushed with argon, then irradiated at ca. 15°C for 6 h in a Rayonet apparatus using lamps with radiation peaked at 254 nm in a Corex vessel. After evaporation of the solvent the residue crystallized from methanol solution. The material from the mother liquor was separated on a 1000 μ, 20 × 20 cm plate using benzene for development. The crystals from methanol and the fastest moving yellow zone were recovered **6** (153 mg). A fast moving mauve zone was shown by mp and ^1H nmr spectrum to be royleanone (28 mg, 18%). The zone with lowest R_f was faintly colored but visible under uv light. It was rich in oxetanol **33** (82 mg, 50%). No other products could be characterized.

A comparable run was made using 207 mg of royleanone ether **6** under argon (7 h), then the products were acetylated by addition of 5 ml of acetic anhydride and 5 ml of pyridine followed by standing overnight at room temperature under argon. Unchanged ether (55 mg) was recovered, and 6 mg of royleanone acetate **1** (R = Ac) and 52 mg of oxetanol **33** isolated following preparative tlc. The photolysis rate was slower but the products identical when lamps peaked at 300 nm were used.

Oxetanol 33

This was purified by preparative tlc separation using 5% methanol in chloroform for development. It crystallized from hexane, mp 162–163°C, $[\alpha]_D$ +80° (*c*, 1.77, ethanol); ν_{max} 3570, 3360, 1710 and 1622 cm^{-1}; λ_{max} 248 (ε 11 700) and 316 nm (ε 1800); Raman spectrum ($CHCl_3$) ν_{max}: 1717 (m) and 1631 (s) cm^{-1}; ^1H nmr δ: 4.88 (1H, d, J = 5 Hz) and 5.15 (1H, d, J = 5 Hz), 4.3 (1H, s, OH), 2.7 (1H, m, —C*H*$(CH_3)_2$), 1.45 (3H, s), 1.18 (6H, d, J = 8 Hz), 0.95 (6H, s); ^{13}C nmr δ: 188.6 (s), 179.3 (s), 153.9 (s), 135.9 (s), 116.1 (s), 84.35 (t), 75.07 (s), 49.5 (m), 41.7 (m), 38.6, 36.7 (m), 33.4 (s + q), 24.5, 21.9, 21.35, 21.1, 20.65, 18.6, 18.0; ms *m/e*: 330 (M^+), 315, 298, 297, 288, 287, 219, and 193. *Anal.* calcd. for $C_{21}H_{30}O_3$: C 76.32, H 9.15; found: C 76.41, H 9.25. The compound was inert to acetic anhydride – pyridine (1:1) at room temperature. When quite pure **33** was purified by separation on a SiO_2 plate using benzene, no royleanone was produced.

Forty-eight milligrams of **33** was added under argon to a mixture of 2 ml of pure dioxane, 1 ml of water, and 100 mg of potassium hydroxide (two phases). The mixture was maintained at 60°C under argon for 1 h. The dioxane-rich phase became purple. The mixture was cooled, acidified, then evaporated to small volume under reduced pressure. Water was added then the products extracted into methylene chloride. After a wash with sodium bicarbonate solution the methylene chloride solution was dried and distilled. The residue was placed on a 500 μ, 20 × 20 cm plate and developed with benzene. The fastest moving zone (brownish-mauve, R_f 0.5) gave 14 mg of yellow material which gave crystals from methanol, mp 165°C. This was recrystallized from acetone–hexane as thin plates recrystallizing to laths at around 150°C, mp 173°C. This gave no mp depression with but gave identical ir and ^1H nmr spectra to those of royleanone.

Royleanone Methyl Ether 6 in Acetic Acid

Royleanone methyl ether (397 mg) in 160 ml of dry acetic acid flushed with argon was irradiated in a Rayonet apparatus with lamps peaked at 254 nm for 2.25 h. The solution was then evaporated to dryness at 40°C on a rotating evaporator. The solution of the residue in 20 ml of methylene chloride was stirred vigorously in air for 45 min. It was then washed with sodium bicarbonate solution, dried and distilled. The nmr spectrum of the products showed the presence of methylenedioxy phenol **30** (R = H) but the acetoxymethoxy compound was not clearly evident. The total product was acetylated overnight at room temperature using 2 ml of acetic anhydride and 2 ml of pyridine. The resulting brown gum was adsorbed on a column of 30 g of tlc silica gel and developed with methylene chloride. Fifteen 15-ml fractions were collected. The first five fractions contained 210 mg, including all the recognizable products. These were purified further by preparative tlc (CH_2Cl_2) giving in decreasing order of R_f 104 mg of methy-

For personal use only.

lenedioxy acetate **30** (R = Ac), 20 mg of royleanone acetate (5%), and 43 mg of acetoxymethoxy quinone **31** (10%).

In a photolysis experiment similar to the above, 125 mg of methyl ether **6** in 40 ml of dry acetic acid was irradiated for 2 h. The product was worked up *without* acetylation, giving 27 mg of the methylenedioxyphenol **30** (R = H) (21%) and 29 mg of the acetoxymethoxyquinone **31** (20%).

Royleanone Methyl Ether in Acetic Acid – Acetic Anhydride

A solution of 224 mg of methyl ether **6** in 50 ml of acetic acid and 20 ml of acetic anhydride was irradiated using 254 nm lamps for 65 min under argon. The solvents were evaporated at 45°C under reduced pressure, then the residue dissolved in methylene chloride and washed with sodium bicarbonate. The resulting mixture was separated on a 1000 μ, 20 × 20 cm plate giving in order of decreasing R_f 80 mg of starting material, 43 mg (26%) of methylenedioxy acetate **30** (R = Ac), 36 mg of acetoxymethoxy quinone **31** (25%), and 15 mg (9%) of the monoacetate of dihydroroyleanone methyl ether **32** (R = Ac).

*Methylenedioxy Acetate **30** (R = Ac)*—This was only obtained as a glass, distilling over a short path at 120°C, 5×10^{-4} Torr; ν_{max} 1750 cm^{-1}; ^1H nmr δ: 5.9 (2H, s), 2.45–3.2 (4H), 2.3 (3H, s), 1.32 (3H, s), 1.23 (6H, d, J = 8 Hz), 0.92 (6H, s); ^{13}C nmr δ: 169.6, 143.7, 142.3, 140.4, 130.3, 121.6, 120.7, 99.9, 51.2, 41.6, 38.2, 36.8, 33.5, 26.2, 21.8, 21.0, 20.5, 19.1, and 18.5 ppm. *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.16, H 8.66; found: C 73.96, H 8.73. The acetate was recovered unchanged from 19 h in solution in 3 ml of methanol containing 0.1 ml of 70% perchloric acid.

*Methylenedioxy Phenol **30** (R = H)*—Potassium carbonate (200 mg) was added to a solution of 100 mg of methylenedioxy acetate **30** (R = Ac) in 5 ml of methanol containing 0.2 ml of water under argon. The mixture was stirred for 2 h under argon, then evaporated to small volume under reduced pressure. The residue was taken up in water, nearly neutralized, then extracted with methylene chloride. The 86 mg of orange gum recovered was a complex mixture by tlc. It was separated on a 20 × 20 cm, 1000 μ plate using double development with benzene. A yellow front zone gave 43 mg of quite pure **30** (R = H). It was followed by a mauve zone (19 mg) which crystallized and had the same R_f and ^1H nmr spectrum as royleanone; ν_{max}: 3600, 1420, 1065, 967, and 875 cm^{-1}; ^1H nmr δ: 6.85 (broad singlet, sharpening when D_2O added), 4.4 (broad s, OH), 3.3 (1H, m), 1.42 (3H, s), 1.30 (6H, s), 1.00 (3H, s), 0.97 (3H, s). The phenol was not appreciably acetylated after 40 h at room temperature in 1:1 acetic acid – acetic anhydride.

*Acetoxymethoxy Quinone **31***—This was obtained as a yellow glass, distilling at 120°C over a short path under 5×10^{-4} Torr; ν_{max}: 1755 and 1650 cm^{-1}; λ_{max}: 273 (ε 1.41×10^4) and 363 nm (ε 330); ^1H nmr δ: 5.9 (1H, d, J = 6 Hz), 5.6 (1H, d, J = 6 Hz), 3.2 (1H, m), 2.12 (3H, s), 1.33 (3H, s), 1.19 (6H, d, J = 7 Hz), 0.93 (6H, s); ^{13}C nmr spectrum had signals at 142.9, 135.8, 87, 51.5, 41.5, 38.7, 36.2, 33.5, 25.7, 24.9, 21.9, 20.7, 20.5, 20.35, 19.0, 17.5 ppm (carbonyl and some olefinic carbons not recorded due to slow relaxation). *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.10, H 8.30; found: C 71.15, H 8.30.

When 27 mg of **31** was added to 3 ml of methanol and 0.5 ml of water containing 100 mg of potassium hydroxide under argon an immediate purple color developed. After 1 h at room temperature the solution was evaporated, water added followed by dilute sulfuric acid to neutralize the base. The yellow product extracted by methylene chloride (25 mg) crystallized spontaneously. After one recrystallization from aqueous methanol it had mp 179°C. This had the same R_f (C_6H_6) as royleanone and gave no mp depression when mixed with it.

*Dihydroroyleanone Methyl Ether Monoacetate **32** (R = Ac)* This was a nearly colorless glass; ν_{max}: 3515 and 1755 cm^{-1}; ^1H nmr δ: 5.9 (1H, s, OH), 3.77 (3H, s), 3.0–3.6 (2H, m), 2.32 (3H, s), 1.35 (3?H, s), 0.94 (6H, s). The signals for the isopropyl methyl groups seemed to be split into a pair of doublets due to restricted rotation. The monoacetate **32** (R = Ac) was only partially converted to a diacetate in acetic anhydride – pyridine at room temperature in 18 h.

A solution of 75 mg of royleanone methyl ether **6** in 3 ml of acetic anhydride containing 30 mg of Adams' platinum oxide catalyst was shaken in a hydrogen atmosphere until colorless. The solution and apparatus was flushed with argon then 0.5 ml of pyridine added. After 19.5 h at room temperature the solution was filtered and evaporated. A solution of the residue in methylene chloride was washed with sodium bicarbonate solution, dried and distilled. The products were separated on a 1000 μ, 20 × 20 cm plate using chloroform. Methyl ether diacetate (δ: 3.73 (3H, s) and 2.37 (6H, s)) (48 mg) and methyl ether monoacetate (28 mg) were obtained. The latter gave a ^1H nmr spectrum identical to the photolysis product described above.

Time resolved fluorescence of aqueous tryptophan[1]

D. M. RAYNER AND A. G. SZABO

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 1, 1977

D. M. RAYNER and A. G. SZABO. Can. J. Chem. **56**, 743 (1978).

The fluorescence decay of aqueous tryptophan is shown to be described by a two exponential decay function whose components have life-times of 3.14 ns and 0.51 ns. These components are assigned as the solvent equilibrated ^1L_a and ^1L_b states respectively. The time-resolved emission spectra are presented and can be resolved into two spectra with λ_{max} at 350 nm and 335 nm corresponding to these two states.

D. M. RAYNER et A. G. SZABO. Can. J. Chem. **56**, 743 (1978).

La décroissance de la fluorescence du tryptophane en solution aqueuse peut être décrite par une fonction de décroissance à deux exponentielles dont les composantes possèdent des temps de vie de 3.14 ns et 0.51 ns. On attribue respectivement ces composantes aux états ^1L_a et ^1L_b en équilibre avec le solvant. On présente les spectres d'émission résolus dans le temps et on peut les résoudre en deux spectres avec des λ_{max} à 350 nm et 335 nm correspondants à ces deux états.

[Traduit par le journal]

The fluorescence properties of the amino acid L-tryptophan and its parent indole ring system have been widely investigated both because of their intrinsic interest and their importance in the interpretation of the fluorescence properties of peptides and proteins.

The fluorescence lifetime of tryptophan in neutral aqueous solution has been reported by workers using instruments of varying degrees of sophistication, to exhibit single exponential decay with a lifetime of $\sim$3 ns (1–6). We have recently developed a fluorescence lifetime system and technique with the express purpose of obtaining data accurate enough to allow the confident determination of multi-exponential decay parameters (7, 8). We can now show that the fluorescence of L-tryptophan in neutral aqueous solution decays by a double exponential process.

The lifetime system was identical to that described previously (7) except a thermostated sample block was used. Solutions were deoxygenated by bubbling with nitrogen. The ratio correction technique developed to correct for the variation of the instrumental time-response function with wavelength (8) was used in all the experiments. Deconvolution was carried out using a non-linear least-squares fitting procedure (9). The quality of fit, and hence our confidence in the decay model and parameters found, was judged primarily by the inspection of weighted residual plots (7, 8). Our instrument and techniques were tested by measuring the fluorescence decay of the scintilator PPD in ethanol for which our confidence criteria were well met, as required, by a single exponential model ($\tau = 1.35 \pm 0.04$).

When we measured the fluorescence decay of L-tryptophan in cacodylate buffer, pH = 7, at 20°C, with $\lambda_{ex} = 280$ nm we found that our confidence criteria required a double exponential function for an adequate fit in the emission wavelength range 310–370 nm. Our results show that the lifetimes are similar at all wavelengths but the ratio of pre-exponentials increases with wavelength and is always positive until at 380 nm only single exponential behaviour is found (Table 1). The recurrence of the same two lifetimes with changing emission wavelength allows us to state that the double exponential decay represents a physical model for the decay process and is not arbitrary mathematical curve fitting. While our experience with the instrument and with the correction and deconvolution procedures gave us a high degree of confidence in these results, the significance of our observations demanded that artifactual explanations be eliminated. We found that similar results were obtained using L-tryptophan from several sources; using samples without prior purification; using samples after several recrystallizations from either water or water–ethanol solutions; and using samples in phosphate rather than cacodylate buffer. Sample decomposition was imperceptible using spectrophotometric and fluorimetric measurements. We confirmed that there was negligible scattered light.

The mean lifetime of the long-lived component is

[a]20°C, pH 7; $\lambda_{ex} = 280$ nm; weighted mean $\tau_1 = 3.13 \pm 0.02$, $\tau_2 = 0.51 \pm 0.04$.

3.13 ± 0.2 ns, the same as the single exponential lifetime found at 380 nm. The mean lifetime of the short-lived component is 0.51 ± 0.04 ns. The fluorescence decay was also measured with $\lambda_{em} = 330$ nm at two other excitation wavelengths, 265 nm and 300 nm. Double exponential decay with the same kinetic parameters as at $\lambda_{ex} = 280$ nm were found in both cases showing that the decay is independent of excitation wavelength. Time resolved spectra have been generated from the decay curves and show a shift to lower energy with time (Fig. 1).

Several physical models which include two excited states or species have been suggested earlier to explain the steady state fluorescence properties of indoles. The concept of a solvent exiplex (10, 11) has been presented to explain the large Stokes shift observed for indole in water ($\lambda_{max} = 350$ nm) compared with non-polar solvents ($\lambda_{max} = 305$ nm). The emission observed at 350 nm in water where none is seen in non-polar solvents is assumed to be due to the exiplex. However, such a system requires that in the spectral region where the exiplex fluorescence predominates the pre-exponentials must be equal but opposite. This is not the case. We favour a physical model based on concepts suggested by other workers (12–16) involving two separate solvent stabilized states. We suggest excitation of tryptophan to its manifold of excited singlet states results in rapid partitioning between the coupled ^1L_a and ^1L_b states which initially have a solvent environment similar to the ground state. While both states have dipole moments which differ from the ground state, the dipole moment change of the ^1L_a state is substantial and solvent relaxation results in the solvent relaxed ^1L_a state being below the ^1L_b state. The population

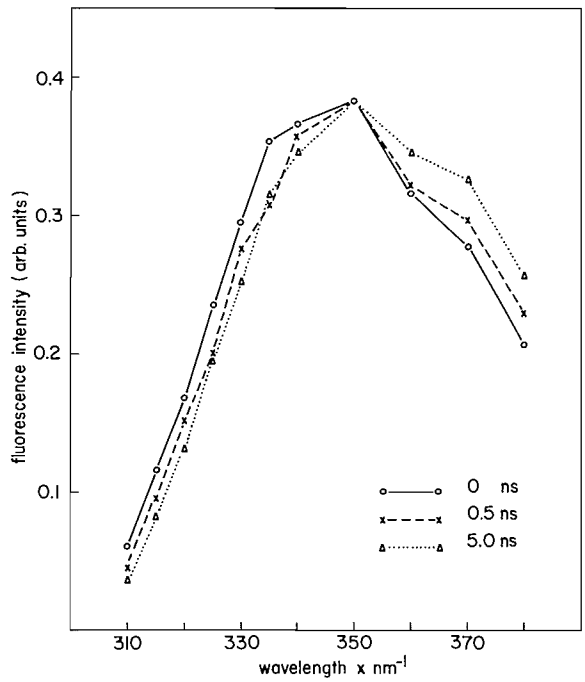

FIG. 1. Time-resolved emission spectra at $t = 0$, 0.5, and 5 ns of aqueous tryptophan normalized to the peak at 350 nm.

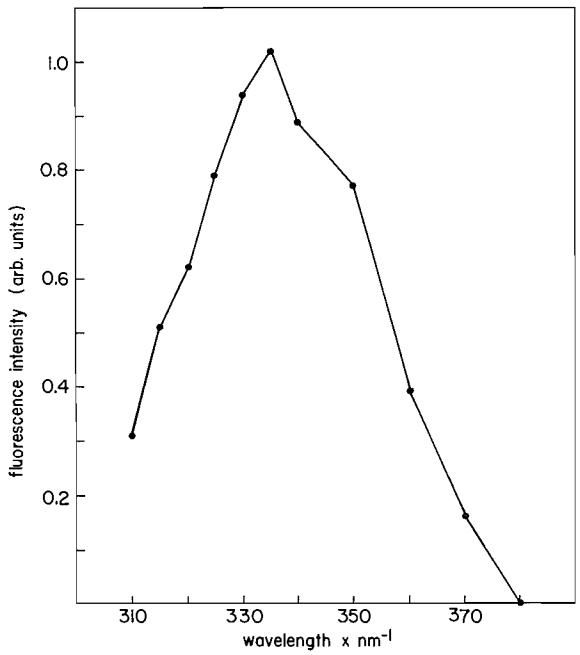

FIG. 2. Calculated (see text) emission spectrum of the fast decay component ($\tau = 0.51$ ns) at $t = 0$ ns.

distribution of the two states is dependent on the initial distribution prior to solvent reorientation after which the two states are no longer readily interconvertible. Hence double exponential decay is observed with the pre-exponentials depending on the overlap of the emission bands of the two solvent re-

laxed states. We can generate the spectrum of the short-lived component from the time resolved spectra assuming only the long-lived component emits at 380 nm (Fig. 2). We find the short-lived component has $\lambda_{max} = 335$ nm. This short-lived component we assign to the solvent equilibrated ^1L_b state. The long-lived component with $\lambda_{max} = 350$ nm we assign to the ^1L_a state.

In conclusion we have demonstrated the double exponential decay of tryptophan fluorescence in aqueous solution. This result can be explained most simply by a model involving two non-interconvertible states which we suggest are the solvent relaxed ^1L_a and ^1L_b states. To confirm or reject this proposal we are currently investigating the effect of temperature and solvent on the fluorescence decay of tryptophan and other indoles. On the other hand our results have implications in the interpretation of protein fluorescence. Current interest in the heterogeneity of protein fluorescence (17) makes the observations of double exponential decay from tryptophan in solution especially important.

Relationship between Taft and Kirkwood–Westheimer equations

BO-LONG POH

School of Chemical Sciences, Universiti Sains Malaysia, Penang, Malaysia

Received July 29, 1977

BO-LONG POH. Can. J. Chem. **56**, 747 (1978).

The relationship between Taft and Kirkwood–Westheimer equations has been derived with the use of the modified MacInnes equation.

BO-LONG POH. Can. J. Chem. **56**, 747 (1978).

Faisant appel à une équation modifiée de MacInnes, on a déduit la relation qui existe entre les équations de Taft et de Kirkwood–Westheimer.

[Traduit par le journal]

Introduction

Two approaches have been used by chemists to correlate the reactivities of molecules with their structures, one based upon fundamental theory and the other purely empirical. The Kirkwood–Westheimer cavity model (1) represents the first approach and Taft equation (2) the second approach, in the correlation of substituent effects upon the ionizations of organic acids in which polar effect is the only contribution. Attempts have been made to give theoretical interpretations (3, 4) to the empirical Taft equation to understand its successes and failures, but the relationships between the parameters of Taft equation (eq. 2) and those of Kirkwood-Westheimer equations (eqs. 5, 6) still remain unsolved. We report in this paper the relationships between them.

Results and Discussion

In an earlier paper (5) we have shown the relationship between our modified MacInnes equation (eq. 1) and Taft equation. The parameter S is related to σ^* in the form of eq. 3 and l_1^2/l^2 related to ρ^* in the form of eq. 4 (S is an empirical constant, l is the distance between the substituent and the ionizing proton, and l_1 refers to this distance in XCH_2-COOH). Equation 1 is also related to Kirkwood–Westheimer eqns. (e refers to the electronic charge, μ is the dipole moment, θ is the angle between the dipole axis and the line joining the reaction site to the dipole, D_e is the effective dielectric constant, k is Boltzmann constant, and T is the absolute temperature). For charged substituents the relationship is

$$[1] \quad pK_a - pK_0 = Sl_1^2/l^2$$

$$[2] \quad pK_a - pK_0 = -\sigma^* \rho^*$$

$$[3] \quad \sigma^* = -0.58S$$

$$[4] \quad \rho^* = 1.72l_1^2/l^2$$

$$[5] \quad pK_a - pK_0 = -e^2/(2.3kTD_e l)$$

for charged substituents

$$[6] \quad pK_a - pK_0 = -e\mu \cos\theta/(2.3kTD_e l^2)$$

for dipolar substituents

$$[7] \quad S = -e^2 l/(2.3kTD_e l_1^2)$$

for charged substituents

$$[8] \quad S = -e\mu \cos\theta/(2.3kTD_e l_1^2)$$

for dipolar substituents

given by eq. 7 which implies that for a given series of acids with the same charged substituent the factor l/D_e is a constant for a given medium and temperature. The results in Table 1 for some ω-substituted amino acids support this prediction. For dipolar substituents the relationship is given by eq. 8 which implies that $\cos\theta/D_e$ is a constant for a given series of acids with the same substituent in a given medium and temperature. The results in Table 2 for some

substituted carboxylic acids show qualitative agreement. The lack of better agreement is probably due to the fact that eqs. 1, 5, and 6 are not exact equations.

A comparison of eqs. 3, 7, and 8 suggests that it would be more consistent with Kirkwood–Westheimer's cavity model if Hammett (6) had originally defined the parameter σ (therefore σ*) as dependent on all the factors characterizing the reaction series instead of as a constant characteristic of the substituent only because eqs. 7 and 8 show the inverse proportionality between S (therefore σ*) and T and D_e. It would also be more consistent if the parameter ρ* were defined as independent of all the factors characterizing the reaction series instead of dependent on them because eq. 4 shows that ρ* could be expressed as inversely proportional to l^2 only. However, owing to Hammett's original arbitrary definitions of σ and ρ, the terms T and D_e for σ* (eqs. 7 and 8) refer to 25°C and water as the solvent respectively, and the inverse proportionality to T and D_e is transferred to the parameter ρ*. Similar conclusions regarding the inverse proportionality between ρ* and T and D_e have also been reported by several workers (4, 7–9). It is hoped that the relationship between Taft and Kirkwood–Westheimer equations given above will lead to better understanding and improvement of these equations and the Hammett equation as well.

Effect of hydrocarbon solutes on electron ranges and free ion yields in liquid xenon[1]

TOYOAKI KIMURA[2] AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 4, 1977

TOYOAKI KIMURA and GORDON R. FREEMAN. Can. J. Chem. **56**, 749 (1978).

The energy transfer efficiency ratio, ETE = $(\sigma_h \Delta E_h / \sigma_x \Delta E_x)$, for hydrocarbons dissolved in liquid xenon has the following values: ethane, 96; propane, 180; *n*-butane, 485; ethylene, 193; propylene, 255; *cis*-butene-2, 425; *trans*-butene-2, 665. The large increase on going from propane to butane is attributed to the energy absorption capability of the C_2H_5 groups through rotation about the central bond in butane. The presence of a double bond in the molecule enhances ETE, presumably through the participation of transient negative ion states in the energy transfer process. The *cis–trans* effect in butene-2 is still not understood.

TOYOAKI KIMURA et GORDON R. FREEMAN. Can. J. Chem. **56**, 749 (1978).

Les valeurs des rapports d'efficacité de transfert d'énergie ETE = $(\sigma_h \Delta E_h / \sigma_x \Delta E_x)$, pour des hydrocarbures dissous dans le xénon liquide sont les suivantes: éthane, 96; propane, 180; *n*-butane, 485; éthylène, 193; propylène, 255; butène-2 *cis*, 425; butène-2 *trans*, 665. On a attribué l'augmentation rapide qui se produit lorsque l'on passe du propane au butane à une capacité d'absorption de l'énergie des groupes C_2H_5 par l'intermédiaire d'une rotation autours du lien central du butane. La présence d'une double liaison dans la molécule augmente la valeur du rapport ETE probablement à cause d'une participation d'états ioniques négatifs de transition dans le processus de transfert d'énergie. On ne comprend toujours pas l'effet *cis–trans* dans le butène-2.

[Traduit par le journal]

Introduction

It has long been known that electrons move more freely in liquid argon than in liquid nitrogen or hydrocarbons (1–4). For many nonpolar substances the freedom of electron motion correlates approximately with the degree of sphericity of the molecules (5). Exceptions are helium (1, 6, 7) and neon (8–10), which have low polarizabilities, and substrates that capture electrons (1).

As a result of the relative freedom of motion, the penetration ranges of low energy electrons into the liquids argon, krypton, and xenon are an order of magnitude greater than those into nonspherical hydrocarbons (11, 12). It is of interest to study the rate at which addition of nonspherical hydrocarbons to a noble liquid decreases the electron penetration range. In this way information can be obtained about electron scattering by individual molecules in the liquid phase. Xenon is a convenient solvent to use for such measurements, because its normal boiling point (165 K) is sufficiently high that simple alkanes will not freeze in it.

Experimental

Materials and Sample Preparation

The hydrocarbons were Phillips research grade and the xenon was Linde research grade from Union Carbide Co. The materials were purified by techniques similar to those reported earlier (11, 12). Potassium mirrors were used for the final treatment of xenon, ethane, ethylene, and propylene, while liquid Na/K alloy (1/4 by weight) was used for the other compounds. The treatments with metal lasted one week, the mirrors being renewed under vacuum twelve times during that period.

The amounts of xenon and hydrocarbons used to make a solution were measured by PVT. They were mixed in the gas phase and condensed together into the conductance cell.

The cell used for xenon and the solutions is shown in Fig. 1*b* of ref. 11*a*, and that for the pure hydrocarbons is described in ref. 13.

The low temperature baths and the method of temperature control were similar to those described in ref. 14.

Determination of the Free Ion Yields

The free ion yields were measured by the charge clearing technique (12, 15). The pulse length was usually 100 ns, but was 1 μs for the pure hydrocarbons and the 70% hydrocarbon solutions. The respective pulse doses were 2×10^{10} and 1×10^{11} eV/g. Thermoluminescent dosimetry was normalized to a more accurate technique (12) that employed solid cesium iodide powder as "dummy xenon" in the cell, because it has an average atomic number equal and a density similar to that of liquid xenon.

Physical Properties of the Liquids

The densities and dielectric constants of the pure compounds were taken from refs. 11*b* and 13. These properties were assumed to be additive in the solutions.

Results

Free ion yields were measured at 168 and 192 K in xenon, in solutions containing 1, 2, 4, 10, 20, 40, and 70 mol% hydrocarbon, and in pure hydrocarbon. The

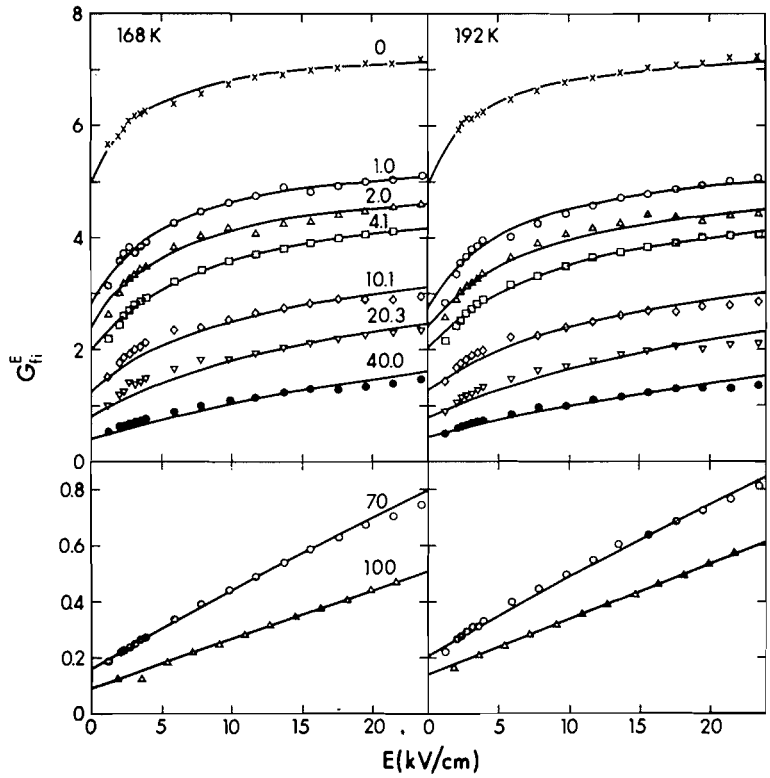

FIG. 1. Free ion yields in xenon/ethane solutions at 168 and 192 K. The numbers labelling the curves are mol% ethane. The solid curves were calculated from the model.

alkanes and olefins used were ethane, propane, *n*-butane, ethylene, propylene, *cis*-butene-2, and *trans*-butene-2.

Addition of 1 mol% of ethane to xenon caused the free ion yield to drop by about 35% (Fig. 1). Further additions decreased the yield monotonically. The yield extrapolated to zero applied field, G_{fi}^{0}, in pure ethane at 168 K was only 2% of that in pure xenon.

The behaviour was similar at 168 and 192 K (Fig. 1). The temperature was changed mainly in an attempt to detect phase separation in the solutions, if it should occur, because the sample in the thermostated box could not be monitored visually. No evidence of phase separation was obtained in any of the solutions.

Propane (Fig. 2) decreased the ion yields somewhat more than did ethane, and butane decreased it still further. To save space, the butane data are not displayed.

The effect of ethylene (Fig. 3) at low concentrations was similar to that of ethane. At higher concentrations ethylene caused a greater lowering of the free ion yield than did ethane, culminating in a tenfold difference between the yields in the pure olefin and alkane (Figs. 1 and 3).

Propylene (data not shown) behaved similarly to propane at low concentrations. The relative effect of propylene increased with concentration. In the pure liquids, G_{fi}^{0}(propane)/G_{fi}^{0}(propylene) = 3.8, in agreement with earlier work (11*b*).

There is a surprisingly large difference between the free ion yields in the *cis* and *trans* isomers of butene-2 (13). These compounds were therefore of particular interest to study in the xenon solutions. In accord with the preceding descriptions, the behavior of the two isomers was similar at low concentrations, but the *trans* compound caused progressively greater decreases of the free ion yields at high concentrations (Figs. 4 and 5).

Model

The most probable distance that the secondary electrons penetrate the liquid away from their geminate ions is denoted b_{GP} (13). Values of b_{GP} were estimated for each solution by fitting the results in Figs. 1–5, and those from the *n*-butane and propylene solutions, to the Onsager model (13, 16). The field dependence of the electron mobility in xenon (17) indicates that the geminate electrons would have energies greater than thermal at the ion–

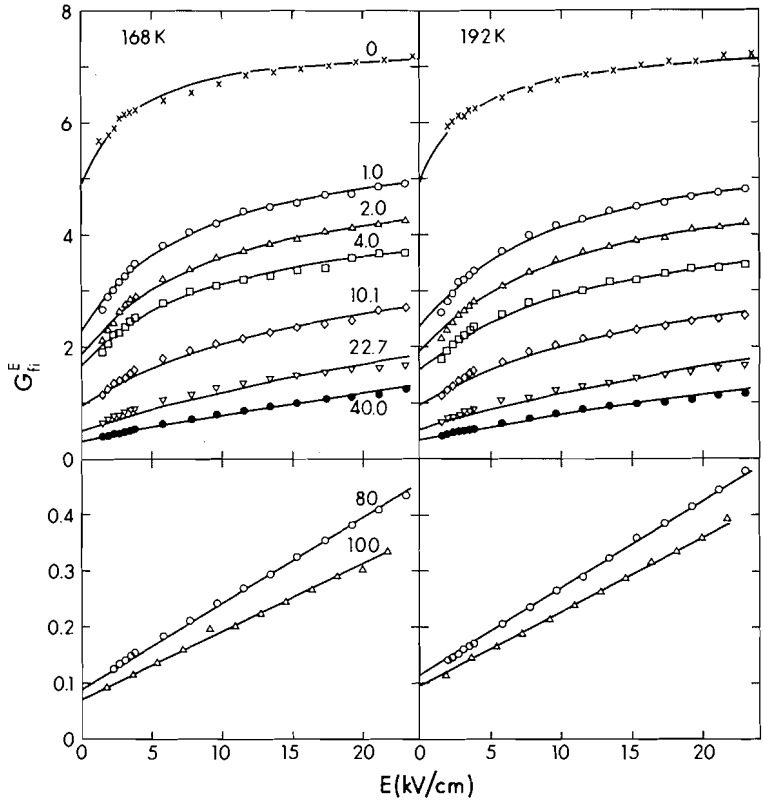

FIG. 2. Free ion yields in xenon/propane solutions at 168 and 192 K. The numbers labelling the curves are mol% propane. The solid curves were calculated from the model.

electron separation distances of major concern to us. However, the effect that the field-heating of the electrons has upon their escape probabilities depends upon the degree of anisotropy of the scattering, which is not known. Isotropic scattering would enhance the escape probability, whereas skew in the field direction would tend to favor recombination. For the lack of better knowledge, we assume that the field-heating effect does not greatly alter the escape probability that would be obtained in its absence.

Assumed values of G_{tot} varied from 3.9 for ethylene and 4.3 for *n*-butane (11*b*) to 7.4 for xenon (positive applied voltage (12)), with intermediate values for the solutions. The values obtained for b_{GP} are given in Fig. 6.

To simplify the following analysis of the secondary electron ranges b_{GP}, the parameter values that depend upon the solution composition, or on the electron energy and scattering angle, are assumed to be averages.

The first attempt was to use the model from ref. 15. However, it was found that it did not fit the results from the xenon/hydrocarbon solutions. The following analysis proved satisfactory.

During the thermalization of a secondary electron of initial energy E_0 it undergoes N_x collisions with xenon, losing energy ΔE_x per collision, and N_h collisions with the hydrocarbon, losing ΔE_h per collision. One can write:

$$[1] \qquad E_0 = N_x\Delta E_x + N_h\Delta E_h + 1.5kT \approx N_x\Delta E_x + N_h\Delta E_h$$

We represent the respective values of b_{GP} in pure xenon, pure hydrocarbon, and a solution as b_x, b_h, and b_s. Then assuming isotropic scattering (18):

$$[2] \qquad b_x \approx \sqrt{2N_x^0}/n_x^0\sigma_x$$

$$[3] \qquad b_h \approx \sqrt{2N_h^0}/n_h^0\sigma_h$$

$$[4] \qquad b_s \approx \sqrt{2N_s}/(n_x\sigma_x + n_h\sigma_h)$$

where n_x^0 and n_h^0 represent the respective numbers of molecules/cm^3, the superscript zeros indicate pure compounds, and

$$[5] \qquad N_s = N_x + N_h$$

Furthermore, the ratio N_x/N_h in a solution is related

For personal use only.

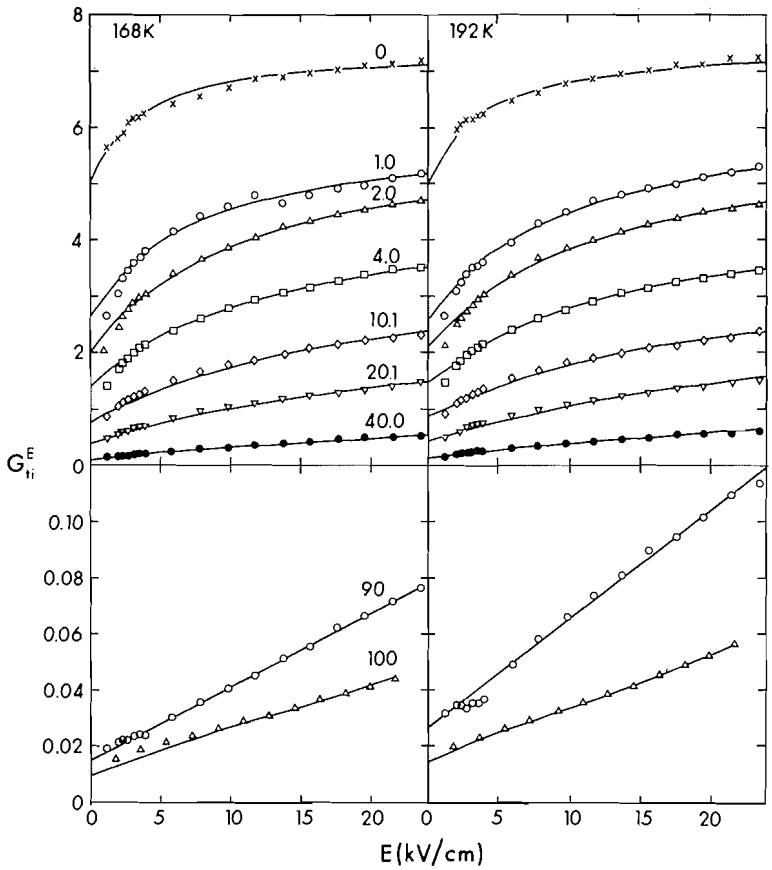

FIG. 3. Free ion yields in xenon/ethylene solutions at 162 and 192 K. The numbers labelling the curves are mol% ethylene. The solid curves were calculated from the model.

to the ratio of collision cross sections σ_x/σ_h through [6].

$$[6] \qquad N_x/N_h = n_x\sigma_x/n_h\sigma_h$$

From [1] and [6] one obtains

$$[7] \qquad N_h = \left(\frac{n_x\sigma_x}{n_h\sigma_h}\frac{\Delta E_x}{E_0} + \frac{\Delta E_h}{E_0}\right)^{-1}$$

and from [5]–[7]

$$[8] \qquad N_s = \left(\frac{n_x\sigma_x}{n_h\sigma_h} + 1\right)\Big/\left(\frac{n_x\sigma_x}{n_h\sigma_h}\frac{\Delta E_x}{E_0} + \frac{\Delta E_h}{E_0}\right)$$

Putting [8] in [4] gives

$$[9] \qquad b_s = \left[2\left(\frac{n_x\sigma_x}{n_h\sigma_h} + 1\right)\Big/\left(\frac{n_x\sigma_x}{n_h\sigma_h}\frac{\Delta E_x}{E_0} + \frac{\Delta E_h}{E_0}\right)\right]^{0.5} \times (n_x\sigma_x + n_h\sigma_h)^{-1}$$

To examine the behavior of [9] we make the gross assumptions that E_0, σ_x, and σ_h have similar values in the solutions and pure components. Then one may write

$$[10] \qquad \Delta E_x/E_0 = 1/N_x^0 = 2/(b_x n_x^0\sigma_x)^2$$

$$[11] \qquad \Delta E_h/E_0 = 1/N_h^0 = 2/(b_h n_h^0\sigma_h)^2$$

and

$$[12] \qquad b_s = \frac{[(n_r\sigma_r + 1)/(n_r\sigma_r E_x + E_h)]^{0.5}}{n_x\sigma_x + n_h\sigma_h}$$

where $n_r = n_x/n_h$, $\sigma_r = \sigma_x/\sigma_h$, $E_x = \Delta E_x/E_0$, and $E_h = \Delta E_h/E_0$.

Discussion

Iterative calculations were done with [12] by assigning values to σ_x and σ_r, and comparing calculated values of b_s with those obtained experimentally. The results were sensitive to the value of σ_r, but not to that of σ_x over a wide range. We therefore arbitrarily took $\sigma_x = 0.1$ Å^2, which is small due to diffraction effects. The 'best fit' values of $\sigma_r^{-1} = \sigma_h/\sigma_x$ are listed in Table 1 and the corresponding curves are displayed in Fig. 6.

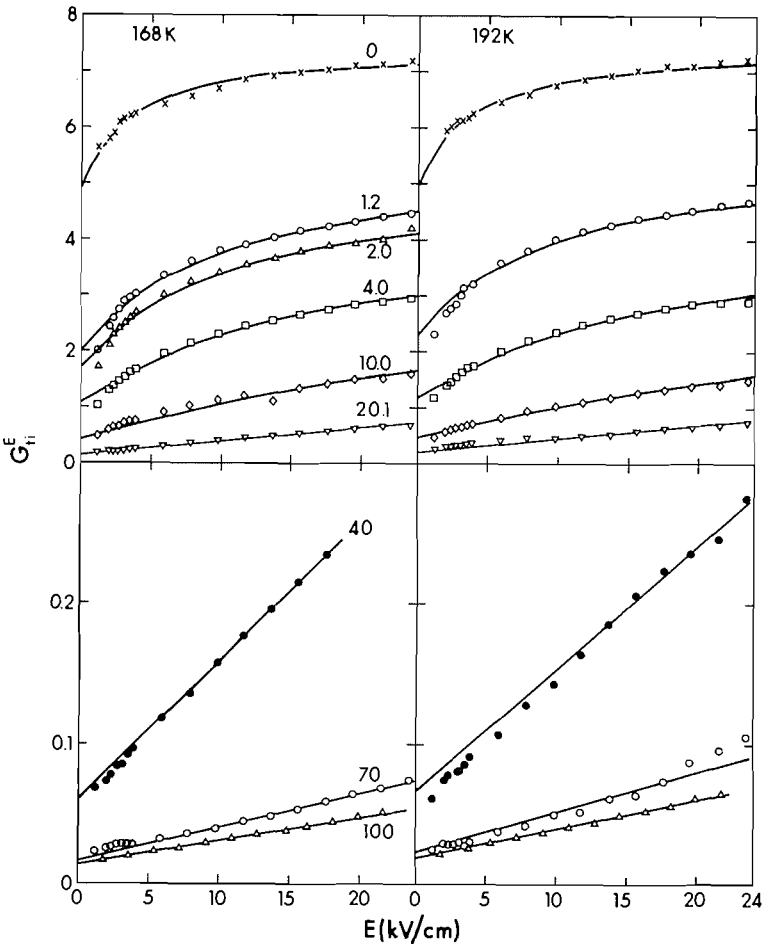

FIG. 5. Free ion yields in xenon/*trans*-butene-2 solutions at 162 and 192 K. The numbers labelling the curves are mol% *trans*-butene-2. The solid curves were calculated from the model.

Values of the energy transfer ratio $\Delta E_h/\Delta E_x$ were calculated from [13].

$$[13] \qquad \Delta E_h/\Delta E_x = (b_x n_x \sigma_x / b_h n_h \sigma_h)^2$$

This ratio is one to two orders of magnitude larger than the cross section ratio σ_h/σ_x (Table 1). However, there are variations within the series that may be associated with shortcomings of the model. At the present state of development a more dependable parameter is the over-all energy transfer efficiency ratio ETE, the product of the cross section and energy transfer ratios:

$$[14] \qquad \mathrm{ETE} = \frac{\sigma_h \Delta E_h}{\sigma_x \Delta E_x} = \frac{\sigma_x}{\sigma_h}\left(\frac{b_x n_x}{b_h n_h}\right)^2$$

Values of ETE range from about 100 in ethane to about 700 in *trans*-butene-2 (Table 1). The large values are related to the energy absorption capability of the vibrational and rotational modes of the polyatomic molecules.

The energy transfer efficiency doubles on going from ethane to propane, and more than doubles again on going to butane. The large increase between propane and butane is attributed to the rotation of the C_2H_5 groups about the central bond in butane.

Addition of a double bond to the molecule doubles ETE in the C_2 compounds and has smaller proportionate effects in the larger molecules (Table 1). The enhancement is attributed to energy transfer by way of transient negative ion states. The value of ETE for *cis*-butene-2 is *smaller* than that for *n*-butane, while that in *trans*-butene-2 is larger. This *cis–trans* effect was noted earlier (13, 19), but is still not understood. It seems to be related to the ease of rotation of the molecules in the liquid.

Effect of hydrocarbon solutes on electron mobilities in liquid xenon[1]

TOYOAKI KIMURA[2] AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 16, 1977

TOYOAKI KIMURA and GORDON R. FREEMAN. Can. J. Chem. **56**, 756 (1978).

Ethylene, propylene, *cis*-butene-2, *trans*-butene-2, ethane, propane, and *n*-butane were added to xenon at 168 and 192 K. At concentrations up to 4 mol%, electrons were scattered by one hydrocarbon molecule at a time and a gas phase model was used to estimate the scattering cross sections. The values for thermal electrons were, in Å^2: ethane, 2.7; propane, 4.6; *n*-butane, 7.2; ethylene, 4.7; propylene, 5.4; *cis*-butene-2, 7.4; *trans*-butene-2, 9.4. The scattering cross sections of the hydrocarbons dissolved in liquid xenon were about half of those in the gas phase, where comparisons could be made.

The mobility of electrons in pure xenon decreases with increasing electric field strength, due to heating of the electrons by the field. Addition of a small amount of hydrocarbon increases the mobility at high fields, eightfold by 4% of ethylene, propylene, or *cis*-butene-2 at 23.4 kV/cm and 192 K. The scattering cross sections of the hydrocarbons are two orders of magnitude larger than the effective cross section of liquid xenon, and the collisions with the hydrocarbons tend to prevent the electrons from becoming heated.

Electrons begin to form localized states in solutions containing 10 mol% hydrocarbon, or 20 mol% in the case of ethane. The mobility decreases approximately exponentially with concentration above these thresholds. The values of μ_0 for these exponential regions reflect the different scattering coefficients of the hydrocarbons: $\mu = \mu_0 \exp(-E_\mu/RT)$. The values of E_μ increase with molecular size in a series, and are greater for olefins than for alkanes. For the C_2 and C_3 hydrocarbons E_μ increases linearly with the mol fraction of hydrocarbon. *cis*-Butene-2 shows anomalous behaviour, as found earlier for electrons in the pure compound.

TOYOAKI KIMURA et GORDON R. FREEMAN. Can. J. Chem. **56**, 756 (1978).

On a ajouté de l'éthylène, du propylène, du butène-2 *cis*, du butène-2 *trans*, de l'éthane, du propane et du butane à du xénon à 168 et à 192 K. A des concentrations allant jusqu'à 4 mol%, les électrons sont dispersés par une molécule à la fois et on peut utiliser un modèle de phase gazeuse pour évaluer la section efficace de dispersion. Les valeurs pour les électrons thermiques sont, en Å^2: éthane, 2.7; propane, 4.6; butane, 7.2; éthylène, 4.7; propylène, 5.4; butène-2 *cis*, 7.4; butène-2 *trans*, 9.4. Dans le cas où il est possible de faire une comparaison, les valeurs des sections efficaces de dispersion des hydrocarbures dissous dans le xénon liquide correspondent à environ la moitié de celles en phase gazeuse.

La mobilité des électrons dans le xénon pur diminue avec une augmentation de l'intensité du champs électrique; ce résultat est dû à un échauffement des électrons par le champs. L'addition de petites quantités d'hydrocarbures augmente la mobilité à des hauts champs, environ 8 fois par l'addition de 4% d'éthylène, de propylène ou de butène-2 *cis* à 23.4 kV/cm et 192 K. Les sections efficaces de dispersion des hydrocarbures sont environ 100 fois plus grandes que la section efficace du xénon liquide et les collisions avec les hydrocarbures ont tendance à empêcher l'échauffement des électrons.

Les électrons commencent à former des états localisés dans des solutions contenant environ 10 mol% d'hydrocarbure, ou 20% dans le cas de l'éthane. La mobilité diminue presque exponentiellement avec la concentration au dessus de ces seuils. Ces valeurs de μ_0 pour ces régions exponentielles sont un reflet des différents coefficients de dispersion des hydrocarbures: $\mu = \mu_0 \times \exp(-E_\mu/RT)$. Les valeurs de E_μ augmentent avec la grosseur moléculaire dans les séries et sont plus grandes pour les oléfines que pour les alcanes. Dans le cas des hydrocarbures en C_2 et C_3, E_μ augmente d'une façon linéaire avec la fraction molaire de l'hydrocarbure. Le butène-2 *cis* présente un comportement anormal tel que trouvé antérieurement pour les électrons dans le liquide pur.

[Traduit par le journal]

Introduction

The mobility of electrons in liquid xenon (1, 2) is several orders of magnitude greater than that in most hydrocarbons (2–4). The high mobility is associated with the spherical shape and high polarizability of the molecules (3). The ability of small hydrocarbon molecules to scatter low energy electrons in the liquid is attributed to the electron interaction with rotational motions through the anisotropy of polarizability of the molecules.

In a continuing attempt to understand the behavior of electrons in liquids, we have added a series of hydrocarbons to xenon and measured their effects

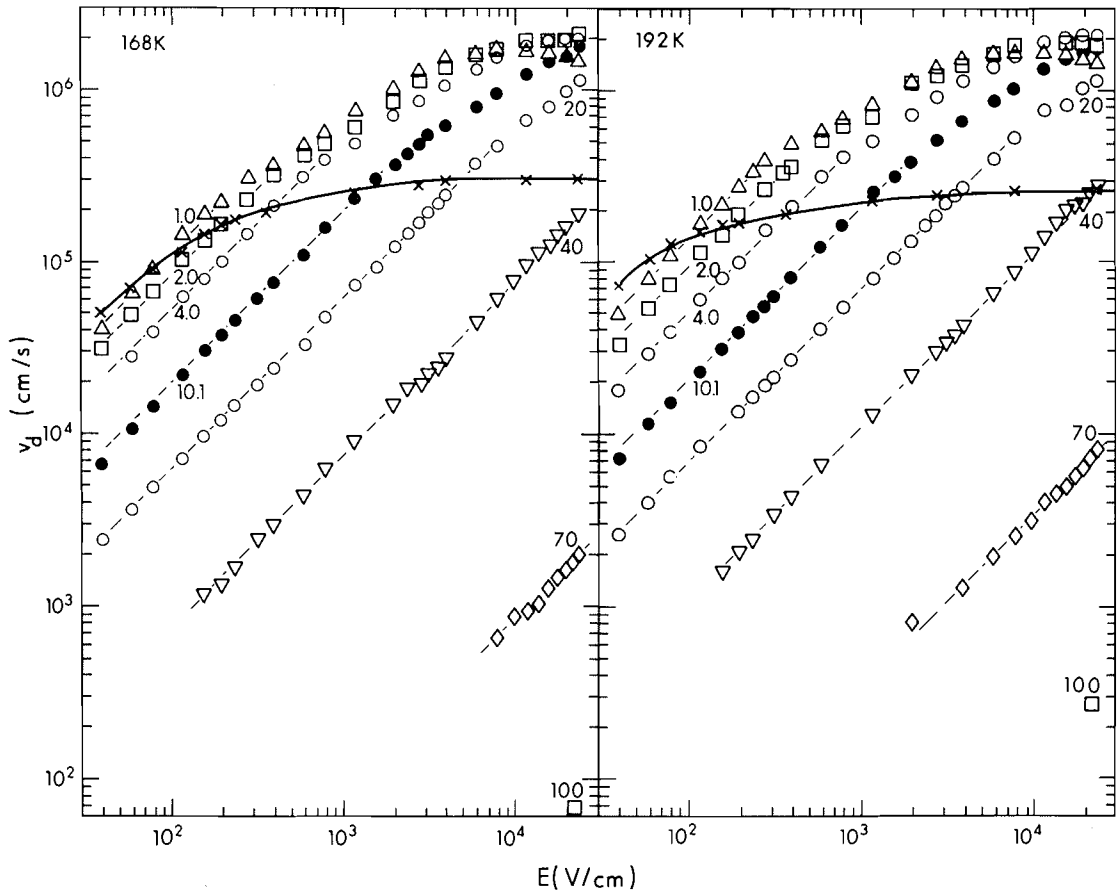

FIG. 1. Electron drift velocities in pure liquid xenon (×) and in xenon/ethylene solutions at 168 and 192 K, as functions of the applied field strength E. The numbers labelling the curves represent mol% ethylene. The dashed lines have slopes of unity.

upon the electron mobility. The concentrations were varied from pure xenon to pure hydrocarbon.

Experimental

The materials and the method of preparation of the samples were the same as those described in ref. 5.

The mobilities, μ, were measured by time-of-flight (6) and conductance (2) methods. The former is based upon [1] and the latter upon [2].

$$[1] \qquad \mu = l^2/Vt_d$$

where l is the distance between the parallel plate electrodes, V is the applied voltage, and t_d is the time required for the electrons to drift from the cathode to the anode.

$$[2] \qquad \mu = G_{fi}{}^E \mu/G_{fi}{}^E$$

where the value of the product of the free ion yield $G_{fi}{}^E$ and the mobility is obtained from the height of the conductance transient after a pulse of radiation, and the free ion yield is measured in a separate, charge clearing experiment. The two methods gave results the same within 15% under conditions where both could be used. The time-of-flight method is preferred because it is more direct and quicker. However, the conductance method is sometimes more dependable at low field strengths.

The radiation pulse length was usually 100 ns, but was 1 μs for the pure hydrocarbons and the 70% hydrocarbon solutions. The respective pulse doses were $\sim 2 \times 10^{10}$ and 1×10^{11} eV/g.

Physical Properties of the Liquids

The densities and dielectric constants of the pure compounds were taken from refs. 2 and 7. These properties were assumed to be additive in the solutions.

Results

The mobility of electrons in xenon is strongly field dependent (1). It is more instructive in this case to discuss the velocity of drift v_d in the direction of the applied electric field E.

$$[3] \qquad v_d = \mu E$$

The drift velocity tends to become independent of field strength at high fields (Fig. 1).

Increasing the liquid temperature from 168 to 192 K increases the drift velocity at low fields, but decreases the plateau value at high fields (compare Figs. 1 and 2). The plateau values are 2.6 km/s at

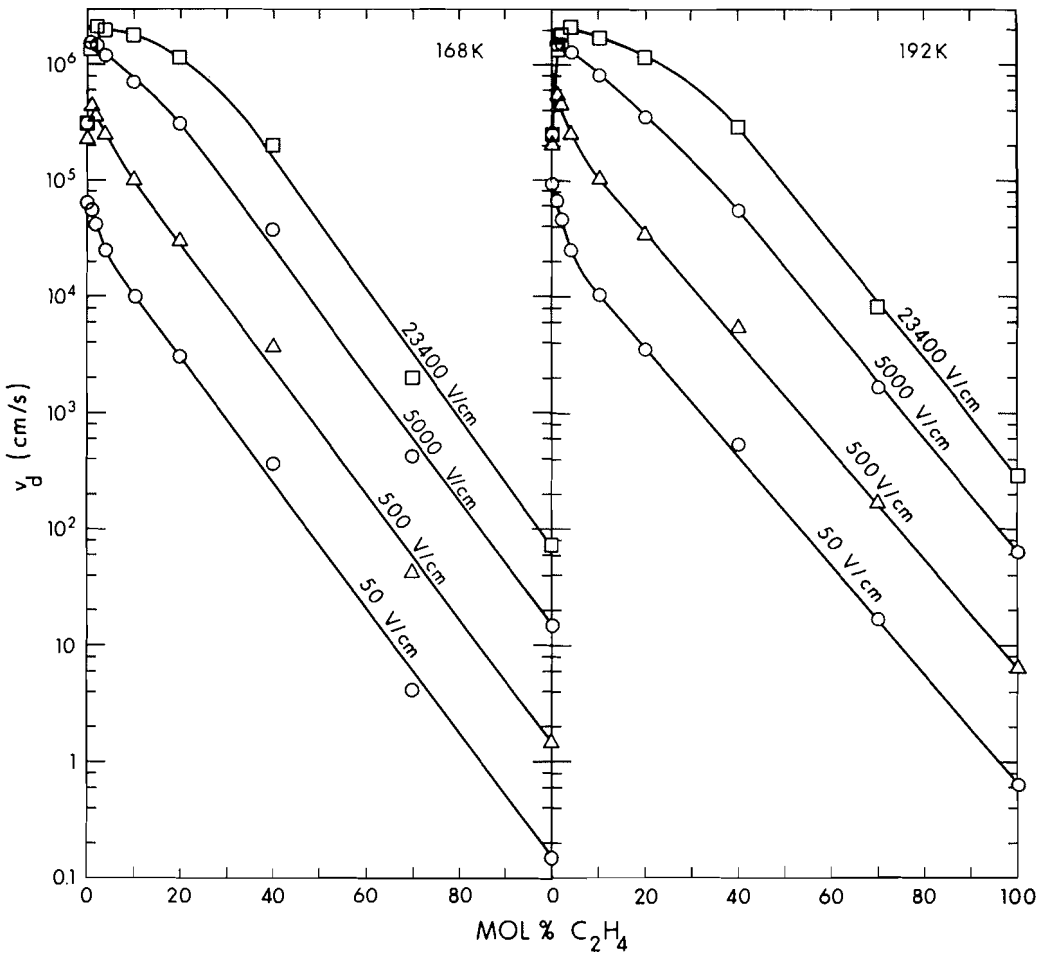

FIG. 2. Effect of ethylene concentration upon the electron drift velocity at constant field stengths in xenon/ethylene solutions at 168 and 192 K.

192 K and 3.1 km/s at 168 K, compared to 2.9 km/s at 163 K reported earlier (1).

Xenon/Ethylene Solutions

Addition of 1 mol% of ethylene to xenon lowers the value of v_d slightly at low fields, but increases it greatly at high fields (Fig. 1). The drift velocity passes through a maximum of 17 km/s at $E = 10$ kV/cm at 168 K.

Further additions of ethylene continue to lower v_d at low fields. However, at the highest field used, 23.4 kV/cm, v_d increases to 21 km/s at 2% ethylene, then decreases monotonically as the ethylene concentration is increased (Fig. 1).

The behavior is similar at 192 K, except for the crossover of the 2% and 4% curves at high fields (Fig. 1). The 1% crosses to below the 2, 4, and 10% curves at both temperatures, at $\sim 10^4$ V/cm.

The effect of ethylene concentration upon the drift velocity at fixed applied field strengths at 168 K is shown in Fig. 2. At 50 V/cm there is an initial relatively rapid decrease in v_d as the first 5% of ethylene is added, followed by a slower but approximately exponential decrease at higher concentrations. Similar behavior is observed at 500 V/cm, except that the first 1% of ethylene causes v_d to increase by a factor of two. At 5000 V/cm, addition of the first 1% of ethylene increases v_d fivefold, while the next 3% have relatively little effect. Further additions cause an exponential decrease in v_d, as at lower fields. At 23 400 V/cm the peak in the v_d/concentration curve is higher and broader than at lower fields. The maximum occurs at 2 mol% ethylene, with a sevenfold increase in v_d over the value in pure xenon (Fig. 2).

The behavior at 192 K is similar to that at 168 K, with small differences in detail (Fig. 2). For example, at 23 400 V/cm the maximum v_d is eightfold the value in pure xenon, and it occurs at 4 mol% ethylene.

Effects of Other Olefins

The effects of ethylene, propylene, and *cis*- and

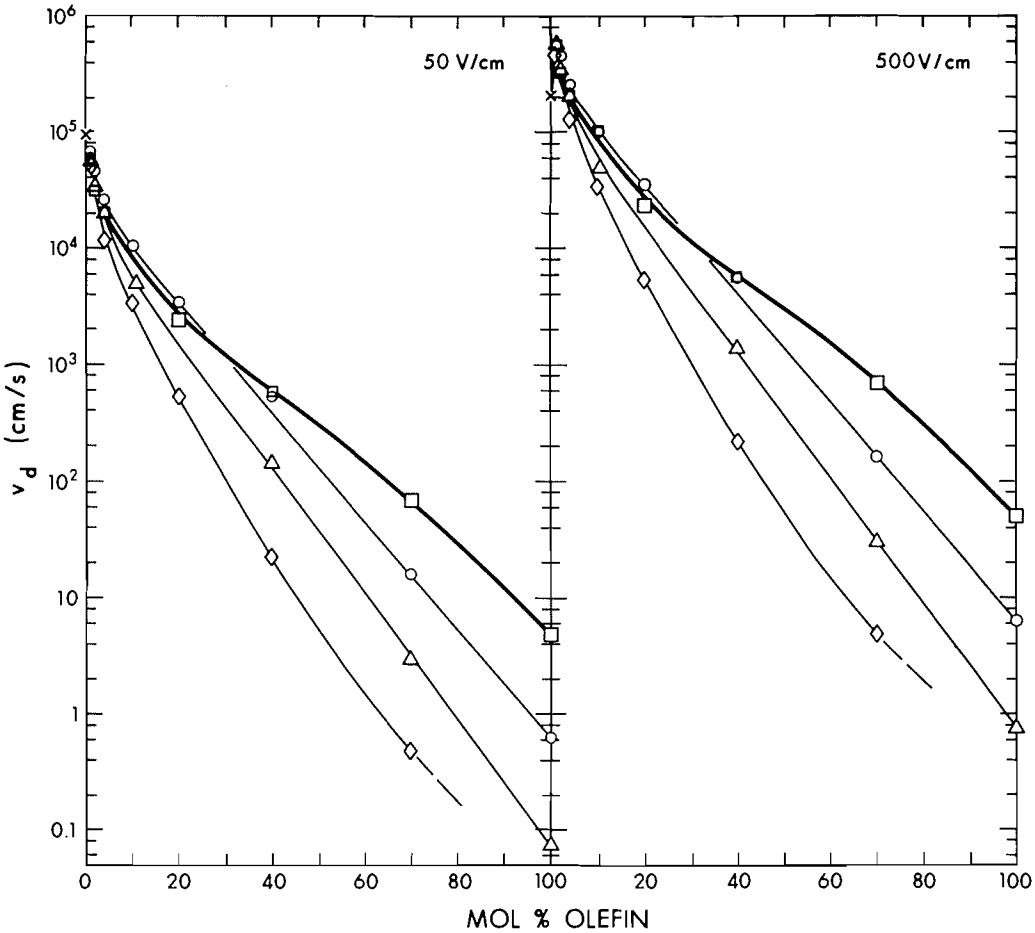

FIG. 3. Effect of olefin concentration upon the electron drift velocity in xenon/olefin solutions at 50 and 500 V/cm, 192 K. ○, Ethylene; △, propylene; □, *cis*-butene-2; ◇, *trans*-butene-2.

trans-butene-2 are compared at each of four different field strengths in Figs. 3 and 4. Similar behavior was observed at 168 and 192 K. To conserve space only the latter are displayed.

At 50 V/cm all the olefins cause a rapid decrease in v_d at low concentrations, followed by a more gradual decrease at high concentrations. The magnitudes of the effects are in the order ethylene < propylene < *trans*-butene-2 (Fig. 3). *cis*-Butene-2 behaves similar to propylene at low concentrations, but is even less effective than ethylene at high concentrations. The crossover of the *cis*-butene-2 and ethylene curves occurs at about 30 mol% olefin, where the mobility is about 30 cm^2/V s.

At 500, 5000, and 23 400 V/cm the addition of 1% olefin causes a large increase in v_d (Figs. 3 and 4). The effects of small concentrations of olefins at 50 and 23 400 V/cm are contrasted in Fig. 5. At 1% concentration all of the olefins are equally effective in increasing v_d at the high field strength. In the subsequent lowering of v_d by higher concentrations, the olefins have relative effectivenesses similar to those observed at 50 V/cm (Figs. 3 and 4). The crossover of the *cis*-butene-2 and ethylene curves shifts slightly at high field strengths. At 23.4 kV/cm the crossover occurs at 40 mol% olefin and $\mu = 12$ cm^2/V s (Fig. 4).

Effects of Alkanes

Data analogous to those in Fig. 1 were also obtained for ethane, propane, and *n*-butane solutions. The trends were the same at 168 and 192 K. The data for 192 K are summarized in Figs. 6 and 7.

Each alkane was less effective than its corresponding olefin in lowering v_d. *n*-Butane is compared here with *trans*-butene-2, because the behavior of the *cis* isomer is anomalous.

At high field strengths v_d increased with the addition of the first percent of alkane (Figs. 6 and 7), as it did with the olefins.

Discussion

Extra electrons in liquid xenon reside in a con-

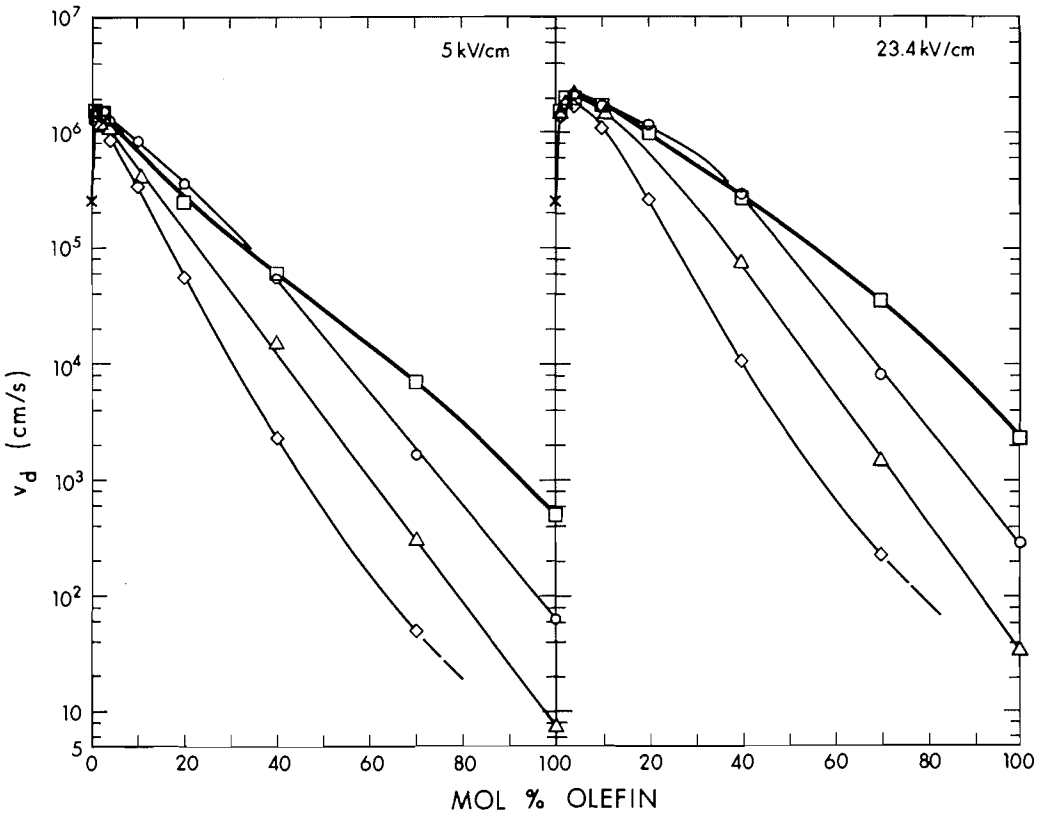

FIG. 4. Effect of olefin concentration upon the electron drift velocity at 5000 and 23 400 V/cm, 192 K. ○, Ethylene; △, propylene; □, *cis*-butene-2; ◇, *trans*-butene-2.

duction band. When the electrons remain in thermal equilibrium with the medium, their drift velocity is directly proportional to the applied field strength. In terms of [3] this means that μ is independent of E. However, at sufficiently large fields the electrons gain more energy from the field than they lose by collisions with the medium, and the mobility becomes a function of the field strength.

The mobility μ_0 of an electron in a conduction band or in a gas is directly proportional to the time between collisions. Thus, μ_0 is directly proportional to the mean free path Λ_v between collisions, and inversely proportional to the relative velocity v of the electrons with respect to the molecules (8, 9).

$$\mu_0 \propto \Lambda_v/v \qquad [4]$$

where Λ_v is a function of v. In the solutions the mean free path may be represented approximately by [5].

$$\Lambda_v = (n_x\sigma_x + n_h\sigma_h)^{-1} \qquad [5]$$

where n_x and n_h are the numbers of xenon and hydrocarbon molecules/cm^3, respectively, while σ_x and σ_h are the corresponding scattering cross sections. In [5], diffraction effects due to multiple interactions in the dense fluid (9) are included for simplicity in the σ's. They are also functions of v.

The variations of μ with E, temperature, and composition in the dilute solutions reflect changes in v and Λ_v. In pure xenon v_d increases less than linearly with field at $E \geq 40$ V/cm (Fig. 1), which means that μ_0 decreases with increasing E. This is due to increases in v and σ_x.

At a given field strength, under steady state conditions the electrons have certain average values of v_d and v, and the medium has a certain average value of σ. The energy gained by the electron from acceleration in the field is removed by collision with the medium

$$eE\Lambda_v = \Delta\varepsilon_v \qquad [6]$$

where $\Delta\varepsilon_v$ is the average amount of energy lost per collision when the average velocity of the electron relative to the molecules is v. In a solution $\Delta\varepsilon_v$ is given by [7].

$$\Delta\varepsilon_v = \frac{n_x\sigma_x\Delta\varepsilon_x + n_h\sigma_h\Delta\varepsilon_h}{n_x\sigma_x + n_h\sigma_h} \qquad [7]$$

where $\Delta\varepsilon_x$ and $\Delta\varepsilon_h$ are the average amounts of energy

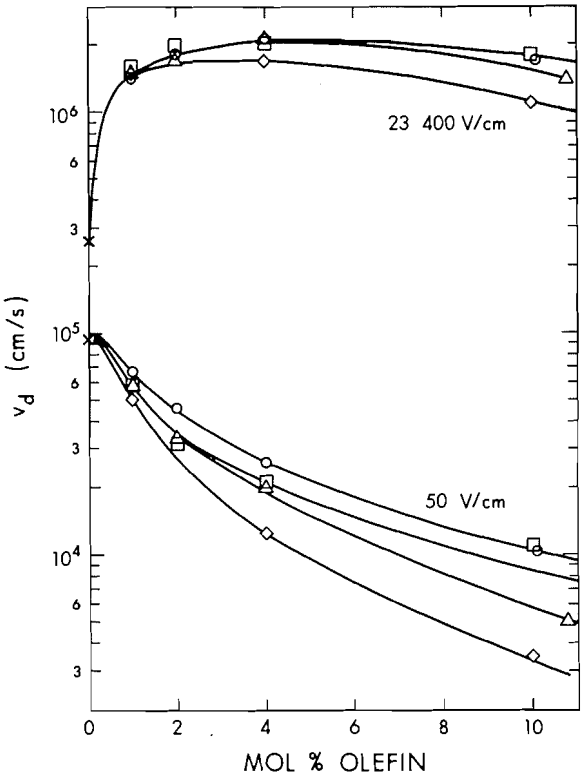

FIG. 5. Effects of low concentrations of olefins on the electron drift velocity at 50 and 23 400 V/cm. Temperature = 192 K. ○, Ethylene; △, propylene; □, *cis*-butene-2; ◇, *trans*-butene-2.

lost per collision with xenon and a hydrocarbon, respectively. The fact that 1 mol% of a hydrocarbon has such a large effect on v_d (Fig. 1) means that $\sigma_h \Delta\varepsilon_h \gg \sigma_x \Delta\varepsilon_x$. Equations 5–7 then imply that the minimum field required to cause electron 'heating' should increase linearly with the hydrocarbon concentration at low concentrations. Such is the case (Fig. 8).

Molecular Scattering Cross Sections for Thermal Electrons in Xenon Solvent

The thermal electron mobilities in the dilute solutions were analysed to determine the electron scattering cross sections of the hydrocarbon molecules dissolved in xenon. The scattering properties of the xenon were assumed to be unaffected by the presence of up to 4 mol% hydrocarbon. The results indicated that collective effects of the hydrocarbon molecules were negligible up to this concentration. The electrons remain in a delocalized state and the drift velocity is given by [8] (9).

$$[8] \qquad v_d = \frac{2}{3}\left(\frac{2}{\pi m k T}\right)^{1/2} eE\Lambda_v$$

where m and e are the electron mass and charge, respectively, k is Boltzmann's constant, and T is the absolute temperature. The values of $\mu = v_d/E$ in pure xenon were taken to be 2000 $cm^2/V\ s$ at 168 K and 2800 $cm^2/V\ s$ at 192 K (10), which gave values of $(n_x\sigma_x)^{-1}$ equal to 1080 and 1610 Å, respectively. Analysis of the mobilities in solutions of up to 4 mol% hydrocarbon, using [5] and [8], gave the values of σ_h listed in Table 1.

In general the scattering cross section of an olefin is greater than that of the corresponding alkane (Table 1). The values for the alkanes are only about half those in the gas phase (11). The reduction could be attributed to dielectric screening by the liquid xenon, which has a dielectric constant of ~1.9 in this temperature region. There might also be a structure factor contribution, but more systems need to be studied in the gas and solution phases to determine it.

The effective value of σ_x is two orders of magnitude

smaller than those of σ_h, due partly to the small value of the structure factor (1, 9), that is, to diffraction effects. Another reason is that the 'atomic' scattering cross section of xenon at these densities appears to be only a small factor greater than that at

*Average of the values at 168 and 192 K.
†ETE = energy transfer efficiency ratio, hydrocarbon/xenon, determined from the secondary electron ranges in the solutions (5).

the gas phase Ramsauer–Townsend minimum (10). The low energy limit of the structure factor $S(0)$ is given by [9] (1).

$$[9] \qquad S(0) = nkT\chi_T$$

where χ_T is the isothermal compressibility (12). The values of $S(0)$ are 0.058 at 168 K and 0.085 at 192 K.

Addition of a hydrocarbon to xenon reduced the penetration ranges of the secondary electrons into the liquid away from their parent positive ions (5). An energy transfer efficiency ratio, hydrocarbon/xenon, was estimated from the results. The energy transfer efficiency ratio for the slowing down of secondary electrons was 2–4 times larger than the corresponding cross section ratios for thermal electrons (Table 1). It is reasonable to assume that the slowing down of secondary electrons is governed by inelastic scattering. The strong correlation between the scattering cross sections determined from the mobilities and the energy transfer efficiency ratios determined from the ranges seems to imply that inelastic scattering makes an important contribution to limiting the mobilities of thermal electrons in these systems.

Collective Effects of the Hydrocarbons

The breakdown of the isolated molecule model for hydrocarbon concentrations ≥ 10 mol% indicates that interactions of an electron with more than one hydrocarbon molecule at a time are important at these concentrations. The average center-to-center distance between hydrocarbon molecules at 10 mol% is $n_h^{-0.33} = 9$ Å. This is about half the distance (15 Å) between xenon atoms where multibody interactions become important in high density xenon gas (10).

The approximately exponential decrease of v_d with increasing ethylene concentration beyond the threshold (Fig. 2) indicates that the decrease is caused by the formation of electron localized states. The straight lines at >9 mol% ethylene for $E = 50$ and 500 V/cm in Fig. 2 follow [10].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$[10] \quad v_d = \mu E = \mu_0 \exp(-E_\mu/RT)E = 250 \exp\left(\frac{-4200[\mathrm{MF}-0.09]}{RT}\right)E$$

where E_μ is the activation energy, MF is the mol fraction of hydrocarbon, and 0.09 is the threshold value. The pre-exponential factor μ_0 must also be affected by MF, although the differences in the shapes of the curves in Figs. 3 and 6 indicate that the manner is not simple. For ethylene, if one took $\mu_0 = 113\ \mathrm{MF}^{-0.33}$ cm^2/V s and $E_\mu = 3800[\mathrm{MF} - 0.09]$ cal/mol K, [10] would follow within a few percent of the 50 V/cm lines in Fig. 2, at all concentrations from 1 to 100 mol%. The significance of that is not known, and is dubious below 9 mol% where the exponential term exceeds unity.

The analogous equation to [10] for propylene is

$$[11] \quad v_d = 120 \exp\left(\frac{-4700[\mathrm{MF}-0.09]}{RT}\right)E$$

The lower pre-exponential factor reflects the greater scattering cross section of propylene (Table 1). The curve is in Fig. 3.

The lower curve for *trans*-butene-2 (Fig. 3) reflects the still larger scattering cross section of that molecule and the deeper traps formed. The approximately linear portion between 10 and 40 mol% corresponds to $\mu_0 = 72$ cm^2/V s and $E_\mu = 6300[\mathrm{MF} - 0.09]$ cal/mol K. The more gentle slope at the lower end is due to a gradual transition to an ion-like transport mechanism, as observed at low temperature in pure *trans*-butene-2 (13).

In dilute solutions *cis*-butene-2 scatters electrons much more strongly than does ethylene (Table 1), but at high concentrations collective interactions of the butene reduce its scattering efficiency. The *cis*-butene-2 curve in Fig. 3 crosses to above the ethylene curve at about 30 mol%. This peculiar behavior of *cis*-butene-2 compared to other olefins was noted some time ago (4), but is not yet understood. It seems to be related to the ease of rotation of the molecules in the liquid. The fact that the permanent dipole of the molecule is perpendicular to the major axis of polarizability might also reduce the net charge – dipole interaction.

Ethane has about double the threshold concentration of ethylene for the formation of localized electron states. The linear portion of the curve in Fig. 6 corresponds to [12].

$$[12] \quad v_d = 194 \exp\left(\frac{-2550[\mathrm{MF}-0.17]}{RT}\right)E$$

The threshold concentrations of propane and *n*-butane to begin to localize electrons are similar to those for the olefins. The approximately linear portion of the propane curve between 10 and 80 mol% in Fig. 6 is satisfactorily described by [13].

$$[13] \quad v_d = 168 \exp\left(\frac{-3300[\mathrm{MF}-0.10]}{RT}\right)E$$

The portion of the *n*-butane curve between 10 and 40 mol% corresponds approximately to $\mu_0 = 88$ cm^2/V s and $E_\mu = 5200[\mathrm{MF} - 0.10]$ cal/mol K. It is not known whether the more gentle slopes towards the bottoms of the propane and butane curves are due to a change from mechanism [10] to small polaron hopping (14), or to interference effects of the type that raised the *cis*-butene-2 curve (Fig. 3).

Field Effect in the Hydrocarbon Solutions

The more gentle negative slopes at the tops of the curves in Figs. 4 and 7 are due to electron heating. This is illustrated by the fact that the slopes at the tops of the 10 and 20 mol% curves in Fig. 1 are less than unity. The heating of the electrons would also inhibit their localization, as observed in dense xenon gas (10). The treatment of the mobilities in this region would therefore be complex.

GAËTAN MAIRESSE, PIERRE BARBIER, JEAN-PIERRE WIGNACOURT, ANNICK RUBBENS, and FRANCIS WALLART. Can. J. Chem. **56**, 764 (1978).

Ammonium tetrachloroaluminate crystallizes in the orthorhombic system $a = 11.022(6)$ Å, $b = 7.072(3)$ Å, $c = 9.257(5)$ Å, $Z = 4$, space group *Pnma*. The structure was determined by direct methods from diffractometer data and refined by full-matrix least-squares procedures to final R and R_ω values of 0.053 and 0.069 respectively, for 596 reflections with $I > 2\sigma(I)$. Hydrogen atoms were not observed. Al—Cl bond lengths are similar to those of other alkaline chloroaluminate salts (Li^+, Na^+, NO^+). The salt is isostructural with NH_4ClO_4.

Crystals and polycrystalline samples of this compound have been studied by Raman scattering above 10 K, and infrared spectra of specimens of a polycrystalline sample have been recorded in Nujol and a fluorolube above 80 K. Both methods enabled us to observe the bands corresponding to the $\nu_1(A_2)$, ν_3, and $\nu_4(F_2)$ vibration modes of the ammonium ion but the infrared spectra contain no band due to combination modes involving the librations of this ion. Nuclear magnetic second moment remains equal to 4 G^2 over the range 298–80 K. These spectroscopic results, compared to those of other ammonium salts, indicate that the ammonium ion seems to be freely rotating.

The four characteristic bands of the $AlCl_4^-$ tetrahedral anion have been studied by Raman scattering in the 298–10 K temperature range.

GAËTAN MAIRESSE, PIERRE BARBIER, JEAN-PIERRE WIGNACOURT, ANNICK RUBBENS et FRANCIS WALLART. Can. J. Chem. **56**, 764 (1978).

Le tétrachloroaluminate d'ammonium cristallise dans le système orthorhombique $a = 11.022(6)$ Å, $b = 7.072(3)$ Å, $c = 9.257(5)$ Å, $Z = 4$, groupe d'espace *Pnma*. La structure a été résolue par les méthodes directes et affinée par celle des moindres carrés (matrice complète) jusqu'à des facteurs d'accord R et R_ω de 0.053 et 0.069, avec 596 réflexions telles que $I > 2\sigma(I)$ enregistrées au diffractomètre. Les atomes d'hydrogène n'ont pas été observés. Les distances Al—Cl sont comparables à celles d'autres sels alcalins (Li^+, Na^+, NO^+). Le sel est isostructural de NH_4ClO_4.

Des échantillons monocristallins et polycristallins du composé ont été analysés par diffusion Raman jusqu'à une température de 10 K ainsi que des suspensions dans le Nujol et le fluorolube par spectrométrie ir jusqu'à 80 K. Les bandes relatives aux fréquences ν_1 d'espèce A_1, ν_3 et ν_4 d'espèce F_2, de l'ion NH_4^+, ont été observées par ces deux techniques. Aucune bande de combinaison due à des modes de libration du cation n'a été mise en évidence sur les spectres d'absorption infrarouge. En rmn du proton, le second moment magnétique nucléaire garde la même valeur (~ 4 G^2) entre 298 et 80 K. Ces résultats spectroscopiques comparés à ceux d'autres sels d'ammonium indiquent que l'ion ammonium semble être en "libre rotation".

Les quatre bandes caractéristiques de l'anion tétraédrique $AlCl_4^-$ ont été étudiées par diffusion Raman dans l'intervalle de température 298–10 K.

Introduction

It seemed worthwhile to extend our structural knowledge of the compounds formed between aluminum trichloride and alkaline chlorides, to the pseudoalkaline salts $NOAlCl_4$ and NH_4AlCl_4, owing to the polyatomic nature of their cations. We have recently shown that in nitrosyl tetrachloroaluminate the nitrosyl ion occupied two different positions at room temperature (1), but seemingly only one at 210 K (2). The present paper reports a similar study of the ammonium salt, using X-ray diffraction, vibration spectrometry, and proton nmr techniques. The results obtained are compared with those of other tetrachloroaluminate alkaline salts and other previously reported data about ammonium salts.

Experimental

Preparation

The reagent-grade aluminum trichloride, contaminated by iron trichloride, was purified through successive sublimations

under hydrogen chloride gas and then dynamic vacuum. Ammonium chloride was dried over phosphorus pentoxide under vacuum. Stoichiometric amounts of $AlCl_3$ and NH_4Cl were inserted in a U-shaped glass apparatus with $SOCl_2$, and then liquid SO_2 was condensed. The reactor was then sealed off and the $AlCl_3$ solution in the mixed solvent reacted with NH_4Cl at room temperature to give a NH_4AlCl_4 solution (3). A difference of temperature between the two parts of the reactor produced a slow distillation of SO_2, giving single crystals of the salt insoluble in $SOCl_2$. These crystals were separated from the remaining solution and then isolated by sealing off the tube. This process enabled us to obtain crystals suitable for both X-ray diffraction or Raman scattering and nmr. These crystals were very hygroscopic and had a fragile texture. They were handled in a glove-box (filled with dry nitrogen) and washed in previously dried carbon tetrachloride.

Crystallographic Study

The irregular shaped crystal selected was coated with dried paraffin, and then sealed off in a quartz capillary. It had the approximate dimensions of ca. 0.25 × 0.35 × 0.20 mm. Preliminary Weissenberg and precession photographs gave the conditions for diffraction as $hk0$ ($h = 2n$) and $0kl$ ($k + l = 2n$) which indicated either $Pnma$ (D_{2h}^{16}) or $Pn2_1a$ (C_{2v}^{9}) as possible space groups. $Pnma$ was ultimately chosen as correct for reasons referred to later in the text.

The unit cell parameters were obtained from a least-squares refinement of the setting angles of 25 reflections which had been carefully centered on a four circle Philips PW 1100 automatic diffractometer using the MoK_α radiation with a graphite monochromator. Crystal data are:

NH_4AlCl_4 fw = 186.83
Orthorhombic, $a = 11.022(6)$ Å, $b = 7.072(3)$ Å, $c = 9.257(5)$ Å, $V = 721.60$ Å^3, $\rho_o = 1.68$, $Z = 4$, $\rho_c = 1.72$ (20°C, MoK_α, $\lambda = 0.7107$ Å, $\mu = 16$ cm^{-1}).

Intensities were collected on the diffractometer by the ω–2θ technique with a ω scan speed of 0.03° s^{-1} and a variable scan width (0.90 + 0.40 tan θ) deg over the $4° < 2\theta < 60°$ range. The weak reflection intensities were measured several times (with a maximum of 5) in order to obtain more precision. Weak reflections with $I_{peak} - 2\sqrt{I_{peak}} < I_{background}$ after the first scan were discarded as being unobserved. The background measurement time t_b was adapted to the strength of the reflection as $t_b = t_s\sqrt{I_b/I_s}$ (with t_s = scanning time, I_b = average intensity per second of the background, I_s = average intensity per second during scanning), this giving the minimum of $(t_s + t_b)\sigma^2(I_{net})$, $(\sigma^2(I_{net}) = I_s/t_s + I_b/t_b$ with $I_{net} = I_s - I_b)$. Three standard reflections $\bar{2}12$, 212, 008 were monitored every 60 reflections throughout the data collection to check crystal stability. No trends were observed in the standards. We collected the intensities in the two octants, hkl and $\bar{h}kl$, and corrected them for Lorentz and polarization effects. No absorption correction was applied because of the irregularities of the crystal surface and the low value of the linear absorption coefficient. After averaging the equivalent reflections we obtained 596 unique reflections with $I > 2\sigma(I)$.

NH_4AlCl_4 seemed to be isostructural to $CsAlCl_4$ and the $NOAlCl_4$ room temperature phase ($BaSO_4$ type centrosymmetric structure) but on account of the previous controversy about the choice of the $Pnma$ or $Pn2_1a$ space group in the NH_4ClO_4 crystal study (4, 5), we solved the structure by direct methods, independently of all a priori considerations, using the multisolution MULTAN computer program (6). The distribution of the normalized structure factors E did not enable us to choose either a centric or acentric distribution.

	Experimental	Theoretical	
		Centrosymmetric	Noncentrosymmetric
E^2	0.999	1.000	1.000
$\lvert E^2 - 1\rvert$	0.825	0.968	0.736
$\lvert E\rvert$	0.856	0.798	0.886

So we tried to resolve the structure in both cases. In each of them, the E map corresponding to the best 'figure of merit' showed the $AlCl_4$ anion atoms. After two cycles of refinement of the positional and isotropic thermal parameters of these atoms, a difference Fourier map revealed the position of the N atom. The full-matrix least-squares refinement of the positional and isotropic, then anisotropic thermal parameters of the Al, Cl, and N atoms, converged smoothly to $R = 0.053$ and $R_\omega = 0.069$ in the space group $Pnma$, and to $R = 0.060$ and $R_\omega = 0.066$ in $Pn2_1a$. At this stage a final difference Fourier map showed no significant residual electronic density in the region of the ammonium group. The maximum residual density (0.3 e Å^{-3} in $Pnma$ and 0.9 e Å^{-3} in $Pn2_1a$) occurred in the regions of the chlorine atoms in the tetrachloroaluminate anion. Attempts to include disordered ammonium groups by using rigid-body constrained refinement techniques (7) were made but gave no significant results. The refinements in both space groups give almost identical results for the geometry of the $AlCl_4^-$ ion as well as for the thermal parameters. Thus, the ambiguity related to the space group was removed through a study of the compound by Raman scattering, which led us, as later explained in this paper, to choose the $Pnma$ centrosymmetric space group.

The least-squares refinement was based on the minimization of $\Sigma\omega(|F_o| - |F_c|)^2$, the weighting scheme used being $\omega = 1/\sigma^2(F)$ where ω is derived from $\sigma^2(I)$ according to $\sigma(I) = [P + 0.25(B_1 + B_2)(T_p/T_b)^2 + (pI)^2]^{1/2}$ where P is the scan count, B_1 and B_2 are the background counts, T_p and T_b are the count times on the peak and background respectively, I is the resulting intensity, and p is the 'ignorance factor' included to avoid overweighting very strong reflections. A value of 0.04 was used for p. The scattering factors for N, Al, and Cl atoms were those calculated by Cromer and Waber (8). The effects of anomalous dispersion were not taken into account.

On the final cycle of refinement the mean parameter shift was 0.43 of its estimated standard deviation (in the centrosymmetric space group).

The final positional and thermal parameters of the atoms are given in Table 1, the intraionic distances and angles in Table 2. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Raman, Infrared, and nmr Studies

For Raman and nmr techniques we used crystals of about 1 cm^3 size, sealed off under dry nitrogen in glass tubes. Polycrystalline fluorescent samples were purified by zone melting. For infrared absorption, the compound was mulled in Nujol or fluorolube and placed between caesium iodide, calcium fluoride, or polythene cell windows.

To record the Raman spectra, we used double and triple monochromator spectrometers built in our laboratory (9, 10). These spectra were excited by the 530.9 nm line of an ionized

krypton laser and the 514.5 nm line of an ionized argon laser (Spectra-Physics). The double monochromator spectrometer was equipped with a fast-scanning system and spectra accumulation fittings (9). Above 80 K, we used cryostats with continuous gaseous nitrogen flux and for lower temperatures cryostats with liquid helium. To record ir and nmr spectra, we used respectively Perkin-Elmer 180 and Varian DP 60 spectrometers.

Results and Discussion

Crystallographic Results

NH_4AlCl_4 belongs to the alkaline tetrachloroaluminate family characterized by: orthorhombic system, space group *Pnma* (D_{2h}^{16}). It is isostructural to $RbAlCl_4$ (11), $CsAlCl_4$ (12), and the $NOAlCl_4$ room temperature phase (1) but different from $KAlCl_4$ (11) that crystallizes in the monoclinic system, space group $P2_1$ (C_2^2). Figure 1 shows the ionic packing of the NH_4AlCl_4 crystal structure (29). The anionic tetrahedron look slightly distorted. The Al—Cl distances and Cl—Al—Cl angles are very close to those found in $NOAlCl_4$. In both NH_4AlCl_4 and $NOAlCl_4$, the chlorine atoms thermal motions are important when compared to those occurring in $LiAlCl_4$ (13) and $NaAlCl_4$ (11). As a comparison, we reported in Table 3, from results obtained in our laboratory, the Cl—Cl and Al—Cl average distances in the $AlCl_4^-$ anions associated with different cations. The $NaAlCl_4$ data resulted from a new refinement with 1160 reflections ($I > 2\sigma(I)$) of those previously reported by Baenziger (14). We obtained final $R = 0.027$ and $R_\omega = 0.039$. (While writing this paper, Scheinert and Weiss (15) published a similar refinement of the $NaAlCl_4$ structure leading to $R_\omega = 0.079$.) There would seem to be a correlation between the slight shortening of the average distances and the increasing of the cation size. In fact, if we go on examining the chlorine atoms and their average equivalent isotropic temperature factors $\langle B_{eq}\rangle$ calculated from the β_{ij} coefficients, it is obvious that the apparent decrease in distances is due to increasing thermal motion (16). A close study of the thermal motion parameters of the $AlCl_4^-$ anion atoms (Table 1) made it clear that the aluminum atom motion is less important than those of the chlorine atoms. From Busing and Levy's work, it can be assumed that the chlorine atoms "ride" upon the

aluminum one. Using the anisotropic thermal parameters, we corrected the bond lengths from the riding motion theory. Thus we obtained: Al—Cl (1): 2.150, Al—Cl (2): 2.155, Al—Cl (3): 2.147, and ⟨Al—Cl⟩: 2.150 Å. This correction greatly reduced the differences in the same $AlCl_4^-$ anion distances. Furthermore, the same correction applied to the other salts brought back all the average Al—Cl distances to 2.14 and 2.15 Å. The Al—Cl distance fluctuations seem to be due to the different thermal motions of the chlorine atoms and not to different interactions between the anionic chlorine atoms and the associated cation. The main distortions of the $AlCl_4^-$ tetrahedron essentially concern the angles but remain relatively weak.

The nitrogen atom of the ammonium ion is surrounded by six chlorine atoms situated between 3.328 and 3.488 Å, four other chlorine being at 3.864 (×2) and 3.871 (×2) Å (Table 4). These 10 atoms belong to 7 anionic tetrahedrons. Some of them form, with the nitrogen atom, Cl—N—Cl angles of about 109°, but they are not enough to constitute a tetrahedral packing around the nitrogen atom. The sole knowledge of the chlorine–nitrogen distances and angles in NH_4AlCl_4 does not appear sufficient to deduce the presence in the crystal of preferential orientations for the ammonium ion by straight H bonds. Referring to the isostructural compound NH_4ClO_4, Choi, Prask, and Prince (17) have proved by neutron diffraction that at 10 K the ammonium ion is stabilized in the lattice owing to a network of four hydrogen bonds with N—H···O angles of 159, 180, and 138° (×2). This equilibrium position already appeared at room temperature but the refinement of the hydrogen atomic positions did not converge on account of their excessively important thermal displacements. These results corroborated Peyronel and Pignedoli's (4) similar observations about this same equilibrium position (done by X-ray diffraction at room temperature).

Molecular Spectroscopy

To make the following chapter more easily understandable, we decided to represent the $AlCl_4^-$ anion frequencies by ν^- and the NH_4^+ cation ones by ν^+.

Choice of the Space Group

The ambiguity related to the space group was removed through a study of the Raman scattering spectra for the $AlCl_4^-$ anion. As a matter of fact, let us consider the $Pn2_1a$ group, and we shall notice four active components ($A_1 + A_2 + B_1 + B_2$) for the ν_1^- band and eight components ($2A_1 + 2A_2 + 2B_1 + 2B_2$) for the ν_2^- band. On the other hand, let us consider *Pnma* as the correct space group and then we shall notice respectively two ($A_g + B_{2g}$) and four ($A_g + B_{1g} + B_{2g} + B_{3g}$) components for these bands.

TABLE 4. Coordination about the nitrogen atom[a]

N ...	Cl(2)	4/000	3.328(6)	N ... Cl(1)	1/000 3.488(6)
	Cl(3)	3/101	3.409(5)	Cl(3)	1/00$\bar{1}$ 3.864(6)
	Cl(3′)	3/1$\bar{1}$1	3.409(5)	Cl(3′)	1/00$\bar{1}$ 3.864(6)
	Cl(3)	2/10$\bar{1}$	3.481(5)	Cl(1)	2/10$\bar{1}$ 3.871(3)
	Cl(3′)	2/1$\bar{1}\bar{1}$	3.481(5)	Cl(1)	2/1$\bar{1}\bar{1}$ 3.871(3)

[a]Coding of equivalent positions: 1: x, y, z; 2: $1/2 - x, 1/2 + y, 1/2 + z$; 3: $\bar{x}, 1/2 + y, \bar{z}$; 4: $1/2 + x, y, 1/2 - z$. N is in position 1. Cl(3) 3/101 means that Cl(3) atom is in position 3 translated by 1*a*, 0*b*, and 1*c*.

With orientated single crystals we could obtain, in the $X(ZY)Z$ and $X(YX)Z$ orientations (18), ν_1^- bands with nearly the same but very low intensity. In the $X(ZX)Z$ orientation the intensity of the ν_1^- band increases; in the last one $X(YY)Z$ we notice a very high intensity. These observations are consistent with the existence of the A_g and B_{2g} modes. Moreover, at temperatures lower than 30 K in the spectral region of the ν_2^- (E) vibration, four maxima appeared at 133 cm^{-1} (B_{3g}), 128 cm^{-1} (B_{1g}), 125 cm^{-1} (A_g), and 120 cm^{-1} (B_{2g}) respectively. That is why we decided to describe the structure in the *Pnma* centrosymmetric space group.

$AlCl_4^-$ Anionic Region

At room temperature, in the low frequency range corresponding to the $AlCl_4^-$ anion vibrations and to the external modes (frequencies lower than 500 cm^{-1}) we observed on the Raman spectrum the four characteristic bands of the anionic tetrahedron with frequency values close to those of the other alkaline salts (19). Nevertheless we noticed that the ammonium salt spectrum was resolved better than the nitrosyl one. On the other hand, during the cooling process from room temperature to liquid nitrogen, there was no change in the NH_4AlCl_4 Raman spectrum contrary to the nitrosyl one (Figs. 2 and 3).

At room temperature, with orientated single crystals, broad bands could be observed and the signal/noise ratio was weak, except for the band related to the symmetric stretching mode. Thus the positions of the components in the above mentioned orientations could not be easily defined and we only reported the values obtained with polycrystalline samples (Table 5). Only at temperatures close to liquid helium could we begin to notice the site and the intermolecular coupling effects. In the $X(YY)Z$ orientation the components assigned to the A_g mode appeared at: 125 cm^{-1} for ν_2^-, 178 and 181 for ν_4^-, 356 cm^{-1} for ν_1^-. The other orientations enabled us to observe components of the B_{1g}, B_{2g}, and B_{3g} species. As for the broad band related to the ν_3^- (F_2) vibration, its intensity at 10 K was too low to enable us to notice its components clearly. But as soon as we reach 80 K,

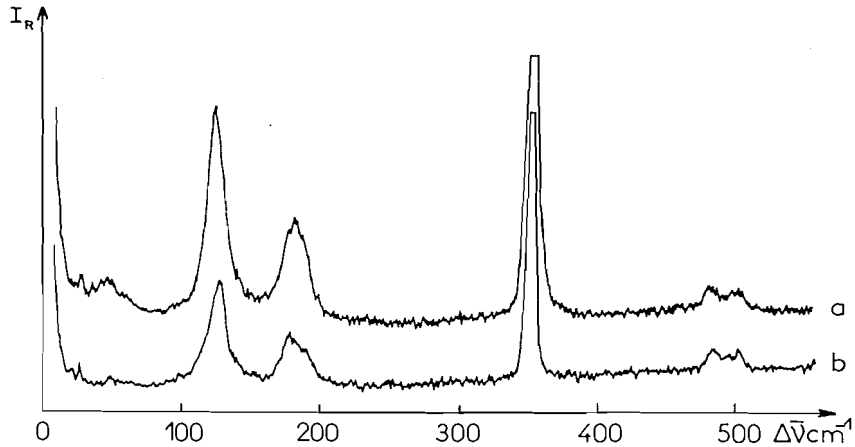

FIG. 2. Raman spectra of NH_4AlCl_4: (*a*) at room temperature, (*b*) at liquid nitrogen temperature.

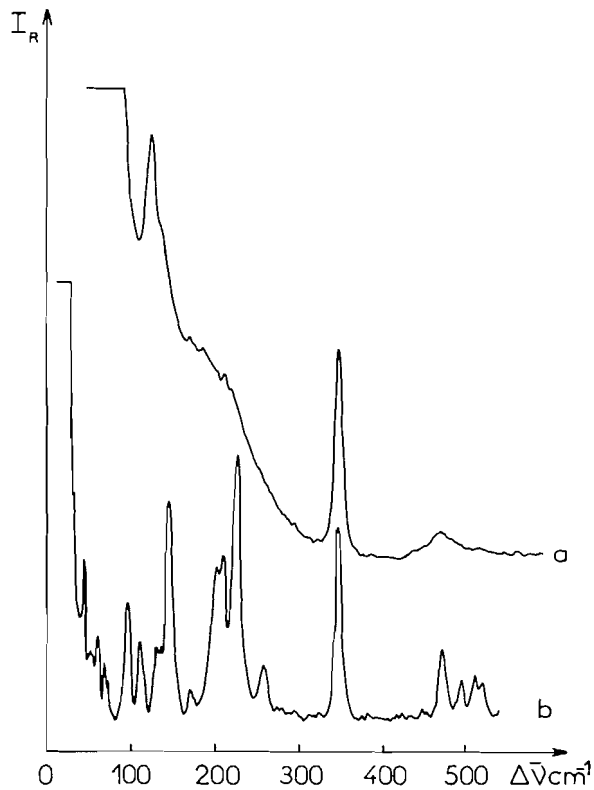

FIG. 3. Raman spectra of $NOAlCl_4$: (*a*) at room temperature, (*b*) at liquid nitrogen temperature.

we observe a splitting corresponding to the site effect (Table 5).

As for the other tetrachloroaluminates, infrared absorption spectra in this frequency range gave no further information on account of the very low intensity of the bands.

NH_4^+ Cationic Region

In Raman spectroscopy, the NH_4^+ ion does not scatter very well, and at room temperature the only band observed on the four ones expected was the ν_1^+ (A_1) band at 3176 cm^{-1}. Its intensity was weak when compared to those of the anion bands, which compelled us to use very wide spectrometer slits. The band width at half-height was about 30 cm^{-1}. During the cooling process, we noticed a slight shape refinement but the band remained wide and asymmetric. At 80 K, using the conventional recording conditions the ν_1^+ band remains the only one observed with a maximum intensity at 3161 cm^{-1}, the very important shift showing its high sensitivity to surroundings. The accumulation of 20 spectra then revealed (Fig. 4) an additional broad weak band (its maximum intensity being 3250 cm^{-1}) that we assigned to ν_3^+ (F_2), the ν_2^+ (E), and ν_4^+ (F_2) bands remaining unobserved. At 10 K, not only the 3161 and 3250 cm^{-1} bands appeared but also the ν_4^+ (F_2) band at 1411 cm^{-1}.

To complete our study in this frequency range, we used infrared spectrometry, for the ammonium ion absorption bands ν_3^+ and ν_4^+ showed a higher intensity than the Raman ones. At room temperature, we observed a broad band centered on 3240 cm^{-1}, with a shoulder at 3160 cm^{-1}, and another one at 1414 cm^{-1} (Fig. 5).

At 80 K, the same lines appeared at 3250, 3158, and 1414 cm^{-1}, respectively, and remained broad and weak. As in the Raman spectrum, we could not see any band in the spectral region of ν_2^+ near 1700 cm^{-1}, whereas this mode is active in the solid state. This band is often missing in spectra of ammonium salts.

The spectra of the deuterated salt were analogous to those of the normal compound. We only studied it above 80 K. The observed frequencies are reported in Table 5.

Numerous authors have tried to characterize hy-

restricted rotation of the cation caused by hydrogen bonding); (*ii*) the broadening of the lattice bands in the far infrared region; (*iii*) the ν_4 frequency. Although we did not, for NH_4AlCl_4, observe any absorption in the 1600–2000 cm^{-1} frequency range, where we should find combination modes (1993 and 1755 cm^{-1} for $\nu_4 + \nu_6$ and $\nu_2 + \nu_6$ respectively, in $(NH_4)_3ZnCl_5$ (21)), the high ν_4 value, 1414 cm^{-1}, compared with the values of the other chlorinated complexes (between 1393 and 1400 cm^{-1} according to ref. 22) should characterize the existence of H bonds. This criterion cannot be sufficient because, in $(NH_4)_2PtCl_6$ and $(NH_4)_2TeCl_6$, H bonds did not seem to exist although the ν_4 values were greater than 1400 cm^{-1}: 1402.8 cm^{-1} and 1409.0 cm^{-1} respectively (23).

Proton nmr

The proton nmr enables one, in the best cases, to evaluate the proton–proton distances and the group orientations, studying the general outline of the band obtained (24). We collected the proton resonance spectra at room temperature on polycrystalline samples and single crystals. The nuclear magnetic second moment value, which represents the mean quadratic value of the resonance line (Fig. 6), is small: 4 G^2. It is much smaller than the theoretical value, 43 G^2, associated with a regular and immobile tetrahedral ammonium ion (25). Moreover the spectrum did not change either by rotating the crystal by 90° in the magnetic field or by cooling the sample down to liquid nitrogen temperature.

This small value of the second moment is often found in ammonium salts at room temperature (26).

Its stability during the cooling process from room temperature to 80 K is similar to the NH_4ClO_4 example given by Ibers (27) and Hennel and Lalowicz (28). According to them this small value of the second moment resulted from reorientation about random axes of the ammonium ion, the dipole interactions within the ion then being averaged to zero by isotropic reorientation, only the weak intermolecular H—H contributions remaining.

Conclusions

NH_4AlCl_4 can be said to be isostructural with the nitrosyl (at room temperature), rubidium, and caesium tetrachloroaluminate salts.

As for the ammonium ion we remark that the hydrogen atoms are invisible on the difference Fourier synthesis. Moreover the Raman scattering bands are broad with low intensities whereas the infrared absorption spectra reveal no $\nu_2 + \nu_6$ or $\nu_4 + \nu_6$ combination bands. And last we observe the very small value of the nuclear magnetic second moment. A comparison between these results and those obtained for other ammonium salts enables us to deduce that the ammonium ion behaves as a 'spherical ion' without any apparent restricting motion.

Acknowledgments

Microwave spectrum of methylthioacetonitrile

R. KEWLEY

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 25, 1977

R. KEWLEY. Can. J. Chem. **56**, 772 (1978).

The microwave rotational spectrum of methylthioacetonitrile has been studied in the frequency range 18–37 GHz. The spectrum found is that of the *gauche* conformer. The non-observation of the spectrum of the *trans* conformer indicates that its abundance is less than about 5%. The rotational and centrifugal distortion constants for the ground vibrational state of the *gauche* conformer are: $A = 7715.123$ MHz, $B = 2641.756$ MHz, $C = 2174.538$ MHz, $D_K = 0.6824$ MHz, $D_{JK} = -2.52$ kHz, and $D_J = 1.96$ kHz. The observed rotational constants are compatible with a dihedral angle of 66 ± 5° and a CSC angle of 104 ± 2°. The dipole moment of the *gauche* conformer has been determined as 3.02 D. Vibrational satellites due to S—CH_2 torsion have been observed and a torsional frequency of 101 cm^{-1} has been estimated from relative intensity measurements.

R. KEWLEY. Can. J. Chem. **56**, 772 (1978).

On a étudié le spectre de microonde de rotation du méthylthioacétonitrile à des fréquences allant de 18–37 GHz. Le spectre trouvé correspond à celui du conformère *gauche*. Le fait que l'on n'a pas observé le spectre de l'isomère *trans* indique que sa quantité présente ne dépasse pas 5%. Les constantes de distortions rotationnelle et centrifuge pour l'état fondamental de vibration du conformère *gauche* sont $A = 7715.123$ MHz, $B = 2641.756$ MHz, $C = 2174.538$ MHz, $D_K = 0.6824$ MHz, $D_{JK} = -2.52$ kHz et $D_J = 1.96$ kHz. Les constantes de rotation observées sont en accord avec un angle dièdre de 66 ± 5° et un angle CSC de 104 ± 2°. On a déterminé que le moment dipolaire du conformère *gauche* est de 3.02 D. On a observé les satellites de vibration dus à la torsion S—CH_2 et on a évalué, à partir de mesures d'intensité relative, que la fréquence de torsion est de 101 cm^{-1}.

[Traduit par le journal]

Introduction

The present investigation represents an extension of our recent interest in straight chain methoxy derivatives. The first microwave spectroscopy study of a molecule closely related to methylthioacetonitrile, CH_3SCH_2CN, was Hirota's (1) work on butyronitrile, $CH_3CH_2CH_2CN$, which was found to be present in the gas phase as both *gauche* and *trans* conformers, related by rotation around the CH_2—CH_2 bond. In addition Hirota concluded that the energy difference between the two conformers is less than 1 kcal mol^{-1}. In our laboratory it was determined that methoxyacetonitrile, CH_3OCH_2CN, is predominantly in the *gauche* form with a small amount of higher energy (by about 1.4 kcal mol^{-1}) *trans* form also present (2). By contrast we found that 3-methoxypropionitrile, $CH_3OCH_2CH_2CN$, exists almost entirely as a fully *trans* conformer (3). Recent microwave studies of molecules of the type CH_3OCH_2X, X = F, Cl, Br, and C≡CH, each resulted in the detection of a sole conformer, the *gauche* (4–7). The Raman and infrared spectra of methyl propargyl ether, $CH_3OCH_2C{\equiv}CH$, are explicable in terms of a predominant *gauche* conformer in the solid, liquid, and vapor states (8). The infrared spectrum of methylthioacetonitrile in the liquid, solid, and dissolved states has been investigated recently by Owen and co-workers (9). They were unable to obtain the gas phase infrared spectrum because of the low vapor pressure of CH_3SCH_2CN at room temperature. Solution infrared spectra were interpreted as showing no evidence of rotational isomerism. On the other hand spectral changes during warming and cooling between the solid and liquid phases did indicate that rotational isomerization was taking place. They also measured the dipole moment of CH_3SCH_2CN in solution in toluene. The observed value of 3.10 D is below the values of 3.2 and 5.0 D which they predicted from bond moments for the *gauche* and *trans* conformers, respectively. This indicates that the proportion of *gauche* conformer is close to 100%.

In view of the ambiguous nature of the results of the infrared and dipole moment study a microwave investigation should be of value since both conformers should be detectable if present in significant amounts, as for methoxyacetonitrile (2). Also a microwave study provides an independent check on the value of dipole moment, which in Owen's study might have been an average over more than one conformer.

Experimental

The sample of methylthioacetonitrile was supplied by the Aldrich Chemical Company and was used without further purification.

Frequency measurements were carried out at room tem-

perature, because of the fairly low vapor pressure of the substance, and at sample pressures in the range 5–50 micron. The frequencies are considered to be accurate to 0.1 MHz or better. However, the lines were all rather broad, about 1 MHz at 30 micron typically, due to unresolved quadrupole structure, so that the frequency accuracy of some of the weaker excited state lines is in the range 0.2 to 0.5 MHz.

Initially scans and frequency measurements were made in the 26.5 to 37 GHz region using the Rice University Hewlett-Packard 8460A MRR spectrometer. Additional frequencies and the Stark shifts were measured at Queen's University with a 100 kHz Hughes-Wilson Stark modulation spectrometer, described earlier (10). Computations were done using the Queen's University Burroughs 6700 computer.

Rotational Spectrum

Predictions, Assignment

Predictions for the normal (^{32}S) species of CH_3SCH_2CN, based on structural parameters taken from the molecules $(CH_3)_2S$ (11) and CH_3CN (12), were that the *gauche* conformer should have $\kappa \simeq -0.88$ with the higher K_{-1} lines of the $J = 6 \leftarrow 5$ and $7 \leftarrow 6$ transitions falling near 29 250 and 34 100 MHz respectively, while the *trans* conformer should have $\kappa \simeq -0.98$ with the $J = 8 \leftarrow 7$ transition near 30 550 MHz and the $J = 9 \leftarrow 8$ transition near 34 350 MHz.

A scan at 150 micron pressure and 100 V cm^{-1} Stark voltage contained the expected transitions of the *gauche* conformer. However scans at low Stark voltages, ~20 V cm^{-1}, failed to reveal any absorption peaks assignable as the *trans* conformer high K_{-1} groups. Under similar conditions the *trans* conformer of methoxyacetonitrile (2) gave easily recognizable lines of about the same intensity as those due to the corresponding *gauche* conformer. Since in methoxyacetonitrile the proportion of *trans* conformer was estimated as about 5% and since the dipole moment components of CH_3OCH_2CN (2) and CH_3SCH_2CN (see below) are rather similar it can be concluded that in methylthioacetonitrile the proportion of *trans* conformer is appreciably less than 5%.

The frequencies in the *a*-type $J = 6 \leftarrow 5$ and $7 \leftarrow 6$ transitions and the *b*-type transitions of the *gauche* conformer were measured with the Hewlett-Packard instrument, those in the *a*-type $J = 4 \leftarrow 3$ and $5 \leftarrow 4$ transitions with the 100 kHz modulation spectrometer. The observed frequencies for the ground vibrational state are given in Table 1. The derived rotational constants and the three symmetric rotor centrifugal distortion constants are shown in Table 2. These constants were obtained from a least-squares fit which employed derivatives of frequency with respect to *A*, *B* and *C*, calculated with the aid of a rigid rotor frequency prediction program (ROTSPE), and the known derivatives with respect to D_K, D_{JK}, and D_J. Compared to *gauche* methoxyacetonitrile, which has $D_J = 2.93$ kHz and $D_{JK} = -23.3$ kHz, for methylthioacetonitrile D_J is similar in magnitude while D_{JK} is a factor of about 10 lower.

The ground vibrational state transition frequencies were also fitted with the computer program CDANAL, originally written by Dr. W. H. Kirchhoff. The resulting parameters are given in the lower part of Table 2. The last three centrifugal distortion coefficients are strongly correlated with correlation matrix elements of about 0.9. These three distortion coefficients are all negative in sign. This appears to be normal since a literature survey of some recently studied substances showed that for widely differing molecules these coefficients were always negative, for example sulfur dichloride (13), 3-chloropyridine (14), and *n*-propyl isocyanide, *trans* and *gauche* conformers (15). It may also be noted that the relationship:

$$[1] \qquad D_{JK} = -D_J - D_K - \tfrac{1}{4}\tau_{aaaa}\hbar^4$$

should be obeyed (16), where $\tau_{aaaa}\hbar^4 = \tau''_{aaaa}$. The calculated value of τ''_{aaaa} from eq. 1, using the *D* values from Table 2, is -2.75 ± 0.02 MHz which is fairly close to the τ''_{aaaa} value from the CDANAL fit of -2.89 ± 0.08 MHz. Better agreement would probably be obtained if a much larger number of transition frequencies were measured, including those of some *c*-type transitions.

Dipole Moment

The electric dipole moment components of *gauche* methylthioacetonitrile were determined from a least-squares fit to the four observed Stark shifts in Table 3. Linear plots of $\Delta\nu$ vs. E^2 were obtained for the four lobes, using Stark voltages in the range 350–4700 V cm^{-1}. The effect of ^{14}N nuclear quadrupole interaction was ignored. The Stark cell was calibrated using the value of $\mu_{OCS} = 0.71512 \pm 0.00003$ D (17). The dipole moment components are given in Table 3. For comparison the corresponding values for *gauche* methoxyacetonitrile are $\mu_a = 2.40$, $\mu_b = 1.37$, $\mu_c = 1.11$, and $\mu = 2.98$ D. The total dipole moment of 3.02 ± 0.03 D for *gauche* methylthioacetonitrile is close to Owen's value in toluene solution of 3.10 D (9) and serves to confirm the conclusion that the amount of *trans* conformer present must be very small.

Torsional Satellites

In addition to the rotational spectrum of the ground vibrational state of the *gauche* conformer two sets of vibrational satellites have been observed to lower frequency. These satellites are assigned as the first and second excited states (*T*1 and *T*2) of the S—CH_2 torsional mode. Transition frequencies for the *T*1 and *T*2 states are given in Table 1 and the derived constants in Table 2.

[a](Observed frequency − calculated frequency) is given in parentheses.

Measurements of intensity relative to the ground state absorption spectrum was carried out for a total of thirteen $T1$ satellite peaks in the $J = 6 \leftarrow 5$ and $7 \leftarrow 6$ transitions. These measurements yielded an average relative intensity of $0.61_4 \pm 0.07_6$ at 25°C, which corresponds to a torsional frequency of $101 \pm 30\ cm^{-1}$. This frequency is similar to those found in closely related molecules of $93\ cm^{-1}$ in CH_3OCH_2CN (2), and of $105\ cm^{-1}$ in CH_3OCH_2-$C{\equiv}CH$ (7).

Neither methyl torsion satellites nor any splitting of ground vibrational state lines by methyl torsion has been observed. If some high J c-type Q branch lines could be assigned then it should be possible to determine the height of the barrier, V_3, from the A–E splitting of the ground state. This has been done by Karlsson (18) for methoxyacetonitrile, giving a V_3 value of 2280 cal mol^{-1}. It might be expected that the value in methylthioacetonitrile would be somewhat lower than this figure in view of the barriers 2720 cal mol^{-1} in $(CH_3)_2O$ (19) and 2132 cal mol^{-1} in $(CH_3)_2S$ (11).

Molecular Structure

Estimates of up to three structural parameters can be made from the three observed rotational constants of the *gauche* conformer if assumptions are made concerning the values of the remaining parameters.

Three angles upon which the rotational constants are fairly strongly dependent are $\angle C_1SC_2$, the dihedral angle between the C_1SC_2 and SC_2C_3 planes, and the angle of tilt which the axis of each

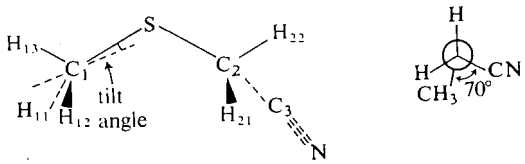
attached group, CH_3 or CH_2CN, makes with the corresponding SC bond. Both attached groups were taken to have the same tilt angle, a positive tilt angle being defined as one that causes a decrease of the $H_{13}C_1S$ and SC_2C_3 angles from the value at zero tilt.



In dimethyl sulfide the methyl groups are tilted at 2.75° so that their axes are at an angle of 104.37° while the CSC angle is 98.87° (11). Including a 2.75° tilt angle for each of the CH_3 and CH_2CN groups the following initial structure was assumed, based on the known r_s structures of $(CH_3)_2S$ (11) and CH_3CN (12).

$C_1S = C_2S$	= 1.802 Å	$\angle H_{13}\,C_1S$	= 106.63°
C_2C_3	= 1.458 Å	HC_1H angles	= 109.57°
C_3N	= 1.157 Å	$\angle C_1SC_2$	= 98.87°
C_1H distances	= 1.091 Å	$\angle SC_2C_3$	= 106.92°
C_2H distances	= 1.12 Å	$\angle C_2C_3N$	= 180°
Dihedral angle	= 70°	$\angle H_{21}C_2H_{22}$	= 109.27°
Tilt angle	= 2.75°	$\angle C_3C_2H_{21}$ = $\angle C_3C_2H_{22}$	= 109.67°

This structure gave calculated rotational constants (in MHz): A = 7686.07, B = 2681.84, and C = 2270.74.

Two procedures were tried in fitting the observed A, B, and C values. First a least-squares fit was performed by allowing the C_1SC_2 angle and the dihedral angle to vary with all the remaining parameters fixed. The best fit occurred at a C_1SC_2 angle of 104.69° and a dihedral angle of 69.02° and yielded calculated rotational constants (in MHz) A = 7700.70, B = 2615.06, and C = 2196.16. In the second procedure the tilt angle was considered as a third variable and the new values of the angles were obtained by solving three simultaneous equations involving the observed rotational constants, those calculated from the initial structure, and the derivatives of A, B, and C with respect to the three angles. The observed rotational constants were reproduced at $\angle C_1SC_2$ = 102.94°, dihedral angle = 63.04°, and tilt angle = −0.32°. On the basis of these calculations reasonable estimates of the two angles of main interest are $\angle C_1SC_2$ = 104 ± 2° and dihedral angle = 66 ± 5°.

The dihedral angle estimate is slightly lower than the one of 69° estimated in methoxyacetonitrile (2). For that molecule the solution (in carbon tetra-

chloride) dipole moment of 2.99 D has been interpreted by Ritchie and co-workers (20) in terms of a single conformer, the *gauche*, with dihedral angle 70°. In this case the microwave study showed the *gauche* form to be present in 95% abundance and to have a dipole moment of 2.98 D. Ritchie has also made some corresponding predictions, which include the effect of bond polarizability, of the dipole moment of *gauche* methylthioacetonitrile for various dihedral angles: 60°, 2.88 D; 65°, 2.98 D; 70°, 3.09 D; and 75°, 3.19 D. The observed dipole moment of 3.02 D in the present study together with an estimated dihedral angle near 66° are in good agreement with Ritchie's predictions.[1]

Application de la spectrométrie ir et Raman à l'étude des complexes en solution aqueuse – $Be^{2+} - H_2C_2O_4$

M. JABER,[1] F. BERTIN ET G. THOMAS-DAVID

Laboratoire de Chimie Analytique II, Université Claude Bernard, Lyon I, 43 boulevard du 11 Novembre 1918, 69621 Villeurbanne, France

Reçu le 28 juin 1977

M. JABER, F. BERTIN et G. THOMAS-DAVID. Can. J. Chem. **56**, 777 (1978).

L'étude des solutions d'oxalate complexe de béryllium, par spectrométrie ir et Raman, a montré la formation des trois espèces complexes: BeC_2O_4, $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$ quel que soit le rapport étudié. Chaque complexe est caractérisé par des fréquences de vibration spécifiques indépendantes du p*H* de la solution. La mesure des hauteurs de certaines bandes de diffusion Raman caractéristiques des complexes nous a permis de calculer la concentration de chaque espèce en fonction du p*H*, ainsi que leurs constantes de stabilité.

M. JABER, F. BERTIN, and G. THOMAS-DAVID. Can. J. Chem. **56**, 777 (1978).

A study of solutions of the oxalate complexes of berylium by ir and Raman spectrometry has demonstrated the formation of three complexed species: BeC_2O_4, $Be(C_2O_4)_2^{2-}$, and $Be_3(OH)_3(C_2O_4)_3^{3-}$ regardless of the ratio used. Each complex is characterized by specific vibrational frequencies which are independent of the p*H* of the solution. It was possible to determine the concentration of each species as a function of p*H*, as well as its stability constant, by measuring the intensities of certain characteristic bands in the Raman scattering spectrum.

[Journal translation]

Introduction

Les complexes du béryllium avec l'acide oxalique ont fait l'objet de plusieurs recherches (1–18) qui conduisent, pour la plupart, à l'existence, tant en solution qu'à l'état cristallisé, de deux espèces BeC_2O_4 et $Be(C_2O_4)_2^{2-}$.

Dragulescu a découvert qu'une espèce hydroxydée polynucléaire $Be_3(OH)_3(C_2O_4)_3^{3-}$ (19) pouvait se former à côté du complexe BeC_2O_4 en dépit d'un excès d'ions oxalate. Dans ce travail l'auteur ne mentionne à aucun moment la formation de $Be(C_2O_4)_2^{2-}$ dont il avait pourtant admis la présence en faible proportion dans une publication antérieure (18).

Plus récemment Faucherre (20) a pu conclure à l'existence à côté de BeC_2O_4 et $Be(C_2O_4)_2^{2-}$ d'une espèce hydroxydée différente de celle de Dragulescu: $Be_2(OH)_2(C_2O_4)_2^{2-}$. Les valeurs des constantes de stabilité données par les auteurs pour les mêmes espèces sont assez différentes.

Ce mémoire présente les résultats obtenus dans l'étude systématique du système Be^{2+}–$C_2O_4^{2-}$ en solution aqueuse par spectrométrie ir et Raman, en suivant l'évolution des spectres en fonction du p*H* pour différents rapports t = [métal]/[coordinat]: mise en évidence des espèces formées et par analogie avec les systèmes H^+–$C_2O_4^{2-}$ et Al^{3+}–$C_2O_4^{2-}$ (22) détermination des concentrations des complexes et calcul de leurs constantes de formation.

[1]Bousier C.N.R.S. Libanais.

Conditions expérimentales

Les solutions étudiées sont de concentrations 0.30, 0.32 et 0.225 *M* en acide oxalique pour des rapports t = [métal]/[coordinat] respectivement $\frac{1}{3}$, $\frac{1}{2}$ et 1. Elles sont obtenues à partir de solutions mères préparées en dissolvant du chlorure de béryllium anhydre $BeCl_2$ et de l'acide oxalique $H_2C_2O_4 \cdot 2H_2O$, produits Merck. Le p*H* des solutions est fixé par addition de soude 13 *N* ou d'acide chlorhydrique PROLABO RP (la soude a été préférée à la potasse pour une question de solubilité). Le p*H* est mesuré au moyen de la chaîne suivante: electrode en verre/solution titrée/NaCl saturé/Hg_2Cl_2–Hg par l'intermédiaire d'un potentiomètre Metrohm E 388. La précision sur la mesure de la concentration en ion H^+ est faible compte tenu de la valeur élevée et variable de la force ionique.

Quant aux solutions dans l'eau deutériée elles sont préparées à partir du chlorure de béryllium anhydre et de l'oxalate neutre de sodium $Na_2C_2O_4$, produits Merck, dans D_2O 99.75%. L'acidité des solutions examinées est fixée par addition de DCl ~ 7.8 *N* dont la teneur en D_2O est 99.5%.

Les spectres Raman sont enregistrés à la température ordinaire (20°C) dans une région de fréquences comprise entre 1800 et 150 cm^{-1} avec un appareil CODERG PHO. La raie excitatrice est la raie 488 nm d'un laser à argon ionisé Spectra Physics. Les conditions d'enregistrement des spectres sont les suivantes: la puissance du laser est 900 mW, la tension d'alimentation du photomultiplicateur refroidi est de l'ordre de 1200 V, les fentes ont une largeur spectrale constante de 6 cm^{-1} et la vitesse de défilement du réseau V = 25 cm^{-1}/mn; l'échantillon à examiner est contenu dans une petite cuve en verre de 1 ml.

Les spectres ir sont réalisés à la température ordinaire entre 2000 et 650 cm^{-1} sur un spectromètre à double faisceau: Perkin-Elmer 457. La cellule est constituée de deux fenêtres d'Irtran II d'épaisseur 27 μm.

Résultats de la spectrométrie Raman

Evolution des spectres Raman en fonction du

rapport [métal]/[coordinat] et du pH des solutions: les modifications spectrales qui se produisent pour les rapports $t = 1$ et $t = \frac{1}{2}$ quand le pH augmente sont données dans les tableaux 1 et 2. Les spectres les plus caractéristiques ont été choisis; h_v représente pour une fréquence $\bar{\nu}$, l'intensité relative des maxima des bandes par rapport à l'intensité de la bande de l'eau à 1640 cm^{-1} prise comme référence (22). Des spectres ont été enregistrés en solution deutériée à différents pH et pour les différents rapports afin de suivre l'évolution des bandes dans la région de fréquences 1400–1800 cm^{-1}. Les différentes observations sont les suivantes.

Spectres Raman des complexes dans un rapport $t = \frac{1}{2}$ *(tableau 1)*

Le domaine de pH: $0.4 \leq$ p$H \leq 7.3$ s'étend du début de formation des complexes à la précipitation de l'hydroxyde de béryllium. Les spectres à p$H < 0.4$ comportent essentiellement les bandes, précédemment attribuées aux espèces $H_2C_2O_4$ et $HC_2O_4^-$ en solution (22) et une bande à 533 cm^{-1} due à l'espèce $Be(H_2O)_4^{2+}$ en solution (21). La neutralisation de la solution nous permet de distinguer trois étapes.

Dans un domaine de pH: $0.4 <$ p$H < 1.6$ il apparait de nouvelles bandes, dues aux complexes dont l'intensité augmente régulièrement avec le pH; ces raies ont une fréquence constante sur toute la gamme définie de pH et se situent à 365, 558, 601, 793, 857, 910, 1093, 1283, 1410, 1698 et 1730 cm^{-1}. Simultanément il y a une diminution d'intensité des bandes dues au coordinat.

A p$H \sim 1.6$ d'autres raies commencent à apparaître aux fréquences 583, 614, 833 et 1743 cm^{-1}. Dans l'intervalle $1.6 <$ p$H < 4.2$ leur position en fréquence reste constante et leurs intensités augmentent régulièrement, tandis qu'on assiste à une diminution d'intensité des raies 601, 793 et 1730 cm^{-1} qui disparaissent complètement à p$H \sim 4.2$, et à un glissement de deux fréquences 365 → 368 et 1410 → 1417 cm^{-1}; de plus l'intensité des bandes 911 et 1417 cm^{-1} augmente considérablement comme nous

1750	0.50										

montre le tableau 1. A p$H \sim 4.1$ les bandes du coordinat existant sur le spectre sont celles attribuées à $C_2O_4^{2-}$ en solution; la concentration de ce dernier, calculée sur les bandes situées à 1308 et 1486 cm^{-1} en utilisant les coefficients de diffusion calculés antérieurement (22), représente 16% de la concentration analytique en coordinat.

A p$H > 4.5$ quatre bandes apparaissent à 498, 1683, 1708 et 1727 cm^{-1}, pendant que disparaissent celles situées à 614, 1698 et 1743 cm^{-1} et que l'intensité des bandes attribuées à $C_2O_4^{2-}$ augmente. L'augmentation du pH entraîne un déplacement progressif important de la fréquence de vibration située à 1417 cm^{-1} suivi d'une diminution d'intensité; en même temps l'intensité de la bande à 368 cm^{-1} diminue.

A p$H \sim 7.3$ les fréquences de vibration des complexes se trouvent ainsi à: 368, 449, 498, 583, 838, 857, 911, 1103, 1283, 1428, 1683, 1708 et 1727 cm^{-1}. Les résidus de deux bandes 614 et 1743 cm^{-1}, très intenses dans l'étape précédente, se présentent ici sous forme d'épaules à peine marquées; en outre la concentration de l'ion $C_2O_4^{2-}$ non engagé constitue presque la moitié de la concentration analytique du coordinat.

Spectres Raman des complexes dans un rapport $t = \frac{1}{3}$

Nous pouvons distinguer aussi trois régions principales analogues à celles que nous avons observées pour un rapport $t = \frac{1}{2}$. Les bandes des complexes de la première étape apparaissent dès p$H \sim 0.3$. Les raies aperçues à p$H \sim 1.6$ dans un rapport $t = \frac{1}{2}$ commencent à apparaître à p$H \sim 1.4$ pour $t = \frac{1}{3}$.

Le spectre des solutions dans l'intervalle $1.4 <$ pH < 4.7 est analogue à la deuxième étape du rapport $t = \frac{1}{2}$, on remarque cependant la présence de bandes caractéristiques du coordinat libre et le déplacement progressif de la fréquence $446 \rightarrow 450$ cm^{-1}. Ce déplacement provient de l'interférence de deux bandes larges dues l'une au coordinat, l'autre aux complexes. Il en résulte une bande de fréquence intermédiaire. Parmi les spectres de cet intervalle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

trois ont été enregistrés aux pH: 3.4, 3.8 et 4.5, dans lesquels nous observons seulement les douze raies à 368, 450, 583, 614, 833, 857, 911, 1093, 1283, 1417, 1693 et 1743 cm^{-1} d'intensité relative constante, et les diverses bandes déjà attribuées au coordinat libre. A ces pH la concentration du coordinat non engagé représente exactement le tiers de la concentration analytique.

Au delà de pH 4.9 on assiste à une diminution d'intensité des bandes observées dans l'étape précédente et en même temps à une apparition des raies nouvelles déjà observée pour $t = \frac{1}{2}$ à p$H > 4.5$. On constate la même évolution dans le rapport $t = \frac{1}{2}$, avec une augmentation d'intensité des raies dues à $C_2O_4^{2-}$ en solution. Les deux fréquences situées à 614 et 1743 cm^{-1} subsistent avec une faible intensité même à p$H \sim 7$, et la quantité de $C_2O_4^{2-}$ en solution représente les $\frac{2}{3}$ de la concentration analytique à cette valeur du pH.

Spectres Raman des complexes dans un rapport t = *1 (tableau 2)*

L'étape intermédiaire observée pour $t = \frac{1}{2}$ et $t = \frac{1}{3}$ est moins claire ici. En effet, les spectres des solutions dans l'intervalle de pH 0.5 < pH < 2.6 comprennent les mêmes fréquences observées dans la première étape des rapports $t = \frac{1}{2}$ et $\frac{1}{3}$, ainsi que celles dues au coordinat libre et $Be(H_2O)_4^{2+}$. Ces dernières disparaissent à p$H \sim 2.6$. Quant à la bande 456 cm^{-1} primitivement attribuée aux trois espèces $H_2C_2O_4$, $HC_2O_4^-$ et $C_2O_4^{2-}$ (22) elle subit une diminution irrégulière d'intensité et un déplacement progressif de 456 à 446 cm^{-1} lorsque le pH augmente. Toutefois son intensité reste importante malgré la disparition complète de toutes les autres raies caractéristiques du coordinat, il y a donc certainement une bande de diffusion due aux complexes dans ce domaine de fréquence, en interférence avec la bande du coordinat.

Sur les spectres des solutions de 2.6 < pH < 4.1 en plus des bandes déjà observées, il apparait d'autres épaulements à 583, 614, 833 et 1743 cm^{-1} correspondant à des bandes intenses pour $t = \frac{1}{2}$ et $t = \frac{1}{3}$ dans le même domaine du pH. La diminution d'intensité des bandes 446, 601 et 793 cm^{-1} et le déplacement progressif de deux fréquences 365 → 368 cm^{-1} et 1410 → 1417 cm^{-1} sont remarqués lorsque le pH augmente.

Les mêmes phénomènes observés précédemment pour $t = \frac{1}{2}$ et $t = \frac{1}{3}$ à p$H > 4.5$ et 4.9 respectivement, sont constatés ici à p$H > 4.1$; cependant la bande située à 601 cm^{-1} se déplace progressivement dans l'intervalle 4.1 < pH < 4.6 pour atteindre 583 cm^{-1}. Enfin l'intensité des bandes très faibles à 1308 et 1486 cm^{-1} dues à $C_2O_4^{2-}$ (22) et apparues à p$H \sim 3.7$ subit une légère augmentation.

Discussion

Identification des différentes espèces complexes

L'observation globale des spectres Raman montre la présence de trois espèces caractérisées par des fréquences assez différentes, quel que soit le rapport étudié. Pour le rapport $t = \frac{1}{3}$, l'espèce intermédiaire caractérisée par les fréquences 368, 450, 583, 614, 833, 857, 911, 1093, 1283, 1417, 1698 et 1743 cm^{-1} est prépondérante dans l'intervalle 3.5 < pH < 4.5; toutes ces bandes conservent une intensité maximum et constante dans ce domaine de pH en présence d'un excès de coordinat libre en solution représentant le $\frac{1}{3}$ de la concentration analytique du coordinat. Si on admet que la quasitotalité du béryllium est complexée ces bandes sont à attribuer au composé $Be(C_2O_4)_2^{2-}$ déjà signalé par d'autres auteurs (3, 10, 11, 18, 20). Ceci est en bon accord avec les résultats obtenus pour $t = \frac{1}{2}$ et explique la faible intensité des bandes de ce composé pour $t = 1$.

Quant à la première étape commune aussi pour tous les rapports, elle correspond à la formation d'un composé possédant les fréquences de vibrations situées à 365, 445, 558, 601, 793, 857, 910, 1093, 1283, 1410, 1698 et 1730 cm^{-1} qui restent fixes quelle que soit l'intensité des bandes. Ce composé précède l'apparition du complexe $Be(C_2O_4)_2^{2-}$. Sa composition, calculée pour $t = 1$, donne une valeur du rapport $[Be]/[C_2O_4]$ très proche de l'unité, il s'agit donc incontestablement de BeC_2O_4.

La dernière étape commune pour tous les rapports, doit correspondre à la constitution d'une espèce hydroxyée caractérisée par les bandes de diffusion: 368, 449, 498, 583, 838, 857, 911, 1103, 1283, 1428, 1683, 1708 et 1727 cm^{-1}. En effet, dans cette étape le béryllium non engagé, pour $t = \frac{1}{2}$ et $t = \frac{1}{3}$ peut être considéré comme nul; la quantité de coordinat complexé indique que ce complexe possède un rapport stoechiométrique $[Be]/[C_2O_4] \sim 1$.

Dans un travail effectué au laboratoire (23), Duc a observé par potentiométrie dans ce domaine de pH la formation du complexe $Be_3(OH)_3(C_2O_4)_3^{3-}$, déjà signalé par Dragulescu (19). Cette espèce qui correspond bien à une stoechiométrie 1/1 en métal/coordinat est probablement celle que nous observons par spectrométrie et nous retenons cette hypothèse.

La fig. 1 représente les spectres des trois complexes BeC_2O_4, $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$, enregistrés dans des conditions telles que chacun d'eux est seul en solution. Sur ces spectres on retrouve les modifications de fréquence et d'intensité mises en

évidence lors de l'étude systématique à t et pH variables.

Confirmation apportée par spectrométrie infrarouge

Grâce à l'existence de certaines bandes très intenses caractéristiques des espèces $HC_2O_4^-$ (1635 cm^{-1}) et $C_2O_4^{2-}$ (1310 et 1570 cm^{-1}) (22), l'étude des oxalatobéryllates dans H_2O et D_2O par spectrométrie ir nous a permis de repérer les différentes raies dues aux complexes sans difficultés majeures.

Pour un rapport $t = \frac{1}{2}$, le déplacement plus ou moins important des fréquences des bandes, les variations d'intensité et l'apparition ou la disparition de nouvelles bandes, en fonction du pH, montrent trois étapes successives en bon accord avec les spectres Raman. La première caractérise une espèce individuelle à p$H < 1.6$. Puis à partir de pH 1.6 un deuxième composé complexe commence à se former dont les bandes apparaissent seules à p$H \sim 4$ environ, après la disparition quasicomplète des bandes du coordinat. A des p$H > 4.5$ une dernière série de bandes est observée, ainsi que toutes les bandes du $C_2O_4^{2-}$ en solution. L'intensité des bandes de $C_2O_4^{2-}$ augmente, dans cet intervalle d'acidité, quand le pH augmente.

Pour $t = 1$ les bandes de la première étape persistent seules jusqu'à p$H \sim 3$. Celles de la dernière apparaissent à p$H > 4$, et simultanément on aperçoit les bandes du coordinat sous faible intensité. Par contre certaines bandes caractéristiques du complexe intermédiaire sont observées comme épaules; cette étape est beaucoup moins nette que les autres pour ce rapport.

Ces observations en fonction du t et du pH recoupent celles que nous avons observées par spectrométrie Raman concernant la formation de trois composés complexes en solution. On donne dans le tableau 3 les fréquences que nous attribuons aux trois complexes en question.

Méthode de détermination des concentrations par spectrométrie Raman des différents complexes formés

Choix des bandes

L'évolution des spectres Raman des oxalatobéryllates, en fonction du pH et du rapport [métal]/[coordinat], montre l'existence des bandes intenses caractéristiques de chaque espèce, surtout dans le domaine de fréquence situé vers 600 cm^{-1}, mais qui ne sont pas sans interférences entre elles. Pour cela notre calcul des coefficients de diffusion aux différentes fréquences est fait en procédant par étapes. La bande de l'eau située à 1640 cm^{-1} est utilisée comme étalon interne (22).

La concentration du coordinat non engagé en complexe est calculée sur les bandes 848 et 868 cm^{-1} dues aux espèces $H_2C_2O_4$ et $HC_2O_4^-$ et 1308, 1486 cm^{-1} caractéristiques de l'espèce $C_2O_4^{2-}$ en solution. Les deux premières ne sont pratiquement pas influencées par la bande très faible des complexes située à 857 cm^{-1}. Les coefficients de diffusion trouvés antérieurement (22) sont utilisés ici pour les quatres fréquences.

Pour déterminer la concentration des trois espèces: BeC_2O_4, $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$ on a pu utiliser l'intensité des bandes aux fréquences

situées à 368, 583, 601, 614, 1417 et 1428 cm^{-1}, indépendantes des bandes du coordinat sous toutes les formes à l'exception des deux dernières; celles-ci sont influencées d'une part par les bandes du triplet 1380–1410–1444 cm^{-1} dû à $HC_2O_4^-$ et la bande située à 1452 cm^{-1} attribuée à $C_2O_4^{2-}$ non engagé d'autre part. Pour cette raison la relation générale exprimant l'intensité à ces deux fréquences tient compte de la contribution de ces deux espèces dont les coefficients de diffusion utilisés B_v et C_v sont calculés sur les spectres de l'acide oxalique en fonction du pH (22) dans des intervalles convenables; les moyennes de dix valeurs reproductibles sont $B_{1417} = 1.34$ et $B_{1428} = 1.10$ pour $HC_2O_4^-$, $C_{1417} = 0.15$ et $C_{1428} = 0.30$ pour $C_2O_4^{2-}$.

Principe de la méthode de calcul des concentrations

Les symboles utilisés dans ce calcul ont toujours la même signification que précédemment (22). De plus, P, Q et R représentent les concentrations de BeC_2O_4, $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$, et D_v, E_v et F_v leurs coefficients de diffusion.

Le principe de la méthode de calcul, peut être résumé de la façon suivante.

Les bandes 848, 868, 1308 et 1486 cm^{-1} permettent de calculer la concentration du coordinat libre selon les relations:

$$[1] \qquad h_{848} = A_{848}X + B_{848}Y$$

$$[2] \qquad h_{868} = A_{868}X + B_{868}Y$$

$$[3] \qquad h_{1308} = C_{1308}Z, \quad h_{1486} = C_{1486}Z$$

Les relations de bilan entrainent:

$$[4] \qquad CL = (X + Y + Z) + P + 2Q + 3R$$

$$[5] \qquad CM = [Be^{2+}] + P + Q + 3R$$

Etant donné l'interférence possible des bandes des différentes espèces complexes et l'interférence des bandes du coordinat aux fréquences 1417 et 1428 cm^{-1}, les relations aux six fréquences observées sont exprimées sous la forme générale:

$$[6] \qquad h_v = B_vY + C_vZ + D_vP + E_vQ + F_vR$$

Enfin à partir des différents coefficients de diffusion (voir ci dessous) et de la concentration du coordinat libre en solution, le programme SPECTRAL (22) permet de déterminer par moindres carrés les concentrations optimales de trois espèces P, Q et R.

Calculs des coefficients de diffusion D_v, E_v *et* F_v *à différentes fréquences*

Pour tous les rapports étudiés, les spectres enregistrés à faible pH nous permettent de calculer la concentration du coordinat libre $(X + Y + Z)$ par les relations [1], [2] et [3] et par conséquent d'obtenir le coefficient D_v, en appliquant les relations [4] et [6] dans un intervalle de pH précédant le début de l'apparition des bandes intenses attribuées à $Be(C_2O_4)_2^{2-}$, Q et R étant nulles. Quinze spectres ont été utilisés pour ce type de calcul.

Sur les spectres des solutions à p$H > 6.5$ pour tous les rapports nous n'observons pratiquement que les bandes attribuées à l'espèce $Be_3(OH)_3(C_2O_4)_3^{3-}$; le résidu très faible de la bande intense à 614 cm^{-1} due à l'espèce $Be(C_2O_4)_2^{2-}$ (et qui ne disparait à aucun moment) est négligé dans notre calcul. Dans ce cas la quantité du coordinat non engagé est calculée par la relation [3] et par suite la relation [6] donne les coefficients F_v, P et Q sont négligeables. Sept spectres enregistrés dans ce domaine de pH donnent des valeurs assez reproductibles de F_v quel que soit le rapport t.

Enfin étant donnée l'interférence des bandes des trois espèces à toutes les fréquences sélectionnées, le calcul des coefficients de diffusion E_v est réalisé indirectement sur les spectres de deux rapports $t = \frac{1}{2}$ et $\frac{1}{3}$ suivant deux voies différentes utilisant les valeurs moyennes des coefficients de diffusion D_v et F_v déjà déterminés.

La première méthode consiste à se placer dans un intervalle $2.8 <$ p$H < 4$ où l'on peut supposer les ions Be^{2+} entièrement complexés et la concentration en espèce $Be_3(OH)_3(C_2O_4)_3^{3-}$ absolument nulle. Dans ces conditions les relations [1], [2] et [3] permettent de déterminer le facteur $(X + Y + Z)$, les relations [4] et [5] les valeurs de P et Q; nous en déduisons E_v d'après la relation [6].

Après la disparition complète des bandes attribuées à BeC_2O_4, les deux espèces $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$ coexistent à des $4.6 <$ p$H < 5.5$. Les relations [2] et [3] nous permettent de connaître $(Y + Z)$, P et X étant nulles à ces pH; par suite Q et R sont données par les relations [4] et [5], et permettent de calculer les coefficients E_v, par la relation [6].

Dans tous nos calculs nous avons supposé que les espèces hydroxydées simples du béryllium étaient absentes ou en quantité négligeable; ceci est confirmé par le fait que les bandes de $Be_3(OH)_3^{3+}$ (21) ne sont observées à aucun moment.

Le tableau 4 donne quelques exemples parmi les 21 spectres enregistrés suivant les deux voies différentes. Il montre que ces valeurs, à l'exemple de celles de D_v et F_v sont reproductibles.

On rassemble dans le tableau 5 les moyennes des différentes valeurs trouvées pour D_v, E_v et F_v aux six fréquences signalées.

diffusion, des hauteurs relatives des bandes aux différentes fréquences et de la concentration du coordinat non engagé, nous avons à l'aide du programme SPECTRAL dont le principe a été décrit dans un travail antérieur (22), calculé les concentrations P, Q et R des différentes espèces présentes en solution en fonction du degré d'acidité pour tous les rapports étudiés.

Ces valeurs des concentrations en complexes sont utilisées pour déterminer les valeurs optimales des constantes des équilibres de formation des complexes:

$$Be^{2+} + C_2O_4^{2-} \rightleftarrows BeC_2O_4 \qquad \beta_1$$

$$Be^{2+} + 2C_2O_4^{2-} \rightleftarrows Be(C_2O_4)_2^{2-} \qquad \beta_2$$

$$3Be^{2+} + 3OH^- + 3C_2O_4^{2-} \rightleftarrows Be_3(OH)_3(C_2O_4)_3^{3-} \qquad \beta_{333}$$

L'affinement par moindres carrés est réalisé à l'aide du programme AFFIBETA à partir de 50 points expérimentaux situés dans un domaine de pH: $0.5 < pH < 7.4$. Sont introduites également les constantes des espèces hydroxydées simples du béryllium (24). Les valeurs obtenues sont:

$$\beta_1 = 1.82 \times 10^3$$

$$\beta_2 = 2.11 \times 10^5$$

$$\beta_{333} = 8.75 \times 10^{39}$$

Nous les avons utilisées pour obtenir la courbe de répartition des complexes à l'aide du programme CALCON. Les figs 2 et 3 représentent cette répartition calculée pour les deux rapports $t = \frac{1}{2}$ et $\frac{1}{3}$. Nous représentons sur ces mêmes figures la répartition obtenue en utilisant les valeurs des constantes

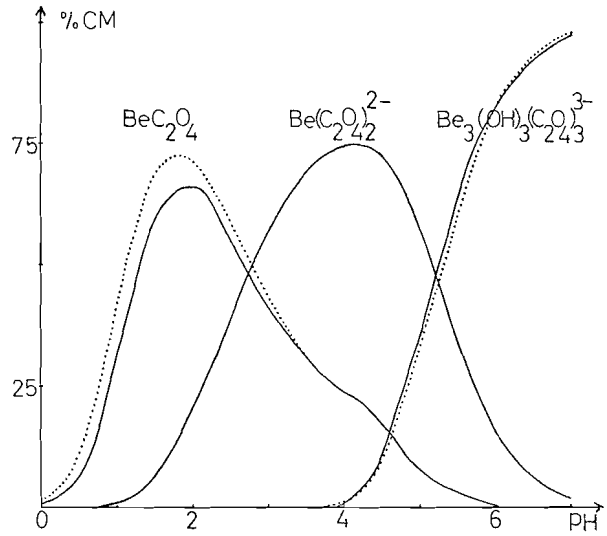

FIG. 2. Courbe de répartition des oxalatobéryllates représentant le pourcentage de la concentration de béryllium engagé dans chaque complexe par rapport à la concentration analytique CM pour $t = \frac{1}{2}$. — Constantes déduites des spectres Raman; ··· constantes obtenues par Duc par la méthode de pH. Pour $Be(C_2O_4)_2^{2-}$ les deux courbes sont confondues.

trouvées par Duc (23) par la méthode de pH pour la concentration 10^{-2} M en coordinat en milieu perchlorate 0.5 M.

Conclusion

L'étude systématique des spectres Raman des oxalatobéryllates en solution aqueuse, en fonction du rapport t = [métal]/[coordinat] et du pH, montre très clairement quel que soit le rapport, la formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

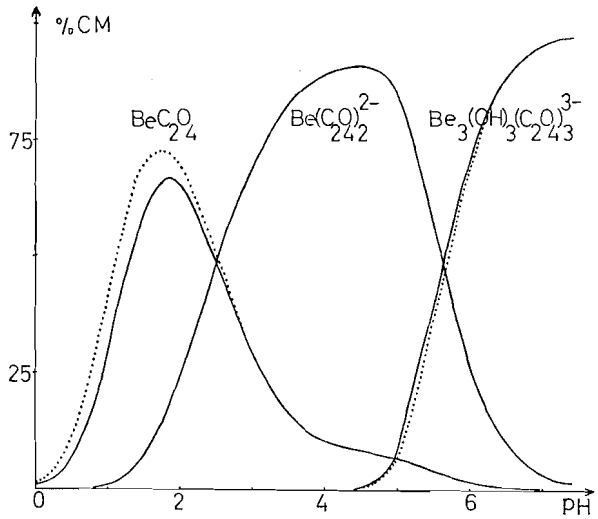

FIG. 3. Courbes de répartition des oxalatobéryllates représentant le pourcentage de la concentration de béryllium engagé dans chaque complexe par rapport à la concentration analytique CM pour $t = \frac{1}{3}$. — Constantes déduites des spectres Raman; ··· constantes obtenues par Duc par la méthode de pH. Pour $Be(C_2O_4)_2^{2-}$ les deux courbes sont confondues.

de trois espèces complexes caractérisées par des fréquences de vibration Raman et infrarouge spécifiques. A partir des spectres des différentes espèces, dont les bandes sont séparées de certaines bandes du coordinat libre, nous avons déterminé le rapport stoechiométrique [métal]/[coordinat] pour chaque complexe et identifié ainsi BeC_2O_4, $Be(C_2O_4)_2^{2-}$ et $Be_3(OH)_3(C_2O_4)_3^{3-}$. Leurs constantes de stabilité sont déduites de la concentration des espèces déterminées sur la hauteur des bandes.

Ces résultats sont en bon accord avec ceux obtenus par Duc (23) pour $t = \frac{1}{2}$ et $\frac{1}{3}$ tant en ce qui concerne la nature des espèces que leur stabilité; comme le montre la comparaison des courbes de répartition sur les figs 2 et 3. Par contre, pour le rapport $t = 1$, cet auteur interprète les résultats potentiométriques obtenus, par la présence d'une seconde espèce hydroxydée $Be_3(OH)_3(C_2O_4)^+$ à côté de $Be_3(OH)_3(C_2O_4)_3^{3-}$. Dans notre étude quel que soit le rapport, les spectres à p$H > 4.5$ montrent une série de bandes de fréquences constantes à l'exception d'un léger déplacement, déjà cité pour $t = 1$ de la bande à 601 cm^{-1} dans l'intervalle $4.1 <$ p$H < 4.6$. Des spectres enregistrés dans ce domaine de pH pour un rapport $t = 1.5$ qui devrait favoriser la formation de l'espèce $Be_3(OH)_3(C_2O_4)^+$ par rapport à $Be_3(OH)_3(C_2O_4)_3^{3-}$ n'ont pas modifié les résultats. La formation du complexe $Be_3(OH)_3(C_2O_4)_3^{3-}$ est donc la plus probable à la concentration étudiée même pour le rapport $t = 1$; de plus, si l'espèce hydroxydée $Be_3(OH)_3(C_2O_4)^+$ existait en possédant les mêmes fréquences de vibration que l'autre, la quantité toujours très faible d'oxalate libre en solution pour $t = 1$ et la valeur constante des coefficients F_v (voir ci dessus) pour tous les rapports, rejettent sa présence, au moins en quantité importante. Le déplacement observé dans les deux rapports $t = 1$ et 1.5 peut s'expliquer par interférence des deux bandes intenses 601 et 583 cm^{-1} dues respectivement à BeC_2O_4 et $Be_3(OH)_3(C_2O_4)_3^{3-}$ (le complexe $Be(C_2O_4)_2^{2-}$ est toujours en faible quantité). Cette interférence est inexistante pour les rapports $t = \frac{1}{2}$ et $\frac{1}{3}$ car la bande à 583 cm^{-1} caractéristique de $Be_3(OH)_3(C_2O_4)_3^{3-}$ n'apparait qu'après la disparition du complexe BeC_2O_4 (bandes à 601 cm^{-1}) et ne peut que renforcer celle du complexe intermédiaire $Be(C_2O_4)_2^{2-}$ à 583 cm^{-1}.

L'examen des solutions d'oxalatobéryllate à p$H >$ 5 (où seuls existent les complexes hydroxydés pour $t = 1$ et 1.5) par la résonance magnétique nucléaire du noyau ^{13}C nous a apporté une confirmation supplémentaire. En effet, pour le rapport $t = \frac{1}{3}$ à p$H \sim 6.5$ un seul signal apparait à 1008 Hz par rapport à C_6D_6 utilisé comme référence externe. Pour $t = 1$ et 1.5 à p$H > 5$ les spectres montrent la présence d'un seul signal situé à 1008 Hz de la référence utilisée. Ceci est en bon accord avec les interprétations que nous avons présentées à propos des spectres Raman et le signal observé pour tous les rapports est dû au complexe $Be_3(OH)_3(C_2O_4)_3^{3-}$ en solution.

La différence que l'on peut noter entre les courbes de répartition déduite des résultats spectrométrique et potentiométrique (figs 2 et 3) peut s'expliquer principalement par l'erreur commise sur la mesure de pH pour les valeurs très acides.

Mechanism of borohydride reductions. Evidence for lack of disproportionation in the reduction of ketones

DONALD C. WIGFIELD AND FREDERICK W. GOWLAND
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received September 26, 1977

DONALD C. WIGFIELD and FREDERICK W. GOWLAND. Can. J. Chem. **56**, 786 (1978).

Examination of unreacted sodium borohydride after reduction of ketones by mixtures of $NaBH_4$ and $NaBD_4$ shows that it is still isotopically pure and that no detectable species $NaBH_nD_{4-n}$ have been formed. Disproportionation of intermediates back to $NaBH_4$ therefore plays no significant role in the reduction.

DONALD C. WIGFIELD et FREDERICK W. GOWLAND. Can. J. Chem. **56**, 786 (1978).

Un examen du borohydrure de sodium qui n'a pas réagit lors de la réduction de cétones par des mélanges de $NaBH_4$ et de $NaBD_4$ indique que ce dernier est encore isotopiquement pur et l'on n'a pas détecté la formation d'entités $NaBH_nD_{4-n}$. La dismutation d'intermédiaires pour reconduire à $NaBH_4$ ne joue donc aucun rôle important.

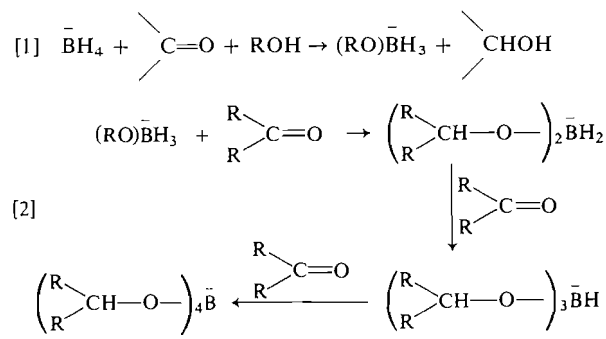
Little is known about the mechanism of borohydride reductions of ketones. Three major questions, of increasing level of molecular detail, exist. Firstly, given the 4:1 stoichiometry, what are the structures of the reducing agents for reduction of each of the four ketone molecules? Secondly, given the structure of the reducing agent(s), what is the mechanism of reduction: is it cyclic or acyclic; does it differ for each reducing species; what role, if any, do the metal cation and the solvent play? Thirdly, given the reducing agent and the mechanism for each reducing species, where on the reaction coordinate do the transition states occur: are they reactant-like, product-like, or somewhere in between? Finally, if one knew the answers to the above questions, presumably the problem of understanding the striking stereoselectivity of the reactions could at least be approached on a rational basis.

With several notable exceptions (see for example refs. 1–3), investigations in this area seem to be a persistent case of the cart before the horse. Speculations concerning the cause of stereoselectivity have been discussed for over twenty years. Speculators do not seem to have been greatly troubled by the almost total lack of knowledge of the reaction mechanism. Similarly, a good deal of effort has been expended to define the degree of hydride transfer in the transition state but the answer to this question is still unsettled. In contrast, little attention has been paid to the first two, rather more fundamental, questions posed above. The questions are not intangible and this communication is aimed at the first of these: what is(are) the structure(s) of the reducing agent(s)?

Results and Discussion

The Problem

All four hydrides of sodium borohydride are available for reduction of simple ketones.[1] While there is not much doubt that the reduction is initiated by reaction of $NaBH_4$ itself with a molecule of ketone, considerable uncertainty exists about what happens then. We have recently shown that the hydroxylic solvent plays a crucial role in this first step (5, 6) and it may therefore be represented as shown in [1], with the alkoxyl group from the solvent, and not from the product alcohol, becoming attached to boron. The question whether this monoalkoxyborohydride species acts directly as a reducing agent in the second stage of the reaction or if it disproportionates back to sodium borohydride now arises. The stepwise (nondisproportionation) mechanism proposed by Garrett and Lyttle (1) and later by Brown *et al.* (2) is shown in eq. 2.[2]



[1] $\bar{B}H_4 + \text{C=O} + ROH \rightarrow (RO)\bar{B}H_3 + \text{CHOH}$

[2] $(RO)\bar{B}H_3 + \text{C=O} \rightarrow \left(\text{CH—O—}\right)_2\bar{B}H_2 \xrightarrow{\text{C=O}} \left(\text{CH—O—}\right)_3\bar{B}H \xrightarrow{\text{C=O}} \left(\text{CH—O—}\right)_4\bar{B}$

[1] At least for simple ketones (4). The identity of the ketones actually used to form the basis of this statement is not stated. A systematic investigation on the generality of the 4:1 stoichiometry does not seem to have been carried out and is presently under investigation.

[2] These equations should now also be modified to take into account the incorporation of solvent alkoxy group (5, 6). However [2] is left unaltered for the sake of simplicity and of emphasizing the important difference between it and the disproportionation equations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In contrast to this stepwise mechanism, the disproportionation mechanism is shown in eqs. 3–5.[3]

[3] $$(RO)\bar{B}H_3 \rightarrow \bar{B}H_4 + (RO)_2\bar{B}H_2$$

[4] $$(RO)_2\bar{B}H_2 \rightarrow \bar{B}H_4 + (RO)_3\bar{B}H$$

[5] $$(RO)_3\bar{B}H \rightarrow \bar{B}H_4 + (RO)_4\bar{B}$$

In this way exactly the same products are eventually formed as with [2] and all four hydrides are available for reduction. The crucial difference, however, is that in the stepwise [2] mechanism there are four different reducing agents of increasing steric bulk involved in reducing ketone molecules, whereas in the disproportionation mechanism all the *reduction* steps are done by $NaBH_4$ itself.

The Existing Evidence

Three pieces of evidence bear on this problem.

(i) The Reaction Kinetics

The kinetics of reduction of ketones by sodium borohydride are known to be second order, first order in both ketone and borohydride (1–3, 7). This observation led Garrett and Lyttle (1) to propose the stepwise (nondisproportionation) mechanism, in which transfer of the first hydride is rate determining. The reduction of the other three ketone molecules then occurs in fast, kinetically, unobservable steps.

This evidence, however, does not rule out disproportionation. If complete disproportionation were to occur, the initial step would give second order kinetics, followed by disproportionation regenerating three out of four sodium borohydride molecules that had reacted. Thus, once again, provided the rate of disproportionation exceeded that of reduction, the observed result would be second order kinetics with a 4:1 stoichiometry.

(ii) Disproportionation of Intermediates

Of the intermediates postulated in the stepwise mechanism [2], i.e. the mono-, di-, and trialkoxyborohydrides, only the latter appear to possess reasonable stability, and only in THF solution (8). Experiments that might be expected to yield mono- or dialkoxyborohydrides (3, 9) (e.g. [6]), give disproportionation products instead.

[6] $$2B_2H_6 + 3NaOCH_3 \rightarrow 3NaBH_4 + B(OCH_3)_3$$

While this evidence does not establish that disproportionation occurs in the reduction reaction, it certainly confirms the tendency of these intermediates toward disproportionation.

(iii) Change of Stereochemistry

If disproportionation did not occur and several different reducing agents of increasing steric bulk (e.g. [2]) were involved in ketone reductions one might expect the reaction to change its stereoselectivity as the reaction proceeded. Rickborn and Wuesthoff (3) showed that detectable, although modest, such changes do occur. This evidence tends to exclude complete disproportionation, but does not rule out mechanisms involving less than complete disproportionation.

Mechanism Distinction. Exchange of Hydrogen Isotopes in $NaBH_4$

If the stepwise mechanism [2] occurs, then any sodium borohydride reisolated after reaction is simply unreacted sodium borohydride. On the other hand, if disproportionation back to sodium borohydride occurs, then sodium borohydride is continually being reformed by the disproportionation interaction between two or more different alkoxyborohydride molecules (eqs. 3–5). This difference becomes experimentally tangible if reduction is carried out using a mixture of sodium borohydride and sodium borodeuteride; reisolated reducing agent must still be $NaBH_4$ and $NaBD_4$ if the mechanism is stepwise reduction; on the other hand the disproportionation equations 3–5 demand that isotopically mixed borohydrides $NaBH_nD_{4-n}$ must be produced. Detection of such mixed isotopic species may be made by the deuterium coupling, and isotope shift of the proton nmr signals of $NaBH_4$ (10).

Accordingly, we have carried out reductions of cyclohexanone with mixtures of $NaBH_4$ and $NaBD_4$. The ketone to borohydride ratio was maintained at approximately 2.0 (i.e. ketone to available hydride ratio 0.5) and reaction taken to completion to ensure that remaining borohydride would have had maximum opportunity for isotopic exchange via the disproportionation mechanism. Ratios of borohydride–borodeuteride were varied with either one in predominance. Spectra of authentic isotopically mixed borohydrides were obtained by hydrolysis of mixtures of sodium borohydride and sodium borodeuteride (10), and the spectral difference between $NaBH_4$ and $NaBH_nD_{4-n}$ is shown in Fig. 1. Results are shown in Table 1. In contrast to borohydride hydrolysis (10), under no circumstances is there any evidence of the formation of isotopically mixed borohydrides. These results are consistent only with the sequential [2] mechanism for borohydride reduction of cyclohexanone and appear to rule out disproportionation back to $NaBH_4$ occurring to any significant extent.

Cyclohexanone, however, is one of the least likely ketones to cause isotopic scrambling of sodium borohydride. Since solvent alkoxy groups become attached to boron in the reduction (5), the rate of disproportionation of intermediates is presumably

[3]For the sake of simplicity these equations are left unbalanced.

TABLE 1. Results of exchange experiments

Ketone	BH_4/BD_4	Hydride/ketone	Nuclear magnetic resonance results
Cyclohexanone	0.429	2.01	No exchange
	0.529	2.00	No exchange
	1.59	1.98	No exchange
3,3,5,5-Tetramethylcyclohexanone	0.550	2.02	No exchange
	0.916	1.97	No exchange

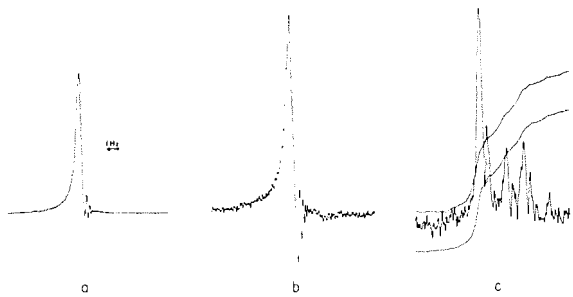


FIG. 1. Proton nmr spectra of (*a*) $NaBH_4$ in the presence of $NaBD_4$, after reduction of cyclohexanone; (*b*) $NaBH_4$ in the presence of $NaBD_4$ after reduction of 3,3,5,5-tetramethylcyclohexanone; (*c*) $NaBH_nD_{(4-n)}$ species prepared by hydrolysis of $NaBH_4$ in D_2O.

All spectra are the second lowest field portion of the borohydride quartet. This avoids the problem of isopropoxide, from hydrolyzed $NaB(OPr\text{-}i)_4$, interference in the spectrum. All spectra were deuterium decoupled.

essentially independent of the ketone being reduced. In contrast, the rate of ketone reduction varies widely. 3,3,5,5-Tetramethylcyclohexanone is reduced more slowly than cyclohexanone by a factor of almost 400 (11, 12), and thus the possibility of disproportionation playing a role is greatly enhanced. The results of Table 1 show that even in this case there is no evidence for the formation of isotopically mixed borohydrides.

Conclusions

Because of the lack of formation of isotopically mixed borohydrides, it is concluded that there is essentially no disproportionation back to $NaBH_4$ during reduction of ketones by $NaBH_4$ in 2-propanol. Disproportionation of the monoalkoxyborohydride [3] therefore does not occur during the reduction process, and this species cleanly reduces the second molecule of ketone to yield a dialkoxyborohydride [2]. The possibility that the dialkoxyborohydride and trialkoxyborohydride intermediates may disproportionate incompletely (i.e. back to monoalkoxyborohydride but not as far as $\overline{B}H_4$) can not at present be ruled out; this is a more difficult problem that is currently under investigation. The present results, however, rule out the complete disproportionation mechanism in which $NaBH_4$ itself reduces all or most of the ketone molecules; since no detectable disproportionation back to $NaBH_4$ occurs, it follows that only 25% of the ketone molecules are reduced by $NaBH_4$ and 75% by intermediate alkoxyborohydrides. This result is clearly of direct relevance to ideas on the stereoselectivity of this reaction.

Experimental

$NaBD_4$ (0.750 g, 0.0179 mol) (Merck, Sharp & Dohme) and $NaBH_4$ (0.250 g, 0.0066 mol) (British Drug House) were stirred magnetically, overnight in 25 ml of 2-propanol (Fisher). These solutions were gravity filtered and standardized using the iodate–thiosulphate standardization procedure (11, 12). Appropriate volumes of the two species were combined and to this solution was added a 1 ml solution of ketone whose concentration would give 50% oxidation of the borohydride species present in the solution. This solution was stirred magnetically for 1–2 h in the case of cyclohexanone and 3 days for 3,3,5,5-tetramethylcyclohexanone to ensure that reduction was complete. The solvent was rotary evaporated and the solid residue dissolved in D_2O. The proton magnetic resonance spectra were obtained in D_2O on a Varian T-60 instrument or a Varian HA-100.

Acknowledgements

We are very grateful to Professor M. M. Kreevoy, University of Minnesota, for furnishing some details of the borohydride hydrolysis and to Professor R. R. Fraser, University of Ottawa, for assistance with the nmr spectra. We thank the National Research Council of Canada for financial support.

The chemistry of 2-methyltetrahydropyran-4-one: An L-Selectride reaction that gives predominantly the equatorial alcohol

DONALD C. WIGFIELD AND STEVE FEINER

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 16, 1977

DONALD C. WIGFIELD and STEVE FEINER. Can. J. Chem. **56**, 789 (1978).

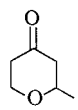
The stereoisomers of 2-methyltetrahydropyran-4-ol have been separated and identified by carbon-13 and proton nmr analysis of the trideuteriomethyl-2,6,6-trideuterio analogue. Stereoisomeric product ratios of reduction of 2-methyltetrahydropyran-4-one (**1**) by $NaBH_4$, KBH_4, L-Selectride, K-Selectride, and $LiBH(n\text{Bu})_3$ have been determined and compared with reductions of 3-methylcyclohexanone. Product ratios in the reduction of the two substrates by the borohydride reducing agents are similar but are quite different in the reduction by the Selectride reducing agents, **1** being reduced by Selectride to give 73% *equatorial alcohol*. Two possible mechanisms of reduction of **1** are proposed, involving intramolecular assistance by the cyclic ether oxygen.

DONALD C. WIGFIELD et STEVE FEINER. Can. J. Chem. **56**, 789 (1978).

On a séparé les stéréoisomères du méthyl-2 tétrahydropyrannol-4 et on les a identifiés par rmn ^{13}C et rmn ^1H de l'analogue trideutériométhyl trideutério-2,6,6. On a déterminé le rapport des produits stéréoisomères lors de la réduction de la méthyl-2 tétrahydropyrannnone-4 (**1**) par $NaBH_4$, KBH_4, L-Sélectride, K-Sélectride et $LiBH(n\text{Bu})_3$ et on les a comparés avec ceux observés lors des réductions de la méthyl-3 cyclohexanone. Les rapports de produit dans la réduction de ces deux substrats par des agents réducteurs du borohydrure sont semblables mais ils sont très différents lors de la réduction par des agents réducteurs Sélectride; le composé I est réduit par le Sélectride pour conduire à 73% *d'alcool équatorial*. On propose deux mécanismes possibles pour la réduction du produit **1** impliquant chacun une aide intramoléculaire par un oxygène éther cyclique.

[Traduit par le journal]

Recently, in an investigation to study the kinetic role of hydroxylic solvent in the borohydride reduction of ketones, an acylic mechanism was proposed involving two molecules of solvent (1). Consideration of other factors led to the suggestion that the axial hydrogen at C-4 of a cyclohexanone might be playing a part in controlling the stereochemistry of these reactions. To pursue this idea further it was of interest to examine the stereochemistry of reduction of a similar substrate lacking an axial hydrogen at C-4. For this purpose 2-methyltetrahydropyran-4-one (**1**) was selected. This communication reports our



1

findings on the reduction of this compound by a variety of reducing agents.

Results and Discussion

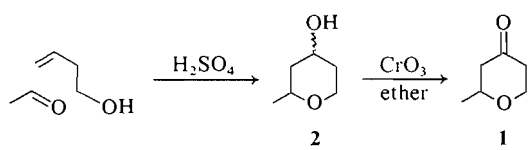
Synthesis of Substrate

2-Methyltetrahydropyran-4-one is not commercially available. A mixture of stereoisomers of 2-methyltetrahydropyran-4-ol, **2**, was obtained by the Prins reaction of 3-buten-1-ol with acetaldehyde according to the method of Hanschke (2). This mixture of stereoisomers was oxidized to 2-methyltetrahydropyran-4-one using the Brown oxidation (3) (Scheme 1).

Stereoisomer Purification

The stereochemistry of the reaction between homoallylic alcohols and carbonyl compounds has only recently been studied (4). Berti *et al.* (5) have reported that the reaction between 3-buten-1-ol and acetaldehyde gave the *cis*-4-ol (*cis*-**2**) as the main product, this conclusion based on nmr analysis. From the proton nmr spectrum of the mixture of stereoisomers of **2** obtained in our hands, however, we were unable to conclude anything; the crucial methine signal due to the proton at C-4 was completely obliterated by the signals of the three protons at C-2 and C-6. We therefore undertook the task of obtaining pure samples and positive identification of each stereoisomer.

Gas–liquid chromatographic analysis of the stereoisomeric mixture of alcohols **2** obtained from



2 **1**

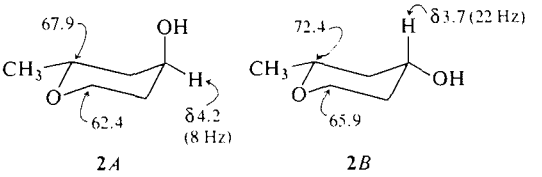
the Prins reaction indicated two products in the ratio 96:4. This glc analysis, however, gave a great deal of difficulty. Previous investigations of similar stereoisomers in this laboratory have used a SCOT-TCEP column; the resolution of this column, and indeed of similar packed columns, was completely ruined by two or three injections of this mixture. This problem was not overcome in this investigation and final stereochemical product ratios arising from reduction of **1** were obtained not by glc but by proton nmr analysis of specifically deuterated samples (*vide infra*). The two stereoisomers were referred to as **2***A* (shorter retention time on glc) and **2***B* (longer retention time on glc). The 96% component in the mixture was **2***B*.

Preparative separation of the stereoisomers **2***A* and **2***B* was achieved on an alumina column, eluted with benzene containing 10% ether. In this way pure samples of **2***B* could be obtained from the crude 96:4 stereoisomeric mixture. Samples of **2***A* were obtained by catalytic hydrogenation of ketone **1** over PtO_2 (giving a 60:40 mixture of **2***A* and **2***B*) followed by column chromatography referred to above.

Stereoisomer Identification

Axial–equatorial stereoisomer identifications previously in this series have been made by nmr examination of the methine proton on the hydroxyl-bearing carbon and by Raney Nickel equilibrations of the pair, the predominant one in the equilibrium mixture being assumed to have the hydroxyl group equatorial. Both methods failed in the present case. We have already mentioned that the methine proton signal at C-4 is masked by those at C-2 and C-6. In the Raney Nickel equilibrations, although the treatment tended to produce **2***B* at the expense of **2***A* when carried out on a mixture, treatment of a pure sample of **2***A* failed to give any conversion. This latter result remains an anomaly. Two somewhat less than conclusive pieces of evidence indicated that stereoisomer **2***B* was the equatorial alcohol: (*i*) **2***B* was the predominant isomer formed in the Prins reaction, (*ii*) **2***A* has a shorter retention time on glc and this seems to be characteristic of the axial isomer of an axial–equatorial pair, not only in our own work but in others' also (6).

In view of this situation, conclusive evidence was sought from carbon-13 and proton nmr spectroscopy. Both of these confirmed that stereoisomer **2***A* was the axial alcohol and stereoisomer **2***B* the equatorial. Carbon-13 nmr spectroscopy of **2***A* showed signals for C-2 and C-6 at δ 67.9 and 62.4, respectively. These signals in stereoisomer **2***B* occurred at δ 72.4 and 65.9, respectively. This upfield shift of approximately 4 ppm of the γ carbons in comparing **2***A* with **2***B* is



2*A* **2***B*

consistent with C-4 bearing an axial substituent in stereoisomer **2***A* (7).

Proton magnetic resonance distinction between **2***A* and **2***B* was achieved by examination of the stereoisomeric 2-trideuteriomethyl-2,6,6-trideuteriotetrahydropyran-4-ols, synthesized as indicated in Fig. 1. Again a 96:4 ratio of stereoisomers **2***B* and **2***A* was obtained; the amount of **2***A* was enhanced again by Brown oxidation and PtO_2 reduction and the stereoisomers separated by column chromatography on alumina. The spectra of these deuterated compounds are shown in Fig. 2. In stereoisomer **2***A* the C-4 methine proton gives a signal at δ 4.20, of half width 8 Hz; in stereoisomer **2***B* the corresponding signal is at δ 3.70 and a half width 22 Hz. These values (8) leave no doubt that the methine hydrogen at C-4 is equatorial in stereoisomer **2***A* and is axial in stereoisomer **2***B*.

Stereochemistry of Reduction of 1

Having established conclusively the stereoisomeric identity of alcohols **2***A* and **2***B*, the stereoselectivity of reduction of **1** by sodium borohydride was studied. In view of the glc difficulties already mentioned, product ratios were determined by nmr integration of the hexadeuterio species, the C-4 methine signals of the stereoisomers being completely separated from each other and from any other signals. The result (Table 1) that 19% axial alcohol is formed in the reduction of **1** is a result that is not markedly different to the stereoselectivity of reduction of 3-methylcyclohexanone (Table 1), despite the absence of any hydrogens at C-4. Consideration of this result, which can be rationalized in a number of ways, led to one possible suggestion involving intra-

molecular assistance to the formation of *cis*-**2**-methyltetrahydropyran-4-ol. This mechanism, shown in Fig. 3, in which the ether bridge flips up and reduction takes place through a temporary boat conformation, is consistent with the apparent need for boron to maintain tetravalency throughout the reduction (1) and here achieving this end intramolecularly rather than, as usually, intermolecularly. It should be noted that reduction through the other boat conformation, in which the carbonyl group flips instead of the ether oxygen, would result in formation of the *trans* alcohol. Molecular models of this situation, however, indicate considerable interference of the C-2 methyl group with borohydride.

If this mechanism of borohydride reduction of **1**

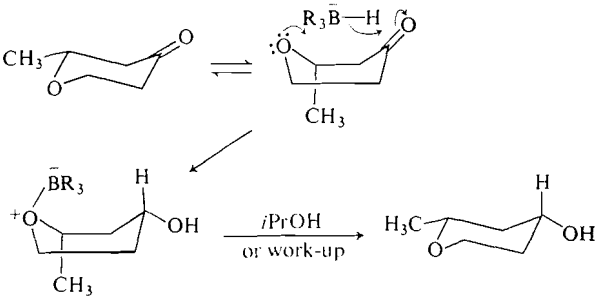

FIG. 3. Proposed mechanism of reduction of 2-methyltetrahydropyran-4-one to yield the *cis*-ol.

were correct, it would have one highly unexpected and unprecedented corollary. While the stereochemical result in the reduction of **1** by $NaBH_4$ is of no great surprise and can be rationalized in several ways, presumably[1] this pathway would also be available to reductions by the very bulky reducing agents, such as L-Selectride (10), and thus L-Selectride would also be predicted to reduce **1** to give predominantly the *equatorial alcohol*. Table 1 reports the stereoselectivity of reduction of **1** and of 3-methylcyclohexanone by three bulky reducing agents; clearly the prediction that these two substrates should be reduced with markedly differing stereoselectivities based on the boat mechanism for **1** is upheld and *the reduction of 1 by L-Selectride gives predominantly the equatorial alcohol*. Whether or not the explanation is correct, this is a somewhat striking result, the first instance, to our knowledge, that L-Selectride has failed to give predominantly the axial alcohol.

Other possible explanations for the dramatic change in stereoselectivity of L-Selectride are worth

[1]Nothing is known of the mechanism of Selectride reductions.

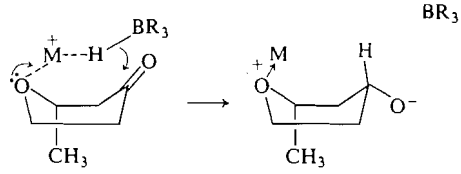

FIG. 4. Alternative mechanism involving the boat conformation of 2-methyltetrahydropyran-4-one.

considering. Any rationalization based on some general effect of having an oxygen in the ring can be discarded since L-Selectride reduction of 2-methyltetrahydropyran-3-one (i.e. ether oxygen in the 3-, rather than 4-position relative to the carbonyl) gives 99% *cis* alcohol (axial OH) (5). The specific effect of the oxygen in the 4-position relative to the carbonyl is consistent with the idea of a boat conformation during reduction. The other main possibility is whether reduction could occur through the alternative *chair* conformation (i.e. methyl group axial), since the methyl group is in an anomeric position. Two factors render this possibility rather unlikely. Firstly the anomeric effect is not known to be marked for nonelectronegative groups (11 and refs. therein), and secondly, in order to account for the results one would need to postulate this alternative chair conformation predominating for Selectride reductions and the normal (equatorial methyl) conformation predominating for sodium borohydride reductions.

Since the original writing of this manuscript, Professor H. C. Brown has pointed out to us that no ether–BR_3 complexes of the type proposed in Fig. 3 have ever been isolated. Professor Brown has suggested to us an alternative mechanism, again involving the same boat conformation, but involving an ether ---M ---H—BR_3 interaction, for which he has recently provided evidence (12, 13). This alternative mechanism is shown in Fig. 4. While one might have expected that this mechanism would have resulted in differing stereoselectivities depending on the nature of the cation, it is clear that the present evidence does not offer firm distinction between the two mechanisms (Figs. 3 and 4). One crucial difference between the two mechanisms is the question of whether boron maintains tetracovalency during the reaction. In this regard it is worth noting that although the mechanism in Fig. 3 achieves this, it does so in a 6-*endo-tet* manner, disfavoured by the Baldwin Rules (14).

In summary, the stereochemical results seem best accounted for by reaction through a boat conformation with involvement of the ether oxygen. Whether the ether oxygen interacts with boron or the metal cation remains uncertain, although the nature of the latter has little effect on the stereochemical outcome.

Experimental

Infrared spectra were obtained on a Perkin-Elmer Model 237-B spectrophotometer and ^{1}Hmr spectra in $CDCl_3$, with TMS as internal standard, on a Varian T-60 instrument. ^{13}C nmr spectra (natural abundance) were obtained on a Varian XL-100-12 nmr spectrometer equipped with a Nicolet Technology Corporation Fourier transform data system. Gas–liquid chromatography was performed on a Hewlett-Packard F and M Model 402 gas chromatograph using 6 ft packed columns or on a Perkin-Elmer 990 gas chromatograph using 50 ft support-coated open tubular columns, both instruments attached to an Infotronics CRS-208 integrator.

1,1-Dideuterio-3-buten-1-ol

A 500 ml three-necked round bottom flask fitted with a dropping funnel, reflux condenser, gas inlet tube, drying tubes, and magnetic stirring bar was charged with a suspension of lithium aluminum deuteride (4.0 g, 9.5×10^{-2} mol) in anhydrous ether (150 ml). The funnel was charged with a solution of vinylacetic acid (8.2 g, 9.5×10^{-2} mol) in anhydrous ether (100 ml). The system was flushed with dry nitrogen for 15 min and the acid solution added dropwise at such a rate as to maintain a gentle reflux. After addition was complete the reaction was stirred at room temperature for 1 h. Water (4 ml), 15% aqueous sodium hydroxide solution (4 ml), and water (4 ml) were added dropwise in that order to the stirred reaction mixture. The white precipitate was removed by suction filtration through a medium sintered glass filter funnel and washed with ether (4 × 20 ml). The combined ether solutions were washed with water (2 × 5 ml) and the combined washings back-extracted with ether (3 × 10 ml). The combined ether solutions were dried (Na_2SO_4), rotary evaporated, taken up in chloroform (25 ml), dried (Na_2SO_4), and evaporated to give a pale yellow liquid (5.1 g, 73%) which was purified by bulb-to-bulb distillation at water aspirator pressure (63% recovery); ν_{max} (neat): 2110, 2220 cm^{-1}; δ: 2.30 (2H, d, J = 6 Hz, CH_2), 3.33 (1H, s, OH), and 4.9 to 6.4 (3H, m, vinyl hydrogens); other properties identical to a nondeuterated commercial sample.

2-Trideuteriomethyl-2,6,6-trideuteriotetrahydropyran-4-ol (Mixture of Stereoisomers)

The procedure of Hanschke (2) for the preparation of the nondeuterated analogue was followed, using 1,1-dideuterio-3-buten-1-ol and acetaldehyde-d_4. Because of the water solubility of the product, neutralization in work-up was done with ammonia gas instead of aqueous sodium hydroxide solution. Water washings were all back-extracted with ether, and the ether solution evaporated, taken up in chloroform, dried, and re-evaporated; 80% yield was obtained; δ: 1.0–2.2 (4H, m, C-3 and C-5 H's), 2.30 (1H, s, OH), and 3.0–4.3 (axial and equatorial C-4 H), other properties identical with a *nondeuterated sample* (**2***A* and **2***B*) prepared in the same way; bp 73–74°C/5 Torr (lit. (2) bp 99°C/20 Torr), n_D^{21} 1.4548 (lit. (2) n_D^{20} 1.4543).

2-Trideuteriomethyl-2,6,6-trideuteriotetrahydropyran-4-one

A 100 ml three-necked round bottom flask fitted with a dropping funnel, thermometer, condenser, and stirring bar was charged with a solution of 2-trideuteriomethyl-2,6,6-trideuteriotetrahydropyran-4-ol (mixture of stereoisomers) (4.1 g, 3.1×10^{-2} mol) in ether (20 ml). Brown's solution (10) (16 ml) was added dropwise at such a rate as to maintain a temperature of 30°C. The mixture was stirred overnight at room temperature, the layers separated, and the aqueous layer extracted with ether (5 × 30 ml). The combined ether extracts were washed with water (2 × 5 ml) and these washings back-extracted with ether (3 × 10 ml). The total ether solution was

For personal use only.

dried (Na_2SO_4), concentrated, taken up in $CHCl_3$ (30 ml), dried (Na_2SO_4), and evaporated to give 3.7 g (90%) of a clear yellow liquid. On occasions when glc indicated incomplete oxidation, re-oxidation was performed using the appropriate amount of oxidant. Bulb-to-bulb distillation gave a clear colourless liquid; ν_{max} (neat): 1720 (C=O), 2110, 2240 (C—D) cm^{-1}; δ: 2.0–2.6 (m, C-3, C-5 H's): other properties identical with a *nondeuterated sample* (**1**) prepared in the same way, bp 30°C/8 Torr (lit. (2) bp 70°C/20 Torr); n_D^{23} 1.4450 (lit. (2) n_D^{20} 1.4469).

Platinum Oxide Catalysed Hydrogenation of Hexadeuterated Ketone ***1***

A 100 ml round bottom flask was charged with platinum oxide (0.16 g) and 95% ethanol (50 ml), equipped with a magnetic stirring bar and a gas inlet tube. The flask was attached to a hydrogenation apparatus and flushed with hydrogen five times. The catalyst was stirred overnight at room temperature under 1.1 atm of hydrogen. The deuterated ketone **1** was then added and hydrogenated overnight at room temperature under 1.1 atm of hydrogen. The flask was then stirred open to the air for 30 min. Aqueous ferrous sulfate (0.25 ml, 0.1 *M*) and further platinum oxide (0.4 g) were then added (15) and the mixture again hydrogenated overnight as before. The reaction mixture was then suction filtered through medium (once) and fine (three times) sintered glass filter funnels, gravity filtered (Whatman No. 42), and dried (Na_2SO_4) to give a clear light green solution with no particulate matter. The solution was rotary evaporated, the residue taken up in ether (30 ml), and the ether solution washed with water (2 × 2 ml). The combined washings were back-extracted with ether (3 × 10 ml) and the combined ether solutions dried (Na_2SO_4), evaporated, the residue taken up in chloroform (25 ml), dried (Na_2SO_4), and evaporated. The glc and nmr analyses of the resulting alcohol mixture showed it to be 60% axial alcohol (*trans*) and 40% equatorial (*cis*).

Separation of cis- *and* trans-*2-Methyltetrahydropyran-4-ol*

The mixture of alcohols (0.48 g) was chromatographed on alumina (Woelm neutral, Activity III, 100 g), fractions of 25 ml being taken. Sixteen fractions of benzene were taken, followed by elution with 10% ether – 90% benzene. The *trans* isomer was contained in fractions 17–64 (^{13}C nmr δ: 21.7 (CH_3), 32.9 (C-5), 40.6 (C-3), 62.4 (C-6), 63.8 (C-4), and 67.9 (C-2); ^{1}Hmr of hexadeuterated sample, δ: 4.20, half width 8 Hz (C-4 H)); the *cis* isomer in fractions 76–170 (^{13}C nmr δ: 21.8 (CH_3), 35.4 (C-5), 43.2 (C-3), 65.9 (C-6), 67.5 (C-4), and 72.4 (C-2); ^{1}Hmr of hexadeuterated sample, δ: 3.70, half width 22 Hz (C-4 H)).

Raney Nickel Equilibration of Stereoisomeric Alcohols ***2***

Raney Nickel equilibrations were carried out as described previously (16) using the procedure of Eliel and Schroeter (17).

Stereoisomeric Product Ratio Determinations

(a) Borohydride Reductions

Reductions were carried out in 2-propanol using a two-fold excess of reductant over hexadeuterated **1**, at room temperature overnight. Concentrated hydrochloric acid was then added until gas evolution ceased. The solution was evaporated, taken up in ether (30 ml), washed with water (1 × 2 ml), the washings back-extracted with ether (3 × 10 ml), and the combined ether solutions dried (Na_2SO_4), the residue taken up in chloroform (25 ml), dried (Na_2SO_4), and evaporated. Product ratios were determined by nmr integration at δ 3.7 (axial C-4 H) and δ 4.2 (equatorial C-4 H).

(b) Selectride Reductions

A 100 ml round bottom three-necked flask fitted with a dropping funnel, stirring bar, gas inlet tube, and drying tube was flushed with nitrogen and charged with anhydrous ether (10 ml) and the reducing agent (4×10^{-3} mol). The flask was cooled (ice-water bath) and the ketone (0.26 g, 2×10^{-3} mol) in anhydrous ether (15 ml) added dropwise with stirring. The reaction was stirred at room temperature for 1 h. Aqueous sodium hydroxide (3 *M*, 1.0 ml) and 30% hydrogen peroxide (5 ml) were then added, the aqueous layer saturated with K_2CO_3, extracted with ether and the washings back-extracted, transferred to chloroform, and product ratios determined as for the borohydride reductions.

Addition of pseudohalogens to unsaturated carbohydrates. VI.[1] Synthesis of 4′-thiocordycepin[2]

R. GEORGE S. RITCHIE, DOLATRAI M. VYAS, AND WALTER A. SZAREK[3]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 28, 1977

R. GEORGE S. RITCHIE, DOLATRAI M. VYAS, and WALTER A. SZAREK. Can. J. Chem. **56**, 794 (1978).

The addition of the pseudohalogen iodine nitrate ($IONO_2$) to the endocyclic alkenic bond in benzyl 2-*O*-benzyl-3,4-dideoxy-α-D-*glycero*-pent-3-enopyranoside (**3**) is described. The stereochemistry and regiochemistry of addition were elucidated by chemical degradation, ^{1}Hmr spectroscopy, mass-spectral analysis, and polarimetry. A synthetic route to 4′-thiocordycepin (**20**) from compound **3**, by way of the intermediacy of the preponderant iodine nitrate adduct of **3**, namely, benzyl 2-*O*-benzyl-3-deoxy-3-iodo-4-*O*-nitro-β-L-lyxopyranoside (**4**), is also described.

R. GEORGE S. RITCHIE, DOLATRAI M. VYAS et WALTER A. SZAREK. Can. J. Chem. **56**, 794 (1978).

On décrit l'addition du pseudohalogène nitrate d'iode ($IONO_2$) à la double liaison endocyclique du *O*-benzyl-2 didéoxy-3,4 α-D-glycéropenténo-3 pyrannoside de benzyle (**3**). On a étudié la stéréochimie et la régiochimie de l'addition par dégradation chimique, par spectroscopie rmn ^{1}H, par spectrométrie de masse et par polarimétrie. On décrit aussi une méthode de synthèse permettant de transformer le composé **3** en thio-4′ cordycépine (**20**) par l'intermédiaire de l'*O*-benzyl-2 déoxy-3 iodo-3 *O*-nitro-4 β-L-lyxopyrannoside de benzyle (**4**), l'adduit formé de façon prépondérante lors de l'addition du nitrate d'iode sur **3**.

[Traduit par le journal]

Introduction

A continuing area of research in this laboratory is the investigation of addition reactions of unsaturated carbohydrates. One particular project is concerned with the addition to these substrates of reagents that have been referred to as pseudohalogens. Many of these reagents are conveniently prepared *in situ* by the reaction of the appropriate silver salts with iodine. The present article describes the reaction of the pseudohalogen iodine nitrate ($IONO_2$) with a pyranoid derivative possessing an endocyclic double bond, namely, benzyl 2-*O*-benzyl-3,4-dideoxy-α-D-*glycero*-pent-3-enopyranoside (**3**). The reaction has led to a facile synthesis of 4′-thiocordycepin (**20**), an analog of the nucleoside antibiotic cordycepin in which the ring oxygen of the carbohydrate moiety is replaced by sulfur.

The addition of iodine nitrate to a furanoid derivative having an exocyclic double bond has already been reported (3); also, reactions with steroidal (4) and other noncarbohydrate olefins (5) have been studied. The pseudohalogen has been prepared by a variety of methods. Birckenbach and Goubeau (6) originally used mercury(II) nitrate, or silver nitrate, and iodine in ether; the reagent has also been generated by the reaction of silver nitrate with iodine in acetonitrile (3), from iodine – dinitrogen tetroxide (4), or by the reaction of iodine chloride with silver nitrate in chloroform–pyridine solution (5).

Results and Discussion

The unsaturated sugar **3** (Scheme 1) was originally prepared (7) by heating benzyl 2-*O*-benzyl-β-L-arabinopyranoside 3,4-thionocarbonate in trimethyl phosphite. In the present work, **3** was more conveniently obtained in high yield from benzyl 2-*O*-benzyl-3,4-di-*O*-(methylsulfonyl)-β-L-arabinopyranoside (**2**) (prepared in almost quantitative yield from the diol **1**) by treatment with a large excess of sodium iodide in refluxing *N*,*N*-dimethylformamide in the

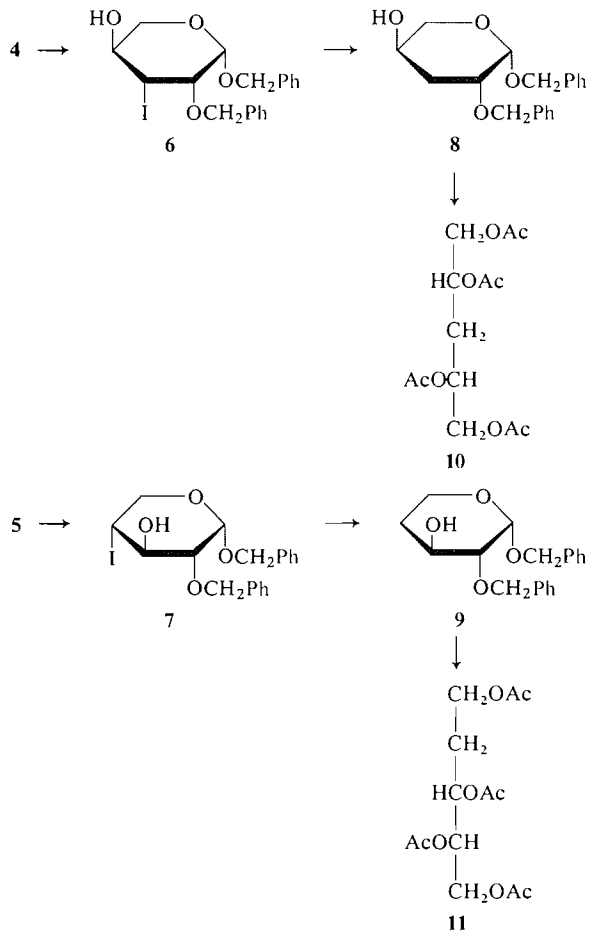
presence of zinc dust (Tipson–Cohen procedure (8)). The reaction of silver nitrate and iodine with **3** in ether was found to be very slow; even after 9 days, only a partial consumption of **3** had been observed. However, the use of acetonitrile, in which silver nitrate is very soluble, resulted in a rapid reaction with **3**; thus, with a solution containing 1.1 equiv. of iodine nitrate, the reaction was complete in 60 min, and in a solution containing 1.25 equiv., all of the unsaturated sugar **3** was consumed within 5 min to give a major component, namely benzyl 2-*O*-benzyl-3-deoxy-3-iodo-4-*O*-nitro-β-L-lyxopyranoside (**4**), and also benzyl 2-*O*-benzyl-4-deoxy-4-iodo-3-*O*-nitro-α-D-xylopyranoside (**5**). The mixture gave a positive spot test for a nitrate, namely, an intense blue coloration on addition of diphenylamine – sulfuric acid (9). The elemental analysis was consistent with an adduct of iodine nitrate and **3**. The proton magnetic resonance (^{1}Hmr) spectrum of the mixture of adducts showed an isolated multiplet, containing at least seven lines centered at τ 4.70, attributable to H-4 with a band width of 15 Hz (2 $J_{ax,ax} + J_{ax,eq}$);[4] the signals of all of the other sugar-ring protons were observed at higher field. It has been reported (11) with a large number of iodine nitrate adducts (5*b*) that the signal for the proton on the carbon bearing the nitrate group occurs at lower field (~ 1 ppm) than that for the proton on the carbon bearing the iodo group. In the present case, the nitrate group in the preponderant adduct is thus assigned to C-4. The band width of the H-4 signal implies the *trans*-diequatorial arrangement of the groups at C-3 and C-4. This observed stereochemistry is consistent with the stereospecific *trans* addition of iodine nitrate reported (4–6) with numerous other cyclic alkenes. Presumably, the iodo and nitrate groups in the minor adduct are also *trans* to each other.

The structures assigned to the two iodine nitrate adducts (**4** and **5**) were elucidated by a chemical degradation procedure (Scheme 2). The first step involved a reductive denitration. A variety of reagents and methods have been employed for selective *O*-denitration; these include acid- or base-catalyzed acetolysis (12), reductive electrolysis (5*b*), hydrazine (13), sodium nitrite (14), lithium aluminum hydride (15), metal (iron/zinc) dusts in boiling acetic acid (16), zinc-copper couple (5*b*), and high pressure catalytic hydrogenolysis over palladium (17). In this laboratory hydrogenolysis using Raney nickel catalyst has been employed effectively for both *O*-denitration (18) and reductive dehalogenation (1, 19).

[4]In the case of a ^{1}Hmr spectral pattern that is amenable to a first-order analysis, the band width may be considered as a measure of the sum of the coupling constants (10).



SCHEME 2

Thus, when a solution of a syrupy mixture of adducts **4** and **5** in ethanol and triethylamine containing Raney nickel was subjected to a hydrogen pressure, there was an initial conversion into three compounds, which were isolated by column chromatography, namely, the unsaturated sugar **3** (11%), the syrupy 3-iodo glycoside **6** (68%), and crystalline benzyl 2-*O*-benzyl-4-deoxy-4-iodo-α-D-*xylo*-pentopyranoside (**7**) (10%). Further hydrogenation of **6** and **7** over Raney nickel afforded the deoxypentopyranoside derivatives **8** and **9**, respectively. The structures assigned to compounds **8** and **9** were corroborated by their conversions into 1,2,4,5-tetra-*O*-acetyl-3-deoxy- and 1,3,4,5-tetra-*O*-acetyl-2-deoxy-L-*threo*-pentitols **10** and **11**, respectively, on *O*-debenzylation with sodium in liquid ammonia, followed by reduction of the resultant free sugars with sodium borohydride, and finally acetylation of the pentitols with acetic anhydride – pyridine. The syrupy tetraacetates **10** and **11**, when subjected to gas–liquid chromatography appeared to be homogeneous products, an observation which supports the contention that no epimeri-

For personal use only.

zation at C-2 had occurred during *O*-debenzylation of benzyl glycosides **8** and **9** with sodium in liquid ammonia. The alditol acetates **10** and **11** were unequivocally characterized as 1,2,4,5-tetra-*O*-acetyl-3-deoxy-L-*threo*-pentitol and 1,3,4,5-tetra-*O*-acetyl-2-deoxy-L-*threo*-pentitol, respectively, on the basis of their specific rotations, mass spectra, and glc retention times. For glc analysis, authentic samples of monodeoxypentitol tetraacetates **12–15** were prepared. Examination of the glc retention times (see Table 1) of tetraacetates **10–15** relative to those of erythritol tetraacetate (R_{Ery}) and ribitol pentaacetate (R_{Rib}), indicated that compound **10** was a 3-deoxy-*threo*-pentitol isomer. Such an unequivocal assignment to alditol acetate **11** was not feasible, based on the comparison of the glc retention times; however, in this respect the mass spectra of **10** and **11** were very useful. According to the mass-spectral investigations of polyol acetates reported by Golovkina *et al.* (20), the peaks at *m/e* 231 in the spectrum of **10**, and at *m/e* 231, 159, and 145 in the spectrum of **11** were consistent with the pertinent fragmentations (see Scheme 3). It was noteworthy that in the spectrum of compound **10**, there were no peaks corresponding to *m/e* 159 and 145; this indicated that compound **11** was the 2-deoxy-*threo* isomer.

Finally, the assignment of the L-configuration to the pentitol acetates **10** and **11** was based on a comparison of their specific rotations in chloroform (see Experimental) with those of the authentic monodeoxypentitol tetraacetates **13** and **14**, respectively. Thus, in light of the above discussion the formation of the L-*lyxo*- and D-*xylo*-iodonitrate adducts **4** and **5**, respectively, from the unsaturated sugar **3**, by pseudohalogen ($IONO_2$) addition could be rationalized in terms of more preferred *trans*-diaxial opening of the initially formed equilibrating iodonium ions by the nitrate anion (see Scheme 4).

In the quest for potent anticancer and antibiotic

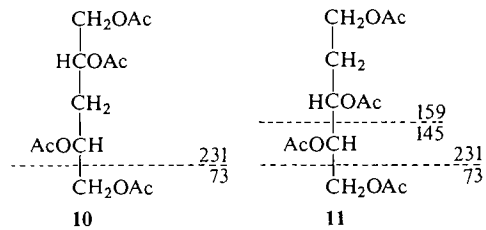
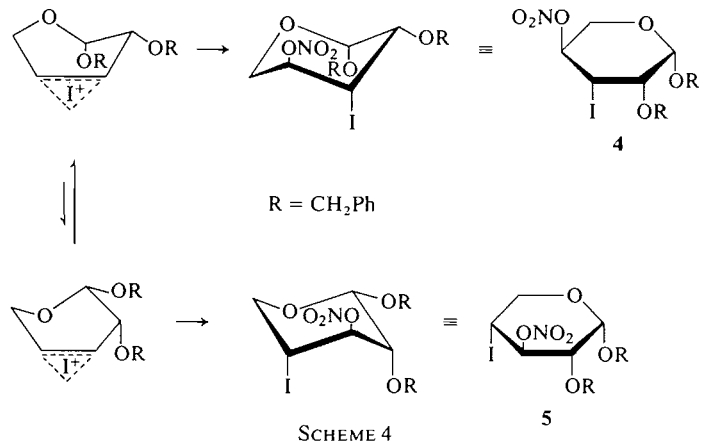


SCHEME 3

agents a number of 4′-thio analogs of naturally occurring and biologically active synthetic nucleosides have been reported (21). These purine and pyrimidine 4′-thio nucleosides have exhibited activity against certain bacteria and tumor cells (21). The effect of substitution of sulfur for the ribofuranosyl-ring oxygen on the biological activity of these nucleosides has been briefly reviewed (21*a*). In the present work, hydration of the readily available unsaturated sugar **3**, by way of the addition of the pseudohalogen iodine nitrate, has provided a viable synthetic route to 4′-thiocordycepin (Scheme 5). The synthesis of the nucleoside antibiotic cordycepin (3′-deoxyadenosine) (22) itself was achieved independently by Moffatt and co-workers (23) and Robins *et al.* (24) from adenosine and adenosine 2′,3′-orthoesters, respectively.

Thus, tosylation of the key intermediate alcohol **8** with *p*-toluenesulfonyl chloride in pyridine afforded the crystalline 4-*O*-*p*-tolylsulfonyl derivative (**16**) in 76% yield. The observation of the ^{1}Hmr signal for H-4 in compound **16** at τ 5.30 as a narrow band (width ~8 Hz) was consistent (10) with the axial orientation of the *p*-tolylsulfonyloxy group and **16** being in the *C*1(L) conformation. Heating the *p*-toluenesulfonate **16** for 48 h at reflux temperature in methanol containing benzyl thiol and sodium methoxide afforded, almost in quantitative yield, the 4-*S*-benzylglycoside (**17**). In the ^{1}Hmr spectrum of **17** the H-4 signal at τ 7.31 appeared as a seven-line multiplet ($J_{4,5ax}$ = 10.0 Hz, $J_{3ax,4}$ = 10.5 Hz, $J_{3eq,4}$ = $J_{4,5eq}$ = 5.0 Hz) indicating the equatorial orientation for the *S*-benzyl group and the *C*1(D) conformation for compound **17**.

All of the benzyl groups in compound **17** were removed with sodium in liquid ammonia, and the resultant free sugar was converted, on treatment with benzoyl chloride – pyridine, into a 1:3 mixture of the α- and β-anomers, respectively, of the 4-thio sugar (**18**). In the ^{1}Hmr spectra of the α- and β-anomers the signals for H-1 at τ 3.39 (doublet, $J_{1,2}$ = 4.3 Hz) and 3.58 (broad singlet, $J_{1,2}$ ~0.5 Hz), respectively, are in agreement with the assigned anomeric configurations. The presence of the thiofuranoid rings in the above anomers was confirmed by the



4

5

SCHEME 4

absence of *S*-benzoyl carbonyl bands in their ir spectra.

Each anomer of the tribenzoate (**18**) was separately treated, in 1,2-dichloroethane for 7 h at reflux temperature, with 6-benzamido-9-chloromercuripurine,

20 R = H

SCHEME 5

in the presence of titanium tetrachloride (25), to give, after column chromatography, the protected nucleoside (**19**) (82 and 78% yields from the α- and β-anomers, respectively). The assignment of the β-anomeric configuration to **19** was based on the splitting pattern observed for the H-2′ and H-5′,H-5″ signals in the ^{1}Hmr spectra of **19** and the α- and β-anomers of **18**. Thus, the observation of the ^{1}Hmr signal for H-2′ in compound **19** and the β-anomer of **18** as a narrow multiplet was consistent with the assigned β-anomeric configuration to **19**. This assignment was further substantiated by the fact that the two H-5′ nuclei were observed as the A_2 portion of an apparent A_2B spin system in the spectrum of the α-anomer of **18**, and as the AB portion of an ABX system in the spectra of **19** and the β-anomer of **18**.

Treatment of the fully benzoylated nucleoside **19** with methanolic sodium methoxide for 2 h at reflux temperature afforded 9-(3-deoxy-4-thio-β-D-*erythro*-pentofuranosyl)adenine (**20**, 4′-thiocordycepin) as white needles in 75% yield. After hydrogen–deuterium exchange in deuterium oxide the ^{1}Hmr spectrum of **20** in methyl sulfoxide-d_6 exhibited the H-1′ signal at τ 4.11 as a doublet with $J_{1',2'} = 3.4$ Hz. Montgomery and Hewson (26) have observed, in the ^{1}Hmr spectra of a number of 9-β-ribofuranosylpurines in methyl sulfoxide-d_6, the chemical shift of H-1′ to be characteristic (τ 4.0–4.2). In contrast, the marked chemical-shift differences expected in the sugar-ring carbon signals in the Cmr spectra of ribofuranosyl and 4′-thioribofuranosyl nucleosides are typified by the chemical-shift data of thiocordycepin (**20**) and cordycepin (**21**) (Table 2). The presence of different hetero atoms in the sugar rings is clearly reflected in the C-1′ and C-4′ chemical shifts. The signal assignments in the above two nucleosides, especially for the purine-ring carbons, was facilitated by the availability of ^{13}Cmr data (27) for adenosine (in methyl sulfoxide) and 2-deoxyadenosine (in *N*,*N*-dimethylformamide). The deshielding (~3.5 ppm) of C-2′ and C-3′ in the spectrum of **20** with respect to the corresponding carbons in the spectrum of **21** is consistent with the observed deshielding of C-3 and C-4 in the spectrum of thiacyclopentane with respect to C-3 and C-4 in tetrahydrofuran (28). The effect of substitution of sulfur for oxygen, in the above compounds, on the shielding of the γ carbons has also been reported previously (29). The origin of this effect has been discussed by Perlin *et al.* (30) in connection with carbohydrates. Similar effects in

TABLE 2. Carbon-13 chemical shifts for cordycepin (**21**) and thiocordycepin (**20**)[a]

Compound	Carbon[b] 1′	2′	3′	4′	5′	2	4	5	6	8
 **21**	92.2	75.5	34.5	81.4	63.6	152.4	149.1	119.3	156.5	139.6
 **20**	68.3	79.0	37.9	50.2	65.1	152.8	149.8	119.7	156.5	139.7

[a]In ppm from tetramethylsilane (TMS) in *N,N*-dimethylformamide and benzene-d_6 (20% solution).
[b]Chemical shifts obtained for the purine ring carbons of adenosine (**27**) measured in methyl sulfoxide are as follows: 153.5 (C-2), 150.1 (C-4), 120.4 (C-5), 157.1 (C-6), 141.2 (C-8).

trans-fused bicyclic hexopyranoside derivatives (31) and dioxanes (32) have been reported. The magnitude of the chemical-shift difference for C-2′ in **20** and **21** further corroborates the assigned β-anomeric configuration in **20**; an α-anomeric configuration in **20** would have resulted in the shielding of C-2′ due to *cis* C-1′,C-2′ substituent interactions (33).

Experimental

Melting points were determined on a Fisher–Johns melting-point apparatus and are uncorrected. Optical rotations were measured with Perkin-Elmer model 141 automatic polarimeter at 26 ± 3°. Infrared spectra were recorded with a Unicam SP 1000 spectrophotometer. The ^{1}Hmr spectra were recorded at 60 MHz in chloroform-*d* with tetramethylsilane as the internal standard, unless otherwise stated. The Cmr spectra were recorded in *N,N*-dimethylformamide–benzene-d_6 on a Bruker HX-90E Fourier transform spectrometer with tetramethylsilane as external or internal standard. Thin-layer chromatography was performed on silica gel G, containing 1–3% of indicator Lumilux Green ZS (Brinkmann Instruments (Canada) Ltd., Rexdale, Ont.), as the adsorbent in the following solvent systems (v/v): (*A*) 3:2 petroleum ether (bp 60–80°C) – ethyl acetate; (*B*) 3:1, (*C*) 5:1; (*D*) 2:3; (*E*) 1,2-dichloroethane; (*F*) 2:1 carbon tetrachloride – ethyl acetate; (*G*) 1:1 acetone – ethyl acetate; (*H*) ethanol; (*I*) ethyl acetate; (*J*) 2:1 toluene–acetone; (*K*) 3:1 chloroform–ethanol. The developed plates were air dried and the detection of components consisted of three stages: irradiation with a short-wavelength uv lamp (UVS-54) to detect benzoates, tosylates, purines, and benzyl ethers; spraying with dilute aqueous permanganate to test for isolated double bonds and divalent sulfur groups; and finally spraying with a solution of 1% cerium sulfate and 1.5% molybdic acid in 10% sulfuric acid and heating the plates at about 150°C. Paper chromatography was performed on Whatman No. 1 paper by the descending method, using aqueous 5% disodium hydrogen phosphate (*L*) and water-saturated *n*-butanol (*M*) as eluants. Detection was by a short-wavelength uv lamp for nucleosides. The term R_{Ad} refers to mobility relative to adenine. Gas–liquid chromatography (glc) was performed on an F & M, model 402, high-efficiency chromatograph employing a flame ionization detector and helium as the carrier gas. The column (U shaped, 120 cm long, 3.8 mm diameter) was packed using 3% (w/w) ECNSS-M on Gas-Chrom Q (100–120 mesh). A carrier-gas flow rate of about 90 ml/min was used, and the oven temperature was kept at 150°C. High resolution mass spectra were determined with a JEOLCO double focusing spectrometer, model JMS-OSIC, equipped with a heated, direct sample-injection system operated at 83°C, and fitted to record data by a photoplate; ionizing potential 75 eV.

Benzyl 2-O-Benzyl-3,4-di-O-(methylsulfonyl)-β-L-arabino-pyranoside (2, R = Ms)

To a solution of benzyl 2-*O*-benzyl-β-L-arabinopyranoside (1, R = H) (34) (68.3 g, 48.3 mmol, R_F (*A*) = 0.09) in pyridine (150 ml), cooled in an ice-water bath, was added in portions methanesulfonyl chloride (55 g) and the mixture was allowed to react overnight at room temperature. Isolation of the product in the usual fashion afforded the crude mesylate (**2**, R = Ms) (94.8 g, 97%). After recrystallization from methanol (on seeding), the compound had mp 97–98°C, $[\alpha]_D$ +140° (*c* 3.20, chloroform); R_F (*A*) = 0.43; ν_{max} (film): 770, 710 (OCH_2Ph), 1370, 1190 cm^{-1} (OMs); ^{1}Hmr τ: 4.90–5.10 (3H, H-1, H-3, H-4) 5.20–5.65 (4H, —OCH_2Ph), 6.00–6.25 (3H, H-2, H-6,6′), 6.93 and 7.09 (two 3H s's, —OSO_2CH_3). *Anal.* calcd. for $C_{21}H_{26}O_9S_2$: C 51.8, H 5.4, S 13.2; found: C 51.9, H 5.5, S 13.0.

Benzyl 2-O-Benzyl-3,4-dideoxy-α-D-glycero-pent-3-eno-pyranoside (3)

A vigorously stirred suspension of a solution of dimesylate (**2**, R = Ms) (88.5 g, 182 mmol, R_F (*A*) = 0.58, R_F (*B*) = 0.16) in *N,N*-dimethylformamide (200 ml), sodium iodide (100 g) and zinc dust (30 g) was refluxed for 2 h. The solids were removed by filtration, and the filtrate was concentrated; the residue was partitioned between chloroform and water.

The chloroform solution was washed several times with water, dried (Na_2SO_4), and then evaporated to give a crude syrup (49.9 g), which, on dissolution in ethanol and cooling, precipitated unreacted dimesylate (5.0 g). The residual syrup (36 g) afforded crystalline material on washing through a short column of alumina (80 g) with carbon tetrachloride (500 ml), concentration to dryness, and cooling. Recrystallization from ethanol afforded pure olefin **3** (24.2 g, 60%) as colorless needles, mp 31–33°C, $[\alpha]_D$ +111° (*c* 3.30, chloroform) (lit. (7) mp 32–35°C, $[\alpha]_D$ +115° (*c* 1.19, chloroform)); R_F (*A*) = 0.85, R_F (*B*) = 0.55; ν_{max} (film): 1640 (HC=CH *cis*), 1605 cm^{-1} (aromatic); ^{1}Hmr τ: 2.54–2.65 (10H, aromatic H's), 4.15 (s, 2H, H-3, H-4), 4.98 (1H, H-1), 5.09, 5.30 (2H AB pattern, anomeric —O*CH*$_2$Ph), 5.39 (s, 2H, —O*CH*$_2$Ph), 5.75–5.92 (3H, H-2, H-5,5′). This olefin is unstable to storage at room temperature.

*Reaction of Benzyl 2-*O*-Benzyl-3,4-dideoxy-*α*-*D*-*glycero*-pent-3-enopyranoside (**3**) with Silver Nitrate and Iodine*

Olefin **3** (7.2 g, 24.3 mmol, R_F (*C*) = 0.45) and silver nitrate (4.5 g, 1.12 equiv.) in dry acetonitrile (150 ml) were added, in one portion, to a stirred solution of iodine (7.0 g, 1.13 equiv.) in dry acetonitrile (150 ml) in a flask covered with aluminum foil. After 60 min,[5] the reaction mixture was filtered, and the filtrate was concentrated to a dark red syrup. The syrupy residue was extracted with carbon tetrachloride, and the extract was washed with aqueous sodium thiosulfate solution, dried over anhydrous magnesium sulfate, and decolorized. The solution was concentrated to a pale yellow oil (11.2 g, 94%). Thin-layer chromatography (solvent *E*) showed that all of the starting olefin had been consumed and revealed the presence of two new components, one as a major spot (R_F = 0.85) the other as a minor component (R_F = 0.88). Attempted distillation of the oil resulted in decomposition. The ir spectrum (film) showed absorptions at 1655, 1648, 1642, 1630, 1276 cm^{-1} (ONO_2); partial ^{1}Hmr of the preponderant compound **4** τ: 4.70 (7-line m, band width = 15 Hz, H-4), 5.32 (d, $J_{1,2}$ = 3.5 Hz, H-1), 5.21, 5.50 (AB pattern, anomeric —O*CH*$_2$Ph), 5.36 (s, —O*CH*$_2$Ph). *Anal.* calcd. for $C_{19}H_{20}INO_6$: C 47.0, H 4.1, I 26.2, N 2.9; found: C 47.2, H 3.8, I 26.7, N 3.1.

*Hydrogenolysis of the Iodine Nitrate Adducts from Olefin **3***

A solution of the mixture of the iodine nitrate adducts **4** and **5** (13.0 g, freshly prepared from 8.2 g of **3** in 90% yield) in ethanol (120 ml) containing triethylamine (25 ml) was hydrogenated over Raney nickel (#28) at 60 psig. The catalyst was removed and the solution was concentrated to dryness; the resultant residue (12.5 g) was partitioned between carbon tetrachloride and water. The carbon tetrachloride solution was washed once with water, dried (Na_2SO_4), and evaporated to afford a crude syrup (9.5 g). Thin-layer chromatography (solvent *B*) indicated the presence of three components having R_F's = 0.60, 0.44 and 0.36. The syrup was chromatographed on silica gel (800 g) and sequentially eluted as follows.

Elution with 1:1 (v/v) petroleum ether (bp 60–80°C) – ethyl acetate afforded olefin **3** (0.8 g, 11%, R_F (*B*) = 0.60), identical in all respects with an authentic sample.

Elution with 3:1 (v/v) carbon tetrachloride – ethyl acetate gave benzyl 2-*O*-benzyl-4-deoxy-4-iodo-α-D-xylopyranoside (**7**) (1.1 g, 10%) as fine needles after crystallization from chloroform – petroleum ether (bp 60–80°C), mp 89–91°C, $[\alpha]_D$ +130° (*c* 1.34, chloroform); R_F (*B*) = 0.44; ν_{max} (KBr): 3480 cm^{-1} (OH), no absorption attributable to ONO_2; ^{1}Hmr τ: 2.70–2.73 (10H, aromatic H's), 5.20–5.82 (6H, H-1, H-4, —O*CH*$_2$Ph), 6.05–6.70 (4H, H-2, H-3, H-5,5′), 6.95 (1H, OH).

[5]This reaction was complete in 5 min (tlc) when 1.25 equiv. of reagents were used.

Anal. calcd. for $C_{19}H_{21}IO_4$: C 52.9, H 4.8, I 28.8; found: C 53.1, H 4.9, I 28.3.

Elution with 2:1 (v/v) carbon tetrachloride – ethyl acetate yielded benzyl 2-*O*-benzyl-3-deoxy-3-iodo-β-L-lyxopyranoside (**6**) as a syrup (7.4 g, 68%), $[\alpha]_D$ +110° (*c* 1.25, chloroform); R_F (*B*) = 0.36; ν_{max} (film): 3480 cm^{-1} (OH), no absorption attributable to ONO_2; ^{1}Hmr τ: 2.60–2.80 (10H, aromatic H's), 5.00–6.40 (10H,) 7.00 (1H, OH).

*Benzyl 2-*O*-Benzyl-3-deoxy-*β*-L-*threo*-pentopyranoside (**8**) and Benzyl 2-*O*-Benzyl-4-deoxy-*β*-L-*threo*-pentopyranoside (**9**)*

Further hydrogenolysis of the products, obtained from the hydrogenation of a mixture of the iodine nitrate adducts (**4** and **5**) (3.8 g, 7.9 mmol), in the usual fashion in ethanol containing triethylamine and a fresh batch of Raney nickel catalyst, afforded a crude syrup (2.4 g). Upon column chromatography on silica gel using 3:2 (v/v) petroleum ether (bp 60–80°C) – ethyl acetate as eluant, the 4-deoxy isomer **9** (0.2 g, 9%) having R_F = 0.36 and $[\alpha]_D$ +137° (*c* 1.1, chloroform), and the 3-deoxy isomer **8** (1.5 g, 55% from **3**) having R_F = 0.20 and $[\alpha]_D$ +135° (*c* 1.8, chloroform) were isolated as syrups. The latter recrystallized from ether – petroleum ether (bp 60–80°C); the crystals had mp 121–123°C and their ir spectrum was virtually identical to that of **6**; ^{1}Hmr τ: 2.50–2.83 (10H, aromatic H's), 5.12 (d, 1H, $J_{1,2}$ = 3.2 Hz, H-1), 5.26, 5.48 (AB q, J_{AB} = 12.5 Hz, anomeric—O*CH*$_2$Ph), 5.55 (s, 2H, —O*CH*$_2$Ph), 5.97–6.80 (5H, H-2, H-5,5′, OH), 7.90–8.20 (narrow m, 2H, H-3,3′).

Compound **9** was characterized as its 4-*O*-trifluoroacetyl derivative, which was an oil, bp 142–149°C/0.1 Torr, $[\alpha]_D$ +114° (chloroform); ν_{max} (film): 1785 cm^{-1} (CF_3C=O), no absorption attributable to OH; ^{1}Hmr τ: 2.50–2.80 (10H, aromatic H's), 4.90 (m, 1H, H-4), 5.07 (d, 1H, $J_{1,2}$ = 3.2 Hz, H-1), 5.31, 5.51 (AB q, anomeric—O*CH*$_2$Ph), 5.53 (s, 2H, —O*CH*$_2$Ph), 6.00–6.60 (3H, H-2, H-5,5′), 7.70–8.00 (m, 2H, H-3,3′). *Anal.* calcd. for $C_{21}H_{21}F_3O_5$: C 61.5, H 5.2; found: C 61.5, H 5.2.

*1,2,4,5-Tetra-*O*-acetyl-3-deoxy-*L*-threo-pentitol (**10**)*

To a stirred suspension of alcohol **8** (1.30 g, 4.1 mmol) in liquid ammonia (120 ml), was added sodium metal (6–8 equiv.) in small portions until the intense blue color persisted. The basic solution, obtained on destroying the excess of sodium with aqueous ammonium chloride and evaporation of ammonia, was diluted with water (100 ml) and then immediately neutralized with strong-acid ion-exchange resin. The solids were removed, and the aqueous solution was extracted with chloroform; the organic solution was decolorized (charcoal), filtered through Celite, and the filtrate was evaporated to give a clear syrup (494 mg, 89%). The major component having R_F (*G*) = 0.40 was recovered by column chromatography on silica gel using 1:1 (v/v) acetone – ethyl acetate as eluant. The ir spectrum of the resulting syrup exhibited a strong band at 3500–3250 cm^{-1} attributable to OH.

The reduction of the above free sugar (125 mg, 0.9 mmol, R_F (*H*) = 0.85) with sodium borohydride (~100 mg) in water (5 ml) in the usual fashion afforded in quantitative yield the deoxypentitol as a yellow syrup (127 mg), $[\alpha]_D$ +25° (*c* 12.7, ethanol); R_F (*H*) = 0.45–0.60.

Acetylation of the above deoxypentitol in acetic anhydride – pyridine afforded **10** as a homogeneous syrup (238 mg, 83%), bp 99–103°C/0.07 Torr, $[\alpha]_D$ +12° (*c* 3.45, chloroform); ν_{max} (film): 1755, 1740 (C=O), 1070–1030 cm^{-1} (C—O), no absorption attributable to OH; ^{1}Hmr τ: 4.83 (2H, H-2, H-4, $J_{1,2} = J_{4,5}$ = 3.9 Hz, $J_{1',2} = J_{4,5'}$ = 6.0 Hz, $J_{2,3} = J_{3,4}$ = 6.1 Hz, $J_{2,3'} = J_{3',4}$ = 7.9 Hz), 5.72 (2H, H-1, H-5, $J_{1,1'} = J_{5,5'}$ = 12.5 Hz), 5.97 (2H, H-1′, H-5′), 7.95 (12H, OCO*CH*$_3$),

For personal use only.

8.10 (2H, H-3,3′); for glc mobilities, see Table 1. *Anal.* calcd. for $C_{13}H_{20}O_8$: C 51.3, H 6.6; found: C 51.5, H 6.6.

1,3,4,5-Tetra-O-*acetyl-2-deoxy*-L-threo-*pentitol* (**11**)

Treatment of benzyl 2-*O*-benzyl-4-deoxy-β-L-*threo*-pentopyranoside (**9**) (0.2 g) in exactly the same sequential fashion as for compound **8** afforded the title compound **11** in low yield as a clear, colorless syrup (10 mg), bp 100–110°C/0.07 Torr, $[\alpha]_D$ −23° (*c* 0.2, chloroform); for glc mobilities, see Table 1.

1,3,4,5-Tetra-O-*acetyl-2-deoxy*-D-erythro-*pentitol* (**12**)

Commercially available 2-deoxy-D-*erythro*-pentose (4 mg), on reduction with sodium borohydride in the usual fashion and followed by acetylation (acetic anhydride – pyridine) of the resulting deoxypentitol, afforded compound **12** as a homogeneous product, $[\alpha]_D$ +20° (*c* 1.65, chloroform); for glc mobilities, see Table 1.

1,2,4,5-Tetra-O-*acetyl-3-deoxy*-L-threo-*pentitol* (**13**)

Acid-catalyzed hydrolysis of 3-deoxy-1,2-*O*-isopropylidene-β-L-*threo*-pentofuranose, (484 mg, 2.78 mmol, R_F (*I*) = 0.54) prepared from D-glucose according to the published procedures of Prokop and Murray (35), with strong-acid ion-exchange resin (2 g) in 50% methanol (40 ml) at reflux temperature for ~3 h afforded 3-deoxy-L-*threo*-pentose (320 mg, 86%); R_F (*I*) = 0.15.

3-Deoxy-L-*threo*-pentose, on reduction with sodium borohydride and followed by acetylation in the usual fashion of the resulting deoxypentitol, gave **13** as a colorless syrup, bp 98–104°C/0.07 Torr, $[\alpha]_D$ +13° (*c* 2.0, chloroform); R_F (*A*) = 0.40; the ir and ^{1}Hmr spectra of this material were identical to those of compound **10**; for glc mobilities, see Table 1.

1,3,4,5-Tetra-O-*acetyl-2-deoxy*-D-threo-*pentitol* (**14**)

To a solution of 3-deoxy-D-*xylo*-hexose (prepared by the acid-catalyzed hydrolysis of 3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-*xylo*-hexofuranose (35)) in water (15 ml) was added with stirring sodium metaperiodate (0.75 g). After 18 h, 2-deoxy-D-*threo*-pentose was obtained as a syrup, on removal by filtration of the iodates and periodates (precipitated by adding barium chloride), followed by evaporation of the filtrate to dryness, extraction of the resulting residue with ethanol, and finally solvent removal.

2-Deoxy-D-*threo*-pentose, on reduction with sodium borohydride (0.4 g) in water (5 ml) and followed by acetylation in the usual manner of the resulting deoxypentitol, afforded **14** as a syrup, $[\alpha]_D$ +20° (*c* 1.65, chloroform). Gas–liquid chromatographic analysis suggested that, in addition to **14**, there was present a minor component.

1,2,4,5-Tetra-O-*acetyl-3-deoxy*-D-erythro-*pentitol* (**15**)

Treatment of methyl 2,3-anhydro-β-L-ribopyranoside (36) (1.2 g, 8.3 mmol) with lithium aluminum hydride (~1 g) in dry tetrahydrofuran (30 ml) afforded methyl 3-deoxy-β-L-*erythro*-pentopyranoside (37). Acid-catalyzed hydrolysis of this product under the conditions reported by Kent *et al.* (38), followed by reduction with sodium borohydride and acetylation in the usual fashion, afforded compound **15** as a clear, colorless syrup, bp 122–128°C/0.1 Torr; ^{1}Hmr τ: 4.65–5.03 (4H, H-2, H-4), 5.73 (2H, H-1, H-5, $J_{1,2} = J_{4,5} = 4.0$ Hz, $J_{1',2} = J_{4,5'} = 6.0$ Hz, $J_{1,1'} = J_{5,5'} = 12.5$ Hz), 5.93 (2H, H-1′, H-5′), 7.95 (12H, OCOCH_3), 8.01 (2H, H-3,3′); for glc mobilities, see Table 1.

Benzyl 2-O-*Benzyl-3-deoxy-4*-O-p-*tolylsulfonyl*-β-L-threo-*pentofuranoside* (**16**)

A solution of alcohol **8** (627 mg, 2.0 mmol R_F (*A*) = 0.20) and *p*-toluenesulfonyl chloride (689 mg, 1.75 equiv.) in pyridine (5 ml) was kept for 2 days at 40°C. Isolation of the product in the usual fashion afforded a crude syrup (855 mg, 91%), which was chromatographed on silica gel, using 3:1 (v/v) carbon tetrachloride – ethyl acetate as eluant, to remove unreacted starting material. The tosylate **16** was obtained as fine, white needles (760 mg, 76%) on cooling of its solution in methanol, mp 57–58°C, $[\alpha]_D$ +99° (*c* 1.33, chloroform); R_F (*A*) = 0.70; ν_{max} (film): 3070, 3040 (aromatic C—H), 2950 aliphatic C—H), 1370–1360, 1095 cm^{-1} (—SO_2OR); ^{1}Hmr τ: 2.60–2.85 (12H, aromatic H's), 5.11 (d, 1H, $J_{1,2} = 3.2$ Hz, H-1), 5.30 (m, 1H, H-4, band width = 8–9 Hz), 5.31, 5.50 (AB q, $J_{AB} = 12.5$ Hz, anomeric —OCH_2Ph), 5.62 (s, 2H, —OCH_2Ph), 6.05–6.66 (3H, H-2, H-5,5′), 7.67 (s, 3H, —OSO_2PhCH_3), 7.60–8.15 (m, 2H, H-3,3′). *Anal.* calcd. for $C_{26}H_{28}O_6S$: C 66.6, H 6.0, S 6.8; found: C 66.7, H 5.7, S 6.7.

Benzyl 2-O-*Benzyl-4*-S-*benzyl-3-deoxy-4-thio*-α-D-erythro-*pentopyranoside* (**17**)

To a well purged (with nitrogen) solution of crystalline tosylate **16** (6.7 g, 14.3 mmol, R_F (*C*) = 0.55) in methanol (150 ml) was added a solution of benzyl thiol (5.0 ml, 3 equiv.) in methanolic sodium methoxide (54 ml, 1.06 *N*, 4 equiv.) and the mixture was refluxed under nitrogen for 30 h. The solution was cooled and concentrated to dryness, and the resulting residue was partitioned between water and ether. The combined ether extract was washed with concentrated aqueous sodium hydroxide (twice) and aqueous sodium chloride (twice), dried (Na_2SO_4), and concentrated to a syrup (5.74 g, 95%). From the crude syrup, **17** was obtained by distillation, bp 168–173°C/0.10 Torr, $[\alpha]_D$ +62° (*c* 1.08, chloroform); R_F (*C*) = 0.45; ^{1}Hmr τ: 2.76 (m, 5H), 2.81 (s, 10H, aromatic H's), 5.22 (d, 1H, $J_{1,2} = 3.2$ Hz, H-1), 5.29, 5.52 (AB q, $J_{AB} = 12.5$ Hz, anomeric —OCH_2Ph), 5.61 (s, 2H, —OCH_2Ph), 6.35 (s, 2H, —SCH_2Ph), 6.22–6.76 (5H, —SCH_2Ph, H-2, H-5,5′), 7.31 (1H, 7-line m, $J_{3eq,4} = J_{4,5eq} = 5.0$ Hz, $J_{3ax,4} = 10.5$ Hz, $J_{4,5ax} = 10.0$ Hz, H-4), 7.80–8.40 (m, 2H, H-3,3′). *Anal.* calcd. for $C_{26}H_{28}O_3S$: C 74.3, H 6.7, S 7.6; found: C 74.3, H 6.7, S 7.5.

1,2,5-Tri-O-*benzoyl-3-deoxy-4-thio*-D-erythro-*pentofuranose* (**18**)

A solution of **17** (5.74 g, 13.7 mmol) in ether (10 ml) was added with vigorous stirring to liquid ammonia (300 ml); sodium metal (2.8 g, 120 mmol) was added to this in small portions over a period of 1 h. Stirring was continued for an additional 30 min and the ammonia and solvent were evaporated then under a stream of nitrogen; the excess of sodium was destroyed by careful addition of water (50 ml) and the resulting aqueous solution extracted with ether. The aqueous solution, on neutralization with strong-acid ion-exchange resin and concentration to dryness, gave a black syrup (2.08 g); pyridine (30 ml) was added, and a black material (0.2 g) was removed by filtration. To the chilled, pyridine filtrate was added, dropwise, benzoyl chloride (5.5 ml, 41 mmol), and the reaction was allowed to proceed for 12 h. The usual processing of the reaction mixture and solvent removal gave a syrup (5.5 g); tlc (solvent *B*) indicated the presence of two major components, having R_F = 0.5 and 0.17, a minor component having R_F = 0.3 (not characterized), and benzoic anhydride. The latter contaminant was separated from the sugar components by column chromatography on silica gel using benzene as eluant. This initial separation afforded pure sugar components (2.0 g, 32%), which on further column chromatography on silica gel with 5:1 (v/v) petroleum ether (bp 60–80°C) – ethyl acetate as eluant yielded the two major benzoylated products.

The first component (R_F (*B*) = 0.5) isolated, upon trituration with methanol containing a little ether, afforded a crystalline solid. Recrystallization from chloroform – petroleum ether (bp 60–80°C) gave 1,2,5-tri-*O*-benzoyl-3-deoxy-4-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

thio-α-D-*erythro*-pentofuranose (596 mg, 9.4%), mp 140–141°C, $[\alpha]_D$ +249° (*c* 1.08, chloroform); ν_{max} (KBr): 1745, 1730, 1710 cm^{-1} (C=O, benzoate); ^{1}Hmr τ: 1.83–2.60 (15H, aromatic H's), 3.37 (d, 1H, $J_{1,2}$ = 4.3 Hz, H-1), 4.21 (1H, 6-line m, $J_{2,3} = J_{2,3'}$ = 8.3 Hz, H-2), 5.56 (2H, 3 lines, an apparent A_2 portion of an A_2B spin system, H-5,5′),5.78-6.22 (m, 1H, H-4), 7.20–7.47 (m, 2H, H-3,3′). *Anal.* calcd. for $C_{26}H_{22}O_6S$: C 67.5, H 4.8, S 6.9; found: C 67.3, H 4.9, S 6.9.

Removal of solvent from the mother liquor of the α-anomer afforded syrupy 1,2,5-tri-*O*-benzoyl-3-deoxy-4-thio-β-D-*erythro*-pentofuranose (769 mg, 12.1%), $[\alpha]_D$ −110° (*c* 1.30, chloroform); R_F (*B*) = 0.52; ir spectrum essentially identical to that of the α-anomer; ^{1}Hmr τ: 1.85–2.92 (15H, aromatic H's), 3.58 (s, 1H, bandwidth = 2 Hz, H-1), 4.10 (m, 1H, bandwidth = 6 Hz, H-2), 5.42, 5.56, 5.83 (m, 3H, $J_{4,5}$ = 7.2 Hz, $J_{5,5'}$ = 11.0 Hz, $J_{4,5'}$ = 5.3 Hz, H-5,5′ and H-4, respectively), 7.34, 7.64 (m, 2H, $J_{3,3'}$ = 14.0 Hz, $J_{3,4}$ = 6.0 Hz, $J_{3',4}$ = 9.0 Hz, H-3,3′).

The second major component (R_F (*B*) = 0.17) isolated was 1,5-di-*O*-benzoyl-3-deoxy-4-thio-β-D-*erythro*-pentofuranose (870 mg, 17.7%), mp 93–96°C (not recrystallized); ^{1}Hmr τ: 1.80–2.80 (10H, aromatic H's), 3.62 (s, 1H, H-1), 5.00–6.25 (5H, H-2, H-5,5′, OH), 5.15 (m, 1H, band width = 6 Hz), 6.12 (1H, OH), 7.20–8.10 (m, 2H, H-3,3′). Benzoylation of this dibenzoate in pyridine (10 ml) and benzoyl chloride (0.3 ml) overnight afforded the α-anomer of the tribenzoate (914 mg, 82%).

*4′-Thiocordycepin (**20**)*

From a mixture of 1,2,5-tri-*O*-benzoyl-3-deoxy-4-thio-α-D-*erythro*-pentofuranose (518 mg, 1.20 mmol, R_F (*A*) = 0.75), 6-benzamido-9-chloromercuripurine (687 mg, 1.25 equiv.), Celite (0.5 g), and 1,2-dichloroethane (80 ml) was distilled 25 ml of the solvent to exclude moisture from the reaction mixture. Titanium tetrachloride (0.15 ml, 1.25 equiv.) in dry 1,2-dichloroethane (2 ml) was added, dropwise, and the reaction mixture was stirred while being heated at reflux temperature. The progress of the reaction was monitored by tlc (solvent *A*) which revealed that all of the starting material (R_F = 0.75) had been consumed after 7 h and a new component (R_F = 0.07) had been formed. Saturated, aqueous sodium hydrogen carbonate (25 ml) was added to the reaction mixture, and after being stirred for 30 min, the mixture was filtered through Celite and the filter cake washed twice with chloroform. The organic solution was sequentially washed with water, 30% aqueous potassium iodide, and water, and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded crude, blocked nucleoside **19** as a white foam (720 mg), which was further purified by column chromatography on silica gel using 1:2 (v/v) carbon tetrachloride – ethyl acetate as eluant. Pure **19** was obtained as a brittle, white foam (554 mg, 82%), mp 134–135°C, $[\alpha]_D$ −25° (*c* 1.05, chloroform); R_F (*I*) = 0.6–0.8; ν_{max} (KBr): 3250 (NH), 1730 (C=O, benzoate), 1700, 1610, 1590 cm^{-1} (aromatic, purine); ^{1}Hmr (50°C) τ: 0.72 (1H, N-H), 1.30 (s, 1H, H-2), 1.60 (s, 1H, H-8), 1.83–2.83 (15H, aromatic H's), 3.62 (d, 1H, $J_{1',2'}$ = 2.5 Hz, H-1′), 3.97 (1H, 4-line m, $J_{2',3'} + J_{2',3''}$ = 7.0 Hz, H-2′), 5.22, 5.34 (AB portion of an ABX system, $J_{4',5'}$ = 6.7 Hz, $J_{4',5''}$ = 6.0 Hz, $J_{5',5''}$ = 11.0 Hz, H-5′,5″, respectively), 5.72 (m, 1H, $J_{3',4'} + J_{3'',4'}$ = 13.3 Hz, H-4′), ~7.37 (m, 2H, H-3′,3″).

Condensation of 1,2,5-tri-*O*-benzoyl-3-deoxy-4-thio-β-D-*erythro*-pentofuranose (1.55 g, 3.6 mmol) with 6-benzamido-9-chloromercuripurine (2.06 g) and titanium tetrachloride (0.45 ml) in 1,2-dichloroethane (250 ml) in the same manner as described above afforded **19** (1.56 g, 78%).

A solution of pure, blocked nucleoside **19** (1.15 g, 2.0 mmol) in methanol (50 ml) containing sodium methoxide (0.5 ml, 1.06 *M* in MeOH) was refluxed for 2 h; tlc (solvents *J* and *K*) revealed that all of **19** was deacylated. The cooled solution was neutralized by adding Rexyn-102 (H^+ form), filtered, and concentrated to dryness with ethanol several times. The residual white powder (441 mg, 82%), on recrystallization from methanol, gave 9-(3-deoxy-4-thio-β-D-*erythro*-pentofuranosyl)adenine (**20**) (4′-thiocordycepin) as white needles (398 mg, 75%), mp 257–260°C (dec.), $[\alpha]_D$ −55° (*c* 0.09, methanol), $[\alpha]_D$ −34° (*c* 1.09, methyl sulfoxide); R_{Ad} = 1.30 (solvent *L*), R_{Ad} = 1.07 (solvent *M*); λ_{max} (MeOH) 260 nm (ε 14 870); ν_{max} (KBr): 3400 (OH), 3270–3160 (NH), 1690, 1615, 1575, 1475 (purine ring), 1425 (C—CH_2), 1060 cm^{-1} (C—O); ^{1}Hmr (methyl sulfoxide-d_6, 60°C)[6] τ: 1.58 (s, 1H, H-2), 1.80 (s, 1H, H-8), 2.88 (unexchanged NH), 4.11 (d, 1H, $J_{1',2'}$ = 3.4 Hz, H-1′), 4.43, 4.92 (unexchanged OH and HOD), 5.33 (m, 1H, band width ~13 Hz, H-2′), 6.10–6.50 (3H, H-4′, H-5′,5″), 7.80–8.00 (m, 2H, H-3′,3″). *Anal.* calcd. for $C_{10}H_{13}N_5O_2S$: C 44.9, H 4.9, N 26.2, S 12.0; found: C 44.8, H 4.9, N 26.4, S 11.9.

Competitive thermal and photochemical processes in cyclopropylketone rearrangements. I. Photolysis of spiro[*n*.2]alkan-2-ones

EDWARD LEE-RUFF AND PRABHAKAR GOVIND KHAZANIE
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received July 22, 1977

EDWARD LEE-RUFF and PRABHAKAR GOVIND KHAZANIE. Can. J. Chem. **56**, 803 (1978).

The series of cyclopropyl ketones **1–6** was irradiated in methanol. Cyclopentanones **1** and **2** gave mainly products of type I reaction whereas ketones **3**, **5**, and **6** gave type II products. Formation of type II products can arise by two different mechanisms. One involves the intermediacy of a dienol which can be trapped with methanol-OD. Photochemical degradation of the cyclopentanones was slower than the corresponding cyclohexanones.

EDWARD LEE-RUFF et PRABHAKAR GOVIND KHAZANIE. Can. J. Chem. **56**, 803 (1978).

On a effectué l'irradiation d'une série de cyclopropyles cétones **1–6** dans le méthanol. Les cyclopentanones **1** et **2** conduisent principalement aux produits de réaction du type I alors que les cétones **3**, **5** et **6** donnent les produits du type II. La formation des produits de type II peut provenir de deux mécanismes différents. L'un implique un diénol comme intermédiaire qui peut être piégé avec du méthanol-OD. La dégradation photochimique des cyclopentanones est plus lente que celle des cyclohexanones correspondantes.

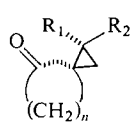
Introduction

The photochemistry of cyclopropyl ketones has been extensively investigated (1–3). Much of the photochemistry of such systems bears close analogy with the thermal reactions for related compounds. Thus, for instance, Norrish type II ring opening of methyl substituted cyclopropyl ketones (4) resembles the thermal 'ene' rearrangement of the same system (5). The oxovinylcyclopropane to dihydrofuran rearrangement occurs both photochemically (6) and thermally (7). It is conceivable that intermediates such as vibrationally excited ground states and diradicals are common to both processes (8). To evaluate the extent to which thermal chemistry overlaps photodeactivation processes we undertook a comparative photochemical and pyrolytic study of a series of spiro[*n*.2]alkan-2-ones. This series was chosen because the favourable bisected conformation of cyclopropyl ketones required for maximum conjugation (9) is incorporated in these compounds. In this part we report the photochemical results.

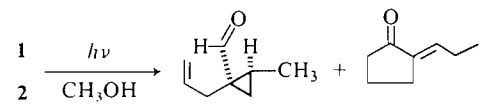
Results

The syntheses of ketones **1–6** have been described elsewhere (10). Irradiation of ketone **1** in methanol



1 $R_1 = H; R_2 = CH_3; n = 3$
2 $R_1 = CH_3; R_2 = H; n = 3$
3 $R_1 = R_2 = CH_3; n = 3$
4 $R_1 = H; R_2 = CH_3; n = 4$
5 $R_1 = CH_3; R_2 = H; n = 4$
6 $R_1 = R_2 = CH_3; n = 4$

using a Vycor filter resulted in the exclusive formation of cyclopropanecarboxaldehyde **7** in the early stages of the reaction. The yield of **7** reached a maximum of 40%[1] after 90 min irradiation and subsequently decreased with concomitant formation of a more complex mixture. Under the photolytic conditions **7** was found to be photolabile and secondary products ensued upon prolonged irradiations. The structure of **7** was assigned based on the spectral and



7 **8**

analytical data. The assignment of the stereochemistry of **7** is based on the nmr chemical shift of the methyl group at δ 1.21 ppm and comparison with the reported value of 1.20 for the methyl signal of *trans*-1-acetyl-2-methylcyclopropane (5). The corresponding value for the *cis*-isomer is slightly higher (δ 1.30).

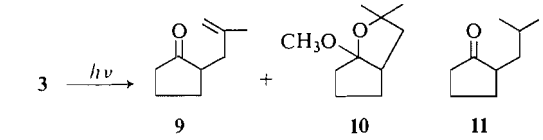
Irradiation of the *syn*-isomer **2** in methanol resulted in a mixture of ketone **1**, 2-propylidenecyclopentanone (**8**), and cyclopropanecarboxaldehyde **7**. The relative yields of photoproducts was a function of irradiation time. Furthermore, **7** appeared to be a secondary photoproduct as was evident from monitoring the photoreaction. The structure of **8** was established from its spectral and analytical data as well as its independent synthesis by condensation of cyclopentanone and propanal. Such reactions generate the thermodynamically more stable *anti*-

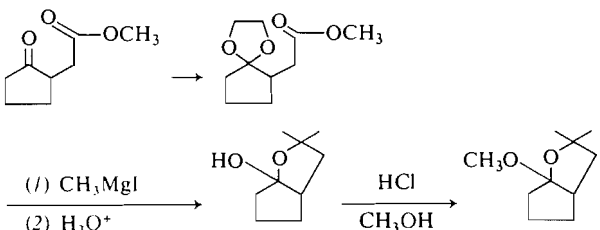
[1]All reported yields are based on vpc peak integrations (using internal standards) unless otherwise specified.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

isomer. The aldehyde **7** obtained from the *syn*-ketone **2** was identical in all respects with the product obtained from the *anti*-isomer **1**.

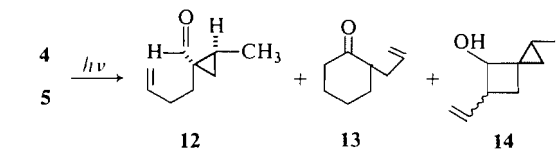
Irradiation of **3** in methanol resulted in the production of enone **9** and ketal **10** in 19 and 58% yields, respectively, based on unreacted starting material. The photoenone **9** was found to be labile under these conditions and in a separate experiment was shown to be transformed to the cyclic ketal **10** in 80% yield. The identity of **10** was established by its independent synthesis from methyl (2-oxocyclopentyl)acetate according to Scheme 1 (11). The identity of enone **9** was deduced from its spectral and analytical data as well as its hydrogenation to **11** which was independently synthesized.

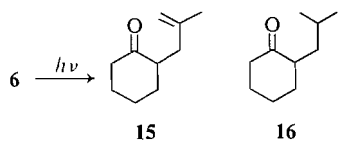




SCHEME 1

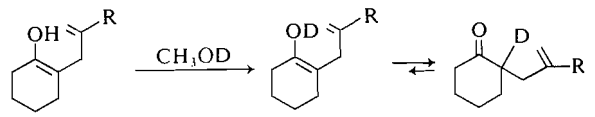
Irradiation of spiroketone **4** gave three products, **12**, **13**, and **14** in 41, 25, and 16% yields, respectively. Upon prolonged irradiation, the yield of cyclobutanol **14** increased at the expense of **12**. The structural assignments of **12** and **14** are based on characteristic group frequency assignments of their ir and nmr spectra as well as elemental analysis. The structure of 2-allylcyclohexanone (**13**) was unambiguously established by its independent synthesis. Irradiation of the isomeric ketone **5** gave a 70% yield of 2-allylcyclohexanone (**13**) and irradiation of ketone **6** resulted in 80% conversion to ketone **15**, the structure of which was assigned from analysis of spectral and analytical data and its hydrogenation to **16** which was independently synthesized.



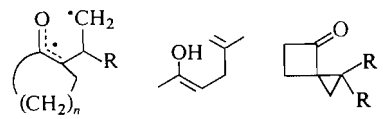


Discussion

The following trends are observed for the photodecomposition of spiro[*n*.2]alkan-2-ones. Norrish type I fragmentation appears to be the dominant pathway in the absence of a suitably disposed γ-hydrogen for type II process. Products from cyclopropane ring opening arise only for *syn*-2-methylcyclopropylketones, and in such cases not all products are derived from type II reaction. For the spiroketones **5** and **6** at least 70% of cyclopropane ring opening can be rationalized as resulting from type II rearrangement from deuterium labelling studies. When the irradiation of **5** and **6** was carried out in CH_3OD, ketones **13** and **15** were obtained



with about 70% deuterium incorporation. Under the same conditions, neither ketones **13** and **15** nor starting materials **5** and **6** underwent deuterium exchange. Type II rearrangement would be expected to yield dienols **17** which would undergo deuterium exchange under these conditions. That *complete* deuterium exchange did not occur can be rationalized in terms of (*A*) keto–enol tautomerism occurring as efficiently as exchange of D with CH_3OD and/or (*B*) ketones **13** and **15** being formed by a pathway not involving dienols **17**. A diradical of type **18** could conceivably also result in the formation of ketones **13** and **15** without proceeding through dienol **17**. That keto–enol tautomerism is not a unimolecular process is indicated by the relatively long lifetime ($\tau_{\frac{1}{2}}$ = 167 s) reported for a similar dienol **19** in the gas phase (8). It is unlikely that under our conditions a sufficient concentration of dienols **19** would be obtained such that bimolecular enol–keto tautomerism competes with proton exchange in methanol. It is noteworthy that no deuterium incorporation accompanied the formation of enones **8** and **9** from



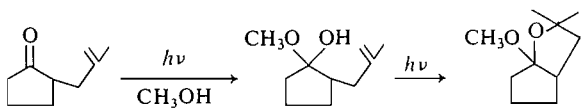
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

2 and **3**, respectively, when irradiations were carried out in CH_3OD. Thus cyclopropane ring opening takes place in these systems by a process other than type II rearrangement and enol formation. For type II reactions to occur, certain stereochemical constraints have to be met, namely that the γ-hydrogen has to lie in close proximity to the vacant n orbital in the n–π* state (12). Model studies show that the methyl hydrogens in the more stable conformations of **5** and **6** are in closer proximity to the carbonyl plane than in the case of **2** and **3**. Thus cyclopropane ring opening in **2** and **3** is expected to proceed by a mechanism other than type II. This is also substantiated by a significant amount of photoisomerization of the *syn*-ketone **2**.

Relative efficiencies of decomposition of these ketones were found in the order **6** ~ **5** > **4** > **3** ~ **2** > **1**. This data is in contrast to the reported greater efficiency of cyclopentanones over cyclohexanones to undergo α-cleavage reactions (13). Extension of the relative decomposition rate studies to include spiroketones **20***a* and *b* (14) showed that these were even slower than ketones **1** and **3**. This is in contrast to the more efficient photodecomposition of other cyclobutanones (14). Further, no type II or other products resulting from cyclopropane ring opening were observed from either **20***a* or *b*. These results point to a stabilizing effect of conjugated cyclopropane in carbonyl photodecompositions. Such effects appear to be maximized when the conjugating effects of cyclopropane are favourable such as in the case of spiroketones **20***a* and *b* where the carbonyl group is oriented in the bisected conformation relative to the cyclopropane ring. Similar effects of conjugated double bonds on carbonyl inertness to photochemistry have been observed for 2-alkylidenecycloalkanones (14).

Also in contrast to 2-alkylcyclohexanones possessing a primary γ-hydrogen (12), type II rearrangement in spirohexanones **5** and **6** is more efficient than type I cleavage. This can be attributed to the greater conformational rigidity of the γ-hydrogens in the latter case.

The anomalous photolytic transformation of **9** to



9 **21** **10**

10 does not appear to be general for 2-allylcycloalkanones. Such a process is formally analogous to cyclization of γ,δ-unsaturated carboxylic acids to δ-lactones (15) and may involve the intermediacy of hemiketal **21**.

Experimental

Melting points were uncorrected. The ir spectra were recorded with a Unicam SP 1000 instrument. The nmr spectra were measured on Varian A-60, HA-100, and EM-360 spectrometers. Samples were dissolved in CCl_4 or $CDCl_3$ solvents using TMS as the internal standard. Vapour phase chromatographic analyses and collections were performed on a Varian Aerograph Series 1700 instrument using a 6 ft glass column (0.25 in. od) packed with 6% SE-30 + 4% QF-1 on Chromosorb W AW, DMCS treated. Microanalyses were performed by Gygli Microanalytical Labs, Toronto. All of the starting materials were prepared according to procedures described in refs. 16 and 17.

General Photolysis Procedure

All irradiations were carried out in quartz tubes (od 1.7 cm) with a 450 W Hanovia high-pressure quartz mercury vapour lamp (679A-36), using a water cooled quartz immersion well containing a Vycor filter. The concentration of all solutions was 10–20 mg/ml. The solutions were purged with nitrogen for 5–10 min preceding photolysis and stoppered. Spectrograde methanol and cyclohexane were obtained from J. T. Baker Chemical Company and from Matheson Coleman & Bell, respectively. The progress of the reaction was followed by withdrawing small portions after every 10 min and injecting a constant volume of the irradiated sample into a vpc instrument. The percentage formation of the products was thus calculated. The photolysis of every sample was repeated at least thrice and the results were reproducible to within 3–9%. At the end of the irradiation, the solution was carefully concentrated, and the residual liquid was subjected to preparative scale vpc. Methanolic solutions of all cyclopropylketones were stirred in the dark to ensure that no dark reaction occurred.

Photolysis of syn-*6-Methylspiro[2.4]heptan-2-one (2)*

A solution of 160 mg of the title compound in 8 ml methanol was photolyzed for ½–1½ hours; vpc (He flow 55 cc/min, 100°C) of the photomixture showed the following components.

Aldehyde **7** (13–24%, retention time 6 min 12 s): ir (CCl_4): 875, 920, 1045, 1430, 1450, 1638, 1712, 2715, 2820, 3070 cm^{-1}; nmr δ; 8.8 (1H, CHO), 4.98 (2H, m), 5.75 (1H, m), 0.8–2.5 (7H, m with a broad singlet at 1.21), 0.5 (1H, m). *Anal.* calcd. for $C_8H_{12}O$: C 77.41, H 9.67; found: C 77.40, H 9.52.

Ketone **8** (5–8%, retention time 12 min 4 s): ir (CCl_4): 1033, 1132, 1204, 1286, 1410, 1462, 1650, 1720, 2875, 2960 cm^{-1}; nmr (CCl_4) δ: 1.06 (3H, t, J = 7 Hz) 1.45–2.84 (8H, m), 6.36 (1H, m).

Ketone **1** (28–34%) identical with a previously synthesized sample (10).

Preparation of anti-*2-Propylidenecyclopentanone (8)*

A mixture of cyclopentanone (16.8 g, 0.2 mol), propionaldehyde (11.6 g, 0.2 mol), and 0.5% KOH (20 ml) was stirred at 0°C for 30 min and then at room temperature for 15 h Work-up of the reaction mixture in ether gave 11.2 g of a fraction, bp 70–100°C/1.2 Torr. This fraction was then treated with orthophosphoric acid to give 6.9 g (27%) of *anti*-2-propylidenecyclopentanone, bp 63–64°C/1.5 mm (lit. (18) bp 81–82°C/11 Torr), mp of 2,4-dinitrophenylhydrazone 203–205°C (lit. (18) 204–205°C).

Photolysis of anti-*6-Methylspiro[2.4]heptan-2-one (1)*

A solution of 200 mg of the title compound in 10 ml methanol was photolyzed as described for ketone **2**; vpc showed only one peak apart from the starting peak. After 90 min of irradiation the solution was concentrated and sub-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

jected to preparative vpc separation to give 52 mg (26%) of starting ketone **1** and 80 mg of aldehyde **7** identical in all respects with a sample obtained from the photolysis of ketone **2**.

*Photolysis of 6,6-Dimethylspiro[2.4]heptan-2-one (**3**)*

A solution of 120 mg of the title compound in 12 ml spectrograde methanol was irradiated for different time periods. After 21 min irradiation, vpc of the irradiation mixture (temperature 100°C, He flow 55 cc/min) showed two photoproducts and 64% of the starting ketone. The products were shown to be compound **10** (21%, retention time 5.47 min) and **9** (7%, retention time 9.37 min), respectively. The structure of compound **10** is based on its characteristic spectral properties and its independent synthesis (see below): ir (CCl_4): 870, 1018, 1097, 1148, 1185, 1366, 1380, 2825, 2865, 2965 cm^{-1}; nmr (CCl_4) δ: 1.1–2.82 (15H, m, 1.25 s). The enone **9** displayed the following spectral data: ir (CCl_4): 898, 1155, 1375, 1417, 1453, 1648, 1740, 2965, 3080 cm^{-1}; nmr (CCl_4) δ: 1.65–2.7 (12H, m, 1.715), 4.7 (2H, a broad singlet). The structure of this compound was confirmed by hydrogenation to a product which was independently synthesized (see below).

When the photolysis was allowed to continue for a longer period, increased amounts of **10** were observed. Compound **10** was shown to be a secondary photoproduct by photolyzing **9** independently under the above conditions.

*Photolysis of **9***

A solution of 80 mg of **9** in 8-ml methanol was irradiated as above; vpc of the 20-min irradiated sample showed complete disappearance of the starting material yielding 79% of **10**, plus three other unidentified products. The ir and nmr spectra of **10** were identical with those of the compound obtained by direct photolysis of **3**.

*Synthesis of Mixed Ketal **10***

The mixed ketal was prepared by the following steps.

A. Preparation of Ethylene Ketal of Methyl (2-Oxocyclopentyl)acetate

A solution of methyl (2-oxocyclopentyl)acetate (7.8 g, 0.05 mol), ethylene glycol (3.6 g, 0.055 mol), and *p*-toluenesulfonic acid (25 ml) in 75 ml dry benzene was refluxed with a Dean Stark trap until no more water was collected. The reaction mixture was neutralized with sodium methoxide and worked up with additional 75 ml benzene to give 8 g (86%) of the title ketal; ir (neat) 950, 1028, 1438, 1738 cm^{-1}; nmr (CCl_4) δ: 1.3–2.67 (9H, m), 3.6 (3H, s), 3.83 (4H, s).

B. Reaction of Ketal from A with Methylmagnesium Iodide

To a solution of methylmagnesium iodide (0.045 mol) in 40 ml diethyl ether was added to the above ketal (4 g, 0.021 mol) in 15 ml ether at room temperature. The mixture was refluxed for 1 h, cooled, decomposed with saturated aqueous solution of ammonium chloride, and worked up in the usual way to give 3.3 g (77%) of 2-(6,9-dioxaspiro[4.4]nonyl)-2′-methyl-2′-propanol. This compound was purified by vacuum transfer at 125°C and 1 Torr pressure; ir (neat): 905, 946, 1023, 1148, 1338, 1470, 3430 cm^{-1}; nmr (CCl_4): 1–2.1 (15H, with a sharp singlet at 1.15), 2.9 (1H, a broad singlet, disappeared with D_2O), 3.85 (4H, s).

C. Hydrolysis of 2-(6,9-Dioxaspiro[4.4]nonyl)-2′-methyl-2′-propanol

The title compound was dissolved in 30 ml acetone and 8 ml water containing 30 mg of *p*-toluenesulfonic acid. The solution was heated to reflux on an oil bath for 1 h. The mixture was cooled, excess acetone removed under reduced pressure, and extracted with ether to give a hemiketal in equilibrium with a small amount of 2-(2′-methyl-2′-hydroxypropyl)cyclopentanone. The hemiketal (64%) was purified by vacuum transfer at 100°C and 5 Torr pressure; ir (neat): 988, 1010, 1075, 1150, 1260, 1313, 1368, 1382, 1454, 1468, 3400 cm^{-1}; nmr (CCl_4) δ: 1.05–2.8 (15H, m, a sharp singlet at 1.23), 4.53 (1H, s).

*D. Preparation of the Mixed Ketal **10***

To 2 ml of an ice cold solution of 1% methanolic HCl was added 100 mg of the hemiketal, while stirring. After stirring for 3 h, the solution was treated with $NaHCO_3$, extracted with 20 ml ether, and ether extract washed with brine until neutral. The extract was dried over anhydrous magnesium sulfate and ether removed under reduced pressure to give the mixed ketal in quantitative yield. The ir and nmr spectra of this compound were identical with those of the compound obtained by photolysis of **3**; ir (CCl_4): 870, 1018, 1097, 1148, 1185, 1366, 1380, 2825, 2865, 2965 cm^{-1}; nmr (CCl_4) δ: 1.1–2.82 (15 H, m, with a broad singlet at 1.25), 3.17 (3H, m). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.59, H 10.60; found: C 70.56, H 10.55.

Preparation of anti-*2-Isobutylidenecyclopentanone*

A mixture of 16.8 g (0.2 mol) of cyclopentanone, 14.4 g (0.2 mol) of isobutyraldehyde, and 20 ml of 0.5% KOH was stirred at 0°C for 30 min and then at room temperature for 12 h. The reaction mixture was worked up to give 12.4 g of a fraction, bp 80–100°C/1.2 Torr, which was then treated with orthophosphoric acid as described for *anti*-2-propylidenecyclopentanone; yield of the product: 7.7 g (28%), bp 62–63°C/1.5 Torr (lit. (19) bp 86°C/11 Torr); ir (CCl_4): 945, 1142, 1178, 1205, 1290, 1410, 1466, 1653, 1722, 2960 cm^{-1}; nmr (CCl_4) δ: 1.02 (6H, d), 1.62–2.8 (7H, m), 6.23 (1H, a doublet of triplets); λ_{max} (EtOH) 246 nm (ε 8004).

Hydrogenation of anti-*2-Isobutylidenecyclopentanone*

The title ketone (58 mg), was hydrogenated at atmospheric pressure with 8 mg of platinum oxide in 6 ml of ethylacetate. One equivalent of hydrogen was taken up whereupon the hydrogen uptake ceased. The solution was filtered and the solvent removed under reduced pressure to give 53 mg of essentially pure product (analyzed by vpc): ir (neat): 1183, 1392, 1410, 1432, 1480, 1492, 1765 (C=O stretch)cm^{-1}; nmr (CCl_4) δ: 0.77–1.1 (6H, two doublets centered at 0.83, J = 1.5 Hz, J = 1.5 Hz), 1.15–2.4 (10H, m).

*Hydrogenation of **9***

A solution of 25 ml of the title compound in 6 ml ethyl acetate was hydrogenated over 5 mg of platinum oxide Work-up and isolation gave 2-isobutylcyclopentanone in almost quantitative yield. This ketone, had ir and nmr spectra identical with those of a sample prepared by hydrogenation of *anti*-2-isobutylidenecyclopentanone.

Photolysis of anti-*7-Methylspiro[2.5]octan-2-one (**4**) in Methanol*

A solution of 200 mg of *anti*-7-methylspiro[2.5]octan-2-one in 10 ml spectrograde methanol (Baker analyzed reagent) was flushed with nitrogen and irradiated at 25°C using a Vycor filter. After 16 min irradiation, vpc of the irradiated sample (100°C, rate of He flow 55 cc/min) showed two products and 52% of the starting material (retention time 12.44 min). The two products were shown to be compounds **12** (26%, retention time 7 min 40 s) and **13** (15%, retention time 10 min), respectively. The spectrum of compound **12** rests on its characteristic properties and analysis: ir (neat liquid) 765, 860, 712, 995, 1394, 1450, 1635, 1708, 2720, 3065 cm^{-1}; nmr (CCl_4) δ: 5.67 (1H, m), 4.95 (2H, m), 0.85–2.35 (9H, m, broad singlet at 1.22), 0.55 (1H, m), 8.68 (1H, s); M^+: *m/e* 138. *Anal.* calcd. for $C_9H_{14}O$: C 78.26, H 10.15; found: C 78.04, H, 10.27.

2-Allylcyclohexanone (**13**) (20) was synthesized independently from ethyl 2-cyclohexanonecarboxylate and allyl bromide, and its spectral properties were compared with those of the synthesized sample. When the photolysis was allowed to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

continue for an additional 14 min, vpc of the mixture showed compound **12** (41%), **13** (25%), starting ketone (16%), and the initially minor peak (**14**, retention time 6 min 2 s) increased in intensity. On prolonged photolysis the peak at 6 min and 2 s increased considerably in size with a subsequent loss of **12**. The ir, nmr, and mass spectra of this compound indicated the structure **14**: ir (CCl_4): 920, 1070, 1108, 1398, 1450, 1635, 3070, 3630 cm^{-1}; nmr (CCl_4, external TMS) δ: 6 (1H, m), 5.25 (2H, m), 4 (1H, d, J = 7 Hz), 2.48 (1H, OH, disappeared with D_2O), 2.72 (1H, m), 1.9 (2H, d, J = 9 Hz), 1.14 (3H, d), 0.05 (1H, m), 0.75 (2H, m); M^+: *m/e* 138.

Photolysis of syn-*7-Methylspiro[2.5]octan-2-one (5) in Methanol*

A solution of 200 mg of the title compound in 10 ml methanol was photolyzed under the same conditions as mentioned in the photolysis of **4**: vpc analysis of the photomixture after 16 min of photolysis showed **13** (58%), starting material 19%), and four other unidentified products totalling 23%. After 30 min of photolysis the mixture was found to contain **13** (69%), starting ketone (3%), and other products totalling 28%. The ir and nmr spectra of the major product were identical with those of the compound obtained by the photolysis of *anti*-7-methylspiro[2.5]octan-2-one.

Photolysis of 7,7-Dimethylspiro[5.2]octan-2-one (6)

A solution of 100 mg of **6** in 10 ml spectrograde methanol was irradiated as described earlier. After 15 min irradiation vpc of the irradiation mixture (85°C, He flow 50 cc/min) showed 47% of a major product (retention time 18 min), 16% of starting ketone (retention time 14 min), and four other minor peaks. The major product was identified as compound **15** on the basis of its spectral data: ir (CCl_4): 890, 1048, 1130, 1450, 1645, 1710, 3060 cm^{-1}; nmr (CCl_4) δ: 1.68 (3H, s), 1.72–2.5 (11H, m). The structure of **15** was confirmed by comparing spectra of its hydrogenated product with those of the synthesized sample (see below).

When the photolysis was continued for a longer period, increased amounts of unidentified products were observed at the expense of **15**. In a separate experiment a solution of **6** (100 mg) in cyclohexane (5 ml) was irradiated for 15 min; vpc of the mixture showed 79% **15** and 10% unreacted ketone **6**.

Preparation of anti-*2-Isobutylidenecyclohexanone*

A mixture of cyclohexanone (19.6 g, 0.2 mol), isobutyraldehyde (14.4 g, 0.2 mol), and 1.5% KOH (50 ml) was stirred at 0°C for 20 min and then at room temperature for 12 h. The mixture was worked up to give 14.5 g of a fraction, bp 93–103°C/1.2 Torr, which was then treated with orthophosphoric acid. Yield of the product was 9.5 g (31%), bp 68–69°C/1.5 Torr (lit. (21) bp 96–98°C/7 Torr); ir (CCl_4): 1140, 1303, 1465, 1620, 1690 (C=O stretch) cm^{-1}; nmr (CCl_4) δ: 0.93 (3H, s), 10.5 (3H, s), 1.5–2 (4H, m), 2.15–2.7 (5H, m), 6.28 (1H, a doublet of triplets).

Hydrogenation of 15

Unsaturated ketone **15** (82 mg) was hydrogenated over 8 mg of platinum oxide in 10 ml methanol. When 1 equiv. of hydrogen was taken up, the solution was filtered and the solvent removed under reduced pressure at room temperature to give 78 mg of essentially pure product **16** (as analyzed by vpc): ir (CCl_4): 883, 1122, 1313, 1368, 1387, 1430, 1450, 1468, 1712 (C=O stretch) cm^{-1}; nmr (CCl_4) δ: 0.82 (3H, s), 0.9 (3H), 1.25–2.6 (12H, m).

Hydrogenation of anti-*2-Isobutylidenecyclohexanone*

This compound was hydrogenated as ketone **15** and gave **16** in quantitative yield. The ir and nmr spectra of this compound were identical with those of a sample prepared by hydrogenation of **15**.

Photolysis in CH_3OD

Solutions of spiroketones **2–6** in CH_3OD (distributed by EM Reagent Division, Brinkmann Instruments, Inc., Westbury, NY) were prepared and irradiated under identical conditions. Enones **8**, **9**, **13**, and **15** were isolated by vpc and the extent of deuterium incorporation determined by the relative intensities of M + 1 and M peaks in their mass spectra (correcting for M − 1 fragmentation). Reinjection of deuterated **13** and **15** through the vpc showed no decrease of deuterium. In the same runs ketones **3**, **4**, and **6** were isolated and shown not to be enriched with deuterium. Nondeuterated ketones **13** and **15** were subjected to identical irradiation conditions and shown not to undergo deuterium exchange in CH_3OD.

Relative Rate Studies

Methanolic solutions (10 ml, 0.05 m) in standard quartz tubes were placed in a merry-go-round apparatus and irradiated with the same photochemical assembly described above. Samples were withdrawn after certain time intervals and the starting ketone concentration monitored by vpc.

Competitive thermal and photochemical processes in cyclopropylketone rearrangements. II. Thermal isomerization of spiro[*n*.2]alkan-2-ones

PRABHAKER G. KHAZANIE AND EDWARD LEE-RUFF

Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received July 22, 1977

PRABHAKER G. KHAZANIE and EDWARD LEE-RUFF. Can. J. Chem. **56**, 808 (1978).

Conformationally-rigid methyl-substituted cyclopropyl ketones with a suitably disposed γ-hydrogen undergo thermal type II reactions efficiently. Comparison of yields of these rearrangements with their photochemical analogs suggest that photochemical type II reactions arise from excited vibrational states. In the absence of a suitably disposed γ-hydrogen, and if strain factors permit, such systems undergo oxovinylcyclopropane to dihydrofuran rearrangement. The inertness of these systems to undergo such thermal rearrangement increased on going from cyclohexanone to the cyclopentanone series.

PRABHAKER G. KHAZANIE et EDWARD LEE-RUFF. Can. J. Chem. **56**, 808 (1978).

Les cyclopropyl-cétones conformationnellement rigides substitués par des groupes méthyles et comportant un hydrogène en γ orienté convenablement subissent des réactions thermiques du type II d'une manière efficace. Une comparaison des rendements de telles transpositions avec celles obtenues dans les réactions analogues photochimiques suggère que les réactions photochimiques de type II proviennent d'état vibrationnel excité. Lorsqu'il n'y a pas d'hydrogène γ orienté convenablement et si les facteurs stériques le permettent, de tels systèmes subissent la transposition oxovinylcyclopropane → dihydrofuranne. L'inertie des transpositions thermique augmente lorsque l'on passe des dérivés de la cyclohexanone à ceux de la cyclopentanone.

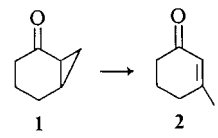
Cyclopropanes and ethylenes exhibit similar electronic properties as far as affecting the chemical nature of neighbouring activated sites. Both show π-releasing and σ-electron-withdrawing behaviour in solvolyses of conjugated sulphonate esters (1, 2). Furthermore the stereochemical orientation of the conjugating group relative to that of the carbonium ion is critical in establishing the amount of π-electron release by these groups. We have shown that ring size and cyclopropyl substitution in spiro[*n*.2]alkan-2-ones play an important role in the photochemistry of cyclopropyl ketones (3). The more rigidly confined the cyclopropyl group is to a bisected geometry with respect to the carbonyl group the greater the inertness towards photochemical degradation. The same pattern is observed in α,β-unsaturated ketones, the decrease in reactivity of such systems attributed to a change in the nature of the lowest excited state (from n-π* to π-π*) and competitive nonchemical deactivation processes (16, 17). The similarity of photoproducts from the spiro[*n*.2]alkan-2-ones with products obtained from the thermal isomerization of acyclic cyclopropylketones prompted us to investigate the thermal reactions of these to evaluate the extent to which excited vibrational states are possibly involved in these photochemical transformations. In addition we were also interested if such 'resonance stabilization' would be reflected in their ground state reactions.

In 1968, Dauben reported (10) that the irradiation of bicyclo[4.1.0]heptan-2-one (**1**) resulted in a 31% conversion to cyclohexanone **2**. The stereoselectivity



1 **2**

of the cyclopropane ring opening was attributed to the bond-weakening of the bond with optimum overlap with respect to the carbonyl group in the excited state. We report that such stereoselectivity of cyclopropane ring opening is also a ground state phenomenon and that the same transformation of **1** to **2** occurs thermally (270°C)[1] with greater efficiency (78%)[2]. Thus, photochemical transformations of cyclopropyl ketones involving cyclopropane ring opening may involve radiationless deactivation to vibrationally excited states. In the first part of this study (3) we reported the results of the photochemistry of a series of spiro[*n*.2]alkan-2-ones. In this paper we report on the thermal labilities of the same series.

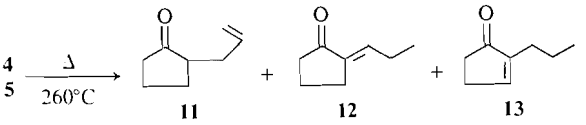
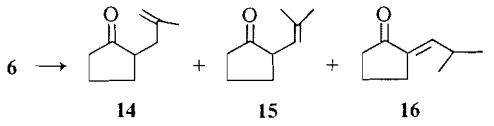
For personal use only.

Ketones **3** and **7** were stable up to 400°C above which both compounds started to char. In the case of **7** a 32% yield of *o*-ethylphenol was isolated and characterized by comparison with an authentic sample. Pyrolysis of **4** at 260°C gave a 90% conversion to 2-allylcyclopentanone (**11**) and a trace of



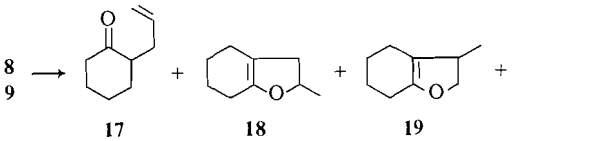
conjugated ketone **12**. Similarly the *anti*-isomer **5** gave **11** as the major product (71%) along with a significantly larger amount of **12** (16%) and cyclopentenone **13** (9%). All products were stable under the pyrolysis conditions. The structures of the products were established by comparison with authentic samples.

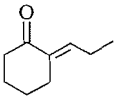
Ketone **6** was found to be most thermally labile in this series and was transformed in 87% yield to enone **14**. In addition to **14**, small amounts of **15** and **16**



were also detected. Upon prolonged reaction times the amounts of **15** and **16** increased at the expense of **14**. In a separate experiment, **14** was shown to be thermally transformed to a mixture of **15** and **16**, and **15** isomerized to **16** and **14** under identical conditions. The structure of enone **16** was assigned unequivocally by comparison with the product obtained from the condensation of cyclopentanone and isobutyraldehyde. The identity of enones **14** and **15** was elucidated from their spectral data and comparison with products obtained from the photolysis of **6** (3).

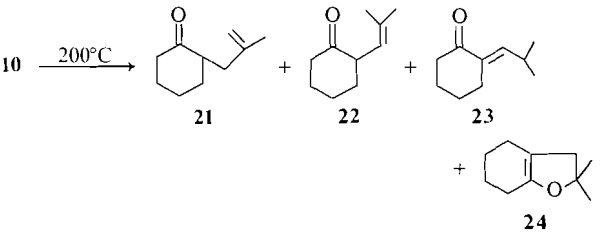
The series of spiro[5.2]octanones **8–10** was shown to be more thermally labile than the corresponding spiro[4.2]heptanones and significant oxovinylcyclopropane to dihydrofuran rearrangements were observed. Ketone **8** was transformed to allylcyclohexanone (**17**) in 82% yield along with a 10% (1:1) mixture of the dihydrofurans **18** and **19**. The isomeric





anti-isomer **9** gave the same mixture; however, the amount of dihydrofurans **18** and **19** (54%) exceeded that of 2-allylcyclohexanone (**17**) (30%). In addition a small amount (8%) of 2-propylidenecyclohexanone (**20**) was isolated from the reaction mixture. Under the same conditions all pyrolysis products were found to be stable and the structures of these were established by independent syntheses (see Experimental).

The thermal rearrangement of **10** at 200°C proceeded to give a mixture of isomers **21**, **22**, **23**, and **24**. The major products were **21** (84%) and **24** (12%),



whereas enones **22** and **23** were formed as secondary products from subsequent thermal rearrangement of **21**.

Discussion

Comparison of the photochemical and pyrolysis data indicates a close similarity in the yields of type II products for the spiro[5.2]octan-2-ones (Table 1), however the extent of such reactions in the corresponding spiro[4.2]heptan-2-ones was significantly greater in the thermolysis of these as compared to their photolyses. The absence of any type II products in the photolysis of **4** and **5** and the absence of deuterium incorporation of enone **14** from the photolysis of **6** has been attributed to the inability of such systems to obtain the stereochemical conformation required for such type II reactions. The propensity of type II products in the thermolysis of **4** to **6** suggest that 'type II' products can arise from pathways other than cyclic six-centered transition states and concerted dienol **25** formation. A 1,3 diradical of type **26** may lead to the same products and would not have to meet the same stereochemical

TABLE 1. Thermal and photoproducts from spiro[*n*.2]alkan-2-ones

Compounds	% type II products *hν*	% type II products Δ	% DHF's from Δ
4	0	90	0

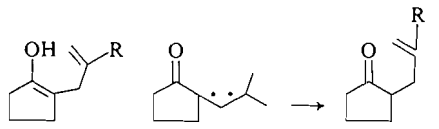
constraints as the type II reaction. The large amount of 2-allylcyclopentanone **11** from the thermolysis of the *anti*-spiroketone **5** bears on this point. Based on our data one cannot, however, rule out the occurrence of an enol intermediate in these thermal conversions.



25 **26** **11** R = H; **14** R = CH_3

Another significant deactivation process of cyclopropyl carbonyl ring-opening reaction is formation of dihydrofurans (DHF). One such thermal reaction has been reported by McGreer and McKinley (4) and their studies support a diradical mechanism.

It is of interest to note that the yields of dihydrofurans show an increase of from 10% for ketone **8** to 54% for ketone **9**. If a 1,3 diradical were common to both **8** and **9** and that DHF's as well as 2-allylcyclohexanone (**17**) were derived from it then the relative yields of enone **17** to DHF's would be expected to be identical in both cases. The larger amount of 2-allylcyclohexanone (**17**) from *syn*-ketone **8** *suggests that most of 17 is derived from a concerted mechanism.* Furthermore if the 30:54 dichotomy of 2-allylcyclohexanone to DHF is used as a measure of 1,3 diradical present the amount of **17** obtained from *syn*-ketone **8** derived from a diradical is calculated as 6%. It follows then, where a γ-hydrogen is predisposed for a type II reaction to be possible such thermal analogs follow a concerted mechanism. The similarity of product distribution from ketone **10** supports this concept.

The absence of DHF's in the spiro[4.2]heptanones can be attributed to the strain of such 5,5 fused bicyclics. Attempts to prepare these by methods similar to the preparation of **18**, **19**, and **24** were unsuccessful.

Relative rates of decomposition of these ketones were determined to follow the order **10** > **6** ~ **8** > **9** ~ **4** > **5** ≫ **7** > **3**. From these results it is apparent that in spite of the larger strain in cyclopentanones (5), the spiro[5.2]octan-2-ones are more labile than the corresponding spiro[4.2]heptan-2-ones. This can be attributed to the greater coplanarity of the cyclopentanone ring compared to cyclohexanone (6) and the possibility of the former to adopt a bisected conformation of the cyclopropylcarbonyl group permitting greater resonance stabilization.

Experimental

Melting points were uncorrected. The ir spectra were recorded with a Unicam SP 1000 instrument. The nmr spectra were measured on Varian A-60, HA-100, and EM-360 spectrometers. Samples were dissolved in CCl_4 or $CDCl_3$ solvents using TMS as the internal standard. Vapour phase chromatographic analyses and collections were performed on a Varian Aerograph Series 1700 instrument using the following column: a 6 ft glass column (0.25 in. od) packed with 6% SE-30 + 4% QF-1 on Chromosorb W AW, DMCS treated. Microanalyses were performed by Gygli Microanalytical Labs, Toronto. All of the starting materials were prepared according to procedures described in refs. 7–9.

General Thermolyses Procedures

Thermolyses were conducted in a muffle furnace with operating temperatures of 200–500°C. The temperature gauge of the oven was calibrated using a thermocouple. Samples were placed in Pyrex tubes, 1 cm diameter, 1 mm thick, and 6–8 cm long. The samples were degassed by five to six freeze-pump-thaw cycles at 10^{-3} Torr pressure, sealed, wrapped in an aluminum foil, and heated for varying lengths of time. The ampules were cooled, opened, and the mixtures analyzed by tlc, vpc, ir, nmr, and mass spectroscopy. The products were then confirmed by their independent synthesis. Known amounts of authentic samples were injected in vpc and the peaks compared with those of the product mixtures. The percentage yield of the products was thus calculated. Negligible amounts of high boiling products or polymers were observed at temperatures below 260°C but above this temperature polymer formation increased substantially. Polymer formation also increased if the sample tubes were not properly degassed.

Pyrolysis of Bicyclo[4.1.0]heptan-2-one (1)

A sample of the title ketone (100 mg) was heated at 270°C for 45 min. The pyrolysate was subjected to preparative vpc which resulted in separations of two volatile products. The more volatile material (36 mg) was identified as 3-methyl-2-cyclohexenone (**2**) based on the spectral data: ir (neat): 1679, 1640, 1380; nmr (CCl_4) δ: 1.60–2.50 (9 H, m with broad singlet δ 1.92), 5.70 (1 H, q); *m/e* 110. This was identical to a commercial sample (Aldrich). The less volatile material was identified as starting ketone **1**. A second pyrolysis was carried out at the same temperature for 95 min and the product yields tabulated (Table 2).

Attempted Pyrolysis of Spiro[2.4]heptan-2-one (3) at Different Temperatures

Four ampules, each containing **3** (100 mg) were thermolyzed at different temperatures for different time intervals. The results are summarized in Table 2. Compound **3**, unlike other

TABLE 2. Thermolyses of ketones **1**, **3**, and **7**

members of the series was very stable up to 360°C and any attempt to carry out thermolysis at higher temperatures resulted in complete charring of the starting material.

Pyrolysis of Spiro[2.5]octan-2-one (7) at Different Temperatures

Five ampules, each containing **7** (125 mg) were degassed and thermolyzed between 200–500°C for different time intervals. The results are summarized in Table 2. The compound was stable up to 360°C for 1 h. However, unlike compound **3**, **7** pyrolyzed at 400°C during 90 mins to give 2-ethylphenol (32%): ir (CCl_4): 1112, 1170, 1325, 1455, 3020, 3630 cm^{-1}; nmr (CCl_4) δ: 1.2 (3H, t, J = 7 Hz), 2.72 (2H, q, J = 7 Hz), 4.56 (1H, OH, disappeared with D_2O), 6.5–7.2 (4H, m); starting ketone **7** (7%); nine minor peaks; and polymeric material. This phenol was synthesized from phenol and absolute ethanol in the presence of anhydrous aluminum chloride. The ir and nmr spectra of this compound were identical with those of the sample obtained by thermolysis of **7**.

Thermolysis of syn-*6-Methylspiro[2.4]heptan-2-one (4) at 260°C*

A sample of the spiroketone **4** (100 mg) was heated at 260°C for different periods of time; vpc analysis (He flow rate 50 cc/min, 100°C) of the sample which was thermolyzed for 15 min, showed 24% conversion to 2-allylcyclopentanone **11** and 68% of the starting ketone (retention time 5 min 5 s). Upon heating for an additional hour, compound **4** gave a mixture containing **11** (90%), **12** (1%), and **5** (4%) as analyzed by vpc and ir. The results are summarized in Table 3. Structural identification for **11** was based on its spectral data: ir (CCl_4): 923, 1160, 1408, 1442, 1455, 1640, 1745, 2960, 3080 cm^{-1}; nmr (CCl_4) δ: 1.3–2.7 (9H, m), 4.8–5.18 (2H, m), 5.42–6.1 (1H, m). An identical material was synthesized (see below) by an alternate method. Compound **12** was identical in all respects with a product obtained from the photolysis of **4** (3).

Thermolysis of anti-*6-Methylspiro[2.4]heptan-2-one (5) at 260°C*

A sample of spiroketone **5** (100 mg) was heated at 260°C initially for 15 min; vpc monitoring (He flow rate 50 cc/min, 100°C) of the thermolyzed sample showed only 8% conversion to 2-allylcyclopentanone (**11**) (retention time 5 min 48 s) and starting ketone (89%, retention time 7 min 5 s). Upon heating for an additional hour, compound **5** gave a mixture containing **11** (55%), *anti*-2-propylidenecyclopentanone (**12**) (12%, retention time 8 min 35 s), ketone **13** (retention time 9 min 20 s), and the starting material (23%). The results are summarized in Table 3. Compounds **11**, **12**, and **13** were collected on vpc and their spectra compared with those obtained by an alternate synthesis (see below).

Preparation of 2-Allylcyclopentanone (11)

A solution of sodium ethoxide (0.80 g Na, 30 ml absolute ethanol) was cooled to 5°C. To this, ethyl 2-cyclopentanonecarboxylate containing 45% methyl ester (5.3 g, 0.035 mol) was added dropwise with stirring over 15 min. The solution was stirred for an additional 15 min, allyl bromide (5 g, 0.042 mol) was added and heated to boiling for 30 min. The solution was cooled, diluted with 100 ml water, and the ester extracted with three 75-ml portions of ether. The combined ether extracts were dried over anhydrous magnesium sulfate and ether removed under reduced pressure. The residue after distillation gave 4.9 g (74%) of allyl derivative of ethyl 2-cyclopentanonecarboxylate, bp 80°C/0.1 Torr; nmr (CCl_4) δ: 1.22 (3H, t, 7 Hz), 1.67–2.82 (8H, m), 3.67 (3H, s), 4.1 (2H, q, J = 7 Hz), 4.83–5.25 (2H, m), 5.32–6.1 (1H, m). The allyl ester was refluxed with 5% aqueous KOH (50 ml) between 80–90°C for 12 h to give 2-allylcyclopentanone in 27% yield, bp 45°C/1.4 Torr (lit. (11) bp 55–57°C/18 Torr); ir (CCl_4): 923, 1160, 1408, 1442, 1445, 1640, 1745, 2960, 3080 cm^{-1}; nmr (CCl_4) δ: 1.3–2.7 (9H, m), 4.8–5.18 (2H, m), 5.42–6.1 (1H, m).

*Preparation of 2-*n*-Propyl-2-cyclopentenone (13)*

A mixture of *anti*-2-propylidenecyclopentanone (1.0 g) (3) and polyphosphoric acid (1:1 mixture of P_2O_5 and H_3PO_4 aged for 10 h at 100°C) was heated at 100°C for 30 min in a flask equipped with a condenser. Water (7 ml) was added to the cooled mixture and 50 ml ether was added for extraction. The ether layer was washed with brine, dried over anhydrous magnesium sulfate, and evaporated to give 0.85 g of a crude liquid which was purified by distillation, bp 59–60°C/1.3 Torr; yield, 0.51 g (51%); ir (CCl_4): 930, 1060, 1105, 1355, 1380, 1405, 1455, 1630, 1715, 2960, 3040 cm^{-1}; nmr (CCl_4) δ: 0.92 (3H, t, J = 7 Hz), 1.12–2.70 (8H, m), 7.2 (1H, m); M^+ m/e 124.

Thermolysis of 6,6-Dimethylspiro[2.4]heptan-2-one (6) at 200°C

Samples of spiroketone **6** (200 mg of each) in two sealed ampules were placed in an oven at 200°C. The tubes were removed from the oven after 17 and 37 min, respectively, and cooled. After opening each tube, the contents were analyzed by vpc (He flow 48 cc/min, 100°C); compound **6** was unstable above 120°C column temperature and a pure sample when injected in vpc at 128°C showed about 3% conversion to **14**. The first compound to elute was identified as **14** (71%, retention time 11 min 40 s) by comparison of its spectra with those of the sample obtained via photolysis of **6** (3). The second compound (4%, retention time 13 min 55 s) was identified as **15** by its characteristic spectral properties: ir (CCl_4): 955, 1380, 1408, 1455, 1745, 2960 cm^{-1}; nmr (CCl_4) δ: 1.56–3.0 (13H, m, a doublet centered at 1.68, J = 5 Hz), 4.88 (1H, m). This compound was hydrogenated to the previously characterized 2-isobutylcyclopentanone (3).

The contents of the second ampule (37 min pyrolysis) under the vpc conditions mentioned above showed three peaks. The peak due to **14** decreased in area, that due to **15** increased in area (30%) and a new peak due to compound **16** (11%, retention time 16 min 30 s) appeared. The spectra of **16** were identical with those of a synthesized sample (3).

Compounds **15** and **16** were suspected to be secondary products of thermolysis, and hence **14**, **15** were thermolyzed separately under the above conditions.

Thermal Rearrangement of 14

Thermolysis of 50 mg of compound **14** was carried out as in the case of spiroketone **6** at 200°C for 37 min. By vpc analysis the product mixture was found to consist of starting ketone **14** (27%), **15** (41%), **16** (28%), and few other minor products totalling 4%. These ketones displayed ir and nmr spectra identical with those of the products obtained by the thermolysis of **6**. The thermolysis results are summarized in Table 4.

Thermal Rearrangement of 15

A 60 mg sample of pure **15** was thermolyzed as above at

TABLE 3. Pyrolysis of ketones **4** and **5** at 260°C

200°C for 37 min. The product mixture was separated by vpc. The results are summarized in Table 4. Enones **14** and **16** were identified by their spectral properties and by their comparison with the spectra of the products obtained in the pyrolysate mixture of **6**.

Attempted Thermal Rearrangement of ***16***

In an attempt to check if **16** isomerized to **14** and/or **15**, a sample of **16** (49 mg) was thermolyzed under the above conditions. The product mixture when analyzed by vpc showed unreacted starting material.

Thermolysis of syn-*7-Methylspiro*[*2.5*]*octan-2-one* (***8***) *at 260°C*

The title compound when pyrolyzed at 260°C for 45 min gave 82% **17**, 5% **18**, 4% **19**, and three other minor products totalling 9% by preparative vpc. These results are summarized in Table 5. The ir and nmr spectra of the ketone and the enol ethers were identical with those of synthesized samples (see below) (12, 13).

Synthesis of 3-Methyl-2,3,4,5,6,7-hexahydrobenzofuran (***19***)

The title compound was synthesized by the following steps.

A. Preparation of Ethyl 2-(2-Cyclohexanone)propionate

To a refluxing solution of 1-(1′-cyclohexenyl)pyrrolidene (14) (7.555 g, 0.05 mol) in 75 ml benzene, ethyl α-bromopropionate (10.86 g, 0.06 mol) was added over a period of 1 h. Upon refluxing for 2 h, the solution was cooled, and excess bromoester and solvent removed under reduced pressure. The residue was then refluxed in 50 ml methanol and 10 ml water for 1 h. The solution was concentrated once again, extracted with ether, and worked up in the usual way to give 1.8 g (18%) of ethyl 2-(2-cyclohexanone)propionate: ir (neat): 1050, 1178, 1253, 1312, 1340, 1378, 1450, 1710 (C=O stretch of the ring), 1730 (C=O stretch of the ester); nmr (CCl_4) δ: 0.9–2.85 (16H, m, with a triplet centered at 1.21, J = 7 Hz), 4.06 (2H, q, J = 7 Hz). This reaction would require more than 2 h reflux period since a lot of cyclohexanone was recovered.

B. Ethylene Ketal of Ethyl 2-(2-Cyclohexanone)propionate

A solution of ethyl 2-(2-cyclohexanone)propionate (*A*) 0.9 g, 0.0045 mol), ethylene glycol (0.28 g, 0.0045 mol), and *p*-toluenesulfonic acid (8 mg) in 25 ml dry benzene was refluxed using a Dean Stark trap until the theoretical amount of water had been collected in the trap. The cooled solution was washed with 7% sodium bicarbonate, then with brine, dried over anhydrous sodium sulfate and the solvent removed under reduced pressure. The compound thus obtained was sufficiently pure to be used in the next step: ir (neat): 808, 865, 927, 950, 1040, 1098, 1170, 1258, 1333, 1376, 1446, 1730 (ester carbonyl); nmr (CCl_4) δ: 0.92–2.82 (16H, m, with a triplet centered at 1.2, J = 7 Hz, and a doublet at 1.05, J = 7 Hz), 3.85 (4H, s), 4.05 (2H, q, J = 7 Hz).

C. Preparation of Ketal Alcohol

To a stirred slurry of lithium aluminum hydride (0.228 g, 0.006 mol) in 20 ml of anhydrous ether, was added the ketal ester *B* (1 g, 0.0041 mol) in 10 ml ether over a period of 20 min. After the addition was complete, the solution was refluxed for 1 h, the work-up gave 0.7 g (85%) of the ketal alcohol: ir (neat): 924, 950, 1030, 1096, 1165, 1220, 1260, 1280, 1340, 1352, 1445, 2935, 3430 cm^{-1}; nmr (CCl_4) δ: 0.83 (3H, d, J = 7 Hz), 1.05–2.2 (10H, m), 3.1–3.8 (3H, m), 3.9 (4H, s).

D. Hydrolysis of the Ketal Alcohol C

Compound *C* (0.7 g, 0.0035 mol) was hydrolyzed by heating for 1 h on an oil bath with 15 ml acetone and 5 ml water containing 15 mg of *p*-toluenesulfonic acid. Work-up of the reaction mixture gave 0.52 g of hemiketal in equilibrium with a minor fraction of γ-hydroxyketone: ir (neat): 810, 950, 1015, 1090, 1260, 1448, 1720 (weak), 3410 cm^{-1}; nmr (CCl_4) δ: 0.7–2.9 (13H, m, with four sharp peaks at 0.78, 0.88, 0.98, and 1.1), 3.05–3.6 (2H, m), 3.3–3.7 (1H, m).

Preparation of 3-Methyl-2,3,4,5,6,7-hexahydrobenzofuran (***19***)

The hemiketal *D* was heated to 130°C and distilled between 35–40 Torr to give the title compound in quantitative yield: ir (neat): 873, 950, 968, 1083, 1140, 1205, 1283, 1388, 1450, 1710 (enol ether C=C), 2880, 2940 cm^{-1}; nmr (CCl_4) δ: 0.9–2.33 (11H, m, with a doublet centered at 1), 2.5–3.17 (1H, m), 4.22 (1H, q, J = 9 Hz), 3.58 (1H, q, J = 9 Hz); M^+ *m/e* 138. These spectra were identical with those of the compound obtained by pyrolysis of spiroketone **8**.

Preparation of 2-Methyl-2,3,4,5,6,7-hexahydrobenzofuran (***18***)

This compound was prepared as described in the literature (13).

Thermolysis of anti-*7-Methylspiro*[*2.5*]*octan-2-one* (***9***) *at 260°C*

A sample of 150 mg of compound **9** was thermolyzed at 260°C for 45 min; vpc analysis (55 cc/min, 100°C) of the thermolyzed mixture showed 28% 2-allylcyclohexanone (**17**) (retention time 10 min 45 s), 9% *anti*-2-propylidenecyclohexanone (**20**) (retention time 20 min), 28% 2-methyl-2,3,4,5,6,7-hexahydrobenzofuran (**18**) (retention time 5 min, 55 s), 23% 3-methyl-2,3,4,5,6,7-hexahydrobenzofuran (**19**) (retention time 6 min, 37 s), 6% starting ketone (12 min, 43 s), and small amounts of volatile fractions. These results are summarized in Table 5. The nmr and ir spectra of ketone **17** and the enol ethers were identical with those of the synthesized samples. The structures of ketone **20** was based on comparison of this sample with a sample synthesized by an alternate route (see below).

Preparation of anti-*2-Propylidenecyclohexanone* (***20***)

Following the procedure described for the preparation of 2-isobutylidenecyclohexanone (3), compound **20** was obtained in 40% yield, bp 56–57°C/1.6 Torr (lit. (15) bp 80–82°C/4 Torr): ir (neat): 820, 1145, 1305, 1615, 1690, 2870, 2940 cm^{-1}; nmr (CCl_4) δ: 1.04 (3H, t, J = 7 Hz), 1.6–2.67 (10H, m), 6.28–6.7 (1H, m).

Thermolysis of 7,7-Dimethylspiro[*2.5*]*octan-2-one* ***10***

Three sealed ampules each containing 240 mg of **10** were placed in an oven at 200°C. The ampules were removed from

23	150	—	—	—	—	Unchanged

the oven after 17, 60, and 150 min; vpc analysis (He flow 50 cc/min, 85°C) of the 17-min thermolyzed sample showed three peaks. The major component (80%, retention time 18 min 15 s) was identified as **21** by its characteristic spectral data. These spectra were identical with those of the product obtained via photolysis of **10** (3). The minor product (11%, retention time 5 min 30 s) was identified as 2,2-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (**24**) and had spectral properties identical with those of the synthesized sample (14).

Ketone **10** on thermolysis for 60 min, showed in addition to **21** and **24**, a new compound **22** (8%, retention time 22 min 11 s). The structure of **22** was based on its spectral data: ir (CCl_4): 1130, 1305, 1380, 1450, 1715 cm^{-1}; nmr (CCl_4) δ: 1.5–2.5 (14H, m, with two singlets at 1.58 and 1.73), 3.05 (1H, m), 5.25 (1H, broad doublet, $J = 8$ Hz). The structure of **22** was confirmed by hydrogenation to the known 2-isobutylcyclohexanone (3).

The sample which was thermolyzed for 150 min, showed in addition to **21**, **24**, and **22**, another new compound **23** (14%, retention time 26 min 42 s), the structure of which was established by independent synthesis. Compounds **22** and **23** were suspected to be secondary thermal products since decrease in the size of the peak due to **21** was observed.

*Thermal Isomerization of **21** at 200°C*

A sample of 42 mg of **21** was heated at 200°C for 2½ hours; vpc of the product mixture showed **22** (52%), **23** (23%), starting ketone **21** (17%), and several other unidentified fractions totalling 8%. The nmr and ir spectra of these ketones were identical with those of the products obtained by the thermolysis of **10**. The thermolysis results are summarized in Table 6.

*Thermal Isomerization of **22** at 200°C*

A sample of 53 mg of **22** was thermolyzed as before at 200°C for 2½ h; vpc analysis of the mixture showed **21** (5%), starting ketone **22** (35%), **23** (48%), and other unidentified products totalling 12%. The results are summarized in Table 6.

*Attempted Thermal Rearrangement of **23** at 200°C*

In an attempt to check if **23** isomerized thermally to **21** and/or **22**, a sample of **23** (120 mg) was thermolyzed at 200°C for 2½ h. The vpc analysis of the product mixture showed 94% of the starting ketone and no other peak.

The reactions of $NaBH_4$ with Co(II) compounds in the presence of triphenylphosphine (P) have been studied in ethanol and benzene solutions. The conditions for the isolation of the Co(I) complexes, $Co(BH_4)P_n$ (n = 2, 3), have been established and the structures of these species are discussed in the light of various physical measurements.

D. G. HOLAH, A. N. HUGHES, B. C. HUI et C. T. KAN. Can. J. Chem. **56**, 814 (1978).

On a étudié les réactions de $NaBH_4$ avec les composés Co(II) en présence de triphénylphosphine (P) dans des solutions dans l'éthanol et le benzène. On a déterminé les conditions permettant d'isoler les complexes Co(I), $Co(BH_4)P_n$ (n = 2, 3) et on discute des structures de ces espèces à la lumière de diverses mesures physiques.

Introduction

This paper is an extension of work we have already published dealing with the reactions of $NaBH_4$ with first row transition metal salts in the presence of tertiary phosphines (1). We present here results of an extensive study of reactions of the Co(II)/P/$NaBH_4$ (P = triphenylphosphine) system in a variety of solvents in an attempt to understand more fully the mechanism of the reduction which has previously been presented in outline form and which is known to lead to a variety of Co(I), (II), and (III) complexes (1, 2).

Results and Discussion

Tetrahydroboratobis(triphenylphosphine)cobalt(I), $Co(BH_4)P_2$

There are a number of reactions which lead to the formation of this highly crystalline air sensitive green Co(I) complex. For example, it is formed from the reaction between $NaBH_4$, Co(II) chloride, and P (~8:1:6) in toluene/ethanol (2:1) or benzene ethanol (2:1). It is interesting to note that when tricyclohexylphosphine (PCy_3) is used instead of P in analogous reactions, only the Co(II) complex $HCo(BH_4)(PCy_3)_2$ is formed (3). This is reasonable since P is a better π-acceptor than PCy_3 (4) and the bulky tertiary phosphines such as PCy_3, PPr_3^i and PBu_3^t etc. have been shown to stabilize BH_4 complexes of transition metals in higher oxidation states (5). The above green complex is also the product when a 10 M excess of $NaBH_4$ (suspension in ethanol) is added to a suspension of $CoClP_3$ in benzene. Also, the reaction between Co(II) perchlorate, P, and $NaBH_4$ (~1:6:10) in ethanol produces the same compound. (As will be seen later, Co(II) chloride behaves quite differently under these conditions, producing a mixture of Co(I) chloride and hydride complexes.) Finally, the complex was made during attempts to recrystallize $Co(BH_4)P_3$ (see later) from benzene or THF in the presence of free P.

Excellent chemical analyses (Co, C, H) for $Co(BH_4)P_2$, together with identical X-ray powder patterns and ir spectra, have been obtained for samples from each of the above preparations including those obtained from the crude crystalline reaction products and samples after either one or two recrystallizations from THF/ethanol solutions. Magnetic moment measurements, however, varied between a maximum value of 6.0 B.M. decreasing to an 'equilibrium value' of ~1.2 B.M. after two recrystallizations. It appears therefore that some decomposition of $Co(BH_4)P_2$ is occurring during crystallization from solution and it became necessary to wash the recrystallized samples with 10% aqueous HNO_3 to remove all traces of the ferromagnetic impurity (thought to be Co metal or boride since these products, which are readily soluble in dilute HNO_3, are readily formed in Co(II)/$NaBH_4$ reactions (2)) leaving the pure diamagnetic $Co(BH_4)P_2$. Chemical analyses, ir spectra, and X-ray powder patterns on samples before and after HNO_3 washings are identical and show that, surprisingly, no decomposition of the BH_4 complex occurs during such washings. The only observable change is that a faint pink coloration appears in the initial wash liquid as the trace amounts of boride are removed. Decomposition of a BH_4–phosphine complex to the metal boride has not been observed before, although it occurs readily in some amine complexes (6). In air, $Co(BH_4)P_2$ is oxidized to a mixture of the phosphine oxide and the borane adduct P–BH_3. The latter is also formed when the complex is dissolved in CH_3CN or CH_3NO_2.

The reflectance spectrum of $Co(BH_4)P_2$ shows a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

band at 14 700 cm^{-1} and an intense charge-transfer maximum at 24 390 cm^{-1}. In THF solution the lower energy band appears at 15 400 cm^{-1} ($\varepsilon \sim 380$) and both the position and intensity of this band are consistent with that found for diamagnetic square planar d^8 systems (especially Ni(II)) and would suggest that the BH_4 group is acting as a bidentate ligand. The ir spectrum shows B—H_t stretches at 2450(s) and 2390(w,sh) cm^{-1} and what could be the symmetric and antisymmetric bridging stretches at 2040 and 1970 cm^{-1}. There appears to be an additional weak band at 1830 cm^{-1}. This part of the spectrum is very similar to that of $Cu(BH_4)P_2$ which is known to contain the bidentate BH_4 group (7). The other expected bands for this type of coordination (8) are the ν_{B-H_b} at 1300–1500 cm^{-1} and the δ_{B-H} at ~1100–1200 cm^{-1} which are not seen and could be hidden under Nujol or ligand bands (the complex decomposes to $CoCl_2P_2$ in hexachlorobutadiene and in other chlorinated hydrocarbon solvents such as $CHCl_3$, CH_2Cl_2, and CCl_4). The ir spectrum of $Co(BD_4)P_2$ shows the terminal ν_{B-D_t} stretching frequency at 1830 cm^{-1} ($\nu_D/\nu_H = 0.747$, consistent with that observed in $DCo(BD_4)(PCy_3)_2$ (3)) although other B—D vibrational modes could not be found. However, the ir data could also be accounted for if the BH_4 group is acting as a tridentate ligand with expected and observed bands at (8) 2600–2450 cm^{-1} (ν_{B-H_t}, singlet), 2200–2100 cm^{-1} (ν_{B-H_b}, doublet), and 1250–1150 cm^{-1}. It is impossible to distinguish between these without X-ray data. (See later discussion.) As expected, the powder pattern of $Co(BH_4)P_2$ is quite different from that of the tetrahedral $Cu(BH_4)P_2$ (7).

Tetrahydroboratotris(triphenylphosphine)cobalt(I), $Co(BH_4)P_3$

In our previous study (1) we reported the preparation of this complex by the reaction of an excess of $NaBH_4$ on $CoXP_3$ (X = Cl, Br, I, prepared *in situ*) in ethanol for 3 h. Further investigation has revealed that this method is unreliable and, in general, leads to complex mixtures. Thus, the products from the Co(II) chloride/P/$NaBH_4$ (1:3:5 to 1:10:20) reactions in ethanol depend mostly on the *rate* of addition of the $NaBH_4$ suspension and less so on the reaction time and the molar ratios of the reactants. If all the $NaBH_4$ suspension is added to the Co(II)/P mixture within ~3 min, a mixture of H_3CoP_3 (9), $HCo(N_2)P_3$ (9), and P–BH_3 is obtained, even though the reaction time may vary from 30 min to 18 h. The formation of these products may be rationalized as follows.

The low solubility of P in ethanol at room temperature (compared with that of Co(II) chloride) means that if the $NaBH_4$ is added too quickly, not enough P is in solution to protect the Co(II) from rapid reduction to the boride. The latter would catalyse the decomposition of $NaBH_4$ to release H_2 (2) thus accounting for the formation of the Co-hydride complexes. The P–BH_3 complex is formed by oxidation of the Co(I)–BH_4–P complexes which are undoubtedly present in the mixture. (In recording X-ray patterns of $Co(BH_4)P_3$, lines of P–BH_3 appear if the capillary is improperly sealed or if the tip is broken during its mounting in the camera.)

If the $NaBH_4$ suspension is added to the Co(II)–P mixture more slowly, e.g., over a period of 30 min, or if 1 mol (per mole of Co(II)) of $NaBH_4$ is first added followed by a large excess, then the major product is the yellow-brown impure $CoClP_3$, While this can be recrystallized from benzene in the presence of P to yield the pure green $CoClP_3$, it appears that the crude material does not undergo further reaction with $NaBH_4$ in ethanol even if the mixture is stirred for up to 3 days.

We have reproducibly prepared the pure green air-sensitive $Co(BH_4)P_3$ in two ways. The complex is formed when $CoClP_3$ and P (1:3) are stirred with an ethanolic suspension of $NaBH_4$ (Co:$NaBH_4$, 1:10) in ethanol for a minimum of 4 days. The greater the excess of P the more easily the conversion takes place. Alternatively $Co(BH_4)P_2$ can be converted to $Co(BH_4)P_3$ by a curious reaction in which a small amount of cobalt boride is added to a mixture of $Co(BH_4)P_2$ and P in ethanol, when conversion occurs over a 4 day period. Similarly, crude samples of $Co(BH_4)P_2$, particularly those prepared from $CoClP_3$ (which contain significant amounts of what is presumably cobalt boride as discussed earlier), when stirred with a 3–6 *M* excess of P in ethanol for 4 days are converted into $Co(BH_4)P_3$ which must then be washed with water, 10% HNO_3, water, ethanol, and ether. The addition of $NaBH_4$ to the reaction mixture speeds up the reaction and $Co(BH_4)P_3$ is produced in 1 day. Pure $Co(BH_4)P_2$ or recrystallized samples prior to HNO_3 washings and which contain only small quantities of boride will not react further with P. All attempts to recrystallize $Co(BH_4)P_3$ from benzene or THF, even in the presence of an excess of P, result in its rapid conversion to $Co(BH_4)P_2$ and not to the N_2 adduct previously reported (1).

The complex is paramagnetic (μ_{eff} = 3.40 B.M.) and is isomorphous with the tetrahedral $CoClP_3$. Its electronic reflectance spectrum is also similar to that of $CoClP_3$ (10) with bands at 6250 ($^3T_1 \rightarrow {}^3T_2$), 7407 ($^3T_1 \rightarrow {}^3A_2$), and 16 390 cm^{-1} ($^3T_1 \rightarrow {}^3T_1$(P)). The complex is closely related to the paramagnetic $Co(p_3)(BH_4)$ (p_3 is the tridentate tripod ligand 1,1,1-tris(diphenylphosphinomethyl)ethane) which is also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

isomorphous with and has similar electronic properties to the corresponding tetrahedral $Co(p_3)Cl$ (11). In $Co(p_3)(BH_4)$, the BH_4 group is a bidentate ligand as shown by X-ray crystallographic studies. The ir spectrum (Fig. 1) of $Co(BH_4)P_3$ shows bands at 2415(s), 2320(s), 2075(sh,m), 2045(m), and 1104 cm^{-1} consistent both with monodentate (8, 12) or bidentate (8) BH_4 coordination. It seems that as more BH_4 complexes are synthesized, the less useful does ir spectroscopy become in distinguishing between the possible coordination modes.

Sacconi and co-workers (11) have described the $M–BH_4$ link in such species in terms of a spherical BH_4 anion with a largely ionic bond to the metal instead of the conventional covalent $M—BH_4$ description. The fact that $Co(BH_4)P_n$ do not react with ($n = 2$) or are decomposed by ($n = 3$) an excess of $NaPF_6$ or $NaBPh_4$ (unlike $NiL_2(BH_4)$, L = 1,10-phenanthroline (13), and $Ni(BH_4)P_3$ (14) where the BH_4 groups are exchanged for PF_6^- and BPh_4^- anions) implies a $Co—BH_4$ bond which is more covalent than ionic. Clearly the bonding between metal ions and BH_4 needs further attention.

The ir spectrum previously reported (1) for $Co(BH_4)P_3$ (1060, 1105, 2340(sh), 2390(s)) is almost certainly that of an oxidized sample as these bands are very close to those of $P–BH_3$ (1060, 1105, 2340(sh), 2388(s)).

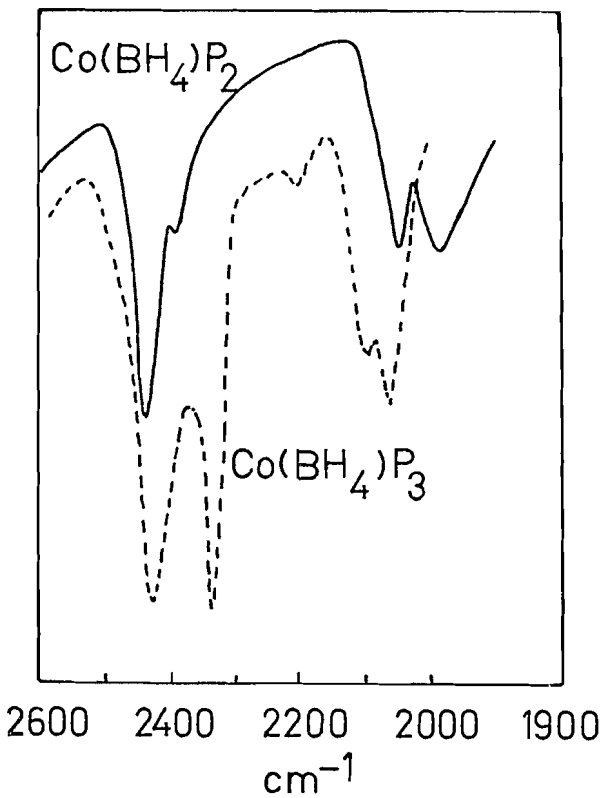

FIG. 1. Infrared spectra of $Co(BH_4)P_2$ and $Co(BH_4)P_3$ in the 1900–2600 cm^{-1} region.

$Co(BH_4)P_3$ cannot be converted to $Co(BH_4)P_2$ in ethanol probably due to the low solubility of the former in this solvent. Like $Co(BH_4)P_2$, $Co(BH_4)P_3$ decomposes to $CoCl_2P_2$ in chlorinated hydrocarbon solvents and to $P–BH_3$ in CH_3CN and CH_3NO_2.

When $Co(BH_4)P_n$ ($n = 2, 3$) is heated under reflux with P in ethanol for several hours, decomposition occurs to give a dark green paramagnetic hydride ($\nu_{Co–H}$ 1920 cm^{-1}). Although this is soluble in both polar and nonpolar solvents (including *n*-hexane and petroleum ether) repeated recrystallizations failed to yield a pure identifiable product.

Mechanism

While only two solvents have been studied in these reductions it is apparent that the solvent does play an important role in determining the nature of the product(s). For example, the reaction of $CoClP_3$ with $NaBH_4$ in ethanol in the presence of P slowly gives $Co(BH_4)P_3$ in 4 days but in a benzene/ethanol mixture, the reaction proceeds much faster and in less than 30 min produces $Co(BH_4)P_2$. If $CoClP_3$ dissociates in benzene, as has been shown to occur extensively with $NiClP_3$ (15), then the following reaction sequence may take place.

$$CoClP_3 \rightleftharpoons [CoClP_2] \rightleftharpoons \underset{\text{(monodentate)}}{[Co(BH_4)P_2]} \begin{matrix} \rightleftharpoons Co(BH_4)P_2 \\ \rightleftharpoons Co(BH_4)P_3 \end{matrix}$$

In this case, no $Co(BH_4)P_3$ is obtained since, as shown earlier, it is rapidly converted to $Co(BH_4)P_2$ in benzene. In pure ethanol, however, $CoClP_3$ is much less soluble, dissociation is repressed, especially in the presence of free P, and therefore $Co(BH_4)P_3$ is probably formed by a direct substitution reaction. On the other hand, the Co(II) perchlorate/P/$NaBH_4$ reaction in ethanol results *only* in the formation of $Co(BH_4)P_2$ probably via an intermediate such as $[CoP_x]^+$.

In summary, this work has established the conditions, in Co(II)—P—$NaBH_4$ reactions, for the isolation of two of the many possible products, the formation of which depends essentially on three factors: (*i*) the rate of addition of $NaBH_4$, (*ii*) the presence of free ligand, and (*iii*) the solvent. The overall reaction sequence remains as outlined previously (2).

Experimental

Materials

All chemicals were reagent grade and were used without purification. Solvents were purified in the usual way, degassed, and stored over molecular sieves (4A).

Physical Measurements

Physical measurements were carried out as previously described (1). Samples were suitably protected from atmospheric oxidation.

Syntheses

All syntheses were carried out under pure N_2 in a glove box, and complexes were produced in high yields (~70–80%).

1. $CoClP_3$

This compound was synthesized by a slight modification to Sacco's method (10). A suspension of $NaBH_4$ (0.14 g, 3.7 m*M*) in ethanol (~8 ml) was added dropwise over a period of ~½ h to a stirred mixture of $CoCl_2 \cdot 6H_2O$ (0.79 g, 3.34 m*M*) and P (3.79 g, 14.4 m*M*) in ethanol (50 ml) at room temperature.

The yellow mixture was stirred for 2 h before the crude product was filtered off, washed with ethanol, water, ethanol, and ether before drying under reduced pressure.

The crude product was dissolved in benzene (~150 ml) containing P (~2 g), stoppered, and allowed to stand for ~½ h. The brownish-green solution was filtered and the residual green solid was extracted into more benzene and filtered again. The filtrates were combined and the volume was reduced by ~⅓ under reduced pressure to yield green crystals of $CoClP_3$.

d-*Spacings* (relative intensities 0–10)—9.60(5), 8.89(10), 5.40(2), 4.94(2), 4.35(2), 3.85(5), 3.57(5), 3.41(3), 2.86(1).

2. $Co(BH_4)P_2$

(a) From Co(II) chloride – P in benzene/ethanol and $NaBH_4$/ethanol—A suspension of $NaBH_4$ (~0.2 g, 5.2 m*M*) in ethanol (~10 ml) was added dropwise to the stirred suspension of $CoCl_2 \cdot 6H_2O$ (0.15 g, 0.63 m*M*) and P (~1 g, 3.8 m*M*) in benzene, toluene, benzene/ethanol (2:1), or toluene/ethanol (2:1) (~10 ml). A gas (presumably H_2) was generated during the initial stages of the $NaBH_4$ addition and the blue suspension changed immediately to green and then brownish-green (within 10 min). After the addition of all the $NaBH_4$ suspension, dark green crystals were produced which were filtered off, washed with ethanol, water, ethanol, and ether, and dried under reduced pressure.

The product was recrystallized from THF, dark green crystals appearing on addition of ethanol. After washing with ethanol, ether, and drying, the product was finally washed with 10% HNO_3 (3 × 10 ml), water (6 × 10 ml), ethanol, and ether. *Anal.* calcd. for $Co(BH_4)P_2$: C 72.3, H 5.7, Co 9.8; found: C 71.7, H 6.0, Co 9.7.

d-*Spacings* (relative intensities)—13.52(8), 9.62(1), 8.70(10), 7.85(2), 6.30(1), 5.77(1), 4.95(1), 4.71(5), 4.37(7), 3.86(3), 3.35(1).

(b) From $CoClP_3$ in benzene and $NaBH_4$ in ethanol—A suspension of $NaBH_4$ (0.2 g, 5.2 m*M*) in ethanol (~10 ml) was added dropwise into a stirred solution of $CoClP_3$ (~0.4 g, 0.45 m*M*) in benzene (~15 ml). The green solution became brownish-green and quickly precipitated dark green crystals which were isolated and purified as described above.

(c) From Co(II) perchlorate/P in ethanol and $NaBH_4$ in ethanol—A suspension of $NaBH_4$ (~0.2 g, 5.2 m*M*) in ethanol (~10 ml) was added dropwise to a suspension of Co(II) perchlorate (~0.15 g, 0.4 m*M*) and P (0.7 g, 2.7 m*M*) in ethanol (15 ml). A gas (presumably H_2) was generated in the initial stages of the addition of the $NaBH_4$ suspension and the color of the solution turned from pink to greenish-yellow. The mixture was stirred for 3 h after which the yellow-green product was filtered off and purified as described above.

(d) From $Co(BH_4)P_3$ in benzene—Co $(BH_4)P_3$ (~0.3 g) was dissolved in benzene (~30 ml) either in the absence of P or with additional P (Co:P up to 1:10). The solution was then filtered and concentrated under vacuum at room temperature until the total volume was reduced to ~15 ml. The dark green product was precipitated by the addition of ether (~20 ml), filtered off, and purified as described above.

3. $Co(BH_4)P_3$

(a) From $CoClP_3$/P/$NaBH_4$ in ethanol—Solid $NaBH_4$ (~0.2 g, 5.2 m*M*) was added in small amounts to a stirred suspension of finally powdered $CoClP_3$ (~0.4 g, 0.45 m*M*) and P (~0.4 g, 1.5 m*M*) in ethanol (~20 ml). After the addition of all the $NaBH_4$, the mixture was stirred for 4 days. The resulting light green precipitate was filtered off, washed with ethanol, water, ethanol, and *n*-hexane, and finally dried under high vacuum for 3 h. *Anal.* calcd. for $Co(BH_4)P_3$: C 75.4, H 5.7, Co 6.8; found: C 74.9, H 5.8, Co 6.8.

d-*Spacings* (relative intensities)—9.67(5), 8.99(10), 5.41(2), 4.91(2), 4.36(2), 3.85(5), 3.58(5), 3.42(2), 2.86(1).

(b) From impure $Co(BH_4)P_2$—Finely powdered $Co(BH_4)P_2$ (~0.3 g, 0.5 m*M*) (prepared as in 2(*b*), but *not* purified) and P (~0.3 g, 1.1 m*M*) were stirred in ethanol (~20 ml) for 4 days during which the color slowly changed from dark to light green. The product was separated, washed, and dried as in 3(*a*) and finally washed with 10% HNO_3 (3 × 10 ml), water (6 × 10 ml), ethanol, and *n*-hexane.

(c) From $Co(BH_4)P_2$ with added boride—Pure $Co(BH_4)P_2$ was treated with P as described in 3(*b*) except that a small amount of cobalt boride (~10 mg) was added. (The latter was prepared by adding ethanol to a Catgen pellet, supplied by Ventron Corporation and consisting of a mixture of $CoCl_2$/$NaBH_4$ in a 1:4 molar ratio. When the effervescence subsided, the dark colored solid was separated, washed with ethanol, water, ethanol, and ether, and dried under vacuum.) The product was isolated and washed as in 3(*b*).

Sphere tensiometry: wall effects and correction factors

E. BAYRAMLI, C. HUH, AND S. G. MASON

Pulp and Paper Research Institute of Canada, McGill University, Department of Chemistry, Montreal, P.Q., Canada H3A 2A7

Received June 20, 1977

E. BAYRAMLI, C. HUH, and S. G. MASON. Can. J. Chem. **56**, 818 (1978).

This paper is a supplement to an earlier one on the new absolute gravimetric method of measuring surface and interfacial tension which takes into account the effect of the wall in circular containers of finite radius which causes the liquid surface to dimple instead of remaining flat as in an unbounded system as assumed earlier.

Using conventional capillarity theory, the basic principles for correcting force–displacement curves, called sphere-tensiograms, are derived. Numerical correction factors calculated from the theory for systems with perfect wetting (zero contact angle) for an experimentally realistic range of parameters, and corroborative experimental data are presented.

E. BAYRAMLI, C. HUH et S. G. MASON. Can. J. Chem. **56**, 818 (1978).

Ce travail s'ajoute à une publication antérieure sur une nouvelle méthode gravimétrique absolue de mesurer les tensions superficielles et interfaciales qui tient compte du fait que la paroi de contenant circulaire de rayons finis provoquent une ondulation de la surface alors que l'on avait fait l'hypothèse antérieurement que cette surface devait demeurer plane dans des systèmes non-entourés.

Faisant appel à la théorie de capilarité conventionnelle, on peut dériver les principes de base permettant de corriger les courbes force-déplacement que l'on appelle tensiogrammes de sphère. On présente des facteurs de corrections numériques calculés à partir de la théorie pour des systèmes avec des mouillages parfaits (angle de contact zéro) pour une variation réaliste au point de vue expérimental des paramètres et on présente des données expérimentales permettant de corroborer la théorie.

[Traduit par le journal]

Introduction

Sphere tensiometry has recently been proposed (1, 2) as an alternative to the (du Nouy) ring and (Wilhelmy) plate gravimetric methods for measuring fluid interfacial (or surface) tensions. It has a number of potential advantages over other absolute methods, especially when the interface is not visible. In making full use of the method, the vertical force – displacement curve of the sphere (which we term the sphere-tensiogram) as it penetrates the interface is determined from which various quantities in addition to the interfacial tension can be calculated (2).

The numerical calculations used to analyze the tensiograms were made for infinite interfaces. This is a restriction which can introduce errors from wall effects of the vessels containing the liquid(s) (2). In this paper we consider these effects in circular cylindrical containers as a function of B/R where B and R are the respective radii of the vertical container and the axially located sphere, as an extension of similar calculations of an infinite horizontal cylinder located midway between two vertical parallel plates (3).

As illustrated in Fig. 1, a container of finite radius introduces an error in the earlier calculations of the interfacial tension γ_{23}, since one of the boundary conditions for solving the Young–Laplace equation was that the slope of the interface at a horizontal radial distance r from the center of the sphere becomes zero at $r = \infty$; instead, the interface now assumes some slope angle $\phi_B \neq 0$ at $r = B$. Also, if the experiment is performed with a constant volume of liquid, as the sphere is pulled vertically along the

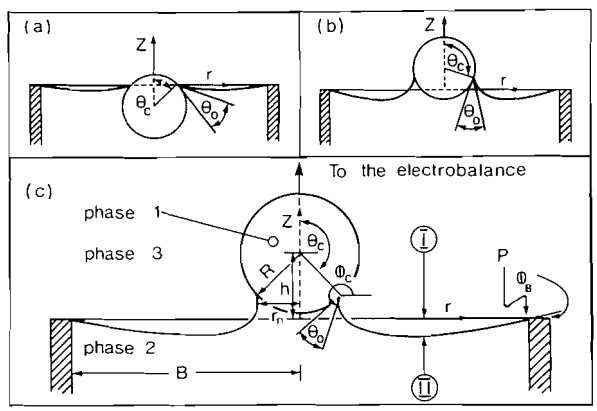

FIG. 1. Sketches showing the three different positions of the sphere used in deriving [4*d*]. In (*a*) $\theta_c < \pi/2$; in (*b*) $\pi/2 \leq \theta_c < \pi$ and $(\theta_c - \pi/2) \leq \theta_0$; and in (*c*) $\pi/2 \leq \theta_c < \pi$ and $(\theta_c - \pi/2) > \theta_0$ the latter being the geometric condition for forming a meniscus neck of $\bar{r} = \bar{r}_n$. In this treatment the 23 interface is made initially flat (interface I) with the sphere (phase 1) completely submerged in phase 2. The sphere is pulled vertically along the axis of the cylindrical container whose upper rim is polished flat so that the 23 interface sticks to the sharp inner edge P(4); on raising the sphere to h the interface assumes shape II.

axis of the cylindrical container, the interface will dimple from shape I into shape II in Fig. 1. The tensiogram obtained will thus differ from that for $B/R = \infty$.

In this paper we outline the method of solving theoretically for the case where the equilibrium contact angle at the sphere surface has all possible values, i.e., $0 \leq \theta_0 < \pi$ and give numerical[1] and experimental results for the particular case $\theta_0 = 0$. We calculate numerically for a range of the nondimensional[2] radius $\bar{R}$ between 0.8 and 1.6, the maximum nondimensional force D, and the maximum nondimensional height $\bar{h}$ (2) as functions of $\bar{R}$ and $\bar{B}$, where

$$[1] \qquad D = 3F/4\pi(\rho_2 - \rho_3)gR^3$$

g being gravity and ρ_2, ρ_3 the densities of phases 2 and 3, respectively (Fig. 1); F is the equilibrium vertical force on a thin thread attached to the sphere, arbitrarily taken (without loss of generality (2)) as zero when the sphere is entirely immersed in phase 2; h is the height of the sphere centre above the initial level of the fluid/fluid interface which for both theoretical and experimental convenience is initially flat and is made to adhere to the sharp edge P of the container (Fig. 1) by utilizing the sharp edge effect which permits the meniscus to rotate about P (4).

Quantitative experiments were performed for $B/R = \bar{B}/\bar{R}$ between 2.5 to 5.0 and $\bar{R}$ between 0.8 to 1.6. On raising the sphere center to h the interface assumed shape II as shown in Fig. 1. The measured D_{mB} gave generally good agreement with the theory, and under certain circumstances yielded values of γ_{23} which were significantly different from uncorrected values based on $B/R = \infty$. As an independent measurement of γ_{23} the standard pendant drop method was used which yielded values very similar to those from sphere tensiometry.

Theoretical Part

(a) General

When the liquid interface is confined in a vertical cylindrical container of finite B, and the sphere moves along its axis, the equilibrium relation between F and H will depend on B and the condition of the interface at the container wall. In this analysis we restrict consideration to the case where the interface is initially flat and remains fixed at the sharp-edged rim of the container as h is increased. As established experimentally by Oliver *et al.* (4), the Gibbs inequality condition holds on such an edge so that it is safe to assume that ϕ_B, the slope angle of the meniscus at $r = B$ can pivot freely between $0 \leq \theta_B \leq \pi/2$.

The interface shape is governed by the classical Young–Laplace equation,

$$[2] \qquad \frac{1}{\bar{r}}\frac{d}{d\bar{r}}(r \sin\phi) = \bar{z} + \bar{z}'$$

The initially flat level of the interface corresponds to a vertical coordinate $\bar{z} = 0$, and $\bar{z}' = 0$ if $B = \infty$; but for finite $\bar{B}$, $\bar{z}' > 0$. In the following force equation $\bar{z}'$ is an additional term to that for $B = \infty$ (2), due to the wall:

$$[3] \quad 2D = 1 - \cos^3\theta_c + \frac{3}{\bar{R}^2}\sin\theta_c \sin\phi_c + \frac{3}{2\bar{R}}\sin^2\theta_c(\bar{h} + \bar{z}')$$

where θ_c, ϕ_c are angles defined with reference to the contact line in Fig. 1. Because the liquid interface will dimple downwards to fill in the volume displaced by the sphere, the following conservation of volume requirement must be met for the three possible states of immersion when $\theta_0 \leq \pi/2$ illustrated in Fig. 1.

1. $0 < \theta_c < \pi/2$ (Fig. 4*a*):

$$[4a] \quad 2\pi\int_0^{\bar{r}_c}[\bar{h} + \sqrt{\bar{R}^2 - \bar{r}^2}]\bar{r}\,d\bar{r} + 2\pi\int_{\bar{r}_c}^{\bar{B}}\bar{z}\bar{r}\,d\bar{r} = 0$$

2. $\pi > \theta_c \geq \pi/2$; $\theta_c - \pi/2 \leq \theta_0$ (Fig. 4*b*):

$$[4b] \quad 2\pi\int_0^{\bar{R}}(\bar{h} + \sqrt{\bar{R}^2 - \bar{r}^2})\bar{r}\,d\bar{r} + 2\pi\int_{\bar{R}}^{\bar{r}_c}(\bar{h} - \sqrt{\bar{R}^2 - \bar{r}^2})\bar{r}\,d\bar{r} + 2\pi\int_{\bar{r}_c}^{\bar{B}}\bar{z}\bar{r}\,d\bar{r} = 0$$

3. $\pi > \theta_c \geq \pi/2$; $\theta_c - \pi/2 > \theta_0$ (Fig. 4*c*):

$$[4c] \quad 2\pi\int_0^{\bar{R}}(\bar{h} + \sqrt{\bar{R}^2 - \bar{r}^2})\bar{r}\,d\bar{r} + 2\pi\int_{\bar{R}}^{\bar{r}_c}(\bar{h} - \sqrt{\bar{R}^2 - \bar{r}^2})\bar{r}\,d\bar{r} + 2\pi\int_{\bar{r}_n}^{\bar{B}}\bar{z}\bar{r}\,d\bar{r} + 2\pi\int_{\bar{r}_c}^{\bar{r}_n}\bar{z}\bar{r}\,d\bar{r} = 0$$

where $\bar{r}_c$ is the contact line radius, $\bar{r}_n$ is the radius of the meniscus neck which forms when $(\theta_c - \pi/2) >$

[1]Photocopies of these tabulations are available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2. They are also deposited at PPRIC Library, Pointe Claire, Montreal, Quebec.

[2]Nondimensional linear dimensions, e.g., $\bar{R}$, $\bar{B}$, $\bar{h}$ are given by multiplying the corresponding scalar quantities by $\sqrt{C_{23}} = [(\rho_2 - \rho_3)g/\gamma_{23}]^{1/2}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

θ_0, and $\bar{z}$ represents the meniscus profile defined by [2]. Inserting [2] into [4*a*, *b*, *c*] we obtain on reduction the identical result for all three cases:

$$[4d] \quad \frac{\bar{R}^2}{2}\sin^2\theta_c(\bar{h}+\bar{z}') + \frac{\bar{R}^3}{3}(1-\cos^3\theta_c) + \bar{B}\sin\phi_B - \frac{\bar{z}'}{2}\bar{B}^2 - \bar{R}\sin\phi_c\sin\theta_c = 0$$

It is readily shown that [4*d*] also applies to $\pi/2 \leq \theta_0 < \pi$ when F can become negative, i.e., the sphere must be pushed downwards through the interface (5).

The values of $\bar{r}_c$, $\bar{z}_c$, and ϕ_c ($\equiv 2\pi - \theta_c + \theta_0$) for the meniscus shape at the contact line should now obey [4*d*] in addition to condition [3] and the following geometric relations:

$$[5a] \quad \bar{r}_c = \bar{R}\sin\theta_c$$

$$[5b] \quad \bar{z}_c = \bar{h} + \bar{R}\cos\theta_c$$

(b) Numerical Calculations

To obtain the values of $\bar{r}_c$, $\bar{z}_c$, and θ_c, we transform [2] into its parametric forms

$$[6a] \quad \frac{d\bar{r}}{d\phi} = \frac{\cos\phi}{\bar{y} - \frac{\sin\phi}{\bar{r}}}$$

$$[6b] \quad \frac{d\bar{y}}{d\phi} = \frac{\sin\phi}{\bar{y} - \frac{\sin\phi}{\bar{r}}}$$

where $\bar{y} \equiv \bar{z} + \bar{z}'$. We then integrate [6] numerically, employing the Runge–Kutta method. The initial conditions employed are

$$[7a] \quad \phi = \phi_c$$

$$[7b] \quad \bar{r} = \bar{R}\sin\theta_c$$

$$[7c] \quad \bar{y} = (\bar{h} + \bar{z}') + \bar{R}\cos\theta_c$$

where $(\bar{h} + \bar{z}')$ is the adjustable parameter which we vary for given $\bar{R}$ and θ_c. The earlier calculations (2) give a unique $\bar{h}$ for various values of $\bar{R}$ and θ_c when $\bar{B} = \infty$, $\bar{z}' = 0$. For finite $\bar{B}$, $(\bar{h} + \bar{z}')$ is larger than that for $\bar{B} = \infty$, and for $\theta_0 = 0°$, we employ 30 values of $(\bar{h} + \bar{z}')$ which are increased from the value at $\bar{B} = \infty$ in increments of 0.0001. Equations 6*a*, *b* are then integrated numerically at increasing ϕ until at a certain set of $(\phi, \bar{r}, \bar{y})$, [4*d*] is satisfied and thus the set assumes the values of $\phi = \phi_B$, $\bar{r} = \bar{B}$, and $\bar{y} = \bar{z}'$. D and $\bar{h}$ can subsequently be calculated from [3] and [5*b*]. The values of $\bar{B}$ obtained generally fall between 1.5 and 10.0 from which we interpolate D and $\bar{h}$ at regularly spaced intervals of $\bar{B}$. Between $\bar{B} = 2.5$ and 5.0, $\bar{R}$ is varied from 0.8 to 1.6 at intervals of 0.2; θ_c from 10° to 90° and from 90° to 160° at intervals of 10° and 2° respectively.

Figure 2 shows the D–$\bar{h}$ curves obtained by numerical calculation for different $\bar{B}$'s for $\bar{R} = 1.0$ and $\theta_0 = 0°$ the only contact angle which is reproducible and thermodynamically significant. From such D–$\bar{h}$ curves we obtained D_{mB} and $\bar{h}_{mB}$ as functions of $\bar{R}$ and $\bar{B}/\bar{R}$ by the Aitken–Lagrange interpolation scheme. Figure 3 shows $(D_{mB} - D_{m\infty})/D_{m\infty}$ as a function of $\bar{R}$ and $\bar{B}/\bar{R}$ where D_{mB} and $D_{m\infty}$ are D maxima at finite $\bar{B}$ and infinite $\bar{B}$, respectively. We see that D_{mB} exceeds $D_{m\infty}$ by more than 1.0% when $\bar{B}/\bar{R} < 5.0$ and $\bar{R} < 0.8$. The wall effect is not as significant for $\bar{R} > 0.8$ in the range of $\bar{B}/\bar{R}$ investigated. For example, when $\bar{R} = 1.6$ and $\bar{B}/\bar{R} = 4.3$, D_{mB} is larger than $D_{m\infty}$ by only 0.1%. To illustrate the wall effect by a practical example, e.g., water/air interface at 25°C, when $\bar{R} = 1.0$ ($R = 2.7$ mm) the minimum ratio, $\bar{B}/\bar{R}$ for an error of less than 1% when the numerical data for $\bar{B} = \infty$ are used is $\bar{B}/\bar{R} = 4.0$.

If the interfacial tension is to be calculated, the $\bar{R}$ value corresponding to the measured D_{mB} is found from the numerical tabulation by linear interpolation among the four closest values with respect to B/R and D_{mB}; since $\bar{R} = R\sqrt{C_{23}}$, where $C_{23} = (\rho_2 - \rho_3)g/\gamma_{23}$, the interfacial tension is given by

$$[8] \quad \gamma_{23} = (\rho_2 - \rho_3)g\left(\frac{R}{\bar{R}}\right)^2$$

Knowing $(\rho_2 - \rho_3)$, g, and R, as we do in the experiment described below, in determining γ_{23} it is un-

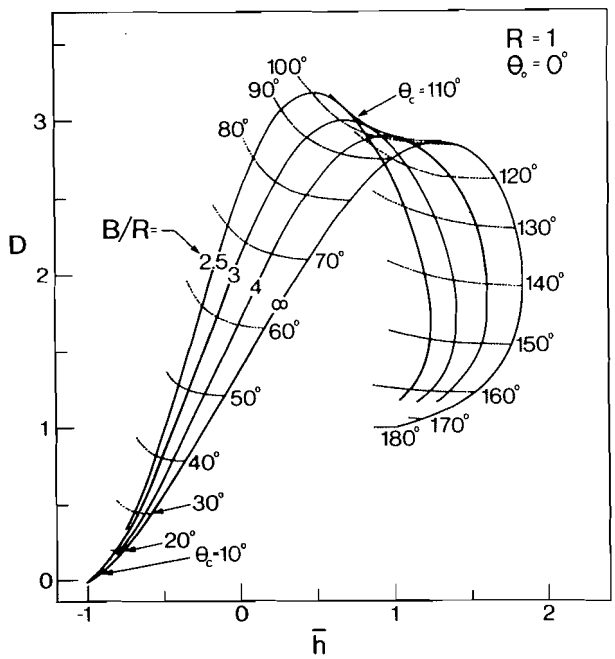

FIG. 2. Numerically calculated equilibrium D–$\bar{h}$ curves for $\bar{R} = 1.0$, $\theta_0 = 0°$ at different $\bar{B}/\bar{R}$. The broken lines indicate loci at fixed values of θ_c.

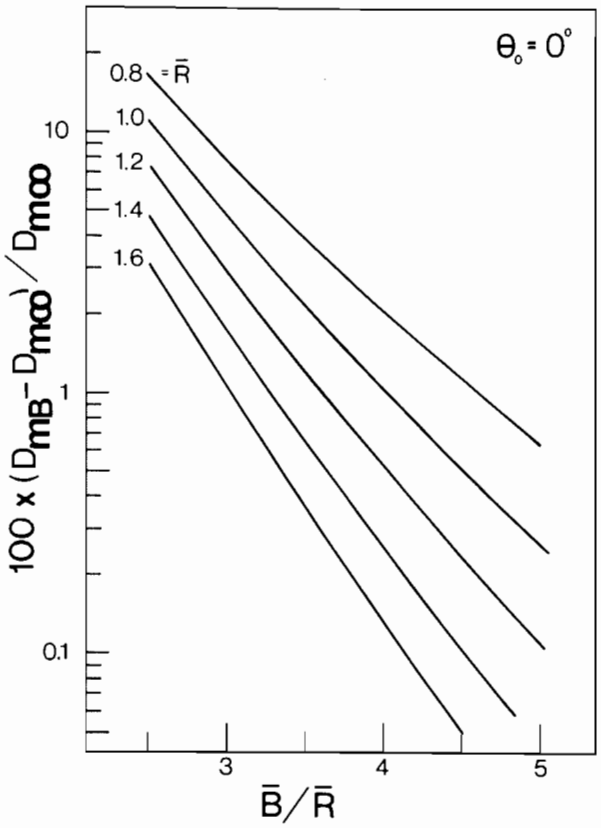

FIG. 3. Variation of maximum force, F_m expressed as $100 \times (D_{mB} - D_{m\infty})/D_{m\infty}$ with $\bar{B}/\bar{R}$ and $\bar{R}$ for $\theta_0 = 0°$.

necessary to use the whole tensiogram (2) but only the maximum force F_m or, less practicably, h_m.

Figure 4 shows $\bar{h}_{mB}/\bar{h}_{m\infty}$ as a function of $\bar{R}$ and $\bar{B}/\bar{R}$, where $\bar{h}_{mB}$ and $\bar{h}_{m\infty}$ at finite $\bar{B}$ and at $\bar{B} = \infty$, respectively. We see that the wall effect is much larger on $\bar{h}_{mB}$ than on D_{mB}; in the range of $\bar{R}$ studied, as much as 10.0% difference occurs in $\bar{h}_m$ when $\bar{B}/\bar{R} = 5$.

Figure 5 shows $\bar{h}_{DB}/\bar{h}_{D\infty}$ as functions of $\bar{B}/\bar{R}$ and $\bar{R}$, where $\bar{h}_{DB}$ and $\bar{h}_{D\infty}$ correspond to D_{mB} and $D_{m\infty}$ respectively. The influence of finite $\bar{B}$ is again quite significant. The large deviation is caused by dimpling of the horizontal interface due to the displacement of the sphere volume when it comes out of phase 2; the value of $\bar{h}$ measured from the base of the dimpled interface rather than the initial flat level, in fact is closer to the value of $\bar{h}_m$ at $\bar{B} = \infty$.

Experimental Part

(a) Methods

The experimental arrangement was basically the same as described earlier (2), with the following additional refinements:

1. The drive system for the platform on which the liquid container rested was hydraulically driven, employing a plunger-type micrometer attached to a variable speed motor and reduction gear with the motor speed controlled by a feedback mechanism to yield stage velocities from 0.1 to 1.0 mm/min, constant to ±0.2%.

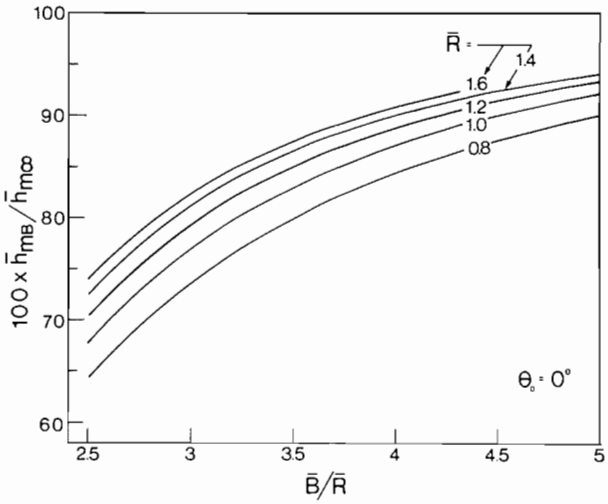

FIG. 4. Variation of maximum height h_m expressed as $100 \times h_{mB}/h_{m\infty}$ with $\bar{B}/\bar{R}$ and $\bar{R}$ for $\theta_0 = 0°$.

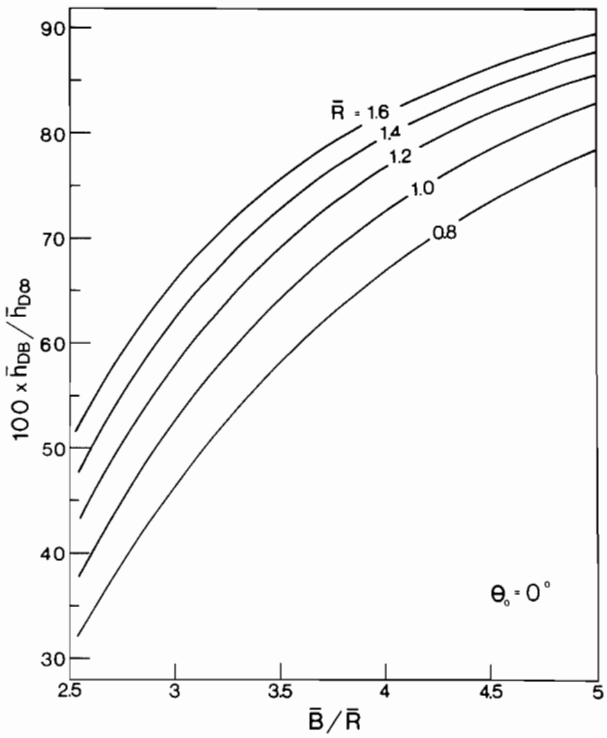

FIG. 5. Equilibrium relation between height h expressed as $100 \times \bar{h}_{DB}/\bar{h}_{D\infty}$ and $\bar{B}/\bar{R}$ at various $\bar{R}$ where $\bar{h}_{DB}$ and $\bar{h}_{D\infty}$ are the height at the maximum force state for container radii B and ∞ respectively.

2. Force–displacement (F vs. h) curves were recorded using a Hewlett-Packard X-Y Recorder (Model HP 7044A); a Hewlett-Packard displacement transducer (Model HP 7DDT-500) attached to the stage and calibrated using a dial type micrometer yielded height displacements accurate to better than 10 μm.

The cylindrical containers were made of Pyrex tubing with

sharply polished edges, with their bottoms cemented to flat microscope slides. They were cleaned ultrasonically in detergent solution and then washed with copious amounts of distilled water and oven dried before use.

(b) Materials

Dow Corning Silicone Oil (200 Fluid, 1cs) was used as the liquid without further purification; its density (0.815 g/cc at 25°C) was determined by a pycnometer. Precision-grade hard nylon spheres (Industrial Tetronics, Inc., Ann Arbor, MI) were used. They were thoroughly cleaned in acetone and hexane, oven heated at 80°C, and rinsed in distilled water 10 times. After evaporating the water by air-drying the spheres were stored in Silicone Oil overnight. The sphere radii R were measured to $\pm 10^{-4}$ cm by Nikon Shadograph; the deviation from sphericity $(R_{max} - R_{min})/R_m$, was always less than 0.1%.

(c) Procedures

The measurements were made at 25 ± 0.5°C. The container was filled by dropwise addition at the tube wall until the sphere was submerged and the liquid/air interface located at the sharp edge was flat. The sphere was connected to the Cahn recording electrobalance arm (2) by a 0.1 mm steel wire which passed through a small hole drilled through the center of the sphere. Since F is taken as zero when the sphere is just below the 23 interface, no buoyancy correction is needed for the hole or the steel thread; the latter may cause an uncertainty of about 0.05 cm in h but this can be eliminated by extrapolating the F–h curve to the base-line at the starting point of the tensiogram.

A tensiogram was obtained by pulling the sphere slowly (0.2 mm/min) from the liquid until the meniscus ruptured. In some experiments the motion of the stage was reversed to check for any contact angle hysteresis; in all such cases the tensiograms were reversible whether or not the meniscus was allowed to rupture, from which we conclude that the contact angle was always 0° (2), as can also be seen from the photograph in Fig. 6*d*. The surface tension of the Silicone Oil was measured independently by the pendant drop technique, using the Nikon Shadowgraph to analyze the photographs of the drop and the numerical tables of Roe *et al.* (6).

Results and Discussion

Figure 7 shows some typical D–$\bar{h}$ curves constructed from the tensiograms; Table 1 summarizes the experimental results and their comparison with numerical calculations. Experiment Nos. 1 and 3–8 fell within the range of the present tabulations on wall effect or the earlier tabulations for $\bar{B} = \infty$ (2). One can see from Fig. 7 (which is similar to Fig. 2) for experiments 5–7 that for a constant θ_c (see Fig. 2) the D(exp) increased and $\bar{h}$(exp) decreased as $\bar{B}/\bar{R}$ diminished. The arrows indicate D_{mB}(theory) and $\bar{h}_{mB}$(theory). Without the use of wall corrections, γ_{23} calculated would have been significantly larger than the true value.

For example, for experiment 9 (Table 1): the measured uncorrected value for γ_{23} was 12.8% greater than the mean corrected γ_{23}'s. The mean corrected interfacial tension values were 17.00 ± 0.10 dyn/cm; γ_{23} determined independently by the pendant drop method was 17.02 dyn/cm. These small differences can be a result of slight fluctuations in chamber temperature (25 ± 0.5°C), deviations from sphericity which is a critical parameter in the calculations, small

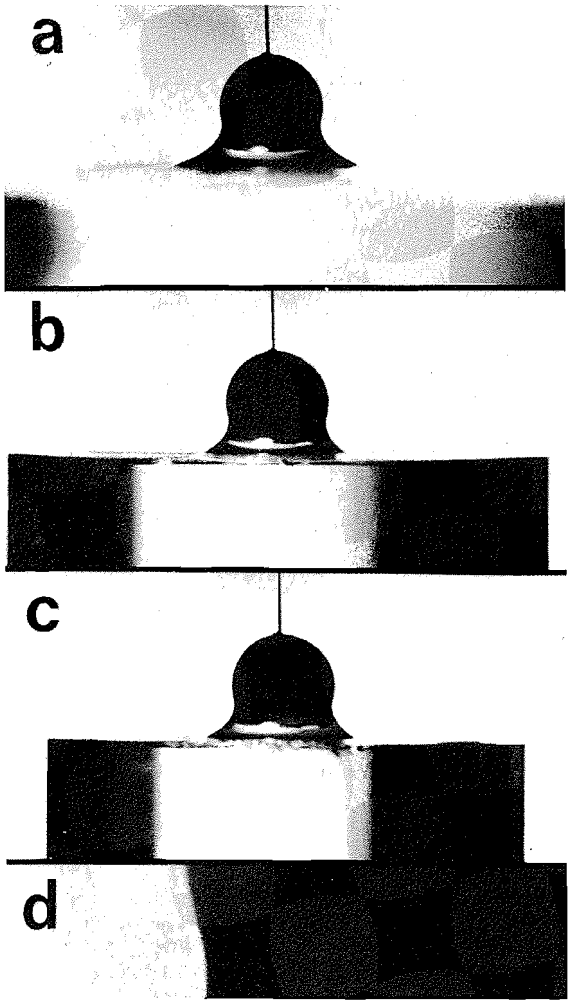

FIG. 6. Photograph of a nylon sphere ($R = 0.1600$ cm) at the Silicone Oil interface in the maximum force state, for values of $\bar{B}/\bar{R} = 29.61$, 4.53, and 3.92 in parts *a*, *b*, and *c*. Due to nonsymmetrical illumination it is not obvious from these photographs that the contact angle θ_0 was zero. At higher magnification (part *d*), however, no discontinuity can be seen at the contact line from which (plus the observation that *F–h* curves were reversible) it is concluded that $\theta_0 = 0$ for this system.

errors in density, and the fact the measurements were made at different times on different aliquots of liquid. Considering all these factors it can be said that excellent agreement exists between experiments and the theory.

The experimental force maximum, D_{mB}(exp), in Table 1 was calculated from experimental F vs. h curves and $\bar{R}$(exp) was found by linear interpolation among the 4 closest values of the B/R and D_{mB}(exp) in numerical tabulations. The theoretical maximum, D_{mB}(theory), was calculated using the average γ_{23} value which was found from runs 1, 5, and 8 all of which had large B/R values, hence it was assumed

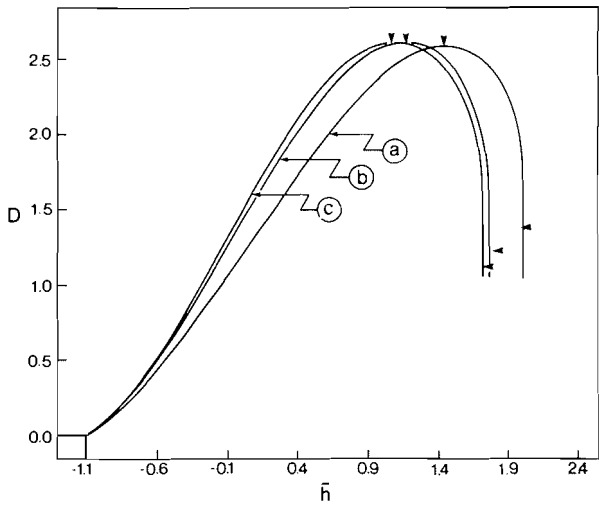

FIG. 7. Typical D–$\bar{h}$ curves (Experiments 5–7, Table 1) constructed from experimental F–h tensiograms for $R = 0.1600$ cm. The vertical arrows indicate D_m(theory) and horizontal arrows are $\bar{h}_m$(theory). The tensiograms *a*, *b*, *c* indicate the cases where container radius to sphere radius ratio, $\bar{B}/\bar{R}$, are equal to 29.61, 4.53, and 3.92 respectively. Note that they are similar in shape to the theoretical curves in Fig. 2 where lines of constant θ_c are also shown.

that they needed no correction due to wall effects. The corrected γ_{23}'s were calculated from [8] using the numerical tabulations which are corrected for wall effects while the uncorrected γ_{23} values were calculated assuming an unbounded interface and using the numerical tables with $\bar{B} = \infty$. The experimental maximum height $\bar{h}_{mB}$(exp) was found from the tensiogram by making use of $\bar{R}$(exp) and C_{23} values for each experiment; $\bar{h}_{mB}$(theory) is the maximum height corresponding to the particular D_{mB}(exp) in the tables.

We can conclude that if D_m alone is to be used to measure γ_{23} (when $\theta_0 = 0°$ is reasonably assured or θ_0 is known), the wall effect is not significant if $\bar{B}/\bar{R} > 5$, but one must recognize that as $\bar{R}$ decreases the wall effect increases for a constant $\bar{B}/\bar{R}$. If $\bar{h}_m$ or other parameters of the tensiogram (2) are to be used, care should be taken to assure a sufficiently large $\bar{B}/\bar{R}$, to avoid the wall effect; it should be noted however that the maximum force, F_m is much more easily measured than the maximum height h_m before rupture.

5-Methylorotate is relatively radiation resistant in aqueous fluid medium, but readily photodimerizes in an ice matrix. Rapid formation of such a matrix made possible the preparative isolation of the photodimer in good yield. The potassium salt of the photodimer crystallizes as the hexahydrate, $C_{12}H_{10}N_4O_8K_2 \cdot 6H_2O$. The crystals are triclinic with space group $P\bar{1}$, $a = 8.139(3)$, $b = 9.759(3)$, $c = 7.398(3)$ Å, $\alpha = 100.28(7)$, $\beta = 74.22(5)$, $\gamma = 108.67(7)°$, and $V = 533.0$ Å^3, $Z = 1$. The structure was solved by Patterson and direct methods; refinement by block-diagonal least-squares converged at $R = 0.041$ for all 1671 observed reflections. The pyrimidine rings of the centrosymmetric photodimer are arranged in *trans–anti* configuration across the planar cyclobutane ring. The potassium ion is seven-coordinated. In aqueous medium the photodimer exhibits a pK_a of 12.8 due to dissociation of the ring N(3) hydrogen. Irradiation in aqueous medium at 254 nm leads to quantitative regeneration of the monomer with a quantum yield of 0.8. Thermal regeneration of the monomer also occurs in neutral and acid aqueous media, but at a slower rate than for the *trans–syn* orotate photodimer. In contrast to the orotate photodimer, which undergoes alkali-catalyzed opening of the 3,4 bonds of the pyrimidine rings, the 5-methylorotate photodimer under these conditions dissociates to the parent monomer.

CAROL P. HUBER, GEORGE I. BIRNBAUM, MICHAEL L. POST, EWA KULIKOWSKA, LUCYNA GAJEWSKA et DAVID SHUGAR. Can. J. Chem. **56**, 824 (1978).

Dans l'eau liquide, le méthyl-5 orotate est assez résistant aux radiations; toutefois il subit facilement une photodimérisation dans une matrice de glace. La formation rapide d'une telle matrice permet d'isoler le photodimère avec de bons rendements à l'échelle préparative. Le sel du potassium du photodimère cristallise sous forme d'hexahydrate, $C_{12}H_{10}N_4O_8K_2 \cdot 6H_2O$. Les cristaux sont tricliniques avec un groupe d'espace $P\bar{1}$, $a = 8.139(3)$, $b = 9.759(3)$, $c = 7.398(3)$ Å, $\alpha = 100.28(7)$, $\beta = 74.22(5)$, $\gamma = 108.67(7)°$ et $V = 533.0$ Å^3, $Z = 1$. On a résolu la structure par les méthodes directes et de Patterson; un affinement par la méthode des moindres carrés (bloc diagonal) converge vers une valeur de R de 0.041 pour les 1671 réflexions observées. Les cycles de pyrimidine du photodimère centrosymétrique sont orientés dans une configuration *trans–anti* à travers le cycle planaire du cyclobutane. L'ion potassium est heptacoordonné. En solution aqueuse, le photodimère présente un pK_a de 12.8 qui est dû à une dissociation à l'hydrogène attaché en position N(3) du cycle. L'irradiation d'une solution aqueuse à 254 nm conduit à une regénération quantitative du monomère avec un rendement quantique de 0.8. La regénération thermique du monomère se produit aussi en milieu aqueux acide et neutre mais à une vitesse plus lente que pour le photodimère orotate *trans–syn*. Par opposition avec le photodimère orotate qui subit une ouverture catalysée par les bases des liens 3 et 4 du cycle pyrimidine, le photodimère du méthyl-5 orotate se dissocie, dans ces conditions, pour régénérer le monomère de base.

[Traduit par le journal]

Introduction

Various cyclobutane photodimers of 2,4-diketopyrimidines are involved in the lethal and mutagenic effects of ultraviolet irradiation, and orotic acid analogues have been extensively used as model systems in studies of the photodimerization reactions. Whereas orotic acid (I), in aqueous medium over the concentration range 10^{-2} *M* to 10^{-4} *M*, readily photodimerizes via a triplet state (1) to yield almost exclusively the *trans–syn* cyclobutane photodimer (2, 3), 5-methylorotate under these conditions is only slightly susceptible to photodimerization at

irradiation wavelengths to the red of 270 nm, and virtually fully resistant when irradiated at 254 nm (4). This situation is reversed in aqueous frozen medium, or in a KBr matrix. In the latter case (5) the quantum yields for photodimer formation from orotate and 5-methylorotate are 0.12 and 0.90, and probably depend on the extent of base stacking in the matrix. We have now found that the degree of photodimerization of 5-methylorotate in an ice matrix may be considerably enhanced by increasing the rate of formation of the matrix from the liquid phase. This has, in turn, made it possible to isolate the main photoproduct in adequate yield for crystallization on a preparative scale, and to examine some of its additional properties in solution, as well as to determine its structure by X-ray diffraction. A different (*cis–anti*) photodimer of 5-methylorotate has also been isolated, in very low yield, from frozen aqueous medium and analyzed crystallographically (6).

Experimental

5-Methylorotic acid was a product of Sigma Chemical Co. The photodimer of orotic acid was prepared as previously described (4).

Ultraviolet absorption spectra and spectral titrations made use of Zeiss (Jena, GDR) and Hilger UVISPEK instruments with 10-mm pathlength quartz cuvettes. ^{1}H nmr spectra were run on Varian 60 and 220 MHz instruments, using solutions in D_2O with sodium 2,2′-dimethyl-2-silapentane-5-sulphonate as internal standard. Infrared spectra were recorded on a Zeiss (Jena, GDR) UR-10 spectrophotometer, using variable pathlength cuvettes fitted with CaF_2 windows. Thin-layer chromatography made use of Merck cellulose F plates with the following solvent systems: (*A*) MeOH – conc. NH_4OH – H_2O (7:1:2), (*B*) *i*-ProOH – MeOH – conc. NH_4OH – H_2O (3:4:1:2), (*C*) *n*-BuOH – acetone – ether – H_2O (8:4.5:4.5:8), (*D*) EtOH – 1 *M* ammonium acetate (4:3). Quantum yields for photodimer dissociation were estimated by chemical actinometry, with the aid of the photohydration reaction of uridine, for which the quantum yield is 0.021.

Preparation of 5-Methylorotate Photodimer

A 10^{-2} *M* solution of 5-methylorotate in 0.01 *N* HCl was gently sprayed onto the surface of a 70 cm × 15 cm glass plate, the lower surface of which was in contact with finely powdered dry ice. Spraying was continued until an approximately 1-mm thick layer of frozen solution had been formed. This layer was then irradiated for a total of about 10–12 min with a Westinghouse 40-W germicidal lamp supported about 2 cm from the surface of the layer; at intervals of 2–3 min during irradiation, the surface of the layer was gently brushed to remove the opaque film formed by condensation from the atmosphere. Upon subsequent thawing of the irradiated frozen solution, a precipitate formed, due to the low solubility of the dimer photoproduct. The precipitate was collected by centrifugation, and the supernatant (the optical density of which was reduced to half of its initial level) concentrated twofold under reduced pressure and further irradiated as above. The final pooled product was extracted several times with small volumes of cold water to remove traces of monomer, dissolved in the minimum volume of 0.02 *N* NH_4OH and centrifuged to remove dust and other impurities. The clear solution was then brought to dryness and the ammonium salt of the 5-methylorotic acid dimer crystallized from water in the form of colourless needles (overall yield 30–35%). The ammonium salt was soluble in water, less so in ethanol and methanol. Suitable crystals for X-ray diffraction could not be obtained with this product, and it was therefore converted to the potassium salt by passage through a column of Dowex 50W-X8. Exposure of an aqueous solution of the potassium salt to ethanol vapour in a desiccator at atmospheric pressure led to precipitation of satisfactory crystals.

Neither the ammonium nor potassium salts exhibited clearly defined melting points, both undergoing initial thermal conversion to the parent 5-methylorotate. For the potassium salt, 20 min heating at 305°C, followed by thin-layer chromatography, showed 90% conversion to monomer, which included some thymine resulting from decarboxylation of the 5-methylorotate. Attempts to thermally decarboxylate the product to thymine photodimer were unsuccessful.

Thin-layer chromatography of the crude ammonium and potassium salts of 5-methylorotate photodimer with solvent systems *A*, *B*, *C*, and *D* showed one major component with R_f values of 0.44, 0.10, 0.08, and 0.21, respectively. The corresponding R_f values for the parent 5-methylorotate were 0.56, 0.37, 0.24, and 0.50. In addition, there were up to three minor spots, amounting to less than 10% of the total, presumably photodimer isomers. Attempts to isolate these by gas chromatography of the trimethylsilylated derivatives were unsuccessful. However, all four isomers in aqueous medium exhibited similar spectral and photochemical characteristics (see below).

Collection and Reduction of X-Ray Data

Preliminary precession photographs indicated triclinic symmetry. The crystal used for data collection was a prism with approximately hexagonal cross section, 0.25 mm across, was 0.57 mm long, and was mounted with b^* as rotation axis; the direction of elongation was parallel to (101). Cell-parameter and intensity measurements were made with a card-controlled Picker four-circle diffractometer equipped with a scintillation counter and pulse-height analyser, using Ni-filtered Cu radiation. Cell dimensions were calculated from 2θ values of high-angle reflections.

$[C_{12}H_{10}N_4O_8]^{2-}\cdot 2K^+\cdot 6H_2O$ fw = 524.5

$P\bar{1}$ (confirmed by the structure analysis), a = 8.139(5), b = 9.759(5), c = 7.398(5) Å, α = 100.28(7), β = 74.22(5), γ = 108.67(7)°. (Delaunay reduced cell: a = 9.393, b = 10.518, c = 7.398 Å, α = 92.57, β = 123.50, γ = 112.20°.) V = 533.0 Å^3, ρ_o = 1.632(5), Z = 1, ρ_c = 1.634 g cm^{-3}. (Cu Kα_1, λ = 1.54051, Cu Kα_2, λ = 1.54433 Å; 20°C.)

One asymmetric unit contains half a dimer anion, one K^+ ion, and three water molecules.

Moving-crystal moving-counter (θ/2θ) scans were used for the intensity measurements; a 10-s background count was accumulated at the end of each scan. All 1818 independent reflections accessible to the diffractometer (2θ ≤ 130°) were measured, and of these, 1671 had net counts above a threshold level which was determined as 20 (deca) counts or 10% of the total background count, whichever was greater. The 147 reflections considered as 'unobservably weak' were excluded from the structure determination and refinement, but included in the final structure-factor calculation. The intensities of two check reflections were monitored periodically during the data collection; fluctuations were less than 2% and appeared to be random. Absorption corrections were applied using a Gaussian integration formula; maximum and minimum transmission factors were 0.428 and 0.136 respectively for μ(Cu Kα) = 46.2 cm^{-1}. The usual Lorentz and polarization corrections were also applied to obtain structure-factor amplitudes.

Determination and Refinement of the Crystal Structure

Positions for eight atoms were deduced from a sharpened

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Patterson synthesis. Extension from this partial structure by tangent refinement (7) gave 17 more atom sites, and a difference synthesis revealed the rest of the structure. Intensity statistics had been inconclusive regarding the presence or absence of a centre of symmetry, and therefore the analysis was carried out in space group $P1$ until the existence of the symmetry centres became obvious. Refinement by block-diagonal least-squares converged at a final R value of 0.041 for all observed reflections. Scattering factors for K^+, O, N, and $C_{valence}$ were taken from International Tables for X-ray Crystallography, Vol. IV (8), and the real part ($\Delta f' = 0.365$) of the anomalous dispersion correction was applied to the K^+ curve. Scattering factor values for bonded H were taken from Stewart *et al.* (9). Non-hydrogen atoms were refined anisotropically and hydrogen atoms, which were all located on difference maps, were refined with isotropic thermal parameters. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, and the final weighting scheme used was

$$w = w_1 w_2$$

where

$$w_1 = 1 \Big/ \left(1 + \left[\frac{F_o - 10.0}{10.0}\right]^2\right)$$

$$1.25 \leq F_o \leq 73.25$$

and

$$w_2 = (\sin^2 \theta / 0.65)^2$$

if $\sin^2 \theta < 0.65$, otherwise $w_2 = 1.0$. An extinction correction (10) was applied near the end of the refinement. The largest (shift/estimated standard deviation) ratio in the final least-squares cycle was 0.30, and the mean (shift/σ) was less than 0.10. A difference synthesis computed[3] from the final structure factors[4] showed two small peaks and a trough (maximum height ± 0.45 e/Å^3) near the K^+ ion site plus a peak (0.38 e/Å^3) near the mid-point of the C(6)—C(5)′ bond, the latter possibly attributable to bonding electron density.

Results

Properties of 5-Methylorotate Photodimer

In neutral aqueous medium the photodimer exhibited only end absorption in the ultraviolet. Spectral titration in alkaline medium, accompanied by the appearance of a clearly defined band at 240 nm, demonstrated the existence of a pK_a of 12.8, corresponding to the known dissociation of the N(3) hydrogen of 2,4-diketopyrimidines with a saturated 5,6 bond (12, 13).

The infrared spectrum of the photodimer in a KBr matrix in the 1600–1700 cm^{-1} region showed two intense bands at 1690 and 1710 cm^{-1}. Similar carbonyl bands were exhibited by the orotate photodimer.

The 60 MHz ^{1}H nmr spectrum of 5-methylorotate in D_2O showed a single sharp singlet at 2.00 ppm, ascribed to the 5-methyl protons. The 220 MHz spectrum of the photodimer in D_2O showed a unique singlet at 1.44 ppm. This shift to higher field is similar to that observed for the 5-methyl protons in thymine photodimers (14) and is consistent, as are the other spectral properties, with a cyclobutane photodimer structure. However, the only noncrystallographic evidence regarding the nature of the isomer present comes from the titration in acid medium of the photodimers of orotate and of 5-methylorotate against the corresponding parent monomers as controls. Each photodimer gave a single titration curve, indicating that each photodimer must have the *trans* configuration.[5]

Lability in Aqueous Medium

Irradiation of a 10^{-4} M solution at 254 nm led to quantitative photodissociation to the parent monomer with a quantum yield of 0.8, as observed for other 2,4-diketopyrimidine cyclobutane photodimers (4). At neutral pH the photoproduct underwent thermal dissociation to the parent monomer. Heating for 15 h at 100°C, at a concentration of 10^{-4} M, led to 8% conversion to monomer at pH 6.5, and 22% conversion in 1 N HCl. Under analogous conditions the *trans–syn* orotate photodimer proved more labile; conversion to the monomer was 24% and 85% in neutral and acid media respectively. In strongly alkaline medium the 5-methylorotate photodimer was slowly converted to the parent monomer. In 1 N NaOH at 60°C the rate constant for this reaction was 6.3×10^{-2} min^{-1}, so that the $t_{1/2}$ was about 11 min. Under such conditions orotate photodimer is more reactive, but its reactivity is manifested by disappearance of the uv absorption band at about 240 nm (4), as in the case of 5,6-dihydro-2,4-diketopyrimidines (12), and appears to be due to opening of the 3,4 bonds in the pyrimidine rings, with retention of the cyclobutane ring as in the case of a thymine photodimer (15).

X-Ray Analysis Results

Final fractional coordinates and thermal parammeters are listed with their esd's in Table 1. Bond lengths and bond angles are shown for the organic anion in Fig. 1, and interatomic distances and angles for the coordination polyhedron around the potassium ion have been deposited.[4] The anisotropic thermal vibrations of the atoms comprising the anion were analysed (16) for rigid-body motion, and the translational and librational motion of the group was found to be very small. Bond length corrections

[3]Unless otherwise indicated, all computations were made with the NRCC set of Crystallographic Programs for the IBM/360 system (11).

[4]Copies of tables of observed and calculated structure factors and of interatomic distances and angles in the K—O coordination polyhedron are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]A *cis* configuration would have led to the known splitting of the pK values for neighbouring carboxyl groups in dicarboxylic acids.

[a]These parameters were multiplied by 10^4. The thermal parameters are expressed as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^2 + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.
[b]The number of the atom to which the hydrogen is bonded is obtained by dropping the least significant digit of the hydrogen atom number. The coordinates were multiplied by 10^3.

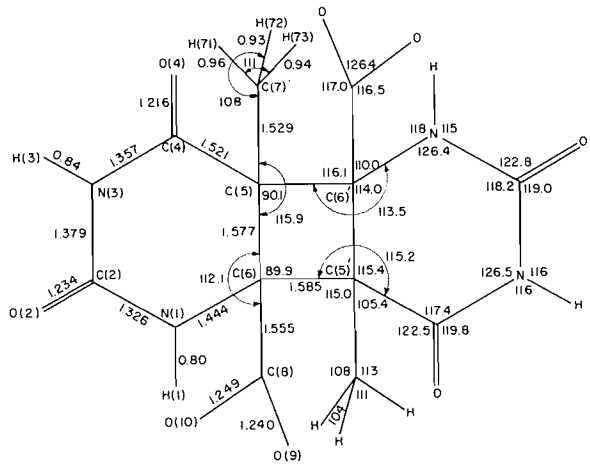

FIG. 1. Bond distances and angles in the 5-methylorotate photodimer anion. The esd's for the distances involving only nonhydrogen atoms are 0.002–0.003 Å; esd's for the corresponding angles are 0.13–0.19°. When hydrogen atoms are involved the esd's are about 10 times larger.

derived from the libration tensor were less than the individual esd's and were therefore not applied.

Discussion of the Crystal Structure

In this photodimer a crystallographic centre of symmetry lies in the centre of the cyclobutane ring, constraining it to be planar. The two pyrimidine rings are fused to the cyclobutane ring in *trans–anti* configuration and the dihedral angle between the cyclobutane ring and the mean pyrimidine ring plane is 121.6°. Each pyrimidine ring is significantly nonplanar, and the endocyclic torsional angles, given in Table 2, indicate that the distortions from planarity are in the direction of a slight twist-boat shape (17). Of the six atoms, C(4) deviates most (0.088 Å) from the mean pyrimidine ring plane, carrying O(4) 0.181 Å out of the plane, thereby increasing the separation between O(4) and C(7) which is, even so, only 2.84 Å. The C(7)···C(8) and C(7)···N(1)′ nonbonded distances, 2.83 and 2.81 Å respectively, are also rather short, indicating the severe overcrowding caused by the full substitution of C(5), C(6), C(5)′, C(6)′.

The bond lengths and angles in this structure are, in general, equal within experimental error to those in the *cis–anti* photodimer of 5-methylorotate (6). The few significant deviations are shown in Table 3, and it is interesting to note that where parameters involving only pyrimidine ring atoms differ, i.e. the N(1)—C(2) bond length and C(6)—N(1)—C(2), C(5)—C(6)—N(1) bond angles, the values found in the present *trans–anti* structure compare rather better with the values in the thymine *trans–anti* photodimer (18). Other significant deviations, involving the

TABLE 2. Torsional angles in the photodimer

(*a*) Endocyclic torsional angles in the pyrimidine ring

N(1)—C(2)—N(3)—C(4)	8.4
C(2)—N(3)—C(4)—C(5)	−16.0
N(3)—C(4)—C(5)—C(6)	9.5
C(4)—C(5)—C(6)—N(1)	2.4
C(5)—C(6)—N(1)—C(2)	−10.9
C(6)—N(1)—C(2)—N(3)	6.5

(*b*) Other torsional angles

C(7)—C(5)—C(6)—C(8)	0.3
C(8)—C(6)—C(5)′—C(4)′	3.6
N(1)—C(6)—C(5)′—C(7)′	2.5
N(1)—C(6)—C(8)—O(10)	−23.2
C(5)—C(6)—C(8)—O(9)	−71.8
C(5)—C(6)—C(8)—O(10)	104.9
C(5)′—C(6)—C(8)—O(9)	29.5

C(4)—C(5)—C(7), N(1)—C(6)—C(8), and C(5)′—C(6)—C(8) angles, probably can be explained as the result of the different distortions necessary to minimize interatomic repulsion in the two isomers.

Partial relief of these forces of interatomic repulsion is also achieved by the lengthening of the C(5)—C(6) and C(6)—C(8) bonds. The C(5)—C(6) bond length in the present structure (1.577 Å), while essentially equal to the corresponding value (1.57 Å) in the *cis–anti* isomer, is significantly longer than in most other pyrimidine photodimers (3, 18–21). The C(6)—C(8) bond lengths in this structure (1.555 Å) and the *cis–anti* isomer (1.56 Å) are significantly longer than corresponding values in the orotic acid monohydrate structure (22) (1.498 Å) and in the *trans–syn* photodimer of methylorotate (3) (1.522 Å).

Differences in the interpyrimidine bond lengths in the present structure and in the *trans–syn* orotate photodimer help partially to explain the differences in lability of the two dimers. In the *trans–syn* crystal structure (3), the C(6)—C(6)′ bond, to which both carboxyl groups are bonded, is abnormally lengthened to 1.628 Å, while the C(5)—C(5)′ bond, 1.556 Å, is close to normal length, as are the intrapyrimidine bonds, 1.544 Å. In the present structure the strain induced by overcrowding is distributed more equally; the interpyrimidine bonds (1.585 Å) are essentially the same length as the intrapyrimidine bonds (1.577 Å). If we assume that the C(6)—C(6)′ bond in (nonesterified) *trans–syn* orotate photodimer has a fairly similar length to that observed in the crystal structure of the methyl ester (and the configurations of the dimer acid and ester have been shown to be identical (2)), then the increased lability in neutral and acid media of the orotate photodimer relative to the 5-methylorotate dimer

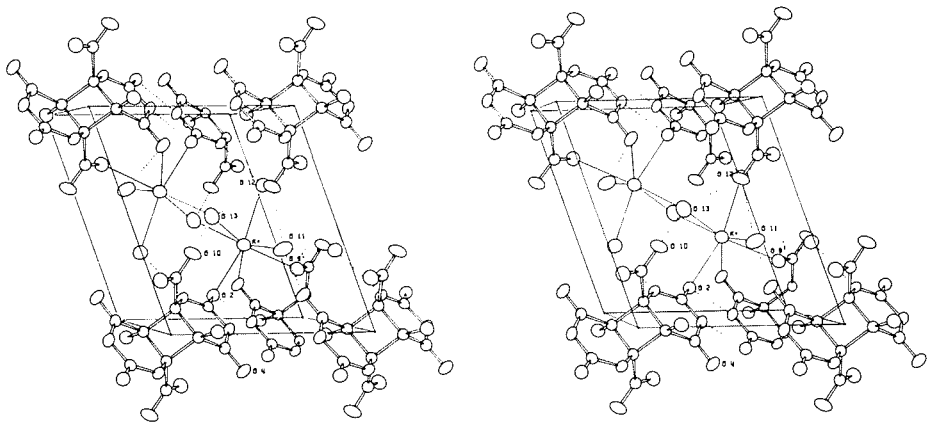

FIG. 2. Stereoscopic view of the packing arrangement drawn by the ORTEP program (23). $K^+\cdots O$ contacts are indicated by single solid lines, hydrogen bonds by dotted lines. Axial directions: $x\rightarrow$, $y\uparrow$, z pointing out of the plane toward the reader.

can be correlated with this longer bond. It is not so easy to understand why, in alkaline solution, the cyclobutane ring is preserved in the case of orotate photodimer (and also a *cis–syn* thymine photodimer (15)), and cleaved in the case of 5-methylorotate photodimer.

The carboxyl groups in the present dimer are both ionized, balancing the two K^+ ions per unit cell, and one would therefore expect delocalization to make the C—O bond lengths equal. The small difference, 0.009 Å, between the observed C(8)—O(9) and C(8)—O(10) bond lengths is possibly not significant, but could be ascribed to different hydrogen bonding patterns at O(9) and O(10) (see below).

The potassium ion is seven-coordinated, by three oxygen atoms from the dimer and by four contacts to water-molecule oxygens. Six of the $K^+\cdots O$ distances are in the range 2.67–2.94 Å, while the seventh is 3.057 Å. There are no other $K^+\cdots O$ distances less than 3.50 Å, and no short contacts to nonoxygen atoms. The six closer oxygens can be described as forming a distorted octahedron, with the seventh oxygen accommodated outside the largest octahedral face. Both the sevenfold coordination of the K^+ ion and the range of $K^+\cdots O$ distances are unexceptional.

Figure 2 gives a stereoscopic view of the packing arrangement and hydrogen bonding, and further geometrical details about the hydrogen bonds are listed in Table 4. All of the available hydrogen atoms are involved in hydrogen bond formation.

The dimer anions are linked into infinite chains along [10$\bar{1}$] by pairs of hydrogen bonds joining N(3) and O(2) of one dimer to O(2) and N(3) respectively of an adjacent dimer. The pairs of pyrimidine rings joined by hydrogen bonds are coplanar within 0.2 Å. Dimer anions within a chain are also linked through participation of O(2), O(4), and O(9), from adjacent dimers, in each potassium coordination polyhedron.

The coordination polyhedra occur in pairs, sharing an edge of which the mid-point is a centre of symmetry. The only linkage of one dimer chain to another by the potassium coordination polyhedron is indirect, via centrosymmetrically related O(2), O(4), and O(9) atoms at opposite ends of each coordination pair.

TABLE 4. Geometrical details of the hydrogen bonds, *D*—H···*A*

D	*H*	*A*	*D*···*A* (Å)	*D*—H (Å)	H···*A* (Å)	*D*—H···*A* (deg)
N(1)	H(1)	O(12)	2.909	0.80	2.11	173
N(3)	H(3)	O(2)	2.849	0.84	2.04	163
O(11)	H(111)	O(10)	2.786	0.87	1.93	168
O(11)	H(112)	O(4)	2.835	0.76	2.08	169
O(12)	H(121)	O(9)	2.832	0.79	2.05	169
O(12)	H(122)	O(11)	2.711	0.88	1.83	176
O(13)	H(131)	O(10)	2.925	0.80	2.13	172
O(13)	H(132)	O(10)	2.859	0.87	2.03	160

Other cohesive forces are provided by the hydrogen bonds involving water molecules. Adjacent dimer chains in the *xz* plane are linked via O(12), while connections in the *y* direction are via O(11) and O(13).

The appearance of the report (6) on the *cis–anti* photodimer of 5-methylorotate, which followed completion of the present analysis, raises the question of why two different isomers were obtained under apparently very similar experimental conditions. (Both photodimers were prepared by irradiation of frozen aqueous solutions of 5-methylorotic acid, and then converted to the particular salts.) It seems possible that the different dimer may have resulted from differences in the procedure employed for preparation of the ice matrix, or that crystallization of the barium salt led to preferential isolation of one of the minor isomers referred to above. Unfortunately, Cheng *et al.* (6) give no quantitative data on yields or chromatographic behaviour of the crude photodimer solution prior to crystallization.

Studies on nucleation phenomena occurring in aqueous solutions supersaturated with calcium sulfate

D. M. KELLER, RONALD E. MASSEY, AND O. E. HILEMAN, JR.
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 8, 1977

D. M. KELLER, RONALD E. MASSEY, and O. E. HILEMAN, JR. Can. J. Chem. **56**, 831 (1978).

The results of a set of experiments designed to delineate the nucleation rate, supersaturation, temperature surface for the system $CaSO_4 \cdot 2H_2O/H_2O$ are reported. The data were obtained using the droplet technique coupled with *in situ* generation of SO_4^{2-} under the conditions that dS/dt was large during the early part of the induction period and it was zero during the actual nucleation events. The observed shape of the surface is compared with that suggested by the classical theory of nucleation and differences are commented on. The critical parameters important in classical nucleation theory are reported.

D. M. KELLER, RONALD E. MASSEY et O. E. HILEMAN, JR. Can. J. Chem. **56**, 831 (1978).

On rapporte les résultats d'un ensemble d'expériences ayant pour but de délimiter la vitesse de nucléation, la sursaturation et la surface de température du système $CaSO_4 \cdot 2H_2O/H_2O$. On a obtenu les données en utilisant la technique des goutellettes de concert avec la formation *in situ* de SO_4^{2-} dans des conditions telles que la valeur dS/dt est plus grande durant la partie initiale de la période d'induction et qu'elle est égale à zéro lorsque la nucléation s'effectue. On a comparé la forme observée pour la surface avec celle qui est suggérée par la théorie classique de la nucléation et on présente des commentaires au sujet des différences. On rapporte les paramètres critiques importants dans la théorie de nucléation classique.
[Traduit par le journal]

Introduction

The classical theory of nucleation arose out of recognition that the observation of supercooling or supersaturation in a system undergoing a phase transformation represents a barrier to that transformation and, additionally, that the description of such a process is a problem in kinetics. Equation 1 summarizes the essence of the theory.

$$[1] \qquad J = A \exp(-\Delta G^*/kT)$$

where J is the rate of nucleation, A is some collection of constant and exponential terms assumed to be constant, ΔG^* represents the free energy barrier to the transformation, and k and T have their usual meanings.

The free energy change accompanying a phase transformation is thought to be composed of two parts: one related to the work of formation of a surface between the new and the mother phase and one related to the difference in chemical potential between a monomer in the new phase and one in the mother phase. If one assumes spherical embryos, the expression for the magnitude of this free energy change has the following form.

$$[2] \qquad \Delta G = \frac{4}{3}\frac{\pi r^3}{\bar{v}}(\phi_n - \phi_m) + 4\pi r^2\sigma$$

where r is the radius of the newly forming phase and ϕ_n is the chemical potential of one of its interior monomers, ϕ_m is the chemical potential of a monomer in the mother phase, σ is the surface tension between the mother phase and the newly forming phase, and $\bar{v}$ is the molecular volume in the new phase.

Because the two terms in eq. 2 are of opposite signs and are of different power dependencies upon r, a maximum occurs in the ΔG, $\phi_n - \phi_m$, r surface. For systems undergoing homogeneous crystal nucleation from a supersaturated solution, the expression for the free energy values along this maximum is given by eq. 3.

$$[3] \qquad \Delta G_{max} = \frac{16\pi\sigma^3\bar{v}^2}{3(kT \ln S)^2} = \frac{4\pi\sigma r_{max}^2}{3}$$

where $(\phi_n - \phi_m)$ has been replaced by $kT \ln S$, S being the level of supersaturation being experienced by the system at the point of nucleation.

In 1926, Volmer and Weber recognized the connection between ΔG^* of eq. 1 and ΔG_{max} of eq. 3; i.e., that the frequency of formation of nuclei by spontaneous fluctuations in solution is proportional to $\exp[-\Delta G_{max}/kT]$ (1). Thus, ΔG_{max} appears to be analogous to the activation free energy of reaction rate theory and could be substituted for it in eq. 1 yielding eq. 4.

$$[4] \qquad J = A \exp\left[-\frac{16\pi\sigma^3\bar{v}^2}{3(kT)^3(\ln S)^2}\right]$$

Outside of the identification of the various components of A, little has been added to the classical theory for 40 or so years (2–7). It is used currently as a guide in the experimental design of and as a

basis for data analysis and interpretation of the results of studies on homogeneous crystal nucleation from supersaturated solutions.

Testing of the classical theory as applied to homogeneous crystal nucleation from solution has been confounded by the catalytic effect of preformed surfaces in solution. Vonnegut was the first to recognize that miniaturization of a macroscopic sample of a condensed phase via subdivision into many non-communicating micro samples sequestered the effect of such surfaces and, thus, allowed the study of homogeneous phase transformations in melts (8). White and Frost extended the technique to homogeneous crystal nucleation from solution (9). Each, however, was limited to those materials that could be caused to nucleate under a driving force created by narrow temperature change ranges. Through research in our laboratories we have extended the applicability of the droplet technique to a rather wide variety of materials by coupling it with either *in situ* generation of the insoluble substance from very soluble precursors or selective extraction of solvent from the droplet population into a surrounding medium (10–16). Recent results from our studies on $CaSO_4$ nucleation have shown that additional problems in testing the theory arise during the reduction of raw 'number–time' data obtained from droplet experiments to nucleation rates if the complications of time dependent supersaturation levels and supersaturation dependent time lags are present. Two of the authors have discussed the former problem in an earlier paper (16).

The purpose of this paper is to describe a set of experiments designed to delineate the response surface of J with respect to S and T. The shape of this response surface suggests an empirical relationship between the observable and the two experimental variables and this may be compared with theory.

Experimental Details

A droplet experiment can be divided into a series of steps, namely, preparation of an aqueous solution containing the precursors for generation of the supersaturation, dispersion of a small, known amount of this solution in an immiscible oil, selection and subsequent preparation of a population of droplets for microscopic observation, generation of the supersaturation, notation of 'number–time' data and then data analysis and interpretation. Additionally, the rate of formation of the supersaturation and the equilibrium solubility of the crystalline product in aqueous medium must be measured.

The reaction between $S_2O_8^{2-}$ and I^- was used to generate SO_4^{2-} *in situ*, in the presence of Ca^{2+}. Supersaturation data for a droplet population were inferred from results of 'beaker' experiments carried out in parallel. The appearance of crystals within the droplet population was recorded photomicrographically. For subsequent analysis, the 'number-time' data were separated on the basis of narrow droplet volume ranges.

Reagents and Apparatus

All salts ($Ca(NO_3)_2 \cdot 4H_2O$ (Baker), $K_2S_2O_8$ (Allied), NH_4I (Baker), and EDTA (Fisher)) were of Reagent Grade quality. Solutions prepared from them were pressure filtered (N_2) through a 0.3 μ PCV filter (Sartorius). Solution A was prepared by mixing, just before use, equal volumes of the $Ca(NO_3)_2 \cdot 4H_2O$ and the $K_2S_2O_8$ solutions. Solution B contained NH_4I. Light and heavy mineral oils (BDH) were used as supplied. The apparatus used has been described elsewhere (16).

Solubility of $CaSO_4 \cdot 2H_2O$

A synthetic matrix was prepared that contained KNO_3 (0.204 *M*), NH_4NO_3 (0.204 *M*), NH_4I (0.146 *M*), and an excess of freshly prepared $CaSO_4 \cdot 2H_2O$. The suspension was stirred for 24 h at the desired temperature and then pressure filtered (N_2). The Ca^{2+} content of the resulting filtrate was determined by an EDTA/Mg^{2+} back titration.

Determination of Supersaturation Data

The change in concentration of I_3^- in solution as a function of time was determined by $S_2O_3^{2-}$ titration. Aliquots of the reaction mixture were removed at increasing reaction time intervals, the reaction was quenched by dilution, and the I_3^- was titrated with standard $S_2O_3^{2-}$ to a starch end point. The reaction was also monitored spectrophotometrically at 610 nm. The transmittance range was set with deionized H_2O (100% T) and an equilibrated reaction mixture (0% T).

Temperature Rise-time

Measurements of temperature rise-times after start-up of the supply of circulating, thermostatted water to the cell holder and the resulting equilibrium temperatures of mineral oil samples contained in the nessler cup put in place on the microscope stage were carried out using a fine wire (iron–constantan) thermocouple and a potentiometer (Leeds–Northrup).

Droplet Experiments

The usual procedure was used to prepared a large population of non-communicating droplets of narrow volume range and situated on an optically flat surface ready for photomicroscopic observation (16). Equal volumes of freshly pressure filtered solutions of A and B were mixed just immediately prior to the experiment. The solution compositions studied are shown in Table 1. 'Number–time' data were collected from the 35 mm slides in the usual manner (16).

Results

From the data obtained during preliminary experiments it was established that $CaSO_4 \cdot 2H_2O$ is the sparingly soluble product formed during the reaction between I^- and $S_2O_8^{2-}$ in the presence of Ca^{2+}. The measured values of the solubility of gypsum were found to be invariant, within experimental error, over the narrow range of ionic strengths encountered in the experiments. The effect of temperature on its solubility is noted in Fig. 1 and, together with calculated or interpolated K_{sp} values, in Table 2.

The result of the spectrophotometric determination of the times required for the generation reaction ($S_2O_8^{2-} + I^-$) to reach equilibrium as a function of various initial I^- concentrations are shown in Fig. 2. Approximately 12 min overall are required for mixing of reagents, droplet preparation and selection and initial microscopic observations. During the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

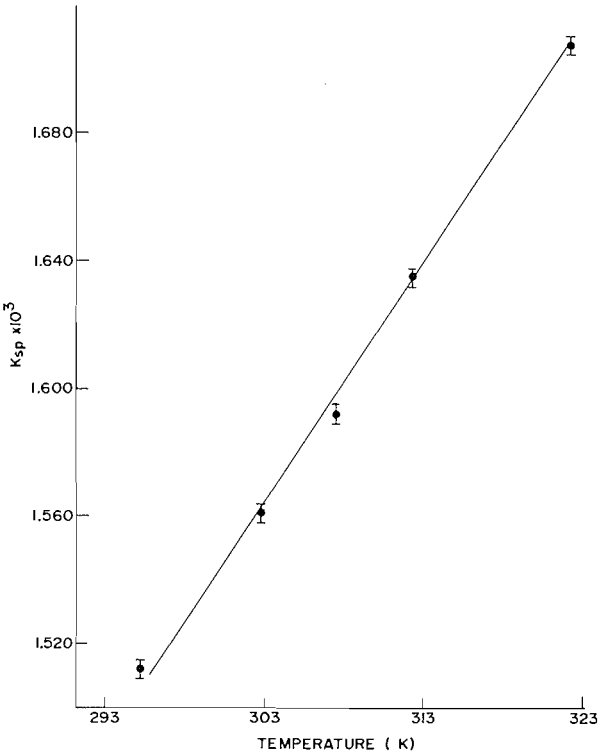

FIG. 1. A plot of the K_{sp} of $CaSO_4 \cdot 2H_2O$ in the matrix solution at various temperatures.

latter part of this time interval, the reaction should reach chemical equilibrium. Additionally, the equilibrium temperature of the reaction mixture must be increased from $\sim 15°C$ to the temperature of interest during this time interval. The results of temperature rise-time studies are shown in Fig. 3. In addition to reaction time considerations enough unreacted I^- must remain at equilibrium to solubilize the I_2 formed (as I_3^-). Taken together, these factors led to use of an initial I^- concentration of 0.350 *M* for each of the nucleation experiments.

'Number–time' data resulting from analysis of the photomicrographic record of nucleation events occurring with each droplet population were fitted to eq. 5 with the aid of a non-linear least squares program 'Gaushaus'.

$$[5] \qquad n_{t,v} = N(1 - \exp[-J_f' v(t_e - \tau)])$$

where $n_{t,v}$ is the count of the number of droplets in a population of volume v in which a crystal has been detected at experimental time t_e, N is the total number of droplets in a population of volume v, J_f' is the best fit nucleation rate, and τ is the lag time. The fit was optimized by adjustment of the two parameters, N and J_f'. Final estimates of τ were found by iteration. The results are shown in Table 3.

TABLE 1. Experimental variables used in the constant driving force experiments

Discussion

Difficulties surrounding the interpretation of results obtained from nucleation studies with a time dependent driving force were presented in a previous publication (15). In this study, an attempt was made to produce a 'step function' change in the driving force and then to follow the subsequent nucleation events; thus, eliminating these difficulties. To this end, a stoichiometric excess of iodide was used to reduce peroxydisulfate. The iodine formed was held in solution by the remaining iodide ion as I_3^-. Thus, $CaSO_4 \cdot 2H_2O$ was the only sparingly soluble species present in solution and its analytical concentration was effectively invariant with time during the experiment. This invariance was negated somewhat at higher levels of the temperature and/or the ion product.

Estimates of J_f', τ, and N values were obtained from the 'number–time' data using eq. 5. Large uncertainties in the values were noted if a particular volume sub-class within the droplet population numbered less than 100. To decrease this uncertainty, data from equivalent volume sub-classes but different populations were combined before analysis. A high degree of negative correlation between the parameters N and J_f' was noted if the maximum $n_{t,v}/N$ ratio was much less than one. Initial estimates

0.05429	J_f' (s^{-1} cm^3)	5.27×10^6	1.36×10^7	1.23×10^8	3.14×10^8
	τ (s)	1.85×10^3	2.30×10^2	2.7×10^1	1.3×10^1

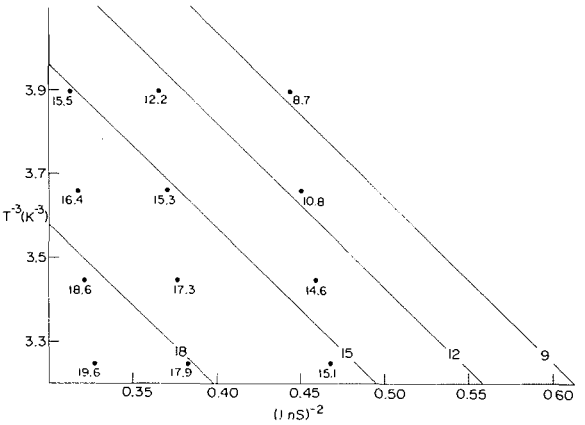

FIG. 4. A contour diagram showing ln J as a function of T^{-3} and $(\ln S)^{-2}$.

of τ were obtained by extrapolation of the steeply rising and nearly linear section of the $n_{t,v}$ vs. time curve to meet the time axis. Improved estimates of it were obtained by plotting ln $(1 - n_{t,v}/N)$ vs. t_c. The resulting straight line intersected the time axis at a value of $t_c = \tau$. Values of the three parameters were not determined simultaneously using 'Gaushaus' because of the large correlations noted among their values. A subsequent paper in this series will focus on the lag time problem in $CaSO_4 \cdot 2H_2O$ nucleation.

To note the effects of temperature and ion product on the rate of $CaSO_4 \cdot 2H_2O$ nucleation studies were carried out over the ranges 295.0 ± 1 to 313.6 ± 1 K and 0.03063 ± 0.00012 to 0.05429 ± 0.00012 respectively. Combinations were selected from these ranges that produced nucleation rate levels such that $n_{t,v}/N > 0.5$ within a 12-h period and also that produced a reasonable number of photomicrographs distributed over the whole of the experimental time interval. Advantage was taken of the rather long lag times observed at low temperature compared with those within the experimental range in that the samples were prepared for observation at low temperature then brought to the desired temperature quickly by start-up of the thermostatted water supplied to the cell holder. Careful attention to the design and fabrication of the observation cup and its holder resulted in a low thermal inertia for the system. The results of these experiments are shown as the dependency of ln J on both the variables $(\ln S)^{-2}$ and T^{-3} in the contour diagram of Fig. 4 as suggested by eq. 4.

Several iso-ln J contour lines have been drawn on the diagram and these accent the shape of the response surface. The curve resulting from the intersection of the response surface and a plane perpen-

dicular to these contour lines is not linear but bends downward (i.e., the observed J values are lower than expected) at increasing levels of T and S. This trend reflects, most likely, limitations to the experimental technique used and not limitations to the theory of nucleation as expressed by eq. 4. The data of Table 3 and Figs. 2 and 3 suggest that temperature rise times in the observation cup become of the same order of magnitude as the measured lag times as S and T mutually increase and that dS/dt effects become important also. These effects, taken together, result in measured J values that are too low.

Estimates of the values of the parameters in eq. 4 obtained from the slopes and intercepts (least-square fit) of the ln J vs. $(\ln S)^{-2}$ curves shown in Fig. 5 are listed in Table 4*a*. For ease of comparison with other data in the literature estimates of n^*, r^*, and ΔG^* were calculated from each S^* value using eqs. 6, 7, and 8.

$$\Delta G^* = \frac{16\pi\sigma^3\bar{v}^2}{3(kT\ln S^*)^2} \quad [6]$$

$$n^* = \frac{32\pi\sigma^3\bar{v}^2}{3(kT\ln S^*)^3} \quad [7]$$

$$r^* = \frac{2\sigma\bar{v}}{kT\ln S^*} \quad [8]$$

where S^* is the value of S found by extrapolation of the ln J vs. $(\ln S)^{-2}$ plot to the point where $J = 1$, n^* is the number of monomers in the critical embryo, and r^* is the radius of the critical embryo assuming it to be spherically shaped. These results along with values of the same parameters calculated from in-

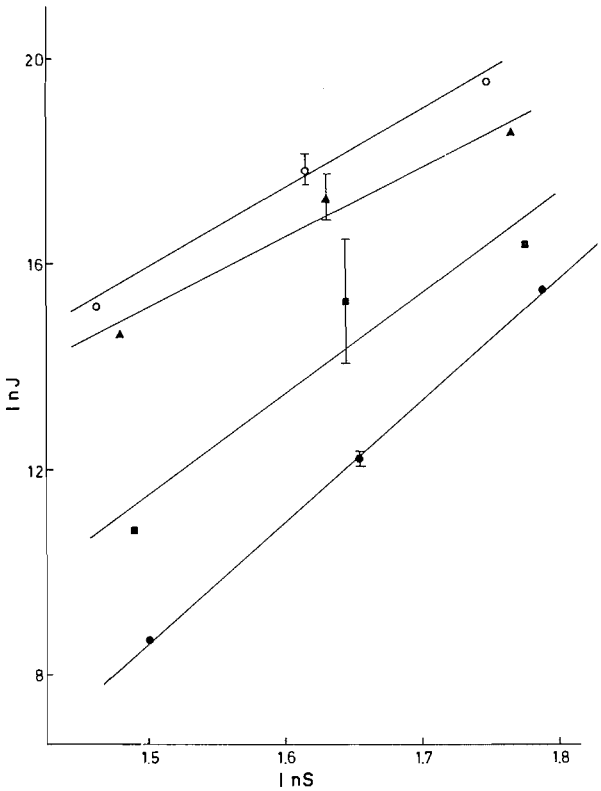

FIG. 6. Plots of ln J vs. ln S at various temperatures: ●, 295.0 K; ■, 301.3 K; ▲, 307.5 K; and ○, 313.6 K.

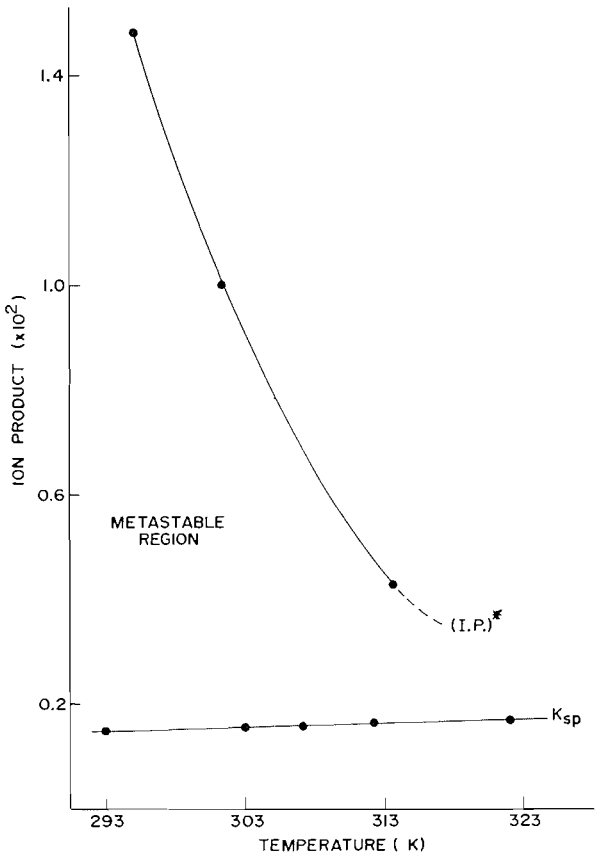

FIG. 7. The Ostwald diagram for $CaSO_4 \cdot 2H_2O$ over the temperature range 295.0 through 313.6 K.

dividual S_b* values obtained by extrapolation to the point where $J = 1$ of the ln J vs. ln S data shown in Fig. 6 and the last mentioned three equations are included in Table 4*a*. Critical ion product values for $CaSO_4 \cdot 2H_2O$ at each temperature were calculated from the tabular S_b* values using eq. 9.

$$[9] \qquad IP^* = (S_b^*)^2 K_{sp}$$

Both IP* and K_{sp} are plotted vs. temperature in Fig. 7 producing an Ostwald diagram for gypsum covering the temperature range 295.0 through 313.6 K.

Trends in the derived data over the temperature range studied can be seen from the results of an investigation into the confidence levels at which the tabular values of each of the parameters are significantly different from each other. This is shown in Table 4*b*. In general comparisons of nearest neighbour tabular values fall below the 50% confidence level while nearest neighbour but two comparisons are above this level. Thus, we can conclude that σ, S^*, and S_b* values tend to decrease with increasing temperature. The same trend in ln A values can be noted but not with the same level of confidence. Each of ΔG^*, n^*, and r^* tend to increase in value as the temperature increases. Large uncertainties, however, erode confidence in the trend when S^* is used in the calculation.

The data obtained in this study tend to confirm the form of the classical theory of nucleation as expressed by eq. 4. Deviations in the observed dependency of J on S and T at combinations of higher values of each are attributed to limitations of the experimental technique used to obtain the data and not to limitations of the theory.

The effect of temperature on the optical spectra and the yields of solvated electrons and ion-pairs in amines[1]

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, AND FRED CHARLES SOPCHYSHYN

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received September 13, 1977

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, and FRED CHARLES SOPCHYSHYN. Can. J. Chem. **56**, 839 (1978).

Optical absorption spectra for the solvated electron, e_s^-, and ion-pairs, (Na^+, e_s^-), have been observed in methylamine (MA), ethylamine (EA), and isopropylamine (IPA), at temperatures ranging from 184 to 338 K. Changes in the (Na^+, e_s^-) spectra, relative to e_s^-, are consistent with a gradual transition in the ion-pair structure toward a more 'electron-like' entity with decreasing temperature and increasing solvent polarity. Extinction coefficients, $\varepsilon_{max}(e_s^-) = 3.3 \pm 0.2, 3.2 \pm 0.5$, and $3.2 \pm 0.5 \times 10^4\ M^{-1}\ cm^{-1}$ in MA, EA, and IPA respectively. Corresponding values for the ion-pairs, $\varepsilon_{max}(Na^+, e_s^-) = 2.5 \pm 0.2, 2.1 \pm 0.2$, and $1.9 \pm 0.2 \times 10^4\ M^{-1}\ cm^{-1}$.

In EA and IPA, the yield $G_{e_s^-}$ (molecules/100 eV) shows a marked solute concentration dependence. This is consistent with an empirical scavenging model from which the escaped solvated $G(e_s^-)_{esc}$ and spur $G(e_s^-)_{spur}$ electrons are estimated as $G(e_s^-)_{esc} = 0.5$ and 0.4, $G(e_s^-)_{spur} = 1.8$ and 1.4, giving $G(e_s^-)_{total} = 2.3$ and 1.8 in EA and IPA, respectively. In MA, $G_{e_s^-} = G(e_s^-)_{esc} = 2.2_5 \pm 0.2$, independent of solute concentration.

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER et FRED CHARLES SOPCHYSHYN. Can. J. Chem. **56**, 839 (1978).

On a observé les spectres d'absorption optique d'électrons solvatés, e_s^-, et de paires d'ion (Na^+, e_s^-) dans la méthylamine (MA), l'éthylamine (EA) et l'isopropylamine (IPA) à des températures allant de 184 à 338 K. Les changements dans les spectres (Na^+, e_s^-) par rapport à e_s^- sont en accord avec une transition progressive d'une structure de paire d'ions vers une structure qui ressemble plus aux électrons au fur et à mesure que la température diminue et que la polarité du solvant augmente. Les coefficients d'extinctions $\varepsilon_{max}(e_s^-)$ sont respectivement $3.3 \pm 0.2, 3.2 \pm 0.5$ et $3.2 \pm 0.5 \times 10^4\ M^{-1}\ cm^{-1}$ dans MA, EA et IPA. Les valeurs correspondantes pour les paires d'ions $\varepsilon_{max}(Na^+, e_s^-)$ sont $2.5 \pm 0.2, 2.1 \pm 0.2$ et $1.9 \pm 0.2 \times 10^4\ M^{-1}\ cm^{-1}$.

Dans EA et IPA, le rendement $G_{e_s^-}$ (molécules/100 eV) varie considérablement avec la concentration du soluté. Ce résultat est en accord avec un modèle empirique de piégeage à partir duquel on peut évaluer que les valeurs de $G(e_s^-)_{esc}$ sont 0.5 et 0.4 et les valeurs $G(e_s^-)_{spur}$ sont 1.8 et 1.4 conduisant à des valeurs respectives de $G(e_s^-)_{totale}$ de 2.3 et 1.8 pour EA et IPA. Dans MA, la valeur de $G_{e_s^-} = 2.2_5 \pm 0.2$ et cette valeur est indépendante de la concentration du soluté.

[Traduit par le journal]

Introduction

The absorption spectra of solvated electrons, e_s^-, and species considered to be alkali metal cation–electron pairs, (M^+, e_s^-), have been observed by pulse radiolysis in several amines at room temperature (1 and references therein). In general, the band maxima for (M^+, e_s^-) show a shift towards higher energies from those found for the corresponding e_s^- absorptions (1–3). The magnitude of this shift is, however, dependent on solvent polarity and for the series methylamine (MA), ethylamine (EA), and isopropylamine (IPA) is in the order MA < EA < IPA. Such shifts show a good correlation with the hyperfine splitting constants obtained for the species of stoichiometry M in alkali metal – amine solutions suggesting that the transient species produced by pulse radiolysis are the same as those studied in steady state metal solutions by electron spin resonance (esr). Depending on the solvating ability of the solvent such species have been considered to range from "tight" (contact) to "loose" (solvent separated) ion-pairs (4, 5).

This interpretation has implications with respect to the "static" and "dynamic" models which have been put forward to explain the effect of temperature on the esr hyperfine spectra. In the former model, a single species is proposed whose structure is markedly affected by temperature (6, 7), whereas the latter visualizes a rapid temperature dependent equilibrium between two (or more) distinct species

whose structures are relatively independent of temperature (8, 9).

This paper describes the effect of temperature on the spectra of e_s^- and (Na^+, e_s^-) in MA, EA, and IPA. Spectral properties are listed and discussed with respect to the nature of ion-pairs in these amines. In addition differences in the yield, $G(e_s^-)$ (molecules/100 eV), as a function of solute concentration, are discussed in terms of an empirical scavenging model (10–12) and are compared with previous values deduced at low temperature (13).

Experimental

Details of the experimental techniques and methods of solvent purification have been described previously (14, 15). In this work all solutions were irradiated in the absence of solvent base using 1.0 cm quartz cells and 0.3 μs pulses of 2.25 MeV electrons. Yields and/or extinction coefficients were deduced from linear plots of optical density against energy absorbed per pulse using doses $\leq 1 \times 10^{20}$ eV ℓ^{-1}.

Sodium tetraphenylboron ($NaB\phi_4$) was used as received.

Results

Solvated Electron Spectra

Figure 1 shows the optical absorption spectra observed at the end of the pulse for e_s^- in pure MA from 184 to 241 K (fp 179 K). The inset displays the shift in band maximum, ν_{max} (cm^{-1}) as a function of temperature, giving the coefficient $d\nu_{max}/dT = -28.1 \pm 2\ cm^{-1}\ K^{-1}$. Extrapolating to room temperature (294 K) indicates a ν_{max} of 5215 ± 100 cm^{-1}. Within experimental error the width of the absorption band at half height, $\Delta\nu_{1/2} = 4800 \pm 100$ cm^{-1}, is independent of temperature.

Similar results were observed for pure EA and IPA over the range 193–294 K (fp 189 K) and 176–294 K (fp 172 K), respectively. In IPA the spectrum appears to narrow ($\sim$300–500 cm^{-1}) with decrease in temperature. Examples of their spectra are given in Fig. 2.

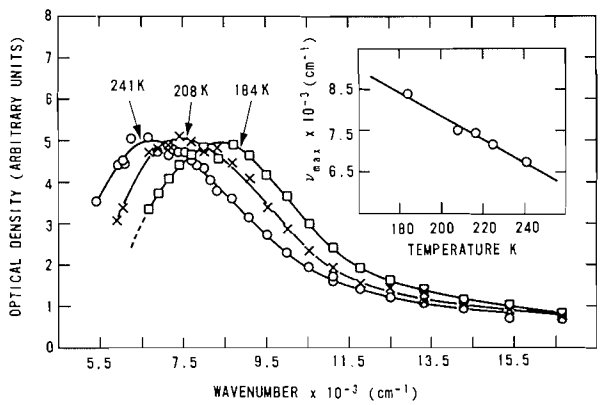

FIG. 1. Optical absorption spectra and band maxima of e_s^- in MA as a function of temperature.

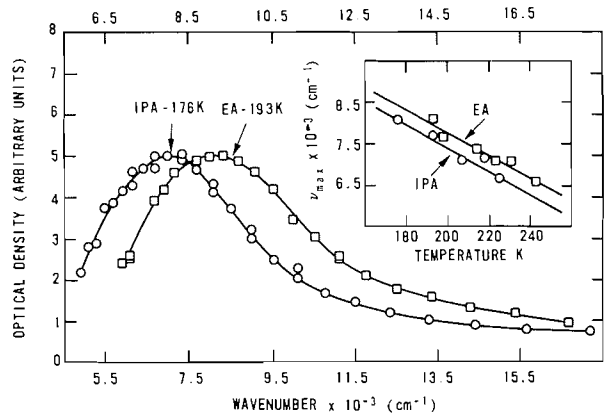

FIG. 2. Optical absorption spectra and band maxima of e_s^- in EA and IPA at low temperatures.

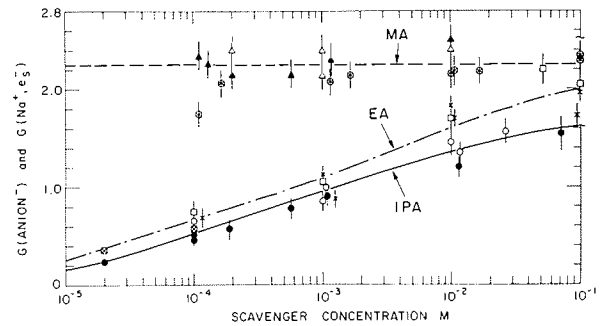

FIG. 3. Anion and ion-pair yields in MA, EA, and IPA as a function of solute concentration. ●, ▲, ⊠, biphenyl (this work); ×, ⊛, biphenyl and pyrene (16); □, ○, △, $NaB\phi_4$.

Yield, Extinction Coefficient, and Oscillator Strength

Yields and extinction coefficients, $\varepsilon_{max}(e_s^-)$ at the band maximum, were deduced at room temperature by comparison with Gε (anion) formed in the presence of biphenyl (B) as an electron scavenger (16). To minimize errors due to solvent absorptions, optical densities for e_s^- were measured at 1400 nm (7140 cm^{-1}) and then corrected to ν_{max} using the overall band shape observed at low temperatures. Figure 3 shows the anion yields as a function of concentration assuming the extinction coefficients $\varepsilon_{B^-} = 4 \times 10^4$ and $1.25 \times 10^4\ M^{-1}\ cm^{-1}$ at 407.5 and 630 nm, respectively (17). Also shown are previous results obtained in MA[2] and EA using B and pyrene (16), or $NaB\phi_4$ (see below), as e_s^- scavengers. The marked solute dependence observed in EA and IPA indicates that the rate of decay of solvated electrons escaping spur recombination must be significant with respect to the scavenging process. Therefore in order to ascertain $G(e_s^-)$ (in the absence

[2]In rechecking these data we found a systematic error which resulted in the previously reported yields for MA being 5% low. The data given in Fig. 3 have been corrected accordingly.

[b]Reference 30.

of solute) and hence $\varepsilon_{max}(e_s^-)$, use is made of an empirical scavenging model originally proposed for hydrocarbons and extended to alcohols (10–12). This procedure is amplified in the discussion.

Table 1 summarizes the spectral properties for e_s^- in the three amines along with those in liquid ammonia for comparison. Lower limits for the oscillator strengths, f, for the absorption bands were estimated from the approximation (18)

$$f \sim 4.32 \times 10^{-9}\ \varepsilon_{max}\Delta\nu_{1/2}$$

Ion-pair Spectra

Figure 4 shows the optical absorption spectra at the end of the pulse in $\sim 10^{-2}$ *M* $NaB\phi_4$ solutions in MA from 185.5 to 243 K. The inset shows the effect of temperature on ν_{max}. Figure 5 shows examples of the corresponding spectra in EA at 194 and 294 K and IPA at 294 K. Since $NaB\phi_4$ precipitated from IPA solutions at 238 K a similar low temperature study was not possible in this solvent. However, in IPA solutions a slight ($\sim 700\ cm^{-1}$) shift to higher energies and broadening ($\sim 300\ cm^{-1}$) was observed in the ion-pair spectrum at 338 K.

Yield, Extinction Coefficient, and Oscillator Strength

Ion-pair yields and extinction coefficients at 294 K were determined by comparison of the optical density of (Na^+, e_s^-) with that of (Na^+, B^-) produced in reaction 1 (19).

[1] $$(Na^+, e_s^-) + B \rightarrow (Na^+, B^-)$$

The procedure is more direct than for e_s^- since for comparable doses per pulse the natural ion-pair decay process is about an order of magnitude slower than observed for e_s^-. Using solutions containing 10^{-3} to 10^{-2} *M* $NaB\phi_4$ and from 10^{-4} to 5×10^{-4} B, the experimental conditions were adjusted such

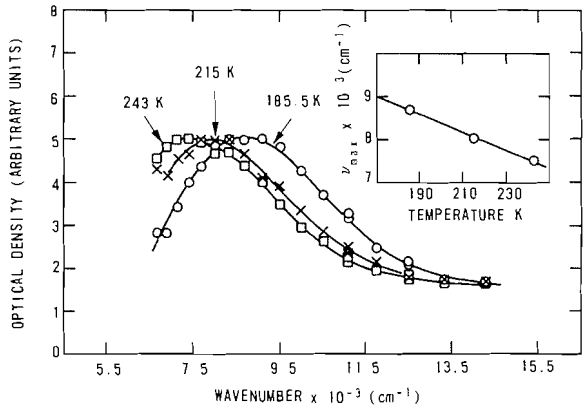

FIG. 4. Optical absorption spectra and band maxima of (Na^+, e_s^-) in MA as a function of temperature.

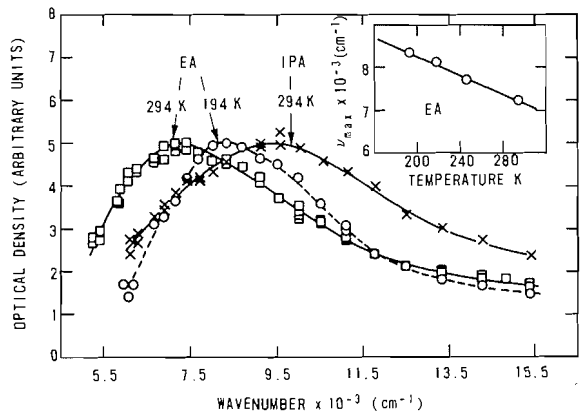

FIG. 5. Optical absorption spectra of (Na^+, e_s^-) in EA and IPA.

that the rate of formation of (Na^+, B^-) was $\geq 10\times$ the rate of decay of (Na^+, e_s^-) in the absence of B. Taking $G(Na^+, B^-) = G(Na^+, e_s^-)$ then $\varepsilon_{max}(Na^+, e_s^-)$ can be calculated. Because of solvent absorp-

[a]Interpolated from $d\nu_{max}/dK$.

tions optical densities for the ion-pair in MA were measured at 1400 nm and then corrected to ν_{max} on the basis of the band shape observed at lower temperatures. In EA and IPA comparisons were made at the appropriate band maxima of 1400 and 1100 nm, respectively.

Values for $G(Na^+, e_s^-) = G(e_s^-)$ as a function of $NaB\phi_4$ concentration are given in Fig. 3 and the spectral properties are summarized in Table 2. Using 10^{-2} M $NaB\phi_4$ solutions, ion-pair yields, as a function of temperature from 185–245 K, were found to be independent of temperature with $G\varepsilon_{max}(Na^+, e_s^-) = 5.3 \pm 0.3 \times 10^4$ and $4.5 \pm 0.3 \times 10^4$ in MA and EA, respectively.

Discussion

Optical Spectra

The spectral properties of e_s^- in each of the three amines are very similar but do show a slight decrease in ν_{max} from MA to IPA (Table 1). These values are also slightly red shifted with respect to liquid ammonia, e_{am}^- (15, 20–24), and follow a trend toward lower energies with decreasing dielectric constant of the solvent. Whereas the band widths and temperature coefficients are greater than for e_{am}^-, values for ε_{max}(amine) are significantly less than $\varepsilon_{max}(NH_3)$ resulting in comparable oscillator strengths throughout the series.

The ion-pair spectra are broadened with respect to e_s^- the extent of which increases markedly in the order MA < EA < IPA. However, in EA the band width also decreases slightly with decreasing temperature. Extinction coefficients are less than those measured for the corresponding e_s^- spectra and tend to decrease from MA to IPA resulting in a relatively constant oscillator strength throughout the series. The ion-pair spectra also have a lower temperature coefficient than is found for e_s^-. Blue shifts in $\nu_{max}(Na^+, e_s^-)$ relative to $\nu_{max}(e_s^-)$ increase markedly from MA to IPA.

These observations are consistent with the blue shift being due to an interaction between e_s^- and Na^+ in the ion-pair, the magnitude of which increases with decreasing dielectric character of the solvent and decreases with decreasing temperature. This is in accord with the marked changes in hyperfine splitting with changes in solvent and temperature (25–27). In each case the data are consistent with the "static" model and a trend toward a more "atom-like" structure or greater M^+–e_s^- interaction (and vice versa) as the temperature is raised or the solvent polarity decreased (4, 5). This situation should be contrasted with ether solutions where we concluded that a combination of both the "static" and "dynamic" model was applicable, either one of which could predominate depending on the coordinating power of the solvent (28).

In common with ether solutions (28) a relatively weak long-lived absorption, peaking at 900 nm and thought to result from reactions involving $B\phi_4^-$, is observed to grow in after the decay of the initial ion-pair absorption. Neither this absorption nor that arising from the formation of small amounts of Na^- give any significant contribution to the ion-pair spectra observed immediately after the pulse.

Yields of e_s^-

The yields of e_s^- escaping spur recombination processes show a marked temperature (13) and solute concentration dependence for EA and IPA but not for MA. As in the case of hydrocarbons (10), the solute concentration dependence for EA and IPA may be described by an empirical equation of the form

$$[2] \quad G_{e_s^-} = G(e_s^-)_{esc} + G(e_s^-)_{spur} \times (\alpha S)^{1/2}/[1 + (\alpha S)^{1/2}]$$

where $G(e_s^-)_{esc}$ and $G(e_s^-)_{spur}$ represent the yields of the solvated escaped and spur electrons, respectively; S is the concentration of the scavenger, and α is a parameter which represents the reactivity of electrons towards the solute relative to their recombination with geminate positive ions or radicals (29). The value of α was estimated experimentally at a constant

dose per pulse. By choosing acceptable values for $G(e_s^-)_{esc} \sim 0.6$ and $G(e_s^-)_{spur}$ 1.2–1.6 (13), [2] only fits the data reasonably well above 10^{-4} M scavenger concentration. Since there is a competition between the homogeneous decay of $(e_s^-)_{esc}$ and the scavenging process, [2] can be modified (11, 12) to give

$$[3] \quad G_{e_s^-} = G(e_s^-)_{esc}\,[\delta S/1 + \delta S] + G(e_s^-)_{spur}(\alpha S)^{1/2}/[1 + (\alpha S)^{1/2}]$$

In this equation, $\delta = k/k_d$ where k_d represents the first order rate constant for the homogeneous decay of $(e_s^-)_{esc}$ and k is the second order rate constant for its scavenging by solute. The solid curves drawn through the points in Fig. 3 represent the best fit of [3] using for EA and IPA, $G(e_s^-)_{total} = 2.3$ and 1.8 with $G(e_s^-)_{esc} = 0.5$ and 0.4; $G(e_s^-)_{spur} = 1.8$ and 1.4; $\alpha = 5 \times 10^4$ and 2.5×10^4 and $\delta = 261$ and 417 M^{-1}, respectively. In turn the values for $G(e_s^-)_{esc}$ were then used to deduce $\varepsilon_{max}(e_s^-)$ at 294 K from the measured values of $G_{e_s^-}\varepsilon_{max}(e_s^-) = 1.61 \times 10^4$ and 1.28×10^4 for EA and IPA, respectively, in the absence of solute.

For MA, $G_{e_s^-} = G(e_s^-)_{esc} = 2.25 \pm 0.2$ (dotted line in Fig. 3).

The above results can be compared with previous values deduced at low temperatures in the pure amines (13). To evaluate $G_{e_s^-}$ the latter study assumed $\varepsilon_{max}(e_s^-) = 3 \times 10^4\ M^{-1}\ cm^{-1}$. Correcting the low temperature results on the basis of $\varepsilon_{max}(e_s^-)$ measured in this work gives $G(e_s^-)_{total} = 2.0 \pm 0.2$, 1.7 ± 0.3, and 1.7 ± 0.3 in MA, EA, and IPA, respectively. These values can also be compared with the low temperature yields obtained in this work in the presence of 10^{-2} M $NaB\phi_4$ as an electron scavenger. Using values of $\varepsilon_{max}(Na^+, e_s^-)$ from Table 2, then $G(e_s^-)_{total} = 2.1_5 \pm 0.2$ and 2.1 ± 0.2 for MA and EA, respectively. The good agreement between the three sets of data provides a self-consistent picture for the quoted extinction coefficients and spectral properties of e_s^- and (Na^+, e_s^-) in these amines. We believe that the lack of both a solute and temperature dependence on $G(e_s^-)$ in MA reflects a much higher mobility of e_s^- relative to the competing spur decay processes than is the case for EA and IPA (13).

Finally it should be noted that $G(e_s^-)_{total}$ is not to be confused with G(total ionization) = 4.8 (13). Thus, as in the case of methanol (29), there is a yield of electrons with $G \geq 2.5$ which presumably recombine in the spur prior to solvation. The product of this recombination appears to be easily scavenged by the solvent base (13), but as yet this mechanism is not understood.

A vapor pressure method for the simultaneous determination of standard thermodynamic functions of both solutes in a ternary dilute solution

CLAUDE TREINER,[1] PIERRE TZIAS, AND MARIUS CHEMLA

Laboratoire d'Electrochimie, Université Pierre et Marie Curie - 4, Place Jussieu, 75230 Paris Cedex 05, E.R.A. 310, France

Received July 21, 1977

CLAUDE TREINER, PIERRE TZIAS, and MARIUS CHEMLA. Can. J. Chem. **56**, 844 (1978).

It is shown that from vapor pressure measurements on dilute solutions of ternary mixtures with one nonvolatile component, the standard free energy of transfer (ΔG_t^0) of both solutes from water to aqueous binary solvents can be determined simultaneously. The method is most useful in the case of volatile components. ΔG_t^0 values are discussed in particular in the case of the transfer of tetrahydrofuran, acetone, and acetonitrile from water to aqueous tetrabutylammonium bromide and urea solutions and compared to the case of the transfer of nonpolar solutes to the same aqueous solution. In each case, the free energy of transfer from water to an aqueous solution of a nonpolar molecule was negative, and introduction in that molecule of a polar group caused the free energy of transfer to be considerably less negative.

CLAUDE TREINER, PIERRE TZIAS et MARIUS CHEMLA. Can. J. Chem. **56**, 844 (1978).

On montre que l'on peut déterminer l'enthalpie libre de transfert ΔG_t^0 de deux solutés d'un mélange ternaire aqueux de l'eau à la solution binaire correspondante à partir d'une même série de mesures de pression de vapeur sur le mélange ternaire. La méthode est surtout utile dans le cas où l'un des solutés est très volatil. Les valeurs de ΔG_t^0 sont discutées en particulier dans le cas du transfert du tetrahydrofurane, de l'acétone et de l'acétonitrile de l'eau à des solutions aqueuses de bromure de tétrabutylammonium et d'urée et comparées au transfert de solutés non polaires aux mêmes solutions aqueuses. Dans chaque cas l'introduction d'un groupe polaire dans une molécule non polaire augmente considérablement l'enthalpie libre standard de transfert de l'eau aux solutions aqueuses considérées.

Introduction

The determination of standard thermodynamic quantities of transfer of solutes between two solvents has been an active field of interest for many years. In the case of ternary solutions, the standard free energy of transfer ΔG_t^0 of a nonvolatile electrolytic solute from water (usually) to a mixture of water and a co-solvent may be obtained from emf, solubility, or vapor pressure measurements (1); in the case of a volatile solute, only the solubility or the distribution method (2) have been used extensively in the limited case of sparingly soluble compounds; an interesting freezing point method has been proposed recently (3) but, of course, enthalpy and heat capacity measurements with the same accuracy are needed in order to obtain ΔG_t^0 values at temperatures different from that of the freezing point.

We propose in this paper the use of a vapor pressure method which, besides being a direct and general method, enables the determination from the same experiments on the vapor pressure variation of a solvent mixture with the addition of a nonvolatile solute, both ΔG_t^0 of the nonvolatile solute from water to the mixture of solvents and the ΔG_t^0 of the co-solvent from water to the mixture with the nonvolatile solute (which may, of course, be an electrolyte). Grunwald and Bacarella (4) have given a thermodynamic derivation which permits the determination $(\partial \bar{G}_3^0/\partial Z_1)$, the rate of change of the standard chemical potential of a nonvolatile solute with respect to solvent composition Z_1 (1 refers to water, 2 to the volatile co-solvent, and 3 to the nonvolatile component). If this quantity is obtained for several Z_1 values and the resulting curve integrated from water to the solvent mole fraction Z_1, then one obtains the quantity ΔG_t^0 $(w \rightarrow w + 2)$ (5). We shall show now how ΔG_t^0 $(w \rightarrow w + 3)$ may be computed from the same experimental data.

[1]To whom correspondence should be addressed.

Theory

The chemical potential of a volatile solute may be written as:

$$[1] \qquad \bar{G}_2 = G_2^{0*} + RT \ln P_2$$

where G_2^{0*} is the chemical potential of pure gaseous 2 in its standard state, and P_2 the partial pressure of 2. In an ideal case, one has:

$$[2] \qquad \bar{G}_2 = \bar{G}_2^{0*} + RT \ln X_2 + RT \ln K_2$$

where K_2 is Henry's law constant. We may put

$$[3] \qquad \bar{G}_2^0 = \bar{G}_2^{0*} + RT \ln K_2$$

where $\bar{G}_2^0$ is the chemical potential of 2 in the infinitely dilute reference state. In water

†Electrolyte molality in binary solvent.
‡Electrolyte molality in water.

[4] $$\bar{G}_2^0(w) = \bar{G}_2^{0*} + RT \ln K_2(w)$$

In a mixture of water and 3

$$\bar{G}_2^0(w + 3) = G_2^{0*} + RT \ln K_2(w, 3)$$

Thus

[5] $$\Delta G_t^0(w \rightarrow w + 3) = RT \ln \frac{K_2(w, 3)}{K_2(w)}$$

In a dilute solution, Henry's law may be applied, then

[6] $$\Delta G_t^0(w \rightarrow w + 3) = RT \ln \frac{PYX_2^0}{p_2^0 y^0 X_2}$$

where P, y, X_2, and p_2^0, y^0, X_2^0 are respectively the total pressure, the vapor phase composition, and the mole fraction of 2 with and without (indicated by superscript zero) the nonvolatile component 3. Finally, eq. 6 may be rewritten as:

[7] $$\Delta G_t^0(w \rightarrow w + 3) = RT \ln \frac{Py}{p^0 y^0} - RT \ln (1 - X_3)$$

where X_3 is the mole fraction of the nonvolatile component.

The precise measurement of the total pressure P above a multi-component solution is easier to obtain experimentally than the vapor-phase composition y. It has been shown previously (5) that from the variation of the total pressure of a binary volatile solvent with solute concentration X_3 it was possible to calculate the vapor-phase composition by making use of the Gibbs–Duhem equation provided the nonvolatile solute was sufficiently diluted (see ref. 5 for details of the procedure). ΔG_t^0 for the volatile solute from water to mixtures of water and the nonvolatile component (considered now as part of the solvent) can thus be calculated using eq. 7.

In order to show that our procedure is essentially correct we give the following example. In the case of a ternary solution of tetrabutylammonium bromide (*n*-Bu_4NBr)/acetone/water (6), ΔG_t^0 $(w \rightarrow w + 2)$ had been calculated for several composition Z_1 of the solvent using Grünwald's thermodynamic derivation; ΔG_t^0 $(w \rightarrow w + 3)$ has now been obtained using eq. 7 from water to a mixture of 0.1 *m* of *n*-Bu_4NBr in water using the results corresponding to the two most diluted acetone solutions, i.e. 4.910 and 7.941 wt% of acetone. ΔG_t^0 $(w \rightarrow w + 3)$ is equal to -12.2 and -12.1 cal mol^{-1} (see Table 1). This example shows that Henry's law does apply up to these acetone concentrations ($Z_2 = 0.0261$ mole fraction) in water.

A further comment is worthwhile. It can be shown by making use of the cross-differentiation identity:

[8] $$\frac{\partial^2 G}{\partial n_2 \partial n_3} = \frac{\partial^2 G}{\partial n_3 \partial n_2}$$

that in a ternary solution one has (4)

[9] $$\frac{1000}{M_{12}} \left(\frac{\partial \bar{G}_2}{\partial m_3}\right)_{Z_1} = -Z_1 \left(\frac{\partial \bar{G}_3}{\partial Z_1}\right)_{m_3} - \left(\frac{\partial \bar{G}_3}{\partial m_3}\right)_{Z_1} \frac{m_3 M_2}{M_{12}}$$

where $M_{12} = Z_1 M_1 + Z_2 M_2$ (M_1 and M_2 are the molecular weights of the two solvents), m_3 is the nonvolatile component molality. When Z_1 goes to 1 (pure water) and m_3 goes to zero, eq. 9 reduces, on the mole fraction scale, to:

[10] $$\frac{1000}{M_1} \left(\frac{\partial \bar{G}_2^0}{\partial m_3}\right)_{Z_1} = -\left(\frac{\partial \bar{G}_3^0}{\partial Z_1}\right)_{m_3} - \nu RT$$

(v = 2 in the case of a 1-1 elctrolyte and 1 for a nonelectrolyte).

Equation 10 presents a special advantage which concerns the use of the vapor pressure method for the evaluation of ΔG_t^0 $(w \rightarrow w+2)$ of a solute between two volatile solvents: $(\partial \bar{G}_3^0/\partial Z_1)$ which is the quantity defined by Grunwald and Bacarella often changes drastically near pure water (7) (Fig. 1) and the integration process used to obtain $\Delta G_t^0(w \rightarrow w+2)$ is difficult leading to relatively large errors on the integrated values; $(\partial \bar{G}_2^0/\partial m_3)_{Z_1}$ is easier to obtain through eq. 7 and can then be used to calculate $\partial \bar{G}_3^0/\partial Z_1$ for $Z_1 = 1$, which will then be used for the integration process of $\partial \bar{G}_3^0/\partial Z_1$ with respect to Z_1.

Equation 10 also shows that when both the solute and the co-solvent are very diluted with respect to water than the energy of interaction of 2 with water and 3 is equal to the energy of interaction of 3 with water and 2. This conclusion is equivalent to that deduced experimentally by Desnoyers *et al.* (8, 9) for enthalpies, volumes, and heat capacities, and theoretically by the same authors using pair interaction parameters of the McMillan–Mayer formalism (10).

Results and Discussion

We have used previously published vapor pressure data of *n*-Bu_4NBr, urea, NaCl, and thiourea in water–tetrahydrofuran, water–acetone, and water–acetonitrile mixtures (5–7, 11). $\Delta G_t^0(w \rightarrow w+3)$ has been calculated for acetone, tetrahydrofuran, and acetonitrile from water to 0.1 *m* *n*-Bu_4NBr, urea, NaCl, and thiourea as some literature values are available for related compounds for the transfer to the same solvent molality. Note that in the case of the electrolyte solutions $\Delta G_t^0(w \rightarrow w+3)$ was assumed to be linear with electrolyte concentration up to 0.1 *m* (2). The results are presented in Table 2 together with some pertinent literature values (2, 12).

Comparison of $\Delta G_t^0(w \rightarrow w+3)$ for the nonpolar alkanes and the polar molecules shows that the transfer to the aqueous *n*-Bu_4NBr solutions becomes less favorable in the latter case. The effect of a CH_2 group is to decrease $\Delta G_t^0(w \rightarrow w+3)$ by about 8 cal mol^{-1}, whereas introduction of a polar group increases $\Delta G_t^0(w \rightarrow w+3)$ by about 30 cal mol^{-1}. Obviously a repulsion term predominates in the interaction energy between a polar and a nonpolar group.

In the case of the transfer of THF and *n*-propane to aqueous urea solutions, the same behavior is observed; however, for such small differences to be discussed, the shape of the molecules should also be taken into account as was shown convincingly by Jolicoeur and Lacroix (13) for the transfer of branched and linear ketones from light to heavy water. Also it is noteworthy that the dependence of $\Delta G_t^0(w \rightarrow w+3)$ on temperature is the same for the polar and the nonpolar molecule for the transfer to the same 0.1 *m* aqueous urea solution; $\Delta H_t^0(w \rightarrow$

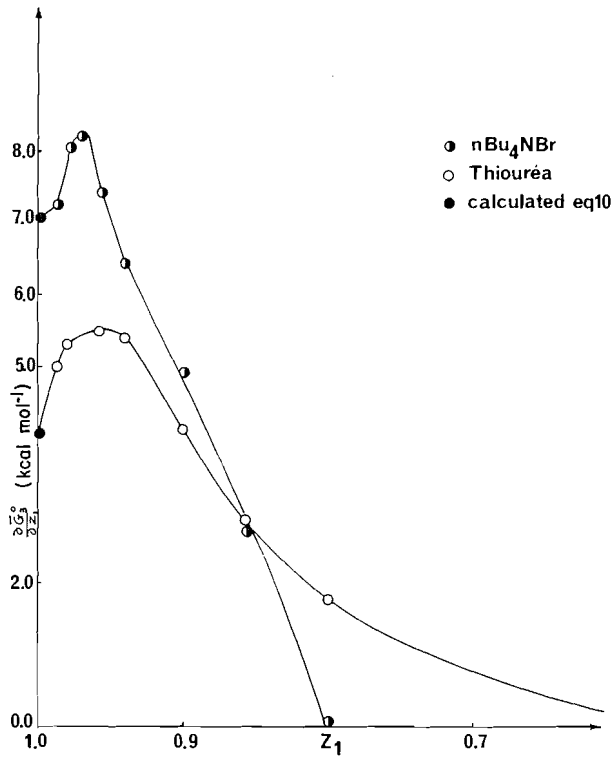

FIG. 1. Rate of change of the standard chemical potential of a solute with solvent composition: n-Bu_4NBr (6) and thiourea (11) in water–tetrahydrofuran mixtures at 298.15K.

$w + 3$) is positive in both cases and of the same order of magnitude, i.e. $+35$ cal mol^{-1} for n-propane and $+20$ cal mol^{-1} for THF.

In conclusion the proposed method for the determination of accurate standard free energy of transfer of polar, soluble molecules in aqueous media should be especially useful in the case of the study of quite volatile solvents.

Polyol–protein interactions. Thermodynamical evidence for a selective solvation of glycerol and hexitols by aqueous β-lactoglobulin

GIUSEPPA DIPAOLA[1] AND BERNARD BELLEAU[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received July 29, 1977

GIUSEPPA DIPAOLA and BERNARD BELLEAU. Can. J. Chem. **56**, 848 (1978).

Apparent specific heat capacities and volumes of the protein β-lactoglobulin have been determined under a variety of solute–solvent and solvent–cosolvent compositions. These quantities were derived from measurements of volumetric specific heats and densities with a flow microcalorimeter and flow densimeter. The effect of homologous polyols on the isothermal denaturation of the protein by urea at 25°C was investigated. The results suggest that polyol binding on the protein is sensitive to structural effects, maximum discrimination being exerted in favor of glycerol and its doubles, the hexitols.

GIUSEPPA DIPAOLA et BERNARD BELLEAU. Can. J. Chem. **56**, 848 (1978).

On détermine les volumes et les capacités calorifiques spécifiques apparentes de la protéine β lactoglobuline dans diverses compositions de soluté–solvant et de solvant–cosolvant. On a calculé ces quantités à partir de mesures de chaleur spécifique volumétrique et de densité faisant appel à un microcalorimètre à écoulement et à un densimètre à écoulement. On a étudié l'effet de polyols homologues sur la dénaturation isotherme de la protéine par l'urée à 25°C. Les résultats suggèrent que les capacités de liaison du polyol sur la protéine sont sensibles à des effets de structures et qu'une discrimination maximale est excercée en faveur du glycérol et de ses analogues doubles, les hexitols.

[Traduit par le journal]

Introduction

It is well known that urea, a statistical structure breaker in water, causes proteins to unfold (1). In marked contrast, aqueous glycerol, which like aqueous urea displays virtually ideal behavior, has a strong stabilizing effect on many proteins (2, 3). Other polyols share to some extent this remarkable property of glycerol and it has been proposed that the stabilizing effects may be mediated through alteration of the water structure (4) and/or the induction of small conformational changes (5). However, we have recently shown that glycerol behaves as a weak structure breaker in water, as judged from the sign of the heat capacities of transfer of a variety of hydrophobic probes (from water to aqueous glycerol) (6). On that basis, we suggested that binding of glycerol on protein nucleation sites for unfolding would account best for the stabilization effects on the native conformation (6). Accordingly, one may expect the nucleation binding sites to be 'guest' selective (through selective solvation) in view of the widespread structural discriminatory capabilities of protein binding domains. Available information is not inconsistent with this expectation (7).

The present work provides evidence that polyol binding on the model protein, β-lactoglobulin (bovine) is indeed markedly sensitive to structural effects, maximum discrimination being exerted in favor of glycerol and its doubles, the hexitols.

Experimental

Heat capacities were measured with a flow microcalorimeter (8) which can detect differences between the volumetric specific heat of a solution (6) and that of a reference solvent (σ_0) to $\pm 3 \times 10^{-5}$ J K^{-1} cm^{-3}, during a temperature rise of 2°C and a liquid flow rate of 0.80 cm^3 min^{-1}. The overall precision on $\Delta\sigma/\sigma_0$ is 0.3% (9). Densities were determined with a flow digital densimeter (10) sensitive to $\pm 3 \times 10^{-6}$ g cm^{-3}, connected in series with the microcalorimeter. Thermostatic control of the instrument was achieved with a closed-loop bath (11) whose stability was better than 0.001°C. Weight specific heats (C_p and C_p^0) (J K^{-1} g^{-1}) were calculated from the volumetric specific heats (σ and σ_0), thus

$$[1] \qquad C_p/C_p^0 = (\sigma/\sigma_0)\,(d_0/d)$$

All experimental measurements of σ/σ_0 were determined at least in duplicate. All heat capacity measurements were made at 25°C. Because of the experimental setup, density measurements were obtained at 24.00°C. The values for C_p and d_0 of pure water were taken as 4.1793 J K^{-1} g^{-1} (12) and 0.997299 g cm^{-3} (13). The error introduced by taking the ratio of densities at 24 rather than 25°C is negligible.

By analogy with apparent molal quantities of simple solutes in solution, an apparent specific heat capacity $\bar{C}_p$ (J K^{-1} g^{-1})[3] and apparent specific volume $\bar{V}$ (cm^3 g^{-1}) (14) can be defined for macromolecular solutes (such as proteins) as follows:

$$[2] \qquad \bar{C}_p = [(1000 + W_p)C_p - 1000\,C_p^0]/W_p$$

and

$$[3] \qquad \bar{V} = [1 - (d - d_0/C_2]d_0$$

where W_p is the number of grams of protein per kilogram solvent and C_2 is the number of grams of protein per millilitre of solution. All other symbols have their usual meaning (6).

All solutions were prepared by weight with doubly-distilled deionized water, and used the same day. Unless otherwise specified, the protein concentration was 0.2% (g/100 ml). All data reported here were obtained after a 10-min exposure of the protein to solvent. Salt-free solutions were used after it was ascertained that the presence of 0.15 *m* NaCl had no effect on the $\Delta\bar{C}_p$ values for isothermal denaturation.

Crystalline β-lactoglobulin was from Sigma (lot No. 15C-0188). The other reagents which met acceptable standards of purity were urea (Schwarz-Mann, Ultra Pure) and D-sorbitol (Sigma). The source of the other polyols has been reported previously (15).

Results and Discussion

Pace and co-workers have shown (16, 17) that urea-induced unfolding of β-lactoglobulin is completely reversible and best represented by a two-state model. The observed $\Delta\bar{C}_p$ for the transition is consistent with the involvement of hydrophobic hydration, as is the case for other proteins (18). We have examined the effects of the polyols listed in Table 1 on this urea-induced transition by measuring the heat capacity changes ($\Delta\bar{C}_p$) accompanying the shift from the folded to the unfolded form of β-lactoglobulin (25°C, p*H* 7).

A typical curve for isothermal unfolding of β-lactoglobulin in the presence of urea is shown in Fig. 1 where dimer dissociation at about 2 *m* urea (plateau at 1.80 ± 0.2 J K^{-1} g^{-1}) gives rise to a minor transition, as previously shown by Pace and co-workers (16, 17); in 10 *m* urea, unfolding virtually reaches a maximum (16, 17). The desired $\Delta\bar{C}_p$ value for unfolding was obtained by subtracting $\bar{C}_p$ in 3 *m* urea from $\bar{C}_p$ in 12 *m* urea.[4] In pure water, the observed $\Delta\bar{C}_p$ (unfolding) in the presence of urea amounted to 10.80 ± 0.36 kJ K^{-1} mol^{-1}, a value in good agreement with the van't Hoff quantity of 9 kJ K^{-1} mol^{-1} reported by Pace and co-workers (16, 17).

The effects of various polyols on $\Delta\bar{C}_p$ (unfolding) (in 10 *m* urea) are summarized in Table 1.

Apart from ethylene glycol, all the polyols examined decrease $\Delta\bar{C}_p$ (unfolding) (by as much as 48% with 2.4 *m* glycerol).[5] Viscosity effects cannot explain the variations in $\Delta\bar{C}_p$ (unfolding) because equimolal concentrations of glycerol and ethylene glycol are essentially equiviscous (19, 20) (ratio of 1.056) at 25°C, yet the former is from four to five times more effective in lowering $\Delta\bar{C}_p$ (unfolding). Specific interactions between urea and the polyols were also ruled out as a possible contributing factor because in 9 *m* urea, the heat capacities of 0.5 *m* polyols are a perfect linear function of the number of hydroxyl groups (or chain length) (21).

When the percentage decrease in $\Delta\bar{C}_p$ (unfolding) caused by low polyol concentrations (0.6 *m*) is plotted against the number of hydroxyl groups (Fig. 2), one observes that glycerol and its doubles, the hexitols, form a separate group displaying enhanced activity against unfolding, glycerol being the most effective on a weight basis.

A complete understanding of the mechanisms underlying the above phenomena is impossible at this time because of the limited amount of work that has been done with polyhydric alcohols – water mixtures. Nevertheless, a number of observations should be kept in mind if one hopes to rationalize

[4]Complete set of tabular data for d_0/d, σ/σ_0, $\bar{C}_p$, and $\bar{V}$ is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]These changes in $\Delta\bar{C}_p$ originate only from a lowering of the apparent specific heat capacity of the unfolded state, the native state values being unaffected by the polyols.

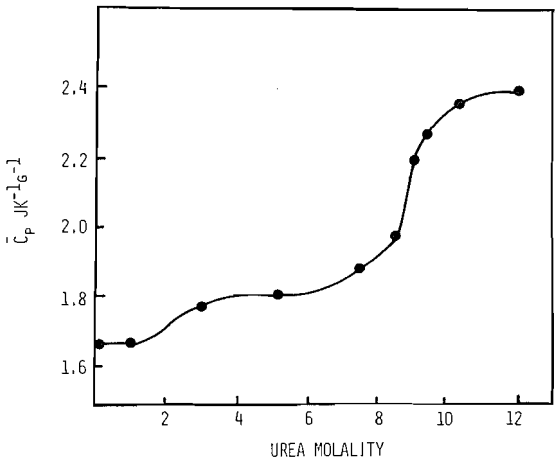

FIG. 1. Isothermal unfolding at 25°C, p*H* 7.0, of β-lactoglobulin (0.2 g% aqueous solution) as measured by the change in heat capacity vs. urea concentration. The $\bar{C}_p$ values are accurate to ± 0.02 J K^{-1} g^{-1}. The minor transition reflects dissociation into monomers.

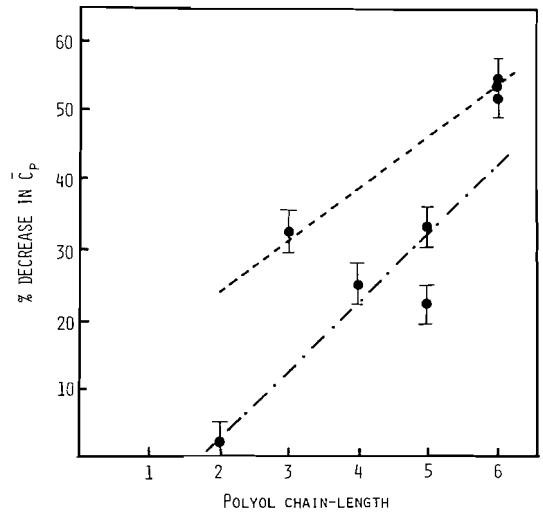

FIG. 2. Percentage decrease in heat capacity of unfolded β-lactoglobulin vs. polyol chain length at 0.57–0.61 *m* (~5–10% by weight) concentrations of polyols. The broken lines represent visual fits.

the results in the future. The idea that the widespread occurrence of glycerol solvation sites on proteins (3) might have fundamental structural significance is worth retaining. In this connection, it may be useful to examine the possible relevance of Warner's models for water–polyol and water–peptide complementation (22). This author has pointed out that glycerol can adopt a conformation where the 1,3-oxygens are spaced by 4.8 Å (parallel projections). This spacing is thus compatible with the second nearest neighbor distance between the oxygens of liquid water (in a hypothetical ice lattice). A similar complementarity was shown to exist for peptide–water interactions, the bonding distances between the C=O and —NH— groups also corresponding to the second nearest neighbor oxygen distance in water. The above results with β-lactoglobulin may be partly relevant to Warner's theory as far as the 'locking' effect of glycerol on the conformation of strategic peptide bonds (or nucleation sites for unfolding) is concerned. It is pertinent to note that among several solvents of extreme polarities, water is uniquely the most efficient in 'freezing' rotation about the amide bond (23), a property which is magnified by the addition of glycerol (24).

Phlegmarine, a likely key intermediate in the biosynthesis of the Lycopodium alkaloids

LOUIS NYEMBO, ANDRÉ GOFFIN, CLAUDE HOOTELÉ,[1] AND JEAN-CLAUDE BRAEKMAN[1]

Service de Chimie Organique, Faculté des Sciences, Université Libre de Bruxelles, 1050 Bruxelles, Belgium

LOUIS NYEMBO, ANDRÉ GOFFIN, CLAUDE HOOTELÉ, and JEAN-CLAUDE BRAEKMAN. Can. J. Chem. **56**, 851 (1978).

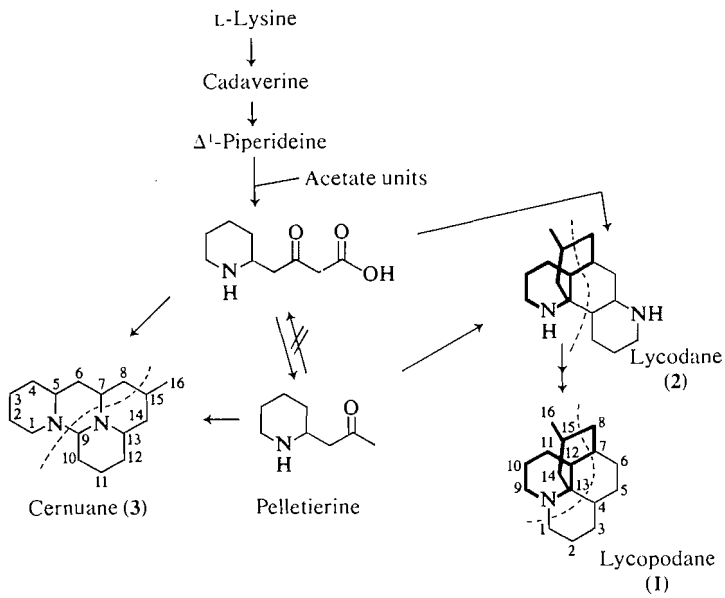
The isolation and structure determination of four novel bases (**6**, **7**, **8**, **9**), representative of a new type of Lycopodium alkaloids, are reported. The phlegmarine skeleton is proposed to be a key intermediate in the biosynthesis of the Lycopodium alkaloids.

LOUIS NYEMBO, ANDRÉ GOFFIN, CLAUDE HOOTELÉ et JEAN-CLAUDE BRAEKMAN. Can. J. Chem. **56**, 851 (1978).

Dans le présent travail nous décrivons l'isolement et la détermination de structure de quatre alcaloïdes tricycliques (**6**, **7**, **8**, **9**) représentatifs d'un type nouveau d'alcaloïdes des Lycopodium. Le squelette phlegmarine est proposé comme intermédiaire clé dans la biosynthèse des alcaloides des Lycopodium.

Lycopodane (**1**), lycodane (**2**), and cernuane (**3**) are the three main skeletons from which the structure of most of the Lycopodium alkaloids can be derived (1, 2). During the study of the biosynthesis of these alkaloids, it was found that acetate, malonate, lysine, cadaverine, Δ^1-piperideine, and pelletierine serve as precursors of lycopodine (**4**) (3–8) and cernuine (**5**) (9, 10). Radioactivity from all except pelletierine is incorporated in such a manner that each of the two 'halves' of lycopodine and cernuine (i.e. C-1 to C-8 and C-9 to C-16) contains 50% of the label. Unexpectedly, pelletierine does not enter the C-1 to C-8 chain while it enters the other one. To explain this apparent anomaly, a biogenetic model has been outlined (7, 10). This model is depicted in Scheme 1. Nevertheless, it could not be corroborated experimentally (8), thus implying that modifications are required.

In this paper, we wish to report the isolation and structure determination of four novel alkaloids, representative of a new type of Lycopodium alkaloids. The structure of these compounds led us to reconsider the problem of the biosynthesis of the Lycopodium alkaloids and to propose a new scheme



SCHEME 1. The biosynthesis of lycopodine and cernuine. A synthesis of the hypothetical pathways proposed in refs. 7 and 10.

to explain the asymmetrical incorporation of pelletierine.

Together with lycopodine,[2] anhydrolycodoline,[2] β-dihydrolycopodine,[2] acetyl-β-dihydrolycopodine,[2] lycodoline,[2] and lycoflexine (11), we have isolated from *L. clavatum* var. *borbonicum* the minor base **6** ($C_{19}H_{34}N_2O$ by hrms). The ir and nmr spectra of **6** suggest the presence of an *N*-acetyl, an *N*-methyl, and a secondary methyl group.

On the other hand, we have isolated from *L. phlegmaria*, together with lycodoline,[2] anhydrolycodoline,[2] lycoflexine (11), lycopodine,[2] and gnidioidine (12), two minor alkaloids, compounds **7** and **8**, structurally related to **6**. Indeed by acetylation, compound **7** yields a monoacetyl derivative identical with compound **6**; by methylation, following the Eschweiler-Clarke procedure (15), the *N,N*-dimethyl derivative **10** is obtained. This latter compound is also obtained by methylation of **8** which could also be acetylated to the *N,N*-diacetyl derivative **11**.

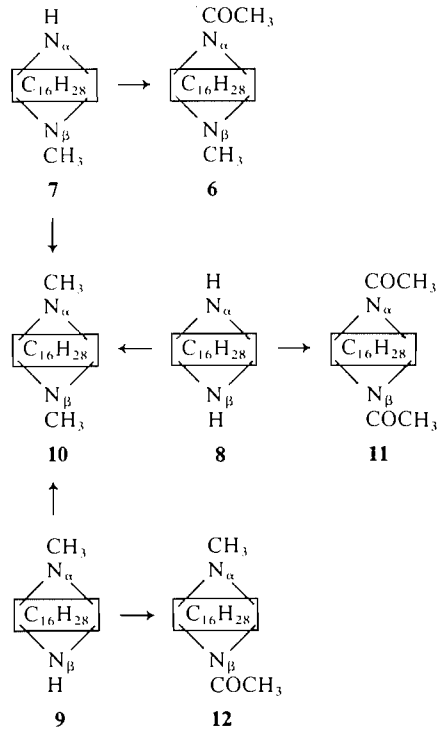
Finally, from *L. cernuum*, we have isolated a fourth minor base, compound **9**, isomeric with **7**. When submitted to an acetylation reaction, **9** yields the monoacetyl derivative **12** isomeric with **6**. By treatment with formaldehyde in the presence of formic acid, **9** is transformed into the *N,N*-dimethyl derivative **10**.

All these facts can be rationalized by considering that the four naturally occurring compounds **6–9** all possess the same skeleton **8**, for which the name phlegmarine was coined and differ only by their nitrogen atom substituents (Scheme 2). The molecular formula of phlegmarine (**8**, $C_{16}H_{30}N_2$) implies three points of unsaturation. Since there is no evidence for the presence of multiple bonds, compounds **6–9** must be tricyclic.

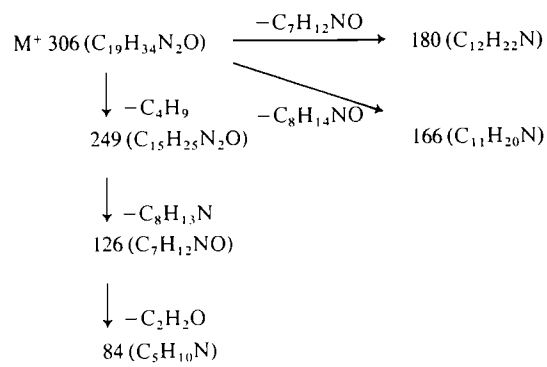
The elementary composition of the more characteristic fragment ions of **6** has been determined by high resolution mass spectrometry and the genetic relationship existing between these fragment ions established by mass analyzed ion kinetic energy (mike) spectrometry (13, 14) as summarized in Scheme 3.

From these data it follows that the two fragment ions appearing at *m/e* 166 and 180 both originate from the molecular ion by an unimolecular decomposition and differ from each other only by a methylene group. Moreover, the fragment ions at *m/e* 180 and 126 account for all the atoms present in the molecular ion. A way to rationalize these facts is to consider that **6** is constituted of a $C_7H_{12}NO$ unit attached to a $C_{11}H_{20}N$ unit through a methylene bridge as depicted in Scheme 4. In such a case, rupture *a* would generate the fragments 180 and 126 whereas rupture *b* would explain the fragment 166.

The composition of the $C_{10}H_{17}NCH_3$ unit is reminiscent of 7-methyl-*N*-methyldecahydroquinoline, a partial structure frequently encountered in the Lycopodium alkaloids (see Scheme 1), while the $C_5H_9NCOCH_3$ unit is compatible with *N*-acetylpiperidine.



SCHEME 2. Chemical intercorrelations between compounds **6–9**.



SCHEME 3. Genetic relationship between the characteristic fragment ions of **6**, obtained by mike spectrometry.

[2]Information about the structure, chemistry, and origin of these alkaloids may be found in refs. 1 and 2.

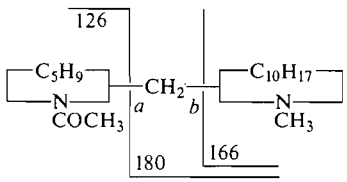
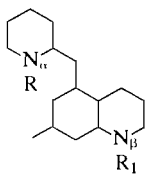


SCHEME 4. Partial structure of **6**.

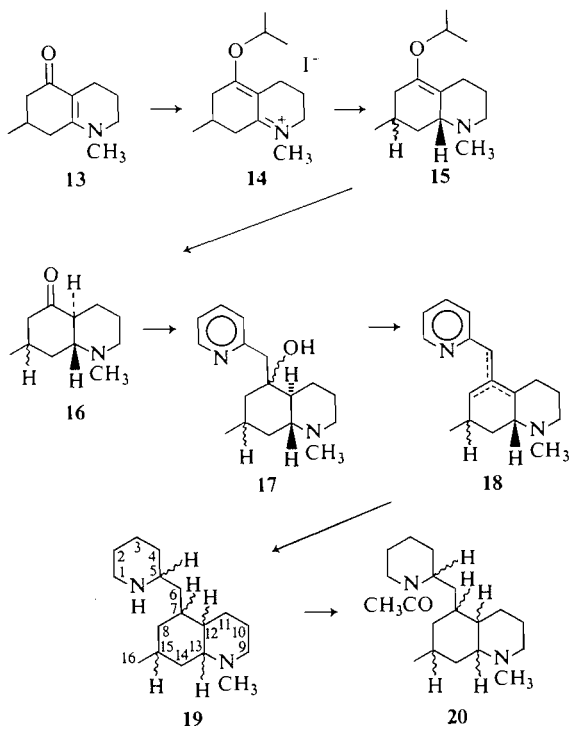
When bringing together all these assumptions and taking into account the biosynthetic origin of the Lycopodium alkaloids, the attractive structures **6–9** may be proposed for phlegmarine (**8**) and its con-



6	R = $COCH_3$, R_1 = CH_3	N_α-Acetyl-N_β-methylphlegmarine
7	R = H, R_1 = CH_3	N_β-Methylphlegmarine
8	R = H, R_1 = H	Phlegmarine
9	R = CH_3, R_1 = H	N_α-Methylphlegmarine

geners. To validate this hypothesis we decided to synthesize compound **6**, or at least a stereoisomer of **6**, following the reactional pathway depicted in Scheme 5.

The starting compound **13** was prepared according to the procedure described by Dugas *et al.* (15) for the synthesis of 12-epilycopodine. Owing to the



SCHEME 5. Scheme of synthesis of **20**.

failure of the direct reduction of **13** into **16** by catalytic hydrogenation, sodium in ammonia or hydride reduction, this conversion was achieved by borohydride reduction of the immonium salt **14**, followed by acidic hydrolysis. This afforded the homogeneous (tlc and gc) aminoketone **16** which could be isolated as its crystalline hydrochloride with an overall yield of 55%. The *trans*-ring fusion attributed to **16** follows finding that it did not epimerize under strongly basic conditions (16). The stereochemistry of the methyl group was not established.

Treatment of **16** with 2-picolyllithium furnished a mixture of two alcohols as observed by gc and tlc. The more polar derivative in tlc crystallized out of a pentane solution and its spectral properties are in good agreement with the structure **17** (see Experimental). By gc–ms it was found that the less polar constituent had the same mass spectrum, suggesting that these two alcohols are epimeric at C-7.

Dehydration of the mixture of the two alcohols with $SOCl_2$ yielded a mixture of three new compounds in the ratio of 29:10:61, as determined by gc. Moreover, it was found by gc–ms that each of these derivatives presents a molecular ion at *m/e* 256 suggesting that they are isomeric anhydro derivatives of **17**. This mixture was without further purification hydrogenated to a new mixture of two perhydro compounds (M^+ 294) which was directly treated with acetic anhydride in pyridine to obtain the corresponding acetates. The gc of these acetates shows two peaks, in the approximate ratio of 50:50, which were subsequently separated using preparative gc. The spectral properties of the acetate having the shorter retention time are in good agreement with structure **20** (see Experimental). The mass spectrum of the second peak was found to be identical with that of the former one, but the nmr spectrum indicates that it is still a mixture, probably of two or more stereoisomers of **20**.

These synthetic compounds were found to be different by tlc and gc from the natural compound **6**. However, the conventional mass spectra of all of them, as well as the mike (13, 14) and collision induced decomposition (cid) spectra (17) of their respective ions at *m/e* 306, 249, 180, 166, and 126 are superimposable. This clearly suggests that they have the same skeleton and that they are diastereoisomers.

In the introduction we pointed out that the biogenetic model outlined in Scheme 1 to explain the asymmetrical incorporation of pelletierine into the Lycopodium alkaloids, could not be corroborated experimentally. The discovery of compounds whose structure derives from the phlegmarine skeleton, leads us to suggest an alternative model in which this entity appears as a key intermediate.

Indeed, it is tempting to assume that the phleg-

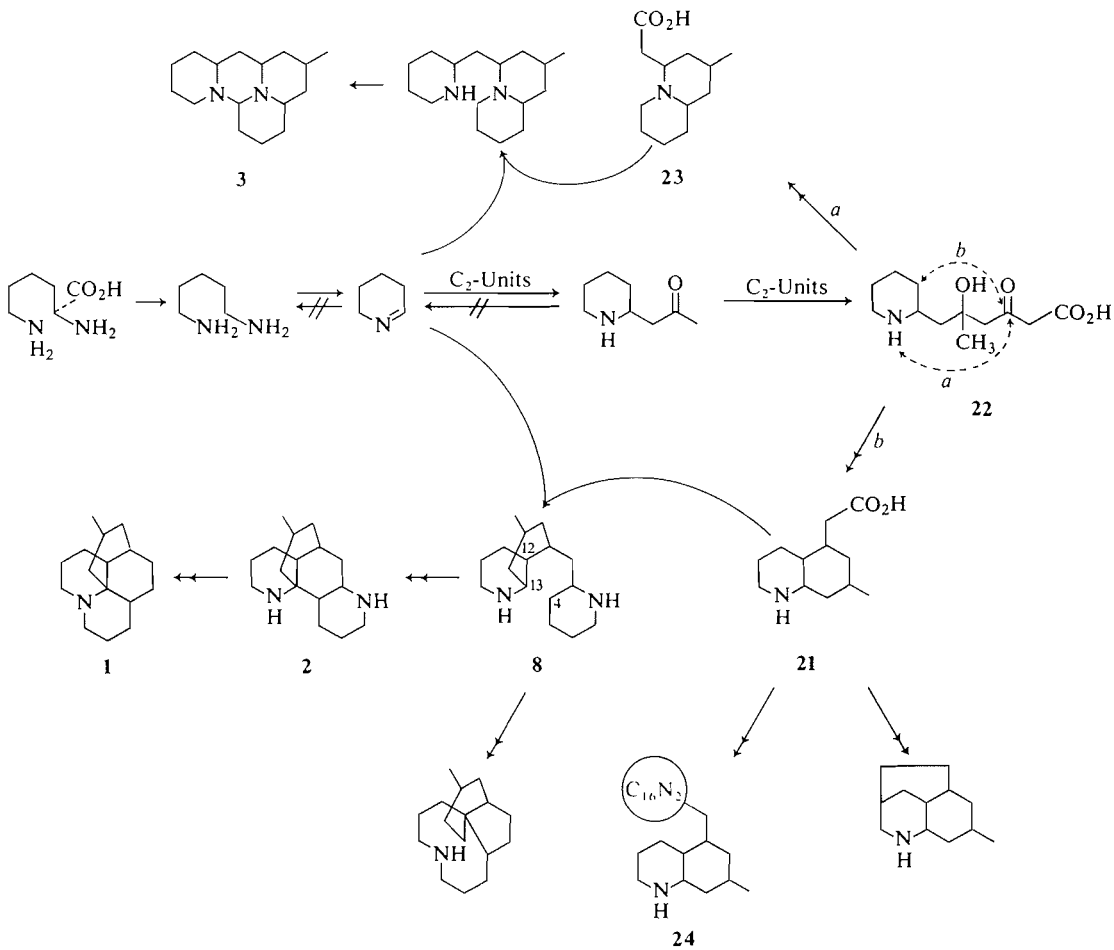
For personal use only.



SCHEME 6. The biogenesis of the Lycopodium alkaloids. A new scheme.

marine type alkaloids derive from the condensation of Δ^1-piperideine with intermediate **21**, this latter arising from the condensation of two C_2-units with pelletierine followed by an internal cyclization (Scheme 6, path *b*). From the key intermediate **8** it is easy, by formation of a bond between C-4 and C-13, to build up the closely related lycodane and lycopodane skeletons, while the fawcettimane skeleton is readily obtained by formation of a bond between C-4 and C-12 and rupture of the C-13—N bond.

Furthermore: (*i*) the formation of cernuane can be imagined to be issued from the substituted quinolizidine **23**, this latter intermediate resulting from the alternative internal cyclization of **22** (Scheme 6, path *a*); (*ii*) it is also possible to derive the lucidulane skeleton as well as the partial structure **24** of the $C_{27}N_3$ Lycopodium alkaloids (18)[3] from the key intermediate **8**.

It is obvious, that the pathway proposed here is, for the clearness of the scheme, only a coarse description of a possible biosynthetic pathway for the Lycopodium alkaloids, and that the represented intermediates are not necessarily on the main route, for instance intermediates having other states of oxidation are also conceivable.

[3]A. Goffin, C. Hootelé, and J.-C. Braekman. Unpublished results.

Experimental

The general experimental details are the same as those previously described (19).

Isolation of the Alkaloids

The procedure described in ref. 20 was used for all the extractions. The extraction of 1.25 kg of powdered *L. clavatum* var. *borbonicum* collected on the Biano plateau, Shaba, Zaïre, yielded 4.5 g (0.36%) of a crude alkaloid mixture. This mixture was fractionated by dry column chromatography (alumina, activity III, 1.60 m; eluent: ethyl acetate); the column was cut up into 10 fractions and the constituents were eluted from the support with MeOH. The numbering of the fractions starts from the front of the solvent. Fractions 1 + 2 yielded 95 mg of anhydrolycodoline (ir, R_f, gc, ms, and nmr). Fractions 3 + 4 (1.33 g) were submitted to a counter-current distribution ($CHCl_3$ – McIlvaine buffer p*H* 6.1; 23 transfers); tubes 7–17 yielded, after crystallization from acetone, 0.85 g of pure lycopodine (ir, R_f, gc, ms, nmr). Fractions 5 + 6 + 7

$C_7H_{12}NO$	126.0918	126.0921	37
$C_5H_{10}N$	84.0813	84.0810	27

(0.622 g) were chromatographed over alumina. Elution with increasing amounts of ethyl acetate in benzene furnished lycopodine (145 mg), lycoflexine (20 mg; ir, ms, gc, nmr, R_f) and β-acetyldihydrolycopodine (150 mg; ir, ms, gc, nmr, R_f). Fractions 8 + 9 (0.67 g) were submitted to a counter-current distribution ($CHCl_3$ – McIlvaine buffer p*H* 7.45; 23 transfers). Tubes 7–15 yielded, after crystallization from acetone, 80 mg of pure lycodoline (mp, ir, ms, R_f, gc, nmr), tubes 16–23 β-dihydrolycopodine (145 mg; mp, R_f, gc, ir, ms, nmr), and tubes 1–14, 43 mg of N_α-acetyl-N_β-methyl-phlegmarine (**6**)[4] further purified by chromatography over alumina (oil $[\alpha]_D$-($CHCl_3$) −11° (*c* 0.7); ir (film) $\nu_{C=O}$: 1640 cm^{-1}; nmr δ: 0.90 (d, 3H, 0.90 *J* = 7 Hz), 2.06 (s, 3H), 2.45 ppm (s, 3H); ms: see Table 1.

The extraction of 425 g of powdered *L. phlegmaria* L., collected at Yangambi, Zaïre, yielded 1.12 g (0.25%) of a crude alkaloid mixture. This mixture was dissolved in 100 ml of $CHCl_3$ and the solution extracted twice with 200 ml of McIlvaine buffer p*H* 6.0. The organic layer furnished after evaporation 420 mg of a brownish residue (F_1). The aqueous layer was made basic with aqueous ammonia and extracted with $CHCl_3$; evaporation of the $CHCl_3$ solution gave 650 mg of a brownish residue (F_2).

From fraction F_1 were isolated, after counter-current distribution ($CHCl_3$ – McIlvaine buffer p*H* 5.3, 23 transfers) and chromatography over alumina, 7 mg of anhydrolycodoline (ir, gc, ms, R_f) and 64 mg of lycoflexine (ir, R_f, nmr, gc, ms).

Fraction F_2 was submitted to a counter-current distribution ($CHCl_3$ – McIlvaine buffer p*H* 7.2, 23 transfers); tubes 2–16 yielded 323 mg of a mixture which was chromatographed over alumina. Elution with $CHCl_3$ yielded 22 mg of gnidioidine (ir, R_f, gc, ms) and 72 mg of crystalline lycodoline (ir, R_f, gc, mp, ms). The mass spectrum of the crude contents of tubes 17–23 (330 mg) showed the presence of at least two products (M^+ at 250 and 264 mu). A 150 mg portion of this mixture was acetylated (acetic anhydride – pyridine) and after several chromatographies over alumina furnished 15 mg of N_α-acetyl-N_β-methylphlegmarine (**6**) identical (ir, R_f, nmr, ms, gc) with the sample isolated from *L. clavatum* and 40 mg of *N,N*-diacetylphlegmarine (**11**)[4] (oil, ir: $\nu_{C=O}$ at 1640 cm^{-1}; nmr δ: 0.9 (d, 3H, *J* = 6 Hz), 2.05 (s, 3H), and 2.06 ppm (s, 3H); ms: 334 (M^+, 11), 292 (3), 291 (17), 209 (11), 208 (29), 195 (5), 194 (7), 166 (3), 152 (6), 150 (6), 140 (3), 138 (25), 127 (28), 126 (100), 112 (4), 98 (5), 97 (4), 96 (5), 85 (7), 84 (92), 83 (8), 82 (6), 81 (5).

A 180 mg portion of the same mixture was methylated using the procedure of Eschweiler-Clarke (15). After the usual work-up and chromatography on alumina, 110 mg of *N,N*-dimethylphlegmarine (**10**)[4] was obtained (oil; $[\alpha]_D(CHCl_3)$ −21° (*c* 1.3); ir ν_{N-CH_3}: 2780 cm^{-1}; nmr δ: 0.93 (d, 3H, *J* = 7 Hz), 2.26 ppm (s, 6H); ms: 278 (M^+, 30), 277 (4), 264 (3), 263 (9), 221 (8), 181 (10), 180 (34), 167 (5), 166 (16), 99 (75), 98 (100), 97 (26), 96 (24).

The crude alkaloid mixture from a sample of *L. cernuum* collected on the Biano plateau, Shaba, Zaïre, was dissolved in $CHCl_3$ and extracted with McIlvaine buffer of p*H* 7. A part of the extract (90 mg) which showed in the ms a molecular ion at 264 mu was acetylated. The residue obtained after the usual work-up furnished after chromatography on alumina 43 mg of N_α-methyl-N_β-acetylphlegmarine (**12**)[4] (oil; $[\alpha]_D(CHCl_3)$ −60° (*c* 0.41)); ir ν_{N-CH_3}: 1640 cm^{-1}; nmr δ: 0.9 (d, 3H), 2.07 (s, 3H), 2.27 ppm (s, 3H); ms: 306 (M^+, 3), 291 (2), 264 (2), 263 (5), 250 (2), 249 (12), 206 (3), 181 (4), 180 (20), 167 (15), 166 (100), 164 (6), 127 (4), 126 (37), 124 (5), 123 (6), 98 (19), 97 (14), 85 (2), 84 (27).

After methylation and fractionation by chromatography on alumina 100 mg of the same extract gave 50 mg of *N,N*-dimethylphlegmarine (**10**).

Synthesis of Compounds ***20***

Compound **14** was prepared according to the procedure described (15).

Ketone ***16*** *from the Immonium Salt* ***14***

A 1.37 g portion of immonium salt **14** was dissolved in 20 ml of methanol and treated with 0.2 g of $NaBH_4$. The reduction is instantaneous. After usual work-up, 1.1 g of the crude vinyl ether **15** was obtained and left for 12 h at room temperature in 100 ml of 10% aqueous HCl. The solution was made basic by addition of aqueous ammonia and extracted with chloroform. Evaporation of the solvent yielded 470 mg of a yellowish oil which was dissolved in anhydrous ether and treated with gaseous HCl. The precipitate was crystallized twice from acetone–ether: **16**·HCl; mp 181°C; ir $\nu_{C=O}$: 1710 cm^{-1}; nmr δ: 1.14 (d, 3H, *J* = 6 Hz), 2.88 (d, 3H, *J* = 5 Hz), 3.49 ppm (m, 1H); ms: 181 (M^+, 12), 139 (40), 124 (42), 97 (100), 82 (13). *Anal.* calcd. for $C_{11}H_{20}NOCl$: C 60.68, H 9.26, Cl 16.28; found: C 60.81, H 9.25, Cl 16.65.

The ketone **16** is recovered unchanged (tlc, gc) after treatment in equilibrating conditions: reflux in MeONa–MeOH for 4 h.

Condensation of Ketone ***16*** *with 2-Picolyllithium*

To 233 mg of finely divided lithium was added dropwise and under nitrogen a solution of 5.03 g of bromobenzene in 50 ml of anhydrous ether. The mixture was stirred until the disappearance of lithium was complete; 4.8 g of 2-picoline was then introduced slowly. Stirring was maintained for 30 min after addition. The resulting solution was added dropwise to an ethereal solution (30 ml) of **16** (520 mg). After stirring (30 min), the mixture was poured on crushed ice and extracted with ether. Evaporation of the solvent yielded 663 mg of a brownish oil which was chromatographed over alumina (eluent: ether–MeOH 9:1). The fractions containing the two epimeric alcohols **17** were combined, evaporated to dryness (568 mg), and dissolved in pentane. Crystals of one isomer separate on standing (mp 128°C; ir (KBr) ν_{OH}: 3300 cm^{-1}, ν_{N-CH_3}: at 2780 cm^{-1}, $\nu_{C=C}$: 1600 cm^{-1}; δ: 0.82 (d, 3H, *J* = 6 Hz) 2.30 (s, 3H), 2.48 (d, 1H, *J* = 14 Hz), 2.82 (d, 1H, *J* = 8 Hz), 5.23 (s, 1H, disappearing on treatment with D_2O), 7.14–8.47 ppm (m, 4H); ms: 274 (M^+, 13), 255 (7), 241 (10), 217 (15), 182 (100), 164 (98).

The mother liquors were constituted of a mixture of the two epimeric alcohols **17** (identical mass spectra by gc and ms).

Dehydration of the Alcohols ***17***

To a solution of 50 mg of the epimeric alcohols **17** in anhydrous pyridine was added 36 mg of $SOCl_2$. The solution was stirred for 1 h at room temperature. The excess of reagent was destroyed by water and the solution evaporated to dryness under reduced pressure. After filtration over alumina, an oily

[4]Compounds **6**, **10**, **11**, and **12** were found to be homogeneous by gc on three different columns: 10% SP2330 (235°C), 1% SP 1000 (190°C), and 4% OVI (185°C).

residue was obtained which was found to contain three isomeric compounds (**18***a*, **18***b*, **18***c*) in the ratio of 29:10:61 (gc 10% SP2330 at 200°C): gc–ms: **18***a*: M^+ 256 (32), 241 (12), 213 (22), 199 (14), 198 (19), 184 (24) 178 (24), 164 (100), 97 (72); **18***b*: M^+ 256 (7), 214 (12), 213 (14), 199 (12), 198 (8), 164 (100); **18***c*: M^+ 256 (18), 241 (9), 213 (14), 212 (18), 199 (24), 198 (32), 184 (70), 171 (46), 170 (42), 164 (100).

After chromatography on alumina (eluent: ethyl acetate – MeOH 9:1) a 40:60 mixture of **18***a* and **18***b* was separated; uv (CH_3OH) λ_{max} 264 nm; nmr δ: 0.92 and 1.01 (d, 2 secondary methyls, J = 7 Hz), 2.31 and 2.34, respectively (s, 2 N—CH_3's); 5.25 (1 multiplet of 0.4H) 7.15–8.50 ppm (aromatic protons); ir (film): 2775, 1650, 1590, and 1470 cm^{-1}.

Catalytic Hydrogenation of Compounds ***18***

Catalytic hydrogenation of compounds **18** was performed at room temperature in acetic acid (Pt, 4 kg/cm^2) for 48 h. After the usual work-up and filtration over alumina, an oily residue was obtained. It shows two peaks by gc (SP 2330 10%, 175°C); ms: M^+ 264 (39), 249 (13), 207 (20), 181 (34), 166 (78) 164 (46), 124 (56), 98 (42), 97 (55), 84 (100); ir ν_{N-CH_3}: at 2760 cm^{-1}, no more aromatic bands; nmr: 2.24 and 2.28 (2 s, N—CH_3), no signals beyond 3.5 ppm.

Without further purification the mixture was acetylated (acetic anhydride – pyridine 24 h at room temperature). The oily residue obtained after the usual work-up presents two peaks by gc (10% SP 2330, 220°C) which were separated by preparative gc. The compound having the shorter retention time was found to be homogeneous on three different columns (10% SP 2330, 235°C; 1% SP 1000, 190°C; 4% OVI, 185°C) and by tlc. Its mass spectrum was superimposable with that of compound **6**; nmr δ: 0.9 (d, 3H, J = 7 Hz), 2.07 and 2.28 ppm (s, 3H); ir (film): 2780, 1640, 1430, and 1270 cm^{-1}. The mass spectrum of the second peak was also superimposable with that of compound **6** but it was found to be still a mixture (tlc, nmr). The R_f value and retention time of the synthetic derivatives **20** were found to be different from those of the natural derivative **6**; however, all compounds had identical mass spectra and identical mike and cid spectra for the peaks at *m/e* 306 (15), 249 (20), 180 (27), 166 (100), 126 (57), 84 (52).

CLAUDE JOUANY ET GÉRARD JUGIE[1]

Laboratoire de Chimie de Coordination du CNRS, B.P. 4142, 31030 Toulouse Cedex – France

Reçu le 8 juin 1977

LUCIEN ELEGANT, JEAN-FRANÇOIS GAL, CLAUDE JOUANY et GÉRARD JUGIE. Can. J. Chem. **56**, 857 (1978).

Les composés d'addition $(Me_2N)_{3-n}(t\text{BuO})_nP \rightarrow BH_3$ (avec $n = 1$, 2 et 3) ont été préparés et caractérisés pour la première fois. L'évolution des paramètres provenant de l'analyse des spectres de rmn (^1H, ^{11}B et ^{31}P) est confrontée avec celle des enthalpies de réaction entre les phosphines libres et le borane et avec les données issues des réactions de déplacement. Il ne semble pas y avoir de corrélation entre $^1J_{BP}$ et la stabilité des complexes.

LUCIEN ELEGANT, JEAN-FRANÇOIS GAL, CLAUDE JOUANY, and GÉRARD JUGIE. Can. J. Chem. **56**, 857 (1978).

The equimolecular adducts between aminoalkoxyphosphines $(Me_2N)_{3-n}(t\text{BuO})_nP$ with $n = 1$, 2, and 3) and borane BH_3 have been prepared and characterised. The nmr study has been undertaken to compare some parameters ($^1J_{BH}$, $^1J_{BP}$, $\delta^{11}B$ etc.) with both those derived from the enthalpies of reaction of diborane with the parent phosphines and from the displacement reactions. No overall correlations between the $^1J_{BP}$ coupling constants and the complex stabilities seem evident.

Les composés d'addition $X_3P \rightarrow BY_3$ constituent des exemples de choix pour une étude de l'évolution des valeurs des déplacements chimiques et des constantes de couplage relatifs tant au donneur qu'à l'accepteur, en fonction de la nature des substituants X et Y fixés sur les deux pôles de la liaison de coordination. En fait, de nombreux travaux (cf. réfs. (1–7)) ont tenté de dégager des relations entre les grandeurs issues des analyses par résonance magnétique nucléaire et la stabilité relative des complexes. C'est dans ce cadre général que se situent nos travaux antérieurs (8); ils revêtent cependant un caractère particulier dans la mesure où nous nous efforçons de prendre en considération les enthalpies de réactions (9) et les réactions de déplacement ce qui nous amène à remettre en cause l'utilisation de certains paramètres rmn comme critère de stabilité des complexes $X_3P \rightarrow BY_3$.

Après avoir considéré, à ce point de vue, les composés d'addition de BH_3 avec les bases phosphorées du type $Me_{3-n}(MeO)_nP$ et $Me_{3-n}(Me_2N)_nP$ ($0 \leq n \leq 3$) (9), nous envisageons ici la série $(Me_2N)_{3-n}(RO)_nP \rightarrow BH_3$ dont les trois termes ont pu être isolés dans un état de pureté convenable en utilisant un reste alcoxylé particulier: le reste tertiobutoxy.

Partie Expérimentale

Obtention des bases phosphorées

Les deux diméthylaminotertiobutoxyphosphines $(Me_2N)_2(t\text{BuO})P$ (**2**) et $(Me_2N)(t\text{BuO})_2P$ (**3**) ont été préparées selon le procédé décrit par Burgada *et al.* (10), qui repose sur une alcoolyse contrôlée de $(Me_2N)_3P$ (**1**) par le tertiobutanol. Les constantes physiques de nos échantillons sont très proches de celles de la littérature. Pour ce qui est du terme extrême de la série constitué par $(t\text{BuO})_3P$ (**4**), il est bien connu qu'il n'est pas possible de le préparer par la méthode envisagée ci-dessus. Mark et Van Wazer (11) ont obtenu ce composé par la méthode générale de préparation des phosphites c'est-à-dire par action de PCl_3 sur l'alcool correspondant, mais la pureté du produit ainsi atteint reste inférieure à 90% en raison de la forte propension de (**4**) à se transformer en phosphonate $(t\text{BuO})_2P(O)H$. Pour notre part, nous sommes parvenus à améliorer notablement le procédé de Mark et Van Wazer (11), sans toutefois parvenir à éliminer totalement le phosphonate, en utilisant le mode opératoire suivant: la réaction

$$3t\text{BuOH} + PCl_3 + 3Et_3N \rightarrow (t\text{BuO})_3P + 3Et_3N, HCl$$

est effectuée dans un filtre muni d'une jaquette thermostatée et dont le couvercle à trois tubulures reçoit une ampoule à brome, un agitateur et une gaine thermométrique et dont la base est constituée par un verre fritté (de porosité G_4). Grâce à la circulation d'un fluide thermostatique (méthanol) dans la jaquette, la température de l'ensemble est très rigoureusement maintenue en dessous de 5°C. Toutes les opérations sont conduites en atmosphère inerte strictement contrôlée; 65 g (0.5 mol) dichlorure de phosphore en solution dans 150 cm^3 d'éther sont ajoutés goutte à goutte à 112 g (1.5 mol) de tertiobutanol et 170 g (1.68 mol) de triéthylamine en solution dans 500 cm^3 d'éther.

Après maintien d'une agitation vigoureuse pendant 48 h, et toujours à 5°C, la solution éthérée est filtrée puis le solvant extrait lentement sous vide; 120 g d'un liquide visqueux légèrement opalescent sont ainsi obtenus, correspondant à un rendement voisin de 95%. Ce liquide, filtré une seconde fois pour le rendre parfaitement limpide, cristallise bien à 0°C et possède un indice de réfraction n_D^{20} 1.426_5. La rmn du

proton a permis de constater que cet échantillon ne contenait au plus que 2% de ditertiobutylphosphonate.

Obtention des composés d'addition avec BH_3

Pour **1**·BH_3, **2**·BH_3 et **3**·BH_3, nous avons utilisé le procédé de préparation de Reetz (12) et isolé les composés d'addition par distillation fractionnée. Par contre, pour **4**·BH_3 nous avons dû prendre en compte l'instabilité thermique de la tritertiobutoxyphosphine: ainsi, nous avons fait réagir directement le diborane gazeux sur une solution benzénique de **4** dont la température était rigoureusement maintenue en dessous de 10°C. La fin de la réaction est observée lorsque B_2H_6 n'est plus absorbé. Après élimination du solvant, on obtient un liquide visqueux qui est purifié par distillation fractionnée et conduit à de beaux cristaux blancs (p.f. 46°C).

Les trois composés **2**·BH_3, **3**·BH_3 et **4**·BH_3 n'ont fait l'objet, à notre connaissance, d'aucune description dans la littérature; leurs principales caractéristiques sont rassemblées dans le tableau 1, dans lequel nous avons également mentionné, à titre de comparaison, quelques données relatives au complexe de la *n*-tributoxyphosphine.

Les spectres de résonance magnétique nucléaire

Les différents spectres rmn ont été enregistrés dans les conditions habituelles au laboratoire (9): les principaux paramètres issus de leur analyse sont rassemblés dans le tableau 2.

Les déterminations calorimétriques

Elles ont été effectuées selon le mode opératoire décrit précédemment (9). Les valeurs obtenues apparaissent dans le tableau 3.

Les réactions de déplacement

Chacun des quatre composés d'addition a été mis en présence, en quantités sensiblement équimoléculaires, des trois autres ligands phosphorés de la série; ainsi, 12 mélanges initiaux ont été réalisés, correspondant deux à deux aux six systèmes suivants:

[1] $(tBuO)_3P + (tBuO)_2(Me_2N)P \rightarrow BH_3 \leftrightarrows (tBuO)_3P \rightarrow BH_3 + (tBuO)_2(Me_2N)P$

[2] $(tBuO)_3P + (tBuO)(Me_2N)_2P \rightarrow BH_3 \leftrightarrows (tBuO)_3P \rightarrow BH_3 + (tBuO)(Me_2N)_2P$

[3] $(tBuO)_3P + (Me_2N)_3P \rightarrow BH_3 \leftrightarrows (tBuO)_3P \rightarrow BH_3 + (Me_2N)_3P$

[4] $(tBuO)_2(Me_2N)P + (tBuO)(Me_2N)_2P \rightarrow BH_3 \leftrightarrows (tBuO)_2(Me_2N)P \rightarrow BH_3 + (tBuO)(Me_2N)_2P$

[5] $(tBuO)_2(Me_2N)P + (Me_2N)_3P \rightarrow BH_3 \leftrightarrows (tBuO)_2(Me_2N)P \rightarrow BH_3 + (Me_2N)_3P$

[6] $(tBuO)(Me_2N)_2P + (Me_2N)_3P \rightarrow BH_3 \leftrightarrows (tBuO)(Me_2N)_2P \rightarrow BH_3 + (Me_2N)_3P$

A la température ambiante, l'évolution des mélanges est faible ou nulle en raison, sans doute, de l'encombrement stérique important des restes tertiobutoxy, et diméthylamino, portés par le phosphore. En conséquence, les systèmes ont été maintenus à une température de 65°C pendant 5 jours. On a pu ainsi atteindre des états finaux bien définis, dont la composition a pu être établie sans ambiguïté par analyse des spectres ^{11}B et ^{31}P. Les proportions relatives des espèces présentes à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

l'équilibre ont été évaluées par intégration des signaux de résonance magnétique du noyau ^{31}P: pour le système [1] on aboutit à un équilibre entre les quatre espèces, déplacé vers la gauche ~75%, pour 25% à droite; pour toutes les autres équations, que le mélange initial soit celui de gauche ou de droite, on parvient toujours au système totalement déplacé vers la gauche.

Discussion des résultats

En raison du caractère original de trois des composés étudiés dans cet article, il convenait avant tout de s'assurer de leur identité en vérifiant que la fixation de l'accepteur BH_3 avait bien lieu sur l'atome central de phosphore et qu'il n'apparaissait pas de réactions de redistribution (composés **2**·BH_3 et **3**·BH_3) ou de dégradation (composé **4**·BH_3) des restes fixés sur l'atome de phosphore. Ainsi, parmi les caractéristiques structurales des spectres rmn (^{11}B, ^{31}P et ^{1}H) nous retiendrons:

(*i*) l'allure de la figure de résonance du noyau ^{11}B qui apparaît dans tous les cas sous forme d'un quintuplet déformé traduisant la combinaison des couplages $^{1}J_{BH}$ et $^{1}J_{BP}$ dont les valeurs absolues sont voisines. Le découplage sélectif des protons a cependant permis d'atteindre les valeurs de $^{1}J_{BP}$ figurant dans le tableau 2 avec une précision convenable; (*ii*) l'importante évolution aussi bien sur le plan des déplacements chimiques que sur l'allure de la raie de résonance du noyau ^{31}P après complexation. Dans tous les cas en effet, nous avons observé que la fixation de BH_3 se traduisait par un déplacement important du massif de résonance vers les champs forts avec apparition plus ou moins marquée de l'éclatement du signal de ^{31}P sous la forme d'un quadruplet ($^{1}J_{BP}$); (*iii*) l'apparition, en résonance de ^{1}H, de quatre doublets B—*H* de pics largement étalés sur la zone spectrale (~300 Hz) et résultant de la combinaison des couplages $^{1}J_{BH}$ et $^{2}J_{PBH}$. Pour **2**·BH_3 et **3**·BH_3 nous avons vérifié, par intégration des massifs de résonance, la bonne répartition des signaux protoniques entre CH_3—N et $(CH_3)_3C$ tandis que pour **4**·BH_3, nous avons pu constater la disparition de tout pic attribuable à $(t\text{BuO})_2\text{P(O)H}$ après distillation du composé d'addition.

Ayant clairement identifié le site donneur de ces ligands, il paraît intéressant, comme il a été déjà fait précédemment, de confronter les échelles de basicité issues des données calorimétriques et des réactions de déplacement, à l'évolution de certains paramètres rmn.

Ainsi, en considérant que les variations d'enthalpies sont essentiellement liées à la rupture et au rétablissement de la liaison de coordination P → B et qu'en première approximation, (13–16), les variations d'entropie sont négligeables puisqu'elles con-

TABLEAU 3. Paramètres issus de l'analyse des déterminations calorimétriques

Composés	$-\Delta H_1$[a] (kcal/mol)	$-\Delta H_2$[a] (kcal/mol)	σ_m[b]	ic_{95}[c]
1 + BH_3	49.53	42.27	0.16	0.41
2 + BH_3	45.63	40.31	0.22	0.62
3 + BH_3	42.19	38.72	0.22	0.57
4 + BH_3	47.27	41.13	0.25	0.57
4′ + BH_3	41.58	38.23	0.09	0.40

[a]Comparez avec réf. 9; ΔH_1 correspond à la valeur expérimentale de l'enthalpie liée à la réaction:

$2(Me_2N)_{3-n}(tBuO)_nP(sol.) + B_2H_6(gaz) \rightarrow 2(Me_2N)_{3-n}(tBuO)_nP \rightarrow BH_3(sol.)$

Connaissant l'enthalpie de dissociation du diborane (35 kcal/mol), on atteint ΔH_2 qui correspond alors à la réaction:

$(Me_2N)_{3-n}(tBuO)_nP(sol.) + BH_3(gaz) \rightarrow (Me_2N)_{3-n}(tBuO)_nP \rightarrow BH_3(sol.)$

[b]σ_m = écart moyen.
[c]ic_{95} = intervalle de confiance à 95%.

cernent des ligands appartenant à une même famille, l'évolution des systèmes [1] à [6] permet d'établir vis-à-vis de BH_3 la séquence suivante:

$$(Me_2N)_3P > (Me_2N)_2(tBuO)P > (Me_2N)(tBuO)_2P \sim (tBuO)_3P$$

Les mesures calorimétriques (cf. tableau 3) conduisent à une séquence identique à l'exception de la tritertiobutoxyphosphine qui occupe une place particulière. Si on fait abstraction de ce dernier composé, cette échelle peut être confrontée à l'évolution de la constante de couplage $^1J_{BP}$ retenue par certains auteurs (4) comme une mesure directe de la basicité des phosphines vis-à-vis du borane; pour la série étudiée présentement, $^1J_{BP}$ passe par un minimum pour le composé d'addition $(Me_2N)_2(tBuO)P \rightarrow BH_3$ et ne rend pas compte de l'échelle de basicité établie. Ce désaccord n'est pas surprenant dans la mesure où de nombreuses restrictions au domaine de validité du critère $^1J_{BP}$ ont déjà pu être relevées (3*b*, 17).

En ce qui concerne le couplage direct $^1J_{BH}$, en retenant le traitement de Pople et Santry (18) l'accroissement de sa valeur absolue devrait traduire un accroissement du caractère *s* de la liaison B—H et donc une diminution de la basicité du dérivé phosphoré entrant en jeu. Dans la limite de la précision de nos déterminations, $^1J_{BH}$ reste constant et traduirait donc des basicités voisines pour ces quatre ligands.

Enfin pour $\delta^{11}B$, son évolution bien que faible, permet de retrouver la même séquence que celle déduite des réactions de déplacement et vient donc s'ajouter aux résultats obtenus par Mooney et coll. (19). Cet accord, cependant ne constitue pas à nos yeux une preuve irréfutable puisque, dans d'autres séries (8*b*) ce critère a pu être mis en défaut.

Conclusions

En définitive, dans la série $(Me_2N)_{3-n}(tBuO)_nP \rightarrow BH_3$ il n'apparaît pas de corrélation évidente entre les critères de basicité habituellement retenus (tels que $^1J_{BP}$ ou $^1J_{BH}$) et la stabilité des complexes telle qu'elle peut être évaluée à partir des données calorimétriques ou des réactions de déplacement. Cette difficulté peut trouver son origine dans la complexité des ligands envisagés (qui possèdent des substituants à fort encombrement stérique et porteurs de doublets électroniques libres) et dans la différence relativement faible de leur affinité pour BH_3.

A Poisson–Boltzmann treatment of the capacitance of a layer of symmetrical spherical dipoles

PENNY DALRYMPLE-ALFORD AND KEITH B. OLDHAM
Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received September 12, 1977

PENNY DALRYMPLE-ALFORD and KEITH B. OLDHAM. Can. J. Chem. **56**, 861 (1978).

The capacitance of a layer of spherical orientable dipoles has been determined. The properties attributed to each dipole are those of two point charges on a diameter of the sphere and equidistant from its centre. A one-dimensional potential distribution is assumed to exist normal to the layer and to be coupled to the charge distribution via Poisson's law. The orientation of the dipoles is random in the absence of polarization, but is taken as governed by Boltzmannian statistics when an applied field is present. The treatment predicts that the capacitance will display a pronounced hump at the point of zero charge. Though this study was motivated by a wish to interpret the inner-layer capacitance at a mercury/aqueous electrolyte solution interface, the treatment is shown to be inapplicable quantitatively to such a system.

PENNY DALRYMPLE-ALFORD et KEITH B. OLDHAM. Can. J. Chem. **56**, 861 (1978).

On a déterminé la capacité d'une couche de dipoles sphériques pouvant être orientés. Les propriétés attribuées à chaque dipole correspondent à celles de charges ponctuelles sur un diamètre de la sphère et équidistantes de son centre. On fait l'hypothèse qu'il existe une distribution de potentiel unidimensionnelle perpendiculaire à la couche et couplée à la distribution de charge par la loi de Poisson. L'orientation des dipoles se fait au hasard en l'absence de polarisation mais on considère qu'elle est gouvernée par des statistiques de Boltzmann lorsqu'on applique un champ. La théorie prédit que la capacité présentera une courbe prononcée au point de la charge zéro. Quoique cette étude ait été motivée par un désir d'interpréter la capacité de la couche interne à l'interface mercure/solution électrolytique aqueuse, on démontre que le traitement ne peut être appliqué quantitativement à de tels systèmes.

Many of the theories proposed in explanation of the so-called inner layer capacity of a mercury/solution interface in the absence of specific adsorption attribute the 'hump' in the graph of capacitance vs. charge density to the orientability of the dipolar molecules that constitute the innermost layer of solvent (see refs. 1–4 for reviews). In this article we evaluate the capacitance of a model system that bears a similarity to some authors' concepts of the inner region of the electrical double layer. This article is a development of an earlier article (5) and uses ideas that have proved very successful in explaining the behaviour of the *diffuse* double layer (6, 7).

Consider the situation depicted cross-sectionally in Fig. 1, in which a layer of spheres is located between two conducting plates. The plates are parallel planes bearing equal and opposite charge densities σ and $-\sigma$. The spheres are close-packed and therefore their number density is $2/3^{1/2}\delta^2$ where δ, the spheres' diameter, equals the distance between the plates. Each sphere contains two point charges of magnitudes $\mu/2Y$ and $-\mu/2Y$ located on a diameter of the sphere at distances Y from the centre. Thus μ is the dipole moment of the sphere. The entire space between the conducting plates has a uniform and constant permittivity ε.

A distance coordinate y is erected as diagrammed, with its origin at the plane occupied by the centres of the spheres. Whatever the orientation of the spheres, their charges cannot penetrate the regions $Y < y < \frac{1}{2}\delta$ and $-\frac{1}{2}\delta < y < -Y$ and therefore the field in these outer regions is given simply by

$$[1] \qquad \frac{d\phi}{dy} = \frac{\sigma}{\varepsilon} \qquad Y \leq |y| \leq \tfrac{1}{2}\delta$$

where ϕ represents the local potential. If $y = 0$ is chosen as the point of zero potential, considerations of symmetry dictate that ϕ be an odd function of y, as depicted in Fig. 2; that is

$$[2] \qquad \phi(-y) = -\phi(y)$$

Likewise,

$$[3] \qquad \phi(Y) = -\phi(-Y) = \Phi$$

where the potentials $\phi = \pm\Phi$ correspond to the extremities of the dipolar influence: ϕ is linear beyond these extremes as indicated in [1]. The total potential between the conducting plates is

$$[4] \quad \phi\left(\frac{\delta}{2}\right) - \phi\left(\frac{-\delta}{2}\right) = 2\phi\left(\frac{\delta}{2}\right) = 2\left[\Phi + \left(\frac{\delta}{2} - Y\right)\frac{\sigma}{\varepsilon}\right]$$

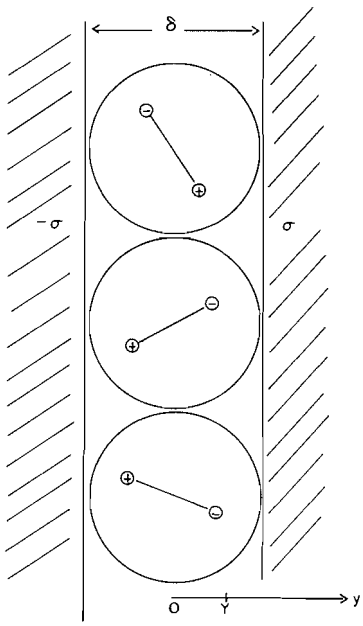

FIG. 1. The model system: a layer of spherical dipoles located between two charged plates. The interaction between dipoles is treated as being solely via an average electric potential ϕ, the magnitude of which depends on y and reflects the degree of dipolar orientation.

and, accordingly, the differential capacitance has a reciprocal given by

$$[5]\quad \frac{1}{C} = \frac{\mathrm{d}}{\mathrm{d}\sigma}\left[\phi\left(\frac{\delta}{2}\right) - \phi\left(\frac{-\delta}{2}\right)\right] = \frac{\delta - 2Y}{\varepsilon} + 2\frac{\mathrm{d}\Phi}{\mathrm{d}\sigma}$$

On account of its two charges being located in regions of different potential, the electrostatic energy of a dipole is

$$[6]\quad U(y) = \left(\frac{-\mu}{2Y}\right)\phi(y) + \left(\frac{\mu}{2Y}\right)\phi(-y) = \frac{-\mu\phi(y)}{Y}$$

where y is the coordinate of its negative pole. Now imagine all the spheres to be superimposed so that the poles come to lie on a smaller sphere of radius Y. The number $\mathrm{d}N$ of negative poles that are aligned at angles between θ and $\mathrm{d}\theta$ to the y-axis is given by the Boltzmann proportionality

$$[7]\quad \mathrm{d}N(\theta) \propto \exp\{-U(\theta)/kT\}(2\pi \sin\theta\, \mathrm{d}\theta)$$

where k is Boltzmann's constant and T the thermodynamic temperature. The $2\pi \sin\theta\, \mathrm{d}\theta$ term is the element of solid angle inclined between θ and $\theta + \mathrm{d}\theta$ to the y-axis. However, $Y\cos\theta = y$ and therefore $-Y\sin\theta\, \mathrm{d}\theta = \mathrm{d}y$, so that [7] becomes

$$[8]\quad \mathrm{d}N \propto -\frac{2\pi}{Y}\exp\left\{\frac{-U}{kT}\right\}\mathrm{d}y$$

or

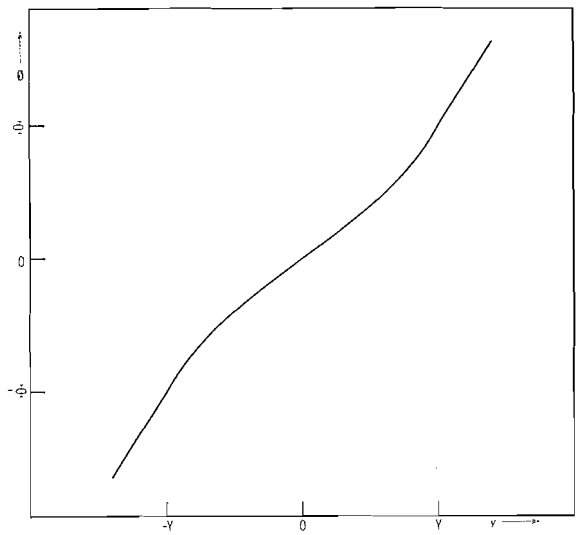

FIG. 2. The potential profile. Beyond $y = Y$ the profile is linear, corresponding to the constant field $(\mathrm{d}\phi/\mathrm{d}y) = \sigma/\varepsilon$. In the central region, $-Y < y < Y$, the profile shape has been accurately drawn for the parameter choices $\Lambda = 2.000$, $m = 0.000$ (see Appendix A).

$$[9]\quad \mathrm{d}N(y) = \frac{n}{Y}\exp\left\{\frac{-U(y)}{kT}\right\}\mathrm{d}y$$

where n is a proportionality factor the value of which will depend on σ. Combination of [6] and [9] produces the equation

$$[10]\quad \mathrm{d}N(y) = \frac{n}{Y}\exp\left\{\frac{\mu\phi(y)}{YkT}\right\}\mathrm{d}y$$

which demonstrates preference for an orientation of negative poles towards the positively charged plate.

The value of the proportionality factor n may be related to the total number density of spheres by the integral

$$[11]\quad \frac{2}{3^{1/2}\delta^2} = \int_{y=-Y}^{y=Y}\mathrm{d}N(y) = \frac{n}{Y}\int_{-Y}^{Y}\exp\left\{\frac{\mu\phi(y)}{YkT}\right\}\mathrm{d}y = \frac{n}{Y}\int_{0}^{Y}\left[\exp\left\{\frac{\mu\phi(y)}{YkT}\right\} + \exp\left\{\frac{\mu\phi(-y)}{YkT}\right\}\right]\mathrm{d}y = \frac{2n}{Y}\int_{0}^{Y}\cosh\left\{\frac{\mu\phi}{YkT}\right\}\mathrm{d}y$$

The last step in [11] is a consequence of property [2].

To this point our treatment parallels that originated by Debye (8) to explain the temperature dependence of the polarizability of polar liquids. To

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

continue in that vein one would ignore the restriction on [1] and substitute it into [10] and [11], a procedure that leads ultimately to a Langevin function. In so doing, however, one is ignoring the effect of the partially oriented dipoles in opposing the applied field σ/ε in the central region. One method of allowing for this is to assume, despite the partially random orientations of the dipoles, that ϕ is an unique function of y. This function, which reflects the average of all the dipolar orientations, will be determined by considering the relationship, expressed by Poisson's law, between the potential and the spatial charge density that arises from the preferred orientation of the spheres. A similar procedure was adopted by Gouy (6) and by Chapman (7) in their successful theory of the diffuse double layer at metal/aqueous solution interface.

Consult Fig. 3 and note that, when y and σ are positive, the charge density $s(y)$ between the planes y and $y + dy$ is due to a number $dN(y)$ of negative charges lying in this zone, together with a smaller number of positive charges there. The latter number, however, equals the number $dN(-y)$ of negative charges lying between planes $-y$ and $-y - dy$. Hence, the local charge density is

$$[12]\quad s(y) = \left(\frac{-\mu}{2Y}\right)\frac{dN(y)}{dy} + \left(\frac{\mu}{2Y}\right)\frac{dN(-y)}{dy}$$

$$= \frac{-\mu n}{2Y^2}\exp\left\{\frac{\mu\phi(y)}{YkT}\right\} + \frac{\mu n}{2Y^2}\exp\left\{\frac{\mu\phi(-y)}{YkT}\right\}$$

$$= \frac{-\mu n}{Y^2}\sinh\left\{\frac{\mu\phi(y)}{YkT}\right\}$$

When Poisson's law

$$[13]\qquad \frac{-s(y)}{\varepsilon} = \frac{d^2\phi}{dy^2} = \frac{1}{2}\frac{d}{d\phi}\left(\frac{d\phi}{dy}\right)^2$$

is invoked, we obtain

$$[14]\qquad \int d\left(\frac{d\phi}{dy}\right)^2 = \frac{2\mu n}{\varepsilon Y^2}\int \sinh\left\{\frac{\mu\phi}{YkT}\right\} d\phi$$

after formal integration. Keeping the lower integration limit indefinite but choosing as the upper limit $y = Y$ (where, by [1] and [3], $\phi = \Phi$ and $(d\phi/dy) = \sigma/\varepsilon$) leads to

$$[15]\quad \left(\frac{d\phi}{dy}\right)^2 = \frac{2nkT}{\varepsilon Y}\cosh\left\{\frac{\mu\sigma}{YkT}\right\} + \frac{\sigma^2}{\varepsilon^2} - \frac{2nkT}{\varepsilon Y}\cosh\left\{\frac{\mu\Phi}{YkT}\right\}$$

after some algebra.

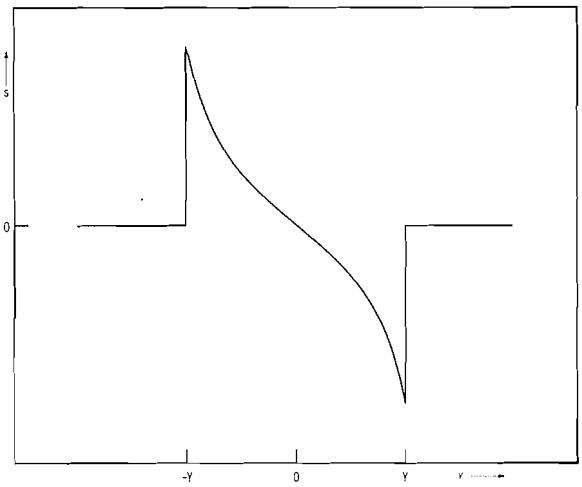

FIG. 3. Charge density as a function of distance. The charge density is zero outside the central region. The same parameter choices as for Fig. 2 were made in drawing the curve, which is accurately shaped.

Extraction of the square root of [15] followed by a further integration with lower limits at $y = 0$ (where $\phi = 0$ by definition) yields a relationship of form $\phi = f(y,n,\sigma)$. This relationship permits integral [11] to be evaluated so that n becomes a known function of σ. In turn, this may be inserted back into $\phi = f(y,n,\sigma)$ to give an expression which, on specialization to $y = Y$, yields a relation between Φ and σ. The mathematics involved is complicated and has been relegated to Appendix A, only the results being presented here. The final result, interrelating Φ and σ, cannot be written explicitly, but only as the equation pair

$$[16]\qquad \frac{\mu\Phi}{YkT} = 2\,\mathrm{arccosh\ dc}\,(\lambda|m)$$

$$[17]\qquad \frac{\mu\sigma}{\varepsilon kT} = 2\lambda(1-m)^{1/2}\,\mathrm{nc}\,(\lambda|m)$$

where λ and m are parameters interrelated by

$$[18]\quad \lambda^2 - 2\lambda E(\lambda|m) + 2\lambda\,\mathrm{sn}\,(\lambda|m)\,\mathrm{dc}\,(\lambda|m) = \Lambda^2$$

Λ being the constant defined by

$$[19]\qquad \Lambda \equiv \frac{\mu}{\delta(3^{1/2}Y\varepsilon kT)^{1/2}}$$

Moreover, [16]–[18] are useful only if m is positive and less than unity. An m value in excess of unity has no physical meaning but m may well be less than zero. When m is negative, the above results are to be replaced by

$$[20]\qquad \frac{\mu\Phi}{YkT} = 2\,\mathrm{arccosh\ nc}\,(\lambda_2|m_2)$$

NOTE: Though Λ, m, λ, m_2, and λ_2 are cited in this table to three or four significant figures only, far greater precision than this is needed to ensure four-figure accuracy in Φ, σ, and C^c. Our calculations used ten significant digits.

$$[21] \qquad \frac{\mu\sigma}{\varepsilon kT} = 2\lambda_2 \, \mathrm{dc}\,(\lambda_2|m_2)$$

and

$$[22] \quad (1 - m_2)\lambda_2{}^2 - 2\lambda_2 E(\lambda_2|m_2) + 2\lambda_2 \, \mathrm{sn}\,(\lambda_2|m_2) \, \mathrm{dc}\,(\lambda_2|m_2) = \Lambda^2$$

where λ_2 and m_2 are related to λ and m as explained in Appendix A. The bivariate function $E(\,|\,)$ is an incomplete elliptic function of the second kind, while dc(|), nc(|), and sn(|) are three of the twelve Jacobian elliptic functions; see Appendix B for a description of these functions and some of their properties.

To utilize results [16] through [22] one proceeds as follows. First, choose a value for the right-hand member of [18]. Second, using the computational techniques described in Appendix B, find pairs of λ,m values that satisfy [18]. (For negative m, switch over to [22] and find λ_2,m_2 pairs.) Third, use [16] and [17] (or [20] and [21] for negative m) to calcalculate Φ and σ. Table 1 lists examples of values computed in this way.

Returning to [5], we note that the capacitance is compounded of two elements in series. The first, of magnitude $\varepsilon/(\delta - 2Y)$, is simply the capacitance of the regions $Y \leqq |y| \leqq \frac{1}{2}\delta$ beyond the dipoles: it is a constant. The second, of magnitude $\frac{1}{2}(d\sigma/d\Phi)$, represents the central region $|y| \leqq Y$ which is subjected to dipolar influence. It is, of course, this second capacitance that is of special interest: we term it the *central capacitance* C^c.

$$[23] \qquad C^c \equiv \frac{1}{2}\frac{d\sigma}{d\Phi} = \left[\frac{1}{C} - \frac{\delta - 2Y}{\varepsilon}\right]^{-1}$$

As we shall see, the value of C^c depends on the extent of polarization of the central capacitor, falling to the saturation value

$$[24] \qquad C_\infty{}^c = \varepsilon/2Y$$

at extreme polarizations. The factor $C/C_\infty{}^c$ represents the enhancement in the central capacitance resulting from dipolar orientation. As was shown earlier (5), the maximum value of this factor occurs at vanishingly small polarizations, being given by

$$[25] \qquad \max\,(C^c/C_\infty{}^c) = C_0{}^c/C_\infty{}^c = \Lambda \coth \Lambda$$

where Λ is the constant defined in [19].

To obtain an analytic expression for the central capacitance, other than at zero or infinite polarization, [16] and [17] (or [20] and [21] for negative m) are differentiated and the ratio of these derivatives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is taken. After much tedious algebra, there emerge the following results for the $0 < m < 1$ and $m < 0$ cases:

$$[26]\quad \frac{C^c}{C_\infty{}^c} = \frac{Y}{\varepsilon}\frac{d\sigma}{d\Phi}$$

$$= \lambda\, sc(\lambda|m)\, dn(\lambda|m) + \frac{\frac{2m}{\lambda}\frac{d\lambda}{dm} + 1 - \frac{dn^2(\lambda|m)}{1-m}}{\frac{2m}{\lambda}\frac{d\lambda}{dm} + 1 - \frac{E(\lambda|m)}{\lambda(1-m)}}$$

$$= \lambda_2(1-m_2)\, sc(\lambda_2|m_2)\, nd(\lambda_2|m_2) + \frac{\frac{2m_2}{\lambda_2}\frac{d\lambda_2}{dm_2} + 1 - nd^2(\lambda_2|m_2)}{\frac{2m_2}{\lambda_2}\frac{d\lambda_2}{dm_2} + 1 - \frac{Nd(\lambda_2|m_2)}{\lambda_2}}$$

where, from [18] and [22],

$$[27]\quad \frac{\lambda}{2m}\frac{dm}{d\lambda} + 1 = \frac{1 + scd(\lambda|m) - cn^2(\lambda|m)E(\lambda|m)}{1 - \lambda\, dn^2(\lambda|m)}$$

and

$$[28]\quad \frac{\lambda_2}{2m_2}\frac{dm_2}{d\lambda_2} + 1 = \frac{scd(\lambda_2|m_2) - sn^2(\lambda_2|m_2)E(\lambda_2|m_2)}{E(\lambda_2|m_2) - (1-m_2)\lambda_2}$$

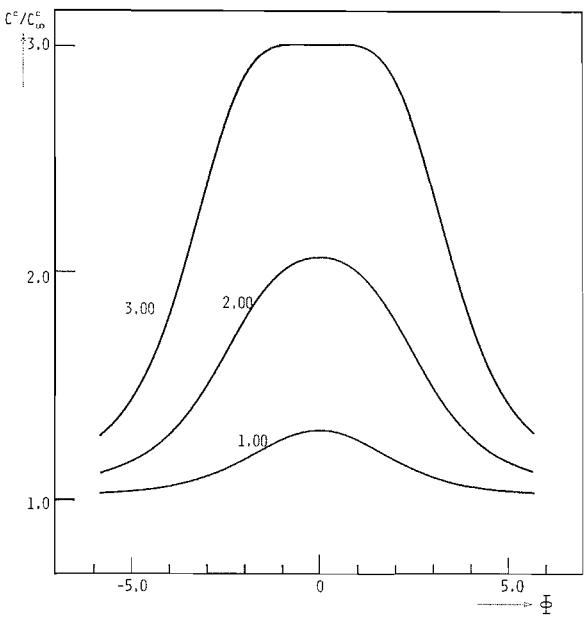

FIG. 4. The central capacitance as a function of applied charge. The units of the abscissa are $\varepsilon kT/\mu$. The value associated with each curve is that of Λ.

respectively. The abbreviations $Nd(\lambda|m) \equiv [E(\lambda|m) - m\, sn(\lambda|m)\, cd(\lambda|m)]/[1-m]$ and $scd(\lambda|m) \equiv sn(\lambda|m)\, cn(\lambda|m)\, dn(\lambda|m)$ have been used in the above.

The equations of the last paragraph were used, for a variety of Λ values, to calculate numerical values of the central capacitance enhancement factor $C^c/C_\infty{}^c$. A convenient procedure is to use the same λ,m pairs (or λ_2,m_2 pairs for negative m) that were previously used to determine Φ and σ. Table 1 contains a column calculated in this way for $\Lambda = 2.000$, while Figs. 4 and 5 show the effect of varying the Λ parameter. It is evident from these results that a Poisson–Boltzmann treatment of orientable dipoles does predict a humped central capacitance, the height and, to a lesser extent, the width of the hump being determined by the constant Λ. The physical significance of this constant (more strictly of Λ^2) is that it assesses the relative magnitudes of the electrostatic energy and the thermal energy of the dipole.

Discussion

There are several ways in which the mathematical treatment of the Fig. 1 model may be criticized. The assumption of a uniform permittivity is a clear oversimplification. Imaging has been ignored, but could be important. We do not know how well the interaction of a particular dipole with its neighbours is simulated by its interaction with the average of all dipoles. One might rather imagine that a clustering of dipoles occurs, in the way proposed by Damaskin and Frumkin (9) and elaborated by Parsons (10).

Still more criticisms can be levelled at any attempt to pass-off the model as a representation of the true state of affairs at the junction between mercury and

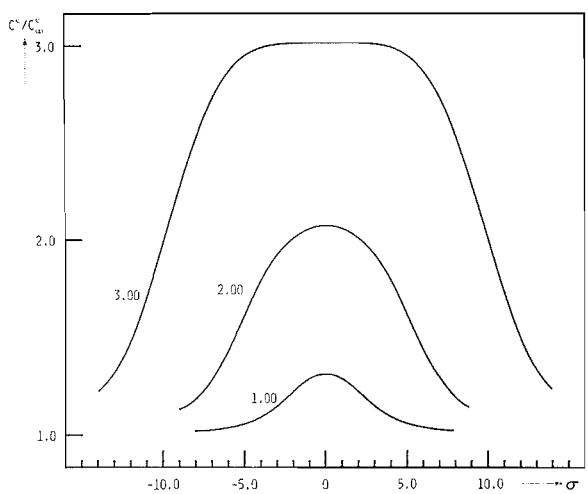

FIG. 5. The central capacitance as a function of the potential Φ. The units of the abscissa are YkT/μ.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

an electrolyte solution. Can dipolar molecules be treated as spheres? What error is introduced by treating their charged regions as point charges? Does Poisson's law hold within molecules? If so, what significance has permittivity? How accurately does Boltzmann's law describe the distribution of orientations? Is the interaction between neighbouring molecules restricted to Coulombic and 'billiard ball' forces, as the model assumes? Can a mercury surface be regarded, on the atomic level, as a uniformly charged, flat, ideal conductor? Is it not even less likely that the bulk electrolyte, and its diffuse layer, will behave as a flat uniformly-charged conductor? Do not the solute ions influence the inner layer of solvent in some way? We have no convincing answers to these, and many other, legitimate questions.

However, there are some encouraging considerations. Foremost is the fact that many of the objections that can be directed against our treatment may also be directed with equal force against the Gouy–Chapman theory (6, 7), which nonetheless appears to hold well: secondly, the treatment does indeed predict a capacity hump at the point of zero charge and of a shape that is not inconsistent with experimental data (3, 10).

We have not sought to compare the theory quantitatively with experimental curves, because no solvent for which capacity data are available can be expected to conform to the *symmetrical* dipole model to which, for mathematical reasons, our treatment is restricted. Water is, of course, the most studied solvent, but structural interpretations (11, 12) of its properties are generally in terms of a tripolar configuration.

In the geometry of the water molecule, according to the model of Lemberg and Stillinger (12), the negative pole is a point charge placed at the centre of mass of the oxygen atom, i.e. very close to the centre of gravity of the molecule as a whole. If the two positive point-charges of the model are resolved into a single pole, then the resulting dipole is 59 pm long, and traverses the centre of the molecule. However, the negative end of the dipole lies only 7 pm from the molecule centre, so that the dipole is extremely asymmetric. The present treatment is therefore inapplicable.

Appendix A

The parameters are defined by

$$[A.1] \quad \cosh^2\left(\frac{\mu\Phi}{2YkT}\right) - \frac{Y\sigma^2}{4n\varepsilon kT} \equiv m \equiv \frac{-m_2}{1-m_2}$$

and

$$[A.2] \quad \mu\sqrt{\frac{n}{Y\varepsilon kT}} \equiv \lambda \equiv (1-m_2)^{1/2}\lambda_2$$

It is also convenient to define the dimensionless variables

$$[A.3] \quad \frac{\mu\phi}{YkT} \equiv \psi$$

and

$$[A.4] \quad \frac{y}{Y} \equiv z$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

as well as the dimensionless constants

$$[A.5] \qquad \frac{\mu\sigma}{\varepsilon kT} \equiv \chi$$

and

$$[A.6] \qquad \frac{\mu\Phi}{YkT} \equiv \Psi$$

By means of the above definitions, the square root of [15] may be formally integrated in the alternative forms

$$[A.7] \qquad \sqrt{2}\int_0 dz = \frac{1}{\lambda}\int_0 \frac{d\psi}{[\cosh\psi - 2m + 1]^{1/2}} = \frac{1}{\lambda_2}\int_0 \frac{d\psi}{[(1-m_2)\cosh\psi + m_2 + 1]^{1/2}}$$

Standard integrals (13) now permit these integrals to be evaluated as elliptic integrals of the first kind, thus

$$[A.8] \qquad z = \begin{cases} \frac{1}{\lambda}F\left(\arctan\frac{\sinh\{\frac{1}{2}\psi\}}{\sqrt{1-m}}, m\right) & 0 < m < 1 \\ \frac{1}{\lambda_2}F(\arctan\sinh\{\frac{1}{2}\psi\}, m_2) & 0 < m_2 < 1 \end{cases}$$

Inversion gives the alternative expressions

$$[A.9] \qquad \cosh\{\tfrac{1}{2}\psi\} = \begin{cases} \mathrm{dc}(\lambda z|m) & 0 < m < 1 \\ \mathrm{nc}(\lambda_2 z|m_2) & 0 < m_2 < 1 \end{cases}$$

which, on specialization to $z = 1$, are equivalent to [16] and [20] of the text.

Equation A.9 was used to provide data for drawing Fig. 2, the choice $m = m_2 = 0$ being made. Though it reduces [A.9] and [18] to the mathematically simple relations $\phi \propto \mathrm{arcsinh}\tan\{\lambda y/Y\}$ and $\tan\lambda = (\Lambda^2 + \lambda^2)/2\lambda$, the selection of $m = 0$ is typical and has no special physical significance. Equation 12 likewise simplifies when $m = 0$ to $-s \propto \sec\{\lambda y/Y\} \times \tan\{\lambda y/Y\}$, a relationship used in drawing Fig. 3.

From definitions [A.1], [A.2], [A.5], and [A.6], the relationships

$$[A.10] \qquad \frac{\chi^2}{4} = \lambda^2[\cosh^2\{\tfrac{1}{2}\Psi\} - m] = \lambda_2{}^2[(1-m_2)\cosh^2\{\tfrac{1}{2}\Psi\} + m_2]$$

follow. Equation A.9 may then be utilized (after specialization to $z = 1$) to replace the $\cosh\{\frac{1}{2}\Psi\}$ terms. It now requires only the application of standard formulas (14) interrelating the squares of Jacobian elliptic functions to generate expressions that, on restoration of the original variables, become [17] and [21].

In terms of dimensionless variables, [11] can be rewritten

$$[A.11] \qquad \Lambda^2 = -\lambda^2 + 2\lambda^2\int_0^1 \cosh\{\tfrac{1}{2}\psi\}\,dz$$

Substitution from [A.9] now gives

$$[A.12] \qquad \Lambda^2 = \begin{cases} \lambda^2\left[-1 + 2\int_0^1 \mathrm{dc}^2(\lambda z|m)\,dz\right] & 0 < m < 1 \\ (1-m_2)\lambda_2{}^2\left[-1 + 2\int_0^1 \mathrm{nc}^2(\lambda_2 z|m_2)\,dz\right] & 0 < m_2 < 1 \end{cases}$$

These are standard definite integrals (14) and lead directly to [18] and [22].

Appendix B

Incomplete elliptic integrals of the first and second kinds are bivariate functions defined respectively by

$$[B.1] \qquad F(\phi,m) \equiv \int_0^\phi (1 - m\sin^2\theta)^{-1/2}\,d\theta = \lambda$$

and

$$[B.2] \qquad E(\phi,m) \equiv \int_0^\phi (1 - m\sin^2\theta)^{1/2}\,d\theta$$

However, instead of regarding E as a function of ϕ and m, it is often preferable to treat E as a function of λ and m: the symbolism $E(\lambda|m)$ is then used.

In a rather similar way, certain trigonometric functions of ϕ can be regarded as bivariate functions of λ and m. Thus

$$[B.3] \qquad \mathrm{sn}(\lambda|m) \equiv \sin\phi$$

$$[B.4] \qquad \mathrm{nc}(\lambda|m) \equiv \sec\phi$$

and

$$[B.5] \qquad \mathrm{dc}(\lambda|m) \equiv (\sec^2\phi - m\tan^2\phi)^{1/2}$$

are three examples of Jacobian elliptic functions. For definitions of the other nine, and for a geometric interpretation of Jacobian functions, see ref. 15.

In this study, there has been a need to calculate Jacobian and other elliptic functions very frequently. We have found the so-called nome expansions, of which

$$[B.6] \qquad \mathrm{sn}(\lambda|m) = \frac{2\pi}{m^{1/2}F(\frac{1}{2}\pi, m)} \times \sum_{j=1}^{\infty}\frac{q^{j-(1/2)}}{1-q^{2j-1}}\sin\left\{\frac{(2j-1)\pi\lambda}{2F(\frac{1}{2}\pi, m)}\right\}$$

TABLE 2. Partial derivatives of 13 elliptic functions

f	$(\partial f/\partial\lambda)_m$	$(\partial f/\partial m)_\lambda$
sn	cn dn	$-$cn dn $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
cn	$-$sn dn	sn dn $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
dn	$-m$ sn cn	sn cn $\{E - \lambda + m\lambda -$ sn dc$\}/2(1 - m)$
sd	cd nd	$-$cd nd $\{E - \lambda + m\lambda - m$ sn dc$\}/2m(1 - m)$
cd	$-(1 - m)$ sd nd	sd nd $\{E - \lambda + m\lambda\}/2m$
nd	m sd cd	$-$sd cd $\{E - \lambda + m\lambda -$ sn dc$\}/2(1 - m)$
sc	dc nc	$-$dc nc $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
dc	$(1 - m)$ sc nc	$-$sc nc $\{E - \lambda + m\lambda\}/2m$
nc	sc dc	$-$sc dc $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
cs	$-$ds ns	ds ns $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
ds	$-$cs ns	cs ns $\{E - \lambda + m\lambda - m$ sn dc$\}/2m(1 - m)$
ns	$-$cs ds	cs ds $\{E - \lambda + m\lambda - m$ sn cd$\}/2m(1 - m)$
E	dn^2	$-$cn$^2\{E - \lambda + \lambda$ dc$^2 -$ sn dc$\}/2(1 - m)$

and

$$[B.7]\quad E(\lambda|m) = \frac{\lambda E(\tfrac{1}{2}\pi, m)}{F(\tfrac{1}{2}\pi, m)} + \frac{2\pi}{F(\tfrac{1}{2}\pi, m)} \times \sum_{j=1}^{\infty} \frac{q^j}{1 - q^{2j}} \sin\left\{\frac{j\pi\lambda}{F(\tfrac{1}{2}\pi, m)}\right\}$$

are examples (see refs. 16–18 for others), to be accurate and efficient for this purpose and to lend themselves well to computer implementation. The nome is defined by

$$[B.8]\quad q \equiv \exp\{-\pi F(\tfrac{1}{2}\pi, m)/F(\tfrac{1}{2}\pi, 1 - m)\}$$

and depends only on the parameter m.

In generating [26] through [28] it was necessary to partially differentiate elliptic functions both with respect to their argument λ and their parameter m. If $f(\lambda|m)$ denotes any one elliptic function, then tables of $(\partial f/\partial\lambda)_m$ are available (14), but corresponding tables of $(\partial f/\partial m)_\lambda$ could not be found in the literature. Accordingly, these partial derivatives had to be determined *ab initio* and, for the benefit of future workers in this area, they are listed in Table 2. For brevity, arguments and parameters are omitted from the tabulation; thus sn means sn$(\lambda|m)$ and E means $E(\lambda|m)$.

An electron spin resonance and CIDEP study of the photoreduction of *tert*-butyl-*p*-benzoquinones

TERRY FOSTER, A. JOHN ELLIOT, BABATUNDE B. ADELEKE, AND JEFFREY K. S. WAN

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 4, 1977

TERRY FOSTER, A. JOHN ELLIOT, BABATUNDE B. ADELEKE, and JEFFREY K. S. WAN. Can. J. Chem. **56**, 869 (1978).

The photoreduction of 2-*tert*-butyl-*p*-benzoquinone and 2,5- and 2,6-di-*tert*-butyl-*p*-benzoquinone were studied by esr spectroscopy. In the photolysis of 2,6-di-*tert*-butyl-*p*-benzoquinone, only one semiquinone radical was observed and its decay kinetics were monitored by esr. The reduction of the triplet 2-*tert*-butyl-*p*-benzoqinone leads to the formation of isomeric semiquinone radicals **1** and **2** in the primary photochemical processes, and this is then followed by a chemical equilibrium between the two isomeric radicals. The relative rates of formation of the two radicals cannot be monitored by conventional esr methods but the CIDEP results show that the formation of radical **2** is about five to seven times faster than that of radical **1**. A secondary reaction of the phenoxy radical with a product benzohydrofuran **4** leads to the observation of a polarized radical **3** which derives all its polarization from the primary phenoxy radical.

TERRY FOSTER, A. JOHN ELLIOT, BABATUNDE B. ADELEKE et JEFFREY K. S. WAN. Can. J. Chem. **56**, 869 (1978).

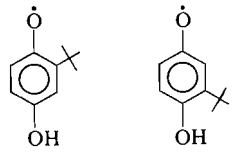
Faisant appel à la rpe, on a étudié la photoréduction de la *tert*-butyl-2 *p*-benzoquinone et des di-*tert*-butyl-2,5 et 2,6 *p*-benzoquinones. Lors de la photolyse de la di-*tert*-butyl-2,6 *p*-benzoquinone, on observe uniquement un radical semiquinone et la cinétique de sa disparition a pu être évaluée par rpe. La réduction du triplet de la *tert* butyl-2 *p*-benzoquinone conduit à la formation des radicaux semiquinones isomères **1** et **2** lors du processes photochimique primaire et celui-ci est alors suivi par un équilibre chimique entre les deux radicaux isomères. On ne peut évaluer les vitesses relatives de formation des deux radicaux par la rpe conventionnelle mais des résultats de CIDEP montrent que la formation du radical **2** est environ cinq à sept fois plus rapide que celle du radical **1**. Une réaction secondaire du radical phénoxy avec un produit benzohydrofuranne **4** conduit à l'observation d'un radical polarisé **3** qui tire sa polarisation du radical phénoxy primaire.

[Traduit par le journal]

Introduction

Electron spin resonance spectroscopy has been commonly used to follow photochemical reactions (1) in solutions because the transient free radicals can be detected and identified, and their decay kinetics easily followed. However, spectra recorded during irradiation often exhibit 'polarizations' which arise from the electron spin states of the radicals being populated in a non-Boltzmann manner. Such 'polarizations' must be accounted for before any meaningful kinetic measurements can be obtained. In general, there are two types of 'polarizations' in photochemically generated radicals (2), the E-A and the initial polarizations. The former arises through the same radical-pair mechanism which generates most of the CIDNP in solution and the latter through the photoexcited triplet mechanism which involves the chemical quenching of a spin polarized triplet state (2). With the coexistence of both types of polarizations well demonstrated, it is now possible to gain information not normally obtained from conventional esr studies for those photochemical reactions which show 'initial polarization' (2, 3) in the CIDEP observations.

In this paper we report the esr results from a kinetic and CIDEP study of the photoreduction of 2-*tert*-butyl-*p*-benzoquinone (*t*BBQ), 2,5- and 2,6-di-*tert*-butyl-*p*-benzoqinones (2,5- and 2,6-d*t*BBQ) by 2-propanol as well as by phenols. Our interest in these systems arose out of our studies of the photoreduction of quinones as model systems in establishing the role of the excited triplet quinones in CIDEP and CIDNP (2). We have found that the primary photoreduction of *t*BBQ leads to the formation of polarized semiquinone radicals in two isomeric forms:



1 **2**

With the CIDEP results, it was also possible to establish that both isomeric radicals **1** and **2** are primary radicals formed by the spin polarized triplet *t*BBQ abstracting from both carbonyl groups. In the previous esr, CIDEP, and CIDNP studies (4, 5) of 2-methyl-*p*-benzoquinone and 2,6-di-*tert*-butyl-*p*-

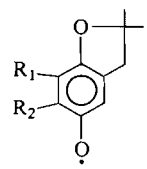
benzoquinone, only one primary semiquinone radical with a structure similar to **1** was observed.

In addition to the semiquinone radicals, we have observed in these systems a polarized secondary radical **3** whose concentration, relative to the semiquinone radicals, depends on the solvent. This radical **3** serves as an interesting example for polarization transfer from a primary radical to a secondary radical, which further demonstrates the usefulness of the CIDEP techniques in mechanistic photochemistry.



3

3*a* $R_1 = R_2 = H$
3*b* R_1 = *tert*-butyl, $R_2 = H$
3*c* $R_1 = H$, R_2 = *tert*-butyl

Experimental

The chemicals used in these experiments were purchased from one of the following companies: Aldrich, Allied Chemicals, Baker, Canlab, Eastman, Fisher, and Thompson-Packard. 2-*tert*-Butyl-*p*-benzoquinone and 2,5-di-*tert*-butyl-*p*-benzoquinone were synthesized by the oxidation of the corresponding hydroquinones using sodium chlorate and vanadium pentoxide in 2 vol% sulfuric acid (6). Because quinones, hydroquinones, and phenols tend to deteriorate on storage; the hydroquinones were recrystallized from benzene, and the phenols and quinones were purified by vacuum sublimation. All solvents were distilled before use.

Unless otherwise stated, the concentration of quinone in the solution was 0.1 mol dm^{-3} and that of the phenol was 0.5 mol dm^{-3}. These solutions were all deoxygenated by bubbling with nitrogen gas immediately before photolysis. In a few specified experiments, flowing solutions (2–10 ml/min) were photolyzed at room temperature in a quartz flat cell inside the microwave cavity of a Varian E-3 X-band spectrometer. However, in most experiments, static samples were photolyzed in Pyrex cells directly in the cavity of a Bruker ER-420 spectrometer with temperature control accessories. The light source used was either a 200 W or a 1 kW super high pressure mercury lamp. The CIDEP experiments were carried out in the Bruker spectrometer interfaced to a Nicolet 1180 computer. The CIDEP method has been described elsewhere (2, 7). In many cases where spectra from different radicals overlapped substantially in the centre, polarization measurements were restricted to outer lines with minimum overlap. In those cases the E-A polarization from the radical-pair component was removed by the method of averaging (2, 7). The viscosity of the solutions was measured with an Ostwald viscosimeter.

Results and Discussions

The Photolysis of tert-*Butyl*-p-*benzoquinones*

The photolysis of 2-*tert*-butyl-*p*-benzoquinone, 2,5- and 2,6-di-*tert*-butyl-*p*-benzoquinone in 2-propanol or in a 10 vol% 2-propanol–toluene solution (with or without a phenol present) leads to the observation of the semiquinone radicals. In the case of *t*BBQ, two isomeric radicals **1** and **2** were observed, whereas for 2,5-d*t*BBQ and 2,6-d*t*BBQ only one semiquinone was observed. The hyperfine coupling constants of all the observed semiquinone radicals, which varied with solvent and temperature, are summarized in Table 1. The assignment of the hydroxylic proton splittings was confirmed by carrying out the photolysis in fully deuterated solvents. In the case of 2,6-d*t*BBQ in which two isomeric semiquinone radicals were expected by analogy to *t*BBQ, the photoreduction was carried out in the above two solvents and also in acetic acid at temperatures ranging between −50 and 50°C. However, the isomeric equivalent of radical **2** was never detected.

When the photoreduction of *t*BBQ was carried out in the presence of a phenol, such as 2-methylphenol or pentachlorophenol, using toluene as a solvent, another radical was predominantly observed which we have assigned to the substituted benzohydrofuran radical **3***a*. If the solvent toluene was replaced by acetic acid both the semiquinone radicals and the radical **3***a* were observed. A typical esr spectrum consisting of all three radicals is shown in Fig.1. The coupling constants of **3***a* are given in Table 1. The assignment of **3***a* was confirmed by the observation of **3***b* and *c* when the corresponding di-*tert*-butyl-benzoquinones were photolyzed under similar conditions (see Table 1).

Using toluene as a solvent, when *t*BBQ was photoreduced in the presence of 2,6-di-*tert*-butylphenol, radical **3***a* was not observed but the esr spectrum of the phenoxy radical was obtained. Intermediate cases showing both radical **3***a* and phenoxy radicals can be obtained by using less hindered phenols such as 2-methyl-6-*tert*-butylphenol and by varying the temperature. This suggested to us that radical **3***a* may be formed in 'secondary' reactions with photoproducts. To prevent the build up of products, we photolyzed flowing solutions of *t*BBQ – phenol – acetic acid and measured the relative intensities of the radicals **1**, **2**, **3***a*. With no flow, the ratios were 2:1:1 but as the flow rate was increased the intensity of **3***a* relative to the first two decreases, until at 10 ml/min the ratio was 2:1:0.1. This supports the hypothesis that **3***a* was formed through a secondary reaction.

It is known that when *tert*-butylbenzoquinones are photolyzed in benzene or acetic acid a substituted benzohydrofuran **5** is formed but when the photolysis is carried out in the presence of 2-propanol, in addition to the expected hydroquinone, a second hydroquinone **4** with a rearranged side group is produced.

Both these reactions are thought to involve internal hydrogen abstractions from the side chain. This species then undergoes a series of reactions depending on the media, but all involve rearrangement of the side group (8). It is almost certainly **5** which is the precursor of radical **3**.

The formation of the semiquinone radicals involves the chemical quenching of the quinone triplet by a hydrogen donor (HD):

[3*a*] $^3(t\text{BBQ}) \xrightarrow{\text{HD}} \mathbf{1, 2}$

[3*b*] $^3(2,6\text{-d}t\text{BBQ}) \xrightarrow{\text{HD}}$ 
[3*c*] $^3(2,5\text{-d}t\text{BBQ}) \xrightarrow{\text{HD}}$ 
If 2-propanol was the hydrogen donor, the counter radical will reduce a ground state quinone molecule to a semiquinone radical.

[4] $\quad Q + (CH_3)_2\dot{C}OH \rightarrow \dot{Q}H + (CH_3)_2CO$

When the hydrogen donor is a phenol, a phenoxy

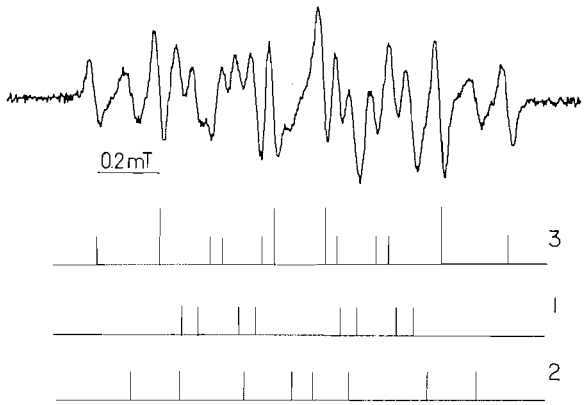

FIG. 1. Electron spin resonance spectrum observed during the photoreduction of *t*BBQ by phenol in acetic acid −12°C.

radical is formed, and its fate is uncertain in solutions containing 2-propanol.

However, as radicals **3***a*, *b*, and *c* are only observed in the absence of 2-propanol, then it is most likely that they are formed by the reaction of the primary phenoxy radical with **5** in reaction 5.

[5] $$\dot{\text{O}}\text{Ph} + \mathbf{5} \rightarrow \mathbf{3} + \text{PhOH}$$

This premise is supported by the fact that when a more stable phenoxy radical (e.g. 2,6-di-*tert*-butylphenoxy) is formed in reaction 3, it is the phenoxy radical that is observed and not radicals **3**. The CIDEP results to be described later also support this reaction.

The low steady state yield of semiquinone radicals in toluene solution is due to a combination of their intensity being reduced by emissive CIDEP and the higher second order termination rate constants found for semiquinones in toluene as opposed to 2-propanol (7, 11).

Kinetic Electron Spin Resonance Study of the Photoreduction of 2,6-dtBBQ

In recent years, Griller and Ingold (9) have demonstrated beautifully the effect of bulky substituents on the persistence of transient radicals. Among the substituted benzoquinones studied in this laboratory, the 2,6-d*t*BBQ is certainly the simplest case for the kinetic esr study of such effects. Although recent CIDEP studies have unequivocally established the excited triplet quinones as the precursors of the polarized semiquinone radicals (2), direct esr detection of the excited triplet quinones remains unattainable. Nevertheless, conventional kinetic esr methods can be applied here to investigate the transfer of the triplet energy from 2,6-d*t*BBQ to naphthalene during the photoreduction.

An alcoholic solution of 2,6-d*t*BBQ containing about 0.02 mol dm^{-3} naphthalene was photolyzed at 77 K within the microwave cavity of an esr spectrometer. A coloured glass filter was used to select light with a wavelength >396 nm so that it would be absorbed only by the quinone. During the irradiation the $\Delta m = 2$ transition belonging to the triplet naphthalene was observed (10). Irradiation with light $\lambda > 396$ nm on naphthalene alone did not produce esr signals. This confirmed the transfer of excitation energy from triplet 2,6-d*t*BBQ to naphthalene.

In a series of photoreduction experiments of 2,6-d*t*BBQ in 2-propanol at room temperature, various concentrations ($4–20 \times 10^{-3}$ mol dm^{-3}) of naphthalene were added to quench the photoreduction. The reactions can be summarized in the following scheme:

[6] $$\text{Q} + h\nu\ (396\ \text{nm}) \xrightarrow{\phi I_a} {}^3\text{Q}$$

[7] $$^3\text{Q} + (\text{CH}_3)_2\text{CHOH} \rightarrow \dot{\text{Q}}\text{H} + (\text{CH}_3)_2\dot{\text{C}}\text{OH}$$

[8] $$(\text{CH}_3)_2\dot{\text{C}}\text{OH} + \text{Q} \rightarrow \dot{\text{Q}}\text{H} + (\text{CH}_3)_2\text{CO}$$

[9] $$^3\text{Q} + \text{C}_{10}\text{H}_8 \rightarrow \text{Q} + {}^3(\text{C}_{10}\text{H}_8)$$

[10] $$\dot{\text{Q}}\text{H} + \dot{\text{Q}}\text{H} \rightarrow \text{Q} + \text{QH}_2$$

Recent CIDEP studies of the photoreduction of quinones in 2-propanol indicate that reaction 8 is an efficient process (7, 11) which accounts for the major fate of the 2-propanol radical. A kinetic analysis of the above scheme yields the following expression for the steady-state concentration of semiquinone radicals $\dot{\text{Q}}\text{H}$ in a continuous photolysis:

[11] $$[\dot{\text{Q}}\text{H}]^{-2} = k_{10}/2\phi I_a\left(1 + \frac{k_9[\text{C}_{10}\text{H}_8]}{k_7[\text{ROH}]}\right)$$

It should be mentioned that for conventional esr kinetic measurements, care must be taken to ensure that the steady-state radical concentration is corrected for any polarization (2). In the present system at room temperature, the semiquinone radical at the steady-state was effectively thermalized as no observable 'initial polarization' was evident in the time profiles of the signal when the light was chopped with the rotating sector.

Figure 2 presents the experimental results by plotting $[\dot{\text{Q}}\text{H}]_0^2/[\dot{\text{Q}}\text{H}]^2$ vs. $[\text{C}_{10}\text{H}_8]$. $[\dot{\text{Q}}\text{H}]_0$ is the steady-state concentration of the semiquinone radicals in the absence of naphthalene. Using an estimated value of 5×10^9 dm^3 mol^{-1} s^{-1} for k_9 (12), the rate constant k_7 for the abstraction reaction by the triplet 2,6-d*t*BBQ can be estimated from the slope and is found to be about 2×10^6 dm^3 mol^{-1} s^{-1}. This value is comparable to the rate constant for the triplet benzophenone abstracting hydrogen from 2-propanol (13), which is found to be 1.3×10^6 dm^3 mol^{-1} s^{-1} by flash photolysis. The abstraction

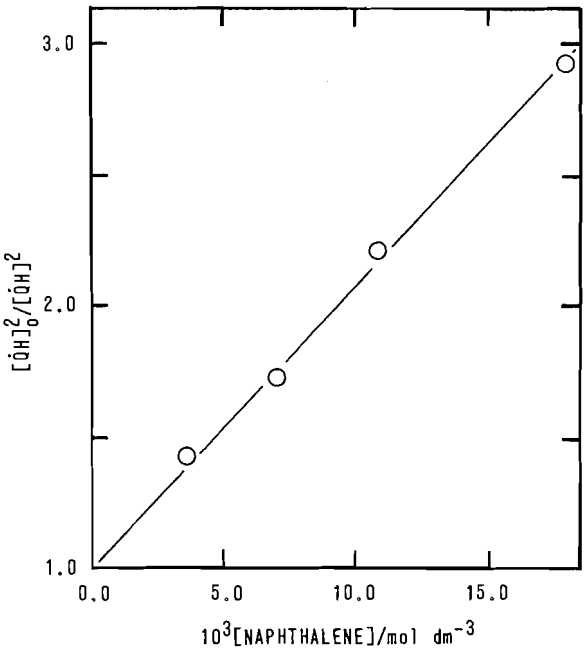

FIG. 2. Variation of steady-state concentration of 2,6-di-*tert*-butylbenzosemiquinone radicals with naphthalene concentration in 2-propanol.

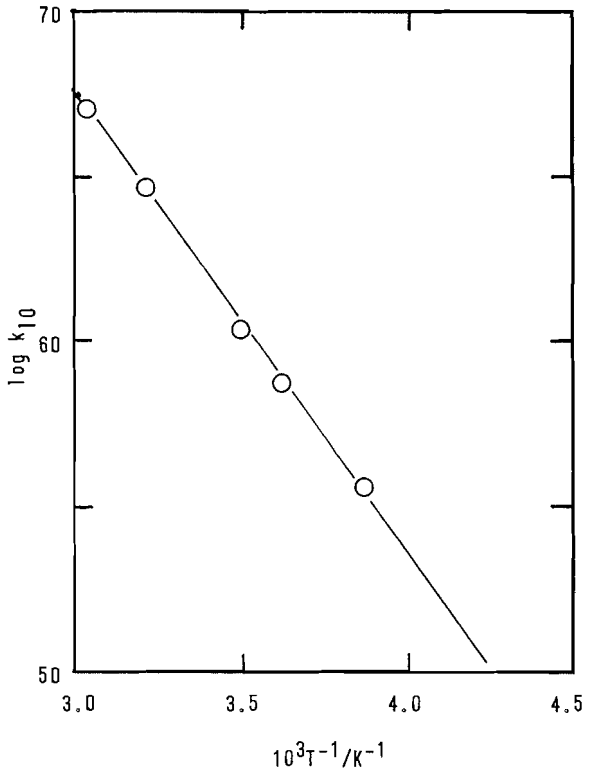

FIG. 3. The Arrhenius plot for the decay of 2,6-di-*tert*-butylbenzosemiquinone radicals in 2-propanol.

reaction between the triplet duroquinone and 2-propanol is, however, much slower (6×10^3 dm^3 mol^{-1} s^{-1}) (14), although the same triplet duroquinone would rapidly react with the durohydroquinone with a rate constant of 2 to 4×10^9 dm^3 mol^{-1} s^{-1} (14–16). In a separate CIDEP study (7) Elliot and Wan have observed that the slow reaction of triplet duroquinone with 2-propanol is rather unique, since most of the other quinones do react with 2-propanol at a reasonable rate to produce 'initial polarization'.

The decay of the transient semiquinone radicals in reaction 10 was also studied by the rotating sector-kinetic esr technique (17) at different temperatures between −20 and 60°C. In all cases the decay curves followed good second order kinetic plots. The Arrhenius parameters of the decay of the 2,6-di-*tert*-butylbenzosemiquinone radicals were obtained from a plot of log k_{10} against $1/T$ K^{-1} as shown in Fig. 3 and summarized in Table 2.

In order to establish the steric effect of the substituents on the kinetic parameters of the semiquinone radicals, a parallel kinetic study of the decay of the 2,6-dimethylbenzosemiquinone radicals was also carried out. The results are given in Table 2, along with those of other semiquinone radicals which have been previously studied in this laboratory (18).

In Table 2 it is seen that the decay of the 2,6-di-*tert*-butylbenzosemiquinone radicals is three orders of magnitude *slower* than that of the other semiquinone radicals. Such a drastic difference parallels the decay of 2,6-di-*tert*-butylphenoxy radicals as compared to the less sterically hindered phenoxy radicals (22). The dramatic steric effect on the persistence of the radicals has been well established by Ingold and coworkers (9).

The comparison between the persistence of 2,6-di-*tert*-butylbenzosemiquinone radicals and that of 2,6-dimethylbenzosemiquinone radicals is rather interesting. It appears that the persistence of the 2,6-di-*tert*-butylbenzosemiquinone radical is a result of a substantial increase in the activation energy of the decay process [12] rather than decrease in the *A*-factor.

[12] 
Thus, the steric effect may be associated with the enthalpy of the reaction, instead of the entropy of the reaction. In reaction 12, one 'unhindered' O—H bond is destroyed while a 'hindered' O—H bond is formed. The dissociation energy of that 'hindered'

TABLE 2. Second-order rate constants and Arrhenius parameters for the self-disproportionation of some semiquinone radicals in 2-propanol (20°C)

Radical	k_{10} (dm^3 mol^{-1} s^{-1})	E_a (kJ mol^{-1})	log A	Reference
2,6-Di-*tert*-butyl-semiquinone	1.7×10^6	26 ± 3	10.9	This work
2,6-Dimethyl-semiquinone	0.3×10^9	14 ± 2	10.9	This work
Durosemiquinone	0.7×10^9	14 ± 2	11.0	18
p-Benzosemiquinone	1.5×10^9	15 ± 2	11.8	18

O—H bond could be as much as 32 kJ less than that of the 'unhindered' O—H bond (20). This may reflect in an increase in activation energy for the process 12. For the decay of 2,6-dimethylbenzosemiquinone radicals, there is not much difference between the two O—H bonds (20), and hence the activation energy of the decay would not be much different from that of the unsubstituted semiquinone radicals.

Since the photoreduction of *t*BBQ in 2-propanol produces two isomeric semiquinone radicals **1** and **2**, it would seem inviting to compare their decay kinetics. The experimental measurements show that there is little difference in their half-lives. However, the CIDEP results given below suggest that there is a very rapid equilibrium between the two semiquinone radicals and our conventional rotating-sector kinetic esr measurements cannot resolve the individual decay versus the rapid equilibrium between them.

CIDEP

In the photoreduction of *t*BBQ in 2-propanol at −20°C, *all* hyperfine lines of the radicals **1** and **2** exhibit emission. In the presence of phenol, the emission magnitude was greatly increased as the abstraction reaction between the triplet quinone and phenol is substantially faster than that with 2-propanol. Such polarization dependence on chemical rates is predicted by the phototriplet mechanism which is now well understood (2). For quantitative CIDEP studies, the photoreduction of *t*BBQ was carried out in a 10% 2-propanol–toluene solution at −20°C in the presence of varying amounts of 2-methylphenol.

The polarization of the radicals **1** and **2** is measured separately from the 'time profile' (Fig. 4) in terms of an enhancement factor, V, which is related to the experimentally measured 'steady-state enhancement factor', V_{ss}, by the following relationship (2);

$$V = V_{ss}t_{1/2}/T_1$$

where $t_{1/2}$ is the radical half-life which can be measured directly from the 'time profile', and T_1 is the spin–lattice relaxation time of the radical. It was

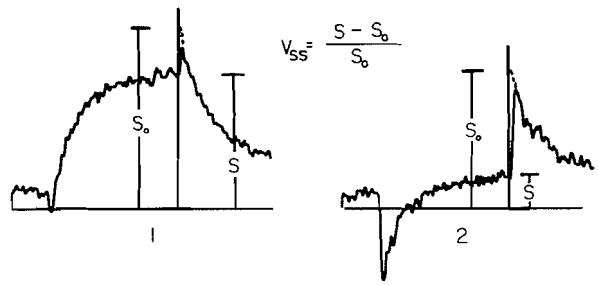

FIG. 4. The time profiles of representative peaks within radicals **1** and **2**, respectively. The downward spike is the 'light on' point and the upward spike is the 'light-off' point. The duration was about 11 ms.

established by a series of power saturation experiments that there is no significant difference in T_1 for radicals **1** and **2**. Since the absolute value of T_1 is not available for radicals **1** and **2**, we used the reported T_1 values for the semiquinone radical anion of *t*BBQ (19) corresponding to the viscosity of the solution containing phenol. The estimation[1] using the semiquinone anion T_1 values has been found to be satisfactory (7). The calculated T_1 increases from 6 μs to 8 μs over the 2-methylphenol concentration range studied.

In the phototriplet mechanism the enhancement value is related to the quencher concentration by the following equation (27)

$$[13] \qquad 1/V = 1/V_0 + 1/(V_0{}^3T_1k_q[\text{phenol}])$$

where V_0 is the enhancement factor at infinite quencher concentration, k_q is the quenching rate constant between the triplet quinone and phenol, and ${}^3T_1$ is the spin–lattice relaxation time for the triplet quinone. A plot of $1/V$ vs. 1/[phenol] is given in Fig. 5 for both radicals **1** and **2**. Equation 13 was applied to the experiments where the concentration of 2-methylphenol was varied from 0 to 2 mol dm^{-3}. However, since V_0 is an intrinsic constant of the quinone triplet, and ${}^3T_1$ tends to increase with viscosity while k_q decreases with increasing viscosity,

[1] T_1 is calculated from the relationship (19) $(T_1)^{-1} = A(T/\eta) + B$ where $A = 6 \times 10^8$ P s^{-1} K^{-1} and $B = 5.4 \times 10^{-10}$ s^{-1}.

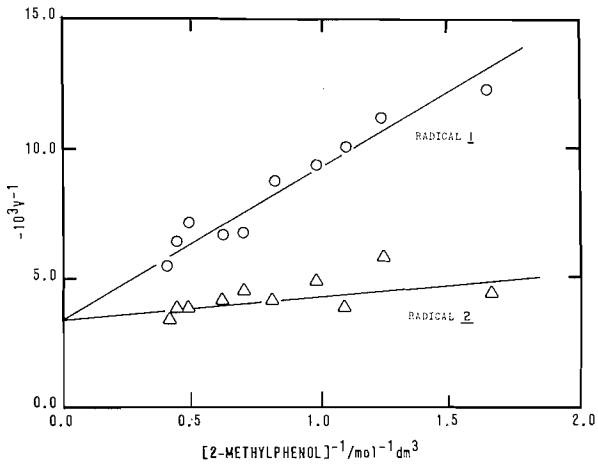

FIG. 5. The plot of reciprocal enhancement factors vs. reciprocal 2-methylphenol concentration for radicals **1** and **2**.

the combination is such that a constant slope may be obtained.

The CIDEP results are consistent with the following phototriplet mechanism:

[14] ^{3}(2-*t*BBQ) + PhOH $\longrightarrow$ PhȮ + **1**

[15] ^{3}(2-*t*BBQ) + PhOH $\longrightarrow$ PhȮ + **2**

In the presence of a phenol, the semiquinone radicals **1** and **2** are produced mainly by reactions 14 and 15. Since both radicals are produced from the primary reactions with the same spin polarized triplet quinone, it is expected that V_0 (a property of the triplet) should have the same value for both radicals **1** and **2**, and this is observed in Fig. 5. The ratio of the two slopes in Fig. 5 suggests that k_{15} is about 5 to 7 times greater than k_{14}. Further examination of the system, however, revealed that the concentration of **1** is always about twice that of radical **2** and that both radicals **1** and **2** appeared to decay with similar half-lives. These results can be explained by an equilibrium between radicals **1** and **2**, probably via the common radical anion intermediate:

[16] 
2 **1**

Thus, although **2** is generated faster than **1** in the primary photochemical reactions, the forward and back reactions are sufficiently fast to maintain the equilibrium under the conditions of the experiment.

The rapid equilibrium in [16] was confirmed by further experiments in which radicals **1** and **2** were generated in different ways. Radicals **1** and **2** were generated by reaction of 2-*tert*-butylhydroquinone (0.8 mol dm^{-3}) with di-*tert*-butyl peroxide (5 vol%) in 10 vol% 2-propanol–toluene at −20°C. The radicals observed were not polarized but their relative concentration was again 2:1.

In the photoreduction of 2-methylanthraquinone (0.05 mol dm^{-3}) by *2-tert-butylhydroquinone* (0.8 mol dm^{-3}) in 10 vol% 2-propanol–toluene solvent at −25°C, both radicals **1** and **2** were generated as the counter radicals:

[17] 
[18]

Both radicals **1** and **2** were totally emissive but the enhancement factor for radical **2** (<0.05) was now actually smaller than radical **1** (V = 0.2). The steady-state concentration of **1**, however, was still about twice as great as radical **2**. The greater V for radical **1** is reasonable since reaction 17 should proceed faster than reaction 18 based on the argument that the two O—H bonds may have different dissociation energy amounting to as much as 32 kJ (20) in favour of forming radical **1**. The relative concentration of **1** and **2** is nevertheless always governed by the equilibrium 16. Finally, when *t*BBQ was used to photoreduce its own 2-*tert*-butylhydroquinone, the enhancement factor of radical **2** was still greater than that of radical **1**. The relative concentration of **1** and **2** remained 2:1.

With the establishment of the equilibrium between **1** and **2**, it is now necessary to consider any possible transfer of polarization from **2** to **1** during the equilibrium. In the extreme case of reactions 14 and 15, **1** may not be formed at all in the primary photochemical reaction, and it would derive the polarization solely from the primary radical **2** via the equilibrium 16. If the rate of approaching equilibrium is greater than the spin–lattice relaxation rate of the polarized radical **2**, the plot in Fig. 5 should have yielded only a single line for both **1** and **2**. If the rate is comparable or smaller than the spin–lattice relaxation rate, the plot in Fig. 5 should have given two *parallel* lines each having an identical slope but with entirely different intercepts. Since the lines are not parallel (Fig. 5), this indicates that radicals **1** and **2** are both produced in the primary photochemical reactions involving the same triplet quinone, with $k_{15} > k_{14}$. Within the experimental errors, there could be some transfer of polarization from **2** to **1** in the equilibrium 16, but the rate of exchange is unlikely to be greater than 10^{-5} s^{-1}, which repre-

sents a typical spin–lattice relaxation rate for semiquinone radicals.

One might expect that radical **1** would be formed predominantly in the photoreduction of *t*BBQ because of steric hinderance from the *tert*-butyl group. In an earlier paper (14), it was suggested that this was indeed the case for 2-methylbenzoquinone since only the equivalent of radical **1** was observed by esr. However, in the present experiments, although the equilibrium 16 favours **1**, the analysis of the CIDEP results clearly indicates that the formation of **2** in the primary photochemical process was 5 to 7 times faster than that of **1**. Conventional product analysis and kinetic esr would have failed to reveal this fact. Furthermore, it should be remembered that not only was the carbonyl group adjacent to the *tert*-butyl group abstracting hydrogen from the surrounding media, but that internal hydrogen abstraction was also occuring at that center.

CIDEP was observed when 2,6- and 2,5-d*t*BBQ were photoreduced in 10 vol% 2-propanol–toluene solutions containing a phenol but because of the long half-life of 2,6-di-*tert*-butylbenzosemiquinone radicals and the rapid depletion of 2,5-d*t*BBQ, quantitative CIDEP studies could not be made. The 2,5-d*t*BBQ depletes because internal hydrogen abstraction can occur at either end.

While the CIDEP study establishes that the triplet *t*BBQ can abstract from both carbonyl end groups to form semiquinone radicals **1** and **2**, it remains unclear why many of the other unsymmetrical benzoquinones only generate one observable semiquinone radical. For example 2,6-d*t*BBQ only leads to a radical with a structure similar to **1**. Perhaps in this case one may argue that the 2,6-d*t*BBQ semiquinone radical **1** would be more persistent than the isomer **2**, and a similar equilibrium 16 may favour entirely the formation of **1**. Experimental results do point to the greater persistence of the isomer **1** in the photoreduction of 2,6-d*t*BBQ. However, there is no compelling evidence that the 2-methylbenzosemiquinone **1** should be more persistent than the analogous **2**, and in the photoreduction of 2-methyl-*p*-benzoquinone (4) only radical **1** was observed.

In the photoreduction of *t*BBQ by phenol in acetic acid or in toluene, the radical **3***a* was found to have all lines in diminished absorption, i.e. in the emissive mode. Evidence has been presented above that radical **3***a* is generated in a secondary reaction 5, and its polarization therefore must derive solely from the primary phenoxy radical. (It is unlikely to be formed in any photoreduction reaction because its concentration will be at most a thousand-fold less than that of the phenol. Polarization derived from the competitive reaction 4 was also unlikely since Fischer (23) had found that this reaction is very slow ($k = 10^3$).) It is further confirmed that it is not just the observation of radical **3***a* that depends on the reactivity of the phenoxy radicals, but the enhancement factor of radical **3***a* also depends on the 'type' of phenoxy radicals present. Such a transfer of polarization can yield some information on the rate of the chemical reaction. For example, in reaction 5 the rate must compete effectively with the spin–lattice relaxation rate of the polarized phenoxy radicals, which usually is in the order of 10^{-5} s^{-1}. Thus, for radical **3***a* to be polarized by the transfer of polarization from the phenoxy radicals, k_5[**5**] must have the magnitude of 10^{-5} s^{-1}. If the photochemical product **5** has a concentration of about 10^{-4} mol dm^{-3}, it follows that k_5 would be about 10^9 mol^{-1} dm^3 s^{-1}, which is near diffusion-controlled.

The CIDEP observation on the analogous radicals **3** in the photolyses of 2,6-d*t*BBQ and 2,5-d*t*BBQ in the presence of phenol are similar to that of *t*BBQ. Thus, the reaction 5 is another example of polarization transfer in a chemical reaction, which is the basic principle underlying the phototriplet mechanism. McLauchlan and Sealy (21) have demonstrated the polarization transfer from a primary triethylamine radical to biacetyl. Such a polarization transfer can be used not only as a probe in reaction mechanism studies but also as a means to derive some kinetic information of the chemical reaction we have shown above. Furthermore, in a system where the T_1 of the radical undergoing the polarization transfer is unknown, a quantitative polarization transfer study as a function of the quencher concentration would lead to an estimate of the T_1 provided the rate constant for the transfer is known.

Conclusions

The results in this report indicate that the combination of CIDEP and conventional esr studies provides a powerful tool with which to study the mechanisms of the free radical reactions in the photochemistry of *tert*-butyl substituted quinones. This technique has enabled us to show that *t*BBQ is photoreduced to form two isomeric semiquinone radicals **1** and **2**, and that both carbonyl groups are undergoing photochemical reduction. Also from the CIDEP results we are able to estimate the magnitude of k_5 for the hydrogen transfer reaction between **5** and the phenoxy radical.

GORDON W. BUSHNELL and KEITH R. DIXON. Can. J. Chem. **56**, 878 (1978).

The crystal structure of *cis*-chlorobis(triethylphosphine)phthalazineplatinum(II) tetrafluoroborate has been determined by single crystal X-ray diffraction and refined to an *R*-value of 0.076 for 1935 reflections. The cell dimensions are $a = 1315.7(2)$, $b = 2462.7(4)$, $c = 899.6(3)$ pm, $\beta = 104.99(2)°$. The space group is $P2_1/c$ with 4 molecules per unit cell, $\rho_o = 1.593$, $\rho_c = 1.613$ g cm^{-3}. The structure is a square planar 4-coordinate platinum(II) complex with an angle of 80.0° between the plane of the phthalazine molecule and that of the coordination. Interatomic distances to platinum are Pt—Cl, 235.4(9); Pt—P(1), 225.2(8); Pt—P(2), 226.9(8); Pt—N(1), 208(3); and Pt—N(2), 297(3) pm, the phthalazine ligand being monodentate. The structure is compared to previous results and discussed in relation to variable temperature nmr studies of solutions, which show that the heterocyclic ligand exchanges its point of attachment to and fro between N(1) and N(2) by a dissociative mechanism at elevated temperatures.

GORDON W. BUSHNELL et KEITH R. DIXON. Can. J. Chem. **56**, 878 (1978).

On a déterminé la structure cristalline du tétrafluoroborate du chlorobis(triéthylphosphine)-phtalazineplatine(II) *cis* en faisant appel à la diffraction de rayons-X de monocristaux et on a affiné la structure jusqu'à un facteur d'accord de 0.076 pour 1935 réflexions. Les dimensions de la maille sont $a = 1315.7(2)$, $b = 2462.7(4)$, $c = 899.6(3)$ pm, $\beta = 104.99(2)°$. Le groupe d'espace est $P2_1/c$ pour quatre molécules par maille, $\rho_o = 1.593$, $\rho_c = 1.613$ g cm^{-3}. La structure correspond à un complexe plan carré tétracoordonné du platine(II) avec un angle de 80.0° entre la molécule de phtalazine et celle de la coordination. Les distances interatomiques vers le platine sont Pt—Cl, 235.4(9); Pt—P(1), 225.2(8); Pt—P(2), 226.9(8); Pt—N(1), 208(3) et Pt—N(2), 297(3) pm, et le ligand phtalazine est monodentate. On a comparé cette structure avec des résultats antérieurs et on en discute par rapport aux résultats obtenus lors d'études rmn en solutions qui montrent qu'à haute température le ligand hétérocyclique échange son point d'attache entre les azotes 1 et 2 par un mécanisme dissociatif.

[Traduit par le journal]

Introduction

A nuclear magnetic resonance study (1) and two crystal structure determinations (2, 3) have been completed for a series of compounds *cis*-$[PtCl(PEt_3)_2L]BF_4$, where L is a potentially bidentate heteroaromatic ligand containing two nitrogen atoms. The ligands used have been dipyridyl or *o*-phenanthroline, naphthyridine, and pyridazine or phthalazine. This is the third crystal structure determination of a series in which the interatomic distance between the nitrogen atoms of the ligand is decreasing. The preceding studies for which L = phen (2) and L = naph (3) have shown that in the crystalline state these ligands are monodentate. The structures of the phenanthroline and naphthyridine ligands prevent the second nitrogen atom from being completely removed from the platinum atom, but a survey of M—N(1) and M—N(2) distances in other known structures showed that the ratio of the bond distances Pt—N(2):Pt—N(1) was extremely high for our compounds (2, 3).

The nuclear magnetic resonance results (1) show that the phenanthroline and naphthyridine complexes in solution at room temperature are undergoing a rapid intramolecular fluxional process in which the point of attachment of the ligand to the platinum is exchanging between N(1) and N(2). By lowering the temperature, the rate of naphthyridine exchange can be reduced sufficiently to obtain a low temperature limiting spectrum at −60°C in which the proton resonances for the two aromatic rings are not equivalent. The fluxional process for the phenanthroline complex is faster and the low temperature limiting spectrum cannot be observed even at −85°C, at which point crystallization and viscosity broadening make further cooling unprofitable.

For the pyridazine and phthalazine complexes the nmr spectra indicate that the fluxional process is much slower (1). The room temperature spectrum is the low temperature limiting spectrum. Above 90°C the peaks coalesce but the absence of Pt or P sidebands shows that the fluxional process is dissociative rather than intramolecular (1).

We have been able to correlate the solid state structures of the phenanthroline and naphthyridine complexes with the nmr kinetics (3). Consideration of the preferred direction of the N sp^2 sigma bonding seemed important in this regard. It was therefore of interest to obtain a crystal structure of *cis*-[$PtCl(PEt_3)_2L$]BF_4 where L was either pyridazine or phthalazine, and the two preferred bonding directions diverge outwards from the nitrogen atoms. Good crystals of the phthalazine containing compound were obtainable and so we have proceeded on this basis.

No previous crystal structure determinations of phthalazine complexes have been found in the literature, but the crystal structure of phthalazine itself is known (4). The crystal structure of a binuclear Ni(II) complex of 1,4-dihydrazinophthalazine has been determined (5), in which both ring nitrogens and both NH_2 groups are coordinated. The phthalazine part of the ligand plays a bridging role between the nickel centres. The crystal structure of [CuCN·pyridazine] has been determined (6) and contains zigzag CuCN chains linked by the N atoms of the organic ligand, the copper atom being approximately tetrahedral. 3,6-Diphenylpyridazine (dphp) reacts with $Fe_2(CO)_9$ to produce [$Fe_2(CO)_6$(dphp)], a compound containing a bridging (dphp) group and an Fe—Fe bond. Crystal structures have been obtained for two derivatives [$Fe_2(CO)_5P\phi_3$(dphp)] (7) in which the N—N bond of the bridging pyridazine ring is transverse to the Fe—Fe bond and the maleic anhydride adduct [$Fe_2(CO)_6$(dphp)($C_4H_2O_3$)] in which the bridging (dphp) group has its N—N bond approximately parallel to the Fe—Fe bond (8). If the phenyl groups in (dphp) are replaced by 2-pyridyl groups we obtain a ligand (dpyp) which is potentially quadridentate. The crystal structure of [$Mn(dpyp)_2(NO_3)_2$] contains both nitrate and (dpyp) as bidentate ligands making the Mn(II) 8-coordinate (9). The (dpyp) ligand resembles 2,2′-dipyridyl in this structure and only one nitrogen of the pyridazine ring forms a coordinate bond. These data suggest that phthalazine is likely to act as a bridging ligand in many compounds but monodentate structures are also a possibility.

Experimental

The preparation and analysis of the compound have already been reported, together with the spectroscopic results (1). The crystal was grown by a vapour diffusion method (ref. 10, p. 65) using methanol and diethyl ether as solvents. The title compound, $C_{20}H_{36}BClF_4N_2P_2Pt$, is monoclinic, space group $P2_1/c$, molecular weight 683.8, and cell dimensions a = 1.3157(2), b = 2.4627(4), c = 0.8996(3) nm, β = 104.99°. The cell having the volume 2.816(1) nm^3 contains 4 molecules and the density is 1.593 g cm^{-3} (measured) and 1.613 g cm^{-3} (calculated). Mo K_α X-rays, λ = 71.069 pm were used for intensity measurements on a crystal of dimensions 0.424 × 0.058 × 1.33 mm. The absorption coefficient was 54.89 cm^{-1}. The space group $P2_1/c$ was established from Weissenberg and precession photographs using Cu radiation. The shape of the crystal chosen for intensity measurements was like the blade of a pointed knife, the mounting direction being the c-axis, along the length of the blade. Only the pointed tip of the blade was not immersed in the beam. The irradiated material changed from colourless to yellow during data collection. The crystal was put on a Picker 4-circle diffractometer. The cell dimensions were refined by least squares using 31 pairs of positive and negative 2θ measurements. The density was measured by flotation in a solution of carbon tetrachloride and bromoform. The diffractometer matrix was refined from 32 pairs of automatic centering measurements. The scan was by 50 steps of 0.04° in 2θ counting for 1 s per step. The background counts were for 10 s at each end of the scan. A set of three standards 8,0,0; 0,−14,0; and 0,0,4 was measured after every batch of 50 reflections. Measurements were completed up to 45° in 2θ, h positive and negative, $k \geq 0$, $l \geq 0$. Reflections for which $I < 3\sigma(I)$ were not output. The intensities were corrected using the current set of standards and the Lorentz and polarization factors were applied. An instrument instability constant of 0.04 was derived from the standards and used to calculate $\sigma(F)$, (ref. 10, p. 454). Absorption corrections were done by numerical integration using a 10 × 4 × 16 Gaussian grid, the program was that of Coppens, Leiserowitz, and Rabinovich (11) modified for our diffractometer. The measurements were then sorted and merged to give 1935 independent observations.

Structure Determination

The structure was solved by the heavy atom method. The programs used were kindly supplied by Penfold (12), and are considerably modified versions of ORFLS, FORDAP, ORTEP, and ORFFE. The atomic scattering factors for P, Cl, and Pt were from Cromer and Waber (13). Pt was treated as an anomalous scatterer (14). The atomic scattering factors for B, C, N, and F were taken from the International Tables (15). All atoms were assumed to be uncharged. The Pt atom was located using a three dimensional Patterson map, and the first structure factor calculation gave an R-value of 0.25. The other atoms were located using Fourier and difference maps and refinement was by full matrix least squares, minimizing $\Sigma w(|F_o| - |F_c|)^2$. When R = 0.081, a weighting scheme was devised having the form $W = [A + B|F_o| + C|F_o|^2 + D|F_o|^3]^{-1}$ with A = 18.96, B = −0.1283, C = 1.740 × 10^{-3}, D = 5 × 10^{-6}. The heavy atoms were given anisotropic temperature parameters and refinement was completed with several cycles of full matrix least squares. The maximum change/error in the final cycle was 0.15 and the mean value 0.011, the larger changes being associated with the BF_4^- ion. The final conventional R-value was 0.076 and the weighted R-value, $(\Sigma(w\Delta^2/wF_o^2))^{1/2}$ was 0.099. The final difference map gave no indications of any misplaced atoms.

The final positional and temperature parameters are given in Tables 1 and 2. The structure factor table is in the Depository for Unpublished Data.[1]

Results and Discussion

The crystal structure contains separate [$PtCl(PEt_3)_2$(phth)]$^+$ and BF_4^- ions. Figure 1 is the packing diagram of one unit cell. Figure 2 gives a

*$T = \exp(-8\pi^2 U_{iso} \sin^2\theta/\lambda^2)$.

picture of the cation displaying the thermal parameters and the atom labelling scheme. Tables 3 and 4 give interatomic distances and bond angles respectively. The triethylphosphine ligands are normal having mean lengths: P—C, 185 pm; C—C, 156 pm, and mean angles: C—P—C, 105°; P—C—C, 112°. The distances and angles in the ligand phthalazine are not significantly different from those which have been measured more accurately in pure crystalline phthalazine (4).

The results of the mean plane calculations have been deposited.[1] Significant non-planarity of the phthalazine ligand was not observed ($\chi^2 = \sum_i |P_i^2 \div \sigma^2(P_i)| = 12$, where P_i = the perpendicular distance of atom i from the plane). Pt was 7.9(1) pm from this plane. A similar treatment for the phthalazine molecule is available, and the small departures from planarity (≤ 1 pm) are discussed (4). The atoms Pt, Cl, P(1), P(2), and N(1) deviate slightly from the least squares plane through them ($\chi^2 = 31$). The deviations are Pt −0.1(1), Cl 4(1), P(1) 3.0(9), P(2) −0.2(9), N(1) −4(3), and C(7) 3(4), C(6) 19(4). The major contributors to χ^2 are P(1) and Cl rather than N(1). The angle between the mean planes for the Pt(II) coordination and the phthalazine ligand is 80.0°.

The tetrafluoroborate anion is not unusual in having fairly high thermal parameters, a mean B—F length of 132 pm, and angles close to the tetrahedral value.

The platinum coordination geometry is best discussed in relation to that of the two previous structures of the series (2, 3). In Table 5*a* the first three entries show that bond lengths which do not involve the heterocyclic ligand are closely similar in the three compounds. The Pt—N(1) bond may be slightly longer for phen than for the other two compounds, but the significance of this is marginal. The lengths Pt—N(2) and N(1)—N(2) are expected to differ, and the observed values are to be compared with values calculated from idealized models in which the ligands have regular hexagonal rings and all bond angles are 120°. Figure 3 gives the idealized geometry for N(1)—N(2), Pt—N(2), Pt—Pt′ distances in our series of compounds. Pt′ is the position the platinum atom would have if it were bonded to N(2) instead of N(1), the ligand position being fixed. The secondary Pt site is relevant to the nmr results and its distance from the primary site is greatest in the phth complex whereas the Pt—N(2) distance is at a maximum for naph. The greatest discrepancy between the observed and idealized distances in Table 5*a* is that Pt—N(2) in the phen complex is 32 pm greater than the value suggested by the model. This is caused by a tilt of the phenanthroline ligand such that the two observed Pt—N(1)—C angles differ by 8.1°.

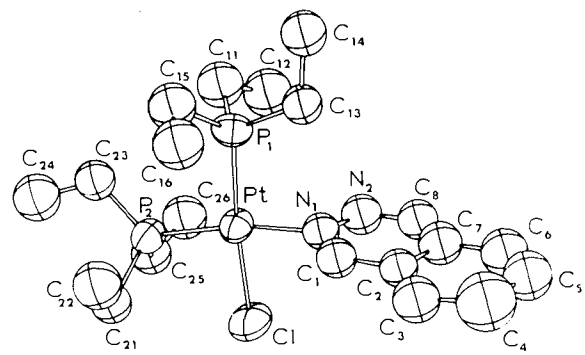

FIG. 2. Molecular structure and atom labelling scheme.

Table 5*b* shows that the bond angles of the platinum coordination are identical for the three complexes except when N(1) is involved. The close agreement shows that these angles are determined by intraionic repulsions, not by the crystal structure which is different for each compound. The conformation of the $Pt(PEt_3)_2$ moiety is identical in the three complexes of the series. The phosphorus atom and the carbon atoms of two of the ethyl groups form a W-shape which runs approximately perpendicular to the coordination plane. The carbon atoms of the third ethyl group of each ligand lie approximately in the coordination plane, avoiding the Cl atom in one ligand, and toward the heterocyclic ligand in the other. When N(1) is involved the angles of the phen complex in Table 5*b* are different from those of the naph and phth complexes, particularly the N(1)—Pt—P(*trans*) angle.

Table 5*c* gives comparable figures from the mean plane calculations for the three complexes. The planes of the ligands are roughly perpendicular to the coordination planes, with the maximum deviation of 10° for the phthalazine ligand which is least hindered for rotation about the Pt—N(1) bond. The decrease in χ^2 for plane 1 in going from phen to phth shows that the planarity is improving. The perpendicular distances of N(1) from the mean planes are given. They show that N(1) is a major contributor to χ^2 for phen and naph, but not for phth. The atoms N(1) and N(2) lie on opposite sides of the mean coordination planes in all cases.

*Defined as the coordination plane.

The X-ray structural results are closely related to the kinetics of the fluxional processes in solution. We have already discussed the relationship between the Pt—Pt′ distance and the activation energy for the exchange process (3). The deviation of the atom N(1) from the mean coordination plane is now correlated with the exchange rate. It seems that for these compounds the crystal structure gives a premonition of what will happen intramolecularly in solution. For the phen complex, N(1) is far from the coordination mean plane, in a direction which suggests exchange, and the exchange rate in solution is fast. For the phthalazine complex there is little or no deviation of N(1) from the plane and intramolecular rearrangement does not occur. The napthyridine complex is the intermediate case.

The structural evidence does not support a model in which the ligand phen is a rigid framework with N(2) attracted to the Pt atom with a force which displaces N(1) from the coordination plane. If this were true we would expect the Pt—N(2) distance to be abnormally short, whereas it is found to be longer than expected. A more suitable theory is that in order to exchange its point of attachment from N(1) to N(2) an idealized phen ligand in a perfectly square planar complex would have to rotate through 60° and translate through a distance of about 70 pm, the Pt—Pt′ distance. The extreme ends of this rotational motion are unfavourable energetically because the lone pair of electrons on N(2) repel the Pt(II) d_{z^2} electrons, hence the long Pt—N(2) distance observed. This repulsive force has a turning moment about Pt and N(1), producing the displacement of N(1) from the coordination plane and the inequality of the Pt—N—C angles. These strains result in economies in the actual motion of the ligand necessary to effect exchange, and a lower activation energy. For the naphthyridine ligand the required motion is mainly

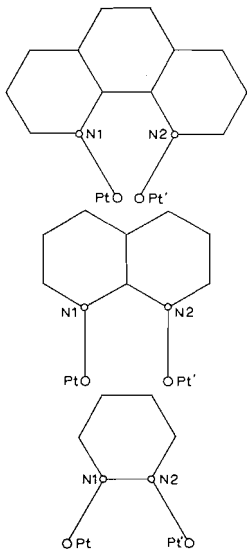

FIG. 3. Idealized structures for the heterocyclic ligands.

translational. The repulsion of the lone pair electrons is less, the resulting strain reduced, and the saving in activation energy is small. In the phthalazine case the orientation of the lone pairs is unsuitable for the five coordinate intermediate required by an intramolecular process and the mechanism of exchange becomes dissociative.

Variational energies for highly excited states of the helium atom

WAI-TAK MA, MARY KURIYAN, and HUW O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received June 13, 1977

WAI-TAK MA, MARY KURIYAN, and HUW O. PRITCHARD. Can. J. Chem. **56**, 884 (1978).

The efficient correlated variational wave functions used previously to study the higher $1sns$ states of helium have been extended to other states of the helium atom, $1snp$ ($n \leq 23$), $2pnp\ ^1P$ ($n \leq 25$), and $2pnp\ ^3P$ ($n \leq 25$); similar uncorrelated wave functions were used for $1snd$ ($n \leq 21$), $2pnp\ ^1D$ ($n \leq 10$), and $2pnp\ ^3D$ ($n \leq 10$). Attempts to use the same techniques for the $2pnp\ ^{1,3}S$ states appear to converge variationally to the energies of the $2s^2\ ^1S$ and $2s3s\ ^3S$ states respectively. Comparison is made with experimental results where appropriate, and agreement is excellent except in the case of the $1snd$ states above $n = 13$.

A search was made for excited states of H^- in each of these configurations, but no new states were found.

WAI-TAK MA, MARY KURIYAN et HUW O. PRITCHARD. Can. J. Chem. **56**, 884 (1978).

On a étendu les fonctions d'onde variationnelles corrélées efficaces, utilisées antérieurement pour étudier les états $1sns$ élevés de l'hélium, à d'autres états de l'atome d'hélium, $1snp$ ($n \leq 23$), $2pnp\ ^1P$ ($n \leq 25$) et $2pnp\ ^3P$ ($n \leq 25$); on a aussi utilisé des fonctions d'onde non corrélées semblables pour les états $1snd$ ($n \leq 21$), $2pnp\ ^1D$ ($n \leq 10$) et $2pnp\ ^3D$ ($n \leq 10$). Des essais en vue d'utiliser les mêmes techniques pour les états $2pnp\ ^{1,3}S$ semblent converger respectivement d'une façon variationnelle vers les énergies des états $2s^2\ ^1S$ et $2s3s\ ^3S$. On a fait une comparaison avec des résultats expérimentaux lorsque ceux-ci étaient disponibles et on a trouvé une excellente corrélation excepté dans le cas des états $1snd$ où $n > 13$.

On a fait une recherche des états excités de H^- dans chacune de ces configurations mais on n'a trouvé aucun nouvel état.

[Traduit par le journal]

Introduction

We have shown previously (1) that by choosing the trial wave function in a certain way, it is possible to obtain very accurate expectation values of the energy for the higher $1sns$ states of the helium atom using expansion lengths N which are only of the order of $n + 3$. In this paper, we explore the extension of these ideas to non-spherical states of helium, $1snp$, $1snd$, and $2pnp$. However, because of the considerable increase in complexity of the problem, the choice of a generalised product wave function in coordinates r_1, r_2, and r_{12} is inconvenient and two other choices were explored, product wave functions in r_1 and r_2, either uncorrelated or correlated with powers of $\cos\theta_{12}$.

$1snp\ ^1P$ and ^3P States

For the $1snp$ states, we follow the derivation of Breit (2) and use a correlated generalised product wave function of the form

$$[1] \quad \psi = F_2(r_1,r_2,\theta_{12})\cos\theta_2 \pm F_1(r_1,r_2,\theta_{12})\cos\theta_1$$

with the (+) sign corresponding to ^1P states and the (−) sign to ^3P states. In eq. 1

$$[2] \quad F_2(r_1, r_2, \theta_{12}) = \sum_{i=0}^{n}\sum_{j=0}^{n'}\sum_{k=0}^{m} c_{ijk}(\zeta r_1)^i(\zeta r_2)^{j+1} \times \cos^k\theta_{12}e^{-\zeta(ar_1+br_2)}$$

and $F_1(r_1,r_2,\theta_{12})$ is the same expression with the electron subscript indices 1 and 2 interchanged; in future equations the conventional symbol $(1 \pm P_{12})$ will be used to represent this antisymmetrising operation. In eqs. 1 and 2, r_1 and r_2, θ_1, and θ_2 are the polar coordinates of the two electrons and θ_{12} is the angle between the two radius vectors r_1 and r_2. For discussion purposes, we will label functions, as before (1), with a descriptor $\sum(i_{max},j_{max},k_{max})$ which indicates the maximum power of r_1, r_2, and $\cos\theta_{12}$ used in any calculation, but in general not the exact combination of terms. The general features of these calculations are very similar to those reported earlier for the $1sns$ states (1): that for low-lying states ($1s2p\ ^1P$, $1s3p\ ^1P$, and $1s2p\ ^3P$), the optimum combination of terms for a given expansion length N contained powers of r_1, r_2, and $\cos\theta_{12}$, e.g. $\sum(2,2,3)$, $N = 36$; on the other hand, for the higher $1snp$ states, it is always preferable to add terms in r_2 rather than r_1, and for n above about 10, addition of another term in r_2 is always preferable to one in $\cos\theta_{12}$. For any expansion length N, the absolute

accuracies of the calculated energy levels are comparable with those for the $1sns$ states given previously, and a table of energy levels using the $\sum(0,25,0)$ approximation for $1snp$, ^1P, and ^3P, ($n \leq 23$) together with the optimum values of the disposable parameter b is available on request.[1] To take just one example, using this approximation, the calculated energies of the $1s20p$ ^1P and ^3P states are both just 0.3 cm^{-1} above the observed values (3).

Previous calculations for $1snp$ states may be divided into two classes. One, these devoted to very accurate treatment of the low-lying ($n \leq 5$) states (4–6); our calculation is not intended to compete with these, but for $1s5p$, our best $N = 26$ results are about 8×10^{-5} au (i.e. 17 cm^{-1}) too high for both singlet and triplet. Two, an exploratory study using 25 hydrogen-like basis functions, by Wang and Weinhold (7) extending up to $1s13p$: in all cases, our $N = 26$ energies are superior to these by (respectively for singlets or triplets) about 37 or 28 cm^{-1} at $1s5p$, 6 or 4 cm^{-1} at $1s9p$, and 2 or 1 cm^{-1} at $1s13p$; the reason for this is that (unlike our eq. 2) Wang and Weinhold use a function with $a = b$.

Following our previous technique (8), we searched for bound $1snp$ states of H^- (and also $1snd$ states), but none was found, in conformity with general expectation (ref. 9, also ref. 5).

$1snd$ ^1D and ^3D States

From the conclusions of the earlier work on $1sns$ and $1snp$ states described above, it would appear that no new principles relating to the efficient choice of wave functions are to be found using our present approach. Consequently, for reasons which will become apparent in the later discussion, we only examined uncorrelated wave functions of the general form

$$[3] \quad \psi = (1 \pm P_{12}) \sum_{i=0}^{n} \sum_{j=0}^{n'} c_{ij}(\zeta r_1)^i(\zeta r_2)^{j+2} \times e^{-\zeta(ar_1+br_2)}(3\cos^2\theta_2 - 1)$$

The agreement of the calculated and observed energy levels for high n is good, as expected, and a table of calculated energies using the $\sum(0,25,0)$ approximation for $1snd$, ^1D, and ^3D, ($n \leq 21$) together with the optimum values of the disposable parameter b is available on request.[1] Earlier configuration–interaction calculations (25) terminated at $1s8d$, where the energies are, understandably, lower than ours by about 1 cm^{-1}.

$2pnp$ ^1P, ^3P, ^1D, and ^3D States

It is possible to choose combinations of two single p-electron wave functions in such a way that the total wave function is ^1P or ^3P, ^1D or ^3D, ^1S or ^3S in character (2, 10): this order of presentation represents the order of increasing difficulty in performing variational calculations.

For the P states of $2pnp$, the following correlated product wave function was used.

$$[4] \quad \psi = (1 \pm P_{12}) \sum_{i=0}^{n} \sum_{j=0}^{n'} \sum_{k=0}^{m} c_{ijk}(\zeta r_1)^{i+1}(\zeta r_2)^{j+1} \times \cos^k\theta_{12} e^{-\zeta(ar_1+br_2)}[(\sin\theta_1 \sin\theta_2 \sin(\phi_1 - \phi_2)]$$

where the (+) sign refers to the ^3P state and the (−) sign to the ^1P state. Calculations were performed up to and including $2p25p$ for both singlets and triplets: the upper limit of n arises, as before (ref. 1, also ref. 7), because of overflow problems in the integrals for $b < 0.025$. The lowest member of each series calculated using our 27th order $\sum(2,2,2)$ wave function is somewhat inferior to those obtained by Drake and Dalgarno (11) and by Doyle, Oppenheimer, and Drake (12) because (see below) $\cos\theta_{12}$ correlation is less efficient than r_{12} correlation: the differences are 22.7 cm^{-1}, 18.8 cm^{-1}, and 2.6 cm^{-1} for the $2p^2$ ^3P, $2p3p$ ^3P, and $2p3p$ ^1P states respectively. A table of these calculated energy levels is available on request.[1] There are, however, no experimental values available for $n > 3$, but judging from the convergence properties for the $1sns$, $1snp$, and $1snd$ energies using these kinds of wave function, it seems likely that these $2pnp$ energies are in general accurate to better than 1 cm^{-1} for n in the range 10–20.

There seems no valid theoretical reason for thinking that these energies represent true upper bounds since there is no guarantee of orthogonality with the $1snp$ manifold below, but it appears empirically that this is the case; likewise for the D states below.

The use of wave functions analogous to [4] to describe the D states of $2pnp$ requires only a straightforward extension (10); however, the calculations would be considerably lengthier because more terms are required in the matrix elements, and we did not explore them for reasons of cost. We did, however, explore the uncorrelated analogue of [4]

[1]Tables similar to Table 3 of ref. 1 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2. They will also be available in thesis form later (W.-T.M.). However, using eq. 9 and the diagrams reproduced later in this paper, it is possible to reconstruct the computed energies to a very high degree of precision.

$$[5]\quad \psi = (1 \pm P_{12}) \sum_{i=0}^{n} \sum_{j=0}^{n'} c_{ij}(\zeta r_1)^{i+1}(\zeta r_2)^{j+1} \times e^{-\zeta(ar_1+br_2)} \times [\sin\theta_1 \sin\theta_2 \cos(\phi_1 - \phi_2) - 2\cos\theta_1 \cos\theta_2]$$

where the (+) sign refers to ^1D and the (−) sign to ^3D, on the basis of our accumulated experience that the energies of highly excited states are adequately represented using uncorrelated wave functions. Calculations were performed up to $n = 10$, which should provide sufficient information[1] to make reasonable estimates of the positions of D resonances by interpolation between the calculated values and the low-lying observed values (3); Rydberg plots such as are shown later in this paper should be excellent for this purpose.

S States, 2*sns* and 2*pnp*

Straightforward modification of the wave function [4] to give the combinations of p-electron functions appropriate to an S state leads to

$$[6]\quad \psi = (1 \pm P_{12}) \sum_{i=0}^{n} \sum_{j=0}^{n'} \sum_{k=0}^{m} c_{ijk}(\zeta r_1)^{i+1}(\zeta r_2)^{j+1} \times \cos^k\theta_{12} e^{-\zeta(ar_1+br_2)} \times [\cos\theta_1 \cos\theta_2 + \sin\theta_1 \sin\theta_2 \cos(\phi_2 - \phi_1)]$$

where the (+) sign corresponds to ^1S and the (−) sign to ^3S. Use of this wave function leads immediately to calculated energies below the observed values for both $2p^2\ ^1S$ and $2p3p\ ^3S$ (for example, with a function $\sum(0,12,1)$, $N = 26$, values of −0.723 and −0.579 au, compared with the observed values (3) of −0.620 and −0.558 au respectively). In common parlance, this is because there is strong configurational mixing between 2*pnp* and 2*sns*, and it is hoped that the following numerical experiments will help to shed some more light on the nature of this problem, insofar as the classic variational approach to the description of these states is concerned (13, 14).

(*ia*) In the case of the ^1S state, one can argue that the wave function [6] is not orthogonal to $2s^2\ ^1S$, and therefore not orthogonal to $1s^2\ ^1S$ either. One can therefore follow established procedures (13, 15) and attempt to project out of the calculated solution the $1s^2$, 1*sns* components (represented by a function such as [8] below). Computed energies with uncorrelated wave functions for $2p^2\ ^1S$ in the range −0.633 to −0.635 au are fairly persistent, occurring over quite a wide range of the disposable parameters a and b: the use of these projection techniques on any of these wave functions immediately pushes these eigenvalues up towards, but not quite up to the experimental level.

(*ib*) The same results can be achieved in a more systematic way. It is usual to make use of Green's theorem in calculating the integrals required in two-electron calculations (16): this ensures that the matrix elements of the Hamiltonian are symmetric. However, one can evaluate these integrals for wave functions like [6] in a straightforward fashion without the use of Green's theorem (17) in which case the secular matrix is slightly unsymmetric: it gives, nevertheless, the same eigenvalues. If we now choose a trial wave function

$$[7]\qquad \psi = \alpha\psi(1s^2\ ^1S) + \beta\psi(2p^2\ ^1S)$$

then in this unsymmetric reduction, certain $1s^2$–$2p^2$ matrix elements appear in the secular matrix: there are no cross terms in T and S, but there are in V. If one now observes the behaviour of the eigenvalue near $E = -0.634$ au, it has the following properties. Increasing the expansion length of the $2p^2$ function lowers the energy, or leaves it the same, as expected. Improving the representation of the $1s^2$ function raises the value of this eigenvalue, again as expected. It seems obvious, then, that the solution to the problem of obtaining a quasi-variational energy for the $2p^2\ ^1S$ state is to use a wave function of the form of [7] with this unsymmetric reduction procedure, and simply increase the expansion lengths for both $1s^2$ and $2p^2$ until convergence is achieved. Unfortunately, this does not work because if the expansion length of the $1s^2$ part is made too great, the target eigenvalue again falls below the observed value: we believe this is due to the fact that since the $1s^2$ part of the function is only a variational approximation, it is not strictly orthogonal to all other approximate wave functions; overlap integrals of the order of 10^{-3} have been shown to be typical (18) in these kinds of variational calculations. Since we have been unable to resolve this difficulty, we will not report the details of these calculations, but they will be made available elsewhere (17).

(*ii*) If one wanted to perform a variational calculation for the $2s^2\ ^1S$ or the $2s3s\ ^3S$ state, using these kinds of correlated wave functions, one might choose

$$[8]\quad \psi = (1 \pm P_{12}) \sum_{i=0}^{n} \sum_{j=0}^{n'} \sum_{k=0}^{m} c_{ijk}(\zeta r_1)^{i}(\zeta r_2)^{j} \times \cos^k\theta_{12} e^{-\zeta(ar_1+br_2)}$$

However, the final angular term in eq. 6 is nothing more than $\cos\theta_{12}$, so that the only difference between the two functions [6] and [8] is that [6] excludes the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

configurations including $r_1^0\ r_2^0$ and $\cos^0\theta_{12}$; consequently, there is little distinction between the trial wave functions for the S states of $2sns$ and $2pnp$. Nor, apart from some reduced efficiency (see below), is [8] really any different from eq. 1 of ref. 1, which can be used to describe the whole $1sns$ manifold of states, so it is actually useless for exploring $2sns$ states. What is interesting, however, if one chooses a wave function containing only powers of r_1^1, r_2^1, and $\cos^k\theta_{12}$, k only even up to very high powers of k, viz. eq. 6 $\sum(0,0,33)$ (or eq. 8 $\sum(1,1,34)$ which is the same function), the energy appears to converge variationally to the energy of the $2s^2\ ^1S$ state, for example with $N = 18$, $E = -0.771$ au compared with the observed value (3) of -0.777 au. Likewise, the 26-term wave function eq. 6 $\sum(0,1,31)$ (or $\sum(1,2,32)$ using eq. 8) gives $E = -0.59744$ au for the $2s3s\ ^3S$ state, compared with other theoretical estimates of around -0.6024 to -0.6026 au (15, 19). Convergence for these wave functions is exceedingly slow, as was found a long time ago for the $\cos\theta_{12}$ correlated treatment of the ground state of helium (20). This shows itself up in two ways. One is the extremely small improvement in energy as terms above $\cos^{30}\theta_{12}$ in [8] are added. The other is the extremely poor correspondence between the higher eigenvalues and the energies of other excited states; this despite the fact that each eigenvalue is obviously an approximation to an individual member of a Rydberg series in the sense that for the nth eigenvalue, the optimum value of b is close to $0.5/n$, for both singlet and triplet and up to $n = 25$.

Rydberg Series

These calculations, and the earlier ones for $1sns$ states (1), show that the non-relativistic Schrödinger equation for the helium atom yields an infinite series of solutions for $1sns$, $1snp$, $1snd$, $2sns$, and $2pnp$; on the other hand, it appears that only a very limited number of solutions exists for H^- (5, 8, 9, 15, 21, 22). Experimentally, relatively few $2pnp$ states of the helium atom are known, and comparison between the experimental and calculated energies has been made, where appropriate, in the foregoing two sections. However, many singly excited states of helium are known (3), and in the case of the $1sns$ states, a simple Rydberg formula provides a very accurate way of representing the energies of the states for large n (1). According to the Heisenberg treatment of highly excited states of helium-like atoms (23), the first-order energies can be written in the Rydberg form

$$[9] \qquad E + \frac{1}{2}Z^2 = -\frac{1}{2}\frac{(Z-1)^2}{(n+\delta_c \pm \delta_A)^2}\ \text{au}$$

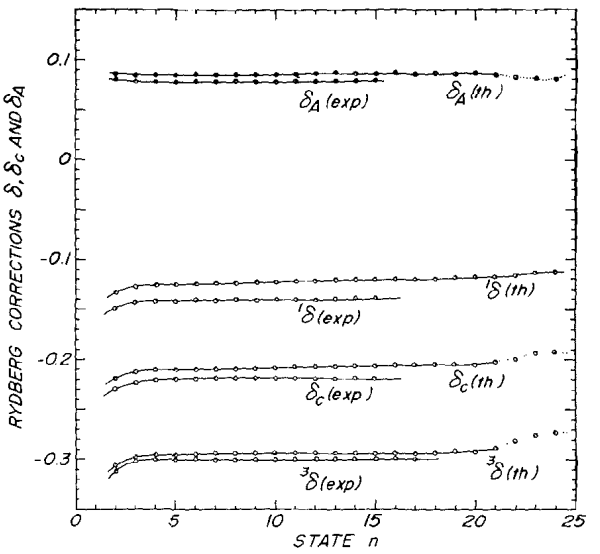

FIG. 1. Plots of the experimental and theoretical values of δ, δ_c, and δ_A for the singlet and triplet $1sns$ states of the helium atom. Note that $\delta_c = \frac{1}{2}(^1\delta + {}^3\delta)$, $\delta_A = \frac{1}{2}(^1\delta - {}^3\delta)$.

or

$$[9a] \qquad E + 2 \simeq \frac{-1}{2(n+\delta_c \pm \delta_A)} \equiv \frac{-1}{2(n+\delta)^2}$$

when $Z = 2$, and for the helium atom, 1 au = 219 444.53 cm^{-1}; δ_c and δ_A are respectively the coulomb and exchange parts of the Rydberg correction term, and $\delta = (\delta_c \pm \delta_A)$ for either singlet or triplet, i.e. $^1\delta$ or $^3\delta$. Figure 1 shows the experimental (3) and theoretical (1) $1sns$ data plotted in this form. Remembering that at $n = 20$, a change in δ of 0.01 corresponds to a change of energy of about 0.25 cm^{-1}, this plot shows that the calculations are properly converged up to $n = 20$, and that both the experimental ($4 \leq n \leq 15$) and theoretical ($4 \leq n \leq 20$) energies can be well represented by eq. 9.

In the $1snp$ case, the theoretical values of $^3\delta$ do not converge to constant values as n increases, but above $n \sim 12$–14, they appear to increase roughly linearly with n, corresponding to a spacing of the upper levels rather greater than predicted by any Rydberg formula; the theoretical values of $^1\delta$ do, however, appear to converge at large n. Figure 2 shows that the experimental results follow the same pattern, and that this curious behaviour does not arise from either the coulomb term or the exchange term alone: both δ_c and δ_A appear to depend on n, but at large n, this dependence cancels for the singlets and reinforces for the triplets.[2]

[2]We are currently investigating (17), along the lines worked out by Ludwig (24), the supposition that this n-dependence of δ_c and δ_A arises within the Heisenberg treatment (23) from neglected second order polarisation terms.

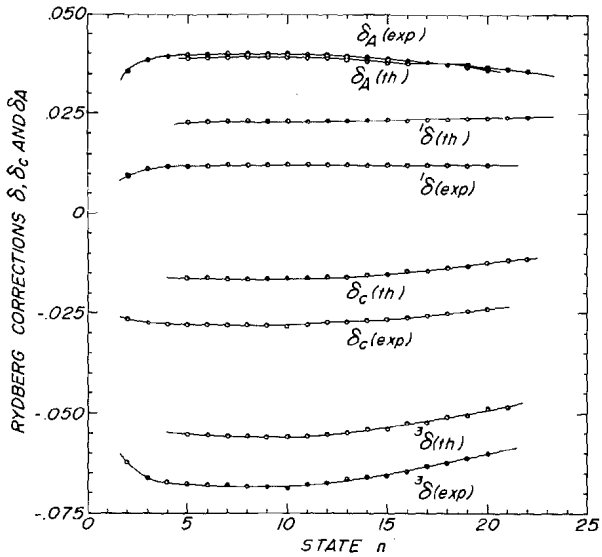

FIG. 2. Plots of the experimental and theoretical values of δ, δ_c, and δ_A for the singlet and triplet 1*snp* states of the helium atom.

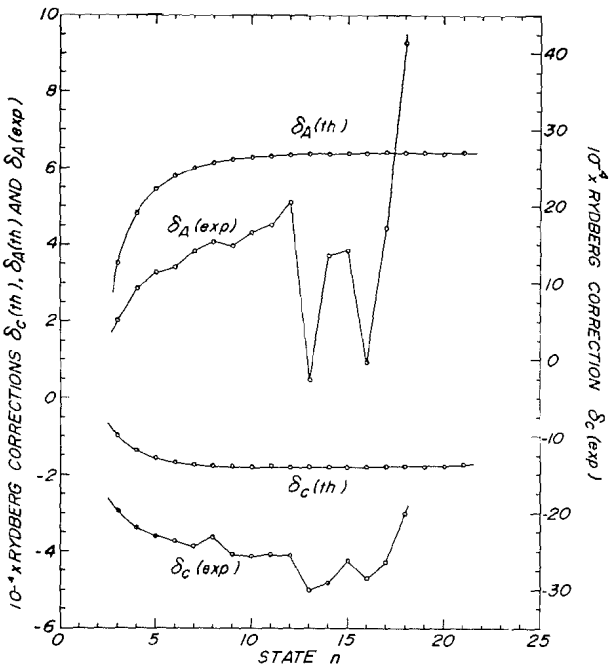

FIG. 3. Plots of the experimental and theoretical values of δ_c and δ_A for the singlet and triplet 1*snd* states of the helium atom; notice the shift of scale between the experimental and theoretical values of δ_c.

In the 1*snd* case, Fig. 3 shows that the theoretical values adhere very closely to the form of eq. 9, and also that the singlet–triplet splitting (δ_A) is much better represented than is the absolute value of the energy (δ_c). However, it is clear that there are significant irregularities in the experimental energies at $n = 8$, and from 13 onwards, although these plots

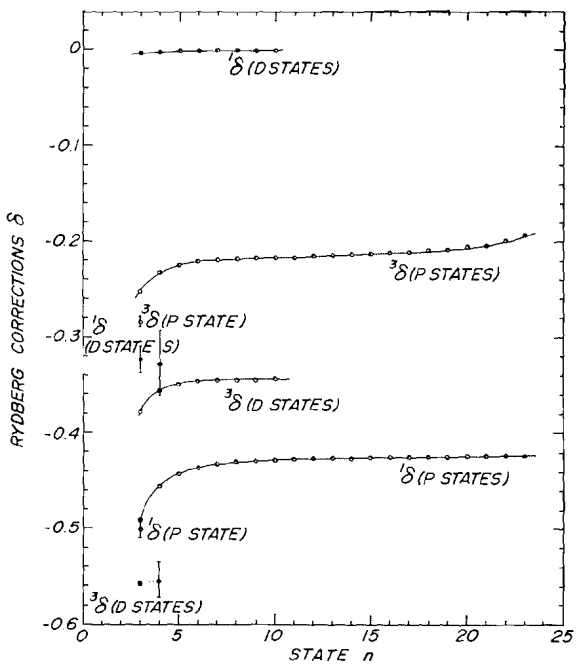

FIG. 4. Plots of the theoretical values of $^1\delta$ and $^3\delta$ for the *P* and *D* 2*pnp* states of the helium atom: experimental points are denoted by open circles with error bars. (For the *P* states, $\delta_A = \frac{1}{2}(^3\delta - {}^1\delta)$, whereas for the *D* states $\delta_A = \frac{1}{2}(^1\delta - {}^3\delta)$ as in Figs. 1–3; this arises because we have avoided the use of the *ortho-* and *para-* designations (23) for these states.)

are extremely sensitive indicators of such irregularities; for example, a change of δ_c of about 0.0002 at $n = 8$ corresponds only to a displacement of about 0.1 cm^{-1}.

Figure 4 shows Rydberg plots of the theoretical values of δ for the *P* and *D* states of 2*pnp*, from which the calculated energies can easily be reconstructed using an appropriately modified form of eq. 9, viz.

$$[9b] \quad E + 0.5 = \frac{-1}{2(n + \delta_c \pm \delta_A)^2} \equiv \frac{-1}{2(n+\delta)^2} \text{ au}$$

The agreement between theory and experiment for the *P* states is good, but for the *D* states, the agreement is less satisfactory.

The crystal and molecular structure of (4-diethylaminophenyl)diazenyltriphenylphosphonium tetrafluoroborate

FREDERICK W. B. EINSTEIN, DEREK SUTTON, AND PETER L. VOGEL

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received September 29, 1977

FREDERICK W. B. EINSTEIN, DEREK SUTTON, and PETER L. VOGEL. Can. J. Chem. **56**, 891 (1978).

The title compound crystallizes in the space group $P2_1/c$ with four formula units in a cell of dimensions $a = 10.146(6)$ Å, $b = 10.593(4)$ Å, $c = 26.31(1)$ Å, $\beta = 103.14(3)°$. Using 1496 observed reflections ($I = 2.3\sigma(I)$) in the range $0° < 2\theta < 40°$ measured on a Picker FACS-1 automatic diffractometer with Mo-Kα radiation, the structure was solved (symbolic addition) and refined (full-matrix least-squares procedure) to $R = 0.062$ ($R_w = 0.058$), with all hydrogen atoms included and all non-hydrogen atoms having anisotropic thermal parameters. The dimensions within the cation are consistent with a delocalized electronic structure which is intermediate between valence formulations involving benzenoid or quinonoid structures for the (4-diethylaminophenyl)diazenyl residue. Some important bond lengths are N3—C22 1.336(7) Å, N2—C19 1.356(7) Å, N1—N2 1.308(6) Å, and P—N1 1.648(5) Å.

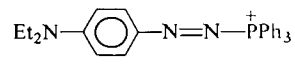
FREDERICK W. B. EINSTEIN, DEREK SUTTON et PETER L. VOGEL. Can. J. Chem. **56**, 891 (1978).

Le composé mentionné dans le titre cristallise dans le groupe d'espace $P2_1/c$ avec quatre formules stoechiométriques par maille dont les dimensions: $a = 10.146(6)$ Å, $b = 10.593(4)$ Å, $c = 26.31(1)$ Å, $\beta = 103.14(3)°$. Utilisant 1496 réflexions observées ($I = 2.3\sigma(I)$) à des angles de $0° < 2\theta < 40°$ mesurés à l'aide d'un diffractomètre automatique Picker FACS-1 avec la radiation Mo-Kα, on a résolu la structure (addition symbolique) et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.062$ ($R_w = 0.058$) en incluant tous les atomes d'hydrogène et tous les atomes qui ne sont pas des hydrogènes possédant des paramètres thermiques anisotropiques. Les dimensions à l'intérieur du cation sont en accord avec une structure électronique délocalisée qui est intermédiaire entre les formulations de valence impliquant des structures benzénoïdes ou quinonoïdes pour le fragment (diméthylamino-4 phényle)diazényle. Parmi les longueurs de liaisons, les plus importantes sont N3—C22 1.336(7) Å, N2—C19 1.356(7) Å, N1—N2 1.308(6) Å et P—N1 1.648(5) Å.

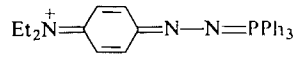
[Traduit par le journal]

Introduction

The reaction of $[p\text{-}Et_2NC_6H_4N_2][BF_4]$ with triphenylphosphine yields bright red crystals of the title complex. Studies by Carroll *et al.* (1) have shown the structural formula $[p\text{-}Et_2NC_6H_4NNPPh_3][BF_4]$ to be consistent with the available spectroscopic evidence. However, the measured values of ν(N=N) and ν(P—N) in the ir and Raman spectra appear to indicate a considerable contribution of the valence-bond formalism **1***b* to the electronic structure of the cation.



1*a*



1*b*

The intense red colour of the compound, and its enhanced stability compared with those with substituents other than NEt_2 are probably a result of this delocalization. The purpose of this work was, therefore, to determine whether additional evidence for a delocalized electronic structure could be found in the molecular structure determined by X-ray diffraction.

Experimental

The deep-red needle shaped crystals of the title compound were elongated along the *b* axis. Photographic information indicated monoclinic Laue symmetry. Systematic absences $h0l$ ($l = 2n + 1$) and $0k0$ ($k = 2n + 1$) unambiguously indicated the space group $P2_1/c$. Cell dimensions were obtained from counter measurement and least-squares refinement of the setting angles of nine reflections with $2\theta > 28°$, using a Picker FACS-1 automatic four-circle diffractometer (λMo-Kα_1 = 0.70962 Å) and a brick-shaped crystal of dimensions 0.11 × 0.15 × 0.51 mm. Intensity measurements for 2576 reflections were recorded in two shells, $0° < 2\theta < 25°$, $25° < 2\theta < 40°$ with beam widths of 1.0° and 0.7° respectively. A total of 1496 reflections were considered observed at the significance level $I/\sigma(I) = 2.3$, where $\sigma(I)$ is the standard deviation derived from counting statistics. A θ–2θ scan technique was employed using Nb-filtered Mo-Kα radiation and a scan speed of 2°/min increased for dispersion. Background measurements of 4 s were taken at the scan limits. Two standard reflections were monitored periodically for the purpose of data scaling. Corrections for Lorentz and polarization effects were applied, but an absorption correction was not considered necessary (μ(Mo-Kα) = 1.57 cm^{-1}).

Symbolic addition techniques followed by a Fourier summation gave coordinates for 30 non-hydrogen atoms. Electron density difference maps interspersed with cycles of full-matrix least-squares refinement gave the positions for the remaining non-hydrogen atoms. With anisotropic temperature factors included for the phosphorus and fluorine atoms, a value of the discrepancy index $R = 0.11$ was obtained, where $R = \Sigma|(|F_o| - |F_c|)|/\Sigma|F_o|$. Including all the hydrogen atoms in calculated positions (with fixed temperature factors $U = 0.076$ Å^2) and with anisotropic thermal motion parameters for all non-hydrogen atoms, the discrepancy index dropped to 0.064. Two final cycles of anisotropic refinement, in which the coordinates of the six methyl hydrogens were also refined, gave a final R value of 0.062 ($R_w = 0.058$).[1]

Unobserved reflections were excluded from all stages of the least-squares refinement. For the initial refinement constant (unit) weights were used, but in the final cycles weights w were used (where $w = 1/\sigma(F_o)^2$). A final electron density difference map showed only two peaks greater than $3\sigma(\rho)$ ($\sigma(\rho)$ = 0.098 e Å^{-3}). These peaks were in the $[BF_4]^-$ region.

Scattering factors for the non-hydrogen atoms, including anomalous dispersion corrections to the phosphorus scattering, were those of Cromer and Waber (2). Hydrogen scattering factors were taken from ref. 3. Crystallographic computer programs used in this work have been cited elsewhere (4).

The crystal data are summarized in Table 1. Final atomic coordinates and thermal motion parameters are listed in Table 2, interatomic distances and angles are given in Table 3, and least-squares planes relevant to the discussion are given in Table 4. Standard deviations in all tables are in parentheses as units in the least significant figure. Tables 2*b* and 4 together with Table 5, a listing of structure factor amplitudes, have been deposited with the Depository of Unpublished Data.[2]

[1]The methyl hydrogen atoms were refined because their positioning was considered to be much more uncertain than that of all the other hydrogen atoms, whose positions could be calculated reliably.

[2]Copies of material on deposit may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion
